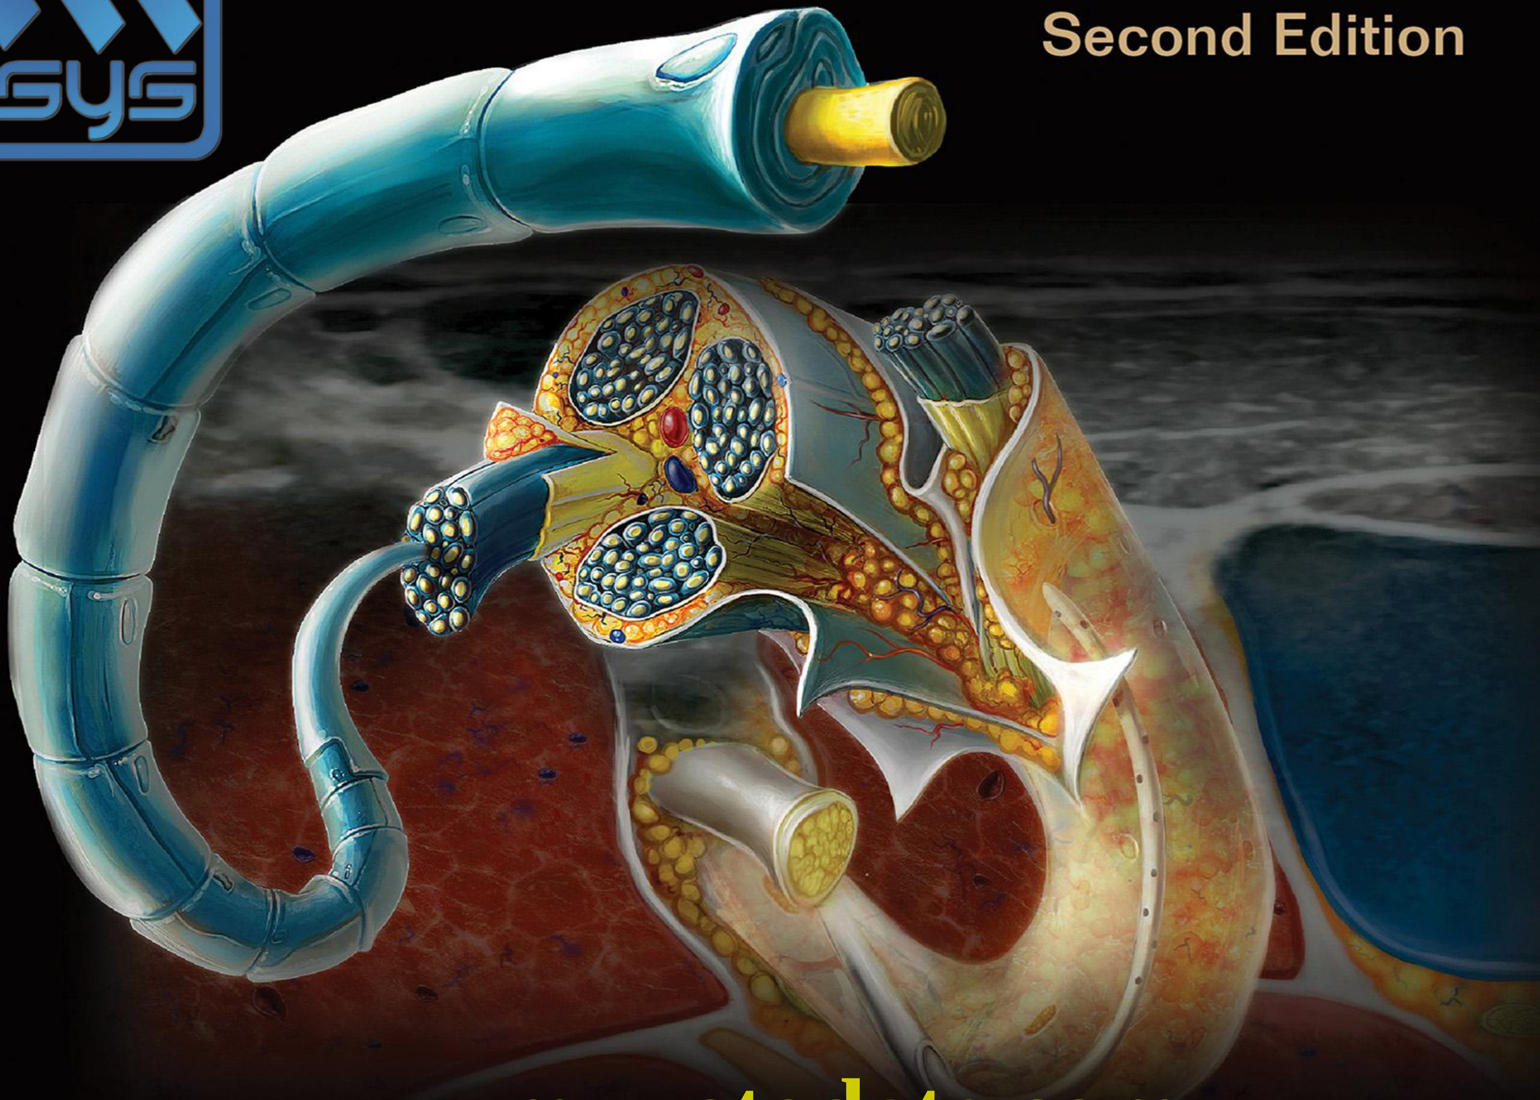
THE NEW YORK SCHOOL OF REGIONAL ANESTHESIA

Hadzic's TEXTBOOK OF Regional Anesthesia AND ACUTE PAIN MANAGEMENT

Second Edition



McGraw Hill Education

Admir Hadzic

UPTODATE

راهنمای نصب آخرین نسخه آپتودیت آفلاین

۱. برای نصب اپلیکشین درگوشی آیفون، برنامه App Store و درگوشی اندروید Play Store را اجرا کرده سپس عبارت Mehrsys medical library را جستجو کنید و برنامه را نصب کنید.

۲. بعد از نصب و اجرای اپلیکیشن در صفحه اول برنامه **برای دریافت** Username و Password به **به تلگرام پشتیبانی و فروش که در زیر تصویر اشاره شده است پیغام دهید.**

@MehrsysSupport

۳. در مرحله بعد حساب کاربری خود را بسازید.

۴. بعد از ورود به برنامه در قسمت یا منوی Download روی آیکون سه نقطه آبی رنگ که رو به روی UpToDate قرار دارد کلیک کنید و گزینه دانلود Download را انتخاب کنید با این عمل می توانید دانلود را به آسانی از طریق اینترنت انجام دهید.

قابلیتهای برنامه

- دسترسی به آخرین نسخه آپتودیت آفلاین با قابلیت بروز رسانی
- امکان جستجو بسیار سریع مطالب بدون نیاز به اینترنت
- امکان مشاهده **abstract** رفرنسهای داخل مقالات آپتودیت
- قابل نصب بر روی گوشی و کامپیوتر
- دسترسی به دیگر منابع پزشکی و دارویی به صورت رایگان
- امکان انتخاب متون، کپی و ارسال آن به برنامه های دیگر
- هایلایت کردن متون در برنامه به رنگهای مختلف
- ذخیره کردن مقالات و عکسهای آپتودیت
- تولید شده توسط شرکت معتبر نرم افزاری و مورد تایید نظام صنفی رایانه ای کشور و شورای عالی انفورماتیک

The New York School of Regional Anesthesia

HADZIC'S TEXTBOOK OF REGIONAL ANESTHESIA AND ACUTE PAIN MANAGEMENT

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Version 1.0

This book is dedicated to Dr. Steven Dewaele (1974–2016), for he, the Ironman and essential marine of NYSORA's team, has inspired many by his zeal for life and the dedication with which he pursued everything he aimed at.

"The most dangerous risk of all is the risk of spending your life not doing what you want on the bet that you can buy yourself the freedom to do it later."

CONTENTS

PART 1

HISTORY

PART 2

FOUNDATIONS OF LOCAL AND REGIONAL ANESTHESIA

PART 3D: Ultrasound-Guided Nerve Blocks

Section 1: Fundamentals of Ultrasound-Guided Regional Anesthesia

Section 2: Ultrasound-Guided Head and Neck Nerve Blocks

Section 3: Ultrasound-Guided Nerve Blocks for the Upper Extremity

Section 4: Ultrasound-Guided Nerve Blocks for the Lower Extremity

Section 5: Ultrasound-Guided Nerve Blocks for Abdominal & Thoracic Wall

PART 3E: Local and Regional Anesthesia for Oral and Maxillofacial Surgery

PART 3F: Local and Regional Anesthesia for the Eye

PART 4

ULTRASOUND IMAGING OF NEURAXIAL AND PERIVERTEBRAL SPACE

PART 5

OBSTETRIC ANESTHESIA

PART 6

PEDIATRIC ANESTHESIA

PART 7

ANESTHESIA IN PATIENTS WITH SPECIFIC CONSIDERATIONS

PART 8

REGIONAL ANESTHESIA IN THE EMERGENCY DEPARTMENT

PART 9

COMPLICATIONS OF LOCAL AND REGIONAL ANESTHESIA

PART 10

LAST: LOCAL ANESTHETIC SYSTEMIC TOXICITY

PART 11

PERIOPERATIVE OUTCOME AND ECONOMICS OF REGIONAL ANESTHESIA

PART 12

ACUTE PAIN MANAGEMENT

PART 13

EDUCATION IN REGIONAL ANESTHESIA

PART 14

STATISTICS AND PRINCIPLES OF RESEARCH DESIGN IN REGIONAL ANESTHESIA AND ACUTE PAIN MEDICINE

PART 15

NERVE STIMULATOR AND SURFACE ANATOMY-BASED NERVE BLOCKS

APPENDICES

CONTRIBUTORS

Sherif Abbas, MD
Anesthesiology Assistant
Catholic University of Leuven
Leuven, Belgium

Jolaade Adebayo, MD, D.ABA
Staff Anesthesiologist
Tanner Health System
Department of Surgery
Carrollton, Georgia

José Aguirre, MD
Team Leader Anesthesia Education and Research
Study Coordination UCAR
Consultant Anesthetist
Balgrist University Hospital
Zurich, Switzerland

Imran Ahmad, FRCA
Honorary Senior Lecturer, King's College
Consultant Anaesthetist
Clinical Lead for Airway Management
Guy's Hospital
Guy's and St. Thomas' NHS Foundation Trust
London, United Kingdom

Omar Ahmed, MD
Anesthesiologist
Premier Care Anesthesia
New York Medical College
Orange County, California

Michael H. Andreae, MD
Department of Anesthesiology
Montefiore Medical Center
Albert Einstein College of Medicine
New York, New York

Riánsares Arriazu, PharmD, PhD
Histology Laboratory
Institute of Applied Molecular Medicine
Department of Basic Medical Sciences
School of Medicine, CEU-San Pablo University
Madrid, Spain

Arthur Atchabahian, MD
Professor of Clinical Anesthesiology
Department of Anesthesiology, Perioperative Care, and Pain Medicine
NYU School of Medicine
New York, New York

Michael J. Barrington, MB, BS, FANZCA, PhD
Associate Professor
University of Melbourne
Senior Staff Anaesthetist
Department of Anaesthesia and Acute Pain Medicine
St. Vincent's Hospital Melbourne, Fitzroy
Victoria, Australia

David Beausang, MD
Assistant Professor
Department of Anesthesiology
Sidney Kimmel Medical College
Thomas Jefferson University and Hospitals
Philadelphia, Pennsylvania

Thomas Fichtner Bendtsen, MD, PhD
Associate Professor of Anesthesiology
Consultant, Anesthesiology
Aarhus University Hospital
Aarhus, Denmark

Honorio T. Benzon, MD
Professor of Anesthesiology
Northwestern University Feinberg School of Medicine
Chicago, Illinois

David J. Birnbach, MD, MPH
Professor of Anesthesiology and Obstetrics and Gynecology
Chief of Women's Anesthesia
Jackson Memorial Hospital
University of Miami
Miami, Florida

Rafael Blanco, MD, BS, FRCA, DEAA
Senior Consultant Anaesthetist
Corniche Hospital
Abu Dhabi
United Arab Emirates

Stephan Blumenthal, MD
Assistant Professor
Head of Institute of Anesthesiology
Bulach Hospital
Bulach, Switzerland

Alain Borgeat, MD
Professor of Anesthesiology
Director, University of Balgrist
Zurich, Switzerland

Herve Bouaziz, MD
Professor of Anesthesiology
Department of Anaesthesiology and Critical Care.
Nancy University Hospital,
Nancy, France

Cedric Bouts, MD
Anaesthesia Resident
Katholieke Universiteit Leuven (KUL)
Ziekenhuis Oost-Limburg, ZOL
Genk, Belgium

Richard Brull, MD, FRCPC
Professor of Anesthesia
University of Toronto
Chief, Department of Anesthesia
Women's College Hospital
Toronto, Ontario, Canada

Robbert Buck, MD
Anaesthesia Resident
University of Antwerp
Ziekenhuis Oost-Limburg, ZOL
Genk, Belgium

Chester "Trip" Buckenmaier III, MD
Professor of Anesthesiology
Director, Defense and Veterans Center for Integrative Pain Management
Uniformed Services University
Rockville, Maryland

Christiana C. Burts, BA, MB, FRCA
Consultant Anesthetist
Papworth Hospital NHS Foundation Trust
Cambridge, United Kingdom

John Butterworth IV, MD
Professor and Chairman
Department of Anesthesiology
Virginia Commonwealth University School of Medicine
Richmond, Virginia

Asokumar Buvanendran, MD
Professor, Department of Anesthesiology
William Gottschalk, Endowed Chair of Anesthesiology
Vice Chair Research and Director of Orthopedic Anesthesia
Rush University Medical Center
Chicago, Illinois

Bram Byloos, MD
Anaesthesia Resident
Katholieke Universiteit Leuven (KUL)
Ziekenhuis Oost-Limburg, ZOL
Genk, Belgium

Kenneth D. Candido, MD
Professor of Clinical Anesthesiology
Clinical Professor of Surgery
University of Illinois Chicago
Chairman, Department of Anesthesiology
Advocate Illinois Masonic Medical Center
Chicago, Illinois

Xavier Capdevila, MD, PhD
Professor or Anesthesiology and Critical Care Medicine
Head, Department of Anesthesiology and Critical Care Medicine
Lapeyronie University Hospital
NeuroScience Institute
Montpellier University
Montpellier, France

Anna Carrera, MD, PhD
Professor of Human Anatomy
NEOMA Research Group
Medical Science Department
Faculty of Medicine, University of Girona
Girona, Spain

Gregory M. Casey, DDS, MD
Cosmetic Facial Surgery Private Practice
Associate Clinical Professor
University of Florida
Oral and Maxillofacial Surgery
Naples, Florida

Tessy Castermans, MD
Anaesthesia Resident
University of Antwerp
Ziekenhuis Oost-Limburg, ZOL
Genk, Belgium

Vincent Chan, MD, FRCPC, FRCA
Professor
Department of Anesthesia
University of Toronto
Toronto, Ontario, Canada

Adrian Chin, MBBS, FANZCA
Department of Anesthesiology
Royal Brisbane and Women's Hospital
Brisbane, Queensland, Australia

Ki Jinn Chin, MBBS, MMed, FRCPC
Associate Professor
Department of Anesthesia,
Toronto Western Hospital
University of Toronto
Toronto, Ontario, Canada

Jason Choi, MD
Attending Anesthesiologist
White Plains Hospital
White Plains, New York

Lynn Choi, MD
Assistant Clinical Professor
Department of Anesthesiology and Perioperative Medicine
University of California, Los Angeles
Los Angeles, California

Stephen Choi, MD, FRCPC, MSc
Assistant Professor of Anesthesiology
Sunnybrook Health Sciences Centre
University of Toronto
Toronto, Ontario, Canada

Olivier Choquet, MD, MSc
Consultant, Associate Professor
Department of Anesthesia and Critical Care Unit
Lapeyronie University Hospital
Montpellier France

Alwin Chuan, MBBS, PhD, PGCertCU, FANZCA
Senior Clinical Lecturer
University of New South Wales
Consultant, Anaesthesiology
Liverpool Hospital
Sydney, Australia

Laura Clark, MD
Professor
Residency Program Director
Director of Regional Anesthesia and Acute Pain
University of Louisville
Louisville, Kentucky

Thomas B. Clark, DC, RVT, RMSK
Professor of Radiology
Logan University
St. Louis, Missouri

Stacy A. Coffin, MD
Anesthesiologist
St. Luke's Hospital of Duluth
Duluth, Minnesota

Kathleen Colfer, MSN, RN-BC
Clinical Nurse Specialist and Manager
Acute Pain Management Service
Department of Anesthesiology
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania

Erika Cvetko, DD, PhD
Professor of Anatomy
Head of the Institute of Anatomy
Faculty of Medicine
University of Ljubljana
Ljubljana, Slovenia

Christophe Dadure, MD, PhD
Professor of Anesthesiology and
Critical Care Medicine
Head of Department of Anesthesiology
Lapeyronie University Hospital
Montpellier, France

Elyad Davidson, MD
Anesthesiologist
Miami, Florida

Jose A de Andrés, MD, PhD, FIPP, EDRA
Professor of Anesthesia
Valencia School of Medicine
Chairman Anesthesia, Critical Care and Pain Management
Department
General University Hospital
Valencia, Spain

Belen De Jose Maria, MD, PhD, ECFMG
Consultant in Pediatric Anesthesia
Hospital Sant Joan de Deu, University of Barcelona
Barcelona, Spain

Rick Delmonte, DPM, FACFAS
Foot and Ankle Surgeon
NYU Langone Medical Center
New York, New York

Gildasio S. De Oliveira Jr, MD, MSCI
Assistant Professor of Anesthesiology
Associate Chair for Research
Department of Anesthesiology
Northwestern University
Feinberg School of Medicine
Chicago, Illinois

Steven Dewaele, MD
Consultant, Anesthesiology
Intensive Care Medicine
Emergency Medicine
Ziekenhuis Oost-Limburg
Genk, Belgium

Franklin Dexter, MD, PhD
Professor, Department of Anesthesia
Director, Division of Management Consulting
University of Iowa
Iowa City, Iowa

Rishi M. Diwan, FRCA, MD, MBBS
Consultant Paediatric Anaesthetist and
Acute Pain Lead
Deputy Clinical Director
Jackson Rees Department of Anaesthetics
Alder Hey Children's NHS Foundation Trust
Liverpool, United Kingdom

Lisa Doan, MD
Assistant Professor
Department of Anesthesiology, Perioperative Care and
Pain Medicine
New York University School of Medicine
New York, New York

Jennifer E. Dominguez, MD, MHS
Anesthesiologist
Duke University Hospital
Durham, North Carolina

Joris Duerinckx, MD
Consultant, Orthopaedic and Hand Surgery
Ziekenhuis Oost-Limburg, ZOL
Genk, Belgium

Dimitri Dylst, MD
Consultant, Anesthesiology
Intensive Care Medicine
Emergency Medicine
Ziekenhuis Oost-Limburg
Genk, Belgium

Hesham Elsharkawy, MD, MSc
Staff, Anesthesiology Institute
Cleveland Clinic
Assistant Professor of Anesthesiology
CCLCM of Case Western Reserve
University of Cleveland
Cleveland, Ohio

Trent Emerick, MD
Assistant Clinical Professor
Department of Anesthesiology and Division of Chronic Pain
University of Pittsburgh
Pittsburgh, Pennsylvania

Hillenn Cruz Eng, MD
Assistant Professor
Department of Anesthesiology and Perioperative Medicine
Penn State Health
Hershey, Pennsylvania

Holly Evans, MD
Assistant Professor, University of Ottawa
Anesthesiologist, The Ottawa Hospital
Ottawa, Ontario, Canada

Paul Fettes, MBChB, BSc
Consultant Anaesthetist and
Honorary Senior Lecturer
Department of Anaesthesia
Ninewells Hospital and Medical School
Dundee, Scotland, United Kingdom

Michael Fettiplace, MD
PhD Student at University of Illinois
College of Medicine
Chicago, Illinois

Peter Foldes, MD
Anesthesiologist
Department of Anesthesiology
Tulane University Medical Center
New Orleans, Louisiana

Elisabeth Fouché, MD
Digital Editor, Designer
Paris, France

Carlo D. Franco, MD
Professor Anesthesiology and Anatomy
Chairman Regional Anesthesia
JHS Hospital of Cook County
Chicago, Illinois

Jeff Gadsden, MD, FRCPC, FANZCA
Associate Professor
Duke University School of Medicine
Chief, Division of Orthopaedic, Plastic and Regional Anesthesiology
Duke University Medical Center
Durham, North Carolina

Elizabeth Gaertner, MD
Department of Anesthesiology
Hautepierre Hospital
Strasbourg, France

Tong J. Gan, MD, MHS, FRCA
Professor and Chairman
Department of Anesthesiology
Stony Brook University
Stony Brook, New York

Zoe S. Gan, BA
Medical Student
University of North Carolina School of Medicine
Chapel Hill, North Carolina

Philippe E. Gautier, MD
Head of Department
Director of Obstetric and Regional Anesthesia
Clinique Ste-Anne St.-Remi
Brussels, Belgium

Andrew J. Gentilin, MD
Anesthesiologist
CAMC Health System
Charleston, West Virginia

Liane Germond, MD
Anesthesiologist
Ochsner Medical Center
New Orleans, Lousiana

Christopher Gharibo, MD
Associate Professor of Anesthesiology and Pain Medicine
Associate Professor of Orthopedics
NYU School of Medicine
New York, New York

Marina Gitman, MD
Assistant Professor of Anesthesiology
University of Illinois Hospital
Chicago, Illinois

Michael S. Gold, PhD
Professor of Anesthesiology
Center for Pain Research
University of Pittsburgh
Pittsburgh, Pennsylvania

Monika Golebiewski, MD
Research Associate
NYSORA Europe
Munich, Germany

Paul M. Greenberg, DPM, FACFAS
Fellow, American College of Foot and Ankle Surgeons
Diplomate, American Board of Foot and Ankle Surgery
NYU Faculty Group Practice-Podiatry Associates Upper West Side
NYU Langone Medical Center
New York, New York

Roy A. Greengrass, MD, FRCP
Professor of Anesthesiology
Fellowship Director Acute Pain and Regional Anesthesia
Mayo Clinic Jacksonville Florida

Yavuz Gürkan, MD
Professor of Anaesthesiology
Kocaeli University Hospital
Kocaeli, Turkey

Patrick J. Hackett, MD
Department of Anesthesiology
Spectrum Medical Group
Maine Medical Center
Portland, Maine

Admir Hadzic, MD, PhD
Professor of Anesthesiology
Director of NYSORA
New York, New York
Consultant, Anesthesiology, Intensive Care, Emergency Medicine
and Pain Therapy
Ziekenhuis Oost-Limburg
Genk, Belgium

Thomas M. Halaszynski, DMD, MD, MBA
Associate Professor of Anesthesiology
Senior Director of Regional Anesthesiology/Acute Pain Medicine
Yale University School of Medicine
New Haven, Connecticut

Sarah Hall, MD
Department of Anesthesiology and Critical Care Medicine
Johns Hopkins Hospital
Baltimore, Maryland

Marie N. Hanna, MD
Associate Professor, Anesthesia and Critical Care Medicine
Chief, Division of Regional Anesthesia and Acute Pain Management
Johns Hopkins Hospital
Baltimore, Maryland

Brian E. Harrington, MD
Anesthesiology/Pain Medicine
Billings Clinic Hospital
Billings, Montana

William Harrop-Griffiths, MD
Consultant Anaesthetist
Imperial College Healthcare NHS Trust
London, England

Ilvana Hasanbegovic, MD, PhD
Professor at Department of Anatomy
Faculty of Medicine
University of Sarajevo
Sarajevo, Bosnia and Herzegovina

James R. Hebl, MD
Professor of Anesthesiology
Regional Vice-President
Mayo Clinic
Rochester, Minnesota

Andrew A. Herring, MD
Assistant Clinical Professor
Department of Emergency Medicine
University of California, San Francisco
Director Emergency Pain and Addiction Treatment
Highland Hospital, Alameda Health System
Oakland, California

Adam T. Hershkin, DMD
Department of Oral and Maxillofacial Surgery
Mount Sinai St. Luke's Hospital
New York, New York

Loreen A. Herwaldt, MD
Department of Internal Medicine
Carver College of Medicine
Program of Hospital Epidemiology
University of Iowa Hospitals and Clinics
Iowa City, Iowa

Anthony M.-H. Ho, MD, FRCPC, FCCP
Professor
Department of Anesthesiology and Perioperative Medicine
Director, Pediatric Anesthesia
Queen's University
Kingston, Ontario, Canada

Paul Hobeika, MD
Assistant Professor of Orthopedic Surgery
Staff Orthopedic Surgeon
St. Luke's–Roosevelt Hospital
College of Physicians and Surgeons
Columbia University
New York, New York

Brian M. Ilfeld, MD, MS
Professor of Anesthesiology
University of California
San Diego, California

Vivian H. Y. Ip, MBChB, MRCP, FRCA
Clinical Assistant Professor
Director, Ambulatory Regional Anesthesia
Staff Anesthesiologist
University of Alberta Hospital
Edmonton, Alberta, Canada

Rasha S. Jabri, MD
Chief, Section of Pain Medicine
Tawam Hospital
Abu Dhabi, United Arab Emirates
Adjunct Assistant Professor of Anesthesiology
Johns Hopkins Hospital
Baltimore, Maryland

Adam K. Jacob, MD
Assistant Professor of Anesthesiology
Mayo Clinic, Indiana
University School of Medicine
Rochester, Minnesota

Hassanin Jalil, MD
Consultant Anesthesiologist
Intensive Care Specialist
Hospital Hasselt
Hasselt, Belgium

Eldan Kapur, MD
Associate Professor of Anatomy
Department of Anatomy
Medicine School
University of Sarajevo
Sarajevo, Bosnia and Herzegovina

Manoj K. Karmakar, MD
Associate Professor
Department of Anaesthesia and Intensive Care
The Chinese University of Hong Kong
Prince of Wales Hospital
Shatin, New Territories
Hong Kong

Joseph Kay, MD
Assistant Professor of Anesthesiology
Department of Anesthesia
Sunnybrook and Women's College Health Sciences Centre
University of Toronto
Toronto, Ontario, Canada

Paul Kessler, MD, PhD
Professor of Anesthesiology
Head of Department of Anesthesiology
Intensive Care and Pain Medicine
Orthopedic University Hospital Frankfurt
Frankfurt, Germany

Kyle R. Kirkham, MD, FRCPC
Lecturer, Department of Anesthesia
University of Toronto
Staff Anesthesiologist-Women's College Hospital and University Health Network-Toronto Western Hospital
Toronto, Canada

Sandra Kopp, MD
Associate Professor of Anesthesiology
Vice Chair, Integration and Convergence, Department of Anesthesiology
Chair, Division of Community Anesthesia
Consultant, Anesthesiology
Mayo Clinic College of Medicine
Rochester, Minnesota

Zbigniew J. Koscielniak-Nielsen, MD, PhD, FRCA
Assistant Professor
Orthopedic Anesthesia Research
Rigshospitalet
Copenhagen, Denmark

Maxine M. Kuroda, PhD, MPH
Epidemiologist/Biostatistician
Clinical Research Manager
NYSORA-SciMedBE
Ziekenhuis Oost-Limburg

Madrid, Spain

Navin A. Mallavaram, MD
Founder, Medical Director
California Pain
Multidisciplinary Pain Management Clinic
Pleasanton, California

Colin J. L. McCartney, MBChB, PhD, FRCA, FCARCSI, FRCPC
Chair of Anesthesiology and Pain Medicine
University of Ottawa
Head of Anesthesiology and Pain Medicine
The Ottawa Hospital
Ottawa, Ontario, Canada

Patrick M. McQuillan, MD
Professor, Anesthesiology and Pediatrics
Department of Anesthesiology and Perioperative Medicine
Penn State Health
Hershey, Philadelphia

Shaun De Meirsman, MD
Anaesthesia Resident
Katholieke Universiteit Leuven (KUL)
Ziekenhuis Oost-Limburg, ZOL
Genk, Belgium

M. Steve Melton, MD
Assistant Professor
Department of Anesthesiology
Duke University Medical Center
Durham, North Carolina

Stavros G. Memtsoudis, MD, PhD, FCCP
Clinical Professor of Anesthesiology and Healthcare Policy and Research
Weill Cornell Medical College
Senior Scientist and Attending Anesthesiologist
Director, Critical Care Services
Hospital for Special Surgery
New York, New York

Marija Meznaric, MD, PhD
Assistant Professor of Anatomy
Institute of Anatomy
Faculty of Medicine
University of Ljubljana
Ljubljana, Slovenia

Andres Missair, MD, EDRA
Associate Professor
University of Miami
Section Chief, Associate Director Fellowship Program, Acute Pain Medicine
Department of Anesthesiology
VA Hospital
Miami, Florida

Amanda M. Monahan, MD
Assistant Clinical Professor
Department of Anesthesiology
University of California
San Diego, California

Hiroaki Murata, MD, PhD
Associate Professor
Department of Anesthesiology
Nagasaki University Graduate School of Biomedical Sciences
Nagasaki, Japan

Tatsuo Nakamoto, MD, PhD
Professor of Regional Anesthesia and Pain Medicine
Department of Anesthesiology
Kansai Medical University
Hirakata, Japan

Joseph M. Neal, MD
Anesthesiology Faculty
Virginia Mason Medical Center
Clinical Professor of Anesthesiology
University of Washington
Seattle, Washington

Andrew Neice, MD
Assistant Professor
Department of Anesthesia and Perioperative Medicine
Oregon Health and Science University
Portland, Oregon

Ariana Nelson, MD
Assistant Professor of Anesthesiology and Pain Medicine
University of California
Irvine Orange, California

Ahtsham U. Niazi, MBBS, FCARCSI, FRCPC
Associate Professor of Anesthesia
University of Toronto
Staff Anesthetist
Toronto Western Hospital
University Health Network
Toronto, Ontario, Canada

Karen C. Nielsen, MD
Associate Professor of Anesthesiology
Duke University Medical Center
Durham, North Carolina

Steven L. Orebaugh, MD
Professor of Anesthesiology
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Tatjana Stopar Pintaric, MD, PhD, DEAA
Associate Professor
Consultant Anaesthesiologist
Clinical Department of Anaesthesiology and Intensive Therapy
University Medical Centre Ljubljana
Ljubljana, Slovenia

Jean M. Pottinger, RN, MA
Program of Hospital Epidemiology
University of Iowa Hospitals and Clinics
Iowa City, Iowa

John-Paul J. Pozek, MD
Assistant Professor
Department of Anesthesiology
Sidney Kimmel Medical College
Thomas Jefferson University and Hospitals
Philadelphia, Pennsylvania

Alberto Prats-Galino, MD, PhD
Professor of Human Anatomy and Embryology
Director, Laboratory of Surgical NeuroAnatomy (LSNA)
Department of Surgery and Medical-Surgical Specialities
Faculty of Medicine, University of Barcelona
Barcelona, Spain

Benaifer D. Preziosi, DMD
Diplomate of the American Board of Oral and Maxillofacial Surgery
Department Chair of Oral and Maxillofacial Surgery
AtlantiCare Regional Medical Center
Linwood, New Jersey

Stavros Prineas, BSc(Med), MBBS, FRCA, FANZCA
Consultant Anaesthetist
Sydney Eye Hospital
Nepean Hospital
Sydney, Australia

John Rae, MBChB
Specialty Trainee in Anaesthesia
Department of Anaesthesia
Ninewells Hospital and Medical School
Dundee, Scotland, United Kingdom

Johan Raeder, MD, PhD
Professor
Faculty of Medicine, University of Oslo
Senior Consultant
Department of Anaesthesiology
Oslo University Hospital
Oslo, Norway

Jayanthie S. Ranasinghe, MD
Professor of Clinical Anesthesiology
University of Miami Health System
Miami, Florida

Miguel A. Reina, MD, PhD
Professor of Anesthesiology
School of Medicine
CEU San Pablo University, Madrid
Senior Associate in Department of Anesthesiology
Madrid-Montepríncipe University Hospital
Madrid, Spain

Steve Roberts, MBChB, FRCA
Consultant Paediatric Anaesthetist
Jackson Rees Department of Anaesthesia
Alder Hey Children's Foundation Trust
Liverpool, United Kingdom

Xavier Sala-Blanch, MD
Associate Professor of Anatomy
Head of Orthopedic Anesthesia
Hospital Clinic de Barcelona
Barcelona, Spain

Alan C. Santos, MD, MPH
Professor of Anesthesiology
Executive Vice-Chairman
Texas Tech University Health Sciences Center
Lubbock, Texas

Leslie Schechter, PharmD
Advanced Practice Pharmacist
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania

Ruben Schreurs, MD
Anaesthesia Resident
Katholieke Universiteit Leuven (KUL)
Ziekenhuis Oost-Limburg, ZOL
Genk, Belgium

Sebastian Schulz-Stübner, MD, PhD
Professor of Anesthesiology
Chief Physician
German Consulting Center for Infection Control and Prevention (BZH GmbH)
Freiburg, Germany

Kara G. Segna, MD
Assistant Professor of Anesthesiology and Critical Care Medicine
Johns Hopkins Hospital
Baltimore, Maryland

Paul J. Seider, MD
Oral and Maxillofacial Surgeon
Fort Lauderdale, Florida

Ann-Sofie Smeets, MD
Resident of Anaesthesiology, KUL
Ziekenhuis Oost-Limburg, ZOL
Genk, Belgium

Chrystelle Sola, MD, MSc
Associate Professor
Pediatric Anesthesia Unit
Department of Anesthesia and Critical Care Medicine
Lapeyronie University Hospital
Montpellier, France

Christina M. Spofford, MD, PhD
Associate Professor of Anesthesiology
Director, Regional Anesthesia and Acute Pain Fellowship
Medical College of Wisconsin
Milwaukee, Wisconsin

Ulrich J. Spreng, MD, PhD
Head of the Department in Anesthesiology, Critical Care and Emergencies
Baerum Hospital
Vestre Viken HF, Norway

Susan M. Steele, MD
Anesthesiologist
American Anesthesiology of North Carolina
Raleigh, North Carolina

Ottokar Stundner, MD
Assistant Professor of Anesthesiology and Intensive Care Medicine
Lecturer, Department of Anesthesiology
Perioperative Medicine and Intensive Care Medicine
Paracelsus Medical University
Salzburg, Austria

Yanxia Sun, MD, PHD
Staff Anesthesiologist
Department of Anesthesiology
Beijing Tongren Hospital
Capital Medical University
Beijing, China

Suzuko Suzuki, MD
Anesthesiology
Brigham and Women's Hospital
Boston, Massachusetts

Anthony R. Tharian, MD
Director of Regional Anesthesia and Acute Pain Management
Advocate Illinois Masonic Medical Center
Clinical Assistant Professor
University of Illinois
Chicago, Illinois

Daniel M. Thys, MD
Professor Emeritus
Columbia University
Chairman Emeritus
St. Luke's–Roosevelt Hospital Center
New York, New York

Luc Tielens, MD
Pediatric Anesthesiologist
Radboud University Medical Center
Nijmegen, The Netherlands

Knox H. Todd, MD, MPH, FACEP
Founding Chair
Department of Emergency Medicine
MD Anderson Cancer Center
Director, EMLine.org
Mendoza, Argentina

Roulhac D. Toledano, MD, PhD
Director, Obstetric Anesthesia
NYU Lutheran Medical Center
New York, New York
Assistant Professor of Anesthesiology
SUNY Downstate Medical Center
Brooklyn, New York

Tony Tsai, MD
Assistant Professor of Anesthesiology
Regional Anesthesiologist
St. Luke's–Roosevelt Hospital
College of Physicians and Surgeons
Columbia University
New York, New York

Ban C. H. Tsui, BPharm, MSc, MD, FRCP(C), PG Dip Echo
Professor of Anesthesiology
Adult and Pediatric Anesthesiologist
Department of Anesthesiology, Perioperative and Pain Medicine
Stanford University School of Medicine

PREFACE

The first edition of *NYSORA's Textbook of Regional Anesthesia and Acute Pain Management* (McGraw-Hill, 2007) was a compendium of knowledge in regional anesthesia and acute pain medicine that quickly became a gold standard for students, practitioners, and test-takers alike. Yet, clinical practice marches on, and over 200 key opinion leaders and the worldwide community of NYSORA's educators worked diligently over the past 4 years to update the first edition. It is now my privilege to present the second edition of the textbook.

The material in this edition has been organized into thematic sections. Writings on history of local and regional anesthesia is often unjustly limited to its very beginnings in the late 1800s and early 1900s. However, a great deal of innovative and pioneering work has taken place in more recent history, that is now featured in the current edition. We have added numerous new anatomical dissections, diagrams, and functional anatomy illustrations developed by the NYSORA team for practitioners of regional anesthesia and pain medicine. NYSORA's teaching of these techniques is based on the principles of injecting local anesthetics within connective tissue sheaths; consequently, significant effort was invested in functional regional anesthesia anatomy and in illustrations that demonstrate the importance of this concept. Sections on connective tissues and the ultrastructural anatomy of the neuraxial meninges were contributed by a group of Spanish collaborators, led by Dr Miguel Angel Reina. Their sections represent a collection of uniquely educational electron microscopic images that offer insights into the mechanisms of neural blockade, causes of failures and the anatomical basis for vulnerability of neural structures to anesthesiology interventions. I believe that these sections and their timeless images will be remain relevant for generations of students to come.

The section on pharmacology features exciting information that is emerging on controlled-release local anesthetics that extend the analgesic benefits of neural blockade. New knowledge on this topic is being published as this textbook is being printed; the reader is suggested to check the latest relevant literature to complement the information that was available at the time of publication.

The section on equipment for peripheral nerve blocks features an expanded chapter on new equipment, such as the development of needles and catheters and novel equipment for needle-nerve and injection monitoring. For instance, Chapter 14 gives an overview of the role of peripheral nerve stimulation in modern practice of ultrasound-guided peripheral nerve blocks and step-by-step algorithms to facilitate understanding of this often-confusing topic.

New to the second edition is an entire section on patient management considerations and regional anesthesia pathways. In Chapter 15, Dr Barrington's team contributes a didactic outline of the steps and processes toward evidence-based clinical pathways that incorporate big data, such as building pathways for specific surgical populations. The section also features two chapters on the effect of local anesthetics and regional anesthesia on cancer recurrence. The immune system and how it can be influenced by surgery and anesthesia are evaluated for possible mechanisms by which regional anesthesia could confer benefits in patients with cancer in Chapters 17 and 18.

Part 3B discusses the clinical practice of regional anesthesia, starting with local and infiltration anesthesia. Dr Raeder's team describes the use of local anesthetics for intra-articular and periarticular infiltration (Chapter 19), and Dr Imran Ahmad shares a wealth of clinical and teaching experience on the use of local anesthetics and ultrasound technology for airway management (Chapter 20).

Intravenous regional (Bier) blocks are still practiced worldwide. A revised chapter on intravenous regional anesthesia for upper and lower extremity surgery was contributed by Dr Alon Winnie and his former students. The chapter features an updated reference list and step-by-step guidance for clinical practice.

In Part 3C, the chapters on neuraxial and epidural anesthesia have been thoroughly updated and feature a wealth of anatomical, practical, and clinical considerations, including complications and their management. A new chapter on the etiology and management of failed spinal anesthesia is highly practical and will be of interest to both students and practitioners of anesthesiology (Chapter 23A). The chapter on epidural anesthesia contributed by Drs Toledano and Van de Velde features vast amount of physiologic, pharmacologic, and practical management information, and it is a good example of the efforts invested in making this edition of the textbook up-to-date.

Chapter 27 on postdural puncture headache now includes a number of electron microscopic images that facilitate understanding of the underlying pathophysiology and instructional diagrams that guide treatment.

Part 3D focuses on the latest techniques and information pertaining to ultrasound-guided nerve blocks. Beginning with equipment and the physics behind image optimization and artifact reduction, the chapters progress to the practical aspects of ultrasound-guided techniques for peripheral nerve blocks of the upper and lower extremities (Chapters 33A–33H) and for truncal blocks (Chapters 34 and 35). The techniques of locoregional anesthesia for maxillofacial and eye surgery have also been updated with highly illustrative, all-new NYSORA illustrations that we developed over the past 3 years. Chapters 39 and 40 focus on ultrasound imaging of the paravertebral and neuraxial space.

The sections on pediatric regional anesthesia and the utility of ultrasound have been greatly expanded by some of most respected practitioners and educators in pediatric anesthesiology and perioperative care.

Part seven features updated and much expanded chapters on the practice of regional anesthesia in patients with specific considerations and comorbidities.

The etiology of and avoiding complications of regional anesthesia are topics of great interest for practitioners of regional anesthesia. Part 9 discusses the mechanisms of and evidence-based recommendations on how to improve the management of patients with neurologic complications, including sections on advances in monitoring and medicolegal documentation.

Medical care is increasingly driven by evidence-based and cost-effectiveness considerations. Consequently, several chapters address the principles of pharmacoeconomics as they relate to regional anesthesia, rehabilitation, and postoperative outcome.

Part 12 of the book discusses the principles and practice of acute pain management, organization of the acute pain service, the role of intravenous patient-controlled analgesia and perineural catheters, and the epidemiology of pain. Special consideration was given to multimodal analgesia and pharmacologic interventions that increase patient's experience of anesthesia and surgery may have a role in preventing persistent postoperative pain (Chapter 75).

Part 13 focuses on education in regional anesthesia and the development of regional anesthesia fellowship programs in the United States.

Although the current trend toward ultrasound guidance is likely to become the most prevalent method of delivering most regional anesthesia techniques in the developed world, surface-based and electrical nerve stimulation techniques will likely continue to be practiced in many geographic areas without expertise ultrasound equipment. Because this edition was envisioned as a standardized text for global education in regional anesthesia and acute pain medicine, for completeness we opted to include principles of peripheral nerve blockade without ultrasound guidance (Part 15). These sections have been thoroughly updated from the previous edition, many practice updates being adopted from what we have learned utilizing ultrasound guidance. These chapters also include fascinating historical perspectives on the development of peripheral nerve block techniques throughout decades passed and how advances in anatomical, pharmacologic, and equipment influenced the their developments. The chapters also contain a wealth of anatomical information, teaching diagrams, and illustrations that add meaningful value to this textbook regardless of the needle guidance and techniques methods.

Finally, the book features two practical appendices. Appendix 1 contains a pragmatic guide for the use of regional anesthesia in the anticoagulated patient adopted for practices in Europe. The Appendix 2 illustrates the principles of disposition of injectates in tissue sheaths in common regional anesthesia techniques, contributed by a true pioneer in this area, Dr Philippe Gautier (BE).

No book is complete or without unavoidable errors regardless of the efforts invested. However, I believe that we have put together one of the most comprehensive texts on regional anesthesia and pain medicine to date and have spared no efforts to accomplish this. I thank and sincerely congratulate all collaborators and cordially invite readers to send along any discrepancies or suggestions to ana.lopez.517@gmail.com. As with the first edition, we will do our best to use the feedback to improve the textbook in a future edition to come a few years from now.

Respectfully,
Prof. Admir Hadzic

ACKNOWLEDGMENTS

Writing a textbook is an overwhelming endeavor; only those who have undertaken the work on a book can understand the efforts and the sacrifice that it entails. Throughout the couple of years it took to compile the new information and collaborate with such a large group of opinion leaders, researchers, and educators, a number of outstanding individuals were crucial to its successful completion.

Sincerest appreciation to my wife, life and work partner, Dr Catherine Vandepitte, without whose wisdom, advice, and esthetic guidance this book would not see the light of the day.

Huge thanks go to NYSORA's incredible illustrator, Vali Lancea. Thank you to Dr Monika Golebiewski's impeccable organizational skills, eye for detail, and beyond-describable work ethics, Monika was truly instrumental in tying the loose ends in the final push to complete this project.

A big thank you to the entire NYSORA support team: NYSORA-Europe, NYSORA's new CREER (Center for Research, Education, and Enhanced Recovery); our top surgeons and nurses at ZOL Anesthesiology; and more. Many thanks to Dr Alex Visan for his advice on the economics of regional anesthesia as well. Thank you to all current and former NYSORA fellows who have inspired much of the work.

The current NYSORA-Europe research team deserves a resounding thank you: Ingrid Meex, Gulhan Ozyurek, Aysu Emine Salviz, Marijke Cipers, Max Kuroda, and Greet Van Meir. You really rock!

Finally, thank you to the amazing managing editor, Brian Belval; your professionalism, common sense, and experience have provided the crucial guidance for this book to come together. Combined with co-managing editor Christie Naglieri, the production supervisor Catherine H. Saggese, and production manager Sonam Arora, we had the best team possible to make this book the gold standard it inspires to be.

Prof. Admir Hadzic

HISTORY

This page intentionally left blank

CHAPTER 1

The History of Local Anesthesia

Alwin Chuan and William Harrop-Griffiths

INTRODUCTION

The history of local anesthesia lacks a distinct *Eureka moment.* It can be argued that regional anesthesia does not have in its history a pivotal day that signified the wholesale change from an era before local anesthesia to the dawn of a new and wonderful age that included parts of the body being rendered insensate for therapeutic reasons. We do not have the equivalent of October 16, 1846, and the trembling hands of William Thomas Green Morton. What we have is a remarkably slow concatenation of the three elements necessary for the administration of the vast majority of local anesthetics: a syringe, a needle, and a local anesthetic drug. Many, however, would argue that to these three need be added several other factors: a detailed knowledge of anatomy and an appreciation of the body's pain mechanisms and more objective methods to localize peripheral nerves and monitor administration of local anesthetics. We make no excuse for concentrating in this chapter on the early history of local anesthesia to dissect the development of these three vital components.

BEFORE COCAINE

The origins of the first attempts at some form of local analgesia or anesthesia are lost in the mists of time. Direct nerve compression and the direct application of ice to peripheries before surgery have distant origins but were certainly in regular use from the latter half of the eighteenth century. The first detailed appreciation of the benefits of local anesthesia was written by James Young Simpson and published in 1848, decades before local anesthesia became a practical possibility (Figure 1–1). In this paper, he also described his own unsuccessful experiments with the topical application of a variety of liquids and vapors in an attempt to produce local anesthesia. The paper was published less than 2 years after Oliver Wendell Holmes had coined the term *anesthesia,* and it therefore almost certainly represents the first use of the term *local anesthesia,* although Simpson would have used the (arguably more correct) English spelling *anaesthesia.* However, Simpson was well aware that his were far from the first attempts to produce peripheral insensibility, for he refers to some ancient methods, which he considered "apocryphal," and also to Moore's method of nerve compression (Figure 1–2).[1]

Another distinguished British physician and president of the Medical Society of London in 1868 was Sir Benjamin Ward Richardson. He spent many years in the attempt to alleviate pain by modifying substances capable of producing general or local anesthesia. He brought into use no fewer than 14 anesthetics and invented the first double-valved mouthpiece for the administration of chloroform. He initially experimented with electricity before turning to the effects of cold as an anesthetic. Cold was known to produce a numbing effect and was used as far back as Napoleon's time when his surgeon, Baron Larrey, used its effects to alleviate pain. He introduced a method of producing local insensibility by freezing the part with an *ether spray,* which became the most practical method of using local anesthesia until cocaine's actions became apparent. The ether spray was utilized as a local agent until it was replaced in 1880 by ethyl chloride[2] (Figure 1–3).

COCAINE ANESTHESIA

The Origins

If local anesthesia has a Eureka moment, then it may have happened in the forests of South America. Centuries ago, an unnamed inhabitant of these climates may have been experimenting by putting leaves of various plants into his mouth and giving them a good chew. We can imagine that this would be a largely unrewarding hobby, but let us focus on the moment when he first placed a coca leaf into his mouth and masticated

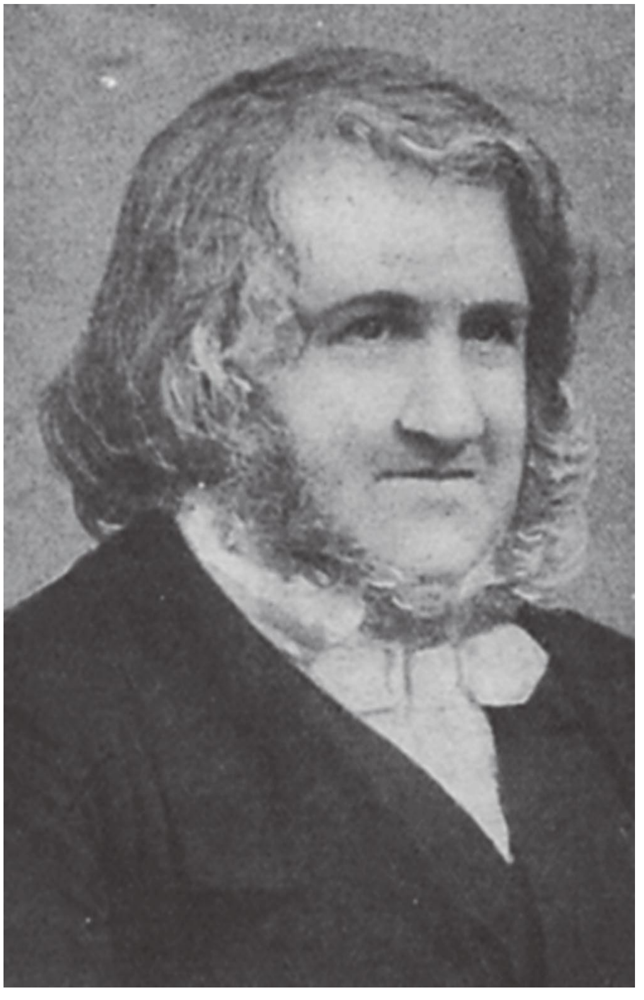

FIGURE 1–1. James Young Simpson.

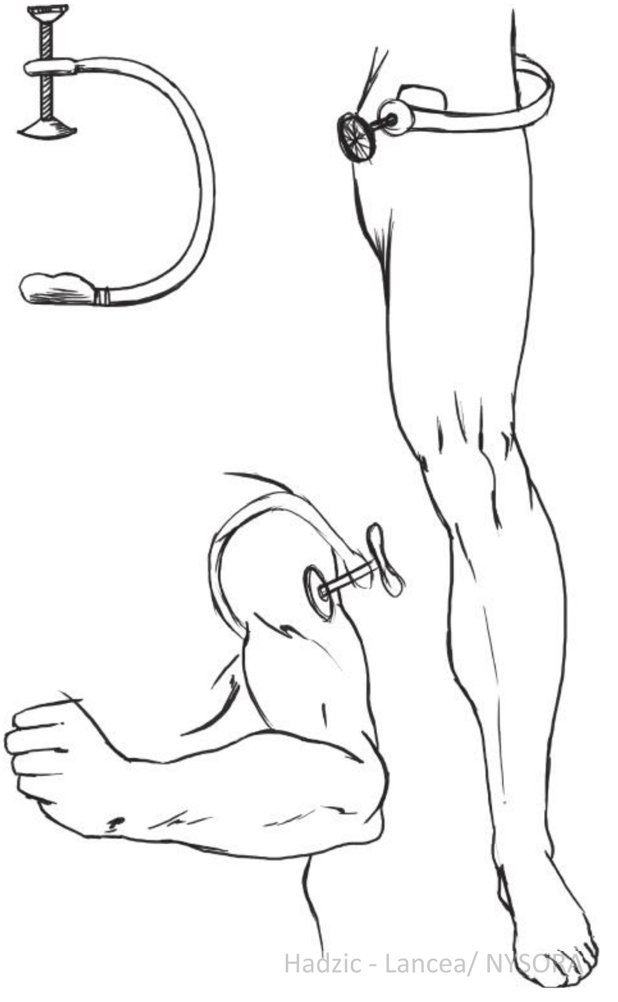

FIGURE 1–2. Nerve compression technique.

vigorously. Did he fall to his knees and shout in wonderment: "My lips have gone numb—surely this is the dawn of a new age of painless surgery!"? Almost certainly not—although he might have later told his friends that he felt somewhat excited, energetic, and euphoric while he chewed the leaves.

For thousands of years, South American peoples have chewed the coca leaf. It is a remarkable plant in that it contains vital nutrients as well as numerous alkaloids, most notably cocaine. The coca leaves are taken from a shrub of the genus *Erythroxylon coca,* named by Patrico Browne because of the reddish hue of the wood of the main species.[3] Many species of this genus have been grown in Nicaragua, Venezuela, Bolivia, and Peru since pre-Columbian times. *Erythroxylon coca* contains the highest concentration of the alkaloid known as cocaine in its leaves[3,4] (Figure 1–4).

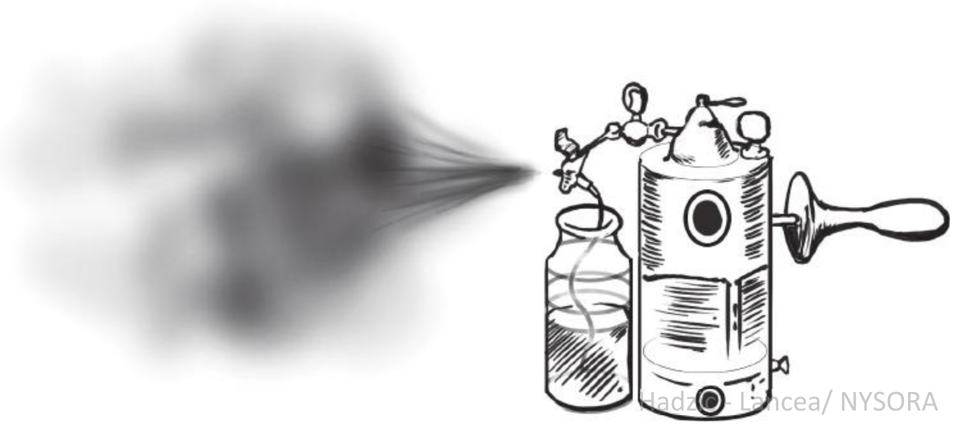

FIGURE 1–3. Ether spray.

FIGURE 1–4. Coca leaf.

Traditionally, the leaves were chewed for social, mystical, medicinal, and religious purposes. The Florentine cartographer Amerigo Vespucci (1451–1512) was arguably the first European to document the human use of the coca leaf.[5,6] In his account of his voyage to America on the second expedition of Alonso de Ojeda and Juan de la Cosa from 1499 to 1500, he reported that the inhabitants of the Island of Margarita chewed certain herbs containing a white powder.[7] Among sixteenth-century Spanish chroniclers, the appearance of coca is associated with Francisco Pizarro's (1475–1541) conquest of the Inca or Tawantinsuyo Empire in 1532. Pedro Pizarro (1515–1571), Francisco Pizarro's cousin, who played a leading role in the capture of the last king of the Incas, described coca consumption by the nobles and high officials of the Inca Empire.[8] After the fall of the Inca Empire in the early 1500s, coca consumption spread to the population at large, creating a drastic change in the entire social system.

When the Spaniards conquered South America, they initially ignored the aboriginal claims that the leaf gave them vigor and liveliness. They self-righteously declared the practice of chewing the leaf the "work of the Devil."[5] But, once they found that the claims of the natives were true, they not only legalized the leaf but also taxed it—taking 10% of the value of each crop. The taxes were then used to support the Roman Catholic Church—the main source of revenue for the church to thrive. In 1609, Padre Blas Valera wrote: "Coca protects the body from many ailments, and our doctors use it in powdered form to reduce the swelling of wounds, to strengthen broken bones, to expel cold from the body or prevent it from entering, and to cure rotten wounds or sores that are full of maggots. And if it does so much for outward ailments, will not its singular virtue have even greater effect in the entrails of those who eat it?"[9] If the padre had been blessed with the ability to foresee the future, perhaps his enthusiasm would have been redirected toward limiting the use of the leaf, and the field of anesthesia might have taken a different turn.

Another member of the clergy, Bernabé Cobo, who spent his life bringing Christianity to the Incas, was the first to describe the anesthetic effects of coca. In a 1653 manuscript, he mentioned that toothaches could be alleviated by chewing the coca leaves. In 1859, an Italian physician by the name of Paolo Mantegazza had witnessed the use of coca by the natives in Peru. He wrote a paper describing the medicinal use in the treatment of "a furred tongue in the morning, flatulence and whitening of the teeth."[10]

Needles and Syringes

If local anesthetic drugs are the bullets used when fighting pain, the gun needed to fire these bullets is made up of a syringe and a needle. Without the bullets, the gun is useless, and just as certainly, without the gun, the bullets will have little effect. The development of the hypodermic syringe and needle was therefore an important prerequisite for the use of cocaine for anything but topical application. A thorough sifting of the available historical evidence and independent reexamination of the sources support the following outline of the facts: In 1845, Francis Rynd described the idea of introducing a solution of morphine hypodermically in the neighborhood of a peripheral nerve to alleviate neuralgic pain.[11] He introduced the solution by means of gravity, passively through a cannula once the trocar had been removed.

Several centuries passed before the development of a syringe to deliver medicine was described by Alexander Wood (Figure 1–5). Wood, a contemporary of James Young Simpson, in 1855 was the first to combine needle and syringe for hypodermic medication. He used the equipment manufactured by a gentleman by the name of Ferguson, who had developed the graduated glass syringe and hollow needle for the purpose of treating aneurysms by injecting ferric perchloride into the aneurysm to form a coagulated mass. Wood, a physician interested in the treatment of neuralgia, reasoned that morphine might be more effective if it were injected close to the nerve supplying the affected area. Although morphine may have some peripheral actions, and the effect of Wood's morphine was almost certainly central, he was nevertheless the first to think of the possibility of producing nerve blockade by direct drug injection. Thus, he has been called the "father-in-law" of local anesthesia—all he lacked was an agent that worked locally. Wood's contribution was therefore his procedure of subcutaneous injection. This technique was subsequently adopted by C. Hunter and renamed hypodermic injection, presumably because Hunter's purpose was to provide systemic absorption of medications injected.[12,13]

The Introduction of Cocaine

The growth in Western science and technology exploded during the nineteenth century. Six years after Charles Darwin's controversial book, *On the Origin of Species by Means of Natural Selection,* Joseph Lister was an important figure in changing the face of surgery. He applied Pasteur's principles of bacterial growth in eliminating sepsis in the operating theatre. Other prominent figures contributed to the understanding of human physiology, such as Sydney Ringer's discovery of the need for calcium and potassium to maintain cardiac excitability, significantly advancing medical care. And then—there was cocaine.

Although the stimulant and hunger-suppressant effects of coca had been known for years, the isolation of the cocaine alkaloid was not achieved until 1855. Scientists attempted to isolate cocaine, but no one was successful for two reasons: Coca did not grow in the colder environment of Europe, and the chemistry involved was unknown at that time. Finally, in 1855, the German chemist Friedrich Gaedcke was able to isolate the cocaine alkaloid and publish the description in the journal *Archiv der Pharmacie*. In 1856, Friedrich Wöhler asked a colleague to bring him a large amount of coca leaves from South America. Wöhler then gave the leaves to Albert Niemann, a PhD student at the University of Göttingen in Germany, who then developed an improved purification process. His dissertation, *On a New Organic Base in the Coca Leaves,* published in 1860, earned him his doctoral degree. Of interest, he described cocaine as having "a bitter taste, promotes the flow of saliva, and leaves a peculiar numbness, followed by a sense of cold when applied to the tongue."[14,15]

Following Niemann, the first experimental study on cocaine was conducted by a former naval surgeon from Peru, Thomas Moreno y Maiz. He discovered that the injection of cocaine solutions caused insensitivity in rats, guinea pigs, and frogs. But, it was not until 1880, when Basil Von Anrep experimented on himself, that the application of cocaine for surgery was appreciated. Von Anrep injected a small amount of cocaine under the skin on his arm and noted that the area became insensitive to pinpricks. He did the same to his tongue with the same effect. He published his findings with the caveat "the animal experiments have no practical application; nevertheless I would recommend trying cocaine as a local anesthetic in persons of melancholy disposition."[16]

The groundwork was in place, but the final step toward the clinical use of cocaine had yet to be taken. Viennese ophthalmologist Karl Koller (1857–1944) rose to the challenge (Figure 1–6). Koller was an intern working in the Viennese General Hospital, where he was befriended by Sigmund Freud[17] (Figure 1–7). Freud wanted to know more about the stimulating action of cocaine, which he hoped might prove useful in curing one of his close friends of morphine addiction. This friend was a pathologist and had developed an agonizingly painful thenar neuroma secondarily to cutting himself during the performance of an autopsy. Freud was able to obtain a supply of cocaine from the pharmaceutical firm Merck. He shared it with Koller, who during the spring of 1884 helped him investigate its effects on the nervous system.[18]

Koller had dreams of achieving an appointment to assistant and knew his chances would be greatly enhanced by the creation of a respectable piece of research. The research he produced proved worthy enough, but interpersonal animosity intervened, and he was not awarded the position. Deeply disappointed, he moved first to the Netherlands, then to the United States.[19] In July 1884, Freud published a review of

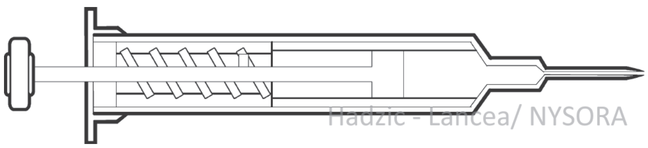

FIGURE 1–5. Early syringe.

FIGURE 1–6. Carl Koller.

cocaine and his experiments with the drug, again noting, but without lending any particular attention to, the alkaloid's anesthetic effect on mucous membranes.[20] It was Koller who grasped the importance of this observation. His discovery was no accident, for he was keenly aware of the limitations of general anesthesia in ophthalmic surgery. Because of his past experience in the field of ophthalmology, Koller understood what others had failed to recognize. Many eye surgeries at that time were still being performed without anesthesia. Almost four decades after the discovery of ether, general anesthesia by mask had a number of limitations for ophthalmic surgery (eg, the anesthetized patient could not cooperate with the surgeon, the anesthesiologist's apparatus interfered with surgical access). At that time, many surgical incisions in the eye were not closed, as fine sutures were not yet available. Vomiting from chloroform or ether threatened to cause extrusion of the internal contents of the globe, markedly increasing the risk of permanent blindness. As a medical student, Koller had worked in a laboratory searching for a topical ophthalmic anesthetic to overcome the restrictions posed by general anesthesia. The medications available at that time had proved to be ineffective.

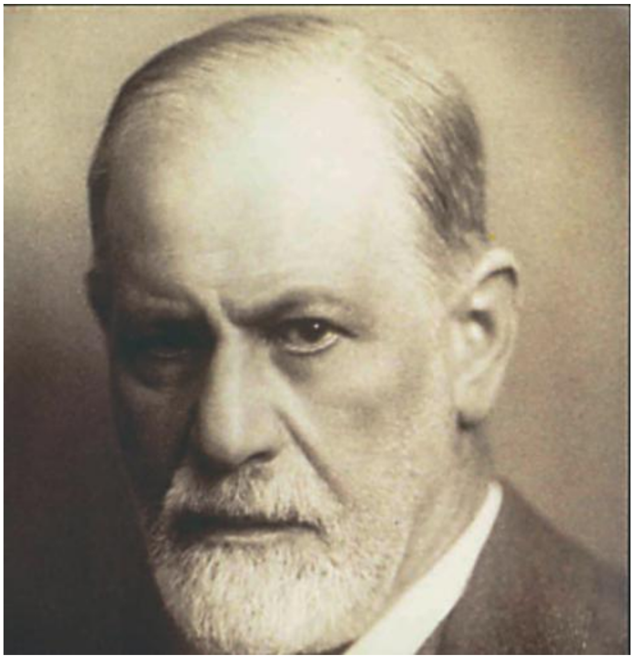

FIGURE 1–7. Sigmund Freud.

One day, Freud gave Koller a small sample of cocaine in an envelope, which he slipped into his pocket (an everyday occurrence in many American and European cities to this day). When the envelope leaked, a few grains of cocaine stuck to Koller's finger, which he casually licked with his tongue. His tongue became numb—if he had been able to mouth the word *Eureka* with a numb tongue, he may well have done so at this precise instant. At that moment, Koller realized that he had found what he had been searching for. He immediately created a suspension of cocaine crystals in his laboratory.[2] Koller realized that this had been noted by all who had worked with cocaine and that "in the moment it flashed upon me that I was carrying in my pocket the local anesthetic for which I had searched some years earlier."[1] In Freud's absence, he and another colleague, Joseph Gartner, dissolved a trace of the white powder in distilled water and instilled the solution into the conjunctival sac of a frog. After a minute or so, "the frog allowed his cornea to be touched and he also bore injury to the cornea without a trace of reflex action or defense." Koller wrote: "One more step had yet to be taken. We trickled the solution under each other's lifted eyelids. Then we placed a mirror before us, took pins, and with the head tried to touch the cornea. Almost simultaneously we were able to state 'I can't feel anything.'"[21,22] Then, he experimented with dog and guinea pig corneas with 2% to 5% cocaine solutions.[23]

Koller soon achieved the extraordinary notoriety he had longed for when in September 1884 he performed the first ophthalmologic surgical procedure using local anesthesia on a patient with glaucoma. The German Ophthalmologist Society Congress was to meet in Heidelberg in September 1884 and Koller was going to present his findings. Unfortunately, he was unable to attend. He asked Dr. Joseph Brettauer, an ophthalmologist from Trieste, to present his paper at the Congress. The effect of his work was immediate. Koller was able to present his findings in October of that year to the Viennese Medical Society. In late 1884, he published his findings.[21]

Physicians in the United States soon heard about Koller's amazing work. Dr. Henry Noyes of New York, an attendee of the Heidelberg Congress, published a summary of Koller's work in the *New York Medical Record*.[24] Another American physician, Dr. Bloom, translated Koller's article into English and published it in *The Lancet* in December of that same year. Koller's work was the trigger for the development of regional/local anesthesia. In the subsequent year, more than 60 publications on local anesthesia with cocaine appeared in the United States and Canada.

One of the most significant publications was that of N. J. Hepburn, an ophthalmologist from New York.[15] Self-experimentation was the standard for drug trials in those days.

To determine whether a drug was safe or effective, the researcher or physician commonly tried the drug personally. It takes courage to try a new drug on a patient, but it takes a particular and much greater form of courage to try that drug on yourself. Hepburn was no different from his colleagues. He gave himself a succession of subcutaneous injections of 0.4 mL (8 mg) of cocaine at 5-min intervals. By the eighth injection, the stimulating effects of the drug were strong enough that he decided it was best to stop. Unfortunately, Hepburn did not stop with those initial injections. He repeated the "experiment" 2 days later and 4 days after that, each time increasing the total amount of cocaine injected. Most likely by this time, he was hopelessly addicted.

By November 1884, the ophthalmologist C. S. Bull reported that he had been able to use cocaine to produce anesthesia of the cornea and conjunctiva in more than 150 cases.[25] He was enthusiastic about the advantages of the drug in that he saved time required for complete anesthesia with ether; patients were less nauseated, the engorgement of the ocular blood vessels (caused by ether) was eliminated, and he was less hampered by the anesthesia equipment required for inhalation anesthesia. Cocaine revolutionized eye, nose, and mouth surgery. Operations that had been exceedingly difficult or painful became routine when topical or injectable cocaine was used. Koller did not forget the contribution of his friend, Freud. He gave him the credit as his muse. Despite his disillusionment at not being foremost with the discovery, Freud is considered by many to be the founder of psychopharmacology because of his initial use of cocaine. He is considered the predecessor in the discovery and experimentation with mescaline, LSD, and amphetamines to modify behavior and to attempt to cure mental illness.[20]

Dangers of Cocaine

The "wonder drug" cocaine was soon sold everywhere and in almost everything. Following its isolation from the coca leaf, cocaine emerged as an ingredient in wine both in the United States and in Europe in amounts up to 7 mg/oz. In the original recipe for Coca-Cola (1866), coca leaves were included in the ingredients. It was not until 1906 when the Pure Food and Drug Act was passed that the Coca-Cola company began using decocainized leaves.[14] Until 1916, cocaine could be purchased over the counter at Harrods in London. It was found in tonics, toothache cures, and medicines (Figure 1–8). Coca cigarettes were sold with the promise of lifting depression. Those who purchased cocaine were promised in ads by the pharmaceutical firm Parke-Davis that it could "make the coward brave, the silent eloquent, and render the sufferer insensitive to pain." In the operatic world, it became commonplace to use cocaine to ease the pain of sore throats and to shrink nasal mucous membranes to enable the singers to improve the resonation of their voices.

Had cocaine's use been restricted to enhancing opera singing and local anesthesia, it would have become the achievement of nineteenth-century medicine. As had happened earlier with brandy, tobacco, morphine, and other drugs, cocaine was administered in too high concentrations and with too few precautions. In 1886, William Hammond, a former US Army Surgeon General, assured an audience of physicians that cocaine addiction did not exist. Based on self-experimentation, he concluded that regular use of cocaine was as easy to stop as quitting coffee. It did not have the addictive qualities of drugs like opium. But, when Hammond finished his lecture, an addiction specialist named Jansen Mattison offered a rebuttal. He related incidences of fierce addictions in patients under his care. He described cocaine's damaging effect on nerves and its ability to produce hallucinations, delusions, and emaciation. Many other practitioners began to encounter serious side effects.[26,27]

Mattison knew what he was talking about. Over the next several years, medical journals published hundreds of case reports of "cocainism." Unfortunately, many of the addicts were medical practitioners who had experimented on themselves, most notably Freud and William Stewart Halsted.[28,29] The opiate

FIGURE 1–8. Cocaine toothache drops.

addicts, promised a cure for their addiction, switched to cocaine, but continued to use both drugs, further compromising their health.

Several researchers deserve the credit for making the infiltration of cocaine safer. Maximillian Oberst, Ludwig Per-nice, and Carl Ludwig Schleich, all from Germany, described the use of low concentrations of cocaine as effective means of local anesthesia.[30] The Parisian surgeon Paul Reclus described the use of very low concentrations of cocaine as effective anesthesia without harmful side effects for tooth extractions and pulpotomies.[31]

About the same time, Halsted was experimenting with low concentrations of cocaine applied by compression devices. Unfortunately, he also became addicted to both cocaine and morphine and could not publish his results.[12,17,29] Over time, the maximum "safe" cocaine dosage for infiltration anesthesia was established at 50 mg.

AFTER COCAINE

As the undesirable effects of cocaine, most notably addiction and toxicity, gradually became known, new anesthetic drugs were sought to replace it. Local methods to provide anesthesia had to await the development of less-toxic drugs. Once the clinical usefulness of cocaine became evident, efforts were made by various researchers to identify the active portion of the cocaine molecule and to create new substances that possessed local anesthetic activity without the adverse side effects. Most of the chemical work involving the creation of local anesthetics took place in Germany from 1900 to 1930.[32]

Niemann, as part of his pioneering work on purifying cocaine, had hydrolyzed benzoic acid from cocaine. In the search for other benzoic acid esters with local anesthetic properties, amylocaine (stovaine) was introduced in 1903. It became popular for spinal anesthesia until it was shown to be an irritant. But, it was the development of procaine in 1904 by the German chemist Alfred Einhorn that revolutionized local anesthetics.[33] On November 27, 1904, Einhorn (1856–1917) patented 18 *para*-aminobenzoic acid derivatives that had been developed in the Meister Lucius and Brüning plants at Höchst, in Hesse, Germany. His compound Number Two was to bring about a radical change in local anesthetic practice. He named the new anesthetic Novocain.[11] Procaine (Novocain) was introduced into clinical practice by Professor Heinrich Braun in 1905. Braun published a study comparing this new anesthetic to stovaine and alypine, two other promising local anesthetics.[34] Procaine was found to be safe and quickly became the standard local anesthetic drug. Within a short time, procaine completely replaced cocaine as the most commonly used local anesthetic. But, because of the short duration of action and prominent allergic potential limiting its clinical effectiveness, the search for longer-lasting compounds continued.[11,18,26,35]

In the years that followed, several local anesthetics were synthesized and used in clinical practice until side effects or other unfavorable characteristics were noted. In 1925, Karl Meischer synthesized dibucaine, and in 1928 Otto Eisleb synthesized tetracaine. Both were effective local anesthetics and had the desirable qualities of longer duration and potency, but systemic toxic effects limited their usefulness for regional techniques other than for spinal anesthesia. Most of the compounds developed during this time were amino ester derivatives, similar to cocaine, with similar allergic potential.

A major breakthrough came in the mid-1940s when the Swedish chemists Nils Löfgren and Bengt Lundquist developed a new local anesthetic they called lidocaine. Lidocaine was an amino amide derivative, a stable compound not influenced by exposure to high temperatures and, most importantly, one that did not have the allergic potential of the ester-type local anesthetics. With the development of this amide-type anesthetic drug, a whole new class of local anesthetics was synthesized. In 1957, Af Ekenstam developed mepivacaine and bupivacaine, and in 1969 Löfgren and Claes Tegnér developed prilocaine. Prilocaine's synthesis began because of a desire to produce a local anesthetic with a potency similar to that of lidocaine but without lidocaine's systemic toxic effects. Unfortunately, it was soon discovered that large doses of prilocaine produced a metabolite that caused methemoglobinemia. Although probably not clinically significant, this discovery severely limited its use in clinical practice.[36] In 1972, etidocaine was introduced to the clinical scene but was soon discovered to lack a differential sensory–-motor blockade. Its clinical usefulness was therefore limited.

The only new ester local anesthetic developed in more recent times is chloroprocaine. Its rapid hydrolysis reduced the possibility of systemic toxicity, but its usefulness was restricted to procedures of short duration that did not produce a high degree of postoperative pain. In modern regional practices, it has been used both in spinal anesthesia and in nerve blocks for short, relatively painless procedures.

Two goals of modern pharmaceutical research have been development of amide anesthetics with lower toxicity and modification in the delivery of local anesthetics. Levobupivacaine and ropivacaine were both introduced commercially in 1996 as purified S-enantiomers rather than racemic solutions, with less risk of cardiac and central nervous system toxicity. More recently, liposomal delivery systems that allow slow release of commonly used local anesthetics have extended the duration of effect beyond 48 hours.

LOCAL ANESTHESIA TECHNIQUES

Infiltration Anesthesia

In 1895, a then-novel approach, termed *infiltration anesthesia,* had been promoted by Karl Ludwig Schleich (1859–1922).[35] Schleich applied the principle that pure water has a weak anesthetic effect but is painful on injection, whereas physiologic saline is not. In 1869, Pierre Carl Edouard Potain first observed that the subcutaneous injection of water produced local anesthesia. Halsted, a surgeon at Roosevelt Hospital in New York City, in a frank letter to the editor of the *New York Medical Journal* in 1885, declared that the "skin can be completely anesthetized to any extent by cutaneous injections of water."[37] In his own practice, Halsted had begun using water instead of cocaine in skin incisions, noting that the anesthesia did not subside completely when hyperemia reappeared.

In the belief that there was a solution capable of performing as a useful anesthetic that would not cause pain on injection, Schleich mixed 0.2% sodium chloride with 0.02% cocaine.

He used the mixture to produce cutaneous anesthesia for sebaceous cystectomy, hemorrhoidectomies, and small abscesses. Although Braun dismissed Schleich's solutions as "nonphysiologic," Schleich's work was important in advancing the application of small quantities of local anesthetics for surgical procedures. Because of the reported serious toxic reactions and fatalities reported with cocaine, enthusiasm for the utilization of local anesthesia had waned considerably. Paul Reclus undoubtedly understood that the cause of death from local anesthetics was related to overdose. He was able to demonstrate that absorption could be limited with lower concentrations of cocaine, a fact that Schleich obviously supported and implemented.[31] Schleich's approach still seems to be relevant, particularly with the recent European enthusiasm for *tumescent anesthesia,* in which sometimes-huge volumes of very dilute local anesthetic are used for surface surgery.

Conduction Anesthesia

With the excitement generated by Koller's report of cocaine anesthesia in 1884, several US surgeons concurrently entertained the idea of injecting cocaine directly into tissues to render them insensitive. William Burke injected five drops of 2% cocaine solution close to a metacarpal branch of the ulnar nerve and then painlessly removed a bullet from the base of his patient's little finger.[38] However, it was William Stewart Halsted (1852–1922; Figure 1–9) and his associate John Hall at Roosevelt Hospital in New York City who most clearly saw the great possibilities of conduction block.[39] Hall experimented on himself by blocking a cutaneous branch of the ulnar nerve in his own forearm.[41] He and Halsted did not stop with upper extremity injections; they also successfully injected the musculocutaneous (superficial peroneal) nerve of the leg. Hall described the manifestation of systemic symptoms such as giddiness, severe nausea, cold perspiration, and dilated pupils, but these symptoms did not stop these daring scientists from further self-experimentation. Halsted blocked Hall's supratrochlear nerve to remove a congenital cystic tumor. One can assume that both Halsted and Hall had run out of minor surgical ailments in themselves and therefore had to look to others on whom they could experiment. In the days long before ethics committees and informed consent, one is tempted to speculate about the true "volunteer" status of the poor, and most likely unsuspecting, medical students. Hall's report was unequivocal in predicting that this mode of administration of cocaine would find wide application in outpatient surgery once the limits of safety had been determined—remarkably prescient of him.[40]

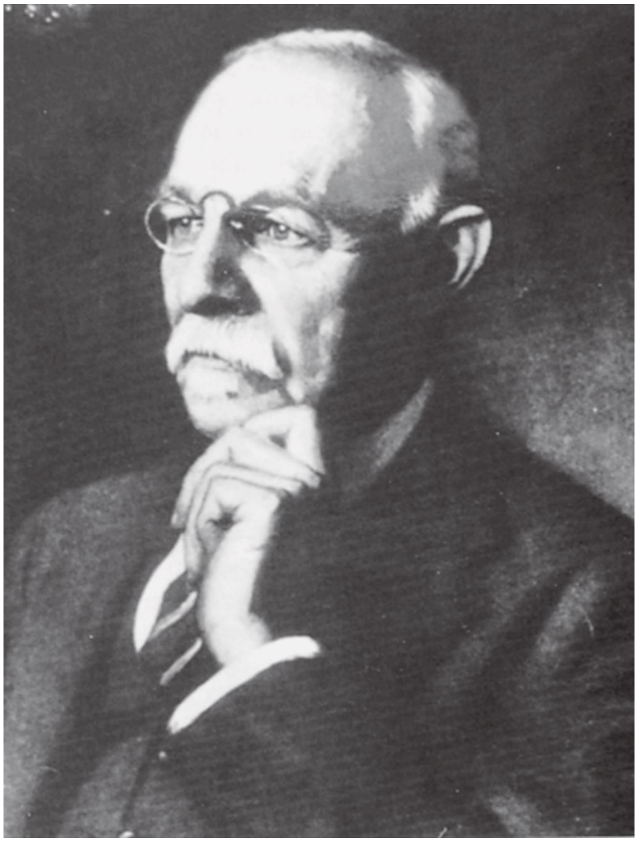

FIGURE 1–9. William Stewart Halsted.

Although the conduction blocks were successful, unfortunately, several members of their group became addicted to cocaine. No further publications about the usefulness of cocaine anesthesia for surgical procedures were presented. It is one of the great sadnesses of the development of analgesic drugs in the history of humankind that two of the most effective agents, morphine and cocaine, are wickedly addictive. They deprived medicine of many of the potential discoveries of its most gifted sons and daughters. However, that Hall and Halsted were the true progenitors of conduction anesthesia can scarcely be doubted.[17,26]

In 1891, François-Franck was the first to apply the term *blocking* to the infiltration of a nerve trunk in any part.[41] He correctly discovered that the effect of the blocking drug was not limited to sensory fibers, but provided blockade of all nerves, both motor and sensory. He noted that sensory anesthesia became apparent more rapidly than the motor paralysis, a fact confirmed by von Anrep's 1880 observations.[16] François-Frank described the action of cocaine as transitory and noninjurious, "physiologic and segmental" anesthesia. He may well have borrowed part of it from J. Leonard Corning, who in 1886 wrote that "the thought of producing anaesthesia by abolishing conduction in sensory nerves, by suitable means, should have been rife in the minds of progressive physicians."[42] Corning most likely got the idea from Halsted because he had frequently observed Halsted and Hall's work at Roosevelt Hospital in New York.

The advantage of utilizing cocaine as a local anesthetic was that it anesthetized only the section of the body where surgery was to be performed, the goal of regional techniques in modern practice. But, the price to be paid was in the duration of action and toxicity, not to mention the more commonly recognized problem of addiction. The dose of cocaine was limited to 30 mg because of rapid absorption. Unfortunately, the duration of anesthesia was therefore no more than 15 minutes. Corning, in 1885, began researching means of prolonging the local anesthetic action of cocaine for surgery. He believed that once cocaine was injected beneath the skin, capillary circulation was responsible for distributing, diluting, and removing the anesthetic substance. In one experiment, he injected 0.3 mL of a 4% solution of cocaine into a cutaneous nerve of the arm and produced immediate anesthesia of the skin of the forearm. By compressing the extremity proximal to the site of injection with an Esmarch bandage, he was able to intensify and prolong the anesthesia to the forearm.[43]

Corning's successes with prolonging the action of local anesthetic with a physical tourniquet inspired Heinrich F. W. Braun to substitute epinephrine, a "chemical tourniquet," for the Esmarch tourniquet.[44] John Jacob Abel had isolated the pure form from the suprarenal medulla in 1897, and it had been subsequently used in ophthalmology to limit hemorrhage and in the treatment of glaucoma.[45] During its use in ophthalmology and subsequently in ear, nose, and throat surgeries, it was discovered that epinephrine prolonged the effect of cocaine, thereby allowing a reduction in dose and limiting side effects. Braun determined the optimal solution of epinephrine with cocaine by once again experimenting on himself. He discovered that the maximal dose that he could tolerate without side effects was 0.5 mg (0.5 mL of a 1:1000 solution of epinephrine). He coined the term *conduction anesthesia* when publishing the results of his experimentation.[46]

Intravenous Regional Anesthesia

The first reported use of intravenous regional anesthesia (IVRA) can be traced back to August Karl Gustav Bier (Figure 1–10), the originator of the infamous **Bier block**. Bier, a German surgeon (1861–1949), influenced surgery, anesthesia, and general medicine with his contributions through the decades. IVRA was first described by Bier in 1908. His method consisted of occluding the circulation in a segment of the arm with two tourniquets. He then injected a solution of dilute procaine through a venous cutdown in the isolated segment. The injected solution diffused through the entire section of the limb quickly, producing **direct vein anesthesia** in just a few minutes.[47] The anesthesia lasted as long as the upper tourniquet was in place. Recovery of sensation was rapid after the tourniquet was removed.[48] Despite his successes, IVRA was not widely used until the technique was reintroduced in the 1960s by C. M. Holmes.[49]

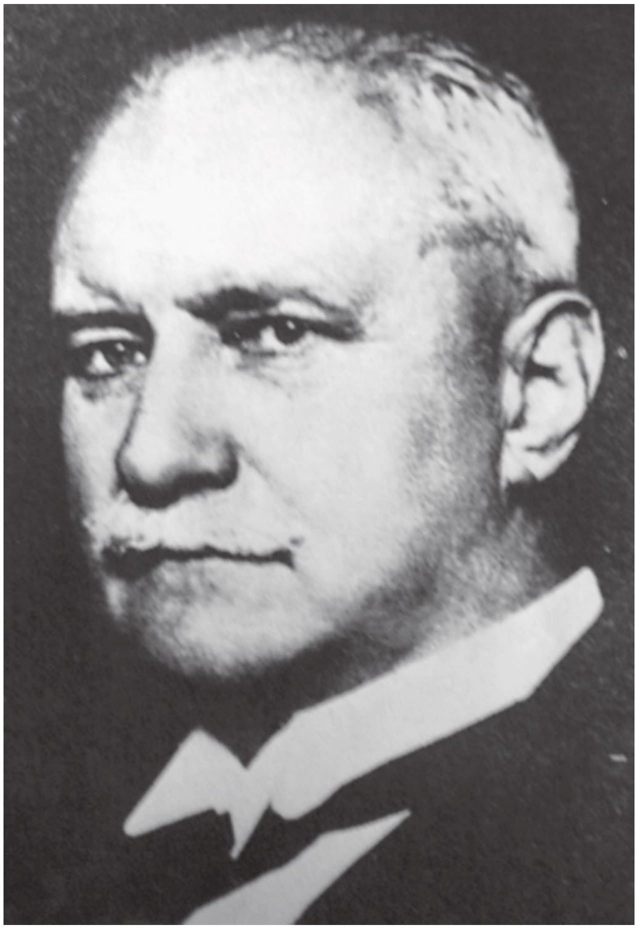

FIGURE 1–10. August Bier.

Spinal Anesthesia

Soon after its introduction in 1884, local anesthesia became popular with surgeons, particularly those in France, Germany, and the United States.[18] This was in large part due to concerns about the safety of inhalational anesthesia, which, increased by the introduction of chloroform, had given rise to significant worries about toxicity. General anesthetic mortality was high at this time, and there was a distinct shortage of personnel trained to administer general anesthesia.[50] In a bizarre twist, the first spinal anesthetic was given some 5 years before the first lumbar puncture. The term *spinal anesthesia* was introduced by Corning, a neurologist, in his famous paper of 1885: "Spinal Anaesthesia and Local Medication of the Cord With Cocaine."[42] He theorized that interspinal blood vessels would carry the local anesthetic (cocaine) via communicating vessels into the spinal cord. He did not mention anything about cerebrospinal fluid or the depth of the needle insertion into the spinal space. It is speculated that he was aiming directly at the spinal cord as he introduced a needle between the 11th and 12th vertebrae. In his paper, he wrote: "I reasoned that it was highly probably that, if the anesthetic was placed between the spinous processes of the vertebrae, it would be rapidly transported by the blood to the substance of the cord and would give rise to anaesthesia of the sensory and perhaps also of the motor tracts of the same. To be more explicit, I hoped to produce artificially a temporary condition of things analogous in its physiological consequences to the effects observed in transverse myelitis or after total section of the cord."[42]

Corning's report was based on a series of two injections: one human and one animal (a dog). After first assessing its action in a dog, producing a blockade of rapid onset that was confined to the animal's rear legs, he administered cocaine to a man who was "addicted to masturbation." It may be that many anesthesiologists have spent much time wondering whether masturbation played any role in local anesthesia—this question can now be answered in the affirmative. Corning administered one dose without effect, and then, after a second dose had been given, the patient's legs "felt sleepy." The man had impaired sensibility in his lower extremity after about 20 minutes. He left Corning's office "none the worse for the experience"—although this experience itself may well have put him off his penchant for onanism. Corning had injected a total of 120 mg of cocaine, about four times the potentially lethal dose, in a period of 8 minutes.

What he achieved in this patient was probably what is now called *epidural,* or *extradural,* anesthesia. The dog probably received a spinal anesthetic with approximately 13 mg of cocaine, as judged by the rate of onset described.

Although Corning most assuredly had an innovative idea, his results were not more than a lucky accident because he injected a fatal dose of cocaine into the man. A direct communication between the extradural capillaries and the spinal cord does not exist. Based on the education that Corning received at the time, he was probably unaware of the existence of the subarachnoid space and cerebrospinal fluid.

Lumbar Puncture/Spinal Anesthesia

Heinrich Irenaeus Quincke (**Figure 1–11**) is credited with the introduction and popularization of the lumbar puncture. It was developed as a treatment for hydrocephalus in children with tubercular meningitis, then later as a diagnostic method for certain central nervous system diseases.[51] He based his approach on sound anatomic knowledge of the subarachnoid space and spinal cord. He used needles with an internal diameter of 0.5 to 1.2 mm and entered the subarachnoid space via a paravertebral approach. Interestingly, he prescribed bed rest for 24 hours following the puncture.

Despite the strides made by Quincke, utilizing his technique for spinal anesthesia did not occur for 8 years after Quincke's first publication. Bier published his renowned paper on spinal anesthesia in 1899. Bier had the good fortune to work at the same institution as Quincke and was most likely familiar with his work. His intention was to use spinal anesthesia with cocaine for major operations. He realized that he could produce a profound block with a minimum amount of the drug, thereby eliminating the majority of the adverse side effects noted by his colleagues. In his experiments, he noted that the extent of anesthesia produced was not always predictable. As was popular with his colleagues, he experimented on himself. He had his assistant, August Hildebrandt, perform lumbar punctures on him. In the first attempt, Hildebrandt was unable to administer an appreciable amount of cocaine before a large volume of cerebrospinal fluid leaked out of Bier. Because of the poor response, they were close to abandoning the experiment. Hildebrandt then offered to be the next "guinea pig" instead. Bier successfully placed the spinal anesthetic and proceeded to "punish" Hildebrandt with blows to the tibia, pulling on his testicle, and even putting out a cigar on Hildebrandt's thigh.[52,53] Unfortunately, both men developed violent headaches that lasted for days, leading Bier to recommend the following practices that are still being followed today: preventing the excessive loss of cerebrospinal fluid, using very fine (small) needles, and following strict bed rest if significant loss of cerebrospinal fluid cannot be avoided.[54] Intelligent prescience was at work again.

Bier was able to demonstrate that small amounts of local anesthetic (cocaine) injected into the subarachnoid space could provide surgical anesthesia for over 67% of the body. The anesthetic condition lasted approximately 45 minutes, an adequate time for many surgical procedures. His work provided the basis of spinal anesthesia as we practice it in modern medicine. Coincidentally, the practice of wearing rubber gloves emerged as a part of aseptic technique prior to Bier's work on spinal anesthesia, thus preventing many of the serious complications that could have occurred without this prophylactic measure.[55]

So, who deserves the laurels for the first spinal anesthetic? The history of anesthesiology is similar to that of other medical branches in that it has had its share of quarrels concerning priority. International disputes between the surgeon August Bier and his former colleague August Hildebrandt regarding the question of who was the actual inventor of spinal anesthesia are well documented. Although Hildebrandt and other colleagues frequently give credit to Corning, Bier insisted that he administered and described the technique of spinal anesthesia. In an extensive review (in the original language) of Corning's publication and those of Bier of Germany, Bier compared key factors, that is, the mention of cerebrospinal fluid, dose of injected cocaine, onset of action, and height of sensory analgesia. He noted that Corning's dose of local anesthetic was eight times higher than the dose given by Bier, yet the onset of analgesia was slower with a lower sensory block. Cerebrospinal fluid was not mentioned in Corning's paper. Bier concluded that Corning's injection was extradural, and that he (Bier) deserved to be acknowledged for introducing spinal anesthesia.[53,56–58]

After Bier's work in spinal anesthesia (published in 1899), interest in spinal anesthesia spread rapidly. Within 2 years of Bier's work, it has been estimated that more than 1000 papers were published relating to spinal anesthesia. Frederick Dudley Tait and Guido Caglieri in San Francisco were the first Americans to use true spinal anesthesia clinically.[59]

FIGURE 1–11. Heinrich Irenaeus Quincke.

Rudoph Matas, head of the Department of Surgery at the University of Louisiana (later known as Tulane University), was the first American to report on spinal anesthesia. In his description of spinal anesthesia, Matas initially dissolved cocaine in water, creating a hypobaric solution. Later, he changed his "standard" mixture to cocaine with morphine, making him a pioneer in the use of spinal opioids to enhance central neuraxial anesthesia.[59]

With the vast interest in spinal anesthesia, serious complications from its application were soon observed. F. Gumprecht published a report of 15 cases of sudden death after spinal anesthesia.[60] Multiple cases of respiratory arrest and hypotension, following Harvey Cushing's introduction of blood pressure measurement, were also reported, leading to spinal anesthesia falling into disfavor.[61,62] Several pioneers sought to determine the causes of the variations in blood pressure from spinal anesthesia. Several theories emerged that have shaped our understanding of physiology today.

An extensive study was undertaken by L. G. Gray and H. T. Parsons of England to evaluate the causes for the changes in blood pressure after spinal anesthesia. They concluded that the decrease in arterial blood pressure was attributed to the diminished negative intrathoracic pressure during inspiration. High spinal anesthesia paralyzed the abdominal and thoracic muscles necessary to maintain that negative pressure.[63] With the understanding that hypotension was a primary danger with spinal anesthesia, G. Smith and W. Porter determined in 1915 that the fall in blood pressure was related to paralysis of the vasomotor fibers in the splanchnic area that regulated the tone of the blood vessels. They concluded that for spinal anesthesia to be effective without serious drops in blood pressure, cephalad diffusion of the local anesthetic should be avoided.[64] Gaston Labat contended that the serious adverse effects of spinal anesthesia were related to cerebral ischemia, not hypotension. He recommended that the patient should be placed in the Trendelenburg position after the spinal injection to keep the brain supplied with blood, therefore avoiding respiratory embarrassment.[65] Rather than looking at the position of the patient during injection, Arthur E. Barker promoted the idea that the baricity of the solution was instrumental in determining the cephalad spread. He made the injected solution stovaine, less toxic than cocaine but more irritating, hyperbaric with 5% glucose.[66] Barker was also a strong advocate for using sterile equipment and medication for spinal techniques. In 1934, Pitkin and Etherington-Wilson experimented with hypobaric solutions and changes in patient position to maintain control of the spread of the anesthetic.[32] Although there were other proponents of hypobaric spinal anesthesia, most had to deal with serious adverse effects, such as respiratory impairment and profound blood pressure changes requiring resuscitative maneuvers. It was not until 1920 that W. G. Hepburn and Lincoln Sise revived Barker's methods. Sise, an anesthesiologist at the Lahey Clinic in Boston, used hyperbaric tetracaine rather than stovaine.

Because of the irritating qualities of stovaine, Sise was interested in finding other local anesthetics that would provide sufficient length of anesthesia with limited side effects—something modern anesthesiologists can relate to in our daily practice. He was frustrated by the short duration of action of novocaine: "The ending of a spinal anesthesia in the midst of an operation is always disturbing and annoying, but when this takes place in the midst of an abdominal operation, with the belly open, it may be dangerous as well."[67] He began using tetracaine because of its longer duration of action but was concerned about controlling the height of the block. Following Barker's recommendations regarding hyperbaric solutions, he added 10% glucose with success. He applied the same technique in 1935 to tetracaine.[67,68]

The most negative consequence of spinal anesthesia came from a trial in 1953. Two healthy young men had received spinal anesthesia on the same day in a hospital in England. Both developed *permanent* painful spastic paresis. Although the exact cause of the neurologic injury was never proven, it was suspected to be caused by contamination of the local anesthetic solution.[69,70] Several other cases of paralysis after spinal anesthesia followed, casting a dark shadow on the future application of this anesthetic technique. Fortunately, a follow-up analysis of over 10,000 spinal anesthetics was published by L. D. Vandam and R. D. Dripps. "The most gratifying result was the failure to discover persistent, progressive major neurological disease," providing the way for the spinal route to again emerge as a safe, effective means of providing anesthesia.[71]

The recurring problem of the inadequate duration of single-injection spinal anesthesia led a Philadelphia surgeon, William Lemmon, to report the development of an apparatus for continuous spinal anesthesia in 1940.[72] Lemmon began with the patient in the lateral position. The spinal tap was performed with a malleable silver needle that was left in position. As the patient was turned supine, the needle was positioned through a hole in the mattress and table. Additional injections of local anesthetic could be administered as required. Malleable silver needles also found a less-cumbersome and more common application in 1942 when Waldo Edwards and Robert Hingson encouraged the use of Lemmon's needles for continuous caudal anesthesia in obstetrics. In 1944, Edward Tuohy of the Mayo Clinic introduced important modifications of the continuous spinal techniques. He developed the now-familiar Tuohy needle as a means of improving the ease of passage of lacquered silk ureteral catheters through which he injected incremental doses of local anesthetic.[73]

Obstetric and Epidural Anesthesia

The origin of epidural analgesia began with Jean Enthuse Sicard, a neurologist, who introduced cocaine through the sacral hiatus for the treatment of sciatica and tabes. Independently, Fernand Cathelin used the same technique for surgical anesthesia.[74,75] In 1921, the Spanish surgeon Fidel Pagés-Miravé used a lumbar approach to the epidural space for surgical patients. His greatest contribution to the field of anesthesia was the introduction of *segmental anesthesia,* thereby eliminating some of the serious side effects of complete neuraxial blocks. Unfortunately, he died in an automobile accident before his methods could be shared by the students he worked with at the time. In 1931, Achille Dogliotti published a report on epidural injection of local anesthetics without knowledge of Pagés-Miravé's work. One of the most important features of

Dogliotti's work was his identification of the epidural space. He produced a textbook of his technique, which was both reproducible and easy to learn.[76] The limitation of epidural anesthesia was similar to that of spinal anesthesia—the duration of anesthesia provided. In 1947, Manuel Martinez Curbelo of Cuba is credited with using the Tuohy needle and a small ureteral catheter to provide continuous lumbar epidural analgesia.[77]

In the practice of obstetrics, religious beliefs obstructed the progress of pain relief for women in labor. It was commonly believed that providing anesthesia for the woman in labor went against God's will. James Young Simpson is credited with providing the first ether anesthetic for a complex obstetric delivery in 1847. He was severely criticized by both his peers and the clergy, but many women, most conspicuously Queen Victoria, began requesting anesthesia for the delivery of their children. There was not much progress in the field of obstetric analgesia/anesthesia from 1860 to 1940 until John Bonica, chief of anesthesia at the University of Washington, took over the management of his wife's anesthesia (and probably saved her life) during labor in 1943. She had a near-fatal complication during open drop ether anesthesia. From the time that he intervened in his wife's care, he devoted his career to the advancement of anesthetic care of the mother and fetus.[78]

When Bonica was chief of anesthesia, caudal anesthesia was the primary means used for providing labor analgesia. This followed a report by W. B. Edwards and R. A. Hingson that analgesia for labor and delivery could be satisfactorily achieved with caudal injections of tetracaine through a needle left in place within the sacral canal.[79] When commercially available catheters became available in the 1970s, continuous epidural analgesia gained popularity. In the years following Bonica's contributions, epidural anesthesia for obstetrics has become the norm. Modifications of the techniques and the introduction of either spinal or epidural opioids have made labor and delivery a more pleasant experience for expecting mothers.

A FEW THOUGHTS ON PAIN

Fundamental to modern neural blockade is the concept that pain is a sensory warning conveyed by specific nerve fibers, amenable, at least in principle, to modulation or interruption anywhere in the nerve's pathway. This outlook may be traced back to developments in the study of physiology that finally supplanted the view, first expressed by Plato and Aristotle, that pain, like pleasure, is a passion of the soul, that is, an emotion and not one of the senses. Philosophical changes growing out of the great revolutions of the eighteenth century and the birth of biology as a science gradually, although not entirely, effaced the religious connotations of pain in Western civilization. The doctrine of specific energies of the senses was first promulgated in 1826 by Johannes P. Müller (1801–1858).[80] This doctrine, although not specific for the conduction of pain, initiated the movement of scientific thought toward analysis and classification of the specific characters of different nerves. The theory that pain was a separate and distinct sense was first definitively developed by Moritz S. Schiff (1823–1896) in 1858. By examining the effect of incisions in the spinal cord, Schiff was able to demonstrate that touch and pain were independent sensations. On animals, he demonstrated that injury to specific sections of the spinal cord resulted in loss of one modality without affecting the other.[81] Müller's theories led Erasmus Darwin (grandfather of Charles Darwin) to suggest the *intensive theory of pain.* Darwin felt that the sensation of pain was not a separate modality, but resulted from "whenever the sensorial motions are stronger than usual," theorizing that sensory overload leads to pain.[82] The theories of pain remained controversial throughout the early twentieth century, but by the middle of the twentieth century, the specificity theory (each sensory modality is transmitted along an independent pathway) became universally accepted as the most credible.

Applying drugs to transmitting nerves to alleviate neuralgic pain was first introduced by Francis Rynd in the early 1800s. Rynd's ideas possibly influenced the later development of both nerve blocks and opioid regional anesthesia.[81] When Carl Koller discovered the utility of cocaine as a surgical local anesthetic, a vast new world of local and regional analgesic therapy began. Corning is credited with the concept of direct application of an analgesic to the spinal cord for alleviation of pain, but it was not until the mechanism of pain was more fully understood that pain therapy could be focused on interrupting pain pathways. Unfortunately, by believing that pain pathway interruption was the complete answer to blocking pain, researchers focused only on that aspect, closing their minds to other related aspects of pain development. When Jean Joseph Emile Letievant described specific neurectomy techniques in the late nineteenth century, myriad surgical interventions, such as rhizotomy, cordotomy, and tractotomy, emerged to treat pain.[83] Unfortunately, most of these techniques were atrocious failures that often created more intense pain than was present prior to the procedure. Ronald Melzack and Patrick Wall's hypothesis that a spinal gate controls the cephalad transmission of nociception led to the modern introduction of electrical stimulation as a method of treating chronic pain. The concept proposed in the theory, that pain perception could be lessened by increasing activity in neural structures not associated with pain, led to chronic stimulation of the deep brain and spinal cord as a modality for the management of chronic pain. Consequently, both the brain and spinal structures emerged as targets for neuroaugmentation.[84,85] Although great strides have been made in our understanding of pain development and treatment, it is only through continued research that our understanding of preemptive pain control, such as those methods used in regional anesthesia, can be complete.

TWENTIETH-CENTURY REGIONAL ANESTHESIA

Orthopedic surgery has always lent itself to regional anesthesia techniques because of the ability to isolate anesthesia to the extremity being operated on. Initially, general anesthesia and nerve blocks were combined (still a somewhat common practice today). Harvey Cushing is credited with coining the name *regional anesthesia* for his method of blocking a nerve plexus under direct vision during general anesthesia. His goal was to decrease the anesthetic requirements and to provide postoperative pain relief. It is amazing to consider that he developed this technique in 1902, more than 100 years ago. A similar approach had been proposed by George Crile, 15 years earlier, to decrease the stress of surgery. Upper extremity anesthesia by blocking the brachial plexus percutaneously was achieved by many of our early colleagues. G. Hirschel is credited with developing the "blind" axillary brachial plexus block and D. Kulenkampff the supraclavicular technique, both in 1911. Because the risk of pneumothorax was high with the technique described by Kulenkampff, it was subsequently modified by A. Mulley using a lateral paravertebral approach. Mulley's approach is most likely the precursor of what is now commonly referred to as the "Winnie block" for the brachial plexus.

The spread of regional anesthesia in the United States was greatly facilitated by the work of Gaston Labat (**Figure 1–12**). Recruited to work at the Mayo Clinic in Rochester, Minnesota, Labat published his influential textbook, *Regional Anesthesia,* in which he described his techniques to the next generation of physicians, most notably Hippolite Wertheim, John Lundy, Ralph Waters, and Emery Rovenstine. Labat worked at the Mayo Clinic, then moved to Bellevue Hospital in New York City, where he worked with Wertheim. Together, they formed the first American Society of Regional Anesthesia. Labat's successor, Emery A. Rovenstine, was recruited to Bellevue to continue Labat's work. It was Rovenstine who was responsible for creating the specialty of anesthesiology in the 1920s and 1930s. He also is responsible for the creation of the first American clinic for the treatment of chronic pain, where he and his associates refined techniques of both lytic and therapeutic injections. Rovenstine and his successors used the American Society of Regional Anesthesia to educate physicians about pain management throughout the United States.[86]

FIGURE 1–12. Gaston Labat.

The development of the multidisciplinary pain clinic was one of many contributions to anesthesiology made by John J. Bonica, a renowned teacher of regional techniques. During his periods of military, civilian, and university service at the University of Washington, John Bonica formulated a series of improvements in the management of chronic pain. His text, *The Management of Pain,* is regarded as a classic of the literature.[87,88]

THE POPULARITY AND USE OF LOCAL ANESTHESIA

Ever since Koller's original work, the popularity of local anaesthesia has waxed and waned, like that of many other medical developments. The announcement of his work produced a massive wave of enthusiasm, which was tempered as the problems of cocaine became increasingly appreciated. The first resurgence of interest came with the introduction of safer drugs at the beginning of the twentieth century and the second as a result of the efforts of Labat, Lundy, Maxson, Odom, and Pitkin in the United States in the years between the two world wars.

In Britain, general anesthesia has traditionally been administered by qualified doctors (although not always by specialists who practiced anesthesia exclusively). Standards have usually been high because the conduct of general anesthesia has been their entire responsibility. By contrast, local and regional techniques, if they were used at all, were performed by the surgeon, whose interest and attention were divided between anesthetic and operation. Regional anesthesia was not seen always to be to the patient's best advantage under such circumstances. Nevertheless, when the examination for the diploma in anaesthesia was instituted in 1935, the curriculum included local anesthesia. This, together with the establishment of anesthesia as an independent specialty within the UK National Health Service in 1948, did much to encourage local anesthetic techniques. Unfortunately, the years between 1950 and 1955 saw a sharp decrease in the use of local, and particularly spinal, anesthesia in the United Kingdom and in the United States. The many advances in general anesthesia then taking place were partly responsible because they encouraged the belief that a local technique was unnecessary. More important, though, was the fear of severe neurologic damage. The report, "The Grave Spinal Cord Paralyses Caused by Spinal Anesthesia," written in 1950 in New York by a British-trained neurologist, Foster Kennedy, was followed by the Woolley and Roe case and led to a virtual extinction of the use of regional techniques (see discussion in the section on spinal anesthesia).[70] After a number of reports of the safe use of local anesthetics for surgical procedures emerged, regional anesthesia techniques once again began to slowly emerge.

Local anesthetic techniques are of value in blocking afferent stimuli even in major surgery because of the reduction in the pain and stress suffered by the patient. This approach is now extending even to cardiac surgery, but the concept is far from new. As early as 1902, Harvey Cushing was advocating the combination of local with general anesthesia to decrease "surgical shock," a concept that was further developed by Crile. The term *balanced anaesthesia* is common today and implies a triad of sleep produced by either inhalational or intravenous route, profound analgesia with opioid drugs, and muscle relaxation by neuromuscular block. But, interestingly, when Lundy first used the term in 1926, he intended that the second and third parts of the triad would be produced by a local anesthetic block, something proponents of regional anesthesia are implementing in modern anesthesia practice.

Other advances, although more difficult to quantify, have directly or indirectly helped the cause of regional anesthesia. For example, developments in the field of medical plastics have resulted in safe and reliable syringes, catheters, and filters, and the anesthesiologist can select from a wide variety of sedative and anxiolytic drugs that, when carefully used, can greatly improve the patient's acceptance of a nerve block. Of great importance has been the understanding of the effects and treatment of sympathetic block. Ephedrine became available in 1924 and was first used to treat hypotension during spinal anesthesia in 1927, but readily available intravenous fluids and equipment for their administration are more recent developments.

Most currently used techniques of regional anesthesia were devised during that first decade of the twentieth century: brachial plexus block, axillary and supraclavicular approaches; IVRA; celiac plexus block; caudal anesthesia; hyperbaric and hypobaric techniques of spinal anesthesia; and all the presently employed nerve blocks for the head and neck as applied in dentistry and plastic surgery. Thereafter, aside from technical innovation and understanding of some of the physiologic and toxicologic responses to local anesthetics, the great impetus to regional anesthesia came from the synthesis of the amide local anesthetics and an understanding of their pharmacodynamic and especially pharmacokinetic properties.[32]

In present-day practice, more advanced techniques of regional anesthesia (eg, continuous catheters, combination blocks, deep plexus blocks) have evolved because of the groundwork put in place by those earlier pioneers. With the advent of the Internet providing easier access to current medical practice, patients are better educated and are becoming advocates for regional anesthetic techniques.

It is appropriate to conclude by mentioning the organizations that seek to promote education and training in the use of regional anesthetic techniques. The American Society of Regional Anesthesia was reborn in 1975 and became firmly established. Its European counterpart (the European Society of Regional Anaesthesia and Pain Medicine) is younger but is now equally well established, and similar societies are flourishing in many other parts of the world. (founded in 1994 by Drs. Hadzic and Vloka), have been developed to continue to promote the safe and effective practice of regional anesthesia.

THE TWENTY-FIRST CENTURY AND BEYOND

The history of local and regional anesthesia did not end in the first half of the twentieth century. In fact, it is often said, "We are making history every day." For instance, important techniques developed in the last few decades have refined our ability to identify peripheral nerves accurately. With the increasingly enthusiastic introduction of the use of ultrasound for nerve location, the rate of development in this area of regional anesthetic practice will increase at a greater pace. Other technological advances have included needles optimized for visualization under ultrasound.

As detailed in other chapters of this textbook, there are current and exciting threads of enquiry on the morphology of nerves, combining insights on nerve electrical stimulation and pressure monitoring and a better understanding of the risks leading to nerve injury. Research continues on better agents and additives that can be used in regional anesthesia.

Perhaps the most important role for the regional anesthesiologists who will make history in the next few decades will be to document the clinical advantages and benefits of local and regional anesthesia. This endeavor will not only manifest itself as enthusiasm and skill but also will be based on the generation of convincing data through careful clinical research and academic cooperation within the regional anesthesia community. Books such as this are a vital part of building the future of regional anesthesia and in themselves will form a part of the history of local and regional anesthesia.

ACKNOWLEDGMENTS

We thank Bonnie Farrell, MD, Christopher Robards, MD, and Lakshmanasamy Somasundaram, MD, for their work on this chapter in the previous edition.

SECTION 1 Anatomy and Histology of Peripheral Nervous System and Neuraxis

CHAPTER 2

Embryology

Patrick M. McQuillan

INTRODUCTION

A thorough understanding of the underlying anatomy is fundamental to a logical approach to the techniques used in regional anesthesia. An appreciation for the embryologic development of tissues and structures can significantly add to the understanding of functional anatomy as it relates to regional anesthesia. In this chapter, I emphasize the embryologic development of the brain, spinal cord, peripheral and autonomic nervous systems, as well as the musculoskeletal system as it pertains to regional anesthesia. Many excellent comprehensive texts on embryology are available. For this chapter, I have relied heavily on information from primary texts and refer the reader to them for a complete discussion of all embryologic development. The first two, *Langman's Medical Embryology*[1] and *Basic Concepts in Embryology,*[2] are valuable for their ease of readability, clarity of figures, and clinical correlations. *Human Embryology and Developmental Biology*[3] is a good contemporary, comprehensive explanation of the molecular genetics of embryologic development. *The Developing Human: Clinically Oriented Embryology*[4] is the time-tested standard text of embryology.

GENERAL EMBRYOLOGY

The prenatal period is divided into two major periods: the embryonic period, from fertilization through 2 months, and the fetal period, from the third month through birth.

Embryonic Period

The embryonic period is the time when all tissues are formed and, particularly during the second month, all organs are formed. The fetal period is a time of organ growth.[2] Embryologic development begins with fertilization, the process by which the male and female gametes unite to give rise to a zygote. Approximately 3 days after fertilization, cells of the compacted embryo divide to form a **morula,** which is composed of an inner and outer cell mass. The inner cell mass gives rise to the tissues of the **embryoblast**, and the outer cell mass forms the **trophoblast**, which later contributes to the placenta. After a period of cell division, during which time the morula enters the uterine cavity, the **blastocoele** forms, and the embryo is known as a **blastocyst** (Figure 2–1).

By the eighth day of development, the blastocyst is partially embedded in the endometrium. At this time, the trophoblast differentiates into an inner and an outer layer. Lacunae develop in the outer layer, maternal sinusoids are eroded, and by the end of the second week a primitive uteroplacental circulation begins to develop.

The inner cell mass, or embryoblast, differentiates into two layers, the **epiblast** and the **hypoblast**, which together form the bilaminar germ disk.

The most characteristic event occurring during the third week of gestation is **gastrulation.** This is the process that establishes all three germ layers: **endoderm, ectoderm,** and **mesoderm** in the embryo (Figure 2–2). Gastrulation begins

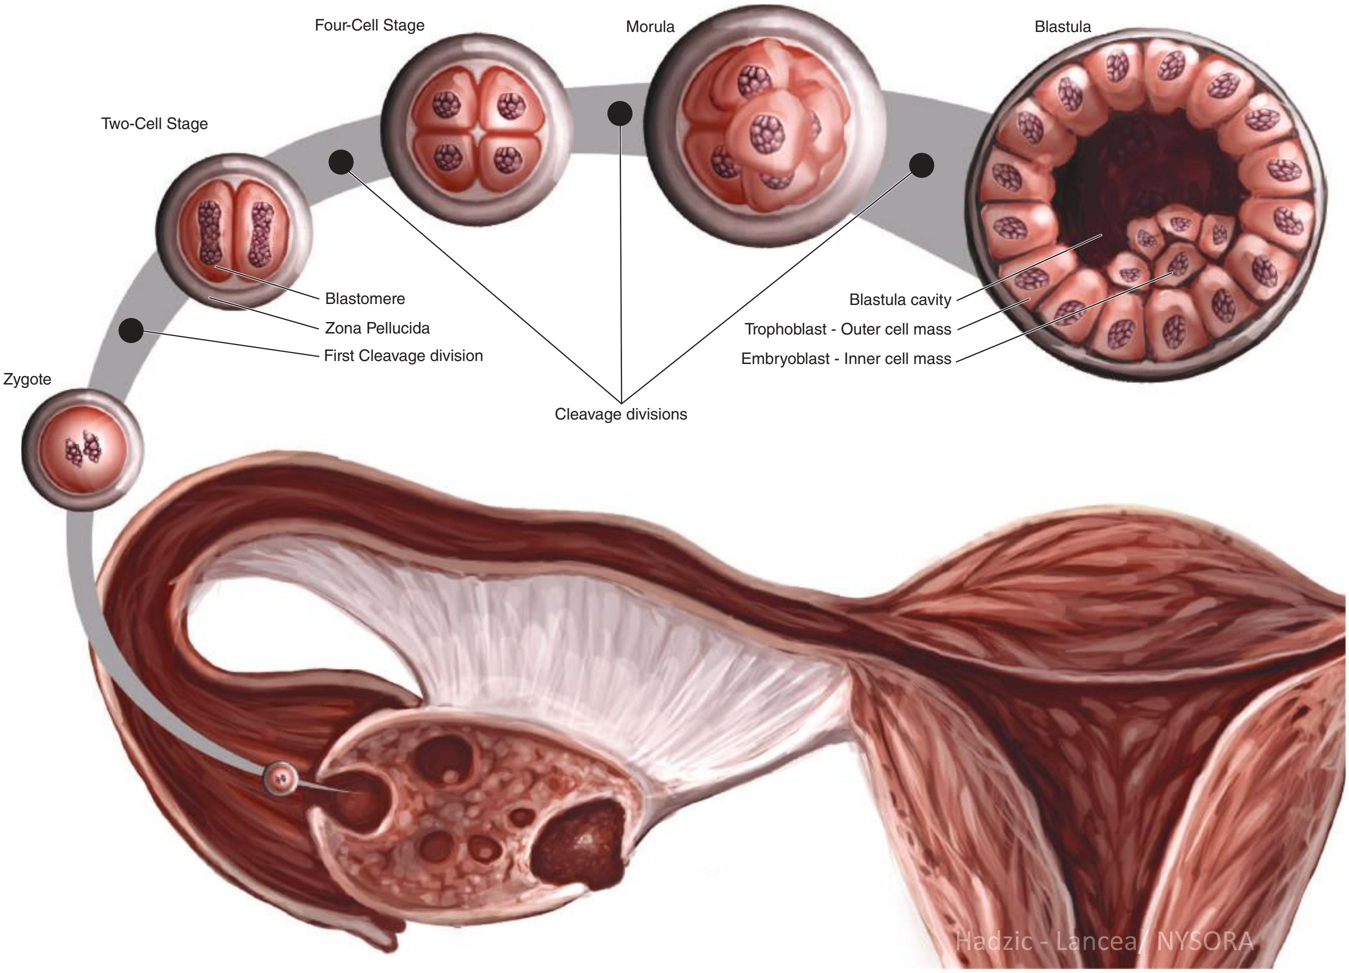

FIGURE 2–1. Formation of the blastocyst.

with the formation of the **primitive streak** on the surface of the epiblast portion of the bilaminar germ disk. Cells migrate toward the primitive streak, detach from the epiblast, and slip beneath it. This inward movement is known as **invagination.** Once the cells have invaginated, some displace the hypoblast, creating the new embryonic endoderm. Other cells come to lie between the epiblast and the newly created endoderm to form the mesoderm. Cells remaining in the epiblast then form the ectoderm. Through the process of gastrulation, the epiblast therefore becomes the source of all the germ layers in the embryo.[1] Developments during the first 3 weeks of the embryonic period produce an embryo with one germ layer (week 1), two germ layers (week 2), and three germ layers with a recognizable three-dimensional body form (week 3)[2] (Figure 2–3).

In general terms, the **ectoderm** germ layer gives rise to organs and structures that allow us to maintain contact with the outside world.[4] It gives rise to the central and peripheral nervous systems; the sensory epithelium of the eye, ear, and nose; the epidermis and its appendages; hair and nails, mammary glands; the hypophysis, subcutaneous glands; and the enamel of the teeth.

The **mesoderm** gives rise to supporting structures of the body, such as cartilage, bone, and connective tissue; striated and smooth muscle; the heart, blood, lymph vessels, and cells; and the kidneys, gonads, and serous membranes lining the body cavities, spleen, and the cortex of the adrenal gland.

The **endoderm** produces the epithelial lining of the gastrointestinal and respiratory tracts, as well as the epithelial lining of the bladder and urethra, tympanic cavity, antrum, and auditory tube. It also engenders the parenchyma of the tonsils, thyroid, parathyroid thymus, liver, and pancreas.

As the embryo forms, it rapidly develops along several axes,[2] the first of which is the craniocaudal axis. It is established while the embryo is still a flat disk or sheet of cells. This axis runs from the future head to the future tail of the body form. The dorsoventral axis is the next to be established. This occurs as the body folds and defines the future front and back sides of the body form.

Establishment of the body axes takes place prior to and during the period of gastrulation. Cells at the posterior margin of the embryonic disk signal the craniocaudal axis. The dorsoventral orientation of tissue is controlled by a complex interaction of proteins and growth factors.

This early orientation of cells in the body is a result of the expression of *Hox* genes. There are four *Hox* gene complexes in vertebrates: *Hox a, b, c,* and *d.* Each consists of a group of between 9 and 11 genes arranged sequentially along a particular chromosome. A cascade of genes producing signaling factors

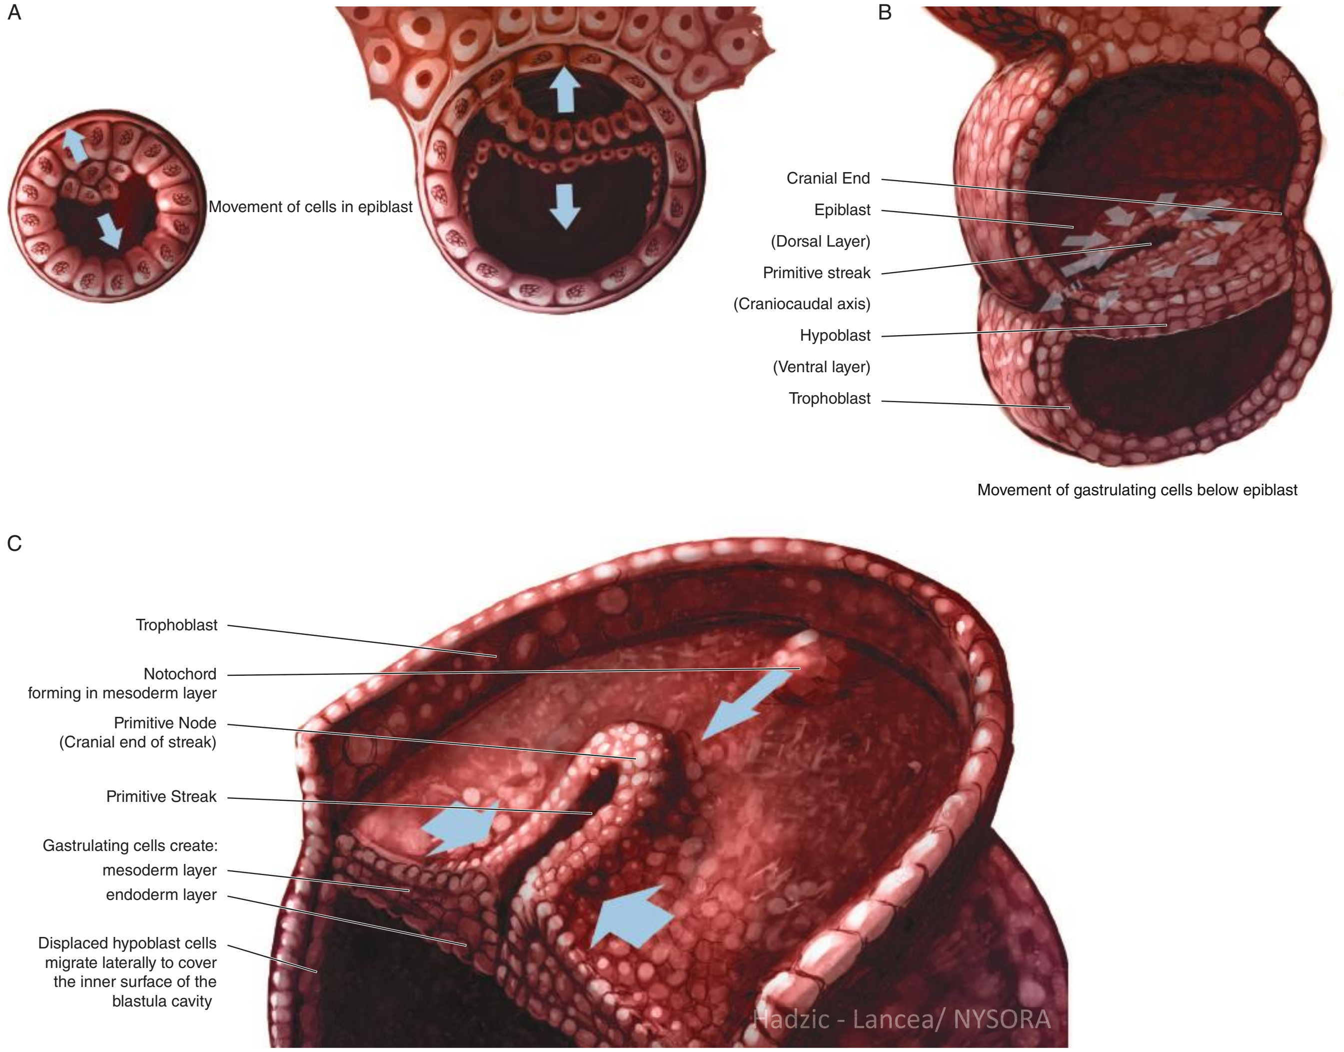

FIGURE 2–2. Establishment of the three basic germ layers in the embryo: endoderm, ectoderm, and mesoderm. **A:** Trophoblast with the shell removed. **B:** Gastrulation viewed from the dorsal surface. Solid arrows show movement of cells in epiblast; dashed arrows show movement of gastrulating cells below the epiblast. **C:** Differentiation of the basic germ layers.

also orchestrates left-right asymmetry, which is established early in development. As a result of complex interactions, for example, the heart and spleen lie on the left side of the body and the main lobe of the liver lies on the right.

Regions of the epiblast that migrate and ingress through the primitive streak have been mapped and their ultimate fates determined. Mesoderm cells that ingress through the cranial region of the primitive node become the notochord; those migrating at the lateral edges of the primitive node and from the cranial end of the primitive streak become the paraxial mesoderm. Cells migrating through the midstreak region become the intermediate mesoderm, and those migrating through the caudal part of the streak form the lateral plate mesoderm. This orientation of the mesoderm is important in understanding limb development.

The embryonic disk, initially flat and almost round, gradually becomes elongated, with a broad cephalic and a narrow caudal end. Expansion of the embryonic disk occurs mainly in the cephalic region. This growth in elongation is caused by continuous migration of cells from the primitive streak region in a cephalad direction. Invagination and migration forward and laterally of surface cells in the primitive streak continue until the end of the fourth week. Germ cell layers in the cephalic region begin their specific differentiation by the middle of the third week, whereas those in the caudal part differentiate beginning by the end of the fourth week. This causes the embryo to develop in a cephalocaudal direction (Figure 2–4).

At the beginning of the third week of development, the ectodermal germ layer has the shape of the disk. The ectoderm gives rise to two subdivisions: neuroectoderm, which forms all neural tissue, and the epidermal covering of the body.[2] Appearance of the notochord and prechordal mesoderm induces the overlying ectoderm to thicken and form the neural plate (Figure 2–5). Cells of the neural plate make up the neuroectoderm, and their induction represents the initial event in the process of **neurulation.** By the end of the third week, the lateral edges of the neural plate become elevated to form neural folds, and the depressed midregion forms the neural groove. Gradually, the neural folds approach each other in the midline, where they fuse, resulting in formation of the neural tube. Neurulation is then complete, and the central nervous

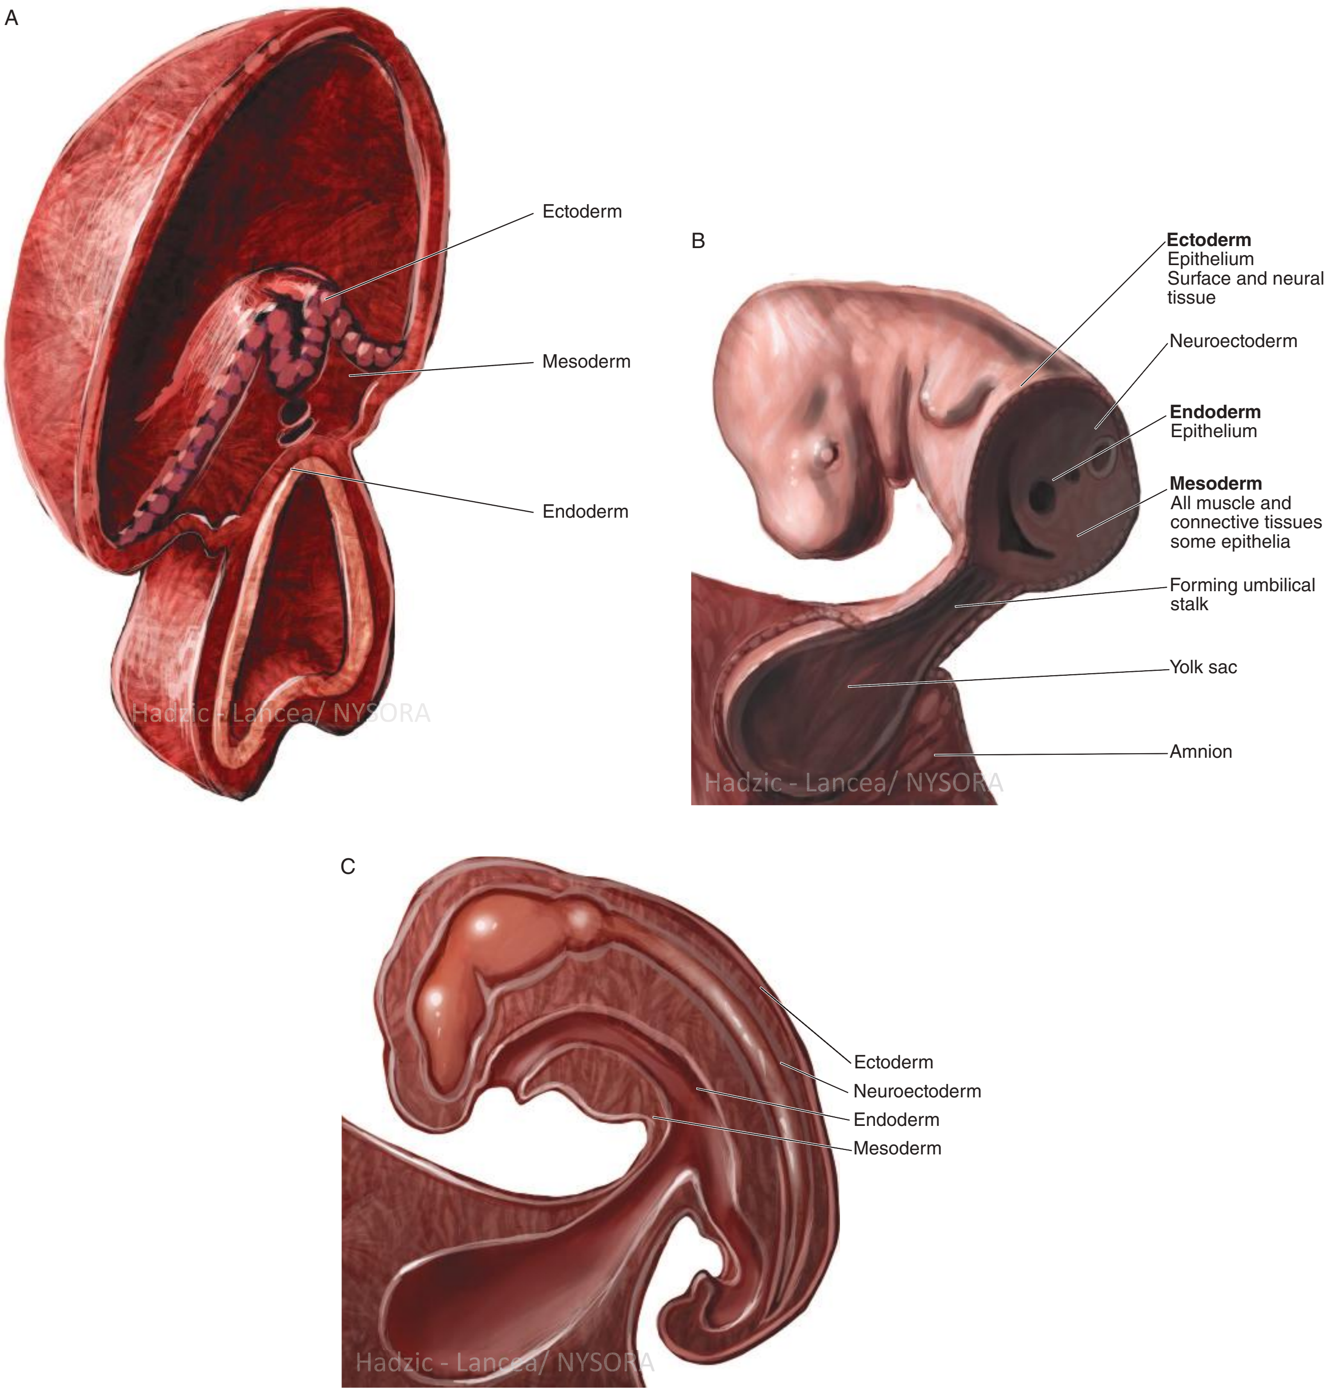

FIGURE 2–3. Cross section of germ layers as they appear during embryonic folding. **A:** Cross section. **B:** Cross section of germ layers after folding is completed. **C:** Longitudinal section.

system (CNS) is represented by a closed tubular structure with a narrow caudal portion, the spinal cord, and a much broader cephalic portion characterized by a number of dilations, the brain vesicles. As the neural folds elevate and fuse, cells at the lateral border begin to dissociate from their neighbors. This cell population, called the **neural crest,** will undergo a transition as they leave the neuroectoderm to enter the underlying mesoderm.

During the body-folding process, the endoderm is formed into an epithelial tube, which runs the length of the body. The derivatives of the endoderm tube are all epithelial tissues (Figure 2–6).

Initially, cells of the mesoderm germ layer form a thin sheet of tissue on each side of the midline.[1] These cells proliferate and form a thick end plate of tissue known as paraxial mesoderm (Figure 2–7). More laterally, the mesoderm remains thin and is known as the lateral plate. This lateral plate divides into two layers: a somatic, or parietal, mesoderm layer and a splanchnic, or visceral, mesoderm layer. Together, these layers form the intraembryonic cavity. Intermediate mesoderm connects the paraxial and lateral plate mesoderm.

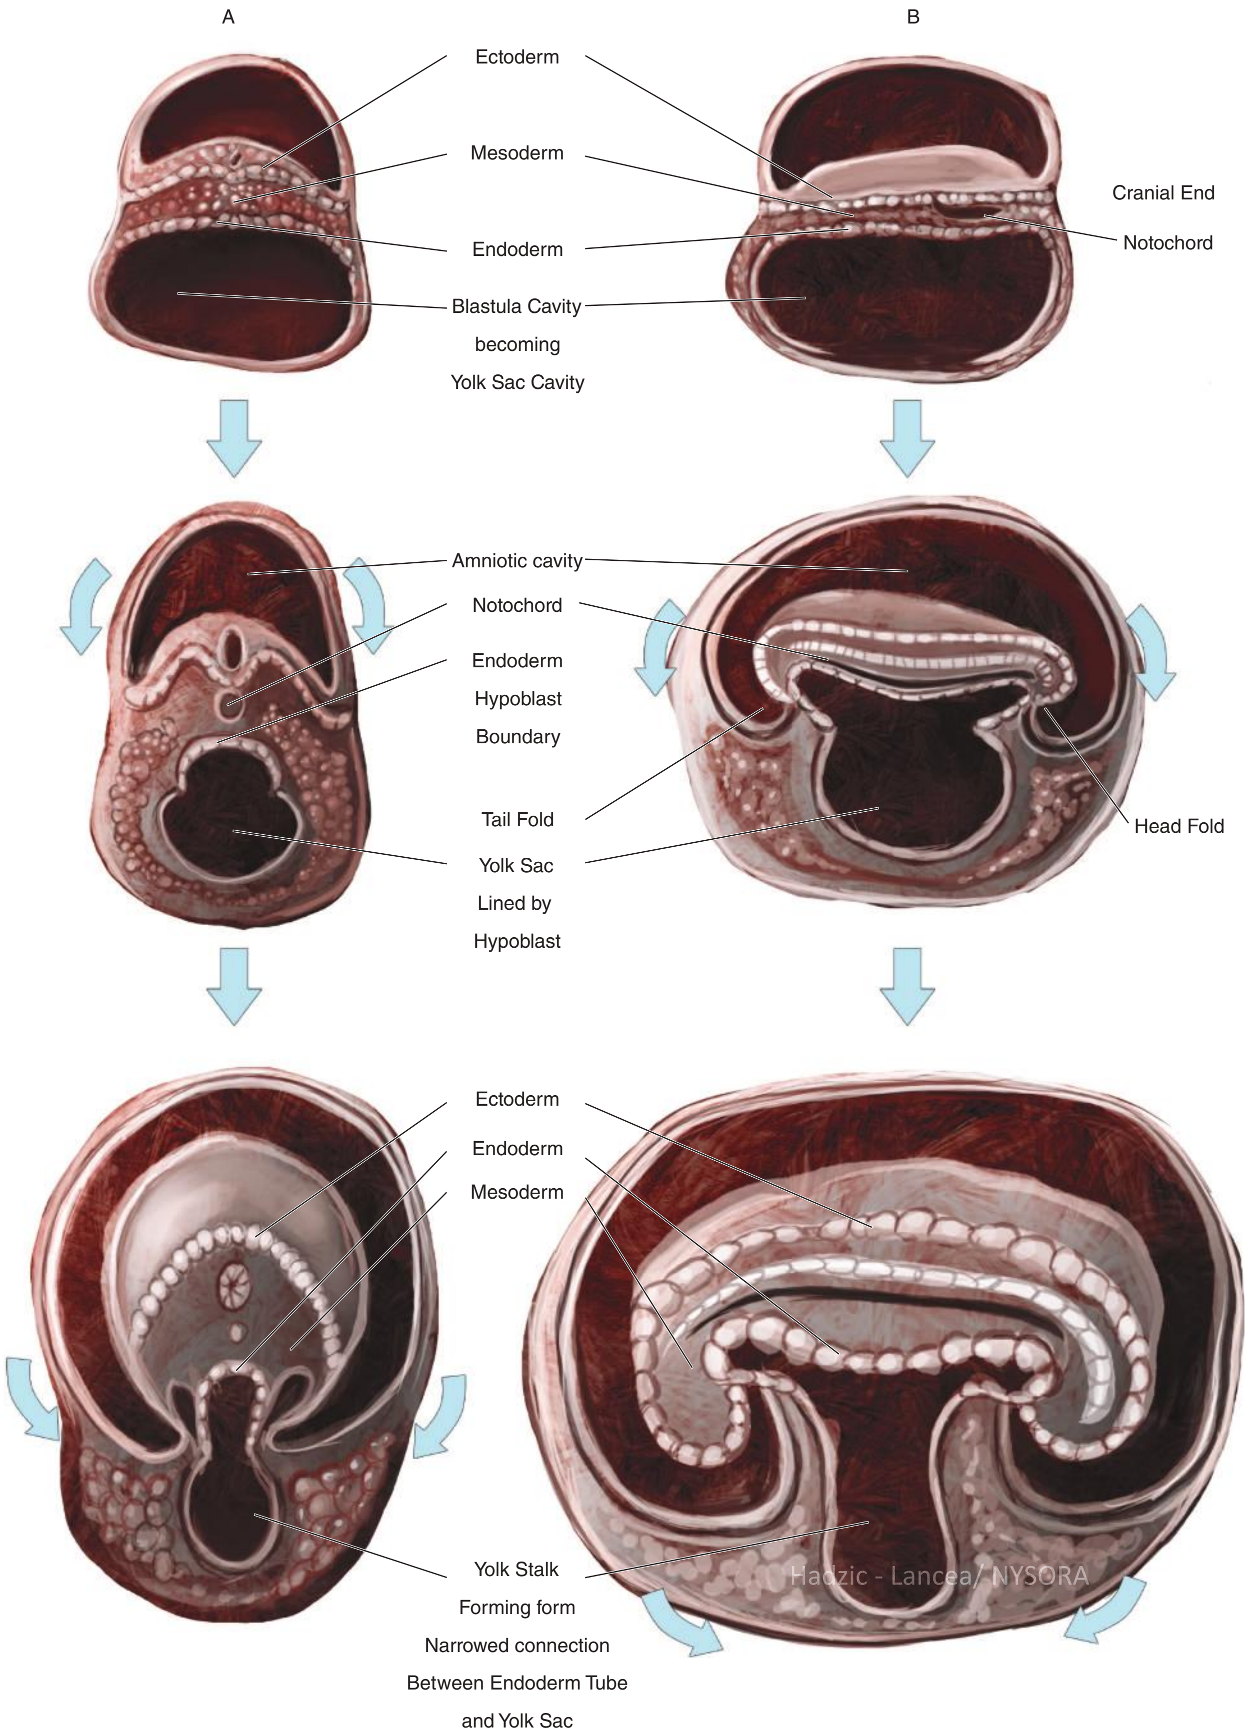

FIGURE 2–4. Development of the embryo in a cephalocaudal direction. **A:** Lateral body folds, cross-sectional views. **B:** Craniocaudal body folds, longitudinal views.

PART 2

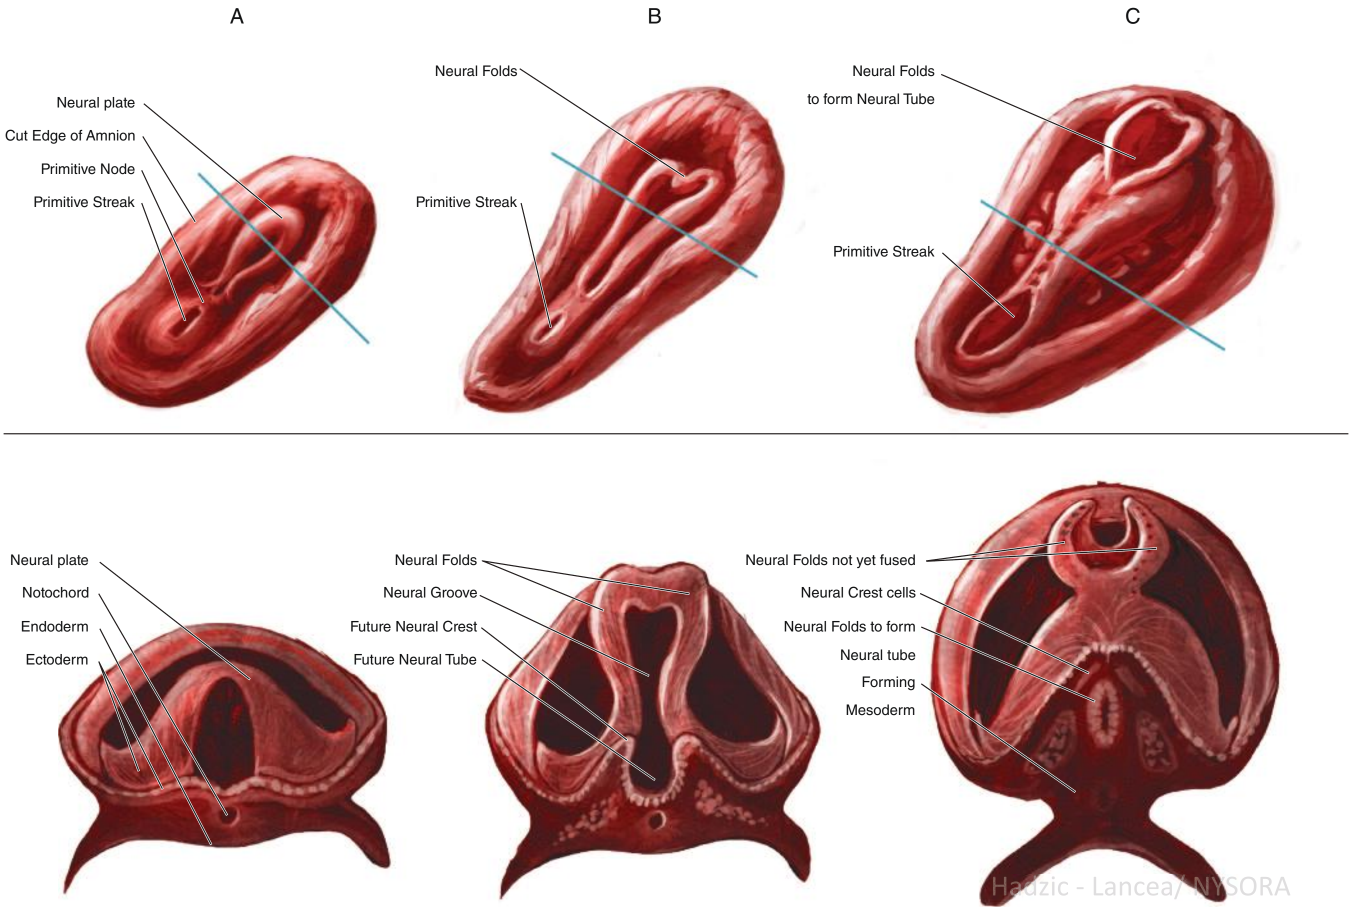

FIGURE 2–5. Formation of the neural plate. **A:** Formation of the neural plate. **B:** Formation of the neural folds and neural groove. **C:** Completion of neurulation, the creation of the neural tube.

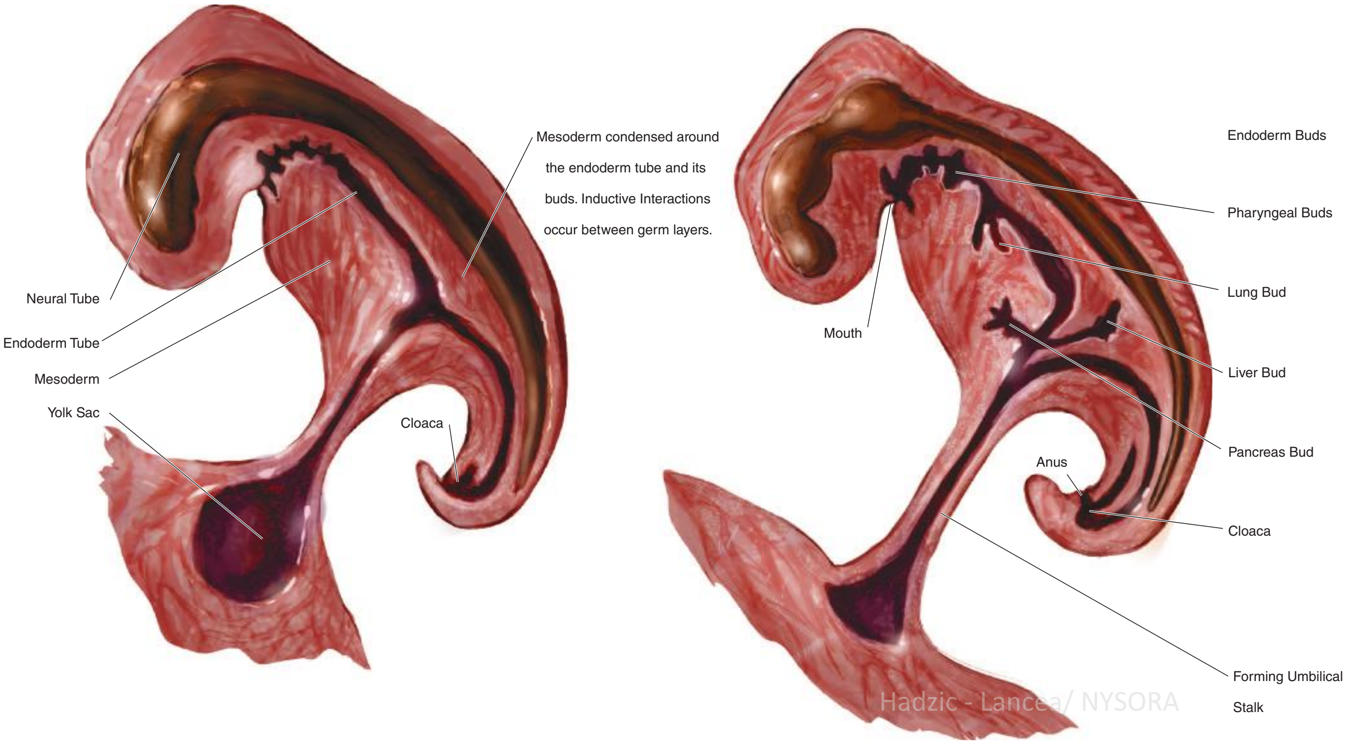

FIGURE 2–6. Formation of the endoderm.

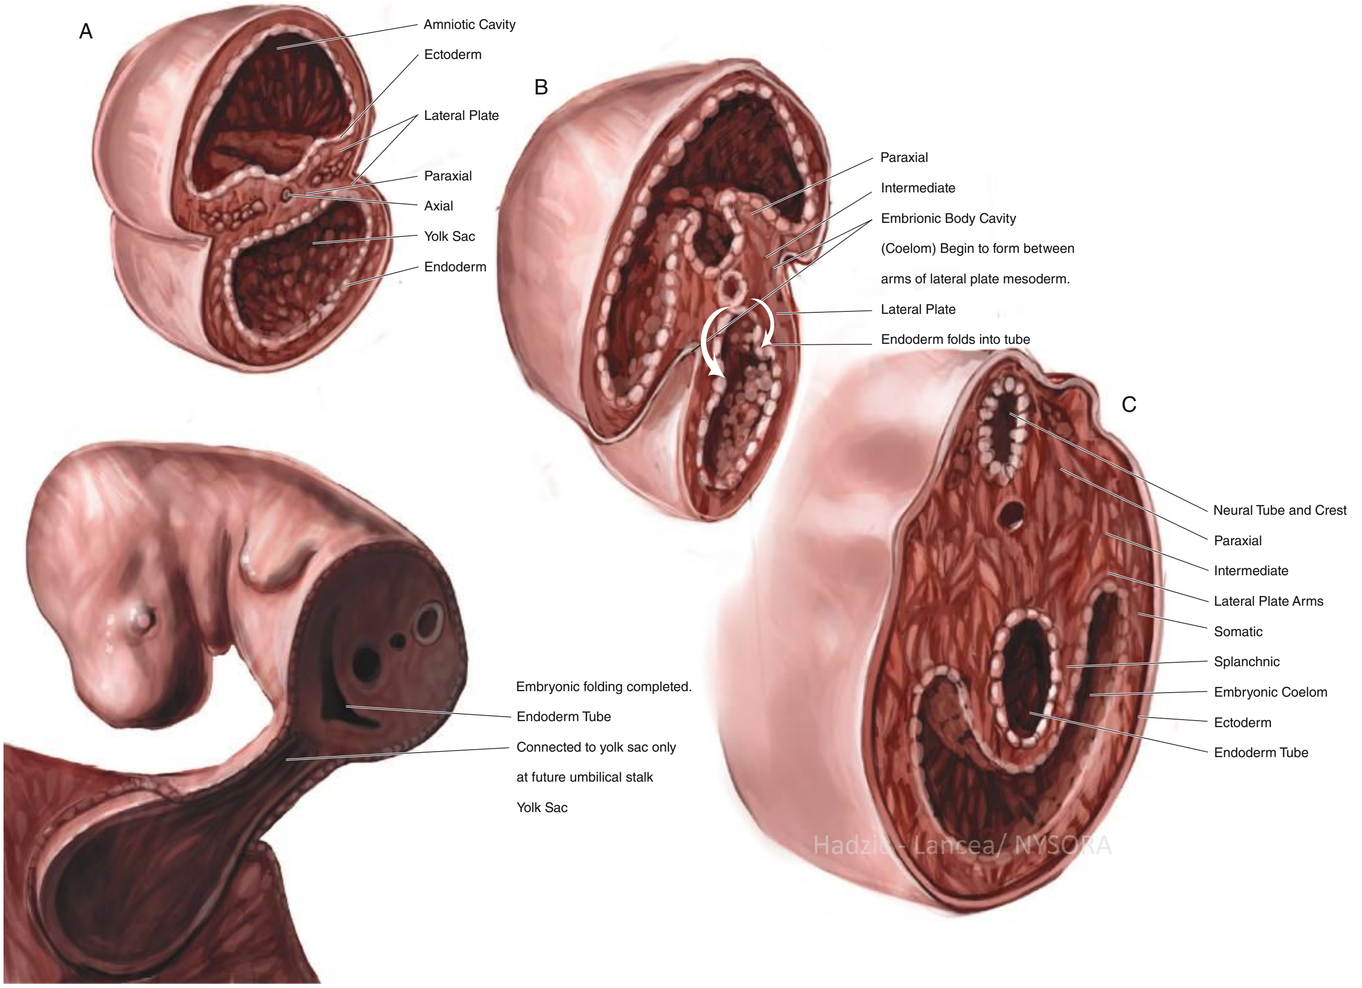

FIGURE 2–7. Formation of paraxial mesoderm (**A**), embryonic cavity (**B**), and embryonic folding (**C**).

By the beginning of the third week, paraxial mesoderm is organized into segments. These segments are known as **somitomeres.** They first appear in the cephalic region of the embryo, and their formation proceeds in a craniocaudal direction. In the head region, somitomeres transition, in association with segmentation of the neural plate, into neuromeres. From the occipital region caudally, somitomeres further organize into **somites.** Somites give rise to the **myotome** (ultimately muscle tissue), **sclerotome** (ultimately cartilage and bone), and **dermatome** (ultimately subcutaneous tissue of the skin). Collectively, these are all supporting tissues of the body (Figure 2–8).

Signaling for this somite differentiation arises from surrounding structures, including the notochord, neural tube, epidermis, and lateral plate mesoderm. By the beginning of the fourth week, cells forming the ventral and medial walls of the somite lose their compact organization and shift their position to surround the notochord (the dense cord of mesoderm that induces neuroectoderm). These cells, collectively known as the sclerotome, form a loosely woven tissue called the mesenchyme. They will surround the spinal cord and notochord to form the vertebral column. Cells at the dorsolateral portion of the somite also migrate as precursors of limb and body wall structures. Following migration of these muscle cells and cells of the sclerotome, cells at the dorsomedial portion of the somite proliferate and migrate down the ventral side of the remaining dorsal epithelium of the somite to form a new layer, the myotome. The remaining dorsal epithelium forms the dermatome, and together these layers constitute the dermomyotome. Each segmentally arranged myotome contributes to muscles of the back, whereas the dermatomes disperse to form the dermis and subcutaneous tissue of the skin. Each myotome and dermatome retains its innervation from the segment of origin, no matter where the cells migrate. Therefore, each somite forms its own sclerotome, the cartilage and bone component; its own myotome, providing the segmental muscle component; and its own dermatome, the segmental skin component. Each myotome and dermatome also has its owns segmental nerve component (Figure 2–9).

During the second month, the external appearance of the embryo is changed greatly by the enormous size of the head and formation of the limbs, face, ears, nose, and eyes.[1] By the beginning of the fifth week, forelimbs and hind limbs appear as paddle-shaped buds (Figure 2–10). The forelimbs are located dorsal to the pericardial swelling at the level of the fourth cervical to first thoracic somites, which explains their innervation by the brachial plexus. Hind-limb buds appear slightly later just caudal to the attachment of the umbilical stock at the level of the lumbar and uppers sacral somites. With further growth, the

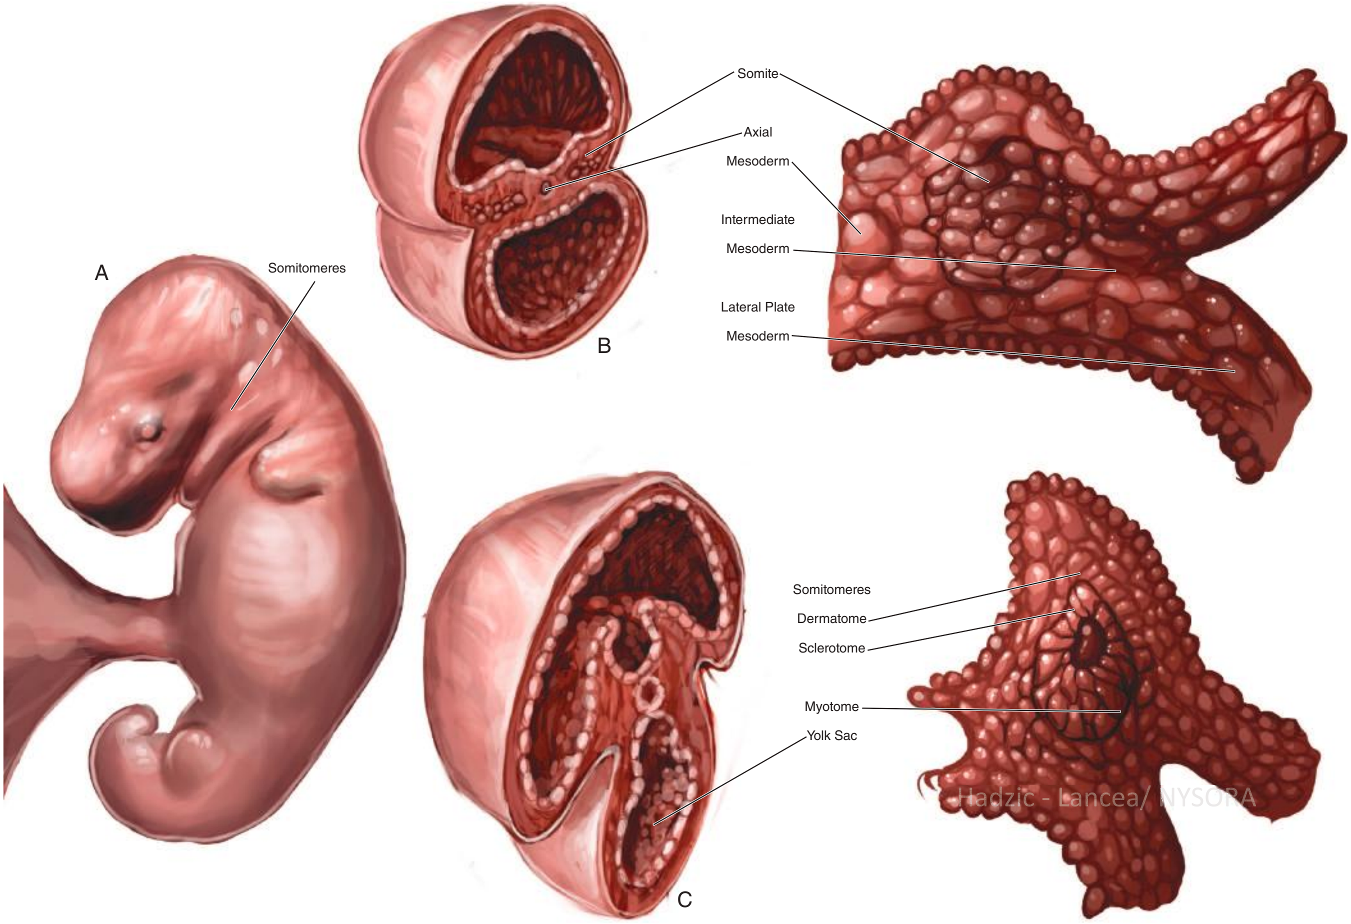

FIGURE 2–8. Development of the supporting tissues of the body myotome (muscle tissue), sclerotome (cartilage and bone), and dermatome (subcutaneous tissue). **A:** Paraxial mesoderm condenses to form the somite. **B:** Somite forms three regions. **C:** Somitomeres develop into somites.

terminal portions of the buds flatten, and a circular constriction separates them from the proximal, more cylindrical segment. Soon, four radial grooves separating five slightly thicker areas appear on the distal portion of the buds. This development foreshadows formation of the digits. These grooves, known as rays, appear in the hand region first and, shortly afterward, in the foot because the upper limb is slightly more advanced in development than the lower limb. While fingers and toes are being formed, a second constriction divides the proximal portion of the buds into two segments, and the three parts characteristic of the adult extremities can be recognized.

Fetal Period

The period from the beginning of the ninth week to the end of the intrauterine life is known as the fetal period.[1] It is characterized by maturation of tissues and organs and rapid growth of the body in length. This is particularly striking during the third, fourth, and fifth months, and increasing weight is most striking during the last 2 months of gestation. During the third month, the face becomes more human looking, and the limbs reach their relative length in comparison with the rest of the body, although the lower limbs are still a little shorter and less well developed than the upper extremities. Primary ossification centers are present in the long bones and the skull by the 12th week.

Skeletal System: Limb Growth and Development

The skeletal system develops from paraxial and lateral plate mesoderm as well as neural crest tissue.[1] The somites (as previously described) differentiate into a ventromedial component called the sclerotome and a dorsolateral component called the dermomyotome. This organization of cells forms a loosely woven tissue called the mesenchyme. The mesenchyme migrates and differentiates into fibroblasts, chondroblasts, and osteoblasts.

At the end of the fourth week of development, limb buds become visible as outpocketings of the ventrolateral body wall.[1] Initially, they consist of a mesenchymal core derived from the somatic layer of lateral plate mesoderm that will form the bones and connective tissue of the limb, covered by a layer of ectoderm. Ectoderm at the distal border of the limb thickens and forms a specialized inducing tissue known as the **apical ectodermal ridge (AER).** The AER exerts an inductive influence on the adjacent mesenchyme, causing it to remain as a population of undifferentiated, rapidly proliferating cells

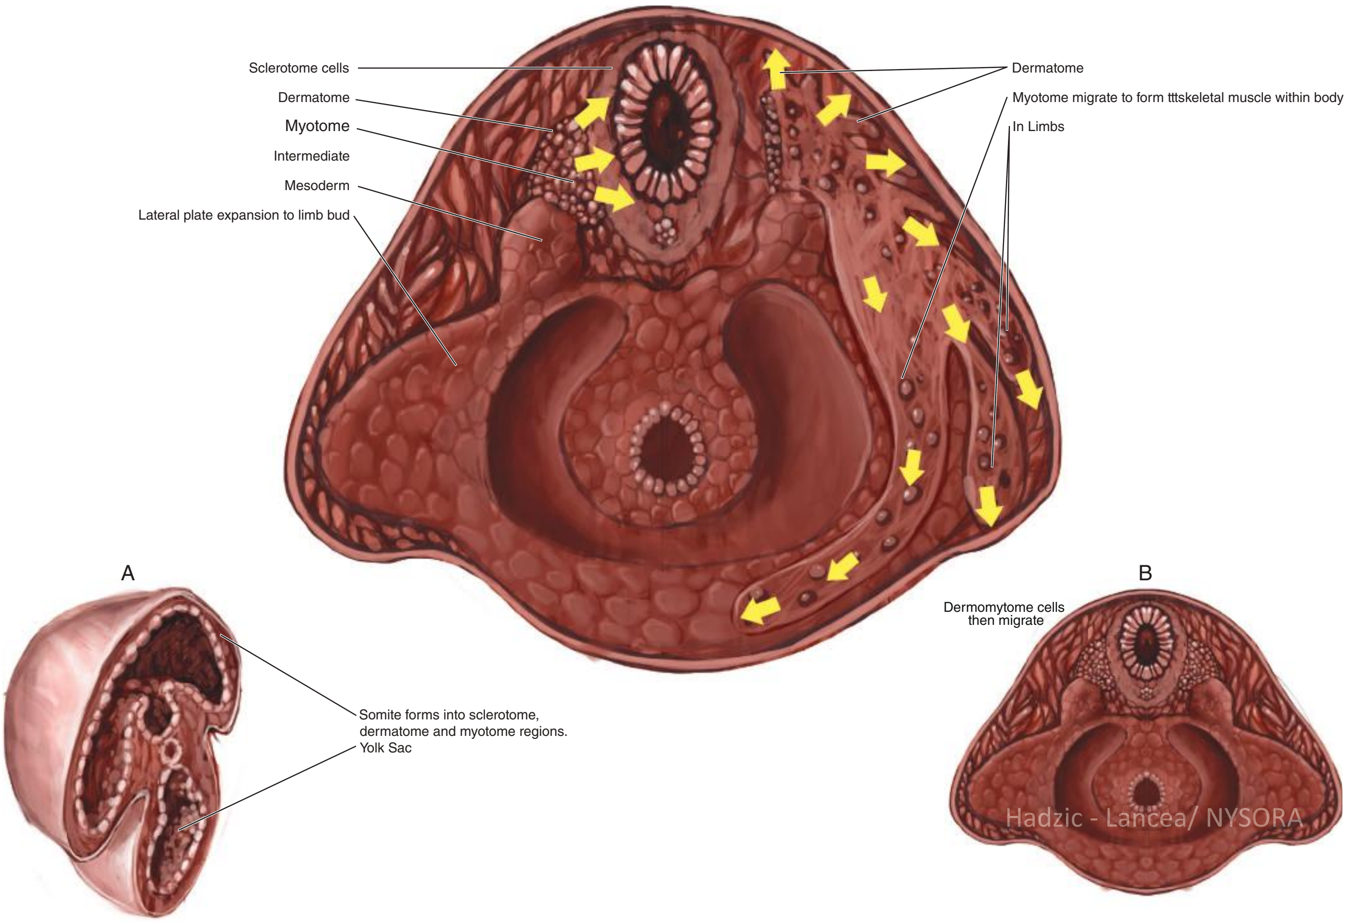

FIGURE 2–9. Cells of each somite region migrate separately to target destinations before forming specific tissues. Each somite forms its own sclerotome, myotome, and dermatome. **A:** Sclerotome cells migrate medially to form bones (vertebrae and ribs). **B:** Dermatome cells then migrate under ectoderm to form connective tissue of skin (dermis).

called the **progress zone.** As the limb grows, cells farther from the influence of the AER begin to differentiate into cartilage and muscle. In this manner of development, the limb proceeds proximodistally. In 6-week-old embryos, the terminal portion of the limb buds becomes flattened to form hand and footplates and is separated from the proximal segment by a circular constriction. Later, a second constriction divides the proximal portions into two segments, and the main parts of the extremities can be recognized.[1] Fingers and toes are formed when programmed cell death in the AER separates this ridge into five parts. Further formation of the digits depends on their continued outgrowth under the influence of the five remaining segments of ridge ectoderm. This results in condensation of the mesenchyme to form cartilaginous digital rays. Development of the upper and lower limbs is similar except that morphogenesis of the lower limb is approximately 1–2 days behind that of the upper limb.

During the seventh week of gestation, a key event occurs that is critical in understanding the final orientation and innervation of the limbs. The limbs rotate in opposite directions. The upper limb rotates 90° **laterally** so that the extensor muscles lie on the lateral and posterior surface and the thumbs lie laterally. The lower limb rotates approximately 90° **medially,** placing the extensor muscles on the anterior surface and the great toe medially.[1] This explains why *homologous joints* of the upper and lower extremities (knees and elbows) *point in opposite directions.* This limb rotation results in the following[2]:

1. The final orientation of the limbs.
2. The final location and orientation of muscle groups (because the muscles are connected to the limb bones prior to rotation).
3. The patterns of sensory innervation of the skin (also because nerve fibers are connected with the dermis layer of the skin prior to rotation and are pulled along).

While the external shape is being established, mesenchyme in the buds begins to condense, and by the sixth week of development, the first hyaline cartilage models can be recognized. Ossification of the bones of the extremities begins by the end of the embryonic period. Primary ossification centers are present in all long bones of the limbs by the 12th week of development.

Molecular Regulation of Limb Development

Positioning of the limbs along the craniocaudal axis in the flank regions of the embryo is regulated by the *Hox* genes expressed

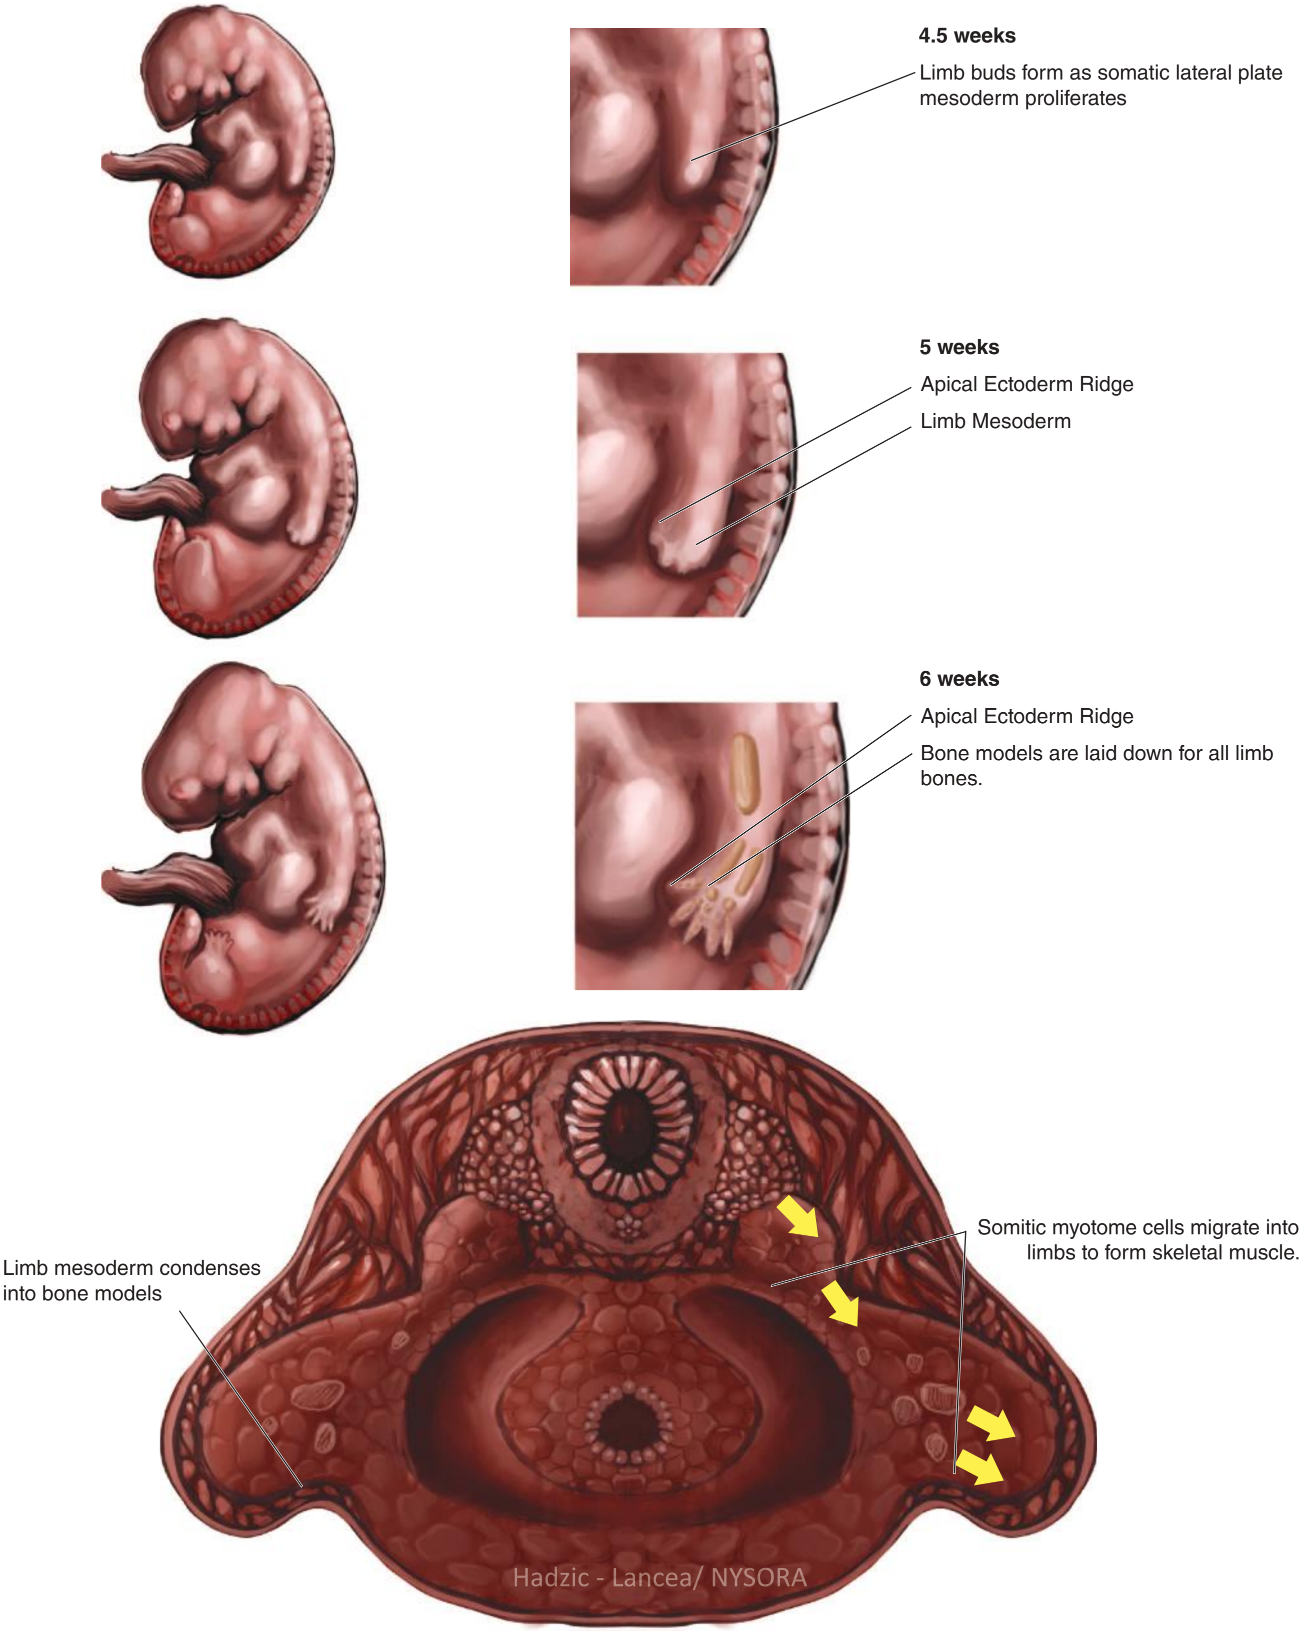

FIGURE 2–10. During the second month of development, the external appearance of the embryo greatly changes by rapid appearance of the large size of the head and formation of the limbs, face, ears, nose, and eyes. By the beginning of the fifth week, forelimbs and hind limbs appear as paddle-shaped buds. The arrows in the figure indicate direction of buds.

along this axis.[1] Once positioning along this axis is determined, growth must also be regulated along the proximodistal, anteroposterior, and dorsoventral axes. Patterning of the anteroposterior axis of the limb is regulated by the **zone of polarizing activity (ZPA),** a cluster of cells at the posterior border of the limb near the flank. These cells produce retinoic acid, which initiates expression of **sonic hedgehog (Shh),** a secreted factor that regulates development along this axis.[1] This regulation results in digits appearing in the proper order, with the thumb on the radial (anterior) side. As the limb grows, the ZPA moves distally to remain in proximity to the posterior border of the AER. The dorsoventral axis is patterned in a similar fashion by the dorsal ectoderm of the limb.

Although patterning genes for the limb axes have been predetermined, it is the *Hox* genes that regulate the types and shapes of the bones of the limbs. These *Hox* genes are nested in overlapping patterns of expression that somehow regulate patterning.[1] As a result, variations in their combinations create patterns of expression that may account for differences in fore- and hind-limb structures.

Vertebral Column

During the fourth week of development, cells of the sclerotome shift their position to surround both the spinal cord and the notochord.[1] During further development, the caudal portion of each sclerotome segment proliferates extensively and condenses. This proliferation is so extensive that it proceeds into the subjacent intersegmental tissue and binds the caudal half of one sclerotome to the cephalic half of the adjacent sclerotome. By incorporation of this intersegmental tissue into the precartilaginous vertebral body, the body of the vertebrae becomes intersegmental (Figure 2–11). *Hox* genes also control this patterning. Mesenchymal cells between cephalic and caudal parts of the original sclerotome form the intervertebral disk. Although the notochord regresses entirely in the region of the vertebral bodies, it persists and enlarges in the region of the intervertebral disk. Here, it contributes to the nucleus pulposus, which is later surrounded by circular fibers of the anulus fibrosus. Together, these structures form the intervertebral disk.[1]

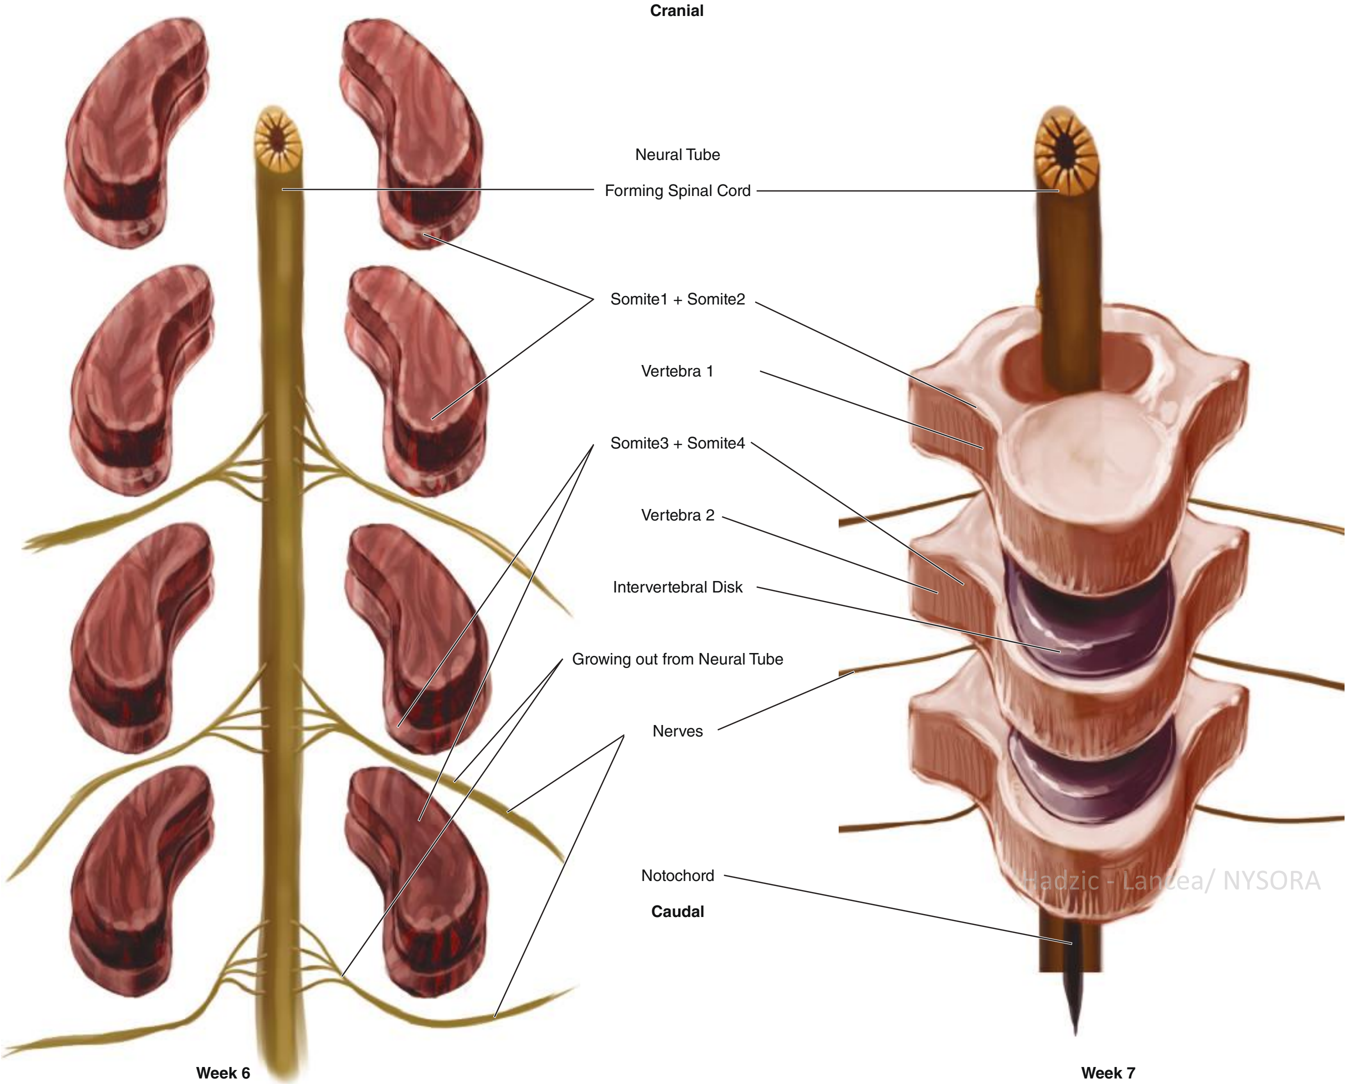

FIGURE 2–11. Formation of the vertebrae by fusion of sclerotome cells from two different somite levels.

Muscular and Peripheral Nervous Systems

With the exception of some smooth muscle tissue, the muscular system develops from the mesoderm germ layer.[1] Skeletal muscle is derived from paraxial mesoderm, which forms somites from the occipital to sacral regions and somitomeres in the head. The somites and somitomeres form the musculature of the axial skeleton body wall, limbs, and head. From the occipital region caudally, somites form and differentiate into this sclerotome, dermatome, and two muscle-forming regions. One of these is in the dorsolateral region of the somite and provides progenitor cells (myoblasts) for the limb and body wall musculature. The other region lies dorsomedially, migrates ventrally to cells that form the dermatome, and forms the myotome. Patterns of muscle formation are under the influence of the surrounding connective tissue into which myoblasts migrate. In the head region, this connective tissue is derived from neural crest cells. In cervical and occipital regions, muscles differentiate from somitic mesoderm, whereas in the body wall and limbs, they originate from the somatic mesoderm. By the end of the fifth week, prospective muscle cells are collected into two parts: a small dorsal portion, the **epimere,** and a larger ventral part called the **hypomere.**[1] Nerves innervating segmental muscles are also divided into a dorsal primary ramus for the epimere and a ventral primary ramus for the hypomere. These nerves remain with their original muscle segment throughout its migration. Myoblasts of the epimere form extensor muscles of the vertebral column, and those of the hypomere give rise to the muscles of the limbs and body wall. The first indication of limb musculature is observed in the seventh week of development as a condensation of mesenchyme near the base of the limb buds. This mesenchyme is derived from dorsolateral cells of the somites that migrate into the limb bud to form the muscles. This connective tissue dictates the pattern of muscle formation and is derived from somatic mesoderm, which also gives rise to the bones of the limb.[1]

With elongation of the limb buds, the muscle tissue splits into flexor and extensor components. The upper limb bud lies opposite the lower five cervical and upper two thoracic segments. The lower limb buds lie opposite the lower four lumbar and upper two sacral segments. As soon as the buds form, ventral primary rami from the appropriate spinal nerves penetrate into the mesenchyme (Figure 2–12). At first, each ventral ramus enters with isolated dorsal and ventral branches, but soon these branches unite to form large dorsal and ventral nerves. Thus, in the upper extremity, the radial nerve supplies all the extensor musculature and is formed by a combination of dorsal segmental branches. The ulnar and median nerves, which supply all the flexor muscles, are formed by a combination of the ventral branches[1] (Figure 2–13). Immediately after the nerves have entered the limb buds, they establish contact

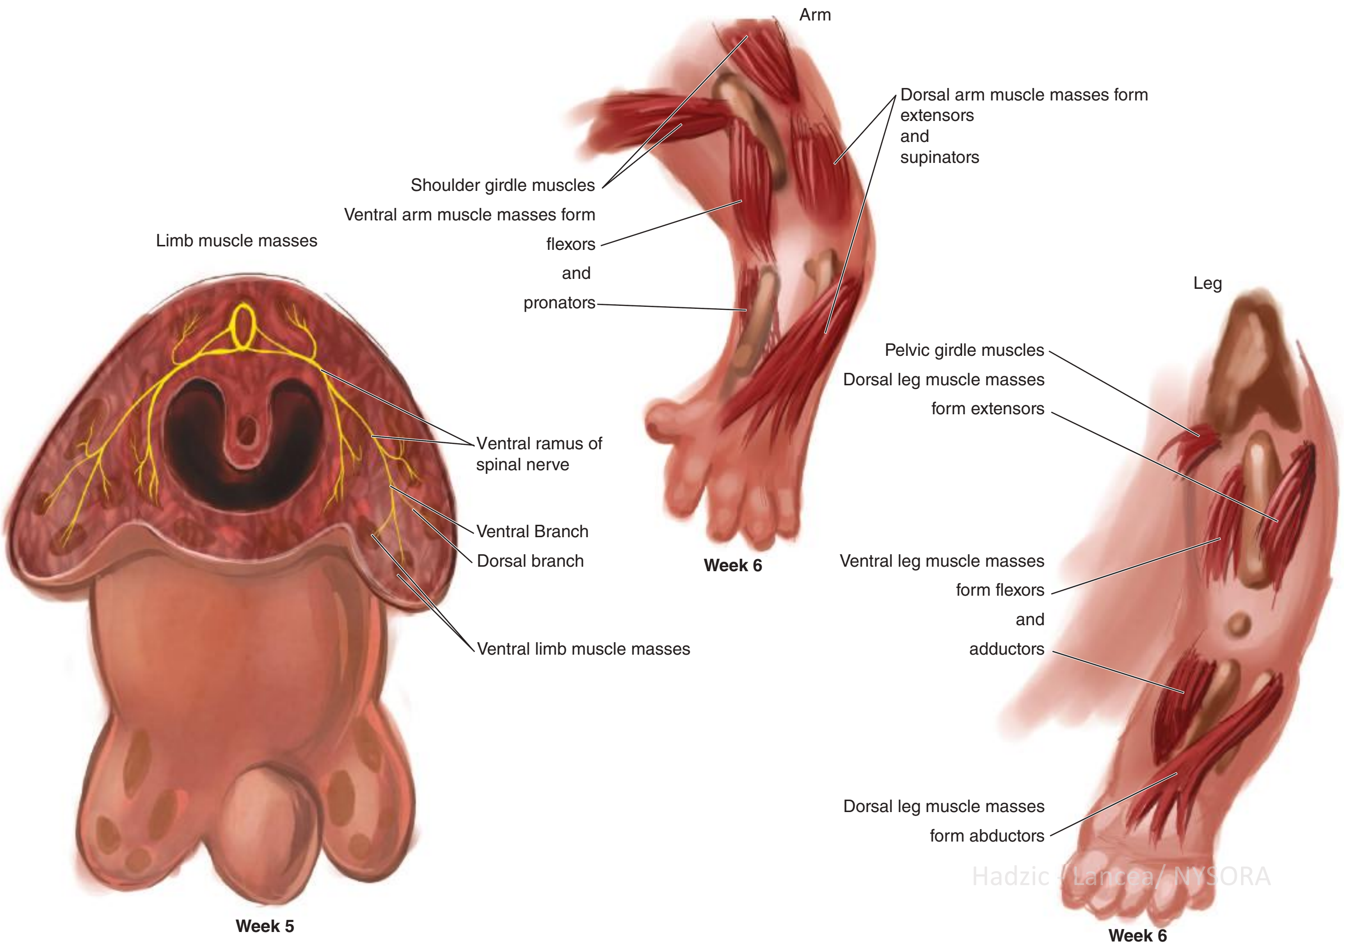

FIGURE 2–12. Formation of the spinal nerves.

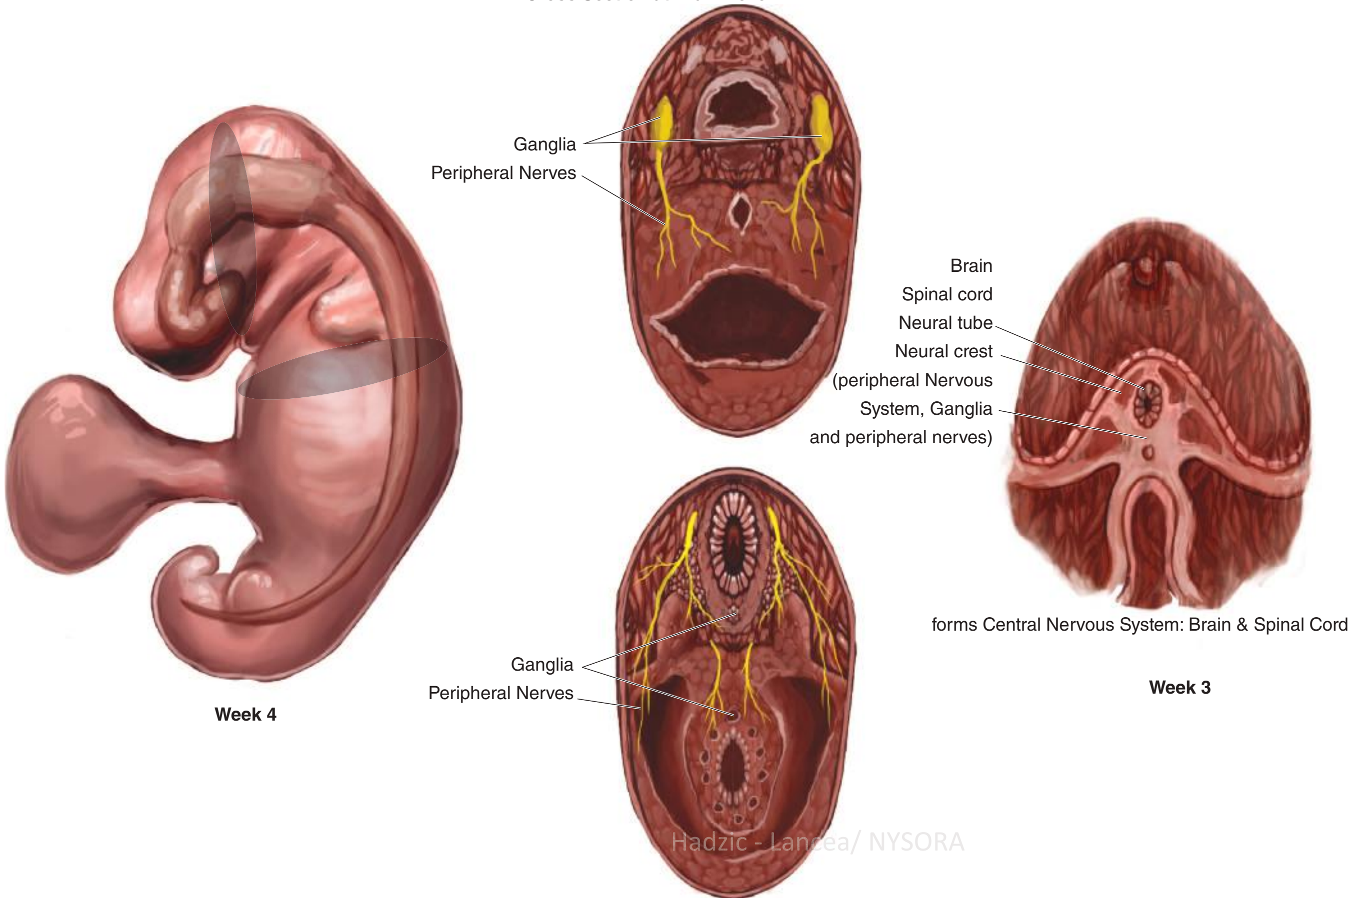

FIGURE 2–13. Development of the peripheral nervous system.

with the differentiating mesoderm condensations. This early contact is a prerequisite for their complete functional differentiation. Spinal nerves therefore play an important role in differentiation and motor innervation of the limb musculature, as well as providing sensory innervation for the dermatomes. Although the original dermatomal pattern changes with growth of the extremities, an orderly sequence can still be recognized in the adult.

Central Nervous System

The CNS originates in the ectoderm and appears as the **neural plate** at the middle of the third week[1] (Figure 2–14). After the edges of the plate fold, the **neural folds** approach each other in the midline to fuse, forming the **neural tube.** The CNS then forms as a tubular structure with a broad cephalic portion (the brain) and a long caudal portion (the spinal cord). A basal plate, containing the motor neurons, and an alar plate, containing the sensory neurons, characterize the spinal cord, which forms the caudal end of the CNS.

The walls of the recently closed neural tube consist of neuroepithelial cells. These cells give rise to another type of cell, the **neuroblasts,** which are primitive nerve cells. They form a **mantle layer** around the neuroepithelial layer. This mantle layer later forms the gray matter of the spinal cord. The outermost layer of the spinal cord, called the **marginal layer,** contains nerve fibers emerging from neuroblasts in the mantle layer. As a result of myelination, this layer takes on a white appearance and is called the white matter of the spinal cord.[1] Because of the continuous addition of neuroblasts to the mantle layer, each side of the neural tube shows ventral and dorsal thickening. The ventral thickening (the basal plates) contains ventral motor horn cells. The dorsal thickening (the alar plates) forms the sensory areas. A group of neurons accumulate between these two areas, forming a small intermediate horn, which contains neurons of the sympathetic portion of the autonomic nervous system and is present only at thoracic and upper lumbar levels of the spinal cord[1] (Figure 2–15).

Spinal Nerves

Motor nerve fibers begin to appear in the fourth week, arising from nerve cells in the basal plates of the spinal cord.[4] They collect into bundles known as ventral nerve roots. Likewise, dorsal nerve roots form as collections of fibers originating from cells in dorsal root ganglia. Central processes from these ganglia form processes that grow into the spinal cord opposite the dorsal horns, and distal processes join the ventral nerve roots to form a spinal nerve. Spinal nerves divide into dorsal and ventral primary rami. Dorsal rami innervate dorsal axial musculature, vertebral joints, and the skin of the back. Ventral primary rami

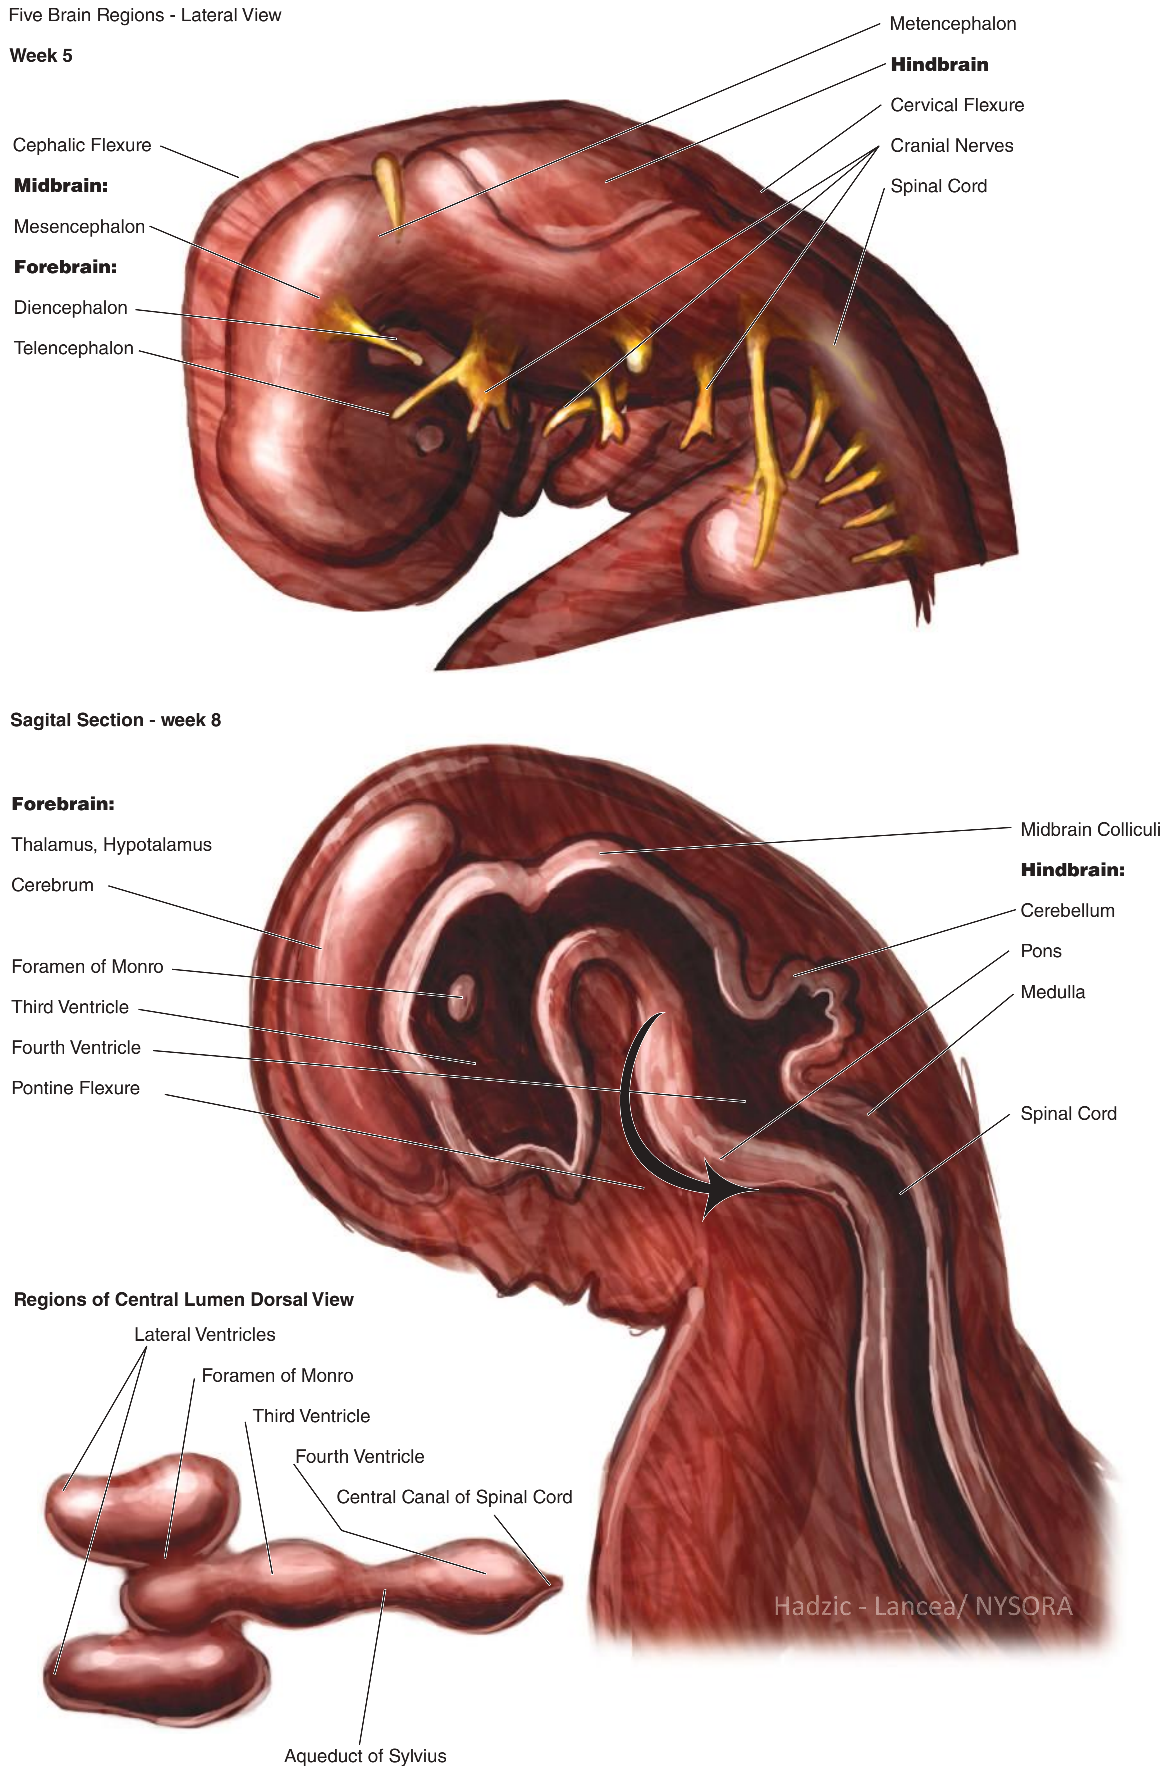

FIGURE 2–14. Development of the central nervous system.

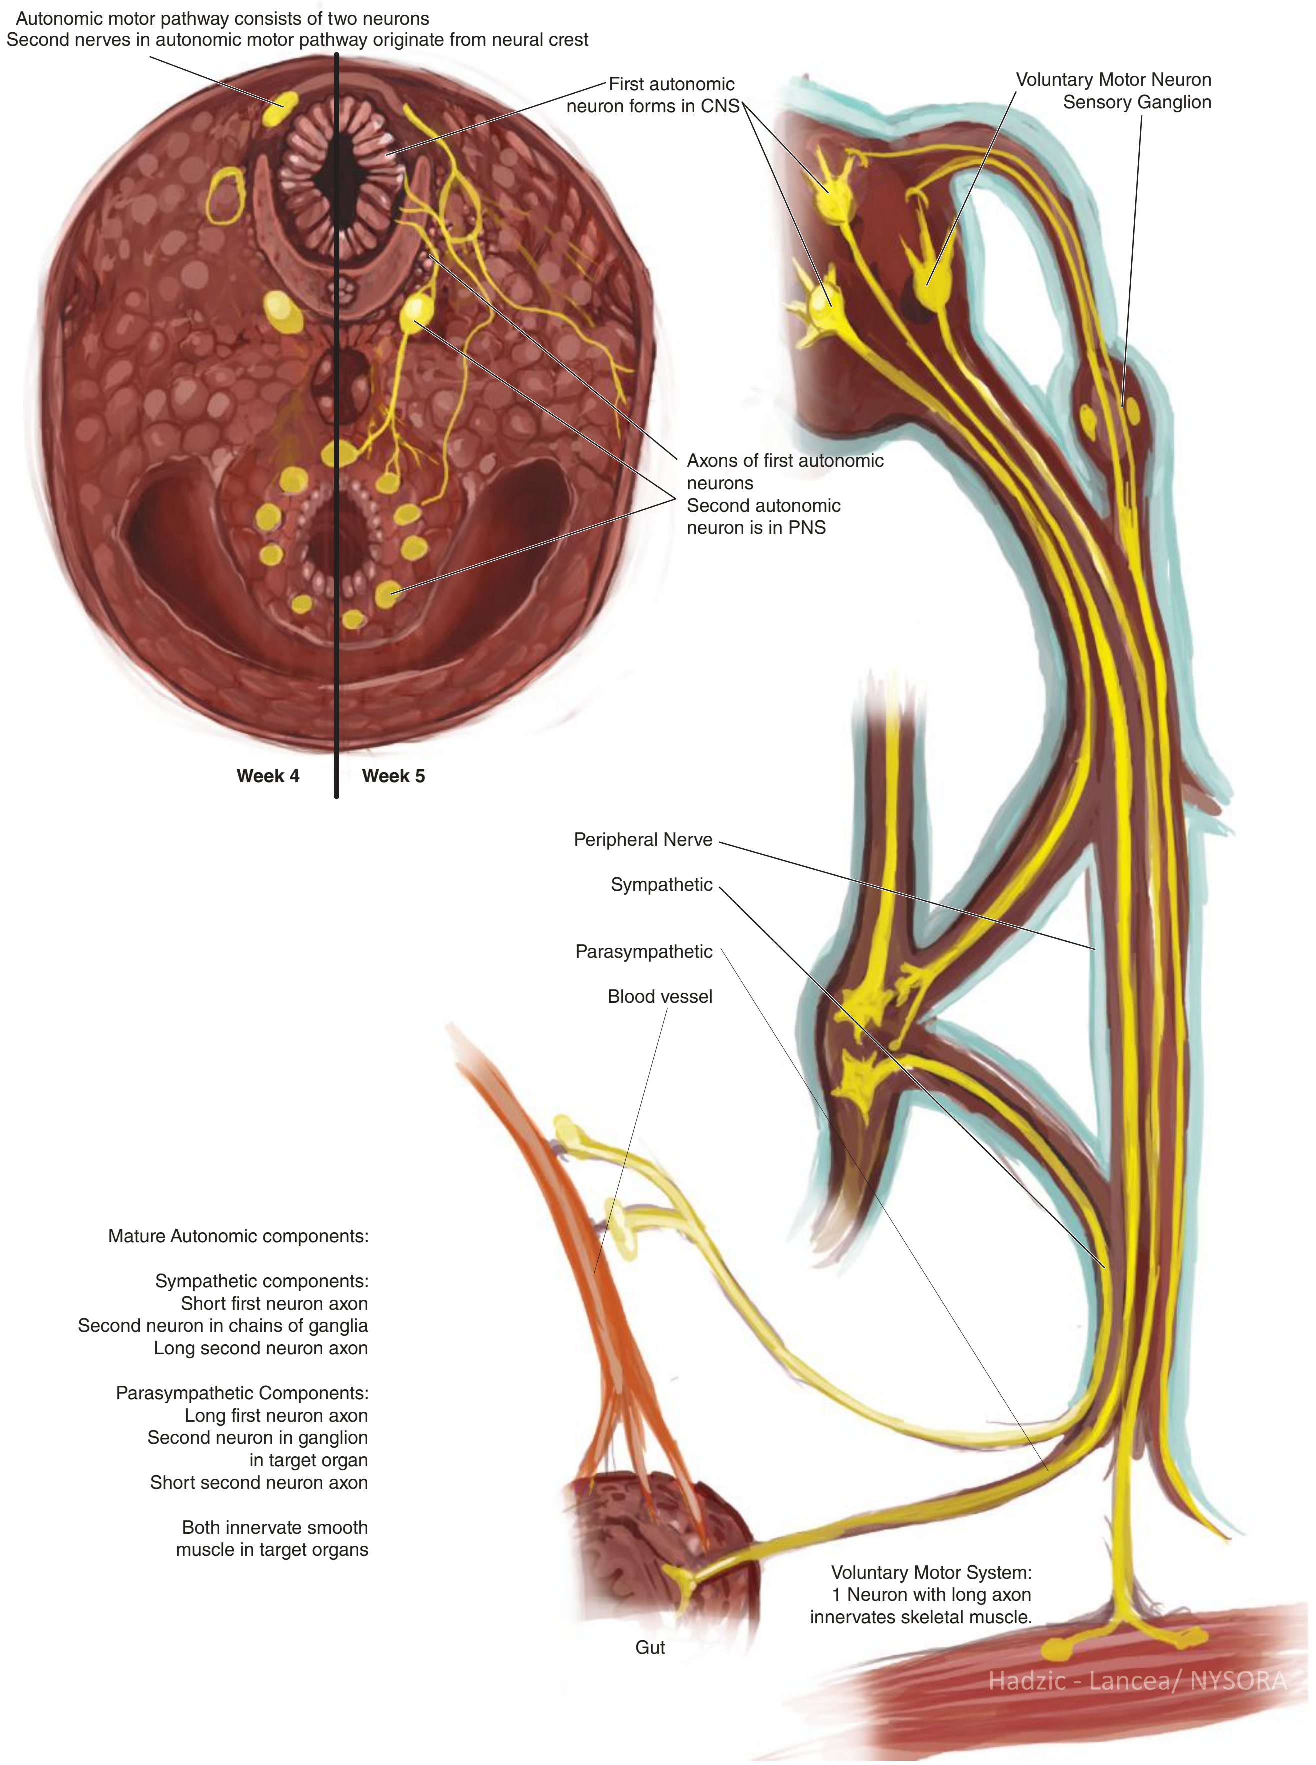

FIGURE 2–15. Development of autonomic nervous system.

innervate the limbs and ventral body wall and form the major nerve plexuses.[1]

In the third month of development, the spinal cord extends the entire length of the embryo, and spinal nerves pass through the intervertebral foramina at their level of origin. With increasing age, the vertebral column and dura lengthen more rapidly than the neural tube, resulting in the terminal end of the spinal cord gradually shifting to a higher level. At birth, this level is at the third lumbar vertebra. In the adult, the spinal cord terminates at the level of L2 to L3, whereas the dural sac and subarachnoid space extend to S2. As a result of this disproportionate growth, spinal nerves run obliquely from their segment of origin in the spinal cord to the corresponding level of the vertebral column. Below L2 to L3, a thread-like extension of the pia mater forms the filum terminale, which is attached to the periosteum of the first coccygeal vertebra and marks the tract of regression of the spinal cord.[1]

The Brain

The brain consists originally of three vesicles: the **rhombencephalon** (hindbrain), **mesencephalon** (midbrain), and **prosencephalon** (forebrain). The rhombencephalon will ultimately form the medulla oblongata, pons, and cerebellum. The mesencephalon resembles the spinal cord with its basal and alar plates. It will contain the anterior and posterior colliculi, forming the relay stations for visual and auditory reflex centers. The prosencephalon will ultimately give rise to the thalamus and hypothalamus as well as the cerebral hemispheres.[1]

Autonomic Nervous System

Functionally, the autonomic nervous system can be divided into two parts: a sympathetic portion in the thoracolumbar region and a parasympathetic portion in the cephalic and sacral regions. Both components of the autonomic nervous system consist of two tiers of neurons: pre- and postganglionic (Figure 2–16).

Sympathetic Nervous System

Preganglionic neurons of the sympathetic nervous system arise from the intermediate horn of the gray matter in the spinal cord.[3] At levels from T1 to L2, their myelinated axons grow from the cord *through* the ventral roots, paralleling the motor axons that supply the skeletal musculature. Shortly after the dorsal and ventral roots of the spinal nerve join, the preganglionic sympathetic axons, derived from the neuroepithelium of the neural tube, leave the spinal nerve via a **white communicating ramus.** They soon enter one of a series of sympathetic ganglia to synapse with neural crest-derived postganglionic neurons. The sympathetic ganglia, the bulk of which are organized as two chains running ventrolateral to the vertebral bodies, are laid down by neural crest cells that migrate from the closing neural tube along a special pathway. Once the migrating sympathetic neuroblasts have reached the site at which the sympathetic chain ganglia form, they spread both cranially and caudally until the extent of the chains approximates that seen in the adult. Some of the sympathetic neuroblasts migrate farther ventrally than the level of the chain ganglion to form a variety of other collateral ganglia. The adrenal medulla can be broadly viewed as a highly modified sympathetic ganglion. The outgrowing preganglionic sympathetic neurons either terminate within the chain ganglia or pass through on their way to more distant sympathetic ganglia to form synapses with the cell bodies of the second-order, or postganglionic, sympathetic neuroblasts. Axons of some postganglionic neuroblasts, which are unmyelinated, leave the chain ganglion as a parallel group and reenter the nearest spinal nerve through the **gray communicating ramus.** Once in the spinal nerve, these axons continue to grow until they reach their peripheral targets.

During the fifth week of development, cells originating in the neural crest of the thoracic region migrate on each side of the spinal cord toward the region immediately behind the dorsal aorta.[1] Here, they form a bilateral chain of segmentally arranged sympathetic ganglia interconnected by longitudinal nerve fibers. Together, they form the sympathetic chains on each side of the vertebral column. From their position in the thorax, neuroblasts migrate toward the cervical and lumbosacral regions, extending the sympathetic chains to their full length. Some sympathetic neuroblasts migrate in front of the aorta to form preaortic ganglia, such as the celiac and mesenteric ganglia. Other sympathetic cells migrate to the heart, lungs, and gastrointestinal tract, where they give rise to sympathetic organ plexuses. Once the sympathetic chains have been established, nerve fibers originating in the intermediate horn of the thoracolumbar segments of the spinal cord penetrate the ganglia of the chain. They are known as preganglionic fibers, have a myelin sheath, and stimulate sympathetic ganglion cells. Passing from spinal nerves to the sympathetic ganglia, they form the **white communicating rami.** Axons of the sympathetic ganglion cells, the postganglionic fibers, have no myelin sheath. They either pass to other levels of the sympathetic chain or extend to the heart, lungs, and intestinal tract. Other fibers, the gray communicating rami, which are found at all levels of the spinal cord, pass from the sympathetic chain to spinal nerves and from there to peripheral blood vessels, hair, and sweat glands.

Parasympathetic Nervous System

Neurons in the brainstem and the sacral region of the spinal cord give rise to preganglionic parasympathetic fibers.[1] Although also organized on a preganglionic and postganglionic basis, the parasympathetic nervous system has a distribution quite different from that of the sympathetic system. Like those of the sympathetic nervous system, preganglionic parasympathetic neurons originate in the intermediate column of the CNS. However, the levels of origin of these neuroblasts are the mid- and hindbrain and in the second to fourth sacral segments of the developing spinal cord. Axons from these preganglionic neuroblasts grow long distances before they meet the neural crest–derived postganglionic neurons. These are typically embedded in small, scattered ganglia or plexuses in the walls of the organs they innervate.

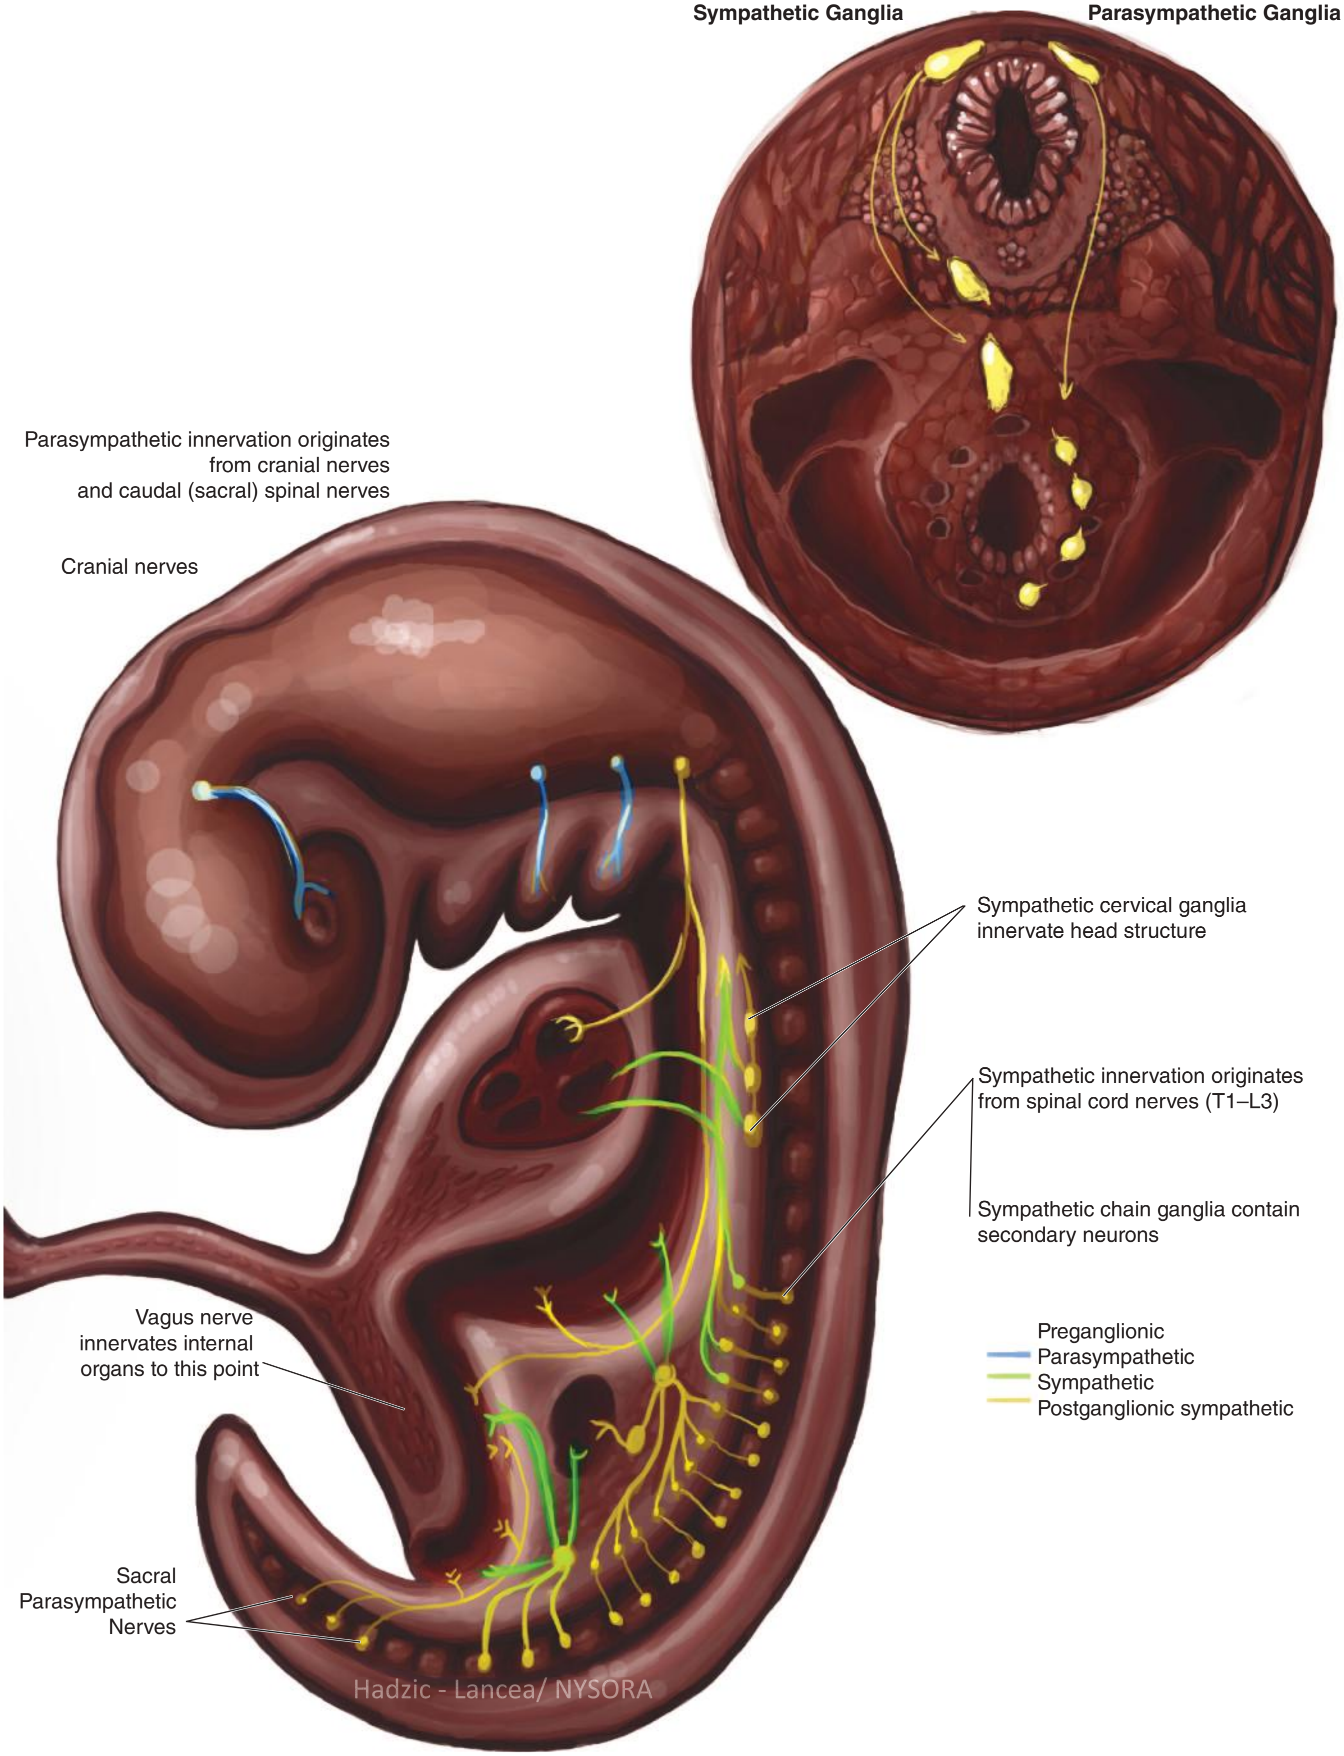

FIGURE 2–16. Development of autonomic nervous system: pre- and postganglionic neurons.

CLINICAL RELEVANCE

Functional Analysis of the Brachial Plexus

The separation of the trunks of the brachial plexus into anterior and posterior divisions places the nerves into relation with muscles formed from primitive anterior and posterior mesoderm masses during the development of the limbs. Once these relationships are established, they are never reversed, and the same fundamental correlation exists in the adult.[5,6] The anterior divisions of the trunks unite to form the lateral and medial chords of the brachial plexus, and the posterior divisions join to form the single posterior cord. Thus, all branches of the lateral and medial chords carry nerve bundles derived from the anterior divisions of the trunks, and the branches of the posterior cord conduct exclusively fibers from the posterior divisions. The discrete compartments of the upper extremity contain muscle groups of similar and related functions as well as the blood vessels and nerves that supply them. This concept is emphasized in the word *preaxial* to designate the component and structures anterior to the bone and fascial plane or axis of the limb and the word *postaxial* to designate structures behind the bony and fascial axis. With the limb in the anatomical position, those parts anterior to the bony axis are all in a continuous plane down the front of the limb, with the ventral axial line extending along the anterior surface of the arm and forearm. The postaxial parts are positioned continuously down the back of the limb.

The branches of the lateral and medial chords are all preaxial and innervate the preaxial muscles of the limb, whereas the posterior cord branches are postaxial and innervate the postaxial musculature. The radial nerve, being the only postaxial nerve below the shoulder, supplies all the postaxial muscles in the remainder of the limb. The median, musculocutaneous, and ulnar nerves share preaxial innervation.

The musculocutaneous nerve is muscular in the arm and cutaneous in the forearm, and it is the sole preaxial muscular nerve in the arm. The preaxial median and ulnar nerves are nerves of passage in the arm, but in the forearm and hand, each contributes to innervation, the median nerve more heavily in the forearm, the ulnar nerve more heavily in the hand.

In the shoulder region, many of the supra- and infraclavicular branches of the brachial plexus arise from recognizable pre- and postaxial cords or divisions. Their origins have the same significance as the major anterior and posterior divisions of the trunks. An example of this is the clavicle and the scapula. The clavicle is an anterior and the scapula a posterior bone. An exception to this designation involves the scapula because its coracoid process has a phylogenetic history as a separate bone and fuses with the scapula. Therefore, all muscles arising from the scapula, exclusive of the coracoid process (pectoralis minor, coracobrachialis, and short head of biceps), belong to a postaxial group at the shoulder, and those from the clavicle and coracoid belong to a preaxial group. The nerve-muscle correlation is maintained in that all muscles of scapular origin are supplied by postaxial branches of the brachial plexus, and all muscles derived from the clavicle and coracoid are supplied by preaxial branches.

Functional Analysis of the Lumbosacral Plexus

The innervation of the lower extremity follows the same pattern of pre- and postaxial orientation as described for the upper extremity. The primordial dermatomal pattern has disappeared, but an orderly sequence of dermatomes can still be recognized. Most of the original ventral surface of the lower limb lies on the back of the adult limb. The ventral axial line extends along the medial side of the thigh and knee to the posteromedial aspect of the leg to the heel.

As previously described, this results from the medial rotation of the lower limb at the end of the embryonic period. The lumbar plexuses are formed by the ventral rami of the first three lumbar nerves and part of the fourth lumbar nerve. The primary preaxial components are the genitofemoral nerve, which derives from L1 and L2, and obturator and accessory obturator nerves, which are derived from L2 and L3, respectively. The primary postaxial components are the lateral femoral cutaneous nerve, derived from L2 and L3, and the femoral nerve, derived from L2 through L4. The sacral plexus combines the ventral rami of part of L4 and L5 and S1 through S3, as well as part of S4. All these nerves, except S4, divide into anterior and posterior branches. Like the brachial plexus, the anterior branches form preaxial nerves related to preaxial muscle masses in skin areas, and the posterior branches form similarly related postaxial nerves. The principal nerve of the sacral plexus is the sciatic, which is composed of a preaxial nerve (the tibial nerve) and a postaxial nerve (the common peroneal), which is enclosed within a single sheath.

SUMMARY

In summary, regional anesthesia may be considered a practice of applied anatomy. Successful neuraxial and peripheral nerve blockade alike require a logical approach to the anatomic principles. Knowledge of the embryologic development of tissues and neural structures can significantly add to the understanding of functional anatomy as it relates to regional anesthesia.

CHAPTER 3

Functional Regional Anesthesia Anatomy

Anna Carrera, Ana M. Lopez, Xavier Sala-Blanch, Eldan Kapur, Ilvana Hasanbegovic, and Admir Hadzic

INTRODUCTION

The practice of regional anesthesia is inconceivable without sound knowledge of the functional regional anesthesia anatomy. Just as surgical technique relies on surgical anatomy or pathology leans on pathologic anatomy, the anatomic information necessary for the practice of regional anesthesia must be specific to this application. In the past, many nerve block techniques and approaches were devised by academicians merely relying on idealized anatomic diagrams and schematics, rather than on functional anatomy. However, once the anatomic layers and tissue sheets are dissected, the anatomy of nerve structures without the tissue sheaths around them is of little relevance to the clinical practice of regional anesthesia. This is because accurate placement of the needle and the spread of the local anesthetic after an injection depend on the interplay between neurologic structures and the neighboring tissues where local anesthetic pools and accumulates, rather than on the mere anatomic organization of the nerves and plexuses. Much research on functional regional anesthesia, a term introduced by Dr. Jerry Vloka in the 1990s, has contributed to better understanding of the anatomy of regional nerve blockade. Moreover, the introduction of ultrasound in the practice of regional anesthesia has further clarified the relationship of the needle and the nerve and the dynamics of local anesthetic spread.

The goal of this chapter is to provide a generalized and rather concise overview of anatomy relevant to the practice of regional anesthesia; more specific anatomic discussions pertaining to individual regional anesthesia techniques are detailed in their respective chapters. The reader is referred to Figure 3–1 for an easier orientation of the body planes discussed throughout the book.

ANATOMY OF PERIPHERAL NERVES

All peripheral nerves are similar in structure. The **neuron** is the basic functional neuronal unit responsible for the conduction of nerve impulses. Neurons are the longest cells in the body, many reaching a meter in length. Most neurons are incapable of dividing under normal circumstances and have limited ability to repair themselves after injury. A typical neuron consists of a cell body (soma) that contains a large nucleus. The cell body is attached to several branching processes, called dendrites, and a single axon. Dendrites receive incoming messages; axons conduct outgoing messages. Axons vary in length, and there is one only per neuron. In peripheral nerves, axons are long and slender. They are also called nerve fibers. The peripheral nerve is composed of three parts: (1) somatosensory or afferent neurons, (2) motor or efferent neurons, and (3) autonomic neurons.

Individual nerve fibers bind together, somewhat like individual wires in an electric cable (Figure 3–2). In the peripheral nerve, individual axons are eveloped by the endoneurium, which is a delicate layer of loose connective tissue around each axon. Groups of axons are closely associated within a bundle called a nerve fascicle that is surrounded by the perineurium, which imparts mechanical strength to the peripheral nerve. In surgical procedures, the perineurium holds sutures without tearing. In addition to its mechanical strength, the perineurium functions as a diffusion barrier to the fascicle, isolating the endoneural space around the axon from the surrounding tissue.[1] This barrier helps to preserve the ionic milieu of the axon and functions as a blood–nerve barrier. The **perineurium** surrounds each fasciculus and splits with it at each branching point. The fascicular bundles in turn are embedded in loose connective tissue called the **interfascicular epineurium,** which

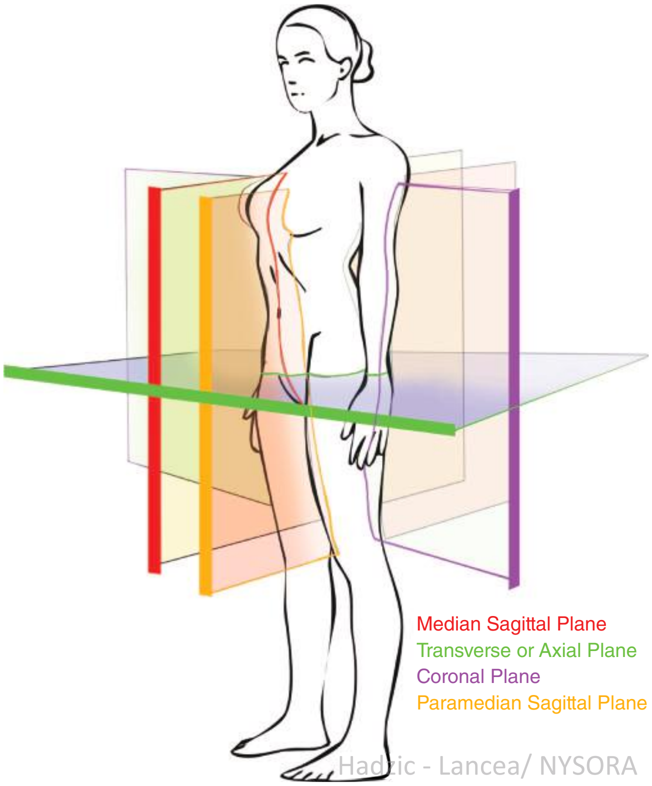

FIGURE 3–1. Conventional body planes.

contains adipose tissue, fibroblasts, mastocytes, blood vessels (with small nerve fibers innervating these vessels), and lymphatics. In contrast, a more dense collagenous tissue forms the **epineurium** that surrounds the entire nerve and holds it loosely to the connective tissue through which it travels.

Of note, the fascicular bundles are not continuous throughout the peripheral nerve. They divide and anastomose with one another as frequently as every few millimeters.[1] However, the axons within a small set of adjacent bundles redistribute themselves so that the axons remain in approximately the same quadrant of the nerve for several centimeters. This arrangement is a practical concern to the surgeons trying to repair a severed nerve. If the cut is clean, it may be possible to suture individual fascicular bundles together. In such a scenario, there is a greater chance that the distal segment of nerves synapsing with the muscles will be sutured to the central stump of motor or sensory axons. In such cases, good functional recovery is more likely. If a short segment of the nerve is missing, however, the fascicles in the various quadrants of the stump may no longer correspond with one another, good axial alignment may not be possible, and functional recovery is greatly compromised or improbable.[1] This arrangement of the peripheral nerve helps explain why intraneural injections may result in disastrous consequences.

The connective tissue of a nerve is tougher, compared to the nerve fibers themselves, and allows a certain amount of "stretch" without damage to the nerve fibers. For instance, the axons are somewhat "wavy," and when stretched, the connective tissue around them is also stretched—giving it some protection. This feature plays a "safety" role in nerve blockade by allowing the nerves to be "pushed" rather than pierced by the advancing needle, as often seen on ultrasound. For this reason, it is prudent to avoid stretching the nerves and nerve plexuses during nerve blockade (eg, in axillary brachial plexus blocks and some approaches to the sciatic block).

The **paraneurium** consists of loose connective tissue that holds a stable relationship between adjacent structures filling the space in between them, such as the neurovascular bundles of intermuscular septae. This tissue contributes to functional mobility of nerves during joint and muscular movement.

Nerves receive blood from the adjacent blood vessels running along their course. These feeding branches to larger nerves are macroscopic in size and irregularly arranged, forming anastomoses to become longitudinally running vessel(s) that supply the nerve and give off subsidiary branches. Although the connective tissue sheath enveloping nerves serves to protect the nerves from stretching, it is also believed that neuronal injury after nerve blockade may be due, at least partly, to the pressure or stretch within connective sheaths that do not stretch well and the consequent interference with the vascular supply to the nerve.

Communication Between the Central and Peripheral Nervous Systems

The functional boundary between the central nervous system (CNS) and the peripheral nervous system (PNS) lies at the junction where oligodendrocytes meet Schwann cells along the axons that form the cranial and spinal nerve. The CNS communicates with the body through spinal nerves. Spinal nerves have both sensory and motor components (Figure 3–3). The **sensory fibers** arise from neurons in the dorsal root ganglia. Fibers enter the dorsolateral aspect of the spinal cord to form the dorsal root. The **motor fibers** arise from neurons in the ventral horn of the spinal cord. The fibers pass through the ventrolateral aspect of the spinal cord and form the ventral root. The dorsal and ventral roots converge in the intervertebral foramen to form a spinal nerve. After passing through the intervertebral foramen, the spinal nerve divides into dorsal and ventral rami. The dorsal ramus innervates muscle, bones, joints, and the skin of the back. The ventral ramus innervates muscle, bones, joints, and the skin of the anterior neck, thorax, abdomen, pelvis, and the extremities.

Spinal Nerves

There are 31 pairs of spinal nerves (Figure 3-4). The spinal nerves are enumerated by region: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. Spinal nerves pass through the vertebral column at the intervertebral foramina. The first cervical nerve (C1) passes superior to the C1 vertebra (atlas). The second cervical nerve (C2) passes between the C1 (atlas) and C2 (axis) vertebrae. This pattern continues down the cervical spine. A shift in pattern occurs at the C8 nerve because there is no C8 vertebra. The C8 nerve passes between the C7 and T1 vertebrae. The T1 nerve passes between the T1 and T2 vertebrae. This pattern continues down the remainder of the spine. The vertebral arch of the fifth sacral and first coccygeal

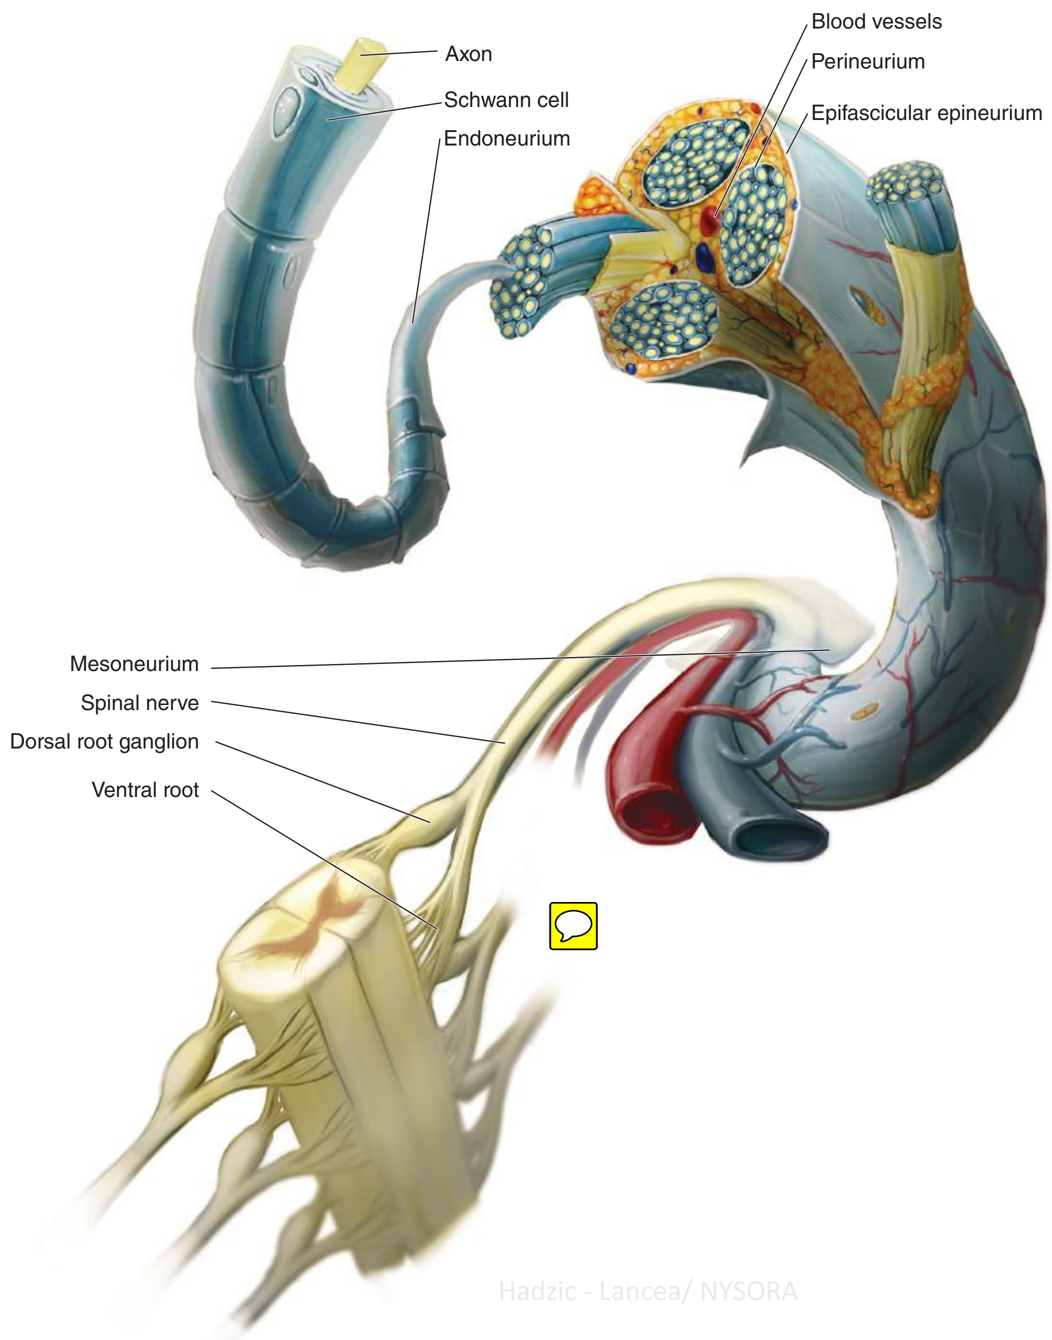

FIGURE 3–2. Organization of the peripheral nerve.

vertebrae is rudimentary. Because of this, the vertebral canal opens inferiorly at the sacral hiatus. The fifth sacral and first coccygeal nerves pass through the sacral hiatus. Because the inferior end of the spinal cord (conus medullaris) in adults is located at the L1 to L2 vertebral level, roots of spinal nerves must descend through the vertebral canal before exiting the vertebral column through the appropriate intervertebral foramen. Collectively, these roots are called the cauda equina.

Outside the vertebral column, ventral rami from different spinal levels coalesce to form intricate networks called plexuses. From the plexuses, nerves extend into the neck, the arms, and the legs.[1,2]

DERMATOMES, MYOTOMES, AND OSTEOTOMES

Dermatomal, myotomal, and osteotomal innervations are often emphasized in regional anesthesiology texts as important for the application of nerve blocks. In clinical practice of regional anesthesia, however, it is more practical to think in terms of which block techniques provide adequate analgesia and anesthesia for specific surgical procedures, rather than attempt to match nerves and spinal segments to the relevant dermatomal, myotomal, and osteotomal territory. Nevertheless, the description of dermatomal, myotomal, and osteotomal innervation is

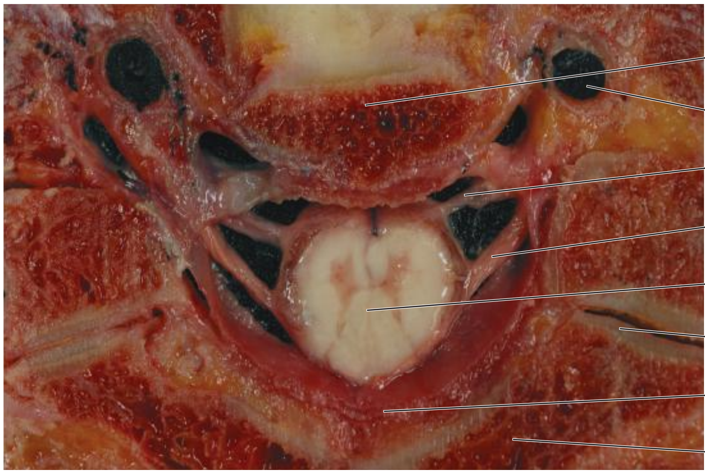

FIGURE 3–3. Transverse section of cervical spine showing the spine with the origin of spinal nerves.

of didactic importance in regional anesthesia and is briefly presented here.

A **dermatome** is an area of the skin supplied by the dorsal (sensory) root of the spinal nerve (Figures 3–5a, 3–5b, and 3–6). In the trunk, each segment is horizontally disposed, except C1, which does not have a sensory component. The dermatomes of the limbs from the fifth cervical to the first thoracic nerve and from the third lumbar to the second sacral vertebrae extend as a series of bands from the midline of the trunk posteriorly into the limbs. It should be noted that considerable overlapping occurs between adjacent dermatomes; that is, each segmental nerve overlaps the territories of its neighbors.[3]

A **myotome** is the segmental innervation of skeletal muscle by the ventral (motor) root(s) of the spinal nerve(s). Major myotomes, their function, and corresponding spinal levels are represented in Figure 3–7. The innervation of the bones and joints (**osteotome**) often does not follow the same segmental pattern as the innervation of the muscles and other soft tissues (Figure 3–8).

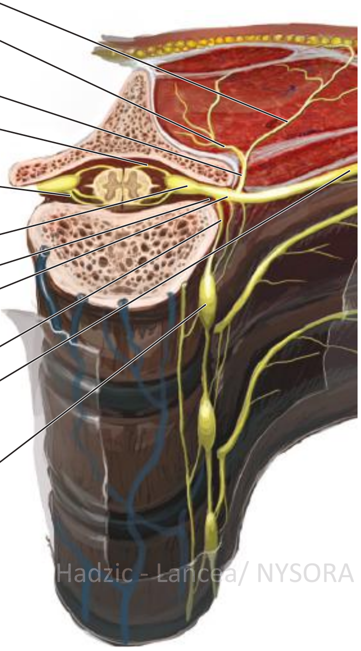

FIGURE 3–4. Anatomy of a spinal nerve (intercostal nerve).

ANATOMY OF PLEXUSES AND PERIPHERAL NERVES

Cervical Plexus

The cervical plexus innervates muscles, joints, and skin in the anterior neck (Table 3–1). It is formed by the ventral rami of C1 through C4 (Figures 3–9 and 3–10). The rami form a loop called the ansa cervicalis that sends branches to the infrahyoid muscles. In addition, the rami form nerves that pass directly to several structures in the neck and thorax, including the scalene muscles, diaphragm, clavicular joints, and skin covering the anterior neck.

Ansa Cervicalis

The ventral ramus of C1 attaches to the ventral rami of C2 to C3. The attachment forms a loop called the ansa cervicalis, which sends branches to the infrahyoid muscles. The infrahyoid muscles consist of the omohyoid, sternohyoid, and sternothyroid muscles. They attach to the anterior surface of the hyoid bone or to the thyroid cartilage. Contraction of these muscles moves the hyoid bone or thyroid cartilage downward, effectively opening the laryngeal aditus, promoting inspiration. The C1 component also sends fibers to the thyrohyoid and geniohyoid muscles. Contraction of these muscles moves the anterior hyoid bone superiorly, closing the laryngeal aditus. Closure of the laryngeal aditus is necessary for swallowing to occur safely. This is one of the reasons why high levels of spinal anesthesia result in airway compromise and the risk of aspiration.

Nerves to Scalene Muscles

The ventral rami of C2 to C4 send branches directly to the scalene muscles, which attach between the cervical spine and ribs. When the cervical spine is stabilized, contraction elevates the ribs. This promotes inspiration. Interscalene block may result in block of the scalene muscles in addition to the phrenic block.

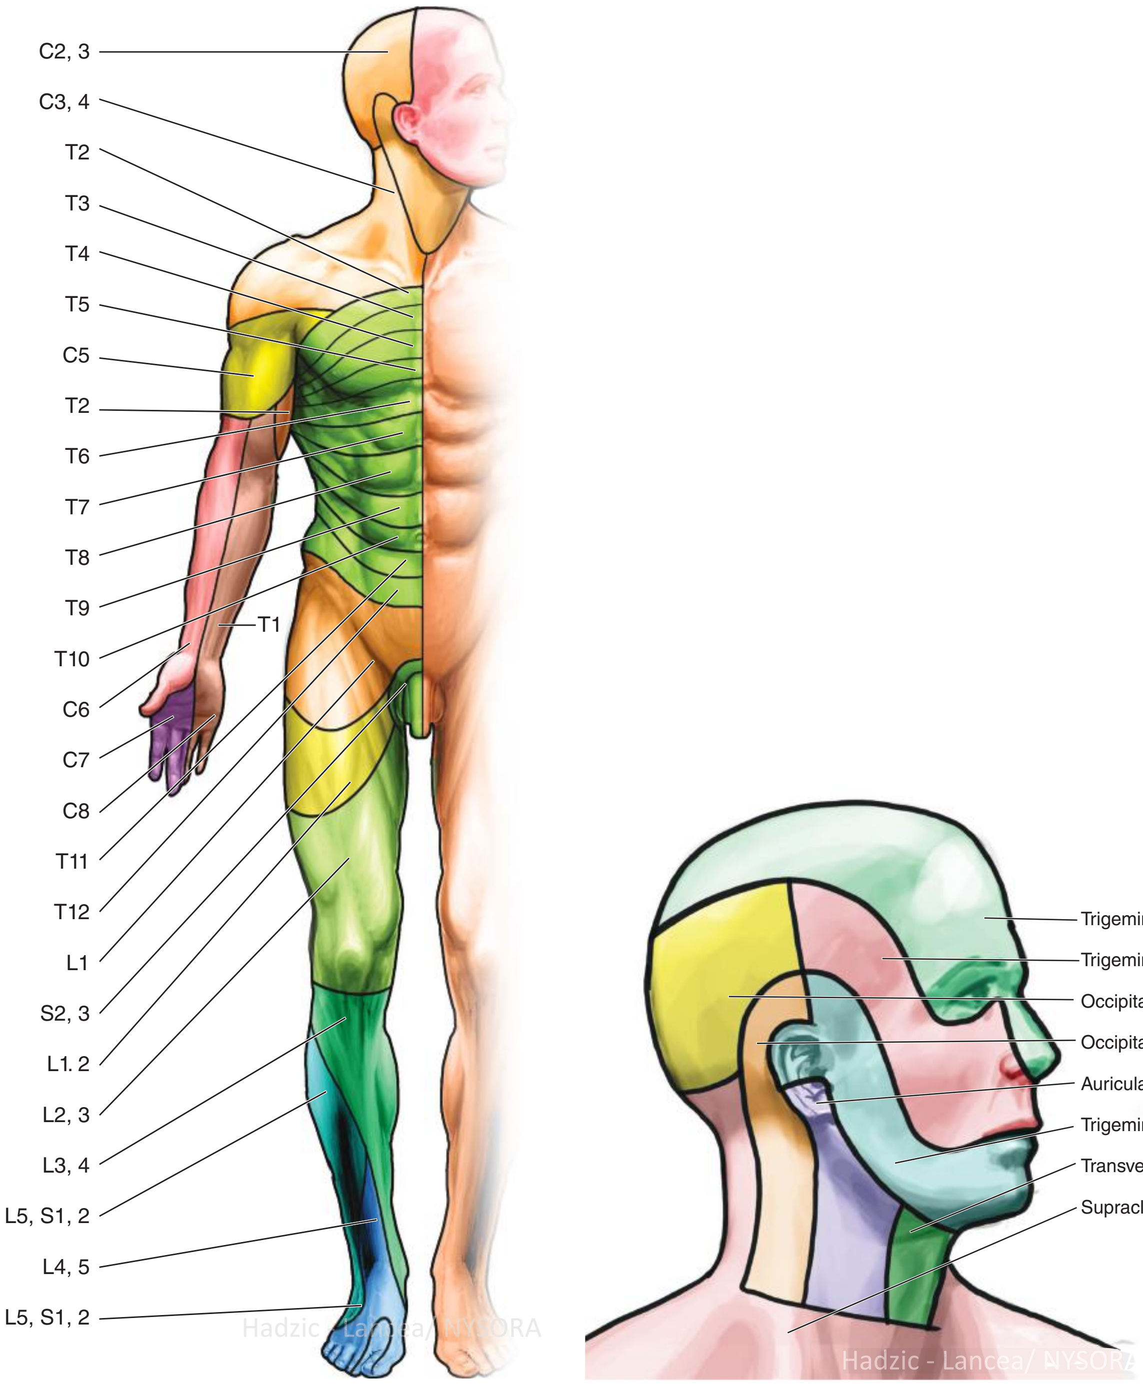

FIGURE 3–5. a, b: Dermatomes, anterior.

This is typically asymptomatic in healthy patients but may result in acute respiratory insufficiency in patients with borderline pulmonary function or in those with an exacerbation of asthma or chronic obstructive bronchitis. It is recommended that more distal approaches to a brachial plexus block and smaller injection volumes be used to limit the cephalad extension of the block, as well as shorter-acting local anesthetics to avoid prolonged blockade in case of respiratory insufficiency.

Phrenic Nerve

The phrenic nerve is formed by junction of fibers from C3 to C5, (Figure 3-10) and it innervates the diaphragm. The phrenic nerve descends through the neck on the anterior surface of the anterior scalene muscle, passing through the superior thoracic aperture and descending on the walls of the mediastinum to the diaphragm. In addition to muscular fibers, the phrenic nerve transmits sensory fibers to the superior and inferior surfaces of the diaphragm. All approaches to the block of the brachial plexus above the clavicle with high volumes result in phrenic blockade (Figure 3-12).

Cutaneous Nerves of the Anterior Neck

Cutaneous sensory nerves arise from the cervical plexus, pass around the posterior margin of sternocleidomastoid, and

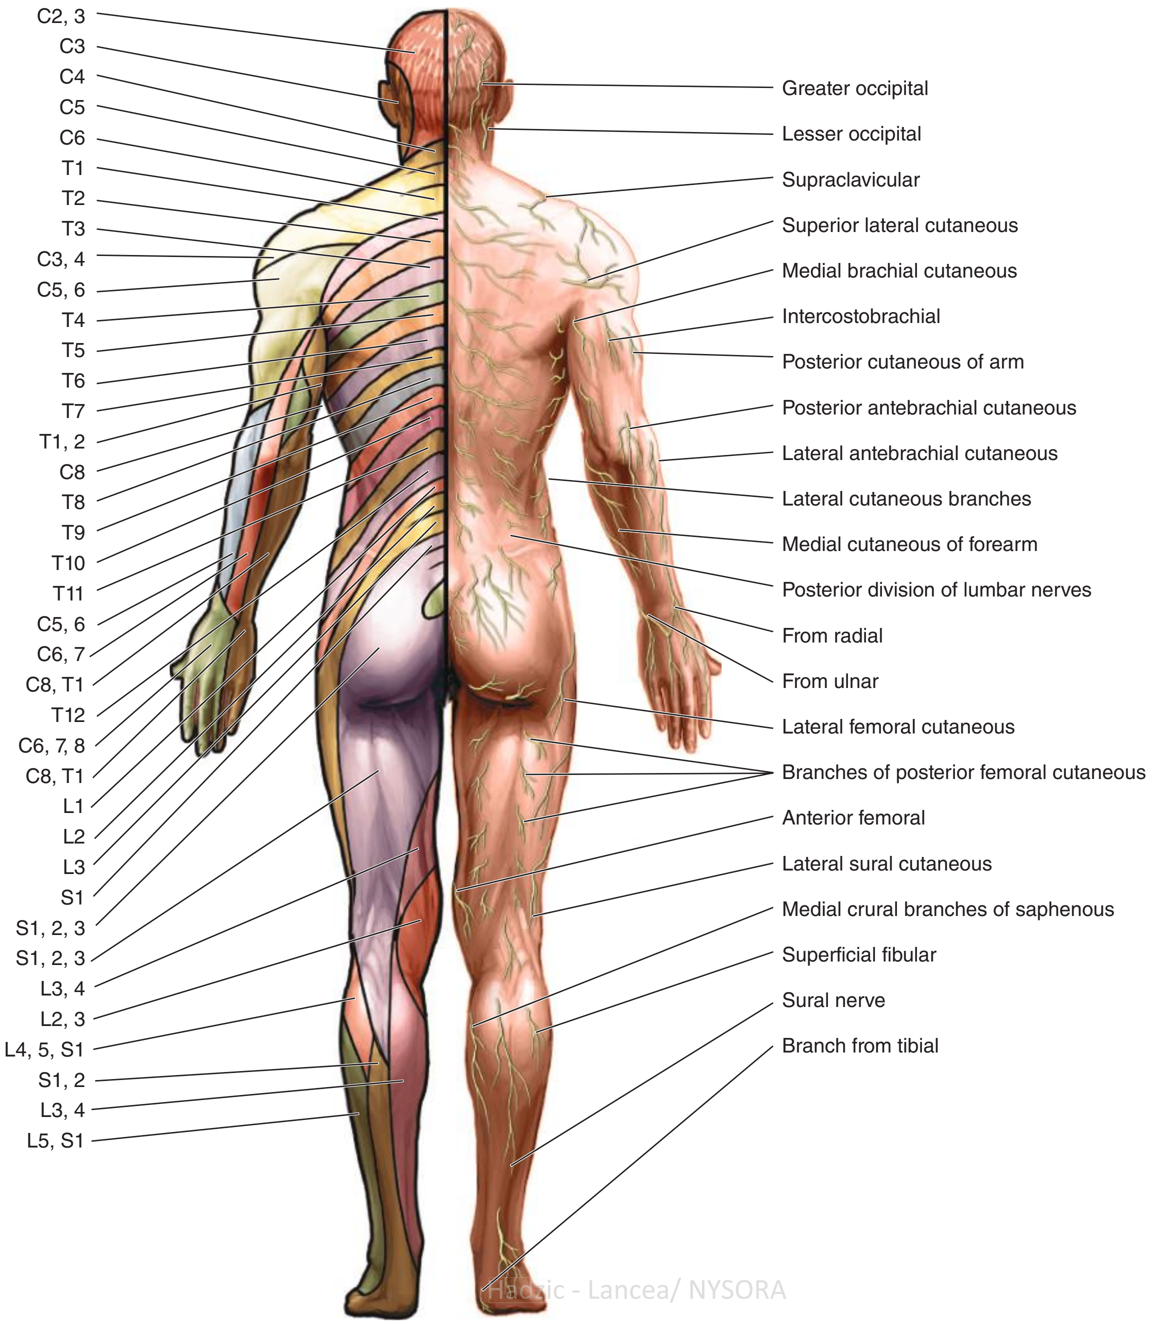

FIGURE 3–6. Dermatomes, posterior.

terminate in the scalp and anterior neck. The minor occipital nerve passes to the posterior auricular region of the scalp. The major auricular nerve passes to the auricle of the ear and to the region of the face anterior to the tragus. The transverse cervical nerve supplies the anterior neck. A series of supraclavicular nerves innervates the region covering the clavicle. Furthermore, the supraclavicular nerves may provide articular branches to the sternoclavicular and acromioclavicular joints.[4]

Brachial Plexus

The brachial plexus innervates bones, joints, muscles, and the skin of the upper extremity (Table 3–2). It is formed by ventral rami of C5 to T1 (Figures 3–11 and 3–12). In the posterior cervical triangle between the anterior and middle scalene muscles, the ventral rami join to form trunks. C5 and C6 join to form the superior trunk. C7 forms the middle trunk. C8 and T1 join to form the inferior trunk. All trunks branch into anterior and posterior divisions. All the posterior divisions join to form the posterior cord. The anterior divisions of the superior and middle trunks join to form the lateral cord. The anterior division of the inferior trunk forms the medial cord. Several terminal nerves arise within the posterior cervical triangle. Because they arise superior to the clavicle, they are called supraclavicular branches. The supraclavicular branches include the dorsal scapular nerve, the long thoracic nerve, the suprascapular nerve, and the nerve to the subclavius.[5–7]

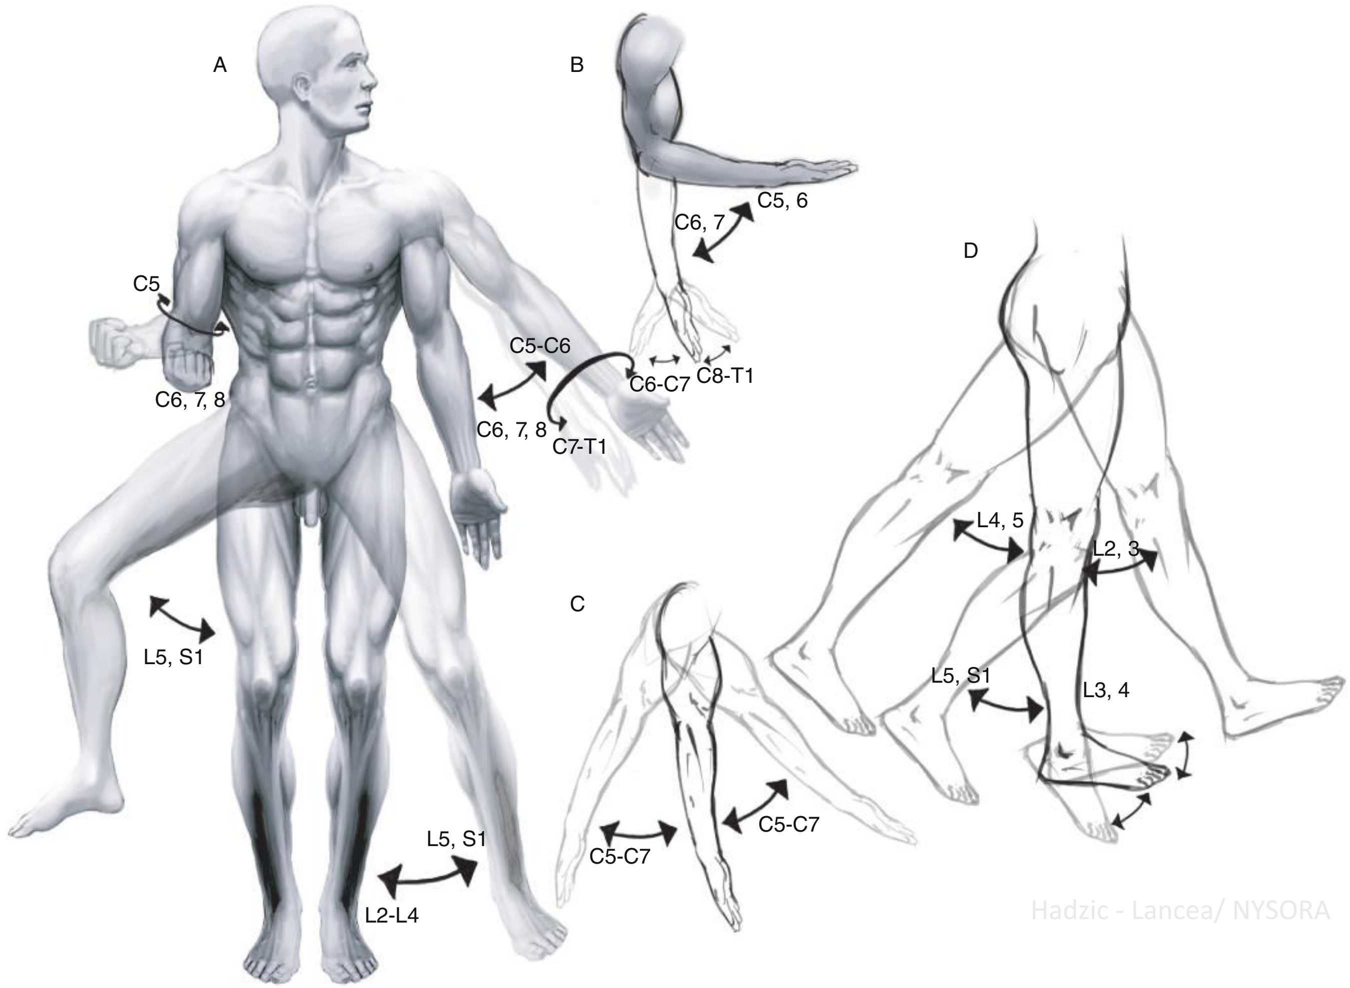

FIGURE 3–7. Functional innervation of the muscles (myotomes): **A:** Medial and lateral rotation of shoulder and hip, pronation and supination of wrist and forearm. Abduction and adduction of shoulder and hip. **B:** Flexion and extension of elbow and wrist. **C:** Flexion and extension of shoulder. **D:** Flexion and extension of hip, and knee. Dorsiflexion and plantar flexion of ankle, lateral views.

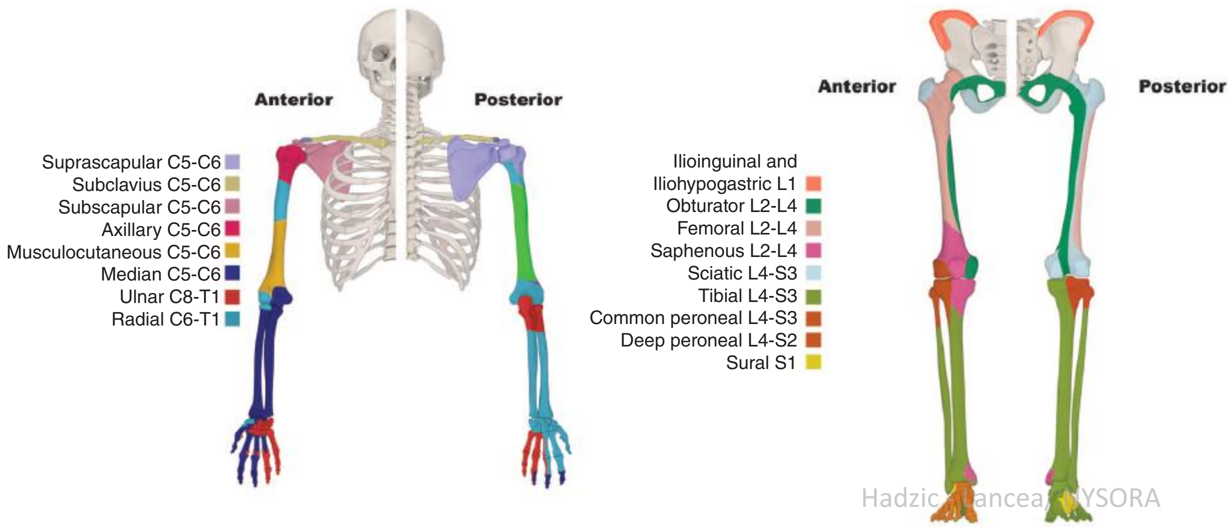

FIGURE 3–8. Innervation of the major bones (osteotomes).

TABLE 3–1. Organization and distribution of the cervical plexus.

Nerves	Spinal Segments	Distribution
Ansa cervicalis (superior and inferior branches)	C1 to C4	Five of the extrinsic laryngeal muscles (sternothyroid, sternohyoid, omohyoid, geniohyoid, and thyrohyoid) by way of CN XII
Lesser occipital, transverse cervical, supraclavicular, and greater auricular nerves	C2 to C3	Skin of upper chest, shoulder, neck, and ear
Phrenic nerve	C3 to C5	Diaphragm
Cervical nerves	C1 to C5	Levator scapulae, scalenes, sternocleidomastoid, and trapezius muscles (with CN XI)

CN = cranial nerve.

Supraclavicular Branches

Dorsal Scapular Nerve

The dorsal scapular nerve arises from the ventral ramus of C5. It follows the levator scapula muscle to the scapula and descends the medial border of the scapula on the deep surface of the rhomboid muscles. In its route, the dorsal scapular nerve innervates the levator scapula and rhomboid muscles.

Long Thoracic Nerve

The long thoracic nerve arises from the ventral rami of C5 to C7. It descends along the anterior surface of the middle scalene to

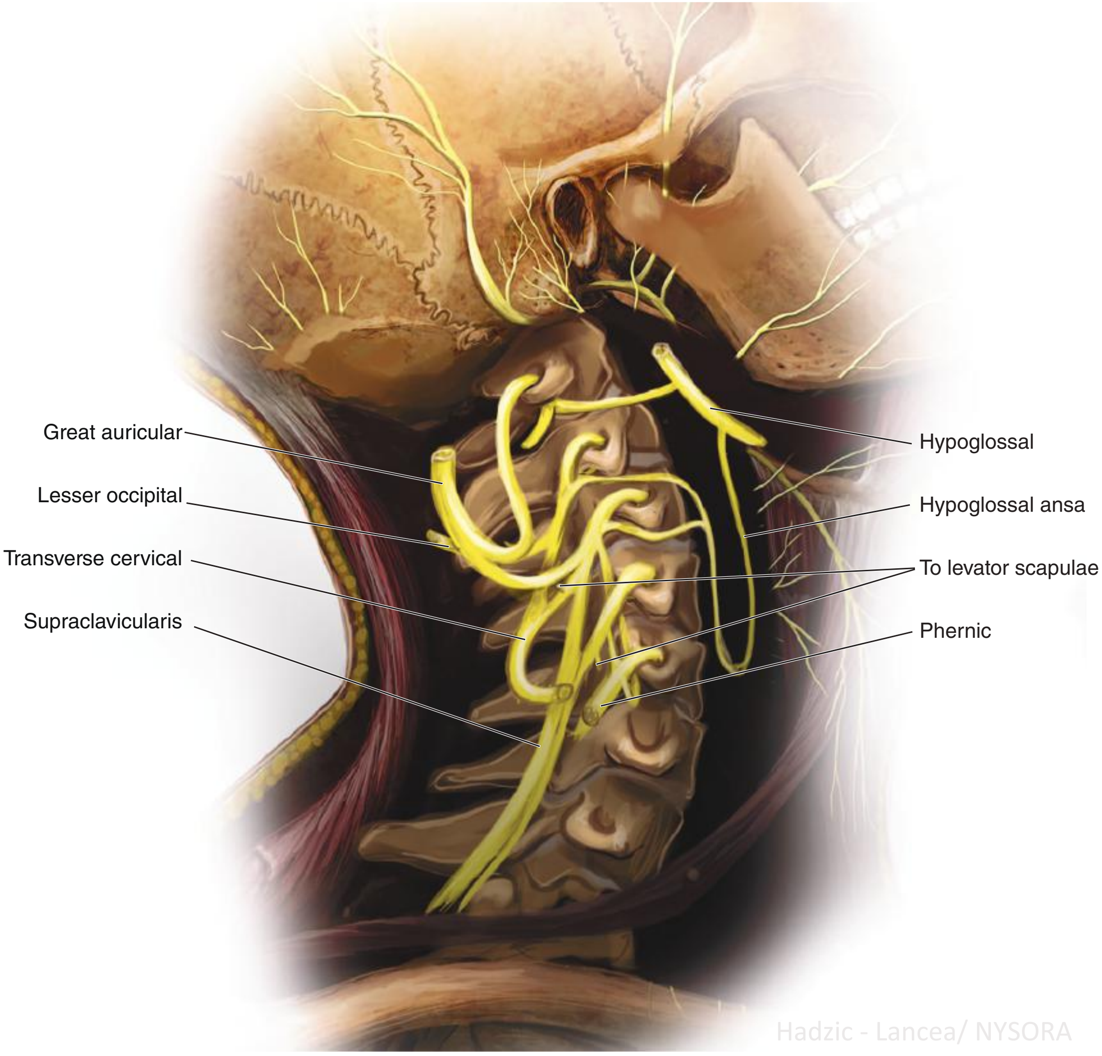

FIGURE 3–9. Cervical plexus.

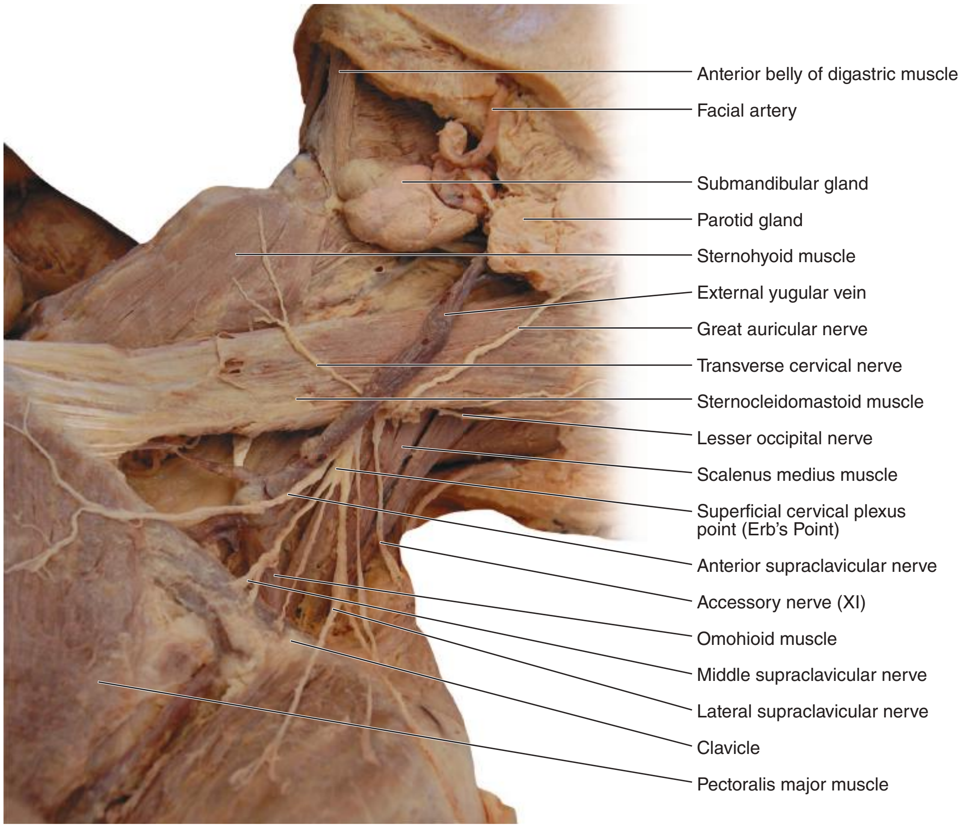

FIGURE 3–10. Dissection of cervical plexus.

TABLE 3–2. Organization and distribution of the brachial plexus.

Nerves(s)	Spinal Segments	Distribution
Nerves to subclavius	C4 to C6	Subclavius muscle
Dorsal scapular nerve	C5	Rhomboid muscles and levator scapulae muscle
Long thoracic nerve	C5 to C7	Serratus anterior muscle
Suprascapular nerve	C5, C6	Supraspinatus and infraspinatus muscles
Pectoralis nerve (median and lateral)	C5 to T1	Pectoralis muscles
Subscapular nerves	C5, C6	Subscapularis and teres major muscles
Thoracodorsal nerve	C6 to C8	Latissimus dorsi muscle
Axillary nerve	C5, C6	Deltoid and teres minor muscles; skin of shoulder
Radial nerve	C5 to T1	Extensor muscle of the arm and forearm (triceps brachii, extensor carpi radialis, supinator and anconeus muscles, and extensor carpi ulnaris muscles) and brachioradialis muscle; digital extensors and abductor pollicis muscle; skin over the posterolateral surface of the arm
Musculocutaneous nerve	C5 to C7	Flexor muscles on the arm (biceps brachii, brachialis, and coracobrachialis muscles); skin over lateral surface of forearm
Median nerve	C6 to T1	Flexor muscles on the forearm (flexor carpi radialis and palmaris longus muscles); pronator quadratus and pronator teres muscles; digital flexors (through the palmar interosseous nerve); skin over anterolateral surface of hand
Ulnar nerve	C8, T1	Flexor carpi ulnaris muscle, adductor pollicis muscle, and small digital muscles; medial part of flexor digitorum profundus muscle; skin over medial surface of the hand

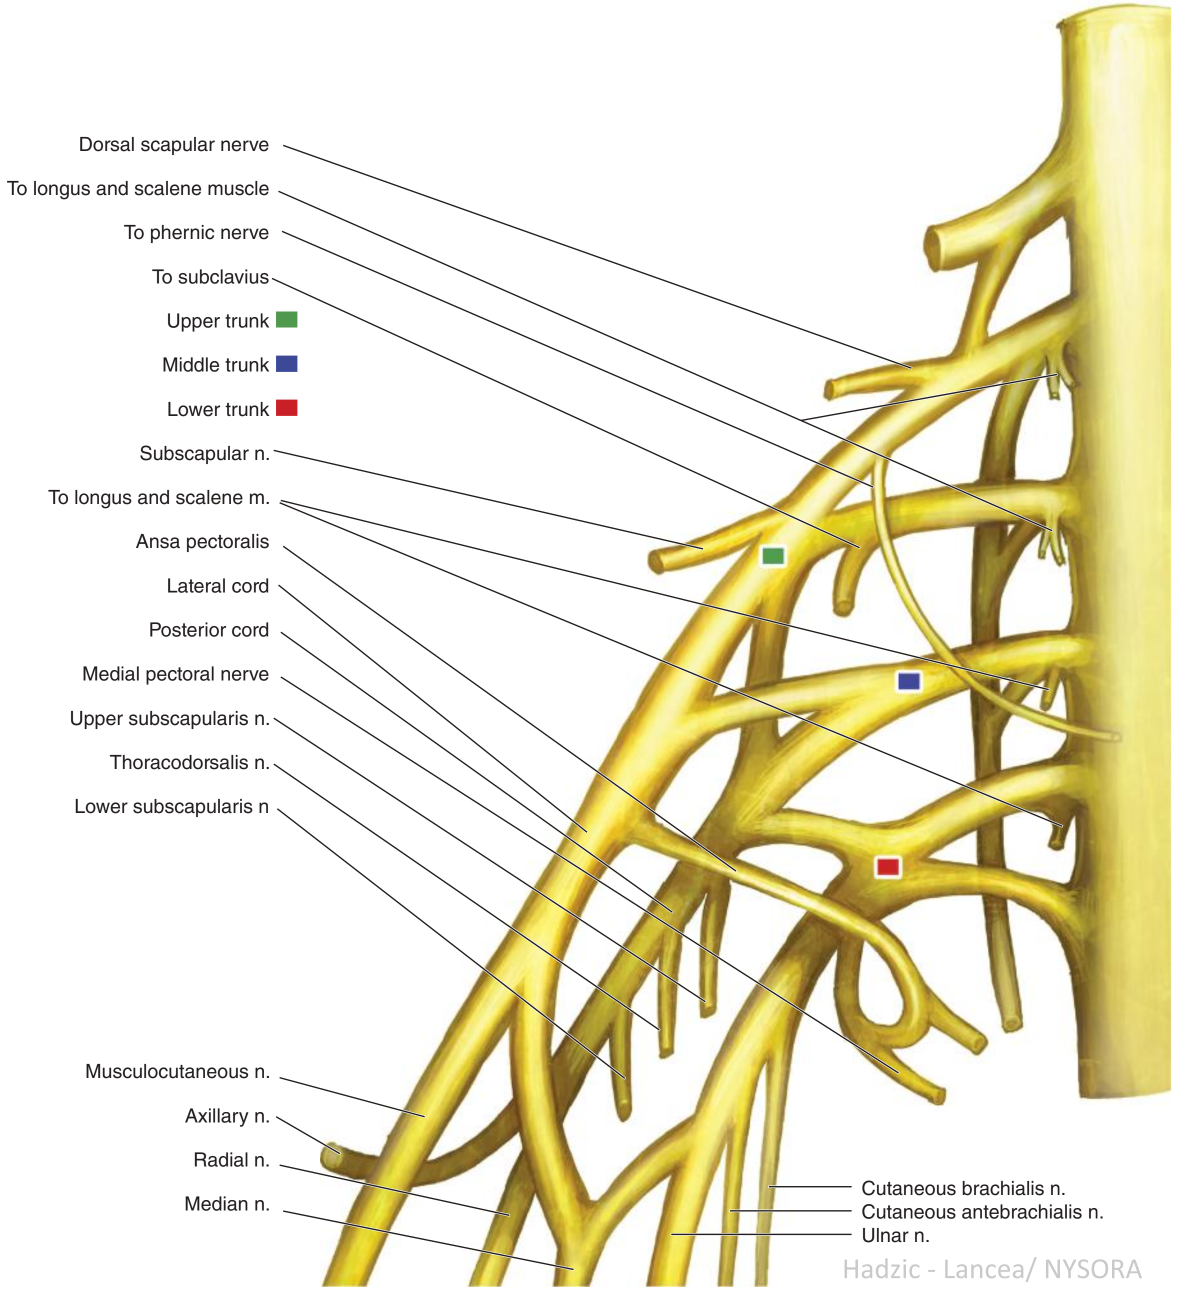

FIGURE 3–11. Scheme of organization of the brachial plexus.

the first rib and then transfers onto the serratus anterior muscle, which it innervates.

Suprascapular Nerve

The suprascapular nerve arises from the superior trunk. It follows the inferior belly of the omohyoid muscle to the scapula; passes through the superior notch into the supraspinatus fossa, where it innervates the supraspinatus muscle; and continues around the scapular notch (lateral margin of the scapular spine) to the infraspinatus fossa, where it innervates the infraspinatus muscle. In addition to muscle, the suprascapular nerve innervates the posterior aspect of the glenohumeral joint, subacromial bursa, and acromioclavicular joint.

Nerve to Subclavius

The nerve to subclavius arises from the superior trunk. It passes anteriorly a short distance to innervate the subclavius muscle and the sternoclavicular joint.

The cords of the brachial plexus leave the posterior cervical triangle and enter the axilla through the axillary inlet. The remainder of the terminal branches arise within the axilla from the cords (Figure 3-12).

Posterior Cord Branches

The posterior cord forms the upper and lower subscapular nerves, thoracodorsal nerve, axillary nerve, and radial nerve.

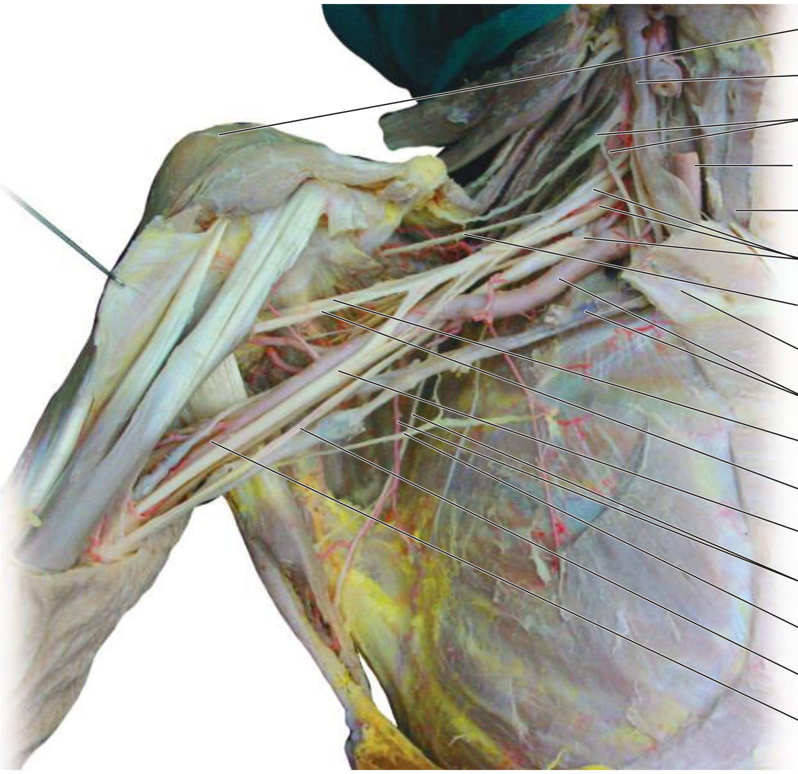

FIGURE 3–12. Dissection of the brachial plexus.

Subscapular Nerves

The subscapular nerves are formed by fibers from C5 to C6. The upper subscapular nerve is the first nerve to arise from the posterior cord. It passes onto the anterior surface of the subscapularis muscle, which it innervates. The lower subscapular nerve arises more distally. It descends across the anterior surface of the subscapularis muscle to the teres major muscle and innervates both the subscapularis and teres major muscles.

Thoracodorsal Nerve

The thoracodorsal nerve is formed by fibers from C5 to C7. It arises from the posterior cord, usually between the subscapular nerves, and descends across the subscapularis and teres major muscle to the latissimus dorsi muscle. It innervates the latissimus dorsi.

Axillary Nerve

The axillary nerve is formed by fibers from C5 to C6 (Box 3–1). It passes from the axilla into the shoulder between the teres major and minor muscles, the long head of triceps and humerus quadrangular space of Velpeau. It innervates the teres minor. The nerve continues posterior to the surgical neck of the humerus to innervate the deltoid muscle. The superior lateral brachial cutaneous branch of the axillary nerve passes around the posterior margin of the deltoid to innervate the skin covering the deltoid. In addition to muscle and skin, the axillary nerve innervates the glenohumeral and acromioclavicular joints. Throughout its course, the nerve is associated with the posterior circumflex humeral artery and its branches.

Radial Nerve

The radial nerve is formed by fibers from C5 to T1 (Box 3–2). It passes from the axilla into the arm through the triangular space. The triangular space is located inferior to the teres major between the long head of the triceps brachii and the humerus. The radial nerve innervates the long head of the triceps muscle and sends a posterior brachial cutaneous branch to the skin covering this muscle. It descends along the shaft of the humerus in the spiral groove in association with the deep radial artery. In the spiral groove, the radial nerve innervates the medial and lateral heads of the triceps brachii as well as the anconeus muscles. In addition to innervating these muscles, it sends an inferior lateral brachial cutaneous nerve to the skin covering the posterior arm and a posterior antebrachial cutaneous branch to the skin

BOX 3–1. Axillary nerve (C5 to C6).

Muscular branches
- Abduction, flexion, or extension of shoulder
  - Deltoid
- Lateral rotation the shoulder; stabilization of glenohumeral joint
  - Teres minor

Articular branches
- Acromioclavicular joint
- Anterior aspect of glenohumeral joint

Cutaneous branch
- Superior lateral brachial cutaneous nerve

BOX 3–2. Radial nerve.

Muscular branches
- Extension of shoulder
  - Triceps brachii—long head
- Extension of elbow
  - Triceps brachii—long, lateral, medial heads
  - Anconeus
- Supination of forearm
  - Supinator
- Extension of wrist
  - Extensor carpi radialis—longus and brevis
  - Extensor carpi ulnaris
  - Extensor muscles of fingers and thumb listed next
- Extension of fingers (metacarpophalangeal and interphalangeal joints)
  - Extensor digitorum communis (index, middle, ring, little fingers)
  - Extensor indicis (index finger)
  - Extensor digiti minimi (little finger)
- Extension of thumb
  - Extensor pollicis longus (metacarpophlangeal and interphalangeal)
  - Extensor pollicis brevis (metacarpophalangeal joint)
- Abduction of thumb
  - Abductor pollicis longus

Articular branches
- Elbow (humeroradial and humeroulnar joints)
- Radioulnar joints—proximal and distal
- Radiocarpal joint

Cutaneous branches
- Posterior brachial cutaneous nerve
- Inferior lateral brachial cutaneous nerve
- Posterior antebrachial cutaneous nerve
- Superficial branch of the radial nerve

covering the posterior surface of the forearm. The radial nerve pierces the lateral intermuscular septum and crosses the elbow anterior to the lateral epicondyle between the brachialis and brachioradialis muscles. Here, it divides into a superficial and deep branch. The superficial branch descends the forearm on the deep surface of the brachioradialis. Proximal to the wrist, it enters the skin, providing innervation over the dorsum of the hand onto the thumb, index, middle, and ring fingers to the level of the distal interphalangeal joint. The deep branch pierces the supinator muscle and descends the forearm along the interosseous membrane as the posterior interosseous nerve. En route, it innervates the brachioradialis, extensor carpi radialis longus and brevis, supinator, extensor digitorum communis, extensor digiti minimi, extensor carpi ulnaris, extensor indicis, extensor pollicis longus and brevis, and abductor pollicis muscles. In addition, it innervates the humerus, elbow, radioulnar, and wrist joints.[8]

Branches From the Lateral Cord

The lateral cord forms the lateral pectoral nerve, musculocutaneous nerve, and part of the median nerve.

BOX 3–3. Musculocutaneous nerve (C5 to C7).

Muscular branches
- Flexion of the shoulder
  - Biceps brachii—long head
  - Coracobrachialis
- Flexion of elbow
  - Brachialis (humeroulnar joint)
  - Biceps brachii—long and short heads (humeroradial joint)
- Supination of forearm
  - Biceps brachii—long and short heads

Articular branches
- Elbow (humeroulnar and humeroradial joints)
- Proximal radioulnar joint

Cutaneous branch
- Lateral antebrachial cutaneous nerve

Lateral Pectoral Nerve

The lateral pectoral nerve is formed by fibers from C5 to C7. It crosses the axilla deep to the pectoralis minor muscle and penetrates the deep surface of pectoralis major muscle, which it innervates. In addition, it innervates the acromioclavicular joint.

Musculocutaneous Nerve

The musculocutaneous nerve is formed by fibers from C5 to C7 (Box 3–3). It pierces the coracobrachialis muscle and descends between the brachialis and biceps brachii muscles (see Figure 3–12). En route, it innervates all of these muscles. At the elbow, the musculocutaneous nerve becomes the lateral antebrachial cutaneous nerve and descends along the superficial surface of the brachioradialis muscle, innervating the skin covering that muscle. In addition to muscle and skin, the musculocutaneous nerve innervates the humerus elbow and proximal radioulnar joints.

Median Nerve

The median nerve is formed by junction of branches from the lateral and medial cords (Box 3–4). It descends the arm in association with the brachial artery and crosses the cubital fossa medial to the artery (see Figure 3–12). At the elbow, it innervates the pronator teres, flexor carpi radialis, and palmaris longus muscles. It passes into the forearm between the humeral and radial heads of the pronator teres muscle and descends in the space between the flexor digitorum superficialis and profundus muscles. En route, it innervates the flexor digitorum superficialis, the lateral part of the flexor digitorum profundus (fibers to the index and middle fingers), the flexor pollicis longus, and the pronator quadratus muscles. In addition, the median nerve sends a palmar cutaneous branch to the skin covering the thenar eminence. At the wrist, the median nerve passes through the carpal tunnel deep to the flexor retinaculum. In the hand, the median nerve sends branches to the thenar muscles, which are the abductor pollicis brevis, flexor pollicis brevis, and opponens pollicis. The median nerve divides into three common palmar digital

BOX 3–4. Median nerve.

Muscular branches

- Flexion of the elbow
  - Flexor carpi radialis
  - Pronator teres
- Pronation of forearm
  - Pronator teres
  - Pronator quadratus
- Flexion of wrist
  - Flexor carpi radialis
  - Palmaris longus
  - Flexor digitorum superficialis and profundus
  - Flexor pollicis longus
- Flexion of fingers
  - Flexor digitorum superficialis (index, middle, ring, little fingers)
  - Flexor digitorum profundus (index, middle fingers)
- Flexion of metacarpophalangeal and extension of interphalangeal joints
  - Lumbricals (index, middle finger)
- Flexion of thumb
  - Flexor pollicis longus
  - Flexor pollicis brevis
- Abduction of thumb
  - Abductor pollicis brevis
- Opposition of thumb
  - Opponens pollicis

Articular branches

- Elbow (humeroulnar and humeroradial joints)
- Radioulnar joints—proximal and distal
- All joints of the wrist and hand

Cutaneous branches

- Palmar branch of median nerve
- Proper palmar digital nerves

branches, which innerve the lateral two lumbrical muscles. The common palmar branches divide into proper palmar branches that innervate the skin of the thumb, index, middle, and ring (lateral half) fingers. The innervation covers the palmar surface and the nail beds. In addition to muscle and skin, the median nerve innervates the diaphysis of the radius and ulna, and the anterior elbow and all joints distal to it.[9,10]

Medial Cord Branches

The medial cord forms the medial pectoral nerve, medial brachial cutaneous nerve, medial antebrachial cutaneous nerve, and ulnar nerve and sends fibers to the median nerve.

Medial Pectoral Nerve

The medial pectoral is formed by fibers from C8 to T1. It pierces the pectoralis minor and ends by branching on the deep surface of the pectoralis major, innervating both muscles. Contraction of the pectoralis minor in conjunction with the serratus anterior and rhomboid muscles pulls the pectoral girdle (clavicle and scapula) against the chest wall when load is applied to the upper extremity. Without this stabilization of the proximal joints, movement of the distal joint in the upper extremity would collapse.

Medial Brachial and Antebrachial Cutaneous Nerves

Both medial brachial and antebrachial cutaneous nerves descend in the arm associated with the brachial artery. The medial brachial cutaneous nerve distributes fibers to the skin covering the medial surface of the arm. Occasionally, the medial brachial nerve joins the lateral cutaneous branch of the second intercostal nerve to form the intercostobrachial nerve. The medial antebrachial cutaneous nerve crosses the cubital fossa and enters the skin to innervate the medial aspect of the forearm.[4]

Ulnar Nerve

The ulnar nerve is formed by fibers from C8 to T1 (Box 3–5). It descends the arm in association with the brachial artery (see

BOX 3–5. Ulnar nerve (C8 to T1).

Muscular branches

- Flexion of wrist
  - Flexor carpi ulnaris
  - Flexor digitorum profundus
- Flexion of fingers
  - Flexor digitorum profundus (ring, little finger)
  - Flexor digiti minimi (little finger)
- Flexion of knuckles and extension of fingers
  - Lumbricals (ring, little finger)
  - Interosseous muscles (index, middle, ring, little fingers)
- Adduction of fingers (metacarpophalangeal joint)
  - Palmar interosseous muscles (index, middle, ring, little finger)
- Abduction of fingers
  - Dorsal interosseous muscles (index, middle, ring finger)
  - Abductor digiti minimi (little finger)
- Opposition of little finger
  - Opponens digiti minimi
  - Palmaris brevis
- Adduction of thumb
  - Adductor pollicis
- Flexion of thumb
  - Flexor pollicis brevis

Articular branches

- Ulnocarpal joint
- All joints of the hand except interphalangeal joint of the thumb

Cutaneous branches

- Dorsal branch of the ulnar nerve
- Palmar branch of the ulnar nerve
- Proper palmar digital branches

Figures 3-11 and 3-12), pierces the medial intermuscular septum, and crosses the elbow posterior to the medial epicondyle. After crossing the elbow, the ulnar nerve descends the forearm between the flexor carpi ulnaris and flexor digitorum profundus, innervating both muscles. The ulnar innervation of the flexor digitorum is limited to fibers affecting the ring and little fingers. Proximal to the wrist, the ulnar nerve sends a palmar branch to the skin covering the hypothenar eminence and a dorsal branch to the skin covering the dorsal and medial surface of the hand and the skin covering the dorsal surface of the ring and little fingers. The ulnar nerve passes through Guyon's canal (deep to the transverse carpal ligament) to enter the hand. It divides into a superficial and a deep branch. The superficial branch sends branches to all muscles of the hypothenar eminence, including the abductor digiti minimi, flexor digiti minimi, and opponens digiti minimi. Then, it divides into common palmar digital branches, which in turn divide into proper palmar digital branches. These branches innervate the skin covering the palmar surface of the ring and little fingers. The innervation continues on to the nail beds of these fingers. The deep branch of the ulnar nerve passes beneath the adductor pollicis muscle, which it innervates. The ulnar nerve sends fibers to all interosseous muscles in the hand and to the lumbrical muscles affecting the ring and little fingers. The ulnar nerve ends by innervating the deep head of the flexor pollicis brevis muscle.[9,10]

Along its course, the ulnar nerve supplies the medial aspect of the elbow joint, the ulna and all joints of the medial aspect of the wrist, hand, and ring and little fingers.

Thoracic Spinal Nerves

Thoracic spinal nerves innervate the muscles, joints, skin, and pleuroperitoneal lining of the thoracic and abdominal walls. Because the nerves travel within the intercostal spaces, they are called intercostal nerves. The intercostal nerves comprise the anterior rami of the upper 11 thoracic spinal nerves. Each intercostal nerve enters the neurovascular plane posteriorly and gives a collateral branch that supplies the intercostal muscles of the space. Except for the first, each intercostal nerve gives off a lateral cutaneous branch that pierces the overlying muscle near the midaxillary line. This cutaneous nerve divides into anterior and posterior branches, which supply the adjacent skin (Figure 3–13). The intercostal nerves of the second to the sixth spaces enter the superficial fascia near the lateral border of the sternum and divide into medial and lateral cutaneous branches. Most of the fibers of the anterior ramus of the first thoracic spinal nerve join the brachial plexus for distribution to the upper limb. The small first intercostal nerve is the collateral branch and supplies only the muscles of the intercostal space, not the overlying skin.

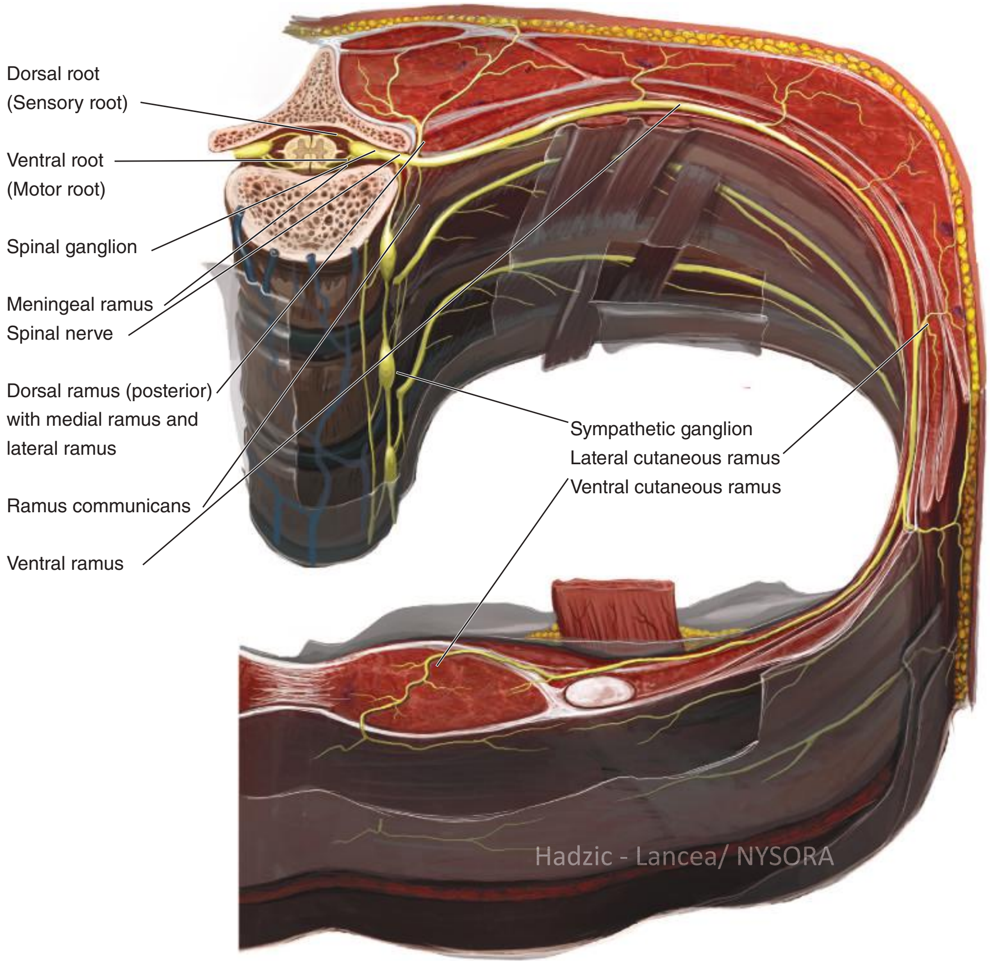

FIGURE 3–13. Organization and distribution of the spinal nerves at the thoracic level.

The intercostal nerves can be divided into two groups. One group is formed by nerves arising from T1 through T5. These nerves remain in the intercostal spaces throughout their course. The second group is formed by nerves arising from T6 to T12. These nerves initially travel in the intercostal spaces, but then cross the costal margin and terminate in the abdominal wall. This subgroup of intercostal nerves is called the thoracoabdominal nerves. The ventral ramus of T12 forms the subcostal nerve. This nerve travels entirely in the abdominal wall.

Intercostal Nerves

The intercostal nerves arise from the ventral rami of T1 through T11. They travel along the inferior margin of the rib of the corresponding number (eg, T1 nerve travels along the inferior margin of rib 1). En route, the nerve is located between the deepest (transverse thoracis muscle) and intermediate layer (internal intercostals muscle) of muscle. It is associated with the intercostal arteries and veins. From the top to the bottom, the neurovascular bundle is arranged as vein, artery, and nerve (mnemonic VAN). The intercostal nerves send branches to the transverse thoracis, internal intercostals, and external intercostal muscles. They innervate the costal joints. Through lateral and anterior cutaneous branches, they innervate the skin covering the respective intercostal spaces as well as the parietal pleura lining the intercostal spaces.

Thoracoabdominal (Intercostals T6 to T11) Nerves

The T6 through T11 intercostal (thoracoabdominal) nerves begin as typical intercostal nerves but then send branches across the costal margin into the muscles of the anterior abdominal wall. These branches innervate the transverse abdominis, internal abdominal oblique, external abdominal oblique, and rectus abdominis muscles. In addition, they innervate the skin of the anterior wall in a metameric manner from the xiphoid process to the umbilicus.

Subcostal Nerve

The T12, or subcostal, nerve never enters an intercostal space. It travels through the abdominal wall, terminating between the umbilicus and the pubic symphysis. It innervates muscle and skin along its course.

Lumbosacral Plexus

The lumbosacral plexus innervates the muscles, joints, skin, and peritoneal lining of the abdominopelvic wall[11,12] (Tables 3–3 and 3–4). It also innervates the inferior extremities. It is formed by the ventral rami of L1 to S5 (Figures 3–14 and 3–15). The ventral rami join to form the terminal nerves. Between the L2 and S3 levels, the plexus is more complex. The ventral rami divide into anterior and posterior divisions that join to form the terminal nerves. The plexus is located in the posterior abdominal wall between the psoas major and quadratus lumborum muscles (see Figure 3-15).

Iliohypogastric Nerve

The iliohypogastric nerve arises from the ventral ramus of L1 and travels in the abdominal wall to the level of the pubic symphysis (see Figures 3-15 and 3-16). It innervates the muscle, skin, and parietal peritoneum along its course.

Ilioinguinal Nerve

The ilioinguinal nerve (see Figures 3-15 and 3-16) arises from the ventral rami of L1, travels in the abdominal wall, pierces in the posterior wall of the inguinal canal, passes through the superficial inguinal ring, and terminates on the anterior scrotum or labia majora. It innervates the muscle, skin, and parietal peritoneum along its course.

TABLE 3–3. Organization and distribution of the lumbar plexus.

Nerves(s)	Spinal Segments	Distribution
Iliohypogastric nerve	T12 to L1	Abdominal muscles (external and internal oblique muscles, transverse abdominis muscles); skin over inferior abdomen and buttocks
Ilioinguinal nerve	L1	Abdominal muscles (with iliohypogastric nerve); skin over superior, medial thigh and portions of external genitalia
Genitofemoral nerve	L1, L2	Skin over anteromedial surface of thigh and portions over genitalia
Lateral femoral cutaneous nerve	L2, L3	Skin over anterior, lateral, and posterior surfaces of thigh
Femoral nerve	L2 to L4	Anterior muscles of thigh (sartorius muscle and quadriceps group); adductor of thigh (pectineus and iliopsoas muscles); skin over anteromedial surface of thigh, medial surface of leg, and foot
Obturator nerve	L2 to L4	Adductors of thigh (adductors magnus, brevis, and longus); gracilis muscle; skin over medial surface of thigh
Saphenous nerve	L2 to L4	Skin over medial surface of leg

TABLE 3–4. Organization and distribution of the sacral plexus.

Nerves(s)	Spinal Segments	Distribution
Gluteal nerves:		
Superior inferior	L4 to S2	Abductors of thigh (gluteus minimus, gluteus medius, and tensor fasciae latae); extensor of thigh (gluteus maximus)
Posterior femoral cutaneous nerve	S1 to S3	Skin of perineum and posterior surface of thigh and leg
Sciatic nerve:	L4 to S3	Three of the hamstrings (semitendinosus and semimembranosus long head of biceps femoris); adductor magnus (with obturator nerve)
Tibial nerve		Flexor of knee and plantar flexors of ankle (popliteus, gastrocnemius, soleus plantaris, and tibialis posterior muscles and long head of biceps femoris muscle); flexors of toes; skin over posterior surface of leg, plantar surface of foot
Common peroneal nerve		Biceps femoris muscle (short head); fibularis (brevis and longus) and tibialis anterior muscles; extensors of toes, skin over anterior surface of leg and dorsal surface of foot; skin over lateral portion of foot (through the sural nerve)
Pudendal nerve	S2 to S4	Muscles of perineum, including urogenital diaphragm and external anal and urethral sphincter muscles; skin of external genitalia and related skeletal muscles (bulbospongiosus, ischiocavernosus muscles)

Genitofemoral Nerve

The genitofemoral nerve arises from the ventral rami from L1 and L2 (see Figure 3–15). It travels in the abdominal wall and passes through the deep inguinal ring into the inguinal canal. A femoral branch pierces the anterior wall of the canal and innervates the skin covering the femoral hiatus in the crural fascia. The genital branch passes through the superficial inguinal ring to innervate the skin on the scrotum or labia majora. En route, it innervates the cremaster muscle. Contraction of the cremaster elevates the scrotum.

Nerve to the Coccygeus and Levator Ani

The nerve to the coccygeus and levator ani muscles arises from the posterior division of the ventral rami at S3 to S4. It travels anteriorly onto the superior surface of the coccygeus and levator ani.

Pudendal Nerve

The pudendal nerve arises from the anterior division of the ventral rami from S2 to S4. It passes from the pelvis through the greater sciatic foramen into the gluteal region. It enters the gluteal region inferior to the piriformis muscle, passes posterior to the ischial spine, then enters the perineum by passing through the lesser sciatic foramen. It innervates the muscle and skin of the perineum, anal canal and external anal sphincter.

Superior Gluteal Nerve

The superior gluteal nerve arises from the posterior division of the ventral rami at L4 to S1. It passes from the pelvis through the greater sciatic foramen to the gluteal region. It enters the gluteal region superior to the piriformis muscle, passes in the plane between gluteal medius and minimus muscles, and terminates in the tensor fascia lata muscle. En route, it innervates the gluteus medius and minimus muscles as well as the tensor fascia lata.

Inferior Gluteal Nerve

The inferior gluteal nerve arises from the posterior division of the ventral rami at L5 to S2. It passes from the pelvis through the greater sciatic foramen into the gluteal region. It enters the gluteal region inferior to the piriformis muscle and terminates on the deep surface of the gluteal maximus muscle, which it innervates.

Nerve to Piriformis

The nerve to piriformis arises from the posterior division of the ventral rami at S1 to S2 and passes onto the deep surface of the piriformis muscle, which it innervates.

Nerve to Obturator Internus and Superior Gemellus

The nerve to the obturator internus and superior gemellus muscles arises from the anterior division of the ventral rami at L5 and S1. It passes from the pelvis through the greater sciatic foramen into the gluteal region. In enters the gluteal region inferior to the piriformis muscle and passes along the deep surface of the superior gemellus to the obturator internus, innervating these last two muscles.

Nerve to the Quadratus Femoris and Inferior Gemellus

The nerve to the quadratus femoris and inferior gemellus muscles arises from the anterior division of the ventral rami at L4 to L5. It passes from the pelvis through the greater sciatic foramen to the gluteal region and enters the gluteal region

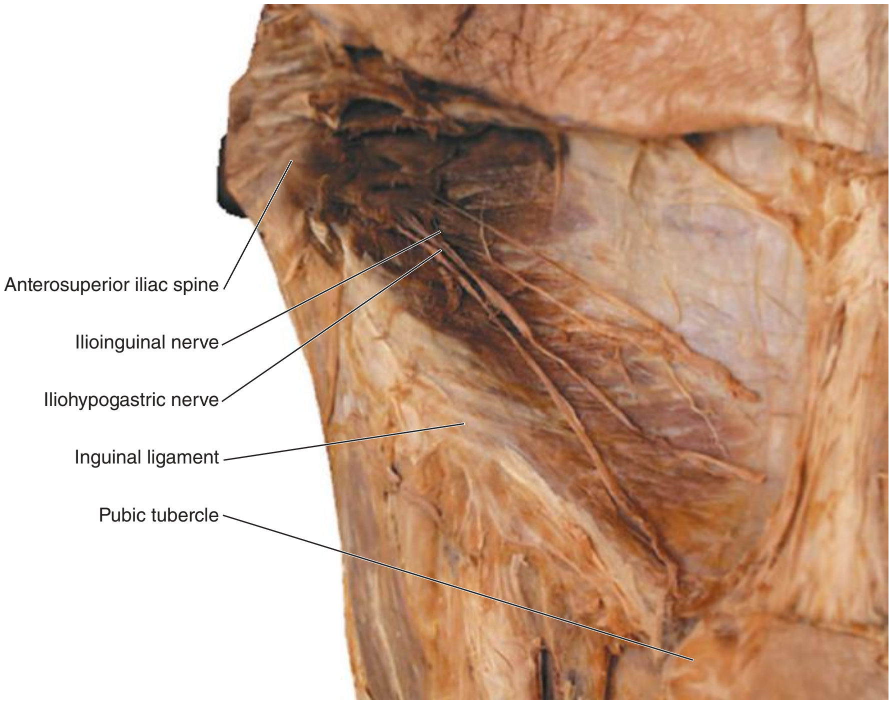

FIGURE 3–16. Dissection of Ilioinguinal and iliohypogastric nerves.

inferior to piriformis, passing deep to the obturator internus to terminate innervating the inferior gemellus and quadratus fermoris, as indicated by its name.

Lateral Femoral Cutaneous Nerve

The lateral femoral cutaneous nerve arises from the posterior divisions of the ventral rami at L2 to L3. It descends the posterior abdominal wall and crosses the iliac crest into the pelvis, where it descends on the iliacus muscle, passes deep to the inguinal ligament at the anterior iliac spine, and distributes cutaneous innervation on the lateral aspect of the thigh to the level of the knee (Figure 3–17).

Posterior Femoral Cutaneous Nerve

The posterior femoral cutaneous nerve arises from the anterior and posterior divisions of the ventral rami at S1 to S3. It passes from the pelvis through the greater sciatic foramen into the gluteal region. It enters the gluteal region inferior to the piriformis muscle, descends in the muscle plane between the gluteus maximus posteriorly and oburator internus anteriorly, and passes into the posterior thigh, where it supplies cutaneous innervation from the hip to the midcalf.[4]

Obturator Nerve

The obturator nerve (Box 3–6) arises from the anterior division of the ventral rami at L2 to L4 (Figure 3–18). It descends through the pelvis medial to the psoas major muscle, crosses the superior pubic ramus inferiorly, and passes through the obturator foramen into the medial compartment of the thigh, where it divides into posterior and anterior branches (see Figure 3–18). The posterior branch descends superficial to the adductor magnus muscle, which it innervates. The anterior branch passes superficial to the obturator externus muscle, descends the thigh in the muscle plane between the adductor brevis and adductor longus, and terminates in the gracilis muscle. En route, it innervates all of these muscles. Furthermore, it provides articular branches to the hip and cutaneous branches to the skin covering the medial thigh.

Femoral Nerve

The femoral nerve arises from the posterior division of the ventral rami at L2 to L4 (Box 3–7). It descends through the pelvis lateral to the psoas major muscle, passes deep to the inguinal ligament, and enters the anterior compartment of the thigh, where it divides into multiple branches supplying the muscle,

joints, and skin in that region. In the femoral triangle–inguinal crease, the nerve is positioned lateral to the femoral artery and vein (mnemonic: NAVEL) (Figure 3–19). Muscular branches innervate the iliacus, psoas major, pectineus, rectus femoris, vastus lateralis, vastus intermedius, vastus medialis, and sartorius muscles. Articular branches innervate the hip and knee.[13]

Of note, the femoral nerve below the inguinal ligament consists of an anterior and a posterior part. The anterior part contains branches to the sartorius muscle and cutaneous branches of the anterior thigh, and the posterior contains the saphenous nerve (most medial part) and branches to the individual heads of the quadriceps muscle.[14]

Saphenous Nerve and Other Cutaneous Branches of the Femoral Nerve

The superficial branches of the femoral nerve supply the skin covering the anterior thigh. One cutaneous branch follows the deep surface of the sartorius muscle to its attachment on the tibia. Here, it passes onto the skin, providing innervation of the medial leg from the knee to the arch of the foot. En route, the nerve is accompanied by the saphenous vein, so it is called the saphenous branch of the femoral nerve (see Figure 3–19). As previously mentioned, the saphenous nerve is the most medial part of the femoral nerve at the inguinal (femoral) crease.[14]

Sciatic Nerve

The sciatic nerve is formed by the junction of the tibial and common peroneal nerves (Box 3–8). The tibial nerve arises from the anterior division of the ventral rami at L4 to S3 (see

Figure 3–14). The common peroneal nerve arises from the posterior division of the ventral rami at L4 to S2. The sciatic nerve passes from the pelvis through the greater sciatic foramen into the gluteal region. It enters the gluteal region inferior to the piriformis muscle, descends in the muscle plane between the gluteus maximus posteriorly and the obturator internus anteriorly, and passes lateral to the ischial tuberosity to enter the posterior thigh (Figure 3–20). In the posterior thigh, it passes between the adductor magnus and the long head of the biceps femoris. It descends in the groove between the biceps femoris medially and the semitendinosus and semimembranosus laterally. En route, it innervates the adductor magnus, biceps femoris, semitendinosus, and semimembranosus muscles.[15] Posterior to the knee, the sciatic nerve descends into the popliteal fossa, where it diverges into the tibial and common peroneal nerves (Figure 3–21).[16]

Of note, these two branches are distinct from the onset and travel together enveloped in the same tissue sheath.[17] The tibial nerves exits the popliteal fossa passing between the heads of the gastrocnemius muscle into the superficial posterior compartment of the leg. Here, it descends deep to the plantaris and superficial to popliteus muscles. It passes between the tibial and fibular heads of the soleus muscle to enter the deep posterior compartment. The nerve passes posterior to the medial malleolus, where it enters the foot and divides into medial and lateral plantar

- Calcaneal branches—medial and lateral
- Plantar nerves—medial and lateral

nerves that innervate the muscle and skin on the plantar surface of the foot. The common peroneal nerve follows the tendon of the biceps femoris to its attachment on the fibula. The nerve passes inferior to the neck of the fibula and divides into superficial and deep branches. The superficial branch enters the lateral compartment of the leg, where it innervates the peroneus longus and brevis muscles. The nerve terminates as cutaneous fibers on the dorsal and lateral surfaces of the foot. The deep peroneal nerve enters the anterior compartment of the leg, where it innervates the tibialis anterior, extensor digitorum longus, and extensor hallucis longus muscles. It crosses the anterior surface of the ankle into the foot, where it innervates the extensor digitorum brevis and extensor hallucis brevis muscles. It terminates as cutaneous fibers supplying skin between the hallux and second toe.[18]

SENSORY INNERVATION OF THE MAJOR JOINTS

Much of the practice of peripheral nerve blocks involves orthopedic and other joint surgery. Consequently, knowledge of the sensory innervation of the major joints is important for better understanding the neuronal components that need to be anesthetized to achieve anesthesia for, or analgesia, after joint surgery. Tables 3–5 and 3–6 summarize the sensory innervation of the major joints of the upper and lower extremities, respectively. Tables 3–7 and 3–8 summarize the innervation and kinetic function of the major muscle groups of the upper and lower extremities respectively.

Shoulder Joint

Innervation to the shoulder joints stems mostly from the axillary and suprascapular nerves (C5–C7). The skin over most medial parts of the shoulder receives nerves from the cervical plexus (see Figure 3-10). Such an arrangement explains why a brachial plexus block at the interscalene level is the most appropriate technique to achieve anesthesia to the shoulder (Figure 3–22).

Elbow Joint

Nerve supply to the elbow joint includes branches of all major nerves of the brachial plexus that cross the joint: musculocutaneous, radial, median, and ulnar nerves (Figure 3–23).

Wrist Joint

The wrist joint is supplied by the radial, ulnar, and median nerves (Figure 3–24), including interosseous branches of the radial and median nerves diverging at the proximal forearm. The cutaneous branches of these nerves, in addition to the antebrachial medial cutaneous and lateral cutaneous nerves, display frequent variations and connections among them at different levels, resulting in overlapping innervation areas.

Hip Joint

Nerves to the hip joint include the nerve to the rectus femoris from the femoral nerve, branches from the anterior division of the obturator nerve, and the nerve to the quadratus femoris from the sacral plexus (Figure 3–25).

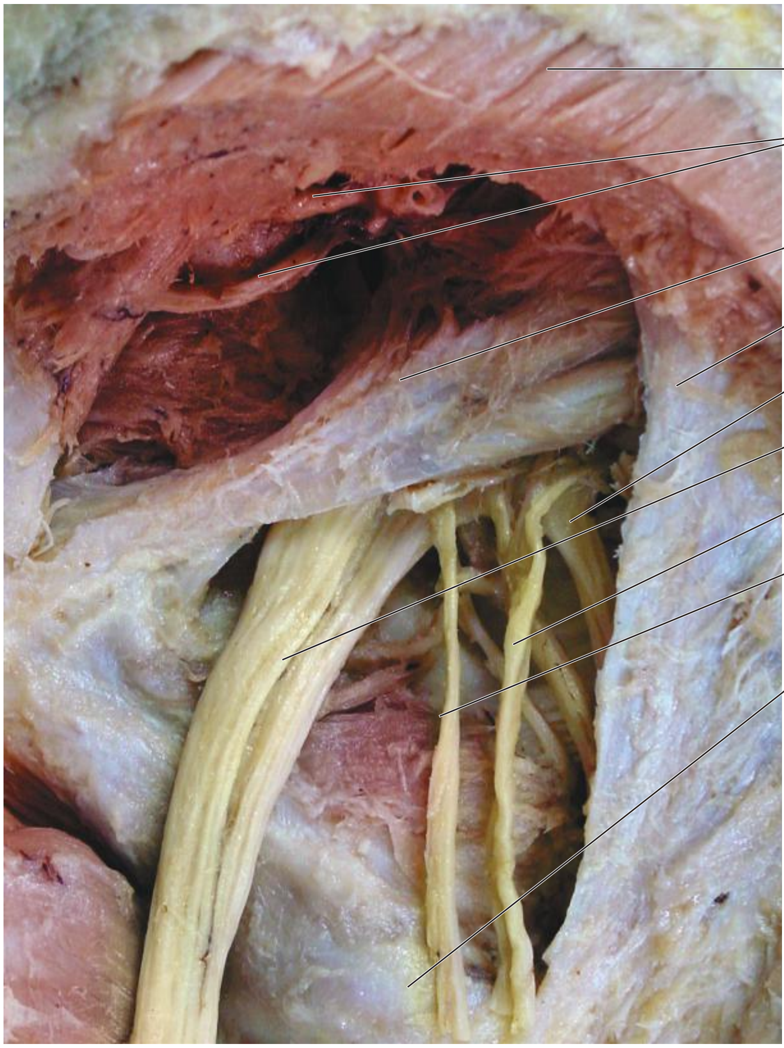

FIGURE 3–20. Anatomy of the sciatic nerve at gluteal level.

Knee Joint

Knee innervation is obtained from branches from the femoral, obturator, and sciatic nerves (Figure 3–26). The femoral nerve suplies the anterior aspect of the joint. Articular branches from the tibial and common peroneal divisions of the sciatic nerve innervate the posterior aspect, while fibers from the posterior division of the obturator nerve may contribute to the innervation of the medial aspect of the joint, together with fibers from the posterior division of the obturator nerve, may also contribute to the innervation of the joint.

Ankle Joint

The innervation of the ankle joint is complex and involves the terminal branches of the peroneal (deep and superficial peroneal nerves), tibial (posterior tibial nerve), and femoral nerves (saphenous nerve). A more simplistic view is that the entire innervation of the ankle joint stems from the sciatic nerve, with the exception of the skin on the medial aspect around the medial malleolus (saphenous nerve, a branch of the femoral nerve; Figure 3–27).

AUTONOMIC COMPONENT OF SPINAL NERVES

All spinal nerves transmit autonomic fibers to glands and smooth muscle in the region they innervate. The autonomic fibers are sympathetic. There are no parasympathetic fibers in spinal nerves. Sympathetic fibers originate in the spinal cord between T1 and L2. They pass from the spinal cord through the ventral roots of the T1 to L2 spinal nerves. They depart from the spinal nerve through white rami communicans to enter the sympathetic trunk. The sympathetic trunk is formed by a series of interconnected paravertebral ganglia, which are adjacent to the vertebral bodies and extend from the axis (C2 vertebra) to the sacrum. The preganglionic fibers synapse on cell bodies of neurons forming the paravertebral ganglia. The axons of the paravertebral ganglia (postganglionic fibers) can remain at the same level or they can change level by ascending or descending the trunk. The fibers pass from the trunk through gray rami communicans to spinal nerves. The sympathetic trunk sends a gray ramus to every spinal nerve. The sympathetic nerves travel along branches of the spinal nerve to the target destination[19] (Figure 3–28).

Parasympathetic fibers arise from the lumbosacral plexus. They originate in the spinal cord between S2 and S4, pass through the ventral roots, and enter the ventral rami of the S2 to S4 spinal nerves. The parasympathetic fibers separate from the ventral rami and form the pelvic splanchnic nerve. This nerve travels across the pelvic diaphragm (formed by levator ani and coccygeus muscles) to synapse on intramural ganglia in the wall of the pelvic viscera.[20,21]

CHAPTER 4

Histology of the Peripheral Nerves and Light Microscopy

Erika Cvetko, Marija Meznarič, and Tatjana Stopar Pintaric

INTRODUCTION

Microscopic anatomy that emphasizes structure-function relations is important to the clinical practice of regional anesthesia. This chapter provides basis for understanding of the structure, classification, and organization of the peripheral nerves and insight into how the characteristics of the peripheral nerves (Figure 4–1) relate to the clinical practice of regional anesthesia.

ORGANIZATION OF THE PERIPHERAL NERVOUS SYSTEM

The nervous system enables the body to respond to continuous changes in its external and internal environments. It controls and integrates the functional activities of the organs and organ systems.

Nervous system cells consist of neurons and neuroglia. Neurons transmit nerve impulses to and from the central nervous system (CNS), thereby integrating motor and sensory functions. Neuroglial cells support and protect the neurons. In the CNS, myelin is produced by oligodendrocytes and in the peripheral nervous system (PNS) by the Schwann cells. Although both Schwann cells and oligodendrocytes are in charge of axon myelination, they have distinct morphological and molecular properties and different embryonic origins, the neural crest and the neural tube, respectively.[1]

The PNS consists of peripheral nerves (craniospinal, somatic, autonomic) with their associated ganglia and connective tissue investments. All lie peripheral to the pial covering of the CNS.[2–6]

Peripheral nerves contain fascicles of nerve fibers consisting of axons. In peripheral nerve fibers, axons are ensheathed by Schwann cells, which may or may not form myelin around the axons, depending on their diameter. Nerve fibers are grouped into fascicles of variable numbers. The size, number, and pattern of fascicles vary in different nerves and at different levels along their paths. Generally, their number increases and their size decreases at some distance proximal to the branching point.

NEURONS

A neuron is the structural and functional unit of the nervous system. It includes the cell body, dendrites, and axon.

The cell body (*perykarion*) is the dilated region of the neuron that contains a large, euchromatic nucleus with a prominent nucleolus and surrounding perinuclear cytoplasm (Figure 4–2). The perinuclear cytoplasm contains abundant rough-surfaced endoplasmic reticulum and free ribosomes. On light microscopy, the rough endoplasmic reticulum with rosettes of free ribosomes appears as small bodies, called Nissl bodies. The perinuclear cytoplasm contains numerous mitochondria, a large perinuclear Golgi apparatus, liposomes, microtubules, neurofilaments, transport vesicles, and inclusions. The presence of the euchromatic nucleus, large nucleolus, prominent Golgi apparatus, and Nissl bodies indicates the high level of anabolic activity needed to maintain these large cells.

Dendrites are elaborations of the receptive plasma membrane of the neuron. Most neurons possess multiple dendrites that typically arise from the cell body as single short trunks that ramify into smaller branches that taper at the ends. Dendrite-branching patterns are characteristic of each kind of neuron. The base of the dendrite contains the same organelles as the cell body, except the Golgi apparatus. Many organelles become sparse or absent toward the distal end of the dendrite. Dendrite branching results in several synaptic terminals and allows a neuron to receive and integrate multiple impulses.

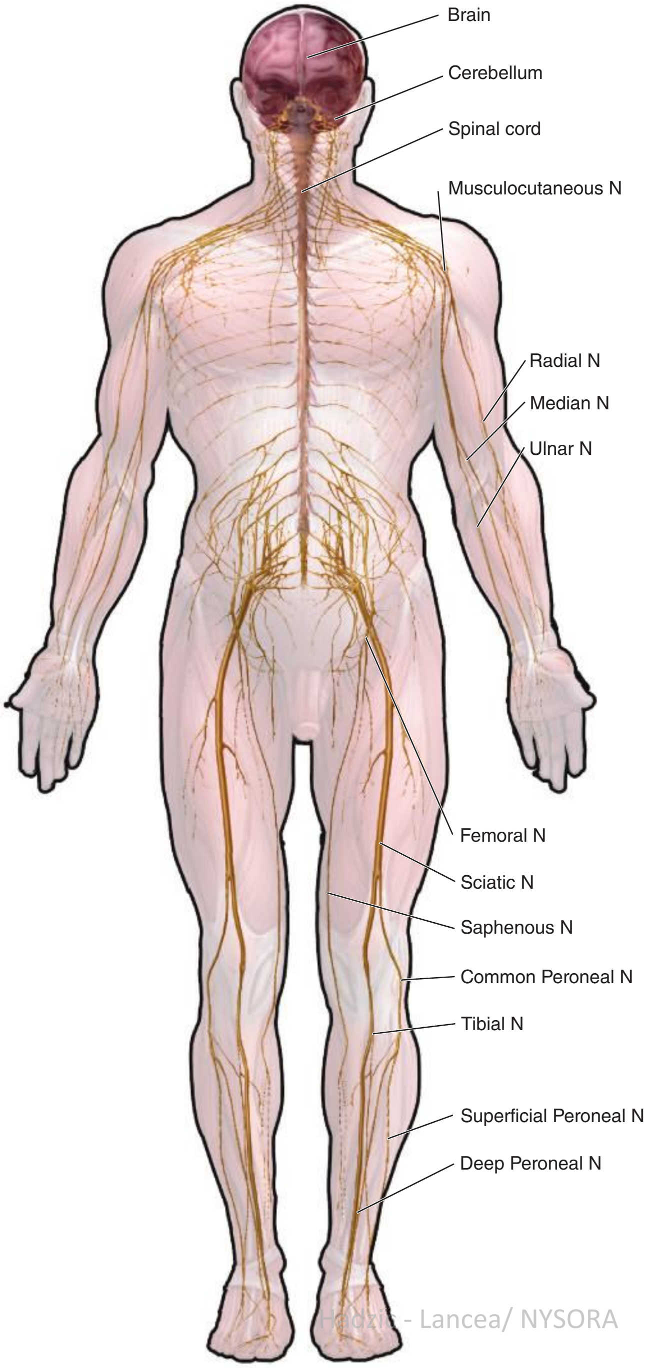

FIGURE 4–1. Peripheral and central nervous system. N = nerve.

The axon arises from the cell body as a single thin process, much longer than the dendrites. Its thickness is directly related to conduction velocity, which increases with axonal diameter. Some axons possess collateral branches. The portion of the axon between the cell body and the beginning of the myelin sheath is the initial segment.[7] At the end of the axon, the ramifications may form many small branches. The axonal cytoplasm is called *axoplasm*.

Almost all of the structural and functional protein molecules are synthesized in the cell body and are transported to distant locations within a neuron in a process known as axonal transport. Crucial to the trophic relations within the axon, axonal transport serves as a mode of intracellular communication carrying molecules and information along microtubules and intermediate filaments from the neuronal cell body to the axon terminal (anterograde transport) or from the axon terminal to the neuronal cell body (retrograde transport). Neurons communicate with other neurons and with effector cells by *synapses.* These special junctions between neurons and effector cells facilitate the transmission of nerve impulses from one (presynaptic) neuron to another (postsynaptic) neuron or from axons to effector (target) cells, such as muscle and gland cells.

Neurons have greater variation in size and shape than any other group of cells in the body. They are classified morphologically into three major types according to their shape and the arrangement of their processes. The most common neuron type, multipolar, possesses a single axon with various arrangements of multiple dendrites emanating from the cell body. The majority of multipolar neurons (Figure 4–2 and Figure 4–3) are motor neurons. A second type of neuron, unipolar or pseudounipolar (Figure 4–3), possesses only one process, the axon emanating from the cell body and opening up into the peripheral and central branches shortly after leaving the cell body. The central branch enters the CNS, while the peripheral branch proceeds to its corresponding receptor in the body. Each of the two branches is morphologically axonal and can propagate nerve impulses, although the very distal part of the peripheral branch arborizes, indicating its receptor function. The majority of unipolar neurons are sensory neurons, whose cell bodies are situated in the dorsal root ganglia of spinal nerves and in the sensory ganglia of cranial nerves. The third type of neuron, bipolar, possesses two processes emanating from the cell body: a single dendrite and a single axon. They can only be found in some cranial nerves.

Functionally, the nervous system has *somatic* and *autonomic* components. Nerve fibers innervating tissues derived from somites (muscles and skin) are described as somatic; nerve fibers innervating endodermal or other mesodermal derivatives (internal organs) are visceral. The somatic nervous system controls functions that are under conscious voluntary control with the exception of the reflex arch. It provides sensory and motor innervation to all parts of the body except the viscera, smooth muscles, cardiac muscle, and glands. The autonomic nervous system provides efferent involuntary innervation to smooth and cardiac muscles and glands. It also provides the afferent sensory innervation of the viscera (pain and autonomic reflexes).

Efferent Axons

Efferent axons arise from either the somatic or the autonomic nervous system. Somatic efferent (motor) neurons innervate skeletal muscle and have cell bodies located in somatic motor nuclei of the brainstem (cranial nerves) or in the ventral horns of the spinal cord (spinal nerves).

Preganglionic visceral efferent neurons of the sympathetic part of the autonomic nervous system arise from the intermediolateral column of the spinal cord between levels T1 and L2 and synapse on *paravertebral* or *prevertebral* (preaortic) ganglia. Peripheral nerves thus contain both preganglionic and postganglionic sympathetic fibers. Preganglionic visceral efferent neurons of the parasympathetic part of the autonomic nervous

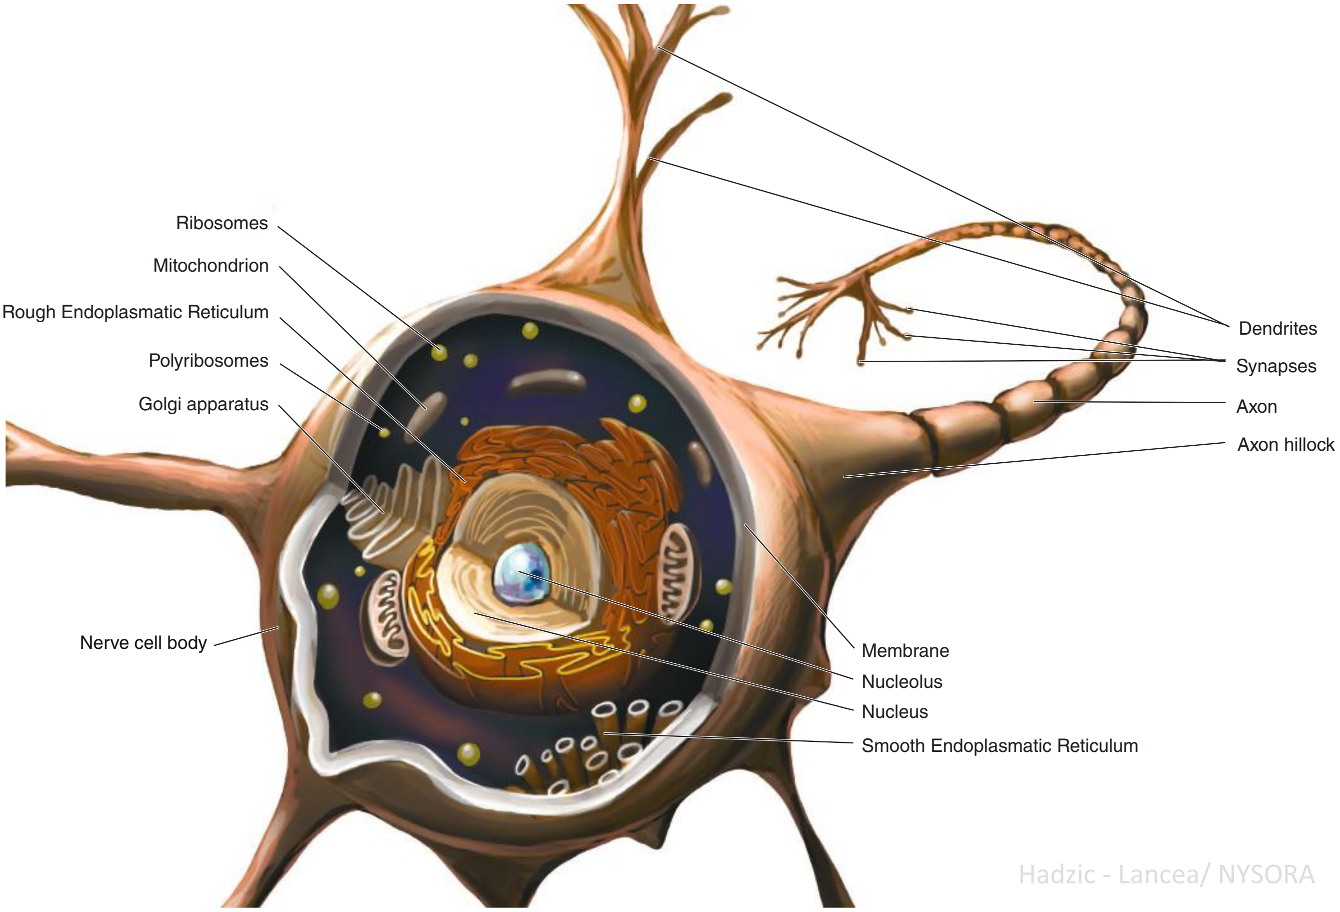

FIGURE 4–2. Diagram of a multipolar neuron. The nerve cell body, dendrites, and proximal part of the axon are within the CNS. The axons exiting the CNS distal to intervertebral foramina or foramina of the skull constitute the main part of the PNS.

system arise from the parasympathetic nuclei within the brainstem (cranial part of parasympathetic nervous system) or sacral spinal cord between the S2 and S4 segments (sacral part of the parasympathetic nervous system). Only preganglionic parasympathetic fibers travel along peripheral nerves to synapse on intramural ganglia in the wall of target organs.

Afferent Axons

Afferent axons are either somatic or visceral and have cell bodies either in the dorsal root ganglia of the spinal nerves or in the sensory ganglia of the cranial nerves. Somatic afferent (sensory) neurons transmit impulses from the receptors for touch, temperature, or pain (nociceptors) located in the body wall (skin) and from the proprioceptors in the skeletal muscles and joints. Visceral afferent neurons transmit information from viscera (interoceptors and nociceptors). The visceral afferent axons travel along the visceral efferent fibers and pass through the communicating branches and dorsal roots of the spinal nerves or along the vagus nerve to enter the CNS.

SCHWANN CELLS

Axons of peripheral nerves are ensheathed by Schwann cells. Their myelin sheath (modified plasmalemma) separates the axons from the endoneurium. Schwann cells are distributed along the axons in longitudinal chains depending on myelination along the axon. The coordinated differentiation of the axons and their myelinating cells requires close communication between neurons and glia.[8] Signals provided by the axons regulate the proliferation, survival, and differentiation of glial cells.[9,10] On the other hand, reciprocal glial signals affect axonal cytoskeleton and transport[11] and are required for axonal survival[12,13] and regeneration.[14] Schwann cells also have a guiding function for growing axons,[15] indicating that glia do more than provide support to the axon.

Schwann cell phenotypes are characterized by distinct morphologies[5] and differential expression of myelin proteins, cell adhesion molecules, receptors, enzymes, intermediate filament proteins, ion channels, and extracellular matrix proteins.[6] All Schwann cells are surrounded by basal lamina, whose extracellular matrix molecules, such as laminin, regulate key aspects of Schwann cell development (for review, see Reference 16).

CLASSIFICATION OF NERVE FIBERS

Nerve fibers are classified according to axonal diameter, conduction velocity, type of receptor, and myelin sheath thickness (Table 4–1).[17] Conduction velocity is related to axonal diameter; that is, the larger the fiber is, the faster the conduction will be.

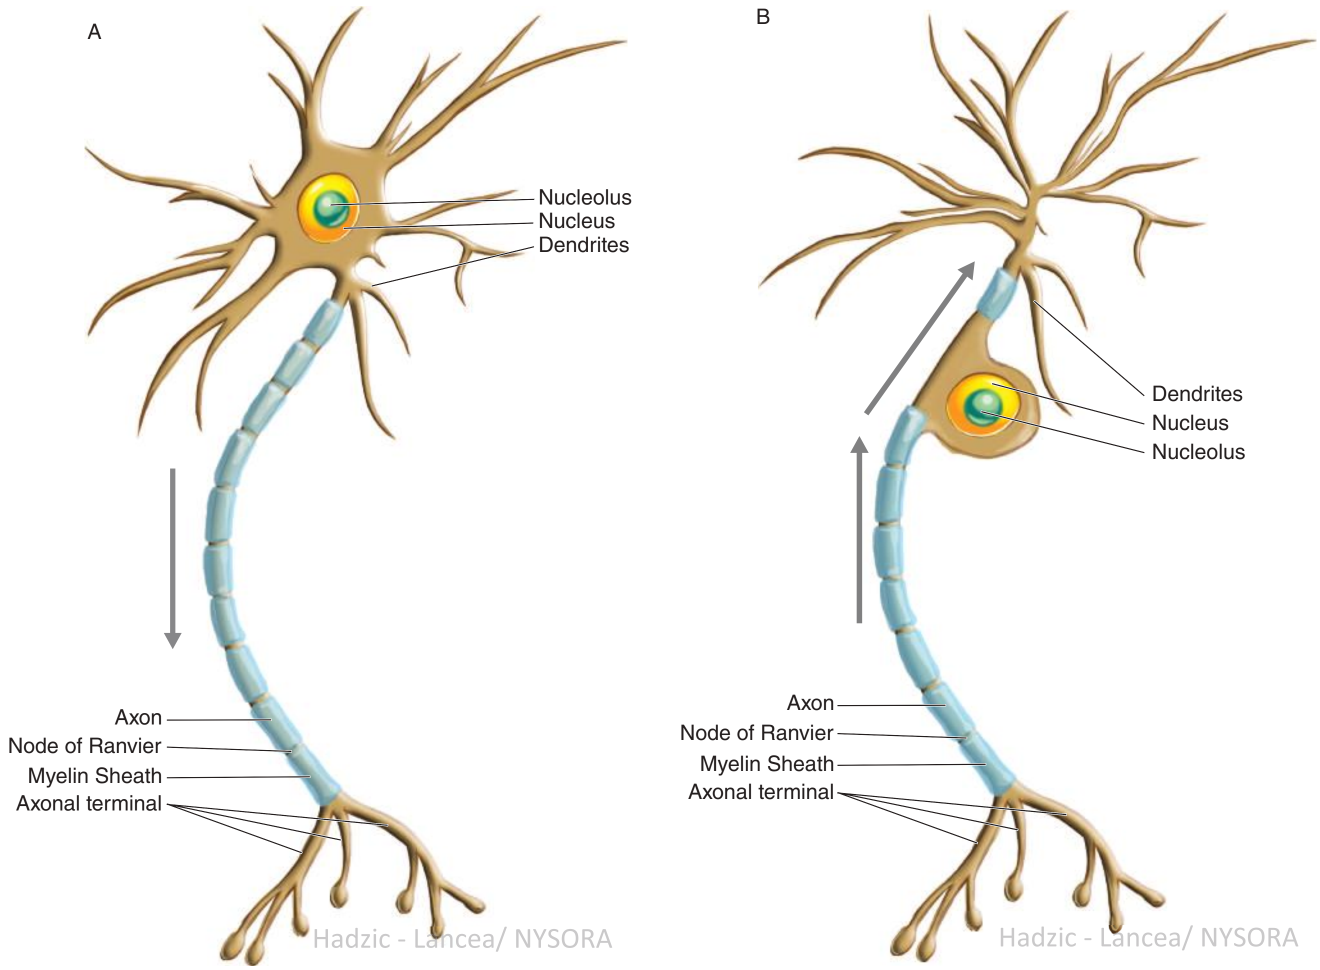

FIGURE 4–3. Diagram illustrating a multipolar (**A**) and unipolar or pseudounipolar (**B**) neuron. Arrows indicate the direction of nerve impulse propagation.

Clinical Pearl

- The larger the fiber, the more concentrated the local anesthetic must be to effect neural blockade.

MYELINATED NERVE FIBERS

Myelinated nerve fibers are ensheathed by myelin, greatly extended and modified plasmalemma of the Schwann cells (Figures 4–4 and 4–5). Myelin formation begins with extension of the Schwann cell cytoplasm and development of the inner mesaxon, which wraps around the axon several times. During the wrapping process, the cytoplasm is nearly extruded between the plasmalemma. Apposing extracellular faces of plasmalemma become "the major dense line," and apposing cytoplasmic faces form an "intraperiod line" of myelin. The proposed molecular structure of myelin fits the concept of plasmalemma as a lipid bilayer with integral and peripheral membrane proteins attached to the extracellular or to the cytoplasmic side of plasmalemma. In contrast to most biological membranes, myelin has a high ratio of lipid to protein (70%–85% lipid, 15%–30% protein), where the latter serve as structural proteins, enzymes, voltage channels, and signal transducers.[18]

Myelin sheath wraps the axon in segments. Areas of the axon covered by concentric lamellae of myelin and a single myelin-producing Schwann cell are called *internodes* and range in length from 200 to 1000 μm. Interruptions, which occur in the myelin sheath at regular intervals along the length of axons and expose the axon, are called nodes of Ranvier (Figure 4–6). Each node indicates an interface between the myelin sheaths of two different Schwann cells located along the axon.

The nodal region and its surroundings can be further subdivided into several domains (Figure 4–6) that contain a unique set of ion channels, cell adhesion molecules, and cytoplasmic adaptor proteins (for review, see Reference 8). In the PNS, the node is in contact with Schwann cell microvilli and covered by its basal lamina (Figure 4–6). An important characteristic of the *nodal* axolemma is its high density of voltage-gated Na^+ channels[19] as compared to the *juxtaparanodal* axolemma, which typically contains a high density of K^+ channels.[20] Na^+ channels potentiate the nerve impulse in a saltatory manner (Figure 4–7) along the myelinated fibers.[21,22] When the membrane at the node is excited, the local circuit that is generated cannot flow through the high-resistance myelin sheath. It therefore flows out and depolarizes the membrane at the next node, which may

TABLE 4–1. Classification of peripheral nerve fibers according to axonal diameter, conduction velocity, type of receptor, and myelin sheath thickness (myelination).

Axonal Diameter (μm)	Conduction Velocity (m/s)	Efferent Fibers	Afferent Fibers[a] (From Cutaneous Receptors)	Afferent Fibers From Skeletal Muscles, Tendons, and Joints	Myelination
12–20	60–120 30–70	Aα (to extrafusal muscle fibers)	Aα (from rapidly adapting mechanoreceptors)	Ia (from muscle spindles) Ib (from Golgi tendon organs)	Heavily myelinated
6–12	25–70		Aβ (from slowly adapting mechanoreceptors)	II (from joint proprioceptors)	Myelinated
3–8	15–30	Aγ (to intrafusal muscle fibers)			Myelinated
1–6	12–30		Aδ (from thermal and mechanical nociceptors and thermoreceptors—cold only)	III (from joint proprioceptors and joint nociceptors)	Thinly myelinated
1–3	3–15	B (preganglionic visceral)			Myelinated
0.2–1.5	0.5–2	C (postganglionic visceral)	C (from mechanical nociceptors and thermoreceptors—cold and warm, polymodal nociceptors)	IV (from joint nociceptors)	Unmyelinated

[a] Visceral afferent fibers (from interoceptors) are classified as Aδ and C fibers.

be 1 mm or farther away. The low capacitance of the sheath means that little energy is required to depolarize the remaining membrane between the nodes, resulting in increased speed of local circuit spreading.[18]

Myelination is an example of cell-to-cell communication in which axons interact with Schwann cells. The number of myelin layers is determined by the axon and not by the Schwann cell. Myelin sheath thickness is regulated by a growth factor called neuregulin 1 (Nrg1). The compaction of myelin sheath is associated with the expression of transmembrane myelin-specific proteins such as protein 0 (P0), a peripheral myelin protein of 22 kilodaltons (PMP22), and a myelin basic protein (MBP). The absence of proteins that regulate myelin sheath formation might result in severe hypomyelination or dismyelination in humans and experimental animals.[18]

UNMYELINATED NERVE FIBERS

Unmyelinated axons are also enveloped by Schwann cells and their basal lamina. An individual Schwann cell can ensheath a single or several unmyelinated axons (Figures 4–8 and 4–9). Unmyelinated fibers predominate in human cutaneous spinal nerves, where the average ratio of unmyelinated to myelinated fiber density is 3.7:1.[23] In unmyelinated fibers, conduction velocity is proportional to the square root of fiber diameter and is much slower compared to saltatory conduction in myelinated fibers (Table 4–1).

CONNECTIVE TISSUE INVESTMENTS OF PERIPHERAL NERVES

In a peripheral nerve, nerve fibers and their supporting Schwann cells are held together by connective tissue organized into three distinctive components that have specific morphological and functional characteristics. The epineurium forms the outermost connective tissue of the peripheral nerve, the perineurium surrounds each nerve fascicle separately, while the individual nerve fibers are embedded in the endoneurium[2] (Figures 4–10 to 4–13).

Epineurium

The epineurium is a condensation of a loose areolar connective tissue that surrounds a peripheral nerve and binds its fascicles into a common bundle (Figure 4–10 and Figure 4–11). Epineurium that extends between the fascicles is the interfascicular or inner epineurium, while epineurium that surrounds the entire nerve trunk is the epifascicular or external epineurium[24,25] called the epineurium comprises 30%–75% of the nerve cross-sectional area[26] but varies along the nerve. It is the thickest where continuous with the dura covering the CNS and more abundant in nerves adjacent to the joints, where nerves are subject to pressure.[27] Susceptibility to compression injury is therefore likely to be greater in unifascicular than in multifascicular nerves because the latter have greater amount of epineurium. As the peripheral nerve divides and the number of fascicles is reduced, the epineurium becomes progressively thinner and eventually disappears around monofascicular nerves.

The epineurium contains collagen, fibroblasts, mast cells, and fat cells. Collagen bundles have a predominant longitudinal orientation; however, an electron microscopy study found epineural collagen in bundles 10–20 μm in width are arrayed obliquely around the circumference of the nerve.[28] Elastic fibers are also present, particularly adjacent to the perineurium,[29,30] which are mainly oriented longitudinally. Collagen and elastic fibers are aligned and oriented to prevent damage by overstretching of the nerve bundle, suggesting that the epineurium is designed to accommodate the stretch.

Human epineurium is constructed predominantly of type I and type III collagen, with the type I predominating.[31] The diameter of the collagen fibrils averages 60–110 nm.[2]

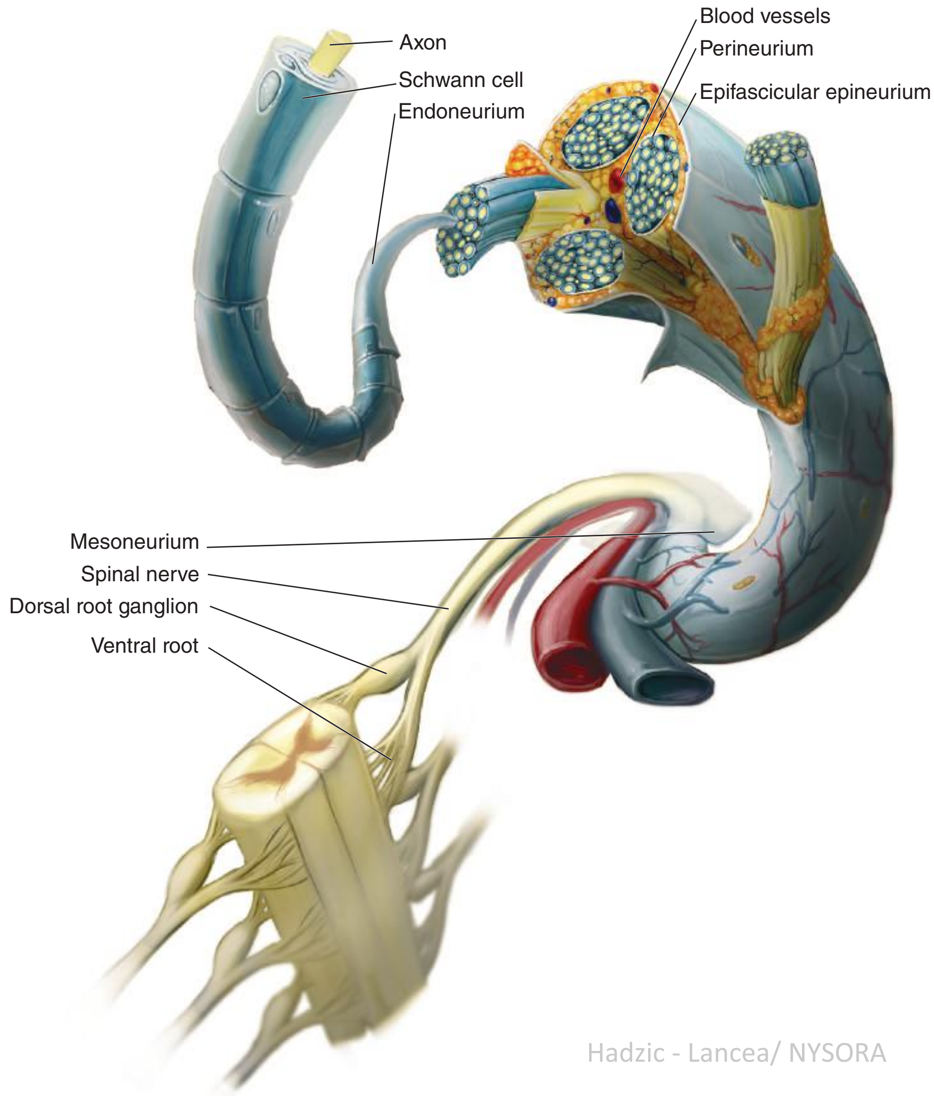

FIGURE 4–10. Connective tissue investments of peripheral nerve. The diagram demonstrates the arrangement of the peripheral nerve. A segment of the spinal nerve is enlarged to show the relation of the nerve fibers to the surrounding connective tissue (endoneurium, perineurium, and epineurium).

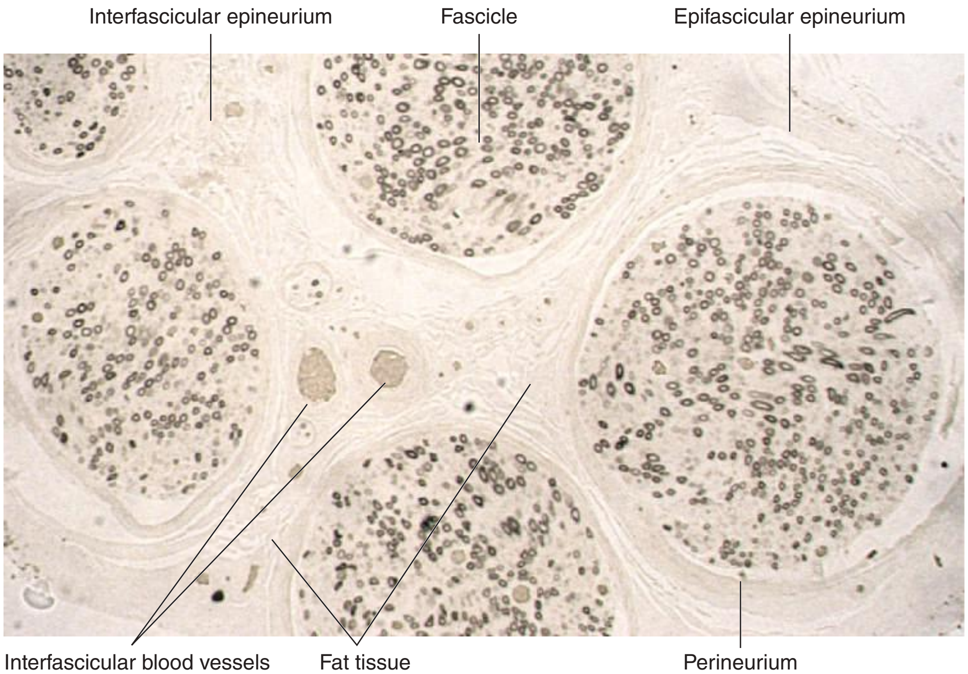

FIGURE 4–11. Semithin section of human sural nerve fixed in osmium tetroxide. The myelin sheaths are preserved and stained black. Perineurium surrounds the nerve fascicle. Streaks of connective tissue originate from epifascicular epineurium inside the nerve as interfascicular epineurium. Fat tissue and blood vessels are localized in interfascicular epineurium.

Adipose tissue inside a nerve surrounds the fascicles and forms adipose sheaths that separate the fascicles from each other. The thickness of adipose sheaths varies from one fascicle to another and is greater in larger nerve trunks, highlighting its protective function in cushioning the fascicles against damage by compression.[27] Loss of epineural fat may present a risk factor for pressure-caused palsies in emaciated, bedridden patients.[2] In contrast, excessive adipose tissue can also delay the diffusion of local anesthetic injected near a nerve, thus interfering with the anesthetic blockade.[32] Epineurium is continuous with the connective tissue called adventitia or mesoneurium that surrounds the nerve when passing through, underneath, or between the muscle fascia, serving as (1) a conduit for the injected local anesthetic, (2) a path allowing for nerve gliding, and (3) a layer of protection against nerve trauma.[25] Because their attachment is loose, nerves are relatively mobile except where tethered by entering vessels or exiting nerve branches.[24]

Perineurium

The perineurium is a specialized connective tissue surrounding individual nerve fascicles (Figures 4–10 and 4–12). This protective cellular layer is thinner than the epineurium and separates the endoneurium from the epineurium.[2] The perineurium consists of alternating layers of flattened polygonal cells, which are thought to be derived from fibroblasts, and collagenous connective tissue,[29] the formation of which is controlled by the

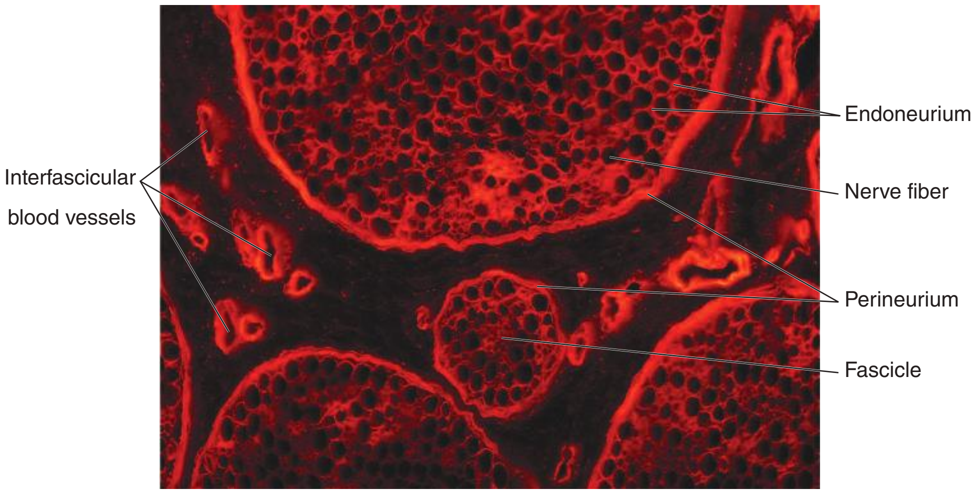

FIGURE 4–12. Transverse section of pig sciatic nerve. Immunohistochemical staining for collagen. Blood vessels course through the interfascicular epineurium, which fills the space around the perineurium and fascicles.

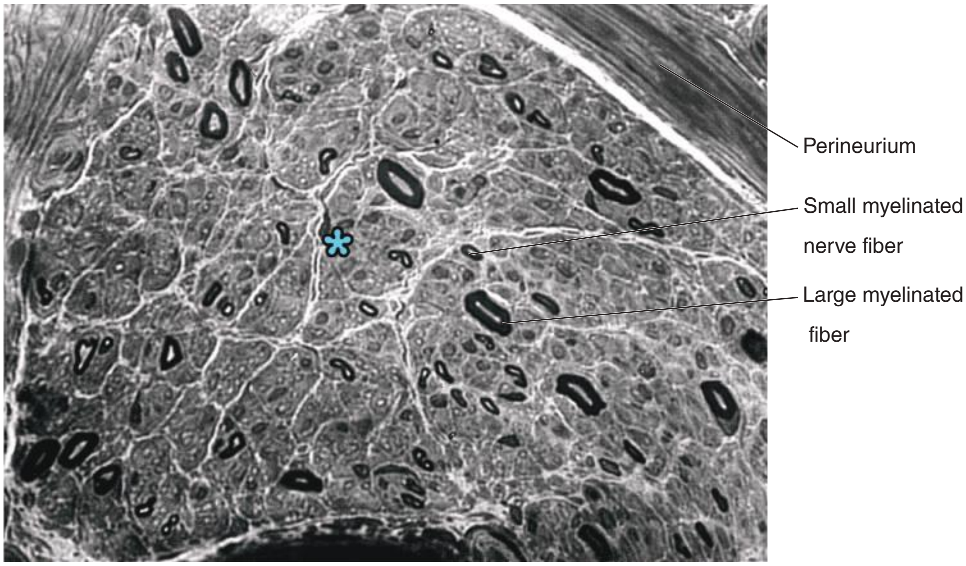

FIGURE 4–13. Semithin section of human sural nerve stained by cresyl violet. Axonal neuropathy with the predominant loss of large myelinated fibers. * Intrafascicular space between myelinated fibers (occupied by endoneurium, Schwann cell nuclei, and unmyelinated fibers).

Schwann cells.[33] The flattened polygonal cells, which constitute the lamellae, are specialized to function as a diffusion barrier.[34] The number of lamellae varies, depending mainly on the diameter of the fascicle; the larger the fascicle is, the greater the number of lamellae.[35] In mammalian nerve trunks, the perineurium contains 15–20 cell layers.[5] Contiguous cells in each layer interdigitate along extensive tight junctions.[30] The cells may branch and give rise to processes and contribute to the adjacent lamellae. Each layer of cells, enclosed by basal lamina, can reach a thickness of up to 0.5 μm in human nerves.[2,5]

Collagen fibers originate in a lattice-like arrangement, in which bundles are circular, longitudinal, and obliquely arranged. The innermost perineural cell layer adheres to a distinct boundary layer of densely woven collagen fibers and subperineurial fibroblasts that mechanically links the perineurium to the endoneurial contents.[28] Collagen fibers are predominantly type III, although type I collagen fibers are also present.[31] The diameter of the collagen fibrils is substantially smaller than that of the epineural fibrils, with an average of 52 nm in the rat sural nerve.[30] The basal lamina of polygonal cells is composed of collagens IV and V, fibronectin, heparan sulfate proteoglycan,[36] and laminin.[37] The ubiquitous presence of pinocytotic vesicles rich in phosphorylating enzymes underlie the assumption that the perineurium functions as a metabolically active diffusion barrier, playing an essential role in maintaining the osmotic milieu and fluid pressure within the endoneurium.[34] For instance, in one of our studies, inflammatory cells accumulated between the nerve fascicles in piglets after exposure of the nerve to ultrasound gel did not penetrate the perineurium.[38] Because of its tightly adherent cellular structure and more longitudinally oriented collagen, the perineurium is less tolerant to elongation than the epineurium. In the rabbit, mechanical failure during elongation coincided with a disruption of the perineurium while the epineurium remained intact.[39] The integrity of the diffusion barrier was maintained after 2 hours of 15% elongation, while 27% elongation caused acute perineural disruption.[39]

Endoneurium

The endoneurium comprises loose intrafascicular connective tissue that does not include the perineural partitions that subdivide the fascicles and surrounds Schwann cells (Figure 4–12). Approximately 40%–50% of the intrafascicular space is occupied by nonneural elements (ie, other than axon and Schwann cells), of which the endoneurial fluid and connective tissue matrix occupy 20%–30%.[40] There are substantial variations among nerves in different species[5] and age groups.[41]

The endoneurium is composed of collagen fibers (produced by the underlying Schwann cells and fibroblasts); cellular components are bathed in endoneurial fluid, contained in substantial intrafascicular spaces. The nerve fibers tend to be grouped into small bundles with intervening clefts. Endoneurial fluid pressure is slightly higher than that of the surrounding epineurium. It is believed that this pressure gradient minimizes endoneurial contamination by toxic substances external to the nerve bundle.[42]

Endoneurial collagen fibrils are smaller than those in the epineurium and range between 30 and 65 nm in diameter in humans.[43] The fibrils run parallel to and around the nerve fibers, binding them into fascicles or bundles. They show condensations around capillaries and nerve fibers. Near the distal terminus of the axon, the endoneurium is reduced to a few reticular fibers surrounding the basal lamina of the Schwann cells. Types I, II, and III collagen are present in endoneurium.[44]

Cellular constituents of endoneurium are fibroblasts, endothelial cells of capillaries, mast cells, and macrophages. Mast cells occur in varying numbers, being especially numerous along blood vessels. Macrophages account for 2%–4% of the intrafascicular nuclei in rat peripheral nerve[45] and are the primary antigen-presenting cells of peripheral nerve. They scavenge extracellular proteins and present them to T cells emerging from circulation. The macrophages mediate immunologic surveillance and participate in nerve tissue repair. Following nerve injury, they proliferate and actively phagocytose myelin debris.

The extracellular matrix is rich in glycoproteins, glycosaminoglycans, and proteoglycans. The best characterized of these include the glycoprotein fibronectin, tenascin C, trombospondin, and the chondroitin sulfate proteoglycans versican and decorin.[46] Expression of these molecules changes after nerve injury, so they are potentially relevant during nerve regeneration.[46]

From a hydrodynamic point of view, the various tissues that comprise a peripheral nerve can be divided into the loose, high-compliance, expansible connective tissue of the epineurium and the low-compliance, disruptable fascicles and fascicular bundles, densely packed within the perineurium. These anatomical differences between connective tissues and fascicles or their bundles explain why an injection into fascicles requires more force (pressure) than injection into the loose connective tissue of the epineurium.[25,47]

Clinical Pearls

- The perineurium is a tough and resistant tissue, that tends to escape slowly advancing a blunt, short-bevel needle during nerve block procedure.[48]
- Higher force (pressure) is required for an injection into a low-compliant fascicle as opposed to the high-compliant epineurium.[49]
- In the interscalene and supraclavicular regions of the brachial plexus, the nerves are more densely packed and oligofascicular, while more distally, they are polyfascicular with a larger amount of stromal tissue.[50]
- Multifascicular nerves are less susceptible to injury as compared to unifascicular due to a reduced fascicular diameter and an increased epineurial protection.
- The abundance of loose epineurial tissue offers an explanation as to why most intraneural injections (intraneural, but extrafascicular) do not result in overt nerve injury.[51]

THE CENTRAL-PERIPHERAL TRANSITION REGION

The transition between the CNS and the PNS in cranial and spinal nerve roots is referred to as the *central-peripheral transition region* or *CNS-PNS border* (Figure 4–14). It represents an abrupt change in the type of myelin, supporting elements, and vascularization. The main glial components in the CNS are astrocytes and oligodendrocytes, while in the PNS the main components are the Schwann cells.[52] The nerve roots of spinal nerves are bathed in cerebrospinal fluid. The *transition region* is the length of the rootlet that contains both central and peripheral nervous tissue. Transition details distinguishing ensheathment of the spinal roots with the meninges and connective tissue investments of the peripheral nerves have not been fully clarified.[5] Their structural arrangements however, are well documented in electron microscopic studies.[53–57]

The cellular components of the endoneurium in the spinal roots resemble those of peripheral nerves. The quantity of collagen is substantially less and is not organized in sheaths around the nerve fibers.[43] The region in which the spinal roots attach to the spinal cord is characterized by an irregularly designed transition from the peripheral nerve to the CNS, the Obersteiner-Redlich zone where Schwann cells are replaced by oligodendrocytes. The central portion of the root is limited at its periphery by marginal glia, composed of astrocytes covered by basal lamina.[5]

The spinal roots traverse the subarachnoid space covered by a multicellular root sheath and penetrate the dura at the subarachnoid angle (Figure 4–14). External to the subarachnoid angle, the nerve roots possess epineurium, perineurium, and endoneurium as in the peripheral nerve trunks. The epineurium is the continuation of the spinal dura, while the endoneurium is developed distal to the junction of the roots with the central nervous tissue. Perineurium ensheaths the spinal ganglia and is proximal to it. It is divided in the outer layers that pass between the dura and the arachnoid to form the "dural mesothelium,"[58] while the inner layers of perineurium continue over the roots as the "inner layer of the root sheath."[5,54]

The root sheath is composed of cellular and fibrous lamellae divided into two layers.[54] The outer layer consists of loosely associated cells bordering on the subarachnoid space. Where the roots become attached to the spinal cord, the cells of the outer layer of the root sheath become continuous with the pia.[59] At the subarachnoid angle, the outer layer becomes reflected to the external meningeal investments of the spinal cord (arachnoidea attached to the inner layer of spinal dura).[56] The inner layer of the root sheath consists of flattened cells that are closely associated with each other, are intermittently invested with a basal lamina, and resemble the perineurium but are not classifiable as perineural cells. It becomes continuous with the perineurium peripherally.

The subarachnoid space opens into a lateral recess that extends between the ventral and dorsal roots and may constitute a *communication* between the subarachnoid and endoneurial spaces.[54] This communication is clinically relevant because it allows inflammation to spread from the subarachnoid space to the endoneurium in the case of polyradiculoneuritides.

Clinical Pearls

- Local anesthetic injection within the epineurial cuff during performance of interscalene or lumbar plexus blocks may lead to spinal anesthesia due to dural cuff extension beyond the intervertebral foramen.[60]
- During performance of lumbar plexus block, epidural spread of local anesthetic is observed particularly when high injection pressure (force) is used during the injection process.[61]

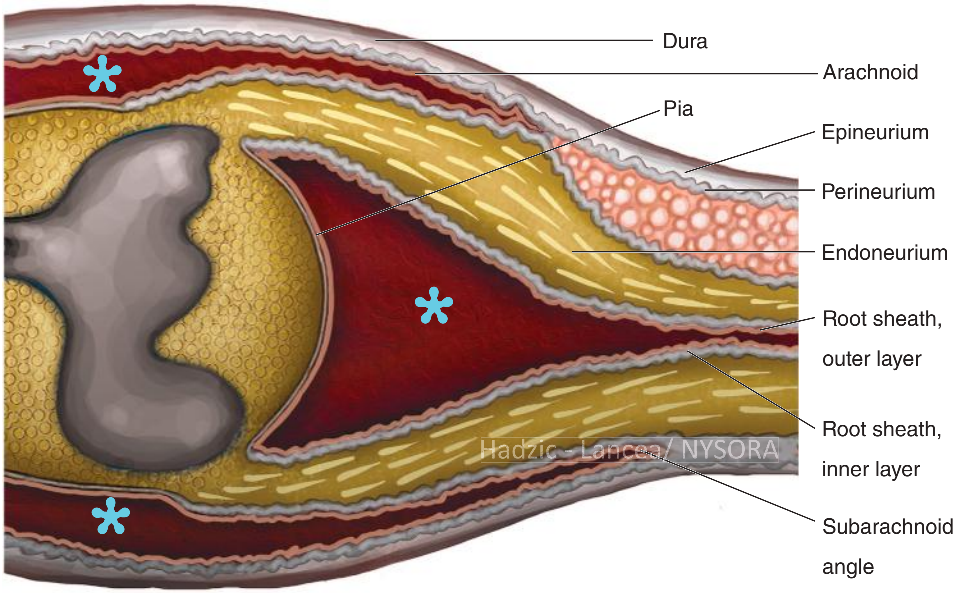

FIGURE 4–14. Central-peripheral transition region. The epineurium becomes continuous with the dura mater. The arachnoid is reflected over the roots at the subarachnoid angle and becomes continuous with the outer layer of the root sheath. At the junction with the spinal cord, the outer layer becomes continuous with the pia mater. The perineurium divides in two layers at the subarachnoid angle: The outer layer separates from the nerve root and runs between the dura and the arachnoid; the inner layer is adherent with spinal roots and constitutes the inner layer of the root sheath. Spinal ganglion is embedded in the perineurium. * Subarachnoid space. (Reproduced with permission from Haller FR, Low FN. The fine structure of the peripheral nerve root sheath in the subarachnoid space in the rat and other laboratory animals. *Am J Anat*. 1971 May;131(1):1-19.)

VASCULAR SUPPLY OF PERIPHERAL NERVES

The peripheral nerve is a well-vascularized structure,[62] supplied by vessels that originate from the nearby large arteries and veins as well as from smaller adjacent muscular and periostal blood vessels (Figure 4–12). Peripheral nerves have two separate, functionally independent, vascular systems: an extrinsic system (regional nutritive vessels and epineural vessels) and an intrinsic system (microvessels in the endoneurium).[63] There are rich anastomoses between the two systems, resulting in considerable overlap between the territories of the segmental arteries.

The epineurium is characterized by a predominantly longitudinal vascular plexus. Transperineural arterioles, 10–25 μm in diameter, pass from the epineurium to the endoneurium through sleeves of perineural tissue.[64] Their course through the perineurium is oblique, rendering them potentially susceptible to changes in intra- or extrafascicular pressure.[62] Epineurial and perineurial vessels have a rich perivascular plexus of peptidergic, serotoninergic, and adrenergic nerves that play an important role in the neurogenic control of endoneurial blood flow.[64]

The endoneurial vasculature is noted for its anatomical dissimilarities from a conventional capillary bed, although, physiologically, it serves similar metabolic functions. Transperineurial arterioles gradually lose their continuous muscle coat and become postarteriolar capillaries. Endoneurial capillaries have atypically greater diameter and intercapillary distances than those in many other tissues.[65] Such angioarchitecture suggests a lower exchange capacity.[66] Endoneurial arterioles have a poorly developed smooth muscle layer and thus limited capacity for autoregulation.[63] The density of endoneurial microvessels varies significantly throughout peripheral nerves; these variations correlate with susceptibility to ischemic neuropathy.[67] This unique pattern of vessels, together with the high basal blood flow relative to metabolic requirements of the nerve, confer a high degree of resistance to ischemia so that nerve dysfunction does not occur during acute ischemia until blood flow is almost zero. The outstanding characteristic of the peripheral neurovascular system is its flexibility. Peripheral nerves may be surgically mobilized, severing their nutrition vessels without clinical consequences, to a surprising degree. However, the distribution of the circulation within the endoneurium is exquisitely sensitive to physical and chemical manipulation.[62]

Clinical Pearls

- Peripheral nerves are relatively resistant to ischemia because nerve dysfunction can only occur when the blood flow is almost zero.
- Local anesthetics have the ability to constrict vasculature and decrease the blood flow to the nerves.[68]

AGE-RELATED CHANGES IN PERIPHERAL NERVES

An intact aged PNS is characterized by several extensive structural, functional, and biochemical changes, which have been documented in both myelinated and unmyelinated fibers.[5,69] In the elderly, myelinated fiber density decreases.[23,41,70–72] A regular relation between internodal length and fiber diameter becomes less precise with aging.[41,73] This is associated with segmental demyelination and remyelination and the axonal degeneration and regeneration clinically evident as mild peripheral neuropathy.[5]

In unmyelinated fibers, regressive changes attributed to aging have been reported.[74,75] In unmyelinated fiber complexes of aging nerves, the proportion of Schwann cell bands devoid of axons increases (so-called collagen pockets; see Figure 4–9). An early age-related change appears to be the budding of Schwann cell processes into numerous flattened tongues, which usually occur in groups.[5] The perineurial index (ratio of perineurium thickness to fascicle diameter) shows a tendency to increase with age,[72] most probably reflecting age-related loss of nerve fibers.

Aging is associated with a decreased number of endoneurial capillaries and an increase in the thickness of capillary walls and the perineurium.[70] The rate of axonal regeneration becomes slower as density and number of regenerating axons decreases. Aging also impairs terminal sprouting of regenerated axons and collateral sprouting of intact adjacent axons, further limiting target reinnervation and functional recovery.[76]

The cause of changes related to aging is uncertain. It is not yet established whether they are the result of neuronal aging, giving rise to distal axonal degeneration and secondary demyelination, or local factors in the nerves, such as ischemia or the consequences of repeated minor trauma. Nevertheless, age-related changes in peripheral nerves probably result from the cumulative, lifelong effect of various pathogenic factors modified by genetic determinants and by a gradual decrease in regenerative capacity.[70]

Clinical Pearls

- Due to age-related nerve degeneration, less local anesthetic at lower concentration may be needed for nerve blockade.
- Age-related changes of the peripheral nerve may be responsible for the typically poorer ultrasonographic images of the peripheral nerves in the elderly as compared to younger subjects.[77]

RESPONSE OF PERIPHERAL NERVE TO INJURY

Injuries to the peripheral nerves result in loss of motor, sensory, and autonomic functions in the denervated segments of the body due to the interruption of axons, degeneration of distal nerve fibers, and eventual death of axotomized neurons.[78] Functional deficits caused by nerve injuries can be compensated by reinnervation of denervated targets by regenerating injured axons or by collateral branching of undamaged axons and remodeling of nervous system circuitry related to the lost functions. Nerve regeneration is possible if the cut ends remain near each other[76] otherwise, regeneration may not be complete or successful.

After an injury, the neuron attempts to repair the damage, regenerate the process, and restore function by initiating a series of structural and metabolic events called *axon reaction*. The reactions to the trauma are localized in three regions of the neuron: at the site of damage (local changes), distal to the site of damage (anterograde changes), and proximal to the site of damage (retrograde changes). Local reaction to injury involves removal of debris by neuroglial cells. The portion of the axon distal to an injury undergoes degeneration and is phagocytosed. The proximal portion of the injured axon undergoes degeneration followed by sprouting of a new axon whose growth is directed by Schwann cells.

Clinical Pearls

- The electrical stimulation threshold for a motor response of the sciatic nerve is increased in patients with diabetic foot gangrene, which may affect nerve identification.[79]
- Many postprocedure nerve injuries occur in nerves with preexisting pathology.[80]

SUMMARY

The knowledge that neural anatomy is unique at different anatomical sites is essential for a safe and effective practice of regional anesthesia. Understanding the peripheral nerve structure and its implication while using state-of-the-art monitors, including ultrasonography, nerve stimulation, and injection pressure monitoring, is helpful in minimizing the potential for patient injury.

CHAPTER 5

Connective Tissues of Peripheral Nerves

Miguel A. Reina, Xavier Sala-Blanch, Fabiola Machés, Riánsares Arriazu, and Alberto Prats-Galino

INTRODUCTION

A better understanding of some features of the fine structure of peripheral nerves may provide us with essential information that can be helpful in anesthetic clinical practice. This chapter reviews the ultrastructure of connective tissues of peripheral nerves to facilitate understanding of its role as the perineurial diffusion barrier and implication in regional anesthesia.

FASCICLES

Nerves and their principal branches (Figures 5–1 to 5–3) consist of parallel bundles of nerve fibers (nerve fascicles, fasciculi). The size, number, and pattern of fasciculi vary among nerves and at different distances from their origin. When the connective tissue of the peripheral nerve is removed, 20 or more tubular structures or fascicles are typically seen.

Inside each nerve, the axons form an intraneural plexus in such a fashion that one axon can contribute to different fascicles along the nerve length (Figure 5–4). In other words, an axon can travel from a peripheral position to a more central position as well as swap the fascicles altogether along its descent more peripherally.[1–4] Indeed, cross-sectional anatomy of nerves at close distance from each other demonstrates that the location and number of fascicles within nerves are highly variable (see Figure 5–3) with the presence of intraneural plexuses (Figures 5–5 and 5–6). The number, size, and location of fascicles in peripheral nerves are also variable even within a single nerve and can vary as much as 23 times along a 4- to 5-cm length of nerve.[5–8]

Clinical Pearl

- Inside each nerve, the axons form an intraneural plexus in such way that an axon can occupy different fascicles.

In a cross section of a sciatic nerve, fascicles comprise 25%–75% of the cross-sectional area (see Figures 5–1 and 5–3). This proportion varies in different nerves and at different levels of the same nerve. Up to 50% of the cross-sectional area is made up of non-neural tissue, including endoneural fluid and connective stroma. The number of fascicles increases at the level of nerve branching. In the proximity of joints, the fascicles are thinner, more numerous and have a thicker perineurium, which may confer better protection against pressure and stretching.[8]

CONNECTIVE TISSUE SHEATHS OF PERIPHERAL NERVES

The connective tissue inside nerves functions to support and protect nerves blood and lymphatic vessels (see Figure 5–1 and 5–2). The connective tissue of peripheral nerves takes different names according to its location.[1–3] On the outside of each peripheral nerve, there is collagenous tissue: *epineurium*. Surrounding every fascicle within the nerve is the *perineurium*. Individual nerve fibers within the fascicles are embedded in *endoneurium*, which fills the space bound by the perineurium. As the peripheral nerve divides and the number of fascicles decreases, the connective tissue sheaths become progressively thinner. For instance, in monofascicular nerves the epineurium is absent, distributed irregularly, or appears integrated with the perineurium. Connective tissue that connect nerves to the surrounding structures are thinner and disperse, often losing any distinguishable feature from that of general connective tissue.[9]

ENDONEURIUM

The endoneurium (Figures 5–7 and 5–8) intimately surrounds Schwann cells and fills the space bounded externally by the perineurium. Endoneurium contains collagen fibers,

fibroblasts, capillaries, and a few mast cells and macrophages. Collagen fibers are permeable and concentrated in a zone beneath the perineurium and around nerve fibers and blood vessels. The collagen fibers surround both myelinated and unmyelinated nerve fibers. However, the endoneurial sheaths around smaller myelinated fibers and around some unmyelinated axons are less well organized (Figure 5–9).

Fibroblasts are among the most abundant cell types of the endoneurium. They are responsible for fiber formation and production of ground substance. When sectioned transversely, endoneurial fibroblasts have triangular or rectangular perikaria. The appearance of fibroblasts varies depending on their functional activity. When the cell is metabolically active, as is the case with growth and in tissue regeneration after injury, the nucleus is larger and nucleoli are more prominent. The cytoplasm also stains more deeply and is basophilic in contrast with the lightly staining, slightly acidophilic cytoplasm of a relatively inactive cell. Like those in the epineurium, fibroblasts in the endoneurium lack a basal lamina.

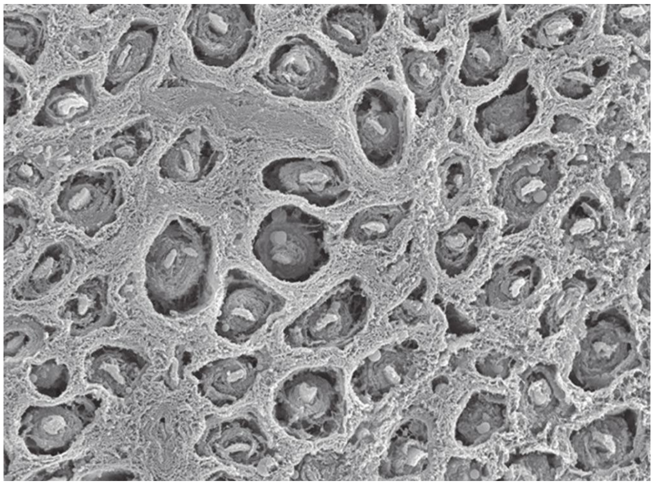

FIGURE 5–7. Endoneurium shaped as multiple canaliculi, enclosing fascicles of tibial nerve. Scanning electron microscopy. Magnification ×900. (Reproduced with permission from Reina MA: *Atlas of Functional Anatomy for Regional Anesthesia and Pain Medicine*. New York: Springer; 2015.)

Mast cells are especially numerous along the course of blood vessels. Mast cell granules are soluble in water and are therefore not easily revealed in sections routinely prepared with hematoxylin and eosin stain. After adequate fixation, the granules stain with most basic dyes and become metachromatic after certain dyes, such as toluidine blue. Electron microphotographs show that the secretory granules are membrane bound, and the granule matrices have varying densities and characteristic helical-type patterns (Figure 5–10). Macrophages are also found frequently around perivascular endoneurium (Figure 5–11). The endoneurium contributes to the stability of the internal medium where the Schwann cells and axons are located.[10] The endoneurium of cutaneous nerves contains more collagen fibers than deep nerves; this probably is related to its protective role. The endoneural collagen is believed to originate from the Schwann cells, which are 9:1 more prominent than fibroblasts. Schwann cells represent 90% of intrafascicular cells, whereas fibroblasts account for less than 5% of the remaining number. The endoneurium along with the epineurium and perineurium contribute to nerve protection against elongation under strain. The sinuous trajectories of axons confer additional protection on nerves. Endoneurial sheaths around axons is demonstrated in

figures 5-7, 5-8 and 5-9. Instead of individually shaped endoneurial layers, the endoneurium appears rather as a continuum, forming several canaliculi into which axons are embedded.

Clinical Pearl

- The endoneurium surrounds Schwann cells and fills the space within perineurium.

PERINEURIUM

Each fascicle is surrounded by a connective tissue sheath, the perineurium.[1–3,11–14] The perineurium consists of concentric layers of flattened cells separated by layers of collagen (Figures 5–12 to 5–16). The number of perineurial cell layers depends on the size of the fascicle. As many as 8–16 concentric layers may be present around large nerve fascicles, but a single layer of perineurial cells surrounds small distal fascicles. In larger peripheral nerves, concentric cell layers alternate with layers of collagen fibers arranged longitudinally, similar to those of the epineurium. Collagen fibers are thinner than those of the epineurium, and only a few elastic fibers are scattered among them. Perineurial cells have a basal lamina on each side that may be considerably dense. At sites known as hemidesmosomes, the perineurial cell plasma membrane strongly adheres to the basal lamina.[3,11]

With electron microscopy, perineurial cells are seen as thin sheets of cytoplasm containing small amounts of endoplasmic reticulum, filaments, and numerous endocytic vesicles. Tight junctions and gap junctions between adjacent cells within the same layer of perineurium are also observed.[3,11] Similar tight junctions may also appear between successive layers of the perineurium when their cells are in close proximity. Tight junctions in the inner layers of the perineurium and tight junctions in endoneurial capillaries form a blood-nerve barrier structure[14–16] (Figures 5–17 and 5–18). The *blood-nerve barrier* is not equivalent to the *blood-brain barrier*[11] as the blood-brain barrier astrocytes help regulate the flow of compounds between blood and the brain. The perineural cells are metabolically active, and their cytoplasms contain enzymes like ATPase (adenosine triphosphatase), 5-nucleotidase, and so on. These cells probably play a role in maintaining electrolyte and glucose balance around the nerve cells.[17]

The perineurium forms a tubular wrapping that allows some axonal movement inside the fascicles. The thickness of the epineurium varies between 1 and 100 μm. As the number of fascicles within a nerve increases, the thickness of the perineurium generally decreases. For instance, along the trajectory of

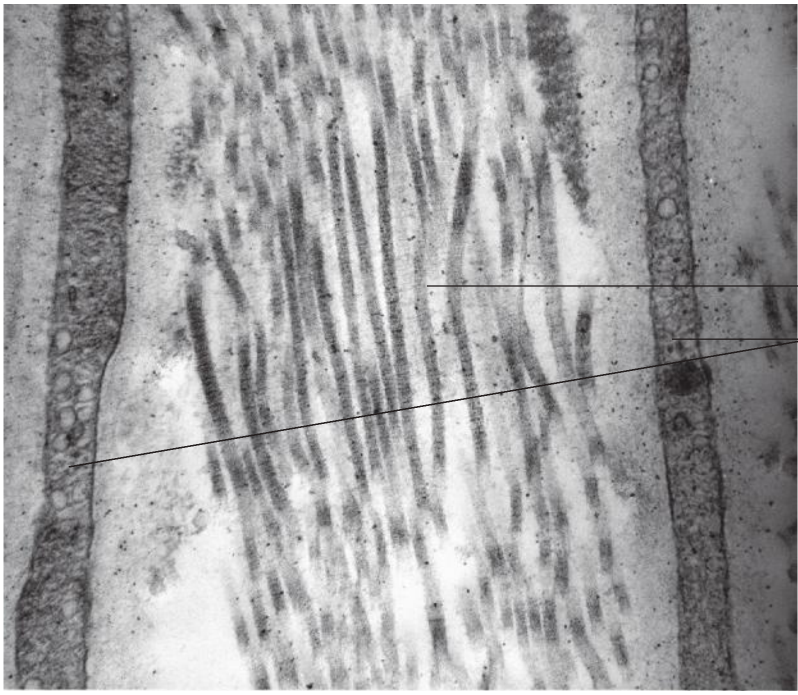

FIGURE 5–14. Collagen fibers among perineurial layers. Transmission electron microscopy. Magnification ×30,000. (Reproduced with permission from Reina MA: *Atlas of Functional Anatomy for Regional Anesthesia and Pain Medicine*. New York: Springer; 2015.)

the median nerve, the epineurium appears proportionally thicker in the wrist than in the axilla. There are three areas where the perineurium is absent and the epineurium becomes in contact with the endoneurium:nerve endings, around blood vessels, and in areas where reticular fibers penetrate the perineurium.

The role of the perineurium is to maintain intrafascicular pressure and to contribute to the barrier effect.[13,16,18] Pressure exerted on the perineurium is transmitted to the endoneurium and ultimately the nerve fibers (axons).[19] The perineurium increases in thickness around points of nerve branching to provide additional protection.[20]

The perineurium may be also protective in limiting the extension of infection and inflammatory reactions. For instance, when a nerve with intact perineurium crosses an infected area, the nerve responds generally by thickening of its perineurial

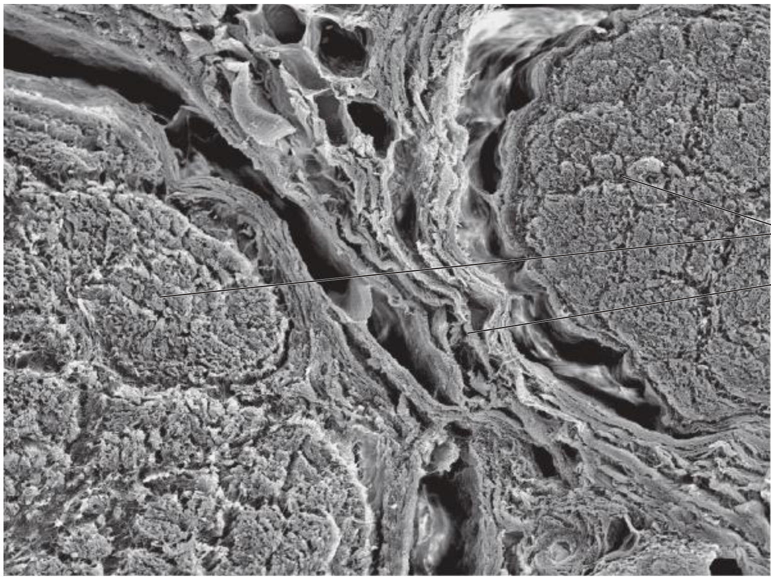

FIGURE 5–15. Perineurium and fascicles: three-dimensional features of perineural layers. Scanning electron microscopy. Magnification ×150. layer. Conversely, when perineurium is not intact, the infection easily spreads across nerve fascicles.[19] Injury to the epineurium, however, does not compromise the axonal safety to the same extent. Söderfelt demonstrated that the barrier effect of the epineurium is preserved for up to 22 hours postmortem in conditions of ischemia.[16] Olsson has studied the loss of the nerve barrier effect in vivo after nerve lesion. He also has demonstrated recovery of the effect between 2 and 30 days postinjury.[13]

Clinical Pearls

- Fascicles within the nerve are surrounded by perineurium which confers structural protection against penetration and over-stretching injury.
- A blood-nerve barrier is formed by tight junctions in the inner layers of the perineurium and tight junctions in endoneurial capillaries.

EPINEURIUM

The outermost sheath of the epineurium consists of moderately dense connective tissue that binds nerve fascicles (Figures 5–3, 5–19, and 5–20). Epineurium merges with adipose tissue surrounding peripheral nerves, particularly in subcutaneous tissue. The amount of epineurial tissue varies along a nerve and is more abundant around joints. The thickness of the epineurium varies in different nerves and in different locations of the same nerve. For instance, the average thickness of the epineurium is 22% of the ulnar nerve at the level of the elbow and 88% of the sciatic nerve at the gluteal level. In general, the epineurium represents between 30% and 75% of the cross-sectional area of a nerve.[8,20,21] The proportion of epineurium is higher in larger nerves with increasing numbers of nerve fascicles. However, the epineurium is absent around monofascicular nerves and at nerve endings.

The epineurium contains adipocytes, fibroblasts, connective tissue fibers, mast cells, small blood and lymph vessels, and small nerve fibers innervating the vessels.[20] Epineurium is a permeable structure,[20,21] and its fibroblasts are ultrastructurally identical to fibroblasts elsewhere in the body. Scattered throughout the epineurium, fibroblasts form the epineurial collagen, the most prominent component of this layer. As collagen is a protein stained by most acid dyes, collagen fibers turn weak pink wiht eosin in preparations stained with hematoxylin-eosin. Under the electron microscope, fibers of mature collagen have frecuent cross bandings. Elastic fibers are also present, and these are considerably more compact than collagen fibers. They stain weak pink in sections stained with hematoxylin and eosin, brown with orcein, and blue-purple with resorcin-fuchsin. In electron micrographs, elastin fibers typically appear more stained (darker) at the periphery and are embedded in a substance containing thinner elastin filaments.

The epineurium of some nerves contains a considerable amount of fat, as is the case with the sciatic nerve. The common peroneal and tibial nerves, however, contain less fat than the sciatic nerve, and usually the former contains less fat than the latter.[8]

Seen under the microscope, intraneural adipose cells resemble honeycombs, with empty vacuoles due to fat dissolution, during the fixation process[22] (Figure 5–21).

Mast cells are distributed throughout connective tissue and are often located in the proximity of small blood vessels.

Vasa nervorum supplying peripheral nerves arise from branches of regional arteries. Branches from these arteries enter the epineurium to form an vascular plexus (Figures 5–22 and 5–23). From the plexus, vessels penetrate the perineurium and enter the endoneurium as arterioles and capillaries. In nerves consisting of several fascicles, arteries, veins, and lymphatics run longitudinally and parallel to nerve fascicles.

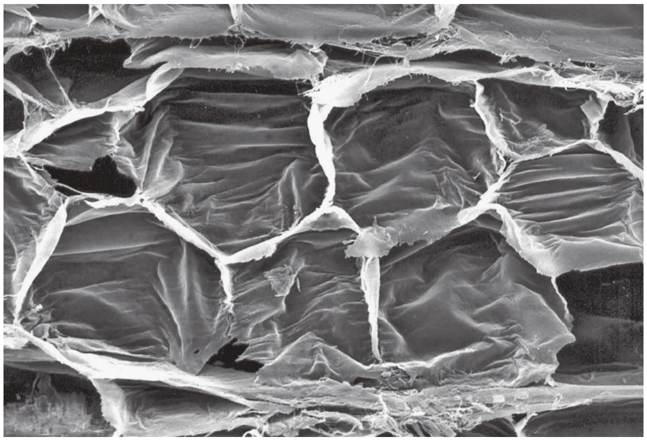

FIGURE 5–21. Adipocytes in interfascicular tissue of sciatic nerve. Scanning electron microscopy. Magnification ×400. (Reproduced with permission from Reina MA, López A, De Andrés JA: Adipose tissue within peripheral nerves. Study of the human sciatic nerve. *Rev Esp Anestesiol Reanim*. 2002 Oct;49(8):397-402.)

Epineurium also projects longitudinal "ondulations" along its trajectory, providing elasticity especially in nerves supplying innervation to the extremities.

Clinical Pearls

- Epineurium is the outermost sheath of peripheral nerves.
- Epineurium is permeable and consists of moderately dense connective tissue that binds nerve fascicles.
- The epineurium contains adipocytes, fibroblasts, connective tissue fibers, mast cells, small lymphatics, as well as blood vessels and small nerve fibers innervating the vessels.

PARANEURAL SHEATHS AND COMMON EPINEURAL SHEATH

Whereas gross anatomy descriptions of distal peripheral nerves accurately identify each connective layer enclosing axons (endoneurium), nerve fascicles or bundles of axons (perineurium), and single peripheral nerves (epineurium), this becomes more complex where the connective tissue binds more than one nerve. An example of this is the sciatic nerve at the popliteal fossa. Various terms, such as paraneurium, paraneural sheaths,[23,24] common epineural sheath,[25] conjuctiva nervorum,[26] or adventitia,[27] are interchangeably used to refer to the same connective tissue.

Small nerves formed by a single group of fascicles feature a layer of perineurium enclosing each fascicle along with scarce amounts of adipose tissue. A connective tissue known as epineurium composed of collagenous fibers encloses the nerve.[3] Specific

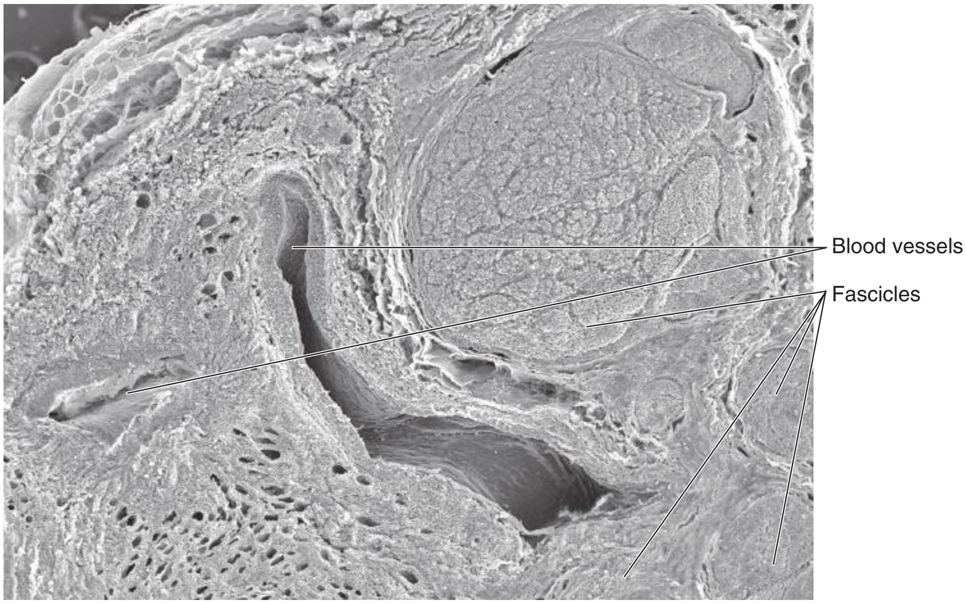

FIGURE 5–22. Interfascicular tissue and vessels in sciatic nerve. Scanning electron microscopy. Magnification ×50. techniques enable identification of perineurium using staining methods positive for EMA (epithelial membrane antigen) and of collagen with Masson trichrome and EMA-negative stain.[3]

Similarly, staining techniques aid in the identification of structures in more complex nerves, such as the sciatic nerve, where groups of variable numbers of fascicles are present. In these types of nerves, EMA staining reveals that perineurium encloses each nerve fascicle, as opposed to connective tissue made up by collagen fibers typically present in epineurium that encloses groups of fascicles (detected with Masson trichromic stain).[3] Microscopic analysis of complex nerve structures such as the sciatic nerve at increasingly proximal locations shows that nerve branches within these nerve structures appear divided by their respective epineurial layers even before physical branch division materializes.

Each peripheral nerve at both plexus and terminal sites is encircled by concentric clusters of fat tissue, which appear just

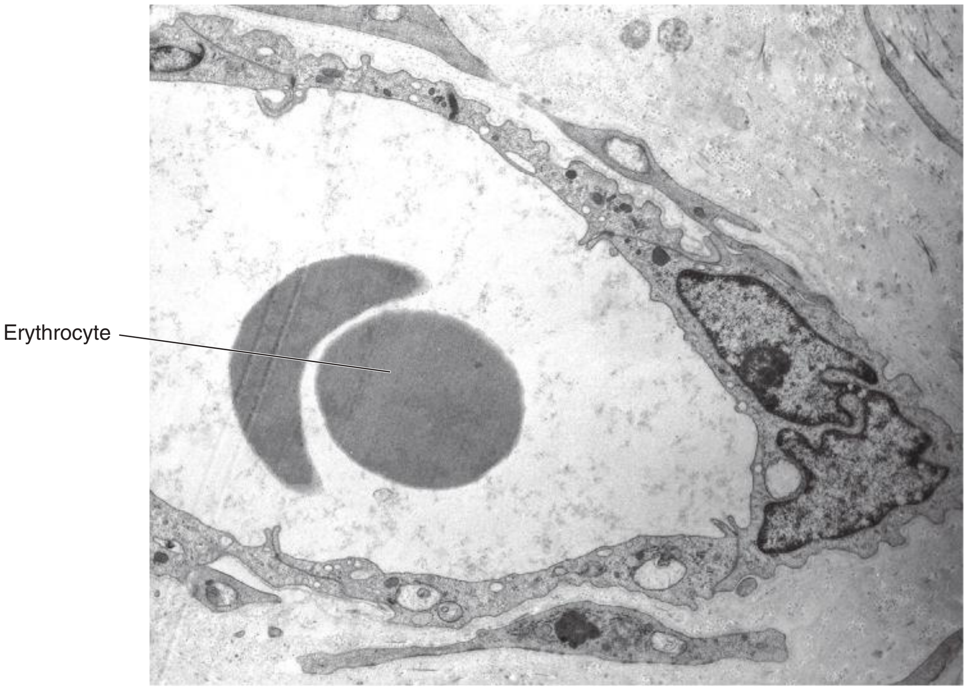

FIGURE 5–23. Blood vessel inside interfascicular tissue of sciatic nerve. Transmission electron microscopy. Magnification ×7000. (Used with permission from Miguel Angel Reina, MD.)

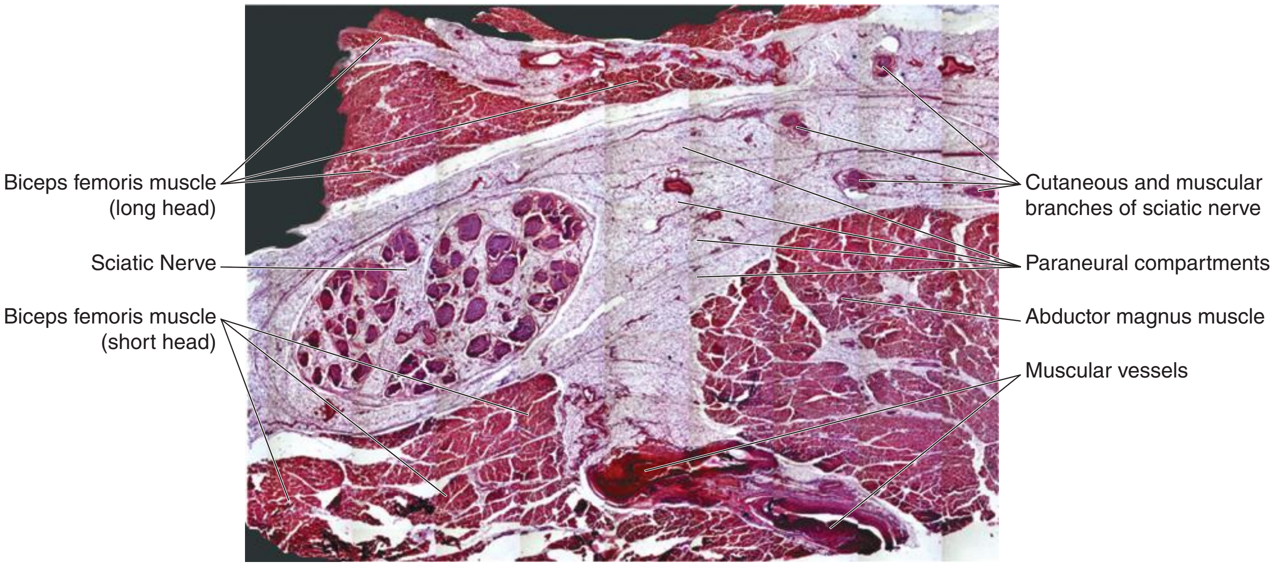

FIGURE 5–24. Sciatic nerve and its surrounding paraneurium at the level of the popliteal fossa. Hematoxylin-eosin. (Reproduced with permission from Reina MA: *Atlas of Functional Anatomy for Regional Anesthesia and Pain Medicine*. New York: Springer; 2015.)

prior to the division of the nerve (Figure 5–24 and 5–25). The adipose tissue extends alongside its collateral or terminal branches. The amount and shape of fat tissue vary along the nerve, progressively losing their concentric contour and becoming unevenly distributed. The collagen layer, similar to the epineurium, that wrapps together the nerve components and the adipose tissue in between has been refered to as paraneurium, paraneural sheath, common epineural sheath, conjuctiva nervorum or adventitia by different authors.

In clinical practice, ultrasound-guided injection of local anesthetics enables the indirect identification of paraneurium as the space between this layer and the nerve expands displaying a concentric shape. Neural layers surrounding fascicles, groups of fascicles, nerves, as well as more complex nerve structures have similar morphology, and they are mainly composed of collagen fibers. Therefore, it may seem reasonable to unify terminology noting that present denominations based on the anatomic location of each neural fascia seems rather confusing.[28,29] However, epineurium and paraneurium may best to avitted terms to avoid the present confusion. Both epineurium and paraneurium have similar functions, which include insulation and protection of nerves from injury. Paraneural compartments

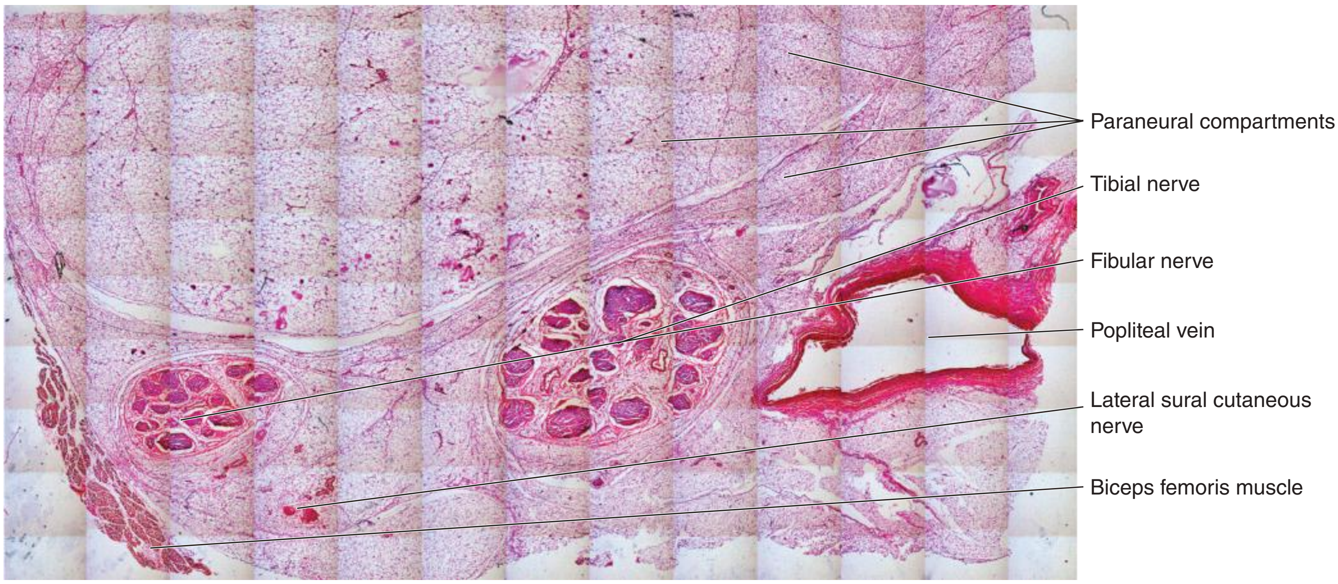

FIGURE 5–25. Tibial nerve, fibular nerve and its paraneurium at popliteal fossa. Hematoxylin-eosin. (Reproduced with permission from Reina MA: *Atlas of Functional Anatomy for Regional Anesthesia and Pain Medicine*. New York: Springer; 2015.)

facilitate longitudinal displacement of nerves controlling body movement. This movement is necessary to neutralize lateral compression by changing their shape.[30] If the tissue is exposed to external irritation, it reacts, leading to interfascicular fibrosis.[30]

In relation to the anatomic features of the sciatic nerves, Andersen et al[24] found the sheath surrounding the sciatic nerve to be a thin transparent structure that was clearly distinctive, both macroscopically and microscopically different from the epineurium. The sheath facilitated the spread of the injectate along the nerve. However, its projections did not completely encircle the nerve. The internal layers of the paraneurium around the sciatic nerve[31] had a similar structure of that sheath. Vloka et al[25] used the term *common epineural sheath*. Tran et al[32] compared the effectiveness of the sciatic nerve block in relation to what they called "subepineural" injection at the "bifurcation," which fills a common paraneural compartment shared by tibial and peroneal nerves close to their macroscopic division.

Orebaugh et al[33] reported that needle-tip placement in the interscalene region and injection of anesthetic solution took place frequently inside the epineurium. This occurred in approximately 50% of the nerve blocks without evidence of fascicular or axonal damage and no trace of dye within fascicles to suggest that the needle had traversed them.[33]

Spinner et al[34] demonstrated that intraepineurial injection of dye results in its dissection along paths of least resistance, suggesting the presence of anatomic constraints among epineurial compartments. When Spinner injected the inner epineurium, the dye expanded within the same compartment but did not cross over or extend to the common external epineurial space. Therefore, the concept of "intraneural injection" should be revised for each nerve examined, avoiding extrapolations based on studies of a single nerve[35,36,37] due to the considerable anatomic variability among peripheral nerves.

Clinical Pearl

- A peripheral nerve at both plexus and terminal sites is encircled by concentric clusters of adipose tissue. This explains why perineural injections result in low opening injection pressure.

PERIPHERAL NERVE BLOCKS

Diffusion of anesthetic into the axons is influenced by the presence and characteristics of the connective tissue sheaths (eg, perineurium, myelin) and the size and location of the axons inside fascicles. During intravenous peripheral anesthesia (Bier block), the local anesthetic most likely reaches the peripheral nerve endings through the intraneural capillary network.

Perineurium and endoneural capillary endothelium protect the axons from foreign substances thanks to their tight junctions between endothelial cells and among perineural cells.

Local anesthetic injected outside the epineurium of a nerve must traverse both the epineurium and perineurium to reach the axons. Subsequently, only a small proportion of the injected anesthetic comes in direct contact with axons leading to delayed onset, incomplete or failed neural blockade. For instance, Popitz and collaborators[38] injected 1% lidocaine into the sciatic nerve of rats and found that when the block was complete, the intraneural amount of local anesthetic was around 1.6% of the injected dose.

SUMMARY

The composition and arrangement of the connective tissue of peripheral nerves play a major role in protection of the peripheral nerves and in the practice of regional anesthesia. Characteristics and variability of the connective tissue may substantially influence the spread of the local anesthetic during nerve block injection and therefore the dynamics and quality of the neural blockade.

CHAPTER 6

Ultrastructural Anatomy of the Spinal Meninges and Related Structures

Miguel A. Reina, Carlo D. Franco, Alberto Prats-Galino, Fabiola Machés, Andrés López, and Jose A de Andrés

INTRODUCTION

Recent research on the ultrastructure of the human spinal dural sac and its contents has enhanced our understanding of the microstructure of the dura mater, arachnoid layer, trabecular arachnoid, pia mater, and nerve root cuffs. This chapter reviews new and traditional concepts regarding these structures and discusses their possible clinical implications. The distribution of epidural fat and its possible role in disposition and kinetics of neuraxial injections are also discussed.

DURAL SAC

The dural sac surrounds the spinal cord inside the vertebral column. It separates the epidural space from the subarachnoid space, ending at the second sacral vertebra. In an idealized shape, the dural sac is cylindrical with its thickness varying from about 1 mm in the cervical region and becoming gradually thinner as it descends (Figures 6–1 and 6–2). In the lumbar region, the thickness of the dural sac reaches 0.3 mm,[1] although measurements taken from anteroposterior or lateral may vary somewhat even at the same vertebral level. The dura mater is the most external layer of the dural sac and is responsible for 90% of its total thickness. This fibrous structure, although permeable, somewhat provides mechanical protection to the spinal cord and its neural elements. The internal 10% of the dural sac is formed by the arachnoid layer, which is a cellular lamina that adds little extra mechanical resistance.[2]

DURA MATER

Dura mater comprises approximately 80 concentric laminas[3–5] (Figure 6–3). Each dural lamina has a thickness of approximately 5 μm and consists of thinner laminas containing mostly collagen fibers (Figures 6–4 and 6–5). The collagen fibers are oriented in different directions but always within the concentric plane of the dural lamina; hence, they do not cross between the laminas. Each collagen fiber has a smooth surface and measures approximately 0.1 μm (Figure 6–6). The elastic fibers are fewer, measuring 2 μm in diameter, and have a rougher surface than that of the collagen fibers[6] (Figure 6–7).

Contrary to the classic description of fibers inside dural laminas being arranged longitudinally and parallel to the long axis of the vertebral column, the fibers are actually distributed multidirectionally at random inside each of the concentric dural laminas (Figures 6–8 to 6–10). Mastocytes and macrophages are also present within the dura mater (Figures 6–11 and 6–12).

ARACHNOID LAYER

Conventionally, the arachnoid layer is described as a fine membrane in close contact with but not adhering to the internal surface of the dura mater. Recent research, however, determined that there is no space between the dura mater and the arachnoid layer (see subdural space). The arachnoid layer is semipermeable and serves as a barrier to limit the passage of substances through the dural sac (Figures 6–13 and 6–14). Its thickness is about 50-60 μm[7] (Figures 6–15 and 6–16). In its interior, arachnoid cells strongly bond by specific membrane junctions with a thickness of about 10–15 μm. Collagen fibers at the center of the arachnoid layer give strength to the lamina and improve its mechanical resistance. Flat, elongated neurothelial cells occupy the outer portion of the layer. Tearing off the arachnoid layer exposes the subdural space. Neurothelial cells can be found attached either to the internal surface of the dura or to the external surface of the arachnoid layer[8,9] (Figure 6–17).

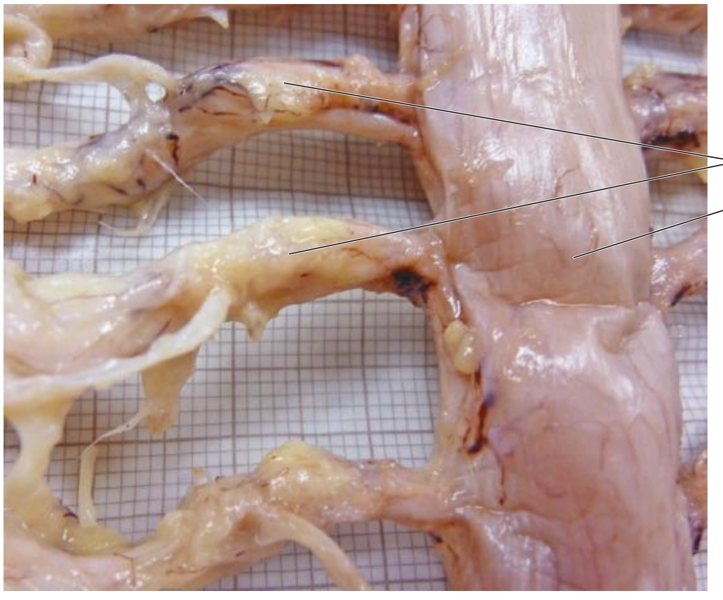

FIGURE 6–1. Human dural sac. (Reproduced with permission from Reina MA, López García A, de Andrés JA, et al: Thickness variation of the dural sac. *Rev Esp Anestesiol Reanim*. 1999 Oct;46(8):344-349.)

NEURAXIAL BLOCKADE AND DURAL LESIONS

Piercing the dural sac during a subarachnoid block causes mechanical disruption of both the dura mater and the arachnoid layer. The cross-sectional area of the puncture site produced by a 25-gauge needle is similar regardless of whether the needle has a pencil point or a cutting end. However, the morphology of the lesion varies depending on the design of the needle tip. Pencil-point needles produce a greater and rougher-appearing injury to the dural fibers, while cutting needles produce a U-shaped lesion or flap resembling the open lid of a tin can[10–12] (Figures 6–18 to 6–31).

When using cutting (long bevel) needles, bevel orientation (eg, parallel or perpendicular to the main axis of the cord) does not significantly affect the size or morphology of the lesions in the dura and arachnoid lamina[10–12] (see Figure 6–24). The lesion that the needle produces in the dural sac has two components, dural and arachnoid. It is believed that the arachnoid component is vital in limiting cerebrospinal

FIGURE 6–2. Human dural sac and end spinal cord. (Reproduced with permission from Reina MA, Pulido P, López A. El saco dural humano: *Rev Arg Anestesiol*. 2007; 65:167-184.)

fluid leakage from the subarachnoid space to the epidural space. Therefore, the size and morphology of arachnoid lesions seem to be more important for laminar sealing and cerebrospinal leakage than the size and morphology of dural lacerations.

The incidence of postdural puncture headache (PDPH) has been thought that is affected by the type of needle used (pencil point versus cutting) and of the bevel.

The traditional belief that cutting needles result in larger dural lesions (tears) was established in the 1940s and may have been the consequence of the imperfections in the needle design of that era. Modern needles, however, produce clean, U-shaped lesion or flap resembling the open lid of a tin can (see Figure 6–24). After needle withdrawal, the U-shaped flap tends to return to its original position due to cerebrospinal fluid pressure and the elastic properties of the dura mater. The dural orifice is almost completely occluded after approximately 15 minutes. On the other hand, lesions produced by pencil-point needles involve a more complex lesion with fiber tearing, sectioning, and separation. The extent of the dural lesion caused by a needle depends on several factors, including the external diameter of the needle, dural and arachnoid sealing mechanisms, needle-tip design, and the quality of needle manufacturing. Needles having the same tip design but different manufacturing methods may not have the same surface quality and may contain microfractures or imperfections, resulting in more or less extensive dural fiber tearing and residual lesions.[13–15]

Deformation of the spinal needle caused by contacts with vertebral bones or other resistant structures during the neuraxial procedure can also increase the size of the dural lesion. Iatrogenic introduction of skin fragments into the subarachnoid space can also occur.[16–18]

POSTDURAL PUNCTURE HEADACHE AND TYPE OF NEEDLES

The etiology of PDPH is multifactorial. While the specific chapter on PDPH focuses on pathophysiology, prevention, and treatment, this section focuses on anatomical and equipment-related factors that may influence the occurrence and severity of PDPH. Initially, it was thought that pencil-point needles resulted in less-traumatic perforations of the dural sac. As the morphology of dural lesions became better known, other explanations have been proposed. Microscopic studies of lesions produced by spinal needles showed that the pencil-point needles produce a "burst"-type lesion with extensive fiber damage. However, the increased fiber tearing produced by pencil-point needles may promote greater inflammatory response at the edges of the lesion that paradoxically results in earlier occlusion and lower incidence of PDPH. Cutting needles, on the other hand, produce a "cleaner" tear of the dura with less inflammatory response that results in delayed puncture sealing, which could increase the incidence of spinal headache.

A needle tip blunted after colliding against bone can cause more damage to the fibers. Tip deformation depends on the collision angle and force applied. Cutting needles are especially susceptible to deformation of the needle tip after colliding against bone, contrary to pencil-point needles. However, because PDPH studies generally involve many anesthetists and different techniques, the definitive impact of the needle deformation on PDPH is difficult to study and at this time remains only hypothetical.

As mentioned, the dural lesion produced by the spinal needle has two components, a dura mater lesion and an arachnoid-layer lesion.[19] While the external or dural component of the sac provides mechanical resistance, it is not elastic enough to prevent cerebrospinal fluid leakage. In contrast, the internal or arachnoid lesion can retract to close the defect created by introduction of the needle into the subarachnoidal space and prevent the leakage of cerebrospinal fluid. Because the arachnoid component is probably more important in pathophysiology of PDPH than the dural itself, these lesions should be referred to as "dura-arachnoid" lesions.

TRABECULAR ARACHNOID

Arachnoid mater consists of two layers, the *trabecular* arachnoid and *arachnoid* layers. The trabecular arachnoid merges with the cellular plane of the pia mater and emits projections to all the structures that cross the subarachnoid space, including blood vessels and nerve roots. The projections that cover the nerve roots are called arachnoid sheaths[20,21] (Figures 6–32 to 6–40).

During movement, these sheaths stabilize and prevent excessive movements of the nerve roots within the dural sac. However, the sheaths confer little mechanical protection against trauma. Characteristics of the arachnoid sheaths in the cauda equina are variable; some are lax, while others are formed by superimposed planes of the same components with a more compact appearance. The thickness of an arachnoid sheath ranges from 10 to 60 μm. In some cases, one or more nerve roots are enveloped by a single arachnoid sheath, and in others, the nerve root has no sheath at all.[20,21]

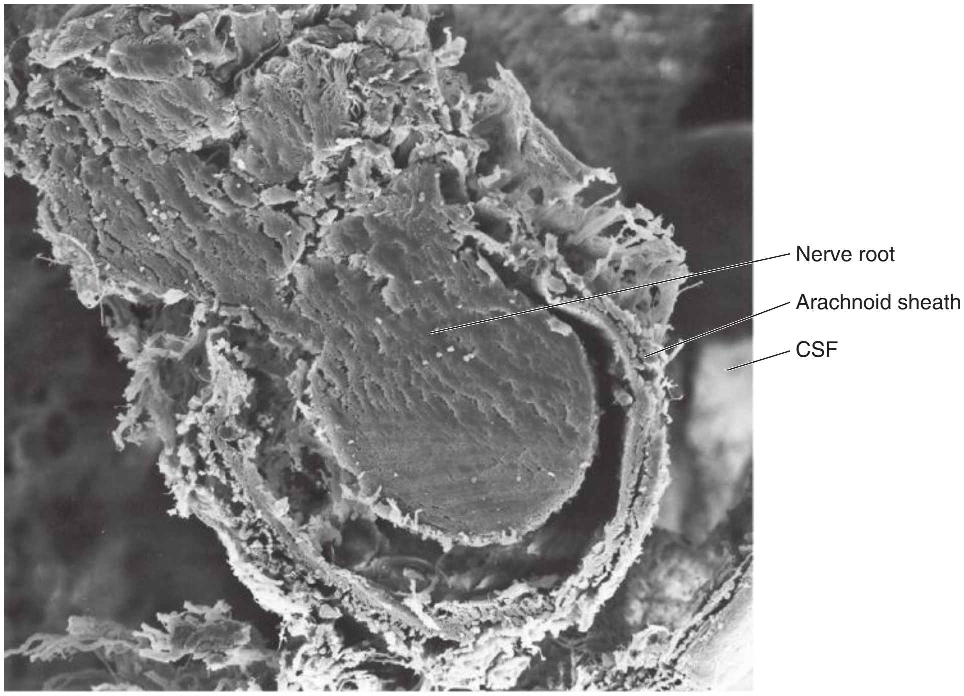

FIGURE 6–32. Trabecular arachnoid layer. The projections of trabecular arachnoid that cover nerve roots are called arachnoid sheaths. CSF = cerebrospinal fluid. Scanning electron microscopy. Magnification ×100. (Reproduced with permission from Reina MA, López A, De Andrés JA: Hypothesis concerning the anatomical basis of cauda equina syndrome and transient nerve root irritation after spinal anesthesia. *Rev Esp Anestesiol Reanim*. 1999 Mar;46(3):99-105.)

ARACHNOID SHEATHS OF NERVE ROOTS AND THEIR POTENTIAL ROLE IN NERVE LESIONS

Some cases of cauda equina syndrome and transient neurological syndrome could be explained by the existence of arachnoid sheaths surrounding nerve roots within the dural sac and the fact that needles or (micro)catheters can be inserted into them. An anesthetic solution accidentally injected into the arachnoid sheath of a spinal nerve may not be diluted by surrounding cerebrospinal fluid, thus exposing the nerve root to a higher anesthetic concentration than expected. Consequently, the concentration of the local anesthetic could be magnitudes higher (eg, 20–25 times) in comparison to the concentration of the anesthetic in the rest of the dural sac.[20,21] Such high local anesthetic concentration inside the arachnoid sheath could have deleterious effects on nerve roots, as opposed to a typical injection of the same anesthetic solution inside the dural sac

but outside the arachnoid sheath. Because it takes time to establish equilibrium inside and outside the sheath, a nerve lesion could develop without direct needle trauma.

Injections of local anesthetic through a microcatheter into these arachnoid sheaths could be more devastating than a single injection. This is because the injection of a single large volume would eventually be diluted by leakage outside the sheath, whereas repeated doses of small volumes may be more likely to lead to neurotoxicity due to the continuous or repeated exposure to a high concentration of local anesthetics. Transient root irritation syndrome and cauda equina syndrome may reflect different degrees of nerve damage related to local anesthetic concentration and duration of exposure. Injection of local anesthetic inside arachnoid sheaths in areas close to the spinal cord or to the conus medullaris could affect several nerve roots, while injection in more distal areas may affect single nerve roots.[20,21]

PIA MATER

The structure of the pia mater includes a cellular layer and a subpial compartment (Figures 6–41 and 6–42). The cellular layer consists of flat, overlapping pial cells with a smooth and bright appearance (Figure 6–43). Its thickness is 3 to 5 pial cells (10–15 μm) at the medullary level (Figures 6–44 to 6–46) and 2 to 3 cells (3–4 μm) at the nerve root level. Amorphous fundamental substance is found around the pial cells, and the cells measure on average 0.5–1 μm.[22-25]

The subpial compartment has large amounts of collagen fibers, amorphous fundamental substance, fibroblasts, and a small number of macrophages and blood vessels. The subpial compartment is enclosed between the pial cellular layer and a basal membrane in contact with neuroglial cells.

The subpial compartment from the low thoracic vertebrae has a thickness of 130–200 μm; here, variations in measurements are more significant than in the pial cellular layer (see Figures 6–41 and 6–42). At the level of the medullary cone, the thickness of the pia mater is reduced to 80–100 μm; its thickness continues to decrease to merely 50–60 μm in the origins

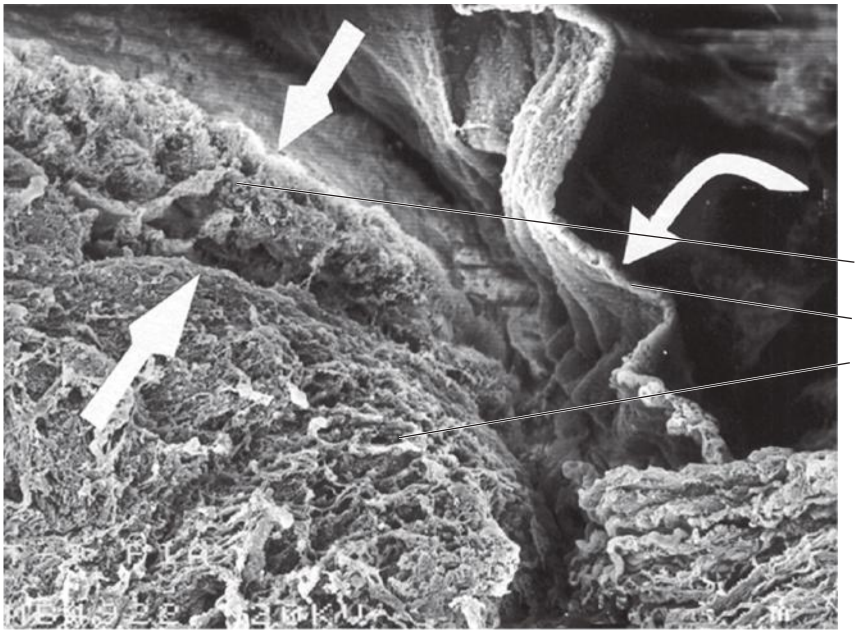

FIGURE 6–41. Human pia mater and spinal cord. Scanning electron microscopy. Magnification ×70. (Reproduced with permission from Reina MA, De Leon Casasola O, et al: Ultrastructural findings in human spinal pia mater in relation to subarachnoid anesthesia. *Anesth Analg*. 2004 May;98(5):1479-1485.)

of the cauda equina. At the nerve root level, the thickness of the subpial compartment is 10–12 μm.

At the level of the medullary cone, there are perforations or circular, ovoid, or elliptical fenestrations over the entire surface of the cellular layer of the pia mater (Figures 6–47 to 6–49). While the size of these fenestrations varies, most measure 12–15 μm in length and 4–8 μm in width. At the nerve root level, the pia mater shows similar fenestrations but smaller size (1–4 μm)[7,22,23] (Figure 6–50).

Numerous macrophages surround the pial cells. The macrophages differ from pial cells in that they lack long cytoplasmic processes, containing membrane-bound inclusions and a varying number of vacuoles, especially in the peripheral areas of their cytoplasm. The macrophages and other inflammatory

cells seen within the pia mater could originate from subpial and subarachnoid blood vessels or from immature pial cells as a result of an unknown stimulus. The fenestrations found in the pia mater appear to be associated with the migration of some immature pial cells as part of an inflammatory response.[23]

DURAL SAC LIGAMENTS

The epidural space contains fibrous formations that cross and anchor the dural sac to the vertebral canal. These connective tissue formations are referred to as the anterior, lateral, and posterior meningo-vertebral ligaments (Figures 6–51 and 6–52). The anterior meningo-vertebral ligament, which connects the dural sac with the posterior longitudinal ligament of the spine, is more compact. In some patients, fibrous flaps that fix the dural sac to the posterior longitudinal ligament may incompletely divide the anterior epidural space. Anterior ligaments extend from C7 to L5 with a craniocaudal orientation and acquire a transverse orientation at thoracic level T8–9. The length of these ligaments varies from about 0.5 to 29 mm. In

the sacral canal, the ligaments thicken to form a perforated medial septum, the "anterior sacral ligament of Trolard." The lateral meningo-vertebral ligament and the posterior ("Giordalengo") meningo-vertebral ligament are thinner and do not affect the circulation of fluids injected in the epidural space.

The "plica mediana dorsalis" is a longitudinal and discontinuous fibrous structure that can be found in the midsagittal region along the posterior epidural space, particularly in the lumbar region.[24,25]

EPIDURAL FAT

Epidural fat extends laterally toward the site where articular facets and ligamentum flavum meet. Located between the vertebral arches and the intervertebral foramina, fat wraps around nerve roots within the dural sleeves but without adhering to them. This allows displacement of the dura within the vertebral canal during flexion/extension.

Epidural fat does adhere in the midline posteriorly by a vascular pedicle at a point where the right and left portions of the ligamentum flavum meet.[26] The amount of posterior epidural fat increases caudally, from L1–2 to L4–5, and can reach 16–25 mm. Its width also increases in the craniocaudal direction from 6 mm at the L1–2 interspace to 13 mm in the L4–5 interspace. The pedicle of the posterior epidural fat corresponds topographically with the plica mediana dorsalis.

Epidural fat deposits are in contact with the posterior surface of the dural sac and the vertebral lamina but adhere only to the vascular pedicle.[26] Regarding the posterior, epidural fat is

homogeneous and is not separated by fibrous septae; laterally, epidural fat appears divided. Sometimes, a septal plane extends between the nerve root exit at the vertebral lamina and the posterior longitudinal ligament. Looking at the anterior, dura mater joins the vertebral canal at the height of the disks. It is in this anterior epidural region where the anterior venous vessels are found.

CHARACTERISTICS OF THE EPIDURAL FAT IN THE CERVICAL, THORACIC, LUMBAR, AND SACRAL REGIONS

The distribution of epidural fat is variable along the spinal canal, but it tends to be more consistent at different vertebral levels. For example, at the *cervical* level, adipose tissue is absent or almost nonexistent and sometimes forms a small posterior deposit seen with magnetic resonance imaging axial sections (C7 to T1), with increased signal intensity on T1-weighted sequences. Epidural fat is not generally found in the anterior and lateral regions.

At the *thoracic* level, epidural fat forms a broad posterior band with "indentations."[26] This band is thicker around the intervertebral space and around the intervertebral disk, becoming thinner at the level of the vertebral bodies and close to the base of the spinal processes of each vertebra. In the middle-upper thoracic region (T1–7), epidural fat follows a continuous pattern with more evident indentations, while in the lower thoracic region (T8–12) epidural fat becomes discontinuous.

At the lumbar level, epidural fat in the anterior and posterior epidural spaces remains separate. The posterior epidural fat is more prominent around the disks of L3–4 and L4–5. In some patients, the posterior epidural fat is cone shaped, with the apex located at the posterior. The thickness of the epidural fat in the lower lumbar zone occupies about 32% of the cross-sectional diameter of the vertebral canal.

Below L4–5, the dural sac ends and the sacral canal begins. Here, nerve roots are enveloped by dural sleeves, and epidural fat is the main component within the sleeves.[26]

The morphology and distribution of epidural fat can be altered in pathological conditions. Epidural lipomatosis, for example, is characterized by an increase in epidural fat volume.[27] Excessive fat deposits around the dural sac can cause spinal cord or nerve root compression, leading to neurological symptoms. In kyphoscoliosis, epidural fat is distributed asymmetrically and adipose tissue predominates in the concave portion of the curvature, while the spinal cord is displaced against the vertebral arch.[27] In patients with spinal canal stenosis, epidural fat is characteristically absent or markedly reduced around the stenotic zone.[27]

FIGURE 6–52. Epidural surface of the dural sac. Scanning electron microscopy. Magnification ×12. (Reproduced with permission from Reina MA, Dittmann M, López A, et al: New perspectives in the microscopic structure of human dura mater in the dorso lumbar region. *Reg Anesth*. 1997 Mar-Apr;22(2):161-166.)

EPIDURAL FAT AND PHARMACOKINETICS OF EPDIURAL INJECTATES

The distribution of epidural fat in the lumbar vertebral canal is uneven, being more abundant in the dorsal region than in the ventral and lateral regions. The total amount, distribution, and morphology of fat in the epidural space and nerve root cuffs affect the diffusion of substances across these compartments.

Changes in the amount of epidural fat during pathological processes may alter absorption of drugs during epidural blockade. However, even in the absence of pathological processes, local variations in the amount of fat within the lumbar spinal canal could alter drug kinetics. It is possible that variations in the distance between fat and neighboring nerve tissues affect the disposition of drugs injected and kinetics of the lipophilic drugs. At present, however, the impact of the ultrastructure of epidural and nerve root cuffs on drug kinetics during epidural injection remains unclear.

SUBDURAL SPACE

In contrast to the classical description of a "subdural space" between the dura mater and the arachnoid dorsalis, studies have shown the presence of a solid but delicate tissue composed of specialized neurothelial cells[8,9] (Figure 6–53). Neurothelial cells

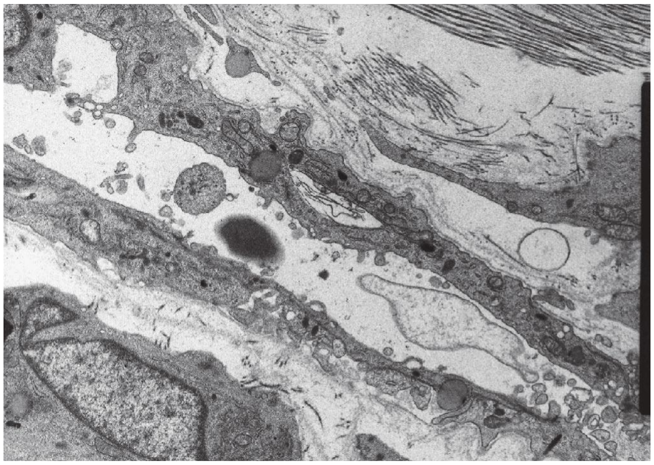

FIGURE 6–53. Neurothelial cells in the subdural compartment. Transmission electron microscopy. Magnification ×5000. (Reproduced with permission from Reina MA, De León Casasola OA, et al: The origin of the spinal subdural space. Ultrastructure finding. *Anesth Analg*. 2002 Apr;94(4):991-995.)

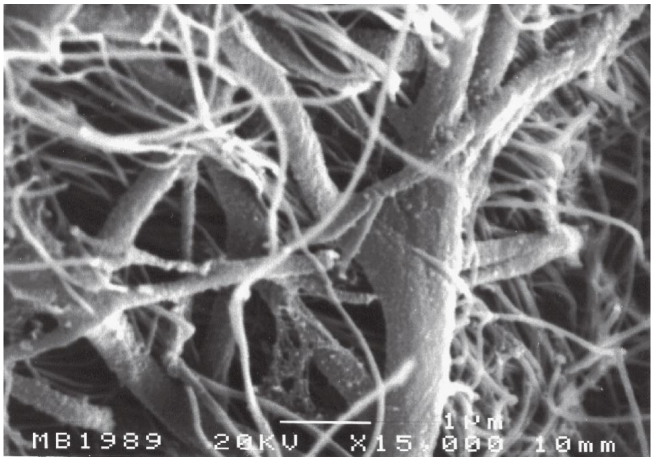

FIGURE 6–55. Neurothelial cells in the subdural compartment. Scanning electron microscopy. Magnification ×15,000. (Reproduced with permission from Reina MA, López A, De Andrés JA, Villanueva MC, Cortés L: Does the subdural space exist? *Rev Esp Anestesiol Reanim*. 1998 Nov;45(9):367-376.)

are also referred to as dural border cells. These elongated, fusiform cells with branched extensions are fragile and scantly cohesive to each other (Figures 6–54 and 6–55). Intercellular junctions between neurothelial cells are most susceptible to tearing, and cellular fragments may be seen next to torn neurothelial cells (Figures 6–56 and 6–57). When tearing occurs along the subdural compartment, small fissures merge into larger ones. Weak cohesive forces between neurothelial cells and lack of collagen fibers facilitate the widening of a fissure, producing the impression of a subdural space. Thus, the classic subdural space appears to be an iatrogenic artifact.[2]

Studying the structure of the subdural compartment may shed light on the origin of cranial and spinal subdural hematomas associated with cerebrospinal fluid hypotension.[28,29]

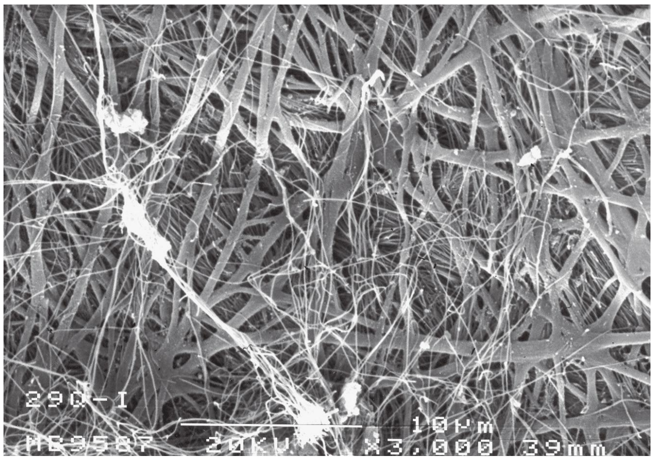

FIGURE 6–54. Neurothelial cells in the subdural compartment. Scanning electron microscopy. Magnification ×3000. (Reproduced with permission from Reina MA, De León Casasola OA, et al: The origin of the spinal subdural space. Ultrastructure finding. *Anesth Analg*. 2002 Apr;94(4):991-995.)

Subdural anesthetic blockade, caused by inadvertent injection of local anesthetic partially or entirely between the dura and arachnoid, results in highly unpredictable spinal or epidural anesthesia and complications due to an unanticipated high-level blockade. Dissection of the weak intercellular junctions between neurothelial cells may allow injected fluids to accumulate in the subdural space. Extent of the subdural block is unpredictable as it depends on the volume of local anesthetic injected and the nature of the dissection (cephalic or circumferential). If the dissection is mainly cephalad, only a few milliliters of anesthetic solution can block cardiorespiratory symptoms.

NERVE ROOT CUFFS

Bilateral projections of the dural sac (matter) onto the nerve roots form the nerve root cuffs or dural sleeves (Figure 6–58). Lateral extensions of the dura mater and the arachnoid layer surround the nerve roots as they exit the vertebral canal. The dural sac may contain a certain amount of cerebrospinal fluid around the nerve root. Nerve root cuffs (sleeves) have internal cellular and external fibrillar components[30] (Figure 6–59). Leptomeningeal cells, similar in nature to arachnoid or pial cells, form the cellular component of root cuffs. These cells are elongated, wider around the nucleus, stratified and oriented longitudinal to the nerve root axis (Figure 6–60).

At the *preganglion level*, the cellular component of a root cuff is 5.8–13 μm thick. These cells have cytoplasmic prolongations that encroach on neighboring cells, leaving little extracellular space. Unions between cell membranes are of the type desmosome and have tight junctions (Figure 6–61). Cells contain mitochondria in their cytoplasm and rough endoplasmic reticulum. Each cell is about 0.15–0.8 μm thick at both ends and 2.2–4.9 μm at the nucleus. The cellular component is arranged in two concentric layers held apart by collagen fibers.[31]

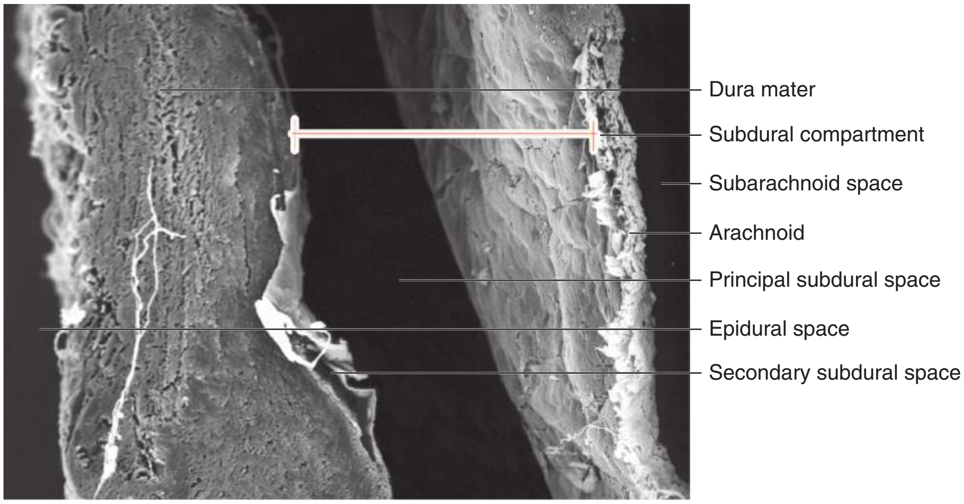

FIGURE 6–56. Human subdural space in the lumbar meninges. Scanning electron microscopy. Magnification ×180. (Reproduced with permission from Reina MA, López A, De Andrés JA, Villanueva MC, Cortés L: Does the subdural space exist? *Rev Esp Anestesiol Reanim.* 1998 Nov;45(9):367-376.)

At the *postganglion level*, the cellular component has 9–14 single-cell concentric layers and measures 18–50 μm. Their unions are of the desmosome type.[31] The morphology of the cellular component at the ganglion level shows transitional changes while retaining many of the characteristics shown at the postganglion level. The cellular component consists of 25–30 concentric single-cell laminas and has a thickness of 55–60 μm.[31] Ultrastructural aspects of the cellular component at the pre-, post-, and ganglion levels are similar. The cells have rough endoplasmic reticulum widely distributed, and some also contain large vacuoles (0.1 μm) that occupy almost half of the cytoplasmic space. A membranous-like structure found in their cytoplasm may be involved in the production of vesicles (0.05–0.07 μm) needed for pinocytosis. Collagen fibers together with myelinated and unmyelinated axons are seen in the inner side of the cellular plane and are part of the endoneurial fibrillar structure. Specialized membrane unions among cells at the pre-, post-, and ganglion levels ensure a barrier effect, limiting the passage of substances from the epidural space to the nerve axons.

The fibrillar component[32] resides in the outer portion of the root cuff and has a thickness of 100–150 μm (Figure 6–62). It consists mostly of collagen fibers arranged in concentric laminas with scarce elastic fibers.[32] Large numbers of adipocytes separate dural laminas in groups of three to five concentric layers (Figure 6–63). Scanning electron microscopy shows adipocytes (Figure 6–63) extending from the dural sac to the dorsal root ganglia. Adipocytes can be found protruding from inside the wall built by the fibrillar component, out of the external epidural surface of the root cuff (Figures 6–64 and 6–65).

The fibrillar portion in the dural sac contains about 80 dural laminas with collagen fibers oriented in different directions and few elastic fibers. Its thickness varies between 270 and 350 μm at the lumbar level. Adipocytes are not found within the

thickness of the dural sac. Variations in dural thickness along the dural sac and differences related to the external fibrillar component do not alter the barrier effect, which is the exclusive responsibility of the cellular component.[33–37]

Scanning electron microscopy has shown that adipocytes measure 50–70 μm and are similar to those found in peripheral nerve samples of the sciatic nerve.[33] The fact that adipocytes appear smaller and lack a spherical shape is most likely due to loss of fat from their vacuoles during sample preparation. Fat in root cuffs covers groups of root axons, although adipocytes are not seen enclosing axons individually. This fat either partially or totally occupies the thickness of the root cuffs' fibrillar component.

ADIPOSE TISSUE IN ROOT CUFFS AND DRUG KINETICS

Adipose tissue can be found in the epidural space and inside the nerve root cuffs. Fat in nerve cuffs is in direct contact with nerve root axons and may play a role in the kinetics of

lipophilic substances injected near the nerve roots. The small space within the root cuffs and the large amount of drugs available in case of an injection into the cuff may expose the neural elements to a high concentration of local anesthetic as well as a retrograde spread toward the subarachnoidal space.[38]

SUMMARY

This chapter outlined the anatomical characteristics of the neuraxial meninges and related structures and discussed their potential clinical implications.

Clinical Pearls

- The shape of the dural sac is cylindrical, and its thickness is variable.
- The dura mater is permeable and occupies 90% of the thickness of the dural sac.
- The arachnoid layer is semipermeable and governs the passage of substances.
- Dura-arachnoid lesions can differ depending on the type of spinal needle.
- Pencil-point needles produce a more destructive lesion, while cutting needles produce a U-shaped lesion, although the sizes of both are similar.
- The trabecular arachnoid covers the nerve roots and forms arachnoid sheaths.
- Pia mater has fenestrations at the level of the medullary cone.
- Epidural fat distribution is variable along the spinal canal but is consistent at different vertebral levels.
- Epidural fat volume is increased in epidural lipomatosis, distributed asymmetrically in kyphoscoliosis, and absent in stenosis.
- The "subdural space" is in fact occupied by delicate tissue composed of specialized neurothelial cells. The tearing of the subdural compartment gives origin to what we know as the subdural space.
- In root cuffs, there is a cellular component that governs the diffusion of substances. Root cuffs also contain large numbers of adipocytes in their thickness.

CHAPTER 7

Clinical Pharmacology of Local Anesthetics

John Butterworth IV

INTRODUCTION

Local and regional anesthesia and analgesia appear to be undergoing a renaissance, as judged by attendance at specialty meetings and substantial increase in research activity, as evidenced by growing number of scientific publications. In contrast to general anesthesia, in which the molecular mechanism remains the subject of speculation, the site at which local anesthetic (LA) drugs bind to produce nerve blocks has been cloned and mutated. This chapter focuses on mechanisms of anesthesia and toxicity, especially as knowledge of these mechanisms will assist the clinician in conducting safer and more effective regional anesthesia.

PREHISTORY AND HISTORY

The Incas regarded coca as a gift from the son of the sun God and limited its use to the "upper crust" of society.[1] They recognized and used the medicinal properties of cocaine long before the compound was brought to Europe for its properties to be "discovered." The Incas sometimes treated persistent headaches with trepanation, and coca was occasionally used to facilitate this procedure. Local anesthesia was accomplished by having the operator chew coca leaves and apply the macerated pulp to the skin and wound edges while using a tumi knife to bore through the bone.

By the sixteenth century, having disrupted Incan society, the conquistadors began paying laborers with cocaine paste. The laborers generally rolled the cocaine leaves into balls (called cocadas), bound together by guano or cornstarch.[1,2] These cocadas released the free-base cocaine as a consequence of the alkalinity of the guano and of the practice of chewing the cocadas with ash or lime (such alkaline compounds increase pH, favoring the free-base cocaine form over the positively charged hydrochloride salt). This practice probably marks the birth of "free-basing" cocaine and is the historic antecedent of the "rock" or "crack" cocaine so often abused in Western societies.

Cocaine was brought back to Vienna by an explorer/physician named Scherzer.[1] In Vienna, the chemist Albert Niemann isolated and crystallized pure cocaine hydrochloride in 1860. The Merck Company distributed batches of this agent to physicians for investigational purposes. Sigmund Freud was the most prominent of these cocaine experimenters. Freud reviewed his experimental work in a monograph devoted to cocaine, *Über Coca*. Freud and Carl Koller (an ophthalmology trainee) took cocaine orally and noticed that the drug rendered their tongues insensible.

Koller and Joseph Gartner began a series of experiments using cocaine to produce topical anesthesia of the conjunctiva. The birth of local and regional anesthesia dates from 1884, when Koller and Gartner reported their success at producing topical cocaine anesthesia of the eye in the frog, rabbit, dog, and human.[2–4]

The use of local anesthesia quickly spread around the world. The American surgeon William Halsted at Roosevelt Hospital in New York reported using cocaine to produce mandibular nerve block in 1884 and to produce brachial plexus block less than a year later.[5] These blocks were accomplished by surgically exposing the nerves, then injecting them under direct vision. Leonard Corning injected cocaine near the spine of dogs, producing what was likely the first epidural in 1885. Spinal

FIGURE 7–1. Examples of products that incorporated cocaine during the time before it became a controlled substance. Wines fortified with cocaine were particularly popular as "tonics." (Used with permission from Addiction Research Unit, University of Buffalo.)

Drug Brand name	Chemical structure	Class
Cocaine		Ester
Procaine Novocaine		Ester
Benzocaine		Ester
Tetracaine Pentocaine		Ester
2-Cloroprocaine Nescaine		Ester
Lidocaine Xylocaine		Amide
Prilocaine Citanest		Amide
Etidocaine Duranest		Amide
Mepivacaine Carbocaine		Amide
Ropivacaine Naropin		Amide
Bupivacaine Marcaine/Sensorcaine/ Levobupivacaine/ Chirocaine		Amide

FIGURE 7–2. Structures of commonly used local anesthetics.

anesthesia with cocaine was first accomplished in 1898 by August Bier. Cocaine spinal anesthesia was used to treat cancer pain in 1898. Caudal epidural anesthesia was introduced in 1902 by Sicard and Cathelin.[5] Bier described intravenous regional anesthesia in 1909. In 1911, Hirschel reported the first three percutaneous brachial plexus anesthesias. Fidel Pages reported using epidural anesthesia for abdominal surgery in 1921.

Cocaine was soon incorporated into many other products, including the original formulation of Coca-Cola devised by Pemberton in 1886. Wine tonics and other "patent" medicines of the day commonly contained cocaine (Figure 7–1). This practice ended when cocaine became regulated by the forerunner of the Food and Drug Administration (FDA) in the early 1900s.

MEDICINAL CHEMISTRY

Cocaine and all other LAs contain an aromatic ring and an amine at opposite ends of the molecule, separated by a hydrocarbon chain, and either an ester or an amide bond (Figure 7–2).[3,4,6,7] Cocaine, the archetypical ester, is the only naturally occurring LA. Procaine, the first synthetic ester LA, was introduced in 1904 by Einhorn.[2] The introduction of the amide LA lidocaine in 1948 was transformative. Lidocaine quickly became used for all forms of regional anesthesia. Other amide LAs based on the lidocaine structure (prilocaine, etidocaine) subsequently appeared. A related series of amide LAs based on 2′,6′-pipecoloxylidide was introduced (mepivacaine, bupivacaine, ropivacaine, and levobupivacaine). Ropivacaine and levobupivacaine are the only commercially available single-enantiomer (single-optical-isomer) LAs. Both are S(–)-enantiomers, avoiding the increased cardiac toxicity associated with racemic mixtures and the R(+)-isomers (this is discussed in a subsequent section). All other LAs either exist as racemates or have no asymmetric carbons.

Clinical Pearl

- All LAs contain an aromatic ring and an amine at opposite ends of the molecule, separated by a hydrocarbon chain, and either an ester or an amide bond.

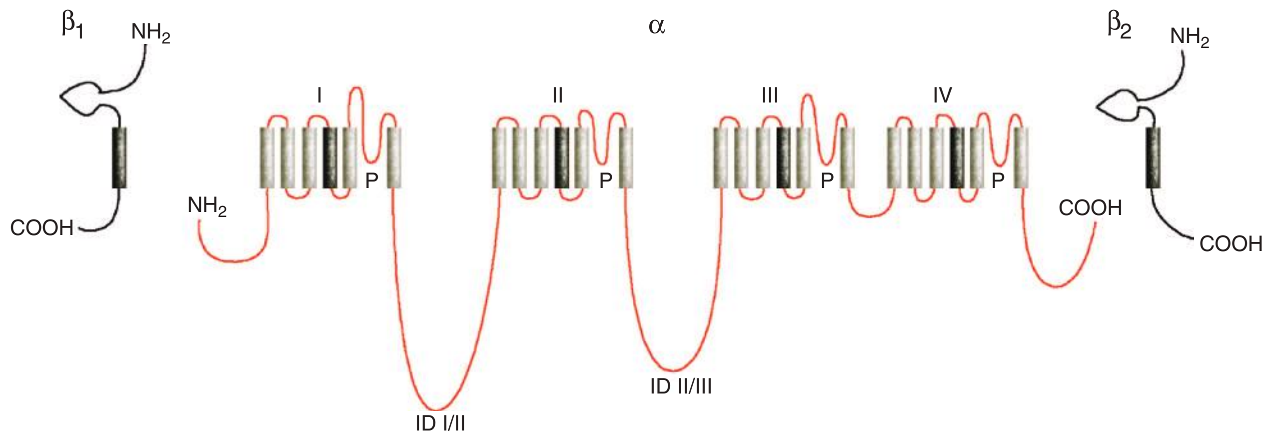

FIGURE 7–3. "Cartoon" structure of Na channel subunits. Note that the α-subunit has four domains that each contain six membrane-spanning segments. BIOPHYSICS OF VOLTAGE-GATED SODIUM CHANNELS AND LOCAL ANESTHETICS

Studies of the mechanisms of LA action on peripheral nerves are studies of interactions between LAs and voltage-gated Na channels because Na channels contain the LA-binding site. Na channels are integral membrane proteins that initiate and propagate action potentials in axons, dendrites, and muscle tissue; initiate and maintain membrane potential oscillations in specialized heart and brain cells; and shape and filter synaptic inputs.[8,9] Na channels share structural features with other similar voltage-gated ion channels that exist as tetramers, each with six transmembrane helical segments (eg, voltage-gated Ca and K channels). Na channels contain one larger α-subunit and one or two smaller β-subunits, depending on the species and the tissue of origin. The α-subunit, the site of ion conduction and LA binding, has four homologous domains, each with six α-helical membrane-spanning segments (Figure 7–3).[8,9] The external surface of the α-subunit is heavily glycosylated, which serves to orient the channel properly within the plasma membrane (Figure 7–4).

Invertebrates have only one or two Na channel α-subunit genes, and the normal physiologic role of these channels is unclear (animals survive when the channels are not present).

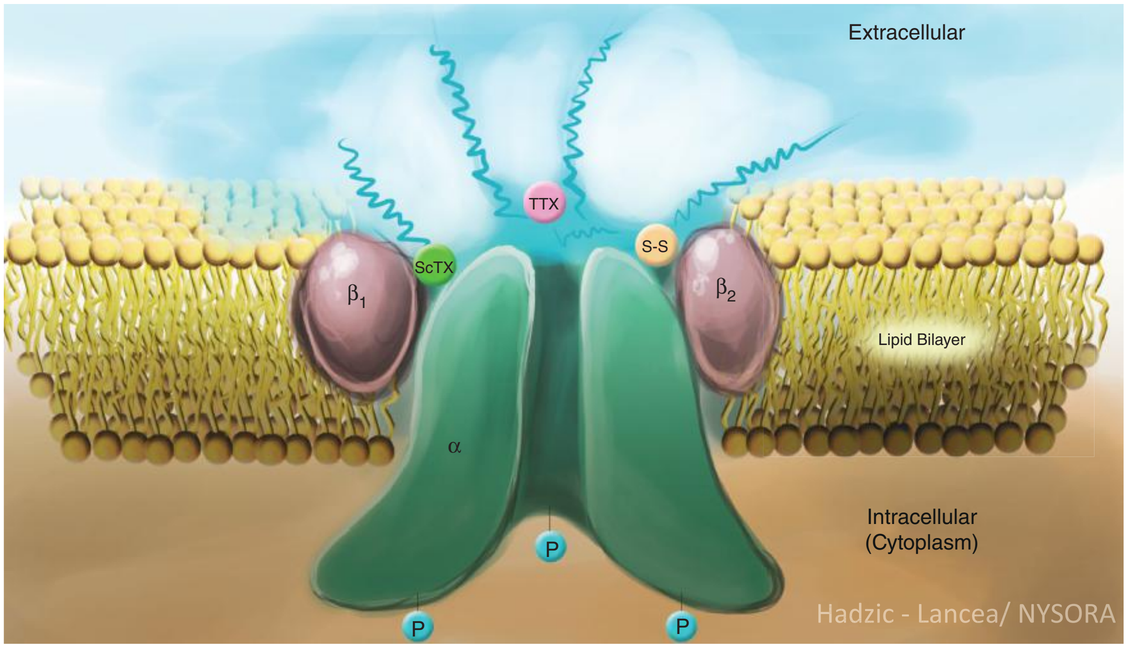

FIGURE 7–4. Cartoon of a Na channel in the plasma membrane. Note that all three subunits are heavily glycosylated on the extracellular side (see "squiggly" lines). In contrast to local anesthetics, note that both scorpion toxins (ScTX) and tetrodotoxin (TTX) have binding sites on the external surface of the channel. Note also that the cytoplasmic side of the channel is phosphorylated. (Reproduced with permission from Catterall WA: Cellular and molecular biology of voltage-gated sodium channels. *Physiol Rev*. 1992 Oct;72(4 Suppl):S15-S48.)

TABLE 7–1. Voltage-gated Na channel—neural isoforms.

	Na_v 1.1	Na_v 1.2	Na_v 1.3	Na_v 1.6	Na_v 1.7	Na_v 1.8	Na_v 1.9

CNS = central nervous system; DRG = dorsal root gamglion; TTX = tetrodotoxin.

Source: Adapted with permission from Novakovic SD, Eglen RM, Hunter JC: Regulation of Na^+ channel distribution in the nervous system. *Trends Neurosci*. 2001 Aug;24(8):473-478.

Humans, in contrast, have nine active Na channel α-subunit genes on four chromosomes, with cell-specific expression and localization of gene products.[10] The Na_v 1.4 gene (by convention, geneticists refer to voltage-gated Na channel isoforms as Na_v 1.x) supplies channels to skeletal muscle, and the Na_v 1.5 gene supplies channels to cardiac muscle, leaving seven Na_v isoforms in neural tissue (Table 7–1). Defined genes contribute specific Na channel forms to each of the unmyelinated axons, nodes of Ranvier in motor axons, and small dorsal root ganglion nociceptors.[10] Whereas all Na channel α-subunits will bind LAs similarly, their affinity for binding neurotoxins varies.

Na channel α- and β-subunit mutations lead to muscle, cardiac, and neural diseases.[11] For example, inherited mutations in Na_v 1.5 have been associated with congenital long QT syndrome, Bruguda syndrome, and other conduction system diseases.[11] It has been shown that certain Na_v isoforms proliferate in animal models of chronic pain. The existence of specific Na_v gene α-subunit products offers the enticing possibility that inhibitors may someday be developed for each specific Na_v α-subunit form. Such developments, already underway for some Na_v isoforms, could revolutionize the treatment of chronic pain.

Blocking of impulses in a nerve fiber requires that a defined length of nerve become inexcitable (to prevent the impulse from "jumping over" the blocked segment). Thus, as the LA concentration increases, it must be applied along a shorter length of nerve to prevent impulse conduction, as is shown in Figure 7–5. Both normal conduction and the way in which LAs inhibit conduction differ between myelinated and unmyelinated nerve fibers. Conduction in myelinated fibers proceeds in jumps from one Ranvier node to the next, a process termed *saltatory conduction*. To block impulses in myelinated nerve fibers, it is generally necessary for LAs to inhibit channels in three successive Ranvier nodes (Figure 7–6). Unmyelinated fibers, lacking the saltatory mechanism, conduct much more slowly than myelinated fibers. Unmyelinated fibers are relatively resistant to LAs, despite their smaller diameter, due to dispersal of Na channels throughout their plasma membranes. These differences among nerve fibers arise during development when Na channels begin to cluster at Ranvier nodes in myelinated axons. Nodal clustering of channels, essential for high-speed signal transmission, is initiated by Schwann cells in the peripheral nervous system and by oligodendrocytes in the central nervous system (CNS).[12]

Na channels may exist in at least three native conformations: "resting," "open," and "inactivated," first described by Hodgkin and Huxley.[13] During an action potential, neuronal Na channels open briefly, allowing extracellular Na ions to flow into the cell, depolarizing the plasma membrane. After only a few milliseconds, Na channels inactivate (whereupon the Na current ceases). Na channels return to the resting conformation with membrane repolarization. The process by which channels go from conducting to nonconducting forms is termed *gating*. Gating is assumed to result from movements of dipoles in response to changes in potential. The process by which voltage-gated channels operate likely involves movements of paddle-shaped voltage sensors within the channel's outer perimeter (Figure 7–7).[14,15] The speed of gating processes differs among

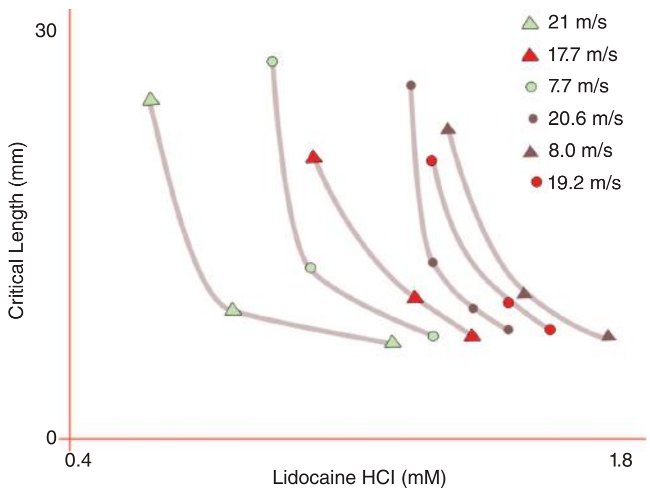

FIGURE 7–5. Note that the concentration of local anesthetic required to produce nerve block declines as the length of nerve exposed to the local anesthetic increases. (Reproduced with permission from Raymond SA, Steffensen SC, Gugino LD, et al: The role of length of nerve exposed to local anesthetics in impulse blocking action. *Anesth Analg*. 1989 May;68(5):563-570.)

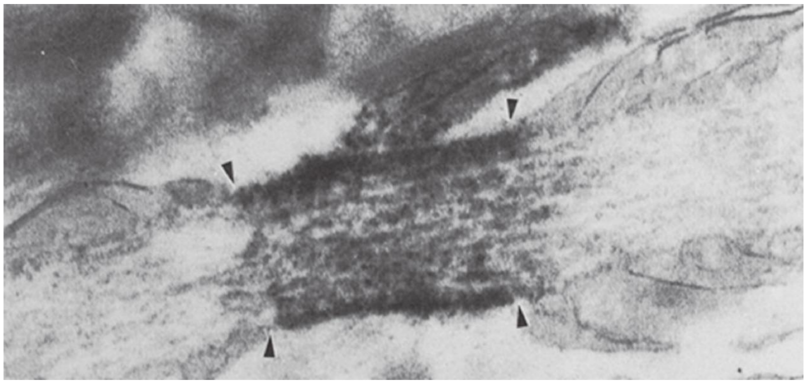

FIGURE 7–6. Electron micrograph of a node of Ranvier. Na channels have been immunolabeled and appear as dense granules within the four arrows. The paranodal region is indicated by "pn," and an astrocyte is indicated by "as." (Reproduced with permission from from Black JA, Friedman B, Waxman SG, et al: Immunoultrastructural localization of sodium channels at nodes of Ranvier and perinodal astro-cytes in rat optic nerve. *Proc R Soc Lond B Biol Sci*. 1989 Oct 23;238(1290):39-51.)

Na_v α-subunit forms: Skeletal muscle and nerve forms gate quicker than cardiac forms.

Anesthesia results when LAs bind Na channels and inhibit the Na permeability that underlies action potentials.[6,8,9,13] Our understanding of LA mechanisms has been refined by several key observations. Taylor confirmed that LAs selectively inhibit Na channels in nerves.[16] Strichartz first observed use-dependent block with LAs, showing the importance of channel opening for LA binding.[17] *Use* (or *frequency*) *dependence* describes how LA inhibition of Na currents increases with repetitive depolarizations ("use").[13,17] Repetitive trains of depolarizations increase the likelihood that an LA will encounter an Na channel that is open or inactivated, with both forms having greater LA affinity than do resting channels (Figure 7–8).[6,13,17] Thus, membrane potential influences both Na channel conformation and Na channel affinity for LAs. Use-dependent block appears important for the functioning of LAs as antiarrhythmics and may also underlie the effectiveness of reduced LA concentrations in managing pain.[6,8] Finally, using site-directed mutagenesis, Ragsdale and Wang[18,19] localized LA binding to specific amino acids in D4S6 of Na_v 1.2 and Na_v 1.4.

Some LA optical isomers confer greater apparent safety than their opposite enantiomer. For example, under voltage clamp, the R(+)-bupivacaine isomer more potently inhibits cardiac Na currents than the S(–)-bupivacaine (levobupivacaine) isomer (Figure 7–9).

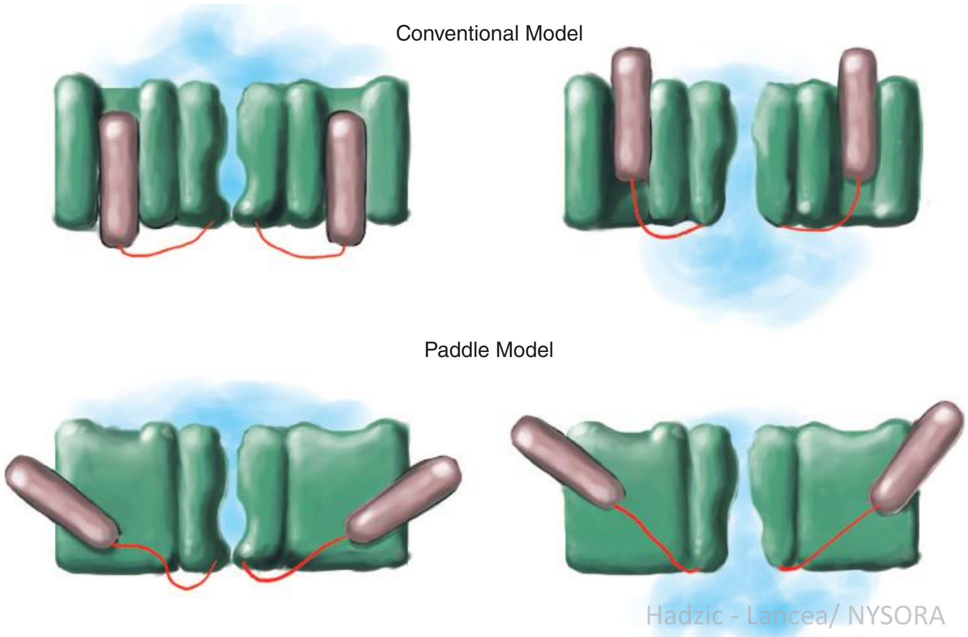

FIGURE 7–7. In the conventional model for voltage gating, the voltage-sensing part of the channel slides "in and out" of the membrane. More recent x-ray diffraction studies of the K channel suggest that a more appropriate mechanism is that of paddle-like structures sliding diagonally through the plasma membrane. (Reproduced with permission from Arhem P: Voltage sensing in ion channels: a 50-year-old mystery resolved? *Lancet*. 2004 Apr 10;363(9416):1221-1223.)

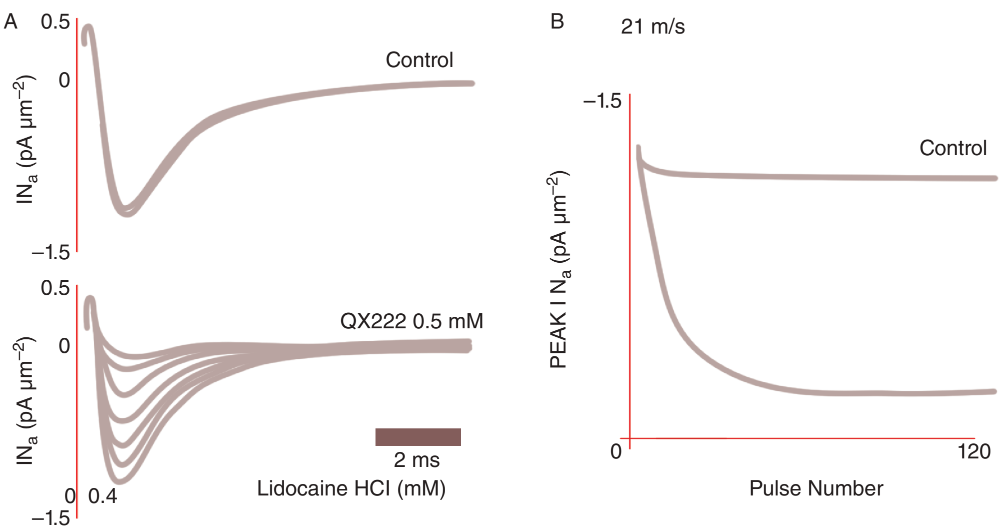

FIGURE 7-8. Use-dependent block of Na currents in Purkinje fibers. Under control conditions, each of a train of impulses results in identical current tracings. In the presence of the local anesthetic QX222, the first impulse is nearly the same size amplitude as under control conditions. Each succeeding impulse is smaller (reduced peak I_{Na}), reflecting an accumulating block of Na channels, until a nadir is reached. (Reproduced with permission from Hanck DA, Makielski JC, Sheets MF: Kinetic effects of quaternary lidocaine block of cardiac sodium channels: a gating current study. *J Gen Physiol*. 1994 Jan;103(1):19-43.)

Many other types of chemicals will also bind and inhibit Na channels, including general anesthetics, substance P inhibitors, α_2-adrenergic agonists, tricyclic antidepressants, and nerve toxins.[6,20–22] Nerve toxins are currently undergoing animal and human testing as possible replacements for LAs.

LOCAL ANESTHETIC PHARMACODYNAMICS

In clinical practice, LAs are typically described by their potency, duration of action, speed of onset, and tendency for differential sensory nerve block. These properties do not sort independently.

Potency and Duration

Nerve-blocking potency of LAs increases with increasing molecular weight and increasing lipid solubility.[23,24] Larger, more lipophilic LAs permeate nerve membranes more readily and bind Na channels with greater affinity. For example, etidocaine and bupivacaine have greater lipid solubility and potency than lidocaine and mepivacaine, to which they are closely related chemically.

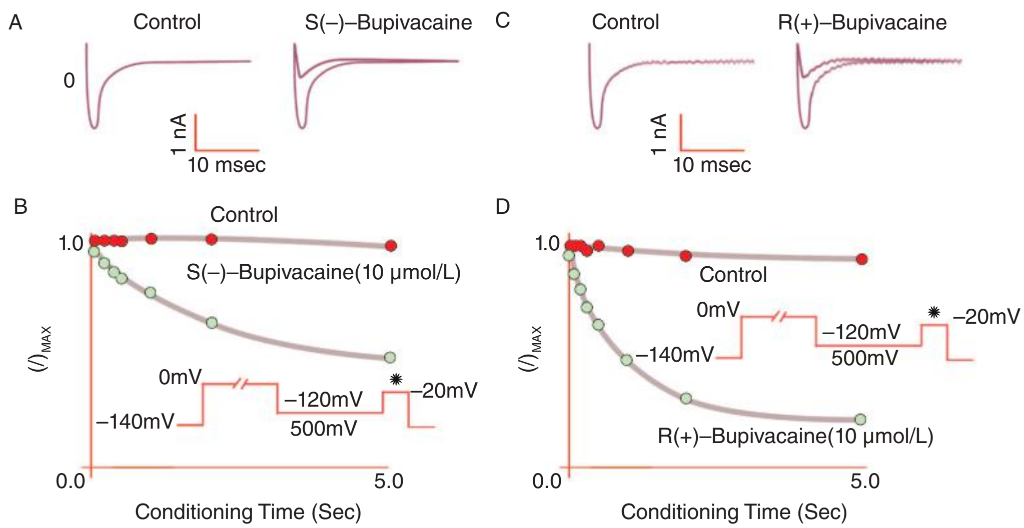

FIGURE 7–9. Reduced potency of *S*(−) bupivacaine relative to *R*(+)-bupivacaine at inhibiting cardiac Na currents under voltage clamp. After a standard "conditioning" depolarization of varying lengths, the *S*(−) isomer produces less reduction of I/I_{max} than the *R*(+) isomer. (Reproduced with permission from Valenzuela C, Snyders DJ, Bennett PB, et al: Stereoselective block of cardiac sodium channels by bupivacaine in guinea pig ventricular myocytes. *Circulation*. 1995 Nov 15;92(10):3014-3024.)

Clinical Pearl

- Nerve-blocking potency of LAs increases with increasing molecular weight and increasing lipid solubility.

More lipid-soluble LAs are relatively water insoluble, highly protein bound in blood, less readily removed by the bloodstream from nerve membranes, and more slowly "washed out" from isolated nerves in vitro. Thus, increased lipid solubility is associated with increased protein binding in blood, increased potency, and longer duration of action. Extent and duration of anesthesia can be correlated with LA content of nerves in animal experiments.[25,26] In animals, blocks of greater depth and longer duration arise from smaller volumes of more concentrated LA, compared with larger volumes of less-concentrated LA.[27]

Speed of Onset

Many textbooks and review articles assert that the onset of anesthesia in isolated nerves slows with increasing LA lipid solubility and increasing pK_a (Table 7–2). At any pH, the percentage of LA molecules present in the uncharged form, largely responsible for membrane permeability, decreases with increasing pK_a.[23,24] However, of the two LAs with the fastest onset, etidocaine is highly lipid soluble and chloroprocaine has a pK_a greater than that of other LAs. Finally, the LA rate of onset is associated with the aqueous diffusion rate, which declines with increasing molecular weight.[28]

Differential Sensory Nerve Block

Regional anesthesia and pain management would be transformed by a LA that would selectively inhibit pain transmission while leaving other functions intact. However, sensory anesthesia sufficient for skin incision usually cannot be obtained without motor impairment.[3,4,6] As was first demonstrated by Gasser and Erlanger in 1929, all LAs will block smaller (diameter) fibers at lower concentrations than are required to block larger fibers of the same type.[29,30] As a group, unmyelinated fibers are resistant to LAs compared with larger myelinated A-δ fibers.[29,30] Bupivacaine and ropivacaine are relatively selective for sensory fibers. Bupivacaine produces more rapid onset of sensory than motor block, whereas the closely related chemical mepivacaine demonstrates no differential onset during median nerve blocks (Figure 7–10).[31] True differential anesthesia may be possible when Na_v isoform-selective antagonists become available. Certain Na_v isoforms have been found to be prevalent in dorsal root ganglia, and (as previously noted) the relative populations of various Na_v isoforms can change in response to various pain states.

TABLE 7–2. Local anesthetic characteristics that tend to sort together.

Physical and Chemical
Increasing lipid solubility
Increased protein binding
Pharmacologic and Toxicologic
Increasing potency
Increasing onset time
Increasing duration of action
Increasing tendency for severe systemic toxicity
In general, all tend to sort together

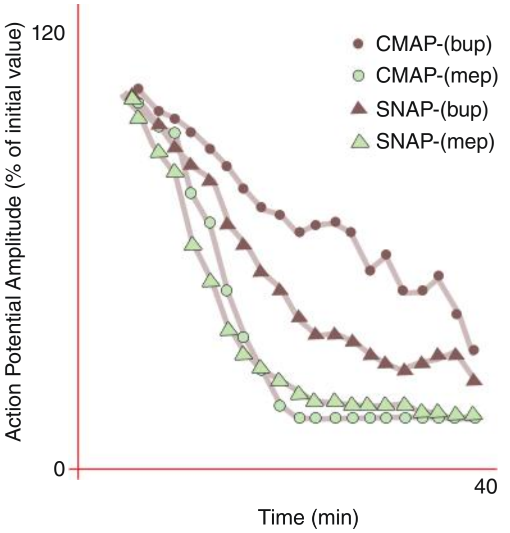

FIGURE 7–10. Differential onset of median nerve block with bupivacaine 0.3% (bup), but not with mepivacaine 1% (mep). Note that the compound motor action potential (CMAP) is inhibited less than the sensory nerve action potential (SNAP) during onset of bupivacaine block in these normal volunteer subjects. At steady state (20 min), CMAP and SNAP are comparably inhibited. On the other hand, mepivacaine produced faster inhibition of both CMAP and SNAP, and there was no differential onset of block. (Reproduced with permission from Butterworth J, Ririe DG, Thompson RB, et al: Differential onset of median nerve block: randomized, double-blind comparison of mepivacaine and bupivacaine in healthy volunteers. *Br J Anaesth*. 1998 Oct;81(4):515-521.)

Other Factors Influencing Local Anesthetic Activity

Many factors influence the ability of a given LA to produce adequate regional anesthesia, including the dose, site of administration, additives, temperature, and pregnancy. As the LA dose increases, the likelihood of success and the duration of anesthesia increase, while the delay of onset and tendency for differential block decrease. In general, the fastest onset and shortest duration of anesthesia occur with spinal or subcutaneous injections; a slower onset and longer duration are obtained with plexus blocks.[33]

Clinical Pearl

- The effectiveness of a given LA is influenced by the dose, site of administration, additives, temperature, and changes in neural susceptibility, as seen during pregnancy.

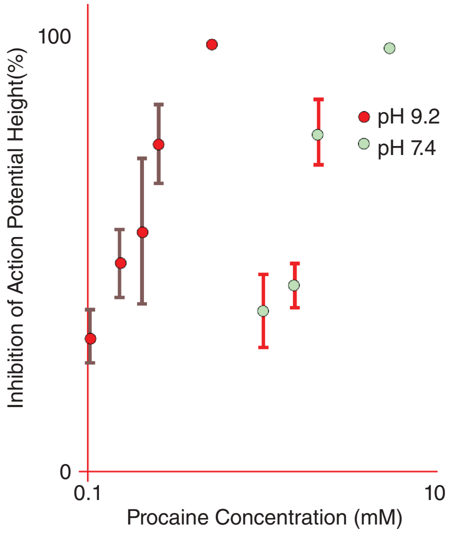

FIGURE 7–11. The potency of procaine at inhibiting compound action potentials in isolated frog sciatic nerves is dramatically increased at pH 9.2 as compared with pH 7.4. (Reproduced with permission from Butterworth JF, Lief PA, Strichartz GR: The pH-dependent local anesthetic activity of diethylaminoethanol, a procaine metabolite. *Anesthesiology*. 1988 Apr;68(4):501-506.)

Epinephrine is frequently added to LA solutions to cause vasoconstriction and to serve as a marker for intravascular injection.[4,7] Epinephrine and other α_1-agonists increase LA duration largely by prolonging and increasing intraneural concentrations of LAs. Blood flow is decreased only briefly, and the block will persist long after the α_1-adrenergic effect on blood flow has dissipated. Other popular LA additions include clonidine, $NaHCO_3$, opioids, dexamethasone, and hyaluronidase.

Uncharged local anesthetics have greater apparent potency at basic pH, where an increased fraction of LA molecules is uncharged, than at more acidic pH (Figure 7–11).[35] Uncharged LA bases diffuse across nerve sheaths and membranes more readily than charged LAs, hastening onset of anesthesia. Some clinical studies showed that the addition of sodium bicarbonate had an inconsistent action during clinical nerve block; however, not all studies demonstrated a faster onset of anesthesia. One might anticipate that bicarbonate would have its greatest effect when added to LA solutions to which epinephrine was added by the manufacturer. Such solutions are more acidic than "plain" (epinephrine-free) LA solutions to increase shelf life. Bicarbonate shortens the duration of lidocaine in animals.[27] Curiously, once LAs gain access to the cytoplasmic side of the Na channel, H^+ ions potentiate use-dependent block.[6,13] Marked prolongation of local anesthesia can be achieved by incorporating LAs into liposomes, as has been done with bupivacaine in the some formulation.

Clinical Pearl

- Pregnancy increases neural susceptibility to LAs.

Pregnant women and pregnant animals demonstrate increased neural susceptibility to LAs.[36–38] In addition, spread of neuraxial anesthesia likely increases during pregnancy due to decreases in thoracolumbar cerebrospinal fluid volume.

BLOOD CONCENTRATIONS AND PHARMACOKINETICS

Peak LA concentrations vary by the site of injection (Figure 7–12). With the same LA dose, intercostal blocks consistently produce greater peak LA concentrations than epidural or plexus blocks.[4,7,33,39] As has been recently discussed by others, it makes little sense to speak of "maximal" doses of LAs except in reference to a specific nerve block procedure, since peak blood levels vary widely by block site.[40]

In blood, all LAs are partially protein bound, primarily to α_1-acid glycoprotein and secondarily to albumin.[3,4,7] Affinity for α_1-acid glycoprotein correlates with LA hydrophobicity and decreases with protonation (acidity).[41] Extent of protein binding is influenced by the concentration of α_1-acid glycoprotein. Both protein binding and protein concentration decline during pregnancy.[42] During longer-term infusion of LA and LA-opioid combinations, concentrations of LA-binding proteins progressively increase.[43] There is considerable first-pass uptake of LAs by the lungs,[44] and animal studies suggest that patients with right-to-left cardiac shunting may be expected to demonstrate LA toxicity after smaller intravenous bolus doses.[45]

Clinical Pearls

- Recommendations on maximal doses of LAs commonly found in pharmacology texts are not terribly useful in the practice of clinical regional anesthesia.
- The serum concentrations of LAs depend on the injection technique, place of injection, and addition of additives to the LA.
- Any recommendation on the maximal safe LA dose can be valid only in reference to a specific nerve block procedure.

Esters undergo rapid hydrolysis in blood, catalyzed by nonspecific esterases.[3,4,7] Procaine and benzocaine are metabolized to para-aminobenzoic acid (PABA), the species underlying anaphylaxis to these agents.[4] Higher doses of benzocaine, typically for topical anesthesia for endoscopy, can lead to life threatening levels of methemoglobinemia. The amides undergo metabolism in the liver. Lidocaine undergoes oxidative N-dealkylation (by the cytochromes CYP 1A2 and CYP 3A4 to monoethyl glycine xylidide and glycine xylidide).[3,4,7] Bupivacaine, ropivacaine, mepivacaine, and etidocaine also undergo N-dealkylation and hydroxylation.[3,4,7] Prilocaine is hydrolyzed to *o*-toluidine, the agent that causes methemoglobinemia.[4,24] Prilocaine doses of as little as 400 mg in fit adults may be expected to produce methemoglobinemia concentrations great enough to cause clinical cyanosis. Amide LA clearance is highly dependent on hepatic blood flow, hepatic extraction, and enzyme function; therefore, amide LA clearance is reduced by factors that decrease hepatic blood flow, such as β-adrenergic

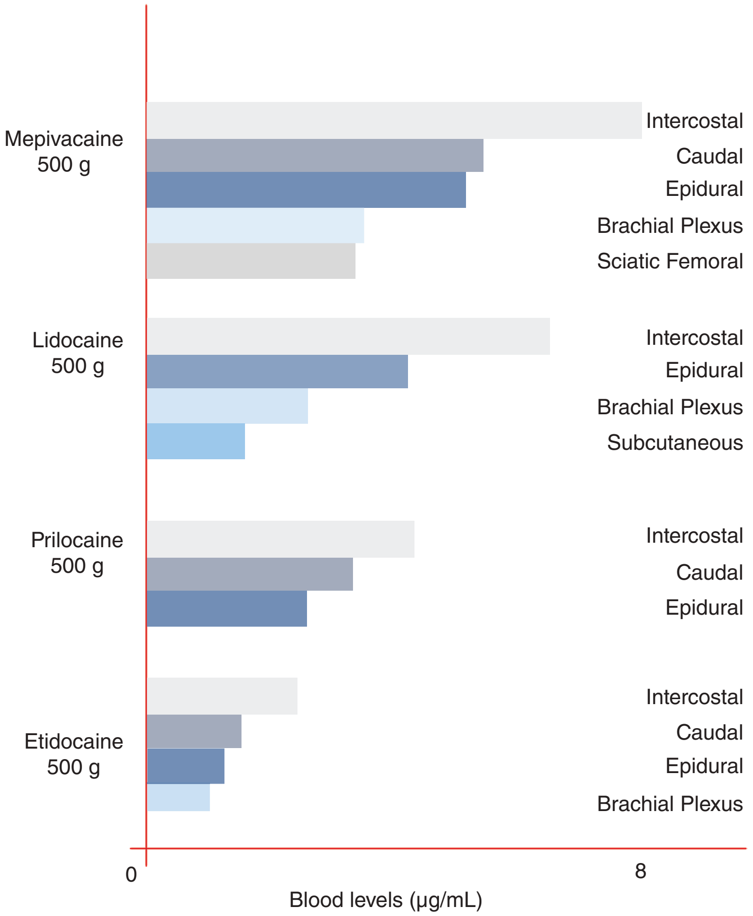

FIGURE 7–12. Peak blood concentrations of local anesthetics after various forms of regional anesthesia. Note that intercostal blocks consistently result in the greatest local anesthetic concentrations in blood, that plexus blocks result in the least local anesthetic concentrations in blood, and that epidural/caudal techniques are in between. (Reproduced with permission from Covino BG, Vassallo HG: *Local Anesthetics: Mechanisms of Action and Clinical Use*. Grune & Stratton; 1976.)

receptor or H_2-receptor blockers, and by heart or liver failure.[3,4,7]

Disposition of amide LAs is altered in pregnancy due to increased cardiac output, hepatic blood flow, and clearance, as well as the previously mentioned decline in protein binding. Renal failure tends to increase volume of distribution of amide LAs and to increase the accumulation of metabolic by-products of ester and amide LAs.

Theoretically, cholinesterase deficiency and cholinesterase inhibitors should increase the risk of systemic toxicity from ester LAs; however, there are no confirmatory clinical reports.

Some drugs inhibit various cytochromes responsible for LA metabolism; however, the importance of cytochrome inhibitors varies depending on the specific LA species. β-Blockers and H_2-receptor blockers inhibit CYP 2D6, which may contribute to reduced amide LA metabolism. Itraconazole has no effect on hepatic blood flow, but inhibits CYP 3A4 and bupivacaine elimination by 20%–25%.[46] Ropivacaine is hydroxylated by CYP 1A2 and metabolized to 2′,6′-pipecoloxylidide by CYP 3A4.[47,48] Fluvoxamine inhibition of CYP 1A2 reduces ropivacaine clearance by 70%. On the other hand, coadministration with strong inhibitors of CYP 3A4 (ketoconazole, itraconazole) has only a small effect on ropivacaine clearance.

DIRECT TOXIC SIDE EFFECTS

It is a common, but misguided, assumption that all LA actions, including toxic side effects, arise from interaction with voltage-gated Na channels. There is abundant evidence that LAs will bind many other targets aside from Na channels, including voltage-gated K and Ca channels, K_{ATP} channels, enzymes, *N*-methyl-D-aspartate receptors, β-adrenergic receptors, G-protein-mediated modulation of K and Ca channels, and nicotinic acetylcholine receptors.[6,49,50] LA binding to any one or all of these other sites could underlie LA production of spinal or epidural analgesia and could contribute to toxic side effects.[6,13,51]

Central Nervous System Side Effects

Local anesthetic CNS toxicity arises from selectively blocking the inhibition of excitatory pathways in the CNS, producing a stereotypical sequence of signs and symptoms as the LA concentration in blood gradually increases (Table 7–3).[3,4,7,33] With increased LA doses, seizures may arise in the amygdala.[3,4] With further LA dosing, CNS excitation progresses to CNS depression and eventual respiratory arrest. More potent (at nerve block) LAs produce seizures at lower blood concentrations and at lower doses than less-potent LAs. In animal studies, both

metabolic and respiratory acidosis decreased the convulsive dose of lidocaine.[52]

Cardiovascular Toxicity

In laboratory experiments, most LAs will not produce cardiovascular (CV) toxicity until the blood concentration exceeds three times that necessary to produce seizures; however, there are clinical reports of simultaneous CNS and CV toxicity with bupivacaine (Table 7–4).[3,4,7] In dogs, supraconvulsant doses of bupivacaine more commonly produce arrhythmias than supraconvulsant doses of ropivacaine and lidocaine.[53] LAs produce CV signs of CNS excitation (increased heart rate, arterial blood pressure, and cardiac output) at lower concentrations than those associated with cardiac depression. Hypocapnia reduces ropivacaine-induced changes in ST segments and left ventricular contractility.[54]

Clinical Pearl

- In laboratory experiments, most LAs will not produce CV toxicity until the blood concentration exceeds three times that necessary to produce seizures.

TABLE 7–4. Convulsive versus lethal doses of local anesthetics in dogs.

	Lidocaine	Bupivacaine	Tetracaine
Dose producing convulsions in all animals (mg/kg)	22	5	4
Dose producing lethality in all animals (mg/kg)	76	20	27

Local anesthetics bind and inhibit cardiac Na channels (Na_v 1.5 isoform).[3,13] Bupivacaine binds more avidly and longer than lidocaine to cardiac Na channels.[55] As previously noted, certain R(+) optical isomers bind cardiac Na channels more avidly than S(–) optical isomers. These laboratory observations led to the clinical development of levobupivacaine and ropivacaine. Local anesthetics inhibit conduction in the heart with the same rank order of potency as for nerve block.[56,57]

Local anesthetics produce dose-dependent myocardial depression, possibly from interference with Ca signaling mechanisms within cardiac muscle.[56,58] These anesthetics bind and inhibit cardiac voltage-gated Ca and K channels at concentrations greater than those at which binding to Na channels is maximal.[6,13,58] The LAs bind β-adrenergic receptors and inhibit epinephrine-stimulated cyclic adenosine monophosphate (AMP) formation.[59,60] In rats, the rank order for cardiac toxicity appears to be bupivacaine > levobupivacaine > ropivacaine.[61–63] In dogs, lidocaine was the least potent, and bupivacaine and levobupivacaine were more potent than ropivacaine at inhibiting left ventricular function as assessed by echocardiography (Table 7–5). In dogs, both programmed electrical stimulation and epinephrine resuscitation elicited more arrhythmias after bupivacaine and levobupivacaine than after lidocaine or ropivacaine administration.[64–66]

The mechanism by which CV toxicity is produced may depend on which LA has been administered. When LAs were given to the point of extreme hypotension, dogs receiving lidocaine could be resuscitated but required continuing infusion of epinephrine to counteract LA-induced myocardial depression. Conversely, many dogs receiving bupivacaine or levobupivacaine to the point of extreme hypotension could not be resuscitated. After bupivacaine, levobupivacaine, or ropivacaine, dogs that could be defibrillated often required no additional therapy.[64–66] Similarly, in pigs, comparing lidocaine with bupivacaine, the ratio of potency for myocardial depression was 1:4, whereas it was 1:16 for arrhythmogenesis.[67] The LAs produce dilation of vascular smooth muscle at clinical concentrations.[68] Cocaine is the only LA that consistently produces local vasoconstriction.

Allergic Reactions

Clinical Pearls

- True immunologic reactions to LAs are rare.
- True anaphylaxis appears more common with ester LAs that are metabolized directly to PABA than other LAs.
- Accidental intravenous injections of LAs are sometimes misdiagnosed as allergic reactions.
- Some patients may react to preservatives, such as methylparaben, included with LAs.

True immunologic reactions to LAs are rare.[69] Accidental intravenous injections of LAs are sometimes misdiagnosed as allergic reactions. True anaphylaxis appears more common with ester LAs that are metabolized directly to PABA than to other

LAs. Some patients may react to preservatives, such as methylparaben, included with LAs. Several studies have shown that patients referred for evaluation of apparent LA allergy, even after exhibiting signs or symptoms of anaphylaxis, almost never demonstrate true allergy to the LA that was administered.[69,70] On the other hand, LA skin testing has an excellent negative predictive value. In other words, 97% of patients who fail to respond to LA skin testing will also not have an allergic reaction to the LA in a clinical setting.

Neurotoxic Effects

During the 1980s, 2-chloroprocaine (at that time formulated with sodium metabisulfite at a relatively acidic pH) occasionally produced cauda equina syndrome following accidental large-dose intrathecal injection during attempted epidural administration. Whether the "toxin" is 2-chloroprocaine or sodium metabisulfite remains unsettled: 2-chloroprocaine is now being tested as a substitute for lidocaine in human spinal anesthesia,[74] and a series of publications suggest that it may be safe and effective. At the same time, other investigators have linked neurotoxic reactions in animals to large doses of 2-chloroprocaine rather than to metabisulfite.[75] There is also controversy about transient neurologic symptoms and persistent sacral deficits after lidocaine spinal anesthesia. The reports and the controversy have persuaded many physicians to abandon lidocaine spinal anesthesia. Unlike other spinal LA solutions, lidocaine 5% permanently interrupts conduction when applied to isolated nerves or to isolated neurons.[76] This may be the result of lidocaine-induced increases in intracellular calcium and does not appear to involve Na channel blockade.[77] While it is impossible to "prove safety," multiple studies suggest that chloroprocaine or mepivacaine can be substituted for lidocaine for brief spinal anesthesias.

Treatment of Local Anesthetic Toxicity

Treatment of adverse LA reactions depends on their severity. Minor reactions can be allowed to terminate spontaneously. Seizures induced by LAs should be managed by maintaining a patent airway and by providing oxygen. Seizures may be terminated with intravenous midazolam (0.05–0.10 mg/kg) or propofol (0.5–1.5 mg/kg) or a paralytic dose of succinylcholine (0.5–1 mg/kg), followed by ventilation with bag and mask (or tracheal intubation).[4] LA CV depression manifested by moderate hypotension, may be treated by infusion of intravenous fluids and vasopressors (phenylephrine 0.5–5 μg/kg/min, norepinephrine 0.02–0.2 μg/kg/min, or vasopressin 40 μg IV). If myocardial failure is present, epinephrine (1–5 μg/kg IV bolus) may be required. When toxicity progresses to cardiac arrest, the guidelines for treatment of LA toxicity as developed by the American Society of Regional Anesthesia and Pain Medicine (ASRA) are reasonable,.[78] and certainly preferable to the chaotic resuscitation schemes identified in a national survey prior to publication of the guideline.[79] It makes sense that amiodarone be substituted for lidocaine and, based on multiple animal experiments, that smaller, incremental doses of epinephrine be used initially rather than 1-mg boluses.[80-82] Animal experiments and clinical reports demonstrate the remarkable ability of lipid infusion to resuscitate from bupivacaine-induced cardiac arrest (Figure 7–13).[83-85] Given the nearly nontoxic status of lipid infusion, one cannot make a convincing argument to withhold this therapy from a patient requiring resuscitation from LA intoxication. With unresponsive bupivacaine cardiac toxicity cardiopulmonary bypass should be considered.[86]

It appears that the threat from severe local anesthetic systemic toxicity may be on the decline, whether from better treatment or from changes in techniques.[87] A minority would argue

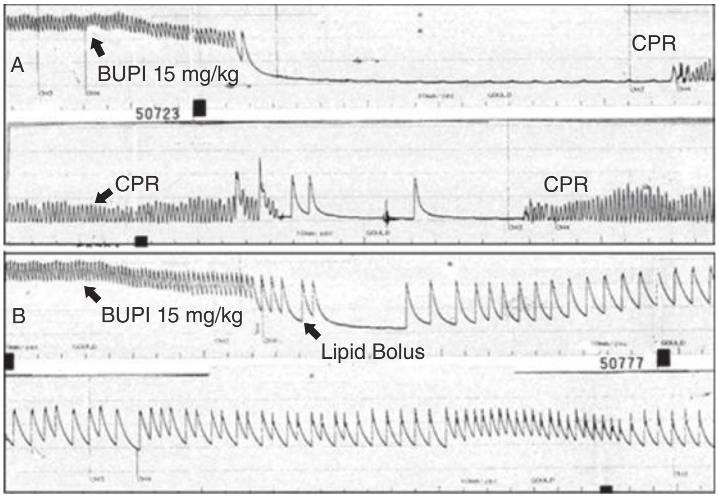

FIGURE 7–13. A: An anesthetized rat is given bupivacaine 15 mg/kg as indicated. The arterial blood pressure rapidly declines to cardiac arrest. Cardiopulmonary resuscitation (CPR) is given, but no arterial pressure is observed when CPR is discontinued. **B:** The same experiment is conducted, but a bolus of lipid is given; note that the arterial pressure is never lost (despite the same dose of bupivacaine being used), and that cardiac arrest does not ensue. (Reproduced with permission from Weinberg G: Current concepts in resuscitation of patients with local anesthetic cardiac toxicity. *Reg Anesth Pain Med*. 2002 Nov-Dec;27(6):568-575.)

that the risk was overstated from the start, at least in experienced hands.[88] Many practitioners believe that ultrasound guidance during peripheral nerve blocks has led to safer practices and less risk. While this view remains controversial, there are studies that support this belief.[89,90]

SUMMARY

After more than a century of use in Western medicine, LAs remain important tools for the twenty-first-century physician. Peripheral nerve blocks are almost certainly the result of LA inhibition of voltage-gated Na channels in neuronal membranes. The mechanisms of spinal and epidural anesthesia remain incompletely defined. The appropriate and safe dose of LAs varies with specific nerve block procedure. The mechanisms by which differing LAs produce CV toxicity likely vary: The more potent agents (eg, bupivacaine) may produce arrhythmias through a Na channel action, whereas the less-potent agents (eg, lidocaine) may produce myocardial depression through other pathways. Fears about LA systemic toxicity have abated with safer LAs, safer regional anesthesia practices, and improved treatments. There is renewed effort to produce clinically applicable delayed-release local anesthetic formulations to extend the duration of the currently available LAs.

CHAPTER 8

Controlled-Release Local Anesthetics

John-Paul J. Pozek, David Beausang, Kara G. Segna, and Eugene R. Viscusi

INTRODUCTION

Local anesthetics (LAs) are among the most useful drugs in anesthesiology practice and pain management. They are cornerstones in postoperative pain management within a multimodal analgesic pathway to reduce or eliminate opioids and their resulting adverse events. However, currently available LAs display a considerable range of onset and duration as well as tolerability across a wide range of uses, including infiltration, peripheral blocks, and epidural and spinal anesthesia. Their main limitation is duration of action, which in the treatment of postoperative pain may prevent adequate therapy of sufficient duration. For that reason, continuous catheter infusion systems are widely used but introduce challenges, such as catheter placement, catheter migration and maintenance, and the burden of the external pump. Therefore, long-acting LAs with predictable onset, delivery, and duration of action would be a near-ideal solution.

Local anesthetics can have considerably different properties depending on the body compartment where they are placed. Controlled-release LAs must be well studied for clinical efficacy and reliability in the various sites and modes of application. At this time, only one controlled-release drug is approved by the Food and Drug Administration (FDA) and is commercially available, although there are several others in development. In this chapter, we summarize the currently available information.

LOCAL ANESTHETIC CARRIERS

Since the 1970s, drug delivery systems for LAs have been the subject of considerable research efforts.[1–3] Development strategies are typically based on interdisciplinary approaches that combine polymer science, pharmaceutics, bioconjugate chemistry, and molecular biology.[4] The goals of these carriers are to provide a LA depot at the target site to prolong the drug effect and to decrease local and systemic toxicity by reducing the LA concentration and increasing LA permeability and absorption. These factors determine the concentration and the effect of the LA on the nervous tissue, influencing the latency, spread, intensity of the blockade, and the duration of action.[1]

Formulation approaches to systemically deliver LA have included the encapsulation in liposomes, complexation in cyclodextrins, association with biopolymers, transdermal nonliposomal carriers, and other carrier systems. Topical delivery systems for LA comprise of a wide spectrum of adjuvants, including viscosity-inducing agents, preservatives, permeation enhancers, and emollients. The physical state of these carriers varies from semisolid (gel, cream, ointment); liquid (emulsion, dispersion); to solid (patch) pharmaceutical forms.[1]

Liposome-Based Local Anesthetic Formulations

Liposomes, widely investigated as drug carriers for improving the delivery of therapeutic agents to specific sites in the body, are nonimmunogenic, biodegradable, nontoxic and work by encapsulating both hydrophilic and hydrophobic materials to deliver drugs.[4] The structural versatility combined with the ability to encapsulate different compounds, such as LAs, is due to microscopic mono- or bi-layer phospholipid vesicles.[1] The polar core of the lipsphere allows hydrophilic drug molecules to become encapsulated. Amphiphilic and lipophilic molecules are solubilized within the phospholipid bilayer according to their affinity.[4]

Channel proteins can be incorporated into the liposome without a loss of activity within the hydrophobic domain of vesicle membranes, acting as a selective filter. Thus, drugs that are encapsulated with channel proteins are effectively protected from premature degradation by proteolytic enzymes and are able to diffuse through the channel driven by concentration gradients between the interior and exterior "nanocage."[4] Various types of liposomes can be prepared, depending on the number of lipid layers, size, surface charge, lipid composition, and methods of vesicle formation. In the case of liposomes and micro- or nanoparticle-based systems, the improved pharmacological action is generated by the slow rate of release of the encapsulated drug from these lipid bilayers.[1]

Benefits

Liposomes, composed of naturally occurring substances, offer the advantage of being nontoxic and biodegradable. The ability to entrap drugs in the aqueous or lipid form enables carrying of both hydrophilic and hydrophobic drugs.[4] The advantages of encapsulating LA in liposomes is controlled delivery via slow drug release to prolong anesthetic effect and reduce the risk of cardiovascular and central nervous system toxicity.[1]

Clinical Pearl

- Liposomes are microscopic spheres containing an aqueous core surrounded by a phospholipid bilayer.

Risks/Limitations

Although liposomes are the carrier of choice in many technologies, their use for LAs has not often been adequately explored. This could be because liposomes are considered unstable colloidal systems, either physically due to their size or chemically, as lipids are prone to oxidation.[4]

DepoFoam®

DepoFoam® consists of microscopic, spherical, lipid-based particles (Figure 8–1A).[5] The particles are composed of numerous polyhedral, nonconcentric, aqueous chambers containing the drug in solution. Each chamber in this multivesicular liposome is separated from adjacent chambers by lipid membranes (Figure 8–1B). DepoFoam particles are distinguished structurally from unilamellar vesicles, multilamellar vesicles, and neosomes (Figure 8–2) by these closely packed, nonconcentric vesicles. The particles are tens of micrometers in diameter and have a large trapped volume. This allows delivery of relatively large quantities of medications in the encapsulated form with only a small volume of the formulation. Importantly, the liposomal platform that encapsulates the drug does so without altering the molecular structure. Therefore, a number of methods based on a manipulation of the lipid and aqueous composition may be used to control the rate of sustained release over a desired period from 1 to 30 days via erosion or reorganization of the lipid membranes.[6] DepoFoam has been used in to-date, two FDA-approved commercial products, including DepoCyt(e)® (cytarabine liposome injection), as well as EXPAREL® (bupivacaine liposome injectable suspension). DepoFoam can be released into the bloodstream via the interstitial space subcutaneously or intramuscularly or it can be delivered locally to a body compartment or joint via intrathecal, intraperitoneal, subcutaneous, epidural, or intraocular methods.[7,8]

Clinical Pearl

- DepoFoam technology consists of lipid-based particles with polyhedral, nonconcentric, aqueous chambers that contain the medication. This technology can be used with a number of different medications.

Benefits

DepoFoam is a ready-to-use product and can be administered with small-gauge needles and pen systems. With a flexible delivery system, it is designed to offer an immediate-release dose, followed by sustained delivery. DepoFoam is less than 3%

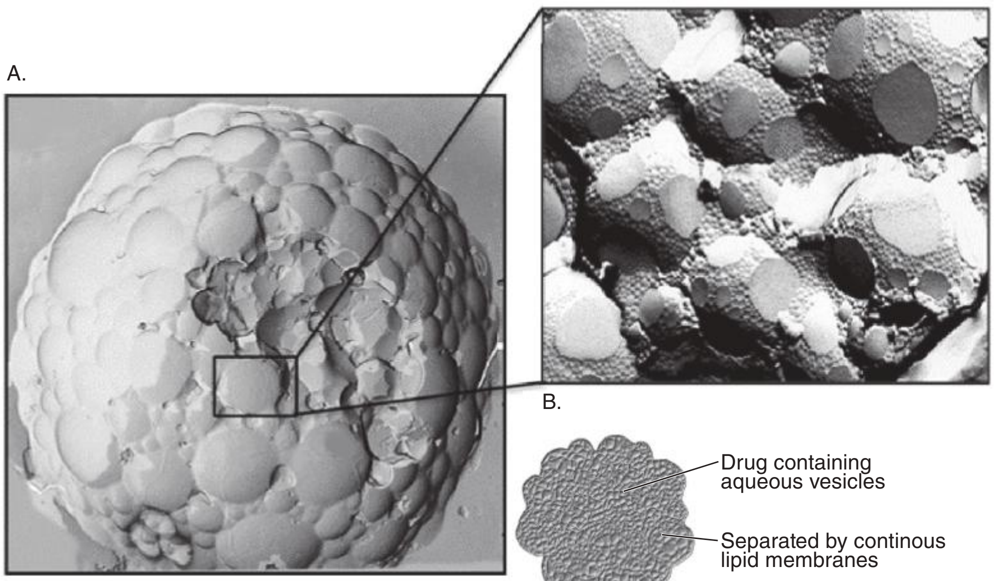

FIGURE 8–1. A: Scanning electron micrographic image of DepoFoam® with bupivacaine. **B:** Diagram representing the polyhedral, nonconcentric aqueous chambers filled with medication. (Used with permission from Pacira Pharmaceuticals, Inc.)

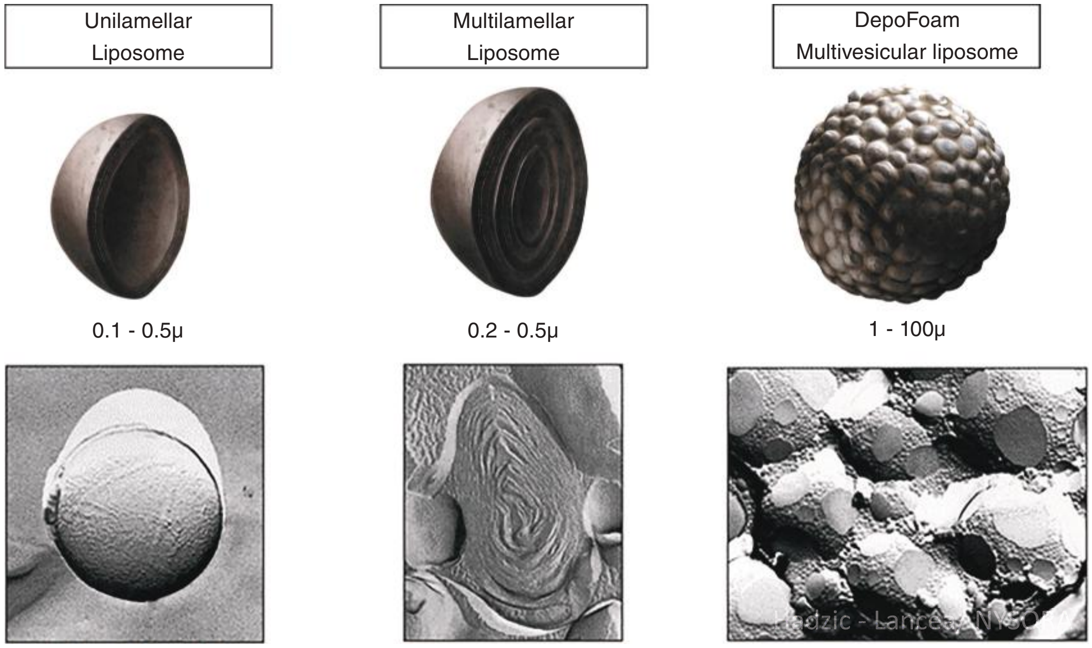

FIGURE 8–2. Comparison of unilamellar, multilamellar, and polylamellar formulations of liposomes.

lipid that is naturally occurring or a synthetic analogue of common lipids, including phospholipids, cholesterol, and triglycerides; therefore, it is biodegradable and biocompatible.[6]

Clinical trials have demonstrated limited to no adverse effects of DepoFoam. There is already considerable clinical experience with the delivery system as the formulation has been in use in products approved by the FDA and European Medicine Agency. Furthermore, at similar doses, this formulation can reduce systemic exposure and toxicity by reducing peak serum levels of a drug.[7,8]

Polymeric Micro- and Nanoparticle Formulations

Polymeric micro- or nanoparticles represent drug delivery systems made of natural or artificial polymer spheres or capsules, which must be biocompatible and biodegradable for drug delivery purposes.[1] Nanoparticles act as potential carriers for several classes of drugs, such as anticancer agents, antihypertensive agents, immunomodulators, and hormones, and for macromolecules such as nucleic acids, proteins, peptides, and antibodies. Nanoparticles can be designed for the site-specific delivery of drugs. The targeting and release capability of nanoparticles is influenced by particle size, surface charge, surface modification, and hydrophobicity. The performance of nanoparticles in vivo is influenced by morphological characteristics, surface chemistry, and molecular weight.[9] Polymer (micro- or nanoparticle) technologies are claimed to be applicable to all commercially available LA compounds.[1]

A variety of natural and synthetic polymers have been explored for the preparation of nanoparticles, of which poly(lactic acid) (PLA) and poly(glycolic acid) (PGA) and their copolymer poly(lactic-co-glycolic acid) (PLGA) have been extensively investigated for their biocompatibility and biodegradability. PLGA, one of the most successfully developed biodegradable polymers,[9] attracted considerable attention due to the FDA and European Medicine Agency giving approval for parenteral administration. Other properties include well-described formulations and methods of production adapted to various types of drugs (eg, hydrophilic or hydrophobic small molecules or macromolecules) and protection of the drug from degradation.

Use of PLGA allows for the possibility of sustained release, the possibility to modify surface properties to provide better interaction with biological materials, and even a possibility toward targeting nanoparticles to specific organs or cells. Of note, after systemic administration, PLGA-based drug delivery systems are preferentially taken up by the reticuloendothelial system (RES) and present a high and selective uptake in inflamed areas. One of the reasons for the success of the carrier is that hydrolysis leads to the metabolite monomers lactic acid and glycolic acid, which are endogenous and easily metabolized by the body via the Krebs cycle. The PLGA delivery system is associated with a nearly negligible potential for toxicity.[10]

Benefits

Biodegradable nanoparticles have been used frequently as drug delivery vehicles due to their improved bioavailability, better encapsulation, and controlled release.[11] The literature describes that micro- or nanoencapsulation of LA greatly prolongs the duration of block and reduces systemic toxicity.[1]

Risks/Limitations

Despite the existing research on biodegradable microparticles containing macromolecular drugs, the effects of critical parameters influencing drug encapsulation are not sufficiently investigated for nanoscale carriers.[12] However, many novel techniques for preparation of drug-loaded nanoparticles are being developed and refined. The crux of the problem is the stability of nanoparticles after preparation, which is being addressed by freeze-drying using different classes of lyoprotectants.[9]

Another issue is that precise determination of the drug content is not easy because nanoparticles are colloidal systems. Encapsulation efficiency of drugs varies from 6% to 90% for dexamethasone and paclitaxel, respectively, while mean encapsulation efficiency is around 60% to 70% for various drugs, such as estradiol or xanthones. Another major pitfall of PLGA-based nanoparticles is that although PLGA-based nanoparticles often can present with high encapsulation efficiencies, the drug loading is generally poor (around 1%, which means that nanoparticles contain 1 mg active ingredient per 100 mg polymers of nanoparticles).

Yet another important pitfall is the consideration of high burst release of drug from nanoparticles. This phenomenon is described for most PLGA-based nanoparticles. Consequently, the drug might not be able to reach the target tissue or cells, leading to a loss of efficacy. Drug release mechanisms depend on the polymer used and on the loading efficiency. Generally, the rapid initial release is attributed to drug adsorbed to the nanoparticles' surface. Work is still being conducted to address these issues.[10]

LIPOSOMAL BUPIVACAINE

In October 2011, the FDA approved the use of single-injection liposomal bupivacaine for surgical site infiltration. To date, this is the only FDA-approved controlled-release LA.[4] Liposomal bupivacaine produces reliable plasma levels of bupivacaine up to 72 hours following infiltration. By comparison, traditional bupivacaine HCl has a duration of action of roughly 7 hours following tissue infiltration.[13] Liposomal bupivacaine encapsulates bupivacaine HCl within the carrier, DepoFoam. Prior to this development, extending the duration of action of an LA relied on indwelling catheters and infusion pumps. Infusion technology with an indwelling catheter carries a risk of infection, drug-filling errors, labeling errors, and variable infusion rates, particularly with elastometric pumps.[14] Replacement of elastomeric bags and targeted catheters with LA encapsulated in a liposome is a novel approach for providing analgesia. To date, liposomal bupivacaine has been studied in patients undergoing soft tissue surgery (hemorrhoidectomy, inguinal hernia repair, augmentation mammoplasty) or orthopedic surgery (bunionectomy and total knee arthroplasty).[5] Currently, it is approved for tissue infiltration.

Clinical Pearl

- Liposomal bupivacaine is a controlled-release LA that is FDA approved for wound (surgical site) infiltration.

Formulation

DepoFoam serves as the lipid-based carrier of bupivacaine HCl. When compared with other carriers, such as DepoDur® and DepoCyt, the major difference is the incorporation of dierucoylphosphatidylcholine into the DepoFoam.[15] It is comprised of nonemetogenic, naturally occurring or synthetic analogues of common lipids, making it generally well tolerated, although a tissue infiltration with DepoFoam bupivacaine in rabbits and dogs resulted in granulomatous inflammation, considered a natural reaction against the liposomes.[16]

Pharmacology

Liposomal bupivacaine is currently packaged in a 20-mL vial at a 1.3% concentration.[5] Single-dose administration is recommended, not exceeding 266 mg (one vial). Approximately 3% of the LA in liposomal bupivacaine is present in the free form. Because of this, the drug exhibits two peaks in plasma concentration T_{max} following tissue infiltration (Table 8–1).[17] This was observed by Langford et al in their study of patients receiving infiltration of liposomal bupivacaine for inguinal hernia repair. The first T_{max} occurs within the first hour, followed by a second T_{max} within 12 hours.[17] Systemic absorption depends on the total dose of drug administered, administration route, and vascularity of the administration site.[13] Liposomal bupivacaine has a 24-hour duration of action.[18]

As with traditional bupivacaine, liposomal bupivacaine is metabolized by the liver following its release from the drug delivery system.[13] Caution is recommended when using liposomal bupivacaine for patients with severe hepatic dysfunction. In phase 1, trial patients with moderate hepatic impairment

TABLE 8–1. Pharmacokinetics of controlled-release local anesthetics.

Drug	Carrier	T_{max} (h)	C_{max} (ng/mL)

had a 1.5-fold increase in the maximum plasma concentration C_{max} compared with healthy controls following single 300-mg infiltration of liposomal bupivacaine.[19] However, this is likely not of great clinical significance with single administration of liposomal bupivacaine. Significant accumulation of bupivacaine or its metabolites is not expected despite impaired liver function. Approximately 6% of bupivacaine is excreted unchanged in urine.[13]

Dosing and Administration

Dilution is recommended with sterile saline up to a maximum total volume of 300 mL.[20] Hypobaric solutions, such as sterile water, may disrupt the liposomal carrier, potentially leading to loss of sustained efficacy and high system drug levels.[18] Diluting liposomal bupivacaine with other drugs, such as lidocaine or bupivacaine HCl, may cause disruption of the carrier, accelerated release of bound bupivacaine and toxicity.[18] Additional LA, of any kind, is not recommended for 24 hours following liposomal bupivacaine administration. The liposomal carrier will maintain its integrity with injection through as small as 30-gauge needles.[18]

Clinical Pearl

- Diluting liposomal bupivacaine with other LA may cause disruption of the lipid carrier, possibly unbinding bupivacaine.

Clinical Evidence

In a phase 3 trial, an infiltration of 266 mg liposomal bupivacaine was compared with placebo in patients receiving hemorrhoidectomy. This randomized, double-blind study of 189 patients found that patients receiving liposomal bupivacaine had significantly less pain and fewer patients required opiate rescue.[21] A significant difference was also observed with regard to 72-hour opioid consumption, which was 45% lower compared with placebo.[21] Following this study, Onel and colleagues compared liposomal bupivacaine to bupivacaine HCl in a similar cohort of patients. This double-blind, randomized, controlled study examined 100 patients for hemorrhoidectomy. Patients had significantly less pain (47%) and required significantly less opioid (66%) over the first 72 hours with liposomal bupivacaine.[22]

Clinical Pearl

- Patients receiving wound infiltration with liposomal bupivacaine had significantly less pain and opioid usage than those who received bupivacaine HCl for hemorrhoidectomy and bunionectomy.

In a double-blind, randomized trial of 193 patients receiving bunionectomy with first-metatarsal osteotomy, liposomal bupivacaine showed significantly reduced pain at 24 and 36 hours when compared with placebo.[23] Although there was no statistically significant difference in pain scores, a liposomal bupivacaine dose-finding study of patients having unilateral inguinal hernia repair demonstrated benefits for secondary endpoints. The liposomal bupivacaine group trended toward lower opioid requirements in patients at all doses (155, 200, 266, 310 mg) compared with 100 mg bupivacaine HCl.[17]

In a randomized trial of women having bilateral breast augmentation surgery, subjects were randomized to injection of either 133 or 266 mg liposomal bupivacaine in one breast and 75 mg bupivacaine HCl in the contralateral breast.[24] In both groups, the subjects complained of more pain in the breast receiving bupivacaine HCl. The difference in opioid consumption between the two groups only reached significance after 48 hours which is commensurate with the delayed release of bupivacaine from liposome carriers.[24]

Use of liposomal bupivacaine in patients after implant-based breast reconstruction demonstrated significantly decreased visual analog scale (VAS) pain scores at 4–24 hours postoperatively when compared to bupivacaine HCl and placebo.[25] There was no difference in opiod and antiemetic usage between the three treatment groups.[25]

Multiple studies investigating analgesic efficacy of liposomal bupivacaine in wound infiltration after total knee arthroplasty have been performed. A study by Bagsby et al[26] compared periarticular injection with 2.6% liposomal bupivacaine versus 0.5% ropivacaine. Patients reported similar mean pain scores at 24 hours, but for the remainder of the hospitalization, pain scores were significantly increased in the liposomal bupivacaine group. Half of the ropivacaine group reported their pain as mild, compared with only 17% of patients receiving liposomal bupivacaine.[26]

A recent, large, randomized, controlled trial compared periarticular injection of liposomal bupivacaine versus bupivacaine HCl. All patients concurrently received multimodal analgesia. The two groups had no significant difference in terms of least, worst, and average daily pain at all time points.[27] Furthermore, there was no difference in consumption of opioids.[27]

A recent randomized prospective study compared local infiltration of liposomal bupivacaine with a single-injection femoral nerve block of ropivacaine and tetracaine. The nerve block group had significantly less pain in the first 24 hours postoperatively, but total opioid consumption was unchanged between the two groups.[28] Interestingly, the nerve block group had less opioid during the first day postoperatively, while the liposomal bupivacaine group consumed less on the second day.[28] The two treatments demonstrated no effect on total ambulation, but a greater percentage of patients ambulating and greater total distance was seen in the liposomal bupivacaine group.[28]

Safety

It is recommended that the dose of liposomal bupivacaine should not exceed the single 266-mg vial. Repeat LA administration is not recommended within 72 hours following infiltration. To ensure the liposomal carrier's integrity, liposomal bupivacaine should be diluted only with normal saline and administered through a needle that is 25 gauge or larger.[18] To avoid possible toxic levels of lidocaine and bupivacaine, liposomal bupivacaine infiltration should follow lidocaine infiltration by at least 20 minutes.[16] Overall, however, in over 1 million patient exposures, liposomal bupivacaine demonstrated a remarkable safety systemic toxicity profile.[29] Safety of liposomal bupivacaine in peripheral nerve blocks (PNBs) is discussed further in the chapter.[30]

Clinical Pearl

- Injection of liposomal bupivacaine should occur at least 20 minutes after infiltration of lidocaine to avoid potential toxicity.

Experimental Applications

Peripheral Nerve Blocks

The use of liposomal bupivacaine in PNBs has generated significant interest as a possible FDA-approved method to prolong nerve blockade without indwelling catheters. At the time of publication, liposomal bupivacaine has not been approved by the FDA for this indication.

Data from preclinical toxicology studies demonstrated no signs of neurotoxicity in animal models.[16,31,32] Similarly, a phase 1 study in healthy volunteers demonstrated no nerve injury with single-injection PNB.[33]

Efficacy of higher-dose liposomal bupivacaine was seen in femoral nerve blocks for patients receiving tricompartment knee arthroplasty. Patients receiving 133 and 266 mg had significantly decreased resting pain at 24 hours when compared with patients receiving 67 mg of liposomal bupivacaine or saline. A study by Ilfeld et al with variable doses of liposomal bupivacaine (0–80 mg) demonstrated prolonged motor and sensory block with higher doses of the medication.[33] All patients had motor and sensory blockade more than 24 hours in the 40-mg treatment group and more than 90% in the 80-mg treatment group.[33]

A recent review of literature examined the safety of liposomal bupivacaine over six studies with healthy volunteers and patients undergoing various surgical procedures. The most common side effects of perineural liposomal bupivacaine injection were nausea, pyrexia, constipation, vomiting, and pruritus.[34] There was no difference in adverse effects between liposomal bupivacaine and placebo. Treatment-related adverse events had lower incidence in the liposomal bupivacaine versus bupivacaine HCL groups, with the most common adverse event being hypesthesia.[34]

Potential deterrents for widespread use of liposomal bupivacaine in PNBs are a possible inability to achieve surgical anesthesia,[33] inferior analgesia compared to bupivacaine HCl over the first 12 postoperative hours, and inability to titrate the LA to effect. Prolonged sensory and motor blockade may affect early rehabilitation and increase fall risks.[35]

If approved for use in PNBs, single-injection liposomal bupivacaine may present a long-acting alternative to continuous PNB. There is potential for increased procedure efficiency and more widespread use of PNBs without the placement and fixation of a perineurial catheter, and the patient would avoid possible adverse events related to catheter placement.[35]

Epidural Anesthesia

Liposomal bupivacaine is currently not approved for epidural administration, although its pharmacologic profile following a single epidural injection has been studied. Viscusi, Candiotti, and colleagues performed a phase 1 randomized, double-blind, active-control, dose-escalating pilot study evaluating a single dose of liposomal bupivacaine at 89, 155, or 266 mg compared with bupivacaine HCl 50 mg in healthy volunteers. Their study concluded that epidural liposomal bupivacaine at 266 mg resulted in a longer duration of sensory block than liposomal bupivacaine 89 or 155 mg or bupivacaine HCl 50 mg.[36]

Interestingly, incidence of some degree of motor blockade was less with liposomal bupivacaine 266 mg versus bupivacaine HCl 50 mg.[36] The liposomal bupivacaine group had fewer patients who were unable to ambulate after 4 hours and a quicker resolution of complete motor blockade.[36] The high sensorimotor block ratio suggests significant utility for liposomal bupivacaine in epidural anesthesia, but further study is needed to document safety and efficacy.

EXPERIMENTAL MEDICATIONS

SABER-Bupivacaine

SABER (sucrose acetate isobutyrate extended release) technology (Durect Corporation) has been developed as a bioerodable injectable depot system with the potential of delivering a drug over a period of days to 3 months.[37]

Formulation

The SABER delivery system consists of sucrose acetate isobutyrate (SAIB), additives, and a solvent. SAIB is a hydrophobic, esterified sucrose derivative that exists as a viscous liquid (Figure 8–3). The SABER system can be mixed with a drug and injected subcutaneously or intramuscularly with up to a 25-gauge needle.[37]

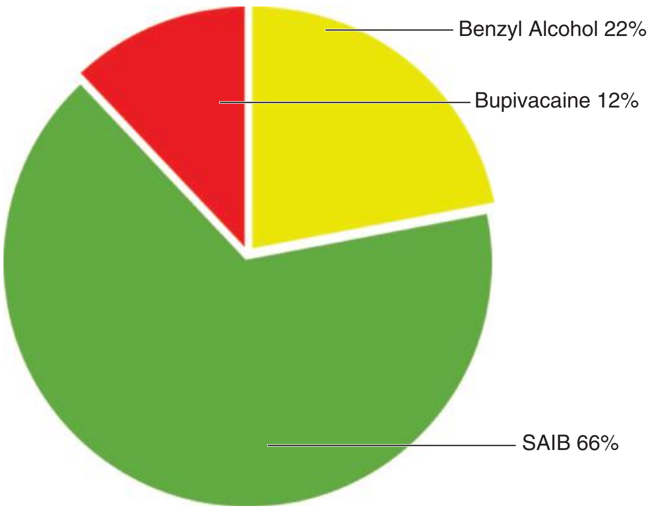

FIGURE 8–3. Formulation of SABER-bupivacaine. (Compiled from data in References 33–36.)

Clinical Pearl

- SABER-bupivacaine consists of a SAIB delivery system that is mixed with LA. After infiltration, the delivery system dissolves within tissues.

SABER-bupivacaine (Posidur™), developed by the Durect Corporation, awaits FDA approval.

Pharmacology

Solvent type and amount, drug loading, and other additives are possible variables to customize the duration of drug delivery. SABER formulations can carry a drug payload as high as 30%. On injection, the drug forms a depot in subcutaneous tissue, and its release begins immediately. The delivery system dissolves in situ, eliminating the need for removal.[38]

In a study comparing differing doses of SABER-bupivacaine (12% bupivacaine), the dose concentration response exhibited linear pharmacokinetics.[37] A large review of 11 clinical trials with both healthy subjects and those undergoing varied surgical procedures demonstrated a varied T_{max} at 24–48 hours (Table 8–1).[39] This seems to differ with surgical procedure, as T_{max} with administration after shoulder surgery was shorter when compared with abdominal surgery.[40] This is possibly due to rapid absorption of the drug when confined to a smaller surgical area.[40]

Clinical Evidence

In a 2012 double-blinded, randomized, controlled trial of 124 patients receiving open hernia repair, SABER-bupivacaine outperformed placebo after surgical site administration. A dose of 5 mL of SABER-bupivacaine (12% bupivacaine) had a significantly lower area under the curve (AUC) for mean pain intensity from 1 to 72 hours, compared to placebo (2.47 vs. 3.61; $p = .0036$). The 5-mL group achieved significantly reduced pain with movement and opioid consumption and increased time to first opioid when compared to placebo.[37]

Notably, the 2.5-mL formulation of SABER-bupivacaine did not reach the same levels of significance. A 2014 multicenter, randomized, double-blind study of 98 patients undergoing abdominal surgery showed clinically and statistically significant decreased pain for 3 days in patients given SABER-bupivacaine.[41]

Safety

Due to incomplete evidence of clinical safety, the FDA did not approve SABER-bupivacaine's new drug application in 2013. In 2012, Hadj et al reported no adverse events resulting from SABER-bupivacaine.[37] Wound healing was unchanged among the groups. Gan et al failed to identify any evidence of bupivacaine toxicity through evaluation of vital signs, physical exam, laboratory results, and Holter monitoring.[41]

Bupivacaine-Collagen Implant

A collagen-based implant with LA that is currently waiting for phase 3 testing is a bupivacaine-collagen implant (XaraColl®). This medication is being developed by Innocoll Pharmaceuticals for implantation in sites of surgical trauma to provide postsurgical analgesia.[42]

Formulation

XaraColl is composed of a biodegradable and fully resorbable collagen matrix that is impregnated with bupivacaine (Figure 8–4). The matrix is implanted during surgery and is purported to begin releasing LA immediately.[42]

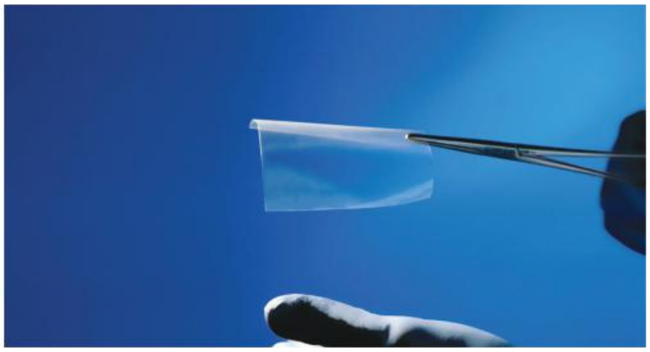
Clinical Pearl

- A bupivacaine-collagen implant is composed of a collagen matrix that is impregnated with LA. While the collagen matrix is resorbed, LA is released.

Pharmacology

Collagen implants have been studied with varying concentrations of bupivacaine. With slow resorption of the collagen matrix, controlled release of LA occurs. Systemic bupivacaine levels were demonstrated to be well below the toxicity threshold with a mean C_{max} of 0.22 μg/mL (Table 8–1).[43] Similar to liposomal bupivacaine, this medication demonstrated a biphasic peak of increased concentration.[43] In a study by Cusack, T_{max} ranged from 30 minutes to 20 hours, depending on which peak predominated.[43]

CollaRx® sponge



Collafilm® membrane

FIGURE 8–4. Delivery system of bupivacaine-collagen implant. (Used with permission from Innocoll Inc. Website. Accessed November 2015.)

Clinical Evidence

Two independent studies in men after unilateral inguinal hernia repair indicated a significant treatment effect for bupivacaine-collagen implants when compared to placebo. In one study, pain scores were significantly decreased in patients treated with implants versus placebo at both 24 and 48 hours with no significant change in opioid usage. In the second study, pain scores did not differ, but opioid usage decreased significantly in patients with bupivacaine-collagen implants. Pooled analysis of these studies suggested that this treatment effect extended over 72 hours postoperatively.[42]

Safety

Most common adverse events after implantation of bupivacaine-collagen implants were constipation, nausea, and headache.[41] One study demonstrated elevated liver enzymes and abnormal phosphorous levels after implantation, although none of these were clinically significant and resolved spontaneously. Visual disturbances possibly indicating bupivacaine toxicity were found in one patient, but serum sampling showed a low systemic concentration of bupivacaine.[43]

Phase 3 trials show a statistically significant decrease in pain scores 48 hours postoperatively in inguinal hernia repair when compared to placebo.[44]

SUMMARY

The clinical practice need for longer duration of analgesia and avoidance of the time-inefficient and procedurally more complex indwelling catheters has spurred interest in controlled-release LAs. Every technology to date has inherent compromises. Evidence to date suggests a clear utility for single-injection extended-released LAs but a continued role for delivery of LA by catheter and indwelling pump. Currently, the only medication in this class with FDA approval is liposomal bupivacaine, which is approved for wound infiltration. The search for new indications has inspired research in multiple modalities. Of particular interest to regional anesthesia and acute pain medicine are its potential use in PNBs and epidural anesthesia. FDA approval for use in these areas has the potential to positively affect the practice of regional anesthesia and quality of postoperative pain management. Controlled-release LAs are likely to become an important inherent part of a multimodal analgesia regimen. Controlled-release LAs, along with other analgesics, may further reduce the reliance on opioids as the primary postoperative analgesia consistent with all current published acute pain guidelines.

CHAPTER 9

Analgesic Adjuvants in the Peripheral Nervous System

Colin J. L. McCartney and Stephen Choi

NB: Several studies authored by Dr. S. Reuben that have since been retracted were referenced in the previous edition of this text. These references have been removed. All references remaining in which Dr. Reuben was involved that have not been retracted are still referenced.

INTRODUCTION

Peripheral nerve blocks provide many benefits for patients, including superior pain control and reduction in general anesthesia-related side effects. To optimize pain relief while reducing the total dose of local anesthetic, it would be of use to add a drug that both speeds onset and prolongs sensory blockade or analgesic effect. Improvements in our knowledge of peripheral nervous system (PNS) pain mechanisms allow us to develop methods of prolonging analgesia while reducing central and peripherally mediated adverse effects.

In the last 20 years, a number of drugs have been tested, and several have proven clinically useful when added to local anesthetic for peripheral nerve block or when used for local infiltration or intra-articular analgesia. These drugs are known as analgesic adjuvants.

This chapter examines the rationale and current evidence base for use of analgesic adjuvants and summarizes the best strategies for optimizing pain control and reducing adverse effects after surgery under peripheral nerve block, local infiltration, or injection of drugs in the intra-articular space.

RATIONALE FOR USE

Pain transmission in the CNS and PNS involves a complex array of neurotransmitters and pathways that are not easily blocked by one drug type or technique alone. Involvement of several classes of neurotransmitter at the injury site, peripheral nerve, dorsal horn of the spinal cord, and supraspinal sites is responsible for the transmission of nociception. Use of agonists at inhibitory receptors and antagonists at excitatory receptors allows a "multimodal" approach with optimization of pain control and reduction of adverse effects.[1]

In 1645, Descartes proposed a mechanism for pain transmission, suggesting that a peripheral pain impulse was transmitted directly from the periphery to the brain by a "hardwired" system without any intermediate modulation (Figure 9–1). This theory of pain transmission was widely held as true until as recently as 40 years ago.

In 1965, Melzack and Wall proposed their groundbreaking gate control theory of pain that suggested that pain could be modulated or "gated" at a number of points in the pain pathway. Subsequent research identified the dorsal horn (lamina II) of the spinal cord as an important site of potential modulation, and subsequent treatments for acute and chronic pain have utilized this knowledge to good effect. Treatments such as the use of spinal opioids and transcutaneous electrical nerve stimulation (TENS) have been developed in the light of this knowledge. The gate theory also changed many (often unsuccessful) pain management strategies from techniques where we tried to ablate pain pathways either chemically or surgically to more recent modulation techniques by which we attempt to inhibit excitatory influences and enhance inhibitory influences within the pain pathway.

In the last few decades, important advances have also occurred in our knowledge of how pain is generated and transmitted from the PNS to the central nervous system (CNS). Modulation of pain in the PNS also involves numerous transmitters and mechanisms that both excite and inhibit nociceptive pathways.

FIGURE 9–1. Descartes model of pain transmission in the peripheral nervous system.

In the PNS, under normal physiologic conditions nociceptive signals are produced when A-α and C fibers are stimulated by heat, pressure, or several chemicals produced by tissue damage and inflammation (potassium, histamine, bradykinin, prostaglandins, adenosine triphosphate [ATP]).[2] Nociceptive signals are transmitted to the superficial layers of lamina II of the dorsal horn in the spinal cord, where they are modulated at both the presynaptic and postsynaptic level and also by excitatory and inhibitory descending control pathways form the brainstem (Figure 9–2).[3] Signals that are successful in crossing this gate travel on to the brainstem and thalamus before reaching the cerebral cortex to produce a pain stimulus.

Chemical mediators in a wide array are produced in the PNS and have both excitatory and inhibitory influences on peripheral sensory nerve transmission[4] in both the acute and the chronic phase of injury (Figure 9–3).[5] These can directly activate the nerve (ATP, glutamate, 5-hydroxytryptamine [5-HT], histamine, bradykinin); enhance depolarization by sensitizing the nerve to other stimuli (prostaglandins, prostacyclin, and cytokines such as interleukins); or provide a regulatory role on the sensory neuron, inflammatory cells, and sympathetic fibers (bradykinin, tachykinin, and nerve growth factor).

RATIONALE FOR USE OF ANALGESIC ADJUVANTS

As previously noted, pain transmission in the CNS and PNS involves a complex array of neurotransmitters and pathways that are not easily blocked by one drug type or technique alone. A number of drugs in the anesthesiologist's armamentarium, including opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), α_2-agonists, dexamethasone, and *N*-methyl-D-aspartate (NMDA) antagonists, have activity at these sites of action and may have benefit if applied in the PNS. Importantly, none has demonstrated neurotoxicity at clinically relevant concentrations.[6]

This knowledge can aid the regional anesthesiologist in a number of ways:

1. In the selection of adjuvants to local anesthetics to speed onset, prolong effect, and reduce total required dose.

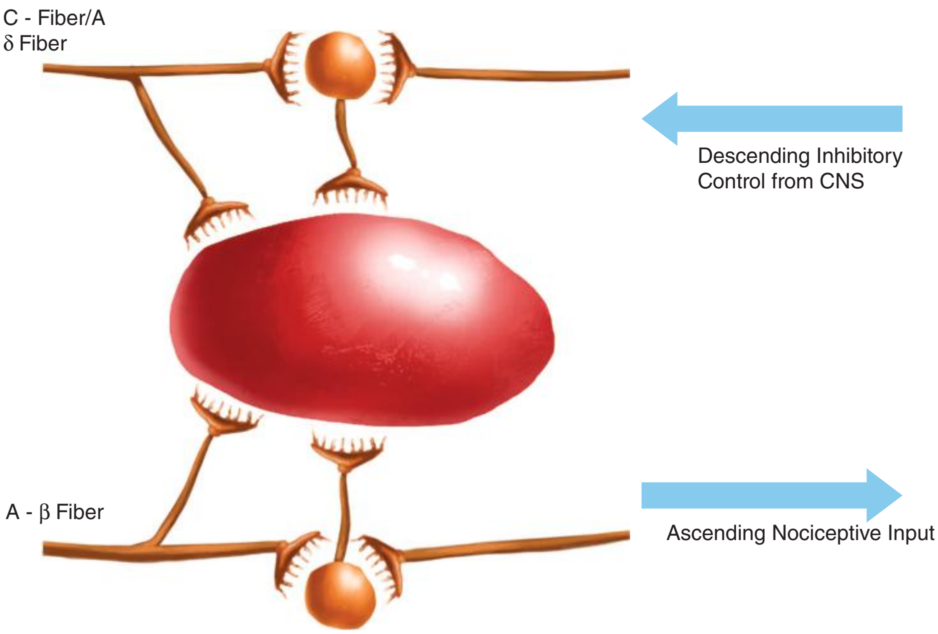

FIGURE 9–2. The gate theory proposed that small (C) fibers activated excitatory systems (black neuron) that subsequently excited output cells; these latter cells had their activity controlled by the balance of large fiber (A-β)-mediated inhibitions (mediated by endogenous opioids) and also by descending control systems from the central nervous system (mediated by norepinephrine and serotonin).

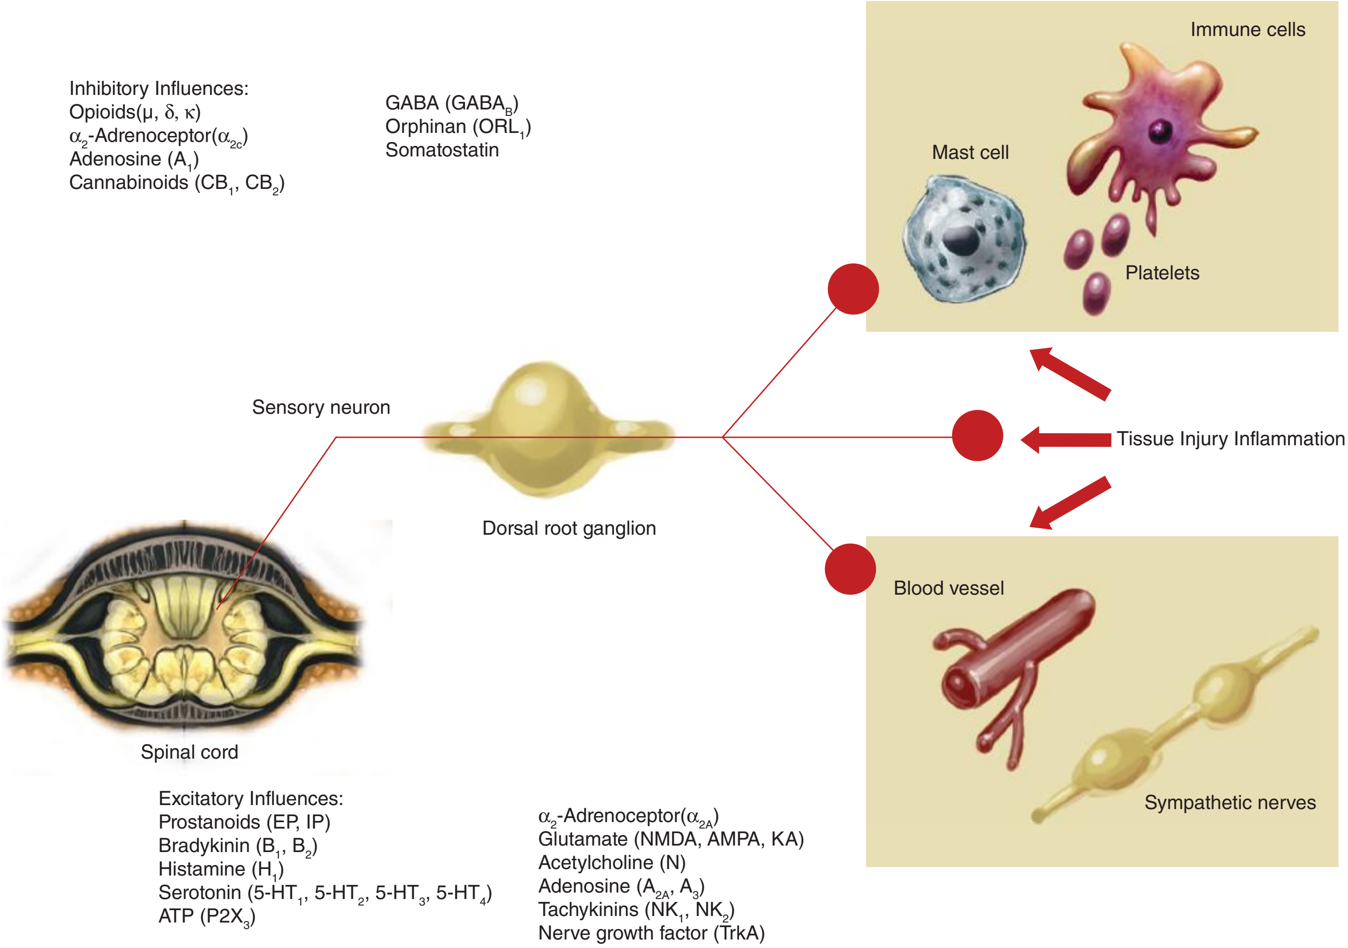

FIGURE 9–3. Excitatory and inhibitory influences on peripheral nerve activity by mediators released by tissue injury and inflammation and by a variety of agents acting on neuroreceptors. AMPA = α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid; KA = kainic acid; NMDA = *N*-methyl-D-aspartate; NK = neurokinin; TrkA = Tropomyosin receptor kinase A.

2. Suggest agents that can enhance postoperative analgesia without prolonging adverse effects of local anesthetics.
3. Suggest agents that predominantly act at peripheral sites without central effects, thereby optimizing analgesia while minimizing CNS side effects.

OPIOID ANALGESICS

During inflammation, opioid receptors are expressed in peripheral sensory fibers and immune cells[7]; moreover, endogenous opioids are released from these cells and balance the increased nociceptive state produced by inflammation.[8] An increasing body of work suggests an intimate relationship between endogenous opioids and the immune system. Christoph Stein and colleagues in Berlin have performed a number of pioneering studies[9,10] that described the ability of the immune system to deliver endogenous opioids and the ability of inflammation to stimulate movement of opioid receptors to the site of injury, thereby allowing antinociception to occur. However, these changes do not occur immediately after injury and can take up to 96 hours to occur.[11]

Opioid receptors and neuropeptides (eg, substance P) are synthesized in the dorsal root ganglion and transported along intra-axonal microtubules into central and peripheral processes of the primary afferent neuron (Figure 9–4). At the terminals, opioid receptors are incorporated into the neuronal membrane and become functional receptors. On activation by exogenous or endogenous opioids (released by immune cells), opioid receptors couple to inhibitory G proteins. This leads to direct or indirect (through decrease of cyclic adenosine monophosphate) suppression of Ca^{2+} or Na^{+} currents and subsequent attenuation of substance P release. The permeability of the perineurium is increased within inflamed tissue, enhancing the ability of opioids to reach target receptors.

Numerous studies have applied opioids in the PNS to either peripheral nerves or the intra-articular space. Although many studies claimed an analgesic benefit of peripherally applied opioids, few studies incorporated a control group with a systemically applied opioid for comparison. Without inclusion of a control, it is impossible to interpret whether the peripheral opioid is having a true peripheral effect or is instead being carried to the CNS to induce analgesia. True peripherally mediated opioid analgesia may be beneficial if this is associated with improved analgesia or reduced adverse effects compared with systemic administration. If the effect is mediated centrally, then there is no clear benefit over systemic administration.

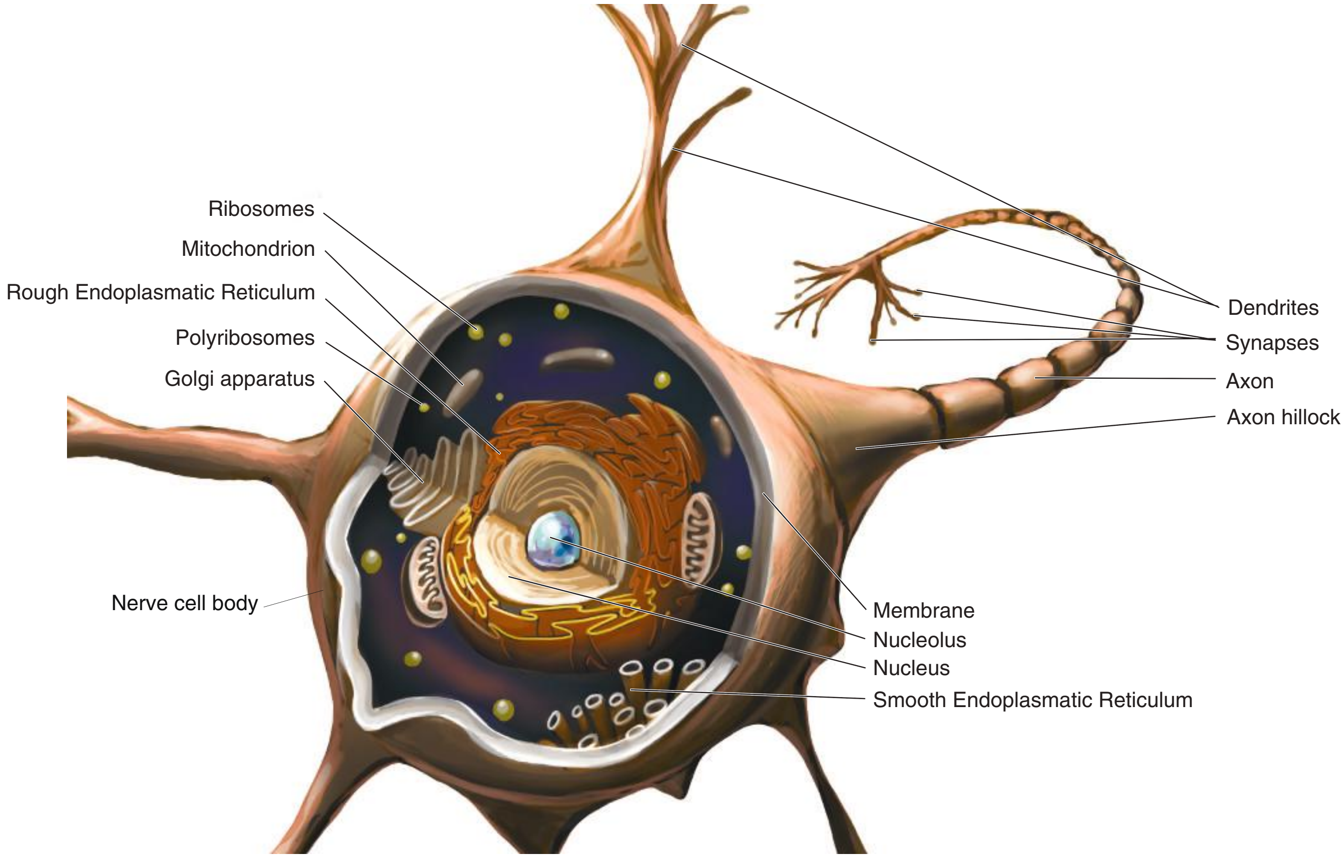

FIGURE 9–4. Opioid receptor transport and signaling in primary afferent neurons.

Perineural Opioids

Opioid receptors identified on primary afferent fibers are transported from the dorsal root ganglion to the site of inflammation; however, while they are undergoing axonal transport, they may not be easily reached by opioid agonists. This may explain the reason that two recent systematic reviews[12,13] published in 1997 and 2000 found little evidence for the benefit of adding opioids to local anesthetics in peripheral nerve blockade. An updated table of studies examining perineuronal administration of opioids[13–17] (excluding buprenorphine and tramadol) shows that analgesic benefit remains equivocal (Table 9–1). In addition, Peng and Choyce[18] reviewed the use of opioids in intravenous regional anesthesia (IVRA) with similar disappointing conclusions.

TABLE 9–1. Outcomes of studies examining the effect of perineuronal/perineural opioids (excluding tramadol and buprenorphine).

Total Studies	Overall Outcomes	Systemic Control Outcomes
19 studies	10 supportive	7 systemic control: 5 supportive; 2 negative
	9 negative	12 no systemic control: 5 supportive; 7 negative.

Despite these disappointing results, the two opioid agonists that have demonstrated analgesic efficacy when administered perineuronally are buprenorphine and tramadol. Buprenorphine is a partial μ-receptor agonist with a very high receptor affinity compared with fentanyl (24-fold) or morphine (50-fold). In addition, it has intermediate lipid solubility, which allows it to cross the neural membrane.[19,20] Candido and colleagues[21] added 0.3 mg buprenorphine (a partial opioid agonist) to a combination of mepivacaine and tetracaine in axillary block and found an almost 100% increase in the duration of analgesia compared with the administration of axillary block plus the same dose of intramuscular buprenorphine with no significant increase in adverse effects. This supports the peripheral analgesic effect of buprenorphine and the earlier findings of two studies that examined buprenorphine without a systemic control group.[22,23] Studies examining buprenorphine are presented in greater detail in Table 9–2.

Tramadol is a weak opioid agonist with some selectivity for the μ-receptor that also inhibits norepinephrine reuptake and stimulates serotonin release in the intrathecal space. Norepinephrine and serotonin are transmitters for the descending control pathway in the spinal cord and enhance analgesia.[24,25] Kapral and coworkers[26] used a 100-mg dose of tramadol as an adjuvant to mepivacaine in axillary brachial plexus block. They divided 60 patients into three groups: One group received mepivacaine 1% with 2 mL saline, the second group received mepivacaine 1% with 100 mg tramadol, and the third group received mepivacaine 1% with 2 mL saline and 100 mg

TABLE 9–2. Studies examining buprenorphine as an analgesic adjuvant with local anesthetics.

Author/ Date	Patients/ Groups	Block Type	Dose	Local Anesthetic	Systemic Control	Results
Viel[23] 1989	20/2	Supraclavicular	3 mcg/kg	Bupivacaine 0.5% 40 mL	No	Prolonged analgesia compared to morphine group (35 vs. 18.25 h); no difference in sensory block.
Bazin[24] 1997	89/4	Supraclavicular	3 μg/kg	Bupivacaine 0.5%	No	Prolonged analgesia compared to control group (20 vs. 11.5 h)
				Lidocaine 1%		
Candido[22] 2001	40/2	Supraclavicular	0.3 mg	Mepivacaine 1%	No	Prolonged analgesia compared to control group (17.4 vs. 5.3 h)
				Tetracaine 0.2%		
Candido[21] 2002	60/3	Axillary	0.3 mg	Mepivacaine 1%	Yes	The mean duration of postoperative analgesia was 22.3 h in axillary group vs. 12.5 h in IM group and 6.6 h in placebo group.
				Tetracaine 0.2%	IM	

IM = intramuscular

tramadol intravenously. This study demonstrated an increased duration of motor and sensory blockade in the axillary tramadol group that significantly ($p < .01$) outlasted both an intravenous and a placebo group. Robaux and colleagues[27] subsequently performed a dose-response study with placebo and 40-, 100-, and 200-mg doses of tramadol added to a fixed dose of mepivacaine 1.5% in axillary block and found that the 200-mg dose provided the best analgesia with no increased adverse effects. Alemanno and colleagues used a 1.5-mg/kg dose of tramadol as an adjuvant to 0.5% levobupivacaine (0.5 mL/kg) for interscalene block.[28] Here, 120 patients were divided into three groups: One group received local anesthetic alone, the second group received local anesthetic with systemic tramadol, and the third group received local anesthetic with perineural tramadol. While both groups receiving tramadol experienced prolonged analgesia compared to placebo, the group receiving perineural tramadol experienced prolonged analgesia compared to systemic tramadol (14.5 vs. 10.1 hours; $p < .001$).[28]

Intra-articular Opioids and Other Peripheral Routes of Administration

Opioid agonists administered into inflamed tissue will bind to opioid receptors on sensory terminals and induce analgesia. Animal studies indicated that these peripheral opioid receptors are expressed 96 hours after the initial inflammatory injury.[11] Intra-articular administration of opioids will therefore only produce analgesia in patients with preexisting inflammation. Kalso and coworkers[29] systematically examined the role of intra-articular opioids in 1997 and established that there existed evidence for a prolonged benefit from intra-articular morphine without significant adverse effects at doses of 1 to 5 mg. No dose response was detected. Recent articles supported this finding and showed the benefit of intra-articular morphine,[30,31] tramadol,[32] buprenorphine,[33] and sufentanil.[34] However, a systematic review of the effects of intra-articular morphine demonstrated only a mild analgesic effect [visual analogue scale for pain (VAS) 12–17 mm reduction] but could not exclude that the effect was mediated by systemic absorption.[35]

ALPHA$_2$-AGONISTS AND CLONIDINE

Clonidine is an α_2-agonist with some α_1-stimulatory effects. It has traditionally been used as an antihypertensive agent and has been noted to have sedative and analgesic effects for many years. More recently, it was determined that α_2-receptors exist in the dorsal horn of the spinal cord, and stimulation of these receptors produces analgesic effects by inhibiting the presynaptic release of excitatory transmitters, including substance P and glutamate.[36–38] Intrathecal clonidine mediates analgesia by increasing acetylcholine levels, which in turn stimulates muscarinic receptors. Muscarinic excitation increases γ-amino butyric acid levels onto the primary afferent fiber, inhibiting the release of the excitatory neurotransmitter glutamate.[39]

Clonidine injected close to peripheral nerves with or without local anesthetic drugs appears to mediate analgesia in a number of ways. Clonidine has local anesthetic properties[40] and tonically inhibited compound action potentials of C fibers greater then A-α fibers in rat sciatic nerve and was comparable to lidocaine in its ability to inhibit C fibers in rabbit vagus nerve.[40,41] Clonidine also has a pharmacokinetic effect on local anesthetic redistribution mediated by a vasoconstrictor effect at the α_1-receptor.[42] Recent animal models have demonstrated and supported earlier work that clonidine predominantly facilitates peripheral nerve block through hyperpolarization-activated cationic current and that this effect is independent of any vasoconstrictor effect.[43]

A more recent addition to the selection of α_2-agonists is dexmedetomidine, which is selective for the α_2-receptor and which at present is mainly studied as a sedative agent in intensive care units. Dexmedetomidine may be expected to produce not only more profound analgesia but also greater adverse effects because of the selectivity of action.

Stimulation of the α_2-receptor produces hypotension, bradycardia, and sedation at higher doses, and these effects may outweigh any analgesic benefits produced by the use of these agents.

Perineuronal Application

Over 30 studies in humans have now examined the effect of clonidine on local anesthetics in peripheral nerve block. There is good evidence from these studies that clonidine in doses up to 1.5 μg/kg prolongs sensory block and analgesia when administered with local anesthetics for peripheral nerve block. This supports the early opinion of Murphy and colleagues[13] that clonidine is a beneficial adjuvant when added to peripheral nerve block and that the effect is most likely mediated in the PNS.

Although a number of studies have examined the effect of clonidine added to peripheral nerve block, only a few have controlled for a systemic effect. Singelyn and coworkers[44] evaluated 30 patients receiving an axillary brachial plexus block with 40 mL of 1% mepivacaine plus epinephrine 5 μg/mL. Patients were randomized to three groups and received (1) local anesthetic alone, (2) local anesthetic plus 150 μg of clonidine administered subcutaneously, or (3) 150 μg of clonidine in the brachial plexus block with local anesthetic. Clonidine added to the axillary brachial plexus block delayed the onset of pain twofold, without adverse effects when compared with systemic control.

Hutschala and coworkers[45] have recently demonstrated the peripheral analgesic effect of clonidine in volunteers when added to brachial plexus block with 0.25% bupivacaine. However, other recent studies demonstrated no overall benefit of adding clonidine to long-acting local anesthetics such as bupivacaine and ropivacaine.[46]

More recently, a meta-analysis by Popping and colleagues estimated that clonidine prolonged postoperative analgesia, sensory block, and motor block by 122, 74, and 141 minutes, respectively.[47] Clonidine, however, also increased the probability of hypotension (odds ratio [OR] 3.61), fainting (OR 5.07), sedation (OR 2.28), and bradycardia (OR 3.09). There was no observed dose response between a range of 30 and 300 μg, with the majority receiving 150 μg.

The addition of clonidine to continuous peripheral nerve blocks is not beneficial. Ilfeld and colleagues[48,49] have demonstrated in two studies that both 0.1 and 0.2 μg/mL of clonidine added to a continuous infusion of ropivacaine 0.2% failed to reduce pain scores or oral analgesic use after upper extremity surgery.

Dexmedetomidine, as previously postulated, does indeed produce a more profound effect on analgesia when applied perineurally in conjunction with local anesthetics. Four studies have recently examined this, and a meta-analysis suggested that dexmedetomidine prolongs the analgesic effects of brachial plexus blocks by 284 minutes. Interestingly, despite initial concerns that dexmedetomidine may have greater hemodynamic effects than clonidine, this does not appear to be the case.[50]

Intravenous Regional Anesthesia

Intravenous regional anesthesia is a useful, simple regional anesthetic technique especially for minor peripheral upper limb procedures that is limited by tourniquet tolerance and poor postoperative analgesia. Clonidine has been demonstrated in a number of studies to improve onset time[51] and intraoperative tourniquet tolerance.[52–54]

Only one study has demonstrated improved postoperative analgesia in the early postoperative period compared with placebo. Reuben and coworkers[49] randomized 45 patients to 40 mL 0.5% lidocaine with clonidine 1 μg/kg, lidocaine alone with intravenous clonidine, and lidocaine alone with intravenous saline. Patients who were given clonidine with lidocaine experienced significantly less pain and requested fewer analgesics then patients in the other two groups. Higher doses of clonidine (150 μg) produced significantly more sedation and incidence of hypotension.[52]

To date only one study has used dexmedetomidine in IVRA. Memis and colleagues[55] added 0.5 μg/kg of dexmedetomidine to 0.5% lidocaine and demonstrated reduction in onset time and improvement in postoperative analgesia compared with placebo with no significant adverse effects.

Intra-articular Techniques

The intra-articular effect of clonidine has been examined when administered with[56] and without local anesthetic[57–59] and been found to have beneficial effects on postoperative analgesia. The addition of morphine and clonidine may be expected to have additive effects. Two studies have examined this question, with one demonstrating improved analgesia[57] and the other no difference.[59]

Preclinical trials have demonstrated that, similar to opioids, clonidine-mediated analgesia is enhanced by inflammation, although at the present time the mechanism is not evident.[60]

DEXAMETHASONE

Dexamethasone is a potent synthetic corticosteroid with approximately seven times the anti-inflammatory potency of prednisolone[61] and very little mineralocorticoid activity. The half-life is approximately 36 to 54 hours in the perioperative setting. The effectiveness of dexamethasone as a postoperative antiemetic (4 to 10 mg intravenously) has been confirmed by over 60 randomized controlled trials, with a recent meta-analysis estimating on OR of 0.31 and a 3.7 number needed to treat (NNT).[62] Given its systemic anti-inflammatory properties, the analgesic effects of a single preoperative intravenous dose of dexamethasone have been investigated in over 24 randomized trials with modest effects up to 24 hours.[63] This meta-analysis, published in 2011, included 2751 patients and estimated that verbal rating scale for pain (VRS) scores were reduced to a maximum of 0.64 points up to 24 hours after dexamethasone administration.

Prior to these reviews, in vitro and murine studies of the specific pharmacologic action of dexamethasone yielded several novel applications in addition to systemic administration.

Perineural Application

Perineural corticosteroids are thought to exert their effect by several mechanisms, including attenuating the release of inflammatory mediators, reducing ectopic neuronal discharge, and inhibiting potassium channel–mediated discharge of nociceptive C fibers.[64–66] It is widely believed that dexamethasone improves the quality and duration of peripheral nerve blockade when administered in conjunction with local anesthetics. The US Food and Drug Administration (FDA) (or any other regulatory body), however, does not approve dexamethasone for perineural administration.

Nonetheless, multiple studies have assessed the effects of combining dexamethasone (4 to 10 mg) with local anesthetic for peripheral nerve blocks.[67–73] Upper and lower extremity peripheral nerve blocks performed with dexamethasone demonstrated prolongation of analgesia or sensory/motor block ranging from approximately 50% to 75% beyond that performed with local anesthetic alone.

Only one study to date has compared perineural to systemic dexamethasone in the context of peripheral nerve blocks.[73] This study randomized patients to interscalene brachial plexus block with placebo or 8 mg of perineural or systemic dexamethasone. The authors demonstrated block prolongation in both dexamethasone groups from 12 hours to approximately 20 and 22 hours for systemic and perineural administration, respectively, and concluded that systemic and perineural dexamethasone administration were equivalent. Further study is required comparing the effects of perineural and systemic dexamethasone before final conclusions can be drawn.

Concerns over complications related to dexamethasone, such as effects on blood glucose and neurotoxicity from the preservative used in multidose vials, have not been apparent in practice. In particular, a single dose of dexamethasone, whether administered perineurally or systemically, did not increase blood glucose to a clinically significant degree.[73–75] Murine studies of sodium bisulfite demonstrated no neurotoxicity with intrathecal administration.[76]

Intravenous Regional Anesthesia

Bigat and colleagues investigated the effects of adding dexamethasone to lidocaine IVRA in a randomized trial.[77] Seventy-five patients were randomized to lidocaine with placebo, 8 mg of dexamethasone with lidocaine, or 8 mg of systemic dexamethasone. In this study, systemic dexamethasone exerted no effect on the efficacy of IVRA, while lidocaine plus dexamethasone demonstrated improved block characteristics.

N-METHYL-D-ASPARTATE RECEPTOR ANTAGONISTS

Within the dorsal horn of the spinal cord both ionotropic [*N*-methyl-D-aspartate (NMDA)], α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA), kainic acid (KA), and metabotropic glutamate receptors are involved in nociceptive signaling and central sensitization in conditions of chronic pain.[78–90] Recently, multiple glutamate receptors have been found in peripheral nerve terminals and may contribute to peripheral pain signaling.[81] Injection of the NMDA receptor agonist glutamate into masseter muscle produces pain in both rats and humans.[82,83] Subsequent injection of NMDA receptor antagonists such as ketamine and dextromethorphan attenuates the pain.[84]

A number of studies have examined the effect of NMDA antagonists in producing peripherally mediated analgesia in patients. Tverskoy and colleagues[85] infiltrated bupivacaine with 0.3% ketamine or placebo for patients having inguinal herniorraphy and found that ketamine significantly enhanced the anesthetic and analgesic actions of a local anesthetic administered for infiltration anesthesia. Ketamine has been used as the sole anesthetic in IVRA, but patients suffered excessive adverse effects on tourniquet deflation.[86] Other workers have added ketamine (0.1 mg/mL) or clonidine (1 μg/kg) to lidocaine for IVRA.[87] Patients in the ketamine group had the best pain control, although both clonidine and ketamine significantly reduced analgesic consumption compared with lidocaine alone, with mild psychomimetic side effects in the ketamine group.

Two studies have examined the use of intra-articular ketamine. Dal and coworkers[88] randomized patients to intra-articular ketamine (0.5 mg/kg), neostigmine, bupivacaine, or placebo. Patients receiving all three drugs had similar improvements in analgesia with knee flexion compared with placebo; however, the ketamine group had the longest duration of analgesia. Brill and colleagues[89] performed a dose-response study using up to 1 mg/kg intra-articular ketamine after knee arthroscopy and found that the analgesic benefit only occurred in the first hour after surgery compared with placebo.

Magnesium has NMDA-blocking effects and blocks the ion channel on the NMDA receptor during normal physiologic states. Persistent nociceptive input in the dorsal horn of the spinal cord removes magnesium, allowing calcium influx and intracellular changes leading to persistent pain states.[80]

Turan et al[90] exploited this analgesic potential in the PNS by adding 1.5 g magnesium to lidocaine 0.5% for IVRA. Magnesium reduced onset time and significantly prolonged analgesic effect up to 6 hours after surgery with no difference in adverse effects.

Overall, NMDA antagonists may have significant potential for producing peripherally mediated analgesia in the future, although currently available agents (except magnesium in IVRA) have limited effects and at higher doses produce excessive adverse effects.

CYCLOOXYGENASE INHIBITION

Prostaglandins sensitize peripheral nerve endings to the effects of endogenous chemical mediators released during tissue injury. NSAIDs inhibit the production of prostaglandins through their well-known effect of inhibiting cyclooxygenase (COX). Application of NSAIDs directly in the PNS would therefore appear to make sense as a means of reducing pain by peripheral mechanism.

Intravenous Regional Anesthesia

A number of authors have added ketorolac to IVRA in doses from 5 to 60 mg, producing an improvement in intraoperative tourniquet tolerance and postoperative analgesia.[90] Steinberg and colleagues[91] performed a dose-response study with ketorolac in IVRA using placebo, 5-, 10-, 15-, 20-, 30-, and 60-mg doses of ketorolac. It was found that 20 mg was the ideal dose, with lower doses producing less analgesia and higher doses being no more effective.

Lysine acetylsalicylic acid 90 mg (equivalent to 50 mg acetylsalicylic acid) has been added to prilocaine for IVRA with prolongation of postoperative analgesia.[92]

Intra-articular Administration

The use of ketorolac alone, with local anesthetic or local anesthetic and morphine, is no more effective then local anesthetic alone when administered in the intra-articular space.

Infiltration

Ketorolac has been successfully infiltrated in a dose of 30 to 60 mg following hernia repair, giving an effect similar to infiltration with bupivacaine. However, local infiltration was found to be no more effective than systemic administration.[93–97]

CHOLINERGIC ANALGESIA

Muscarinic receptors mediate analgesia in the dorsal horn of the spinal cord, and neostigmine has produced analgesia when administered to both the intrathecal and epidural space.

Neostigmine has also been applied in the PNS in a number of studies, with generally disappointing results. Van Elstraete and coworkers[98] and Bone and colleagues[99] added neostigmine 500 μg to local anesthetic in axillary brachial plexus block. One study demonstrated no difference,[97] and the other found only significant reduction in pain at 24 hours, with no difference at other time points.[98]

Neostigmine added to local anesthetic for IVRA has also been disappointing. Turan and coworkers[100] added 500 μg neostigmine to prilocaine 0.5% and found improvement in sensory and motor block onset and offset with prolonged time to first analgesic request. However, McCartney and colleagues[101] performed a similar study using neostigmine 1 mg added to lidocaine 0.5%, with no differences found between groups. Overall, neostigmine appears disappointing as an analgesic adjuvant for peripheral nerve block or IVRA.

Neostigmine, however, has been used successfully as an analgesic adjuvant for intra-articular use after knee arthroscopy.[88,101–103] Yang and coworkers[102] performed a dose-response study and found 500 μg to be most effective, which was more effective than 2 mg of intra-articular morphine.

The effectiveness of the intra-articular cholinergic analgesic pathway compared with the poor results with perineuronal application may be related to the presence of the inflammatory response in the intra-articular space, increasing the analgesic efficacy of acetylcholine by a mechanism that is yet to be defined.

TABLE 9–3. Best analgesic adjuvants in the peripheral nervous system by route of administration.

Route	Agent and Dose
Perineuronal/ perineural	Dexamethasone 4–10 mg; buprenorphine 0.3 mg; clonidine 1–2 μg/kg; tramadol 200 mg
IVRA	Dexmedetomidine 0.5 μg/kg; magnesium 1.5 g
Intra-articular	Clonidine 150 μg; morphine 5 mg
Local infiltration	Ketamine 3 mg/mL

SUMMARY

Peripheral nerve blocks provide significant anesthetic and analgesic benefits for our patients. Analgesic adjuvants such as opioids, α_2-agonists, NMDA receptor antagonists, and other agents can be added to local anesthetics both to facilitate onset and to prolong anesthetic and analgesic effects by mechanisms existing in the PNS. Several agents are effective when administered in the perineuronal or intra-articular space and when given in IVRA or local infiltration (Table 9–3). The effect size of each particular adjuvant is variable, with dexamethasone producing the largest effect size.

Our evolving knowledge of nociceptive mechanisms in the PNS will allow novel techniques to be developed in the future to further improve pain management.

CHAPTER 10

Local Anesthetic Mixtures for Peripheral Nerve Blocks

Jason Choi and Jeff Gadsden

INTRODUCTION

Peripheral nerve blocks (PNBs) provide numerous advantages for surgical patients when used either as an analgesic supplement or as an alternative to general anesthesia. These advantages include superior pain control and avoidance of adverse effects associated with volatile anesthetics and opioids.[1] However, the benefits of PNBs are limited by the pharmacodynamics of the local anesthetic agents injected. Analgesia provided by PNBs lasts only as long as the duration of action of the local anesthetic at specific tissue sites. Typically, local anesthetics are characterized according to their latency ("onset time") and duration of action. For practical clinical purposes, local anesthetics can be grouped into one of three categories: (1) rapid onset and short duration (eg, chloroprocaine, procaine); (2) rapid onset and intermediate duration (eg, lidocaine, mepivacaine); and (3) slower onset and long duration (eg, bupivacaine, ropivacaine, tetracaine).[2]

An ideal local anesthetic for a PNB would have a fast onset coupled with a long duration and low toxicity.[3] At present, no such drug exists. In an attempt to achieve a single-injection PNB with characteristics close to ideal, mixtures of local anesthetics (most commonly, faster-onset, intermediate-duration local anesthetic and slower-onset, long-duration local anesthetic) for PNBs have been used clinically and have remained a common practice for over a century.[3–6] While compounding two drugs to obtain the "best" features of each is compelling, few studies have objectively examined the pharmacodynamics of mixtures of local anesthetics. Moreover, because many of the existing studies were conducted before the era of ultrasound guidance, it is difficult to extrapolate those data to current practice given the reduced volumes and doses of local anesthetic ultrasound guidance affords. This chapter examines the evidence base for utilizing local anesthetic mixtures for PNBs and summarizes the advantages and disadvantages of mixing local anesthetics. This chapter does not address the eutectic mixture of lidocaine and prilocaine used for topical analgesia.

PHARMACODYNAMICS OF LOCAL ANESTHETICS

In clinical practice, local anesthetics are described according to their clinical properties: potency, duration, latency, and toxicity. These clinical properties are not independent and are determined by each local anesthetic's structural, stereochemical, and physicochemical properties, such as pK_a, lipid solubility, and molecular weight (Table 10–1).

Latency is largely determined by pK_a and lipid solubility. The more nonionized drug present at the lipid membrane of the nerve, the more of the drug that can permeate to the sodium channel inside the axon. As such, drugs with lower pK_a's tend to have shorter latencies—for example, lidocaine (pK_a 7.8) has a faster onset than bupivacaine (pK_a 8.1). Local anesthetics with lower lipid solubilities tend to also have a prolonged latency (eg, bupivacaine and ropivacaine are far more lipid soluble than lidocaine). It may be difficult to predict latency based on a sole factor, as the individual factors combine to provide an overall latency. For example, two of the fastest local anesthetics are exceptions to the rules, as chloroprocaine has a high pK_a and etidocaine is highly lipid soluble. Molecular weight is often referred to as an important factor affecting latency, as smaller molecules have faster aqueous diffusion rates. Practically, however, local anesthetics have roughly similar molecular weights.

Duration of action is associated with the lipid solubility of the local anesthetic. This is due to a greater affinity of the drug to lipid membranes and, therefore, greater proximity to its sites

TABLE 10–1. Physicochemical properties of commonly used local anesthetics.

	Molecular Weight (Da)	pK_a (at 25°C)	Nonionized at pH 7.4 (%)	Octanol/Buffer Partition Coefficient (Lipid Solubility)	Protein Binding (%)
Chloroprocaine	271	9.0	5	810	[a]
Tetracaine	264	8.5	7	5822	94
Lidocaine	234	7.8	24	366	64
Mepivacaine	246	7.7	39	130	77
Ropivacaine	262	8.2	17	775	94
Bupivacaine	288	8.1	17	3420	95

[a]The percentage protein binding of chloroprocaine is unknown.

of action. The longer the drug remains in the vicinity of the membrane, rather than being absorbed, the longer the effect on the Na^+ channel in the membrane. Greater lipid solubility also increases potency and therefore toxicity, decreasing the therapeutic index for highly lipophilic drugs. At standard pH and body temperature, bupivacaine has an aqueous solubility of 0.83 mg HCl salt/mL, compared to 15 mg HCl salt/mL for mepivacaine and 24 mg HCl salt/mL for lidocaine, and is therefore much more lipophilic than these two drugs with intermediate duration.[7]

Clinical Pearl

- A common misconception is that block duration is related to protein binding. In fact, dissociation times of local anesthetics from Na^+ channels are measured in seconds and do not have a bearing on the speed of recovery from the block. More important is the extent to which local anesthetic remains in the vicinity of the nerve. This is determined largely by three factors: lipid solubility, the degree of vascularity of the tissue, and the presence of vasoconstrictors that prevent vascular uptake.

LATENCY AND DURATION OF MIXTURES OF LOCAL ANESTHETICS

Early Investigations and Landmark-Based Techniques

Despite decades of clinical use of various local anesthetic combinations for PNBs, little has been published about the clinical properties of local anesthetic mixtures, with surprisingly few randomized controlled trials comparing specific local anesthetic mixtures versus single agents. As a resultant, substantial controversy still exists regarding advantages and disadvantages of various mixtures, and there are few available data to guide clinical practice.

In 1972, Moore et al reported on the safety and efficacy of a combination of tetracaine with several intermediate-duration local anesthetics, such as lidocaine, mepivacaine, and chloroprocaine, in a retrospective analysis of over 10,000 regional anesthetic procedures.[3] Compared to rapid-onset local anesthetics alone, the onset of action of the local anesthetic mixture was unchanged by the addition of tetracaine, whereas the duration of action of the intermediate-duration local anesthetic was prolonged with the addition of tetracaine. In this report, however, the duration of the mixture was shorter than that of tetracaine alone. The authors suggested that the mixing of local anesthetics confers the optimal characteristics of each component for a single-dose technique. However, this retrospective study was limited both by the large variability of techniques and surgical procedures that were included and by the focus on epidural and spinal techniques. PNBs made up only a small minority of the data and consisted of a heterogeneous mix of PNBs.

Bromage and Gertel combined carbonated lidocaine 1% with bupivacaine 0.25% with epinephrine to perform supraclavicular brachial plexus blocks and compared the combination to single agents.[8] Again, latency of the mixture compared to bupivacaine alone was reduced but duration of action was compromised by up to 100 minutes, resulting in rapid block onset but moderate duration. However, the inconsistency in methodology between the two groups limits the interpretation of the data and its applicability to current practice. Although 60 mL total volume was used in the mixture group, only 25 to 50 mL of volume was used in the groups with a single local anesthetic.

Most of the earlier studies of local anesthetic mixtures involved epidural analgesia. Yet, there are few data, and much of these data are difficult to interpret due to methodological inconsistencies. Defalque et al in 1966 reported that, for mixtures of local anesthetics for epidurals in dogs, the mixture properties depended on the ratios of each component.[9] Latency was determined by the faster-acting component, while duration tended to reflect but did not equal the longer-acting component. The authors concluded that shorter latency comes at the expense of shorter duration than a single long-acting agent alone. Moreover, duration of the local anesthetic mixture varied and was less predictable.

Cohen et al compared epidural chloroprocaine 3% versus bupivacaine 0.5% versus an equal mixture of chloroprocaine 1.5% and bupivacaine 0.375% for labor analgesia and observed the latency and duration.[10] All three groups had similar onset times and block quality, although the bupivacaine 0.5% group had an extended time to two-segment regression compared to the other groups. In a separate study, Raj et al compared a mixture of chloroprocaine and bupivacaine to lidocaine and bupivacaine in both epidural and brachial plexus block models and found that latency was similar, although the authors pointed out that the plasma concentrations of chloroprocaine were significantly less, which may offer a safety advantage.[11] However, duration of action for either group was not measured. The authors suggested that chloroprocaine and bupivacaine act independently of each other, providing analgesia with rapid onset and long duration, but no reference or data were cited to substantiate this claim.

Seow et al randomized patients undergoing abdominal surgery to receive various ratios of lidocaine 2% and bupivacaine 0.5% (eg, ratios of 3:1, 2:2, 1:3), as well as each drug alone, by epidural administration.[12] Somewhat surprisingly, no difference in either latency or duration of action was observed when mixing bupivacaine 0.5% or lidocaine 2% versus either alone, although there was a slight trend toward prolonged duration in the bupivacaine alone group.

In the first randomized trial comparing a local anesthetic mixture with an individual agent, bupivacaine 0.5% was compared to a mixture of chloroprocaine 3% and bupivacaine 0.5% for axillary brachial plexus blocks in 25 subjects undergoing arm surgery.[13] In this case, the authors reported latency reductions of almost 50% with addition of chloroprocaine compared to bupivacaine alone. In addition, bupivacaine's latency was less predictable and with greater variation. Surprisingly, there was no difference in sensory duration between the two groups. However, the study was limited by its small sample size and the lack of a control group of chloroprocaine alone. It is important to note that unequal volumes of the compounded agents were used (10 mL of chloroprocaine and 20 mL of bupivacaine). This may limit the comparison of these results to other studies where 1:1 mixtures are used.

More recently, a double-blind, randomized, controlled trial involving equal volume mixtures of bupivacaine 0.5% or ropivacaine 0.75% with lidocaine 2% versus long-acting agents alone for both femoral and sciatic nerve blocks in patients undergoing lower extremity surgery reported significantly shorter latency by 33% to 50% with mixtures containing lidocaine.[14] Consistent with the majority of prior studies, equal-volume mixtures of lidocaine 2% with bupivacaine or ropivacaine resulted in significantly shorter duration than bupivacaine or ropivacaine alone by up to 4 to 9 hours. Interestingly, no significant decrease in postoperative analgesic requirements was found when comparing the three groups.

Although not considered a PNB, retrobulbar block performed using 2% lidocaine, 0.5% bupivacaine, or a 1:1 mixture of both resulted in identical latency of analgesia and eyeball akinesia, as well as first report of pain postoperatively following vitreoretinal surgery.[15]

The Age of Ultrasound

The use of ultrasound has a significant effect on PNB pharmacodynamics, with the majority of studies demonstrating decreased time to block onset and improved block success rates compared to landmark-based techniques.[16] The first randomized controlled trial to evaluate combinations of short- and long-acting local anesthetic with ultrasound-guided PNBs compared a mixture of 15 mL of mepivacaine 1.5% with 15 mL bupivacaine 0.5% compared to equal volumes (30 mL) of bupivacaine 0.5% or mepivacaine 1.5% alone for interscalene block.[17] All three groups demonstrated similar onset times, whereas duration was variable: Mepivacaine alone had the shortest duration, bupivacaine alone had the longest duration, and the mixture group had an intermediate duration. The authors concluded that there is no tangible benefit to mixing these two local anesthetics for ultrasound-guided interscalene block, and that individual agents should be chosen on the basis of desired duration. For example, at our institution we typically use mepivacaine 1.5% alone for arteriovenous (AV) fistula creation, a procedure with limited postoperative pain intensity; bupivacaine 0.5% is frequently used for rotator cuff repair, where a prolonged duration of quality analgesia is required. The authors did note that 30 mL is a volume larger than normally given for interscalene brachial plexus block (ISBPB) and may account for the lack of difference in onset of block. Another potential factor in a lack of difference in onset is the possibility that the local anesthetic was more precisely placed in the interscalene sheath with ultrasound guidance compared to landmark techniques, effectively reducing any previously observed differences in time for the local anesthetic to diffuse across fascial planes and exert its effect. Of note, the mepivacaine group did have significantly greater predilection for block of the inferior trunk, which landmark-based interscalene brachial plexus block is known to variably cover.[18] The authors hypothesized that the hydrophilic nature of mepivacaine may have resulted in greater spread and thus more complete coverage of the brachial plexus.

The same group of investigators followed this study by comparing sequencing rather than mixing of local anesthetic to see if any differences were detectable by administering short-acting local anesthetic (mepivacaine 1.5%) before long-acting local anesthetic (bupivacaine 0.5%) during interscalene brachial plexus block or vice versa.[19] The rationale for this frequently used clinical sequencing seems logical, if unsubstantiated: Exposing roots and trunks of brachial plexus first to a solution of mepivacaine before injecting bupivacaine could result in the faster onset of interscalene block (ISB) (characteristics of the intermediate-acting drug), while the long-acting local anesthetic would provide a longer duration of action than the intermediate-acting drug alone. As reported by these authors, the onset times and duration for both groups were identical, showing that, if a mixture *is* administered, it does not matter which drug is injected first or last (Figures 10–1 and 10–2).

In the only other study using ultrasound guidance of PNB to investigate properties of local anesthetic mixtures, Laur et al compared 40 mL of bupivacaine 0.5% and 40 mL of mepivacaine 1.5% with an equivalent volume combination of each (total 40 mL) during ultrasound-guided infraclavicular block.[20] They reported that latencies were equal for the mepivacaine and mixed group and longer for the bupivacaine group. Similar to the studies by Gadsden et al, duration of action of the mixed group was shorter than bupivacaine alone, but longer than mepivacaine alone. The duration of sensory and motor block in the mixture group seemed unpredictable, with a wide range among subjects, echoing previous studies[9]. Another interesting finding was the substantially higher failure of blocks in the bupivacaine group, despite the same practitioners

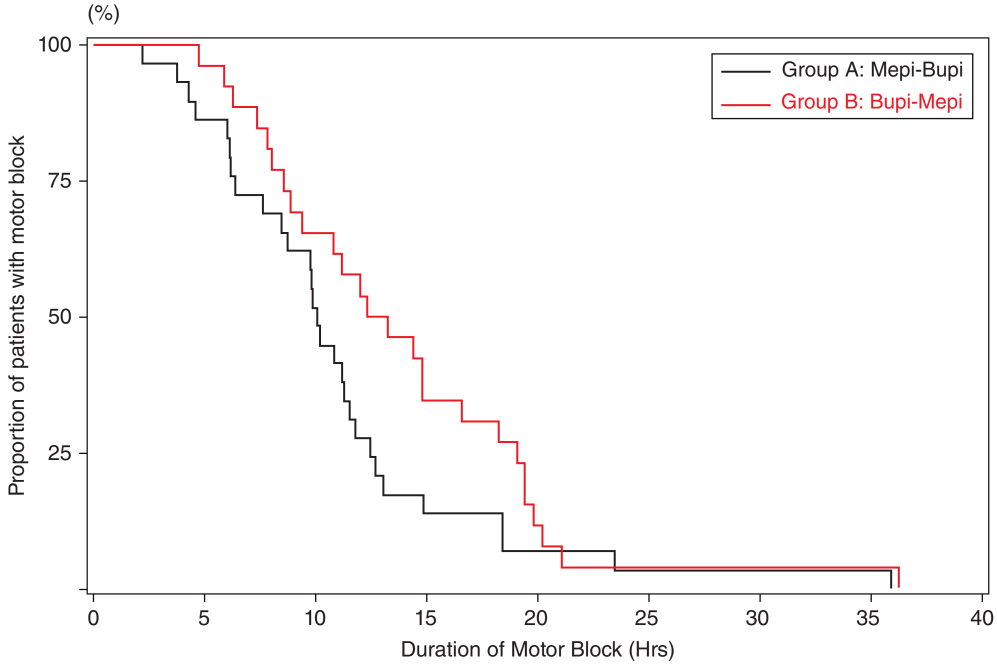

FIGURE 10–1. Decay curve showing proportion of patients with a motor block following administration of mepivacaine followed by bupivacaine (Group A: Mepi-Bupi) versus bupivacaine followed by mepivacaine (Group B: Bupi-Mepi).

and technique. With the use of ultrasound, onset time of PNBs appeared to be significantly less than observed in prior studies. While Laur et al demonstrated a significant difference in onset time of roughly 30%–50%, sensory onset was achieved by 12 minutes versus 6 minutes in 75% of subjects in the bupivacaine versus other groups. The controversy remains if this is a clinically relevant difference. Moreover, the question must be asked if an advantage of less than 10 minutes in latency justifies a roughly 50% reduction in duration.

Clinical Pearl

- For ultrasound-guided brachial plexus blocks, mixing short- and long-acting local anesthetics appears to have little influence on speed of onset. However, blocks performed with such a mixture will not last as long as a similar volume block performed with long-acting local anesthetic alone.

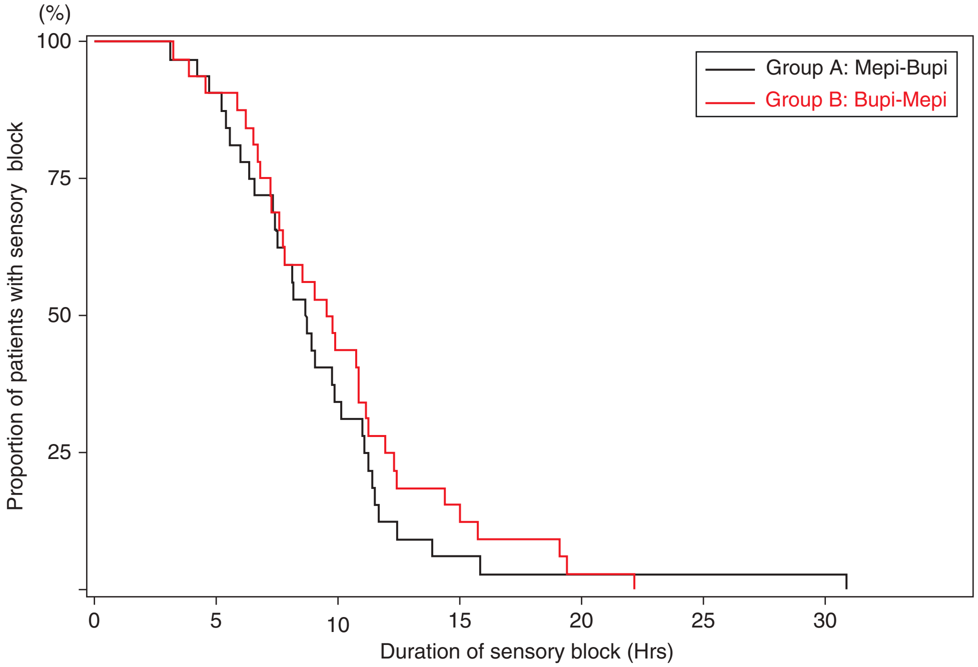

FIGURE 10–2. Decay curve showing proportion of patients with a sensory block following administration of mepivacaine followed by bupivacaine (Group A: Mepi-Bupi) versus bupivacaine followed by mepivacaine (Group B: Bupi-Mepi).

Overall, the evidence, with different methodologies, lack of standardization of technique, and various volumes, is difficult to extrapolate and apply clinically. While these more recent ultrasound-guided studies offer the most insight regarding current clinical practice, additional randomized trials of specific PNBs are needed to draw any conclusions.

Local Anesthetic Systemic Toxicity and Mixtures

Concern over systemic toxicity of local anesthetics grew primarily due to increasing numbers of toxic complications from bupivacaine used in regional anesthesia. Bupivacaine's elevated cardiac toxic potential highlighted a need for safer local anesthetic practices. Therapeutic and toxic windows are different for each local anesthetic. In particular, bupivacaine exhibits a narrow therapeutic window that has all too often led to local anesthetic systemic toxicity (LAST) and devastating consequences.

One of the theoretical advantages of compounding local anesthetics was decreased toxicity. By reducing the dose of each local anesthetic used, toxic levels of any individual drug should be decreased compared with a larger dose of each alone, which appears to be the case.[21] In a report of over 10,000 interventions, most of which involved neuraxial techniques, Moore et al showed mixtures of local anesthetics to be safe, and without increased risk of toxicity versus single agents alone, supporting the safety of admixing local anesthetic agents.[3]

However, toxicity of local anesthetic is additive,[22] and the calculation of the dose of each drug in a mixture required to avoid toxicity is unclear. Daos et al used a small-animal model to compare local anesthetic mixtures on the incidence of cardiotoxicity. These authors found that the addition of tetracaine to procaine, chloroprocaine, mepivacaine, or lidocaine reduced the time to cardiac arrest significantly, in some cases by 75%.[23] Another study investigated the possible synergistic or antagonistic role of amide-amide and amide-ester local anesthetic combinations in rats and determined that there was no evidence of either—the use of admixed local anesthetics resulted in the same additive toxic risk as if either parent drug had been administered sequentially.[24]

While cardiovascular adverse events are uncommon and ropivacaine and lidocaine are both considered to be relatively safe local anesthetics with clinically appropriate dosages, Reinikainen et al reported sudden cardiac arrest in a 97-kg young patient immediately following a landmark-based interscalene brachial plexus block.[25] The local anesthetic mixture used consisted of ropivacaine (150 mg) and lidocaine with epinephrine (360 mg), which represent 52% and 53% of the maximum recommended weight-based doses (3 mg/kg and 7 mg/kg), respectively. This highlights that, although each drug was under the maximum recommended limits, the total combined delivered dose was 105% of the recommended maximum. It is noteworthy that the use of epinephrine did not prevent this complication, neither in its role as an intravascular marker nor as a means to truncate the peak plasma concentration, further highlighting the need to carefully monitor dosages.

Clinical Pearl

- Local anesthetic toxicity is additive. When mixing local anesthetics, individual fractional contributions to overall maximum recommended dose limits should be considered.

To what extent these reports apply to the modern practice of regional anesthesia is unclear. In current clinical practice with ultrasound-guided regional anesthesia, much smaller volumes and doses are being used compared to the practice a decade ago. For instance, interscalene brachial plexus blocks can be achieved with as little as 5–7 mL compared to 40 mL historically.[26] Although the reality of most clinical practices lies somewhere in between, local anesthetic doses have dramatically decreased and are well under the recommended maximum limits, and there is now evidence that ultrasound guidance significantly reduces LAST compared to landmark-based techniques.[27]

Anatomical Considerations

Anatomical considerations must be considered in the examination of the latency and duration of PNBs, as it can have a significant effect on characteristics of individual PNBs. The popliteal sciatic nerve block is one particular instance for which anatomy and location of local anesthetic deposition significantly determine nerve block characteristics, as the components of the sciatic nerve in this location are surrounded by a tough connective tissue paraneural sheath. Recently, ultrasound-guided popliteal nerve blocks performed within the paraneural sheath have been shown to result in a more rapid onset compared to techniques where local anesthetic is placed outside the sheath, probably due to an increased exposure of the nerve's surface area to local anesthetic.[28,29] For this reason, latency for nerve blocks that rely on placement of local anesthetic within a sheath may have more to do with technique than choice of local anesthetics.[17,19] However, more studies are needed to corroborate these findings. No study to date has compared latency of various local anesthetics and their mixtures using ultrasound-guided intraneural injections at the popliteal sciatic nerve.

SUMMARY

The ideal local anesthetic for single-dose PNB with short latency and long duration has yet to be developed. Local anesthetic mixtures have long been used for PNBs in an attempt to create improved pharmacodynamics. However, interpreting the literature on this topic is difficult because (1) the literature is relatively scant and spread out over six decades; (2) the methodology is heterogeneous, with varying combinations of block locations, drug combinations, and evaluative methods; and (3) the results are somewhat conflicting. However, in considering the more recent, and especially the ultrasound-guided, PNB studies, a pattern emerges that suggests that latency is not significantly affected when high-potency, long-acting agents are admixed with low-potency, short-acting agents. At the same time, duration of neural blockade appears to suffer when bupivacaine alone is mixed with a shorter-acting agent.

With the precision of ultrasound-guided PNBs, latency of block onset is less an obstacle than duration. Duration of block is the most important determining characteristic in choosing local anesthetics. Due to the current shortcomings of local anesthetics, specifically duration, when utilized for single-injection PNBs, alternative solutions have been investigated. Adjuvants to local anesthetics have been used and are discussed in Chapter 9. Continuous methods have been developed and consist of a large portion of modern regional anesthesia practice today. Finally, recent advances in encapsulation of local anesthetic in liposomes offer promise, as these could extend the analgesic profile well beyond the usual 16–24 hours typically seen with our longest-acting agents.

CHAPTER 11

Continuous Peripheral Nerve Blocks: Local Anesthetic Solutions and Infusion Strategies

Amanda M. Monahan and Brian M. Ilfeld

INTRODUCTION

Continuous peripheral nerve blocks are accomplished by infusion or intermittent boluses of local anesthetic solutions. Overwhelming plethora of options are available for nearly every aspect of continuous infusion administration, from the choice of infusate to choice of infusion rate and bolus regimen, to infusion pump selection.[1] An ideal perineural local anesthetic solution would provide analgesia while minimizing sensory, motor, and proprioception deficits. In addition, desirable attributes include a favorable toxicity profile and cost-efficacy. The optimal infusion strategy may be modified for the large number of clinical scenarios that the regional anesthesiologist will encounter in daily practice. Considerations include the indication for perineural catheter placement, the number and location of catheters, patient weight, and ambulatory versus inpatient status.

INFUSATES AND LOCAL ANESTHETIC CONCENTRATION

Local anesthetics were described[2] in continuous perineural infusions as early as 1946. Intermediate-duration local anesthetics such as mepivacaine have been used,[3] but long-acting local anesthetics such as ropivacaine, bupivacaine, and levobupivacaine are most frequently described.[1] These long-acting agents provide a favorable differential sensory-to-motor block. At the termination of an infusion, it is desirable for sensory and motor block to resolve quickly and predictably. Studies have suggested that sensory-and-motor block regresses faster with ropivacaine than with bupivacaine.[4]

It is currently unclear if local anesthetic concentration—or simply the total delivered dose—influences continuous block effects.[5,6] While the evidence suggests that for infusions involving the femoral nerve, local anesthetic concentration is of minimal importance compared with total dose, data for the sciatic nerve are lacking, and the brachial plexus information is conflicting.[7–9] Therefore, at this time it remains unknown if there is an "optimal" concentration of local anesthetic. Commonly described concentrations include ropivacaine 0.1%–0.4%,[4,6,10–13] bupivacaine 0.125%–0.15%,[4,14] and levobupivacaine 0.1%–0.125%.[15,16]

Clinical Pearl

- An infusion with ropivacaine 0.1%–0.2% is easier to titrate due to faster resolution of an insensate extremity but bupivacaine 0.1%–0.125% provides the same degree of analgesia and costs less in most regions and hospitals.

LOCAL ANESTHETIC DELIVERY STRATEGIES

Infusates are typically delivered using an infusion pump with a basal infusion, bolus dose, or combination of the two modalities. Regimens are often reported as basal rate (mL/hour)/bolus volume (mL)/bolus lockout time (minutes). The delivery regimen should minimize total local anesthetic consumption, supplemental opioid requirements, and disturbance of daily functioning/sleep. No single delivery regimen has proven ideal for all anatomic locations and clinical situations. In many cases, providing a basal infusion minimizes breakthrough pain and supplemental analgesic requirements.[1] Adding a patient-controlled bolus usually decreases the required basal infusion rate,[4,17,18] incidence of an insensate extremity,[19] and local anesthetic consumption, the last allowing for a longer infusion duration in the ambulatory setting.[20,21] For example, in the upper extremity, an interscalene infusion that includes a basal infusion has been found superior to a bolus-only regimen.[22]

Regarding specific basal infusion rates, the evidence is mixed, with many studies reporting few differences among various rates.[1] One study involving interscalene catheters suggested that a relatively large basal rate with small-volume bolus doses (8 mL/h basal, 2-mL bolus, 60-minute lockout) provides improved analgesia and functioning, but with higher overall local anesthetic consumption compared with a slower basal rate and larger bolus doses.[23] At the infraclavicular location, utilizing a basal infusion with bolus (in comparison to basal only or bolus only) also has been found to provide improved analgesia with decreased severity and incidence of breakthrough pain, sleep disturbances, as well as higher patient satisfaction.[24] Studies of axillary catheters are mixed.

In the lower extremity, some differences in dosing effects have been found in randomized controlled trials (RCTs) examining femoral versus popliteal sciatic locations. Findings of RCTs at the femoral or fascia iliaca location have not demonstrated an overwhelming preference for a specific regimen.[25–27] Sensory and motor effects are similar when comparing repeated, scheduled hourly bolus doses to a continuous basal infusion of the same hourly volume and dose.[17] Nearly all studies reported the total local anesthetic dose reduced with bolus-only dosing.[1]

Clinical Pearl

- Analgesia is optimized with an infusion pump that delivers both an adjustable basal rate and patient-controlled bolus doses.

INFUSATE ADDITIVES AND ADJUVANTS

Adjuvant pharmaceuticals have been added to the local anesthetic infusate in an attempt to improve analgesia quality, spare local anesthetic consumption, and minimize motor block. Many substances have been described with single-injection regional techniques. However, no analogous, clinically relevant benefits have been demonstrated for continuous peripheral nerve blocks.[28–31] In addition, no additive medications are currently approved for continuous perineural administration, and some additives that have been reported in clinical trials have unacceptable side effects.[32,33]

Clinical Pearl

- At this time, there are few data to support adding additives (adjuvants) to local anesthetic for perineural infusions.

INFUSION PUMPS

While intermittent clinician-administered boluses are theoretically possible, simply logistical considerations explain why most local anesthetic is administered using an infusion pump. The device used for administering a continuous infusion should be accurate, reliable, portable, and programmable. It is desirable for the pump to be quiet, inexpensive, and easy to refill.[34] In the ambulatory setting, the local anesthetic reservoir should accommodate enough infusate for 2 to 3 days.[34] Pumps can be arbitrarily categorized as nonelectronic and electronic (Figure 11–1). Examples of nonelectronic mechanisms include spring- and vacuum-powered devices, as well as elastomeric pumps. Due to issues with accuracy/consistency and reservoir volume,[35,36] spring- and vacuum-powered models are not typically used for the purposes of continuous peripheral nerve blocks.

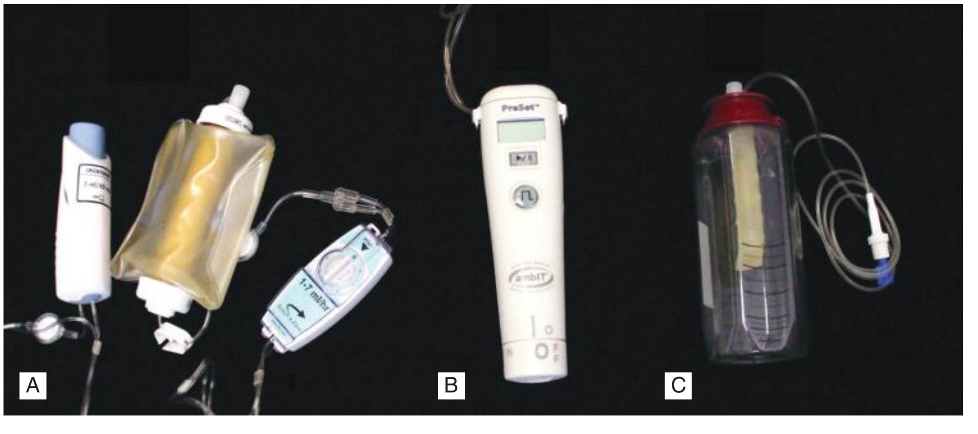

FIGURE 11–1. Examples of three infusion pumps designed for perineural local anesthetic infusion. **A**: An elastomeric device with adjustable basal infusion rate and 5-mL patient-controlled bolus function (ON-Q* C-bloc with ONDEMAND* and Select-A-Flow*, I-Flow/Kimberly-Clark, Lake Forest, CA). **B:** an electronic device with programmable basal infusion rate, patient-controlled bolus, lockout duration, and maximum total infused volume (ambIT Preset, Summit Medical Products, Sandy, UT). **C:** An elastomeric device with a manufacturer-determined/fixed basal infusion rate without a patient-controlled bolus function (LV5 Infusor, Baxter Healthcare International, Deerfield, IL).

Elastomeric pumps have been studied in depth for the purpose of continuous regional anesthesia. The acoustic silence of this modality may be desirable to many patients to minimize sleep disturbances. With regard to accuracy, these devices will infuse 110%–130% of the set basal rate in the first 3–8 hours and repeat this high rate in the final hours before pump emptying.[35–38] Some models allow for an adjustable basal rate as well as patient-controlled bolus dosing. The physics of the internal reservoir of the elastomeric devices limit ability to refill the pump, and even when technically possible,[39] it is neither recommended by manufacturers nor approved by regulatory bodies.[40]

Electronic pumps are reported to be the most accurate and consistent over the length of an infusion, usually within 5% of the programmed basal rate.[35–38] There are multiple models that are highly programmable, with various basal, patient controlled regional analgesia (PCRA) bolus, and lockout options. These pumps may emit noise during regular basal infusion and if/when an alarm is triggered. For models with an external reservoir, replacing the local anesthetic reservoir is easy to provide prolonged infusions. National pharmacologic guidelines have been developed for the preparing of regional anesthesia local anesthetic solutions. These guidelines require that the pump reservoir must be filled in an "ISO (International Organization for Standardization) class 5" environment. This entails compounding by a pharmacy using a "clean room" laminar flow workbench.[40]

Regardless of equipment type, it is important to educate patients both preoperatively and postoperatively regarding appropriate use of the pump functions. Preoperative counseling is desirable before any sedation is administered, and ideally a caretaker should be present in addition to the patient. Education should include the basic details and duration of the perineural infusion. Instructions should be given regarding when and how to use a patient-controlled bolus function. Patients are shown where the bolus button is located and how to deploy the button. They are counseled to use the bolus button whenever they have breakthrough pain and to expect a lag between bolus and local anesthetic effect. There is a risk for patients to have confusion about the roles of continuous perineural infusions and opioids as part of their multimodal analgesic plan. Patients may be instructed to use their bolus button, and if their pain is not at an acceptable level after 20 minutes, to add an oral opioid (or increase the basal infusion rate, depending on the pump capabilities). For ambulatory patients, written instructions are given with on-call contact information, as well as instructions for using the bolus button for pain, pausing the infusion in the event of an insensate extremity, or increasing/decreasing the basal rate, if necessary.

Clinical Pearl

- Electronic pumps provide a more stable basal infusion rate over the course of the infusion relative to elastomeric devices.

POSTOPERATIVE MANAGEMENT AND INFUSION STRATEGIES

As described in other chapters, the local anesthetic infusion strategy may be modified to manage common postoperative issues, such as breakthrough pain or an insensate extremity. To tailor the infusion strategy to a specific patient, the overall analgesic goals must be addressed. For example, a patient having major orthopedic surgery may require steady, around-the-clock analgesia, best provided with a continuous basal infusion in addition to patient-controlled bolus doses. In contrast, a patient following surgery for burns may primarily require the benefits of a larger bolus dose for daily bedside dressing changes and very low—if any—basal infusion. Because local anesthetics are bacteriostatic or -toxic, a continuous basal infusion rate is theoretically beneficial in reducing the risk of infection. Duration of local anesthetic infusion is an important postoperative consideration. While numerous infusion benefits have been demonstrated by RCT, longer duration of infusion (greater than 48 hours) has been associated with increased infection risk.[41] However, case reports of prolonged infusions have been described (34–85 days) without identified infection.[42,43]

Clinical Pearl

- An adjustable basal infusion rate allows an increase in the case of inadequate analgesia and a decrease in the case of an insensate extremity.

SUMMARY

An ideal continuous regional anesthesia infusate and administration strategy should provide reliable analgesia with minimal adverse effects. At this time, long-acting local anesthetics are favored due to the desire to minimize motor block. No pharmacologic additives or adjuvants have demonstrated additional benefits. Numerous administration strategies have been described, most combining a basal infusion with a patient-controlled bolus option. Both electronic and nonelectronic pumps are capable of providing these regimens. Optimal patient use of the infusion and pump bolus function requires appropriate perioperative counseling and support. Finally, infusion duration must balance analgesic and functional benefits with the risk of infection.

SECTION 3 Equipment for Peripheral Nerve Blocks

CHAPTER 12

Equipment for Regional Anesthesia

Vivian H. Y. Ip and Ban C. H. Tsui

INTRODUCTION

Regional anesthesia has become commonplace in many practices worldwide due to the increasing evidence of patient benefit, such as reduction in pulmonary[1] and thromboembolic[2] complications, reduction in opioid consumption,[3] as well as reduced pain and time to discharge and better quality of life in the immediate postoperative period.[4] The increased popularity of regional anesthesia has resulted in advancement in techniques and equipment. The practice has evolved from using paresthesia for nerve localization to electrical nerve stimulation and, currently, to ultrasound. This chapter gives an overview of the equipment available in the practice of peripheral nerve blocks. It also outlines the equipment needed at various stages of the regional anesthesia procedure to ensure that it proceeds in an efficient and safe manner. The practice of regional anesthesia comprises equipment, protocols, and skills necessary to ensure that the block proceeds as smoothly and safely as possible—before, during, and after the block is administered.

REGIONAL BLOCKADE PREPARATION AND SETUP

Area and Monitoring

A quiet environment with all equipment necessary to perform regional anesthesia, together with resuscitation drugs and equipment within reach, is of paramount importance. An ideal location is an induction room where the patient can be monitored, premedicated and the regional block performed before transferring to the operating theater. A designated block area can be used to provide suitable, monitored procedure environment while optimizing operating room efficiency.

When performing the block, an assistant trained in regional anesthesia should be present to prepare and handle equipment and help with the injectate. The assistant should also be trained in performing resuscitation if it becomes necessary.

Regardless of where the block is performed, it is essential to have all equipment, drugs, and monitoring readily available. The best way to gather all the necessary equipment and drugs is the setup of a storage cart (Figure 12–1), which should be well labeled with the supplies readily identifiable.

Clinical Pearl

- An equipment cart should contain all of the drugs, needles, and catheters necessary for regional anesthesia as well as resuscitation medications and equipment.

Block Area General Equipment

Commonly used items should be stocked in the storage cart and refilled when necessary. The storage cart should contain the following:

- Sterile skin preparation solution, sponges/gauze, drape, marking pen, ruler for landmark identification, ultrasound gel, hypodermic needles for skin infiltration and drawing up 5% dextrose (5% dextrose in water, D5W).

FIGURE 12–1. Equipment storage cart with clear identification of supplies and medication.

- A selection of sedatives, for example, midazolam (0.5–3 mg IV), and short-acting opioids such as fentanyl (50–100 μg IV), and propofol (20–100 mg IV) for nerve blocks that are more uncomfortable and require deeper sedation (eg, ankle block).
- Local anesthetics and normal saline for drug dilution if necessary. Local anesthetics are ideally stored in a separate compartment from intravenous drugs to avoid drug error.
- Intravenous cannulas. All patients should have an intravenous cannula inserted in case of local anesthetic toxicity.
- Dressings for intravenous cannulas, clear dressings for covering the ultrasound transducer used in single-shot nerve blocks, transducer cover, gel, and dressings for nerve block catheter insertion.

Emergency Drugs and Resuscitation Equipment

The use of ultrasound allows the visualization of the injectate and therefore, it has significantly reduced, but not eliminated, the risk of severe local anesthetic systemic toxicity (LAST). However, resuscitation equipment and medications should always be immediately available in the block area.[5]

Resuscitation Equipment

- Oxygen supply, nasal airway, and O_2 masks
- Oral airways of different sizes, laryngeal masks, and endotracheal tubes
- Laryngoscopes (Macintosh and Miller blades)
- Bag-mask ventilation device
- Suction
- Selection of various size intravenous cannulas
- Defibrillator

Resuscitation Drugs and Suggested Doses Intravenously

- Atropine (300–600 μg).
- Epinephrine (10–100 μg).
- Suxamethonium (40–100 mg).
- Ephedrine (5–15 mg).
- Phenylephrine (100–200 μg).
- Glycopyrrolate (200–400 μg).
- Intralipid® 20% (1.5 mL/kg over 1–2 minutes as an initial bolus, which can be repeated two to three times for persistent asystole. After the bolus, an infusion can be started at 0.25 mL/kg/min for 30 to 60 minutes; increase the infusion rate for refractory hypotension).[6–8] Ideally, Intralipid should be kept in a container with a protocol for use and equipment to draw up the drug.

Clinical Pearl

- During ultrasound-guided peripheral nerve block, visualization of injectate spread can minimize the risk of intravascular injection. The entire dose of local anesthetic should never be injected without seeing the spread of injectate on ultrasound, as this is suggestive of an intravenous injection

Documentation

A preblock checklist is paramount to ensure correct block performance at the appropriate site on the patient's body and includes documenting preoperative conditions (eg, relevant neurological deficits and comorbidities) and discussing risks and benefits and obtaining proper consent. In most countries, standardized medical documentation protocols have been established for induction and maintenance of general anesthesia. This documentation includes information about arterial blood pressure, heart rate, oxygenation, and details of common procedures such as maintaining airway status and providing endotracheal intubation. Likewise, there are similar standard guidelines for documenting neuraxial anesthesia, including information about block level; sterility provisions; equipment and technique used; incidence of cerebrospinal fluid, blood, or paresthesia; and local anesthetic injection. In contrast, no such guidelines exist for documenting peripheral nerve blocks, even though they are used routinely in clinical practice and possess the same medicolegal implications as general and neuraxial

anesthesia. One limitation of the lack of a documentation protocol for peripheral nerve blocks is the relative dearth of information available for those who wish to retrospectively review a regional procedure for quality assurance, research, or legal reasons. An example of block documentation is seen Figure 12–2.

More information about monitoring and documenting of PNBs is addressed in Chapter 63.

EQUIPMENT FOR INDUCTION OF REGIONAL ANESTHESIA

Needles for Single-Shot Nerve Blocks

Currently, there are many different types of peripheral nerve block needles on the market. Insulated needles are commonly used with nerve stimulation. With the introduction of ultrasound, echogenic needles have been used widely for better visualization.[9] Commercially available needles for single-shot nerve blocks usually come with preattached extension tubing to facilitate aspiration and injection of D5W or local anesthetics and feature a female attachment for connection to a nerve stimulator. One should note that the Luer lock for the attached tubing may occasionally be loose, which can lead to leakage of injected local anesthetic as well as air on aspiration.

Needle-Tip Design

Nerve injury can be caused by direct nerve penetration or forceful needle-nerve contact. The bevel of the needle can have an impact on the extent of damage on needle insertion close to a nerve. Short-beveled needles (Figure 12–3) may have the advantage of reducing nerve damage caused by cutting or penetration of the nerve, whereas long-beveled (14°) needles have been shown to be more likely to penetrate perineurium and cause fascicular injury than a short-beveled (45°) needle, especially when oriented transversely to the nerve fibers.[10–12] On the other hand, short-beveled needles can cause greater injury in case of nerve or fascicular penetration.[13] Blunt, noncutting needles and Tuohy needles provide better feedback and enhanced feel for the "pop" that occurs when puncturing through fascia. However, a needle that is too blunt may hinder fascial puncture, resulting in higher applied pressure and potentially "overshooting" after puncturing the fascia. Pencil-point and Tuohy needles can also cause greater post-traumatic inflammation, myelin damage, and intraneural hematoma.[14,15]

Neuraxial blocks can be performed with needles of different tip styles. Despite their description as atraumatic, Whitacre or Sprotte needles (Figure 12–4) can be traumatic to the tissues on entry, with tearing and severe disruption of collagen fibers (see Chapter 6). This contrasts with the Quincke needle, a so-called cutting needle[16] (Figure 12–4), also used for neuraxial blocks. Nevertheless, the overall consensus is that neuraxial blocks performed with an atraumatic needle is associated with less risk of postdural puncture headache.[17,18]

Needle Length

The choice of the needle length depends on the specific block. For instance, deeper blocks, such as sciatic nerve block, will require longer needles (eg, 100–120 mm). The use of ultrasound can help determine the distance of the trajectory toward

FIGURE 12–3. Short- (top) versus long-beveled needle (bottom).

FIGURE 12–4. Different needles for spinal anesthesia: Whitacre (top), Sprotte (middle), and Quincke (bottom).

the target nerve. A needle that is too short will not reach the target site, while a long needle may be difficult to maneuver and may be advanced too deeply. Needles should have depth markings (Figure 12–5) for monitoring of the depth of penetration into the tissue. The correct needle length (shortest possible) will allow for better handling and manipulation.

Needle Gauge

In general, 22-gauge insulated needles are probably used most commonly for single-shot peripheral nerve blocks. With needle size, a balance must be sought between patient comfort and bending of the needle as it punctures through the skin. Because longer needles tend to bend more easily during advancement and are more difficult to steer during deep blocks, a larger-gauge needle may be required, as smaller-gauge needles lack rigidity and bend more readily. Larger-gauge needles should be used with caution, as they are associated with increased severity of tissue injury and hematoma, while smaller-gauge needles carry the more serious risk of the tip being inserted intrafascicularly.[15] Also, resistance tends to be increased on injection with smaller-gauge needles, and it also takes longer for blood to be aspirated back should the tip be intravascular.

Echogenic Needles

Since the introduction of ultrasound-guided peripheral nerve blocks, there has been an effort to manufacture needles with improved visibility on ultrasound. Echogenic needles reflect ultrasound beams through a variety of mechanisms, including a special coating that traps micro–air bubbles, grooves near the needle tip, or echogenic "dots" made by "cornerstone" reflectors (see distal end of needle in Figure 12–5). Needles with enhanced echogenicity may reduce visualization time during ultrasound-guided procedures.[9] An echogenic needle, with or without ultrasound beam steering, is better visualized compared to a nonechogenic needle at 60°–70° angles of insertion. In contrast, the nonechogenic needle with beam steering was more visible at a 40° insertion angle compared with the echogenic needle.[19]

FIGURE 12–5. Nerve block needle showing centimeter markings that can be used as an example to monitor depth of penetration. Cornerstone reflectors to aid in visualization under ultrasound can also be seen at the distal end.

Continuous Catheter Assemblies

Continuous infusion of local anesthetic has proved effective in providing long-term postoperative analgesia in a variety of settings. Peripheral nerve block catheters also enable titration of medication in small-dose aliquots. Equipment for continuous peripheral nerve blocks is discussed in detail in Chapter 13. Catheter-over-needle assemblies have been gaining popularity for delivering continuous regional anesthesia and analgesia and are discussed briefly in this chapter.

Historically, it has been well recognized that perineural catheters are associated with leakage and migration. However, the catheter-over-needle system design may reduce these obstacles and has renewed interest in continuous regional techniques.[20,21] The difference between this assembly and traditional catheter-through-needle assemblies is also the position of the needle in relation to the catheter, whether within or surrounding the catheter (Figure 12–6). With catheter-through-needle assemblies, a gap is left between the skin and the catheter on removal of the needle. In contrast, withdrawal of the needle in the catheter-over-needle assembly does not affect the snug fit of the catheter in the skin because the needle is housed inside the catheter.[22]

There are a few variations on this design that are marketed by different brands. For example, Contiplex (B-Braun Medical, Melsungen, Germany) design features the catheter-over-needle as a single unit (Figure 12–7).

Another variation is the recently introduced E-Cath (Pajunk MEDIZINTECHNOLOGIE GmbH, Geisingen, Germany kit with a "catheter-within-catheter" design, which features two components, the outer catheter sheath and the flexible inner catheter, that create a nonkinkable unit (Figure 12–8). The initial device resembles an intravenous cannula, with a needle within the outer catheter, which is inserted proximal to the target nerve under ultrasound guidance. The distal end of the needle protrudes for its electrical conductive property. Once in place, the needle is withdrawn from the unit, leaving the outer catheter in situ, and an inner catheter is inserted *into* the outer catheter to replace the needle and is Luer locked in place for injection (Figure 12–8). The inner catheter literally replaces the needle, and the inner catheter tip is essentially at the exact location where the needle tip was before needle withdrawal.

Several advantages of the catheter-over-needle design include potential:

- Simple to use with an insertion technique compared to that of a single-shot nerve block
- Less leakage from the catheter insertion site, for example, during shoulder surgery when the patient is in a

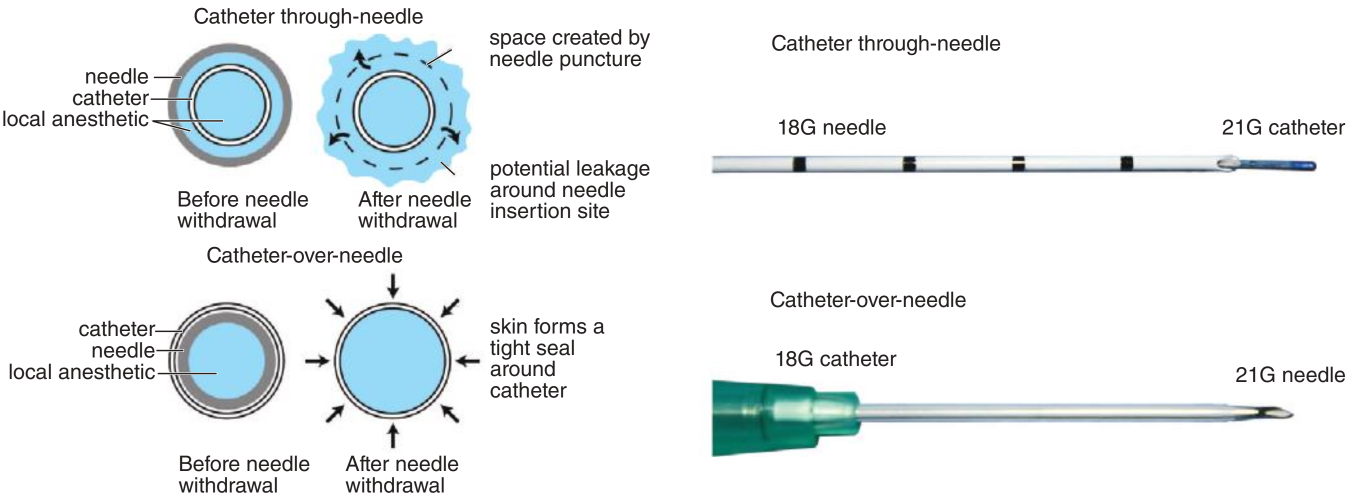

FIGURE 12–6. Left, schematic showing the difference between traditional catheter-through-needle (top) and catheter-over-needle (bottom) designs with respect to risk of leakage from the skin puncture site. In the former, the needle hole diameter is larger than the catheter diameter, leaving space for local anesthetic to leak when injected. In the latter, the puncture hole is smaller than the catheter diameter, allowing the catheter to be held tightly by the surrounding skin. Right, differing distal ends of catheter-though-needle (top) and catheter-over-needle (bottom) assemblies.

sitting position with a potential for surgical field contamination[23]

- Less risk of dressing adhesive disruption
- Fewer steps and less risk of dislodgement[24]
- Easy visualization of the catheter, especially the catheter tip[25]

Nerve-Locating Devices

Peripheral Nerve Stimulators

Peripheral nerve stimulators were the primary nerve-seeking device in the decades preceding widespread use of ultrasound guidance. The combined use of ultrasound and nerve stimulation creates a more objective method of achieving accurate and safe blocks while allowing monitoring and visualization of the block needle and targets in real time. With the introduction of ultrasound, the role of nerve stimulators has changed from nerve seeking to monitoring for needle-nerve contact or intraneural needle tip placement. In addition, nerve stimulation can be used as a confirmation technique and guide in placing epidural catheters using the electrical epidural stimulation (Tsui) test.[26] Details of the physical properties underlying nerve stimulation are discussed in Chapter 18; key properties of commercially available nerve stimulators are briefly highlighted next (Figure 12–9).

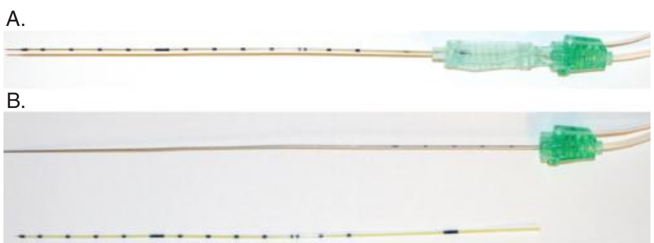

FIGURE 12–7. **A:** The Contiplex (B-Braun Medical, Melsungen, Germany) catheter-over-needle assembly, which features a long needle covered by the catheter and a clip that can be moved along the needle length for easy manipulation of the unit. **B:** B. FIGURE 12–9. Peripheral nerve stimulators allowing measurement of stimulus amplitude, pulse width, frequency, and electrical impedance.

Constant Current Output and Display Most modern models now deliver constant current, and current output can be set in frequency, pulse width, and current milliamperes (mA). The primary advantage of a constant current output nerve stimulator is its ability to deliver a stable current output in the presence of varied resistances.

Display A clear digital display with accuracy to two decimal places is an important feature of the electrical nerve stimulator. This display must indicate the actual current delivered to the patient and not simply the target current setting. Some nerve stimulators are equipped with low- (up to 6 mA) and high-output (up to 80 mA) ranges. The lower range is used primarily to alert for potential intraneural needle placement, while the higher range is mainly used for the epidural stimulation test (1–10 mA).

Variable Pulse Width Short pulse widths (ie, 0.04 ms) are a better indicator of the distance between the needle and the nerve, based on changes in current. In contrast, with long pulse widths (ie, 1 ms), there is little difference in the current required to stimulate the nerve, regardless of whether the stimulating needle is in direct contact with the nerve or 1 cm away. At a pulse width of 0.04 ms, there is a large difference in the stimulating current required when comparing direct contact with the nerve versus a distance of 1 cm away.

Pulse width also has a role in successful use of the electrical epidural stimulation test. The proper pulse width must be used for different applications of the test, be it a peripheral or neuraxial block. Table 12–1 summarizes the appropriate pulse width for different applications.

Clearly Marked Polarity of the Electrodes The polarity of the needle will affect its ability to stimulate the nerve at a given current and should be clearly marked. The cathode (black) is selected as the stimulating electrode because it is three to four times more effective than the anode at depolarizing the nerve membrane.

Variable Pulse Frequency Most new stimulators have an option to change the frequency at which the electrical pulse is delivered. Although some commercially available peripheral nerve stimulators can allow adjustment of frequency up to 5 Hz, the optimal frequency of the electrical pulse is between 0.5 and 4 Hz. Most users select a frequency of 2 Hz. When using a lower frequency, such as 1 Hz (one stimulus per second), the needle must be advanced slowly to avoid missing the nerve between stimulations.

Disconnect and Malfunction Indicators The disconnection and malfunction of nerve stimulators should be easily detectable, and an indication of battery power is essential. Most

TABLE 12–1. Pulse widths for different applications during peripheral nerve block and neuraxial block.

Pulse Width	Application	Typical Threshold Range
0.1 ms	Motor peripheral nerve	Avoid < 0.3 mA
0.2 ms	Epidural space Intrathecal space	1–15 mA <1 mA
1 ms	Epidural space	6 mA

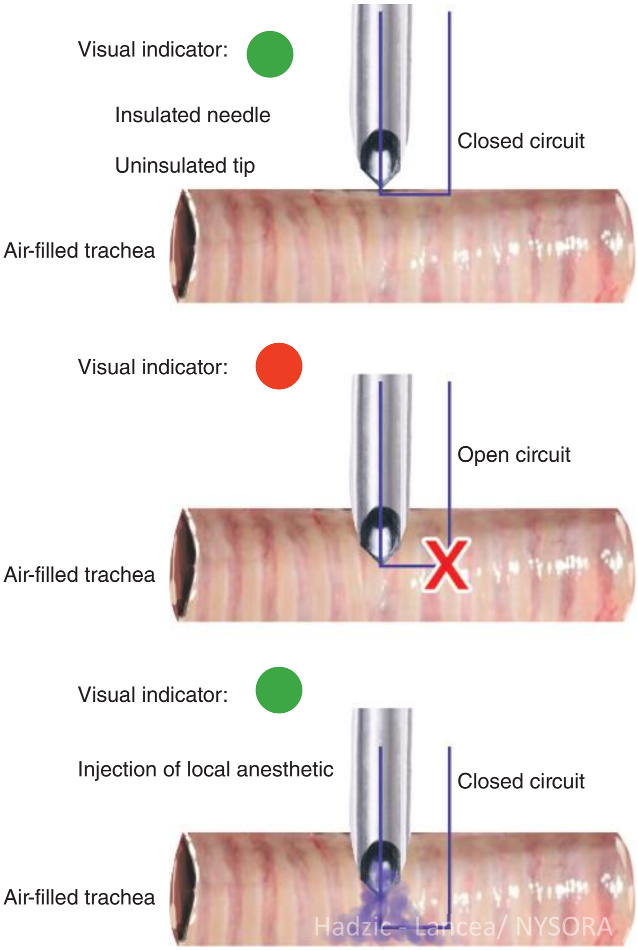

FIGURE 12–10. Change in peripheral nerve stimulator light and tone signal on entry of uninsulated needle tip into tracheal lumen during airway topicalization (top and middle). With injection of local anesthetic, electrical current is closed, causing another light/tone signal change (bottom).

nerve stimulators use a change in tone or light to warn when the circuit is not complete and if the pulse current cannot be delivered. The value of the tone/light change on disconnection of the circuit was demonstrated recently with a novel use for a peripheral nerve stimulator in guiding an insulated needle with an uninsulated tip into the tracheal lumen for airway topicalization.[27] The change in tone/light indicated whether the tip was in contact with tissue (closed circuit) or suspended in the air-filled trachea (open circuit) (Figure 12–10).

Electrical Impedance Some modern nerve stimulators display the total impedance between the needle tip and ground electrode. The significance of this property in monitoring intraneural needle-tip placement is discussed in the section on monitoring devices in this chapter.

Other Accessories A probe may be used for performing percutaneous electrode guidance during surface nerve mapping (Figure 12–11). A small remote hand control or foot pedal allows a single operator to adjust the current output of a nerve

FIGURE 12–11. Surface nerve mapping probe for percutaneous electrode guidance.

stimulator without an assistant, although this is seldom used clinically (Figure 12–12).

Ultrasound

The introduction of ultrasound technology has revolutionized the field of regional anesthesia, allowing nerve structures, needles, and other subcutaneous objects to be visualized in real time. Ultrasound undoubtedly can improve the safety and ease of performing nerve blocks; however, this is largely operator dependent.

There are a number of commercially available portable ultrasound machines that are suitable for regional anesthesia (Figure 12–13). These machines can be transported easily, and image quality and resolution are equivalent or similar to those of stationary ultrasound machines. The transducer (or probe) is the most important element of the ultrasound machine; transducers of various footprints and beam planes are available, allowing the user to scan most surfaces on individuals of various body habitus. The quality of ultrasound machines is constantly improving, with better ergonomic options and ease of use, higher resolution with improved transducers, improved portability, and reduction in cost. A more thorough discussion of ultrasound technology and application in regional anesthesia can be found in Chapters 28-30.

Monitoring Devices

Monitoring for the Patient

It is important to apply routine monitoring for patients undergoing regional anesthesia with or without sedation. Toxicity from local anesthetic overdose and intravascular injection and oversedation are potential complications of regional anesthesia. Therefore, one should be vigilant with regard to patient monitoring. One should also be aware that toxicity from local anesthetic can occur within the first half hour after injection of medication due to the peak in plasma concentration (typically 20–30 minutes).[28] Local anesthetic systemic toxicity is discussed in detail elsewhere.

FIGURE 12–12. Remote hand-controlled (left) and foot-controlled (right) devices for adjusting nerve stimulator current output.

General monitoring for the patient includes examining the following:

- Electrocardiogram.
- Noninvasive blood pressure.
- Pulse oximetry.
- For ventilation: The adequacy of ventilation for regional anesthesia without sedation can be performed by qualitative clinical monitoring. However, for patients who require sedation, capnography should be used unless it is precluded by the patient, procedure, or equipment.

FIGURE 12–13. Portable ultrasound machine.

Monitoring for Intraneural Injection

Paresthesia Prior to the introduction of nerve stimulation technology, paresthesia was the only means of nerve localization. However, there has been emerging evidence suggesting painful paresthesia can lead to persistent neurological symptoms and neuropathy. Thus, most clinicians are not only abandoning seeking paresthesia but also, with awake or lightly sedated patients, are using paresthesia as a signal to warn of needle-nerve proximity.

Electrical Nerve Stimulation The role of the nerve stimulator has shifted since the introduction of ultrasound. In most cases, nerve stimulation is no longer used as a primary tool for nerve localization but is instead used for monitoring to minimize intraneural injection. Nerve stimulators allow the user to monitor two electrophysiological properties during nerve block performance: the nerve stimulation threshold and electrical impedance.

Nerve stimulation threshold: A nerve stimulation threshold of less than 0.2 mA may suggest intraneural needle-tip location or needle-nerve contact.[29,30] When used alone, nerve stimulation lacks sensitivity[31] and should therefore be used in conjunction with other monitoring as described in this section. Observation of a motor response signifies needle-nerve proximity with a low threshold current; however, a lack of motor response at a 0.2 mA or less threshold with a pulse width of 0.1 ms does not always rule out intraneural needle placement.

Electrical impedance: Many modern nerve stimulators are capable of measuring impedance. In an electrical circuit, direct current (DC) is the flow of electric charge in only one direction, whereas alternating current (AC) describes flow of electric charge that reverses direction periodically. In nerve stimulation, pulsating DC is used. Because pulsating DC shares characteristics of both AC and DC waveforms, the electrical resistance of the nerve stimulation circuit is often referred to as impedance. Impedance is highly sensitive to tissue composition and varies depending on the water content of the tissue.[32] Because there is variation in water and lipid content between intraneural and extraneural spaces, with the former having a considerably greater amount of nonconduction lipid and lower water content, a significant difference in intraneural and extraneural impedance has been demonstrated.[33] A recent study in adult patients also showed that an increase in impedance greater than 4.3% may indicate intraneural needle placement.[34] Furthermore, discrimination between nerve tissue and other tissue types has been improved by combining several impedance variables at multiple measurement frequencies to increase precision.[35] Electrical impedance also changes on intravascular and perineural injection of D5W.[36] A change in impedance may therefore warn against injection in a location that could potentially cause nerve damage or other sequelae.

Clinical Pearl

- A sudden change in impedance may indicate that the needle is entering different tissues.

Ultrasound Imaging With the rising popularity of ultrasound guidance for peripheral nerve blocks, there has been a common misunderstanding that ultrasound can help avoid intraneural injection. To improve the safety margin, the needle tip should be visualized at all times during advancement of the needle during an in-plane approach; however, this can be challenging, even in experienced hands. In addition, there is a significant learning curve associated with using ultrasound in regional anesthesia, both with in-plane and out-of-plane approaches. When an out-of-plane approach is used, the needle shaft could be mistaken for the tip, which would be further downstream of the ultrasound beam. During injection, nerve swelling as a result of intraneural injection can also be difficult to note in real time. Moreover, by the time nerve swelling is noticed, it may be too late to prevent nerve injury as it takes only a miniscule volume of local anesthetic to rupture the perineurium when the needle is placed intrafascicularly. Finally, current ultrasound resolution is not high enough to recognize intrafascicular injection, the most severe event in terms of nerve damage. As such, nerve injury with peripheral nerve blocks despite the use of ultrasound continues to be reported.[37–39] The rate of residual paresthesia or numbness after ultrasound-guided peripheral nerve block is estimated to be 0.18% up to 16%.[40–43] Therefore, ultrasound should not be used as the sole guidance device but, rather, should be used in conjunction with other monitoring modalities to minimize the risk of intraneural injection.[44,45]

Injection Pressure Monitoring Monitoring injection pressure can help distinguish needle-tip location in the perineural tissue versus the needle-nerve contact or intrafascicular needle placement (ie, perineural vs. intraneural-intrafascicular).[46,47] Results of several studies suggest that high-pressure injection into the intraneural space, even with small volumes, can be a major contributor to mechanical injury of neurological tissue during peripheral nerve blocks.[48,49] The rationale and basis for nerve damage from high-pressure injection are likely a combination of mechanical injury from breaching the perineurium, leading to interference with endoneural microcirculation, and chemical injury from neurotoxicity of local anesthetics.[49–53]

Using canine models, it was shown that high injection pressure (>20 psi) can result in persistent neurological damage indicative of intrafascicular injection.[48] However, not all intraneural injection results in high injection pressure and subsequent neurological deficit.[31,54] This could be due to an intraneural extrafascicular injection or the beveled needle tip not being completely within the nerve. In these cases, the injectate may push the nerve out of the way, avoiding a high-pressure injection. Nevertheless, intraneural injection is generally not recommended. Forceful needle-nerve contact and displacement have also been shown to cause inflammatory changes to nerves.[55,56] Since a recent study demonstrated that high opening injection pressure (≥15 psi)—the pressure that must be overcome before injection can commence—may be indicative of intraneural needle placement, it is important to monitor injection pressure carefully during local anesthetic injection.[47] Furthermore, high injection pressure can also cause undesired neuraxial spread during certain regional blocks close to the neuraxis, for example, lumbar plexus block or brachial plexus block.[57,58]

Clinical Pearl

- It has been suggested that opening injection pressure should be kept below 15 psi to improve safety. Opening pressure is not dependent on needle size, needle type, injection speed, and syringe size.[47]

Methods of monitoring injection pressure include the following: syringe feel, in-line pressure manometer, and compressed air injection technique (CAIT).

Syringe feel. Traditionally in clinical practice, a subjective "syringe feel" technique has been used to assess resistance to injection of local anesthetic and is performed by the anesthesiologist or assistant while the anesthesiologist

FIGURE 12–14. Commercially available disposable in-line pressure-monitoring device for monitoring injection pressure during peripheral nerve block (BSmart, BBraun Medical, Melsungen, GE).

maintains the correct needle position. Needless to say, this subjective approach is not reliable and is operator dependent.[59,60] Different needle lengths, diameter, and syringe types also affect the feel.

In-line pressure manometer. Commercially available objective disposable devices to measure injection pressure, such as BSmart™ (B-Braun Medical, Melsungen, Germany) (Figure 12–14), continuously displays the pressure during injection, allowing clinicians to quantify the injection pressure information, which can be documented. The manometer is color coded such that when the pressure is 20 psi or greater, the indicator will be red to warn the operator. The in-line pressure monitor is placed proximal to the needle and in line with the nondistensible tubing. The other end of the pressure monitor is attached directly to the syringe. The principle is the same as in-line pressure sensors in devices such as syringe pumps for continuous pressure monitoring. The main principle behind the use of an injection pressure monitor is that a certain amount of injection pressure (opening pressure) must be reached before the injection (the flow of the anesthetic) can commence. The critical opening pressure necessary to inject local anesthetic when the needle is in contact with the nerve or is intrafascicular has been estimated in several studies to be more than 15 psi.[46,47] Therefore, if the injection is halted before the opening pressure is reached and flow of anesthetic is initiated, injection in vulnerable needle-nerve interaction can be avoided.

Compressed air injection technique. This is the clinical application of Boyle's law (Pressure × Volume = Constant). At a constant temperature, a set volume of gas (air) varies inversely with the pressure; for instance, if the volume of the gas is reduced by 50%, the pressure will be increased from 1 atmosphere to 2 atmospheres. This technique, designed by Tsui, involves aspirating a set amount of air above a volume of injectate within a syringe.[61] During injection, the volume of air is compressed and maintained at a certain percentage (Figure 12–15).

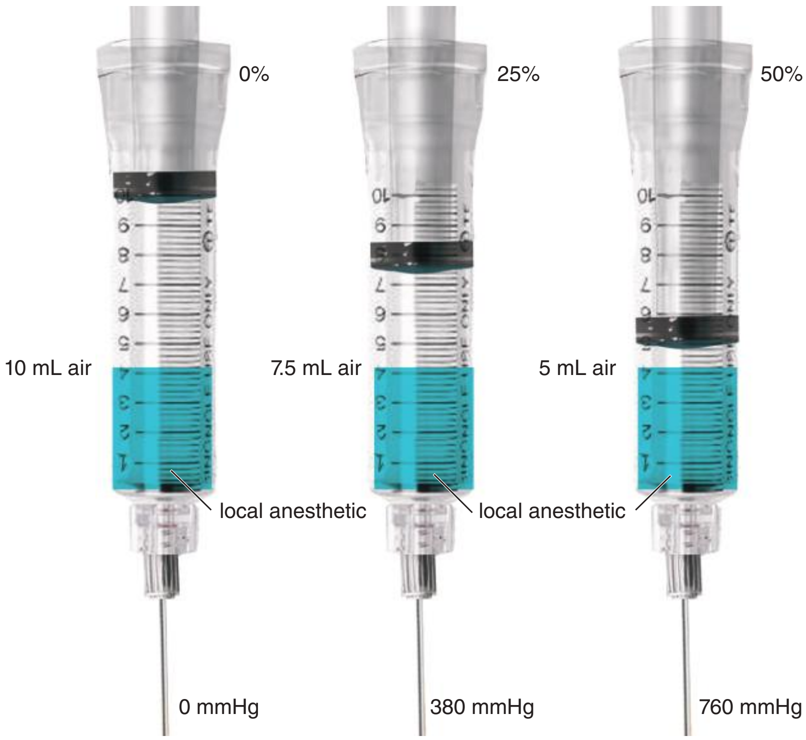

FIGURE 12–15. Compressed air injection technique (CAIT) to prevent high injection pressure; 50% compression of air volume in the syringe corresponds to an injection pressure of 760 mm Hg.

At 50% air compression, the injection pressure was 760 mm Hg or less, well below the threshold of less than 25 psi (1293 mm Hg).[61] CAIT is a simple and practical way to standardize the local anesthetic injection pressures in real time, ensuring the injection pressure is constantly below the threshold and minimizing the risk of clinically significant nerve injury. This method also inevitably reduces the speed of injection, which in turns decreases the risk of intrafascicular injection or siphoning the local anesthetic to unwanted tissue planes. The pressures generated by CAIT also remain consistently stable throughout the injection period, unlike the syringe feel technique, which produces high peak pressures. This is likely due to the "cushioning" effect from the volume of air, which dampens the initial high pressure.

Clinical Pearls

- In the era of ultrasound-guided peripheral nerve blocks, it is important not to dismiss the value of nerve stimulator and injection pressure monitoring to minimize the potential for nerve injury.
- It is important to use a combination of monitors to minimize the risk of intraneural, intrafascicular injection and needle-nerve trauma.

EQUIPMENT FOR POSTBLOCKADE MANAGEMENT

Block Assessment Tools

Various tools and techniques are available to monitor the progress of a regional block (Figure 12–16). Ideally, the monitoring tool or device should be as objective as possible, but due to physiological differences among individuals receiving a block, this is rarely the case. To date, there is no consensus on which is the most effective method. Nevertheless, most block-monitoring tools generally offer an acceptable interpretation of when surgical anesthesia is achieved. Similarly, tools and scales used to assess sensory and motor blockade vary greatly and offer subjective feedback on the degree to which a nerve block is achieving its desired goal. Commonly, pain scales or scores are used to indicate a patient's comfort level; as with block-monitoring tools, these scales and scores provide a more objective and reproducible means to assess the severity of pain.

Sensory (Dermatome) Testing

Regional block assessment tools are based on the assumption that the patient will not be able to perceive a stimulus on the area being blocked. These stimuli are usually temperature based (ice, alcohol swab), but a graded filament can also be used to measure diminishing and returning cutaneous sensation. In the case of trunk/neuraxial blocks, these methods can help

FIGURE 12–16. Selection of nerve block–monitoring equipment, including devices to measure current perception threshold (upper left), monofilaments and alcohol swabs for sensory perception (lower left), infrared scanning device (lower right), and force transducers with wireless data collection capability (upper right).

determine and follow block spread by observing which dermatomes are responsive to the stimulus.

Temperature/Infrared Recording

Recently, infrared thermal imaging has also been tested as a means to monitor block progression.[62,63] This test is based on the knowledge that skin temperature in the digits increases following brachial plexus block. The studies showed that infrared thermography of the digits had high positive predictive value for block success following brachial plexus anesthesia.

Current Perception Threshold

Current perception threshold (CPT) is a means of applying electrical current via a percutaneous electrode connected to a specialized current generator (eg, Neurometer[64]) to test sensory level. This method has been used to quantify degrees of neuropathy in conditions such as diabetes mellitus.[65,66] Recently, the reproducibility of this method has been tested in volunteers with acceptable results using a common peripheral nerve stimulator.[67] In this study, a peripheral nerve stimulator (see previous discussion) was used to apply an electrical stimulus to the blocked area; if the current required to elicit a sensory response was greater over time than the baseline (preblock or unblocked region) current, this was an indicator of block progression. Indeed, a subsequent study demonstrated that CPT can be an objective, reliable tool to monitor block onset in clinical scenarios.[68]

Pain Assessment

Numerous validated pain rating scales exist, with the most popular being variations on the 0–10 scale, where 0 indicates "no pain at all," and 10 indicates "worst pain ever." The numeric rating scale (NRS) and visual analog scale (VAS)[69] are two examples of this type. Other pain rating scales, such as the Defense and Veterans Pain Rating Scale (DVPRS),[70] feature notes on how the pain affects everyday living that can be used to more precisely define the severity of the pain. The DVPRS also features facial cartoons that can be used to obtain feedback on pain severity from individuals with limited communication ability. For elderly patients, the Pain Assessment Checklist for Seniors With Limited Ability to Communicate (PACSLAC)[71] can be used to assess pain in individuals with dementia or cognitive impairment and who have trouble communicating. For children, a variety of pain scales are available that can be used for different age groups and communication abilities.

Motor Block Assessment

The most common motor assessment tool is the Bromage score,[72] a 4-point scale ranging from 0 (full movement) to 3 (complete block/no movement). The original Bromage score was applied for cases of lower extremity block but can also be adapted to assessment of upper extremity block. Another more objective method that can assess onset of and recovery from a nerve block is strength testing. This can be performed with a portable force transducer: The patient is asked to exert force against the transducer with the limb or body part that has been blocked (eg, elbow extension to assess radial nerve function). Some modern force transducers come equipped with a universal serial bus (USB) stick that, along with a portable computer, allows force data to be collected wirelessly in real time (Figure 12–16).

Maintenance of Regional Anesthesia

Regional anesthesia practice has relied on infusion pumps to provide continuous delivery of local anesthetic through a perineural catheter. This method remains the most popular method of continuous regional anesthesia, but new developments in technology and practice have allowed for flexibility in postoperative analgesia. Conventional methods for continuous nerve blocks are discussed in more detail in Chapters 11 and 13; new developments are covered here briefly.

Intermittent Bolus

In addition to the traditional continuous infusion regimen, it has become increasingly popular to use intermittent bolusing for continuous peripheral nerve block management. With its ability to target nerve structures with precision, catheter-over-needle technology (see previous discussion) greatly reduces the risk of catheter migration or dislodgement. An advantage of intermittent boluses is that the risk of local anesthetic toxicity is also reduced because constant delivery of local anesthetic is avoided and total dose is generally reduced.[73–75] An intermittent bolus regimen can be achieved by either a patient-controlled or preprogrammed approach.

Clinical Pearls

- One should consider and select pumps that allow delivery of intermittent boluses as well as continuous infusion.
- Because infusion pumps will be maintained and transported by the patient if they are mobile, the pump should be portable and easy to use.

Future Advances

Recently, the exciting prospect of controlling local anesthetic infusion by remote control was described.[76] In this system, pumps were set to adjust to patient need based on responses to questions about their pain control, and, in the event that settings needed to be changed, the practitioners were able to access the pump information via a secure server remotely, avoiding the need for a nurse or physician to be physically present.

CONCLUSION

With improvements in technology and equipment, regional anesthesia has progressed from an "art" practiced by few to a "science" that, with adequate training and experience, can be practiced by many. Regardless of who is performing the block or where it is being performed, there are several key guidelines that should be followed to ensure safe and effective regional anesthesia. It is essential that there be a designated area for performing nerve blocks and that all drugs and equipment are readily available. Careful documentation of the block procedure should be every institution's standard. Adequate patient monitoring is essential and should include standard ASA monitoring as well as objective ultrasound–nerve stimulator and injection pressure monitoring to help prevent nerve injury. The use of proper equipment, including appropriate needle length and gauge, will result in easier and more accurate needling. If a continuous block is desired, new catheter-over-needle assemblies can help mitigate the problems of traditional catheter-through-needle designs, and recent developments in long-term local anesthetic delivery methods, including intermittent bolus and remote control, represent valuable options.

In summary, current regional anesthesia practice depends on numerous tools, methods, and monitoring equipment. Although time is needed to gain adequate competency with some of these methods and tools, they are critical for ensuring that the regional block is performed in the safest and most effective manner possible during every stage of the procedure.

CHAPTER 13

Equipment for Continuous Peripheral Nerve Blocks

Holly Evans, Karen C. Nielsen, M. Steve Melton, Roy A. Greengrass, and Susan M. Steele

INTRODUCTION

Continuous peripheral nerve blocks (CPNBs) provide a number of advantages in the perioperative period. These techniques provide the flexibility to prolong intraoperative anesthesia while avoiding the risks and side effects of general anesthesia. Following surgery, CPNBs offer extended postoperative analgesia. When compared to parenteral opioid analgesia, CPNBs are associated with superior analgesia, reduced opioid consumption, and decreased opioid-related side effects such as postoperative nausea and vomiting, sedation, and respiratory depression.[1–11] Analgesia of similar quality to epidural anesthesia is the result; however, less hypotension, urinary retention, pruritus, and mobility restrictions occur with CPNBs.[7,12–14] There is also evidence supporting the beneficial effect of CPNBs on postoperative sleep patterns and cognitive function[15,16] as well as early rehabilitation.[7,8] Concurrent sympathectomy is ideal following microvascular, reimplantation, and free-flap surgery,[17,18] as well as for treatment of accidental intra-arterial drug injection.[19–21] Extended analgesia can also be provided for patients with chronic pain[22] and those requiring palliation of terminal illness.[23] Finally, preoperative use can reduce phantom limb sensation in patients undergoing amputation.[24]

Despite these benefits, CPNBs have historically been relatively underused. This early lack of popularity was multifactorial; however, inadequate CPNB equipment likely contributed. The development of CPNB needles, catheters, and nerve localization technology has been essential for the safe use and advancement of these regional anesthesia techniques. This chapter summarizes the equipment required for continuous plexus anesthesia and will review the chronology of the development of modern-day CPNB equipment.

PRE-BLOCK CONSIDERATIONS

Block Room

A perineural catheter can be placed in a block room just as the preceding patient's procedure is finishing. This enhances operating room efficiency and flow. A block room allows the supplies and monitors discussed next to be stocked and stored in one location. The block room should be a clean, semi-sterile room in close proximity to the operating room suite.

Block Cart

Table 13–1 outlines block cart supplies necessary for the performance of CPNBs. Supplies are sterile where applicable.

Monitoring

Patients receiving a perineural catheter often receive sedation and large doses of local anesthetic. They should have standard American Society of Anesthesiologists (ASA) monitors applied. Furthermore, these patients should be monitored by an individual with Advanced Cardiac Life Support (ACLS) resuscitation knowledge and skills.

Resuscitative Medication and Equipment

A number of life-threatening complications can occur during placement of a CPNB. Table 13–2 lists the resuscitative medications and equipment that should be readily available.

Premedication and Sedation

Table 13–3 lists various agents that can be used to provide sedation and analgesia for perineural catheter placement.

TABLE 13–1. Block cart supplies necessary for continuous peripheral nerve blocks.

Sterile gloves ± gown for anesthesiologist
Disinfecting solution (2% chlorhexidine gluconate with 70% isopropyl alcohol)
Clear drapes
Needles for subcutaneous local anesthetic infiltration (ie, 25-gauge 1½ inch)
Syringes for subcutaneous local anesthetic infiltration (ie, 3 mL)
2 × 2 in. gauze
Selection of block needles and catheter sets of appropriate diameter and length
Nerve stimulator and electrodes
Ultrasound machine
Selection of ultrasound probes of appropriate frequency, shape, and size
Sterile ultrasound probe covers
Sterile gel for ultrasound imaging
Dextrose 5% in water
Local anesthetics and adjuvants (see below)
Occlusive dressing, Epi-Guard, tape, Mastisol, Dermabond®
Connectors for proximal tip of catheter
Oxygen source
Oxygen masks
Suction

Most advocate the use of light sedation, thus allowing communication with the patient regarding potential side effects.

Local Anesthetic Solutions and Adjuvants

Block Initiation

A variety of local anesthetics should be available on the block cart to initiate the nerve block. Short-acting agents such as lidocaine or mepivacaine allow for rapid onset yet early recovery of the sensorimotor block. This facilitates prompt assessment of neurological function following surgery and prior to starting a continuous perineural infusion. Block initiation with long-acting agents such as bupivacaine or ropivacaine extend the duration of dense anesthesia and analgesia. Ropivacaine is often selected instead of bupivacaine for its more favorable safety profile. Concentrated solutions provide effective intraoperative anesthesia and analgesia. Dilute local anesthetic solutions can provide selective sensory anesthesia while minimizing motor block after surgery.

TABLE 13–2. Necessary resuscitative medications and equipment.

ACLS drugs (ie, epinephrine, vasopressin, atropine)
Cardioverter/defibrillator
Intralipid® 20% (1.5-mL/kg bolus over 1 minute and every 3–5 minutes up to 3 mL/kg, 0.25 mL/kg/min infusion, maximum total dose 8 mL/kg)

TABLE 13–3. Agents for sedation and analgesia for perineural catheter placement.

Benzodiazepines (ie, midazolam)
Opiates (ie, fentanyl)
N-Methyl-D-aspartate antagonists (ie, ketamine)
Alpha-2 antagonists (ie, clonidine, dexmedetomidine)
Anesthetics (ie, propofol, etomidate)

When appropriate, epinephrine 1:200,000 or 1:400,000 is added to the local anesthetic solution. The epinephrine serves as a marker of intravascular injection and can limit the systemic absorption of perineurally placed local anesthetic.

Further adjuvants such as clonidine and dexamethasone have been used to enhance the duration and quality of analgesia.

Continuous Infusion

The nerve block is typically maintained with a continuous infusion of dilute, long-acting local anesthetic. Patient-controlled boluses are often added to the continuous infusion to enhance analgesia. The local anesthetic solution should be prepared in a clean environment, such as in a pharmacy using a laminar flow workbench. Minimizing bacterial contamination is critical to reducing the likelihood of infectious neurological complications.

Clinical Pearl

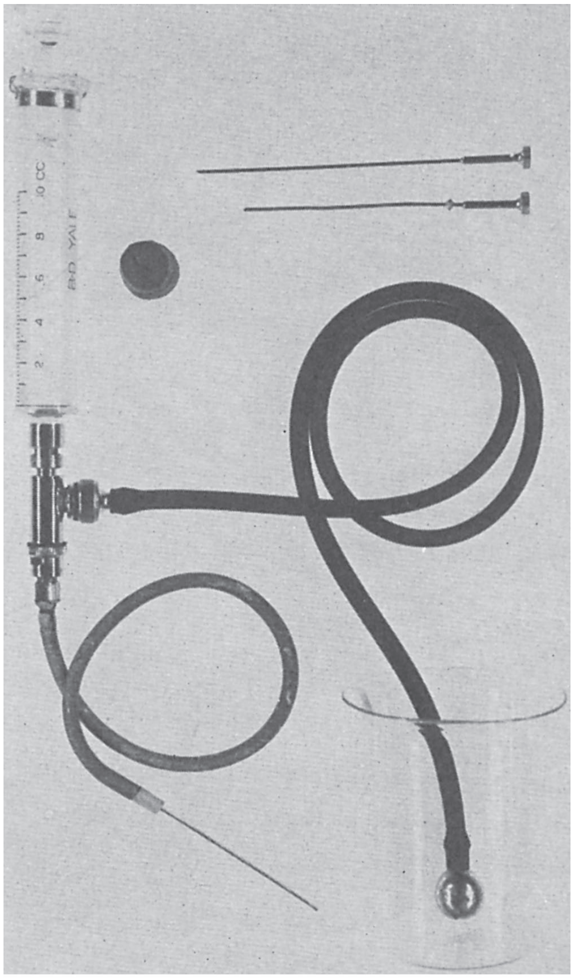
- Safe practice of regional anesthesia requires the immediate availability of monitors, resuscitation drugs, and equipment as well as a health care practitioner familiar with ACLS protocols.

NEEDLE-AND-CATHETER SYSTEMS

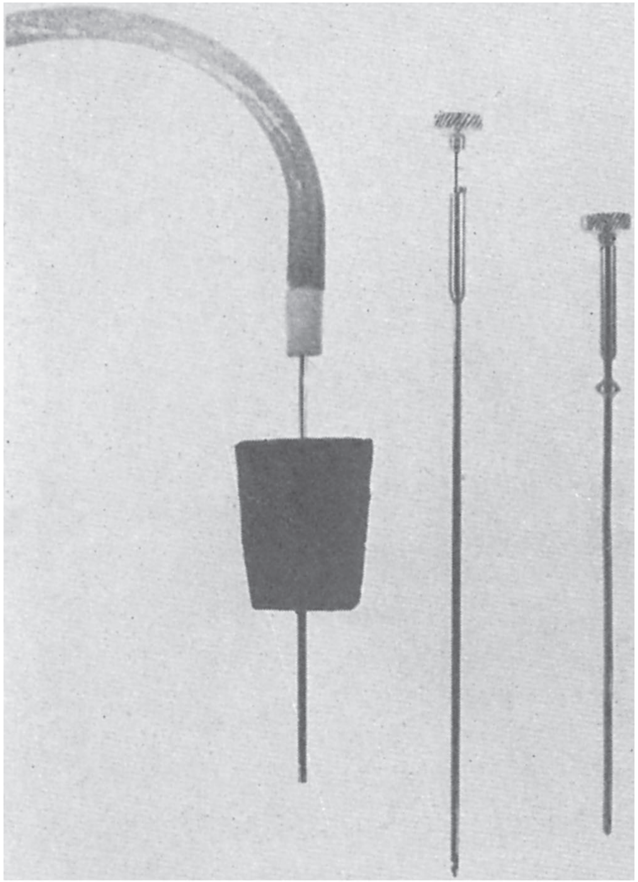
Historical Perspective

The earliest report of CPNB is attributed to Ansbro's 1946 work[25] (Figure 13–1). He attached a malleable blunt needle to injection tubing and a syringe. The needle was placed blindly in the supraclavicular area lateral to the pulsations of the subclavian artery and approximately 1 cm cephalad to the midpoint of the clavicle. A cork stopper from a can of ether was used to secure the needle in place. Intermittent injections of procaine were given to 27 patients to extend the duration of intraoperative anesthesia for up to 4 hours and 20 minutes.

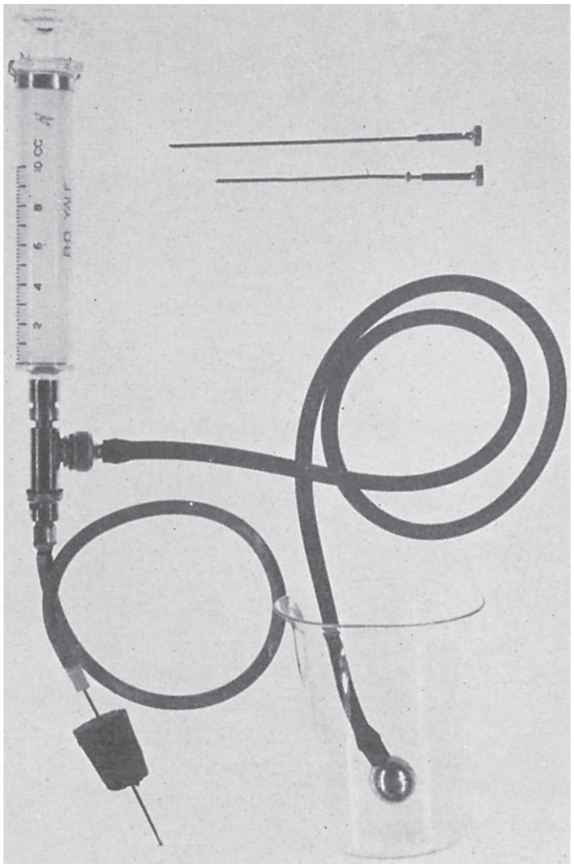
Almost a quarter century later, continuous subclavian perivascular, interscalene, and axillary brachial plexus blocks were reported by DeKrey et al,[26] Winnie,[27] and Selander[28] (Figure 13–2), respectively. In all reports, the authors used an intravenous-type needle-and-cannula set. The brachial plexus was identified with a paresthesia or fascial pop technique, the inner needle was removed, and the outer plastic cannula was advanced into a perineural location.



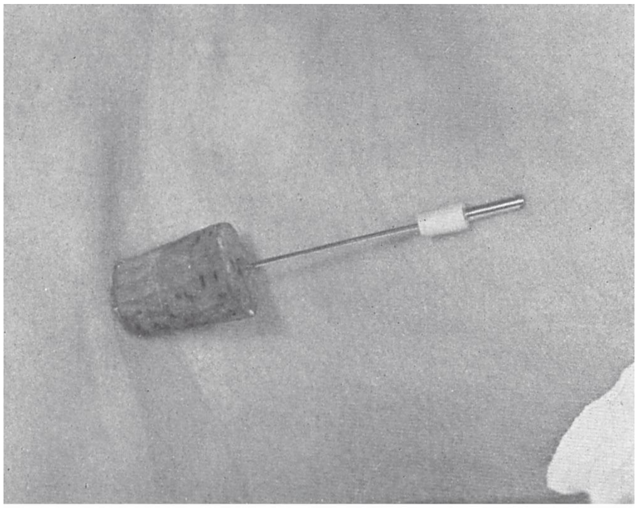
A



C

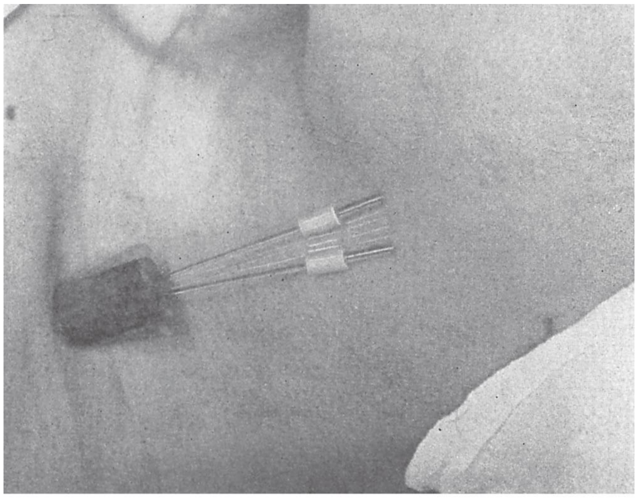


B

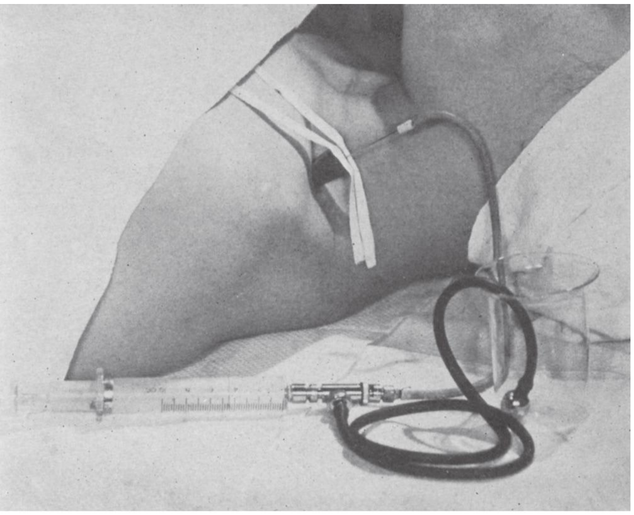


D

FIGURE 13–1. **A:** Apparatus consists of a 10-mL Luer lock syringe and the two-way valve as used in the Hingson-Edwards continuous caudal method. The tubing can be of any desired length (18 inches is sufficient). A malleable needle (Becton-Dickinson & Company) that has been filed to a blunt end to prevent perforation of blood vessels is used. A cork stopper from an ether can completes the apparatus. **B:** Apparatus with needle through the cork, usually 4 to 6 cm. **C:** Close view of blunted needle through the cork guard. The cork, when placed flush with the skin in the supraclavicular area, prevents the needle from going in deeper. **D:** Needle in place in the supraclavicular area. The cork prevents displacement inward and holds it upright.



E



F

FIGURE 13–1. (*Continued*) **E:** Pulsation of the needle indicating its close apposition to the subclavian artery. If the needle is placed lateral to the artery and on top of the first rib, of necessity it is in close proximity to the plexus. Injection of 30 to 40 mL of 1% procaine will induce anesthesia within 15 minutes. **F:** Apparatus in place and ready for fractional injections. The adhesive strapping over the cork keeps the needle in place and prevents its outward displacement. The cork firmly holding the needle prevents its inward displacement. (Reproduced with permission from Ansbro FP: A method of continuous brachial plexus block. *Am J Surg*. 1946 Jun;71:716-722.)

While these early accounts primarily involved "cannula-over-needle" devices, subsequent descriptions also included "catheter-through-needle" equipment. In the earliest report of a continuous lower extremity block, Brands and Callahan[29] performed continuous lumbar plexus blocks that lasted 72 to 96 hours for patients who sustained femoral neck fractures. The authors used an 18-gauge, 15 cm long needle and the loss-of-resistance method to identify the lumbar plexus psoas compartment and subsequently threaded an epidural catheter through the needle.

B

FIGURE 13–2. A, B: The Venflon cannula. (Reproduced with permission from Selander D: Catheter technique in axillary plexus block. Presentation of a new method. *Acta Anaesthesiol Scand*. 1977;21(4):324-329.)

The identification of important neuroanatomical features occurred concurrently with the description of these early CPNBs. This knowledge was instrumental to the further understanding of plexus anatomy and to the development of continuous regional anesthesia techniques. Landmark papers were published by Winnie[27] as well as Thompson and Rorie[30] outlining the existence of a brachial plexus sheath and suggesting the potential for continuous plexus anesthesia. Tuominen et al[31] provided early evidence for the safety of continuous plexus infusions of local anesthetic when they studied blood levels of bupivacaine during continuous axillary brachial plexus infusion.

Reflecting the popularity of the paresthesia, fascial pop, and loss-of-resistance techniques from the 1970s through the early 1990s, the majority of subsequent reports of CPNBs also involved the use of intravenous-type needles and cannula (cannula-over-needle devices)[31–36] as well as epidural-type needles and catheters (catheter-through-needle equipment).[23,37–40]

Development of Insulated Systems

In the late 1970s, concern surfaced in the regional anesthesia literature over the potential for long-bevel needles and the paresthesia technique to cause neurologic complications.[41,42] The introduction of nerve stimulator techniques[43] led to a decline in the popularity of the paresthesia, fascial pop, and loss-or-resistance methods in favor of identification of neural structures by electrolocation. Uninsulated, short-bevel needles could be used with nerve stimulators; however, insulated needles were found to provide more focused current output and consequently more accurate localization of neural structures.[44] As nerve stimulator techniques came into more widespread use in the 1990s, commercially insulated single-injection needles became available, but the design of CPNB needles and catheters initially failed to keep pace. For many years, regional anesthesia practitioners assembled intravenous access, spinal, and epidural equipment to create their own insulated CPNB apparatus.

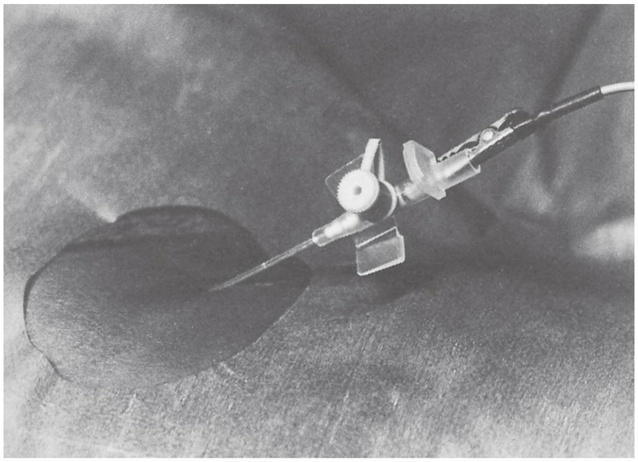
Numerous reports described connecting an intravenous needle and cannula to a current source to enable nerve stimulation. For example, Anker-Moller et al[45] adapted a 14-gauge intravenous needle and cannula set (Viggo, Sweden) to provide a continuous femoral nerve block. The nerve stimulator was attached inside the hub of the metal needle. The femoral nerve was identified with nerve stimulator assistance, the inner needle was removed, and a 16-gauge epidural catheter (Portex, UK) was inserted through the intravenous cannula (Figure 13–3).

Ben-David et al[46] inserted the metal needle of a 20-gauge intravenous catheter (Venflon, Viggo, Sweden) inside the proximal end of a 16-gauge central venous pressure needle (Secalon, Viggo, Sweden). They attached the negative electrode of the nerve stimulator to the exposed metal needle of the 20-gauge intravenous catheter and obtained appropriate stimulation during lumbar plexus block. The over-the-needle central venous cannula was then advanced beyond the tip of the needle and used for continuous lumbar plexus block (Figure 13–4).

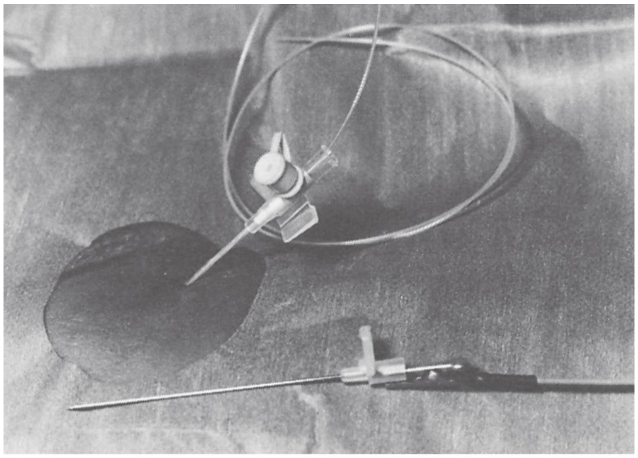
Concepcion[47] wrapped the stylet of a 26-gauge spinal needle around the metal introducer of a typical intravenous over-the-needle cannula. An alligator clip was then attached to the stylet to allow electrical stimulation using a nerve stimulator.

Prosser[48] devised yet another method to provide nerve stimulation during CPNBs for pediatric patients. This author connected a jackplug electrode into the hub of an intravenous cannula (Abbocath-T Venisystems, Abbott, Ireland) to make an electrical contact between the nerve stimulator and the central metal needle of the intravenous set (Figure 13–5). The surrounding Teflon®-coated sheath insulated all but the tip of the cannula. This adaptation was successful with 20-, 22-, and 24-gauge intravenous catheters and consequently was ideal for the pediatric population.

Further advancing pediatric regional anesthesia, Tan et al[49] used a radial artery catheterization set (#RA-04120; Arrow, Reading, PA) with a 20-gauge cannula over a 22-gauge, thin-walled, short-beveled needle for continuous axillary brachial plexus block. The set had a 0.018-inch integral spring wire that this group connected via an alligator clip to the negative pole of a nerve stimulator to enable electrolocation of the brachial plexus. Using a Seldinger technique, the guidewire was then advanced and used to direct the cannula into the brachial plexus sheath.



A



B

FIGURE 13–3. A: Placement of the infusion cannula. Nerve stimulator attached to the trocar (lateral view). **B:** The catheter is inserted through the infusion cannula (lateral view). (Reproduced with permission from Anker-Møller E1, Spangsberg N, Dahl JB, et al: Continuous blockade of the lumbar plexus after knee surgery: a comparison of the plasma concentrations and analgesic effect of bupivacaine 0.250% and 0.125%. *Acta Anaesthesiol Scand*. 1990 Aug;34(6):468-472.)

Spinal and epidural equipment has similarly been adapted for CPNBs performed with nerve stimulators. Several groups[1,50] have placed an 18-gauge intravenous cannula over a 22-gauge spinal needle to provide insulation to the distal part of the needle. A current source was then attached to the bare proximal metal needle, and local anesthetic was injected on identification of neural structures. The cannula was then threaded off the spinal needle into the perineural space and used for continuous infusion of local anesthetic for up to 2 days.

Alternatively, spinal needles and microcatheters have been used. The spinal microcatheters, however, were of such small size that injection was difficult, and they were prone to kinking. This equipment was eventually withdrawn from the market due to neurotoxicity associated with continuous spinal anesthesia.

While these designs allowed nerve stimulation through an insulated needle, a number of drawbacks still existed. Many

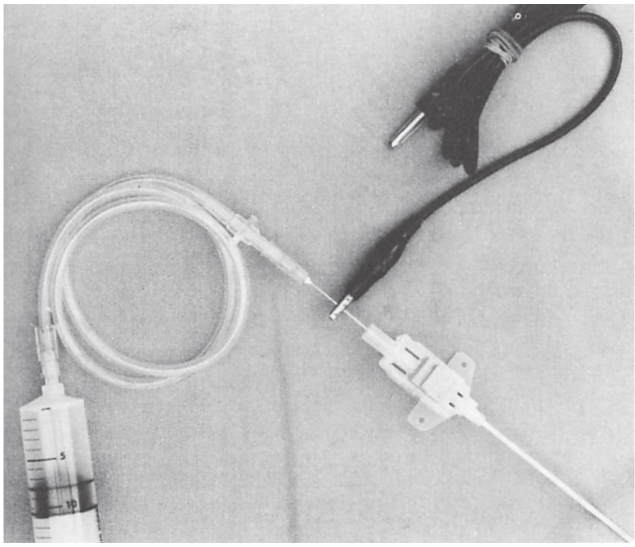


FIGURE 13–4. Assembly shows a 21-gauge needle inserted into the proximal end of the 16-gauge Secalon (Viggo, Sweden) central venous pressure catheter. Metal contact of the smaller needle inside the larger needle allows an electrical impulse to be conveyed to the Secalon needle tip. An alligator clip from the electrical stimulator is attached to the shaft of the 21-gauge needle. Intravenous extension tubing inserts into the hub of the 21-gauge needle. (Reproduced with permission from Ben-David B1, Lee E, Croitoru M: Psoas block for surgical repair of hip fracture: a case report and description of a catheter technique. *Anesth Analg*. 1990 Sep;71(3):298-301.)

steps were required between identification of the nerve and threading the catheter. This increased the risk of catheter misplacement and the likelihood of committing a breach in sterility. Despite the insulation provided by an intravenous-type cannula over a metal needle, the uninsulated area of the distal needle tip was of significant size and could adversely affect the accuracy of nerve location. Unfortunately, in these self-assembled systems, the cannula rarely provided a snug fit over the needle. In addition, there was continued concern about the risk of neurologic complications from long-beveled intravenous-type needles. Finally, the shape of the needle tip did not facilitate catheter threading in directions other than parallel to the course of the needle.

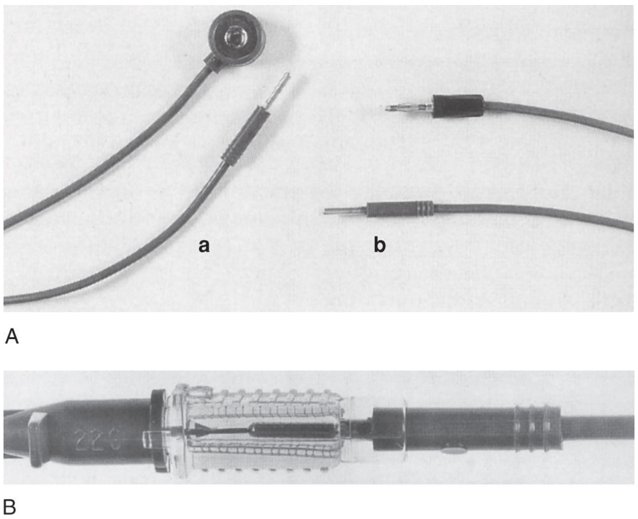

FIGURE 13–5. **A:** Peripheral nerve stimulator lead fitted with (a) standard press stud and jackplug connectors; (b) modified connectors, press stud replaced with second jackplug. **B:** Electrical contact between the Abbocath's central metal cannula and original jackplug from the lead. Increased effort into the development of CPNB equipment and the introduction of the safer long-acting local anesthetic ropivacaine (Astra, Westborough, MA) in the 1990s further stimulated the expansion of CPNB techniques.

Commercially available cannula-over-needle systems were developed and marketed by various companies. B. Braun introduced a set that consisted of a cannula over a short-bevel needle with an accompanying catheter. The advantage was that the components were designed to fit snugly together (Figure 13–6). Both Pajunk (Geisengen, Germany) and B. Braun subsequently developed systems that involved a short-bevel needle with an integrated wire for nerve stimulation and with connection tubing for concurrent aspiration and injection (Figure 13–7). There was an accompanying catheter that could be threaded through the cannula. Some manufacturers offered the option of a Sprotte or Facet needle tip and a variety of sizes, some suitable for pediatric patients. Early Arrow equipment involved a bullet-tip needle for enhanced sensation of fascial penetration and a theoretical reduction in neurology injury (Figure 13–8).

Clinical Pearls

- Short-bevel block needles were used with the paresthesia technique to minimize nerve injury.
- Insulated needles are used with nerve stimulation to locate the nerve or plexus.
- The design of CPNB needles and catheters initially lagged behind the development of single-injection PNB equipment.

Modern Insulated Systems

The next advance in the development of insulated CPNB equipment involved catheter-through-needle systems (ie, Contiplex® Tuohy,[51] B. Braun Medical, Bethlehem, PA, and Plexolong®, Pajunk). A Tuohy needle was insulated along its length with the exception of a pinpoint area at its most distal tip. A stimulating wire was attached to the needle. Early prototypes involved a detachable wire with an alligator clip on one end and a plug for a nerve stimulator on the other end (Figure 13–9). In subsequent models, the stimulating wire was permanently affixed to the metal needle (Figures 13–10 and 13–11). This wire also served as a marker for the open face of the needle bevel distally. A 20-gauge, multiorifice epidural catheter and connector were included. The curved distal tip of the Tuohy needle facilitated advancement of the catheter parallel to the nerve(s) in question. Various needle lengths were

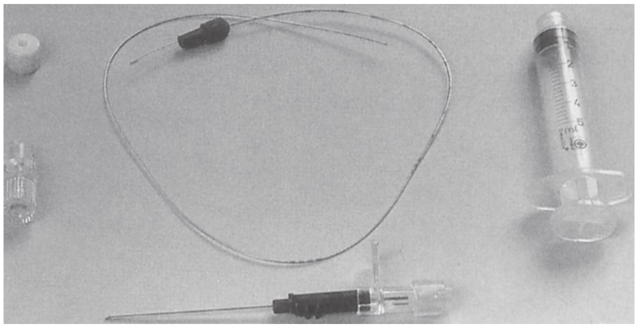

FIGURE 13–6. Brachial plexus infusion kit as used in this study (Contiplex®, B. Braun Australia Pty. Ltd.). The introducing cannula is 18 gauge, with a 0.85-mm diameter catheter, which is threaded into the axillary brachial plexus sheath. The needle within the cannula is a short-bevel type (30°). (Reproduced with permission from Mezzatesta JP, Scott DA, Schweitzer SA, et al: Continuous axillary brachial plexus block for postoperative pain relief. Intermittent bolus versus continuous infusion. *Reg Anesth*. 1997 Jul-Aug;22(4):357-362.)

manufactured, allowing CPNB of nerves of varying depths. Sprotte and Facet needle tips were also manufactured to enable catheter threading at various needle angle approaches.

Some CPNB equipment (Contiplex Tuohy[51]) incorporates an adapter with a Luer lock head and a hemostatic valve that can be fitted to the proximal end of the needle (Figure 13–10). The adapter has a central diaphragm that allows passage of a catheter through a port separate from where aspiration and injection occur. This eliminates the need for equipment disconnection and minimizes the likelihood of needle movement, catheter misplacement, and secondary block failure. This adapter also has a side arm connected to extension tubing that allows for continuous aspiration for blood and injection of solution by an assistant.

Catheters initially manufactured for epidural use have been adapted for CPNBs. They are well suited for this application as they are nonirritating and flexible and generate minimal friction on passage through needles. Graduated markings provide an indicator of insertion depth and radiopacity provides an additional method to confirm placement location. Some advocate the use of styletted catheters, believing that they are easier to advance; however, these may result in greater tissue or blood vessel trauma. Multiorifice catheters have a closed distal tip and

FIGURE 13–10. The Contiplex® Tuohy (B. Braun, Melsungen AG, Germany) consists of an insulated Tuohy needle with a pinpoint uninsulated tip, an integrated stimulating wire, extension tubing, and a connector with a hemostatic valve allowing the insertion of a catheter. This design enables simultaneous nerve stimulation, aspiration, and injection and allows for an immobile needle during catheter insertion. (Used with permission from Holly Evans, MD.)

three distal openings (0.5, 1.0, and 1.5 cm from the tip). Single-orifice catheters have a single opening at the distal end of the catheter (Figure 13–12). Multiorifice catheters provide better spread of local anesthetic solution that is administered by bolus; consequently, they are associated with improved analgesia compared to single-orifice catheters.[52]

Clinical Pearls

Continuous peripheral nerve block equipment typically includes the following:

- An insulated, large-bore needle (ie, Tuohy tip) with an integrated wire to allow nerve stimulation
- A flexible, atraumatic catheter that is threaded through the needle into a perineural location
- Clear, flexible tubing that can be attached to needle or catheter for injection and aspiration

Stimulating Catheters

Stimulating catheters provide the ability to conduct current to their distal end. They were developed as a tool to assess the proximity of the catheter's distal tip to the neural structures and in an attempt to reduce the likelihood of secondary block failure. In one of the first published reports, Sutherland[53] used a 1.0-mm outer-diameter ureteral catheter (Portex-Boots, Kent, UK) with a metal stylet. This author adapted the catheter by removing 50 mm from its distal tip and by rethreading the metal stylet so that it just protruded from the distal end (Figure 13–12). The proximal part of the stylet was folded over the proximal end of the catheter to maintain the correct length and to facilitate an electrical connection to the nerve stimulator. This equipment was used successfully for continuous sciatic nerve block following foot surgery.

Boezaart et al[54] subsequently described their adaptation of a wire-reinforced epidural catheter for use as a stimulating catheter. They used a polyurethane (Tecothane®) thermoplastic catheter

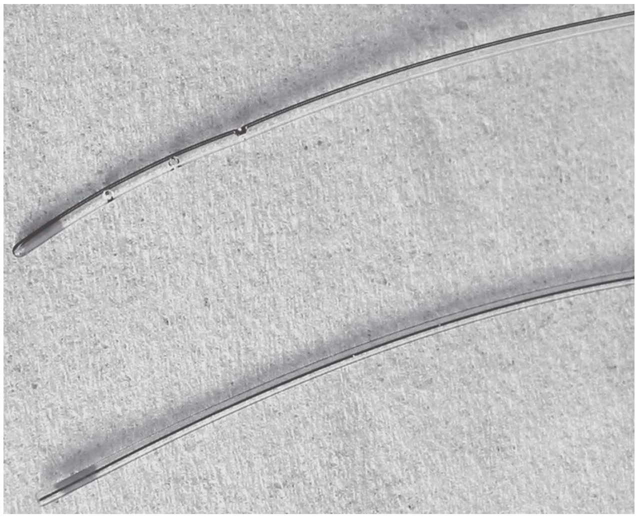

FIGURE 13–12. A closed-tip multiorifice catheter (top) and an open-tip single-orifice catheter (bottom). (Used with permission from Holly Evans, MD.)

with an inner steel spring reinforcement and a nonferromagnetic stainless steel stylet (Arrow Theracath®) and removed part of the outer catheter to provide a 5-mm unsheathed metal tip. These authors described removing the inner stylet from an uninsulated 17-gauge Tuohy needle and advancing the epidural catheter through the needle such that the metal tip of the catheter did not make contact with the metal needle. This effectively allowed electrolocation during needle and catheter placement for continuous interscalene brachial plexus block. A later modification involved the addition of an insulated needle with an inner metal stylet to the set (StimuCath®, Arrow International).[55,56] Further revisions resulted in the addition of an alligator clip to allow direct connection to a nerve stimulator (Figure 13–13) and, more recently, the addition of an integrated stimulating wire attached to the needle.

While this stimulating catheter was a significant advancement, several limitations existed. The needle bevel was sharper relative to other manufacturers' equipment and was associated with concern about neural injury. The opacity of the blue 20-gauge and white 19-gauge catheters made identification of aspirated blood challenging. The relatively large uninsulated segment at the distal tip of the needle could decrease the accuracy of nerve identification. And, there was a risk that the area of exposed wire at the distal tip of the catheter could uncoil in vivo if cut or traumatized.

In an attempt to address some of these shortcomings, Kick et al[57] developed another stimulating catheter (Stimulong® Catheter Set, Pajunk) and reported its reliability in a series of 10 supraclavicular brachial plexus blocks (Figures 13–14A and 13–14B). It consisted of a 20-gauge, single-hole, 400-mm polyamide catheter with a 405-mm indwelling removable conducting stylet. The metal wire stylet was insulated with Teflon coating along its length with the exception of the distal 0.3 mm. The proximal end had a plug to allow connection to a nerve stimulator. Subsequent modification involved incorporation of an integrated wire within the catheter (Stimulong Plus®, Pajunk)[58] (Figure 13–15).

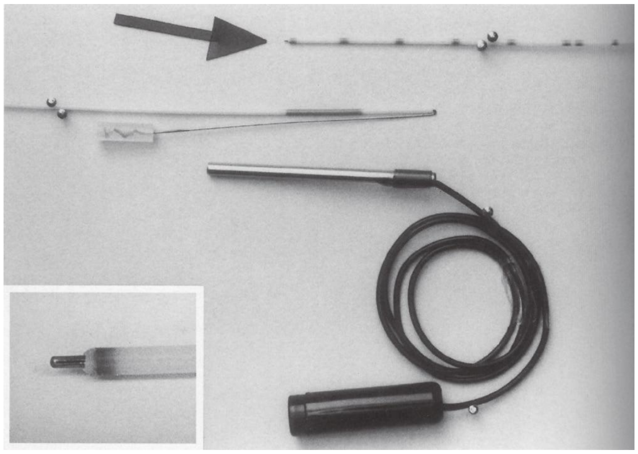

FIGURE 13–13. Shortened catheter with stylet just protruding from the distal end (inset) and folded over to maintain the position at the proximal end. Electrical connection is made by sliding a firmly fitting metal tube over the proximal end of the catheter. Stimulating catheters have been compared to nonstimulating catheters for CPNB. A stimulating catheter is associated with lower local anesthetic consumption and reduced requirement for additional opioid analgesia,[59–61]; however, it may be more technically challenging to place under ultrasound guidance.[62,63]

Clinical Pearl

- A stimulating catheter can confirm perineural location and may reduce the requirement for supplemental analgesia.

Echogenic Systems

The use of ultrasound to assist in the placement of CPNBs is now routine. Consequently, many manufacturers have incorporated echogenic features into their CPNB equipment. B. Braun incorporates laser reflectors into the needle of their Contiplex Ultra series. Pajunk catheters are wire reinforced and contain radiocontrast strips at their distal end.

Clinical Pearl

- Echogenic needles and catheters improve visualization of equipment inserted under ultrasound guidance.

NERVE LOCALIZATION SYSTEMS

Nerve Stimulator

Nerve stimulators generate an electrical current that passes through to the tip of an insulated needle or stimulating catheter to stimulate a nerve/plexus. A motor twitch appropriate for the nerve in question is sought. The limits of this technique must be appreciated. Studies of nerve blocks performed with both nerve stimulation and ultrasound guidance have shown that a needle tip can contact a nerve without resulting in a motor twitch. Furthermore, a needle tip can be within a nerve even when there is no motor twitch at relatively low current.[64]

Ultrasound

Neural and perineural anatomy can be viewed with ultrasound imaging. Anatomical variants can be seen. The precise location and depth to neural structures can be estimated. Surrounding structures and vasculature can be identified and avoided. An image of the nerve block needle, catheter, and local anesthetic injection can be seen in relation to the nerve/plexus in real time. Though associated with the need for additional operator training and greater equipment expense, potential advantages of ultrasound include enhanced block success and reduced complications. Further details are provided in the relevant chapters.

Global Positioning System (Ultrasonix)

One of the newest nerve localization techniques involves the use of a global positioning system (ie, SonixGPS, Ultrasonix, Richmond, BC, Canada). Both the needle and the ultrasound probe contain sensors. As a result, the ultrasound screen displays the predicted needle trajectory and the location where the needle will intersect with the ultrasound beam.

Other: Fluoroscopy, Paresthesia, Fascial Click

There are additional nerve localization techniques. Fluoroscopy uses continuous x-ray imaging to localize a nearby bony structure. When appropriate, injection of contrast dye can be used to outline the location of perineural structures.

The paresthesia technique involves advancing the nerve block needle to contact a nerve/plexus. While sensory paresthesia may result, it is not guaranteed. Consequently, the paresthesia technique may be inaccurate and potentially harmful.

The fascial click technique involves a tactile "pop" sensation as a nerve block needle penetrates fascial layers. While this technique may be used for field blocks (i.e., fascia iliaca), its accuracy for nerve localization is limited.

Clinical Pearls

- Nerve stimulation can assist with identification of neural structures; however, limitations exist.
- Ultrasound guidance allows identification of important neural and perineural structures and allows confirmation of appropriate perineural injection of solute.

POSTBLOCK CONSIDERATIONS

Catheter Fixation Systems

One of the most common etiologies of secondary CPNB failure involves catheter displacement. Various techniques can be used to reduce the chance of catheter dislodgement. Subcutaneous tunneling of the catheter can be used in suitable locations. A liquid adhesive can be applied where the catheter exits the skin and under the clear occlusive dressing. There are adhesive dressings that have been specifically designed to fix a catheter to the skin (i.e., Epi-Guard, Copenhagen MedLab, Glostrup, Denmark).

Infusion Pumps

The infusion pump selected should be reliable and accurate. It should contain an appropriate volume of local anesthetic solution for the anticipated duration of infusion. The pump should be adjustable and have the ability to provide a continuous infusion as well as patient-controlled boluses at specifically timed intervals. These features enable the CPNB to be tailored to changing patient requirements.

Outpatient perineural infusion pumps must be reliable, accurate, and compact in size. Electronic or elastomeric pumps are available for outpatient use. Some are disposable, whereas others are reusable and must be returned by the patient to the hospital.

Patient Follow-up

Patients with perineural catheters must be followed daily. The catheter site is inspected for cleanliness, integrity, and possible dislodgement. The catheter site is evaluated for signs of infection, such as redness, warmth, or purulent discharge. Adequacy of analgesia is assessed, and modifications to the pain management plan are made. The patient is educated about the care of the numb extremity and fall prevention strategies if applicable. Symptoms of local anesthetic toxicity are sought. Pump function is reviewed.

Outpatient Perineural Catheters

Outpatients are contacted daily by telephone, at which time the follow-up outlined previously is performed. The procedure for catheter removal is discussed and performed by the patient and the patient's caregiver at home. Disposable pumps are placed in the trash, while nondisposable pumps are returned in person or mailed to the hospital.

Clinical Pearl

- The safety and efficacy of CPNBs relies on properly securing the catheter to prevent dislodgement, appropriate follow-up by a knowledgeable health care worker, and adequate patient education regarding the care of the numb extremity, potential complications, and local anesthetic pump function.

CONCLUSION

This chapter highlights the equipment required for safe and effective perineural infusion of local anesthetic solutions. The development of specialized needle-and-catheter systems for this purpose was initially slow; however, currently available systems are reliable and applicable to most clinical situations.

When considering deterrents to the more widespread adoption of CPNBs, lack of operator training has frequently been cited in the past. Currently, there are numerous learning opportunities available, including hands-on courses, preceptorships, virtual reality, and simulation training. There has also been improvement in patient and surgeon education regarding the potential benefits of CPNBs. Nevertheless, some concern persists about potential side effects, including nerve injury and falls. While ongoing research has enhanced our understanding of the mechanism of nerve injury related to regional anesthesia, further information is required. Other factors limiting the clinical application of CPNBs may be institutional and should be addressed at a local level. These include time pressure in busy operating rooms, lack of qualified assistants for block performance, lack of funds for equipment, or lack of support for postoperative care.

CHAPTER 14

Electrical Nerve Stimulators and Localization of Peripheral Nerves

André van Zundert and Admir Hadzic

INTRODUCTION

Peripheral nerve stimulation (PNS), an important tool to aid administration of peripheral nerve blocks. Improvements in electrical nerve localization technology have led to a number of commercially available nerve stimulators that are superior and more advanced compared to older devices. With the introduction of ultrasound-guided nerve blocks, however, there has been confusion on the role of nerve stimulation in the setting of ultrasound-guided nerve blocks. This review focuses on the foundation of nerve stimulation with a short historical background, the latest developments in the technology, and the role of nerve stimulation with ultrasound-guided peripheral nerve blocks.

HISTORY

Quick Facts

- 1780: Luigi Galvani[1] was the first to describe the effect of electrical neuromuscular stimulation in a frog experiment.
- 1912: Perthes[2] developed and described an electrical nerve stimulator.
- 1955: Pearson[3] introduced the concept of insulated needles for nerve location.
- 1962: Greenblatt and Denson[4] introduced a portable solid-state nerve stimulator with variable current output and described its use for nerve location.
- 1973: Montgomery et al[5] demonstrated that noninsulated needles require significantly higher current amplitudes than the insulated needles.
- 1984: Ford et al[6] reported a lack of accuracy with noninsulated needles once the needle tip passed the target nerve.
- Ford et al suggested the use of nerve stimulators with a constant current source, based on the comparison of the electrical characteristics of peripheral nerve stimulators.[7,8]
- In 2004, Hadzic & Vloka defined the electrical characteristics and suggested manufacturing standard for modern nerve stimulators.[9]

It took nearly 100 years from the concept of nerve stimulation to adoption of electrolocalization during peripheral nerve blockade in the 1990s. The more widespread introduction of nerve stimulation in the practice of peripheral nerve blockade led to research on the needle-nerve relationship and the effect of stimulus duration.[10,11] More recently, the principles of electrical nerve stimulation were applied to surface mapping of peripheral nerves using percutaneous electrode guidance[12–15] for confirmation and epidural catheter placement[16–18] and peripheral catheter placement.[19] This chapter discusses the electrophysiology of nerve stimulation, electrical nerve stimulators, various modes of localization of peripheral nerves, and integration of the technology into the realm of ultrasound-guided regional anesthesia.

What Is Electrical Peripheral Nerve Stimulation?

Electrical nerve stimulation in regional anesthesia is a method of using a low-intensity (up to 5 mA) and short-duration (0.05 to 1 ms) electrical stimulus (at 1- to 2-Hz repetition rate) to obtain a defined response (muscle twitch or sensation) to locate a peripheral nerve or nerve plexus with an (insulated) needle before injecting local anesthetic in close proximity to the nerve to block nerve conduction for surgery or acute pain management. The use of nerve stimulation can recognize an intraneural or intrafascicular needle placement injection, prevent further needle advancement intraneurally and help reduce the risk of nerve injury.

Electrical nerve stimulation can be used for a single-injection technique, as well as for guidance during the insertion of continuous nerve block catheters. More recently, ultrasound guidance in

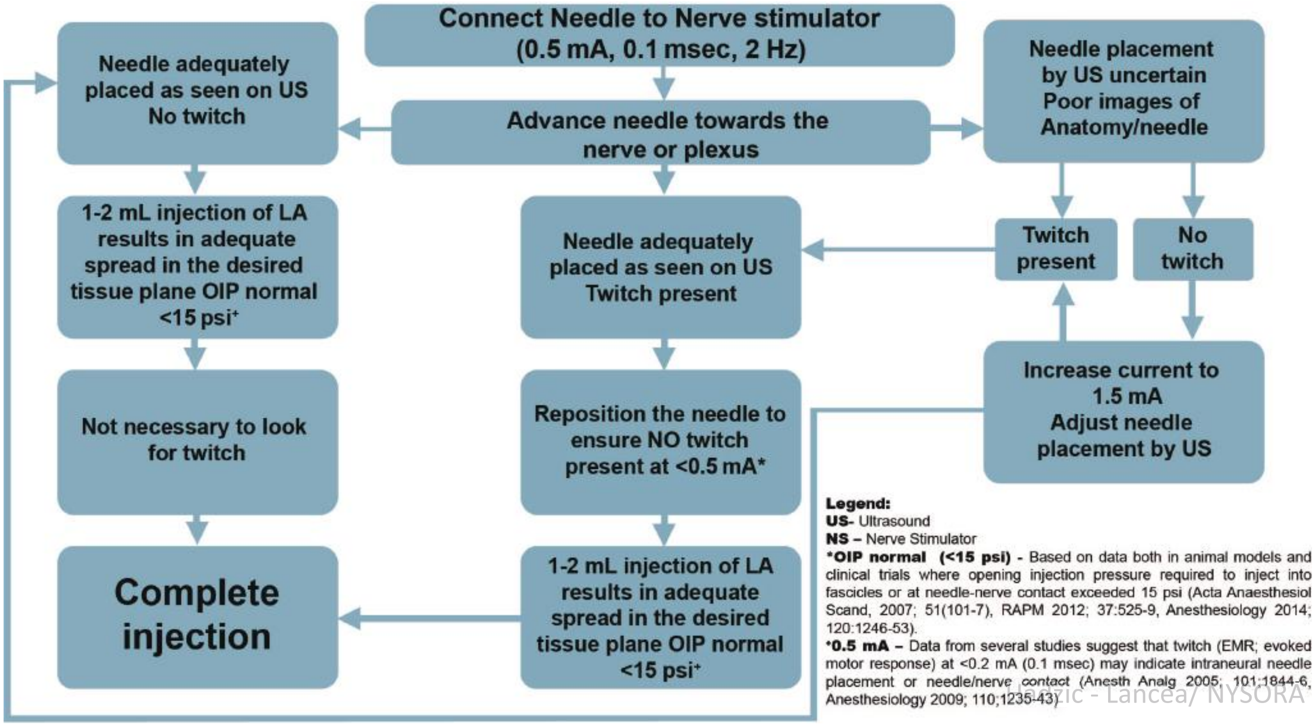

FIGURE 14–1. An algorithm for use of nerve stimulation with ultrasound-guided nerve blocks. Please note that the nerve stimulator here is used primarily as a safety-monitoring tool, rather than a nerve localization tool. The stimulator is set at 0.5 mA (0.1 ms), and the current is rarely manipulated. Instead, a motor response is obtained; extra caution is exercised as this indicates an intimate needle-nerve relationship. Instead of adjusting the current intensity to determine at which current the motor response extinguishes, the needle is slightly withdrawn to abolish the response and distance the needle tip from the nerve. A small amount of local anesthetic is then injected to determine the needle tip location while avoiding an opening pressure greater than 15 psi. LA, local anesthetic; OIP, opening injection pressure.

combination with nerve stimulation ("dual monitoring") has become a common practice to guide needle placement and robust medicolegal documentation of nerve block procedures.

Indications for the Use of PNS

In principle, almost all plexuses or other large peripheral nerves can be located using PNS.[20] When used with ultrasound guidance, PNS becomes primarily a safety tool. The goal of nerve stimulation is to place the tip of the needle (more specifically, its orifice for injection) in close proximity to the target nerve to inject the local anesthetic within the tissue space that contains the nerve. When used with ultrasound guidance, PNS becomes primarily a safety tool. An unexpected motor response during needle advancement may alert the operator that the needle is in immediate vicinity to the nerve and therefore, prevent further needle advancement when the needle tip position is not well seen on ultrasound. The motor response (twitch) to PNS is objective, reliable and independent from the patient's (subjective) response. Even with ultrasound guidance, nerve stimulation is often helpful to confirm that the structure imaged is actually the nerve that is sought. Likewise, the needle-nerve relationship may not always be visualized on ultrasound; an unexpected motor response can occur, alerting the operator that the needle is already in close proximity to the nerve. The occurrence of a motor response at a current intensity of less than 0.5 mA can serve as an indicator of a needle-nerve contact or intraneural needle placement.[21,22] Although this response may not be present even with an intraneural needle position (low sensitivity), its presence is essentially always indicative of intraneural placement (high specificity). An algorithm for using nerve stimulation as a monitoring tool during ultrasound-guided blocks is provided in Figure 14–1.

The disadvantages of PNS include the need for additional equipment (nerve stimulator and insulated needles), the greater cost of insulated needles, and exceptional cases for which it may be difficult to elicit a motor response.

Clinical Pearls

- Occurrence of a motor response at 0.5 mA (0.1 ms) indicate needle-nerve contact or intraneural needle placement.
- Occurrence of the motor response at 0.5 mA should prompt caution. The practitioner should stop advancing the needle, withdraw the needle by 1 mm, and inject 1 mL of local anesthetic (assuming the opening pressure is less than 15 psi) to determine the needle tip position and adjust the needle and injection process accordingly.
- PNS should not be relied on in a patient receiving muscle relaxants.
- The presence of spinal or epidural anesthesia does not negatively affect the reliability of PNS.
- Multiple injection techniques may decrease PNS sensitivity due to the partial nerve blockade that occurs between injections.

BASICS OF NEUROPHYSIOLOGY AND ELECTROPHYSIOLOGY

Membrane Potential, Resting Potential, Depolarization, Action Potential, and Impulse Propagation

All living cells have a **membrane potential** (a voltage potential across their membrane, measured from the outside to the inside), which varies (depending on the species and the cell type) from about –60 to –100 mV. Nerve and muscle cells in mammals typically have a membrane potential (resting potential) of about –90 mV.

Only nerve and muscle cells have the capability of producing uniform electrical pulses, called **action potentials** (sometimes called spikes), which are propagated along their membranes, especially along the long extensions of nerve cells (nerve fibers, axons). A decrease in the electric potential difference (eg, from –90 to –55 mV, or **depolarization**) elicits an action potential. If the depolarization exceeds a certain *threshold,* an action potential or a series of action potentials is generated by the nerve membrane (also called firing) according to the all-or-nothing rule, resulting in propagation of the action potential along the nerve fiber (axon). To **depolarize** the nerve membrane from outside the cell (extracellular stimulation), the negative **polarity** of the electrical stimulus is more effective in removing the positive charge from the outside of the membrane. This in turn decreases the potential across the membrane toward the threshold level.

There are various types of nerve fibers. Each fiber type can be distinguished anatomically by its diameter and degree of myelination. Myelination is formed by an insulating layer of Schwann cells wrapped around the nerve fibers. These characteristics largely determine the electrophysiologic behavior of different nerve fibers, that is, the speed of impulse propagation of action potentials and the threshold of excitability. Most commonly, the distinguishing features are motor fibers (eg, Aα, Aβ) and pain fibers (C). The Aα motor fibers have the largest diameter and highest degree of myelination and therefore the highest speed of impulse propagation and a relatively low threshold for external stimulation. The C fibers (which transmit severe, dull pain) have little to no myelination and are of smaller diameter. Consequently, the speed of propagation in these fibers is relatively low, and the threshold levels to external stimulation, in general, are higher.

There are several other efferent fibers, which transmit responses from various skin receptors or muscle spindles (Aδ). These are thinner than Aα fibers and have less myelination. Some of these (afferent) sensory fibers, having a relatively low threshold level, transmit the typical tingling sensation associated with a lower level of pain sensation when electrically stimulated (similar to the sensation when hitting the "funny bone"). Such sensation can occur during transcutaneous stimulation before a motor response is elicited.

The basic anatomic structure of myelinated Aα fibers (motor) and nonmyelinated C fibers (pain) is shown schematically in Figure 14–2. The relationship between different stimuli and the triggering of the action potential in motor and

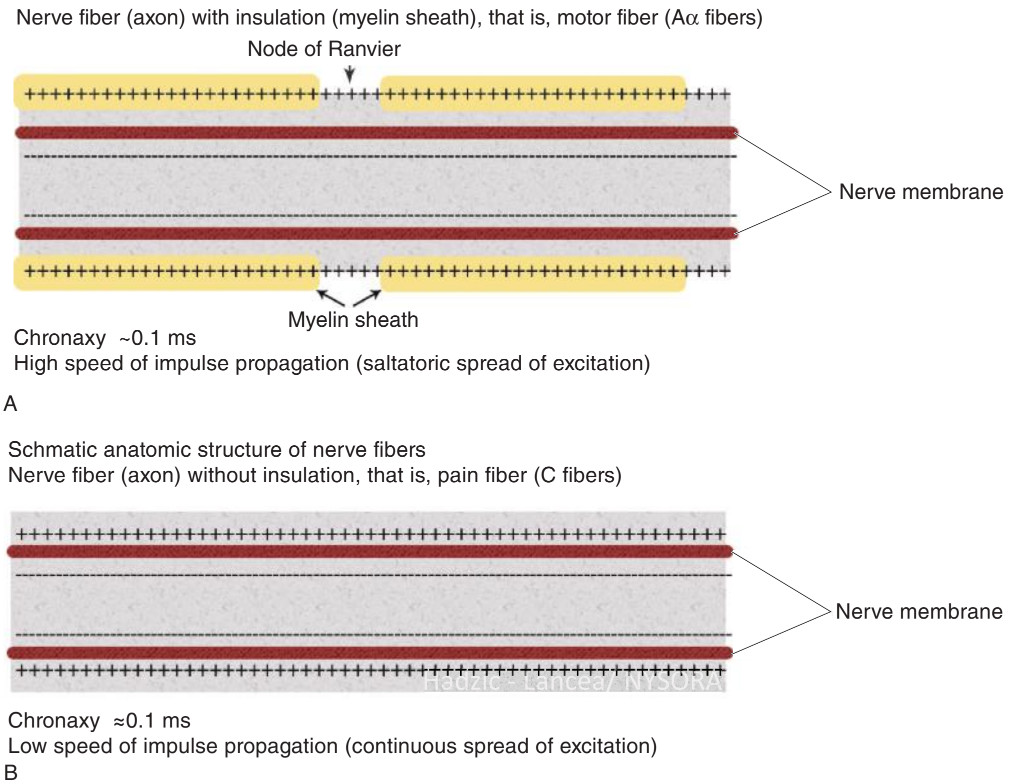

FIGURE 14–2. Schematic anatomic structures of nerve fibers. **A:** Nerve fiber (axon) with insulation (myelin sheath), (Aα fibers). **B:** Nerve fiber (axon) without insulation (C fiber).

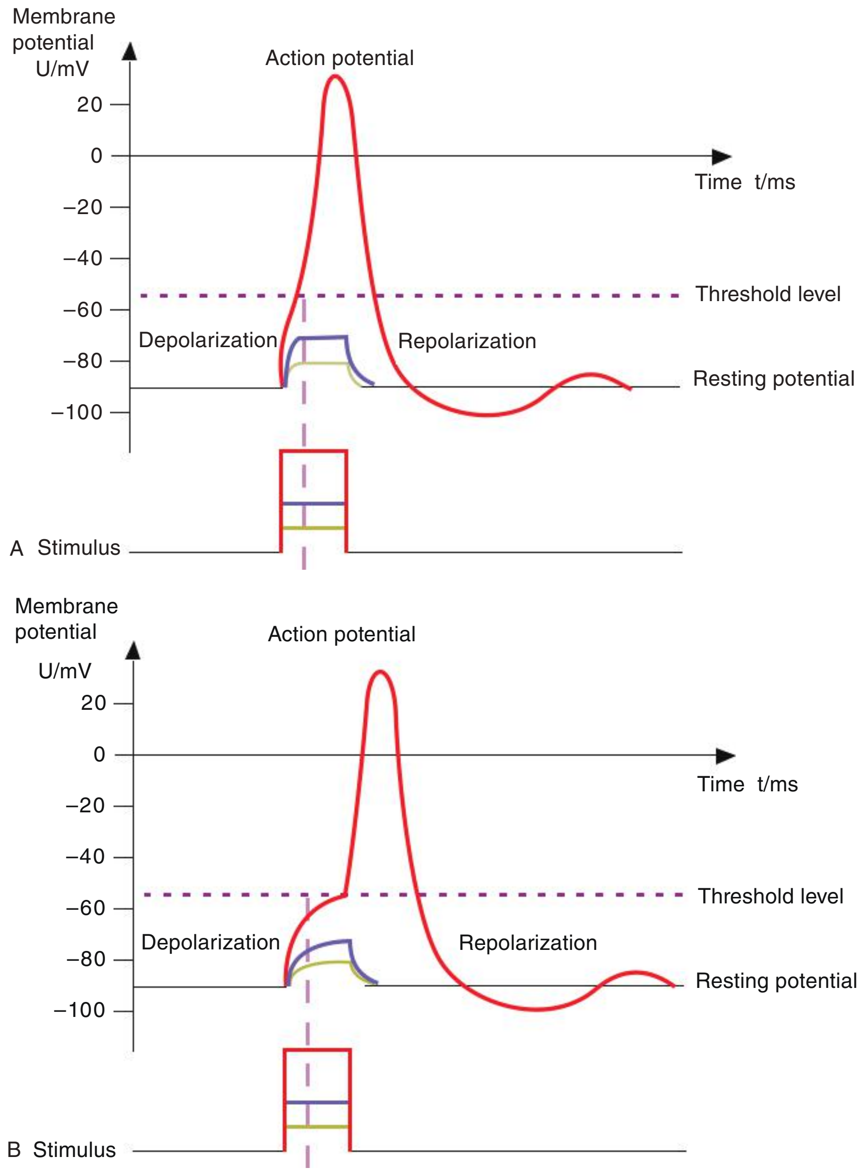

FIGURE 14–3. **A:** Action potential, threshold level, and stimulus. Motor fibers have a short chronaxy because of the relatively low capacitance of their myelinated membrane (only the area of the nodes of Ranvier count; see Figure 14–1); therefore, it takes only a short time to depolarize the membrane up to the threshold level. **B:** Action potential, threshold level, and stimulus. Pain fibers have a long chronaxy because of the higher capacitance of their nonmyelinated membrane (the entire area of the membrane counts); therefore, it takes a longer time to depolarize the membrane up to the threshold level. Short impulses (as indicated by the vertical dotted line) would not be able to depolarize the membrane below the threshold level.

pain fibers is illustrated in Figures 14–3A and 14–3B, respectively.

Threshold Level, Rheobase, Chronaxy

A certain minimum current intensity is necessary at a given pulse duration to reach the **threshold level** of excitation. The lowest threshold current (at infinitely long pulse durations) is called **rheobase**. The pulse duration (pulse width) at double the rheobase current is called **chronaxy**. Electrical pulses with the duration of the chronaxy are most effective (at relatively low amplitudes) to elicit action potentials. This is the reason why motor response can be elicited at such short pulse duration (eg., 0.1 ms) at relatively low current amplitudes while avoiding the stimulation of C-type pain fibers. Typical chronaxy figures are 50–100 μs (Aα fibers), 170 μs (Aδ fibers), and 400 μs or greater (C fibers). The relationship of the rheobase to chronaxy for motor fibers versus pain nerve fibers is illustrated in Figure 14–4.

Impedance, Impulse Duration, and Constant Current

The electrical circuit is formed by the nerve stimulator, the nerve block needle and its tip design, the tissue characteristics

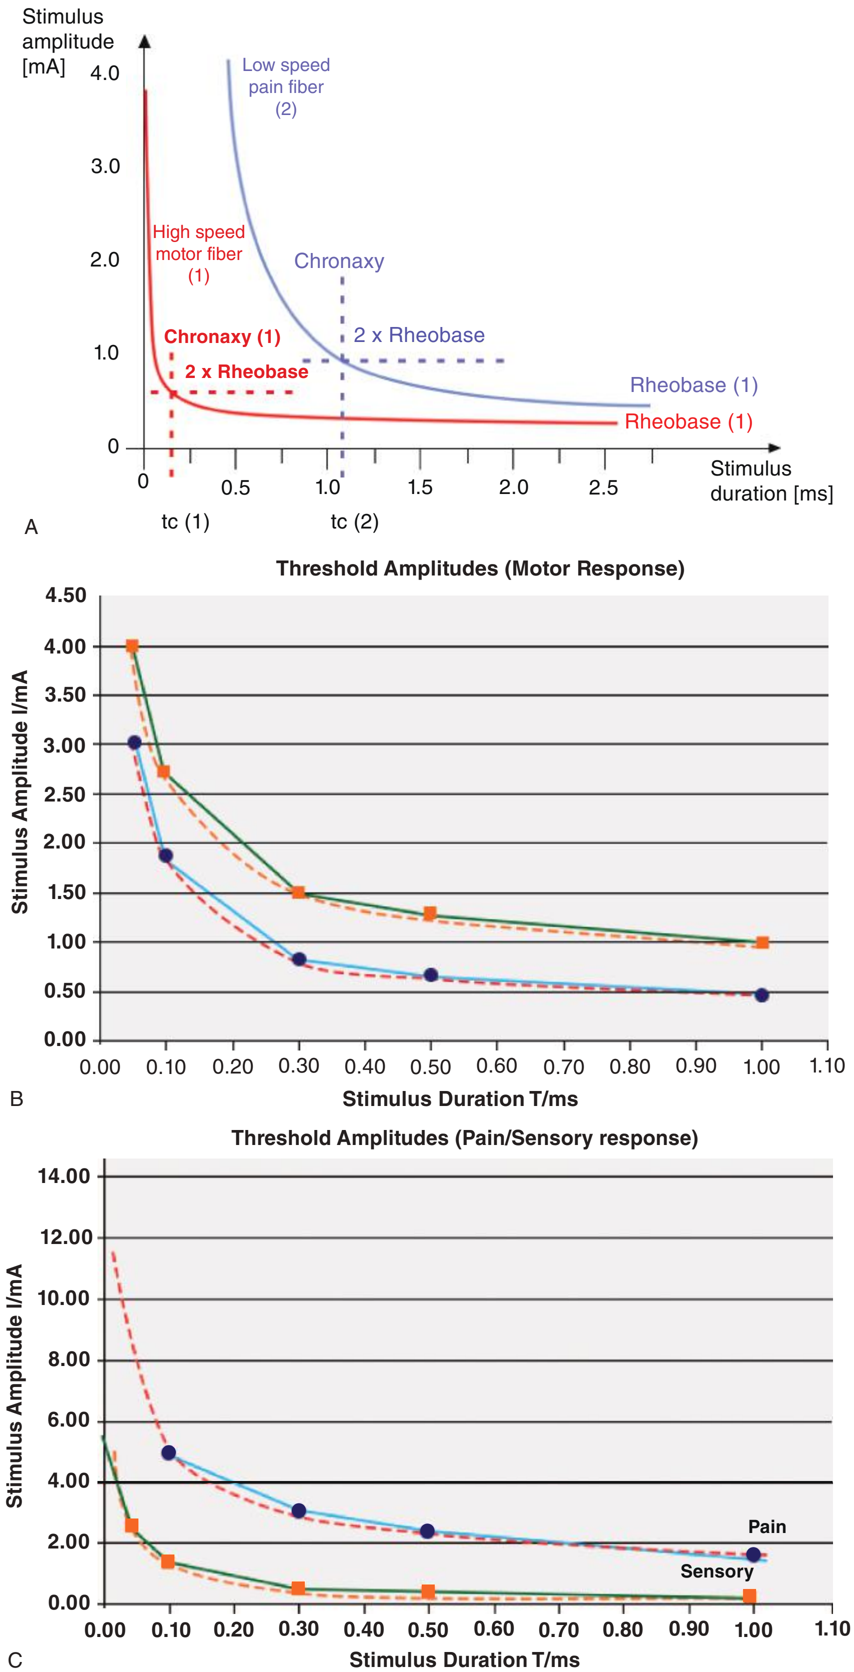

FIGURE 14–4. **A:** Comparison of threshold curves, chronaxy, and rheobase level of motor (high-speed) and pain (low-speed) fibers. **B:** Experimental data, threshold amplitudes obtained with percutaneous stimulation (Stimuplex Pen and Stimuplex HNS 12). Stimulation obtained with percutaneous stimulation of the median nerve near the wrist looking for motor response of the thumb. **C:** Threshold amplitudes obtained with percutaneous stimulation (Stimuplex Pen and Stimuplex HNS 12). Stimulation of the median and radial nerves near the wrist and at the midforearm looking for electric paresthesia (tingling sensation) in the middle and ring fingers (median nerve) or superficial pain sensation near the wrist (radial nerve), respectively.

of the patient, the skin, the skin electrode (grounding electrode), and the cables connecting all the elements. The resistance of this circuit is not just a simple Ohm's resistor equation because of the specific capacitances of the tissue, the electrocardiographic (ECG) electrode-to-skin interface, and the needle tip, which influence the overall resistance. The capacitance in the described circuit varies with the frequency content of the stimulation current, and it is called *impedance* or a *complex resistance,* which is dependent on the frequency content of the stimulus. In general, the shorter the impulse, the higher its frequency content is and, consequently, the lower the impedance of a circuit with a given capacitance. Conversely, a longer pulse duration has a lower frequency content. As an example, for a 0.1-ms stimulus, the main frequency content is 10 kHz plus its harmonics, whereas for a 1.0-ms impulse, the main frequency content is 1 kHz plus harmonics). In reality, the impedance of the needle tip and the electrode-to-skin impedance have the highest impact. The impedance of the needle tip largely depends on the geometry and insulation (conductive area). The electrode-to-skin impedance can vary considerably between individuals (eg, type of skin, hydration status) and can be influenced by the quality of the ECG electrode used.

Because of the variable impedance in the circuit, created primarily by the needle tip and electrode-to-skin interface, a nerve stimulator with a constant current source and sufficient (voltage) output power is necessary to compensate for the wide range of impedances encountered clinically.

CLINICAL USE OF PERIPHERAL NERVE STIMULATION

Setup and Checking the Equipment

The following are a few important aspects for successful electrolocalization of the peripheral nerves using PNS:

- Use only a nerve stimulator specifically manufactured for nerve blocks.
- Use insulated nerve stimulation needles (Table 14–1).
- Use high-quality skin electrodes with a low impedance.
  - Some lower-priced ECG electrodes can have too high an impedance/resistance.
- Before starting the procedure, check for the proper functioning of the nerve stimulator and the connecting cables.
- During the procedure, check frequently to assure that the current is being delivered and leads disconnect does not occur.

TABLE 14–1. Stimulation needle sizes recommended for various nerve blocks.

	Single-Shot Technique		Catheter Technique (Introducer Needle)	
Nerve Block	**Length (mm)**	**Size, OD (mm/G)**	**Length (mm)**	**Size, OD (mm/G)**
Anterior interscalene	25–50	0.5–0.7/25–22	33–55	1.1–1.3/20–18
Posterior interscalene	80–100	0.7/22	80–110	1.3/18
Vertical infraclavicular (VIB)	50	0.7/22	50–55	1.3/18
Axillary blockade	35–50	0.5–0.7/25–22	40–55	1.3/18
Suprascapular	35–50	0.5–0.7/25–22	40–55	1.3/18
Psoas compartment	80–120	0.7–0.8/22–21	80–150	1.3/18
Femoral nerve	50	0.7/22	50–55	1.3/18
Saphenous nerve	50–80	0.7/22	55–80	1.3/18
Obturator	80	0.7/22	80	1.3/18
Parasacral sciatic	80–120	0.7–0.8/22–21	80–110	1.3/18
Transgluteal sciatic	80–100	0.7–0.8/22–21	80–110	1.3/18
Anterior sciatic	100–150	0.7–0.9/22–20	100–150	1.3/18
Subtrochanteric sciatic	80–100	0.7–0.8/22–21	80–110	1.3/18
Lateral distal sciatic	50–80	0.7/22	55–80	1.3/18
Popliteal sciatic	50	0.7/22	55	1.3/18

OD = outside diameter; ON = Obturator nerve

Note: The nerve localization needle sizes given are only estimates; depending on the patient's size, a slightly shorter or longer size needle may be needed. Some manufacturers also offer smaller needle sizes for pediatric use.

Needles that longer than necessary for a given block procedure should not be used because the risk of complications may increase when inserting the needle too deeply.

- The design of the connectors should prevent a faulty polarity connection.
- Connect the nerve stimulation needle to the nerve stimulator (which should be turned on) and set the current amplitude and duration to the desired levels.
  - For superficial blocks, select 1.0 mA as a starting current intensity.
  - For deep blocks, select 1.5 mA as a starting current intensity.
  - Select between 0.1 and 0.3 ms of current duration for most purposes.
- With ultrasound guidance, select the current as 0.5 mA; it is rarely necessary to change the current as motor response with ultrasound guidance is not sought. However, when unexpectedly elicited, it warns the operator that the needle is in the immediate vicinity of the nerve or intraneurally placed.

Transcutaneous (Surface) Nerve Mapping

When ultrasound guidance is not used, a nerve-mapping pen can be used to locate superficial nerves (up to a maximum depth of approximately 3 cm) with transcutaneous nerve stimulation before the nerve block needle is inserted. Transcutaneous nerve mapping is particularly useful when identifying the best site for needle insertion in patients with difficult anatomy or when the landmarks prove difficult to identify. Figure 14–5 shows several available nerve-mapping pens.

Nerve mapping is also useful when teaching surface anatomy. It should be noted that longer stimulus duration (eg, 1 ms) is needed to accomplish transcutaneous nerve stimulation, as larger energy is required to elicit a motor response from the neural structures transcutaneously. The electrode tip of the pen should have an atraumatic, ball-shaped tip. The conductive tip diameter should not be larger than approximately 3 mm to provide sufficient current density and spatial discrimination, which may not be the case with larger tip diameters. Be aware that many nerve stimulators do not provide the required impulse duration of 1 ms or a strong enough constant current source (5 mA at minimum, 12 kΩ output load) to reliably use a nerve-mapping pen. Therefore, it is recommended that the mapping pen and the nerve stimulator be paired, ideally, by acquiring them from the same manufacturer.

The transcutaneous stimulation from a nerve-mapping pen can cause several kinds of sensation due to the stimulation of various sensory cells in the skin. This may be felt as tingling, a pinprick, or even a slight burning sensation. The perception varies greatly between individuals. Most patients tolerate transcutaneous stimulation with a nerve-mapping pen well; however, some individuals describe it as uncomfortable or even painful (depending on the stimulus amplitude and duration). However, the amount of energy delivered by nerve stimulators with a maximum output of 5 mA at 1-ms pulse duration is far too low to create any injury of the skin or the nerves. Moderate premedication is usually sufficient to make the procedure well tolerated by patients. Surface mapping was suggested as a useful tool in residents' training and particularly became popular in pediatric regional anesthesia in the 2000s. However, its use has been infrequent with the advent of ultrasound guidance.

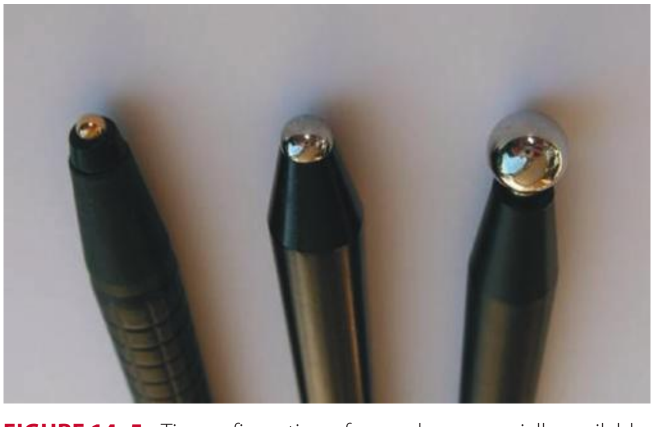

FIGURE 14–5. Tip configuration of several commercially available nerve-mapping PNS. From left to right: Stimuplex Pen (B. Braun, Melsungen (Germany); nerve-mapping pen (Pajunk, Germany); NeuroMap (HDC, USA).

Percutaneous Electrode Guidance

Percutaneous electrode guidance[10,11] combines transcutaneous nerve stimulation (nerve mapping) with nerve block needle guidance. In essence, a small aiming device is mounted and locked onto a conventional nerve block needle, which allows the conductive needle tip to make contact with the skin without scratching or penetrating the skin. Once the best response is obtained, the needle is advanced through the skin in the usual fashion, and the remainder of the apparatus continues to stabilize the needle and guide it toward the target. The device also allows the operator to make indentations in the skin and tissue so that the initial distance between the needle tip at the skin level and the target nerve is reduced, and the nerve block needle has less distance to travel through tissue. The technique allows for prelocation of the target nerve(s) prior to skin puncture (Figure 14–6).

Operating the Nerve Stimulator

The starting amplitude used for nerve stimulation depends on the local practice and the projected skin-nerve depth. For superficial nerves, an amplitude of 1 mA to start is chosen in most cases. For deeper nerves, it may be necessary to increase the initial current amplitude between 1.5 and 3 mA until motor response is elicited at a safe distance from the nerve. Too high current intensity, however, can lead to direct muscle stimulation or discomfort for the patient, both of which are undesirable.

Once the sought-after muscle response is obtained, the current intensity amplitude is gradually reduced, and the needle is slowly advanced farther. The needle must be advanced slowly to avoid too rapid advancement between the stimuli. Advancement of the needle and current reduction are continued until the desired motor response is achieved with a current of 0.2–0.5 mA

FIGURE 14–6. Percutaneous electrode guidance technique using Stimuplex Guide (B. Braun, Melsungen, Germany) during a vertical infraclavicular block procedure.

at 0.1-ms stimulus duration. The threshold level and duration of the stimulus are interdependent; in general, a short pulse duration is a better discriminator of the distance between the needle and the nerve.[20] When the motor twitch is lost during needle advancement, the stimulus intensity first should be increased to regain the muscle twitch rather than move the needle blindly. Once the needle is positioned properly, close enough to the nerve at around 0.3-mA current amplitude and 0.1-ms pulse duration, 1–2 mL of local anesthetic is injected as a test dose using low opening injection pressure, which abolishes the muscle twitch. The highly conductive injectate (eg, local anesthetic or normal saline solution) short-circuits the current to the surrounding tissue, effectively abolishing the motor response. In such situations, increasing the amplitude may not bring back the muscle twitch. Tsui and Kropelin[23] demonstrated that injection of dextrose 5% in water (D5W; which has low conductivity) does not lead to loss of the muscle twitch if the needle position is not changed. Then, the total amount of local anesthetic appropriate for the desired nerve block is injected.

It should be remembered that the absence of the motor response with a stimulating current of up to 1.5 mA does not rule out intraneural needle placement (low sensitivity). However, the presence of a motor response with a low-intensity current (≤0.2 mA, 0.1 ms) occurs only with intraneural and, possibly, intrafascicular needle placement. For this reason, if the motor response is still present at 0.2 mA or less (0.1 ms), the needle should be slightly withdrawn to avoid the risk of intrafascicular injection. The principle of the needle-to-nerve approach and its relation to the stimulation is depicted in Figures 14–7A, 14–7B, and 14–7C.

To avoid or minimize discomfort for the patient during the nerve location procedure, it is recommended that too high stimulating current be avoided. Again, the needle should not be advanced too fast because this can increase the risk of injury. Also, the best needle position, producing a good near-threshold motor response, may be missed.

The Role of Impedance Measurement

Measurement of the impedance can provide additional information if the electrical circuit is optimal. Theoretically, impedance can identify intraneural or intravascular placement of the needle tip. Tsui and colleagues[24] reported that the electrical impedance nearly doubles (12.1 to 23.2 kΩ), which is significant, when the needle is advanced from an extraneural to intraneural position in a porcine sciatic nerve. Likewise, injection of a small amount of D5W, which has a high impedance, results in a significantly higher increase of impedance in the perineural tissue than it does within the intravascular space.[25] Thus, measurement of the impedance before and after dextrose injection can potentially detect intravascular placement of the needle tip, thus identifying the placement prior to the injection of local anesthetic. In this report, the perineural baseline impedance (25.3 ± 2.0 kΩ) was significantly higher than the intravascular (17.2 ± 1.8 kΩ). On injection of 3 mL of D5W, the perineural impedance increased by 22.1 ± 6.7 kΩ to reach a peak of 50.2 ± 7.6 kΩ and remained almost constant at about 42 kΩ during the 30-s injection time. By contrast, intravascular impedance increased only by 2.5 ± 0.9 kΩ, which is significantly less compared to the perineural needle position. At present, however, more data are needed before these findings can be incorporated as an additional safety-monitoring method in clinical practice, although there have been significant recent advances in this regard.

Sequential Electrical Nerve Stimulation

Current nerve stimulation uses stimuli of identical duration (typically 0.1 ms), usually at 1- or 2-Hz repetition frequency. A common problem during nerve stimulation is that the evoked motor response is often lost while moving the needle to optimize its position. In such cases, it its recommended that the operator either increase the stimulus amplitude (mA) or increase the impulse duration (ms), the latter of which may not be possible. Alternatively, the operator can take a couple of steps, depending on the type of nerve stimulator used. The SENSe (sequential electrical nerve stimulation) technique incorporates an additional stimulus with a longer pulse duration after two regular impulses at 0.1-ms duration, creating a 3-Hz stimulation frequency.[26] The third longer impulse delivers more charge than the first two and therefore has a longer reach into the tissue. Consequently, an evoked motor response often is elicited at 1 Hz, even when the needle is distant from the nerve. Once the needle tip is positioned closer to the nerve, muscle twitches are seen at 3 Hz. The advantage of the SENSe technique is that a motor response (at 1/s) is maintained even when the twitches previously elicited by the first two impulses are lost due to slight needle movement. This feature prevents the operator from moving the needle "blindly."[26]

Figure 14–8 shows examples of the particular SENSe impulse patterns at different stimulus amplitudes. Eventually,

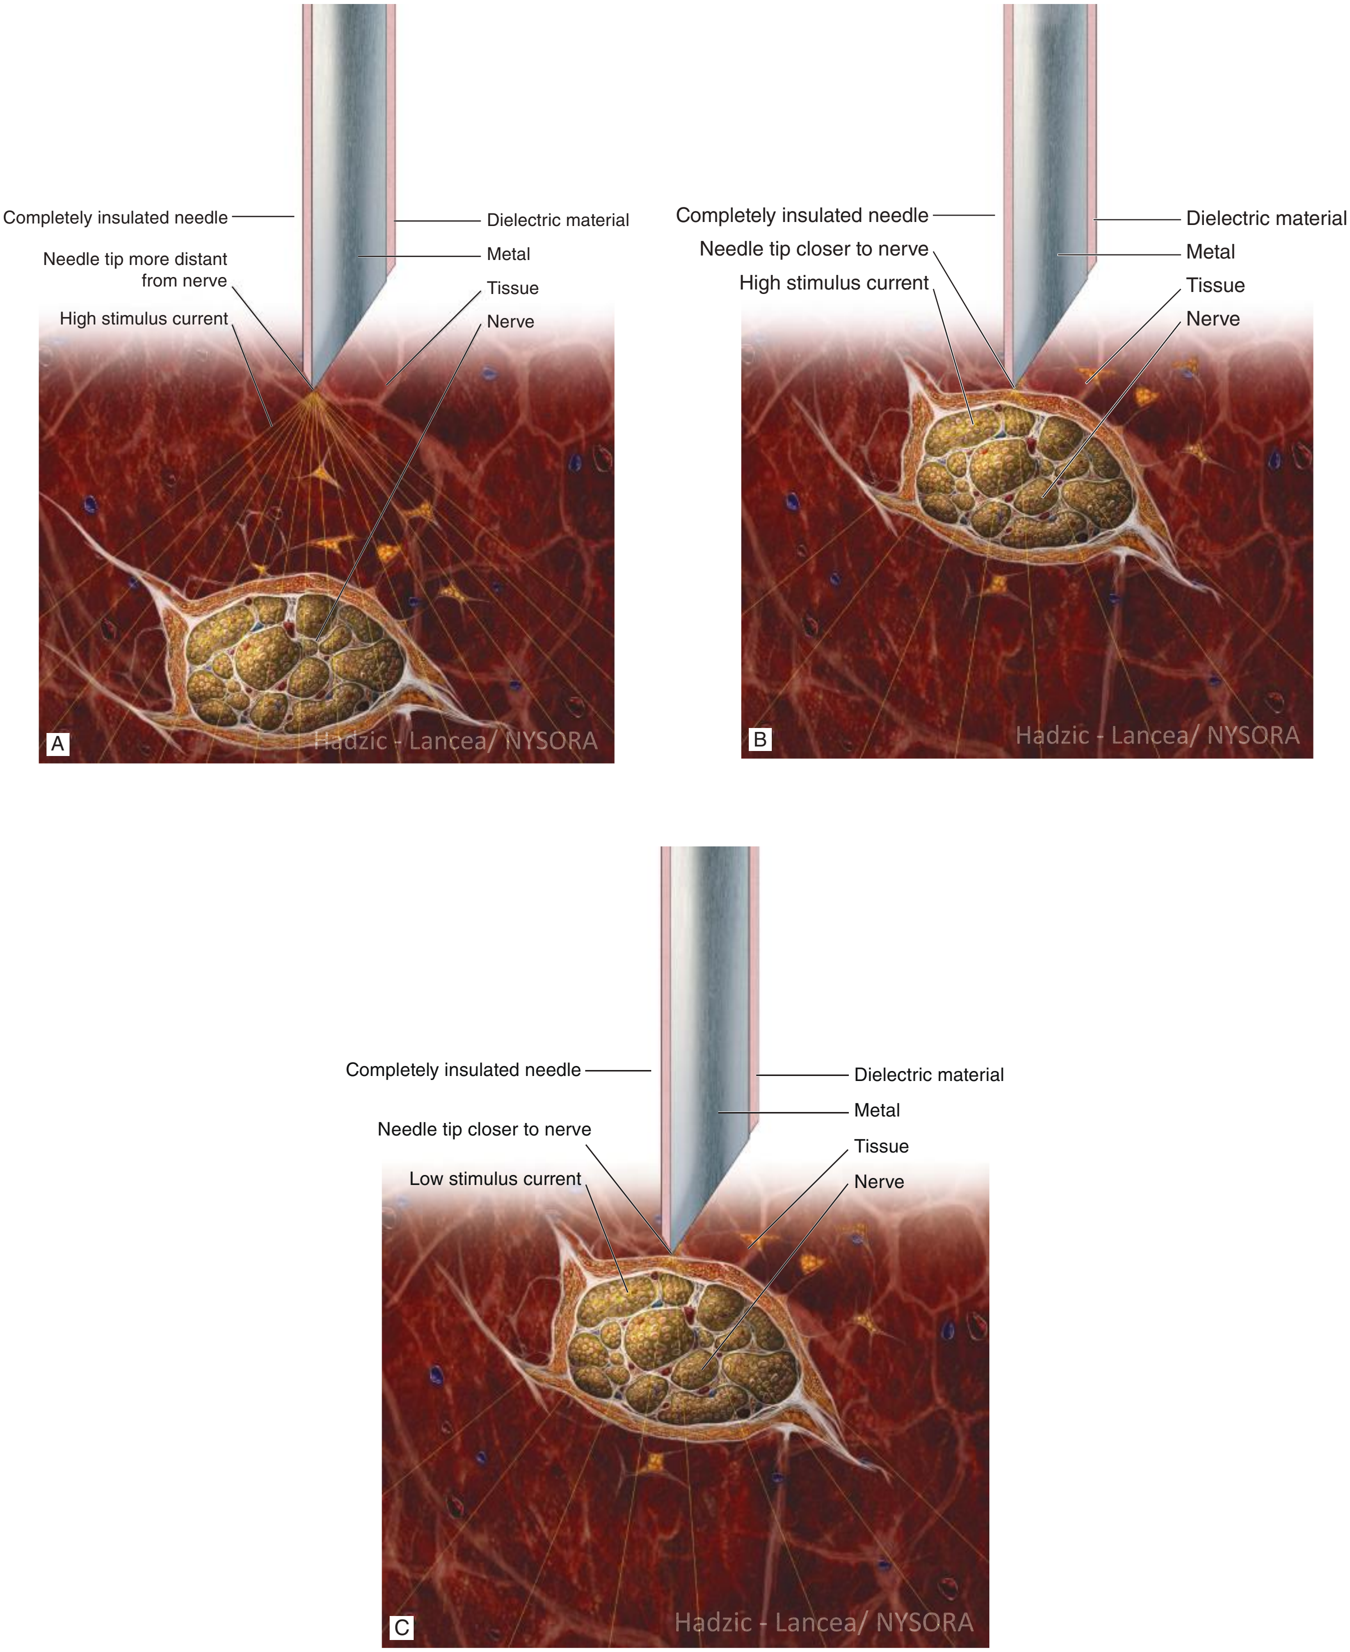

FIGURE 14–7. **A:** Stimulation needle at a distance to the nerve and high stimulus current eliciting a weak motor response. **B:** Stimulation needle close to the nerve and high stimulus current eliciting a strong motor response. **C:** Stimulation needle close to the nerve and low (near-threshold) stimulus current eliciting a weak motor response.

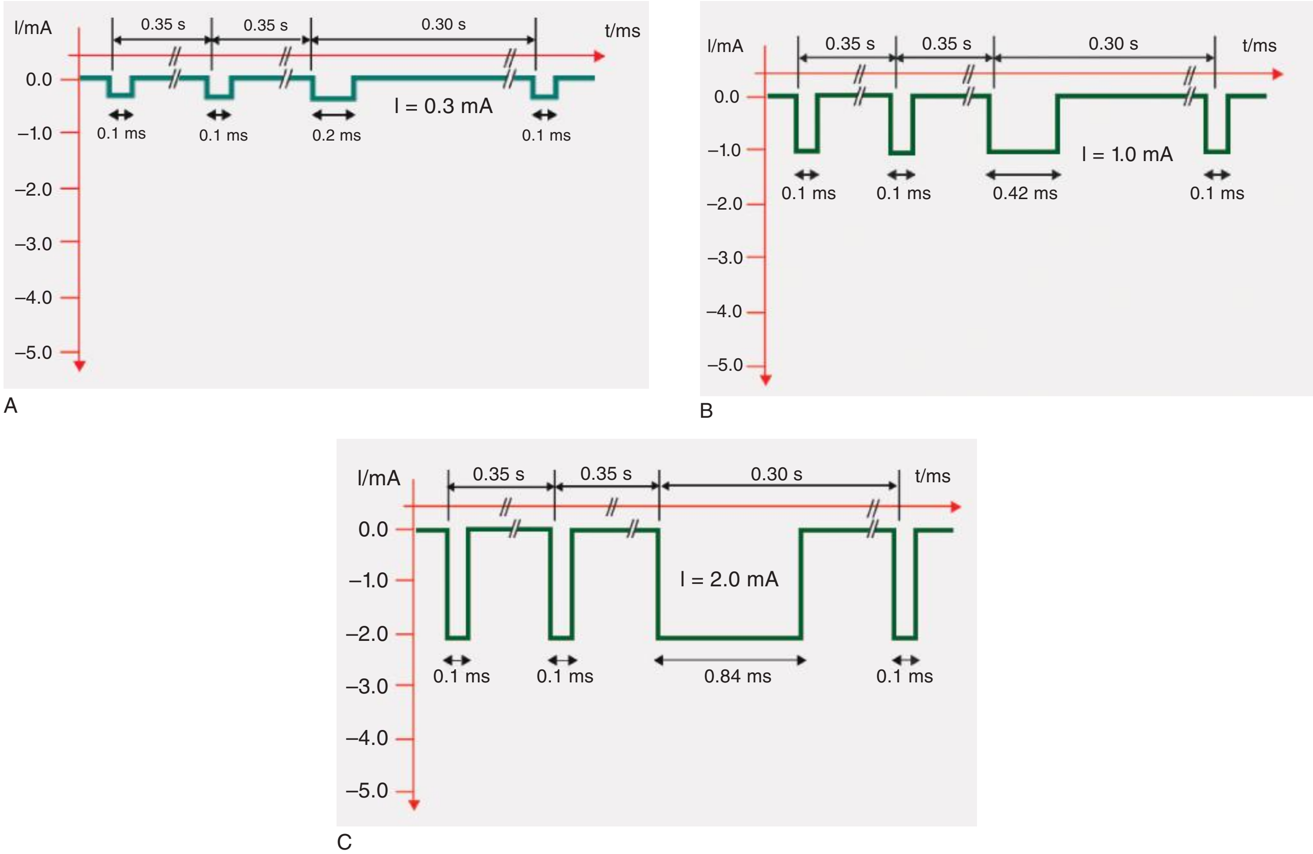

FIGURE 14–8. Sequential Electrical Nerve Stimulation (SENSe) impulse pattern of the Stimuplex HNS 12 nerve stimulator (B. Braun, Melsungen, Germany) depending on the actual stimulus amplitude. The impulse duration of the third impulse decreases with the stimulus amplitude below 2.5 mA from 1.0 ms to a minimum of 0.2 ms compared to the constant impulse duration of 0.1 ms of the first two impulses. **A:** Impulse pattern at 0.3 mA (threshold level). **B:** Impulse pattern at 1.0 mA. **C:** Impulse pattern at 2.0 mA.

the target threshold amplitude remains the same as usual (about 0.3 mA) but at 3 stimuli per second. With the SENSe technique, a motor response at only 1/s indicates that the needle is not yet placed correctly. Similar to the surface mapping, the utility of this technology has substantially decreased.

Troubleshooting During Nerve Stimulation

Table 14–2 lists the most common problems encountered during electrolocalization of the peripheral nerves and the corrective action.

TABLE 14–2. Common problems encountered during electrolocalization of peripheral nerves and corrective action.

Problem	Solution
Nerve stimulator does not work at all.	Check and replace battery; refer to stimulator operator's manual.
Nerve stimulator suddenly stops working.	Check and replace battery.
No motor response is achieved despite the appropriate needle placement.	Check connectors, skin electrode, cables, and stimulation needle for an interrupted circuit or too high impedance.
	Check and make sure that current is flowing—no disconnect indicator on the stimulator.
	Check the setting of amplitude (mA) and impulse duration.
	Check stimulator setting (some stimulators have a test mode or pause mode, which prevents current delivery).
Motor response disappears and cannot be regained even after increasing stimulus amplitude and duration.	Check for the causes listed previously. Can be caused by injection of local anesthetic.

CHARACTERISTICS OF MODERN NERVE STIMULATORS FOR NERVE BLOCKS

Most Important Features of Nerve Stimulators

This section addresses the most important features of nerve stimulators for monitoring during nerve block procedures.[20,27]

Electrical Features

- An adjustable constant current source with an operating range of 10 kΩ, minimally, output load (impedance), and ideally at 15 kΩ or greater.
- Adjustable stimulus amplitude (0–5 mA).
- A large and easy-to-read digital display of actual current delivered.
- A selectable pulse duration (width), at least between 0.1 and 1.0 ms (motor fibers are stimulated more easily with currents of shorter duration [0.1 ms] whereas sensory fibers require a longer stimulus duration [1.0 ms]).
- A stimulus frequency between 1 and 3 Hz (meaning 1 to 3 pulses per second). The best compromise is 2 Hz, which should be the default.
- A monophasic rectangular output pulse to provide reproducible stimuli.
- Configurable startup parameters so that the machine will comply with the hospital protocol and to avoid mistakes when multiple users are working with the same device (0.5 mA on startup, 0.1-ms pulse duration, 2-Hz stimulating frequency).
- A display of the circuit impedance (kΩ) is recommended to allow the operator to check the integrity of the electrical circuit and to detect a potential intraneural or intravascular placement of the needle tip.
- An automatic self-check process of the internal functioning of the unit with a warning message if something is wrong with the circuit.

Safety Features

- Easy and intuitive use.
- A large and easy-to-read display.
- Limited current range (0–5 mA) because an amplitude that is too high may be painful or uncomfortable for the patient.
- A display of all relevant parameters, such as amplitude (mA) (alternatively stimulus charge [nC]), stimulus duration (ms), stimulus frequency (Hz), impedance (kΩ), and battery status.
- Clear identification of output polarity (negative polarity at the needle).
- Meaningful instructions for use, with lists of operating ranges and allowed tolerances.
- Battery operation of the nerve stimulator, as opposed to electrical operation, provides intrinsic safety; there is no risk of serious electric shock or burns caused by a short circuit to the main supply of electricity.
- The maximum energy delivered by a nerve stimulator with 5 mA and 95-V output signal at 1-ms impulse duration is only 0.475 mWs.
- Combined units for *peripheral* (for peripheral nerve blockade) and *transcutaneous* (for muscle relaxation measurement) electrical nerve stimulation should not to be used because the transcutaneous function produced an unwanted high energy charge.

Alarms/warnings:

- Open circuit/disconnection alarm (optical and acoustic).
- Warning/indication if impedance is too high, that is, the desired current is not delivered.
- Displaying actual impedance is advisable.
- Near-threshold amplitude indication or alarm.
- Low-battery alarm.
- Internal malfunction alarm.

Table 14–3 provides a comparison of the most important features of commonly used nerve stimulators.

Stimulating Needles

Needles

A modern stimulating needle should have the following characteristics:

- A fully insulated needle hub and shaft to avoid current leakage
- Depth markings for easy identification and documentation of the needle insertion depth

Figures 14–9A and 14–9B show a comparison of the electrical characteristics of noninsulated and insulated needles with uncoated bevel (Figure 14–9A) and fully coated needles with a pinpoint electrode (Figure 14–9B). Even though a noninsulated needle provides for some discrimination (change in threshold amplitude) while approaching the nerve, there is virtually no ability to discriminate once the needle tip has passed the nerve. Therefore, spatial discrimination near the nerve is more precise in needles with a pinpoint electrode tip (Figure 14–9B) compared to needles with an uncoated bevel (Figure 14–9A).

Connectors

Connectors and cables should be fully insulated and include a safety connector to prevent current leakage as well as the risk of electric charge if the needle is not connected to the stimulator. Extension tubing with a Luer lock connector should be present for immobile needle technique.

Visualization of the Needle Under Ultrasound Imaging

Because ultrasound imaging is used more frequently (in particular with the use of the "dual-guidance" technique), the importance of good visualization of the nerve block needle is becoming an additional important feature. The visibility (distinct reflection signal) of the needle tip certainly is the most important aspect because this is the part of the needle that is placed in the target area next to the nerve. However, in

particular when using the in-plane approach, the visibility of the needle shaft is of interest as well because it helps to align the needle properly with the ultrasound beam to visualize the entire length to the target nerve.

Stimulating Catheters

In principle, stimulating catheters function like insulated needles.[28] The catheter body is made from insulating plastic material and usually contains a metallic wire inside, which conducts the current to its exposed tip electrode. Usually, such stimulating catheters are placed using a continuous nerve block needle, which is placed by first using nerve stimulation as described. It acts as an introducer needle for the catheter. Once this needle is placed close to the nerve or plexus to be blocked, the stimulating catheter is introduced through it, and the nerve stimulator is connected to the catheter. Stimulation through the catheter should reconfirm that the catheter tip is positioned in close proximity to the target nerve(s). However, it must be noted that the threshold currents with stimulating catheters may be considerably higher. Injection of local anesthetic or saline (which is frequently used to widen the space for threading the catheter more easily) should be avoided because this may increase the threshold current considerably and can even prevent a motor response. D5W can be used to avoid losing a motor response.[23] Since the introduction of ultrasound monitoring of the distribution of the local anesthetic after needle or catheter placement, stimulating catheters have become nearly obsolete. This is because the ultimate test of the placement of the catheter tip in the therapeutic position is the distribution of the injectate in the tissue plane that contains the nerve or the plexus. Because the stimulating catheter can be placed in the proper position without obtaining the motor response, using the stimulation through the catheter will often lead to unnecessary needle and catheter manipulation. Nerve stimulation monitoring of the single-injection or continuous needle placement is useful to avoid needle-nerve contact or intraneural placement and help decrease the risk of nerve inflammation or intraneural injection and consequent injury. In contrast, catheters are pliable and highly unlikely to cause nerve trauma or be inserted into a fascicle.[21]

Clinical Pearls

- Use low-intensity current nerve stimulation (0.5 mA) with ultrasound-guided nerve blocks and do not change the current intensity during the procedure.
- For nerve stimulator–guided nerve blocks, adjust the stimulus current amplitude: 1 mA (superficial blocks), 2 mA (deeper blocks) (eg, psoas compartment and deep sciatic blocks), 0.1 ms.
- Do not inject if the threshold current is 0.2–0.3 mA or less (0.1 ms) or opening injection pressure.

APPENDIX: GLOSSARY OF PHYSICAL PARAMETERS

Voltage, Potential, Current, Resistance/Impedance

Voltage U is the difference in electrical potential between two points carrying different amounts of positive and negative charge. It is measured in volts (V) or millivolts (mV). Voltage can be compared to the filled level of a water tank, which determines the pressure at the bottom outlet (Figure 14–10A). In modern nerve stimulators using constant-current sources, voltage is adapted automatically and cannot (or does not need to) be influenced by the user.

Current I is the measure of the flow of a positive or negative charge. It is expressed in amperes (A) or milliamperes (mA). Current can be compared to the flow of water.

A total charge **Q** applied to a nerve equals the product of the intensity I of the applied current and the duration t of the square pulse of the current: $Q = I \times t$.

The minimum current intensity I required to produce an action potential can be expressed by the relationship

$$I_{Threshold} = \frac{I_{Rheobase}}{1 - e^{-t/c}}$$

where t is the pulse duration, c is the time constant of nerve membrane related to chronaxy.

The **electrical resistance R** limits the flow of current at a given voltage (see Ohm's law) and is measured in ohms (Ω) or kilo-Ohms (kΩ).

If there is capacitance in addition to Ohm's resistance involved (which is the case for any tissue), the resistance becomes a so-called complex resistance or **impedance**. The

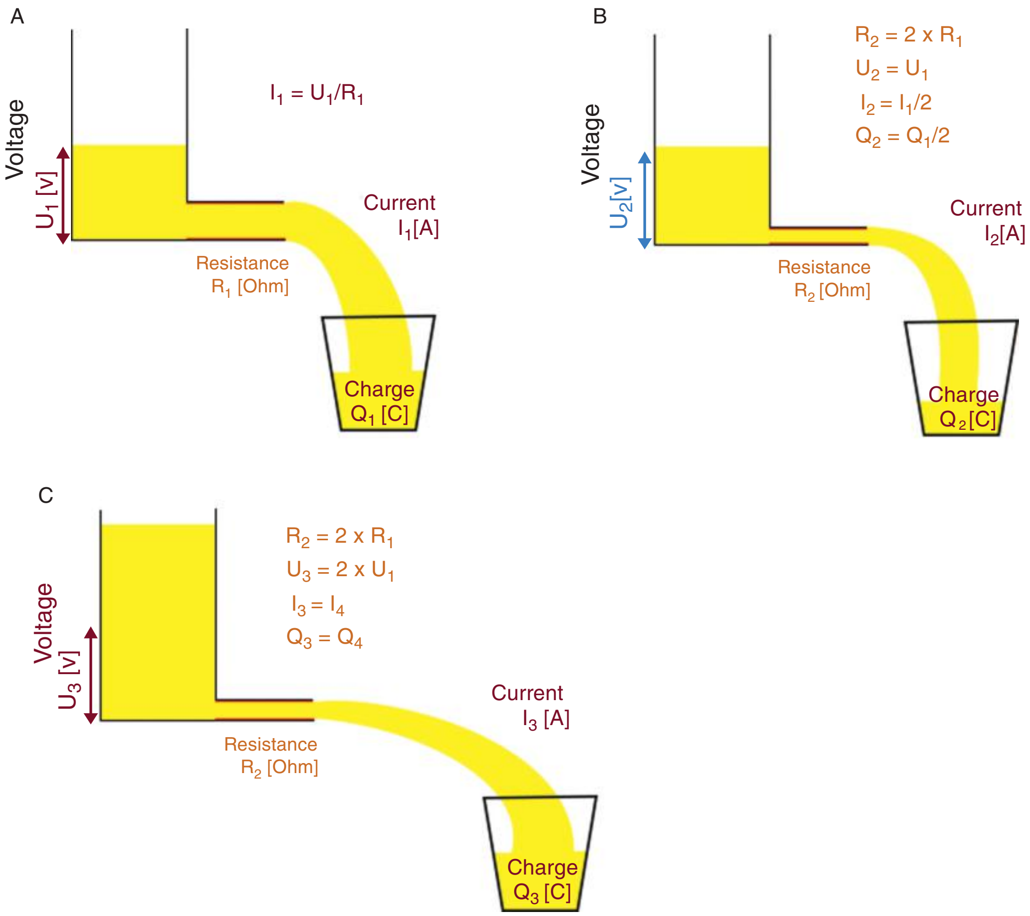

FIGURE 14–10. Ohm's law and principle of a constant-current source. Functional principle of a constant-current source. **A:** Low-resistance R_1 requires voltage U_1 to achieve desired current I_1.**B:** High-resistance $R_2 = 2 \times R_1$ causes current I to decrease to $I_2 = I_1/2$ if voltage U remains constant ($U_2 = U_1$). **C:** Constant-current source automatically increases output voltage to $U_3 = 2 \times U_1$ to compensate for the higher-resistance R_2; therefore, current I increases to the desired level of $I_3 = I_1$.

main difference between the two is that the value of the impedance is dependent on the frequency of the applied voltage/current, which is not the case for an Ohm's resistor. In clinical practice, this means that the impedance of the tissue is higher for low frequencies (ie, a long pulse duration) and lower for higher frequencies (ie, a short pulse duration). Consequently, a constant-current source (which delivers longer-duration impulses, eg, 1 ms vs. 0.1 ms) needs to have a stronger output stage (higher output voltage) to compensate for the higher tissue impedance involved and to deliver the desired current. However, the basic principles of Ohm's law remain the same.

Ohm's Law

Ohm's law describes the relationship between voltage, resistance, and current according to the equation

$$U[V] = R[\Omega] \times I[A]$$

or conversely,

$$I[A] = U[V]/R[\Omega]$$

This means that, at a given voltage, current changes with resistance. If a constant current must be achieved (as needed for nerve stimulation), the voltage has to adapt to the varying resistance of the entire electrical circuit. For nerve localization in particular, the voltage must adapt to the resistance of the needle tip, the electrode-to-skin interface, and the tissue layers. A constant-current source does this automatically. Ohm's law and the functional principle of a constant-current source are illustrated in Figures 14–10A, 14–10B, and 14–10C.

Coulomb's Law, Electric Field, Current Density, and Charge

According to **Coulomb's law,** the strength of the **electric field,** and therefore the corresponding **current density J**, in relation to the distance from the current source is given by

$$\mathbf{J(r) = k \times I_0/r^2}$$

where k is a constant, and I_0 is the initial current. This means that the current (or charge) that reaches the nerve decreases by a factor of 4 if the distance to the nerve is doubled, or conversely, it increases by a factor of 4 if the distance is divided in half (ideal conditions assumed).

The **charge Q** is the product of current multiplied by time and is given in ampere-seconds (As) or coulombs (C). As an example, rechargeable batteries often have an indication of Ah or mAh as the measure of their capacitance of charge (kilo = 1000 or 10^3; milli = 0.001 or 10^{-3}; micro = 0.000001 or 10^{-6}; nano = 0.000000001 or 10^{-9}).

Energy of Electrical Impulses Delivered by Nerve Stimulators and Related Temperature Effects

According to a worst-case scenario calculation, the temperature increase caused by a stimulus of 5-mA current and 1-ms duration at a maximum output voltage of 95 V would be less than 0.5 C if all the energy were concentrated within a small volume of only 1 mm^3 and no temperature dissipation into the surrounding tissue occurred. This calculation can be applied for the tip of a nerve stimulation needle.

The maximum energy E of the electrical impulse delivered by a common nerve stimulator would be

$$E \leq U \times I \times t = 95\text{ V} \times 5\text{ mA} \times 1\text{ ms} = 0.475\text{ mWs} = 0.475\text{ mJ}$$

The caloric equivalent for water is $c_w = 4.19\text{ J g}^{-1}\text{ K}^{-1}$.

One stimulus creates a temperature difference ΔT within 1 mm^3 of tissue around the tip of a nerve stimulation needle. For the calculation that follows, it is assumed that tissue contains a minimum of 50% water, and the mass M of 1 mm^3 of tissue is 1 mg.

$$\Delta T \leq 2 \times E/(M \times c_w) = 2 \times 0.475 \times 10^{-3}\text{ J}/(10^{-3}\text{ g} \times 4.19\text{ g/K}) = 0.45\text{ K}$$

That is, the maximum temperature increase in this worst-case scenario calculation is less than 0.5 C. In practice, this means that the temperature effect of normal nerve stimulation on the tissue can be neglected.

SECTION 4 Patient Management Considerations

CHAPTER 15

Developing Regional Anesthesia Pathways

Andrew Neice and Michael J. Barrington

INTRODUCTION

Regional anesthesia is best practiced in the context of a standardized anesthetic and surgical protocols; these plans are generally referred to as anesthetic pathways. For a patient having surgery that uses an anesthetic pathway, many of the decisions about the patient's care are made not at the bedside in the immediate preoperative period, but instead long before the surgery by carefully considering the risks and benefits of various anesthesia and perioperative treatment options.

When well designed, anesthetic pathways can improve patient care by ensuring that patients receive consistent, coordinated, evidenced-based care. They can also reduce costs by eliminating unnecessary interventions and reducing complications. Of course, pathways should not be indiscriminately adhered to as some patients will require modification to atone for specific medical conditions or patient preferences. Regardless, anesthetic pathways allow clinicians to focus on the unique characteristics of a patient instead of the common characteristics of an entire cohort, which were already examined during pathway development.

At their core, anesthetic pathways (or clinical pathways in any field) are a series of medical decisions. As leaders of the perioperative surgical home, anesthesiologists are best suited to lead their design. There are often many subtle issues that arise in the development of a pathway that may not be familiar to anyone other than a clinician who is frequently and personally involved in patient care. In addition, anesthesiologists' working relations with surgeons, administrators, and the entire operating room team are paramount in development and success of patient pathways. Interspecialty coordination is vital to the successful development of anesthetic pathways. Anesthetic decisions will frequently affect patients' ability to rehabilitate in the immediate postoperative period, so anesthetic and surgical pathways must be designed by a team effort.

Because there is evidence that use of regional anesthesia may affect the mortality and morbidity[1–5] of common surgeries, and because pain control in the postoperative period is often challenging, regional anesthesia (either neuraxial or peripheral block) is often a key feature of anesthetic pathways. Therefore, development of pathways is of particular interest to practitioners whose clinical practice includes regional anesthesia.

Designing and implementing clinical pathways require skills often not taught during residency training. Physicians tailor their treatments with the unique characteristics of each patient in mind. This is related to physician training designed to elicit and synthesize data for a specific patient. Clinical pathways, in contrast, must be designed to optimize the average experience of a cohort of patients, often making trade-offs and compromises in the process. Knowledge of epidemiology and statistics are vital to effective clinical pathway design. Numerically estimating probable outcomes, and choosing those that rate most favorably, is central to the development of the pathway.

Benefits of an anesthesia pathway will of course depend on the peculiarities of the pathway itself, the institution, the surgical and anesthetic techniques, and the other health-care providers using the pathway (such as nursing care, physical therapy, etc.). A pathway designed for one institution may not be appropriate for another institution, which is why in this chapter we have chosen to emphasize the process of pathway development instead of presenting specific pathways. Furthermore, the goals of an anesthetic pathway may vary—some pathways may be designed to reduce morbidity or mortality, while others may be focused on reducing cost while maintaining a high level of patient care. Common goals of an anesthetic pathway include reducing in-hospital morbidity and mortality, reducing length of hospital stay, reducing costs, improving patient satisfaction, reducing readmissions, and improving long-term functional outcomes.

Despite this heterogeneity, there is evidence that, generally speaking, clinical pathways improve patient care. A recent meta-analysis of clinical pathways found that they were associated with lower rates of patient complications (eg, wound infections, bleeding, and pneumonia), as well as improved documentation.[6] Most of the studies included in the meta-analysis also showed a reduction in the length-of-stay and hospital costs without increased risk of readmission rates and mortality. However, it is possible that some clinical pathways actually could improve these outcomes as well. The considerable heterogeneity of successful clinical pathways has not allowed investigators to identify features common to successful (or unsuccessful) clinical pathways.[6] Nevertheless, basic principles of risk management may be deployed to aid in the design of clinical pathways, and developing a reusable, common framework for approaching clinical pathways seems likely to increase the probability of success.

In this chapter, we present a framework for developing clinical pathways and review some of the prerequisite knowledge required for this process. We also present case scenarios that illustrate the subtleties in applying existing medical literature to clinical pathways. Finally, we present components of a surgical pathway for total knee arthroplasty.

FRAMEWORK FOR ANESTHETIC PATHWAYS

An example of a single component of a clinical pathway is shown in Table 15–1. This is a component of a larger pathway for total joint arthroplasty, which is further discussed in the final section of this chapter. This component describes the standard oral premedications for the surgery and contains specific information about dose, common contraindications, and common additions to the pathway that may be needed for some patients. Although developing a clinical pathway often involves lengthy analyses with uncertainties, final pathway elements should be brief and specific. Besides recommended premedications, pathways may have many different elements; for example, see those shown in Table 15–2.

TABLE 15–1. Example of a pathway item: oral premedication for total knee arthroplasty.

Recommended Oral Premedications Prior to Surgery (Example Only)	
Acetaminophen 1 g by mouth	Avoid in those with cirrhosis, elevated liver function tests
Celecoxib 400 mg by mouth	Avoid in those with sulfa allergy, renal dysfunction
Gabapentin 600 mg by mouth	Avoid in patients with renal dysfunction, outpatients, patients with advanced age or dementia

Note: This is an example of a pathway element only, not a formal recommendation.

TABLE 15–2. Examples of pathway elements.

Enumeration of the goals of the pathway
Criteria for patient selection, preparation for surgery, and education prior to surgery
Preoperative optimization (eg, blood pressure goals, hematocrit goals, associated pharmacologic interventions)
Recommended surgical anesthesia
Recommended systemic multimodal anesthetic technique
Recommended regional anesthesia/analgesia for the treatment of postoperative pain
Recommended prophylactic therapy for postoperative nausea and vomiting
Recommended intraoperative fluid or hematocrit goals or transfusion criteria
Recommended intraoperative management of hemodynamics (eg, preferred blood pressures, preferred pressors, etc.)
Recommended adjuvant drugs (eg, preferred antibiotics, anticoagulation, antifibrinolytics)
Recommended adjuvant monitoring (eg, evoked potentials, bispectral index, cerebral oxygenation)

It should be noted that although the pathways developed by anesthesiologists are primarily concerned with the anesthetic management of the patient, they are designed to dovetail with the corresponding surgical pathway. For example, the choice of regional anesthesia may allow the patient to complete physical therapy on postoperative day 1.

A process for developing clinical pathways is shown in Figure 15–1. This process consists of the following:

1. Identifying the goals of the pathway and different treatment options to help achieve those goals. This should include all stages of anesthesia and surgery, including postoperative recovery.
2. Identifying ways in which each treatment interacts with the others (eg, the type of regional anesthesia may affect the patient's ability to perform physical therapy postoperatively, premedications may delay discharge due to sedation).
3. Identifying possible risks, costs, and benefits of each treatment, including mortality, morbidity, patient satisfaction, institutional capabilities, financial cost, and other factors.
4. Making numerical estimates of the risks, costs, and benefits identified in step 3. Some of this information (eg, information on cost) can be gathered and tabulated. However, most of the information cannot be known with

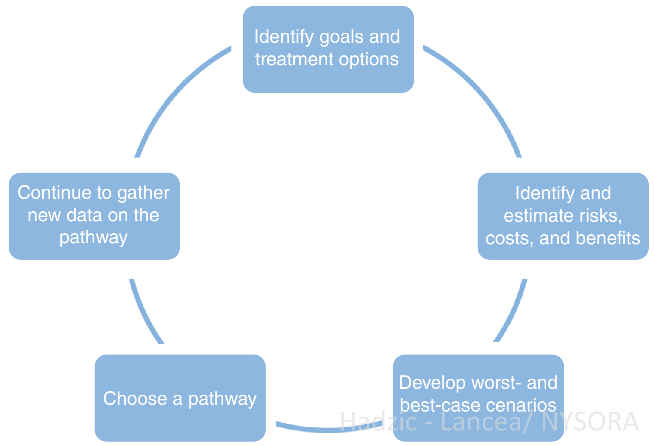

FIGURE 15–1. Summary of steps involved in developing a clinical pathway.

any certainty. In many cases, the medical literature can provide estimates of the probabilities involved, as long as the physician understands the limitations of a particular study.

5. Use the estimates developed in step 4 to develop probable outcomes and worst-case and best-case scenarios for each pathway.
6. Choose the pathway most likely to benefit the patient based on step 5.
7. Continually refine the estimates of the risks, costs, and benefits as new information becomes available and refine the clinical pathways.

If we could quantify the risks and benefits of each intervention as easily as we could quantify the financial costs of procedures and equipment, steps 4, 5, and 6 would be trivial. However, this is rarely the case. In many cases, there may be not adequate published data to guide the process. Sometimes, there may be some incongruity between available studies and the desired information—the only studies available may have been done on similar, but different, patient populations; have analyzed similar, but different, surgical procedures; or may describe interventions that you cannot exactly replicate at your institution. Nevertheless, the closest match to one's institutional conditions can be used to estimate probabilities used in step 5.

Another risk to consider includes those complications that may not manifest until well after the treatment period. For instance, recently introduced drugs, procedures, or therapies by definition will have unknown long-term risks. Recognizing the limitations of the existing evidence for each intervention in the literature is crucial in protocol development. Although inferential statistics enhances a physician's judgment beyond what can be achieved simply by relying on their historical personal observations, unfortunately any given study may have unforeseen biases that may make the study less than an ideal guidance for the protocol being developed. As such, when developing "worst-case" and "best-case" scenarios, one needs to take into account the possibility that a study has made a type I or (more commonly) a type II error.

REVIEW OF STATISTICAL CONCEPTS RELEVANT TO THE DEVELOPMENT OF ANESTHETIC PATHWAYS

A good analogy for the role of statistics in enhancing clinician judgment is comparing it to the role that a magnifying lens plays in enhancing vision. Drugs or interventions that have large, consistent effects (eg, the effect of insulin on glucose or epinephrine on heart rate) can be easily appreciated by the clinician without any sort of corroborating study, just as a magnifying lens is generally not necessary to see frank pus in a wound. Likewise, a study that is underpowered may be unable to detect subtle effects, just as a simple hand lens is not powerful enough to image individual bacteria. While few clinicians would attempt to diagnose a bacterial infection with only a magnifying glass, clinicians frequently make the error of assuming that a reported negative result is synonymous with no effect, without considering the limit of detection of the study. Rare but catastrophic complications are of particular concern as extremely large numbers of patients may be required to properly power a study.

A statistical test may report either that observed data are consistent with random chance (the null hypothesis, a "negative" result) or reject the null hypothesis and assert that there is an association between a treatment and an outcome (a "positive" result). In reality, there may or may not be an association between a treatment and an outcome. There are therefore four possibilities for any statistical test, two of which involve drawing the correct conclusion, and two of which are errors. These are traditionally shown using a 2 × 2 table as shown in Table 15–3.

The two types of possible errors are a type I error (alpha), which involves incorrectly concluding that an association exists when one does not, and a type II error (beta), which involves incorrectly concluding that no association exists when in fact one does. Obviously, the probabilities of making the two types of errors are related. Imagine a statistical test that always asserts there is an association between the treatment and outcome, regardless of the data. This technique will frequently make type I errors but will never make a type II error (because it never asserts a negative result).

By convention, statistical tests compute the probability that a set of data is due to random chance (the p value) and if this is below some fixed threshold (alpha), the notion that the data are due to random chance is rejected. Generally, a confidence interval is reported as well. When alpha is fixed, most commonly at 0.05, beta will be a function of the other features of the statistical test. One of the simpler formulas relating alpha, beta, change in mean, standard deviation of the data, and sample size

TABLE 15–3. Possible outcomes of a statistical test.

	Hypothesis Is True	Hypothesis Is False
Hypothesis is accepted	Correct decision	Type I error (alpha)
Hypothesis is rejected	Type II error (beta)	Correct decision

is shown in Equation 15–1. Equation 15–1 describes power relationships for a test of a large sample of a continuous outcome variable in a single population with known mean and standard deviation:

$$ES = \frac{Z_{1-\alpha/2} + Z_{1-\beta}}{\sqrt{n}} = \frac{|\mu - \mu_0|}{\sigma} \quad (15\text{–}1)$$

where n is sample size, σ is sample standard deviation, μ is the sample mean, μ_0 is the population mean, ES is effect size, and Z is the Z-score corresponding to the value in subscript. Different statistical tests (eg, t tests for continuous variables, t tests for proportions, χ^2 tests, analysis-of-variance [ANOVA] tests, etc.) will have somewhat different formulas for beta, but in general beta (and hence the probability of a type II error) will decrease with larger sample sizes, less-restrictive choices of alpha, smaller standard deviations in the data, and larger effect sizes.

Statistical power is simply $1–\beta$ and is more frequently referenced than β. While alpha is most commonly fixed at 0.05, a statistical power of 0.8 is generally considered adequate for detection of associations, although in some cases[4] this is increased to 0.9. Unfortunately, while the choice of alpha is almost always explicitly stated in a publication, it is often left to the clinician to infer the power of the study, particularly for secondary outcomes. Fortunately, formulas such as Equation 15–1 can be readily found in common textbooks or in statistical software packages. In addition, many academic statistics departments have made online tools available to calculate statistical power (eg, References 7 and 8). Formulas such as Equation 15–1 can be used to calculate the smallest effect size that a particular study is likely to detect. It then falls to the clinician to decide whether this effect size is small enough that smaller effect sizes are clinically irrelevant. If smaller effect sizes are still clinically relevant, then the clinician developing a pathway needs to take into account the possibility that there is a small but real effect size, a type II error was made, and adjust the best- or worst- case scenarios accordingly.

EXAMPLES OF PATHWAY DEVELOPMENT

We now provide a few illustrative examples of the analysis discussed previously. First, we present a case scenario that illustrates the type of analysis described. Then, we review some examples of drugs that were introduced to routine surgical protocols that caused patient harm; this illustrates pitfalls in pathway development. Last, we present components of a pathway for total knee replacement.

Illustrative Case: Adjuvants to Spinal Anesthesia

Suppose a novel drug (drug X) has been developed that increases the duration of spinal anesthesia when added to bupivacaine. Your group performs total hip and knee arthroplasty under spinal anesthesia but occasionally has to convert to general anesthesia due to unexpectedly long surgical times. The total joint pathway currently uses bupivacaine-only spinals but is considering adding drug X to the total joint pathway to prolong the length of spinal anesthetic and reduce unexpected conversions to general anesthesia.

An initial study compared spinal anesthesia with bupivacaine versus drug X plus bupivacaine, with 500 patients in the treatment group and 500 in the control group. The study found that spinal anesthesia with bupivacaine provided adequate surgical anesthesia only for 180 minutes, while bupivacaine with drug X provided adequate surgical anesthesia for 200 minutes (95% CI 195–205 minutes, $p < .05$). Secondary outcomes included incidence of vomiting on postoperative days 1–3 and urinary retention requiring Foley catheterization. In the control arm, 3% and in the treatment arm 4% of patients vomited postoperatively, but this result was not statistically significant. In the control arm, 2% and in the treatment arm 3% of patients had urinary retention; however, this was also not statistically significant. The drug costs \$50 per dose.

Analysis of Costs and Benefits

Even for a relatively simple (and contrived) question such as this, a complete analysis can become complex. We therefore present an abbreviated version of the procedure:

1. **Identify goals and treatment options**. We limit ourselves to the goal of lengthening spinal anesthesia to reduce conversions to general anesthesia. Alternatives to the inclusion of drug X should be explored. Drug X must be evaluated not in a vacuum but instead in competition with other techniques. For example, other drugs may be available that lengthen spinal anesthesia for a comparable time, or simply increasing spinal dosage may be feasible to lengthen surgical anesthesia. Alternatively, the subpopulation likely to have longer operative time may be identified, and these patients could automatically receive general anesthesia or drug X could be reserved for them only. The risks and benefits of each of these options must be individually considered and compared with the routine use of drug X.
2. **Identify ways each treatment interacts with the rest of the pathway**. Although no restrictions were mentioned, we would need to confirm that the use of drug X does not require special postoperative monitoring (such as continuous pulse oximetry), an alteration in nursing care (such as changing fall precautions), or change in physical therapy (such as delaying mobilization) or require alterations to other parts of the anesthetic and surgical pathway. If any restrictions or interactions are identified, they must be accounted for in step 3.
3. **Identify risks, costs, and benefits**. For this illustration, we restrict the analyses to the risks, benefits, and costs alluded to in the study. The primary benefit would be increased duration of surgical anesthesia and a reduced need to convert to general anesthesia, which of course carries a number of attendant risks and costs. The risks include increased risk of urinary retention and postoperative

vomiting. Although the initial study did not link either of these outcomes to drug X, we shall see in step 4 that the worst-case scenario must include the risk that this study made a type II error. The costs are easiest to quantify: This will add $50 in drug costs to each surgery.

4. **Make numerical estimates of the risks, costs, and benefits identified in step 3.** The benefits of this drug will depend on the specifics of your institution. For example, suppose in reviewing your records, you find that you performed 500 total joint arthroplasties in the past year, and 5 of them required unexpected conversion to general anesthesia. The total surgical times for the five cases were 195, 250, 200, 190, and 220 minutes. Using the published confidence interval, use of drug X may have eliminated need to convert to general anesthesia in 2 of the cases (if it lengthens time to 195 minutes) to 3 of the cases (if it lengthens time to 205 minutes).

   The costs of this drug, if used on all patients, would be an extra $25,000 annually. If a high-risk subpopulation could be identified for use of the drug, this could potentially be reduced.

   The study found no link between urinary retention or postoperative vomiting with drug X, so in the best-case scenario, adding drug X does not introduce any new risks of complications. However, let us consider the power of this study. Presumably, the data on urinary retention and postoperative vomiting were analyzed using a *t* test for proportions.

   Using online power calculators or statistics packages,[6] we can estimate the effect size that would be detected. Assuming a baseline rate of urinary retention of 2% (based on the control arm of the study), the drug would need to increase the rate to 5%–6% to achieve a power of approximately 0.8. Effect sizes lower than this will not be reliably detected. For postoperative vomiting, a power of 0.8 corresponds to the drug increasing the rate of vomiting to 7%.

   If rates of postoperative vomiting and urinary retention more than doubled, most clinicians would consider that a clinically relevant increase, but it would not be reliably detected by the study discussed. Therefore, we must consider the possibility that the study made a type II error and adjust our worst-case scenario appropriately.

   If the study did make a type II error, what should we use for our estimates of effect size? The most reasonable estimate can be obtained by examining the study itself; as subjects are added, the rates converge toward their true values and eventually may cross a threshold of statistical significance. In the study discussed, postoperative vomiting was 3% in the control arm and 4% in the treatment arm, and urinary retention was 2% in the control arm and 3% in the treatment arm. We can use these increases to inform our estimates.

   Assuming that our institution has similar rates of vomiting on postoperative days 1–3 (3%) and similar rates of urinary retention (2%), we would estimate that they would increase to 4% and 3%. With a surgical volume of 500 patients per year, this corresponds to 5 extra cases of urinary retention and 5 extra cases of postoperative vomiting per year.

5. **Use the estimates to construct best- and worst-case scenarios.** Best case: Eliminate three conversions to general anesthesia per year. Add $25,000 to health-care costs. Worst case: Eliminate two conversions to general anesthesia per year. Add $25,000 to health-care costs. Create five extra cases of urinary retention and five extra cases of postoperative vomiting.

   In this particular case, we note that the benefits of the drug may be improved if we can accurately identify a subpopulation likely to benefit. For example, if the drug is only given to the 10% of patients with the highest risk of long surgical times, both the cost and the morbidity associated with postoperative vomiting and urinary retention would decrease by a factor of 10. If the subpopulation is accurately identified, the number of general anesthesia conversions may be unaffected or minimally affected.

6. **Choose the pathway most likely to benefit the patient.** Depending on the risks involved in conversions to general anesthesia, this drug may or may not be worth adding to the anesthetic pathway. Ultimately, clinical judgment is required to make a decision. However, by using the framework discussed, the clinician is significantly better informed than if the clinician simply made a decision based on intuition alone.

7. **Continually refine the estimates of risks, costs, and benefits.** In this scenario, the institution's annual surgical volume (500) is equal to the number of patients involved in each arm of the study. Given this, if the institution tracks its own complication rates before and after the change, it should be able to quickly ascertain the true risks, benefits, and costs of the intervention and make a more informed decision than the initial analysis.

   Surprisingly, it is often the case that the number of patients enrolled in studies in the published literature is much smaller than the number of surgeries performed at even small institutions. For example, a recent meta-analysis on the effects of spinal opioids only included approximately 100–150 subjects and controls for an analysis of postoperative vomiting and urinary retention for intrathecal fentanyl, despite the long and widespread use of fentanyl in spinal anesthesia.[9] Because of this, analysis of internal data is often helpful in evaluating pathway success or failure. Use of internal data also sidesteps the problem of published studies using slightly different patient populations, drugs, or techniques than used at the home institution.

EXAMPLES OF PATHWAYS THAT CAUSED PATIENT HARM

The previous section was a hypothetical illustration of the development of one part of a pathway. In this section, we take a moment to discuss historical instances in which patient harm resulted from the introduction of a new drug as part of routine perioperative care. Although these drugs were introduced before the notion of surgical and anesthetic pathways became common, the experience with these drugs provides insight into some of the hazards of applying new treatments to large patient cohorts.

Enoxaparin and Venous Thromboembolism Prophylaxis

Enoxaparin was the first low molecular weight heparin approved by the United States Food and Drug Administration for general use. Shortly after the drug's approval in May 1993, it entered widespread, routine use as prophylaxis for venous thromboembolism. Because many orthopedic surgeries, including total joint arthroplasty, pose a high risk for venous thromboembolism, and epidural or spinal anesthesia was frequently the preferred anesthetic for these cases, enoxaparin was often used in conjunction with neuraxial anesthesia.

Prior to the development of enoxaparin, unfractionated subcutaneous heparin had been widely used for venous thromboembolism prophylaxis. While the risk of epidural hematoma associated with enoxaparin administration was felt to be comparable to that of subcutaneous heparin administration initially, the pharmacological differences between low molecular weight and unfractionated heparin had been underestimated.[10]

Shortly after introduction, the US Food and Drug Administration began to receive reports of epidural hematoma associated with enoxaparin administration. In December 1997, the administration issued a public health advisory stating that it had received over 30 reports of postneuraxial epidural hematoma associated with enoxaparin and required that enoxaparin carry a black box warning indicating significant risk of patient harm.[11] By April 1998, the number of reports had increased to more than 40.[10,12] The United States Food and Drug Administration approached the American Society of Regional Anesthesia and Pain Medicine to develop new guidelines for use of enoxaparin with neuraxial anesthesia. These guidelines were published in November 1998 and recommended much more conservative use of enoxaparin.[8]

Aprotinin and Reduction of Perioperative Transfusions

Aprotinin is a small peptide molecule that acts as an antifibrinolytic by inhibiting trypsin and related proteolytic enzymes. It was used most commonly in cardiac surgery[13,14], where it was shown to significantly reduce transfusion requirements, and its use was investigated in other types of surgeries, such as orthopedic procedures.[15,16] Although one meta-analysis showed no increased risk of mortality, myocardial infarction, or renal failure,[17] large observational studies[18,19] contradicted these findings and demonstrated an increased risk of postoperative renal failure. Further observational studies[20] focused on long-term follow-up and confirmed increased morbidity and mortality associated with aprotinin, particularly with regard not only renal failure, but also stroke, death, and nonfatal myocardial infarction. Sales of aprotinin were halted in 2008; aprotinin has been largely superseded by tranexamic acid and aminocaproic acid. There remains some controversy regarding whether the observed increases in renal failure were due to the effect of aprotinin or some other confounder.[21]

Discussion

In both of these examples, significant patient harm resulted from the introduction of a new drug into an anesthetic and surgical pathway because there were insufficient data to indicate potential for patient harm. Risks became apparent only after a larger number of patients were treated and significant patient complications had occurred.

In the first case, low molecular weight heparins and neuraxial anesthesia, the difficulty in predicting patient harm was due in large part to the extremely low frequency of the adverse event. If it is assumed that the baseline risk of spinal hematoma is 1:150,000, even a relatively large increase in the risk of hematoma requires large sample sizes to detect an increased risk.[22] Sample sizes this large often cannot be realistically obtained prior to a drug's introduction, and only postapproval surveillance or the development of high-quality clinical registries will detect such uncommon rare, but potentially catastrophic, adverse events.

In the second case, aprotinin and renal failure, a number of factors can be identified. Initial investigations were not focused on increased risk of renal failure and either they did not investigate this risk or the study was underpowered. In addition, some believed that the complications associated with aprotinin were transient in nature,[17] and that there were no long-term risks associated with aprotinin. Obviously, this could not be investigated until years after aprotinin came into use.

These cases highlight the risks associated with new therapeutic agents or old therapeutic agents used in new situations. Preliminary studies may investigate the wrong risks or may be underpowered, or risks may be long term and may not become evident until well after the study period. Given this, when considering the risks and benefits to the patient, the clinician must also consider unknown or unquantified risk and include the agent only if the ratio of known, quantifiable risks and benefits is overwhelmingly positive. For drugs with a long history of use and well-defined risks, less caution is warranted.

COMPONENTS OF A FULL PATHWAY: TOTAL KNEE ARTHROPLASTY

In this section, we present components of a surgical pathway for total knee arthroplasty. This is shown in Table 15–4. However, instead of presenting final recommendations (as would be done in a completed pathway), we highlight the common issues that are faced when developing different aspects of the pathway, as well as drugs and techniques that are frequently employed. This is done to avoid implying that there is a final consensus around the "correct" pathway for total joint arthroplasty—even if such a consensus existed, it would rapidly become out of date as new studies, drugs, and techniques become available. Providers with different patient populations and different subspecialties may develop different pathways appropriate to their institution.

TABLE 15–4. Components of a total knee arthroplasty pathway, highlighting some common decisions that must be made during pathway development. (*Continued*)

Anesthetic Pathway for Total Joint Arthroplasty

Goals of the pathway

The goals of the pathway should be clearly stated and commonly include reduction in mortality, morbidity, and costs; increases in patient satisfaction; and improved pain control. Goals should involve real clinical endpoints when possible and be agnostic to means, for example, *reduce postoperative pain scores* is a more appropriate goal than *reduce postoperative opioid consumption.*

Patient selection

Modifiable risk factors, such as smoking, poorly controlled diabetes, obesity, and recreational drug use, may affect rates of surgical complications.[23] The pathway may address when surgery should be delayed to address these factors. In addition, nonmodifiable comorbidities may create an unacceptable surgical risk; criteria for patient selection may be included in a pathway. Obviously, this must be coordinated with orthopedics.

Preoperative education and preadmission planning

Frequently, patients are seen routinely in an anesthesia preoperative clinic. This part of the pathway provides an opportunity to identify patient characteristics that conflict with the default elements in the anesthetic pathway and address them preoperatively. For example, a patient with a penicillin allergy may receive skin-prick testing to determine whether the patient may be administered cephalosporins. In addition, if the pathway includes continuous peripheral nerve catheters, this may provide an opportunity for patient education.

Preprocedure checklist

This element of the pathway frequently includes patient identification, site marking, confirmation of allergies and comorbidities, confirmation of availability of blood products, confirmation of anticoagulation status, and final checks of laboratory values.

Oral premedication/multimodal analgesia

Optimization of pain control must be balanced with undesirable side effects such as excessive sedation. The following lists common agents used, along with their benefits and drawbacks.

Agent	Benefits	Drawbacks
Acetaminophen	Reduce postoperative pain scores, opioid sparing[24]	Hepatotoxicity
Gabapentin/pregabalin	Reduce postoperative pain scores, opioid sparing,[25] may reduce incidence of chronic postsurgical pain[26] and have benefit in patients with existing chronic pain[27]	Increased sedation, particularly in elderly; increased respiratory depression with doses > 300 mg[28]
Cyclooxygenase 2 inhibitors	Reduce postoperative pain scores, opioid sparing[29]	Renal impairment; evidence base weakened by retracted publications
Oral opioids (eg, oxycodone SR)	Reduce postoperative pain scores[30]	Increased risk of respiratory depression with oxycodone dose > 10 mg[28]

(*continued*)

Anesthetic Pathway for Total Joint Arthroplasty

Use of regional anesthesia for postoperative pain control

A wide spectrum of regional anesthetic techniques associated with total knee arthroplasty exists, along with significant variation in cost and efficacy. The choice of technique will affect other elements of the anesthetic and surgical pathway. Furthermore, approaches are rapidly evolving as new techniques, equipment, and agents become available. The following lists common sites used for regional anesthesia, along with benefits and drawbacks.

Technique	Benefits	Drawbacks
Epidural block	Considered the gold standard for postoperative analgesia for a range of surgeries	The side-effect profile may interfere with modern care pathway and small risk of catastrophic outcome (eg, epidural hematoma).[31,32]
Femoral nerve block	Relieves majority of postoperative pain, without drawbacks of epidural[33]; associated with improved outcomes at 6 weeks in one trial[34]	Muscle weakness may interfere with rehabilitation. Small risk (2–4 per 10,000) of long-term nerve injury,[35] but overall choice of anesthetic does change risk of nerve injury.[36]
Sciatic nerve block	Reduced posterior knee pain[37]	Risk of neuropathy similar to femoral nerve block. Results of studies vary, ranging from improving analgesia and early mobilization[38] to adding little or no analgesia to existing femoral block.[39] Sciatic block use is controversial[40] and unlikely to improve long-term outcomes.[41]
Selective tibial nerve block	Reduced likelihood of foot drop[42]	Injection closer to popliteal crease; risk of peroneal nerve injury with lateral-to-medial approach or vascular injury.
Adductor canal	Similar pain relief to femoral nerve block with reduced muscle weakness[43]; effective in treating existing severe pain[44]	Closer to surgical site; evolving technique.
Local infiltration analgesia	Easy and quick to perform, no muscle weakness	Evolving evidence for efficacy in this context.[29] However, experts point to poor quality of some of the existing studies.[45] Success of technique likely operator-dependent. Associated with transient peroneal nerve palsy.[46]

Once a site or sites is chosen for regional anesthesia, the provider may utilize different techniques to obtain postoperative analgesia, summarized next.

Technique	Benefits	Drawbacks
Single shot	Quick to perform; low cost; effective.[33]	Shortest duration (may be benefit if rapid recovery of muscle strength is required for physical therapy).
Nerve catheter	Improved analgesia compared to single-injection technique.[47] Longest duration of analgesia; titratable; control over degree of motor block by changing flow rate.	More difficult and time consuming to perform; more expensive; requires postoperative surveillance.
Extended-release formulations of local anesthetic (eg, liposomal bupivacaine)	As quick to perform as single-shot block, with longer block duration.	Compared with bupivacaine, currently little evidence of efficacy.[48] Costly. Limits ability to redo block. Safety and side-effect profile currently emerging.[49]

Surgical anesthesia

Options for surgical anesthesia are summarized next.

Anesthesia	Benefits	Drawbacks
Spinal	Associated with improved outcomes,[2] decreased requirements for critical care services.[50]	Can be technically difficult on certain patients. Occasional catastrophic outcomes (eg, epidural hematoma).[31,32] Duration of spinal anesthesia may be inadequate for surgery. Patients may be reluctant to be "awake" for surgery.
Epidural	Similar benefits as spinal, but can be used for postoperative analgesia and longer-duration surgeries.	Can be technically difficult on certain patients. Occasional catastrophic outcomes (eg epidural hematoma).[31,32] Patients may be reluctant to be "awake" for surgery.
General	Complete amnesia.	Associated with poor outcomes compared to spinal. Occasional catastrophic outcome (eg, difficult airway); increased risk of respiratory depression.[28]

Neuraxial anesthesia has been associated with improved outcomes[1,2]; however, this modality is not always the preferred modality.[51] If neuraxial anesthesia is employed, decisions regarding the inclusion or exclusion of long- or short-acting opioids must be made; this decision can be complex as it affects many subsequent pathway elements (postoperative monitoring, rehabilitation, etc.). Even patients who receive neuraxial anesthesia usually require sedation, and some pathways may specify the desired agents or levels of sedation, in part to avoid excessively sedating the patients. In addition, some patients are likely unsuited for neuraxial anesthesia, for example, due to expected surgical time for joint revisions; this and other criteria (such as difficult spinal) for proceeding to general anesthesia can be described in this section.

Intraoperative drugs

Intraoperative drugs may include first- and second-line antibiotics, preferred antiemetics for spinal anesthesia versus general anesthesia, and preferred sedatives if spinal or epidural anesthesia is chosen. Anticoagulation is usually started in the postoperative period by the surgery team but may be commented on here. Of note, intraoperative dexamethasone appears to improve postoperative pain scores as well as providing an effective antiemetic, without increasing risk of infection or other perioperative complications.[52]

(*continued*)

TABLE 15–4. Components of a total knee arthroplasty pathway, highlighting some common decisions that must be made during pathway development. (*Continued*)

Anesthetic Pathway for Total Joint Arthroplasty

Intraoperative transfusion goals and blood conservation options

Blood transfusion has a number of risks,[53] and one of the goals of the pathway may be to minimize blood loss and hence transfusion requirements. A wide variety of techniques can minimize blood loss, some of which are summarized next.

Technique	Benefits	Drawbacks
Intraoperative hypotension	Reduced blood loss.	Increased vigilance and monitoring required. Risk of end-organ ischemia. Underresuscitation may contribute to postoperative orthostatic intolerance, impairing early mobilization.
Tourniquet use	Reduced blood loss and protocols exist for appropriate use.[54]	Risk of ischemic injury or axonal neuropathy[55–57] or effect on quadriceps function.[58]
Appropriate thermoregulation	Reduced blood loss via maintenance of coagulation cascade, improved recovery.	
Cell scavenging	Reduced allogenic blood product requirements.	Added cost and complexity.
Reinfusion drains	Reduced allogenic blood product requirements.	Added cost and complexity.
Tranexamic acid	Reduced blood loss due to antifibrinolysis.[59]	Association with seizures.[60] No known increased risk of thrombotic events but has only recently come into use in this surgical population.

Postoperative pain control

Pathways often address pain control for patients with chronic pain or opioid use, as well as those without. Generally, this section will comment on both the expected infusion rates for any peripheral nerve catheters, as well as adjuvants such as patient-controlled opioid administration, ketamine, or other agents.

Considerations regarding orthopedic surgical pathway

Pathways sometimes comment on ways in which they interact with the surgeon's pathway to make it clear why particular recommendations are made.

The individual elements of the pathway include such diverse topics as preoperative planning, patient education, intraoperative anesthetic management, postoperative pain management, and fluid and hemodynamic goals. A completed pathway, in addition to containing firm, detailed recommendations on management, would contain an addendum that outlines the evidence that was used to make pathway decisions. As we have seen, however, even after identifying the appropriate literature, there is often a significant amount of analysis and judgment that must be used in applying the literature to the pathway.

A final pathway is only useful if it is distributed widely to all relevant providers. In addition to electronic distribution, pathways can be displayed in the form of a poster. This allows the anesthesia provider to have the steps in the pathway easily available at different phases of the patient's care. Common places to display pathway information include preoperative areas, regional anesthesia bays, operating rooms, and anesthesia workrooms. In addition, with the advent of electronic health record systems, many institutions have the capability to create order sets, which automatically create orders associated with the pathway.

CONCLUSION

Perioperative anesthesia and analgesia pathways provide a unique way of improving patient care and lowering cost by deploying existing resources and technology in an evidence-based way. Pathway development should therefore be considered a vital component of the anesthesiologist's practice.

CHAPTER 16

Infection Control in Regional Anesthesia

Sebastian Schulz-Stübner, Jean M. Pottinger, Stacy A. Coffin, and Loreen A. Herwaldt

INTRODUCTION

Infectious complications related to regional anesthesia are rare. Because most of the information is available in case reports and retrospective surveys, it is likely that these complications are underreported. It is hoped that recent surveillance[1] and prospective registry projects[2] using standardized surveillance definitions and the integration of such in national quality assurance projects (American Society of Regional Anesthesia [ASRA] Acute-POP/AQI)[3] will generate more comprehensive data for risk assessment and evaluation of infection control recommendations in the future. Integration of a structured surveillance tool into the electronic medical record and a hospital's quality management system[4] will ease the workload for clinicians and facilitate surveillance compliance (Table 16–1).

While we have to work on reducing infectious complications associated with regional anesthesia because of the potential severe individual consequences, some studies demonstrate a reduction of surgical site infections with the use of local anesthesia—opening the research arena regarding whether the avoidance of general anesthesia, intrinsic properties of local anesthetics, or a combination of both is responsible for this observation.[5]

The objective of this chapter is to summarize information from the literature on infections complications associated with regional anesthesia, as well as to discuss the mechanism and suggest strategies to prevent these complications.

PATHOGENESIS OF INFECTIONS ASSOCIATED WITH CENTRAL NEURAXIAL BLOCKADE

Microorganisms from exogenous or endogenous sources may gain access to the subarachnoid, epidural, or tissue space surrounding peripheral nerves in several ways. Microorganisms from the patient's or anesthesia practitioner's flora can be inoculated directly when a catheter or needle is inserted into those spaces.[6] Several reports in the literature suggested that infections are on occasion caused by the anesthesia practitioner's flora.[7–9] For example, Trautmann and colleagues reported a case of meningitis caused by a *Staphylococcus aureus* strain that was identical by pulsed-field gel electrophoresis to the *S. aureus* isolated from the anesthesiologist's nose.[8] Rubin et al could trace to a single anesthesiologist *Streptococcus salivarius* as the responsible agent for six cases of meningitis following spinal anesthesia,[10] and the Centers for Disease Control and Prevention (CDC) reported five cases in Ohio and one case in New York between 2008 and 2009 with the same organisms.[11]

Microorganisms can also enter the epidural space by hematogenous spread from other body sites, such as infected skin,[8,12] or by migrating along the catheter tract.[13,14] Several case reports suggested that infection was caused by spread of bacteria from infected sites through the bloodstream to the epidural space.[15–17] Others maintained that infections at distal sites are *not* contraindications to epidural anesthesia. For example, Newman concluded that distal infections did not increase the risk of epidural infection because traumatic injuries are often infected, and no epidural catheter-related infections were identified among over 3000 patients who had epidural neural blockades for postoperative or posttraumatic analgesia.[18] Gritsenko and coworkers analyzed the charts of 474 patients who underwent removal of an infected hip or knee prosthesis under neuraxial anesthesia and found in 0.6% of the cases clinical signs of central neuraxial infections (meningitis or epidural abscess) and three other anesthesia-related complications, including a psoas abscess beside an epidural hematoma and back pain.[19]

TABLE 16–1. Regional anesthesia surveillance system complication definitions.

	A: Essential Criteria	B: Contributory Criteria
Epidural infection		
EI1: Superficial soft tissue infection 2 A and B criteria needed	Swelling Local tenderness	Fever (>38.0°C) Drainage Positive culture from the area Leukocytosis (>12/nL or CRP > 20 mg/L) Local erythema
EI2: Epidural abscess 1 A and 3 B criteria needed	Radiological evidence of a mass in the epidural space consistent with an epidural abscess within 30 days after epidural/spinal needle/catheter placement/catheter removal or attempted epidural/spinal placement	Fever (>38.0°C) Drainage Positive culture from surgical exploration or puncture Leukocytosis (12/nL or CRP > 20 mg/L) Local erythema Local tenderness Focal back pain Neurologic deficit[a]
EI2N[a]	Same as above: Classified as EI 2 N if neurologic deficit is present as a contributory criterion	
EI3: Epidural infection with sepsis 1 A and 4 B criteria needed	Diagnostic criteria of EI1 or EI2 or EI2N[a] puncture site or abscess	Positive blood culture with the same organism isolated from Fever > 38.0°C or hypothermia < 36°C Leukocytosis > 12 nL or leukopenia < 4 nL BP systolic < 90 mm Hg Tachycardia > 90 bpm Respiratory failure (AF > 20, $paCO_2$ < 32 mm Hg, PaO_2 < 70 mm Hg breathing spontaneously or PaO_2/FiO_2 < 175 on mechanical ventilation)
EI3N	Same as above: Classified as EI3N if EI2N[a] criteria are present	
Peripheral nerve block–associated other infection		
OI1: Superficial soft tissue infection	Swelling along the catheter or needle placement track Local tenderness along the catheter or needle placement track	Fever (>38.0°C) Drainage Positive culture from the area Leukocytosis (>12/nL or CRP > 20 mg/L) Local erythema
OI2: Abscess or deep tissue infection	Evidence of an abscess or fluid collection consistent with an infectious process by imaging or surgical exploration within 30 days after peripheral nerve block needle placement/catheter removal or attempted placement	Fever (>38.0°C) Drainage Positive culture from surgical exploration or puncture Leukocytosis (>12/nL or CRP > 20 mg/L) Local erythema Local tenderness Focal back pain Neurologic deficit[a]

(continued)

TABLE 16–1. Regional anesthesia surveillance system complication definitions. (*Continued*)

	A: Essential Criteria	B: Contributory Criteria
OI2N[a]	Same as above: Classified as OI2N if neurologic deficit is present as contributory criterion	Positive blood culture with the same organism isolated from puncture site or abscess Fever > 38.0°C or hypothermia < 36°C Leukocytosis > 12 nL or leukopenia < 4 nL BP systolic < 90 mm Hg Tachycardia > 90 bpm Respiratory failure (AF > 20, $PaCO_2$ < 32 mm Hg, PaO_2 < 70 mm Hg breathing spontaneously or PaO_2/FiO_2 < 175 on mechanical ventilation)
OI3: Infection with sepsis 1 A and 4 B criteria needed	Diagnostic criteria of OI1 or OI2 or OI2N[a]	Positive blood culture with the same organism isolated from puncture site or abscess Fever > 38.0°C or hypothermia < 36°C Leukocytosis > 12 nL or leukopenia < 4 nL BP systolic < 90 mm Hg Tachycardia > 90 bpm Respiratory failure (AF > 20, $PaCO_2$ < 32 mm Hg, PaO_2 < 70 mm Hg breathing spontaneously or PaO_2/FiO_2 < 175 on mechanical ventilation)
OI3N	Same as above: Classified as OI3N if OI2N[a] criteria are present	New onset of central neurologic symptoms Headache Stiff neck Fever > 38.0°C Positive CSF culture Meningitis-specific antibiotic therapy started Spinal or epidural block (catheter insertion/removal) in the past 72 h
Neurologic deficit		
ND1: Neurologic deficit	Residual sensory and/or motor and/or autonomic block 72 h after last injection of local anesthetic without other identifiable etiology New onset of sensory and/or motor and/or autonomic deficit 24 h after resolution of the original block without other identifiable etiology If regional anesthetic-/analgesia-related infection is present classify, as EIXN/OIXN[a]	Electrophysiological evidence of new nerve damage (MEP, SEP, nerve conduction study, electromyography)
2 A and 1 B criteria needed		New loss of deep tendon reflexes New loss of vibration sensation New onset of neuropathic pain in affected nerve distribution area Paresthesia in affected nerve distribution area Sensory and/or motor and/or autonomic deficit consistent with dermatomes or nerve distribution area

[a]CRP: C-reactive protein; BP: Blood pressure; AF: Air flow (Respiratoty rate); CSF: cerebrospinal fluid; MEP: Motor evoked potentials; SEP: Sensory evoked potentials. If regional anesthetic-/analgesia-related infection is present, classify as EI XN/OI XN.

Clinical Pearls

- Streptococcal species, *S. aureus,* and *Pseudomonas aeruginosa* are the most common causative agents but multiresistant species also emerge as causative pathogens as their endemic impact grows within health-care systems.
- Microorganisms from the patient's or anesthesia practitioner's flora can be inoculated directly when a catheter or needle is inserted into the epidural or subarachnoid space.
- Because it is easy to contaminate the needle or the catheters, aseptic measures.

The anesthetic agents injected into the subarachnoid or epidural space are another possible source of infection. Infections from contaminated multidose vials are likely rare because most anesthetic drugs are weak bases dissolved in acidic solutions that inhibit growth of bacteria and fungi.[20–22] Besides most multidose local anesthetic solutions contain a bacteriostatic agent. Nevertheless, the case report by North and Brophy suggested that contaminated multidose vials still can be a source of infection. These authors reported an infection in which *S. aureus* with matching phage types were Isolated from an abscess and a multidose lidocaine vial.[7]

A report by Wong et al[23] described, besides other infection control violations, the use of single-dose medications for multiple patients as the culprit in an outbreak of *Klebsiella pneumoniae* and *Enterobacter aerogenes* bacteremia in a pain clinic. Breaches in aseptic technique for medication preparation can be detrimental, especially if a compound pharmacy is involved: In 2012, more than 200 patients suffered fungal infections with *Exserohilum rostratum* after use of contaminated methyprednisolone injections for interventional pain procedures in multiple institutions in the United States.[24]

To assess whether contamination of the anesthetic agent or the equipment (needles, syringes, tubing) is related to subsequent infections, investigators have cultured these items after they have been used with patients or during simulations. In four studies, 0%–29% of used catheters were contaminated,[25–28] and James and coworkers found that 5 of 101 syringes used to inject anesthetic agents were contaminated.[25] Ross and coworkers drew up 0.25% bupivacaine into control syringes and into syringes used to induce continuous lumbar epidural neural blockade (test syringe) in 18 obstetric patients.[29] After each dose from the test syringe, the investigators cultured the contents of both the test and the control syringes. Six of 18 test syringes were contaminated with bacteria, compared with only 1 of 18 control syringes. Raedler and associates cultured 114 spinal and 20 epidural needles after use for single lumbar injections.[30] Twenty-four cultures (17.9%) grew microorganisms: 15.7% coagulase-negative staphylococci; 1.5% yeasts; and 0.8% each enterococci, pneumococci, and micrococci. The authors concluded that it is easy to contaminate the needle, and that anesthesiologists need to improve their hygienic measures. Despite finding contaminated equipment or anesthetic solutions, no infected patient was identified[25–29]; thus, none of the authors was able to correlate contamination with infection. However, Loftus and coworkers examined the contamination of intravenous stopcocks during general anesthesia and showed, for the first time, postoperative infections with the same organism.[6] It is therefore conceivable that contamination during the placement of a regional block, and, even more likely, during handling of continuous catheter systems, can cause infections. Although the risk for such infections would be less likely than that of manipulating intravenous lines.

INFECTIONS ASSOCIATED WITH EPIDURAL BLOCKADE

The numerous case reports in the literature of infections occurring after epidural neuraxial blockade, attest to the fact that such complications do occur and can be severe (Table 16–2).[7,15,17,30–69] Of 57 patients in these case reports, 41 acquired epidural or intraspinal abscesses, 1 developed a subcutaneous abscess, 2 had meningitis without epidural abscess formation, and 1 developed sepsis. Four patients had injections only, 1 patient had injections and several catheters, and the remaining patients had catheters. Among the 38 patients who had catheters and for whom the duration of catheterization was specified, the median duration of catheterization was 3 days (range 50 minutes to 6 weeks). The median time to onset of the first signs or symptoms of infection was 4 days (range 1 day to 4.8 months) after catheter placement. *Staphylococcus aureus* caused 27 of 43 infections from which bacterial pathogens were isolated. *Pseudomonas aeruginosa* caused five infections and *Streptococcus* spp. caused five. Methicillin-resistant *S. aureus* (MRSA) was isolated in one case; three patients died.

Clinical Pearls

- Epidural catheters inserted for long-term pain control become infected more frequently than those used for short periods of time.
- Malignancy and reduced immunocompetence might be additional risk factors for catheter infection.
- Case reports of infections occurring after epidural neuraxial blockade point out that complications from infection can be severe and often lead to epidural or intraspinal abscesses.

It should be kept in mind that the number of reported cases does not allow us to assess the true frequency of infections after epidural neural blockade. However, several investigators have performed studies to assess this risk. When reviewing 350 reports in the literature, Dawkins in 1969 found no reports of infection after thoracic or lumbar epidural block but identified 8 (0.2%) reports of infection after 3767 sacral epidural blocks used for operative procedures and for obstetrics.[74] More recently, Dawson reviewed the literature and found rates of deep

TABLE 16–2. Infections associated with epidural neural blockade.

Author (Reference)	Year	Indication	Epidural Site	Filter Used	Catheter Duration	Type of Infection	Time From Insertion to Symptoms	Signs and Symptoms	Microorganism	Outcome

infection ranging from 0% to 0.7% and rates of superficial infection ranging from 1.8% to 12%.[75]

Scott and Hibbard surveyed all obstetric units in the United Kingdom and identified one epidural abscess in approximately 506,000 epidural neural blocks.[76] In contrast, Palot and colleagues identified three cases of meningitis in 300,000 patients who had undergone epidural blocks.[77] Three smaller series of obstetric epidural neural blockades (some 12,000 patients) did not identify any infections.[78–80] Similarly, in a recent study by the French SOS group on complications of regional anesthesia, Auroy and coworkers did not identify any infections in 29,732 epidural neural blocks given for obstetrical procedures.[81] Together, the results of these five studies suggest that four or five serious infectious complications (ie, epidural abscesses or meningitis) occur per 1 million obstetric epidural neural blocks.

A number of studies have assessed infections associated with epidural neural blockades performed for operative procedures or for short-term pain relief. However, these studies reported fewer patients than the studies of epidural neural blockade for obstetric procedures. Findings from 10 studies are summarized in Table 16–3.[58,62,81–87] Brooks and collaborators found four infections among 4832 (0.08%) patients undergoing epidural neuraxial blockade for surgical procedures or for labor and delivery.[88] All four infections occurred in healthy young women who underwent cesarean sections; two infections were superficial (0.04%), and two involved the epidural space (0.04%). In contrast, Holt and colleagues reported 53 (1.8%) local infections and 11 (0.4%) central nervous system infections related to approximately 3000 epidural catheters.[89,90] The median duration of catheterization was 8 days for patients with local infections and 15 days for those with generalized symptoms (p = .01). Catheters removed from patients with clinical symptoms were more heavily colonized than those removed from asymptomatic patients. However, 59 of 78 catheters with positive cultures were removed because patients were symptomatic, suggesting that this observation may have been affected by ascertainment bias.

Given that the incidence of infections identified in all studies has been low, the results reported by investigators who calculated the upper boundaries of the infection risk associated with epidural neural blockade are particularly important because they provide a better estimate of the true risk than do studies that reported only the number of infections and the number of procedures. For example, Strafford and coworkers did not identify skin infections or epidural abscesses among 1458 pediatric patients who had epidural analgesia to control perioperative pain.[91] These investigators calculated the incidence of clinical infection to be 0 with a 95% confidence interval from 0% to 0.03%, or three infections per 10,000 procedures. Auroy and colleagues, as noted previously, did not identify any infections among 29,732 procedures done for deliveries.[81] They calculated 95% confidence intervals of 0/10,000 to 1/10,000 procedures. Darchy and associates evaluated 75 patients, 9 (12%; incidence density rate of 2.7/100 catheter-days) of whom acquired local infections. None of the patients acquired deep infections.[83] Based on these data, Darchy and associates estimated the upper risk of spinal space infections to be 4.8% for catheters that remained in place for 4 days. Of note, these estimates are considerably higher than those of Strafford and coworkers[91] and higher even than the rates found by Du Pen and collaborators among patients with epidural catheters for long-term pain control.[92]

TABLE 16–3. Infections after epidural neural blockades done for surgical procedures or short-term pain relief.

Auroy et al[81]	2002	5561	1 meningitis
Volk et al[140]	2009	5057	136 exit site infections

Source: Data from Mayhall CG: *Hospital Epidemiology and Infection Control*, 3rd ed. Philadelphia: Lippincott, Williams and Wilkins; 2004.

In general, epidural catheters inserted for long-term pain control become infected more frequently than those used for short periods of time. Du Pen and associates identified 30 superficial (9.3/10,000 catheter-days), 8 deep catheter track (2.5/10,000 catheter-days), and 15 epidural space (4.6/10,000 catheter-days) infections among 350 patients who had long-term epidural catheters.[92] Similarly, Zenz and colleagues identified two cases of meningitis among 139 patients (1.4%, or 2.1/10,000 catheter-days) treated for pain due to malignancy.[93] Coombs reported that 10 of 92 (10.9%) cancer patients acquired local infections, and 2 (2.2%) acquired meningitis.[94] Malignancy and reduced immunocompetence might be additional risk factors in the population with long-term catheters.

Whether newly developed transparent dressings with integrated chlorhexidine patches might be beneficial for this vulnerable population remains to be seen.

INFECTIONS ASSOCIATED WITH SUBARACHNOID BLOCKADE

Case reports in the literature indicated that serious infections can occur as complications of subarachnoid neural blockade (Table 16–4).[8–11,13,14,95–112] Of the 471 infections reported in these case reports, 272 were meningitis, 4 were epidural abscesses, 2 were soft tissue abscesses, 2 were infections of a disk or of a disk space, 1 developed cerebral and spinal abscesses, and 1 was a case of severe necrotizing fasciitis. In the last case mentioned, the authors speculated about a contaminated reused multiuse vial of local anesthetic as the cause.[112] The median time to onset of signs or symptoms of infection was 1 day (range 1 hour to 2 months) for all infections and 18 hours (range 1 hour to 10 days for meningitis). Streptococcal species caused 24 of the 37 infections from which bacterial pathogens were identified; *S. aureus* caused 2 infections; *Pseudomonas* spp. caused 4; and an extended spectrum betalactamase *Serratia marcescens* caused 1. Compared with infections after epidural neural blockade, infections associated with subarachnoid neural blockade were more likely to be caused by streptococci, and patients were more likely to recover fully. Table 16–5 reviews data from 10 studies or reviews that, if taken together, suggest that the rate of infection was approximately 3.5 per 100,000 subarachnoid neural blockades.[81,109,115–123]

INFECTIONS ASSOCIATED WITH COMBINED EPIDURAL AND SUBARACHNOID BLOCKADE

At present, there are few reports in the literature about infectious complications as a result of using combined epidural-subarachnoid (CSE) neural blockade. In 11 case reports of infections with a total number of 12 patients after combined procedures[62,124–130] (Table 16–6), the median time to onset of signs or symptoms of infection was 21 hours (range 8 hours to 9 days) for all infections and 18 hours (range 8 hours to 3 days) for meningitis. Signs or symptoms of epidural abscesses were first noted 1–9 days after the procedures. Streptococcal species caused three of six cases of meningitis, and *S. aureus* caused all three epidural abscesses. Ten of twelve patients recovered fully. Cascio and Heath assessed rates of infection associated with combined procedures and identified one case of meningitis after about 700 (≈0.1%) CSE neural blockades.[124]

INFECTIONS ASSOCIATED WITH PERIPHERAL NERVE BLOCKS

Continuous regional anesthetic techniques utilizing peripheral nerve blocks have become more popular in recent years for postoperative pain management, especially for orthopedic procedures.[132,133] Only a few studies have addressed infectious complications related to these procedures. The study by Auroy and coworkers of French anesthesiologists did not identify any infections after 43,946 peripheral blocks.[52] Bergman and colleagues identified 1 patient among 368 patients (405 axillary catheters) who had a local *S. aureus* skin infection in the axilla after 48 hours of axillary analgesia.[134] The patient recovered fully with antibiotic treatment. Meier and colleagues reported eight superficial skin infections among 91 patients who had continuous interscalene catheters for an average of 5 days.[135] Nseir described a case of fatal streptococcal necrotizing fasciitis following axillary brachial plexus block.[136] Adam reported a psoas abscess complicating a femoral nerve block catheter.[137]

Cuvillion and coworkers obtained cultures of 208 femoral catheters when they were removed after 48 hours.[138] Of the catheters, 54% were colonized with potentially pathogenic bacteria (71% *Staphylococcus epidermidis,* 10% *Enterococcus* spp., and 4% *Klebsiella* spp.). These investigators also reported three episodes of transient bacteremia, but they did not identify any abscesses or episodes of clinical sepsis.[136] None of the groups provided information about the aseptic techniques used for catheter insertion.

Compère reported a single infection in 400 continuous popliteal sciatic nerve blocks (0.25%),[139] while Volk and coworkers from the German regional anesthesia network reported in 2009 a 1.3% incidence of infectious complications for peripheral blocks in 3724 procedures compared to a higher rate for neuraxial techniques (2.7% in 5057 procedures).[140]

Between 2002 and 2009, Reisig[141] and coworkers collected data on 10,549 peripheral catheter procedures in an observations study that included the implementation of a comprehensive infection control bundle. While the definitions of inflammation and infection used in this study remain somewhat vague, they could show a rate of 4.2% for inflammation and 3.2% for infections in 3491 procedures before the intervention and a reduction to 2.6% for inflammation and 0.9% for infections in 7053 procedures after the interventions.

Other reports included cases of osteomyelitis following digital blocks[141] and hematoma block for fracture repair,[142] as well as orbital cellulites from sub-Tenon anesthesia,[143,144] mediastinitis following continuous interscalene block,[145] *Aspergillus caldioustus* infection after unspecified lower back nerve block,[146] and two cases with sepsis after femoral nerve catheters.[147]

All these reports emphasize the importance of maintaining strict asepsis when performing continuing peripheral nerve blocks.

TABLE 16–4. Infections associated with subarachnoid neural blockade.

Author (Reference)	Year Indication	Indication	Type of Infection	Incubation Period	Signs and Symptoms	Microorganism	Outcome	Comments
Corbett and Rosenstein[96]	1971	1. Vaginal delivery	Meningitis	36 h	Fever, headache, stiff neck	*Pseudomonas aeruginosa*	Full recovery	Three patients infected when a physician rinsed the spinal needle stylet in saline used for consecutive deliveries
		2. Vaginal delivery	Meningitis	3 days	Fever, headache, stiff neck, neck pain, nuchal rigidity	*P. aeruginosa*	Full recovery	
		3. Vaginal delivery	Meningitis	4 days	Fever, headache, nausea	*P. aeruginosa*	Full recovery

PREVENTION OF INFECTIONS ASSOCIATED WITH REGIONAL ANESTHESIA

Anesthesiologists disagree about the necessity of certain infection control precautions.[148–154] For example, several surveys indicated that only 50%–66% of anesthesia staff wore masks when performing epidural and subarachnoid neural blockades.[155–157]

Clinical Pearls

- Wearing a mask during insertion of indwelling neuraxial or peripheral nerve catheters is suggested.
- Sterile gown should be warn during insertion of epidural or nerve block catheters.
- Sterile ultrasound transducer cover should be routinely used with ultrasound-guided procedures.
- Surveillance for catheter site infections is one of the most effective methods for reducing the incidence and consequence of indwelling catheter–related infections.

The review of studies on infections associated with epidural anesthesia indicated that there is no consensus regarding patient risk factors for infectious complications of epidural neural blockade.[133] Few studies assess risk factors for infection associated with epidural or subarachnoid neural blockades, possibly in part because these infections are uncommon. In fact, only one case-control study was performed to evaluate risk factors for infections associated with epidural neural blockade.[158] Dawson and colleagues evaluated epidural neural blockades performed for postoperative pain relief and found that procedures done between April and August had a sixfold higher risk than those done during other months (95% CI 1.28–28.12, p = .009). The risk of infection was lower if a bag rather than a syringe was used to administer the anesthetic agent (odds ratio 0.17, 95% CI 0.02–1.34, p = .05). Of the two risk factors identified by this study, only the latter, use of syringes, could be addressed by practice changes.

Assuming that the respiratory tract of anesthesia personnel could be a source of infection, Philips and associates conducted a simulation to assess the efficacy of masks.[159] They seated anesthesia staff with and without masks in a room with controlled environment and asked them to speak in front of blood agar plates placed 30 cm away. The number of bacteria on the plates was significantly lower when masks were worn. However, the clinical significance of this finding is unknown.

Chlorhexidine has been shown to reduce the risk of catheter-associated bloodstream infections significantly compared with povidone-iodine.[160] Several investigators have tried to determine whether a particular disinfectant provides more effective skin antisepsis before epidural neural blocks than do other agents.[161–164] However, none of the studies was large enough to assess rates of infection; instead, the outcomes evaluated were catheter or skin colonization.

Kasuda and colleagues randomly assigned 70 patients to have their skin prepared with either a 0.5% alcoholic solution of chlorhexidine or 10% povidone-iodine.[162] After a median of 49 ± 7 hours, the investigators removed the catheters and obtained cultures of the insertion sites and catheter tips. There was no difference in rates of positive cultures.

Kinirons and associates (the only investigators who reported a power calculation) obtained cultures from catheters removed from 96 children who had epidural catheters longer

TABLE 16–6. Infections associated with combined subarachnoid and epidural neural blockade.

Author (Reference)	Year	Indication	Type of Infection	Time of Symptom Onset	Signs and Symptoms	Microorganism	Outcome	Comments
Cascio and Heath[124]	1995	Vaginal delivery	Meningitis	16 h after delivery, ≈ 20 h after insertion	Fever, headache, chills, photophobia, mild nuchal rigidity	*Streptococcus salivarius*	Full recovery	Anesthesiologist wore mask, cap, and sterile gloves and used povidone-iodine spray for skin antisepsis
Harding et al[125]	1994	1. Vaginal delivery	Aseptic meningitis	21 h after the injection	Severe headache, faint feeling, shortness of breath, urinary retention, aphasia, tingling right side of face, neck stiffness, positive Kernig sign, low-grade temperature	No growth	Full recovery	Anesthesiologist scrubbed, wore sterile gown and gloves, and used alcoholic chlorhexidine for skin antisepsis
		2. Vaginal delivery converted to emergency cesarean section	Meningitis	3 days after the operation	Headache, fever, vomiting, severe stiff neck, elevated white blood cell count, hypotension, bradycardia	*Staphylococcus epidermidis*	Full recovery	Alcoholic chlorhexidine used for skin antisepsis
Stallard and Barry[126]	1994	Analgesia during labor, subsequent cesarean section	Meningitis	18 h after the operation	Acute confusion, fever, aphasia, ignored left side, elevated white blood cell count	No growth	Full recovery	Did three procedures to achieve adequate analgesia; anesthesiologist used alcoholic chlorhexidine for skin antisepsis and wore mask, gown, and gloves

TABLE 16–6. Infections associated with combined subarachnoid and epidural neural blockade. (*Continued*)

Author (Reference)	Year	Indication	Type of Infection	Time of Symptom Onset	Signs and Symptoms	Microorganism	Outcome	Comments
Aldebert and Sleth[127]	1996	Vaginal delivery	Meningitis	8 h after puncture	Headache, nausea, fever, agitation, nuchal rigidity, positive Babinski sign	Nonhemolytic streptococcus	Full recovery	Anesthesiologist wore mask, gown, cap, and sterile gloves
Dysart and Balakrishnan[128]	1997	Cesarean section	Epidural abscess	9 days after the operation	Backache, fever, foot drop, weakness of ankle eversion and inversion, absent ankle jerk reflex, decreased pinprick sensation from L5 to perianal region, elevated erythrocyte sedimentation rate	*Staphylococcus aureus*	Nearly full recovery; patient had residual numbness in L5 distribution	Anesthesiologist wore a mask, gown, and gloves and used chlorhexidine for skin antisepsis
Schroter et al[129]	1997	Anesthesia for vascular surgery	Epidural abscess	1 day after procedure	Back pain, fever, slight nuchal rigidity, erythema and induration at puncture site and purulent drainage from puncture site, elevated white blood cell count	*S. aureus*	Full recovery	Anesthesiologist wore a mask, surgical hood, sterile gloves, and gown and used povidone-iodine for skin antisepsis
Bouhemad et al[130]	1998	Cesarean section	Meningitis	14 h after delivery	Fever, severe headache, photophobia, drowsiness, stiff neck, positive Kernig sign	*S. salivarius*	Full recovery	Anesthesiologist wore gown, gloves, face mask, and cap and used tincture of iodine for skin antisepsis
Rathmell et al[114]	2000	Labor analgesia in patient with multiple trauma	Epidural abscess	7 days after catheter placement	Back pain, purulent discharge from insertion site	*S. aureus*	Full recovery	

Phillips et al[62]	2002	Surgical anesthesia and postoperative analgesia	Epidural abscess LI–L2	Day 6	Discomfort at the epidural site and severe radicular pain in L2 dermatome, erythema and swelling at site, decreased strength, light touch, and pinprick, and loss of ankle jerk reflex	*S. aureus*	Discharged from hospital 3 months after first operation	Anesthesiologist wore a cap, gown, and sterile gloves and used 10% povidone-iodine for skin antisepsis
Sandkovsky et al[131]	2009	Delivery	Meningitis	NS	NS	*Streptococcus* spp.	NS	
Pitkänen et al[113]	2013	Total hip arthroplasty	Epidural abscess	NS	NS	NS	Full recovery	

Source: Adapted with permission from Mayhall CG: *Hospital Epidemiology and Infection Control*, 3rd ed. Philadelphia: Lippincott, Williams and Wilkins; 2004 than 24 hours.[163] The colonization rate was lower for catheters removed from children whose skin was prepared with a 0.5% alcoholic solution of chlorhexidine (1/52 catheters, 0.9/100 catheter-days) than for those removed from children whose skin was prepared with povidone-iodine (5/44 catheters, 5.6/100 catheter-days) (relative risk 0.2, 95% CI 0.1–1.0).

Sato and coworkers enrolled 60 patients who were undergoing back operations under general anesthesia.[164] After preparing the site with either 0.5% alcoholic chlorhexidine or 10% povidone-iodine, the investigators obtained skin biopsies. Cultures from skin prepared with the alcoholic chlorhexidine were less likely to be positive (5.7%) than were cultures from skin prepared with povidone-–iodine (32.4%; $p < .01$). However, microscopy was as likely to identify bacteria in the hair follicles of skin prepared with the alcoholic solution of chlorhexidine (14.3%) as skin prepared with povidone-iodine (11.8%).

This has led to the recommendation to use alcoholic chlorhexidine for skin preparation despite some concerns about potential neurotoxicity. The latter might be the reason American Society of Anesthesiologists (ASA) members were equivocal on the issue during the consensus process, while external experts were in favor of the recommendation.

Sviggum et al published the experiences from the Mayo Clinic analyzing almost 12,000 spinal anesthetics between 2006 and 2010 that used alcoholic chlorhexidine.[165] They did not observe any change in neurological complications, considering the practice to be safe. Unfortunately, no data about infectious complications were reported.

The safety of alcoholic chlorhexidine was underlined in an experimental study by Doan and coworkers. They found damage to neuronal cell cultures with chlorhexidine as well as with 10% iodine they could also show that a relevant toxic concentration of skin disinfectants cannot be reached if the puncture is performed through dry skin.[166] Therefore, allowing the skin to completely dry once disinfected before performing the block is more important than the choice of the solution in order to prevent any neurotoxic effect.

Malhotra et al[167] demonstrated in a study of 309 healthy volunteers that single application of 0.5% chlorhexidine gluconate in 70% ethanol was as effective as two applications.

The fact that infections rarely complicate neuraxial blockades suggests that the infection control practices used for these procedures are usually adequate. Given the very low rates of infection associated with epidural and subarachnoid neural blockade, it will be difficult to prove that additional infection control practices such as wearing masks and using full barrier precautions (ie, the anesthesiologist wears a cap, mask, sterile gloves, and sterile gown and uses a large drape to cover the patient) reduce the risk of infection. However, bacteria that colonize the skin, respiratory tract, or water caused most reported infections after epidural and subarachnoid neural blockades. Masks have been shown to decrease spread of organisms when anesthesiologists are talking.[159] Thus, a mask would allow the anesthesiologist to talk to the patient while doing the procedure and could decrease the risk of contaminating the insertion site with oral or respiratory flora. This has also been incorporated in the ASA "Practice Advisory for the Prevention, Diagnosis, and Management of Infectious Complications Associated With Neuraxial Techniques."[168]

Furthermore, epidural and subarachnoid neural blockades are at least as invasive as placing central venous catheters, and the consequences of subsequent infections are at least as bad as those for catheter-associated bloodstream infections. Because the use of full barrier precautions reduces the incidence of catheter-related bloodstream infections,[169] aseptic measures similar to those used for placing central venous catheters should be used during the placement of catheters that will remain in place for several days or longer.[75] While the ASA practice advisory still uses the term *hand washing* before putting on sterile gown and gloves, hand disinfection with an alcoholic hand rub (with 70% alcohol) is the internationally preferred standard.[4,170]

Anesthesia personnel should observe their patients closely for signs and symptoms of infection so that infections can be diagnosed and treated immediately. Pegues and coworkers reviewed medical records from 1980 to 1992 of patients who had short-term epidural catheters to identify those who acquired infections. They followed patients prospectively from January 1993 until June 1993.[170] In 1990, they introduced a standardized procedure for inspecting temporary epidural catheters. During the entire 12.5-year period, the investigators identified seven infections, all of which occurred after catheters were inspected routinely. The increased incidence of infection could have resulted from ascertainment or misclassification bias associated with the retrospective review or from increased use of epidural catheters for pain management during the later time period. On the other hand, it could indicate that infections were not diagnosed when catheters were not inspected routinely for signs of infection.

Because it may be difficult to draw up opioids in a sterile manner from ampoules, some have suggested that these drugs be drawn through a filter into a syringe, which is then double wrapped and sterilized in ethylene oxide.[171] However, the benefit of such extreme precautions is highly hypothetical.

Brooks and coworkers were among the first to implement and report on structured infection control measures for continuous neuraxial blocks in their hospital.[88] In 2008, we reviewed the literature and compared the infection control recommendations of the ASRA and the German Society of Anesthesiology and Intensive Care (DGAI)[172] and noticed some discrepancies, especially regarding the use of masks and gowns or filters. In 2010, new guidelines by the ASA were developed in a consensus process among ASA members and external experts to clarify some of the issues. However, the evidence supporting many of the recommendations remains sparse, and extrapolation from other areas of practical implementation of infection control is needed.

The ASA "Practice Advisory for the Prevention, Diagnosis, and Management of Infectious Complications Associated With Neuraxial Techniques"[168] has published the following guidelines for the placement of neuraxial blocks:

- Before performing neuraxial techniques, a history and physical examination relevant to the procedure and review of relevant laboratory studies should be conducted to identify patients who may be at risk of infectious complications. Consider alternatives to neuraxial techniques for patients at high risk.
- When neuraxial techniques are indicated in a known or suspected bacteremic patient, consider administering preprocedure antibiotic therapy.

- Selection of neuraxial technique should be determined on a case-by-case basis, including consideration of the evolving medical status of the patient.
- Lumbar puncture should be avoided in the patient with a known epidural abscess.
- Aseptic techniques should always be used during the preparation of equipment (eg, ultrasound) and the placement of neuraxial needles and catheters, including the following:
  - Removal of jewelry (eg, rings and watches); hand washing; and wearing of caps, masks (covering both mouth and nose and consider changing before each new case), and sterile gloves
  - Use of individual packets of antiseptics for skin preparation
  - Use of chlorhexidine (preferably with alcohol) for skin preparation, allowing for adequate drying time
- Sterile draping of the patient.
- Use of sterile occlusive dressings at the catheter insertion site.
- Bacterial filters may be considered during extended continuous epidural infusion.
- Limit the disconnection and reconnection of neuraxial delivery systems to minimize the risk of infectious complications.
- Consider removing unwitnessed accidentally disconnected catheters.

Catheters should not remain in situ longer than clinically necessary.

The following recommendations are given for the diagnosis and management of infectious complications after neuraxial block:

- Daily evaluation of patients with indwelling catheters for early signs and symptoms (eg, fever, backache, headache, erythema, and tenderness at the insertion site) of infectious complications should be performed throughout the patients' stay in the facility.
- To minimize the impact of an infectious complication, promptly attend to signs or symptoms.
- If an infection is suspected:
  - Remove an in situ catheter and consider culturing the catheter tip.

TABLE 16–7. Summary of recommendations for infection control practice.

	Single-Shot PNB	Continuous Catheter PNB	Single-Shot Neuraxial Block	Continuous Neuraxial Catheter	Long-Term Implanted Device/ Catheter (eg, Intrathecal Pump)
2% chlorhexidine in 70% alcohol skin prep[a]	+	+	+	+	+
Small sterile drape	(+)		+		
Large sterile drape		+		+	+
Sterile gloves	+	+	+	+	+
Sterile gown		+ (especially for stimulating catheters)		(+)	+
Mask		+	+	+	+
Hair cover		+	+	+	+
Prophylactic antibiotics	–	–	–	–	+ single perioperative dose
Filter on injection/infusion system	–	(+)	–	(+)	NA
OR or special procedure room					+
Tunneling of catheter		+ (to prevent dislocation)		+ if used for more than 3 days	
Preparation of injection/ infusion solution under sterile conditions (pharmacy)		(+) for continuous infusion		(+) for continuous infusion	

+ strongly recommended; (+) consider; – not recommended; NA = not applicable; PNB = peripheral nerve block.

[a]Alternatively, 10% povidone-iodine or 80% alcohol or a mixture of 70%–80% alcohol with povidone-iodine for at least 3 minutes. Choice of agent also depends on type of block (eg, eye blocks, etc.).

  - Order appropriate blood tests.
  - Obtain appropriate cultures.
  - If an abscess is suspected or neurologic dysfunction is present, imaging studies should be performed, and consultation with other appropriate specialties should be promptly obtained.
- Appropriate antibiotic therapy should always be administered at the earliest sign or symptom of a serious neuraxial infection.
- Consultation with a physician with expertise in the diagnosis and treatment of infectious diseases should be considered.

However, guidelines and standard operating procedures alone are not enough to ensure proper aseptic technique. Friedman and coworkers showed in a videotape analysis of 35 epidural placements by second-year residents a significant increase in manual skills with growing experience, but there was no increase in aseptic technique.[173] This highlights the need for a special focus on aseptic technique in residency and during infection control audits of anesthesia providers.

PERIPHERAL BLOCKS AND PERIPHERAL CONTINUOUS CATHETERS

Recent studies indicated that infection control protocols similar to the recommendations for neuraxial block can reduce the incidence of infectious complications associated with placement of continuous peripheral nerve catheters.[174] Unfortunately, the effectiveness of each step is hard to assess, a problem familiar from all the other recommended approaches in infection control, such as the ones for prevention of central line–associated bloodstream infections[175] or ventilator-associated pneumonia.[176]

With the increasing use of real-time ultrasound, the correct handling of the ultrasound probe becomes an additional concern. To maintain the aseptic field, the cable and the probe should be covered with a sterile sheath to avoid contamination in the case of needle contact. Sterile contact gel or sterile saline should be used within the sheath. Puncture aids fixating the needle to the probe must be sterile.[4] After the procedure, ultrasound probes need to be cleaned removing any residual gel and disinfected with an appropriate disinfectant that cannot damage the probe. Alternative techniques using ultraviolet light to disinfect ultrasound probes are under investigation.[177,178]

SUMMARY

Although rare, infectious complications from regional anesthesia and analgesia do occur and can be serious. Recent guidelines offer practice recommendations especially for neuraxial blocks. Table 16–7 summarizes the key recommendations for decreasing the risk of infections related to regional anesthesia procedures. Surveillance systems should be implemented as part of national quality assurance programs to allow benchmarking and process optimization as well as providing data from large population databases, which would be beneficial in addressing some of the unanswered questions about infections after regional anesthesia procedures.

CHAPTER 17

Local Anesthetics, Regional Anesthesia, and Cancer Recurrence

Alain Borgeat, José Aguirre, and E. Gina Votta-Velis

INTRODUCTION

Surgical excision is the cornerstone of treatment for solid tumors. Metastatic disease is the most important cause of cancer-related death patients affected with cancer. The likelihood of tumor metastases depends on the balance between the metastatic potential of the primary tumor and the antimetastatic host defenses. Among them, cell-mediated immunity and natural killer (NK) cell function are critical components.

A wealth of basic science data supports the hypothesis that the surgical stress response increases the likelihood of cancer dissemination during and after cancer surgery. Therefore, anesthetic management can potentially influence mid- and long-term outcome. Au contraire, surgery can inhibit major host defenses and promote the occurrence of metastases. Anesthetic techniques and drug choice also can affect the immune system. Together, these two interventions can have profound interactions with a patient's immune defenses. The aims of this chapter are to review how the immune system can be influenced by surgery and anesthesia and discuss the possible mechanisms behind a potential benefit of one intervention over the other in this setting.

THE IMMUNE SYSTEM: THE IMPORTANCE OF TH1/TH2 RATIO

Intact immune responses to cancer cells are crucial in preventing and inhibiting tumor occurrence. The modern concept of immunoediting includes these processes: elimination, equilibrium, and escape.[1,2] This implies that impairment in immune surveillance during the elimination process allows the escape of cancer cells from the protective immune attack. The appearance of clinically apparent tumors through the equilibrium process may occur, rendering the tumor cells more resistant to the immune system.

The NhK, $CD4^+$ Th1 (T helper 1), and $CD8^+$ CTL (cytotoxic lymphocyte) cells are the major antitumor immune effector cells, whereas Th2 (T helper 2), tumor-associated macrophages (TAM), and regulatory T (Treg) cells are the among the most important cells in the promotion of tumor settlement, growth, and progress by inhibiting the immune responses against cancer.[3,4] Other mediators like proinflammatory cytokines,[5] catecholamines,[6] prostaglandins,[6] and high levels of signal transducer and activator of transcription 3 (STAT3) factor activity[7] are also involved in the process of postoperative metastases. NK cells have a crucial role particularly in eliminating metastases without prior sensitization and major histocompatibility complex (MHC) restriction.[8] Therefore, preservation or activation of the function of NK cells is important. In this context, Th1 cells, characterized by interleukin (IL) 2, IL-12, and interferon gamma (IFN-γ) secretions are mandatory to induce antitumor CTL[9] and to activate NK cells.[8] On the other hand, Th2 cells differentiated by IL-4 and IL-10 can induce Th17 cells, Treg cells, TAMs, and myeloid derived suppressor cells (MDSCs),[10] which have a major role in promoting tumor growth and metastasis by inhibiting antitumor immune responses like Th1 induction, CTL function, and NK activity.[11]

The role of proinflammatory cytokines (IL-6, tumor necrosis factor alpha [TNF-α], IL-13) should be outlined because release from infiltrating leukocytes close to the primary tumor site can activate nuclear factor κB (NF-κB) and STAT3 in cancer cells and can contribute to cancer proliferation and survival.[12] NK cell function can also be downregulated by prostaglandins, especially prostaglandin E_2 (PGE_2) by shifting cytokine balance toward Th2 dominance[13] and promoting tumor angiogenesis.[10]

Th1-type responses are necessary for antitumor immunity. It has been shown that, in general, cancer patients have a Th2-dominant status.[14] Surgery per se induces the Th1/Th2 balance toward Th2 immune response.[15] This is explained by the surgical activation of the sympathetic nervous system and the hypothalamic-pituitary-adrenal axis.[16]

ANESTHETIC INTERVENTIONS AND POTENTIAL EFFECTS ON IMMUNOMODULATION

Anesthetic techniques or drugs may have a direct impact on the immune balance of cancer patients. This section reviews the established and hypothetical effects of various anesthetic interventions, pharmacological agents and perioperative occurrences that may affect immunomodulation.

Hypotension, Hypovolemia, and Hypoxia

The occurrence of hypotension/hypovolemia during surgery is are some of the factors responsible for the activation of the sympathetic system. The resulting tissue hypoxia may increase the expression of the intercellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1) as well as P-selectin and E-selectin in vascular endothelium.[17] This initiates the systemic inflammatory response syndrome (SIRS), responsible for a depressed Th1 response[18] and therefore a shift toward the Th2 response phenotype.

Hypothermia

Hypothermia is a common occurrence during surgery. In vitro human investigation has demonstrated that monocytes incubated at temperature lower than 36°C reduced human leukocyte antigen (HLA)-DR expression, delayed TNF-α clearance, and increased IL-10 release.[19] In vivo animal studies have shown a suppression of NK cell activity.[19]

Hyperglycemia

Hyperglycemia during surgery is the result of the activation of the stress response. Acute hyperglycemia inhibits glucose-6-phosphatase dehydrogenase, the enzyme necessary for the formation of nicotinamide adenine dinucleotide phosphate,[20] which will block the functions of monocytes and neutrophils. The risk of infection is increased, and the occurrence of microvascular inflammation engenders an increased release of proinflammatory cytokines (IL-6, TNF-α) from immune cells.[20]

However, no data showing that perioperative hyperglycemia is associated with tumor spread or metastasis are available.

Blood Transfusion

Allogenic blood transfusion is recognized to have diverse negative immunomodulatory effects. However, blood transfusion is also a marker for sicker patients. In this context, it has been shown that anemia per se also has negative immune effects. Therefore, it is important to find the right balance, and avoiding unnecessary transfusions.

Volatile Anesthetics

Volatile anesthetics have been shown to have suppressive effects on immune cells. Halothane,[21] isoflurane,[22] and sevoflurane[23] suppress NK cell activity. The precise mechanism by which these agents interact with the immune system is not clear. However, a recent study showed that pretreatment with isoflurane can enhance resistance to apoptosis of colon cancer cells after exposure to anticancer drugs in vitro via a caveolin-dependent mechanism.[24]

Propofol

Propofol at a clinical concentration does not appear to have significant effects on NK cells and lymphocytes. Propofol, but not thiopental or ketamine, does not suppress NK cell activity in whole blood and does not increase susceptibility to tumor metastases.[21] A comparison between propofol and isoflurane[25] showed that propofol, but not isoflurane, increased the Th1/Th2 ratio, which is beneficial for patients with cancer. On the other hand, sevoflurane anesthesia[26] increased proinflammatory cytokine IL-17 and decreased the Th1/Th2 ratio. Propofol also has inhibiting activity against cyclooxygenase (COX) 2.[27] This is beneficial because in most human cancer cells COX-2 is overexpressed. COX-2 expression is critical for the production of PGE_2, which promotes tumor progression, VEGF (vascular endothelial growth factor) production in cancer cells, NK cell inhibition, and Th2 polarization.[27]

Midazolam and Ketamine

Midazolam[28] and ketamine[29] impair dendritic cell induction of Th1-type immune response in vitro and in vivo. Dendritic cells and Th1-type cells are important players in host defense against tumor. Ketamine also upregulates PGE_2[30] and increases lung metastases through NK cell inhibition in rat models.

Opioids

Morphine-induced immunosuppression is mediated by its binding to a member of the seven-transmembrane G-protein-coupled μ-opioid receptors (MORs) on immune cells.[31] The μ-receptor, which is morphine sensitive, is responsible for its immunomodulation.[32] Interestingly, fentanyl, despite sharing analgesic properties with morphine, does not bind to μ_3-receptor.[33] However, morphine administration reduces CTL and NK cell functions[31,34] and IL-2 and IFN-γ expression in T cells.[35,36] It also enhances IL-4 expression in T cells[37] favoring Th2 differentiation. Fentanyl was shown to have a suppressive effect on NK activity in nonsurgical individuals but to have a positive effect in operative subjects.[38] In contrast, remifentanil did not impair NK activity.[39]

Epidemiologic studies suggested that patients who receive general anesthesia with opioids rather than local anesthetics (LAs) or regional anesthetics may have a greater rate of cancer recurrence.[40] Beilin et al[41] investigated NK cell cytotoxic activity in 40 patients undergoing major surgery, who were randomized to receive either a high-dose fentanyl anesthesia regimen, including midazolam as a single dose and isoflurane if necessary, or low-dose fentanyl, with isoflurane and nitrous oxide used for anesthetic maintenance. In vitro NKA was suppressed in all patients, but high-dose fentanyl resulted in a slower rate of recovery of NK cell activity compared to low-dose fentanyl.

Sacerdote et al[42] studied the effects of morphine and tramadol in patients undergoing abdominal surgery for uterine carcinoma. Phytohemaglutinin-induced T-lymphocyte proliferation and NKA were evaluated. In the morphine group, lymphoproliferative values were attenuated by surgical stress and stayed depressed after the administration of morphine, whereas in the tramadol group these values came back to baseline after the administration of tramadol. NKA was increased by tramadol.

Gupta et al[43] demonstrated that morphine stimulates angiogenesis by activating proangiogenic signaling via Gi/Go-coupled G-protein receptors and nitric oxide. In clinically relevant plasma concentrations, morphine stimulated human microvascular endothelial cell proliferation and promoted tumor neovascularization in a human breast tumor xenograft model in mice, which led to the progression of the tumor.

Singleton et al[44] showed that μ-opioid agonists in clinical concentrations transactivate the VEGF receptors, and that the opioid-induced angiogenesis was blocked by both naloxone and the peripheral MOR antagonist methylnaltrexone. This group suggested that because μ-opioid agonists can alter the endothelial barrier integrity and affect vascular permeability, during tumor surgery, they could potentially facilitate transmigration of cells through the endothelium. This process was shown to be attenuated by methylnaltrexone.[45]

Mathew et al[46] reported that the expression of MORs was increased in lung cancer cells (Lewis lung carcinoma) and that the silencing of MOR in those cells reduced tumor growth and metastasis in mouse models.

Subsequently, Lennon et al[47] published the results of their more recent study where the effect of overexpression of the MOR on lung cancer progression was examined. The authors tested their hypothesis in vitro (H358 human non-small cell lung cancer [NSCLC] cells) and in vivo (human lung cancer xenograft models/nude mouse model). They demonstrated that MOR1 overexpression in H358 human NSCLC cells increased proliferation, migration, invasion, transendothelial migration, and activation of two serine/threonine kinases implicated in cancer progression (Akt [protein kinase B] and mammalian target of rapamycin [mTOR]). In addition, the same effect of increased tumor growth and lung metastasis was observed in human NSCLC xenografts. The authors suggested that these results may provide a plausible explanation for the differences in recurrence rates observed in different contexts.[40,48–50]

In conclusion, there are currently epidemiologic, animal, and cellular studies that suggest a possible role of MOR on tumor growth and metastasis that warrants further investigation.

REGIONAL ANESTHESIA AND CANCER METASTASES

Local Anesthetics and Cancer In Vitro

In vitro studies have demonstrated the antiproliferative or cytotoxic effect of LAs on cancer cells. Martinsson et al[51] evaluated the effect of ropivacaine on the proliferation of human colon adenocarcinoma cells in vitro. Ropivacaine inhibited the growth of these cells in a dose-dependent manner. The effective concentrations were within the therapeutic range, similar to the ones found in the colon of the patients treated rectally with ropivacaine. In the same study, lidocaine was found to be less potent than ropivacaine in inhibiting cell proliferation.

Sakaguchi et al[52] investigated the effects of lidocaine on proliferation of a human tongue cancer cell line that has a high level of epidermal growth factor receptor (EGFR) expression. Lidocaine in clinical concentrations suppressed EGF-induced proliferation of the malignant cells and inhibited EGF-stimulated tyrosine kinase activity of EGFR without cytotoxicity.

Lucchinetti et al[53] reported the results of the antiproliferative effects of LAs on mesenchymal stem cells (MSCs) and the potential implications for tumor spreading and wound healing. MSCs play a key role in tumor growth and metastasis by releasing growth factors, enhancing angiogenesis, immunomodulation, and epithelial-to-mesenchymal transformation. MSCs also contribute to tissue repair. The authors tested the effect of increasing concentrations of the amide LAs lidocaine, ropivacaine, and bupivacaine on proliferation, colony formation, in vitro wound healing, and bone differentiation assays of culture-expanded bone-marrow–derived murine MSCs. They demonstrated that MSCs are sensitive to the antiproliferative effects of LAs at concentrations of 10–100 μM. Their results suggested that mechanisms involved in this antiproliferative action may include the inhibition of NF-κB-ICAM-1 signaling pathway as well as the inhibition of mitochondrial respiration with adenosine triphosphate (ATP) depletion.

Effects of Anesthetic Techniques on Cellular Immunity

In the absence of surgery, general or epidural anesthesia has only minor effects on immune cell functions.[54] However, several preliminary studies in humans have indicated the beneficial effects of epidural anesthesia on immune cell functions in the setting of surgery-induced tissue trauma/stress.

Koltum et al[55] compared, in 20 patients who underwent colectomy under laparotomy for various diagnosis, the effect of awake epidural anesthesia (AEA) versus general endotracheal anesthesia (GETA) on natural killer cell cytotoxicity (NKCC). They found that AEA significantly preserved perioperative NKCC compared to GETA.

Hole et al[56] evaluated the phagocytic capabilities as well as the ability of monocytes to induce lysis of malignant cells in 18 patients undergoing total hip arthroplasty performed under either general or epidural anesthesia. While the phagocytic function of the monocytes derived from patients in the epidural group was found to be increased, the ability to induce lysis in malignant cells of the monocytes derived from patients who underwent general anesthesia was significantly reduced.

Wada et al[23] demonstrated in a rat model that sevoflurane anesthesia and laparotomy diminished tumoricidal activity in liver mononuclear cells (Th cells). On the contrary, a spinal block attenuated this effect. Bar-Yosef et al[57] showed the beneficial effects of spinal anesthesia on lung tumor retention in rats. The group with laparotomy plus general anesthesia had a

17-fold increase in lung metastasis. Spinal block reduced this effect by 70%. The authors concluded that surgical stress in rats promoted the development of metastasis, which was significantly attenuated by regional anesthesia.

Data from Retrospective Studies

In recent years, a number of retrospective studies suggested that regional anesthesia may have a beneficial effect on reducing cancer recurrence and metastasis.

Such studies are often limited by the accuracy of the available medical records, the lack of control in selection and measurement bias, and multiple uncontrolled confounding factors that could have an impact on cancer recurrence.

In one of the first published retrospective studies indicating the beneficial effects of regional anesthesia, Schlagenhauff et al[58] evaluated the prognostic impact of general and regional anesthesia for the excision of primary cutaneous melanoma. The authors examined follow-up data of 4329 patients. The study concluded that there was a significantly increased risk of death for patients treated with general anesthesia for the primary excision of melanoma, thus favoring regional anesthesia for this procedure.

Exadaktylos et al[59] conducted a small retrospective study based on the review of the medical records from patients that underwent mastectomy and axillary dissection for breast cancer. The patients had received either general anesthesia combined with paravertebral anesthesia/analgesia or general anesthesia combined with patient-controlled morphine analgesia. The authors examined the records of 129 patients who had a follow-up time of 32 ± 5 months. Their results suggested that the use of paravertebral anesthesia and analgesia for breast cancer surgery versus opioid use was associated with a metastasis/recurrence-free survival benefit of 94% versus 77% at 37 months.

Christopherson et al,[48] in a retrospective study, evaluated the long-term survival after resection of colon cancer under general anesthesia with or without epidural anesthesia in 177 patients. Analysis was performed separately for patients with and without metastasis because the presence of distant metastasis had the greatest effect on survival. Their results suggested that the patients with epidural analgesia had an improved survival (p = .012), up to 1.5 years; thereafter, the type of anesthesia did not appear to affect survival (p = .27).

Biki et al[49] evaluated retrospective date for prostate cancer recurrence in patients who received either general anesthesia with epidural anesthesia/analgesia (n = 102) or general anesthesia with postoperative opioid analgesia (n = 123). The primary outcome measure was the incidence of "biochemical recurrence," that is, an increase in prostate-specific antigen (PSA) after radical prostatectomy compared with its immediate postoperative peak value, which was the cause for initiation of adjuvant treatment. Adjustment for confounding factors was performed, and the results showed that patients who received general anesthesia combined with epidural analgesia had a 57% (95% CI, 17%–78%) lower risk of cancer recurrence than patients who had general anesthesia and postoperative opioids.

Tsui et al[50] evaluated the effect of adjunctive epidural LA and opioid infusion on disease recurrence following radical prostatectomy for adenocarcinoma under general anesthesia. This study was a retrospective analysis of a small randomized trial conducted for other purposes, such as pain control, blood loss, and the need for perioperative blood transfusion. The authors conducted a prolonged follow-up chart review to determine clinically evident or biochemical recurrence of prostate cancer. The median follow-up time was 4.5 years, and no difference in disease-free survival between the epidural and the control group was observed. Because the study had a different endpoint, it was significantly underpowered for evaluating cancer recurrence.

Ismail et al[60] examined retrospective data to determine the effect of neuraxial anesthesia in the progression of cervical cancer in 132 patients who were treated with brachytherapy. The use of neuraxial anesthesia during the first brachytherapy (most invasive one) was not associated with a reduced risk of local or systemic recurrence, long-term mortality from tumor recurrence, or all-cause mortality after adjusting for other prognostic factors. The study have failed to demonstrate a difference between the general and the regional anesthesia groups due to the underpowered sample size. Other factors that might have contributed to this result are the minimally invasive nature of the therapeutic procedure used for this treatment and the short duration of the neuraxial anesthesia.

Gottschalk et al[61] reviewed the records of 669 patients undergoing colorectal surgery to determine the association between perioperative epidural analgesia and cancer recurrence. The primary outcome of the study was time to cancer recurrence. In this study, the epidural and nonepidural groups were compared in all available potential confounders, and their relationship with cancer recurrence was analyzed by using a multivariable Cox proportional hazards regression model. Overall, no association between epidural use and recurrence was found (p = .43), with an adjusted estimated hazard ratio (HR) of 0.82 (95% CI 0.49–1.35). However, the authors found that the epidural-by-age interaction was statistically significant (p = .03). Epidural analgesia was associated with reduced cancer occurrence in patients older than 64 years, suggesting that age and tumor type may play an important role.

Wuethrich et al[62] evaluated the effect of anesthetic technique on disease progression and long-term survival in patients receiving general anesthesia plus intraoperative and postoperative thoracic epidural analgesia (n = 103) in comparison to patients receiving general anesthesia alone (n = 158). The patients underwent open retropubic radical prostatectomy with extended lymph node dissection. The authors' assessment was more detailed in that they evaluated biochemical recurrence-free survival, clinical progression-free survival, cancer-specific survival, and overall survival. It was demonstrated that general anesthesia combined with epidural analgesia resulted in improved clinical progression-free survival (HR 0.45, 95% CI 0.27–0.75, p = .002). No significant difference was found between general anesthesia plus postoperative ketorolac-morphine analgesia and general anesthesia plus intraoperative and postoperative thoracic epidural analgesia in biochemical recurrence-free survival, cancer-specific survival, or overall survival. The authors used a historical control group, which represented a limitation.

Myles et al[63] conducted a large (n = 503) retrospective study as a follow-up to the Multicenter Australian Study of Epidural Anaesthesia and Analgesia in Major Surgery (MASTER). This multicenter randomized clinical trial tested the hypothesis that combined epidural and general anesthesia reduced the frequency of major postoperative complications compared with general anesthesia and opioid analgesia. The goal was to compare long-term recurrence of cancer and survival in patients who underwent major abdominal surgery under general anesthesia with the supplement consisting of intraoperative and postoperative epidural analgesia (epidural group n = 263) or under general anesthesia and postoperative opioids for analgesia (control group n = 240). The median time to recurrence of cancer or death was 2.8 (95% CI 0.7 to 8.7) years in the control group and 2.6 (0.7 to 8.7) years in the epidural group (p = .61). Recurrence-free survival was similar in both epidural and control groups. However, the fact that 50% of the epidurals did not work is a major weakness of this study and raised serious doubts concerning the validity of the results.

De Oliveira et al,[64] in a recent retrospective study, studied any association between intraoperative neuraxial regional anesthesia and decreased ovarian cancer recurrence. The study reviewed data from 182 patients who underwent primary cytoreductive surgery for ovarian cancer. All the patients received general anesthesia. Of those, 127 received intravenous opioids for postoperative pain control, and 55 received epidural catheters. Of these patients, 26 received epidural anesthesia intra- as well as postoperatively for analgesia. The rest of the patients had the epidural only for postoperative pain control. The authors found that in the intraoperative/postoperative epidural group the mean time to cancer recurrence was 73 (56–91) months, which was longer than for either the epidural postoperative group at 33 (21–45) months (p = .002) or the nonepidural group at 38 (30–47) months (p = .001).

In a recently published retrospective study, Cummings et al[65] compared the effects of epidural analgesia and traditional pain management on survival and cancer recurrence after colectomy. A cohort of 42,151 patients over 66 years old who underwent colectomy was identified from the Medicare-Surveillance, Epidemiology and End Results database. Of these patients, 22.9% (n = 9670) had an epidural at the time of resection. The results of this study demonstrated that the epidural use was associated with improved survival in patients with nonmetastatic colon cancer. Five-year survival was 61% in the epidural group and 55% in the nonepidural one.

Day et al[66] undertook a retrospective analysis of the effect of postoperative analgesia on survival in patients after laparoscopic resection of colorectal cancer. The data of 424 patients were analyzed. The three groups (epidural = 107, spinal block = 144, and patient-controlled analgesia = 173) were similar regarding patient and surgical characteristics. In the epidural group, patients received a mixture of bupivacaine and fentanyl for 48 hours. The authors did not find any difference between the groups in overall survival.

Some of the discussed retrospective studies provided results suggesting that regional anesthesia might have a beneficial affect in reducing cancer recurrence and some did not. The interpretation of the results of these investigations is complex because neither the LAs nor the concentration and the time and duration of application are known. Moreover, some analgesic regimens were a mixture of LA and opioid. Consequently, no clear-cut conclusions or recommendations for clinical care can be made (Table 17–1).

Clinical recommendations are also precluded because the clinical assessment of these results is even more difficult as no information regarding surgical technique is available. Although the possibility that regional anesthesia may reduce the incidence of metastasis is exciting, currently it is a hypothesis as adequately powered prospective randomized clinical trials are needed to validate the current observational results. What is known however, is that LAs have anti-inflammatory properties and do affect the mediators of inflammation at the molecular level. There is also evidence that inflammatory mechanisms may play a role in cancer metastasis.

INFLAMMATION AND CANCER

Epidemiological studies and molecular investigations of genetically modified mice and led to the conclusion that the mechanisms leading to inflammation and cancer may be linked.[67–70] The presence of inflammatory cells and inflammatory mediators in tumors, tissue remodeling, and angiogenesis is similar to that seen in chronic inflammatory responses that precede and constitute the hallmark of cancer-related inflammation.

Cancer and inflammation are connected by two pathways: an intrinsic one and an extrinsic one.[71] The intrinsic pathway is activated by genetic events such as mutations, chromosomal rearrangements, and so on that affect oncogenes. Cells that are transformed by these events produce inflammatory mediators, thereby generating an inflammatory microenviroment in the tumor area. By contrast, in the extrinsic pathway it is the inflammatory or infectious condition that is responsible for the risk of developing cancer at certain sites, such as colon, prostate, and pancreas. The two pathways lead to a common one and follow the activation of the nuclear transcription factor NF-κB and other transcription factors.

These factors regulate the production of inflammatory mediators such as cytokines and chemokines, which in turn recruit and activate various leukocytes. The cytokines activate the same key transcription factors in inflammatory cells, stromal cells, and tumor cells. This results in the subsequent release of more inflammatory mediators and the formation of a cancer-related inflammatory milieu (Figure 17–1).[71]

Role of the ICAM-1 and Src Protein Tyrosine Kinase on Inflammation and Metastasis

The role of cell adhesion molecules (CAMs) such as ICAM-1, VCAM-1, E-selectin, and P-selectin has been studied extensively in the process of inflammation.[72] Similarly, CAMs have been implicated in tumor progression.[73] Some circulating cancer cells have been shown to extravasate to a secondary site using a process similar to inflammatory cells.[74] This process shared by inflammatory and cancer cells may partially explain the link between inflammation and the occurrence of

TABLE 17–1. Retrospective studies.

Study	Which LA	Dosage	Duration	Time of First Application	Results	Remarks
Exadaktylos et al 2006: breast[59]	Levobupi 0.25%	0.2-mL/kg bolus of 0.25% infusion of 0.25% (rate?)	48 h postop	Before surgical cut	++	Retrospective paravertebral block T2–T3

bupi = bupivacaine; levobupi = levobupivacaine; ropi = ropivacaine.

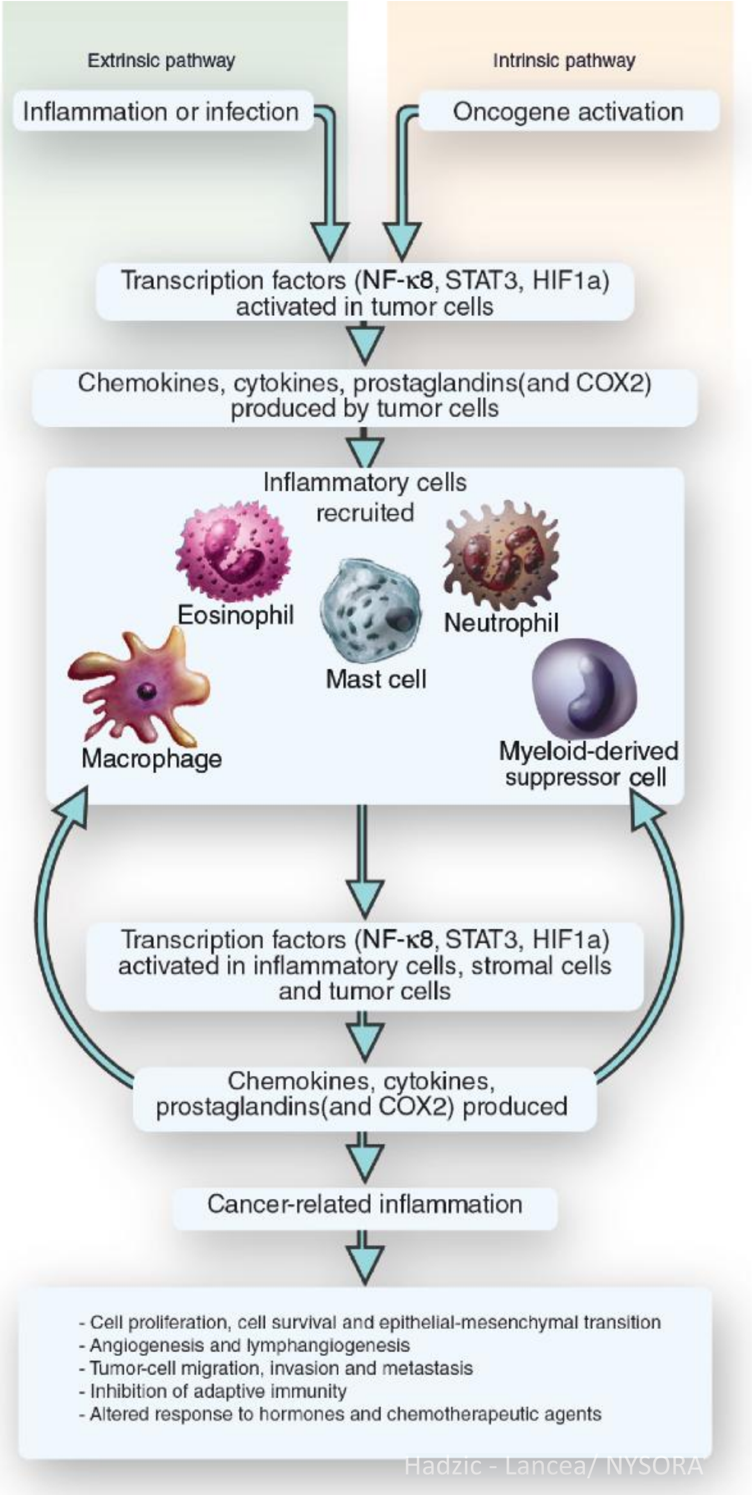

FIGURE 17–1. Pathways that connect inflammation and cancer. Cancer and inflammation are connected by two pathways: the intrinsic pathway and the extrinsic pathway. The intrinsic pathway is activated by genetic events that cause neoplasia. These events include the activation of various types of oncogene by mutation, chromosomal rearrangement or amplification, and the inactivation of tumor suppressor genes. Cells that are transformed in this manner produce inflammatory mediators, thereby generating an inflammatory microenvironment in tumors for which there is no underlying inflammatory condition. By contrast, in the extrinsic pathway, inflammatory or infectious conditions augment the risk of developing cancer at certain anatomical sites. The two pathways converge, resulting in the activation of transcription factors, mainly nuclear factor kappa B (NF-κB), signal transducer and activator of transcription 3 (STAT3), and hypoxia-inducible factor 1α (HIFIα), in tumor cells. (Reproduced with permission from Mantovani A, Allavena P, Sica A, et al: Cancer-related inflammation. *Nature*. 2008 Jul 24;454(7203):436-444.)

metastasis. Furthermore, it may help to understand the therapeutic benefit of anti-inflammatory drugs in cancer treatment.

Scientific evidence has implicated a role of ICAM-1 in tumor invasion in vitro and in metastasis in vivo and hence in the malignant potential of various types of cancer. Kageshita et al[75] have demonstrated that ICAM-1 expression in primary lesions and the serum of patients with malignant melanoma was associated with a reduction in the disease-free interval and survival. Also, a significantly higher level of serum ICAM-1 (sICAM-1) was detected in the patients with liver metastasis, and its levels were increased in serial blood samples obtained from patients with progressing disease. Similar results were reported in a study that examined the role of ICAM-1 in the invasion of human breast cancer cells.[74]

Maurer et al[76] determined that overexpression of ICAM-1, V-CAM-1, and endothelial leukocyte adhesion molecule 1 (ELAM-1) influenced the tumor progression in colorectal cancer. High expression of ICAM-1 in tumors was an indicator of metastatic potential and poor prognosis.[77] Because ICAM-1 is associated with a variety of cancer types and has a role in cancer metastasis, it can be also used as a biomarker for tumor prognosis as well as a target for therapeutic interventions.[78–80]

Current evidence has shown that the binding of apical cell surface associated mucin (MUC-1) on circulating tumor cells to the ICAM-1 on the endothelial cells could represent one of the first crucial steps in metastasis. This molecule is a mucin-glycosylated phosphoprotein that lines the apical surface of epithelial cells in the lung and several other organs. Roland et al[81] proposed that this binding results in a release of cytokines and chemokines that attract macrophages and upregulate tumor production of ICAM-1. Macrophages produce more cytokines that attract neutrophils (polymorphonuclear neutrophils, PMNs), which adhere to the ICAM-1 of the tumor cell surface. This interaction causes degranulation of the PMNs, releasing proteases, with subsequent deterioration of the endothelial barrier promoting extravasation of the tumor cells and formation of metastatic sites.[82–85]

Another potent regulator of endothelial permeability and the inflammatory responses in tissue cells is Src kinase.[86] Src protein tyrosine kinase (PTK) family members have been identified as essential for the recruitment and activation of monocytes, macrophages, neutrophils, and other immune cells.[87] The Src family of nonreceptor protein tyrosine kinases plays a critical role in a variety of cellular signal transduction pathways, regulating such diverse processes as cell division, motility adhesion, angiogenesis, and survival. Activation of Src family kinases is common in a variety of human cancers, may occur through different mechanisms, and is frequently a critical event in tumor progression. Src kinases appear to be important in the proliferation of the tumor, disruption of cell/cell contacts, migration, invasiveness, and resistance to apoptosis. Src family kinases are thus attractive targets for use as anticancer theurapeutics.[88]

It has been demonstrated that once tumor cells leave their primary site, they enter the blood vessels and again they extravasate to form satellite lesions. It was shown in mice that endothelial barrier disruption by VEGF-mediated Src activation potentiated tumor cell extravasation and metastasis. Some of the metastatic tumor cells secrete VEGF, which subsequently activates Src and compromises the endothelial barrier by disrupting a VE-/-β-catenin complex in lung endothelial cell-cell junctions. This is supported by the findings that mice genetically deficient in the c-Src are resistant to tumor cell metastasis.[89] Src is also an upstream regulator of Rho family GTPases (guanosine triphosphatases) such as Rac and Rho, which together regulate dynamic changes in the cytoskeleton and control the disassembly of actin-based cytoskeletal structures and cell-matrix adhesions.[90]

Finally, another protein that plays a role in inflammation by attracting monocytes and macrophages to the site is the monocyte chemoattractant protein 1 (MCP-1). This is a chemokine that exerts strong chemoattractant activities on monocytes, T cells, and NK cells.[91] In addition to promoting the transmigration of circulating monocytes into tissues, MCP-1 exerts various other effects on these cells, including superoxide anion induction chemotaxis and calcium flux.[92] Its production is also associated with angiogenesis and tumor invasion. Goede et al[93] analyzed the angiogenesis-inducing capability of MCP-1 and found it was a potent angiogenic factor when implanted into the rabbit cornea, with an effect similar to the specific angiogenic VEGF. Moreover, serum levels of MCP-1 have been found to be elevated in lung cancer patients with bone metastases.[94]

Evidence of Antimetastatic Effect of Local Anesthetics

Anti-inflammatory properties of ropivacaine have been demonstrated in different experimental models of lung injury.[95] Lidocaine also has well-documented anti-inflammatory properties and a safer profile for systemic toxicity. As mentioned, inflammatory processes involving Src tyrosine protein kinase and ICAM-1 play a role in cancer metastasis. It could be hypothesized that the amide LAs might attenuate the metastatic process of cancer cells in a similar manner to the inflammatory one.

In a recent study, we showed that lidocaine and ropivacaine may inhibit inflammatory cytokine signaling, proliferation, and migration of lung adenocarcinoma cells.[96] The following in vitro study was performed: NCI-H838 lung cancer cells were incubated with TNF-α in the absence/presence of ropivacaine or lidocaine (1 nM, 1 μM, 10 μM, 100 μM). Cell lysates were analyzed for Src activation (phosphor-Y419 Src) and ICAM-1 phosphorylation (phosphor-Y512 ICAM-1) via Western blot. MCP-1 production, cell proliferation, and migration were also evaluated. The results of this work showed that both lidocaine and ropivacaine inhibited Src activation induced by inflammatory mediators TNF-α (Figures 17–2 and 17–3). We also showed that both lidocaine and ropivacaine attenuated TNF-α-induced MCP-1 production in H838 cancer cells, and that they inhibited their proliferation and migration as well (Figure 17–4). Interestingly, the ester LA chloroprocaine did not demonstrate these properties, suggesting these effects were specific to the amide type of LAs.

To support the direct inhibition of Src tyrosine protein kinase by the amide LAs, the cells were treated with veratridine, a sodium channel activator and tetrodotoxin (TTX), a non-LA

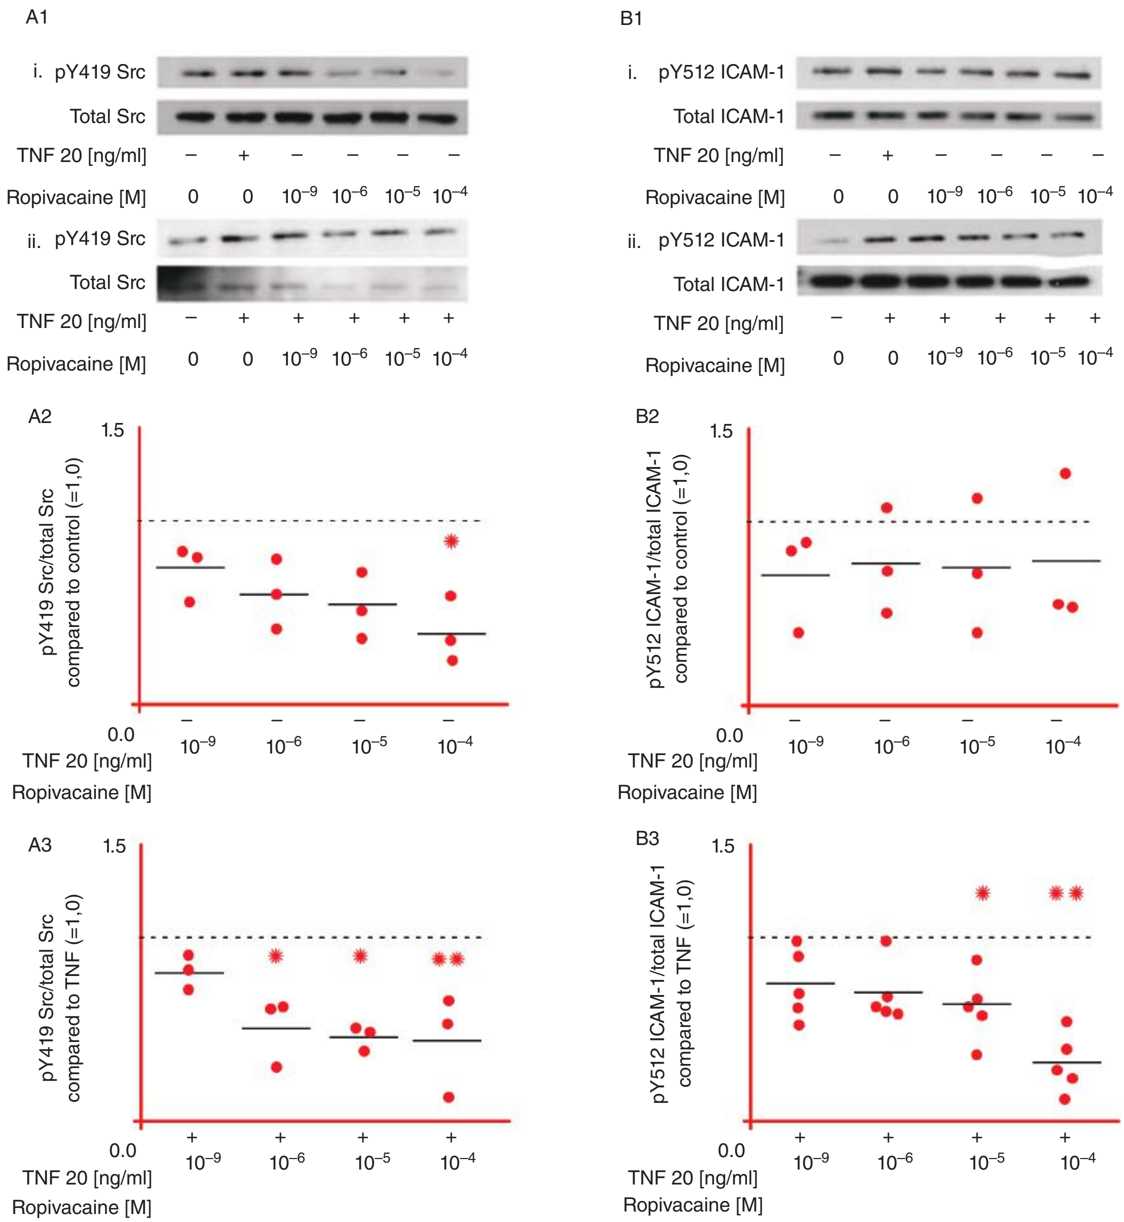

FIGURE 17–2. A: Effect of ropivacaine on the phosphorylation status of Src in NCI-H838 lung cancer cells. A. (i) Representative Western blot of NCI-H838 cell Src, phosphorylated at tyrosine 419 (pY419 Src, row 1) and total Src (row 2) after treatment with either tumor necrosis factor alpha (TNF-α) (20 ng/mL) or with different concentrations of ropivacaine (1 nM, 1 μM, 10 μM, 100 μM) for 20 minutes. (ii) Representative blot of NCI-H838 lung cancer cell pY419 Src (row 1) and total Src (row 2) after treatment with TNF-α (20 ng/mL) with or without different concentrations of ropivacaine (1 nM, 1 μM, 10 μM, 100 μM) for 20 minutes. B. Relative density of the Western blot bands of pY419 Src normalized to the densitometry values of total Src compared with control (= 1.0, dashed line) in the absence of TNF-α expressed. Data from three independent experiments shown as scatter plot ($n = 3$). Horizontal line indicates mean for each group; $^*p < .05$ versus control. C. Relative density of the Western blot bands of pH419 Src normalized to the densitometry values of total Src after coincubation of ropivacaine with TNF-α (20 ng/mL) compared with TNF-α alone (= 1.0, dashed line). (i) Representative Western blot of NCI-H838 lung cancer cell ICAM-1, phosphorylated at tyrosine 512 (pY512 ICAM-1, row 1) and total ICAM-1 (row 2) after treatment with either TNF-α (20 ng/mL) or different concentrations of lidocaine (1 nM, 1 μM, 10 μM, 100 μM) for 20 minutes. (ii) Representative blot of NCI-H838 cell pY512 ICAM-1 (row 1) and total ICAM-1 (row 2) after treatment with TNF-α (20 ng/mL) in the presence or absence of different concentrations of lidocaine (1 nM, 1 μM, 10 μM, 100 μM) for 20 minutes. B. Relative density of the Western blot bands of pY512 ICAM-1 normalized to the densitometry values of total ICAM-1 compared with control (= 1.0, dashed line) in the absence of TNF-α. Data from three independent experiments shown as scatter plot ($n = 3$). Horizontal line indicates mean for each group. C. Relative density of the Western blot bands of pY512 ICAM-1 normalized to the densitometry values of total ICAM-1 after coincubation of lidocaine with TNF-α (20 ng/mL) compared with TNF-α alone (= 1.0, dashed line). Data from three independent experiments shown as scatter plot ($n = 3$). Horizontal line indicates mean for each group. **$p < .01$ versus TNF-α. (Reproduced with permission from Piegeler T, Votta-Velis EG, Liu G, et al: Antimetastatic potential of amide-linked local anesthetics: inhibition of lung adenocarcinoma cell migration and inflammatory Src signaling independent of sodium channel blockade. *Anesthesiology.* 2012 Sep;117(3):548-559.)

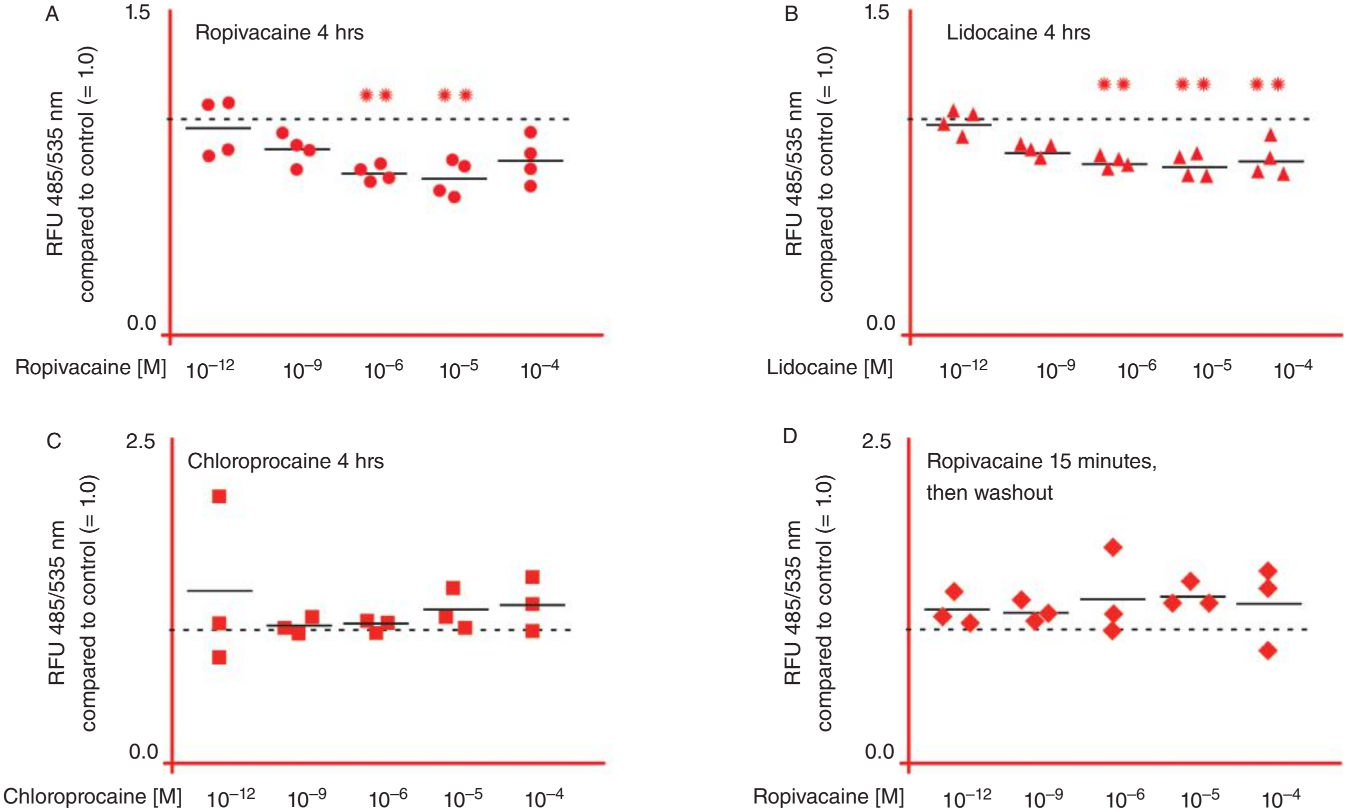

FIGURE 17–4. Migratory ability of NCI-H838 lung cancer cells in the presence of ropivacaine, lidocaine, and chloroprocaine. Determination of in vitro transmigration of NCI-H838 cells through a polycarbonate membrane after 4 hours in the absence or presence of different concentrations (1 pm, 1 nM, 1 μM, 10 μM, 100 μM) of **A**, ropivacaine; **B**, lidocaine; and **C**, chloroprocaine. **D**. Determination of in vitro transmigration of NCI-H838 cells through a polycarbonate membrane after 4 hours in the absence or presence of different concentrations (1 pm, 1 nM, 1 μM, 10 μM, 100 μM) of ropivacaine for only 15 minutes followed by a wash of the cells with fresh medium right before the start of the assay. Cells were stained with a fluorescent dye before the start of the assay and lysed after migration through the membrane. Fluorescence was measured at 435/535 nM (excitation/emission). Values for untreated cells were set as 1.0 (dashed line). Data from four (A and B) or three (C and D) independent experiments shown as scatter plot. Horizontal line indicates mean for each group. $^{**}p < .01$ versus control. RFU = relative fluorescence units. (Reproduced with permission from Piegeler T, Votta-Velis EG, Liu G, et al: Antimetastatic potential of amide-linked local anesthetics: inhibition of lung adenocarcinoma cell migration and inflammatory Src signaling independent of sodium channel blockade. *Anesthesiology.* 2012 Sep;117(3):548-559.)

sodium channel inhibitor. We did not observe any alteration in the phosphorylation status of Src and ICAM-1 after treatment with veratridine compared to untreated cells, indicating that the phosphorylation of these two proteins was independent from sodium channel activation. The application of TTX had no effect on the phosphorylation status of these proteins, neither after treatment with TTX alone compared to untreated cells nor after coincubation with TNF-α compared to TNF-α alone. Taken together with the results obtained in the experiments with veratridine, we postulated that the observed effects of the inhibition of Src and ICAM-1 phosphorylation were independent of sodium channel inhibition.

Metastatic disease after cancer surgery remains a crucial issue. Cancer dissemination is a multistep process in which many cellular and molecular regulatory mechanisms may be involved and are targets for therapeutic interventions.

Traditional systemic therapy is delayed for weeks after major surgery to allow wound healing and thus avoiding the risks of immunosuppression and postoperative infections. However, recent studies demonstrated that cellular and molecular events that are critical to the metastatic process may be significantly influenced during and immediately after surgery.[97] The perioperative period may be a window of therapeutic opportunity because metastasis may be initiated during this period. Preliminary studies using LAs have shown encouraging results for cancer outcomes. So far, the potential beneficial effect of regional anesthesia to improve long-term outcome after cancer surgery has contributed mainly to the inhibition of the neuroendocrine stress response to surgery and to the reduction in the requirements of the volatile anesthetics and opioids.

CONCLUSION

The amide LAs block TNF-α-induced Src activation and ICAM-1 phosphorylation in vitro. Both of these processes may favor the extravasation of tumor cancer cells and metastasis. Cytokines such as TNF-α increase the expression of

ICAM-1 in the H838 NSCLC. Src protein tyrosine kinase, which lies both upstream and downstream of activated ICAM-1, functions as a regulator of endothelial permeability and is also involved in signaling epithelial-to-mesenchymal transformation and extravasation of cancer cells, a process necessary for tumor metastasis. The activity of these two systems is significantly inhibited in vitro by the application of amide-type LAs. The immediate postoperative period is a crucial time in surgical oncology because no treatment will be started for a few weeks. The application of amide-type LAs in the perioperative period may be beneficial in preventing metastasis. However, the current preliminary data require further studies before any clinical recommendations can be made.

CHAPTER 18

Perioperative Regional Anesthesia and Analgesia: Effects on Cancer Recurrence and Survival After Oncological Surgery

Zoe S. Gan, Yanxia Sun, and Tong J. Gan

INTRODUCTION

The effects of perioperative regional anesthesia (RA) on cancer recurrence and overall survival after surgery have been a subject of much interest and controversy. This chapter discusses the available evidence and possible mechanisms by which RA could have beneficial effects in these patients.

Surgical treatment of cancer is well established. An important consideration with oncological surgery is that the procedure may disseminate tumor cells in patients with micrometastases.[1,2] Metastatic recurrence, rather than the primary cancer, accounts for approximately 90% of cancer-related deaths.[3] Cancer cell development in local and metastatic recurrence is dependent on the interplay between the host defenses and the tumor's ability to seed, proliferate, and attract new blood vessels.[4,5] However, these in turn may be influenced by surgery, general anesthesia, and opioid administration, which are three of several perioperative factors that may contribute to metastatic spread.

There are several mechanisms through which these perioperative factors potentially affect cancer cell evolution. Surgery itself is a major physiological stress that may depress cell-mediated immunity, particularly the activity of natural killer (NK) cells and macrophages that would otherwise destroy various tumor cells.[6] This immunosuppression may be induced by factors such as neuroendocrine stress responses,[7] blood transfusion,[8] and hypothermia.[9] Surgery may also reduce antiangiogenic factors while increasing proangiogenic[10] and growth factors that cause malignant cells to proliferate.[11,12] In addition, general anesthesia with halogenated volatile agents or intravenous drugs such as thiopental may contribute to postoperative immune suppression by inhibiting the function of NK cells, neutrophils, dendritic cells, and macrophages.[12,13] Intraoperative and postoperative opioid use has been shown to interfere with immune function, specifically by altering the levels of NK cells, B cells, and T lymphocytes, as well as stimulate angiogenesis via alterations in cytokine levels.[13] Thus, these perioperative factors may complicate surgical treatment of cancer by increasing growth factors and modulating host immunity (Figure 18–1).

Regional anesthesia and analgesia are commonly used for perioperative pain management and may have implications in both short- and long-term outcomes following oncological surgery. Regional anesthesia could potentially attenuate the stress response related to surgery, preserve immune function, and slow the surgical promotion of metastases.[6,14] Furthermore, it decreases the intraoperative use of volatile anesthetics and perioperative opioids.[15] In combination, these effects may lead to better preservation of perioperative immune function and a reduced incidence of cancer recurrence.

A recently published systematic review and meta-analysis evaluated these effects.[16] The meta-analysis included studies that compared the effects of RA on cancer recurrence and mortality with those of general anesthesia.

A total of 20 studies published between 2006 and 2014 met inclusion criteria and yielded 54,541 patients; 16,618 of these individuals received perioperative RA, with study sample sizes ranging from 94 to 42,151 (Table 18–1). Studies were most frequently excluded for the following reasons: not investigating RA for recurrence-free survival or overall survival; lacking original data; lacking cancer-related outcomes (time to cancer recurrence, all-cause mortality, disease-free survival, or cancer recurrence-free survival); or performing repeated analysis in a single population.

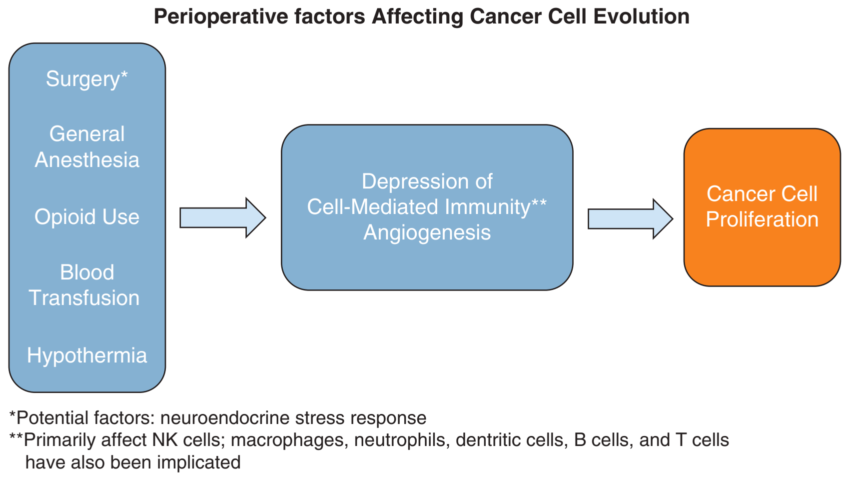

FIGURE 18–1. Perioperative factors affecting cancer cell evolution.

OVERALL PATIENT SURVIVAL

Overall survival was assessed in 13 studies.[17–27] There was a significantly positive association between RA and overall survival (hazard ratio [HR] = 0.84, 95% CI 0.75 to 0.94, I^2 = 41%) (Figure 18–2). This association held true when different cancer types were analyzed, including colorectal cancer (HR = 0.80, 95% CI 0.66 to 0.97); prostate cancer (HR = 0.77, 95% CI 0.61 to 0.97); and ovarian cancer (HR = 0.83, 95% CI 0.71 to 0.97).

CANCER RECURRENCE

The effect of RA on cancer recurrence-free survival was analyzed among 15 studies.[17,19,21,22,24–34] There was no overall effect on cancer recurrence-free survival among the RA and control groups (HR = 0.93, 95% CI 0.79 to 1.10, I^2 = 70%) (Figure 18–3). Subgroup analyses showed that different types of cancer had slightly different pooled HRs, but the differences were not statistically significant. Cancer types analyzed included colorectal cancer (0.86, 95% CI 0.67 to 1.12); ovarian cancer (0.73, 95% CI 0.39 to 1.37); and prostate cancer (0.82, 95% CI 0.58 to 1.14). Based on influence analyses, no individual study substantially influenced the pooled HR.

Perioperative RA may improve overall survival following oncologic surgery (HR = 0.84, 95% CI 0.75 to 0.94, I^2 = 41%). However, there was no positive association found between RA and reduced cancer recurrence (HR = 0.91, 95% CI 0.70 to 1.18, I^2 = 83%).

There are several potential explanations for the discrepancy between overall survival and cancer recurrence. First, some experimental studies have suggested that RA may not significantly influence recurrence, but rather slows cancer progression by reducing surgery-induced immunosuppression and postoperative pain, resulting in prolonged survival.[35,36] Second, RA may increase survival through means that are independent of the underlying disease, such as better rehabilitation, anti-inflammatory properties, and less chronic pain.[37] Finally, lack of statistical power could limit the demonstration of a true association between RA and cancer recurrence. This issue may be addressed in the future with additional prospective trials.

There is considerable variation in tumor biology from organ to organ, and it is likely that any potential effects of RA may vary from site to site. Although the effects of RA on cancer recurrence may be specific to certain tumors, subgroup analyses indicated that the absence of an effect was consistent for different types of cancer (colorectal, prostate, and ovarian cancer). It appears that RA does not differentially affect recurrence or overall survival for various cancer types.

Of several recently published trials on this topic, the meta-analysis by Sun et al[16] provides the most up-to-date analysis of the effects of RA on cancer recurrence and survival. It includes seven recently published studies[17,26,27,32,33,38,39] with higher-quality scores that were not identified in the previous meta-analysis, as well as five new studies[17,26,27,32,33] and three studies[21,22,25] excluded by previous meta-analysis. Importantly, the findings discussed in this chapter are consistent with those of prior meta-analyses.

While meta-analysis allows for a more comprehensive assessment of RA's potential effects on cancer recurrence and survival, several limitations should be kept in mind. First, because the included studies were retrospective, meta-analysis of these studies may have been susceptible to biases and confounding factors present in the original studies.[40] When available, adjusted estimates were used to control for possible sources of confounding factors. Unfortunately, the estimates could not be consistent in all studies. Sensitivity analyses were conducted for previous randomized controlled trials (RCTs) with limited bias. However, initial randomization in those RCTs was not stratified for tumor characteristics, and there may have been residual confounding factors or bias.

Finally, heterogeneity across studies may have affected the pooled estimates. Factors contributing to heterogeneity include type of surgical procedure, type of cancer, differences in study populations, assessment of covariates, and the definition and validation of survival endpoints. Several of the studies may have had follow-up periods of varying duration. Outcomes may have also been affected by the use of different RA strategies across studies. For example, one included study[34] found that intraoperative, rather than postoperative, use of epidural anesthesia led to delayed cancer recurrence following surgery in ovarian

FIGURE 18–3. Meta-analysis and pooled hazard ratio (HR) of the effect of perioperative regional anesthesia and analgesia on cancer recurrence-free survival after cancer surgery. GA = general anesthesia; intra = epidural anesthesia initiated during surgery; post = epidural anesthesia initiated after surgery; RA = regional anesthesia and analgesia.

cancer patients. However, neither subgroup analyses nor meta-regression based on RA strategy were conducted due to the limited number of studies included.

Publication bias also remains a limitation of any meta-analysis. The Begg's test and Egger's test conducted in this analysis did not exhibit significant asymmetry, thus indicating that there was no significant evidence of publication bias for either overall survival or cancer recurrence-free survival. However, this cannot completely rule out publication bias.[41] Finally, because the findings do not necessarily suggest causation, one cannot simply deduce that the use of perioperative RA would improve prognoses for cancer patients.

CONCLUSIONS

Based on the available data, it is possible that the use of RA perioperatively may improve overall survival after oncologic surgery. However, the current data do not suggest a positive association between RA and cancer recurrence-free survival. Based on the biological and clinical effects of local anesthetics and RA, RA may be beneficial in some patients undergoing cancer surgery, most likely through preservation of the immune system and attenuation of the stress response to surgery. Understanding the true clinical implications of RA, however, awaits additional well-designed, higher-powered prospective clinical trials.

LOCAL AND INFILTRATIONAL ANESTHESIA

CHAPTER 19

Intra-articular and Periarticular Infiltration of Local Anesthetics

Johan Raeder and Ulrich J. Spreng

INTRODUCTION

Infiltration or instillation of local anesthetics around and into the joint as an analgesic adjunct for postoperative joint surgery pain has been used for decades. However, there has been a renewed interest in local infiltration analgesia (LIA), partly due to the work in 2008 of Kerr and Kohan,[1] who demonstrated superior analgesia after total knee or hip arthroplasty with extended, diluted infiltration of local anesthesia with epinephrine and ketorolac added and repeated injections through intra-articular catheters. The interest in using LIA in knee and hip surgery may be also due to the lack of the simpler regional anesthesia alternatives that exist for other joints. For instance, analgesia after shoulder and upper extremity surgery can be accomplished with a simple, single injection block of the brachial plexus, whereas analgesia for hip and knee joints requires multiple and more technically challenging nerve blocks. Also, while motor weakness is common with nerve blocks, infiltration analgesia typically spares the motor function.

THE CONCEPT OF LOCAL INFILTRATION ANALGESIA

There are three basic components of the LIA concept: high volume of diluted, long-acting local anesthetic; nonlocal anesthetic adjuvants; and catheter bolus injections (top-ups) for 1–3 days.

High Volume of Diluted Long-Acting Anesthetic Drug

A problem with local anesthetic infiltration for major surgery is that many different structures and layers must be infiltrated. In doing so, a certain minimum volume of local anesthetic is required for an effective local infiltration to cover all relevant structures. With conventional concentrations of local anesthetic solutions, such high volumes carry an unacceptable risk of systemic toxicity (see Chapter 65, Local Anesthetic Systemic Toxicity). However, anesthesia of the small nerve endings in and around joints does not require high-concentration local anesthetic. Thus, the concentration of local anesthetic may be lowered and the volume increased, keeping the total dose within safe limits. Further, as the major joints are devoid of major blood vessels, the risk of inadvertent injection of a large bolus directly into circulation is small.

Nonlocal Anesthetic Adjuvants

As careful injections of local anesthetic are made close to the site of surgical injury, there is a potential for targeting the source of pain caused by local inflammation and pain to supply effective treatment close to the origin of pain. This is an alternative to the systemic approach to analgesia by which a potentially higher total dose of drug is needed and carries a higher potential of general side effects. Nonlocal anesthetic adjuvants such as anti-inflammatory agents, nonsteroidal anti-inflammatory drugs (NSAIDs—traditional or cyclooxygenase [COX] 2 inhibitors) and steroids, as well as opioids and ketamine have all been used.

The role of epinephrine or clonidine in the LIA mixture, however, has not been well studied. While both drugs have an analgesic effect on the spinal α_2 receptors when given epidurally or spinally, there is no documentation on any specific analgesic effect or target mechanism of these drugs when used peripherally.[2] Epinephrine is often empirically included "just in case" due to the potential to prolong effect of other locally active drugs as their clearance from the local site is delayed due to the epinephrine-induced vasoconstriction.[3]

Catheter Top-ups for 1 to 3 Days

Long-acting local anesthetics used for infiltration, perioperative injections, and infiltration all have a limited duration and wear off within a few hours after injection. Because repeated injection of the local anesthetic is painful or inconvenient, one approach is to leave one or more catheters in the wound or joint to provide the vehicle for boluses or continuous infusion of local anesthetics. The use of catheters in a setting of major joint replacement, however, is controversial because of the potential for infection.[4] The routine use of catheter is also challenged in the United States by the recent development and FDA approval of long-acting depot bupivacaine, (liposomal bupivacaine) although the role and potential of this drug in the LIA concept requires more scrutiny.[5]

EVIDENCE-BASED INFORMATION ON EFFICACY AND SAFETY OF LOCAL INFILTRATION ANALGESIA

As often is the case with new methods and techniques, the initial enthusiasm for LIA expressed in clinical practices, professional gatherings, and case reports,[1] awaits evidence-based scrutiny before recommendations for everyday clinical use can be made.[6,7] The following are important questions that need scrutiny:

1. Is the method sufficiently efficacious?
2. What components of the new method are efficient?
3. How does LIA compare to other common methods in terms of safety, quality, and cost?

If a new method is tested as a component of a multimodal regimen and shows superiority versus controls, we may have the answer to the first question, but questions 2 and 3 remain unanswered. The logical next steps are to put to test each component individually (keeping all the rest unchanged and standardized) in controlled and standardized conditions to elucidate which components of the multimodal protocol are actually beneficial. The LIA should be compared with the best potential alternatives used under optimal conditions: intrathecal opioid, epidural analgesia, femoral nerve block, other nerve blocks, or just optimal multimodal analgesia, including local anesthesia wound infiltration.

We do know that infiltration of local anesthetics confers analgesia after knee replacement surgery, assuming that local anesthetic is skillfully infiltrated in all relevant tissues.[8] In a study of hernia repair with bupivacaine infiltration analgesia, Aasboe et al showed improved pain relief for as much as 1 week after the procedure.[9] Still, such results are to some extent procedure specific and not reproduced with LIA by others. In the study of Andersen et al on knee arthroplasty, the preoperative ropivacaine infiltration was superior to placebo at 6 hours but not at 24 hours.[4] The success of LIA may be dependent on how extensive the local infiltration technique is performed in terms of including all relevant structures, not only the superficial wound layers.[5]

With all new concepts, one must find a balance between rapidly incorporating the benefits into everyday practice while waiting for objective documentation from quality studies. The studies done so far on the efficacy of LIA do not have the power, standardization, or quality to provide a clear answer or even provide quality pooled data for meta-analyses.[6] One reason for the paucity of the evidence is that randomized, blinded studies incorporating LIA are somewhat difficult to design because all injections, catheters, and refilling, need to be done in the placebo group as well.[10] Even then,[8] such a placebo group would not be relevant because in clinical practice saline injections in wound structures and catheters would not occur, and yet, saline injections alone may have analgesic benefits.[11] This is because infiltration of saline into the knee joint has analgesic effect,[10,11] possibly by cooling and dilution of inflammatory local proteins, or placebo.

As there are many confounders, ideal studies on the efficacy of LIA should address only one or a few specific items at a time, controlling or standardizing the others. Such specific items include one specific type of surgery, systemic controls for all active drugs in the LIA mixture, and sham or placebo infusions or top-ups when testing postoperative LIA.

Analgesic effects of ketorolac[12] and ropivacaine when given systemically are well known. Likewise, intra-articular administration will also result in systemic absorption and systemic effects. It should be remembered that LIA may never be well standardized as a defined dose of a single intravenous drug or a specific nerve block for a few reasons. First, different types of surgery and joints vary in anatomical composition, acceptability for and spread of LIA, and degree of postoperative pain.[13] Second, differences in infiltration techniques may influence the analgesic benefits.

Clinical impression suggests that the morning injection the day after surgery seems to have an analgesic effect on patients in pain, although this was not demonstrated convincingly in controlled studies.[7,8,10] This may be because control patients in studies usually receive a placebo injection and often have low-to-moderate pain and thus not much potential or statistical power for showing improvements for the whole group.

Two further aspects of clinical interpretation of studies are important: If the control group receives an effective multimodal analgesic regimen resulting in low pain scores, it makes it difficult to demonstrate additional benefits of a new method. However, if a new method is equally effective but not better, it does not mean that the new method is of no value. In contrast, this simply provides a choice of two different methods with differences in side-effect profile, risks, and practical and economic aspects.

The benefits of LIA may be in various aspects of nursing care, less need for patient compliance, lower total dose of NSAID, lower need for opioids, lower need for gabapentinoids and their potential side effects, and so on. Still, the number of patients in many studies is too low to address the questions of safety and less-frequent side effects. Studies must carefully examine serious, but rare, side effects, as well as how to use LIA as a tool to improve rehabilitation, shorten hospital stay, and achieve a better functional outcome.

What are the alternatives to LIA for knee or hip arthroplasty? In terms of "most effective" pain relief, it is hard to better epidural analgesia.[14] However, epidural analgesia does not provide any analgesic benefits beyond the period of active use. In addition, during the analgesic treatment, the technique is resource demanding and impairs mobilization and physiotherapy.[14] There are also risks of urinary retention, hypotension, and epidural hematoma.

The femoral nerve block for knee arthroplasty provides more specific treatment but does not cover all nerves involved in knee innervation and results in quadriceps muscle weakness. As with epidural block, this technique may be associated with very rare but serious nerve damage. In a recent study comparing LIA and femoral block for knee arthroplasty, Affas et al showed less pain with activity with LIA at 24 hours and an advantage in terms of ease of performance and lower costs.[15] Other nerve blocks may provide more focused single-knee pain relief without motor block, such as an adductor canal block of the saphenous and obturator nerves.[16]

Intrathecal opioid, as used in the study of Essving et al[17] may be beneficial as well. Morphine appears to be the best drug in terms of prolonged effect after a single shot. However, a dose higher than 0.1 mg may in some cases prolong the effect, but with a higher risk of side effects.[18]

The expert, evidence-based, procedure-specific recommendation for knee arthroplasty (see http://www.postoppain.org/image.aspx?imgid=654) is the combination of either spinal anesthesia without opioid or general anesthesia with femoral block as the first choice for anesthesia. Either should be supplemented with acetaminophen plus NSAID plus an opioid for breakthrough pain. The recommendation for avoiding intrathecal morphine was based on nausea in a study with a morphine dose of 0.25 mg[18] and may not be relevant with the 0.1-mg dose used by Essving et al.[17] Although used by some, there are no convincing data that steroids[19] or gabapentinoid[20] confer additional analgesic benefits.

POTENTIAL AND DOCUMENTED PROS AND CONS OF LOCAL INFILTRATION ANALGESIA AND ALTERNATIVES

Pros

A major benefit of LIA is the lack of motor impairment often seen with alternative techniques of nerve blocks, such as femoral or sciatic nerve blocks, or epidural analgesia. With LIA, there is also a minor risk of hematoma formation, which is a feared complication of deep blocks, such as lumbar block or epidural analgesia. Also, LIA is not contraindicated in cases of increased bleeding risk from other causes, such as therapeutic anticoagulation, platelet inhibition, or even use of traditional NSAIDs or low-dose acetylsalicylic acid.

Another argument for LIA is its simplicity; the infiltration is can be done by the surgeon intraoperatively or anesthesia providers using ultrasound. Postoperative top-ups of one or more catheters may be done easily by a nurse on the ward.

Cons

Some of the specific cons of LIA have to do with the potential dangers of supplying a potent drug close to delicate joint structures. The local anesthetic may be neurotoxic to small nerves when supplied repeatedly, although diluted ropivacaine has proven to be safe for 2–3 days of continuous infusion.[21] A more serious concern may be the chondrotoxic effect, especially with bupivacaine.[22] Because in most hip and knee replacement surgeries the cartilage is removed as a part of the procedure, this consideration may not be of practical concern.

Adding NSAIDs, COX-2 inhibitors, or glucocorticoids may slow or impair tissue healing or growth, although practical impact has not yet been shown in human clinical studies in patients having hip or knee replacement. A concern has been voiced regarding a potential for increased risk of infection with LIA. This concern arises mainly from the postoperative use of a catheter with the risk of contamination from multiple injections as well as bacteria migration along the indwelling catheter, rather than from the sterile infiltration done during surgery. It is also theorized that epinephrine may impede circulation, oxygenation, and macrophage function. To minimize the risk of infection, it is important to use strict aseptic procedures for all top-ups and refills of infusions.

LOCAL INFILTRATION ANALGESIA FOR HIP ARTHROPLASTY

Kehlet et al[6] reviewed six available studies in 2011, whereas McCarthy and Iohom[23] extended the review by including additional additional studies. Since then, the two studies of Rikalainen-Salimi[26] and Murphy et al[25] have also been published.

The early studies of Kerr and Kohan et al[1] and Otte et al[26] reported favorable analgesia and rapid mobilization with LIA; however, there were no control groups. In the Parvataneni et al[27] and Busch et al[28] studies, LIA was compared to intravenous opioid analgesia. Both studies reported lower pain scores with LIA; the Parvataneni et al study reduced hospital stay by 1 day with LIA.

Four studies have compared LIA versus placebo. The first placebo-controlled trial of Bianconi et al[29] from 2003 used only 40 mL of ropivacaine 5 mg/mL were used for infiltration, but infusion of 10 mg/h continued for 35 hours. The LIA group had lower pain scores at rest and during mobilization up to 72 hours postoperatively and a lower need for opioids. The study of Andersson et al[30] used infiltration, followed by bolus the next day, and demonstrated less pain and opioid consumption from 4 hours postoperatively up to 2 weeks, whereas joint function was improved at 1 week. Murphy et al[25] compared infiltration with 60 mL levobupivacaine 2.5 mg/mL versus placebo. The morphine consumption was reduced by 4% in the LIA group during the first 12 hours, but quality of analgesia and side effects were similar. In the placebo-controlled study of Lunn et al,[31] the placebo group received an optimal multimodal analgesic regimen of acetaminophen, celecoxib, and gabapentin with equal results as in the LIA group.

Andersen et al[32] compared LIA with top-up injections to epidural analgesia and found less opioid consumption, better mobilization, and shorter hospital stay with LIA. Specht et al[33] found that a top-up bolus at 10 and 22 hours was no better than placebo in patients who received perioperative LIA.

Rikalainen-Salmi et al[24] compared LIA with a top-up morning after surgery to morphine 0.1 mg given as a part of the spinal anesthetic. The LIA technique resulted in less opioid consumption on the day of surgery and better early mobilization, without any difference in pain scores and patient satisfaction; the LIA top-up, however, did not confer any benefit. Taken together, LIA appears to be better than placebo for hip replacement surgery, whereas in comparison with other optimized methods, the results are mixed.

Whether the adjuncts in the LIA solutions have a specific local effect compared with systemic administration has not been studied properly in hip surgery.

LOCAL INFILTRATION ANALGESIA FOR KNEE ARTHROPLASTY

A wide range of LIA techniques for total knee arthroplasty have been described in recent literature. In earlier studies, the volume of the mixture of local anesthetics and adjuvants used was lower than 50 mL.[29,34–36]

In the study of Kerr and Kohan, a mixture of ropivacaine (2 mg/mL, maximum 300 mg), ketorolac (30 mg), and epinephrine (10 μg/mL) was diluted with saline to a volume of 150–170 mL. The mixture was injected into the different knee structures during the knee arthroplasty in three stages: after preparation of bone surfaces (30–50 mL), after insertion of the prosthesis components (35–50 mL), and into subcutaneous tissue (25–50 mL). At the end of surgery, an 18-gauge epidural catheter was inserted with the catheter tip placed anterior to the posterior capsule, and 10–15 mL of the mixture were injected. This catheter was used for a further injection 15–20 hours postoperatively, when another 50 mL of the mixture were injected through the catheter.

To our knowledge, the first randomized studies regarding high-volume intra- or periarticular multimodal drug injection in total knee arthroplasty were published by Busch et al[37] and Vendittoli el al.[38] Several reviews regarding LIA following total knee arthroplasty have been published recently.[6,39,40] The most recent review by Gibbs et al[41] included a total of 29 randomized studies. However, this number in Gibbs and colleagues' review also included some local infiltration studies in which low volumes of LIA (<100 mL) were used.[34,36] Most of the individual studies lacked adequate blinding. However, when comparing different treatment modalities (eg, LIA vs. epidural analgesia), a proper trial would require invasive procedures in the placebo group, which may be unethical and therefore difficult to execute. Andersen and colleagues conducted a double-blind, placebo-controlled study in patients undergoing bilateral total knee arthroplasty and demonstrated the effectiveness of the LIA technique.[42]

However, based on the current information, effectiveness of a postoperative top-up dose is questionable and may carry a risk of infection.[7] Regardless, several authors reported that postoperative top-up injections are associated with less opioid consumption and lower pain scores.[8,14,43,44] To date, no study reported an increased incidence of postoperative infections with LIA catheters.

> **Clinical Pearls**
>
> Is LIA of sufficient clinical benefit to warrant routine clinical use?
>
> A. Hip replacement surgery
>
> LIA is not better than preoperative spinal anesthesia followed by multimodal analgesia with acetaminophen + NSAID/COX-2 inhibitor + either glucocorticoid or gabapentinoid.
>
> In patients in whom multimodal therapy is contraindicated LIA may be a valuable analgesic method, reducing the need for rescue opioids.
>
> B. Knee replacement surgery
>
> Yes, even with an optimal preoperative spinal (or other nerve blocks) and three-component systemic multimodal analgesia, preoperative LIA still provides additional analgesia for 24–48 hours.

Compared to no injections or saline injections, all studies showed LIA had a beneficial analgesic effect.[8,37,38,43,45] The two studies comparing LIA to femoral nerve block, however, showed conflicting results. While Toftdahl and colleagues[44] concluded that LIA was superior to a continuous femoral nerve block regarding opioid consumption and pain scores during the first postoperative day, Carli et al[46] suggested that the femoral nerve is better. Of note, patients in the Carli et al study received an infiltration with ropivacaine, ketorolac, and epinephrine into the posterior capsule of the knee joint during surgery (in addition to LIA or femoral nerve block).

Both studies comparing LIA with epidural analgesia (Table 19–1) demonstrated that LIA can reduce both postoperative opioid consumption and postoperative pain scores.[14,47] Moreover, LIA was associated with faster mobilization and earlier readiness for hospital discharge.[14]

The LIA recipe (ie, volume, content, as well as the use of adjuvants) is not well defined. Two recently published studies have shown that ketorolac is an important factor in the LIA mixture.[14,48] Moreover, Spreng and colleagues showed that local administration of ketorolac and morphine may also have a local effect.[14]

Application of a compression bandage for 24 hours postoperatively[49] and infiltration of superficial layers in the knee joint with local anesthetics are also important for the effectiveness of the LIA.[42]

Several recent studies have been published regarding continuous infusion of local anesthetics with or without adjuvants.[50,51] Gomez-Cardero and Rodriguez-Merchán[50] compared continuous LIA for 60 hours (ropivacaine) with placebo and found reduced opioid consumption and pain scores for the first 3 days after surgery. Ong and colleagues[51] examined the use of continuous intra-articular infusion or bolus dose and demonstrated reduced opioid consumption and lower pain scores compared to intravenous pain treatment only.

TABLE 19–1. Comparison of local infiltration analgesia with other techniques.

Author (Reference Number)	Patients (*n*)	Groups Intraoperative	Treatment Intraoperative	Groups Postoperative	Treatment Postoperative	Findings of LIA
1. Studies Comparing LIA With No Injections or Saline Injections						
Busch et al (2006)[37]	64	LIA (100 mL) No injection	400 mg ropivacaine 30 mg ketorolac 5 mg epimorphine 0.6 mg epinephrine	All patients	No injections into the knee Morphine PCA	Opioid consumption ↓ (0–24 h) Pain ↓ (0–4 h)
Vendittoli et al (2006)[38]	42	LIA (160 mL) No injection	275 mg ropivacaine 30 mg ketorolac 0.5 mg epinephrine	LIA (15 mL) No injection	150 mg ropivacaine after 16–24 h	Opioid consumption ↓ (0–48 h) Pain ↓ (0–48 h)
Andersen et al (2008)[8]	12 (24 knees)	LIA (170 mL) Control	340 mg ropivacaine 1.7 mg epinephrine Saline (170 mL)	LIA Control	8 h: 40 mg ropivacaine + 0.2 mg epinephrine (20 mL) 24 h: 100 mg ropivacaine + 0.5 mg epinephrine (50 mL) 8 h + 24 h: saline (20 + 50 mL)	Pain ↓ (0–24 h)
Kazak et al (2010)[45]	60	LIA (150 mL) LIA (150 mL) Control	200 mg bupivacaine 0.5 mg epinephrine 200 mg levobupivacaine 0.5 mg epinephrine Saline (150 mL)	LIA (25 mL) LIA (25 mL) Control	10 h + 22 h: 120 mg bupivacaine 10 h + 22 h: 120 mg levobupivacaine + 0.5 mg epinephrine 10 h + 22 h: saline (25 mL + 25 mL)	Opioid consumption ↓ (0–48 h) Pain ↓ (0–48 h)
Essving et al (2010)[43]	48	LIA (166 mL) No injection	400 mg ropivacaine 30 mg ketorolac 0.5 mg epinephrine	LIA (22 mL) Control	21 h: 200 mg ropivacaine + 30 mg ketorolac + 0.1 mg epinephrine 21 h: saline (22 mL)	Opioid consumption ↓ (0–48 h) Pain ↓ (0–27 h)
2. Studies Comparing LIA With Femoral Nerve Block						
Carli et al (2010)[46]	40	LIA (102 mL) → peri- and intra-articularly FNB (8mL) *All patients:* → Infiltration postoperative capsule (51 mL)	200 mg ropivacaine 30 mg ketorolac 0.5 mg epinephrine + 8 mL saline in femoral catheter 16 mg ropivacaine + 100 mL saline into periarticular catheter 100 mg ropivacaine 15 mg ketorolac 0.25 mg epinephrine	LIA (50) mL FNB	24 h: 250 mg ropivacaine + 30 mg ketorolac + 0.25 mg epinephrine + 8 mL/h saline through femoral catheter for 48 h Ropivacaine 2 mg/mL 8mL/h for 48 h + 50 mL saline into periarticular catheter 24 h after surgery	Opioid consumption ↑ (0–48 h) for LIA group (peri- and intra-articular infiltrations)

Toftdahl et al (2007)[44]	77	LIA (152 mL) FNB (20 mL)	300 mg ropivacaine 30 mg ketorolac 0.5 mg epinephrine 200 mg ropivacaine 4 mg morphine + 50 mg bupivacaine through drain (intra-articular)	LIA (22 mL) FNB	12 h + 24 h: 200 mg ropivacaine + 30 mg ketorolac + 0.5 mg epinephrine Ropivacaine 2 mg/mL at 10 mL/h for 48 h	Opioid consumption ↓ (0–24 h) Pain ↓ (0–24 h)
3. Studies Comparing LIA With Epidural Analgesia						
Andersen et al (2010)[47]	40	LIA (152 mL) EDA	300 mg ropivacaine 30 mg ketorolac 0.5 mg epinephrine Test dose 3 mL: lidocaine + epinephrine	LIA EDA	Continuous infusion at 4 mL/h for 48 h (380 mg ropivacaine, 60 mg ketorolac) Continuous infusion at 4 mL/h for 48 h (ropivacaine 2 mg/mL) Ketorolac 15 mg IV × 6	Opioid consumption ↓ (0–48 h) Pain ↓ (0–72 h)
Spreng et al (2010)[14]	99	LIA (150 mL) LIA IV (150mL) EDA	150 mg ropivacaine 30 mg ketorolac 5 mg morphine 0.5 mg epinephrine 6 mL saline IV 150 mg ropivacaine 0.5 mg epinephrine 6 mL saline (LIA) 30 mg ketorolac IV 5 mg morphine IV Test dose 3 mL: lidocaine + epinephrine	LIA (20 mL) LIA IV (20 mL) EDA	22–24 h: 142.5 mg ropivacaine + 30 mg ketorolac 1 mL saline IV 22–24 h: 142.5 mg ropivacaine + 1 mL saline (LIA) 1 mL ketorolac IV 6–10 mL/h for 48h : fentanyl 2 μg/mL + bupivacaine 1 mg/mL + epinephrine 1 μg/mL	Opioid consumption ↓ (0–72 h) Pain ↓ (24–72 h)
4. Studies Comparing Different LIA Techniques						
Andersen et al (2008)[49]	48	LIA ± compression bandage	340 mg ropivacaine 1 mg epinephrine (170 mL)	LIA ± compression bandage	6 h + 12 h: 40 mg ropivacaine + 0.2 mg epinephrine (20 mL) 24 h: 100 mg epinephrine (50 mL)	Pain ↓ (0–8h) with compression bandage
Andersen et al (2010;p984)	43	*All patients:* LIA (150 mL)	300 mg ropivacaine 1 mg epinephrine	LIA (20 mL) LIA (10 mL)	6 h + 24 h: ropivacaine 5 mg/mL 6 h + 24 h: ropivacaine 10 mg/mL	No differences between the groups
Andersen et al (2010;p543)[42]	16 (32 knees)	LIA (150 mL) LIA (100 mL)	200 mg ropivacaine 1 mg epinephrine 100 mg ropivacaine to superficial layers 200 mg ropivacaine 1 mg epinephrine 50 mL saline to superficial layers	LIA (20 mL) Control (20 mL)	24 h: 100 mg ropivacaine subcutaneously 24 h: saline subcutaneously	Pain ↓ (0–6 h) with infiltration of superficial layers, but no difference after 24 h

Author (Reference Number)	Patients (*n*)	Groups Intraoperative	Treatment Intraoperative	Groups Postoperative	Treatment Postoperative	Findings of LIA
Andersen et al (2010;p904)	60	*All patients:* LIA (150 mL)	300 mg ropivacaine 1 mg epinephrine	LIA (20 mL) intracapsular LIA (20 mL) intra-articular	6 h + 24 h: 100 mg ropivacaine	No differences between the groups
Andersen et al (2008;p800)[49]	32	*All patients:* LIA (170 mL)	340 mg ropivacaine 1.2 mg epinephrine	LIA LIA	6 h + 12 h + 24 h: 40 mg ropivacaine + 0.2 mg epinephrine (20 mL). Additional 60 mg ropivacaine + 0.3 mg epinephrine (30 mL) during catheter retraction 6 h + 12 h + 24 h: 40 mg ropivacaine + 0.2 mg epinephrine (20 mL). Additional 30 mL saline during catheter retraction	No differences between the groups
Spreng et al (2010)[14]	99	LIA (150 mL) LIA IV (150 mL) EDA	150 mg ropivacaine 30 mg ketorolac 5 mg morphine 0.5 mg epinephrine 6 mL saline IV 150 mg ropivacaine 0.5 mg epinephrine 6 mL saline (LIA) 30 mg ketorolac IV 5 mg morphine IV Test dose 3 mL: lidocaine + epinephrine	LIA (20 mL) LIA IV (20 mL) EDA	22–24 h: 142.5 mg ropivacaine + 30 mg ketorolac 1 mL saline IV 22–24 h: 142.5 mg ropivacaine + 1 mL saline (LIA) 1 mL ketorolac IV 6–10 mL/h for 48 h (fentanyl 2 µg/mL + bupivacaine 1 mg/mL + epinephrine 1 µg/mL)	Opioid consumption ↓ (0–72 h) when ketorolac and morphine were infiltrated into the knee Pain ↓ (0–72 h) when ketorolac and morphine were infiltrated into the knee
Andersen et al (2013)[48]	60	LIA (151 mL) LIA (151 mL)	300 mg ropivacaine 30 mg ketorolac 300 mg ropivacaine 1 mL saline	LIA (10 mL) LIA (10 mL)	Every 6 h for 48 h: 100 mg ropivacaine + 15 mg ketorolac Every 6 h for 48 h: 100 mg ropivacaine + 1 mL	Opioid consumption ↓ (0–48 h) in the ketorolac group Pain ↓ (0–48 h) in the ketorolac group

EDA = epidural analgesia; IV = intravenous; LIA = local infiltration analgesia; FNB = femoral nerve block; PCA = patient-controlled analgesia.

LOCAL INFILTRATION ANALGESIA RECIPES

LIA in Total Knee Arthroplasty

The LIA Recipe

The solution, which is infiltrated into the knee, should be prepared under aseptic conditions (Figure 19–1). The total volume of the solution is 150 mL and contains the following:

- 200 mg ropivacaine (2 mg/mL) (amount of infiltrated ropivacaine in published studies varied: 150 mg,[14] 200 mg,[52] 300 mg,[1] 400 mg[37])
- 30 mg ketorolac (30 mg/mL)
- 0.5 mg epinephrine (1 mg/mL)
- Isotonic saline (dilution to 150 mL total)

FIGURE 19–1. In the operating room, a sterile bag with ropivacaine from the pharmacy receives the addition of 30 mg (1 mL) ketorolac and 0.5 mg (0.5 mL) epinephrine.

Clinical Pearls

Although there are numerous recipes, the following formula is efficacious for both knee and hip replacement surgery:

- Total volume 150 mL (add normal saline according to the number of milliliters used by the other drugs)
- 200 mg ropivacaine (use any practical preparation: 2, 5, 7.7 mg/mL, dilute)
- 30 mg ketorolac

The addition of epinephrine (eg, 0.5 mg in 150 mL) may have a beneficial effect on hemostasis.

The solution, which is infiltrated into the knee catheter postoperatively (top-up dose), should also be prepared under aseptic conditions. The total volume of the solution should be 15–20 mL for each injection and contains the following:

- 150 mg ropivacaine (5–7.5 mg/mL)
  - 30 mg ketorolac (30 mg/mL)
  - Isotonic saline (dilution to 15–20 mL total)

Injection Technique

- After surgical preparation of the knee joint, 40 mL of the LIA solution are infiltrated into posterior capsule structures by the orthopedic surgeon. A "moving needle technique" is preferable (Figure 19–2, area marked I).
- After the joint replacement, 50–60 mL of the solution are infiltrated circularly around the prosthesis (Figure 19–2, area marked IIa and IIb).
- An 18-gauge epidural catheter with a bacterial filter can be placed from the lateral side into the knee joint (optional) (Figure 19–2, sinusoidal line, marked III; Figure 19–3).
- After closure of the capsule, another 50 mL of the solution are infiltrated into the fascia and subcutis (Figure 19–4).
- If a catheter is used, 10 mL of the solution are injected through the knee catheter at the end of surgery to verify fluid flow (Figure 19–5).
- Aseptic top-up injections into the knee catheter (15–20 mL, according to the actual knee size) after 8, 16, and 24 hours (Figure 19–6).
- The knee catheter is removed during the last injection with subsequent spread into the fascia and subcutis.

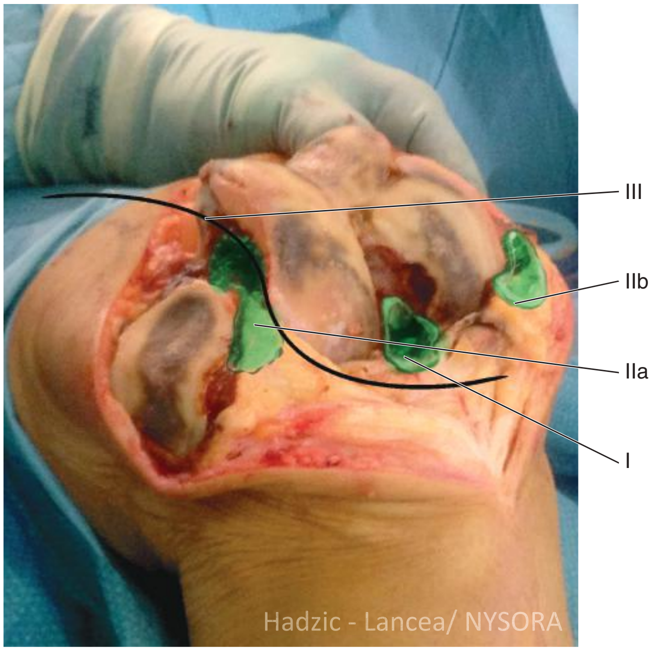

FIGURE 19–2. Four steps LIA injection technique in patients having knee replacement.

FIGURE 19–3. The catheter is placed into the knee laterally.

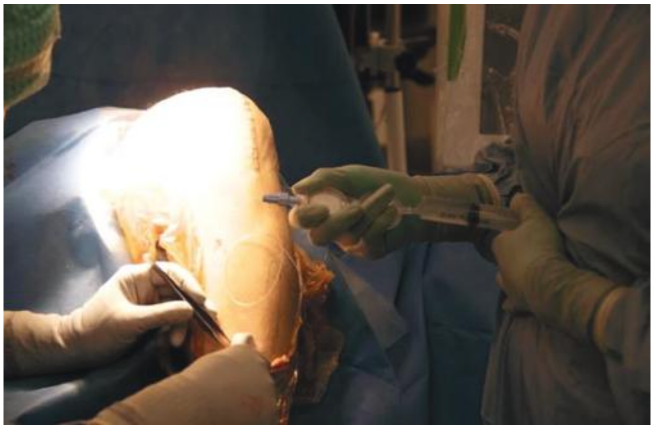

FIGURE 19–5. The last injection through the catheter: 10 mL for analgesia and for testing the catheter.

LIA in Total Hip Arthroplasty

The LIA Cocktail

The LIA cocktail solution, which is infiltrated into the hip, should be prepared under aseptic conditions (Figure 19–1). The total volume of the solution is 100 mL and contains the following:

- 200 mg ropivacaine (2 mg/mL)
- 30 mg ketorolac (30 mg/mL)
- 0.5 mg epinephrine (1 mg/mL)
- Isotonic saline (dilution to 100 mL total)

Injection Technique

Depending on the size of the surgical incision and choice of surgical approach, 100 mL of the LIA solution are injected in two stages:

- After surgical preperation of the acetabulum, 50 mL of the solution are infiltrated into capsule structures (if remaining), into adductor muscles and into the gluteus medius muscle.

FIGURE 19–4. The fascia and subcutaneous tissue are infiltrated with 50 ml. of LIA solution.

Clinical Pearls

Should we include catheters for peri- or intra-articular infusion/top-ups when using LIA?

- No, there is strong evidence for no benefit of catheter after hip prosthesis.
- After knee prosthesis, the evidence is more conflicting, mostly indicating no extra effect when compared with optimal multimodal systemic analgesia, but some effect if not all components of the multimodal regimes are used.
- A recent report of an increased rate of infections[55] with catheters, added to anecdotal reports of similar results, added to the evidence in disfavor of catheter use.

- After insertion of the femoral component, another 50 mL are infiltrated into the external rotators (quadratus femoris muscle, obturator muscle, and the tendon of the gluteus maximus muscle) (Figure 19–6).

CHAPTER 20

Regional and Topical Anesthesia for Awake Endotracheal Intubation

Imran Ahmad

INTRODUCTION

Awake endotracheal intubation can be achieved using a variety of equipment, such as video laryngoscopes, optical stylets, and fiber-optic scopes. Appropriate anesthesia of the airway and sedation can enable any of these techniques to be used successfully.

The commonest method used to perform an awake endotracheal intubation is with a flexible fiberscope, and an awake fiber-optic intubation is regarded as the gold standard for the endotracheal intubation of patients with an anticipated difficult airway. This procedure requires skills and knowledge that should be familiar to all anesthesiologists.

Recently, there have been many advances in regional anesthesia, allowing for more complicated and innovative procedures to be done under regional block techniques; however, not all of these cases can be done solely under regional anesthesia. Often, a combination of regional and general anesthesia is required; therefore, all anesthesiologists must be familiar with awake intubation techniques, especially if the patient has an anticipated difficult airway. Anesthetizing patients with an anticipated difficult airway is often a source of anxiety and trepidation, but appropriate airway topicalization and sedation techniques can create the appropriate conditions for a safe and stress-free procedure for both the patient and the anesthesiologist.

It is difficult to give precise figures on the incidence of difficult airways due to a variety of reasons, including population differences, operator skill variation, operator reporting, and an inconsistency in the definition of a difficult airway. In the general population, the approximate figures for the incidence of Cormack and Lehane laryngoscopy grades 3 and 4 is 10%, difficult intubation is 1%, and difficult bag mask ventilation is 0.08%–5%.[1–4]

Endotracheal intubation is usually performed under general anesthesia, but if a difficult airway is anticipated, then this should ideally be done under regional anesthesia (with or without sedation) as this allows the patient to breathe spontaneously, maintain airway patency, and cooperate with the operator. If any untoward difficulties are experienced, then the procedure can be abandoned with minimum risk to the patient. There are obvious exceptions to performing an awake intubation, such as patient refusal, young children, and uncooperative patients (due to confusion or learning disabilities).

To successfully perform an awake endotracheal intubation, one should be familiar with the following:

- Sensory innervation of the upper airway
- Agents available for topicalization
- Application techniques available to topicalize the airway
- Regional anesthesia techniques, landmark or ultrasound guided
- Safe sedation techniques

SENSORY INNERVATION OF THE AIRWAY

The upper airway is divided into the nasal and oral cavities, the pharynx, and the larynx. The sensory innervation to the upper airway is supplied by the trigeminal, glossopharyngeal, and vagus nerves (Figure 20–1).

Nose

The nose is entirely innervated by branches of the trigeminal nerve. Septum and anterior parts of the nasal cavity are affected by the anterior ethmoidal nerve (a branch of the ophthalmic nerve). The rest of the nasal cavity is innervated by the greater and lesser palatine nerves (branches of the maxillary nerve).

PART 3

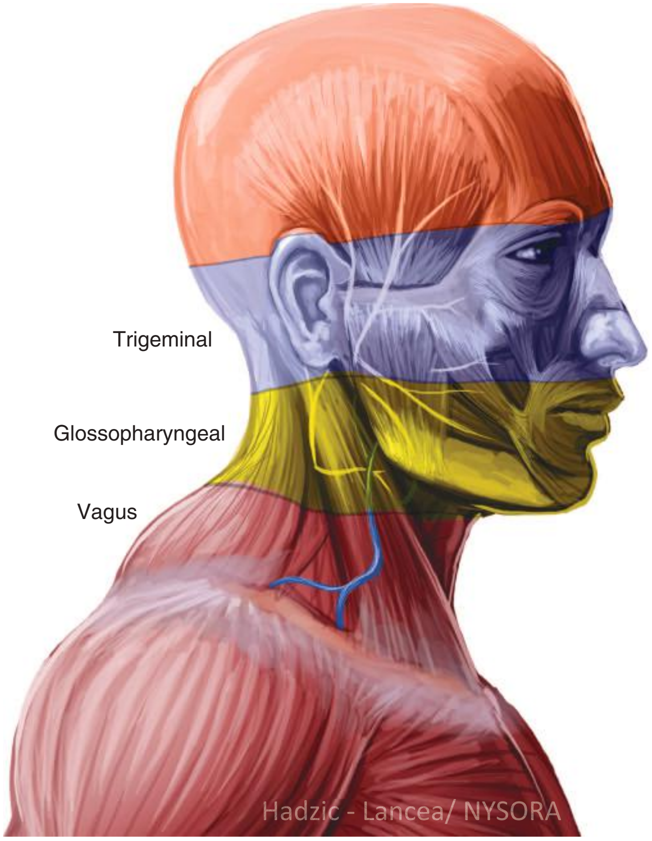

FIGURE 20–1. Innervation of the upper airway.

The palatine nerves are relayed through the pterygopalatine ganglion, found in the pterygopalatine fossa, which is situated close to the sphenopalatine fossa, located just posterior to the middle turbinate.

Pharynx

The pharynx is largely innervated by the glossopharyngeal nerve. Innervation of the whole pharynx, posterior third of tongue, the fauces, tonsils, and epiglottis is from the glossopharyngeal nerve.

Oropharynx

The oropharynx is innervated by branches of the vagus, trigeminal, and glossopharyngeal nerves. The posterior third of the tongue, vallecula, and anterior surface of the epiglottis are innervated by the tonsillar nerve (a branch of the glossopharyngeal nerve). The posterior and lateral wall of the pharynx are innervated by the pharyngeal nerve (a branch of the vagus nerve). The tonsillar nerve affects the tonsils. The anterior two-thirds of the tongue are innervated by the lingual nerve (branch of the mandibular division of the trigeminal nerve).

Larynx

The larynx is innervated by the vagus nerve (Figure 20–2). Above the vocal cords (base of tongue, posterior epiglottis, aryepiglottic folds, and arytenoids), the internal branch of the superior laryngeal nerve (a branch of the vagus nerve) supplies innervation. For the vocal cords and below the vocal cords, the recurrent laryngeal nerve (a branch of the vagus nerve) is the supplier.

Clinical Pearls

- The greater and lesser palatine nerves provide sensation to the nasal turbinates and posterior two-thirds of the nasal septum.
- The anterior ethmoid nerve innervates the remainder of the nasal passage.
- The glossopharyngeal nerve provides sensory innervation to the posterior third of the tongue, the vallecula, the anterior surface of the epiglottis (lingual branch), the walls of the pharynx (pharyngeal branch), and the tonsils (tonsillar branch).
- The superior laryngeal nerve innervates the base of the tongue, posterior surface of the epiglottis, aryepiglottic fold, and the arytenoids.
- The recurrent laryngeal nerve provides sensory innervation to the trachea and vocal folds.

TOPICAL ANESTHESIA

Cocaine

Cocaine is the only local anesthetic with vasoconstrictor properties; therefore, it is particularly useful for topical anesthesia of the nasopharynx, which is highly vascular. Cocaine is available as a 5% or 10% solution and in paste form; the maximum recommended dose is 1.5 mg/kg. It should be used with caution in patients with coronary artery disease, hypertension, and pseudocholinesterase deficiency.

The mixture of 2 mL of 10% cocaine, 1 mL 1:1000 adrenaline, 2 mL sodium bicarbonate, and 5 mL sodium chloride makes 10 mL of Moffett's solution.[5] This is commonly used in rhinological procedures to provide local anesthesia, vasoconstriction, and decongestion. It is also used to topicalize the nasal mucosa to provide the optimal conditions for nasal intubations.

Lidocaine

Lidocaine is the most commonly used local anesthetic for airway topicalization. The 4% solution and 10% spray are most often used (Figure 20–3). Systemic absorption from topical application to the upper airways is lower than expected, so in practice higher doses can be used than the recommended 2 mg/kg.[3,6]

Vasoconstrictors

Vasoconstrictors should be used when the nasal mucosa is being anesthetized; this is because the mucosa is highly vascular, and bleeding can readily occur on instrumentation, which can obscure the view seen on the fiberscope.

As mentioned, cocaine has inherent vasoconstrictor properties, so it is a suitable agent to use for the nasal mucosa. Vasoconstrictor agents such as xylometazoline and phenylephrine are prepared with lidocaine to produce local anesthesia and vasoconstriction. These mixtures are also suitable agents for preparation of the nasal mucosa.[6]

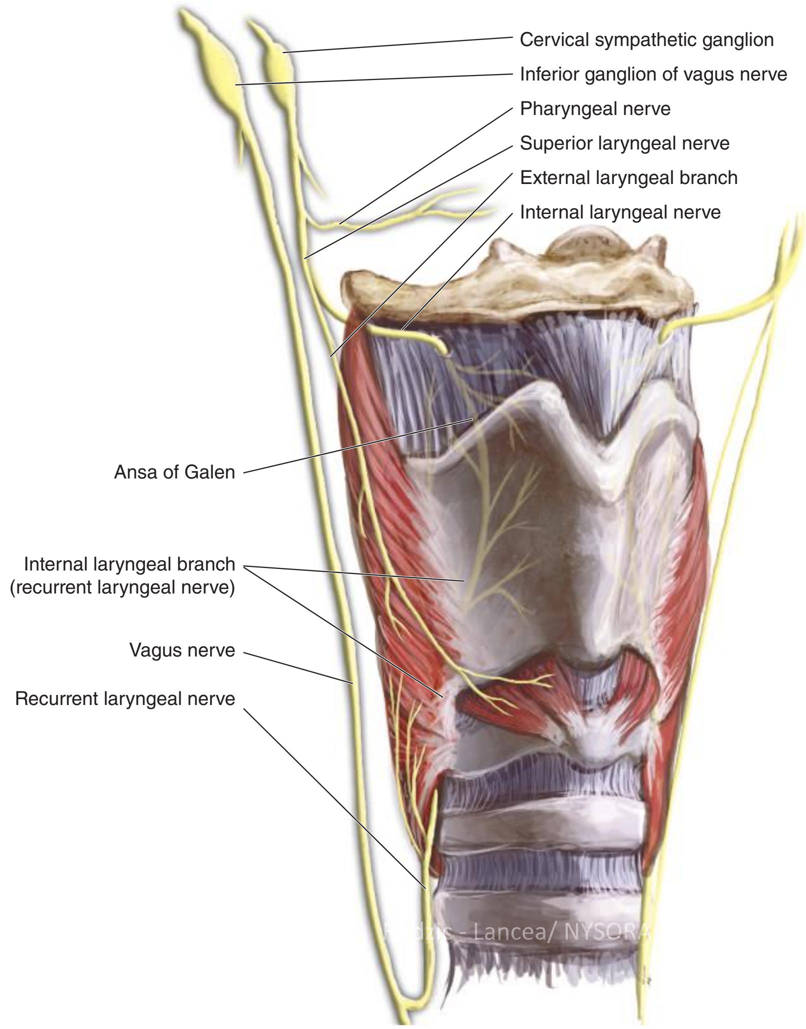

FIGURE 20–2. Innervation of the larynx.

FIGURE 20–3. Lidocaine, 10% and 4%.

Clinical Pearls

- The use of vasoconstrictors reduces the bleeding "shrinks" the nasal mucosa resulting in better surgical exposure.
- Shrinking of the nasal mucosa increases the size of the nasal airway passages, creating more space for the fiberscope and endotracheal tube.
- Appropriate time should be allowed for the vasoconstrictor to take effect before commencing fiberoscopy

APPLICATION TECHNIQUES

There are various techniques available to topicalize the upper airway in preparation for awake intubation.[7,8] The nasopharynx and oropharynx can be sprayed directly from the container of local anesthetic preparations, sprayed using the McKenzie technique, or sprayed via a mucosal atomization device (MAD).

The McKenzie technique uses a 20-gauge cannula attached to oxygen bubble tubing via a three-way tap. The other end of

FIGURE 20–4. Setup for McKenzie technique.

bubble tubing is then attached to an oxygen source, which is turned on to deliver a flow of 2–4 L/min. As the local anesthetic is slowly administered via a 5-mL syringe attached to the top port of the cannula, a jetlike spray effect is seen, which greatly increases the surface area of the local anesthetic and allows directed topicalization of the nasal and oral mucosa (Figure 20–4).

Clinical Pearls

- Maintain a tight seal between the tubing and the cannula to prevent leakage of local anesthetic from these areas.
- Slow, continuous pressure on the 5-mL syringe containing local anesthesia will result in a "hissing" sound as a fine mist is sprayed out of the cannula.

Commercially available mucosal atomizers allow a similar mistlike effect as seen with the McKenzie technique by just attaching them to the end of a syringe (Figure 20–5). These devices are available for nasal and oral applications.[6]

Adding approximately 5 mL of 4% lidocaine to a nebulizer, then delivering it with oxygen for up to 30 minutes is a safe and noninvasive way to topicalize the airway all the way down to the trachea (Figure 20–6). It is well tolerated and is a useful technique to topicalize the whole airway. It also allows the topicalization of patients with limited mouth opening, where atomizers cannot be passed into the mouth to topicalize the oropharynx.[6]

The vocal cords can also be sprayed directly with local anesthetic using the spray-as-you-go (SAYGO) technique.[9] Here, the distal end of a 16-gauge epidural catheter is cut 3 cm from the end and then fed through the working channel of a fiberscope. The Luer lock connector is connected to the proximal end of the catheter and then attached to a 5-mL syringe prepared with 4% lidocaine. The distal end should protrude out of the fiberscope, so that the tip is just visible. The local anesthetic is then dripped onto the vocal cords prior to the fiberscope being introduced into the trachea. This reduces patient discomfort and coughing when the fiberscope and endotracheal tube are introduced into the trachea.

FIGURE 20–5. Mucosal atomization device (MAD).

Usually, a combination of techniques (Table 20–1) is used to deliver local anesthetic to the airway mucosa in preparation for awake intubation. For example, to prepare the nasopharynx, preprepared local anesthetic solution can be sprayed into the nasal mucosa using the nozzle from the container. The oropharynx could be prepared using local anesthetic sprayed using the McKenzie technique, and the vocal cords could be sprayed using the SAYGO method. Alternatively, the MADs can be used to spray the nasal and oral mucosa. Whichever technique or combination of techniques is used, the aim should be to have an airway adequately anesthetized in preparation for instrumentation.

Clinical Pearls

- Sitting the patient in an upright position will help with oxygenation and topicalization.
- Always administer supplementary oxygen.
- Start and establish the sedation before commencing the topicalization process, which can be uncomfortable.
- Asking the patient to "sniff" while spraying the nasopharynx can aid in the distribution of local anesthetic.

REGIONAL ANESTHESIA TECHNIQUES

Nerve blocks can provide anesthesia for awake intubation but can be technically more challenging to perform than topical anesthesia of the airway. They do carry a higher risk of complications, such as intravascular injection and nerve damage, and more than one nerve needs to be blocked. These are the glossopharyngeal, superior laryngeal, and recurrent laryngeal nerves, as they supply the innervation to the oropharynx and larynx. Therefore, the nerve blocks required to anesthetize the airway are the glossopharyngeal, superior laryngeal, and translaryngeal blocks.

The nasal passages are supplied by the palatine nerves and anterior ethmoidal nerve. These nerves need to be blocked to allow for awake nasal fiber-optic intubation. These nerves are usually blocked by the topical application of local anesthetic to the nasal passages, usually by inhalation, spray topicalization, or the application of cotton applicators soaked in anesthetic.

Landmark Technique

Glossopharyngeal Nerve Block

The glossopharyngeal nerve provides sensation to the posterior third of the tongue and the vallecula and provides the sensory limb for the gag reflex; therefore, this block is particularly useful in abolishing this reflex. There are two approaches described for this block: intraoral and peristyloid.

For the intraoral approach, the patient requires sufficient mouth opening to allow adequate visualization and access to the base of the posterior tonsillar pillars (palatopharyngeal arch) (Figure 20–7). After adequate topical anesthesia (lidocaine spray) has been applied, the tongue is retracted medially with a laryngoscope blade or a tongue depressor, allowing access to the posterior tonsillar pillar. Then, using a 22- or 25-gauge needle, 2–5 mL of 2% lidocaine are injected submucosally, after negative aspiration. The point of injection is at the caudal aspect of the posterior tonsillar pillar (approximately 0.5 cm lateral to the lateral edge of the tongue where it joins the floor of the mouth; Figure 20–8). This is then repeated on the other side.

Alternatively, a gauze soaked in local anesthetic can be firmly applied to this region for a few minutes. This method avoids the risk of intravascular injection but is not as successful as when the local anesthetic is injected.

The peristyloid approach aims to infiltrate local anesthetic just posterior to the styloid process where the glossopharyngeal nerve lies. In close proximity to this is the internal carotid artery, so care must be taken when using this approach.

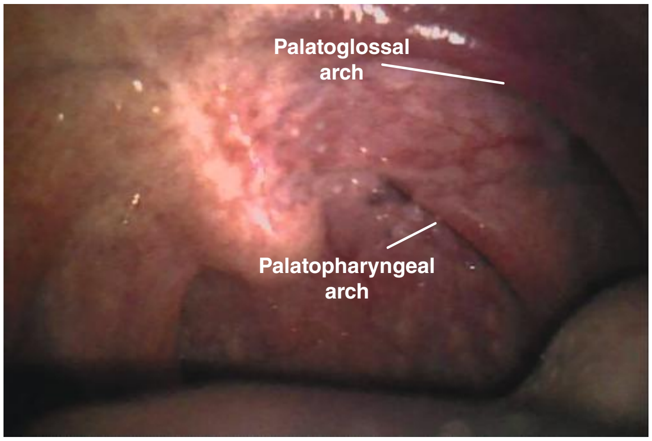

FIGURE 20–7. Palatopharyngeal arch.

The patient should be placed in a supine position with the head placed neutrally. The styloid process is located at the midpoint of a line drawn from the angle of the jaw to the tip of the mastoid process. It can be palpated using deep pressure, but this may be uncomfortable for the patient; a needle is inserted perpendicular to the skin, aiming to hit the styloid process. Once contact has been made (usually 1–2 cm deep), the needle should be reangled posteriorly and walked off the styloid process until contact is lost, then 5–7 mL of 2% lidocaine can be injected after negative aspiration. This is then repeated on the other side.

Clinical Pearls

- The glossopharyngeal nerve is most easily blocked where it crosses the palatoglossal arch.
- It can be blocked by spraying local anesthetic, by applying gauze or pledgets soaked in local anesthetic directly over the nerve, or by direct injection of local anesthetic around the nerve.
- This helps to abolish the gag reflex, but this block on its own will not provide adequate conditions for an awake fiber-optic intubation.

Superior Laryngeal Nerve Block

The superior laryngeal nerve provides sensation to the laryngeal structures above the vocal cords and lies inferior to the greater cornu of the hyoid bone; here, it splits into the internal and external branches. The internal branch then penetrates the thyrohyoid membrane about 2–4 mm inferior to the greater cornu, continuing submucosally in the piriform recess (Figure 20–9 and Figure 20–10). The external branch does not penetrate the thyrohyoid membrane; it descends on the larynx deep to the sternothyroid muscle. The superior laryngeal nerve can be blocked using the external or internal approach.

To perform the block using the external approach, the patient is placed in the supine position and will need a degree of neck extension to facilitate identification of the hyoid bone. Once identified, the hyoid bone is gently displaced to the side where the block is to be performed and a 25-gauge needle is

FIGURE 20–8. Glossopharyngeal nerve block.

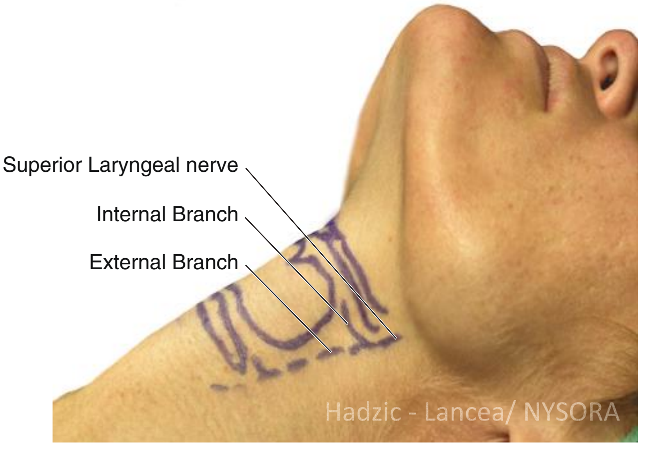

FIGURE 20–10. Surface anatomy of superior laryngeal nerve and branches.

inserted from the lateral side of the neck, aiming toward the greater cornu.[10] Once contact has been made, the needle is walked off the bone inferiorly, and injecting 2 mL of 2% lidocaine here will block both the internal and the external branches of the superior laryngeal nerve (Figure 20–11). If the needle is advanced a few millimeters, it will pierce the thyrohyoid membrane, and a "give" is felt. Injecting local anesthetic here will result in only the internal branch of the superior laryngeal nerve being blocked. As with all blocks, careful aspiration must be performed prior to injection, especially as the carotid artery is in close proximity.

If it is difficult to identify the hyoid bone, the superior cornu of the thyroid cartilage can be identified instead. This is located by identifying the thyroid notch, tracing the upper edge posteriorly until the superior cornu can be palpated as a small round structure. This lies just inferior to the greater cornu of the hyoid bone. The needle can be inserted, aiming for the superior cornu of the thyroid cartilage, then walked cephalad, then local anesthetic is injected once the needle loses contact with the superior cornu. If the thyrohyoid membrane is pierced, then inject 2 mL of local anesthetic here and a further 2 mL as the needle is withdrawn; this will increase the chances of both the internal and external branches of the superior laryngeal nerve being blocked.[11]

The internal approach uses gauze or pledgets soaked in local anesthetic and placed in the piriform fossae using Krause's forceps. These need to be kept in place for 5-10 minutes to allow sufficient time for the local anesthetic to take effect.[12]

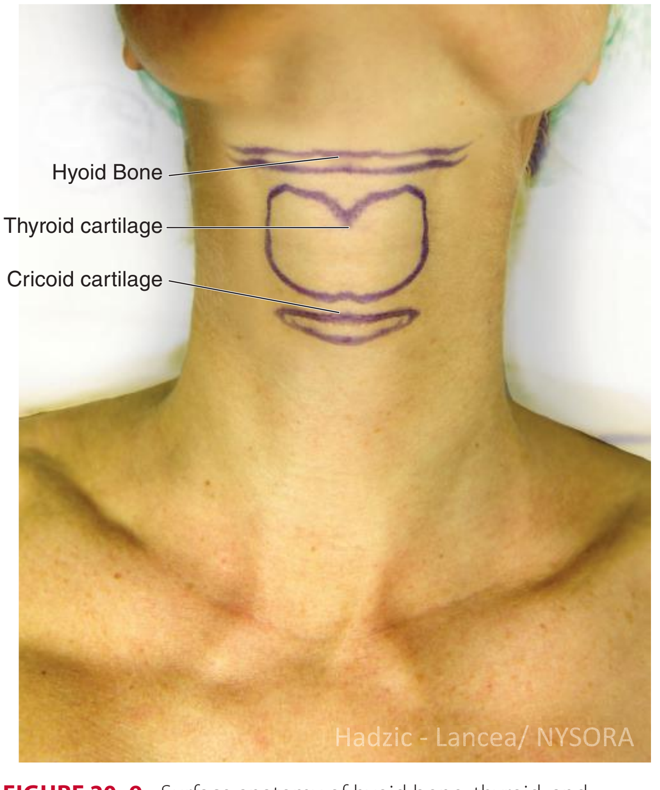

FIGURE 20–9. Surface anatomy of hyoid bone, thyroid, and cricoid cartilages.

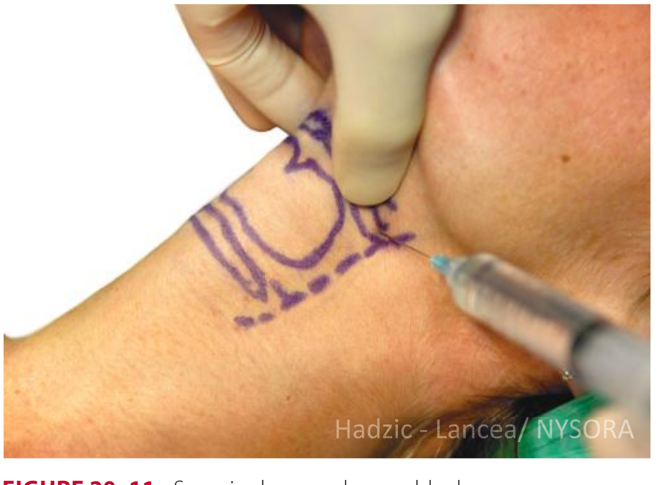

FIGURE 20–11. Superior laryngeal nerve block.

Recurrent Laryngeal Nerve Block

The sensory innervation of the vocal cords and trachea is supplied by the recurrent laryngeal nerves. These ascend along the tracheoesophageal groove and also provide the motor supply to all the intrinsic muscles of the larynx except the cricothyroid muscle. Direct recurrent laryngeal nerve blocks are not performed as they can result in bilateral vocal cord paralysis and airway obstruction, as both the motor and the sensory fibers run together. Therefore, this nerve is blocked using the translaryngeal block.[13]

To perform this, the patient should be supine, with the neck extended be identified in the midline, then the palpating finger should be moved in a caudad direction until the cricoid cartilage is palpated. The cricothyroid membrane lies between these two structures, immediately above the cricoid cartilage. The thumb and third digit of one hand should stabilize the trachea at the level of the thyroid cartilage, then a 22 or 20 gauge needle should be inserted perpendicular to the skin with the aim to penetrate the cricothyroid membrane (above the cricoid cartilage) (Figure 20–12). This should be done with continuous aspiration of the syringe, as the appearance of bubbles will indicate that the needle tip is now in the trachea. At this point, immediately stop advancing the needle; otherwise, the posterior laryngeal wall can be punctured. Rapid injection (and then removal of the needle) of 5 mL of 4% lidocaine will result in coughing, which will help to disperse the local anesthetic and blockade of the recurrent laryngeal nerve.

Clinical Pearls

- Appropriate position of the patient will aid in the correct identification of the cricoid and thyroid cartilages and the cricothyroid membrane.
- The neck should be extended, which makes these structures more prominent.
- Placing a liter bag of infusion fluids between the shoulder blades can help achieve this position.

Ultrasound-Guided Techniques

Ultrasound can be used to help increase the success rate of performing some of the blocks described (Table 20–2). Ultrasound can increase the accuracy of the deposition of local anesthetic around the greater cornu of the hyoid bone for the superior laryngeal nerve block and can be used to identify the cricothyroid membrane for translaryngeal blocks.[14–16]

Superior Laryngeal Nerve Block

Sometimes, it can be difficult to identify the landmarks (eg, in obese patients) when trying to perform this block. Ultrasound can therefore be used to facilitate the deposition of local anesthetic to the correct place. The hyoid bone can be visualized on ultrasound (Figure 20–13), and an in-plane technique can be used to deposit local anesthetic around the surface of the greater cornu of the hyoid bone to achieve the block.[17]

Place the transducer probe in the sagittal plane to identify the greater cornu of the hyoid bone; the transducer is then rotated transversely to identify the superior lateral aspect of the thyrohyoid membrane. The superior laryngeal nerve can be seen superficial to the thyrohyoid membrane when the medial aspect of the probe is rotated cephalad. The internal branch of the superior laryngeal nerve runs along with the superior laryngeal artery, just below the greater cornu of the hyoid bone.

An alternative approach is to identify the hyoid bone, which appears as a hyperechoic curved bright structure on ultrasound in the midline. If the probe is moved laterally, the greater cornu of the hyoid bone can be seen as a bright structure medial to the superior laryngeal artery. The internal branch of the superior laryngeal nerve runs with the superior laryngeal artery just below the level of the greater cornu of the hyoid bone. Using an in-plane technique, a needle is passed perpendicular to the skin, aiming just below the greater cornu of the hyoid bone. Then, 1–2 mL of local anesthetic can be injected here after negative aspiration[18] (Figure 20–14).

This technique has been shown to have a success rate of over 90%. Failure is thought to be due to variations in the anatomical position of the superior laryngeal nerve in relation to the hyoid bone.

Translaryngeal Block

Sometimes, the correct location of the cricothyroid membrane is difficult to identify by palpation only. Ultrasound can be used to identify the thyroid and cricoid cartilages and the cricothyroid membrane (Table 20–3), ensuring that the local anesthetic is deposited correctly and a successful translaryngeal block is achieved[19] (Figure 20–15).

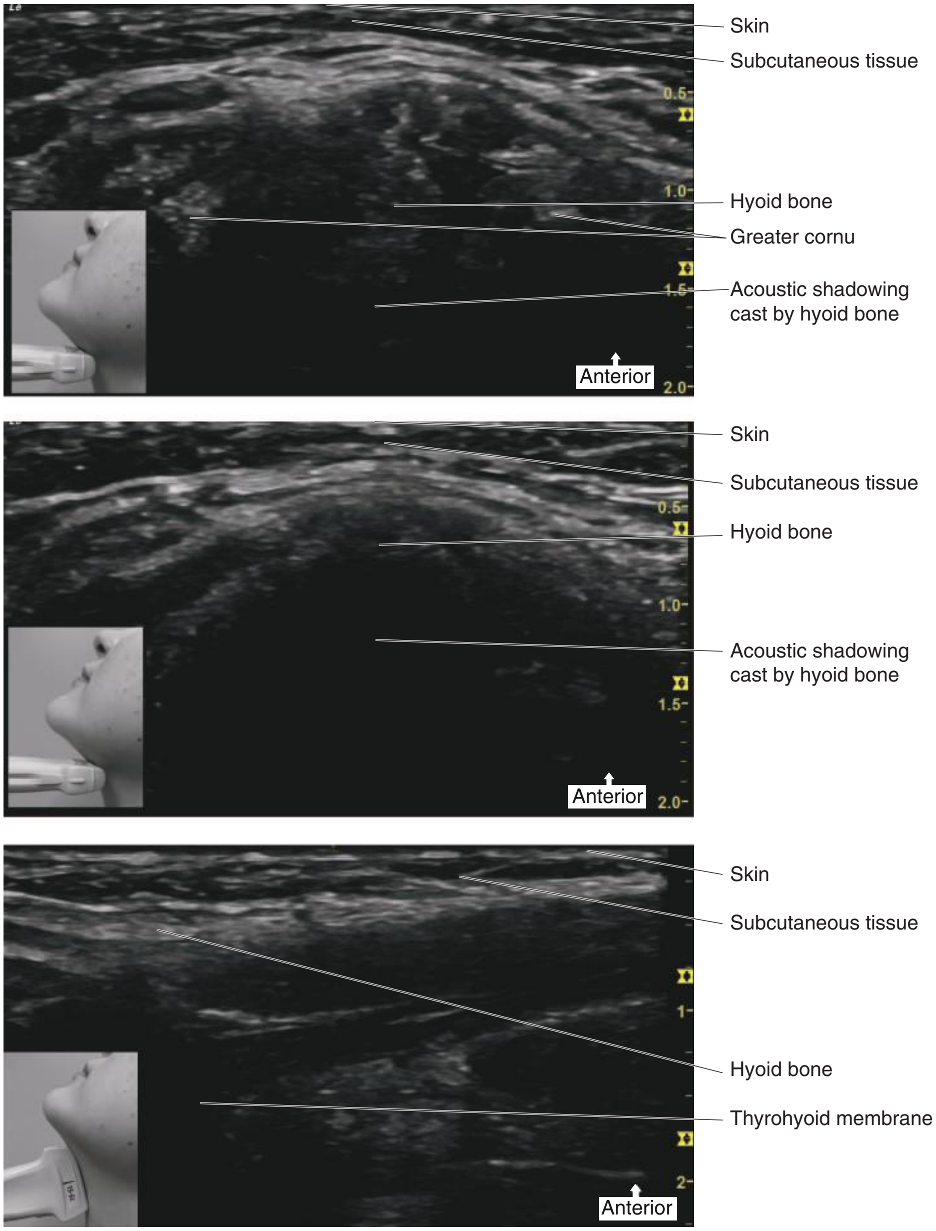

FIGURE 20–13. Ultrasound images of hyoid bone.

FIGURE 20–14. Ultrasound-guided superior laryngeal nerve block.

If the probe is placed longitudinally in the midline of the neck, the tracheal rings can be seen. If the probe is then advanced cranially, the cricoid cartilage can be seen next; this is a slightly elongated structure that is larger and more superficial than the tracheal rings. If the probe is further advanced cranially, the thyroid cartilage can be seen. The cricothyroid membrane lies between the caudal border of the thyroid cartilage and the cephalad border of the cricoid cartilage. Keep the probe in the midline with the cricothyroid membrane in the middle

of the image seen on the monitor; then, the exact location on the patient's neck can be marked using a marker pen. Now that the position of the cricothyroid membrane has been located, the translaryngeal block can be performed.

The block can also be performed under real-time sonography by simply tilting the probe from the midline to a parasagittal position, keeping the cricoid cartilage in view. The needle entry point should be just cranial to the cricoid cartilage and can be seen on the ultrasound monitor (Figure 20–16). Once air is aspirated, this confirms that the needle is through the membrane and in the trachea.

SEDATION TECHNIQUES

Awake endotracheal intubation can be an unpleasant experience for the patient, even if thorough topicalization of the airway has been done. The aim of conscious sedation is not only to allow the patient to tolerate the procedure but also to provide optimal intubating conditions. There are various techniques available to achieve the desired level of sedation; whichever is used, the priority is to avoid oversedation of the patient. Oversedation could lead to an unresponsive patient with loss of airway, which could result in serious consequences.

The ideal sedation conditions would involve a comfortable patient responsive to commands with a maintained airway, spontaneous breathing, and a degree of amnesia (Table 20–4).[20]

Two drugs are becoming increasingly popular and have growing evidence to support their use for conscious sedation: remifentanil and dexmedetomidine.[20] Remifentanil is an ultrashort-acting opioid, and dexmedetomidine is a highly selective α_2 agonist (Table 20–5).

Remifentanil has been found to provide good intubating conditions, is well tolerated, and has high patient satisfaction scores, although there is a high incidence of recall when used as a solo agent. Best results are seen when a target controlled infusion (TCI) technique is used.[21–23]

The advantage of dexmedetomidine is that a state of cooperative sedation is achieved; it also has antisialagogue effects. There is level 1 evidence to support its use for good intubating conditions, patient tolerance, and patient satisfaction. It is usually administered as a slow bolus over 120 minutes followed by an infusion.[24–26]

Benzodiazepines are usually administered in combination with an opioid as intermittent boluses and have been used as a sedative for awake fiber-optic intubation. The disadvantage of

Intravenous infusion (propofol, remifentanil, dexmedetomidine)
Combination of intravenous infusions (propofol and remifentanil)

using boluses of benzodiazepines is that intermittent boluses are associated with overshooting; therefore, there is a risk of oversedation and apnea.[27,28]

Propofol can be administered as intermittent boluses or as an infusion. Both techniques have been shown to be safe and well tolerated by patients. There is now increasing popularity of administering propofol as a TCI, either as a sole agent or in combination with remifentanil. Whichever technique is used, it is important to maintain a balance of an appropriate level of sedation and avoidance of underdosing or overdosing.[29]

The combination of propofol and remifentanil TCI has proven to be a safe technique for fiber-optic intubation with consistent pharmacodynamic effects and allows for a more predictable level of sedation.[29]

Clinical Pearls

- Safe sedation can be achieved by slowly administering the sedative drugs and continually communicating with the patient.
- Bispectral Index (BIS) monitoring can also be used to aid and guide sedation level.

AUTHOR'S PREFERRED TECHNIQUE FOR PERFORMING AN AWAKE FIBER-OPTIC INTUBATION

There are numerous techniques available for performing an awake fiber-optic intubation. Next is described a well-accepted and successful technique I use on a regular basis:

- Sit patient as upright as tolerable.
- Administer supplemental oxygen (via Hudson mask or nasal cannulae).
- Attach full monitoring.
- Start remifentanil (1–3 ng/mL) and propofol (0.5–1 μg/mL) TCI infusion. Do *not* give a bolus dose. Titrate the dose according to the patient's level of sedation.
- Start to topicalize the nasopharynx with Moffett's solution sprayed via MAD.
- Topicalize the oropharynx with 4% lidocaine using a MAD.
- After topicalization, suction any secretions using a soft suction catheter; this also tests the effectiveness of the local anesthetic.
- If patient does not tolerate the suction catheter, spray oropharynx with 2–4 sprays of 10% lidocaine.
- Preload the fiberscope with a nasal endotracheal tube (ETT) (size 6/6.5 outer diameter [OD]).
- Start fiberoscopy via the nasopharynx and visualize the vocal cords.
- Pass the fiberscope into the trachea.
- "Railroad" the lubricated ETT over the scope gently into the trachea, trying not to touch the carina with the fiberscope.
- Confirm correct placement of the ETT by visualizing the carina and ETT.
- Connect the ETT to the anesthetic circuit and capnography.
- Gently inflate the cuff of the ETT.
- Keep hold of the ETT until it has been safely secured.
- Patient is now safe to anesthetize.

SUMMARY

To successfully perform awake intubation in a patient with an anticipated difficult airway, it is important that you have an understanding of and are competent in all of the following:

- Innervation of the upper airway
- Knowledge of appropriate local anesthetic techniques and vasoconstrictor drugs
- Techniques available to topicalize/anesthetize the upper airway
- Prudent sedation techniques
- Oxygenation techniques during the procedure
- Techniques used for the correct placement of the endotracheal tube

This will enable a safe, stress-free, and successful awake intubation with high levels of patient satisfaction.

PART 3-B

INTRAVENOUS REGIONAL BLOCK FOR UPPER & LOWER EXTREMITY

CHAPTER 21

Intravenous Regional Block for Upper and Lower Extremity Surgery

Kenneth D. Candido, Anthony R. Tharian, and Alon P. Winnie

INTRODUCTION

The technique of intravenous regional anesthesia (IVRA), or "Bier block," was first introduced in 1908 by the German surgeon August Bier.[1] A Bier block essentially consists of injecting local anesthetic solutions into the venous system of an upper or lower extremity that has been exsanguinated by compression or gravity and that has been isolated by means of a tourniquet from the central circulation. In Bier's original technique, the local anesthetic procaine in concentrations of 0.25% to 0.5% was injected through an intravenous cannula, which had been placed between two Esmarch bandages utilized as tourniquets to divide the arm into proximal and distal components.[2–4] After injecting the local anesthetic, Bier noted two distinct types of anesthesia: an almost-immediate onset of "direct" anesthesia between the two tourniquets and then, after a delay of 5 to 7 minutes, an "indirect" anesthesia distal to the distally placed tourniquet. By performing dissections of the venous system of the upper extremity in cadavers after injecting methylene blue, Bier was able to determine that the direct anesthesia was the result of local anesthesia bathing bare nerve endings in the tissues, whereas the indirect anesthesia was most probably due to local anesthesia being transported to the substance of the nerves via the vasa nervorum, where a typical conduction block occurs. Bier's conclusion was that two mechanisms of anesthesia were associated with this technique: peripheral infiltration block and conduction block. The technique, as originally described by Bier, remains essentially unchanged in modern practice for the past 106 years, except for the introduction of the pneumatic-type double-tourniquet preparation used in current clinical practice[5–7] (Figure 21–1).

A Bier block can be used for brief surgical procedures or manipulations of the upper or lower extremity. However, the technique has found its greatest acceptance for use for the upper extremity because tourniquet problems and other safety issues seem to arise more frequently when IVRA is used on the lower extremities. Bier block is also a procedure that has found utility as a treatment adjunct for patients suffering from complex regional pain syndromes (CRPSs) (formerly known as reflex sympathetic dystrophy, with sympathetically maintained pain) as an alternative to repeated sympathetic ganglion blocks. In this regard, IVRA has been shown to decrease neurogenic inflammation, a phenomenon possibly associated with CRPS, with little impairment of sensory function, at least when mepivacaine is the local anesthetic chosen for the block. Sensibility to cold is significantly decreased 10 to 30 minutes after the block, even with a reduction in the skin temperature on the blocked side.[8] Chemical sympathectomy using IVRA with agents such as guanethidine or bretylium may last up to 5 days, as compared with local anesthetic blocks, which typically provide analgesia lasting only several hours. Quantitative sensory testing (QSART, quantitative sudomotor axon reflex testing) before and after such blocks demonstrated that it is possible to predict which patients will have long-lasting pain alleviation using IVRA guanethidine blocks following traumatic injury or surgery.[9]

Although IVRA is a safe and effective method of administering local anesthetics for extremity block both for surgery and for pain control, one large published survey noted that most third-year (CA-3) anesthesia residents had performed fewer than 10 such blocks during the entire course of their training.[10]

ANATOMY

The only relevant anatomy is the location and distribution of the veins of the hand, of the antecubital fossa, and of the foot and ankle region.

FIGURE 21–1. Double pneumatic tourniquet system for use in intravenous regional anesthesia of the upper or lower extremity.

INDICATIONS

Upper Extremity

Intravenous regional anesthesia using local anesthetic, most commonly lidocaine 0.5%–1% (prilocaine 1% in Europe), is appropriate for surgery and manipulation of the extremities requiring anesthesia of up to 1 hour's duration. It is most suited for peripheral, soft tissue operations such as ganglionectomy, carpal tunnel release, Dupuytren's contracture surgery, or reduction of fractures. However, the necessity of exsanguinating the extremity using an Esmarch bandage, a potentially painful maneuver, may preclude certain procedures from being undertaken with this technique (Figures 21–2 and 21–3). Likewise, manipulations of the ulnar, median or radial nerves may cause paresthesias, which may require the use of adjuvant parenteral analgesics or sedatives. A novel use of IVRA is for anesthetizing the hand prior to injecting botulinum toxin A (BTX-A) for the treatment of hyperhidrosis. BTX-A significantly reduces sweat production, as measured by Minor's test and as quantified by corneometer analysis, but the injection is painful unless the hand is anesthetized beforehand; IVRA has been found to be suitable for this purpose.[11,12] According to a recent study, there was no difference in the degree and duration of analgesia between IVRA and stellate ganglion block (SGB) using a combination of 70 mg of lidocaine and 30 μg of clonidine in patients with CRPS type 1 affecting the upper extremities. The study concluded that IVRA was preferable to SGB in this setting due to its lower risk of undesirable side effects and easier execution than SGB.[13]

Upper extremity IVRA has been utilized occasionally for prolonged analgesia/anesthesia (ie, surgeries expected to persist for longer than 1 hour), with a mandatory tourniquet deflation period of at least 1 minute prior to reestablishing the anesthetized state.[14]

FIGURE 21–2. Beginning of the exsanguination process of the elevated left upper extremity using a tightly wrapped Esmarch bandage from the distal hand to the proximal upper extremity at the base of the distal tourniquet.

FIGURE 21–3. Keeping the Esmarch bandage tightly wrapped, first distal, then proximal tourniquets are to 50-100 mm Hg above the systolic arterial blood pressure.

Lower Extremity

Intravenous regional anesthesia may be used for brief surgical interventions of the lower extremity in a manner analogous to that described for upper extremity surgery. Surgical procedures that may be completed using this approach include excision of a mass; digital nerve repair; phalangeal fracture/dislocation surgery; and accessory navicular excision. Any foot, ankle, or distal lower extremity orthopedic procedure requiring approximately 45 minutes or less to complete may be amenable to this modality. Although IVRA has been associated with an increased incidence of compartment syndrome when treating tibial shaft fractures and has therefore been deemed contraindicated in such cases, a study in volunteers showed no significant difference in tissue pressures before and after tourniquet inflation regardless of the volume of saline used (≤1.5 mL/kg) or as a function of time following saline injection during tourniquet inflation. The authors concluded that, in the normal atraumatic limb, simulated IVRA using normal saline (NS) does not increase tissue pressure within the anterior compartment of the leg.[15]

Pediatrics

Intravenous regional anesthesia has been an acceptable choice in selected pediatric patients for the reduction of fractures of the upper extremity. A retrospective study comparing IVRA and conscious sedation for the reduction of pediatric forearm fractures found IVRA to be a safe, efficient, and cost-effective method of reducing pediatric forearm fractures.[16] There were 600 patients in the IVRA group and 645 patients in the conscious sedation group. No patient experienced compartment syndrome or a need for readmission secondary to cast application. Some intervention to their cast because of tightness was needed by 28 patients (4.34%) in the procedural sedation group and 13 patients (2.16%) in the IVRA group.[16]

CONTRAINDICATIONS

The only absolute contraindication to IVRA is patient refusal. Relative contraindications include the following:

- Crush injuries of an extremity
- Inability to locate peripheral veins
- Local skin infections
- Cellulitis
- Compound fractures
- Patients with convincing history of allergy to local anesthetics
- Patients with severe vascular injuries to the extremity
- Preexisting vascular arteriovenous shunts and patients in whom a tourniquet is unsuitable (ie, patients with severe peripheral vascular disease)
- Sickle cell disease
- Surgery planed for >1 hour are typically not good indication for IV regional anesthesia due to occurrence of Tourniquet pain.

EQUIPMENT

Figures 21–1 to 21–8 show equipment used in IVRA.

1. Local anesthetic agents: lidocaine HCl, 0.25%–0.1% (alternative is prilocaine, 0.5%)
2. One rubber tourniquet (Penrose drain) 12–18 in. in length (30–45 cm) and 7/8-in. wide (2.3 cm) for use prior to placing the intravenous cannula
3. One 20- or 22-gauge intravenous extracatheter (catheter over needle) (Figure 21–5)
4. One 500-mL or 1-L bag of intravenous solution connected to an infusion set (vs. a hep lock) to be connected to the intravenous cannula to maintain its patency until the anesthetic solution is injected in the isolated extremity (may substitute a saline-flushed intravenous port instead)
5. Standard American Society of Anesthesiologists (ASA) monitors (electrocardiograph, blood pressure, pulse oximeter)
6. Resuscitation equipment (intravenous catheter, crystalloid solution, and infusion set for the contralateral upper extremity) (for upper extremity IVRA)
7. Two pneumatic tourniquets of appropriate size for the selected extremity (Figures 21–6 and 21–9)
8. One Esmarch bandage 60 in. in length (152 cm) *and* 4 in. wide (10 cm) for exsanguinating the arm (Figures 21–2, 21–3, and 21–7)

FIGURE 21–4. Equipment for IVRA consists of Esmarch bandage, local anesthetic vials, rubber tourniquet, intravenous (IV) extracatheter (catheter over needle), alcohol swabs, and a syringe to draw up local anesthetic.

FIGURE 21–5. Intravenous cannula and Hep-Lock placed in a distal vein of the hand in preparation for IVRA.

FIGURE 21–7. Elevation of the extremity to allow passive exsanguination.

9. Sterile skin preparatory set
10. A 30- or 50-mL Luer lock syringe
11. One graduated measuring cup for the mixing of solution, preferably with a 100-mL capacity
12. Adhesive tape, various sizes

PATIENT PREPARATION

The patient lies in the dorsal recumbent position as long as the vein selected for placement is readily accessible. The resuscitative equipment is checked, and the pneumatic tourniquets are tested and prepared for use. For surgery on the elbow, the needle will be placed in the forearm or antecubital fossa. For procedures on the hand or forearm, a vein in the dorsum of the hand is best selected (Figure 21–5).

For lower extremity procedures, a vein on the foot, ankle, or lower leg is chosen. After obtaining intravenous access in a nonoperated extremity (alternatively, a central venous access may be secured), a full complement of ASA monitors is applied, and baseline vital signs are assessed. If the patient is in severe pain, small aliquots of intravenous analgesics may now be administered (ie, fentanyl 1–2 μg/kg) to facilitate the exsanguination process. Because total patient cooperation is not essential to be successful, small doses of water-soluble benzodiazepine (ie, midazolam 15–25 μg/kg) may alternatively be administered for anxiolysis. An important benefit to choosing a benzodiazepine is the suppression of the convulsant response associated with local anesthetic toxicity, a valid concern in the patient undergoing IVRA due to the large volume of the agent being directly administered into the vascular system.

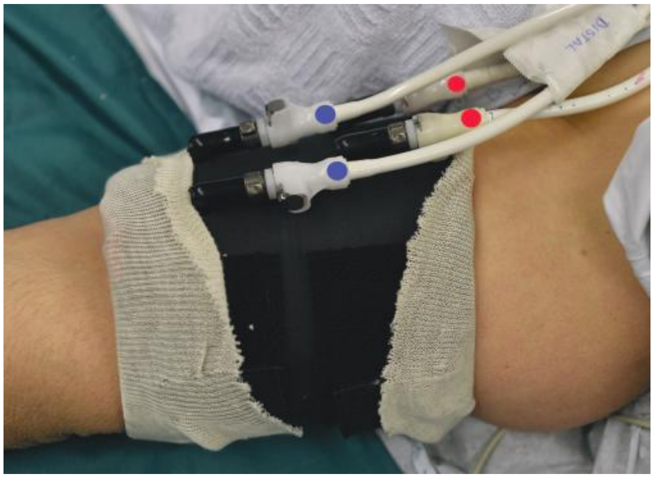

FIGURE 21–6. Clearly labeled proximal (RED) and distal (BLUE) tourniquet of the double tourniquet system. The tourniquet is always inflated in the following order: Distal, Proximal. Once the functionality is checked, the distal tourniquet (BLUE) is deflated.

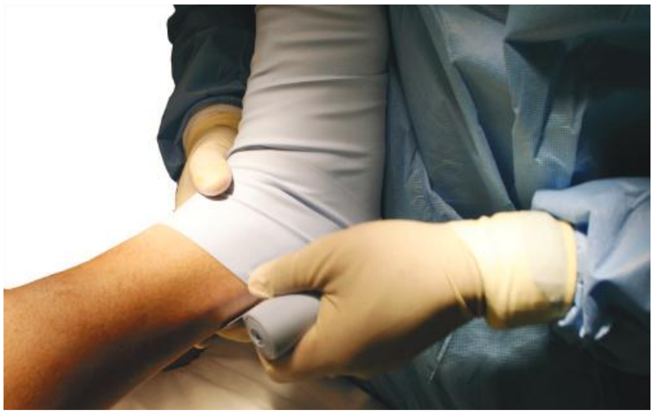

FIGURE 21–8. The elevated right lower extremity is wrapped with a tightly wound Esmarch bandage to the tourniquet.

TECHNIQUE

Upper Extremity IVRA

The following is the technique for IVRA for upper extremity procedures:

1. **An indwelling plastic catheter is inserted** into a peripheral vein as far distally as possible under strict aseptic precautions (Figure 21–5).
2. **A double-pneumatic tourniquet is placed on the proximal cuff high on the upper arm** (Figures 21–6 and 21–7). While by convention the tourniquets are placed on the biceps area, one study found that the dosage of lidocaine could be almost halved when the tourniquet was placed in the forearm instead of the upper arm.[17] Twenty patients undergoing forearm and hand surgeries received IVRA with a combination of lidocaine 1.5 mg/kg and ketorolac 0.15 mg/kg with a tourniquet placed on the forearm. Another 20 patients undergoing similar procedures received IVRA with double the dose of the same medications and with the tourniquet placed on the upper arm. Surgical anesthesia was assessed as excellent in all 20 patients in the upper arm tourniquet group, while it was rated as excellent in 19/20 patients in the forearm tourniquet group. Onset as well as regression of sensory block were similar in both groups.[17] A recent study comparing forearm tourniquet placement (n = 28) with 8 mL of 2% lidocaine and 10 mg ketorolac and upper arm tourniquet placement (n = 28) with 15 mL of 2% lidocaine and 20 mg ketorolac found that patients in the forearm tourniquet group experienced less discomfort, fewer sedation interventions, and a greater likelihood of bypassing the postanesthesia care unit (PACU) when compared with the group with the upper arm tourniquet.[18]
3. **The entire arm is elevated to allow passive exsanguination** (Figure 21–7), and a rubber Esmarch bandage is wound around the arm spirally from the fingertips of the hand to the distal cuff of the double tourniquet to exsanguinate the arm (Figures 21–2 and 21–3).
4. **The axillary artery is digitally occluded**, and while pressure is maintained on it, the proximal pneumatic cuff is inflated to 50–100 mm Hg above the systolic arterial blood pressure, after which the Esmarch bandage is removed.
5. **Following inflation of the proximal cuff and removal of the Esmarch bandage, 30–50 mL of 0.5% lidocaine HCl are injected** via the indwelling plastic catheter, the volume depending on the size of the arm being anesthetized.
6. To the level of the procedure table, the intravenous cannula in the surgical extremity is withdrawn, and pressure is quickly applied over the site using sterile gauze.
7. **About 25–30 minutes after the onset of anesthesia or when a patient complains of tourniquet pain, the distal cuff is inflated and the proximal cuff is deflated** to minimize the development of tourniquet pain.

Lower Extremity IVRA

The only significant difference in IVRA for the upper and lower extremities is that the IVRA technique for the lower extremity requires relatively larger volumes of local anesthetic solutions by virtue of the obvious size disparity between upper and lower extremities. This is necessary to more completely fill the larger vascular compartment of the lower extremity from the distally placed intravenous cannula to the proximal tourniquet (100 mL vs. 50 mL).

PHARMACOLOGIC CONSIDERATIONS

Local Anesthetic Considerations

Lidocaine is the prototypical local anesthetic used for IVRA in the United States. In Europe, however, prilocaine may be more commonly used and in fact has been the subject of most clinical trials. Attempts have been made to maximize the efficacy of lidocaine while minimizing side effects or toxicity of the agent. Alkalinization of 0.5% lidocaine (using 1.4% sodium bicarbonate) for IVRA was studied in 31 patients. The authors found no clinical advantage to the practice of alkalinization of lidocaine with respect to sensory block, motor block, or the appearance of postoperative pain.[19] When lidocaine was compared with alkalinized and nonalkalinized 2-chloroprocaine, both used as 0.5% concentrations and used exclusively for hand surgery, alkalinized chloroprocaine behaved similarly to lidocaine, but plain chloroprocaine offered no benefit and produced more side effects than seen with lidocaine.[20]

Another study comparing IVRA with low-concentration/high-volume lidocaine (0.5% concentration of 30–50 mL lidocaine) and higher-concentration/low-volume lidocaine (2% concentration of 12–15 mL lidocaine) in patients undergoing upper extremity surgery showed a faster onset and delayed regression of sensory block in the higher-concentration/low-volume group. There were no significant differences in hemodynamic data such as systolic and diastolic blood pressure, mean blood pressure, and heart rate between the two groups.[21]

Lidocaine has been compared with ropivacaine for upper extremity IVRA in two separate studies. Two doses of ropivacaine (1.2 and 1.8 mg/kg) were compared with one dose of lidocaine (3.0 mg/kg) in 15 volunteers. Recovery of sensory and motor block after tourniquet release was slowest with the high-dose ropivacaine group. More patients in the lidocaine group (5 of 5) experienced light-headedness following tourniquet release, versus only 1 in the high-dose ropivacaine group.[22] In the second study, 51 patients were randomized to receive either ropivacaine 0.375% or lidocaine 0.5% in a volume of 0.4 mL/kg up to 25 mL. Postoperative analgesia as measured by first request for analgesics was superior in the ropivacaine group.[23]

The progression of sensory blockade in the hand following IVRA with 20 mL of 0.3% ropivacaine and a double tourniquet placed in the forearm was studied in 10 healthy volunteers.[22] The local anesthetic was injected through a 22-gauge intravenous catheter placed in a prominent vein on the dorsum of the hand after exsanguination of the hand using an Esmarch bandage and sequentially inflating the distal tourniquet to

150 mm Hg or 20 mm Hg above the systolic blood pressure (whichever was higher) and the proximal tourniquet to 250 mm Hg. The distal tourniquet was then deflated, and the Esmarch bandage was removed. Baseline values for cold and touch sensation were determined before the block, and updated values were obtained repeatedly and continuously, beginning 5 minutes after the local anesthetic injection and continuing until loss of sensation was obtained in all areas. There was an almost-immediate loss of cold perception followed by a delayed and uneven spread of loss of touch sensation. The initial spread of anesthesia was noted both proximally and distally in the dorsum of the hand and then progressed to the fingertips, with a delayed proximal spread over the palmar surface of the hand to the wrist.[24]

Prilocaine has been compared with lidocaine, as well as with other local anesthetics used for IVRA. While evaluating the onset of sensory and motor block, 40 mL of 0.5% prilocaine (100 mg) was compared with the same volume and same concentration of chloroprocaine in 10 volunteers undergoing IVRA. Motor block onset did not differ between groups, and sensation was recovered almost equally well. However, recovery of motor function was shorter in the prilocaine group, and more chloroprocaine patients demonstrated signs of venous irritation or antecubital urticaria for 30–45 minutes after tourniquet deflation. Heart rate changes were also more notable in the chloroprocaine group.[25] The same group of investigators expanded their study to include 60 patients, 30 in each of the respective groups detailed previously. Now, the investigators found that complete recovery of sensory block was faster in the prilocaine group (7.1 vs. 9.8 minutes). Otherwise, the incidence of side effects remained higher in the chloroprocaine group.[26]

Next, these investigators compared 0.5% prilocaine with the same concentration of articaine (a newer amino amide-type local anesthetic that contains thiophene and is pharmacologically similar to mepivacaine) for upper extremity IVRA. Articaine, a potent local anesthetic with a low degree of toxicity by virtue of its rapid metabolism with esterases, was felt to be a suitable alternative to prilocaine. Ten volunteers participated in this double-blind, crossover comparison of the two agents. They found no significant difference between the two with respect of onset of anesthesia or motor block or in recovery of sensory or motor function. However, 80% of the subjects experienced skin rashes after receiving articaine, versus 20% in the prilocaine group.[27]

When 0.5% prilocaine was compared with the same concentrations of articaine or lidocaine in three groups of 10 patients each for IVRA, it was found that the onset of sensory block was significantly shorter in the articaine group, which also had the lowest peak plasma concentrations of local anesthetic following tourniquet release.[28] Plain prilocaine 1% has been compared with the same local anesthetic combined with four different additives for IVRA: bupivacaine 0.25%, clonidine 150 μg, sufentanil 25 μg, or tenoxicam 20 mg. The sufentanil-added group demonstrated the most rapid onset of sensory block; postoperative pain scores were improved by adding either clonidine or tenoxicam. Otherwise, there were no significant differences among the five groups with respect to onset and duration of sensory block.[29] Unlike the situation noted for lidocaine with addition of bicarbonate as an adjuvant, the addition of bicarbonate to prilocaine does seem to shorten onset time and prolong the duration of anesthesia during IVRA.[30,31]

The use of mepivacaine for IVRA has been studied. Sixteen patients were evaluated using 1.4 mg/kg in 40 mL total for IVRA versus saline blocks performed in the same individuals on the contralateral arm. Arterial occlusion was maintained for 20 minutes. Reactive hyperemia was attenuated in the mepivacaine-treated arm for the 60-minute evaluation period, indicating that mepivacaine is a potent vasoconstrictor having a long duration of action. This finding has implications for the use of mepivacaine in individuals either with compromised upper extremity blood flow or with CRPS, for whom it probably should not be considered the local anesthetic of choice.[32]

The same study group evaluated the effects of mepivacaine IVRA on intracutaneous capsaicin-induced burning pain and on microvascular skin blood flow as measured by Doppler perfusion imaging. The reactive hyperemia was less in the mepivacaine-treated arm 10 minutes after tourniquet release, and the area of the flare was smaller after capsaicin in the mepivacaine-treated arms. The authors concluded that mepivacaine IVRA had no effects on post-IVRA sensory function of thin afferent fibers, but differentially decreased the spread of capsaicin-induced flare.[33]

Clinical Pearls

- Lidocaine is the prototypical drug used for IVRA in the United States; prilocaine is favored in Europe.
- Alkalinization of lidocaine confers minimal, if any, advantage to commercial lidocaine for IVRA.
- The potent vasoconstrictive properties of mepivacaine detract from its overall attractiveness as a primary agent for IVRA.

Adjuncts to Local Anesthetics for IVRA

A systematic review of the literature was undertaken to evaluate the use of adjuncts to local anesthetics for IVRA. Twenty-nine studies met the criteria of being randomized, double blind, and controlled. Data on 1217 study subjects were reviewed, and the agents studied included opioids (fentanyl, sufentanil, meperidine, and morphine); clonidine; muscle relaxants (atracurium, pancuronium, mivacurium); tramadol; nonsteroidal anti-inflammatory agents (NSAIDs) (ketorolac, tenoxicam, acetylsalicylate); alkalinization using sodium bicarbonate; the addition of potassium; and temperature alterations. The authors found solid evidence supporting the use of NSAIDs in general and ketorolac in particular for improving postoperative analgesia and prolonging tourniquet tolerance during IVRA. Opioids fared poorly when used for IVRA, with only meperidine in doses of 30 mg or greater showing substantial postoperative benefits at the expense of postdeflation nausea, vomiting, and dizziness. Muscle relaxants improved postoperative motor block and were beneficial in fracture reduction in which muscular relaxation is imperative for good results.[34]

Alpha$_2$ Agonists (Clonidine and Dexmedetomidine)

Clonidine has been added to both prilocaine and lidocaine as an adjunct to IVRA for extremity surgery. When 2 μg/kg were added to prilocaine 0.5% in a randomized, double-blind fashion in 56 patients undergoing upper extremity surgery, there was no difference between groups regarding sensory or motor block onset or duration. The patients who had clonidine had a significant reduction in arterial blood pressure after tourniquet release (24%–48%), while heart rates remained unchanged. The authors concluded that clonidine was of limited benefit as an adjunct to local anesthetics.[35] The addition of clonidine to prilocaine dramatically suppressed tourniquet pain, but it did not alter postoperative pain following tourniquet deflation.[36] Clonidine was found to provide no measurable benefits when added to lidocaine for IVRA in patients undergoing carpal tunnel release.[37]

Dexmedetomidine is appropriately eight times more selective toward the α-adrenoreceptors than clonidine. As such, it has been used in IVRA to determine if it might advance some of the beneficial findings noted with the latter agent. Thirty patients undergoing hand surgery under IVRA received 0.5% lidocaine alone or lidocaine plus dexmedetomidine 0.5 μg/kg. The dexmedetomidine group showed a more rapid onset of sensory and motor block; prolonged sensory and motor block recovery; prolonged tolerance for the tourniquet; and improved quality of analgesia compared with the group that received local anesthetic only.[38]

A shortened sensory block onset time; prolonged sensory and motor block recovery times; prolonged duration of analgesia for tourniquet; and prolonged postoperative analgesia were noted in patients undergoing IVRA with dexmedetomidine in another randomized, double-blind study comparing the effects of lornoxicam or dexmedetomidine in IVRA with prilocaine in patients undergoing hand or forearm surgery. In this study, IVRA was achieved with 2% prilocaine at 3 mg/kg in the control group (n = 25), 2% prilocaine at 3 mg/kg plus dexmedetomidine 0.5 μg/kg in the dexmedetomidine group (n = 25), and 2% prilocaine at 3 mg/kg plus lornoxicam 8 mg in the lornoxicam group (n = 25). In each group, the drugs were diluted with 0.9% normal saline to a total volume of 40 mL.[39]

A more recent study comparing the effects of dexmedetomidine when added to lidocaine for IVRA and when administered parenterally as premedication before IVRA found that both these groups had similarly improved quality of anesthesia and perioperative analgesia. This study was done on patients undergoing carpal tunnel release randomized into three groups. IVRA was done using 40 mL of 0.5% lidocaine. A single dose of dexmedetomidine 0.5 μg/kg and placebo (saline) solution in a total volume of 20 mL was administered to group P (n = 15) and group S (n = 15), respectively, before IVRA. Dexmedetomidine at 0.5 μg/kg of was added to lidocaine in group A (n = 15) during IVRA. The onset and recovery time of sensory and motor block, intraoperative-postoperative visual analog scale (VAS), Ramsay sedation score (RSS), analgesic requirements, hemodynamic variables, and side effects were noted. Significantly shortened sensory block onset and recovery time in groups P and A, shortened motor block onset time in group P, and decreased intraoperative VAS scores and analgesic requirement in groups P and A were found. Intraoperative RSS in group P and postoperative RSS in groups P and A were higher than in group S. Intraoperative and postoperative heart rate and postoperative mean arterial blood pressure (MAP) of group P were significantly lower than in groups A and S, respectively.[40]

Opioids

Because opiate receptors were discovered to exist in the peripheral nervous system[41,42] and with the demonstration that opioids may produce effective, long-lasting analgesia when injected in conjunction with local anesthetics for brachial plexus block,[43–47]several investigators have attempted to decrease the potential for toxicity from local anesthetic–only IVRA by adding opioids to reduce the concentration of lidocaine. Although it has not been proven that the addition of fentanyl to lidocaine for IVRA results in improved analgesia while reducing the risks,[48,49] the addition of fentanyl in 200-μg doses to prilocaine 0.5% did result in more complete analgesia than in patients who had 100 μg added, or when plain prilocaine was used for IVRA. Postoperative nausea and central nervous system side effects were higher in the fentanyl-added groups versus those who received local anesthetic alone.[50] Two other studies, however, found that the addition of opioids to prilocaine did not improve success with the technique.[51,52] More research on the effects of the addition of opioids to prilocaine for IVRA may ultimately resolve this discrepancy.

Some investigators have found that adding opioids and muscle relaxants to 0.25% lidocaine provides the same analgesia and muscular relaxation as that provided by 0.5% lidocaine alone, while reducing the likelihood of systemic toxicity. Adjuvants added to lidocaine have included fentanyl 50 μg plus pancuronium 0.5 mg,[53,54] fentanyl plus rocuronium,[55] fentanyl plus D-tubocurarine,[56] and fentanyl plus vecuronium.[57] In each case, the authors reported outstanding operating conditions, and because the lidocaine concentration was able to be reduced to 0.20% (ie, more than one-half the normal used), the potential for systemic toxicity was at least halved.

When meperidine 0.25%, 40 mL (100 mg), was used as a solitary agent for IVRA, complete motor block was produced, just as effective as that produced by lidocaine. Motor block onset was as rapid as or more rapid than sensory block onset in each of the 15 patients in this study group. However, when compared with plain lidocaine in this study, there was a higher incidence of dizziness, nausea, and pain at the injection site.[58]

Tramadol

Tramadol has been evaluated for use in IVRA of the upper extremity. Sixty volunteers divided into four groups of 15 patients each received IVRA with 40 mL of tramadol 0.25% (100 mg), 0.9% normal saline, lidocaine 0.5%, or lidocaine plus tramadol 0.25%. The onset and recovery of sensory and motor block were similar between the tramadol and normal saline–only groups. However, the addition of tramadol to lidocaine resulted in faster onset of sensory block at the expense of an increase in skin rash and painful burning sensations at the injection site. The conclusion of the authors was that tramadol alone does not possess local anesthetic effects but might modify the effects if added to a local anesthetic such as lidocaine.[59]

In another study comparing 0.5% lidocaine with and without 50 mg of tramadol for upper extremity IVRA, the tramadol-added group experienced less tourniquet pain than the local-only group, but as in the study mentioned previously, there were several cases of skin urticaria in the tramadol group but not in the lidocaine-only group.[60] Tramadol (100 mg) added to lidocaine for IVRA for upper extremity anesthesia acted similarly to sufentanil (25 μg) or clonidine (1 μg/kg) added to the local anesthesia with respect to intraoperative hemodynamic data, time to recovery of sensory block, onset and recovery of motor block, sedation scores, and postoperative pain.[61] In summary, tramadol is ineffective as a solo agent for IVRA but may confer some advantage when added to lidocaine. This advantage, however, may be offset by the significant incidence of dermatologic side effects of tramadol given intravenously in an exsanguinated extremity.

Muscle Relaxants

A small dose of nondepolarizing muscle relaxant may be chosen as an adjunct to the local anesthetic administered for IVRA; however, because D-tubocurarine releases histamine even in judicious doses, it is probably best to avoid this agent altogether. Atracurium has been added to lidocaine in an effort to improve muscular relaxation during IVRA, particularly during the reduction of upper extremity fractures and dislocations. Adding 3 mg of atracurium to lidocaine for IVRA resulted in a decrease in the onset time of analgesia in the hand, but not at the tourniquet site. There was no added benefit to adding this agent or adding alfentanil to lidocaine in the same study.[62] A study using 2 mg of atracurium added to 40 mL of 0.5% lidocaine for IVRA for hand surgery in 40 patients randomized to one of two groups found that the addition of the atracurium provided a greater degree of muscle relaxation, easier reduction of fractures, and better operating conditions, as well as less pain after surgery.[63]

Neostigmine

Neostigmine has been suggested as a coanalgesic when used for epidural and intrathecal analgesia and anesthesia, but evidence of its benefit in the peripheral nervous system is lacking. In two studies, one using neostigmine added to lidocaine and the other using the adjuvant added to prilocaine, there have been conflicting findings. When neostigmine (1 mg) was added to 0.5% lidocaine for IVRA in a study of 54 volunteers randomized into one of three study groups, it was found that the addition of the adjuvant provided no benefit in terms of analgesia or anesthesia compared with controls.[64] When one-half of the dose of neostigmine (0.5 mg) was added to prilocaine (3 mg/kg) for IVRA in 30 patients randomized to one of two treatment groups, it was found that the adjuvant group demonstrated shortened sensory and motor block onset times, prolonged sensory and motor block recovery times, improved quality of anesthesia, and prolonged time to first analgesic requirement versus the plain prilocaine group.[65]

A more recent study looking at the effect of adding 0.5 mg neostigmine to 40 mL of 0.5% lidocaine for IVRA in patients undergoing elective or emergency forearm and hand surgeries randomized into two groups, with 1 mL of isotonic saline added to 40 mL of 0.5% lidocaine in the control group, noted significantly shorter sensory and motor block onset times and longer recovery times in the neostigmine group when compared to the control group. The quality of intraoperative anesthesia and frequency of tourniquet pain were similar in both groups.[66] It appears that the conflicting findings with two different doses of neostigmine added to lidocaine for IVRA will need to be confirmed by additional work incorporating larger patient sample sizes to resolve the discrepancy in the two small studies mentioned previously.

Nonsteroidal Anti-inflammatory Agents

Other attempts to improve IVRA with lidocaine have included using NSAIDs to suppress tourniquet pain while enhancing postoperative analgesia. Although ketorolac has shown some efficacy, other NSAIDs have not fared as favorably. Ketorolac was studied as an adjuvant to lidocaine using either a forearm or an upper arm tourniquet in patients undergoing hand or forearm surgery.[67] In this study, the patients were randomized in to two groups: group UA, consisting of 20 patients undergoing IVRA with an upper arm tourniquet; and group FA, consisting of 20 patients undergoing IVRA with a forearm tourniquet. Patients in the upper arm tourniquet group received IVRA with 0.5% lidocaine at the dose of 3 mg/kg plus ketorolac 0.3 mg/kg. IVRA in the forearm tourniquet group was established with 0.5% lidocaine at 0.15 mg/kg plus ketorolac 0.15 mg/kg. There was no statistically significant difference in the onset and duration of sensory block and the need for analgesic supplementation between the two groups. Postoperative pain scores were also similar between the two groups. The authors concluded that forearm tourniquet IVRA with 0.5% lidocaine at a dose of 1.5 mg/kg plus ketorolac 0.15 mg/kg is a safe and clinically viable option that provides similar perioperative anesthesia and analgesia as that provided by upper arm tourniquet IVRA with 0.5% lidocaine at a dose of 3 mg/kg plus ketorolac 0.3 mg/kg, while reducing the dose of lidocaine and ketorolac by half.[67]

Another NSAID, tenoxicam, was added to prilocaine in one study of 45 total patients. A 20-mg dose of the NSAID was used in patients undergoing IVRA for reduction of Colles fractures, with patients divided into three groups. One group received local anesthetic only; one received local plus tenoxicam; and one group had IVRA with local anesthetic only plus an intravenous NSAID. In this last group, the tenoxicam (20 mg) was injected in the contralateral arm, opposite the IVRA procedure arm. The group receiving the NSAID added to the local anesthetic had superior analgesia and lower pain scores than either of the other two groups of patients.[68]

A more recent study comparing the intraoperative and postoperative analgesic effects of lornoxicam and fentanyl when added to lidocaine for IVRA in patients undergoing hand surgery showed increased sensory block recovery time and first analgesic requirement time in the lornoxicam group, with no increased incidence of side effects, when compared to the lidocaine-only group and the lidocaine with fentanyl group. In this study, a total of 45 patients were randomized into three groups. Patients in group 1 received 3 mg/kg of 2% lidocaine (40 mL); group 2 received 3 mg/kg lidocaine, 38 mL plus lornoxicam 2 mL (4 mg/mL); and group 3 received 3 mg/kg lidocaine, 38 mL plus 2 mL fentanyl (0.05 mg/mL). This study also concluded that addition of fentanyl to lidocaine IVRA (group 3) seemed to be superior to lidocaine IVRA (group 1) and lornoxicam added to lidocaine IVRA (group 2) in decreasing tourniquet pain; however, this was at the expense of increasing side effects like itching.[69]

Dexketoprofen is another NSAID that has been studied as an adjunct to lidocaine for IVRA. In this prospective, randomized, placebo-controlled study, patients scheduled for elective hand or forearm soft tissue surgery were randomly divided into three groups. All 45 patients received 0.5% lidocaine as IVRA. Dexketoprofen 50 mg was given either intravenously or added into the IVRA solution, and the control group received an equal volume of saline both intravenously and as part of the IVRA. The times of sensory and motor block onset, recovery time, and postoperative analgesic consumption were recorded. Compared with controls, the addition of dexketoprofen to the IVRA solution resulted in more rapid onset of sensory and motor block, longer recovery time, decreased intra- and postoperative pain scores, and decreased postoperative analgesic requirements. The pharmacological formulation of dexketoprofen used in this study contained ethanol as an excipient. The authors stated that the neurolytic effect of ethanol may have contributed to the faster development of sensory and motor blockade and longer recovery times in the IVRA group in this study.[70]

Other Specific Agents: Corticosteroids

The anti-inflammatory properties of glucocorticoid-type steroids have been evaluated when these agents have been added to local anesthetics for IVRA in patients with rheumatoid arthritis (RA). In a randomized, double-blind, crossover, placebo-controlled study, 20 patients with RA received either 50 mg methylprednisolone in mepivacaine 0.25% or mepivacaine plain for upper extremity IVRA. The other extremity received the opposite treatment. One week later, the same medications were injected into the contralateral extremities, respectively. Fifty percent of patients reported subjective improvement at 1 and 6 weeks; objective parameters like grip strength did not change until the 6-week evaluation, at which time a significant increase was noted, as was the reduction in grip diastasis and movement-invoked pain. This report suggested that corticosteroids administered by IVRA may provide sustained analgesia in certain RA sufferers.[71]

Steroid IVRA has also been used as adjunctive treatment of CRPS type 1. Methylprednisolone (40 mg) was added to lidocaine for IVRA in a randomized, double-blind, placebo-controlled fashion in 22 patients. Treatments were applied once per week, for up to three sessions of blocks. The investigators found no benefit in adding the steroid to the local with regard to improvement in pain severity or shortening the course of the disease.[72]

Interestingly, a case series involving 168 patients with CRPS type 1 of the upper extremity treated with IVRA using 25 mL of 0.5% lidocaine and 125 mg of methylprednisolone diluted in 10 mL of normal saline and followed up over a 5-year period reported complete absence of pain in 92% of patients at the end of the follow-up period. IVRA was performed with the tourniquet kept inflated for 20 minutes, during which time the affected extremity was manipulated in an attempt to increase the range of motion. The tourniquet was then gradually deflated to avoid rapid entry of the injected agents to the circulation. The same process was repeated once or twice a week depending on the intensity and persistence of the patient's symptoms, and in between sessions patients were kept under mild physical therapy, which was not prolonged or stressful. An average of 4.8 sessions was needed to relieve the symptoms and to provide a functional extremity. The authors attributed the clinical results to the early stage of CRPS type 1 on initiating treatment and the increased dosing of methylprednisolone when compared to previous studies.[73]

Acetaminophen

Because of its known analgesic effects, acetaminophen (APAP) (paracetamol) has been studied as an adjuvant to local anesthetics in patients undergoing hand surgery under IVRA. Sixty patients undergoing hand surgery were randomized into three groups. All groups received IVRA lidocaine (3 mg/kg) diluted with normal saline to a total volume of 40 mL. Group 1 received IVRA lidocaine plus intravenous saline. Group 2 received IVRA lidocaine and an APAP (300 mg) admixture plus intravenous saline; and group 3 received IVRA lidocaine plus intravenous APAP (300 mg). Sensory and motor block onset time, tourniquet pain, and analgesic use were assessed during surgery. After tourniquet deflation, VAS scores at 1, 2, 4, 6, 12, and 24 hours; the time to first analgesic requirement; total analgesic consumption in first 24 hours; and side effects were noted. There was no significant difference in the onset of sensory blocks between the three groups; however, the duration of sensory block was significantly longer in group 2. Motor block onset time was shorter and duration of motor block was longer in group 2. Tourniquet pain was reduced and the quality of anesthesia scores as reported by the anesthesiologist, who was blinded to the study drug, was also significantly higher in group 2. There was no demonstrable decrease in postoperative pain scores between the three groups. The authors did point out the arbitrary dosing of APAP (300 mg) as a deficiency of the study. Further dose-ranging studies are required to optimize the dosing of paracetamol when used as an adjuvant to lidocaine for IVRA.[74]

Another study evaluating the effect of APAP, when added to lidocaine in IVRA, on sensory and motor block onset time, tourniquet pain, and postoperative analgesia found a shorter sensory block onset time; delayed tourniquet pain onset time; and reduced postoperative pain scores and analgesic consumption. The dosing of acetaminophen was identical to the earlier study (0.5% lidocaine diluted with 300 mg of intravenous APAP to a total volume of 40 mL). The control group received

0.5% lidocaine diluted with 0.9% normal saline to a total volume of 40 mL. Time of onset and duration of motor block were not assessed in this study. In an attempt to explain the faster onset time of the sensory block in the lidocaine-acetaminophen group, the authors investigated the pH of the lidocaine-acetaminophen mixture and found that the pH value of this mixture was 5.88, which was lower than the pH of the lidocaine–normal saline mixture, which was 6.16. This contradicts the fact that the higher the pH of the local anesthetic, the greater the nerve penetration and hence faster onset of neural blockade. In this study, the authors attributed the faster onset of sensory blockade to possible antinociceptive effects of APAP at peripheral sites.[75]

Nitroglycerine

The effect of nitroglycerine (NTG), when added to lidocaine for IVRA, was studied in a prospective, randomized, double-blind study.[76] Thirty patients undergoing hand surgery were randomly assigned to two groups. The control group (group C, n = 15) received a total dose of 40 mL with 3 mg/kg of lidocaine diluted with normal saline, and the NTG group (group NTG, n = 15) received an additional 200 μg NTG. Shortened sensory and motor block onset times; prolonged sensory and motor block recovery times; decreased tourniquet pain; and improved quality of anesthesia were noted in the NTG group. Postoperative analgesic requirements were also significantly decreased in the NTG group. The authors attributed the shorter onset time of sensory and motor blockade to the vasodilatory effects of NTG that promotes the distribution of local anesthetic to the nerves. Some of the other mechanisms that may contribute to the improved analgesia with NTG may include the metabolism of NTG to nitric oxide, which in turn causes an increase in the intracellular concentration of cyclic guanosine monophosphate, which produces pain modulation in the central and peripheral nervous system.[77,78] Nitric oxide generators have also been shown to induce anti-inflammatory effects and analgesia by blocking hyperalgesia and the neurogenic component of inflammatory edema by topical application.[79]

Midazolam

Midazolam has been shown to hasten the onset of sensory and motor blockade and improve postoperative analgesia when added to bupivacaine for brachial plexus block.[80,81] Midazolam was shown to have analgesic effects mediated through GABA (γ-aminobutyric acid) receptors in the spinal cord in animal studies.[82] GABA receptors have also been found in peripheral nerves.[83–85] Midazolam was also shown to reduce A-delta and C-fiber activity.[86]

In a study designed to evaluate the effect of midazolam when added to lidocaine for IVRA, 40 patients undergoing hand surgery were randomly assigned to two groups. The control group received 3 mg/kg lidocaine 2% diluted with saline to a total volume of 40 mL, and the midazolam group received an additional 50 μg/kg of midazolam. There were no statistically significant differences in the sensory and motor block onset and recovery times between the two groups. However, a subjective pain assessment score using the numeric rating scale (NRS) for tourniquet pain was significantly decreased in the midazolam group. Anesthesia quality as evaluated by the patient and the surgeon was also significantly better in the midazolam group. Postoperative NRS pain scores were also significantly lower in the midazolam group for the initial 2 hours postoperatively. However, postoperative sedation scores were also higher in the midazolam group. The authors indicated that the enhanced postoperative analgesia after tourniquet deflation may be explained by the systemic effect of midazolam in addition to the peripheral analgesic effect.[87]

Another study involved 60 patients undergoing hand surgery randomized into two groups, with the control group and the midazolam group receiving IVRA with exactly identical dosing of lidocaine and midazolam as in the previous study. This study showed shortened sensory and motor block onset times and prolonged sensory and motor block recovery times in addition to decreased tourniquet pain scores and postoperative pain scores.[88] The conflicting findings with regard to the sensory and motor block onset times may warrant further studies with greater sample sizes to resolve the discrepancy. At present, all that can be stated is that midazolam appears to hold some promise as an adjunct to local anesthetic when used for upper extremity IVRA.

Ketamine

Ketamine is a potent analgesic agent whose principal mechanism of action is antagonism of N-methyl-D-aspartate (NMDA) glutamate receptors that play a crucial role in the pain-processing mechanism at the level of the spinal cord. Animal studies have indicated the presence of NMDA receptors in peripheral nerves.[89] Ketamine has also been shown to produce transient blockade of peripheral nerve sodium and potassium channels.[90] The possible presence of NMDA receptors in peripheral nerves as well as the ability of ketamine to block sodium channels locally points to a possible peripheral site of action for ketamine, in addition to its well-established central sites of action.

Ketamine was studied as an adjuvant in lidocaine IVRA in patients undergoing hand surgery and its efficacy in controlling intraoperative tourniquet pain, postoperative analgesia, and side effects was compared to the same dosage of ketamine administered systemically. In this randomized, double-blind, systemic control study, 40 patients undergoing outpatient hand surgery were randomized into two groups. In group "IVRA," 0.1 mg/kg ketamine in 1 mL of normal saline was added to the IVRA lidocaine, and 1 mL of normal saline was administered via a peripheral intravenous line. In group "systemic," 1 mL of normal saline was added to the IVRA syringe, and 0.1 mg/kg ketamine in 1 mL of normal saline was administered via a peripheral intravenous line. Both groups received 40 mL of 0.5% lidocaine for IVRA. The study found no difference between the groups in the study parameters mentioned, and the authors concluded that IVRA ketamine and systemic intravenous ketamine were indistinguishable in terms of intraoperative tourniquet pain and postoperative analgesic consumption. The speed of onset and the duration of sensory and motor block were not measured in this study.[91]

Another study comparing the efficacy of ketamine and clonidine when they are added separately to 40 mL of 0.5% lidocaine for IVRA in patients undergoing hand or forearm surgery found delayed onset of tourniquet pain and decreased analgesic consumption in both these groups when compared to the control group receiving 40 mL of 0.5% lidocaine with saline added to it. Ketamine had a more potent effect on the study parameters when compared to clonidine. In this study involving 45 patients randomized into three groups, IVRA was performed using 40 mL of 0.5% lidocaine and saline, 1 μg/kg clonidine, or 0.1 mg/kg ketamine.[92]

Specific IVRA Treatments for CRPS

Adrenergic blocking agents or antagonists, particularly those effective at the α receptor, have shown promise in the treatment of CRPS, particularly when these agents are used for IVRA. Other adrenergic adjuvants release and then subsequently prevent the reuptake of norepinephrine at the neurovascular junction. Their use in CRPS is intuitive because the pathophysiology of the disease is suspected to include the α receptor and to be mediated by norepinephrine. However, there is significant controversy regarding this topic, particularly when current research is compared with the findings of studies conducted almost 40 years ago. Guanethidine, reserpine, and bretylium have all been evaluated for IVRA for CRPS. When 15 mg guanethidine were added to 0.5% prilocaine in a group of 57 patients with CRPS of the upper extremity and hand, the guanethidine was not found more effective than normal saline in treating allodynia and burning pain of CRPS following distal radius fractures.[93]

These findings corroborated work done in a double-blind, randomized, multicenter study 7 years earlier. Sixty patients with Reflex sympathetic dystrophy (RSD)/causalgia received four IVRA blocks at 4-day intervals with either guanethidine or placebo in 0.5% lidocaine. Long term, there was no difference noted between the placebo group and the guanethidine group, and only 35% of patients overall in all groups had a resolution of their problem.[94]

Bretylium has been used as well in CRPS. In a randomized, controlled trial, 0.5% lidocaine was compared with the same local anesthetic to which bretylium 1.5 mg/kg were added. A decrease in pain of 30% or more was considered significant. The bretylium-local group had pain relief for 20 ± 17.5 days, as opposed to the lidocaine-only group, wherein analgesia persisted for only 2.7 ± 3.7 days. The bretylium was far superior to the local anesthetic alone in treating CRPS in this study.[95]

Intravenous regional anesthesia with bretylium was utilized to demonstrate that a reduction in sympathetic tone of exercising forearm muscles would increase blood flow, reduce muscle acidosis, and attenuate reflex responses. IVRA with bretylium increased blood flow as well as oxygen consumption in the exercising forearm, although both venous potassium and hydrogen ion content were elevated during the exercise phase, implying that reflex effects were unaffected by bretylium block.[96]

COMPLICATIONS

Complications due to IVRA may be classified either as drug or equipment (ie, tourniquet) related. Drug-related complications depend on the agents, including local anesthetics and adjuvants, being administered directly into the vascular system. Equipment-related complications include all devices and techniques used to isolate the vascular space from the systemic circulation. Inadvertent or unintentional deflation of the cuff, cuff failure, a sudden increase in venous pressure within the occluded tissue to a level higher than cuff pressure, and an intact interosseous circulation may all contribute to complications of IVRA.

Lidocaine is the most commonly utilized local anesthetic for IVRA and is therefore the agent about which most complications have been reported. Fortunately, lidocaine does not accumulate to any great extent at sodium channels at therapeutic plasma concentrations, and because it both rapidly binds to and dissociates from the channel, toxic accumulations of the drug at the channel are atypical.[97,98] Excessive plasma concentrations of lidocaine, as are associated with intravenous boluses of large doses with a faulty tourniquet system, result in peripheral vasodilation and diminished cardiac contractility, usually seen clinically as hypotension. The usual onset of IVRA using lidocaine in 0.5% concentrations is rapid (about 4.5 ± 0.3 minutes), and the termination of anesthesia once the tourniquet has been deflated is also rapid (5.8 ± 0.5 minutes).[99] Usually, there are no signs or symptoms of cardiovascular or central nervous system toxicity if the tourniquet is deflated at least 30 minutes after the drug is injected into the venous system, although tinnitus has been noted at the 20- and 27-second postdeflation periods following standard inflation times.[100]

However, a literature search in the American National Library of Medicine's PubMed®, in Embase®, and in MEDLINE®, spanning the period from 1950 to 2007 revealed 24 cases of seizures, with seizures reportedly occurring in 12 cases while the cuff was still inflated and in 9 cases after the cuff was deflated. Information was not available in three cases. Seizures occurring during tourniquet inflation were reported with tourniquet pressure exceeding the initial systolic arterial blood pressure by 150 mm Hg. Seizures occurring after tourniquet deflation were reported with tourniquet times as long as 60 minutes and with a delay of up to 10 minutes after tourniquet deflation. The lowest dose of local anesthetic associated with a seizure was 1.4 mg/kg for lidocaine, 4 mg/kg for prilocaine, and 1.3 mg/kg for bupivacaine.[101]

Although about 70% of the administered lidocaine dose remains within the tissues of the isolated limb after tourniquet deflation, the remaining 30% enters the systemic circulation during the ensuing 45 minutes.[98] Much more drug is released from the tissues of the isolated limb into the circulation after tourniquet deflation if the limb is inadvertently exercised, emphasizing the importance of maintaining the previously anesthetized extremity quiescent for some time immediately following tourniquet deflation.

The other commonly utilized local anesthetic used for IVRA, prilocaine, is associated with the formation of methemoglobin (MetHb), which occurs about 4 to 8 hours after its administration.[97] Fortunately, significant methemoglobinemia has not been reported when prilocaine has been used for IVRA. Prilocaine (0.5%) administered for IVRA has an onset of analgesia of about 11 minutes (±6.8 minutes), and termination of analgesia following tourniquet deflation averages 7.2 minutes (±4.6 minutes).[25] The use of this agent for IVRA appears to be extraordinarily safe. Indeed, in one survey of 45,000 prilocaine IVRA blocks, there were no serious side effects and no deaths from using this drug via this technique.[102] In terms of effectiveness, prilocaine seems to be equivalent to lidocaine when used for IVRA.

When opioids are administered in combination with local anesthetics for IVRA in an attempt to prolong analgesia following cuff deflation, occasional side effects typically attributed to opioids administered systemically may be noted following cuff deflation. These include nausea, vomiting, and mild sedation.[48,51] When neurovascular blocking drugs are administered in conjunction with local anesthetics to improve surgical conditions in patients undergoing fracture reduction, there have been no reports of complications from these adjuvants.

Clinical Pearls

- An intact tourniquet system is essential for the successful and safe performance of IVRA.
- Unintentional deflation of the tourniquet or the presence of a vascular communication even with an intact, functioning tourniquet may result in severe systemic toxicity.
- When the surgical procedures is shorter than 30 minutes, intermittent cuff deflation and inflation may effectively prolong the time to achieve peak arterial concentrations of the local anesthetic but may not be entirely reliable in minimizing toxicity due to release of local anesthetic into the circulation.[103]
- The tourniquet should not be deflated until at least 30 minutes has elapsed from the time local anesthetic (and adjuvants, if used) is injected into the isolated venous system.

In addition, the tourniquet itself may be a source of complications because it may cause ischemic pain and discomfort. Systemic hypertension may result from tourniquet inflation that is sustained or prolonged. Equipment misuse or malfunction is an important, and avoidable, source of complications due to this technique. Even an intact, fully functional tourniquet may be associated with leakage of administered drugs from a supposedly isolated extremity into the systemic circulation.[104,105]

Lower limb IVRA has an almost 100% incidence of local anesthetic leakage from beneath the tourniquet, versus about a 25% incidence for upper extremity block.[106] As a corollary to this leakage phenomenon, the use of IVRA for lower extremity analgesia has an associated high incidence of poor-quality block (almost 40% in one prospective study).[107] Drug may leak past an apparently fully functioning cuff and gain access to the systemic circulation via the interosseous circulation, which is not affected by the occlusion of muscles, soft tissues, and the accompanying vascular channels included therein. This factor has been recognized for almost 50 years, yet it does not appear to be significant in the production of complications due to IVRA.[108]

Tourniquet deflation after IVRA is associated with signs and symptoms of systemic local anesthetic toxicity, ranging from mild events related to the central nervous system, such as tinnitus and perioral numbness, to seizures, and finally to devastating cardiovascular collapse. These correlate with local anesthetic concentrations in arterial blood and not to venous concentrations.[103,109]

Another complication due to IVRA is tourniquet pain, which not uncommonly occurs if a double pneumatic device is not utilized[105] (Figures 21–1 and 21–9). We recommend the use of such a tourniquet for any procedure performed using IVRA that is expected to last longer than 30 minutes. Even when such guidelines are followed, however, untoward events occur following tourniquet deflation after a "safe" time interval.[101]

Very rare, isolated reports of neurologic complications, including damage to the median, ulnar, and musculocutaneous nerves, are associated with IVRA.[110] The cause of such complications appears to be direct pressure of the tourniquet applied to these nerves, which subsequently exhibit histologic changes resembling crush injuries. It is recommended that tourniquet time not exceed 2 hours to reduce the likelihood of capillary and muscle damage secondary to tissue acidosis.[110,111]

Compartment syndrome may occur rarely following IVRA, especially when IVRA is used for reduction of long-bone lower extremity fractures, and may be due both to the large volume of local anesthetic injected to effect analgesia and to inadequate or incomplete exsanguination of the limb prior to performing the block.[112,113] There is a case report of this complication following inadvertent injection of hypertonic saline solution when local anesthetic was intended to be injected.[114]

A 33-year-old pregnant patient undergoing IVRA for endoscopic carpal tunnel release experienced a severe episode of phantom limb sensation after the injection of the local anesthetic. The symptoms resolved on dissipation of the IVRA.[115] There is one report of the devastating necessity for amputation of the arm in a 28-year-old patient whose radial and ulnar arteries thrombosed following IVRA after a brief tourniquet occlusion time.[116] Whether this resulted from unsuspected intraarterial injection of drug, a drug administration error, or perhaps an idiosyncratic drug reaction is purely speculative. Three cases including either death or permanent brain damage associated with IVRA were reported in the ASA Closed Claims Project for the years 1980 to 1999. Specifics of these cases are not known.[117]

FIGURE 21–9. The double tourniquet system is placed on the proximal right thigh, in preparation for IVRA of the right lower extremity.

Local Anesthetic Toxicity

Although lidocaine is the most commonly utilized local anesthetic agent for IVRA in the United States, in Europe prilocaine 0.5% is more routinely chosen. Prilocaine, however, is metabolized to orthotoluidine, an oxidizing compound capable of converting hemoglobin to MetHb. This is usually only of concern when the dose of prilocaine exceeds 600 mg, which, even for lower extremity IVRA in which volumes as large as 100 mL are utilized, should not be attained (ie, 100 mL × 0.5% prilocaine = 500 mg).

Clinical Pearls

- Severe methemoglobinemia is a medical emergency requiring prompt recognition and appropriate treatment.
- A good history and high level of suspicion are required to make the diagnosis.
- For methemoglobinemia due to drug exposure, traditional first-line therapy consists of the infusion of methylene blue (MB).
- Dextrose should be given because the major source of NADH (reduced [hydrogenated] nicotinamide adenine dinucleotide) in the red blood cells is the catabolism of sugar through glycolysis. Dextrose is also necessary to form NADPH (reduced [hydrogenated] NAD phosphate) through the hexose monophosphate shunt, which is necessary for MB to be effective.
- The dose of MB is 1 to 2 mg/kg IV over 5 minutes (total dose should not exceed 7–8 mg/kg).
- MB can cause dyspnea, chest pain, or hemolysis.
- MB provides an artificial electron transporter for the reduction of MetHb via the NADPH-dependent pathway. The response is rapid; the dose may be repeated in 1 hour if the level of MetHb is still high 1 hour after the initial infusion.
- Rebound methemoglobinemia may occur up to 18 hours after MB administration due to prolonged absorption of lipophilic agents (benzocaine) from adipose tissue. It is reasonable to perform serial measurements of MetHb levels following treatment with MB. MB should not be administered to patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency because the reduction of MetHb by MB is dependent on NADPH generated by G6PD (hemolysis). An alternative treatment for these patients is ascorbic acid (2 mg/kg).
- Blood transfusion or exchange transfusion may be helpful in patients who are in shock. Hyperbaric oxygen has been used with anecdotal success in severe cases.

Deflation of the tourniquet after surgery is a critical step in minimizing the possibility of toxicity associated with IVRA. First, it is absolutely mandatory that the tourniquet not be deflated unless at least 30 minutes have elapsed since the injection of the local anesthetic,[33] even if the duration of surgery or of the manipulation has been brief. If the surgery is brief, and the patient needs to recover in the PACU, it is acceptable to clamp off the distal tourniquet while it is inflated, remove the patient from the operating area (with the tourniquet inflated), and transfer the patient to a monitored care setting. At no time should anyone remove the clamped tourniquet, however, until the 30-minute period commencing with the injection of local anesthetic solution has elapsed. At such time, the patient should be continually monitored for at least 15 minutes following tourniquet unclamping in the PACU. At least one case of cardiac arrest has been reported when the tourniquet was released soon after the injection of local anesthetic, where the duration of surgery was extremely short.[118]

Second, it is absolutely essential that the tourniquet deflation be accomplished in a "cyclical" fashion as follows: The cuff is deflated (after a minimum of 30 minutes) and is immediately reinflated. The patient is observed or questioned carefully for the occurrence of symptoms associated with local anesthetic toxicity, such as tinnitus, light-headedness, metallic taste in the mouth, and so on. Obviously, signs of stimulation of the central nervous system may also represent local anesthetic toxicity and must also be sought. If there are no such signs or symptoms after about 1 minute, the cuff is once again deflated and again immediately reinflated for a period of about 1 to 2 minutes, with the patient being observed and queried for systemic local anesthetic toxicity. If none appears by this time, the tourniquet may be safely deflated and removed from the extremity. The safety of such cycled deflating/reinflating is that, with each deflation, only a small fraction of the administered (and unbound) local anesthetic is allowed to enter the systemic circulation, minimizing the possibility of a sudden, sustained increase in the blood level of the local aneshtetic.[103]

SUMMARY

Intravenous regional anesthesia is a valuable adjunct to the armamentarium of clinicians in any specialty dealing with the acutely injured patient. The simplicity of the technique and the relative safety (if strict adherence to the previously listed protocol is maintained) make it an attractive alternative to brachial plexus block (for upper extremity surgery or manipulation) and spinal or epidural block (for lower extremity surgery or manipulation). Simply being able to identify and access a peripheral vein and apply a pneumatic tourniquet make this one of the most "user-friendly" regional block modalities in clinical practice. There is no requirement for being facile with a peripheral nerve stimulator or interpreting images obtained from an ultrasound machine. One of the only potential disadvantages associated with IVRA is the finite duration of anesthesia/analgesia associated with its use. A relative inability to prolong analgesia long into the postprocedure period detracts from its utility. For those occasions, continuous catheter insertion and maintenance by way of plexus anesthesia ensures offering an attractive alternative.

PART 3-C

NEURAXIAL ANESTHESIA

SECTION 1 Spinal Anesthesia

CHAPTER 22

Neuraxial Anatomy (Anatomy Relevant to Neuraxial Anesthesia)

Steven L. Orebaugh and Hillenn Cruz Eng

INTRODUCTION

The vertebral column forms part of the axis of the human body, extending in the midline from the base of the skull to the pelvis. Its four primary functions are protection of the spinal cord, support of the head, provision of an attachment point for the upper extremities, and transmission of weight from the trunk to the lower extremities. Pertinent to regional anesthesia, the vertebral column serves as the landmark for a wide variety of regional anesthesia techniques. It is important, therefore, that the anesthesiologist be able to develop a three-dimensional mental image of the structures comprising the vertebral column.

ANATOMIC CONSIDERATIONS

The vertebral column consists of 33 vertebrae (7 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 4 coccygeal segments) (Figure 22–1). In the embryonic period, the spine curves into a C shape, forming two primary curvatures with their convex aspect directed posteriorly. These curvatures persist through adulthood as the thoracic and sacral curves. The cervical and lumbar lordoses are secondary curvatures that develop after birth as a result of extension of the head and lower limbs when standing erect. The secondary curvatures are convex anteriorly and augment the flexibility of the spine.

Vertebrae

A typical vertebra consists of a vertebral **arch** posteriorly and a **body** anteriorly. This holds true for all vertebrae except C1. Two **pedicles** arise on the posterolateral aspects of each vertebra and fuse with the two **laminae** to encircle the **vertebral foramen**[1] (Figures 22–2A, 22–2B). These structures form the vertebral canal, which contains the spinal cord, spinal nerves, and epidural space. Fibrocartilaginous disks containing the **nucleus pulposus**, an avascular gelatinous body surrounded by the collagenous lamellae of the annular ligament, join the vertebral bodies. The **transverse processes** arise from the laminae and project laterally, whereas the **spinous process** projects posteriorly from the midline union of the laminae (Figures 22–2A, 22–2B). The spinous process is frequently bifid at the cervical level and serves as an attachment for muscles and ligaments.

C1 (**atlas**), C2 (**axis**), and C7 (**vertebra prominens**) are described as *atypical* cervical vertebrae due to their unique features. C1 is a ringlike bone that has no body or spinous process. It is formed by two lateral masses with facets that connect anteriorly to a short arch and posteriorly to a longer, curved arch. The anterior arch articulates with the dens, and the posterior arch has a groove where the vertebral artery passes (Figure 22–3A). The odontoid process (dens) of C2 protrudes superiorly, hence the name axis (Figure 22–3B). Together, the atlas and axis form the axis of rotation for the atlantoaxial joint. The C7 (vertebra prominens) has a long, nonbifid spinous process that serves as a useful landmark for a variety of regional

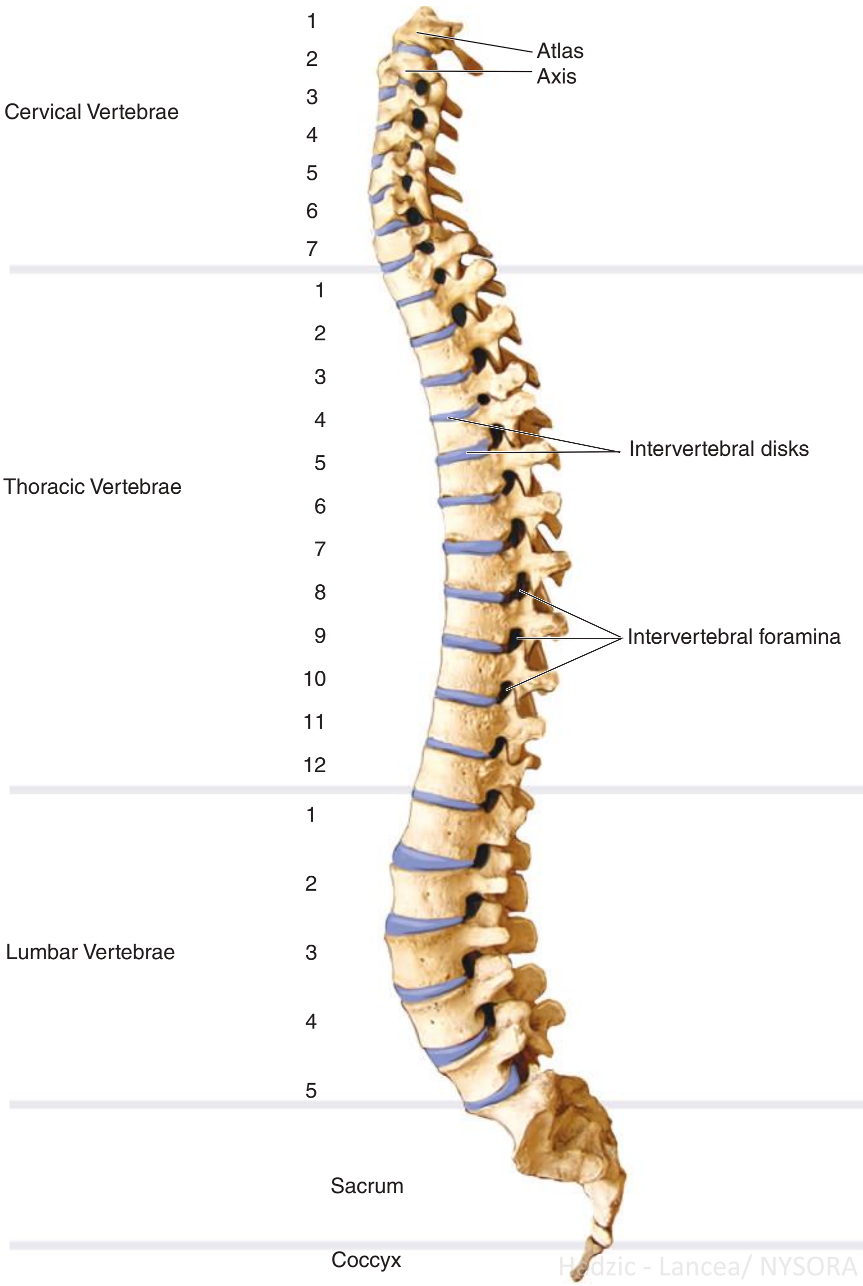

FIGURE 22–1. The vertebral column and the curvatures of the adult spine, lateral view.

anesthesia procedures (Figure 22–3C). The C7 transverse process is large and has only one posterior tubercle.

The interlaminar spaces in the thoracic spine are narrow and more challenging to access with a needle due to overlapping laminae. In contrast, the laminae of the five lumbar vertebrae do not overlap. The interlaminar space between adjacent lumbar vertebrae is rather large.[2]

Vertebral **facet** (**zygapophyseal**) **joints** articulate posterior elements of adjacent vertebrae. The junction of the lamina and pedicles gives rise to **inferior** and **superior articular processes** (Figures 22–2A, 22–2B). The inferior articular process protrudes caudally and overlaps the inferiorly adjacent vertebra's superior articular process. This alignment is important to understand when performing interventional pain procedures such as facet joint injections, intra-articular steroid injections or radio-frequency denervation. Joint surfaces in the cervical spine are oriented halfway between the axial and coronal planes. This alignment allows an ample degree of rotation, flexion, and extension but little resistance to backward and forward shearing forces. Facet joints in the thoracic region are oriented in a more coronal plane, which provides greater protection against shearing forces but reduced rotation, flexion, and extension.

In the lumbar spine, joint surfaces are curved, with a coronal orientation of the anterior portion and a sagittally oriented posterior portion.[3] Thoracic facets are located anterior to the

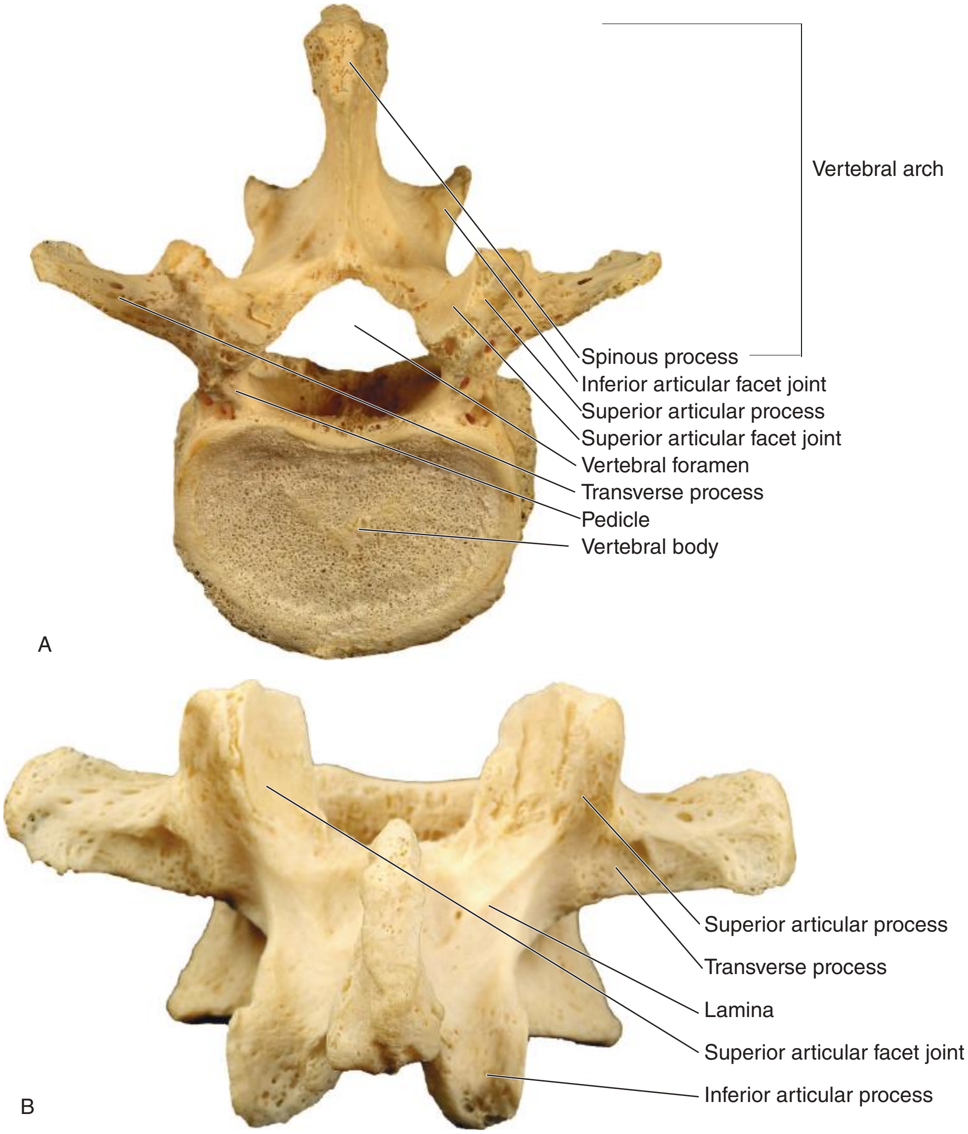

FIGURE 22–2. A typical vertebra. **A:** Superior view of the L5 vertebra. **B:** Posterior view of the L5 vertebra.

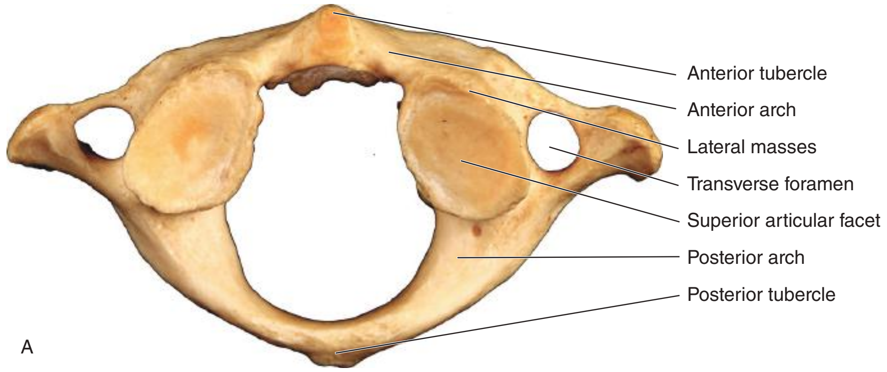
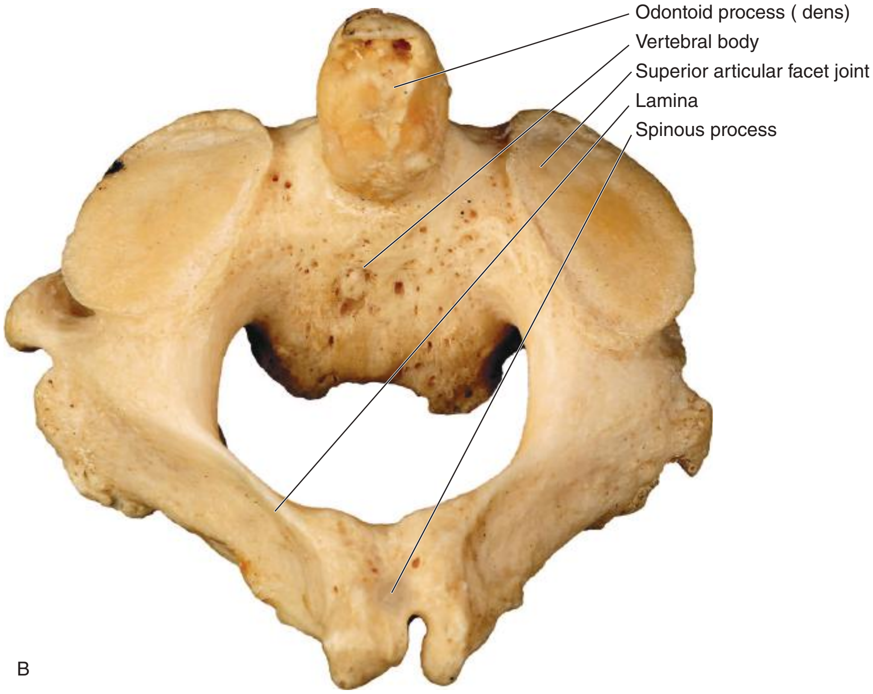
transverse processes, whereas cervical and lumbar facets are located posterior to their transverse processes. Five sacral vertebrae fuse to form the wedge-shaped **sacrum**, which connects the spine with the iliac wings of the pelvis[4] (Figures 22–4A, 22–4B). In childhood, the sacral vertebrae are connected by cartilage, which progresses to osseous fusion after puberty, with only a narrow remnant of sacral disk remaining in adulthood. Fusion is generally complete through the S5 level, although there can be complete lack of any posterior bony roof over the sacral vertebral canal. The **sacral hiatus** is an opening formed by the incomplete posterior fusion of the fifth sacral vertebra. It lies at the apex of the coccyx, which is formed by the union of the last four vertebrae (Figure 22–4C). This hiatus provides a convenient access to the caudal ending of the epidural space, especially in children. The **sacral cornu** are bony prominences on each side of the hiatus that are easily palpated in small children and serve as landmarks for a caudal epidural block.

Intervertebral Ligaments

The vertebral column is stabilized by a series of ligaments. The **anterior** and **posterior longitudinal ligaments** run along the anterior and posterior surfaces of the vertebral bodies, respectively, reinforcing the vertebral column. The **supraspinous ligament**, a heavy band that runs along the tips of the spinous processes, becomes thinner in the lumbar region (Figure 22–5). This ligament continues as the **ligamentum nuchae** above T7 and attaches to the occipital external protuberance at the base of the skull.[5] The **interspinous ligament** is a narrow web of tissue that attaches between spinous processes; anteriorly it fuses with the ligamentum flavum and posteriorly with the supraspinous ligament (Figure 22–5).

The **ligamentum flavum** is a dense, homogenous structure, composed mostly of elastin which connects the lamina of adjacent vertebrae[5,6] (Figure 22–5). The lateral edges of the ligamentum flavum surround facet joints anteriorly, reinforcing their





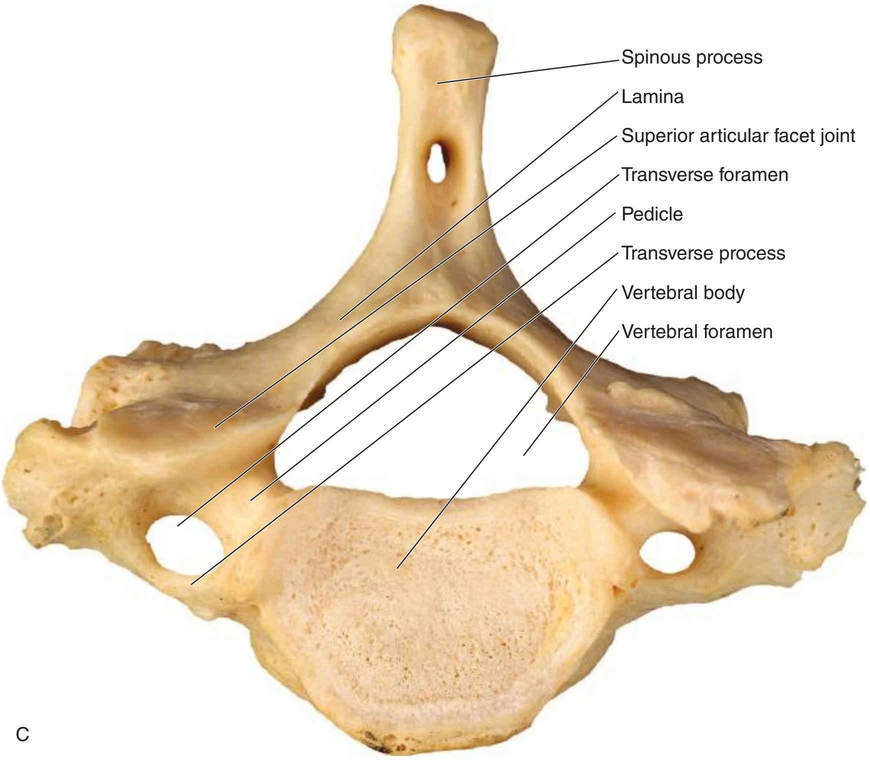


FIGURE 22–3. The atypical vertebrae. **A:** Superior view of the C1 vertebra (atlas). **B:** Superior view of the C2 vertebra (axis) with a bifid spinous process. **C:** Superior view of the C7 vertebra; the spinous process is nonbifid.

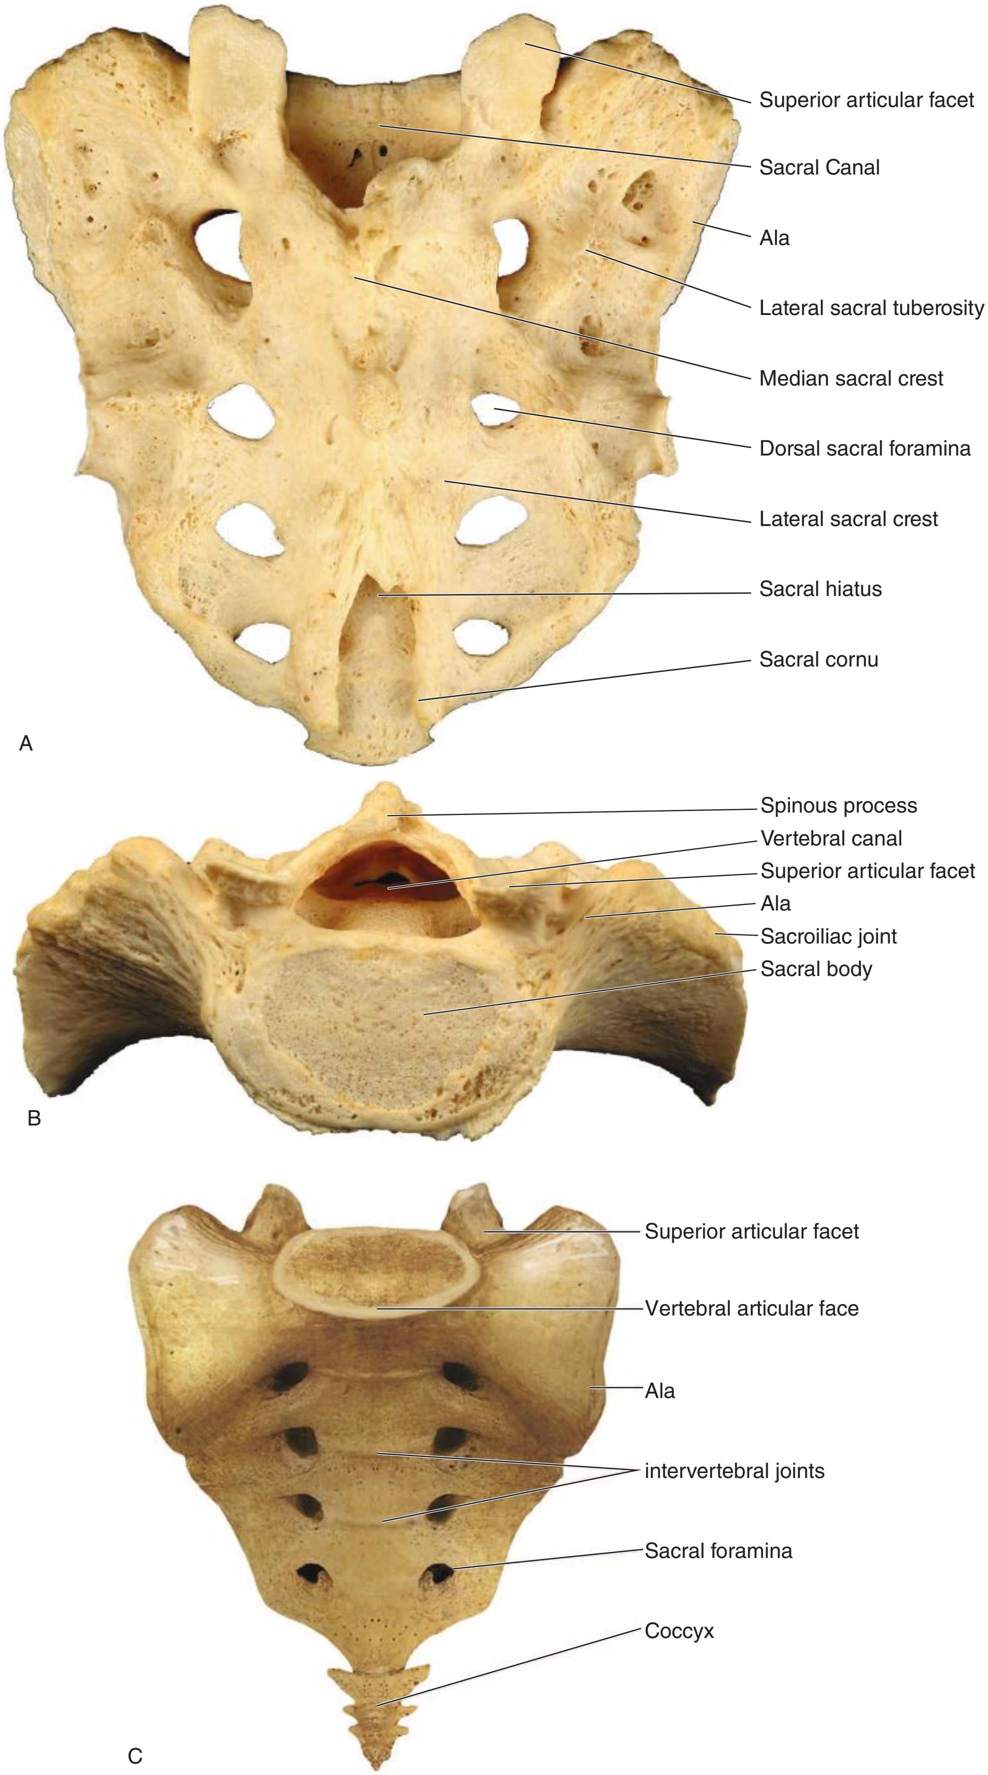

FIGURE 22–4. The sacrum and coccyx. **A:** Posterior view of the sacrum; the sacrum curves anteriorly proximal to its narrowing tip where it articulates with the coccyx. **B:** The base of the sacrum is directed upward and forward. **C:** Anterior view of the coccyx.

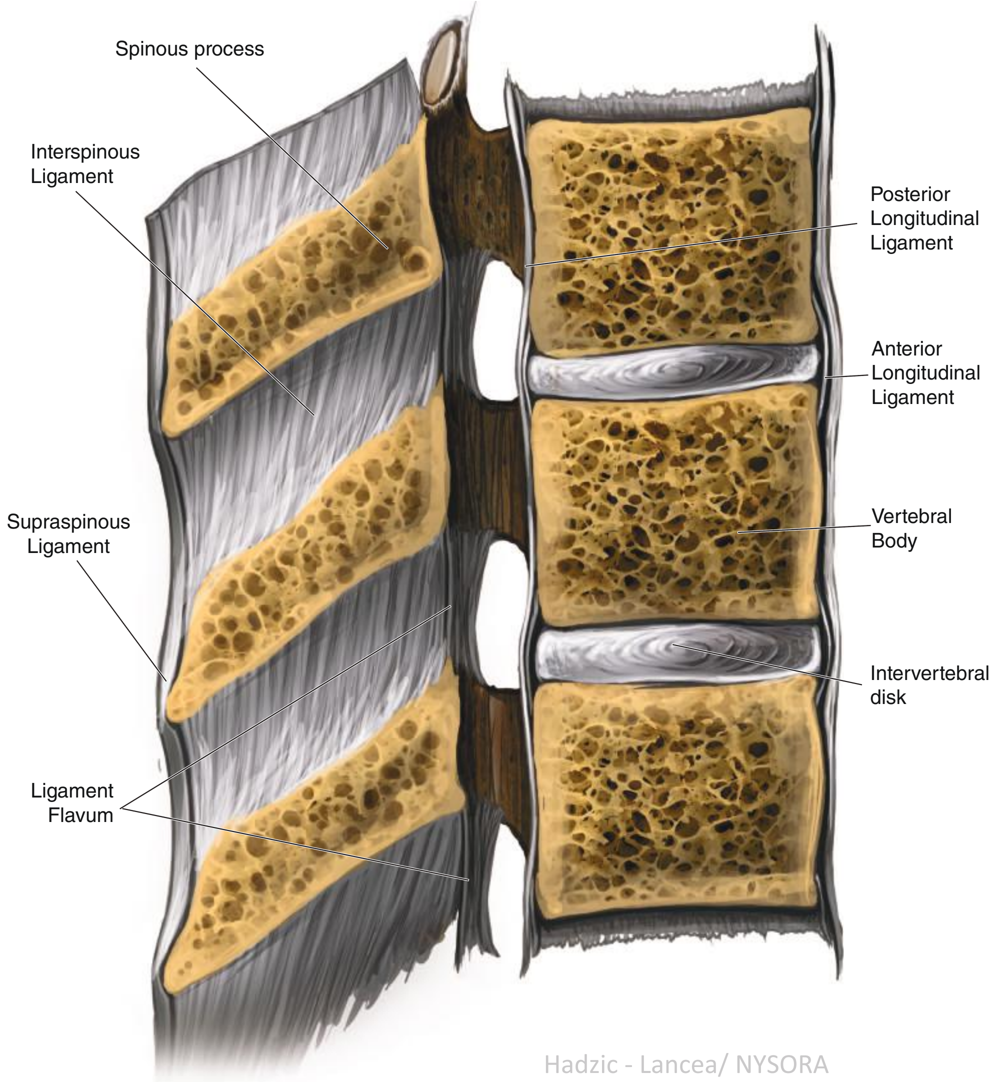

FIGURE 22–5. A cross-sectional view of the vertebral canal with the intervertebral ligaments, vertebral body, and spinous process.

joint capsule. When a needle is advanced toward the epidural space, there is an easily perceptible *increase in resistance* when the ligamentum flavum is encountered. More importantly for the practice of neuraxial anesthesia, a perceptible, sudden *loss of resistance* is encountered when the tip of the needle passes through the ligamentum and enters the epidural space.

The ligamentum flavum consists of right and left halves that join at an angle of less than 90°. Importantly, this midline fusion may be absent to a variable degree depending on the vertebral level.[2] These fusion gaps allow for veins to connect to vertebral venous plexuses.[7] Of note, the fusion gaps are more prevalent at cervical and thoracic levels. Yoon et al reported that midline gaps between C3 and T2 occur in 87%–100% of individuals. The incidence of the midline gap decreases at lower vertebral levels, with T4–T5 the lowest (8%).[7] In theory, a midline gap poses a risk of failure to recognize a loss of resistance at the cervical and high thoracic levels when using the midline approach, resulting in an inadvertent dural puncture.

The ligamentum flavum is thinnest in the cervical and upper thoracic regions and thickest in the lower thoracic and lumbar regions.[8,9] As a result, resistance to needle advancement is easier to appreciate when a needle is introduced at a lower level (eg, lumbar).[7,8] At the L2–L3 interspace, the ligamentum flavum is 3- to 5-mm thick. At this level, the distance from the ligamentum to the spinal meninges is 4–6 mm.[6] Consequently, a midline insertion of an epidural needle at this level is least likely to result in an inadvertent meningeal puncture with epidural anesthesia-analgesia.

The lateral wall of the vertebral canal has gaps between consecutive pedicles known as **intervertebral foramina** (Figure 22–1A). Because the pedicles attach more cephalad of the middle of the vertebral body, the intervertebral foramina are centered opposite the lower half of the vertebral body, with the vertebral disk at the caudal end of the foramen. As a consequence, the borders of the intervertebral foramina are the pedicle at the cephalad and caudal ends, the vertebral body (cephalad) and the disk (caudally) on the anterior aspect, a portion of the next vertebral body most inferiorly, and posteriorly the lamina, facet joint, and ligamentum flavum.

Spinal Meninges

The spinal cord is an extension of the medulla oblongata. It has three covering membranes: the dura, arachnoid, and pia maters (Figure 22–6A). These membranes concentrically divide the vertebral canal into three distinct compartments: the epidural, subdural, and subarachnoid spaces. The epidural space contains fat, epidural veins, spinal nerve roots, and connective tissue (Figure 22–6B) The subdural space is a "potential" space between the dura and the arachnoid and contains a serous fluid. The subdural compartment is formed by flat neuroepithelial cells that have long interlacing branches. These cells are in close contact with the inner dural layers. This space can be expanded

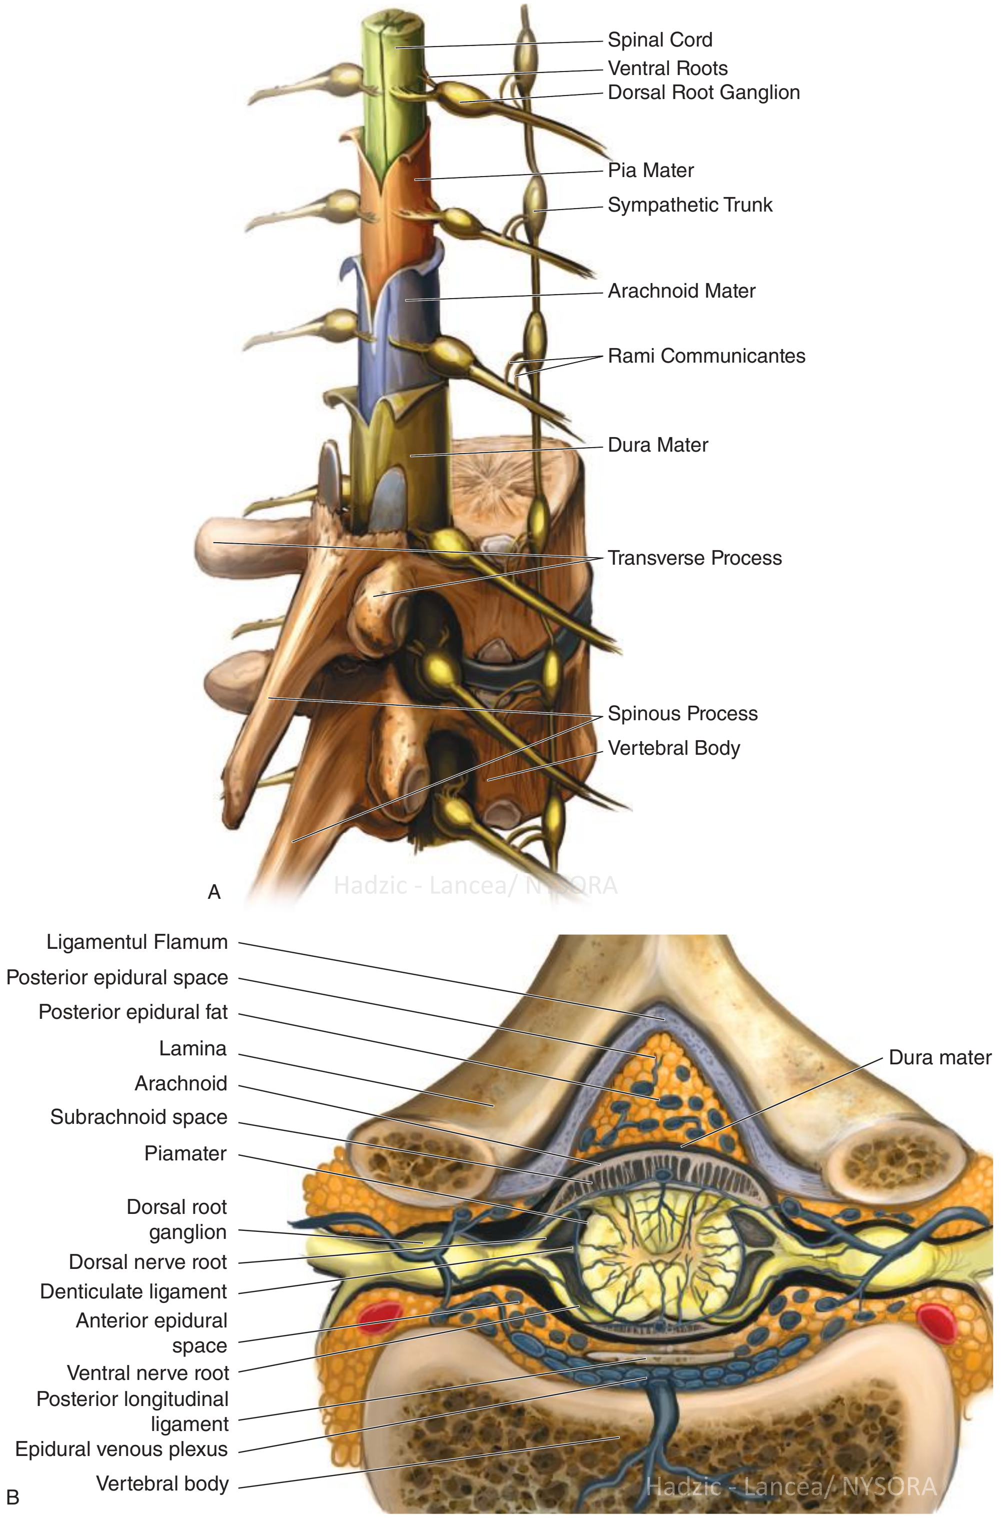

FIGURE 22–6. A. Sagittal view of the spinal cord with meningeal layers, dorsal root ganglia, spinal nerves, and sympathetic trunk. **B.** Cross-sectional view of the spinal cord depicting the ligamentum flavum in respect to the posterior epidural space. Notice the close proximity of the posterior epidural space to the subarachnoid space.

by shearing the neuroepithelial cell layer connections with the collagen fibers of the dura mater. This expansion of the subdural space can be caused mechanically by injecting air or a liquid such as contrast media or local anesthetics, which, by applying pressure in the space, separates the cell layers.[10] The subarachnoid space is traversed by threads of connective tissue extending from the arachnoid mater to the pia mater. It contains the spinal cord, dorsal and ventral nerve roots, and cerebrospinal fluid (CSF). The subarachnoid space ends at the S2 vertebral level.

Spinal Cord

There are eight cervical neural segments. The eighth segmental nerve emerges between the seventh cervical and first thoracic vertebrae, whereas the remaining cervical nerves emerge above their same-numbered vertebrae. Thoracic, lumbar, and sacral nerves emerge from the vertebral column below the same-numbered bony segment[1] (Figure 22–6A). Anterior and posterior spinal nerve roots arise from rootlets along the spinal cord. The roots of the upper and lower extremity plexuses (brachial and lumbosacral) are significantly larger compared to other levels.[11]

The dural sac is continuous from the foramen magnum to the sacral region, where it spreads distally to cover the filum terminale. In children, the dural sac terminates lower, and in some adults, the sac termination can be as high as L5. The vertebral canal contains the dural sac, which adheres superiorly to the foramen magnum, to the posterior longitudinal ligament anteriorly, the ligamentum flavum and laminae posteriorly, and the pedicles laterally.

The spinal cord tapers and ends as the **conus medullaris** at the level of the L1–L2 intervertebral disk (Figure 22–7A). The **filum terminale**, a fibrous extension of the spinal cord, extends caudally to the coccyx. The **cauda equina** is a bundle of nerve roots in the subarachnoid space distal to the conus medullaris[12] (Figure 22–7A).

The spinal cord receives blood primarily from one **anterior** and two **posterior spinal arteries** that derive from the **vertebral arteries** (Figure 22–7B). Other major arteries that supplement blood supply to the spinal cord include the **vertebral, ascending cervical, posterior intercostal, lumbar**, and **lateral sacral arteries**. The single anterior spinal artery and two posterior spinal arteries run longitudinally along the length of the cord and combine with segmental arteries in each region. The **major segmental artery** (**Adamkiewicz**) is the largest segmental artery and is found between the T8 and L1 vertebral segments. The Adamkiewicz artery is the major blood supplier to two-thirds of the spinal cord. Injury of this artery may result

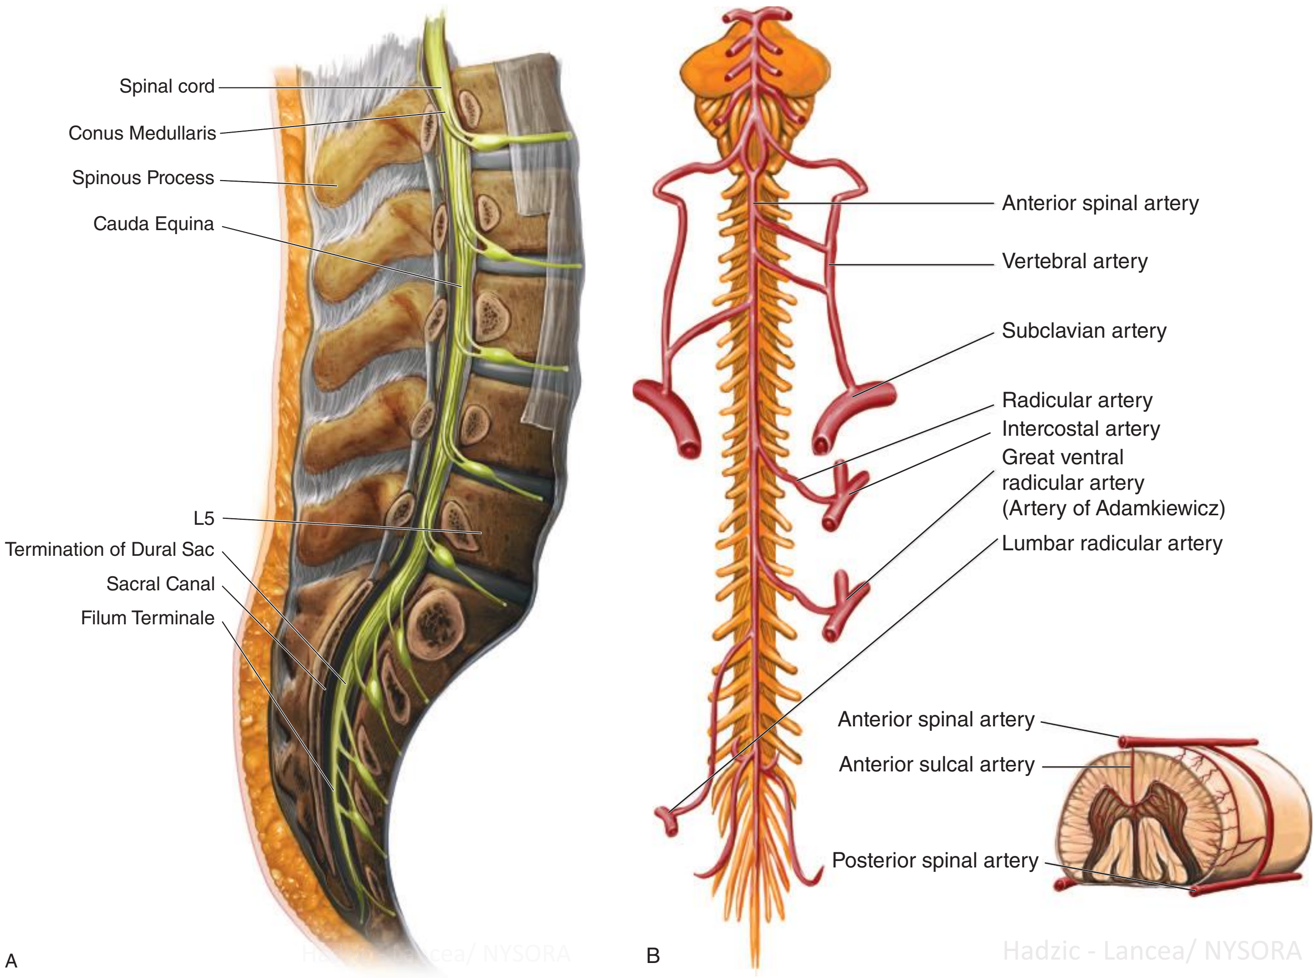

FIGURE 22–7. A. Sagittal view of the lumbar vertebrae. The spinal cord terminates at the L1-L2 interspace. **B.** Arterial supply to the anterior spinal cord. The Artery of Adamkiewicz emerges from T8-L1 vertebral segments. The small insert demonstrates the blood supply to the spinal cord (one anterior and two posterior arteries).

in *anterior spinal artery syndrome,* characterized by loss of urinary and fecal continence as well as impaired motor function of the legs.[1] The **radicular arteries** are branches of the spinal arteries and run within the vertebral canal and supply the vertebral column. **Radicular veins** drain blood from the vertebral venous plexus and eventually drain into the major venous system: the **superior** and **inferior vena cava** and the **azygos venous system of the thorax**.[1]

MOVEMENTS OF THE SPINE

The fundamental movements through the vertebral column are flexion, extension, rotation, and lateral flexion in the cervical and lumbar spine. Movement between individual vertebrae is relatively limited, although the effect is compounded along the entire spine. Thoracic vertebrae, in particular, have limited mobility due to the rib cage. Flexion is greatest in the cervical spine, whereas extension is greatest in the lumbar region. The thoracic and sacral regions are the most stable.

SPECIAL CONSIDERATIONS

In the United States and most developed countries, there is an increase in aging population. This trend carries with it an increased prevalence of spinal deformities, such as spinal stenosis, scoliosis, hyperkyphosis, and hyperlordosis. Elderly patients present anesthetic challenges when neuraxial techniques are required. With advancing age, a diminishing thickness of intervertebral disks results in decreased height of the vertebral column. Thickened ligaments and osteophytes also contribute to difficulty in accessing both the subarachnoid and epidural spaces. The frequency of spinal deformities in older adults can be as high as 70%.[13]

Adult scoliosis, in particular, is frequently encountered in older adults. In fact, Schwab et al demonstrated that scoliosis was present in 68% of an asymptomatic volunteer population older than 60 years of age. A thorough understanding of the scoliotic spine will aid in successfully performing central neuraxial blockade in this patient population. In the scoliotic spine, vertebral bodies are rotated toward the convexity of the curve, and their spinous processes face *into* the concavity of the curve[14] (Figure 22–8).

The diagnosis of scoliosis is made when there is a Cobb angle of greater than 10° in the coronal plane of the spine in a skeletally mature patient.[15] The Cobb angle, which is used to measure the magnitude of scoliosis, is formed between a line drawn parallel to the superior endplate of one vertebra above the curve deformity and a line drawn parallel to the inferior endplate of the vertebra one level below the curve deformity[16] (Figure 22–8). In untreated patients, there is a strong linear relationship between the Cobb angle and the degree of vertebral rotation in both thoracic and lumbar curves, with maximum rotation occurring at the apex of the scoliotic curve.[17,18] A compensatory curvature of the spine always occurs in the opposite direction of the scoliotic curve.

Scoliosis usually presents in childhood or adolescence and is diagnosed during routine physical examination. Untreated, it may become progressive and result in respiratory impairment and gait disturbances. Scoliosis may also go undiagnosed and present later in life as back pain.[15,19]

Treatment depends on the severity of the scoliosis. Mild scoliosis (11°–25°) is usually observed. Moderate scoliosis (25°–50°) in the skeletally immature patient frequently progresses and therefore is most often braced. Patients with severe scoliosis (>50°) are usually treated surgically.[20]

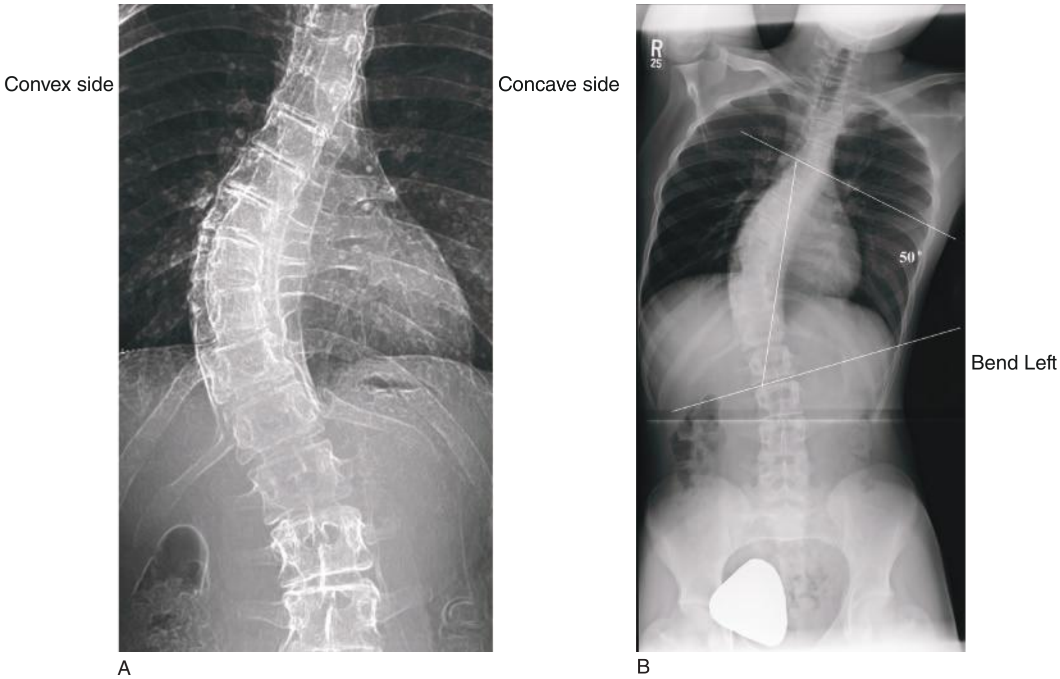

FIGURE 22–8. Adolescent scoliotic spine. **A:** S-shaped scoliosis of the thoracolumbar spine. **B:** Cobb angle of 50°.

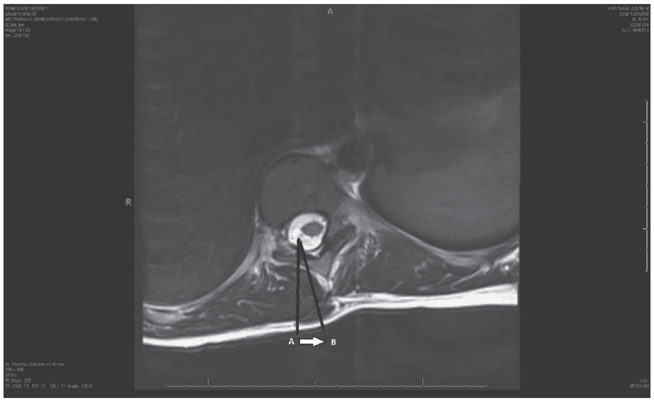

FIGURE 22–9. Paramedian approach in a scoliotic spine; arrow B represents the needle realignment towards the convex side of the scoliotic spine compared to arrow A, which depicts the usual paramedian approach in a normal spine.

The degree of vertebral body rotation along the long axis of the spine influences the orientation of a needle during insertion for neuraxial anesthesia. In the patients with scoliosis, the vertebral body rotates toward the convex side of the curve. As a result of this rotation, the spinous processes point toward the midline (the concave side). This results in a larger interlaminar space on the convex side of the spine.[21,22] A direct path to the neuraxial space is created by this vertebral body rotation, allowing the use of a paramedian approach from the convex side of the curve (Figure 22–9). Surface landmarks, particularly the spinous process, may be difficult to identify in the severe scoliotic spine. X-rays, and most recently preprocedural ultrasound scanning, may be useful to determine the longitudinal angulation of the spine, the location and orientation of the spinous process, as well as the depth of the lamina.[23–25]

Clinical Pearls

- The spinal cord ends at the L1-to-L2 level; performing spinal anesthesia at or above this level is not recommended.
- Failure of the ligamentum flavum to fuse in the cervical and upper thoracic levels may reduce the sense of *loss of resistance* with a midline approach to epidural anesthesia. A paramedian approach may be more suitable at these levels because the needle is advanced to a point where the presence of a ligamentum flavum is most reliable, enabling successful access to the epidural space.
- In patients with scoliosis, a paramedian approach from the convex side may be more successful.

CHAPTER 23

Spinal Anesthesia

Adrian Chin and André van Zundert

THE HISTORY OF SPINAL ANESTHESIA

Carl Koller, an ophthalmologist from Vienna, in 1884 first described the use of topical cocaine for analgesia of the eye.[1] William Halsted and Richard Hall, surgeons at Roosevelt Hospital in New York City, took the idea of local anesthesia a step further by injecting cocaine into human tissues and nerves to produce anesthesia for surgery.[2] James Leonard Corning, a neurologist in New York City, in 1885 described the use of cocaine for spinal anesthesia.[3] Because Corning was a frequent observer at Roosevelt Hospital, the idea of using cocaine in the subarachnoid space may have come from observing Halsted and Hall performing cocaine injections. Corning first injected cocaine intrathecally into a dog and within a few minutes the dog had marked weakness in the hindquarters.[4] Next, Corning injected cocaine into a man at the T11–T12 interspace into what he thought was the subarachnoid space. Because Corning did not notice any effect after 8 minutes, he repeated the injection. Ten minutes after the second injection, the patient complained of sleepiness in his legs but was able to stand and walk. Because Corning made no mention of cerebrospinal fluid (CSF) efflux, most likely he inadvertently gave an epidural rather than a spinal injection to the patient.

The presence of a neuraxial fluid was first noted by Galen in AD 200, and CSF was later studied in the 1500s by Antonio Valsalva.[5] Dural puncture was described in 1891 by Essex Wynter[6] followed shortly by Heinrich Quincke 6 months later.[7] Augustus Karl Gustav Bier, a German surgeon, used cocaine intrathecally in 1898 on six patients for lower extremity surgery.[8,9] In true scientific fashion, Bier decided to experiment on himself and developed a postdural puncture headache (PDPH) for his efforts. His assistant, Dr. Otto Hildebrandt, volunteered to have the procedure performed after Bier was unable to continue due to the PDPH. After injection of spinal cocaine into Hildebrandt, Bier conducted experiments on the lower half of Hildebrandt's body. Bier described needle pricks and cigar burns to the legs, incisions on the thighs, avulsion of pubic hairs, strong blows with an iron hammer to the shins, and torsion of the testicles. Hildebrandt reported minimal to no pain during the experiments; however, afterward he suffered nausea, vomiting, PDPH, and bruising and pain in his legs. Bier attributed the PDPH to loss of CSF and felt the use of small-gauge needles would help prevent the headache.[10]

Dudley Tait and Guido Caglieri performed the first spinal anesthetic in the United States in San Francisco in 1899. Their studies included cadavers, animals, and live patients to determine the benefits of lumbar puncture, especially in the treatment of syphilis. Tait and Caglieri injected mercuric salts and iodides into the CSF, but worsened the condition of one patient with tertiary syphilis.[11] Rudolph Matas, a vascular surgeon in New Orleans, described the use of spinal cocaine on patients and possibly was the first to use morphine in the subarachnoid space.[12,13] Matas also described the complication of death after lumbar puncture. Theodore Tuffier, a French surgeon in Paris, studied spinal anesthesia and reported on it in 1900. Tuffier felt that cocaine should not be injected until CSF was recognized.[14] Tuffier taught at the University of Paris at the same time that Tait was a medical student there and most likely was one of Tait's mentors. Tuffier's demonstrations in Paris helped popularize spinal anesthesia in Europe.

Arthur Barker, a professor of surgery at the University of London, reported on the advancement of spinal techniques in 1907, including the use of a hyperbaric spinal local anesthetic, emphasis on sterility, and ease of midline over paramedian dural puncture.[15] Advancement of sterility and the investigation of decreases in blood pressure after injection helped make spinal anesthesia safer and more popular. Gaston Labat was a strong proponent of spinal anesthesia in the United States and performed early studies on the effects of Trendelenburg position on blood pressure after spinal anesthesia.[16] George Pitkin attempted to use a hypobaric local anesthetic to control the level of spinal block by mixing procaine with alcohol.[17] Lincoln

Sise, an anesthesiologist at the Lahey Clinic in Boston, used Barker's technique of hyperbaric spinal anesthesia with both procaine and tetracaine.[18–20]

Spinal anesthesia became more popular as new developments occurred, including the introduction in 1946 of saddle block anesthesia by Adriani and Roman-Vega.[21] However, in 1947 the well-publicized case of Woolley and Roe (United Kingdom) resulted in two patients becoming paraplegic in one day.[22] Across the Atlantic, reports of paraplegia in the United States similarly caused anesthesiologists to discontinue the use of spinal anesthesia.[23] The development of novel intravenous anesthetic agents and neuromuscular blockers coincided with the decreased use of spinal anesthesia. In 1954, Dripps and Vandam described the safety of spinal anesthetics in more than 10,000 patients,[24] and spinal anesthesia was revived.

In the field of obstetrics, over 500,000 spinals had been performed on American women by the mid-1950s.[25] Despite spinal anesthesia being the most frequently used technique for vaginal delivery and cesarean section in the 1950s, subsequent improvements in epidural technology resulted in a decline in obstetric spinal anesthesia in the late 1960s. The Third National Audit Project (NAP3) estimated 133,525 obstetric spinals were performed in 2006 in the United Kingdom.[26]

The early development of spinal needles paralleled the early development of spinal anesthesia. Corning chose a gold needle that had a short bevel point, flexible cannula, and set screw that fixed the needle to the depth of dural penetration. Corning also used an introducer for the needle, which was right angled. Quincke used a beveled needle that was sharp and hollow. Bier developed his own sharp needle that did not require an introducer. The needle was larger bore (15 or 17 gauge) with a long, cutting bevel. The main problems with Bier's needle were pain on insertion and the loss of local anesthetic due to the large hole in the dura after dural puncture. Barker's needle did not have an inner cannula, was made of nickel, and had a sharp, medium-length bevel with a matching stylet. Labat developed an unbreakable nickel needle that had a sharp, short-length bevel with a matching stylet. Labat believed that the short bevel minimized damage to the tissues when inserted into the back.

Herbert Greene realized that loss of CSF was a major problem in spinal anesthesia and developed a smooth-tip, smaller-gauge needle that resulted in a lower incidence of PDPH.[27] Barnett Greene described the use of a 26-gauge spinal needle in obstetrics with a decreased incidence of PDPH.[28] The Greene needle was popular until the introduction of the Whitacre needle. Hart and Whitacre[29] used a pencil-point needle to decrease PDPH from 5%–10% to 2%. Sprotte modified the Whitacre needle and in 1987 published his trial of over 34,000 spinal anesthetics.[30] Modifications of the Sprotte needle occurred the 1990s to produce the needle that is in use today.[31]

Spinal anesthesia has progressed greatly since 1885. Every aspect, from improved equipment and pharmacological agents, to greater understanding of physiology and anatomy, have made spinal anesthesia increasingly safer. Changing clinical knowledge has seen shifts in what is considered a contraindication to spinal anesthesia, and the evolution of novel techniques, such as the use of ultrasound, have allowed spinal anesthesia in what would once have been thought impossible situations. Nonetheless, no technique is risk free, and every effort must be made to prevent complications. Learning how to perform spinal anesthesia is an invaluable skill that all anesthesiologists should have in their armamentarium.

THE RISKS AND BENEFITS OF SPINAL ANESTHESIA

Before offering a patient spinal anesthesia, an anesthesiologist not only must be aware of the indications and contraindications of spinal anesthesia but also must be able to weigh the risks and benefits of performing the procedure. This requires a thorough understanding of the available evidence, in particular how the risk-benefit ratio compares to that of any alternative, and an ability to apply the evidence to a given clinical scenario. Thus, an informed anesthesiologist can facilitate the patient in making an informed decision.

Contraindications and Risks of Spinal Anesthesia

Contraindications to Spinal Anesthesia

There are absolute and relative contraindications to spinal anesthesia (see Table 23–1). Absolute contraindications include patient refusal; infection at the site of injection; severe, uncorrected hypovolemia; true allergy to any of the drugs; and increased intracranial pressure, except in cases of pseudo–tumor cerebri (idiopathic intracranial hypertension). High intracranial pressure increases the risk of uncal herniation when CSF is lost through the needle. Spinal anesthesia is also contraindicated when the operation is expected to take longer than the duration of the block or result in blood loss such that the development of severe hypovolemia is likely.

Coagulopathy, previously considered an absolute contraindication, may be considered depending on the level of derangement. Another relative contraindication of spinal anesthesia is sepsis distinct from the anatomic site of puncture (eg, chorioamnionitis or lower extremity infection). If the patient is on antibiotics and the vital signs are stable, spinal anesthesia may be considered. Spinal anesthesia is relatively contraindicated in cardiac diseases with fixed cardiac output (CO) states. Aortic stenosis, once considered to be an absolute contraindication for

TABLE 23–1. Contraindications to spinal anesthesia.

Absolute Contraindications	Relative Contraindications
• Patient refusal • Infection at the site of injection • Uncorrected hypovolemia • Allergy • Increased intracranial pressure	• Coagulopathy • Sepsis • Fixed cardiac output states • Indeterminate neurological disease

spinal anesthesia, does not always preclude a carefully conducted spinal anesthetic.[32–34]

Indeterminate neurological disease is a relative contraindication. Multiple sclerosis and other demyelinating diseases are challenging. In vitro experiments suggest that demyelinated nerves are more susceptible to local anesthetic toxicity. However, no clinical study has convincingly demonstrated that spinal anesthesia worsens such neurologic diseases. Indeed, with the knowledge that pain, stress, fever, and fatigue exacerbate these diseases, a stress-free central neuraxial block (CNB) may be preferred for surgery.[35–39]

Spinal anesthesia in the immunocompromised patient also presents a challenge for the anesthesiologist and is the subject of a consensus statement.[40] Although this consensus statement does not provide prescriptive advice for every situation, it does summarize the available evidence. Previous spinal surgery was once thought to be a contraindication. Dural puncture may be difficult, and spread of local anesthetic may be restricted by scar tissue. However, there are case reports of successful spinal anesthesia in this setting, particularly with the assistance of ultrasound.[41–43] There are theoretical risks in inserting a hollow-body needle through tattoo ink.[44] However, there are no reported complications from inserting a spinal or epidural needle through a tattoo.[45] Stylets may decrease the likelihood of transmitting a core of tissue to the subarachnoid space, and if concerned, a small skin incision may be made prior to needle insertion. Introducers serve to prevent contamination of the CSF with small pieces of epidermis, which could lead to the formation of dermoid spinal cord tumors.

Risks of Spinal Anesthesia: Complications

Complications of spinal blockade are often divided into major and minor complications. Reassuringly, most major complications are rare. Minor complications, however, are common and therefore should not be dismissed. Minor complications include nausea, vomiting, mild hypotension, shivering, itch, hearing impairment, and urinary retention. PDPH and failed spinal blockade are significant, and not uncommon, complications of spinal anesthesia. We therefore consider them as moderate complications (see Table 23–2). Failure of spinal anesthesia has been mentioned as between 1% and 17% and is discussed further in this chapter.

Minor Complications of Spinal Anesthesia

Nausea and Vomiting Nausea and vomiting presenting after spinal anesthesia are distressing for the patient and may impede the surgeon. Incidence of intraoperative nausea and vomiting (IONV) in nonobstetric surgery can be up to 42% and may be as high as 80% in parturients.[46]

Causes are complex and multifactorial. Causes unrelated to the spinal may include patient factors (eg, anxiety, reduced lower esophageal sphincter tone, increased gastric pressure, vagal hyperactivity, hormonal changes); surgical factors (exteriorization of the uterus, peritoneal traction); and other factors (eg, systemic opioids, uterotonic drugs, antibiotics, movement).[46,47] Spinal anesthesia itself may cause IONV or postoperative nausea and vomiting (PONV) via a variety of mechanisms, including hypotension, intrathecal additives, inadequate block, or high block. Risks factors for IONV under spinal include peak block height greater than T6, baseline heart rate (HR) 60 beats/minute or more, a history of motion sickness, and previous hypotension after spinal block.[48]

Hypotension must be the *first* consideration when a patient complains of nausea, especially immediately after onset of spinal anesthesia. This has been long known. Evans, in his 1929 textbook on spinal anesthesia, noted that "the sudden fall in blood pressure is followed by nausea."[49] Mechanisms and management of hypotension are covered in greater detail elsewhere (see section on cardiovascular effects of spinal anesthesia).

A variety of intrathecal additives have been shown to increase IONV or PONV. Intrathecal morphine, diamorphine, clonidine, and neostigmine all increase nausea and vomiting. Intrathecal fentanyl, however, reduces IONV, perhaps by improving block quality, decreasing supplemental opioids, or decreasing hypotension.[46]

While low spinal block can cause nausea from surgical stimulation, high sympathetic spinal block (with relative parasympathetic overactivity) can also result in nausea. Glycopyrrolate was shown to be better than placebo in reducing nausea during cesarean section, although the rate of nausea was still high (42%).[50] However, prophylactic glycopyrrolate can increase hypotension after spinal anesthesia.[46]

A recent meta-analysis suggested metoclopramide (10 mg) was effective and safe for prevention of IONV and PONV in the setting of cesarean delivery under neuraxial block.[47]

TABLE 23–2. Complications of spinal anesthesia.

Minor	Moderate	Major
• Nausea and vomiting • Mild hypotension • Shivering • Itch • Transient mild hearing impairment • Urinary retention	• Failed spinal • Postdural puncture headache	• Direct needle trauma • Infection (abscess, meningitis) • Vertebral canal hematoma • Spinal cord ischemia • Cauda equina syndrome • Arachnoiditis • Peripheral nerve injury • Total spinal anesthesia • Cardiovascular collapse • Death

Another meta-analysis showed the serotonin 5-HT_3 receptor antagonists reduced the incidence of nausea and vomiting and the need for postoperative rescue antiemetic when intrathecal morphine was used for cesarean section.[51]

Despite some studies showing a benefit of P6 (pericardium 6 nei guan point) stimulation, based on Chinese acupuncture, a 2008 systematic review found inconsistent results in preventing IONV and PONV.[52]

Hypotension Mechanisms and management of hypotension are covered elsewhere (see section on cardiovascular effects of spinal anesthesia).

Shivering Crowley et al reviewed shivering and neuraxial anesthesia.[53] Spinal and epidural anesthesia, and indeed general anesthesia, may induce shivering. The incidence of shivering secondary to neuraxial block is difficult to assess given the heterogeneity of studies but is about 55%. In the first 30 minutes after block, spinal anesthesia decreases core body temperature faster than epidural anesthesia. After 30 minutes, both techniques cause temperature to fall at the same rate. Despite this, shivering after spinal anesthesia is no greater than after epidural anesthesia.[54] Indeed, the intensity of shivering seems to be higher with epidurals. Postulated mechanisms for this include an inability to shiver due to more pronounced motor blockade with spinal anesthesia and a decreased shivering threshold with more dermatomes (and thus thermoregulatory afferents) blocked during spinal anesthesia. Several strategies have been suggested to reduce neuraxial shivering (see Table 23–3).

Itch Pruritis is a well-known side effect of opiates and is more common with administration via the spinal route (46%) compared with epidural (8.5%) and systemic routes.[55] The severity of pruritis is proportional to intrathecal morphine dose but not epidural morphine dose.[56] Pruritis associated with neuraxial opioids is often distributed around the nose and face. Although symptoms may not be mediated via opioid receptors, pruritis can be treated with the opioid receptor antagonist naloxone.[55]

TABLE 23–3. Suggested strategies to prevent and treat neuraxial anesthesia shivering.

Prevention	Treatment
• Prewarm with forced air warmer for 15 minutes • Avoid cold epidural or intravenous fluids • Intrathecal fentanyl 20 μg • Intrathecal meperidine 0.2 mg/kg or 10 mg • Intravenous ondansetron 8 mg • Epidural fentanyl • Epidural meperidine	• Intravenous meperidine 50 mg • Intravenous tramadol 0.25 mg/kg or 0.5 mg/kg or 1 mg/kg • Intravenous clonidine 30, 60, 90, or 150 μg

Source: Adapted with permission from Crowley LJ, Buggy DJ: Shivering and neuraxial anesthesia. *Reg Anesth Pain Med*. 2008;May/June;33(3):241–252.

There are reports of ondansetron being used for opioid-induced pruritis, suggesting a role of serotonin receptors in morphine-induced pruritis.[57] A 2009 meta-analysis of obstetric patients who had received intrathecal morphine showed that 5-HT_3 receptor antagonists did not reduce the incidence of pruritis but did reduce the severity of itching and the need to treat pruritis. The 5-HT_3 receptor antagonists were useful in treating established pruritis (number needed to treat [NNT] = 3).[51]

Hearing Impairment Hearing loss, particularly in the low-frequency range, has been reported after spinal anesthesia. Quoted incidences vary widely (3%–92%).[58] Otoacoustic emissions, an objective measurement of hearing that reflects outer hair cell function, demonstrated hearing loss to be more common than suspected, but transient, with full recovery occurring in 15 days.[59] Other authors have similarly concluded that hearing loss commonly disappears spontaneously.[58] A comparison of hearing loss after general and spinal anesthesia concluded that hearing loss occurs irrespective of technique.[58] Hearing loss may or may not be associated with PDPH and may improve with an epidural blood patch.[60] Hearing loss after spinal block may be related to needle gauge[61] and may be less common in the obstetric population.[62] Finegold showed that hearing loss did not occur in women having elective cesarean sections when 24-gauge Sprotte needles or 25-gauge Quincke needles were used.[62] It has been suggested that consent for spinal anesthesia should include a discussion for medicolegal reasons of possible hearing loss.[59,63]

Postoperative Urinary Retention Micturition is the product of a complex interplay of physiology. Postoperative urinary retention (POUR), therefore, is often multifactorial in origin. Patient risk factors for POUR include male sex and previous urologic dysfunction. Surgical risk factors include pelvic or prolonged surgery. Anesthetic factors include anticholinergic drugs, opioids, and fluid administration (>1000 mL).[64] POUR can occur with both neuraxial and general anesthesia.

Occurrence of POUR after neuraxial block is due to neural interruption of the micturition reflex as well as bladder overdistention. Neuraxial opioids exert an effect at the spinal cord and the pontine micturition center. The parasympathetic blockade induced by spinal anesthesia must end before voiding occurs. This usually corresponds with return of the S2–S4 segments.[64] The type and dose of local anesthetic, as well as the use of neuraxial opioid, influence the return of spontaneous micturition. Time to micturition is quickest with 2-chloroprocaine and slowest with bupivacaine.[65]

A recent systematic review found six studies that compared the effect of neuraxial anesthesia with other techniques.[65] Four studies compared local infiltration with intrathecal anesthesia; three of these found lower incidences of urinary retention with local infiltration. The other two studies found no difference in time to micturition when intrathecal anesthesia was compared with general anesthesia in the first instance and general anesthesia and peripheral nerve block in the second instance.

Postdural Puncture Headache Postdural puncture headache, often classified as a minor[66] (or at least not a major[26]) complication, can be severe and debilitating and has been considered *the* neurological complication of spinal anesthesia.[67] It is a common cause for medicolegal claims. The incidence of PDPH is influenced by patient demographics and is less common in elderly patients.[68] In a high-risk group, such as obstetric patients, the risk after lumbar puncture with a Whitacre 27-gauge needle is about 1.7%.[69] Needle size and type influence PDPH rate. Other risk factors include lesser body mass index (BMI), female gender, history of recurrent headaches, and previous PDPH.[5]

Postdural puncture headache should be thought of as neither a common "minor" complication nor a rare "major" complication, but as a not uncommon "moderate" complication. The reader is referred to Chapter 27 for further detailed information.

Major Complications of Spinal Anesthesia Major complications of spinal anesthesia include direct needle trauma, infection (meningitis or abscess formation), vertebral canal hematoma, spinal cord ischemia, cauda equina syndrome (CES), arachnoiditis, and peripheral nerve injury. The end result of these complications may be permanent neurologic disability. Other major complications include total spinal anesthesia (TSA), cardiovascular collapse, and death.

Direct Needle Trauma Neurologic injury can occur after needle introduction into the spinal cord or nerves. Although the elicitation of paresthesias during spinal anesthesia has been implicated as a risk factor for persistent neurologic injury, it is not known whether an intervention after paresthesia can prevent development of neurologic complications.[70] A retrospective analysis found 298 of 4767 (6.3%) patients experienced paresthesia during spinal needle insertion. Of the 298, four patients had persistent paresthesia postoperatively. A further two patients with postoperative paresthesia did not have paresthesia during needle insertion. All six patients had resolution of symptoms by 24 months.[71] When paresthesia occurs, the spinal needle may be adjacent to or penetrating neural tissue; if the latter is the case, injection of local anesthetic into the spinal nerve may result in permanent neurologic damage. Analogous controversies exist with peripheral nerve blockade; the implications of paresthesia techniques and extraneural and intraneural injection are the subject of much debate.[72]

Meningitis Meningitis, either bacterial or aseptic, can occur after spinal anesthesia is performed.[73] Sources of infection include contaminated spinal trays and medication, oral flora of the anesthesiologist, and patient infection. Most cases of meningitis after spinal anesthesia in the first half of the 20th century were aseptic and could be traced to chemical contamination and detergents.[74,75] Marinac showed that causes of drug- and chemical-induced meningitis include nonsteroidal anti-inflammatory drugs, certain antibiotics, radiographic agents, and muromonab-CD3. There also appears to be an association between the occurrence of the hypersensitivity-type reactions and underlying collagen, vascular, or rheumatologic disease.[76] Carp and Bailey performed lumbar puncture in bacteremic rats, and only those with a circulating *Escherichia coli* count greater than 50 CFU/mL at the time of lumbar puncture developed meningitis.[77] Although meningitis after lumbar puncture has also been described in bacteremic children,[78] the incidence of meningitis after diagnostic lumbar puncture is not significantly different in bacteremic patients compared with spontaneous incidence of meningitis.[79] Oral flora can contaminate the CSF when a spinal anesthetic is being performed, underlying the importance of wearing a mask. *Streptococcus salivarius*, *Streptococcus viridans*, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Acinetobacter*, and *Mycobacterium tuberculosis* have all been isolated in cases of bacterial meningitis after spinal anesthesia or lumbar puncture.[80–83]

Vertebral Canal Hematoma Vertebral canal hematoma formation is a rare but devastating complication after spinal anesthesia. Although most spinal hematomata occur in the epidural space due to the prominent epidural venous plexus, a few reports have mentioned subarachnoid bleeding as the cause of neurologic deficits. The source of the bleeding can be from either an injured artery or an injured vein. Spinal hematoma and spinal cord ischemia have a poorer prognosis than infective complications.[26] If new or progressive neurologic symptoms develop, an immediate neurosurgery consultation should be obtained, and magnetic resonance imaging (MRI) of the spine should be performed as soon as possible.

Spinal Cord Ischemia The superficial arterial system of the spinal cord consists of three longitudinal arteries (the anterior spinal artery and two posterior spinal arteries) and a pial plexus.[84] The posterior cord is relatively protected from ischemia by abundant anastomoses. The central area of the anterior spinal cord is reliant on the anterior spinal artery and therefore more prone to ischemia. Proposed mechanisms for spinal cord ischemia secondary to spinal blockade include prolonged hypotension, the addition of vasoconstrictors to local anesthetics, and compression of arterial supply by vertebral canal hematoma.[70]

Cauda Equina Syndrome Cauda equina syndrome (CES) has been reported with the use of continuous spinal microcatheters.[85–88] The use of hyperbaric 5% lidocaine for spinal anesthesia is associated with an increased incidence of CES,[89–91] although other local anesthetics have been implicated.[92–95] Other risk factors for CES include lithotomy position, repeated dosing of local anesthetic solution through continuous spinal catheters, and possibly multiple single-injection spinal anesthetics. Suggestions for prevention of CES from spinal anesthesia include aspiration of CSF before and after local anesthetic injection. Some suggest that when CSF cannot be aspirated after half the dose is injected, a full dose not be administered. Limiting the amount of local anesthetic given in the subarachnoid space may help prevent CES.

Arachnoiditis Arachnoiditis can occur after spinal injection of local anesthetic solution but is also known to occur after intrathecal steroid injection.[96–99] Causes of arachnoiditis include infection; myelograms from oil-based dyes; blood in the intrathecal space; neuroirritant, neurotoxic, or neurolytic substances; surgical interventions in the spine; intrathecal corticosteroids;

and trauma. Arachnoiditis has been reported after traumatic dural puncture and after unintentional intrathecal injection of local anesthetics, detergents, antiseptics, or other substances.[100]

Peripheral Nerve Injury Spinal anesthesia may indirectly result in peripheral nerve injury. The sensory block induced by spinal anesthesia temporarily abolishes normal protective reflexes. Therefore, care must be taken with appropriate positioning, avoidance of tight plaster casts, and observation of distal circulation. Hence, it is imperative that there is good nursing care of limbs rendered insensate by spinal anesthesia.

Total Spinal Anesthesia Total spinal anesthesia (TSA) results in respiratory depression, cardiovascular compromise, and loss of consciousness. This may or may not be preceded by numbness, paresthesia, or weakness of the upper limb; shortness of breath; nausea; or anxiety. The mechanism of TSA is unclear.

The importance of providing cardiorespiratory support and anxiolysis is illustrated by the management of *intentional* TSA. Total spinal anesthesia has been used therapeutically for intractable pain.[101] After injection of 20 mL of 1.5% lidocaine at the L3–L4 level, patients were tilted head down. Thiopental was given to prevent unpleasant sensations. After loss of consciousness, paralysis (without muscle relaxant), and pupil dilation, a laryngeal mask airway (LMA) was inserted and positive pressure ventilation applied. Ephedrine and atropine were used for cardiovascular support if required. Mechanical ventilation was required for about an hour, after which the LMA was removed.

Cardiovascular Collapse Cardiovascular collapse can occur after spinal anesthesia, although it is a rare event. Auroy and coworkers reported 9 cardiac arrests in 35,439 spinal anesthetics performed.[102] Refer to the section on Cardiovascular Effects of Spinal Anesthesia.

Estimating the Risks of the Major Complications of Spinal Anesthesia

While minor risks are often thought of as side effects, major complications are of more concern to clinicians and patients. Perception of risk can be influenced by sensational case reports, such as given by Woolley and Roe.[22] Early efforts to assess risk were hampered by lack of good numerator (number of complications) and denominator (number of spinal blocks) data. Vandam and Dripps, in an attempt to redress "unsubstantiated clinical impressions" of mid-20th century anesthesiologists, examined the records of over 10,000 spinal anesthetics.[103] They concluded that objections to spinal anesthesia were undeserved. Retrospective evidence from Finland for the period 1987–1993 estimated the risk of major complication following spinal anesthesia at 1 in 22,000.[104] A no-fault compensation scheme was thought to increase data veracity. Swedish data (Moen)[92] from the period 1990–1999 found a similar risk of 1 in 20,000–30,000. Although good evidence at the time, the Scandinavian evidence was criticized because of retrospective design, which risks underreporting. Moreover, numerator data sourced from administrative databases may not indicate either causation or final outcome.

Auroy attempted to address weaknesses of an earlier study[105] by setting up a telephone hotline, allowing contemporaneous assessment of causality.[102] This prospective study from 1998 to 1999 investigated complications from any type of regional anesthesia. Auroy's results relied on voluntary contribution by French anesthesiologists (<6% participation rate) and may have been skewed by differing complication rates in those willing to participate. A 2007 review found a much higher incidence of neurological complications after spinal anesthesia in Auroy's work (3.7–11.8 per 10,000) compared with Moen's work (0.4 per 10,000).[106] Auroy, unlike Moen, included peripheral neuropathy and radiculopathy in the numerator data.

Designing a prospective study to accurately quantify the risk of spinal anesthesia has been difficult due to the low incidence of major complications. The NAP3 of the Royal College of Anaesthetists is the best evidence to date on major complications after CNB.[26] NAP3 is notable for a variety of reasons: It is the largest prospective audit of CNB to date; it achieved a 100% return rate; and it gathered numerator and denominator data from a variety of sources. It also investigated causality and outcome.

Numerator data in NAP3 pertained to major complications over a 12-month period (2006–2007). Reports came from local hospital reporters and clinicians. Litigation authorities, medical defense organizations, journals, and even Google searches of media reports were reviewed to identify missed complications. Complications were classified as infections, hematomata, nerve injuries, cardiovascular collapses, and wrong-route errors. Notably, PDPH was not included as a major complication. Complications were examined by a panel, and the likelihood of CNB as the cause was established. Denominator data were sourced from a 2-week census and validated by contacting a number of organizations and databases.

The findings of permanent harm were presented optimistically or pessimistically (see Table 23–4). Optimistic figures

TABLE 23–4. Useful numbers for quoting risk to patients.

Central Neuraxial Blockade	Risk (Pessimistic)	Risk (Optimistic)
Permanent harm from major complication	1 in 25,000	1 in 50,000
Death and paraplegia	1 in 50,000	1 in 150,000

The following summarize the risks of central neuraxial blockade:
Figures have been simplified to aid memory. See text for actual risks.
Risk quoted as "pessimistic" or "optimistic" based on interpretation of NAP3 data.
Major complications include spinal infection or bleeding, major nerve damage, wrong-route injection error, and death.
Figures relate to all neuraxial blocks and therefore are not limited to spinal anesthesia. The incidence of complications from epidural and combined spinal-epidural blocks were at least twice those of spinal or caudal blocks.

excluded complications where recovery was likely or causality tenuous. Permanent harm after *any type of* CNB was pessimistically 1:23,500 and optimistically 1:50,500. The risk of death or paraplegia after *any type of* CNB was pessimistically 1:54,500 and optimistically 1:141,500. The incidences of complications of spinals and caudals were at least half that of epidurals and combined spinal-epidural (CSE) blocks. Of approximately 700,000 CNBs, 46% were spinals. Although the authors cautioned against subgroup analysis, the obstetric setting was found to have a low incidence of complications, while the adult perioperative setting had the highest complications. Complete or near-complete neurological recovery occurred in 61% of cases.

Importantly, NAP3 did not examine minor complications or major complications without permanent harm. For example, patients may have had cardiovascular collapse requiring intensive care or have had meningitis, but as they made a full recovery were excluded from even the pessimistic calculation. These are complications a patient would consider severe. The authors did acknowledge their figures represent a minimum possible incidence of complications; however, others have speculated that they may have overestimated risk.[107] As there was no control group, NAP3 cannot answer if CNB is safer than other techniques such as general anesthesia.

The NAP3 study reassured us that permanent harm as a result of spinal anesthesia is rare. The large scope and excellent methodology of NAP3 mean a similar audit is unlikely to be repeated soon. Efforts should be made in ameliorating "minor" and "moderate" complications that are more likely to trouble our patients. In particular, PDPH deserves special attention.

Major complications, nonetheless, do happen, and every effort must be made to prevent them. Awareness of the low risk of serious complications should not give rise to complacency. Indeed, a given complication may become so rare that a single anesthesiologist is unlikely to encounter it in a lifetime of practice. However, given the catastrophic nature of such complications, ongoing vigilance is of paramount importance.

Indications and Benefits of Spinal Anesthesia

Indications

Spinal anesthesia provides excellent operating conditions for surgery below the umbilicus. Thus, it has been used in the fields of urological, gynecological, obstetric, and lower abdominal and perineal general surgery. Likewise, it has been used in lower limb vascular and orthopedic surgery. More recently, spinal anesthesia has been used in surgery above the umbilicus (see section on laparoscopic surgery).[108–113]

Benefits of Spinal Anesthesia

Although spinal anesthesia is a commonly used technique, with an estimated 324,950 spinal anesthetics each year in the United Kingdom alone,[26] mortality and morbidity benefits are difficult to prove or disprove. It was hypothesized that due to beneficial modulation of the stress response, regional anesthesia would be safer than general anesthesia. However, clinical trials have been contradictory, and debates continue over the superiority of one technique over the other. Evaluations of the benefits of spinal blockade are troubled by the heterogeneity of studies and arguments about whether analysis should include intention to treat.[114] In addition, much of the evidence for the benefits of neuraxial blockade pertains to epidurals, and some reviews do not differentiate between spinal and epidural anesthesia. For example, CNB has been shown to reduce blood loss[115] and thromboembolic events.[116] However, the authors of these studies were wise not to analyze spinal and epidural anesthesia individually, as the subgroup sample size would have been inadequate. Further studies are required to elucidate the relative benefits of each technique.

An obvious benefit of spinal anesthesia is the avoidance of the many risks of general anesthesia. However, it must be remembered that there is always the possibility of conversion to general anesthesia, and an emergent general anesthesia may be riskier than a planned general anesthesia.

Spinal anesthesia is advantageous in certain clinical settings. It is now commonplace for women having cesarean delivery to have a neuraxial block. Spinal anesthesia avoids the problems associated with general anesthesia in the pregnant patient, notably risks of difficult airway, awareness, and aspiration. Maternal blood loss has been found to be lower with spinal compared with general anesthesia.[117] Falling maternal mortality rates have been attributed to the increase in the practice of regional anesthesia. Moreover, regional anesthesia allows a mother to be awake for childbirth and a partner to be present if desired. However, a Cochrane review found no evidence of the superiority of regional anesthesia over general anesthesia with regard to major maternal or neonatal outcomes.[117] Likewise, a 2005 meta-analysis showed cord pH, an indicator of fetal well-being, to be lower with spinal compared with epidural and general anesthesia, although this may have been due to the use of ephedrine in the studies analyzed.[118] Nonetheless, spinal anesthesia remains the technique of choice for many obstetric anesthesiologists because of safety, reliability, and patient expectation.

A 2005 review of "best practice" for hip fractures found spinal anesthesia to have consistent benefits, and recommended the use of regional anesthesia "whenever possible."[119] Benefits cited included reduced mortality, deep vein thrombosis (DVT), transfusion requirements, and pulmonary complications. However, these recommendations, based on two reviews, illustrate the shortcomings of the available evidence. The first review had a heterogeneous population and limited power for subgroup analysis; extrapolating the findings to spinal anesthesia for hip fracture surgery is therefore questionable.[120] The second review found only a borderline difference in mortality at 1 month and no difference at 3 months. Moreover, all included studies had methodological flaws.[121]

The stress response to cardiac surgery is reduced by intrathecal bupivacaine in combination with general anesthesia[122] and partially attenuated by intrathecal morphine.[123] Low-dose intrathecal morphine (259 ± 53 μg) has been shown to facilitate early extubation after cardiac surgery.[124] A meta analysis of intrathecal morphine in cardiac surgery showed a modest decrease in morphine use and pain scores, although earlier extubation was only seen in a subset of patients receiving less than 500 μg of intrathecal morphine.[125]

As modern anesthesia and perioperative care become safer, it will become increasingly more difficult to prove an advantage of one technique over another. The ideal technique may in fact be a permutation of general anesthesia, neuraxial block, peripheral nerve blockade, or local infiltration analgesia.

Spinal Anesthesia: The Final Risk-Benefit Analysis

Once armed with the evidence regarding the risks and benefits of spinal anesthesia, the anesthesiologist must decide whether the evidence applies to the individual patient and clinical situation. Although complications can be devastating, NAP3 reassured us that major complications from spinal anesthesia are rare. Compelling benefits are harder to prove, yet there are advantages in certain clinical situations. Furthermore, the risk-benefit ratio must be compared with the risk-benefit ratio of available alternatives. The historical rise in safety of spinal anesthesia has been paralleled by a rise in safety of alternative techniques, including epidural anesthesia, peripheral nerve blockade, local infiltration analgesia, and of course general anesthesia. This competition between alternate techniques is likely to continue. Moreover, different modalities can be used in conjunction, complicating the final decision. The modern anesthesiologist must consider this matrix of risk-benefit ratios, which is beyond the scope of this chapter.

FUNCTIONAL ANATOMY OF SPINAL BLOCKADE

In reviewing the functional anatomy of spinal blockade, an intimate knowledge of the spinal column, spinal cord, and spinal nerves must be present. This chapter briefly reviews the anatomy, surface anatomy, and sonoanatomy of the spinal cord.

The vertebral column consists of 33 vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 4 coccygeal segments. The vertebral column usually contains three curves. The cervical and lumbar curves are convex anteriorly, and the thoracic curve is convex posteriorly. The vertebral column curves, along with gravity, baricity of local anesthetic, and patient position, influence the spread of local anesthetics in the subarachnoid space. Figure 23–1 depicts the spinal column, vertebrae, and intervertebral disks and foramina.

Five ligaments hold the spinal column together (Figure 23–2). The supraspinous ligaments connect the apices of the spinous processes from the seventh cervical vertebra (C7) to the sacrum. The supraspinous ligament is known as the ligamentum nuchae in the area above C7. The interspinous ligaments connect the spinous processes together. The ligamentum flavum, or yellow ligament, connects the laminae above and below together. Finally, the posterior and anterior longitudinal ligaments bind the vertebral bodies together.

The three membranes that protect the spinal cord are the dura mater, arachnoid mater, and pia mater. The dura mater, or tough mother, is the outermost layer. The dural sac extends to the second sacral vertebra (S2). The arachnoid mater is the middle layer, and the subdural space lies between the dural mater and arachnoid mater. The arachnoid mater, or cobweb mother, also ends at S2, like the dural sac. The pia mater, or soft mother, clings to the surface of the spinal cord and ends in the filum terminale, which helps to hold the spinal cord to the sacrum. The space between the arachnoid and pia mater is known as the subarachnoid space, and spinal nerves run in this space, as does CSF. Figure 23–3 depicts the spinal cord, dorsal root ganglia and ventral rootlets, spinal nerves, sympathetic trunk, rami communicantes, and pia, arachnoid, and dura maters.

When performing a spinal anesthetic using the midline approach, the layers of anatomy that are traversed (from posterior to anterior) are skin, subcutaneous fat, supraspinous ligament, interspinous ligament, ligamentum flavum, dura mater, subdural space, arachnoid mater, and finally the subarachnoid space. When the paramedian technique is applied, the spinal needle should traverse the skin, subcutaneous fat, paraspinous muscle, ligamentum flavum, dura mater, subdural space, and arachnoid mater and then pass into the subarachnoid space.

Clinical Pearls

When performing a spinal anesthetic using the midline approach, the layers of anatomy that are traversed (from posterior to anterior) are

- Skin
- Subcutaneous fat
- Supraspinous ligament
- Interspinous ligament
- Ligamentum flavum
- Dura mater
- Subdural space
- Arachnoid mater
- Subarachnoid space

When performing a spinal anesthetic using the paramedian approach, the spinal needle should traverse

- Skin
- Subcutaneous fat
- Paraspinous muscle
- Ligamentum flavum
- Dura mater
- Subdural space
- Arachnoid mater
- Subarachnoid space

The anatomy of the subdural space requires special attention. The subdural space is a meningeal plane that lies between the dura and the arachnoid mater, extending from the cranial cavity to the second sacral vertebrae.[126] Ultrastructural examination has shown this is an acquired space that only becomes real after tearing of neurothelial cells within the space.[127] The subdural space extends laterally around the dorsal nerve root and ganglion. There is less potential capacity of the subdural space adjacent to the ventral nerve roots. This may explain the sparing of anterior motor and sympathetic fibers during subdural block (SDB) (Figure 23–4).[126]

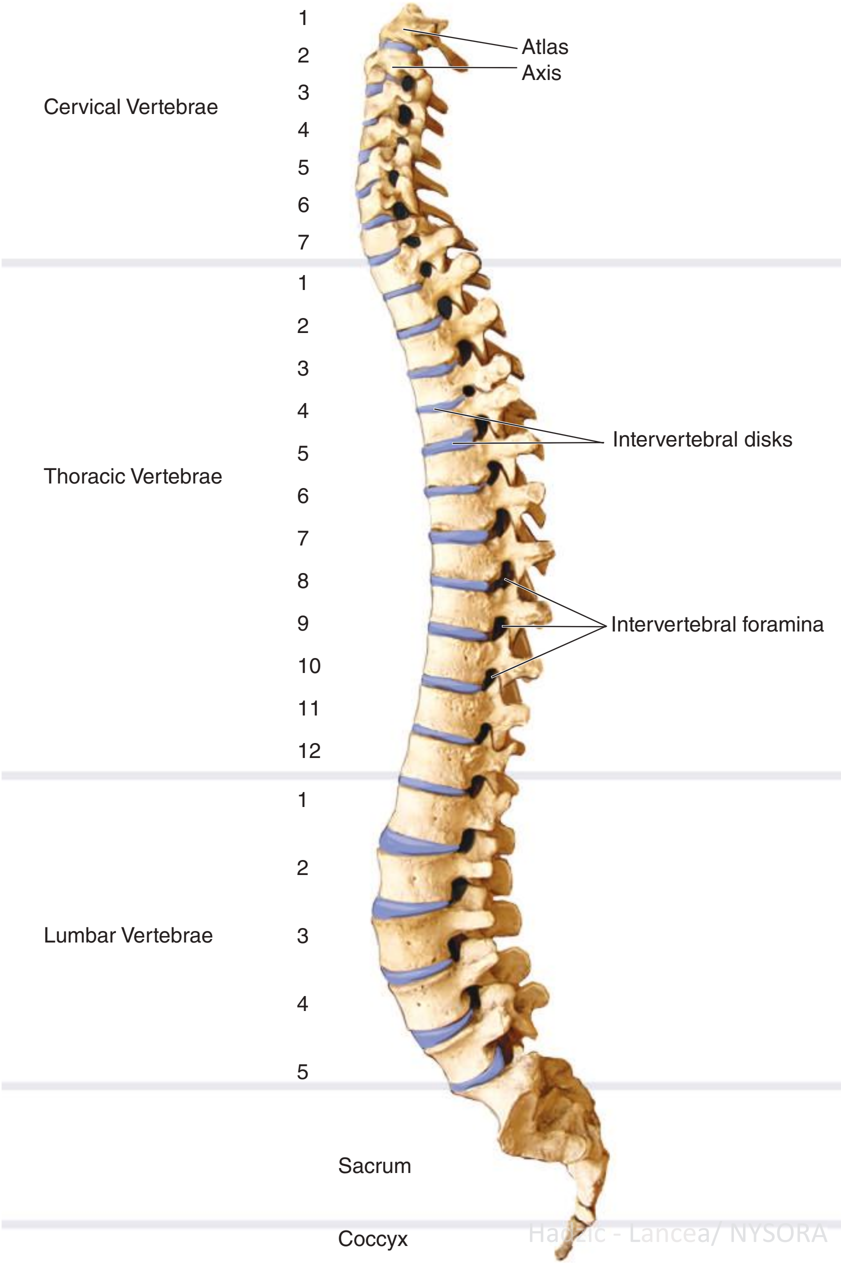

FIGURE 23–1. Spinal column, vertebrae, and intervertebral disks and foramina.

The length of the spinal cord varies according to age. In the first trimester, the spinal cord extends to the end of the spinal column, but as the fetus ages, the vertebral column lengthens more than the spinal cord. At birth, the spinal cord ends at approximately L3. In the adult, the terminal end of the cord, known as the conus medullaris, lies at approximately L1. However, MRI and cadaveric studies have reported a conus medullaris below L1 in 19%–58% and below L2 in 0%–5%.[128] The conus medullaris may lie anywhere between T12 and L3.[129] Figure 23–5 shows a cross section of the lumbar vertebrae and spinal cord. The typical position of the conus medullaris, cauda equina, termination of the dural sac, and filum terminale are shown. A sacral spinal cord in an adult has been reported, although this is extremely rare.[130] The length of the spinal cord must always be kept in mind when a neuraxial anesthetic is performed, as injection into the cord can cause great damage and result in paralysis.[131]

There are eight cervical spinal nerves and seven cervical vertebrae. Cervical spinal nerves 1 to 7 are numbered according to the vertebral body *below*. The eighth cervical nerve exits from below the seventh cervical vertebral body. Below this, spinal nerves are numbered according to the vertebral body *above*. The spinal nerve roots and spinal cord serve as the target sites for spinal anesthesia.

Surface Anatomy

When preparing for spinal anesthetic blockade, it is important to accurately identify landmarks on the patient.

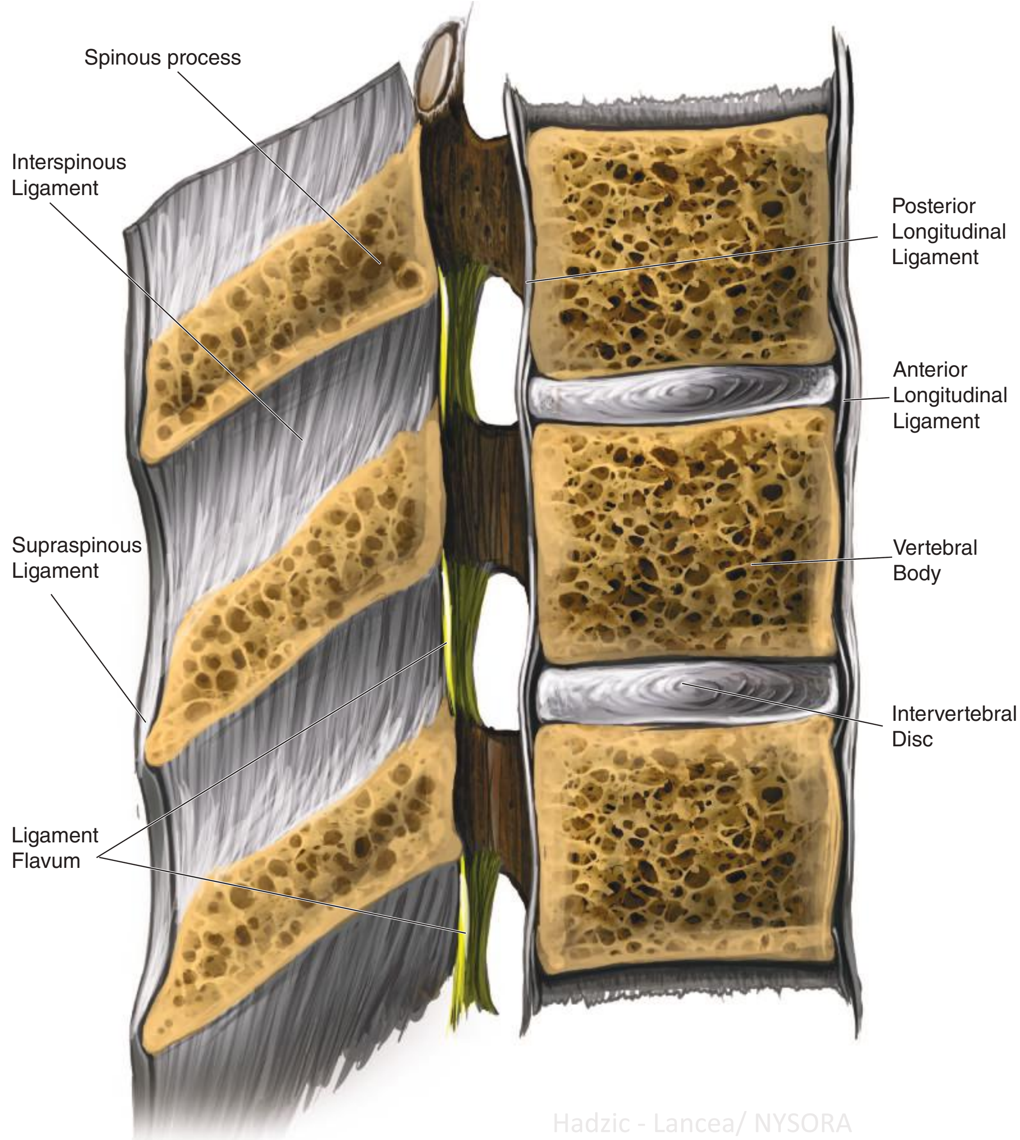

FIGURE 23–2. Cross section of the spinal canal and adjacent ligaments. (Reproduced with permission from Leffert LR, Schwamm LH: Neuraxial anesthesia in parturients with intracranial pathology: a comprehensive review and reassessment of risk. *Anesthesiology*. 2013 Sep;119(3):703-718.)

The midline is identified by palpating the spinous processes. The iliac crests usually are at the same vertical height as the fourth lumbar spinous process or the interspace between the fourth and fifth lumbar vertebrae. An intercristal line can be drawn between the iliac crests to help locate this interspace. Care must be taken to feel for the soft area between the spinous processes to locate the interspace. Depending on the level of anesthesia necessary for the surgery and the ability to feel for the interspace, the L3–L4 interspace or the L4–L5 interspace can be used to introduce the spinal needle. Because the spinal cord commonly ends at the L1-to-L2 level, it is conventional not to attempt spinal anesthesia at or above this level. More recently, segmental thoracic spinal anesthesia has been described.[108,109]

It would be incomplete to discuss surface anatomy without mentioning the dermatomes that are important for spinal anesthesia. A dermatome is an area of skin innervated by sensory fibers from a single spinal nerve. The tenth thoracic (T10) dermatome corresponds to the umbilicus, the sixth thoracic (T6) dermatome the xiphoid, and the fourth thoracic (T4) dermatome the nipples. Figure 23–6 illustrates the dermatomes of the human body. To achieve surgical anesthesia for a given procedure, the extent of spinal anesthesia must reach a certain dermatomal level. Dermatomal levels of spinal anesthesia for common surgical procedures are listed in Table 23–5.

Clinical Pearls

- T10 dermatome corresponds to the umbilicus.
- T6 dermatome corresponds to the xiphoid.
- T4 dermatome corresponds to the nipples.

Sonoanatomy

"Surface" anatomy refers to structures close enough to the integument that they are palpable. However, due to body habitus, this may not be possible.[128,132] Neuraxial ultrasound allows sonoanatomical visualization of these structures and deeper structures. However, as the ultrasound beam cannot penetrate the bony vertebrae, specialized ultrasonic windows are required to visualize the neuraxis. The technique of neuraxial ultrasound is discussed elsewhere (see section on recent developments in spinal anesthesia).

PHARMACOLOGY

The choice of local anesthetic is based on potency of the agent, onset and duration of anesthesia, and side effects of the drug. Two distinct groups of local anesthetics are used in spinal anesthesia, esters and amides, which are characterized by the bond that connects the aromatic portion and the

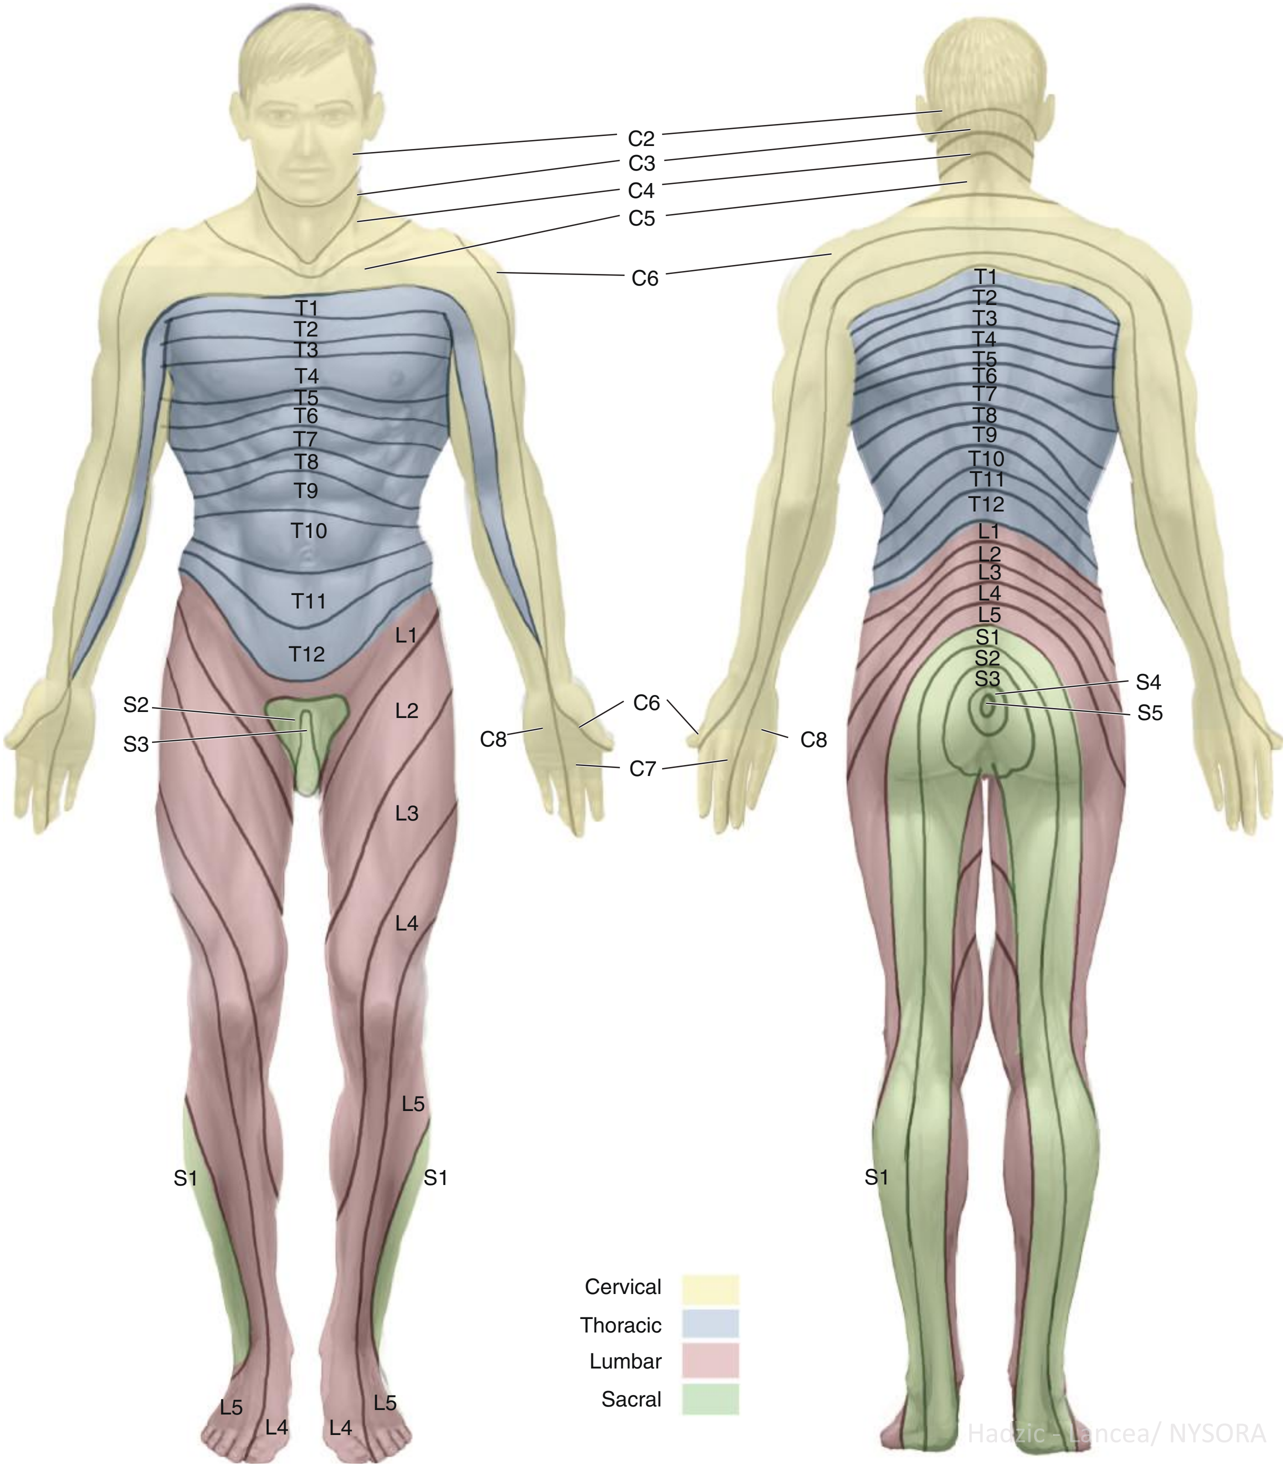

FIGURE 23–6. Dermatomes of the human body.

intermediate chain. Esters contain an ester link between the aromatic portion and the intermediate chain, and examples include procaine, chloroprocaine, and tetracaine. Amides contain an amide link between the aromatic portion and the intermediate chain, and examples include bupivacaine, ropivacaine, etidocaine, lidocaine, mepivacaine, and prilocaine. Although metabolism is important for determining activity of local anesthetics, lipid solubility, protein binding, and pK_a also influence activity.[133]

Clinical Pearls

- Potency of local anesthetics is related to lipid solubility.
- The duration of action of a local anesthetic is affected by the protein binding.
- The onset of action is related to the amount of local anesthetic available in the base form.

TABLE 23–5. Dermatomal levels of spinal anesthesia for common surgical procedures.

Procedure	Dermatomal Level
Upper abdominal surgery	T4
Intestinal, gynecologic, and urologic surgery	T6
Transurethral resection of the prostate	T10
Vaginal delivery of a fetus and hip surgery	T10
Thigh surgery and lower leg amputations	L1
Foot and ankle surgery	L2
Perineal and anal surgery	S2 to S5 (saddle block)

Lipid solubility relates to the potency of local anesthetics. Low lipid solubility indicates that higher concentrations of local anesthesia must be given to obtain nerve blockade. Conversely, high lipid solubility produces anesthesia at low concentrations. Protein binding affects the duration of action of a local anesthetic. Higher protein binding results in longer duration of action. The pK_a of a local anesthetic is the pH at which ionized and nonionized forms are present equally in solution, which is important because the nonionized form allows the local anesthetic to diffuse across the lipophilic nerve sheath and reach the sodium channels in the nerve membrane. The onset of action relates to the amount of local anesthetic available in the base form. Most local anesthetics follow the rule that the lower the pK_a, the faster the onset of action and vice versa. Please refer to Chapter 7 (Clinical Pharmacology of Local Anesthetics).

Pharmacokinetics of Local Anesthetics in the Subarachnoid Space

Pharmacokinetics of local anesthetics includes uptake and elimination of the drug. Four factors play a role in the uptake of local anesthetics from the subarachnoid space into neuronal tissue: (1) concentration of local anesthetic in CSF, (2) surface area of nerve tissue exposed to CSF, (3) lipid content of nerve tissue, and (4) blood flow to nerve tissue.[134,135]

The uptake of local anesthetic is greatest at the site of highest concentration in the CSF and is decreased above and below this site. As discussed previously, uptake and spread of local anesthetics after spinal injection are determined by multiple factors, including dose, volume, and baricity of local anesthetic and patient positioning.

Both the nerve roots and the spinal cord take up local anesthetics after injection into the subarachnoid space. The more surface area of the nerve root exposed, the greater the uptake of local anesthetic.[136–139] The spinal cord has two mechanisms for uptake of local anesthetics. The first mechanism is by diffusion from the CSF to the pia mater and into the spinal cord, which is a slow process. Only the most superficial portion of the spinal cord is affected by diffusion of local anesthetics. The second method of local anesthetic uptake is by extension into the spaces of Virchow-Robin, which are the areas of pia mater that surround the blood vessels that penetrate the central nervous system. The spaces of Virchow-Robin connect with the perineuronal clefts that surround nerve cell bodies in the spinal

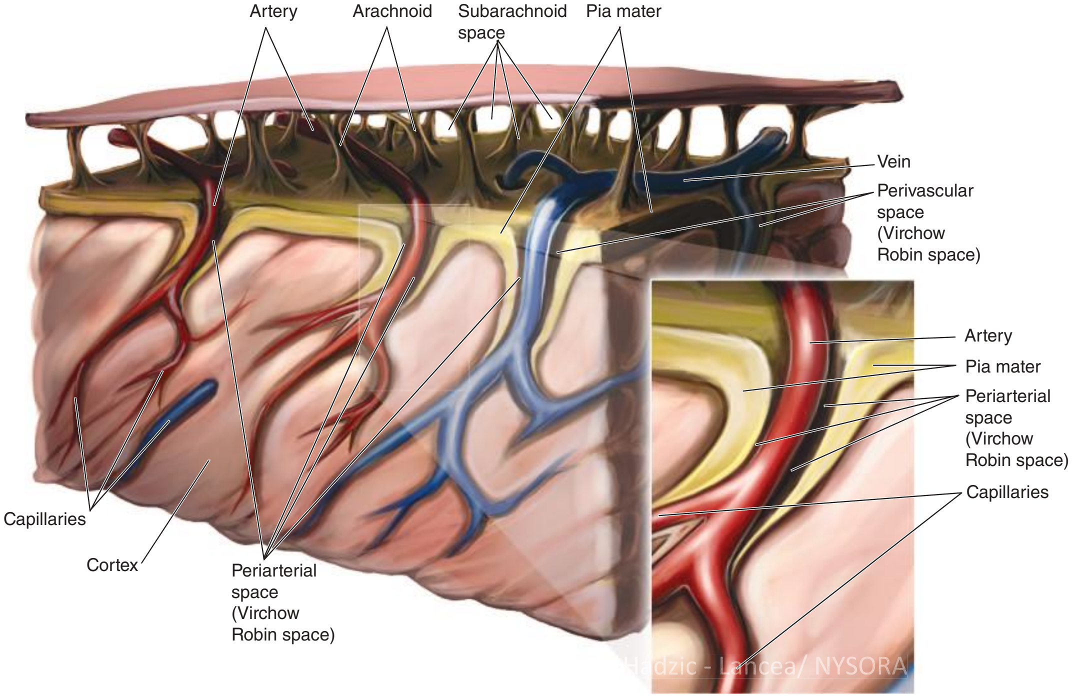

FIGURE 23–7. Virchow-Robin space.

cord and penetrate through to the deeper areas of the spinal cord. Figure 23–7 is a representation of the periarterial Virchow-Robin spaces around the spinal cord.

Clinical Pearls

The three most important modifiable factors in determining distribution of local anesthetics are

- Baricity of the local anesthetic solution
- Position of the patient during and just after injection
- Dose of the anesthetic injected

Lipid content determines uptake of local anesthetics. Heavily myelinated tissues in the subarachnoid space contain higher concentrations of local anesthetics after injection. The higher the degree of myelination, the higher the concentration of local anesthetic, as there is a high lipid content in myelin. If an area of nerve root does not contain myelin, an increased risk of nerve damage occurs in that area.[140]

Blood flow determines the rate of removal of local anesthetics from spinal cord tissue. The faster the blood flows in the spinal cord, the more rapid the anesthetic is washed away. This may partly explain why the concentration of local anesthetics is greater in the posterior spinal cord than in the anterior spinal cord, even though the anterior cord is more readily accessed by the Virchow-Robin spaces. After a spinal anesthetic is administered, blood flow may be increased or decreased to the spinal cord, depending on the particular local anesthetic administered; for example, tetracaine increases cord flow, but lidocaine and bupivacaine decrease it, which affects elimination of the local anesthetic.[141–143]

Elimination of local anesthetic from the subarachnoid space is by vascular absorption in the epidural space and the subarachnoid space. Local anesthetics travel across the dura in both directions. In the epidural space, vascular absorption can occur, just as in the subarachnoid space. Vascular supply to the spinal cord consists of vessels located on the spinal cord and in the pia mater. Because vascular perfusion to the spinal cord varies, the rate of elimination of local anesthetics varies.[134]

Distribution

The distribution and decrease in concentration of local anesthetics is based on the area of highest concentration, which can be independent of the injection site. Many factors affect the distribution of local anesthetics in the subarachnoid space. Table 23–6 lists some of these factors.[144]

TABLE 23–6. Determinants of local anesthetic spread in the subarachnoid space.

Properties of local anesthetic solution
• Baricity
• Dose
• Volume
• Specific gravity
Patient characteristics
• Position during and after injection
• Height (extremely short or tall)
• Spinal column anatomy
• Decreased cerebrospinal fluid volume (increased intra-abdominal pressure due to increased weight, pregnancy, etc.)
Technique
• Site of injection
• Needle bevel direction

Baricity plays an important role in determining the spread of local anesthetic in the spinal space and is equal to the density of the local anesthetic divided by the density of the CSF at 37°C.[145–152] Local anesthetics can be hyperbaric, hypobaric, or isobaric when compared to CSF, and baricity is the main determinant of how the local anesthetic is distributed when injected into the CSF. Table 23–7 compares the density, specific gravity, and baricity of different substances and local anesthetics.[144,145,147,153,154]

Hypobaric solutions are less dense than CSF and tend to rise against gravity. Isobaric solutions are as dense as CSF and tend to remain at the level at which they are injected. Hyperbaric solutions are more dense than CSF and tend to follow gravity after injection.

Hypobaric solutions have a baricity of less than 1.0 relative to CSF and are usually made by adding distilled sterile water to the local anesthetic. Tetracaine, dibucaine, and bupivacaine have all been used as hypobaric solutions in spinal anesthesia. Patient positioning is important after injection of a hypobaric spinal anesthetic because it is the first few minutes that determine the spread of anesthesia. If the patient is in Trendelenburg position after injection, the anesthetic will spread in the caudal direction and if the patient is in reverse Trendelenburg position, the anesthetic will spread cephalad after injection.

The baricity of isobaric solutions is equal to 1.0. Tetracaine and bupivacaine have both been used with success for isobaric spinal anesthesia. Gravity does not play a role in the spread of isobaric solutions, unlike with hypo- or hyperbaric local anesthetics. Therefore, patient positioning does not affect spread of isobaric solutions. Injection can be made in any position, and then the patient can be placed into the position necessary for surgery.

Hyperbaric solutions have baricity greater than 1.0. A local anesthetic solution can be made hyperbaric by adding dextrose or glucose. Bupivacaine, lidocaine, and tetracaine have all been used as hyperbaric solutions in spinal anesthesia. Patient positioning affects the spread of the anesthetic. A patient in Trendelenburg position would have the anesthetic travel in a cephalad direction and vice versa.

Dose and volume both play a role in distribution of local anesthetics after spinal injection. For further information, please refer to the section Volume, Concentration, and Dose of Local Anesthetic.

TABLE 23–7. Density, specific gravity, and baricity of different substances and local anesthetics.

		Density	Specific Gravity	Baricity
Water		0.9933	1.0000	0.9930
Cerebrospinal fluid		1.0003	1.0069	1.0000
Hypobaric				
• Tetracaine	0.33% in water	0.9980	1.0046	0.9977
• Lidocaine	0.5% in water	N/A	1.0038	0.9985
Isobaric				
• Tetracaine	0.5% in 50% CSF	0.9998	1.0064	0.9995
• Lidocaine	2% in water	1.0003	1.0066	1.0003
• Bupivacaine	0.5% in water	0.9993	1.0059	0.9990
Hyperbaric				
• Tetracaine	0.5% in 5% dextrose	1.0136	1.0203	1.0133
• Lidocaine	5% in 7.5% dextrose	1.0265	1.0333	1.0265
• Bupivacaine	0.5% in 8% dextrose	1.0210	1.0278	1.0207
• Bupivacaine	0.75% in 8% dextrose	1.0247	1.0300	1.0227

Effects of the Volume of the Lumbar Cistern on Block Height

Cerebrospinal fluid is produced in the brain at 0.35 mL/min and fills the subarachnoid space. This clear, colorless fluid has an approximate adult volume of 150 mL, half of which is in the cranium and half in the spinal canal. However, CSF volume varies considerably, and decreased CSF volume can result from obesity, pregnancy, or any other cause of increased abdominal pressure.[155] This is partly due to compression of the intervertebral foramen, which displaces the CSF.

Clinical Pearl

- Due to the wide variability in CSF volume, the ability to predict the level of the spinal blockade after local anesthetic injection is very poor, even if BMI is calculated and used.

Multiple factors affect the distribution of local anesthesia after spinal blockade,[144] one being CSF volume. Carpenter showed that lumbosacral CSF volume correlated with peak sensory block height and duration of surgical anesthesia.[156] The density of CSF is related to peak sensory block level, and lumbosacral CSF volume correlates to peak sensory block level and onset and duration of motor block.[157] However, due to the wide variability in CSF volume, the ability to predict the level of the spinal blockade after local anesthetic injection is poor, even if BMI is calculated and used.

Local Anesthetics

Cocaine was the first spinal anesthetic used, and procaine and tetracaine soon followed. Lidocaine, 2-chloroprocaine, bupivacaine, mepivacaine, and ropivacaine have also been used intrathecally. In addition, there is a growing interest in medications that produce anesthesia and analgesia while limiting side effects. A variety of medications, including vasoconstrictors, opioids, α_2-adrenergic agonists, and acetylcholinesterase inhibitors, have been added to spinal medications to enhance analgesia while reducing the motor blockade produced by local anesthetics.

Lidocaine was first used as a spinal anesthetic in 1945, and it has been one of the most widely used spinal anesthetics since. Onset of anesthesia occurs in 3 to 5 minutes with a duration of anesthesia that lasts for 1 to 1.5 hour. Lidocaine spinal anesthesia has been used for short-to-intermediate length operating room cases. The major drawback of lidocaine is the association with transient neurologic symptoms (TNSs), which present as low back pain and lower extremity dysesthesias with radiation to the buttocks, thighs, and lower limbs after recovery from spinal anesthesia. TNSs occur in about 14% of patients receiving lidocaine spinal anesthesia.[158,159] Lithotomy position is associated with a higher incidence of TNSs. Because of the risk of TNSs, lidocaine has mostly been replaced by other local anesthetics.

Intrathecal use of 2-chloroprocaine was described in 1952. In the 1980s, concerns were raised regarding neurotoxicity with the use of 2-chloroprocaine. Studies have suggested that sodium bisulfite, an antioxidant used in combination with 2-chloroprocaine, is responsible. Chronic neurologic deficits have been reported in rabbits when sodium bisulfite was injected into the lumbar subarachnoid space, but when preservative-free 2-chloroprocaine was injected, no permanent neurologic sequelae were noted.[160] Results from clinical trials have shown preservative-free 2-chloroprocaine to be safe, short acting, and acceptable for outpatient surgery.[161,162] However, addition of epinephrine is not recommended due to an association with flu-like symptoms and back pain.[161] Intrathecal 2-chloroprocaine is not currently approved by the Food and

Drug Administration (FDA), although package labeling states it may be used for epidural anesthesia.[163] Onset time is fast, and the duration is around 100 to 120 minutes. The dose ranges from 20 to 60 mg, with 40 mg as a usual dose.

Procaine is a short-acting ester local anesthetic. Procaine has an onset time of 3 to 5 minutes and a duration of 50 to 60 minutes. A dose of 50 to 100 mg has been suggested for perineal and lower extremity surgery. However, there is a 14% incidence of block failure associated with procaine 10%.[164] Concerns about the neurotoxicity of procaine have limited its use.[165] For all these reasons, procaine is currently rarely used for spinal anesthesia.

Bupivacaine is one of the most widely used local anesthetics for spinal anesthesia and provides adequate anesthesia and analgesia for intermediate-to-long-duration operating room cases. Bupivacaine has a low incidence of TNSs.[166–168] Onset of anesthesia occurs in 5 to 8 minutes, with a duration of anesthesia that lasts from 90 to 150 minutes. For outpatient spinal anesthesia, small doses of bupivacaine are recommended to avoid prolonged discharge time due to duration of block. Bupivacaine is often packaged as 0.75% in 8.25% dextrose. Other forms of spinal bupivacaine include 0.5% with or without dextrose and 0.75% without dextrose.

Clinical Pearls

- Use of intrathecal lidocaine is limited by TNSs.
- Bupivacaine has a very low incidence of TNSs.
- Onset of anesthesia occurs in 5 to 8 minutes with bupivacaine and a duration of anesthesia that lasts from 210 to 240 minutes; thus, it is appropriate for intermediate-to-long operating room cases.

Tetracaine has an onset of anesthesia within 3 to 5 minutes and a duration of 70 to 180 minutes and, like bupivacaine, is used for cases that are intermediate to longer duration. The 1% solution can be mixed with 10% glucose in equal parts to form a hyperbaric spinal anesthetic that is used for perineal and abdominal surgery. With tetracaine, TNSs occur at a lower rate than with lidocaine spinal anesthesia. The addition of phenylephrine may play a role in the development of TNSs.[169–171]

Mepivacaine is similar to lidocaine and has been used since the 1960s for spinal anesthesia. The incidence of TNSs reported after mepivacaine spinal anesthesia varies widely, with rates from 0% to 30%.[172–174]

Ropivacaine was introduced in the 1990s. For applications in spinal anesthesia, ropivacaine has been found to be less potent than bupivacaine.[175] Dose range-finding studies have demonstrated the ED95 of spinal ropivacaine in lower limb surgery (11.4 mg),[176] pregnant patients (26.8 mg),[177] and neonates (1.08 mg/kg).[178] Intrathecal use of ropivacaine is not widespread, and large-scale safety data are awaited. An early study identified back pain in 5 of 18 volunteers injected with intrathecal hyperbaric ropivacaine.[179] TNSs have been reported with spinal ropivacaine,[175] although the incidence is not as common as seen with lidocaine.[159] Other small studies have not demonstrated any major side effects.[180–182]

Table 23–8 shows some of the local anesthetics used for spinal anesthesia and dosage duration and concentration for different levels of spinal blockade.[161,183–191]

Additives to Local Anesthesia

Vasoconstrictors have been added to local anesthetics, and both epinephrine and phenylephrine have been studied. Anesthesia is intensified and prolonged with smaller doses of local anesthetics when epinephrine or phenylephrine is added. Tissue vasoconstriction is produced, thus limiting the systemic reabsorption of the local anesthetic and prolonging the duration of action by keeping the local anesthetic in contact with the nerve fibers. However, ischemic complications can occur after the use of vasoconstrictors in spinal anesthesia. In some studies, epinephrine was implicated as the cause of CES because of anterior spinal artery ischemia. Regardless, many studies do not demonstrate an association between the use of vasoconstrictors for spinal anesthesia and the incidence of CES.[192,193] Phenylephrine has been shown to increase the risk of TNSs and may decrease block height.[171,194]

Epinephrine is thought to work by decreasing local anesthetic uptake and thus prolonging the spinal blockade of some local anesthetics. However, vasoconstrictors can cause ischemia, and there is a theoretical concern of spinal cord ischemia when epinephrine is added to spinal anesthetics. Animal models have

TABLE 23–8. Dose, duration, and onset of local anesthetics used in spinal anesthesia.

	Dose (mg)		Duration (minutes)		
	To T10	to T4	Plain	With Epinephrine	Onset (minutes)
Commonly used Bupivacaine 0.75%	8–12	14–20	90–110	100–150	5–8
Less commonly used					
• Lidocaine 5%	50–75	75–100	60–70	75–100	3–5
• Tetracaine 0.5%	6–10	12–16	70–90	120–180	3–5
• Mepivacaine 2%	N/A	60–80	140–160	N/A	2–4
• Ropivacaine 0.75%	15–17	18–20	140–200	N/A	3–5
• Levobupivacaine 0.5%	10–15	N/A	135–170	N/A	4–8
• Chloroprocaine 3%	30	45	80–120	N/A	2–4

not shown any decrease in spinal cord blood flow or increase in spinal cord ischemia when epinephrine is given for spinal blockade, even though some neurologic complications associated with the addition of epinephrine exist.[141,143,195,196]

Clinical Pearls

- Adding 0.1 mL of 1:1000 epinephrine to 10 mL of local anesthetic yields a 1:100,000 concentration of epinephrine.
- Adding 0.1 mL of 1:1000 epinephrine to 20 mL of local anesthetic yields a 1:200,000 concentration and so on (0.1 mL in 30 mL = 1:300,000).

Dilution of epinephrine with local anesthetic is a potential source of drug error, with mistakes potentially incorrect by a factor of 10 or 100. If using epinephrine packaged as 1 mg in 1 mL, which is a 1:1000 solution, a simple rule can be followed. Adding 0.1 mL of epinephrine to 10 mL of local anesthetic yields a 1:100,000 concentration of epinephrine. Adding 0.1 mL of epinephrine to 20 mL of local anesthetic yields a 1:200,000 concentration, and so on (0.1 mL in 30 mL = 1:300,000).

Epinephrine prolongs the duration of spinal anesthesia.[197–199] In the past, it was thought that epinephrine had no effect on hyperbaric spinal bupivacaine using two-segment regression to test neural blockade.[200] However, another study showed that epinephrine prolongs the duration of hyperbaric spinal bupivacaine when pinprick, transcutaneous electrical nerve stimulation (TENS) equivalent to surgical stimulation, and tolerance of a pneumatic thigh tourniquet were used to determine neural blockade.[201] There is controversy regarding prolongation of spinal bupivacaine neural blockade when epinephrine is added.[202–205] The same controversy exists about the prolongation of spinal lidocaine with epinephrine.[206–210]

All four types of opioid receptors are found in the dorsal horn of the spinal cord and serve as the target for intrathecal opioid injection. Receptors are located on spinal cord neurons and terminals of afferents originating in the dorsal root ganglion. Fentanyl, sufentanil, meperidine, and morphine have all been used intrathecally. Side effects that may be seen include pruritus, nausea and vomiting, and respiratory depression.[211–215]

The α_2-adrenergic agonists can be added to spinal injections of local anesthetics to enhance pain relief and prolong sensory and motor block. Enhanced postoperative analgesia has been demonstrated in cesarean deliveries, fixation of femoral fractures, and knee arthroscopies when clonidine was added to the local anesthetic solution. Clonidine prolongs the sensory and motor blockade of a local anesthetic after spinal injection.[216–218] Sensory blockade is thought to be mediated by both presynaptic and postsynaptic mechanisms. Clonidine induces hyperpolarization at the ventral horn of the spinal cord and facilitates the action of the local anesthetic, thus prolonging motor blockade when used as an additive. However, when used alone in intrathecal injections, clonidine does not cause motor block or weakness.[219] Side effects can occur with the use of spinal clonidine and include hypotension, bradycardia, and sedation. Neuraxial clonidine has been used for the treatment for intractable pain.[220,221]

Acetylcholinesterase inhibitors prevent the breakdown of acetylcholine and produce analgesia when injected intrathecally. The antinociceptive effects are due to increased acetylcholine and generation of nitric oxide. It has been shown in a rat model that diabetic neuropathy can be alleviated after intrathecal neostigmine injection.[222] Side effects of intrathecal neostigmine include nausea and vomiting, bradycardia requiring atropine, anxiety, agitation, restlessness, and lower extremity weakness.[223–225] Although spinal neostigmine provides extended pain control, the side effects that occur do not allow its widespread use.

PHARMACODYNAMICS OF SPINAL ANESTHESIA

The pharmacodynamics of spinal injection of local anesthesia are wide ranging. The cardiovascular, respiratory, gastrointestinal, hepatic, and renal effect consequences of spinal anesthesia are discussed next.

Cardiovascular Effects of Spinal Anesthesia

It is well recognized that spinal anesthesia results in hypotension. In fact, a degree of hypotension often reassures the anesthesiologist that the block is indeed spinal. However, hypotension may cause nausea and vomiting, ischemia of critical organs, cardiovascular collapse, and in the case of the pregnant mother may endanger the fetus. Historically, there have been shifts in the definitions, suggested mechanisms, and management of hypotension.

Defining hypotension is troublesome. One study found 15 different definitions of hypotension in 63 publications.[226] Some definitions used a single criterion (decrease of 80% from baseline), while others used combinations (a fall of 80% from baseline *or* a systolic blood pressure less than 100 mm Hg). The incidence of hypotension in a single cohort of patients varied from 7.4% to 74.1% depending on the definition used.

There have been many suggested mechanisms for spinal anesthesia–induced hypotension, including direct circulatory effects of local anesthetics, relative adrenal insufficiency, skeletal muscle paralysis, ascending medullary vasomotor block, and concurrent respiratory insufficiency. The primary insult, however, is the preganglionic sympathetic block produced by spinal anesthesia.[227,228] It therefore follows that because the block height determines the extent of sympathetic blockade, this in turn determines the amount of change in cardiovascular parameters. However, this relationship cannot be predicted. Sympathetic block may be variably between two and six dermatomes above the sensory level and incomplete below this level.[227] The sudden sympathetic block with spinal anesthesia gives little time for cardiovascular compensation, which may account for a similar sympathetic block with epidural anesthesia, but less hypotension.[229]

Clinical Pearls

- Spinal anesthesia block the sympathetic chain, which is the main mechanism of cardiovascular changes.
- The block height determines the level of sympathetic blockade, which determines the degree of change in cardiovascular parameters.

Sympathetic block causes hypotension via its effects on preload, afterload, contractility, and HR—in other words, the determinants of cardiac output (CO)—and by decreasing systemic vascular resistance (SVR). Preload is decreased by sympathetic block-mediated venodilation, resulting in pooling of blood in the peripheries and decreased venous return.[229] During sympathetic block, the venous system is maximally vasodilated and therefore reliant on gravity to return blood to the heart. Thus, patient positioning, and aortocaval compression in the case of a gravid uterus, markedly influences venous return during spinal anesthesia.[227,230]

Arterial vasomotor tone can also be decreased by sympathetic block, decreasing SVR, and afterload. Arterial vasodilation, unlike venodilation, is not maximal after spinal blockade, and vascular smooth muscle continues to retain some autonomic tone after sympathetic denervation. This residual vascular tone can be lost in the presence of hypoxia and acidosis, which may account for cardiovascular collapse after high spinal anesthesia without cardiorespiratory support.[227] Although there is vasodilation below the level of spinal blockade, there is compensatory vasoconstriction above, mediated by carotid and aortic arch baroreceptors. This is important for two reasons. First, blockade at higher dermatomal levels may result in less compensation. Second, use of vasodilatory drugs such as glyceryl trinitrate (GTN), sodium nitroprusside, or volatile anesthetics may abolish this compensatory mechanism and worsen hypotension or even result in cardiac arrest.[231]

There may be an initial increase in CO associated with a decreased afterload.[229] Alternatively, CO may fall due to decreased preload.[232] Some studies have shown that CO is unchanged or slightly reduced during onset of spinal anesthesia. Others, in elderly patients, have shown a biphasic change in CO with an initial increase in the first 7 minutes, followed by a fall (Figure 23–8).[233] This may be attributed to a fall in afterload preceding a fall in preload.

Contractility may be affected by blockade of the upper thoracic sympathetic nerves.[227] Interestingly, a study investigating the common phenomenon of ST segment depression in healthy women undergoing cesarean section (25-60%) found ST depression to be associated with a hyperkinetic contractile state.[234]

The effect of spinal anesthesia on HR is complex. HR may increase (secondary to hypotension via the baroreceptor reflex) or decrease (either from sympathetic block of cardiac accelerator fibers originating from T1–T4 spinal segments, or via the *reverse* Bainbridge reflex).[228] The reverse Bainbridge reflex is a decrease in HR due to decreased venous return, detected by stretch receptors in the right atrium, and is weaker than the baroreceptor reflex. The Bezold-Jarisch reflex (BJR) is another reflex that decreases HR. The BJR has been implicated as a cause of bradycardia, hypotension, and cardiovascular collapse after central neuraxial anesthesia, in particular spinal anesthesia.[235,236] The BJR is a cardioinhibitory reflex and is usually not a dominant reflex. The association with spinal anesthesia is probably weak.[237,238] The BJR has been blamed for bradycardia after spinal anesthesia, especially after hemorrhage.[239] Vigorous contractions of an underfilled heart may initiate the BJR. This is more likely with the use of ephedrine rather than phenylephrine.[228]

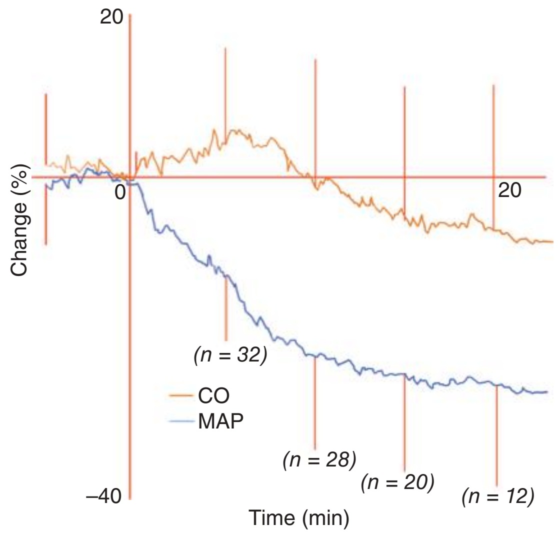

FIGURE 23–8. Figure from the work of Meyhoff et al showing a fall in mean arterial pressure (MAP) and biphasic cardiac output (CO) after spinal anesthesia. Average CO and MAP changes plus or minus standard deviation during onset of spinal anesthesia in elderly patients. Subarachnoid injection is given at time = 0 minutes. After termination of data collection, the last CO and MAP recording are still represented in the average throughout the rest of the graph. Each line is thus hypothetical as it consists of averages of 32 patients even after data termination; this is done for illustration purposes only. (Reproduced with permission from Meyhoff CS, Hesselbjerg L, Koscielniak-Nielsen Z, et al: Biphasic cardiac output changes during onset of spinal anaesthesia in elderly patients. *Eur J Anaesthesiol*. 2007 Sep;24(9):770-775.)

Young, healthy (American Society of Anesthesiologists class 1) patients have a higher risk of bradycardia. Beta-blocker use also increases the risk of bradycardia. The incidence of bradycardia in the nonpregnant population is about 13%.[48] Even though bradycardia is usually well tolerated, asystole and second- and third-degree heart block can occur, so it is wise to be vigilant when monitoring a patient after spinal anesthesia and treat promptly.[240]

Risk factors associated with hypotension include hypovolemia, preoperative hypertension, high sensory block height, age older than 40 years, obesity, combined general and spinal anesthesia, chronic alcohol consumption, elevated BMI, and urgency of nonobstetric surgery.[48,241–243] Hypotension is less likely in women who are in labor compared with those undergoing elective cesarean section.[244]

Management of Hypotension After Spinal Anesthesia

Changing Beliefs Shifting beliefs in the theoretical basis of spinal-induced hypotension have been echoed by changes in management. For example, if decreased preload is believed to be of primary importance, then positioning and fluid therapy are the treatments of choice,[245] and similarly if vasodilation is the culprit, then a vasoconstrictor should be first line.[228] This has led to vigorous debate.[246] In the 1970s, it was suggested not to give vasopressors until "all other methods of combating hypotension" were utilized,[245] underlining the importance of preload. Evidence to support this was extrapolated from flawed studies on pregnant ewes undergoing general anesthesia, which suggested vasopressors adversely effected the uteroplacental circulation. The title *vasopressor of choice* has similarly generated much controversy. Ephedrine was traditionally nominated as it preserved uterine blood flow (in the aforementioned animal studies). Work by Ngan Kee, among others, has suggested phenylephrine may be the vasopressor of choice,[228] at least in the elective obstetric setting.

Management Management of hypotension following spinal anesthesia should include frequent (every minute initially) monitoring of blood pressure, in addition to electrocardiogram (ECG), oxygen saturation, and fetal monitoring in the case of a pregnant patient. Consideration should be given to invasive blood pressure monitoring if the patient has significant cardiac comorbidities. Fluid therapy should be used in a dehydrated patient to restore volume prior to commencing spinal anesthesia.

Nonpharmacological methods to treat hypotension include positioning, leg compression, and uterine displacement. Trendelenburg positioning can increase venous return to the heart. This position should not exceed 20° because extreme Trendelenburg can lead to a decrease in cerebral perfusion and blood flow due to increases in jugular venous pressure. If the level of spinal anesthesia is not fixed, the Trendelenburg position can alter the level of spinal anesthesia and cause a high level of spinal anesthesia in patients receiving hyperbaric local anesthetic solutions.[247] This can be minimized by raising the upper part of the body with a pillow under the shoulders while keeping the lower part of the body elevated above heart level. A Cochrane review in pregnant women found lower limb compression to have some benefit, although different methods had varying efficacies.[248] Aortocaval compression from a gravid uterus should be avoided. Full lateral positioning results in less hypotension than left lateral tilt, although this may not be practical. A wedge under the right hip, or a tilting table, can be used to achieve left lateral tilt. However, the optimal degree of tilt is unknown, and there may be considerable variability among different patients.[229]

There have been conflicting opinions on appropriate fluid management during spinal anesthesia. Early studies suggested crystalloid "preloading" prior to spinal blockade was effective. More recent work showed minimal effect of preloading.[249,250] Colloid preloading does seem to be effective,[251] although this must be balanced against the risk of allergic reactions and increased costs. "Coloading" (rapid administration of fluid immediately after spinal anesthesia) with crystalloid is better than preloading at preventing hypotension.[252]

Hypotension can be limited by lowering the dose of spinal local anesthetic. One review found 5–7 mg of bupivacaine to be sufficient for cesarean section. However, complete motor block was rare, duration was limited, and an epidural catheter for early top-up doses was essential.[253] A meta-analysis in 2011 found lower doses of bupivacaine to be associated with lower anesthetic efficacy but less hypotension and nausea.[254]

Conflicting opinions exist regarding the vasopressor of choice for spinal-induced hypotension. Ephedrine and phenylephrine have been the two main contenders; however, others have been used. Ephedrine is a direct and indirect α- and β-receptor agonist. It was felt to be safer than phenylephrine because it limited vasoconstriction of the uteroplacental circulation in early animal studies. However, ephedrine has a slow onset of action, is subject to tachyphylaxis, and has limited efficacy in treating hypotension.[229] Of more concern is the increased risk of fetal acidosis.[255] Whether this translates to poorer clinical outcomes is uncertain.

Phenylephrine is an direct α_1-receptor agonist. It was used successfully in the 1960s for spinal anesthesia in New York,[256] but fell out of favor due to concerns about poor tissue perfusion. In particular, uteroplacental vasoconstriction was noted in (somewhat-flawed) pregnant animal models. Recent work has shown that fetal acidosis does not occur when usual doses are used.[257] In addition, phenylephrine seems superior to ephedrine in reducing hypotension and nausea.[228] Phenylephrine has been used as a bolus or as an infusion and has been used to treat hypotension prophylactically as well as reactively (Table 23–9). Optimal dosing regimens are yet to be established. Ngan Kee effectively prevented hypotension in elective obstetric patients by using a combination of crystalloid coload with a prophylactic infusion of phenylephrine.[258]

Phenylephrine is the current vasopressor of choice for spinal hypotension, at least in the elective obstetric setting. There are, however, drawbacks. First, phenylephrine results in decreased CO, although the significance of this is uncertain.[228,259] Second, intravenous phenylephrine has been shown to decrease spinal block height in pregnant[228] and nonpregnant patients.[260] Third, Cooper referred to two case reports of hypertensive crisis involving phenylephrine and atropine, resulting in significant morbidity.[228] It is suggested that hypertension induced by vasopressors is limited by a reflex decrease in HR. Atropine, *in this setting*, can therefore result in hypertensive crisis. Finally, the usual presentation of phenylephrine is highly concentrated (10 mg/mL) and needs to be diluted in a 100-mL bag of saline (100 μg/mL). Anesthesiologists more familiar with ephedrine may find this tiresome or, worse still, may commit a drug concentration error. Moreover, as a usual case requires much less than a 100-mL bag of phenylephrine, there is a risk of cross contamination if bags are reused.

Cardiovascular collapse can occur after spinal anesthesia, although it is a rare event. Auroy and coworkers reported 9 cardiac arrests in 35,439 spinal anesthetics performed.[102] Bradycardia usually precedes cardiac arrest,[236,261–263] and early, aggressive treatment of bradycardia is warranted. Treatment of bradycardia includes intravenous atropine, ephedrine, and epinephrine. In cases of cardiac arrest after spinal anesthesia, epinephrine should be used early, and the Advanced Cardiac Life Support (ACLS) protocol should be initiated.[264]

Further work on spinal-induced hypotension is required. Although treatment is usually aimed at systolic blood pressure,

TABLE 23–9. Phenylephrine Infusion Regimen.

1. Cycle blood pressure measurement at 1-minute intervals until delivery of baby.
2. Prepare phenylephrine solution 0.1 mg/mL: Add 1 ampoule of phenylephrine 10 mg to 100 mL normal saline.
3. Draw this solution into 20- or 50-mL syringe to be delivered via infusion pump.
4. At completion of injection of spinal drug, start phenylephrine infusion at 60 mL per hour.
5. Commence rapid intravenous infusion of 1 L of crystalloid.
6. Subsequent phenylephrine infusion can be given by a variety of regimens:

A. On/off infusion regimen:

For first 2 minutes:

ON: unless systolic blood pressure was greater than 120% of baseline

Second minute until the time of uterine incision:

ON: If systolic blood pressure equal to or less than baseline

OFF: If systolic blood pressure greater than baseline.

B. Sliding scale infusion regimen:

Systolic Blood Pressure (mm Hg)	Infusion rate (mL/h)
≥140	0
≥120	15
≥100	30
≥80	45
≥60	60

Bolus Regimen

Prepare phenylephrine solution 0.1 mg/mL:

Add 1 ampoule of phenylephrine 10 mg to 100 mL normal saline.

Draw this solution into a 10-mL syringe:

If systolic blood pressure is less than 80%, baseline, give 1 mL together with bolus intravenous field.

Source: Reproduced with permission from Khaw KS, Ngan Kee WD, Lee SW: Hypotension during spinal anaesthesia for Caesarean section: Implications, detection, prevention and treatment. *Fetal Matern Med Rev*. 2006;17(2):157-183.

mean blood pressure may be a better target.[265] Different receptors may also be targeted. For example, prophylactic intravenous ondansetron has been shown to reduce hypotension, perhaps by modulating the BJR.[266] Different patient subpopulations may require different therapies. Most evidence pertains to the elective, healthy obstetric setting, and the extent to which this can be extrapolated to other groups remains to be seen. Last, despite published evidence of the benefits of phenylephrine over ephedrine for elective cesarean section, there is reluctance to change practice.[267] Psychological and institutional barriers to change need to be addressed.

Respiratory Effects of Spinal Anesthesia

In patients with normal lung physiology, spinal anesthesia has little effect on pulmonary function.[268] Lung volumes, resting minute ventilation, dead space, arterial blood gas tensions, and shunt fraction show minimal change after spinal anesthesia. The main respiratory effect of spinal anesthesia occurs during high spinal blockade when active exhalation is affected due to paralysis of abdominal and intercostal muscles. During high spinal blockade, expiratory reserve volume, peak expiratory flow, and maximum minute ventilation are reduced. Patients with obstructive pulmonary disease who rely on accessory muscle use for adequate ventilation should be monitored carefully after spinal blockade. Patients with normal pulmonary function and a high spinal block may complain of dyspnea, but if they are able to speak clearly in a normal voice, ventilation is usually adequate. The dyspnea is usually due to the inability to feel the chest wall move during respiration, and simple assurance is usually effective in allaying the patient's distress.

Clinical Pearls

- Arterial blood gas measurements do not change during high spinal anesthesia in patients who are spontaneously breathing room air.
- Because a high spinal usually does not affect the cervical area, sparing of the phrenic nerve and normal diaphragmatic function occurs, and inspiration is minimally affected.

Arterial blood gas measurements do not change during high spinal anesthesia in patients who are spontaneously breathing room air. The main effect of high spinal anesthesia is on expiration, as the muscles of exhalation are impaired. Because a high spinal usually does not affect the cervical area, sparing of the phrenic nerve and normal diaphragmatic function occurs, and inspiration is minimally affected. Although Steinbrook and colleagues found that spinal anesthesia was not associated with significant changes in vital capacity, maximal inspiratory pressure, or resting end-tidal PCO_2, an increased ventilatory responsiveness to CO_2 with bupivacaine spinal anesthesia was seen.[269]

Gastrointestinal Effects of Spinal Anesthesia

The sympathetic innervation to the abdominal organs arises from T6 to L2. Due to sympathetic blockade and unopposed parasympathetic activity after spinal blockade, secretions increase, sphincters relax, and the bowel becomes constricted.

Increased vagal activity after sympathetic block causes increased peristalsis of the gastrointestinal tract, which can lead to nausea. Nausea may also result from hypotension-induced gut ischemia, which produces serotonin and other emetogenic substances.[46] The incidence of IONV in nonobstetric surgery can be up to 42% and may be as high as 80% in parturients.[46]

Hepatic and Renal Effects of Spinal Anesthesia

Hepatic blood flow correlates to arterial blood flow. There is no autoregulation of hepatic blood flow; thus, as arterial blood flow decreases after spinal anesthesia, so does hepatic blood flow.[270] If the mean arterial pressure (MAP) after placing a spinal anesthetic is maintained, hepatic blood flow will also be maintained. Patients with hepatic disease must be carefully monitored, and their blood pressure must be controlled during anesthesia to maintain hepatic perfusion. No studies have conclusively shown the superiority of regional or general anesthesia in patients with liver disease.[271–275] In patients with liver disease, either regional or general anesthesia can be given, as long as the MAP is kept close to baseline.

Clinical Pearls

- If mean blood pressure is maintained after placing a spinal anesthetic, neither hepatic nor renal blood flow will decrease.
- Spinal anesthesia does not alter autoregulation of renal blood flow.

Renal blood flow is autoregulated. The kidneys remain perfused when the MAP remains above 50 mm Hg. Transient decreases in renal blood flow may occur when MAP is less than 50 mm Hg, but even after long decreases in MAP, renal function returns to normal when blood pressure returns to normal. Again, attention to blood pressure is important after placing a spinal anesthetic, and the MAP should be as close to baseline as possible. Spinal anesthesia does not affect autoregulation of renal blood flow. It has been shown in sheep that renal perfusion changed little after spinal anesthesia.[276–279]

FACTORS AFFECTING LEVEL OF SPINAL BLOCKADE

Many factors have been suggested as possible determinants of spinal blockade level.[144] The four main categories of factors are (1) characteristics of the local anesthetic solution, (2) patient characteristics, (3) technique of spinal blockade, and (4) diffusion. Characteristics of local anesthetic solution include baricity, dose, concentration, and volume injected. Patient characteristics include age, weight, height, gender, intra-abdominal pressure, anatomy of the spinal column, spinal fluid characteristics, and patient position.[280] Techniques of spinal blockade include site of injection, speed of injection, direction of needle bevel, force of injection, and addition of vasoconstrictors. Although all these factors have been postulated as affecting spinal spread of anesthetic, not many have been shown to change the distribution of blockade when all other factors that affect blockade are kept constant.

Site of Injection

The site of injection of local anesthetics for spinal anesthesia can determine the level of blockade. In some studies, isobaric spinal 0.5% bupivacaine produces sensory blockade that is reduced by two dermatomes per interspace when injection at L2–L3, L3–L4, and L4–L5 interspaces are compared.[281,282] However, no difference in block height exists when hyperbaric bupivacaine or dibucaine is injected as a spinal anesthetic in different interspaces.[283–285]

Age

Some studies have reported changes in block height after spinal anesthesia in the elderly patient as compared with the young patient, but other studies have reported no difference in block height.[286–289] These studies were performed with both isobaric and hyperbaric 0.5% bupivacaine.

Clinical Pearl

- Baricity plays a major role in determining block height after spinal anesthesia in older populations.

Isobaric bupivacaine appears to increase block height, and hyperbaric bupivacaine does not appear to change block height with increasing age. If there is a correlation between increasing age and spinal anesthesia height, it is not strong enough by itself to be a reliable predictor in the clinical setting.[290,291] Just as with site of injection, it appears that baricity plays a major role in determining block height after spinal anesthesia in older populations, and age is not an independent factor.

Position

Positioning of the patient is important for determining level of blockade after hyperbaric and hypobaric spinal anesthesia, but not for isobaric solutions. Sitting, Trendelenburg, and prone jackknife positions can greatly change the spread of the local anesthetic due to effect of gravity.[292–294]

Clinical Pearl

- Positioning of the patient is important for determining level of blockade after hyperbaric and hypobaric spinal anesthesia, but not for isobaric solutions.

The combination of baricity of the local anesthetic solution and patient positioning determines spinal block height.[295] The sitting position in combination with a hyperbaric solution can produce analgesia in the perineum. Trendelenburg positioning will also affect spread of hyperbaric and hypobaric local anesthetics due to the effect of gravity.[247,296] Prone jackknife positioning is used for rectal, perineal, and lumbar procedures with a hypobaric local anesthetic.[153,297] This prevents rostral spread of the spinal blockade after injection.

Flexion of the supine patient's hips and knees flattens lumbar lordosis and decreases sacral pooling of local anesthetic. Combined with Trendelenburg positioning, this may help cephalad spread.[298] This position may inadvertently be attained when a urinary catheter is placed after spinal insertion.

Speed of Injection

Speed of injection has been reported to affect spinal block height, but the data available in the literature are conflicting.[299] In studies using isobaric bupivacaine, there is no difference in spinal block height with different speeds of injection.[300–302] Even though spinal block height does not change with speed of injection, a smooth, slow injection should be used when giving a spinal anesthetic. If a forceful injection is given and the syringe is not connected tightly to the spinal needle, the needle might disconnect from the syringe with loss of local anesthetic.

> **Clinical Pearl**
>
> - Even though spinal block height does not change with speed of injection, use a smooth, slow injection when giving a spinal anesthetic.

Volume, Concentration, and Dose of Local Anesthetic

It is difficult to maintain volume, concentration, or dose of local anesthetic constant without changing any of the other variables; thus, it is difficult to produce high-quality studies that investigate these variables singly. Axelsson and associates showed that volume of local anesthetic can affect spinal block height and duration when equivalent doses are used.[303]

Peng and coworkers showed that concentration of local anesthetic is directly related to dose when determining effective anesthesia.[304] However, dose of local anesthetic plays the greatest role in determining spinal block duration, as neither volume nor concentration of isobaric bupivacaine or tetracaine alter spinal block duration when the dose is held constant.[305,306] Studies have repeatedly shown that spinal block duration is longer when higher doses of local anesthetic are given.[148,303,307–309] When performing a spinal anesthetic, be cognizant of not only the dose of local anesthetic but also the volume and concentration so the patient is not overdosed or underdosed.

> **Clinical Pearl**
>
> - When performing a spinal anesthetic, be cognizant of not only the dose of local anesthetic but also the volume and concentration so the patient is not overdosed or underdosed.

The use of hyperbaric solutions minimizes the importance of dose and volume except when doses of hyperbaric bupivacaine equal to or less than 10 mg are used. In those cases, there is less cephalad spread and a shorter duration of action.[293] A dose of hyperbaric bupivacaine between 10 and 20 mg results in similar block height.[283] When using hyperbaric solutions, it is important to note that patient positioning and baricity are the most influential factors on block height, except when low doses of hyperbaric bupivacaine are used.

EQUIPMENT FOR SPINAL ANESTHESIA

Maintaining Asepsis

No single intervention guarantees asepsis. Therefore, a multi-prong approach is advisable.

In the past, most institutions had reusable trays for spinal anesthesia. These trays required preparation by anesthesiologists or anesthesia personnel to ensure that bacterial and chemical contamination would not occur. Currently, commercially prepared, disposable spinal trays are available and are in use by most institutions. These trays are portable, sterile, and easy to use. Figure 23–9 shows the contents of a standard, commercially prepared spinal anesthetic tray.

The ideal skin preparation solution should be bactericidal and have a quick onset and long duration. Chlorhexidine is superior to povidone iodine in all these respects.[114] In addition, the ideal agent should not be neurotoxic. Unfortunately, bactericidal agents are neurotoxic. It is therefore prudent to use the lowest effective concentration and allow the preparation to dry. Although subject to debate, 0.5% chlorhexidine in alcohol 70% is currently recommended by some groups.[310] Contamination of equipment with skin preparation can theoretically lead to the introduction of neurotoxic substances into neural tissue. Of more concern is accidental neuraxial injection of antiseptic solution, possibly from antiseptic solution and local anesthetic being placed in adjacent pots. Therefore, after skin preparation, unused antiseptic should be discarded before commencement of the procedure (and intrathecal drugs should be drawn directly from sterile ampules). Tinted antiseptic solutions may decrease the likelihood of drug error and allow easy identification of missed skin during application.

Proving a benefit of individual infection control measures is difficult due to the rarity of infectious complications. Past evidence has been contradictory. For example, it has been suggested that shedding of skin scales from mask "wiggling" may occur,[311] increasing bacterial contamination. Yet, in 1995 there were calls for

FIGURE 23–9. Contents of a standard, commercially prepared spinal anesthetic tray.

routine face mask use after it was unambiguously proven, using polymerase chain reaction (PCR) fingerprinting, that a case of *Streptococcus salivarius* meningitis originated in the throat of the doctor who had performed a lumbar puncture.[312] It is our strong belief that face mask wearing should be mandatory when performing spinal anesthesia. A 2006 American Society of Regional Anesthesia and Pain Medicine (ASRA) practice advisory recommended mask wearing in addition to removing jewelry, thorough hand washing, and sterile surgical gloves for all regional anesthesia techniques. Major components of an aseptic technique also included a surgical hat and sterile draping.[313] Other international professional bodies have similar guidelines.[314]

Prophylactic antibiotics are unnecessary for spinal anesthesia. If, as it happens, antibiotic prophylaxis is required for the prevention of surgical site infection, it may be prudent to administer antibiotics before insertion of a spinal needle.

The reader is referred to Chapter 16 (Infection Control in Regional Anesthesia) for more information.

Resuscitation and Monitoring

Resuscitation equipment must be available whenever a spinal anesthetic is performed. This includes equipment and medication required to secure an airway, provide ventilation, and support cardiac function. All patients receiving spinal anesthesia should have an intravenous line.

The patient must be monitored during the placement of the spinal anesthetic with a pulse oximeter, blood pressure cuff, and ECG. Fetal monitoring should be used in the case of a pregnant patient. Noninvasive blood pressure should be measured at 1-minute intervals initially, as hypotension may be sudden. Shivering and body habitus may make noninvasive blood pressure measurement difficult. Consideration should be given to invasive blood pressure monitoring if the patient has significant cardiovascular disease.

Needles

Needles of different diameters and shapes have been developed for spinal anesthesia. The ones currently used have a close-fitting, removable stylet, which prevents skin and adipose tissue from plugging the needle and possibly entering the subarachnoid space. Figure 23–10 shows the different types of needles used along with the type of point at the end of the needle.

The pencil-point needles (Sprotte and Whitacre) have a rounded, noncutting bevel with a solid tip. The opening is located on the side of the needle 2–4 mm proximal to the tip of the needle. The needles with cutting bevels include the Quincke and Pitkin needles. The Quincke needle has a sharp point with a medium-length cutting needle, and the Pitkin has a sharp point and short bevel with cutting edges. Finally, the Greene spinal needle has a rounded point and rounded noncutting bevel. If a continuous spinal catheter is to be placed, a Tuohy needle can be used to find the subarachnoid space before placement of the catheter.

Pencil-point needles provide a better tactile sensation of the layers of ligament encountered but require more force to insert than bevel-tip needles. The bevel of the needle should be

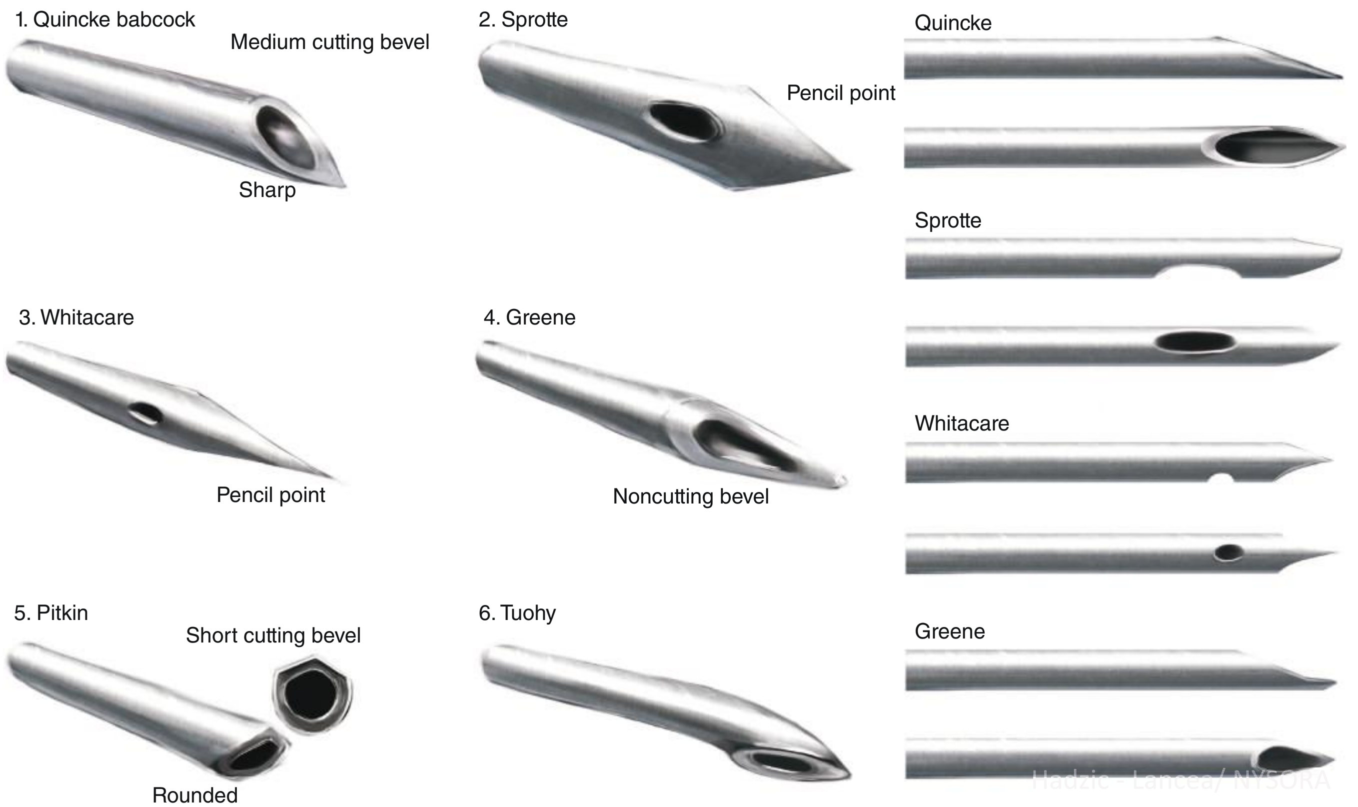

FIGURE 23–10. Different types of needles.

directed longitudinally to decrease the incidence of PDPH.[315] Small-gauge needles and needles with rounded, noncutting bevels also decrease the incidence of PDPH but are more easily deflected than larger-gauge needles. The reader is referred to Chapter 6 (Ultrastructural Anatomy of the Spinal Meninges and Related Structures) and Chapter 23 (Postdural Puncture Headache).

Clinical Pearls

- Pencil-point needles provide a better tactile sensation of the layers of ligament encountered but require more force to insert than bevel-tip needles.
- The use of introducers help preventing the passage of epidermic contaminants to the CSF.

Introducers have been designed to assist with the placement of spinal needles into the subarachnoid space due to the difficulty in directing needles of small bore through the tissues. Introducers also serve to prevent contamination of the CSF with small pieces of epidermis, which could lead to the formation of dermoid spinal cord tumors. The introducer is placed into the interspinous ligament in the intended direction of the spinal needle, and the spinal needle is then placed through the introducer.

POSITION OF THE PATIENT

Proper positioning of the patient for spinal anesthesia is essential for a fast, successful block. It has been shown to be an independent predictor for successful first attempt at neuraxial block.[316] Many factors come into play for positioning of the patient. Before beginning the procedure, both the patient and the anesthesiologist should be comfortable. This includes positioning the height of the operating room table, providing adequate blankets or covers for the patient, ensuring a comfortable room temperature, and providing sedation for the patient if required. Personnel trained in positioning patients are invaluable, and commercial positioning devices may be useful.

When providing sedation, it is important to avoid oversedation. The patient should be able to cooperate before, during, and after administration of the spinal anesthetic. There are three main positions for administering a spinal anesthetic: the lateral decubitus, sitting, and prone positions.

Lateral Decubitus Position

A commonly used position for placing a spinal anesthetic is the lateral decubitus position. Ideal positioning consists of having the back of the patient parallel to the edge of the bed closest to the anesthesiologist, with the patient's knees flexed to the abdomen and neck flexed. Figure 23–11 shows a patient in the lateral decubitus position.

It is beneficial to have an assistant to help hold and encourage the patient to stay in this position. Depending on the operative site and operative position, a hypo-, iso-, or hyperbaric solution of local anesthetic can be injected.

FIGURE 23–11. Patient in lateral decubitus position.

Clinical Pearls

- A commonly used position for placing a spinal anesthetic is the lateral decubitus position.
- Ideal positioning consists of having the back of the patient parallel to the edge of the bed closest to the anesthesiologist, knees flexed to the abdomen, and neck flexed.

Sitting Position and "Saddle Block"

Strictly speaking, the sitting position is best utilized for low lumbar or sacral anesthesia and in instances when the patient is obese and there is difficulty in finding the midline. In practice, however, many anesthesiologists prefer the sitting position in all patients who can be positioned this way. The sitting position avoids the potential rotation of the spine that can occur with the lateral decubitus position. Using a stool for a footrest and a pillow for the patient to hold can be valuable in this position. The patient should flex the neck and push out the lower back to open up the lumbar intervertebral spaces. Figure 23–12 depicts a patient in the sitting position, and the L4–L5 interspace is marked.

When performing a "saddle block," the patient should remain in the sitting position for at least 5 minutes after a hyperbaric spinal anesthetic is placed to allow the spinal anesthetic to settle into that region. If a higher level of blockade is necessary, the patient should be placed supine immediately after spinal placement and the table adjusted accordingly.

Clinical Pearls

- The sitting position is utilized for low lumbar or sacral anesthesia and in instances when the patient is obese and there is difficulty in finding the midline in the lateral position.
- When performing a saddle block, the patient should remain in the sitting position for at least 5 min after a hyperbaric spinal anesthetic is placed to allow the spinal to settle into that region.

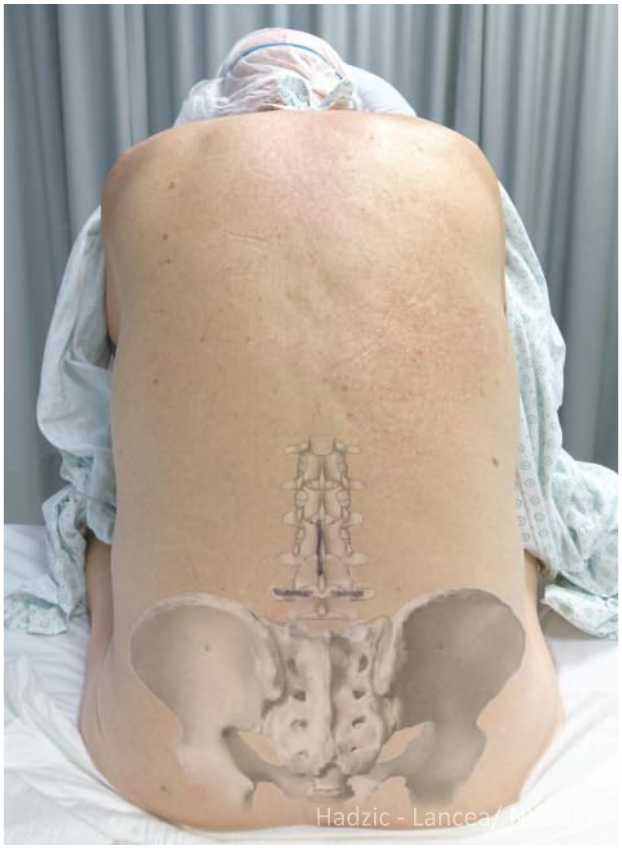

FIGURE 23–12. Patient in sitting position with the L4–L5 interspace marked.

Prone Position

The prone position can be utilized for induction of spinal anesthesia if the patient needs to be in this position for the surgery, such as for rectal, perineal, or lumbar procedures. A hypobaric or isobaric solution of local anesthetic is preferred in the prone jackknife position for these procedures. This avoids rostral spread of the local anesthetic and decreases the risk of high spinal anesthesia.

> **Clinical Pearl**
>
> - The prone position is utilized for spinal anesthesia if the patient needs to be in this position for the surgery, such as for rectal, perineal, or lumbar procedures.

Another, less-elegant solution is to inject a hyperbaric solution of local anesthetic with the patient in the *sitting* position and wait until the spinal anesthesia "sets in," which is typically 15–20 minutes after injection. The patient is then positioned in the prone position with vigilant monitoring, including frequent verbal communication with the patient.

TECHNIQUE OF LUMBAR PUNCTURE

When performing a spinal anesthetic, appropriate monitors should be placed, and airway and resuscitation equipment should be readily available. All equipment for the spinal blockade should be ready for use, and all necessary medications should be drawn up prior to positioning the patient for spinal anesthesia. Adequate preparation for the spinal reduces the amount of time needed to perform the block and assists with making the patient comfortable.

Proper positioning is the key to making the spinal anesthetic quick and successful. Once the patient is correctly positioned, the midline should be palpated. The iliac crests are palpated, and a line is drawn between them to find the body of L4 or the L4–L5 interspace. Other interspaces can be identified, depending on where the needle is to be inserted.

The skin should be cleaned with skin preparation solution such as 0.5% chlorhexidine, and the area should be draped in a sterile fashion. The skin preparation solution should be allowed to dry, and unused skin preparation solution must be removed from the anesthesiologist's workspace. A small wheal of local anesthetic is injected into the skin at the planned site of insertion. More local anesthetic is then administered along the intended path of the spinal needle insertion to the estimated depth of the supraspinous ligament. This serves a dual purpose: additional anesthesia for the spinal needle insertion and identification of the correct path for spinal needle placement. Care must be taken in thin patients to avoid dural puncture, and inadvertent spinal anesthesia, at this stage.

> **Clinical Pearls**
>
> - When performing a spinal anesthetic, appropriate monitors should be placed, and airway and resuscitation equipment should be readily available.
> - All equipment for the spinal blockade should be ready for use, and all necessary medications should be drawn up prior to positioning the patient for spinal anesthesia.

Midline Approach

If the midline approach is used, palpate the desired interspace and inject local anesthetic into the skin and subcutaneous tissue. The introducer needle is placed with a slight cephalad angle of 10° to 15°. Next, the spinal needle is passed through the introducer. The needle passes through the subcutaneous tissue, supraspinous ligament, interspinous ligament, ligamentum flavum, epidural space, dura mater, and subarachnoid mater to reach the subarachnoid space.

Resistance changes as the spinal needle passes through each level on the way to the subarachnoid space. Subcutaneous tissue offers less resistance to the spinal needle than ligaments. When the spinal needle goes though the dura mater, a "pop" is often appreciated. Once this pop is felt, the stylet should be removed from the needle to check for flow of CSF. For spinal needles of higher gauge (26–29 gauge), this usually takes 5–10 seconds, but in some patients, it can take a minute or longer. If there is no flow, some suggest rotating the needle 90° as the needle orifice might be obstructed. Debris can obstruct the orifice of the spinal needle. If necessary, withdraw the needle and clear the orifice before attempting the spinal anesthetic again. A common cause of failure to obtain CSF flow is the spinal needle being off the midline. The midline should be reassessed and the needle repositioned.

If the spinal needle contacts bone, the depth of the needle should be noted and the needle placed more cephalad. If bone is contacted again, the needle depth should be compared with that of the last bone contact to determine what structure is being contacted. For instance, if bone contact is deeper than the first insertion, the needle should be redirected more cephalad to avoid the inferior spinous process. If bone contact is at roughly the same depth as the original insertion, it may be lamina being contacted, and the midline should be reassessed. If bone contact is shallower than the original insertion, the needle should be redirected caudally to avoid the superior spinous process.

Clinical Pearls

- When the spinal needle goes though the dura mater, a "pop" is often appreciated.
- Once this pop is felt, the stylet should be removed from the introducer to check for flow of CSF.
- For spinal needles of a higher gauge (26–29 gauge), this usually takes 5–10 seconds, but in some patients, it can take longer.
- If there is no flow, the needle might be obstructed by a nerve root and rotating it 90° may be helpful.

When the spinal needle needs to be reinserted, it is important to withdraw the needle back to the skin level before redirection. Only make small changes in the angle of direction when reinserting the spinal needle as small changes at the surface lead to large changes in direction when the needle reaches greater depths. Bowing and curving of the spinal needle when inserting through the skin or introducer can also steer the needle off course when attempting to contact the subarachnoid space.

Paresthesias may be elicited when passing a spinal needle. The stylet should be removed from the spinal needle, and if CSF is seen and the paresthesia is no longer present, it is safe to inject the local anesthetic. A cauda equina nerve root may have been encountered. If there is no CSF flow, it is possible that the spinal needle has contacted a spinal nerve root traversing the epidural space. The needle should be removed and redirected toward the side opposite the paresthesia.

After free flow of CSF is established, inject the local anesthetic slowly at a speed of less than 0.5 mL/s. Additional aspiration of CSF at the midpoint and end of injection can be attempted to confirm continued subarachnoid administration but may not always be possible when small needles are used. Once local anesthetic injection is complete, the introducer and spinal needle are removed as one unit from the back of the patient. The patient should then be positioned according to the surgical procedure and baricity of local anesthetic given. The table can be tilted in either the Trendelenburg or the reverse Trendelenburg position as needed to adjust the height of the block after testing the sensory level. The anesthesiologist should carefully monitor and support vital signs.

FIGURE 23–13. Landmarks used in a paramedian approach to spinal anesthesia.

Paramedian (Lateral) Approach

If the patient has a calcified interspinous ligament or difficulty in flexing the spine, a paramedian approach to achieve spinal anesthesia can be utilized. The patient can be in any position for this approach: sitting, lateral, or even prone jackknife. After palpating the superior and inferior lumbar spinous processes of the desired interspace, local anesthetic is infiltrated 1 cm lateral to the superior aspect of the inferior spinous process. The needle should be directed slightly medially. A 10° and 15° medial angulation of the needle will reach the midline at a depth of about 5.7 cm (tan 80°) and 3.7 cm (tan 75°), respectively. This demonstrates that small changes in angulation can have pronounced effects on needle-tip placement. Although slight cephalad angulation is also required, a common error is too steep an initial approach. If lamina is contacted, the needle should then be angled cephalad and "walked off" the lamina into the subarachnoid space.

Other methods have been described. All techniques involve a similar vertical axis for the puncture site (1–1.5 cm from the midline). They differ in the horizontal axis (eg, 1 cm lateral to the spinous process, 1 cm lateral to the interspace, 1 cm lateral and 1 cm inferior to the interspace, 1 cm lateral and 1 cm inferior to the inferior aspect of the superior spinous process) and the degree of cephalad angulation required.

Figure 23–13 shows the landmarks used for a paramedian approach to spinal anesthesia. Figure 23–14 depicts successful performance of a paramedian spinal anesthetic.

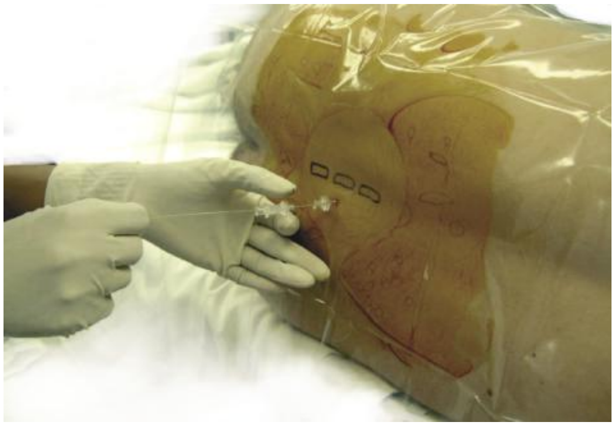

FIGURE 23–14. Paramedian approach: needle placement.

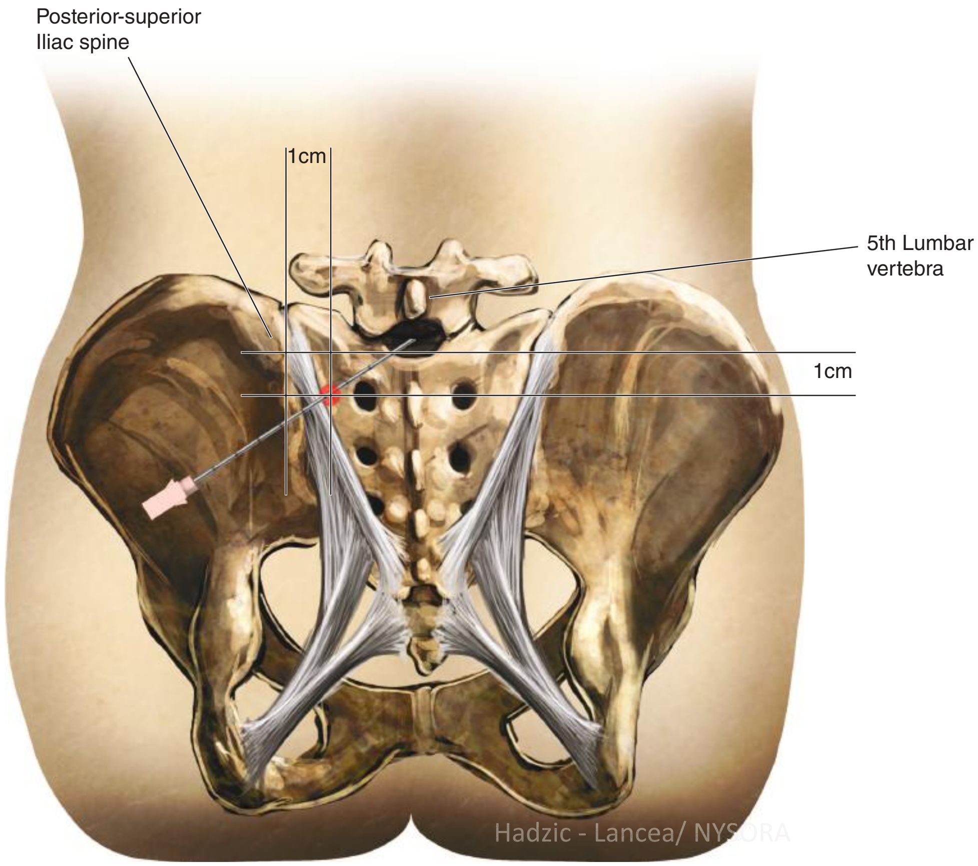

FIGURE 23–15. Taylor approach to spinal anesthesia.

Clinical Pearls

For the paramedian approach:

- After palpating the superior and inferior lumbar spinous processes of the desired interspace, local anesthetic is infiltrated 1 cm lateral to the superior aspect of the inferior spinous process.
- The needle should be angled in a slight medial and cephalad direction.
- If lamina is contacted, the needle should then be angled cephalad and "walked off" the lamina into the subarachnoid space.
- The ligamentum flavum is usually the first resistance identified.

Taylor Approach

The Taylor, or lumbosacral, approach to spinal anesthesia is a paramedian approach directed toward the L5–S1 interspace. Because this is the largest interspace, the Taylor approach can be used when other approaches are not successful or cannot be performed. As with the paramedian approach, the patient can be in any position for this approach: sitting, lateral, or prone.

The needle should be inserted at a point 1 cm medial and inferior to the posterior superior iliac spine, then angled cephalad 45°–55° and medially. This angle should be medial enough to reach the midline at the L5–S1 interspace. After needle insertion, the first significant resistance felt is the ligamentum flavum, and then the dura mater is punctured to allow free flow of CSF as the subarachnoid space is entered. Figure 23–15 shows the Taylor approach to spinal anesthesia. Real-time ultrasound-guided prone spinal anesthesia via the Taylor approach has been described[317] and may improve patient comfort and compliance during the procedure.

Clinical Pearls

For the Taylor approach:

- The needle should be inserted at a point 1 cm medial and inferior to the posterior superior iliac spine, then angled cephalad 45°–55° and medially.
- This angle should be medial enough to reach the midline at the L5–S1 interspace.
- After needle insertion, the first significant resistance felt is the ligamentum flavum.

CONTINUOUS CATHETER TECHNIQUES

An indwelling catheter can be placed for continuous spinal anesthesia. Local anesthetics can be dosed repeatedly through the catheter and the level and duration of anesthesia adjusted as necessary for the surgical procedure. Placement of a continuous spinal catheter occurs in a similar fashion as a regular spinal anesthetic except that a larger-gauge needle, such as a Tuohy, is used to enable the passage of the catheter. After insertion of the Tuohy needle, the subarachnoid space is found, and the spinal catheter is passed 2–3 cm into the subarachnoid space. If there is difficulty in passing the catheter, attempt to rotate the Tuohy needle 180°. Never withdraw the catheter back into the needle shaft because there is a risk of shearing the catheter and leaving a piece of it in the subarachnoid space. If the catheter needs to be withdrawn, withdraw the catheter and needle together and attempt the continuous spinal at another interspace. Communication is critical to avoid a spinal catheter being mistaken for the more common epidural catheter. This involves labeling, documentation, handover, and vigilance.

Clinical Pearls

- After insertion of the Tuohy needle, the subarachnoid space is entered and the spinal catheter is passed 2–3 cm into the subarachnoid space.
- If there is difficulty in passing the catheter, attempt to rotate the Tuohy needle 180°.
- Communication is critical to avoid a spinal catheter being mistaken for the more common epidural catheter.

Because the needle used to pass the spinal catheter is a large-bore needle, there is a much higher risk of PDPH, especially in young female patients. Cauda equina syndrome can occur with small spinal catheters, so the FDA has advised against using catheters smaller than 24 gauge for continuous spinal anesthetics.[85–88,318]

In 2008, a randomized clinical trial (FDA Investigational Device Exemption) reported on the safety of continuous spinal "microcatheters" in obstetric patients. A 28-gauge catheter was placed in 329 patients; there were no reported permanent neurological outcomes. The trial compared continuous spinal analgesia with epidural analgesia and found lower initial pain scores, higher patient satisfaction, and less motor block in the spinal group, with no difference in neonatal or obstetric outcomes.[319] However, the spinal group had higher pruritis scores and a trend toward more PDPH (9% compared with 4% in the epidural group). Intrathecal catheters were more difficult to remove than epidural catheters. One patient had an intrathecal catheter broken on removal, albeit by an untrained individual, leaving a fragment in the patient's back.

CLINICAL SITUATIONS ENCOUNTERED IN THE PRACTICE OF SPINAL ANESTHESIA

The Difficult and Failed Spinal

Spinal anesthesia has long been considered a reliable block, with failure rates less than 1%. Conversion to general anesthesia was as low as 0.5% in a prospective cohort study of obstetric patients.[320] However, failure rates as high as 17% have been reported.[321] Failed spinal anesthesia may present as complete absence of block, partial block, or inadequate duration of block.

Although expertise may reduce the chance of a failed spinal, even experienced clinicians will be confronted with failed spinal blocks. After being reassured by the appearance of CSF, a subsequent failed or patchy block can leave an anesthesiologist frustrated and bewildered. A methodical approach is required when managing failed spinal blockade.

In an excellent review article, Fettes et al classified failure of spinal anesthesia into five groups: failure of lumbar puncture, failure of solution injection, solution spread in the CSF, drug action on the nerve roots and cord, and patient management.[298] Their review is summarized next.

Failed Lumbar Puncture

Whenever there are problems with placing a spinal anesthetic, the anesthesiologist should reassess the position of the patient. A member of the operating room personnel who is trained to assist with patient positioning should be used. Alternatively, positioning of the patient can be enhanced with commercially available positioning devices. These devices can help maintain spinal flexion and create a stable support for the patient, which can be useful if no trained operating room personnel are available to assist with positioning.

If the proposed interspace cannot be found, the interspace above or below the original site of spinal injection can be attempted. When the sitting position cannot be used or is unsuccessful, the lateral decubitus position can be used. Either the midline or the lateral paramedian technique can be attempted. The largest interlaminar space is at L5, and this can be sought via Taylor's approach, described previously in this chapter.

Three independent predictors of success when performing neuraxial block have been identified: adequate positioning, the anesthesiologist's experience, and the ability to palpate anatomical landmarks.[316] Improper positioning may be due to patients' inability to flex the spine rather than anesthesiologists' failure to encourage flexion. A predictably difficult back should not be used to teach inexperienced trainees. If anatomical landmarks are imperceptible spinal ultrasonography can be used to assist lumbar puncture (see section on neuraxial ultrasound).

Failure of Solution Injection

Because of the small volumes of injectate used in spinal anesthesia, apparently trivial reductions in the volume of solution may result in a less-than-adequate block. Reductions in solution injected may be the result of loss of injectate when the spinal syringe is attached to the needle hub or loss into tissues adjacent to the subarachnoid space due to needle orifice migration or the orifice straddling a number of potential spaces (eg, the subarachnoid and subdural or epidural spaces). Intentional reductions in dose, usually to decrease side effects, may also result in decreased efficacy.[254]

Failure of Solution Spread Within the CSF

Failure of solution spread within the CSF may be due to spinal deformities such as kyphosis or scoliosis, previous surgery, transverse or longitudinal spinal septae, spinal stenosis, or extradural cysts. Tarlov cysts are a type of extradural cyst seen incidentally on MRI scans and have an incidence as high as 9%. Although usually asymptomatic, they contain CSF and may account for positive aspiration of CSF yet failure of complete block.[322] Lumbar CSF volume is an important determinant of spread.[156]

Failure of Drug Action

Failure of drug action may result from the incorrect drug being administered. The correct drug may be inactive as the result of physicochemical instability (less likely with modern agents) or may be impaired due to chemical incompatibilities when two or more agents are used. The phenomenon of local anesthetic resistance has been questioned in the literature.

Failure of Patient Management

Descartes's classic 17th-century picture of pain showing a connection between a boy's burning foot and his brain via the middle of his back—"just as when you pull one end of a string, you cause a bell hanging at the other end to ring"—could lead one to believe spinal anesthesia can cure all pain. However, pain perception is far more complex, and despite perfect spinal blockade, a patient may experience discomfort or pain. Patients should be counseled preoperatively about expected "normal" sensations such as pulling, pushing, and stretching. Preoperative testing of spinal blockade to reassure both the patient and the anesthesiologist may paradoxically distress the patient if performed too early. Intraoperatively, a patient may require supplemental anxiolysis and analgesia or general anesthesia.

Management of a failed spinal block will depend on whether it occurs preoperatively or intraoperatively and the nature of the failure. Options to optimize spinal anesthesia include changing the patient's position to improve spread and repeating the spinal block. Two important principles must be remembered when repeating a spinal block. First, the second attempt must not be identical to the first. This is not only to avoid a repeat failure but also perhaps to prevent a second dose of local anesthetic accumulating in a restricted space, which can lead to neurological injury. Second, a repeat dose may result in excessive spread of local anesthetic. Alternatives such as epidural anesthesia, peripheral nerve blockade, local infiltration, systemic analgesia, and general anesthesia should be considered based on the merits of the case and are beyond the scope of this chapter.

Inadvertent Subdural Block

Failed subarachnoid block may be the result of inadvertent subdural injection and deserves special attention. The subdural space is a potential space that only becomes real after tearing of neurothelial cells within the space[127] as a result of iatrogenic needle insertion and fluid injection (see Figure 23–4). Characteristic features of a SDB are a high sensory level with motor and sympathetic sparing. This may be the result of the limited ventral capacity of the space, which results in sparing of the anterior motor and sympathetic fibers. However, a SDB may also present in a number of different ways: failed block, unilateral block, Horner syndrome, trigeminal nerve palsy, respiratory insufficiency, or unconsciousness due to brainstem involvement.[126] Onset of nerve blockade is slower than subarachnoid block but faster than epidural block and usually resolves after 2 hours.

The incidence of subdural injection after contrast myelography ranges between 1% and 13%. The incidence of SDB after attempted spinal anesthesia is unknown.[126] Because the dura is intentionally breached during attempted spinal anesthesia, the incidence of SDB may be higher compared with epidural block (variously quoted as between 0.024% and 0.82%). The size of the acquired subdural space is probably proportional to the volume of fluid injected. Therefore, typical volumes used with spinal anesthesia may not be as significant as volumes used with epidural anesthesia.[323]

Outpatient Spinal Anesthesia

Each year, the number of surgeries increase, and more are performed on an outpatient basis. As anesthesiologists, we are always looking for new ways to provide efficient anesthetic care that is safe, controls pain, allows the patient to be discharged home in a timely fashion as per postanesthesia care unit protocol, and is easily performed and reproducible. It has previously been suggested that spinal anaesthesia may be incorporated into the outpatient surgery model.[324]

Unilateral Spinal Block

Use of a unilateral spinal block for elderly patients and outpatient surgery has undergone a resurgence. Unilateral spinal anesthesia was described in 1950 by Ruben and Kamsler. Their report concerned 116 patients for surgical reduction of hip fracture performed under unilateral spinal blockade.[325] No deaths were reported, and no increase in the hazard of operation was found. Recently, attention has returned to the use of unilateral spinal anesthesia in elderly patients[326] and for outpatient surgery.[327]

Use of unilateral spinal anesthesia results in decreased changes in systolic, mean and diastolic pressures, or oxygen saturation in elderly trauma patients (eg, hip fracture). Keeping the operative side up and using a hypobaric spinal solution in a low dose for these cases results in excellent anesthesia and remarkable hemostability when the patient is kept in the lateral position for 5–10 minutes before repositioning supine. When using hyperbaric solutions, the operative side should be dependent.

Outpatient surgery using hyperbaric 0.5% bupivacaine takes about 16 minutes for development of surgical anesthesia from time of injection with unilateral spinal anesthesia and 13 minutes with traditional bilateral spinal anesthesia. Less hemodynamic changes are found in the unilateral spinal anesthesia group, with quicker regression of the block and equal time to discharge home.[328]

Compared with other outpatient surgery, less motor block is required for knee arthroscopy. Doses of hyperbaric bupivacaine as low as 4–5 mg are effective when combined with unilateral positioning. Higher doses delay recovery. Addition of intrathecal opioids improves analgesia but increases opioid-related side effects. Ropivacaine does not improve recovery time.[329]

In performing unilateral spinal anesthesia, use of a pencil-point 25-gauge or 27-gauge needle with the orifice directed at the operative side is suggested. Low-dose bupivacaine should be used, with hyperbaric bupivacaine (operative side down) in outpatient surgery and hypobaric bupivacaine (operative side up) in the elderly trauma patient.[330] A slow injection rate should be used to produce laminar flow that will assist in producing a unilateral blockade. There is little evidence that keeping a patient in the lateral position for more than 15 minutes is helpful.

The Obstetric Patient

In 1901, Kreis described the first spinal anesthetic for vaginal delivery.[331] The following year, Hopkins performed the first successful spinal anesthetic for cesarean section in a woman with placenta previa.[229] Spinal anesthesia for labor and delivery has progressed greatly since that time. Although many arguments are made against general anesthesia in the pregnant woman due to increased risk of aspiration and difficult intubation, the anesthesiologist must be prepared to induce general anesthesia in the face of a failed or total spinal anesthetic.

Obstetric regional anesthesia is a topic in itself, and as such is covered in Chapter 41 (Obstetric Regional Anesthesia). Examples of how spinal anesthesia differs in the obstetric population are listed in Table 23–10.

The Anticoagulated Patient

As the population ages, more patients are presenting for surgery with pre-, intra-, or postoperative requirements for antiplatelet, anticoagulant, or thrombolytic therapy. Novel agents continue to be developed, giving rise to concerns in patients undergoing spinal anesthesia. These concerns led to the evolution of the ASRA evidence-based guidelines on regional anesthesia in the patient receiving antithrombotic or thrombolytic therapy, now up to its third edition.[332]

The reader is referred to Chapter 52 (Neuraxial Anesthesia and Peripheral Nerve Blocks in Patients on Anticoagulants) for an in-depth discussion on the use of neuraxial anesthesia in the anticoagulated patient.

Other Clinical Situations

Spinal anesthesia in the pediatric patient and the patient with preexisting neurology are covered in Chapters 43 and 49, respectively.

RECENT DEVELOPMENTS IN SPINAL ANESTHESIA

Neuraxial Ultrasound

Conventional palpation of surface anatomy has been shown to be unreliable.[128,132] Neuraxial ultrasound aims to overcome the inaccuracies of surface anatomy with sonoanatomy. The first description of ultrasound-assisted lumbar puncture[333] was in 1971. More recently, neuraxial ultrasound has been used as a preprocedure scan and for real-time needle placement. Much of the evidence regarding neuraxial ultrasound pertains to preprocedural scanning prior to epidural insertion, especially in the setting of obstetric anesthesia, and has been produced by a limited number of specialized centers. This evidence shows that scanning decreases needle attempts, accurately predicts depth to the epidural space, and may improve the success rate of junior trainees.[334–336]

Spinal ultrasonography in the setting of single-shot spinal anesthesia is less well studied. Ultrasonography allows increased accuracy at identifying lumbar interspaces.[334] This is important as palpation of the lumbar spine is likely to generate a higher interspace than expected,[128] and the conus medullaris has been shown to be at times lower than the conventionally taught L1 level. These two facts not only pose a theoretical risk but also have resulted in persistent neurological injury.[132] An observational study in orthopedic patients demonstrated accurate ultrasonographic prediction of the depth to the dura prior to spinal insertion.[337] Preprocedural ultrasonography has been used to achieve spinal anesthesia in clinically difficult situations such as obesity, kyphoscoliosis, and previous spinal surgery, including Harrington rods.[41–43,338] Real-time ultrasound-guided spinal anesthesia has been described in technically difficult patients[339] and in the prone position via Taylor's approach.[317] A randomized trial comparing preprocedural scanning with standard palpation for spinal anesthesia in patients with difficult surface anatomical landmarks showed a twofold difference in first attempt success (62% ultrasound vs. 32% control).[340]

Ultrasound scanning of the neuraxis is best learned in tailored workshops and simulations. Real-time ultrasound advancement of a spinal needle into the subarachnoid space is an expert skill, and practitioners should possess considerable probe and needle skills. Preprocedure scanning and marking of a patient's back require less hand-eye coordination but may also be difficult to learn.[341] Competence at identifying designated spinous processes has been achieved after scanning 22–36 patients.[342] Here, we outline six sonoanatomical views of the lumbar spine and a simplified method for performing a neuraxial preprocedure scan and outline common beginner pitfalls.

Sonoanatomy

Different researchers have described varying numbers of necessary sonographic views, often associated with fanciful monikers. Karmakar refers to "horse heads," "camel humps," and "trident" signs (longitudinal paramedian views), whereas Carvalho refers to a "saw" (longitudinal view) and a "flying bat" (transverse view).[343] The novice should not become bewildered by the varying nomenclature, as they are simply tools of pattern recognition.

Specialized ultrasonic windows are required to visualize the neuraxis due to the bony structures that encase it. Six basic views are shown in Table 23–11.

The anterior and posterior complexes are useful terms for identifying structures. The anterior complex represents the *anterior* dura, posterior longitudinal ligament, and posterior vertebral body. The posterior complex represents the

TABLE 23–10. Spinal anesthesia in the obstetric patient.

Consent	• May be difficult to obtain truly informed consent in a laboring patient.
Risks	• Lower risk of major permanent complications compared with neuraxial blockade for nonobstetric surgery.[26] • Higher risk of postdural puncture headache. • A 2005 meta-analysis showed cord pH, an indicator of fetal well-being, to be lower with spinal compared with epidural and general anesthesia, although this may be attributed to the use of ephedrine in the studies analyzed.[118]
Benefits	• Avoidance of maternal risks of general anesthesia, in particular the three As: aspiration, awareness, and difficult airway. • Avoidance of fetal exposure to general anesthesia drugs. • Early maternal bonding with the newborn. • Partner or support person may be present.
Indications	• Spinal anesthesia may be used for labor analgesia, forceps delivery, cesarean delivery, manual removal of placenta, perineal repair, or nonobstetric surgery in the obstetric patient.
Anatomy	• Exaggerated lumbar lordosis during pregnancy can increase the height of the intercristal line such that 6% of term women have an intercristal line at or above L3.[352] • The pronounced lumbar flexion required to perform spinal anesthesia may be difficult due to the gravid uterus.
Physiology	• Aortocaval compression from a gravid uterus may worsen spinal-induced hypotension, posing risks for both mother and fetus.
Pharmacology	• Pregnant women require less local anesthetic to achieve the same level of anesthesia as nonpregnant women. This observation is likely due to both hormonal and mechanical factors.
Technique	• Be prepared to convert to general anesthesia. Prior to placement of a spinal anesthetic, the pregnant patient should receive 30 mL of 0.3 M sodium citrate orally to decrease stomach acidity. Equipment and drugs necessary to administer general anesthesia should be readily available. • After the spinal anesthetic is given, the patient should be in the supine position with left uterine displacement. Fetal heart rate should be monitored by Doppler or fetal scalp electrocardiogram (ECG). • A T4-level block is usually required for a cesarean section due to traction on the peritoneum and uterine exteriorization. • Some patients complain of dyspnea due to abdominal and intercostal motor blockade, but if the patient is able to speak clearly, reassurance and monitoring is usually all that is required. Sensory loss in the upper limb or inability to extend the forearm (C7/C8) should warn the clinician regarding impending diaphragmatic paralysis (C3/C4/C5). • If the mother wants to nurse the newborn, an assessment of upper limb strength should be made. Adequate staffing should allow someone other than the anesthesiologist to be responsible for the well-being of the newborn. • Hypotension and nausea are common, especially in the elective setting (see section on management of hypotension after spinal anesthesia). Prophylactic phenylephrine and "coloading" with fluid effectively prevents hypotension and nausea. Table 23–9 provides a suggested regimen for managing hypotension during elective cesarean section.

ligamentum flavum, epidural space, and posterior dura. While the "target" of spinal anesthesia is the posterior complex, the visualization of the anterior complex denotes a clear ultrasonographic window through the interlaminar space.[335]

Neuraxial Ultrasound Preprocedure Scan

1. After positioning the patient in a conventional manner, **apply a low-frequency (2- to 5-MHz) curved array probe** to the middle of the patient's lower back in a transverse orientation.
2. **Optimize the image** for depth, frequency, and time-gain compensation.
3. **Mark the midline.** This is done by simply aligning the transversely oriented probe such that there is symmetry of the ultrasound appearance (left side of screen being a mirror of the right side). This will correspond to either the transverse spinous process or transverse interlaminar view. Sliding the transversely applied probe in a cephalad direction, a marking pen is used at intervals to mark the skin adjacent to the middle of the long edge of the probe.

TABLE 23–11. Sonoanatomical views of the lumbar spine.

View	Probe Footprint	Ultrasound View	Pattern Recognition Image	Notes
Transverse spinous process view				A distinct midline shadow is cast by the spinous process. Note the laminae (L) are visible, but the anterior and posterior complexes are obscured.
Transverse interlaminar (interspinous) view				"Flying Bat" The articular processes/facet joints (APFJ) and transverse processes (TP) are visible. Tilting the probe will highlight the posterior (PC) and anterior (AC) complexes.
Paramedian sagittal transverse process view				The "trident" sign represents finger-like shadowing behind the transverse processes.

(*continued*)

TABLE 23–11. Sonoanatomical views of the lumbar spine. (*Continued*)

View	Probe Footprint	Ultrasound View	Pattern Recognition Image	Notes
Paramedian sagittal articular process view				"Camel humps" represent continuous hyperechoic bone due to vertebrae being "connected" by articular processes. The anterior and posterior complexes are not seen.
Paramedian sagittal laminar view				"Horse heads" "Sawtooth" The hyperechoic bone is not continuous due to the interlaminar space. This space allows visualization of the posterior and anterior complexes.
Paramedian sagittal oblique view				Slight medial tilt optimizes the view of the posterior and anterior complexes (AC). The dura is seen as a thin hyperechoic line. This view can be used for real-time ultrasound-guided needle advancement.

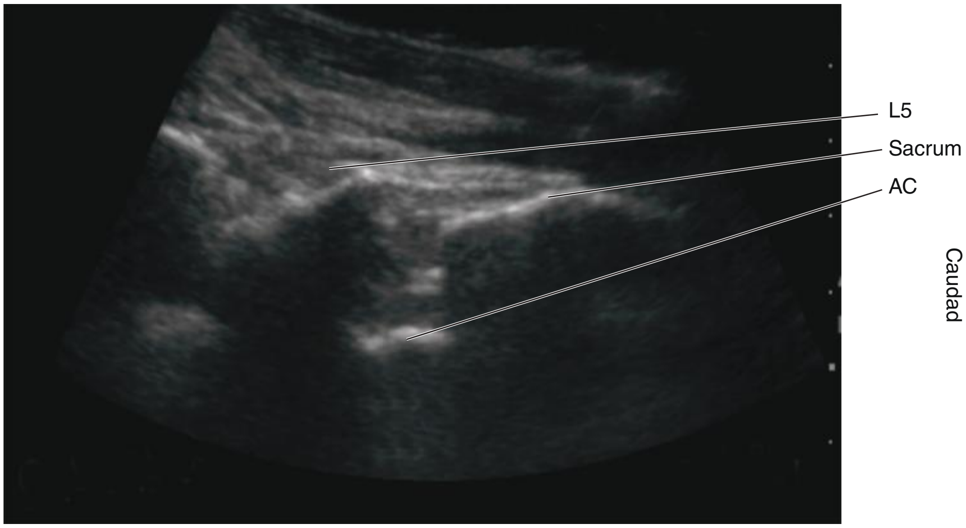

FIGURE 23–16. Ultrasound image of the lumbosacral junction. A continuous hyperechoic line (sacrum) is seen. An anterior complex (AC) should be seen between the sacrum and fifth lumbar lamina.

Practically, it helps to start low and mark above the probe on skin free of ultrasound gel. This technique assumes there is actual symmetry in the patient's anatomy (no scoliosis, rotation, or metalwork).

4. **Identify the lumbosacral junction.** The probe is oriented to obtain a paramedian sagittal laminar view. After identifying the lamina, the probe is slid caudally until a continuous hyperechoic line (sacrum) is seen. An anterior complex should be seen between the sacrum and fifth lumbar lamina (see Figure 23–16).
5. **Mark the lamina** of L1–L5. The probe, maintaining a paramedian orientation, can then be moved cephalad as a marking pen, again at the midpoint of the long edge of the probe, and is used to mark the lamina or interlaminar spaces.
6. **Obtain a transverse interlaminar view at the desired level.** The probe is rotated transversely at the desired level (eg, L3–L4). Slight cephalad-caudal tilting and sliding are necessary to optimize the appearance of the posterior and anterior complex.
7. **Identify the dura** (posterior complex) and mark the depth with calipers.
8. **Note the tilt of the probe** (usually slightly cephalad). This indicates the required angulation of the needle once inserted at the optimal insertion point.
9. **Mark the optimal needle insertion point.** A pen is used to mark the four midpoints of the long and short edges of the probe. The probe is put down, and a horizontal and vertical line is constructed. Where they intersect is the optimal needle insertion point. The vertical line should correspond with the previously marked midline.
10. **Check the optimal insertion point by reapplying probe** and ensuring a good view of the anterior complex.

Additional views of the spine can be obtained by placing the probe in a paramedian sagittal orientation and sliding laterally through the paramedian laminar, articular process, and transverse process views. The paramedian oblique view is obtained by tilting the probe medially, aiming to highlight the posterior and anterior complexes through the interlaminar space. This view can be used for real-time ultrasound-guided spinal anesthesia.

Pitfalls

The most significant pitfall is, after initial training, waiting for the difficult patient before attempting neuraxial ultrasound. Ultrasound scanning requires pattern recognition, and skills need to be attained by scanning "easy" backs. Imprecise skin marking has been postulated as a reason for failure.[341] Care should be taken to ensure the curved array probe is perpendicular to the skin when using a marking pen. Confusing the anterior complex for the posterior complex risks gross overestimation of the depth to the (posterior) dura. When measuring dural depth, the probe may indent the skin, thereby underestimating depth. Misidentification of the lumbosacral junction or failing to recognize anomalies of the junction, present in 12% of the population,[344] will result in incorrect labeling of the interlaminar spaces. Last, ultrasound gel should be cleaned from the skin prior to performing neuraxial block.

Laparoscopic Surgery With Lumbar Spinal Anesthesia

Lumbar spinal anesthesia has been used in the settings of laparoscopic extraperitoneal[345] and intraperitoneal[346] inguinal hernia repair, outpatient gynecological laparoscopy,[347] laparoscopic cholecystectomy,[110,111] and laparoscopic ventral hernia repair.[348] Laparoscopic surgery with an awake patient requires some special considerations. First, patient selection and education are paramount. Caution should be used when interpreting general anesthesia conversion rates in clinical trials as patients who consent to the trial may be more likely to tolerate an awake procedure. Anxiolysis should be offered, and patients should be counseled about expected sensations. Pneumoperitoneum can be perceived as a weight on the abdomen.[347] The possibility of conversion to general anesthesia, which is often due to shoulder tip pain, should be discussed.

Surgical technique and trocar sites may need to be modified.[110] Pneumoperitoneum with nitrous oxide insufflation has been used to avoid peritoneal irritation and pain thought to be associated with conventional carbon dioxide insufflation.[110] However, carbon dioxide insufflation has subsequently been used.[111,113] Avoidance of head-up left lateral tilt that is associated with diaphragmatic irritation has been suggested.[112] Some studies have limited insufflation to less than 11 mm Hg and used a nasogastric tube to decompress the stomach and reduce aspiration risk.[110,111] Others did not modify surgical technique except for low-flow insufflation (nasogastric tubes were avoided and maintained carbon dioxide insufflation at 15 mm Hg).[113] Addition of intrathecal fentanyl[349] or clonidine[350] may decrease shoulder tip pain.

The main two drawbacks of spinal anesthesia for laparoscopic cholecystectomy seemed to be shoulder tip pain resulting in patient dissatisfaction or conversion to general anesthesia and a high rate of PDPH (up to 10%).[349] Due to the small numbers and heterogeneous techniques in previous studies, it has been difficult to establish the ideal technique.

Tzovaras and colleagues in 2008 published an interim analysis of a randomized trial.[112] One hundred patients were randomized to either general or spinal anesthesia for laparoscopic cholecystectomy. Both arms of the study had nasogastric tubes and carbon dioxide insufflation to a maximum of 10 mm Hg. The spinal group had 3 mL of 0.5% hyperbaric bupivacaine, 250 μg morphine, and 20 μg fentanyl injected at the L2–L3 level via a 25-gauge pencil-point needle in the right lateral decubitus position. The patient was then placed in the Trendelenburg position for 3 minutes. Despite intraoperative shoulder tip discomfort or pain in 43% patients of the spinal group, only half of these patients required fentanyl, and no patient required conversion to general anesthesia. Of those in the spinal and general anesthesia groups, 96% and 94%, respectively, were highly or fairly satisfied with their procedure. Moreover, postoperative pain was less in the spinal group compared with the general anesthesia group. The trial was discontinued as the primary endpoint (pain) was reached with the first 100 patients. No patient in the spinal group had a classic PDPH (G. Tzovaras, personal communication, 2012).

Thoracic Spinal Anesthesia

Thoracic spinal anesthesia was described in the early 1900s by Professor Thomas Jonnesco, although he was criticized by his contemporaries, including Professor Bier.[351] He called his technique “general spinal analgesia” and described two puncture sites, the T1–T2 and T12–L1 interspaces, depending on the surgery required. In his article, he made astounding claims of being able to perform head and neck surgery, including total laryngotomy, under high-thoracic analgesia and incorrectly predicted in 1909 that his technique would “in a short time be universally accepted.”

In 2006, thoracic spinal anesthetic for a patient requiring laparoscopic cholecystectomy was reported.[109] Segmental thoracic spinal anesthesia for laparoscopic cholecystectomy was shown to be effective in a small number of healthy patients, although the authors cautioned that the technique, still in its infancy, should not be used in routine practice.[108]

Spinal anesthesia is traditionally performed in the lumbar region below the level of the conus medullaris to avoid injury to the spinal cord. However, MRI images, albeit in a supine position, have shown that the mid- to lower thoracic segment of the cord lies anteriorly, such that there is a CSF-filled space between the dura and the cord (see Figure 23–17).

FIGURE 23–17. Midline MRI of the spinal column. In the thoracic segments, the spinal cord is positioned anteriorly leaving a significant space (*) between the posterior dura and the spinal cord. At the lumbar level, the space disappears almost completely. (Reproduced with permission from van Zundert AA, Stultiens G, Jakimowicz JJ, et al: Segmental spinal anaesthesia for cholecystectomy in a patient with severe lung disease. *Br J Anaesth*. 2006 Apr;96(4):464-466.)

SUMMARY

Spinal anesthesia is a reliable, safe, and effective form of anesthesia. Much has changed since its beginnings in the late 19th century. Mastery of spinal anesthesia comes with practice, diligence, and knowledge of physiology, pharmacology, and anatomy.

Patient safety must always be at the forefront when considering performing a spinal anesthetic. Spinal anesthesia is an indispensable technique in the practice of modern anesthesia.

CHAPTER 23A

Mechanisms and Management of Failed Spinal Anesthesia

John D. Rae and Paul D. W. Fettes

INTRODUCTION

In busy clinical practice it is not uncommon that an intrathecal injection of local anesthetic in attempt to accomplish spinal anesthesia, perfectly performed, fails. Indeed, despite the reliability of the technique, the possibility of failure can never be completely eliminated. Managing a patient with an ineffective or inadequate spinal anesthetic can be challenging, and prevention is better than cure.

In this chapter, we discuss systematically the potential mechanisms by which spinal anesthesia may fail: detail strategies to decrease the failure rate and protocols for managing an incomplete spinal anesthetic.

Clinical Pearl

- Inability to reach the subarachnoid space, errors in drug preparation or injection, unsatisfactory spread of the injectate within the cerebrospinal fluid (CSF), ineffective drug action on neural tissue, and difficulties relating to patient expectations and psychology rather than genuine block failure.

The dense neuraxial blockade obtained by the administration of a spinal (intrathecal) injection of local anesthetic is widely held to be among the most reliable regional techniques. The anatomy is usually straightforward to palpate and identify, the technique for needle insertion simple and easy to teach, and the presence of CSF acts as both a definite endpoint for needling and a medium for carriage of local anesthetic within the subarachnoid space. The simplicity of the procedure was succinctly described by Labat, one of the pioneers of regional anesthesia, almost 100 years ago.[1]

> Two conditions are, therefore, absolutely necessary to produce spinalanaesthesia: Puncture of the dura mater and subarachnoid injection of an anesthetic agent.
>
> Gaston Labat, 1922

Yet, despite this simplicity, failure is not uncommon. What constitutes failure? At the most basic level, a spinal anesthetic has been attempted but the satisfactory conditions for proceeding with surgery are not obtained. Failure encompasses a spectrum that includes the total absence of any neuraxial block or the development of a partial block that is of insufficient height, duration, or quality.

In experienced hands, most anesthesiologists would expect the failure rate of spinal anesthesia to be low, probably less than 1%. A retrospective analysis of almost 5000 spinal anesthetics by Horlocker and colleagues[2] reported inadequate anesthesia in less than 2% of cases, and failure rates of under 1% have been described.[3] Yet, the "failed spinal" demonstrates remarkable interinstitutional variation, and in some published reports, it may be much higher. One American teaching hospital quoted a surprising failure rate of 17%, with the majority of failures deemed "avoidable."[4] A second institution reported a 4% failure rate—more in keeping with expectations, but nonetheless significant.[5] Analyzing their failures, "errors of judgement" were felt to be the main causative factor. The suggestion from these reports is that with meticulous attention to detail and appropriate management, most failures of spinal anesthesia could be prevented.

Patients undergoing an operation under spinal block expect reliable surgical anesthesia, and an inadequate block will generate anxiety for both patient and clinician. In addition, by conducting this invasive procedure, such as spinal anesthesia, we subject patients to small but well-established risks. For these reasons and to improve our own clinical practice, we must strive to minimize the incidence of failure, and to do this we must understand why failure occurs. Broadly, there are three areas where shortfalls may occur: faulty technique, lack of sufficient experience to troubleshoot "on the go" and the lack of attention to detail.[6] It is helpful to distill the procedure into five distinct phases and analyze the keys to success at each stage. In sequence, these phases are lumbar puncture, injection of local anesthetic solution, spread of solution through the CSF, drug action on neural tissue, and patient management.

MECHANISMS OF FAILURE

Unsuccessful Lumbar Puncture

The most evident cause of failure is an inability to successfully access the subarachnoid space. This may occur due to incorrect needling technique, poor patient positioning, anatomical abnormality, or equipment-related factors. The first two factors are operator and experience dependent and therefore can be considered modifiable. Anatomical difficulties such as scoliosis, kyphosis, vertebral collapse, calcified ligaments, or obesity may increase the difficulty of lumbar puncture, particularly in the geriatric population, but can be overcome at least to some degree by good positioning and clinical experience. Issues with equipment may result in a lack of CSF flow despite correct placement of the needle within the subarachnoid space. Manufacturing problems resulting in a needle with a blocked lumen are a theoretical possibility, but obstruction of the lumen by clot or tissue is more likely. For these reasons, the needle and stylet should be visually checked before starting the procedure, and to prevent blockage, the stylet should always be in place when the needle is advanced.

Clinical Pearls

- The needle and stylet should be visually checked before starting the procedure.
- Failure to obtain CSF flow despite an apparently successful needle placement(s) should raise the suspicion of needle blockage and prompt needle withdrawal and "flush test" to assure patency.

Positioning

Optimal positioning is vital to facilitate needle placement, particularly in more challenging cases. The choice of sitting or lateral position is of personal preference. Sitting may allow easier identification of the midline, particularly in the obese, and is often seen as the position of choice for "difficult" spinals; however, the reverse may also be true. In any event, the patient should be on a firm, level gurney or bed that can be adjusted in height for ergonomic ease. The patient should be asked to curl up, flexing the entire spine to maximize the space for needle insertion between spinous processes. Flexing of the hips, knees, and neck increases the effectiveness of this procedure. The presence of a skilled assistant to "coach" the patient and discourage any lateral or rotational movement is invaluable.[7]

Clinical Pearls

- A useful position tip is to ask the patient to "try to touch their knees with their chin".
- This typically leads to a satisfactory flexing of the spine and facilitates needle passage into epidural or subarachnoidal space.

Needle Insertion

The classically described site for lumbar puncture is in the midline between the spinous processes of the third and fourth lumbar vertebrae. This level can be estimated by drawing a line between the anterior superior iliac spines: Tuffier's line. Evidence has shown that this landmark may be very accurate at estimating their level of needle insertion,[8] and more detailed palpation and making sure that the presumptive L3/4 level makes sense ("reality check"). It must be emphasized that great care must be taken to insert needle below the conus medullaris, which in some individuals may be as low as the second lumbar interspace. The needle should be perpendicular to the skin in both planes and advanced with caution. Fine adjustments to the needle angle may be required if an obstruction is encountered, with a slight cephalad angulation most commonly required. Lateral alterations in needle angle may be required, especially in patients with significant scoliosis and when needle-bone contact occurs at a greater depth (beyond spinal process), suggesting needle-contact with the laminae and the need to re-adjust the needle path lateral-medial. A clear knowledge of vertebral 3D-spacial anatomy and a mental image of where the needle tip is thought to lie will assist the operator in interpreting tactile feedback from the needle and guide alterations in needle angle.

In addition to the midline technique, lateral or paramedian approaches can be used. These have the advantage of avoiding ossified midline ligaments, particularly a problem in the elderly, but are more technically challenging procedures. If difficulty should be encountered, the same basic principles apply: Ensuring the patient is optimally positioned and a thorough understanding of the path of the needle and the likely obstacle may yield results.

Adjuncts

The ideal means of achieving the optimal spinal position is with a patient who is comfortable and calm, understands what is being asked of him or her, and has full trust in the anesthesia provider. Preprocedure counseling, establishment of rapport, and a reassuring, professional manner can facilitate this during the spinal procedure. A small dose of anxiolytic medication may assist proceedings, but sedation should be titrated carefully on the basis that it is easier to give more drug than to mitigate the effects of overdosing. Care must be taken to infiltrate local anesthetic to provide effective analgesia without distorting the spinal anatomy; an initial intradermal injection will help to facilitate this. The purpose of these adjuncts is to attain the ideal position, allay patient concern, and minimize movement, thus providing the best possible conditions for lumbar puncture.

Ultrasound

The ubiquitous use of ultrasound in regional anesthesia has not been adopted as a routine neuraxial procedure but has several advantages to offer over a landmark technique. A preprocedure scan can be useful in patients with abnormal or impalpable anatomy to identify the midline and level of injection and to assess the depth of dura from the skin. Its use in epidural techniques has been shown to increase success rates, reduce the need for multiple punctures, and improve patient comfort; it seems logical that this would translate to increased success with spinal anesthesia.[9] Real-time scanning of needle placement for epidural insertion has been described but is not a technique in widespread use. The main obstacles to uptake of ultrasound in neuraxial block are lack of awareness of the technique and limited training in this area, with the technique requiring knowledge of the sonoanatomy of the spine and a high degree of dexterity.

Pseudosuccessful Lumbar Puncture

Rarely, the flow of a clear fluid of noncerebrospinal origin through the spinal needle may mimic successful lumbar puncture without this having occurred. There are two scenarios in which this may occur. "Topping up" a lumbar epidural in obstetric practice for cesarean section may result in a reservoir of local anesthetic in the epidural space. Epidural spread of injectate has also been reported following lumbar plexus block.[10] This may be mistaken for CSF at subsequent spinal injection.

Traditionally, bedside testing for glucose has been advocated to distinguish this fluid from CSF; however, a positive glucose test does not definitely confirm the presence of CSF as the fluid in the epidural space will rapidly equilibrate with extracellular fluid. Another, potential source of fluid mimicking CSF is the presence of a congenital arachnoid cyst.[11] Tarlov cysts are meningeal dilatations of the posterior spinal nerve root, reportedly present in 4.5%–9% of the population.[12] Such a cyst could result in CSF flow through the needle, but anesthetic injected may fail to result in anesthesia. The actual clinical relevance and occurrence of failed spinal anesthesia due to the "false CSF" flow from arachnoidal cysts is unknown.

Solution Injection Errors

Successful lumbar puncture is an absolute requirement for spinal anesthesia but does not preclude failure by a number of other mechanisms. To ensure a block suitable for surgery, a proper dose of local anesthetic must be calculated, prepared, and delivered to the site of action.

Dose Selection

Research into intrathecal drug spread has demonstrated that, providing a dose within the therapeutic range is selected, alterations in drug dose have a relatively minor part to play in the height of spinal block achieved but are significant in governing the duration and quality of the result.[13,14] The dose selected is dictated by a number of factors, including choice of local anesthetic, baricity of the solution, patient positioning, the nature of block desired, and the extent and length of planned surgery. To choose a suitable dose, the clinician must have knowledge of the clinical characteristics and pharmakokinetics of the intrathecally injected local anesthetics.

Trials of drug dosing during continuous intrathecal anesthesia have demonstrated that a satisfactory block can be achieved with relatively low anesthetic doses.[15] Given that failure of a "single-shot" spinal is distressing for the patient and can be associated with increased morbidity (eg, the requirement for general anesthesia and airway management during cesarean section), doses used in practice are often deliberately in excess of the bare minimum required. The clinician must weigh the difficulties of managing hypotension or prolonged anesthesia versus the risk of block failure.

Studies have shown that in many circumstances, lower than commonly-used doses (ie, 5–10 mg rather than 15 mg of hyperbaric bupivacaine) can be used sufficient to achieve effective blockade.[16] This has the advantage of potentially lessening hypotension and, by increasing the speed of block regression, aiding postoperative mobility or decreasing the need for bladder catheterization. While these techniques can be successfully used in experienced hands and appropriately selected cases, the margin for error is significantly decreased. It becomes imperative that the entire volume of the syringe is successfully delivered into the subarachnoid space. Loss of even a small amount of injectate either via spillage (see the next section) or simply in the dead space of the needle and hub may result in an ineffective anesthetic.

Loss of Injectate

Leakage may occur at the Luer connection between needle and syringe or from a deficiency at the joint between needle hub and shaft.[17] Considering the small volumes involved, even the smallest leak of solution may result in a significant decrease in the dose of drug delivered. This pitfall can be avoided by ensuring a good connection between the syringe and needle hub and visually verifying that no leak is occurring.

Misplaced Injection

It is crucial that during the process of ensuring a leak-tight connection between needle and syringe, meticulous attention is paid to avoid accidental movement of the needle. Once the syringe is securely connected, aspiration of CSF can be used to confirm that the tip is still within the subarachnoid space. This maneuver in itself carries potential for needle displacement, as does the injection of anesthetic solution. For this reason, it is imperative that the operator secure the needle position prior to any further manipulation. This can be achieved by stabilizing the dorsum of one hand against the patient's back and anchoring the hub of the needle between thumb and forefinger while the other hand has control of the syringe.[18] Many anesthesiologists would advocate aspirating CSF postinjection to ensure the needle position has not moved during the process. Although there is no evidence to suggest this reduces the failure rate, it may at least alert the anesthetist to the possibility that not all of the drug has reached its intended destination.

Clinical Pearl

The following steps can be undertaken to assure that the needle has been in the subarachnoidal space throughout the cycle of injection:

- Gentle aspiration of 0.5-1 ml before injection to assure CSF retrieval from the subarachnoidal space.
- Gentle aspiration of 0.5-1ml at the end of the spinal injection can be done to assure that the needle tip stayed in the subarachnoidal space throughout the injection process.
- The aspirated 0.5ml-1ml is then re-injected and the needle is withdrawn.

Stabilization of the needle during injection is important with all types of spinal needle but particularly so with "pencil-point" needles commonly in use. In these needles, the opening through which injectate emerges is some distance proximal to the tip; therefore, minimal posterior displacement of the needle can result in this opening being outside the subarachnoid space and subsequent block failure.[19] As the length of the opening of pencil-point needles is significantly longer than the bevel of a Quincke needle, it is also possible for the dura to bridge this opening[20] (Figure 23A–1). This problem may be compounded by the dura mater working as a flap valve. The opening CSF pressure results in an initial successful flow of CSF through the needle (Figure 23A–2a), but on injection, the dura moves forward and a portion of the solution flows into the epidural space (Figure 23A–2b). As with leakage between the needle and syringe, given the small volumes involved, loss of even a small amount of injectate may substantially influence the quality of the block.

If the needle tip is misplaced such that the arachnoid mater acts as the flap valve, local anesthetic will spread into the subdural space (Figure 23A–2c). Subdural block is well recognized as a potential side effect of epidural anesthesia[21] (where it may result in a more extensive, prolonged, or unpredictable effect because of the larger volume of local anesthetic used for epidural anesthesia), but it has also been recorded as a consequence of attempted spinal anesthesia.[22,23] Subdural injection is seen relatively frequently during myelography and its occurrence in daily clinical practice of anesthesiology is likely underestimated.[24]

Due to the initial flow of CSF and minute distances between the layers of the dura, these subtle misplacements are difficult to identify or eliminate. One suggested solution, once CSF has been successfully located, is to rotate the needle a full 360° before aspirating. Theoretically, this may lessen the chance of the dura layers catching on the opening of the needle.

Inadequate Intrathecal Spread

Even when the entire volume of injectate is successfully delivered to the intrathecal space, the spread of solution within the CSF can be somewhat unpredictable.[25] The practitioner must have an understanding of the common factors affecting intrathecal spread and the degree to which they may be manipulated.

Anatomical Abnormality

Dispersion of injectate within the CSF is dictated by the complex interaction between the anatomy of the spinal canal, the physical properties of the solution, and gravity.

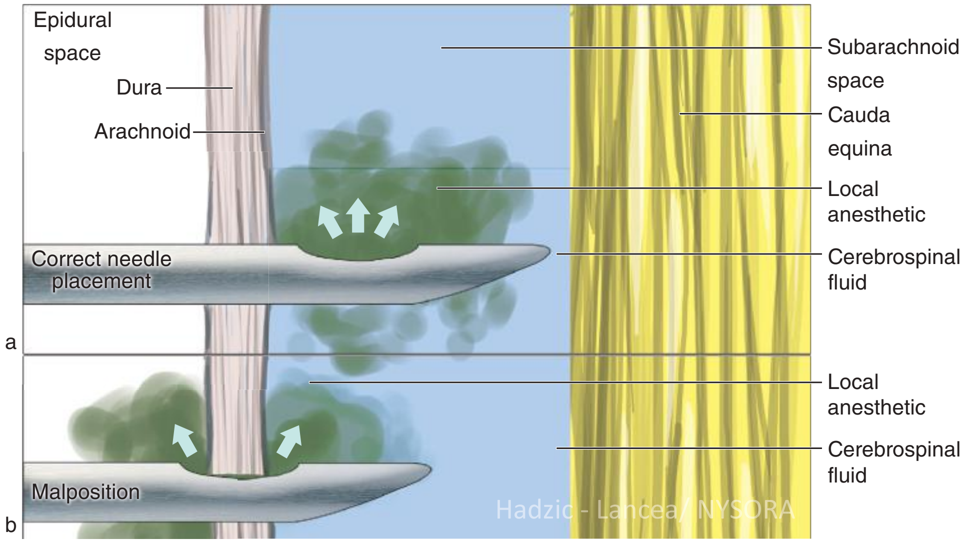

FIGURE 23A–1. Correct needle placement with (**A**) all drug delivered to CSF and (**B**) malposition where some of the drug is lost into the epidural space.

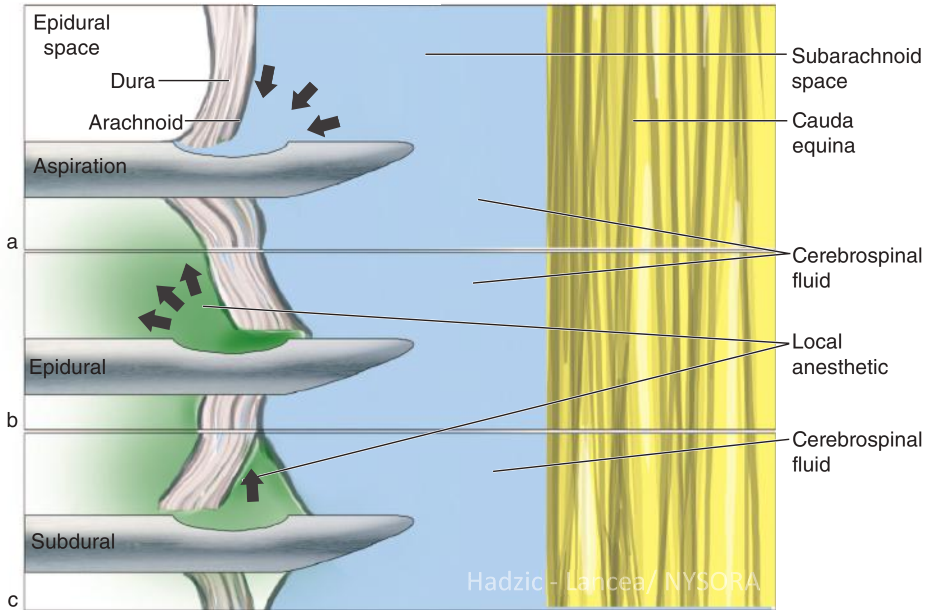

FIGURE 23A–2. The flap valve effect: (**A**) CSF is aspirated but on injection the meningeal layers move, resulting in (**B**) epidural or (**C**) subdural injection of drug.

The normal kyphotic and lordotic curvatures of the vertebral column are important anatomical factors affecting the spread of solution, and the presence of anatomical abnormality, including scoliosis, will alter this. Preoperative examination of the patient may allow identification of such anatomical abnormalities. The actual effect of anatomical deviations on the block quality is unpredictable; variability in the block height is probably more common than block failure.

To achieve a uniform symmetrical block, the local anesthetic should diffuse freely within CSF, without anatomical barriers. For instance, it is also possible for the ligaments that support the spinal cord to form a barrier to the spread of anesthetic within the subarachnoid space. By acting as septae, these anomalies, although uncommon, may cause a unilateral block,[26] or limited cephalad spread. Other examples of spinal pathologies that may impede the spread or effect of injectate include spinal stenosis and adhesions from spinal surgery or from previous administration of intrathecal chemotherapy.[27,28]

In one case report, two occurrences of failed spinal anesthesia in the same patient were investigated with magnetic resonance imaging (MRI) and revealed larger-than-normal CSF volume in the dural sac below the termination of the cord.[29] The volume of CSF within the subarachnoid space has since been shown to be an important cause of the interindividual variation in the degree of cephalad spread of anesthetic.[30] MRI studies found negative correlation between lumbosacral CSF volume and peak sensory block height. A similar picture may be encountered in patients with connective tissue diseases, including Marfan syndrome, who may develop dural ectasia, a pathological enlargement of the dura.[31]

Density of the Local Anesthetic Solution

Density of the injected solution relative to the CSF is another important determinant of intrathecal spread. "Plain" bupivacaine is commonly regarded as isobaric, although it is in fact slightly hypobaric compared to CSF at 37°C. Its spread through CSF is by local turbulent currents and diffusion, which results in a block of somewhat unpredictable spread (in some cases no higher than the second lumbar dermatome[32]) with a relatively slow onset to maximal block height. However, it tends to give reliable anesthesia to the lower extremities with limited spread to the thoracic level. The combination of the slow onset and lower block height results in less risk of cardiovascular instability.[33]

The use of hyperbaric solutions to influence the spread within CSF was described more than 100 years ago by Barker, an early proponent of neuraxial blockade in the United Kingdom.[34] This is typically achieved by addition of dextrose to accomplish a density higher than that of the CSF. Commercial preparations of hyperbaric local anesthetic contain up to 8% glucose, although even preparations containing 1% glucose will result in a predictable block. Following the injection of a hyperbaric solution at the level of L3/L4 in a supine subject, this solution travels predominantly by bulk flow under the influence of gravity "downward" along the curvature of the spine. It naturally moves to the concavity of the thoracic curve (Figure 23A–3), exposing the neuraxial tissue to local anesthetic. If, however, the level of injection is more caudal, the hyperbaric solution may be descend below the lumbar lordosis and fail to spread more cephalad (Figure 23A–4), particularly if the injection is performed while sitting and the patient is not quickly placed supine.

This manifests clinically as a block of only the sacral nerve roots, as reported with a caudally placed spinal catheters.[35] In some circumstances, a "saddle" block is intentionally sought.

Drug Failure

Assuming successful lumbar puncture, adequate drug delivery, and normal anatomy, the final possible cause of an ineffective

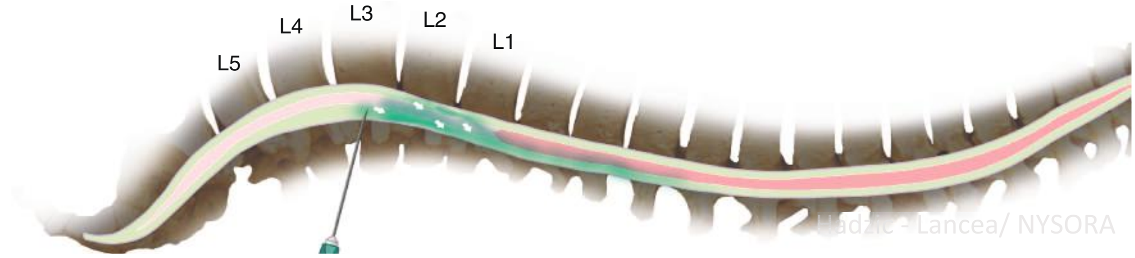

FIGURE 23A–3. Injection at the second or third lumbar interspace will normally result in a significant fraction of the drug spreading cranially from the point of injection (but too high an injection risks inadvertent damage to the spinal cord).

spinal anesthetic is a failure of drug to exhibit blockade on the neural tissue.

Injection of Incorrect Drug

Anesthetics for intrathecal use are commonly supplied in ampoules of aqueous solution, ready for use. Preparations of local anesthetics specifically made for use in spinal anesthesia minimize the opportunity for errors during drug preparation. Nevertheless, the presence of other clear solutions on the spinal tray gives the potential for confusion and inadvertent injection of the wrong drug, with consequent block failure or neurotoxicity. Local anesthetic used for skin preparation is the common culprit; chlorhexidine solution may also be present, although recent guidelines advise separating this from the procedural area due to the risk of contamination and possible adhesive arachnoiditis. The relatively high incidence of so-called syringe swaps in general anesthetic practice has led to almost-universal use of syringe labels. The potential for syringe swaps can be further decreased by meticulous preparation, reducing the number of unnecessary drug ampoules on the tray, and adopting a consistent system for drawing up solutions—for example, always using a certain size of syringe for each particular drug.

Physicochemical Incompatibility

The common practice of utilizing adjuvants to local anesthetic in spinal injections necessitates the mixing of solutions, introducing the possibility of a chemical reaction, potentially reducing efficacy. Clinical experience has shown that the commonly used opioids appear compatible with local anesthetics, but there are few hard data to support this and even fewer for mixing with other adjuncts, such as midazolam, clonidine, or ketamine. The mixing of three substances for intrathecal injection, not uncommon in today's practice, must further raise the opportunity for chemical interaction. This reaction could result in formation of a precipitate, which would be obvious within the syringe, but less evident would be a reduction in pH of the solution. This could decrease the fraction of un-ionized drug within the injectate, thereby reducing the mass of local anesthetic capable of diffusing into neural tissue and available for neural blockade. One example of this effect may be illustrated by a case report of a higher failure rate following addition of vasoconstrictor to the local anesthetic solution.[36]

Inactive Local Anesthetic Solution

Amide local anesthetics such as bupivacaine, ropivacaine, and lidocaine are stable compounds, which are heat sterilized in solution and may be stored for years without significant impact on their efficacy. Regardless, several cases of spinal anesthetic failure thought to be related to local anesthetic inactivity have been published.[37–40] Local anesthetic inactivity may be more common with ester-type anesthetic agents, which are less chemically stable and over time may undergo hydrolysis, degrading their effectiveness.

Local Anesthetic Resistance

Several cases of failed spinal anesthesia have been attributed to local anesthetic resistance.[41,42] These authors postulated that the causes were altered activity of local anesthetic at the sodium channel as a result of mutation of the sodium channel. This altered activity, however, has not been demonstrated at cellular level, nor mutations found in the patients described. Mutations of sodium channels (channelopathies) do occur but they are rare, and are associated with significant neurological disease.

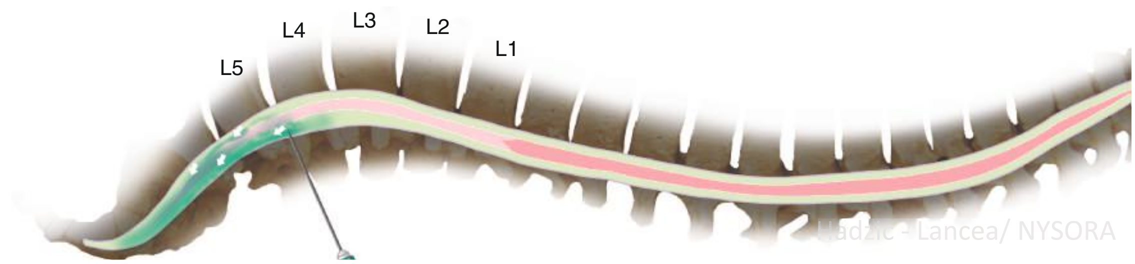

FIGURE 23A–4. Injection at the fourth interspace or lower reduces the risk of cord damage, but it may result in predominantly caudal spread of the drug and an inadequate block for surgery.

Specifically $Na_v1.1$ mutations are associated with intractable epilepsy[43] and $Na_v1.7$ mutations are associated with chronic pain.[43, 44] To our knowledge mutations of the sodium channel, however, do not exist in asymptomatic individuals.

Failure of Subsequent Management

A well executed spinal anesthetic typically results in reliable anesthesia. However, perioperative management of a patient under spinal anesthesia is just as important for success. For instance, the patient may perceive unblocked sensations of movement, pressure, or traction experienced intraoperatively to be painful or uncomfortable experiences. This likelihood is heightened by awareness of the clinical environment and the patient's underlying views, fears, and expectations of the hospital setting, potentiated by the stress of undergoing a surgical procedure. Failure to address these psychological aspects of spinal anesthesia can lead to anxiety, distress, and the need to convert an adequate spinal anesthetic to general anesthesia.

Even for the most composed patients, lying supine in operating theater completely awake while undergoing an operative procedure may be unnatural and anxiety-provoking experience. The surgery being performed may require the patient to lie in an awkward position for a considerable time (eg, during hip arthroplasty). Operating tables are primarily designed to provide good surgical conditions and are often narrow and uncomfortable. Manipulation of the intra-abdominal viscera may result in activation of unblocked parasympathetic nerves and the experience of unpleasant sensations. Patient selection and expectation management are also important to success. Adequate preprocedure patient counseling, positive suggestion, and a supportive, reassuring manner intraoperatively are all essential ingredients to success. A judicious use of sedative adjunctive medications such as benzodiazepines and intraoperative infusions of propofol and remifentanil can further contribute to the patient acceptance of the spinal anesthesia, satisfaction and improve overall perioperative experience. With appropriate monitoring and cautious dosing, there are few situations outside obstetric anesthesia for which sedation would be contraindicated. Some patients can also benefit from or prefer alternative distraction techniques, such as listening to music.

Testing the Block

There are wide variations in practice regarding the assessment of adequacy of a spinal anesthetic, but some form of test is commonly carried out, particularly in obstetric anesthesia. Common techniques include testing for motor effect by asking the patient to move his or her legs and then testing the different sensory modalities, such as light touch, cold, or pinprick sensation. Carried out well, this can be a confidence-building procedure; however, it also may instill doubt in the patient about the quality of the block or the anesthetist. If testing is commenced prematurely, without allowing adequate time for the spinal anesthesia to "set in", the patient may assume that the anesthetic failed and become anxious. For similar reasons, it is recommended that testing should start in the lower dermatomes, where the onset of the block will be the most rapid. By moving cephalad from this point, the development of anesthesia can be demonstrated and anxiety prevented.

It should be noted that achievement of a block *height* adequate for surgery does not guarantee that the *quality* of the block is sufficient for surgery, particularly when pinprick or perception to cold are used as testing modalities. Provided the patient is not deeply sedated, block quality can be assessed by asking the operator to covertly apply a painful stimulus prior to incision without warning the patient. This can be achieved by pinching the skin with surgical forceps out of the patient's line of sight.

Combined Spinal-epidural and Catheter Techniques

Most commonly, intrathecal anesthetic techniques utilize a one-off injection that, as discussed, may not always provide satisfactory surgical anesthesia. The placement of an intrathecal catheter or a combined spinal-epidural (CSE) technique can be useful to extend the height of the block or prolong its duration, which adds an versatility. The presence of an accurately placed catheter will allow an inadequate block to be supplemented or infusion of local anesthetic can be used to provide continuous analgesia. Placement and maintenance of these catheters however, requires a higher level of knowledge and technical expertise on the part of the operator. The subarachnoidal injection during CSE requires small volume of local anesthetic thus, the discussed issues whereby a proportion of the injectate is lost via leakage or dead-space remain pertinent. Use of intrathecal catheters has declined as of late because of the increased potential for infection with the introduction of a catheter into the CSF and because of case reports of arachnoiditis resulting from the concentrated effect of local anesthetic on nerve roots.[45] Insertion can be technically challenging, and leaving an excessive length of catheter in situ may result in local anesthetic pooling in the caudal portion of the dural sac. Finally, the relatively uncommon use of the spinal catheters may be related to the potential risk of error whereby intrathecal catheter could be confused with an epidural catheter, which is much more commonly used in clinical practice. This may lead to an error in "toping up" and overdose with consequent development of high spinal anesthesia.

FAILED SPINAL ANESTHESIA

Despite meticulous technique and local anesthetic and dose selection, subarachnoidal injection caries a small risk of failed spinal anesthesia. Moreover, even when the level of spinal blockade appears to be adequate during testing, spinal anesthesia can fail to provide adequate operating conditions intraoperatively. To the patient, this may be a source of pain, anxiety, and psychological trauma and to the anesthesia provider one of stress, complaints, and potential medicolegal sequelae. For that reason, the possibility of block failure should be discussed with all patients as part of the consent process to ensure that both parties are cognizant of the possibility of this occurring and the steps to be taken if it does. If the duration or extent of the planned procedure is unclear, an alternative technique should be considered. In patients with severe comorbidities, respiratory compromise or a difficult airway, the traditional conversion to general anesthesia may be hazardous. For these reasons, prevention is better than cure, and meticulous attention to detail is crucial.

Management of the Failed Spinal Anesthesia

The strategy for managing an inadequate spinal anesthetic is dictated by two factors: the time at which failure is detected and the nature of the failure. After the subarachnoidal injection, the anesthesia provider should closely monitor the patient for the expected signs of neuraxial blockade. The consequences of autonomic nervous system blockade, such as decrease of blood pressure with or without the presence of compensatory tachycardia provide early clue of onset of spinal anesthesia even without any formal testing. Lack of autonomic response or slower-than-expected development of motor or sensory block should alert the clinician to potential of inadequate or failed spinal anesthesia. Although usually swift, the development of anesthesia can be more gradual in some patients,[6] and additional observation time should be contemplated before starting surgery or assuming failure. If 15 minutes have lapsed since intrathecal injection and the spinal block does not follow a typical onset pattern, anticipated, it is highly likely that the spinal anesthetic will be inadequate for surgery and additional anesthetic interventions will be required. The possible flaws in the block, their likely origins, and suggested solutions are outlined (Table 23A–1):

1. *No block*: An incorrect solution was injected, the solution was injected into an incorrect anatomical location, or the local anesthetic is defective. The options are to repeat the process or administer a general anesthetic. If repeating the spinal injection, sufficient time (20 minutes) must be allowed to pass to ensure that there is truly no block developing. If a second injection is performed after a successful but slowly developing first procedure, a "total spinal" may result.
2. *Spinal block of insufficient height*: Potential causes are that the local anesthetic has been lost during injection (eg, leakage at needle-syringe connection), lumbar puncture was in too low a lumbar interspace, or an anatomical barrier is preventing diffusion of anesthetic. Manipulating posture and utilizing gravity may overcome these difficulties. If hyperbaric formulation was used, the patient should be placed in Trendelenburg position with the hips and knees flexed. This will flatten the lumbar lordosis, allowing injectate to travel cephalad. Change in position after injection of isobaric bupivacaine is unlikely to be successful.
3. *Unilateral block*: The most common problem is patient position, although an anatomical barrier to spread formed by the longitudinal ligaments could lead to unilateral spinal anesthesia. Bilateral spread of the block can be encouraged by moving the patient so that the unblocked side is downward (although again positional change is less likely to be helpful when plain solutions have been used). A unilateral block should be sufficient for ipsilateral lower limb surgery, but the surgeon must be warned that the other limb is not anesthetized.
4. *Patchy block*: This describes a block that appears to have spread adequately but is of inconsistent quality with variable sensory and motor blockade. There are multiple possible explanations but most common is administration of an insufficient dose of anesthetic drug, either due to underdosing or solution not reaching the target. Additional sedation and opiate analgesia, may prove successful particularly if anxiety is a prominent factor. Alternatively, conversion to general anesthesia may be required.

TABLE 23A–1. Mechanisms of failure and suggested management.

Clinical Presentation	Possible Cause	Suggested Management
No block	Injection not into CSF Syringe swap Faulty local anesthetic	Repeat injection (with caution) General anesthesia
Insufficient block height or density	Insufficient drug delivered Injection site too low Anatomical abnormality	Postural maneuvers Intravenous analgesia/sedation
Unilateral block	Patient positioning Anatomical abnormality	Postural maneuvers Proceed with care (if correct side blocked)
Patchy block	Insufficient drug delivered Anatomical abnormality	Repeat injection (with caution) Intravenous analgesia/sedation General anesthesia
Inadequate duration	Insufficient drug delivered Syringe swap Lengthy procedure	Intravenous analgesia/sedation General anesthesia

5. *Inadequate duration*: The most likely culprit is the delivery of an insufficient dose of local anesthetic. Another possibility is a "syringe swap" by which a short-acting agent such as lidocaine is injected instead of the intended bupivacaine. Last, the procedure may have lasted longer than anticipated. As previously stated, the only realistic solutions are additional intravenous analgesia, sedation, or general anesthesia.

In all these scenarios, judicious use of analgesia and sedation will prove invaluable in the management of unsatisfactory block. Intravenous infusions of propofol and remifentanil, can be used at low concentrations to good effect. Postoperative documentation of events and patient follow-up are important.

Repeating the Block

If no appreciable block is seen at 15–20 minutes, then the most logical step is to repeat the injection, taking steps to eliminate the proposed cause of previous failure. Unless the previous injection is complete failure, repeating subarachnoidal injection should not be done routinely. This is because high concentrations of local anesthetic intrathecally can be neurotoxic, and repeating the procedure may lead to such a concentration,[46] particularly if there is an anatomical barrier preventing spread. Lesions of the cauda equina have been reported following multiple injections via an indwelling an intrathecal catheter.[47] Repeating the procedure, particularly in the context of a patchy or low block, can lead to unpredictable extensive cephalad spread[48] with the potential for cardiovascular instability, respiratory embarrassment, or total spinal anesthesia.

Moreover, if block failure is secondary to anatomical factors, then repeat injection is unlikely to produce a more favorable result. A unilateral block thought secondary to a longitudinal anatomical barrier may tempt the anesthetist into performing a second injection on the opposite side, but there is no guarantee that this will not follow the path of the first attempt. An obstruction to intrathecal spread may also distort the epidural space, so epidural anesthesia may prove no more successful.

Postoperative Management

Documentation and Follow-up

At the postoperative visit, the patient should be given a full explanation of events. A detailed account of proceedings should be documented in the medical record to inform future anesthetic procedures. Rarely, unusual patterns of failure may signal the presence of serious neurological pathology, and if there are other signs or symptoms, then neurology consultation is advised. If a patient has experienced failure of spinal anesthesia on more than one occasion, MRI of the spine may be used to exclude or delineate abnormal anatomy.

Investigating "Faulty" Local Anesthetic

Although spinal anesthetic failure is an uncommon occurrence, certain circumstances may lead the anesthetist to closely scrutinize the local anesthetic agent. Lack of effect following a technically undemanding procedure or multiple failures within the same theater or department raises the possibility of a faulty batch of local anesthetic. Hyperbaric bupivacaine is the most commonly reported culprit, most likely due to its prevalence in current practice.[37–40] Amide local anesthetics are chemically stable compounds that undergo heat sterilization as part of normal preparation. In addition to this, modern quality control procedures mean that drug failure is a rare occurrence, but if all other factors are eliminated, it must be considered. If the anesthetic used in the procedure has been retained, some authorities advocate infiltrating the skin to test its efficacy. Corroboration with reports from colleagues, pharmacy, and other hospitals will help to establish if others have had similar problems, although concerns of anesthetic failure have rarely been borne out by case reports.

SUMMARY

With proper technique, training, and meticulous attention to detail, failure rate of spinal anesthesia should be less than 1%. Good communication and appropriate management can mitigate against many of the common difficulties. Even best practice cannot completely eliminate the possibility of failure; thus, the careful assessment of the adequacy of the spinal blockade and management strategy should the failure occur intraoperatively should always be contemplated.

SECTION 2 Epidural Anesthesia

CHAPTER 24

Epidural Anesthesia and Analgesia

*Roulhac D. Toledano and Marc Van de Velde**

INTRODUCTION

Clinical indications for epidural anesthesia and analgesia have expanded significantly over the past several decades. Epidural analgesia is often used to supplement general anesthesia (GA) for surgical procedures in patients of all ages with moderate-to-severe comorbid disease; provide analgesia in the intraoperative, postoperative, peripartum, and end-of-life settings; and can be used as the primary anesthetic for surgeries from the mediastinum to the lower extremities. In addition, epidural techniques are used increasingly for diagnostic procedures, acute pain therapy, and management of chronic pain. Epidural blockade may also reduce the surgical stress response, the risk of cancer recurrence, the incidence of perioperative thromboembolic events, and, possibly, the morbidity and mortality associated with major surgery.

This chapter covers the essentials of epidural anesthesia and analgesia. After a brief history of the transformation from single-shot to continuous epidural catheter techniques, it reviews (1) indications for and contraindications to epidural blockade; (2) basic anatomic considerations for epidural placement; (3) physiologic effects of epidural blockade; (4) pharmacology of drugs used for epidural anesthesia and analgesia; (5) techniques for successful epidural placement; and (6) major and minor complications associated with epidural blockade. This chapter also addresses several areas of controversy concerning epidural techniques. These include controversies about epidural space anatomy, the traditional epinephrine test dose, methods used to identify the epidural space, and whether particular clinical outcomes may be improved with epidural techniques when compared to GA. More detailed information about local anesthetics (LAs), the mechanism of neuraxial blockade, the combined spinal-epidural (CSE) technique, obstetric anesthesia, and complications of central neuraxial blockade is provided elsewhere in this textbook.

BRIEF HISTORY

The neurologist J. Leonard Corning proposed injecting an anesthetic solution into the epidural space in the 1880s, but devoted his research primarily to subarachnoid blocks. Despite coining the term *spinal anesthesia*, he may unknowingly have been investigating the epidural space. The French physicians Jean Sicard and Fernand Cathelin are credited with the first intentional administration of epidural anesthesia. At the turn of the 20th century, they independently introduced single-shot caudal blocks with cocaine for neurologic and genitourinary procedures, respectively.[1] Nineteen years later, the Spanish surgeon Fidel Pagés Miravé described a single-shot thoracolumbar approach to "peridural" anesthesia, identifying the epidural space through subtle tactile distinctions in the ligaments.[2] Within a decade and seemingly without the knowledge of Pagés's work, the Italian surgeon Achille Dogliotti popularized a reproducible loss-of-resistance (LOR) technique to identify the epidural space.[3] Contemporaneously, the Argentine surgeon Alberto Gutiérrez described the "sign of the drop" for identification of the epidural space.

*The authors would like to thank Michael A. Maloney, MB, BAO, ChB, for his help with the tables and figures.

A number of innovations by Eugene Aburel, Robert Hingson, Waldo Edwards, and James Southworth, among others, attempted to prolong the single-shot epidural technique. However, Cuban anesthesiologist Manual Martinez Curbelo is credited with adapting Edward Tuohy's continuous subarachnoid technique for the epidural space in 1947. His efforts were facilitated by an extensive knowledge of anatomy, a first-hand experience observing Tuohy at the Mayo Clinic, and the availability of 16-gauge Tuohy needles and small, gradated 3.5-French ureteral catheters, which curved as they exited the tip of the needle.[4] Several modifications of the Tuohy needle, itself a modification of the Huber needle, have since emerged.

The epidural catheter has also evolved from its origins as a modified ureteral catheter. Several manufacturers currently use nylon blends to produce thin, kink-resistant catheters of appropriate tensile strength and stiffness. The wire-reinforced catheter represents the most recent technological advance in epidural catheter design. The addition of a circumferential stainless steel coil within a nylon or polyurethane catheter confers greater flexibility compared to standard nylon catheters and may decrease the incidence of venous cannulation, intrathecal placement, catheter migration, and paresthesias.

INDICATIONS

This section presents common and controversial indications for the use of lumbar and thoracic epidural blockade in lower extremity, genitourinary, vascular, gynecologic, colorectal, and cardiothoracic surgery. It also reviews less common and novel indications for epidural anesthesia and analgesia, including for the treatment of patients with sepsis and uncommon medical disorders (Table 24–1). The use of neuraxial blockade for obstetric patients, pediatric surgery, and chronic pain and in the ambulatory setting is covered in greater detail elsewhere in this textbook.

TABLE 24–1. Examples of applications for epidural blockade.

Specialty	Surgical Procedure
Orthopedic surgery	Major hip and knee surgery, pelvic fractures
Obstetric surgery	Cesarean delivery, labor analgesia
Gynecologic surgery	Hysterectomy, pelvic floor procedures
General surgery	Breast, hepatic, gastric, colonic surgery
Pediatric surgery	Inguinal hernia repair, orthopedic surgery
Ambulatory surgery	Foot, knee, hip, anorectal surgery
Cardiothoracic surgery	Thoracotomy, esophagectomy, thymectomy, coronary artery bypass grafting (on and off pump)
Urologic surgery	Prostatectomy, cystectomy, lithotripsy, nephrectomy
Vascular surgery	Amputation of lower extremity, revascularization procedures
Medical conditions	Autonomic hyperreflexia, myasthenia gravis, pheochromocytoma, known or suspected malignant hyperthermia

Lumbar Epidural Blockade

Epidural anesthesia has been administered most commonly for procedures involving the lower limbs, pelvis, perineum, and lower abdomen but is increasingly being used as the sole anesthetic or as a complement to GA for a greater diversity of procedures. This section examines several common indications for lumbar epidural blockade, including lower extremity orthopedic surgery, infrainguinal vascular procedures, and genitourinary and vaginal gynecologic surgeries. When applicable, it reviews the benefits and drawbacks of the use of neuraxial techniques versus GA for specific procedures.

Lower Extremity Major Orthopedic Surgery

Both perioperative anticoagulant thromboprophylaxis and the increasing reliance on peripheral nerve blocks have influenced the current use of continuous lumbar epidural blockade for lower extremity surgery. Nonetheless, neuraxial blockade as a sole anesthetic or as a supplement to either GA or peripheral techniques is still widely used for major orthopedic surgeries of the lower extremities. The effective postoperative pain control provided by either peripheral or neuraxial blocks, or a combination of the two techniques, improves patient satisfaction, permits early ambulation, accelerates functional recuperation, and may shorten hospital stay, particularly after major knee surgery. Other potential benefits of the use of neuraxial blockade in lieu of GA include the reduced incidence of deep vein thrombosis (DVT) in patients undergoing total hip[5] and knee[6] replacement surgery, improved postoperative cognitive function, and decreased intraoperative blood loss and transfusion requirements.[7] A recent meta-analysis also demonstrated a statistically significant reduction in operative time when neuraxial blockade was used in patients undergoing elective total hip replacement, although the authors did not distinguish between spinal and epidural techniques.[8]

Major orthopedic procedures that can be performed under epidural, CSE, or integrated epidural and GA include primary hip or knee arthroplasty, surgery for hip fracture, revision arthroplasty, bilateral total knee arthroplasty, acetabular bone grafting, and insertion of long-stem femoral prostheses (Table 24–2). Spinal anesthesia may be the preferred technique in some of these cases, particularly if anticipated postoperative pain is slight or negligible (eg, total hip arthroplasty) or if a

TABLE 24–2. Orthopedic surgeries suitable for epidural, combined spinal-epidural, or integrated epidural–general anesthesia.

Procedure	Sensory Level Required
Closed reduction and external fixation of pelvis	Neuraxial technique seldom adequate for surgery; epidural useful for postoperative analgesia
Hip arthroplasty, arthrodesis, synovectomy	T10
Open reduction internal fixation of acetabular fracture	T10
Open reduction internal fixation of femur, tibia, ankle, or foot	T12
Closed reduction and external fixation of femur and tibia	T12
Above- and below-knee amputation	T12 (T8 with tourniquet)
Knee arthrotomy	T12 (T8 with tourniquet)
Arthroscopy of knee	T12
Repair/reconstruction of knee ligaments	T12
Total knee replacement	T12 (T8 with tourniquet)
Distal tibia, ankle, and foot procedures	T12
Ankle arthroscopy, arthrotomy, arthrodesis	T12
Transmetatarsal amputation	T12

supplemental peripheral nerve block is planned. Anesthesia to T10 with needle placement at L3 to L4 is adequate for most of these procedures.

The use of neuraxial anesthesia for major orthopedic surgery is not without risks and challenges. Elderly patients, trauma victims, and individuals with hemophilia who develop complications from recurrent bleeding into their joints may not be appropriate candidates for regional blockade. In general, epidural procedures are well tolerated in patients with age-related comorbidities, such as restrictive pulmonary disease, prolonged hepatic clearance of drugs, hypertension (HTN), coronary artery disease (CAD), and renal insufficiency. Elderly patients may benefit from the decreased postoperative confusion and delirium associated with regional anesthesia, provided intraoperative hypotension is kept to a minimum.[9] However, prevention of excessive sympathectomy-induced hemodynamic changes can be challenging, as these patients are both less capable of responding to hypotension and more prone to cardiac decompensation and pulmonary edema in response to rapid fluid administration. An epidural technique with a sensory level below T10, as appropriate for many orthopedic surgeries, and judicious administration of fluids and vasopressors may minimize these risks.

Elderly patients commonly present for surgery on anticoagulant or antiplatelet medications and may pose a risk for neurologic injury related to central neuraxial blockade. If an epidural technique is selected for these or other high-risk patients, appropriate timing of both blockade initiation and catheter removal relative to the timing of anticoagulant drug administration must be taken into account. For trauma patients, attaining proper positioning for administration of epidural anesthesia may present a challenge. Initiation of neuraxial blockade in the lateral position may improve chances of success.

Intraoperatively, tourniquet pain can be anticipated with either spinal or epidural blockade, but occurs more frequently with the latter. While the mechanism remains poorly understood, it commonly presents within an hour of tourniquet inflation, increases in intensity over time, and is accompanied by tachycardia and elevated blood pressure. The administration of intrathecal or epidural preservative-free morphine may delay the onset of tourniquet pain.[10]

Lower Limb Vascular Surgery

There are several potential benefits of the use of neuraxial anesthesia and analgesia for lower extremity vascular procedures. Patients undergoing vascular surgery commonly have multiple major systemic diseases, such as CAD, cerebrovascular disease (CVD), diabetes mellitus (DM), chronic renal insufficiency, chronic HTN, and chronic obstructive pulmonary disease (COPD). Patients who present for arterial embolectomy may also have conditions that predispose them to intracardiac thrombus formation, such as mitral stenosis or atrial fibrillation. Avoiding GA in this high-risk patient population possibly enhances graft patency, reducing the need for reexploration and reducing the risk of thromboembolic complications; these are some of the advantages of using regional anesthesia. However, management of these individuals is often complicated by the high probability that they are taking presurgical antiplatelet or anticoagulant medications and will require additional systemic anticoagulation intraoperatively and postoperatively. Thus, these patients are considered at an increased risk for epidural hematoma; a careful risk-benefit analysis is necessary prior to initiating epidural blockade. Consideration must also be given to the type of vascular procedure to be performed, the anticipated length of the procedure, the possible need for invasive monitoring, and the timely removal of the epidural catheter before transitioning to oral anticoagulation therapy. Maintaining normothermia, ensuring that motor strength can be promptly assessed postoperatively, and providing appropriate sedation during lengthy procedures are additional challenges.

Infrainguinal vascular procedures that are suitable for epidural blockade include arterial bypass surgeries, arterial embolectomy, and venous thrombectomy or vein excision

TABLE 24–3. Examples of vascular procedures performed with epidural blockade.

Abdominal aortic aneurysm repair (neuraxial technique seldom adequate as sole anesthetic)
Aortofemoral bypass
Renal artery bypass
Mesenteric artery bypass
Infrainguinal arterial bypass with saphenous vein or synthetic graft
Embolectomy
Thrombectomy
Endovascular procedures (intraluminal balloon dilation with stent placement; aneurysm repair)

(Table 24–3). Slow titration of LAs to attain a T8–T10 level, while maintaining hemodynamic stability, is optimal. The addition of epinephrine to LAs is controversial due to concerns that its vasoconstrictive effect may jeopardize an already-tenuous blood supply to the spinal cord. Studies to date have failed to demonstrate a difference in cardiovascular and pulmonary morbidity and mortality with the use of epidural anesthesia as compared with GA for these procedures,[11] although epidural techniques may be superior for promoting graft survival.

Lower Genitourinary Procedures

Lumbar epidural blockade as either a primary anesthetic or as an adjunct to GA is an appropriate option for a variety of genitourinary procedures. Epidural anesthesia with a T9–T10 sensory level can be used for transurethral resection of the prostate (TURP), although spinal anesthesia may be preferred due to its improved sacral coverage, denser sensory blockade, and shorter duration. Both techniques are considered superior to GA for several reasons, including earlier detection of mental status changes associated with TURP syndrome; the ability of the patient to communicate breakthrough pain if an untoward complication such as perforation of the prostatic capsule or bladder occurs; the potential for decreased bleeding; and the decreased risks of perioperative thromboembolic events and fluid overload (Table 24–4).[12] In addition, patients presenting for this and other prostate surgeries are generally elderly, with multiple comorbidities, and have a low risk for certain complications of neuraxial blockade, such as postdural puncture headache (PDPH).

Other transurethral procedures, such as cystoscopy and ureteral stone extraction, can be performed under GA, topical anesthesia, or neuraxial blockade, depending on the extent and complexity of the procedure, patient comorbidities, and patient, anesthesiologist, and surgeon preference. Of note, paraplegic and quadriplegic patients comprise a subset of patients who present for repeated cystoscopies and stone extraction procedures; neuraxial anesthesia is often preferred in these patients

TABLE 24–4. Benefits of central neuraxial blockade versus general anesthesia for transurethral resection of the prostate.

Early detection of mental status changes
Early detection of breakthrough pain (indicative of capsular/bladder perforation)
Reduced blood loss
Decreased incidence of deep vein thrombosis
Decreased incidence of circulatory overload
Improved postoperative pain control

because of the risk of autonomic hyperreflexia (AH) (see separate section on this topic). Because these procedures are done on an outpatient basis, lengthy residual epidural blockade should be avoided. Although there is some interindividual variability, a sensory level as high as T8 is required for procedures involving the ureters, while a T9–T10 sensory level is appropriate for procedures involving the bladder (Table 24–5).

Vaginal Gynecologic Surgeries

Several vaginal gynecologic surgeries can be performed with epidural blockade, although single-shot spinal or GA and, in some cases, paracervical block or topical anesthesia may be more appropriate (Table 24–6). A dilation and curettage (D&C) can be performed under paracervical block, GA, or

TABLE 24–5. Sensory level required for genitourinary procedures.

Procedure	Sensory Level Required
Nephrectomy	Consider combined general-epidural anesthesia
Cystectomy	T4
Extracorporeal shock wave lithotripsy	T6
Open prostatectomy	T8
Ureteral stone extraction	T8
Cystoscopy	T9
Transurethral resection of prostate	T9
Surgery involving testes	T10
Surgery involving penis	L1
Urethral procedures	Sacral block

Dilation and curettage
Hysteroscopy (with or without distention media)
Urinary incontinence procedures
Hysterectomy

neuraxial blockade. If neuraxial anesthesia is selected, a T10 sensory level is appropriate. While outpatient diagnostic hysteroscopy can be performed under LA,[13] hysteroscopy with distention media typically requires general or neuraxial anesthesia. Epidural anesthesia may have the disadvantage of increased glycine absorption compared to GA.[14] However, mental status changes related to absorption of the hypotonic irrigation solution are more easily detected in awake patients. For urinary incontinence procedures, epidural anesthesia offers the advantage of permitting the patient to participate in the intraoperative cough test, which theoretically decreases the risk of postoperative voiding dysfunction, although the incidence of this untoward outcome does not appear to be increased under GA.[15] A T10 sensory level provides sufficient anesthesia for bladder procedures, but the level should be extended to T4 if the peritoneum is opened. Vaginal hysterectomy can be performed under general or neuraxial (most commonly spinal) anesthesia. A T4–T6 sensory level is appropriate for uterine procedures.

Thoracic Epidural Anesthesia and Analgesia

The benefits of and indications for thoracic epidural anesthesia (TEA) are expanding (Table 24–7). TEA offers superior perioperative analgesia compared with systemic opioids,[16] decreases postoperative pulmonary complications,[17] decreases the duration of postoperative ileus,[18] and decreases mortality in patients with multiple rib fractures, among other things.[19] This section explores the role of TEA as either a primary anesthetic or as an adjuvant to GA for cardiac, thoracic, abdominal, colorectal, genitourinary, and gynecologic surgery (Figure 24–1). It also reviews the expanding role of TEA for video-assisted thoracic surgery (VATS) and laparoscopic surgery.

TABLE 24–7. Benefits of thoracic epidural anesthesia and analgesia.

Improved perioperative analgesia compared with other modalities
Decreased postoperative pulmonary complications
Decreased duration of postoperative ileus
Decreased duration of mechanical ventilation
Decreased mortality in patients with rib fractures

Cardiac Surgery

High TEA (blockade of the upper five thoracic segments) as an adjuvant to GA in cardiac surgery with cardiopulmonary bypass (CPB) has gained interest over the past several decades. Purported benefits include improved distribution of coronary blood flow,[20] reduced oxygen demand, improved regional left ventricular function, a reduction in the incidence of supraventricular arrhythmias,[21] attenuation of the surgical stress response,[22] improved intraoperative hemodynamic stability, faster recovery of awareness, improved postoperative analgesia, and a reduction of postoperative renal and pulmonary complications. Several of these potential benefits can be attributed to selective blockade of cardiac sympathetic innervation (the T1–T4 spinal segments). However, the insertion of an epidural catheter in patients requiring full heparinization for CPB carries the risk of epidural hematoma.

The evidence in support of high TEA for cardiac surgery is not conclusive. A study by Liu and colleagues comparing TEA with traditional opioid-based GA for coronary artery bypass grafting (CABG) with CPB found no difference in the rates of mortality or myocardial infarction, but demonstrated a statistically significant reduction in the risk of postoperative cardiac arrhythmias and pulmonary complications, improved pain scores, and earlier tracheal extubation in the TEA group.[23] In contrast, a recent randomized control trial comparing the clinical effects of fast-track GA with TEA versus fast-track GA alone in over 600 patients undergoing elective cardiac surgery (both on pump and off pump) found no statistically significant difference in 30-day survival free from myocardial infarction, pulmonary complications, renal failure, or stroke.[24] The duration of mechanical ventilation, length of intensive care unit (ICU) stay, length of hospital stay, and quality of life at 30-day follow-up were also similar for the two groups. Overall, the role of TEA as an adjuvant to GA for cardiac surgery with CPB remains controversial.

The role of high TEA in off-pump coronary artery bypass (OPCAB) surgery is also debated in the literature. TEA offers the advantages of avoiding intubation of the trachea in selected CABG cases, earlier extubation in patients receiving GA, and reduced postoperative pain and morbidity. But, concerns remain about compromised ventilation with a high sensory blockade, hypotension due to sympathicolysis, and epidural hematoma, despite the vastly reduced heparin dose compared with CPB cases. A recent prospective, randomized controlled trial of more than 200 patients undergoing OPCAB surgery found that the addition of high TEA to GA significantly reduced the incidence of postoperative arrhythmias, improved pain control, and improved the quality of recovery.[25] Until more definitive outcome data are available, the role of neuraxial techniques in OPCAB surgery remains uncertain.

Thoracic and Upper Abdominal Surgical Procedures

Epidural anesthesia and analgesia are commonly used for upper abdominal and thoracic surgery, including gastrectomy, esophagectomy, lobectomy, and descending thoracic aorta procedures

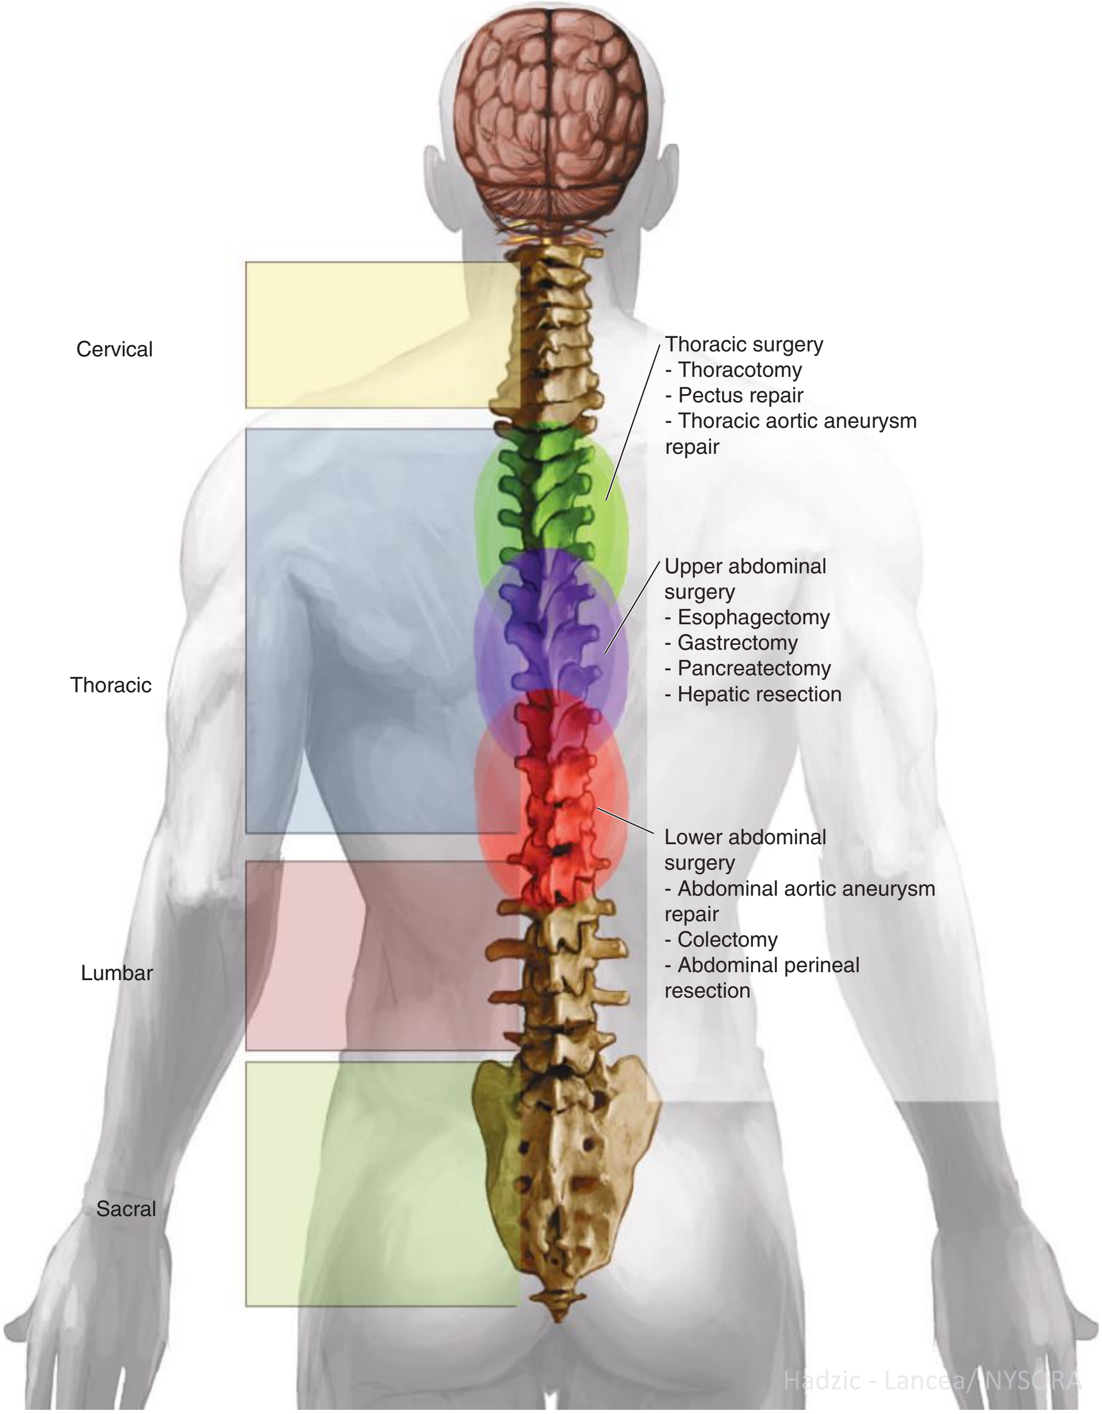

FIGURE 24–1. Level of placement in surgeries performed with thoracic epidural anesthesia and analgesia.

(Table 24–8). It is less commonly used for VATS, unless conversion to an open procedure is highly anticipated or if the patient is at high risk for complications from GA. Epidural blockade for many of these procedures commonly serves as an adjuvant to GA and as an essential component of postoperative pain management. Concurrent administration of high TEA with GA, however, carries risks of intraoperative bradycardia, hypotension, and changes in airway resistance. There is some debate regarding whether intraoperative activation of epidural blockade is required to appreciate the analgesic benefits of TEA or if postoperative activation produces equivalent benefits. A systematic review by Møiniche and colleagues found that the timing of several types of analgesia, including epidurals, intravenous opioids, and peripheral LAs, did not influence the quality of postoperative pain control.[26]

Thoracic epidural anesthesia initiated at the mid- to upper thoracic region can also be used for breast procedures. Benefits may include superior postoperative analgesia, decreased incidence of postoperative nausea and vomiting (PONV), improved patient satisfaction, and avoiding tracheal intubation in patients

TABLE 24–8. Indications for thoracic epidural anesthesia and analgesia.

Anatomic Region	Procedure
Thorax	Thoracotomy
	Pectus repair
	Thoracic aneurysm repair
	Thymectomy
	Video-assisted thoracic surgery
Upper abdomen	Esophagectomy
	Gastrectomy
	Pancreatectomy
	Cholecystecomy
	Hepatic resection
Lower abdomen	Abdominal aortic aneurysm repair
	Colectomy
	Bowel resection
	Abdominal perineal resection
Urogenital/ gynecologic	Cystectomy
	Nephrectomy
	Ureteral repair
	Radical abdominal prostatectomy
	Ovarian tumor debulking
	Pelvic exenteration
	Total abdominal hysterectomy

with moderate-to-severe comorbidities.[27] The sensory level required depends on the procedure: A level extending from T1–T7 is adequate for breast augmentation; C5–T7 is required for modified radical mastectomy; and C5–L1 is required for mastectomy with transverse rectus abdominis myocutaneous (TRAM) flap reconstruction (Table 24–9).[28] The epidural catheter can be introduced at T2–T4 to achieve segmental blockade of the thoracic dermatomes for most breast procedures; placement at T8–T10 is appropriate for TRAM flap reconstruction.

TABLE 24–9. Sensory level required for breast procedures.

Surgery	Segmental Blockade
Modified radical mastectomy	C5–T7
Mastectomy with transverse rectus abdominus flap	C5–L1
Partial mastectomy; breast augmentation	T1–T7

Epidural blockade provides a useful adjuvant to GA for procedures within the thoracic cavity, such as lung and esophageal surgery. The benefits of TEA for these procedures include enhanced postoperative analgesia; reduced pulmonary morbidity (eg, atelectasis, pneumonia, and hypoxemia); swift resolution of postoperative ileus; and decreased postoperative catabolism, which may spare muscle mass. Segmental epidural blockade of T1–T10 provides sensory blockade of the thoracotomy incision and the chest tube insertion site.

Upper abdominal surgeries that can be performed with epidural anesthesia and analgesia include esophagectomy, gastrectomy, pancreatectomy, hepatic resection,[29] and cholecystectomy. Laparoscopic cholecystectomy with epidural blockade[30] and distal gastrectomy with a combined general-epidural anesthetic have also been reported.[31] Midthoracic epidural catheter placement with segmental blockade extending from T5 (T4 for laparoscopic surgery) to T8 is appropriate for most upper abdominal procedures and, due to lumbar and sacral nerve root sparing, has minimal risk of lower extremity motor deficits, urinary retention, hypotension, and other sequelae of lumbar epidural anesthesia.

Suprainguinal Vascular Procedures

An upper midthoracic epidural can be used as an adjuvant to GA for surgeries of the abdominal aorta and its major branches. Epidural blockade for aortofemoral bypass, renal artery bypass, and repair of abdominal aortic aneurysms may provide superior postoperative pain control, facilitate early extubation of the trachea, permit early ambulation, and decrease the risk of thromboembolic events in patients who are at particularly high risk for this untoward complication. However, intraoperative epidural blockade may complicate management of hemodynamic changes associated with aortic cross-clamping and unclamping, as well as compromise early assessment of motor function in the immediate postoperative period. A sensory level from T6 to T12 is necessary for an extensive abdominal incision; a level extending from T4–T12 is required to attain denervation of the viscera.

Extracorporeal Shock Wave Lithotripsy, Prostatectomy, Cystectomy, Nephrectomy

Extracorporeal shock wave lithotripsy (ESWL) with or without water immersion can be performed under general or neuraxial anesthesia. A T6–T12 sensory level is necessary when neuraxial techniques are selected. Epidural blockade is associated with less intraoperative hypotension than a single-shot spinal, although both techniques serve to avoid GA in potentially high-risk patients.

Open prostate surgery, radical cystectomy and urinary diversion, and simple, partial, and radical nephrectomy can be performed under neuraxial blockade, either alone or in combination with GA, depending on the procedure. Some potential advantages of neuraxial compared with GA for radical retropubic prostatectomy include decreased intraoperative blood loss and transfusions,[32] a decreased incidence of postoperative thromboembolic events, improved analgesia and level of activity up to

9 weeks postoperatively,[33] faster return of bowel function,[34] and several other still-disputed advantages of neuraxial anesthesia, such as faster time to hospital discharge and reduced hospital costs. For the open procedure, patients may require generous sedation in the absence of a combined general-neuraxial technique. A T6 sensory level is required, with catheter placement in the midthoracic region. Radical cystectomy is performed on patients with invasive bladder cancer and may have improved outcomes with a combined general-epidural anesthetic compared to GA alone. Epidural blockade can provide controlled hypotension intraoperatively, contributing to decreased blood loss, and optimize postoperative pain relief.[35] A midthoracic epidural with a T6 sensory level is appropriate. Although GA is often required for radical nephrectomy due to concerns for patient positioning, intraoperative hypotension, and the potential for significant intraoperative blood loss, epidural analgesia provides more effective postoperative pain relief than systemic opioids while avoiding the adverse effects of the latter.

Several other urologic-related surgeries can be performed with neuraxial blockade as the sole anesthetic or as an adjuvant to GA. The use of a combined GA-epidural technique in patients with functional adrenal tumors undergoing laparoscopic adrenalectomy is safe and effective and may have the added benefit of minimizing fluctuations in hormone levels. Of note, however, epidural blockade may not diminish the pressor effects of direct tumor stimulation. The use of epidural anesthesia for retroperitoneal laparoscopic biopsy for patients who are not candidates for percutaneous biopsy has also been reported.[36]

Lower Abdominal and Gynecologic Surgeries

Total abdominal hysterectomy is often performed under GA, a combined general-epidural anesthetic, or neuraxial anesthesia with or without sedation. Although still not routine, gynecologic laparoscopy is increasingly being performed under neuraxial anesthesia, commonly with decreased Trendelenburg tilt, reduced CO_2 insufflation pressures (below 15 mm Hg), and supplemental opioids or nonsteroidal anti-inflammatory drugs (NSAIDs) to minimize referred shoulder pain. Epidural blockade for open procedures has the advantages of providing prolonged postoperative analgesia, decreasing the incidence of PONV and perioperative thromboembolic events, and potentially influencing perioperative immune function and, relatedly, the recurrence of cancer in patients undergoing hysterectomy for ovarian or related cancer. The proposed preemptive analgesia effect provided by neuraxial blockade during abdominal hysterectomy requires further investigation.[37] A sensory level extending to T4 or T6 provides sufficient anesthesia for procedures involving the uterus. Either epidural catheter insertion in the lumbar region with high volumes of LAs to raise the sensory level or low- to midthoracic placement is appropriate. The visceral pain associated with bowel and peritoneal manipulation decreases as the level of the blockade is increased; a T3–T4 level may be optimal.[38]

Open and laparoscopic colectomy, sigmoidectomy, and appendectomy are among other lower abdominal surgeries that can be performed under neuraxial anesthesia, with or without GA. Of particular interest in patients undergoing bowel surgery, thoracic epidural blockade decreases the duration of postoperative ileus, possibly without affecting anastomotic healing and leakage.[39] The superior postoperative analgesia associated with continuous epidural infusions, with or without opioids, most likely improves postoperative lung function in patients undergoing gastrointestinal (GI) surgery, although specific randomized controlled trials have not been conducted. In combination with early feeding and ambulation, TEA plays a role in early hospital discharge after certain GI surgeries.[40] A similar outcome has been demonstrated after laparoscopic colonic resection, followed by epidural analgesia for 2 days and early oral nutrition and mobilization (ie, multimodal rehabilitation).[41] Epidural catheter placement between T9 and T11 is usually appropriate for lower abdominal procedures; a sensory blockade extending to T7 or T9 is required for most colonic surgeries (sigmoid resection, ileotransversostomy, hemicolectomy).

Uncommon Medical Disorders and Clinical Scenarios

Epidural anesthesia and analgesia may also be indicated in the perioperative management of patients with specific medical conditions or coexisting disease, such as myasthenia gravis (MG), AH, malignant hyperthermia (MH), COPD, pheochromocytoma (see previous discussion), and sepsis. Several other subsets of patients may benefit from continuous epidural catheter techniques, including palliative care patients, parturients with comorbidities, and patients at risk for recurrent malignancy.

Myasthenia Gravis

Patients with MG pose particular challenges to anesthesiologists, including abnormal responses to depolarizing and nondepolarizing neuromuscular blocking agents; potential difficulty reversing residual neuromuscular blockade in patients taking cholinesterase inhibitors; prolonged postoperative mechanical ventilation requirements; risk of postsurgical respiratory failure; and postoperative pain management concerns.[42] Epidural blockade eliminates the need for intraoperative muscle relaxants in myasthenic patients and provides superior postoperative pain relief compared with opioids, while minimizing the risk of opioid-induced respiratory depression and pulmonary dysfunction.[43] Due to the possibility that ester LA metabolism may be prolonged in patients taking cholinesterase inhibitors, amide LAs may be preferred for the management of myasthenic patients. Reduced doses of LAs may also be appropriate. Concerns for compromising a myasthenic patient's respiratory function with a high epidural appear to be unfounded.[44]

Autonomic Hyperreflexia

Epidural techniques are appropriate for the perioperative management of patients with AH. AH occurs in up to 85% of patients with spinal cord injuries at or above T4–T7 as a result of uninhibited sympathetic activity. In response to visceral or cutaneous stimulation below the level of the lesion and in the absence of descending central inhibition, patients may develop acute, extreme sympathetic hyperactivity. Generally, intense vasoconstriction occurs below the level of the spinal cord lesion, with vasodilation above. Patients may experience sweating, nausea, flushing, pallor, shivering, nasal obstruction, blurred vision, headache, difficulty breathing, seizures, and cardiac arrhythmias. Reflex bradycardia is seen in the majority of cases. Severe life-threatening HTN can result in intracranial hemorrhage, myocardial ischemia, pulmonary edema, and death. Epidural blockade as the sole anesthetic, as a supplement to GA, or for labor analgesia attenuates the physiologic perturbations associated with AH, although incomplete block of sacral segments or missed segments may contribute to a high failure rate.[45] Spinal anesthesia, which blocks the afferent limb of this potentially lethal reflex, and deep GA more reliably prevent AH.[46]

Malignant Hyperthermia

The anesthetic management of MH presents a challenge to the anesthesiologist. MH is a clinical syndrome of markedly accelerated metabolism triggered primarily by volatile agents and the depolarizing agent succinylcholine. Susceptible patients may develop fever, tachycardia, hypercarbia, tachypnea, arrhythmias, hypoxemia, profuse sweating, HTN, myoglobinuria, mixed acidosis, and muscle rigidity in response to exposure to volatile agents or succinylcholine, although cases have been reported in which there is no evident triggering agent. Late complications may include consumptive coagulopathy, acute renal failure, muscle necrosis, pulmonary edema, and neurologic sequelae. Avoiding exposure to triggering agents is a cornerstone in the management of MH-susceptible patients. Whenever suitable, local, peripheral, or central neuraxial blocks are recommended, as these techniques are reported to be safer than the use of GA.[47] Both ester and amide LAs are considered safe in MH-susceptible patients, as is epinephrine, although controversy remains in the literature.

Chronic Obstructive Pulmonary Disease

Epidural blockade is a reasonable anesthetic option for patients with COPD undergoing major surgery due to concerns for prolonged mechanical ventilation. However, whether epidural techniques reduce pulmonary complications in patients with COPD is not known. In a recent propensity-controlled analysis of more than 500 patients with COPD undergoing abdominal surgery, epidural analgesia as an adjuvant to GA was associated with a statistically significant reduction in the risk of postoperative pneumonia.[48] Patients with the most severe type of COPD benefited disproportionately. The study also found a nonsignificant beneficial effect of epidural analgesia on 30-day mortality, a trend that has been demonstrated in other studies.[7]

Pediatric Surgery

There is a considerable body of literature dedicated to the use of regional anesthesia for pediatric surgery in both the inpatient and the ambulatory settings. Advantages of neuraxial blockade for the pediatric population include optimal postoperative analgesia, which is particularly important in extensive scoliosis repair, repair of pectus excavatum, and major abdominal and thoracic procedures; decreased GA requirements; earlier awakening; and earlier discharge in the ambulatory setting. Certain subsets of pediatric patients, such as those with cystic fibrosis, a family history of MH, or a history of prematurity, also benefit from the use of neuraxial anesthesia in lieu of GA. However, parental refusal, concerns about performing regional blocks in anesthetized patients, and airway concerns in patients with limited oxygen reserves pose challenges to the routine use of neuraxial blockade in this patient population.

The single-shot caudal approach to the epidural space, with or without sedation, is commonly used in pediatric patients for a variety of surgeries, including circumcision, hypospadias repair, inguinal herniorrhaphy, and orchidopexy. Continuous caudal catheters may be advanced cephalad to higher vertebral levels and used as the sole anesthetic or as an adjuvant to GA. Lumbar anesthesia and TEA provide a more reliable sensory blockade at higher segmental levels in older children. See Chapter 42 on pediatric regional anesthesia for a more detailed discussion of caudal blocks.

Ambulatory Surgery

Spinal anesthesia or peripheral nerve blocks are preferred over epidural techniques for most clinical scenarios in the ambulatory setting due to concerns for the relatively slow onset of epidural blockade, urinary retention, prolonged immobility, PDPH, and delayed discharge. The use of short-acting LAs, when appropriate, may obviate these concerns. Epidural techniques have the advantages of permitting slow titration of LAs, the ability to tailor block height and duration to the surgical procedure, and a decreased risk of transient neurologic symptoms (TNS) when compared with spinal anesthesia. Total hip arthroplasty, knee arthroscopy, foot surgery, inguinal herniorrhaphy, pelvic laparoscopy, and anorectal procedures are among the many outpatient surgeries that can be performed with neuraxial blockade as the primary anesthetic.[49] Regional blockade in the ambulatory setting is discussed in greater detail elsewhere in this volume.

Labor Analgesia and Anesthesia

Parturients comprise the single largest group to receive epidural analgesia. For adequate pain relief during the first stage of labor, coverage of the dermatomes from T10 to L1 is necessary; analgesia should extend caudally to S2–S4 (to include the pudendal nerve) during the second stage of labor. Epidural placement at the L3–L4 interspace is most common in laboring patients. However, surface anatomic landmarks may be difficult to appreciate in obstetric patients and may not reliably identify the intended interspace in this subset of patients due to both the anterior rotation of the pelvis and exaggerated lumbar lordosis. Several other factors may affect the ease of epidural placement and spread of epidurally administered LAs in parturients, including engorgement of epidural veins, elevated hormonal levels, and excessive weight gain. Refer to Chapter 41 for additional information on epidural techniques in laboring patients.

Miscellaneous

Several nonanesthetic applications for epidural procedures have emerged. Epidural catheter infusion techniques are being used increasingly for pain control at the end of life in both children and adults, including those with cancer-related pain.[50] There is also an evolving interest in whether epidural anesthesia and analgesia may have a protective role in sepsis. Of particular interest is whether critically ill patients may benefit from the increased splanchnic organ perfusion and oxygenation, as well as immunomodulation, seen in healthy patients who have received epidural anesthesia. However, additional studies are needed to evaluate the risk and benefits of epidural techniques in sepsis.[51] Another novel application for epidural LAs proposes that continuous infusions may improve placental blood flow in parturients with chronically compromised uterine perfusion and intrauterine growth restriction.[52]

There is a growing body of literature devoted to the potential beneficial effects of epidural analgesia in patients with cancer, although the data are preliminary and at times contradictory. Surgical stress and certain anesthetic agents suppress the host's immune function, including its ability to eliminate circulating tumor cells, and can predispose patients with cancer to postoperative infection, tumor growth, and metastasis. Recent studies have demonstrated improved perioperative immune function with the use of TEA in patients undergoing elective laparoscopic radical hysterectomy for cervical cancer.[53] Regional adjuncts to anesthesia have also been shown to have beneficial effects against recurrence of breast[54] and prostate[55] cancer. These protective effects may reflect both the decreased opioid requirements and the reduced neurohumoral stress response associated with epidural blockade.[56]

CONTRAINDICATIONS

Serious complications of epidural techniques are rare. However, epidural hematomas, epidural abscesses, permanent nerve injury, infection, and cardiovascular collapse, among other adverse events, have been attributed to neuraxial blockade. As a result, an understanding of the conditions that may predispose certain patient populations to these and other complications is essential. This section reviews the absolute, relative, and controversial contraindications to epidural placement (Table 24–10). Ultimately, a risk-benefit analysis with particular emphasis on patient comorbidities, airway anatomy, patient preferences, and type and duration of surgery is recommended prior to initiation of epidural blockade.

Absolute Contraindications

Although the contraindications to epidural blockade have been classified historically as absolute, relative, and controversial, opinions regarding absolute contraindications have evolved with advances in equipment, techniques, and practitioner experience. Currently, patient refusal may be considered the only absolute contraindication to epidural blockade. Although coagulopathy is considered a relative contraindication, initiating neuraxial blockade in the presence of severe coagulation abnormalities, such as frank disseminated intravascular coagulation (DIC), is contraindicated. Most other pathologic conditions comprise relative or controversial contraindications and require careful risk-benefit analysis prior to initiation of epidural blockade.

TABLE 24–10. Contraindications to epidural blockade.

Absolute	Patient refusal
	Severe coagulation abnormalities (eg, frank disseminated intravascular coagulation)
Relative and controversial	Sepsis
	Elevated intracranial pressure
	Anticoagulants
	Thrombocytopenia
	Other bleeding diatheses
	Preexisting central nervous system disorders (eg, multiple sclerosis)
	Fever/infection (eg, varicella zoster virus)
	Preload dependent states (eg, aortic stenosis)
	Previous back surgery, preexisting neurologic injury, back pain
	Placement in anesthetized adults
	Needle placement through tattoo

Relative and Controversial Contraindications

Sepsis

There is growing interest in using epidural anesthesia and analgesia to modulate inflammatory responses and to prevent or treat myocardial ischemia, respiratory dysfunction, and splanchnic ischemia in septic patients. However, there is insufficient evidence to determine whether epidural blockade is harmful or protective in sepsis.[57] Despite the potential benefits of regional techniques in this setting, many anesthesiologists may be reluctant to initiate epidural blockade in septic patients due to concerns for relative hypovolemia, refractory hypotension, coagulopathy, and the introduction of blood-borne pathogens into the epidural or subarachnoid space. If regional anesthesia is selected, a slow-onset dosing technique after or with concurrent antibiotic, intravenous fluid, and vasopressor administration may be feasible.

Increased Intracranial Pressure

Accidental dural puncture (ADP) in the setting of elevated intracranial pressure (ICP) with radiologic evidence of obstructed cerebrospinal fluid (CSF) flow or mass effect with or without midline shift can place patients at risk of cerebral herniation and other neurological deterioration.[58] Patients with increased ICP

TABLE 24–11. Signs and symptoms of elevated intracranial pressure.

Headache
Drowsiness
Nausea and vomiting
New-onset seizures
Decreased level of consciousness
Papilledema
Pupillary changes
Focal neurologic signs

at baseline may also experience an additional increase in pressure on epidural drug injection.[59] Consultation with a neurologic expert is strongly recommended, and localizing neurologic signs and symptoms should be ruled out by history and physical examination prior to initiation of neuraxial blockade in patients with new neurologic symptoms or known intracranial lesions[60] (Table 24–11). A decision tree may aid in assessing whether it is safe to proceed with neuraxial techniques in the presence of intracranial space-occupying lesions (Figure 24–2).

Coagulopathy

Coagulopathy is a relative contraindication to epidural placement, although thorough consideration of the etiology and severity of the coagulopathy is warranted on a case-by-case basis. Anticoagulants increase the risk of epidural hematoma and should be withheld in a timely fashion before initiation of epidural blockade. Precautions should also be taken before epidural catheter removal, as catheter removal may be as traumatic as catheter placement.[61]

Clinical Pearl

- Epidural needle and catheter placement both carry a risk of epidural hematoma in patients on anticoagulants. Similar precautions should be observed during placement and removal of epidural catheters.

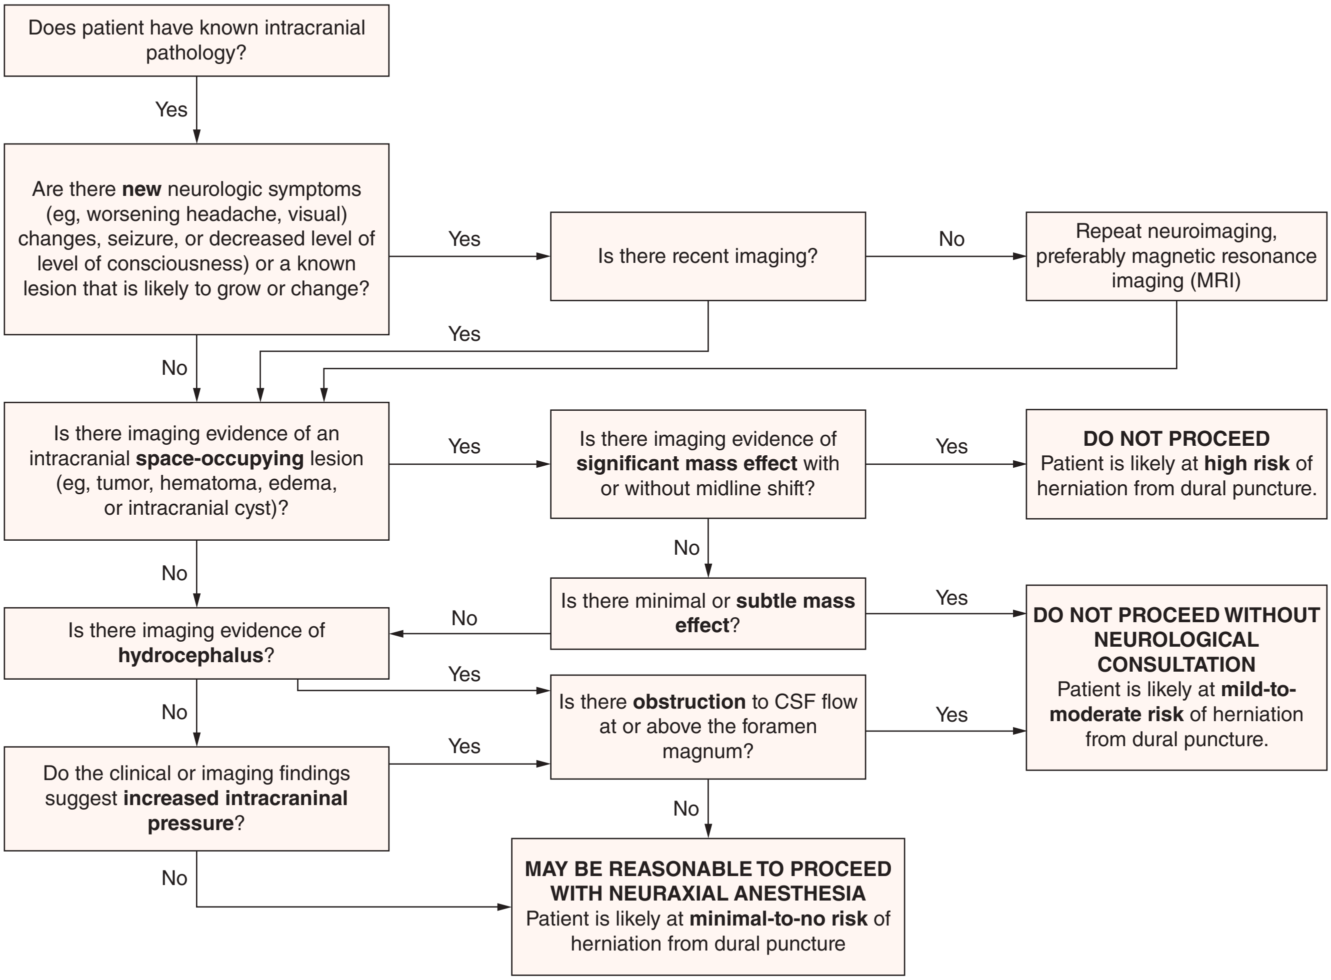

FIGURE 24–2. Safety algorithm for neuroaxial blockade in patients with intracranial space-occupying lesions. CSF = cerebrospinal fluid. (Reproduced with permission from Leffert LR, Schwamm LH: Neuraxial anesthesia in parturients with intracranial pathology: a comprehensive review and reassessment of risk. *Anesthesiology.* 2013 Sep;119(3):703-718.)

TABLE 24–12. Epidural blockade in patients receiving antithrombotic therapy.

NSAIDs (aspirin)	No contraindication
Clopidogrel	Wait 7 days before epidural placement
5000 U subcutaneous UFH every 12 hours	No contraindication
>10,000 U subcutaneous UFH daily	Safety not established
Intravenous heparin	Wait at least 60 minutes after instrumentation before administration of heparin; consider aPTT and wait 2–4 hours prior to catheter removal
LMWH thromboprophylactic dose	Wait 12 hours before epidural placement
LMWH therapeutic dose	Wait 24 hours before epidural placement
Warfarin	Wait for INR to normalize before neuraxial block; remove neuraxial catheter when INR < 1.5

INR = international normalized ratio; LMWH = low molecular weight heparin; NSAIDs = nonsteroidal anti-inflammatory drugs; UFH = unfractionated heparin.

The American Society of Regional Anesthesia and Pain Medicine periodically updates its guidelines for the initiation of regional anesthesia in patients receiving antithrombotic or thrombolytic therapy.[62] Briefly, neuraxial techniques in patients receiving subcutaneous unfractionated heparin (UFH) with dosing regimens of 5000 U every 12 hours are considered safe (Table 24–12). The risks and benefits of thrice-daily UFH or more than 10,000 U daily should be assessed on an individual basis; vigilance should be maintained to detect new or worsening neurodeficits in this setting. For patients receiving heparin for more than 4 days, a platelet count should be assessed before neuraxial block or catheter removal due to concerns for heparin-induced thrombocytopenia (HIT). In patients who receive systemic heparinization, it is recommended to assess the activated plasma thromboplastin time (aPTT) and discontinue heparin for 2 to 4 hours prior to catheter manipulation or removal. Administration of intravenous heparin intraoperatively should be delayed for at least 1 hour after epidural placement; a delay before administration of subcutaneous heparin is not required. In cases of full heparinization for CPB, additional precautions include delaying surgery for 24 hours in the event of a traumatic tap, tightly controlling the heparin effect and reversal, and removing catheters when normal coagulation is restored.

Epidural blockade in patients taking aspirin and nonaspirin NSAIDs is considered safe, as the risk of epidural hematoma is low. Needle placement should be delayed for 12 hours in patients receiving low molecular weight heparin (LMWH) thromboprophylaxis and for 24 hours in those receiving therapeutic doses. It is recommended that warfarin be discontinued for several days prior to surgery and that the international normalized ratio (INR) return to baseline prior to initiation of epidural techniques. An INR below 1.5 is considered sufficient for catheter removal, although many clinicians may be comfortable manipulating catheters with higher INR values. Refer to Chapter 52 for more detailed information on these and newer agents.

Neuraxial techniques are contraindicated in the setting of DIC, which may complicate sepsis, trauma, liver failure, placental abruption, amniotic fluid embolism, and massive transfusion, among other disease processes (Table 24–13). If DIC develops after epidural placement, the catheter should be removed once normal clotting parameters have been restored.

Thrombocytopenia and Other Common Bleeding Disorders

Thrombocytopenia, which may be caused by several pathologic conditions, is a relative contraindication to neuraxial anesthesia.

TABLE 24–13. Conditions associated with disseminated intravascular coagulation.

Sepsis
Trauma (head injury, extensive soft tissue injury, fat embolism, massive hemorrhage)
Massive transfusion
Malignancy (pancreatic carcinoma, myeloproliferative disease)
Peripartum (amniotic fluid embolism, placental abruption, HELLP [hemolysis, elevated liver enzymes, and low platelet count] syndrome, abnormal placentation)
Vascular disorders (aortic aneurysm, giant hemangioma)
Immunologic disorders (hemolytic transfusion reaction, transplant rejection, severe allergic reaction)
Liver failure

While there is currently no universally accepted platelet count below which epidural placement should be avoided, many clinicians are comfortable with a platelet count above 70,000 mm^3 in the absence of clinical bleeding.[63] The cutoff may be higher or lower, however, depending on the etiology of the thrombocytopenia, the bleeding history, the trend in platelet number, individual patient characteristics (eg, a known or suspected difficult airway), and provider expertise and comfort level. In general, platelet function is normal in conditions such as gestational thrombocytopenia and immune thrombocytopenic purpura (ITP).

Clinical Pearl

- The etiology of thrombocytopenia, the patient's bleeding history, and the trend in platelet count must be taken into account when determining the safety of initiation of epidural blockade in thrombocytopenic patients. Certain conditions, such as ITP and gestational thrombocytopenia, are associated with functioning platelets despite a low platelet count.

A platelet count below 50,000 mm^3 in the setting of ITP may respond to corticosteroids or intravenous immunoglobulin (IVIG), when necessary. Functional platelet defects may be present in several less-common conditions, such as HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count); thrombotic thrombocytopenic purpura (TTP); and hemolytic uremic syndrome (HUS). Other conditions such as systemic lupus erythematous (SLE), antiphospholipid syndrome, type 2B von Willebrand disease (vWD), HIT, and DIC are associated with thrombocytopenia of varying degrees (Table 24–14).

A standard platelet count has not been established for catheter removal. While some sources suggest 60,000 mm^3 is appropriate, catheter removal without adverse sequelae has been reported at counts below that cutoff.[64] If platelet number or function is impaired after an epidural catheter has been placed, such as in the case of intraoperative DIC, the catheter should remain in situ until the coagulopathy has resolved.

Other common bleeding diatheses that comprise relative contraindications to the initiation of epidural blockade include hemophilia, vWD, and disorders related to lupus anticoagulants and anticardiolipin antibodies. Hemophilia A and B are X-linked diseases characterized by deficiencies in factors VIII and IX, respectively. Although specific guidelines are lacking, neuraxial procedures are considered safe in carriers of the disease with normal factor levels and no bleeding complications. Neuraxial techniques have been performed without adverse sequelae in homozygous patients after factor replacement therapy once factor levels and the aPTT have normalized. Patients with lupus anticoagulants and anticardiolipin antibodies are predisposed to platelet aggregation, thrombocytopenia, and, because of interactions between antibodies and platelet membranes, thrombosis. As a result, many of these patients are anticoagulated with heparin in the peripartum or perioperative period. Heparin levels should be monitored with a blood heparin assay, thrombin time, or activated clotting test prior to performing neuraxial blockade. Of note, the aPTT is elevated at baseline in these patients and is likely to remain elevated after discontinuation of heparin due to interactions between the circulating antibodies and the coagulation tests.

	Sulfamethoxazole
Lymphoproliferative disorders	
Hemolytic uremic syndrome	

Von Willebrand disease is the most common inherited bleeding disorder. It is characterized by either a quantitative (type 1 and type 3) or qualitative (type 2) deficiency in von Willebrand factor (vWF), a plasma glycoprotein that binds to and stabilizes factor VIII and mediates platelet adhesion at sites of vascular injury. The clinical presentation of vWD varies: Patients with type 1, the most common type, experience mucocutaneous bleeding, easy bruising, and menorrhagia; patients with type 2 vWD may experience moderate-to-severe bleeding and, in the case of type 2B, thrombocytopenia; type 3, which is rare, presents with severe bleeding, including hemarthroses (Table 24–15). Both treatment options and the decision to proceed with neuraxial blockade also vary with the different disease presentations. Type I responds to desmopressin (DDAVP), which promotes secretion of stored vWF from endothelial cells and results in a rapid rise in both plasma vWF and factor VIII. Factor VIII concentrates and cryoprecipitate are treatment options for type 2 and type 3 vWD. Specialized laboratory tests may help confirm the diagnosis and type of vWD but are not widely available; standard coagulation tests may serve to rule out other bleeding disorders. In addition to a thorough history and physical examination, collaboration with a hematologist and other team

TABLE 24–15. Classification of von Willebrand disease.

Type	Underlying disorder	Clinical Presentation/Characteristics
1	Deficient quantity of vWF	Mucocutaneous bleeding, epistaxis, easy bruising, menorrhagia
2A	Defect in quality of vWF	Moderate bleeding
2B	Abnormal vWF	Moderate bleeding; thrombocytopenia; risk of thrombosis
2M	Abnormal vWF binding	Rare; significant bleeding
2N	Inactive vWF binding sites	May see low factor VIII and normal vWF levels
3	Severe deficiency of vWF	Severe bleeding, hemarthroses, muscle hematomas

vWF = von Willebrand factor.

members, and a review of any pertinent laboratory results, a risk-benefit analysis should be performed prior to initiation of epidural procedures in patients with vWD.

Preexisting Central Nervous System Disorders

Historically, the administration of neuraxial blockade has been contraindicated in patients with preexisting central nervous system (CNS) disease, including multiple sclerosis (MS), post-polio syndrome (PPS), and Guillain-Barré syndrome (GBS). In the case of MS, demyelinated nerves were thought to be more vulnerable to LA-induced neurotoxicity. An early study by Bader and colleagues suggested an association between MS relapse and higher concentrations of epidural LA among parturients,[65] although a subsequent study in the same patient population failed to demonstrate an adverse effect of epidural anesthesia on either the rate of relapse or the progression of disease.[66] A more recent retrospective study by Hebl and colleagues found no evidence of MS relapse after spinal or epidural anesthesia in 35 patients, 18 of whom received epidural blockade.[67] While it is unlikely that epidural anesthesia and analgesia cause MS exacerbations, definitive studies on pharmacological properties of LAs in MS, optimal dosing regimens, and whether LAs interact directly with MS lesions are lacking.[68] Until further data are available, it is reasonable to use low-concentration LAs and perform a thorough assessment and documentation of disease severity and neurologic status prior to initiation of central neuraxial blockade in patients with MS. These patients should also be informed of possible aggravation of symptoms, irrespective of anesthetic technique.

The decision to perform epidural anesthesia in patients with PPS, the most prevalent motor neuron disease in North America, requires careful analysis of the potential risks and benefits on a case-by-case basis. PPS is a late-onset manifestation of acute poliomyelitis infection that presents with fatigue, joint pain, and muscle atrophy in previously affected muscle groups. Epidural techniques in this patient population can be complicated by difficult puncture related to abnormal spinal anatomy, potential worsening of symptoms, and transient respiratory weakness. Alternatively, GA presents challenges related to sensitivity to muscle relaxants and sedatives and risks of respiratory compromise and aspiration. Although data are limited, there is no evidence that epidural techniques contribute to worsening of neurologic symptoms in patients with PPS.

Evidence linking epidural techniques to either activation or recurrence of GBS is also lacking. GBS presents with progressive motor weakness, ascending paralysis, and areflexia, most likely attributable to a postinfection inflammatory response. Older age at onset and severe initial disease are among the risk factors for prolonged neurologic dysfunction. Epidural anesthesia has been used successfully in patients with GBS, most commonly in obstetric patients, although exaggerated hemodynamic responses (hypotension and bradycardia), higher-than-normal spread of LAs, and worsening of neurologic symptoms have been reported.[69] As always, a risk-benefit analysis is warranted prior to performance of epidural blockade in patients with GBS, as are assessment and documentation of neurologic examination of the patient and a thorough discussion of the risks of anesthesia. It is reasonable to avoid regional techniques during periods of acute neuronal inflammation.

Patients with spina bifida may also present a unique challenge to anesthesiologists. Spina bifida occulta occurs when the neural arch fails to close without herniation of the meninges or neural tissues. It is most commonly limited to one vertebra, although a small percentage of affected individuals have involvement of two or more vertebrae with associated neurologic abnormalities, underlying cord abnormalities, and scoliosis. In general, the use of epidural techniques is not contraindicated in patients with spina bifida occulta, although placement at the level of the occulta lesion, most commonly at L5 to S1, may have an increased risk of dural puncture and patchy or higher-than-normal response to LAs. In contrast, epidural placement in patients with spina bifida cystica has several potential risks, including risk of direct injury to the cord due to a low-lying conus medullaris, unpredictable or higher-than-expected spread of LAs, and increased risk of dural puncture.

Fever or Infection

Controversy exists regarding the administration of neuraxial anesthesia in febrile patients and in individuals infected with human immunodeficiency virus (HIV), herpes simplex virus type 2 (HSV-2), and varicella zoster virus (VZV). The use of regional anesthesia in the presence of a low-grade fever of infectious origin is controversial due to concerns of spreading the infectious agent to the epidural or subarachnoid space, with subsequent meningitis or epidural abscess formation. Fortunately, infectious complications of regional anesthesia are rare, and studies to date have failed to demonstrate a causal relationship between neuraxial procedures, with or without dural puncture, and subsequent neurologic complications. While no universal guidelines exist, available data suggest that fever does not preclude the safe administration of epidural anesthesia and analgesia. The anesthetic management of febrile patients should be based on an individual risk-benefit analysis. Whether general or regional anesthesia is chosen, antibiotic therapy should be either completed prior to or underway during initiation of the anesthetic. Adherence to strict aseptic techniques and postprocedure monitoring to detect and treat any complications are essential.

Historically, there have been concerns about the safety of neuraxial procedures in individuals infected with HIV due to both the theoretical risk of inoculation of the virus into the CNS and the possibility that neurologic manifestations of HIV may be attributed to the anesthetic technique.[70] However, the CNS is infected early in the course of HIV infection, and there is no evidence that neuraxial instrumentation, including an epidural blood patch (EBP) for the treatment of PDPH, confers additional risk of viral spread to the CNS. There also is no evidence that the introduction of HIV-infected blood into the CSF might exacerbate a preexisting CNS infection, such as meningitis. Concerns that neurologic sequelae of HIV might be attributed to the neuraxial technique also appear to be unsubstantiated, as a temporal relationship between the epidural placement and the onset of neurologic deficits is unlikely. Nonetheless, thorough documentation of any preexisting neurologic deficit is recommended, given that neurologic complications of HIV are not uncommon and that HIV-positive individuals are at high risk for other sexually transmitted diseases that affect the CNS. Potential risks should be discussed in advance, and, as always, strict aseptic technique to protect both the patient and the anesthesiology provider must be maintained.

Areas of concern regarding the use of regional anesthesia in patients with HSV-2 include the risk of introducing the virus into the CNS during administration of neuraxial anesthesia; the possibility that a disseminated infection that develops after a regional anesthetic might be ascribed to the anesthetic itself, despite the lack of a causal relationship; and the safety of neuraxial techniques in primary HSV-2 outbreaks, which may be silent and difficult to distinguish from secondary outbreaks, but more commonly present with viremia, constitutional symptoms, genital lesions, and, in a small percentage of patients, aseptic meningitis. There are no documented cases of septic or neurologic complications following neuraxial procedures in patients with secondary (ie, recurrent) HSV infection; however, the safety of regional anesthesia in patients with primary infection has not been established. Crosby and colleagues conducted a 6-year retrospective analysis of 89 patients with secondary HSV infection who received epidural anesthesia for cesarean delivery and reported that no patients suffered septic or neurologic complications.[71] Similarly, in their retrospective survey of 164 parturients with secondary HSV infection who received spinal, epidural, or GA for cesarean delivery, Bader et al reported no adverse outcomes related to the anesthetic.[72] Based on the findings in these and other reported series, it appears safe to use spinal or epidural anesthesia in patients with secondary HSV infection. Pending more conclusive data, however, it seems prudent to avoid neuraxial blockade in patients with HSV-2 viremia.

Concerns also exist regarding the use of regional anesthesia in adults with either primary or recurrent VZV infections, such as herpes zoster (ie, shingles) and postherpetic neuralgia (PHN). However, neuraxial procedures, including epidural steroid injections, are not uncommonly used to treat acute herpes zoster, prevent PHN, and treat the pain associated with PHN, often in conjunction with antiviral therapy. The presence of active lesions at the site of injection is considered a contraindication to these and other neuraxial techniques. For the small subset of patients who are infected with primary VZV as adults, severe complications such as aseptic meningitis, encephalitis, and varicella pneumonia may result. The performance of regional anesthesia in this setting is more controversial but may be preferable to GA in some cases, primarily due to concerns for pneumonia.[73] Ultimately, a careful risk-benefit analysis, in addition to assessment and documentation of any preexisting neurologic deficits, is recommended prior to initiation of neuraxial blockade in these patients.

Localized skin infection at the site of intended needle puncture is another relative contraindication to neuraxial blockade, primarily due to concerns that spinal epidural abscess (SEA) or meningitis may result. Hematogenous spread of a localized infection has been implicated in SEA, although a causal relationship is not clearly established in the reported cases. Maintenance of strict sterile precautions and a low index of suspicion in the presence of neurologic signs may minimize the risk. Needle insertion should be attempted after appropriate antibiotic administration, and a site remote from the localized infection is recommended.

Previous Back Surgery, Preexisting Neurologic Injury, and Back Pain

Traditionally, a history of previous back surgery was considered a relative contraindication to neuraxial blockade due to concerns for infection, exacerbation of preexisting neurologic deficits, and an increased likelihood of difficult or unsuccessful block. Technical difficulties may be related to degenerative changes above or below the level of fusion, adhesions in the epidural space, epidural space obliteration, dense scar tissue at the point of intended needle entry on the skin surface, the presence of graft material, and the presence of extensive rods that preclude identification of or access to midline. Despite these concerns, one large retrospective study of patients with a history of spinal stenosis, peripheral neuropathy, or lumbar radiculopathy found that previous spinal surgery did not affect the success rate or frequency of technical complications.[74] In patients with metal rods (eg, Harrington rods), anteroposterior and lateral radiographs or a copy of the operative report may help to identify the extent of instrumentation, as well as the presence of additional anatomic abnormalities. Ultrasound may aid in the identification of midline in challenging epidural cases. Potential complications, such as irregular, limited, or excessive cranial spread of LAs and an increased risk of PDPH if multiple attempts at placement are required, should be discussed with the patient during the informed consent process. Of note, similar technical difficulties encountered during the original technique can be expected during an EBP procedure. Because of these and other concerns, spinal anesthesia may be preferred, when appropriate, over epidural blockade.

Back pain is a ubiquitous problem that should not be considered a contraindication to neuraxial blockade and, rather, is a relatively common indication for epidural steroid and LA injections. One recent study found a higher than previously reported rate of new neurologic deficits and worsening of preexisting symptoms in patients with compressive radiculopathy or multiple neurologic disorders (spinal stenosis or lumbar disk disease) who received neuraxial anesthesia.[74] However, a causal relationship was not clearly established. Many of the concerns regarding neuraxial procedures in patients with back pain can be addressed prior to initiation of neuraxial anesthesia with a thorough history and physical examination; not uncommonly, the cause of back pain is not neurologic in origin. In these cases, regional techniques are not associated with new-onset back pain and are unlikely to exacerbate the preexisting condition. Because patients with preexisting neurologic conditions may be at increased risk of postoperative neurologic complications after neuraxial techniques, a careful risk-benefit analysis is warranted on a case-by-case basis. Preexisting neurologic deficits or symptoms and their severity should be documented.

Preload-Dependent States

Traditionally, neuraxial blockade has been considered contraindicated in patients with severe aortic stenosis (AS) and other preload-dependent conditions, such as hypertrophic obstructive cardiomyopathy (asymmetric septal hypertrophy, ASH), due to the risk of acute decompensation in response to decreased systemic vascular resistance (SVR). The later stages of AS are associated with decreased diastolic compliance, impaired relaxation, increased myocardial oxygen demand, and decreased perfusion of the endocardium.[75] Decreased SVR in the setting of either GA or neuraxial blockade leads to decreased coronary perfusion and contractility, with a further reduction in cardiac output (CO) and worsening hypotension. Bradycardia, tachycardia, and other dysrhythmias are also poorly tolerated. The current evidence regarding regional anesthesia in patients with AS is based on case reports and lacks the scientific validity provided by randomized controlled trials. However, it appears that carefully titrated CSE and continuous epidural and spinal techniques, most commonly with invasive monitoring, may be acceptable options for patients with AS. Single-shot spinal anesthetics are generally contraindicated, as gradual onset of sympathetic blockade is essential.

Anesthetic goals for patients with ASH are similar, with emphasis on maintaining preload, afterload, euvolemia, and vascular resistance, while avoiding tachycardia and enhanced contractility. Invasive monitoring and, if necessary, intermittent transthoracic echocardiography may help guide fluid and vasopressor requirements, as well as guide management in the event of acute decompensation.[76]

Epidural Placement in Anesthetized Patients

Initiation of epidural blockade in adults under GA is controversial due to concerns that these patients cannot respond to pain and may therefore be at increased risk for neurologic complications. Indeed, paresthesias during block performance and pain on LA injection have been identified as risk factors for serious neurologic deficits after regional techniques. Consequently, some experts consider close communication with the patient an essential component of safe epidural performance.[77] Current data support the practice of epidural insertion in awake or minimally sedated patients, but needle and catheter placement in anesthetized adults may be an acceptable alternative in selected cases. Studies of lumbar epidural insertion while patients are undergoing GA have demonstrated that the risk of neurologic complications is small.[78] Overall, the relative risk of administration of epidural blockade in anesthetized patients, compared with epidural placement in awake patients, is unknown due to the low overall incidence of serious neurologic complications associated with regional anesthesia.

Needle Insertion Through a Tattoo

Concerns that puncturing a tattoo during epidural placement may have adverse sequelae appear unsubstantiated in the literature. Theoretical risks are related primarily to the introduction of a potentially toxic or carcinogenic pigment into the epidural, subdural, or subarachnoid space. However, to date no significant complications related to inserting a needle through a tattoo have been reported in the literature, although potential long-term consequences cannot be dismissed.

ANATOMY

An understanding of the anatomy of the vertebral column, spinal canal, epidural space and its contents, and commonly encountered anatomic variations among individuals is essential for the safe and effective initiation of epidural blockade. A three-dimensional mental image of vertebral column anatomy also aids in troubleshooting when identification of the epidural space is equivocal or when complications of epidural catheterization, such as unilateral blockade, intravascular cannulation, or catheter migration, occur. This section presents the basic anatomic considerations for successful epidural anesthesia and analgesia and reviews several controversies in the field of applied anatomy, including the accuracy of anatomic landmarks to estimate the spinous process level, the existence (or lack thereof) of a subdural compartment, and the contents of the epidural space.

Vertebral Column

General Appearance

Seven cervical, 12 thoracic, 5 lumbar, 5 fused sacral, and 3 to 5 (most commonly 4) fused coccygeal vertebrae comprise the

FIGURE 24–3. Physiologic spinal curves: anterior, posterior, and lateral views (left to right).

vertebral column. The vertebral column is straight when viewed dorsally or ventrally. When viewed from the side, the cervical and lumbar regions are concave posteriorly (lordosis), and the thoracic and sacral regions are concave anteriorly (kyphosis) (Figure 24–3). The four physiologic spinal curves are fully developed by 10 years of age and become more pronounced during pregnancy and with aging. In the supine position, C5 and L3 are positioned at the highest points of the lordosis; the peaks of kyphosis occur at T5 to T7 and at S2.

Clinical Pearl

- C5 and L3 comprise the highest points of lordosis in the supine position; the highest points of kyphosis are T5 to T7 and S2.

Structure of Vertebrae

With the exceptions of C1 and C2 and the fused sacral and coccygeal regions, the general structure of each vertebra consists of an anterior vertebral body (corpus, centrum) and a posterior bony arch. The arch is formed by the laminae; the pedicles, which extend from the posterolateral margins of the vertebral body; and the posterior surface of the vertebral body itself. In addition to the spinous processes, which are formed by the fusion of the laminae at midline, the vertebral arch supports three pairs of processes that emerge from the point where the laminae and pedicles join: two transverse processes, two superior articular processes, and two inferior articular processes. Adjacent vertebral arches enclose the vertebral canal and surround portions of the longitudinal spinal cord. The spinal canal communicates with the paravertebral space by way of gaps between the pedicles of successive vertebrae. These intervertebral foramina serve as passageways for the segmental nerves, arteries, and veins.

There is substantial variation in the size and shape of the vertebral bodies, the spinous processes, and the spinal canal at different levels of the vertebral column (Figure 24–4). C3 through C7 have the smallest vertebral bodies, while the spinal canal at this level is wide, measuring 25 mm. These cervical vertebrae, with the exception of C7, have short, bifurcated spinous processes. C7, the vertebra prominens, has a long, slender,

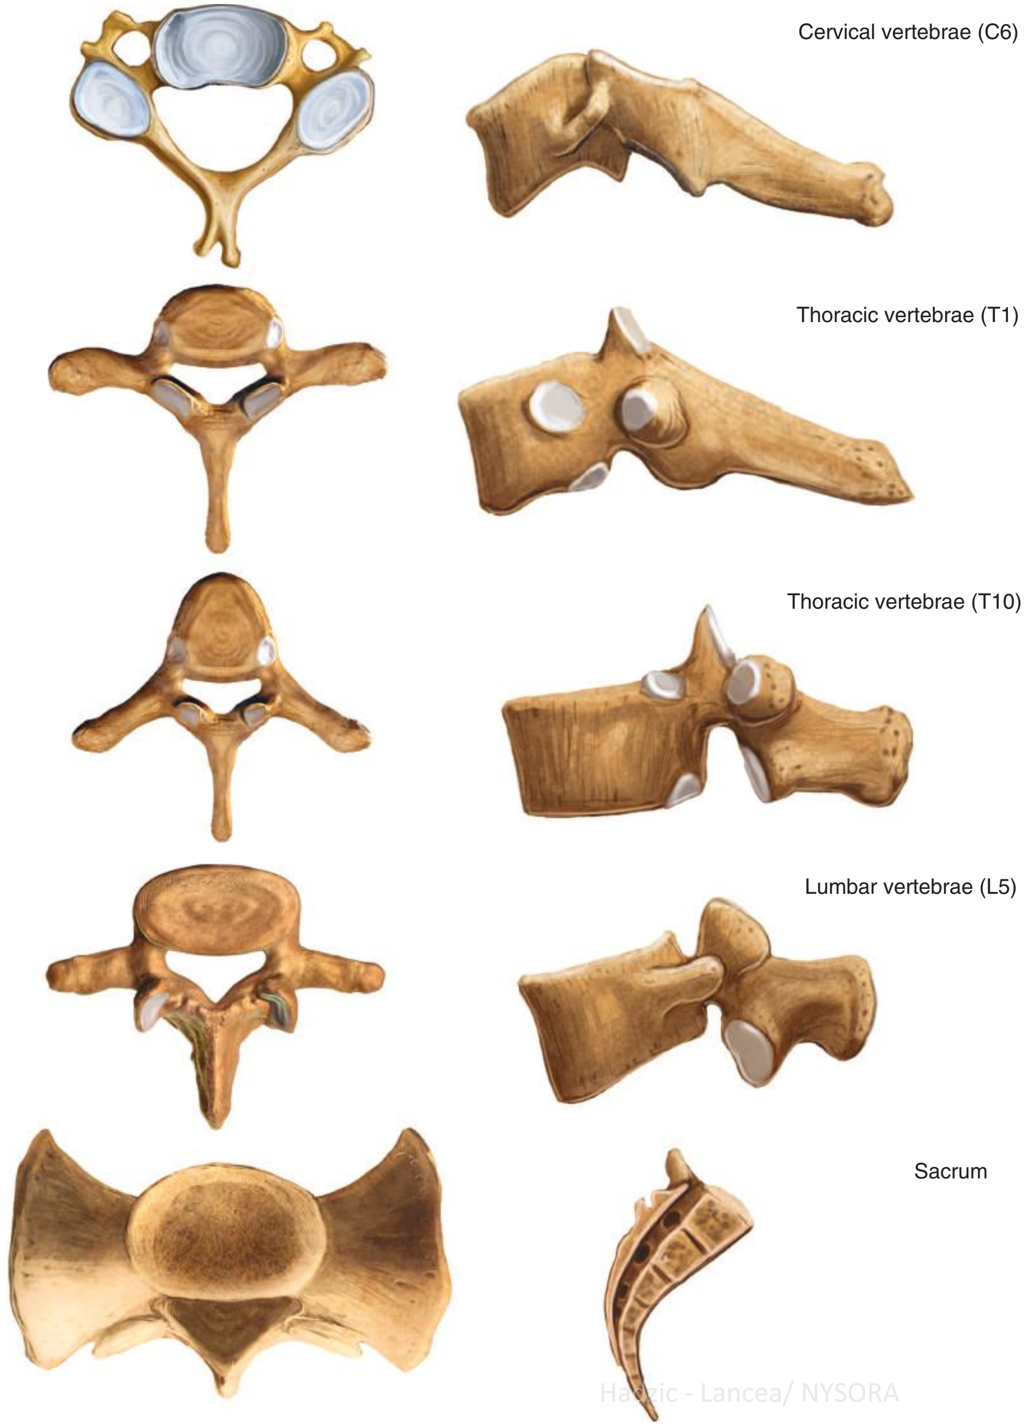

FIGURE 24–4. Size and shape of the vertebral bodies at different spinal levels.

and easily palpable horizontal spinous process protruding at the base of the neck that often serves as a surface landmark during epidural procedures. However, the first thoracic spinous process may be equally or more prominent than C7 in up to one-third of male individuals, as well as in thin patients and in patients with scoliosis and degenerative diseases.[79] The vertebra prominens may also be difficult to distinguish from C6 in up to half of individuals, most commonly females.[80]

The thoracic vertebral bodies are larger than the cervical vertebral bodies and are wider in the posterior than anterior dimension, contributing to the characteristic thoracic curvature. The long and slender thoracic spinous processes, with tips that point caudally, are most sharply angled between T4 and T9, making insertion of the epidural needle in the midline more difficult in the midthoracic region. Beyond T10, they increasingly resemble those in the lumbar region. Each thoracic vertebra articulates with ribs along the dorsolateral border of its body, a feature that may help distinguish the lower thoracic and upper lumbar regions. The inferior angle of the scapula and the 12th rib are widely used in clinical practice to estimate the level of the

TABLE 24–16. Anatomic landmarks to identify vertebral levels.

Vertebra prominens	C7
Root of spine of scapula	T3
Inferior angle of scapula	T7
Rib margin	L1
Superior aspect of iliac crest	L3, L4
Posterior superior iliac spine	S2

spinous processes of T7 and T12, respectively. The imaginary line connecting the caudal-most margin of the 12th ribs is often presumed to cross the L1 spinous process (Table 24–16).

The lumbar vertebrae are the largest movable segments, with thicker anterior than posterior dimensions that contribute to the characteristic lumbar curvature. The spinous processes in this region are blunt and large, with tips that point posteriorly. Anatomic variations in the lumbosacral region that may have clinical implications are not uncommon. Sacralization of the last lumbar vertebra, marked by fusion of L5 to the sacral bone, and lumbarization of S1 and S2, in which fusion is incomplete, may make numbering and identification of the correct lumbar level difficult.[81] Although probably not of clinical significance, patients with sacralization have also been found to have a higher position of the conus medullaris, which demarcates the cone-shaped terminus of the spinal cord, than those with lumbarization or without lumbosacral transitional vertebrae.[82] In the absence of these transitional vertebrae, the largest and most easily palpable interspace corresponds to L5 to S1.

Surface Anatomic Landmarks to Identify the Spinal Level

Surface landmarks are often used to identify the intended spinal level during initiation of epidural anesthesia (Figure 24–5). However, palpation and inspection of surface anatomical landmarks may fail to help localize the correct intervertebral space, particularly when considering individual variations in the vertebral level of these landmarks, the varying termination of the conus medullaris between the middle third of T12 and the upper third of L3,[83] and anesthesiologists' poor record of identifying the correct interspace.

Common pitfalls to using skeletal landmarks to identify the level of puncture include the following: The vertebra prominens is commonly confused with C6 and T1; the scapula may be difficult to identify during TEA placement in obese patients; tracing the vertebra attached to the 12th rib can be misleading, particularly in obese patients; and the line connecting the posterior superior iliac spines, often used to identify S2, commonly crosses the midline at variable levels between L5 and S1.[84] Several studies have demonstrated that Tuffier's line (also known as Jacoby's line or the intercristal line), which joins the superior aspect of the iliac crests, may cross midline at least one, and perhaps two, levels higher than the predicted L4–L5 interspace,[85] particularly in pregnant,[86] elderly, and obese patients.

Anesthesiologists have a poor record of estimating the correct interspace based on external landmarks. Van Gessel and colleagues found that the level of lumbar puncture is misidentified up to 59% of the time.[87] In a more recent study, Broadbent and coworkers found that practitioners identify the correct lumbar level in only 29% of cases; the space is misidentified by two spinal levels, with the actual level higher than that predicted, in 14% of cases.[88] Lirk et al confirmed the tendency of trained anesthetists to place the epidural needle more cranially than intended, most often within one interspace of the predicted level, also in the cervical and thoracic spinal column.[89] Overall, given the importance of selecting the correct site of puncture, caution is advised when using surface anatomic landmarks to identify intervertebral spaces. The increasing reliance on ultrasound determination of the spinal level may decrease the incidence of complications related to misidentification of the intended interspace.

Joints and Ligaments of the Vertebral Column

General

Adjacent vertebrae of the cervical, thoracic, and lumbar regions, excluding C1 and C2, are separated and cushioned by fibrocartilaginous intervertebral disks. The soft, elastic core of each disk, the nucleus pulposus, is composed primarily of water, as well as scattered elastic and reticular fibers. The fibrocartilaginous annulus fibrosis surrounds the nucleus pulposus and attaches the disks to the bodies of adjacent vertebrae. The disks, which account for up to one-quarter of the length of an adult vertebral column, lose their water content as we age, contributing to the shortening of the vertebral column, reducing their effectiveness as cushions, and rendering them more prone to injury, particularly in the lumbar region.

The articular processes arise at the junction between the pedicles and laminae. Superior and inferior articular processes project cranially and caudally, respectively, on both sides of each vertebra. The vertebral arches are connected by facet joints, which link the inferior articular processes of one vertebra with the superior articular processes of the more caudal vertebra. The facet joints are heavily innervated by the medial branch of the dorsal ramus of the spinal nerves. This innervation serves to direct contraction of muscle that moves the vertebral column.

The Longitudinal Ligaments

The anterior and posterior longitudinal ligaments support the vertebral column, binding the vertebral bodies and intervertebral disks together (Figure 24–6). The posterior longitudinal ligament, which forms the anterior wall of the vertebral canal, is less broad than its anterior counterpart and weakens with age and other degenerative processes. Clinically, disk herniation occurs primarily in the paramedian portion of the posterior disk, at weak points in the posterior longitudinal ligament. This area comprises the anterior epidural space, as opposed to the more clinically relevant posterior epidural space, and should not interfere with epidural needle placement.

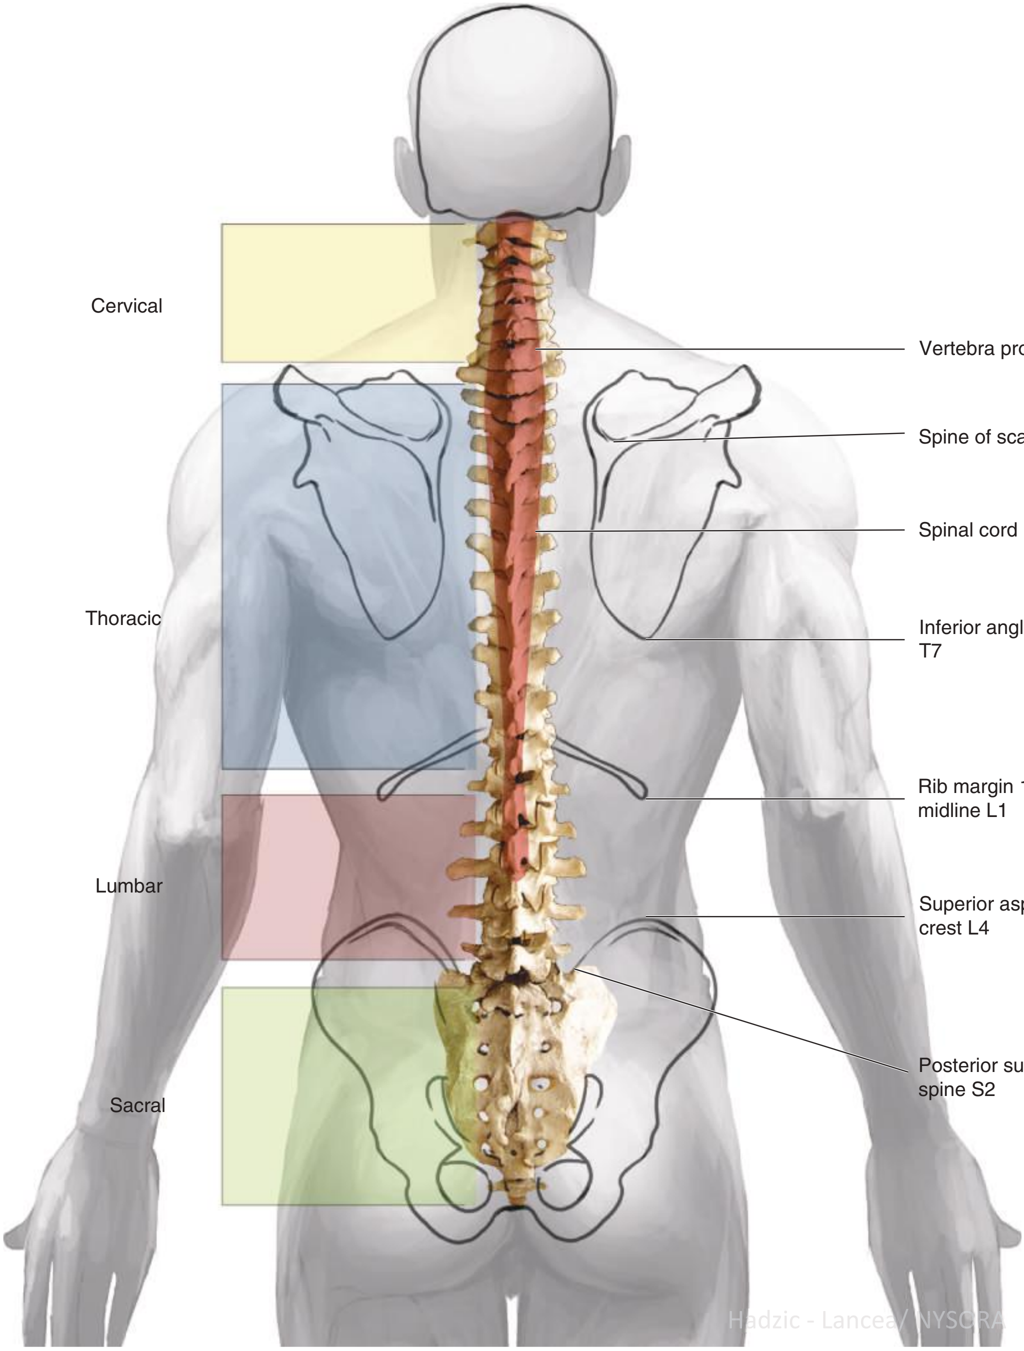

FIGURE 24–5. Skeletal landmarks used to determine the level of epidural placement.

Clinical Pearl

- Disk herniation occurs primarily at weak points in the posterior longitudinal ligament in an area that comprises the anterior epidural space, as opposed to the more clinically relevant posterior epidural space.

Nonetheless, thorough documentation of preexisting pain and neurologic deficits in patients with known disk herniation is recommended prior to initiation of epidural anesthesia. Also of clinical relevance, a membranous lateral extension of the posterior longitudinal ligament may serve as a barrier to the spread of epidural solutions and appears to cordon the veins anterior to the dura away from the rest of the epidural space.[90]

Clinical Pearl

- A membranous lateral extension of the posterior longitudinal ligament appears to cordon off the veins in the anterolateral epidural space, where epidural vein puncture and catheter cannulation are more likely to occur.

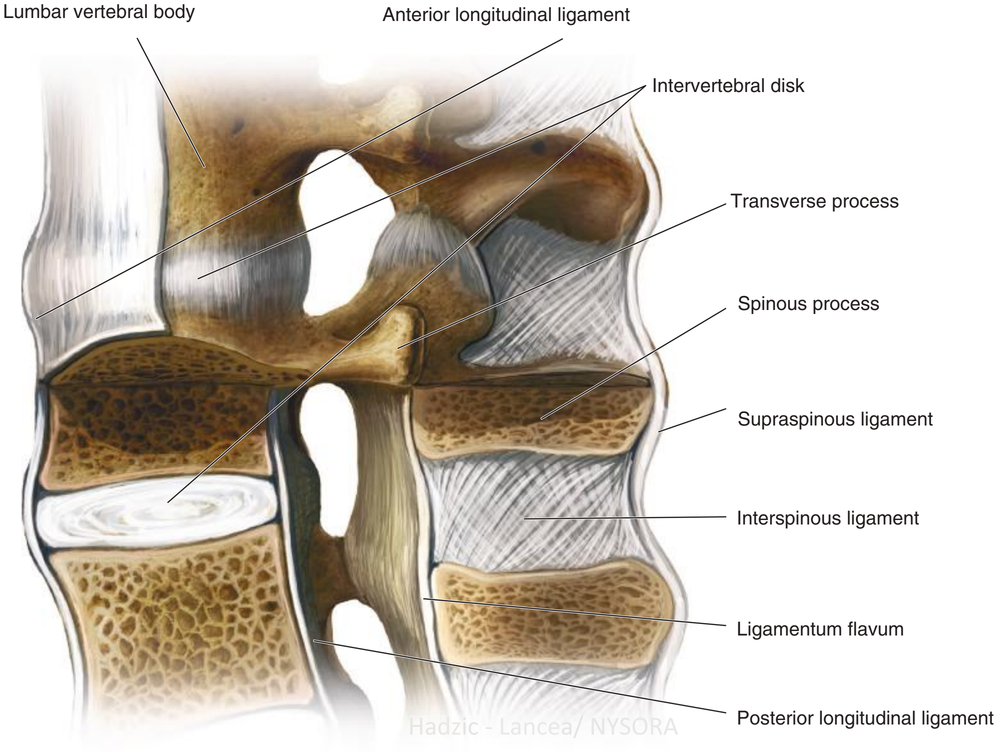

FIGURE 24–6. Ligaments of the vertebral canal.

The Supraspinous and Interspinous Ligaments

Several other ligaments that support the vertebral column serve as key anatomic landmarks during epidural needle placement. The supraspinous ligament connects the tips of the spinous processes from C7 to L5; above C7 and extending to the base of the skull, it is called the ligamentum nuchae. This relatively superficial, inextensible ligament is most prominent in the upper thoracic region and becomes thinner and less conspicuous toward the lower lumbar region.[91] The interspinous ligament, directly anterior to the supraspinous ligament, traverses the space between adjacent spinous processes in a posterocranial direction. It is less developed in the cervical region, which may contribute to a false LOR during cervical epidural procedures.[92] On histological examination, the interspinous ligament appears to have intermittent midline cavities filled with fat.

Both the supra- and interspinous ligaments are composed of collagenous fibers that make a characteristic "crunching" sound or distinct tactile sensation as the epidural needle advances. During initiation of epidural placement via the midline approach, these ligaments serve as appropriate sites to engage the needle, although some practitioners may engage the needle closer to the epidural space, in the ligamentum flavum. A "floppy" epidural needle that angles laterally prior to attachment of the LOR syringe may indicate an off-midline approach, away from the supra- or interspinous ligaments.

The Ligamentum Flavum

The ligamentum flavum connects the lamina of adjacent vertebrae from the inferior border of C2 to the superior border of S1. Laterally, it extends into the intervertebral foramina, where it joins the capsule of the articular process. Anteriorly, it limits the vertebral canal and forms the posterior border of the epidural space. At each spinal level, the right and left ligamentum flava join discontinuously in an acute angle with the opening oriented in the ventral direction, occasionally forming midline gaps filled with epidural fat.[93] In contrast to the collagenous inter- and supraspinous ligaments, the ligamentum flavum comprises primarily thick, elastic fibers arranged longitudinally in a tight network. Areas of ossification of the ligamentum flavum occur at different levels of the vertebral canal and appear to be a normal variant. These bony spurs, which may contribute to preexisting neurological symptoms and could potentially impede epidural needle advancement, are most commonly encountered in the lower thoracic region, between T9 and T11, and diminish in both frequency and size in the caudal and cranial directions.[94]

The ligamentum flavum has variable characteristics, many of which are disputed in the literature, at different vertebral levels. First, its thickness varies at different levels and, possibly, in different physiologic states, with a range of 1.5–3.0 mm in the cervical segment, 3.0–5.0 mm in the thoracic segment, 5.0–6.0 mm in the lumbar segment, and 2.0–6.0 mm in the caudal region (Table 24–17).[95] In isolated pregnant patients, the ligamentum flavum has been reported to be as thick as 10 mm, presumably due to edema.[96] Also of note, the flavum's thickness varies within the interspace itself, with the caudal region being significantly thicker than the rostral.

TABLE 24–17. Thickness of the ligamentum flavum at different vertebral levels.

Vertebral Level	Thickness (mm)
Cervical	1.5–3.0
Thoracic	3.0–5.0
Lumbar	5.0–6.0
Caudal	2.0–6.0

Clinical Pearl

- The ligamentum flavum varies in thickness at different spinal levels and is thickest in the lumbar region. Its thickness also varies within each interspace.

Clinically, these varying degrees of thickness may influence the risk of inadvertent dural puncture or determine whether injection of an anesthetic solution into the epidural space is possible with the skin infiltration needle.

Another controversy concerns the incidence and location of gaps formed by the incomplete fusion of the right and left ligamentum flava. In their study of 52 human cadavers, Lirk and colleagues found that up to 74% of the flava in the cervical region are discontinuous at midline.[97] These gaps vary in location, with some occupying the entire height of the ligamentum flavum between successive vertebral arches and others occupying the caudal third portion only (Figure 24–7). Veins connecting the posterior external and internal vertebral venous plexuses not uncommonly traverse the caudal portion of the gaps. In another cadaveric study, Lirk et al determined that thoracic midline gaps were less frequent than cervical gaps but more frequent than those in the lumbar region, with an incidence as high as 35.2% at T10 to T11.[98] In cadaveric studies of the lumbar ligamentum flavum, gaps were found most commonly at L1 and L2 (22.2%) and decreased caudally (11.4% at L2 to L4; 9.3% at L4 to L5; 0% at L5 to S1).[99] Clinically, these gaps may contribute to failure to identify the epidural space using the LOR technique at midline. The characteristic "pop" sound and tactile sensation conferred by penetration of the elastic fibers of the ligamentum flavum may be absent in the setting of a discontinuous ligamentous arch. The depth to the epidural space at midline may also be affected.

Clinical Pearl

- Ligamentum flavum midline gaps represent incomplete fusion of the right and left ligamentum flava. They are common in the cervical spine and decrease in frequency in the thoracic and lumbar regions. The variable thickness of the ligamentum flavum and the presence of midline gaps may contribute to failure to identify the epidural space.

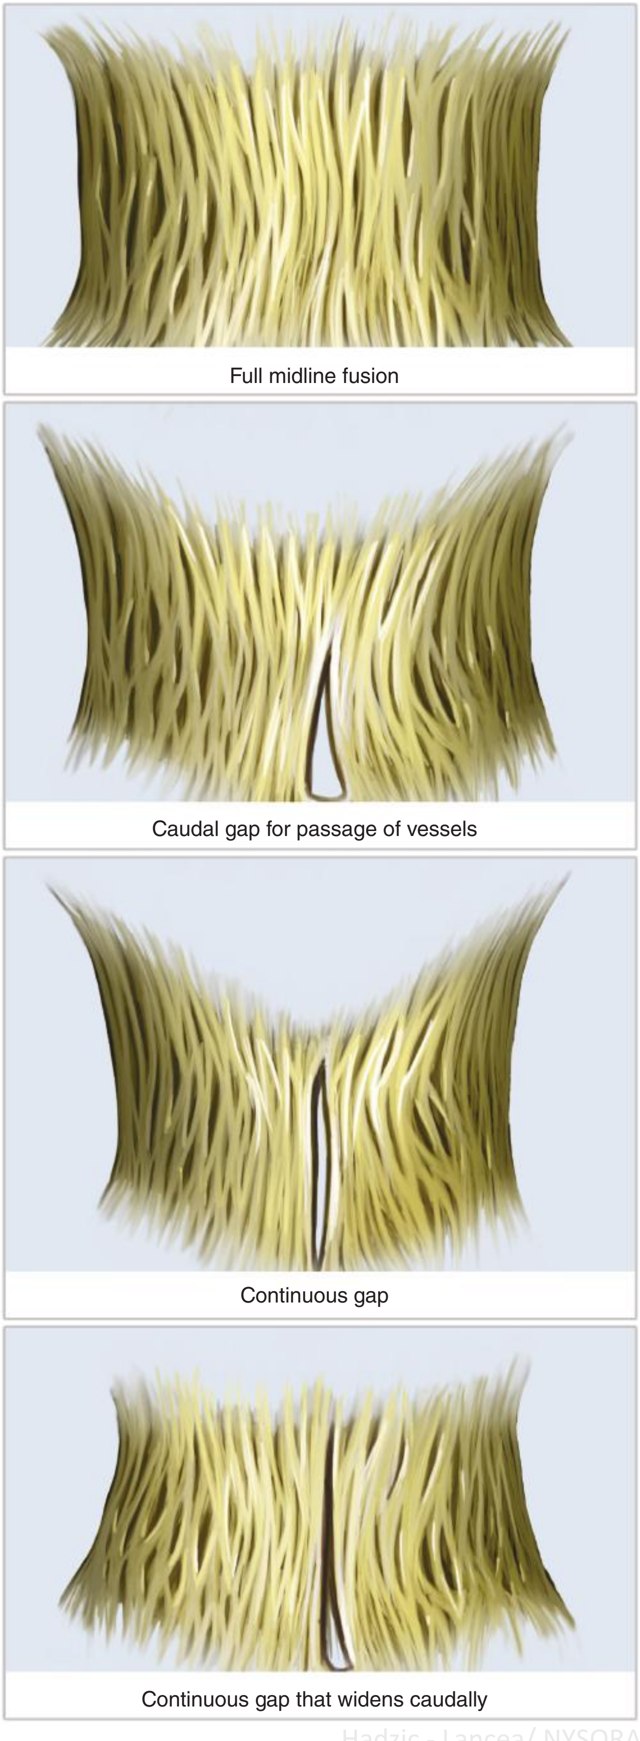

FIGURE 24–7. Ligamentum flavum with different types of midline gaps.

The Spinal Canal

General

The vertebrae serve primarily to support the weight of the head, neck, and trunk; transfer that weight to the lower limbs; and protect the contents of the spinal canal, including the spinal cord. An extension of the medulla oblongata, the spinal cord serves as the conduit between the CNS and the peripheral nerves via 31 pairs of spinal nerves (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal) (Figure 24–8). The adult cord measures approximately 45 cm or 18 inches and has two regions of enlarged diameter at C2–T2 and at T9–L2, areas that correspond with the origin of the nerve supplies to the upper and lower extremities. However, its level of termination varies with age, as well as among individuals of similar age groups. As a result of a discrepancy in the pace of growth of the spinal cord and vertebral column during development, the spinal cord at birth ends at approximately L3. By 6–12 months of age, the level of termination parallels that of adults, most commonly at L1. Below the conus medullaris, the long dorsal and ventral roots of all the spinal nerves below L1 form a bundle known as the cauda equina, or horse's tail. A collection of strands of neuron-free fibrous tissue enveloped in pia mater comprises the filum terminale and extends from the inferior tip of the conus medullaris to the second or third sacral vertebra.

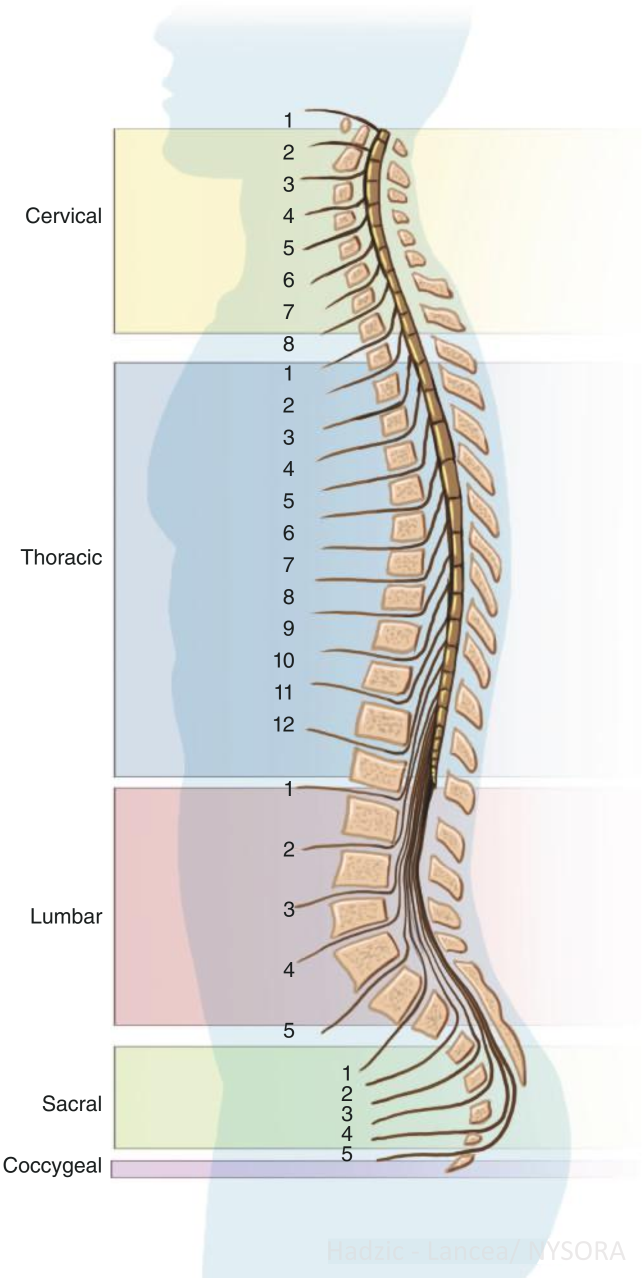

FIGURE 24–8. Vertebral column with spinal nerves.

Spinal Nerves

Spinal nerves are classified as mixed nerves because they contain both a sensory and a motor component and, in many cases, autonomic fibers. Each nerve forms from the fusion of dorsal (sensory) and ventral (somatic and visceral motor) nerve roots as they exit the vertebral canal distal to the dorsal root ganglia, which contain the cell bodies of sensory neurons on either side of the spinal cord and lie between the pedicles of adjacent vertebrae. In general, dorsal roots are larger and more easily blocked than ventral roots, a phenomenon that may be explained in part by the larger surface area for exposure to LAs provided by the bundled dorsal roots.

At the cervical level, the first pair of spinal nerves exits between the skull and C1. Subsequent cervical nerves continue to exit above the corresponding vertebra, assuming the name of the vertebra immediately following them. However, a transition occurs between the seventh cervical and first thoracic vertebrae, where an eighth pair of cervical nerves exits; thereafter, the spinal nerves exit below the corresponding vertebra and take the name of the vertebra immediately above. The spinal nerves divide into the anterior and posterior primary rami soon after they exit the intervertebral foramina. The anterior (ventral) rami supply the ventrolateral side of the trunk, structures of the body wall, and the limbs. The posterior (dorsal) primary rami innervate specific regions of the skin that resemble horizontal bands extending from the origin of each pair of spinal nerves, called dermatomes, and the muscles of the back. Clinically, knowledge of dermatomes is essential when planning anesthetics to specific cutaneous regions (Figure 24–9), although anesthesia may not be conferred reliably to the underlying viscera due to a separate innervation, and there is significant overlap in spinal nerve innervation of adjacent dermatomes (Table 24–18).

An intricate relationship exists between the spinal nerves and the autonomic nervous system (Figure 24–10). Preganglionic sympathetic nerve fibers originate in the spinal cord from T1 to L2 and are blocked to varying degrees during epidural anesthesia. They exit the spinal cord with spinal nerves and form the sympathetic chain, which extends the entire length of the spinal column on the anterolateral aspects of the vertebral bodies. The chain gives rise to the stellate ganglion, splanchnic nerves, and the celiac plexus, among other things. There are potential benefits and marked drawbacks to epidural blockade of the sympathetic nervous system. TEA appears to increase GI mobility by blocking the sympathetic supply to the inferior mesenteric ganglia, thereby reducing the incidence of postoperative ileus. Epidural anesthesia may also block the systemic stress response

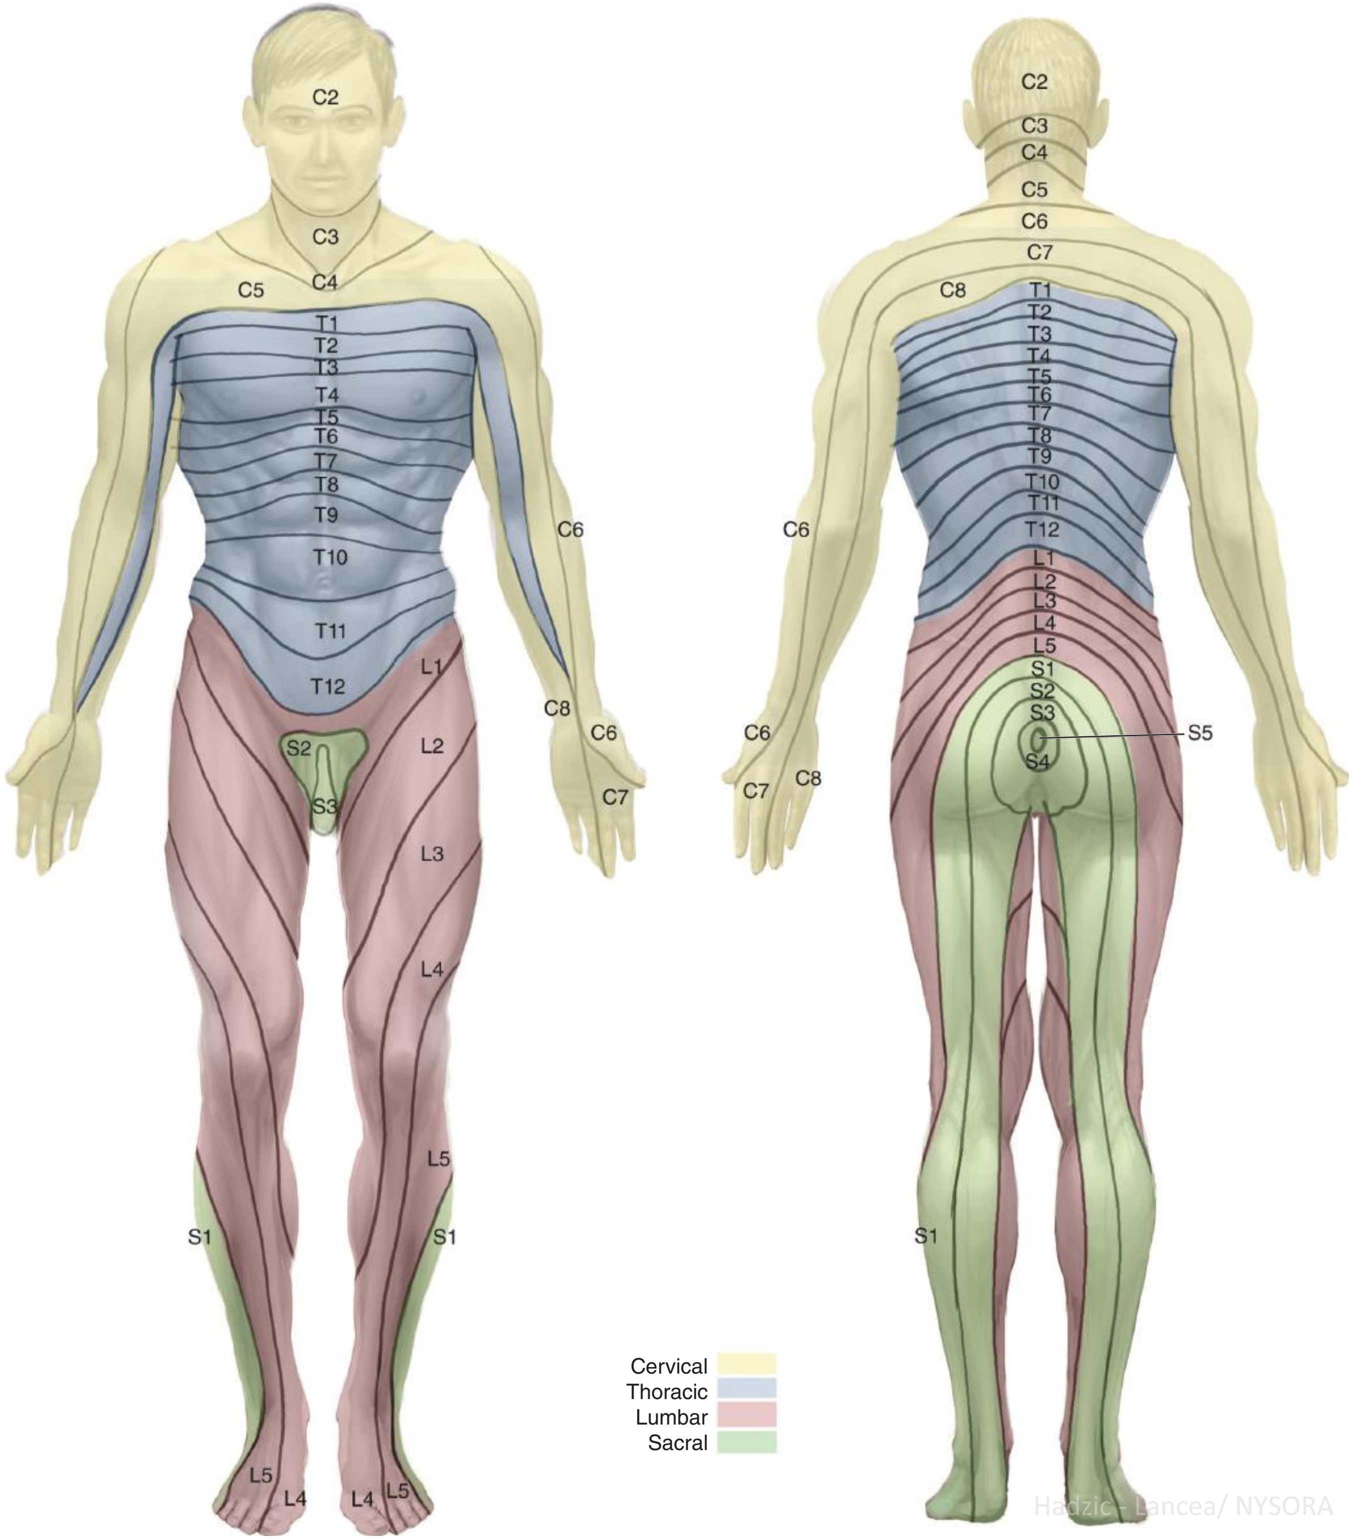

FIGURE 24–9. Distribution of dermatomes.

to surgery, in part by blockade of the sympathetic nervous system. However, mid- to low-thoracic sympathetic blockade may be associated with dilation of the splanchnic vascular beds, a marked increase in venous capacitance, a decrease in preload to the right heart, and many of the other undesirable effects (see Physiologic Effects of Epidural Blockade).

Cranial and sacral components comprise the parasympathetic nervous system. The vagus nerve, in particular, provides parasympathetic innervation to a broad area, including the head, neck, the thoracic organs and parts of the digestive tract. Parasympathetic innervation of the bladder, the descending large intestine, and the rectum originate at spinal cord levels S2 to S4.

Spinal Meninges

Spinal meninges cover the cord and nerve roots and are continuous with the cranial meninges that surround and protect the brain (Figure 24–11). The tough, predominantly collagenous outermost layer, the dura mater, encloses the CNS and provides localized points of attachment to the skull, sacrum, and vertebrae to anchor the spinal cord within the vertebral canal. Cranially, the spinal dura mater fuses with periosteum at the level of the foramen magnum; caudally, it fuses with elements of the filum terminale and contributes to formation of the coccygeal ligament; laterally, the dura mater surrounds nerve roots as they exit the intervertebral foramina. The dura mater touches the spinal canal in areas, but does not adhere to it except in pathologic conditions. It also confers both permeability and mechanical resistance to the dural sac, which terminates at S1 to S2 in adults and S3 to S4 in babies. The spinal nerve root cuffs, which have been postulated to play a role in the uptake of epidurally administered LAs, are lateral projections of both the dura mater and the underlying arachnoid lamina.[100]

The flexible arachnoid mater, the middle meningeal layer, is loosely attached to the inner aspect of the dura and encloses the spinal cord and surrounding CSF within the subarachnoid space. It is composed of layers of epithelial-like cells connected by tight and occluding junctions, which impart its low permeability. The cell layers of the arachnoid mater are oriented parallel to the long axis of the spinal cord (cephalocaudad), a finding that has led some investigators to claim that the architecture of the arachnoid mater, rather than the dura mater, accounts for the difference in headache rates between perpendicular and parallel insertions of beveled spinal needles.[101] By virtue of its flexibility, the arachnoid mater may "tent" and resist puncture by an advancing needle during initiation of spinal or CSE anesthesia. A discontinuous subarachnoid septum (septum posticum) that stretches from the posterior spinal cord to the arachnoid may contribute to irregular spread of LAs in the subarachnoid space.

The innermost meningeal layer, the pia mater, closely invests the underlying spinal cord and its blood vessels, as well as nerve roots and blood vessels in the subarachnoid space, and appears to have fenestrated areas that may influence the transfer of LAs during subarachnoid blocks.[102] Caudally, the pia mater continues from the inferior tip of the conus medullaris as the filum terminale and fuses into the sacrococcygeal ligament.

It is possible that a cavity can be created at the arachnoid-dura interface that may explain patchy or failed epidural blocks with higher-than-expected cephalad spread (so-called subdural blocks). Early research suggested that the subdural extra-arachnoid space comprised a true potential space, with serous fluid that permitted movement of the dura and arachnoid layers alongside each other. Blomberg used spinaloscopy in cadaver studies to demonstrate its existence in up to 66% of humans.[103] However, recent evidence suggests that, unlike a potential space, this arachnoid-dura interface is an area prone to mechanical stress that shears open only after direct trauma, such as air or fluid injection.[104] It is also possible that these clefts may actually occur between layers of arachnoid instead of between dural border cells at the arachnoid-dura interface. More information on spinal meninges and related structures are detailed in Chapter 6.

Clinical Pearl

- Clefts may form at the arachnoid-dura interface as a result of mechanical stress and direct trauma. Injection of a large volume of LA intended for the epidural space in this area may result in a subdural block.

Blood Supply

Vertebral and segmental arteries supply the spinal cord. A single anterior spinal artery and two posterior spinal arteries, and their offshoots, arise from the vertebral arteries and supply the anterior two-thirds of the spinal cord and the remainder of the cord, respectively (Figure 24–12). The anterior artery is thin at the midthoracic level of the spinal cord, an area that also has limited collateral blood supply. Segmental arteries, which emerge from branches of the cervical and iliac arteries, among others, spread along the entire length of the spinal cord and anastomose with the anterior and posterior arteries. The artery of Adamkiewicz is among the largest segmental arteries and is most commonly unilateral, arising from the left side of the aorta between T8 and L1. With regard to the venous system, anterior and posterior spinal veins, which anastomose with the internal vertebral plexus in the epidural space, drain into the azygos, the hemiazygos, and internal iliac veins, among other segmental veins, via intervertebral veins. The internal vertebral venous plexus consists of two anterior and two posterior longitudinal vessels with a variable distribution and is postulated to be involved in bloody or traumatic epidural needle and catheter placements.[105]

Epidural Space

The epidural space surrounds the dura mater circumferentially and extends from the foramen magnum to the sacrococcygeal ligament. The space is bound posteriorly by the ligamentum flavum, laterally by the pedicles and the intervertebral foramina, and anteriorly by the posterior longitudinal ligament. Of the

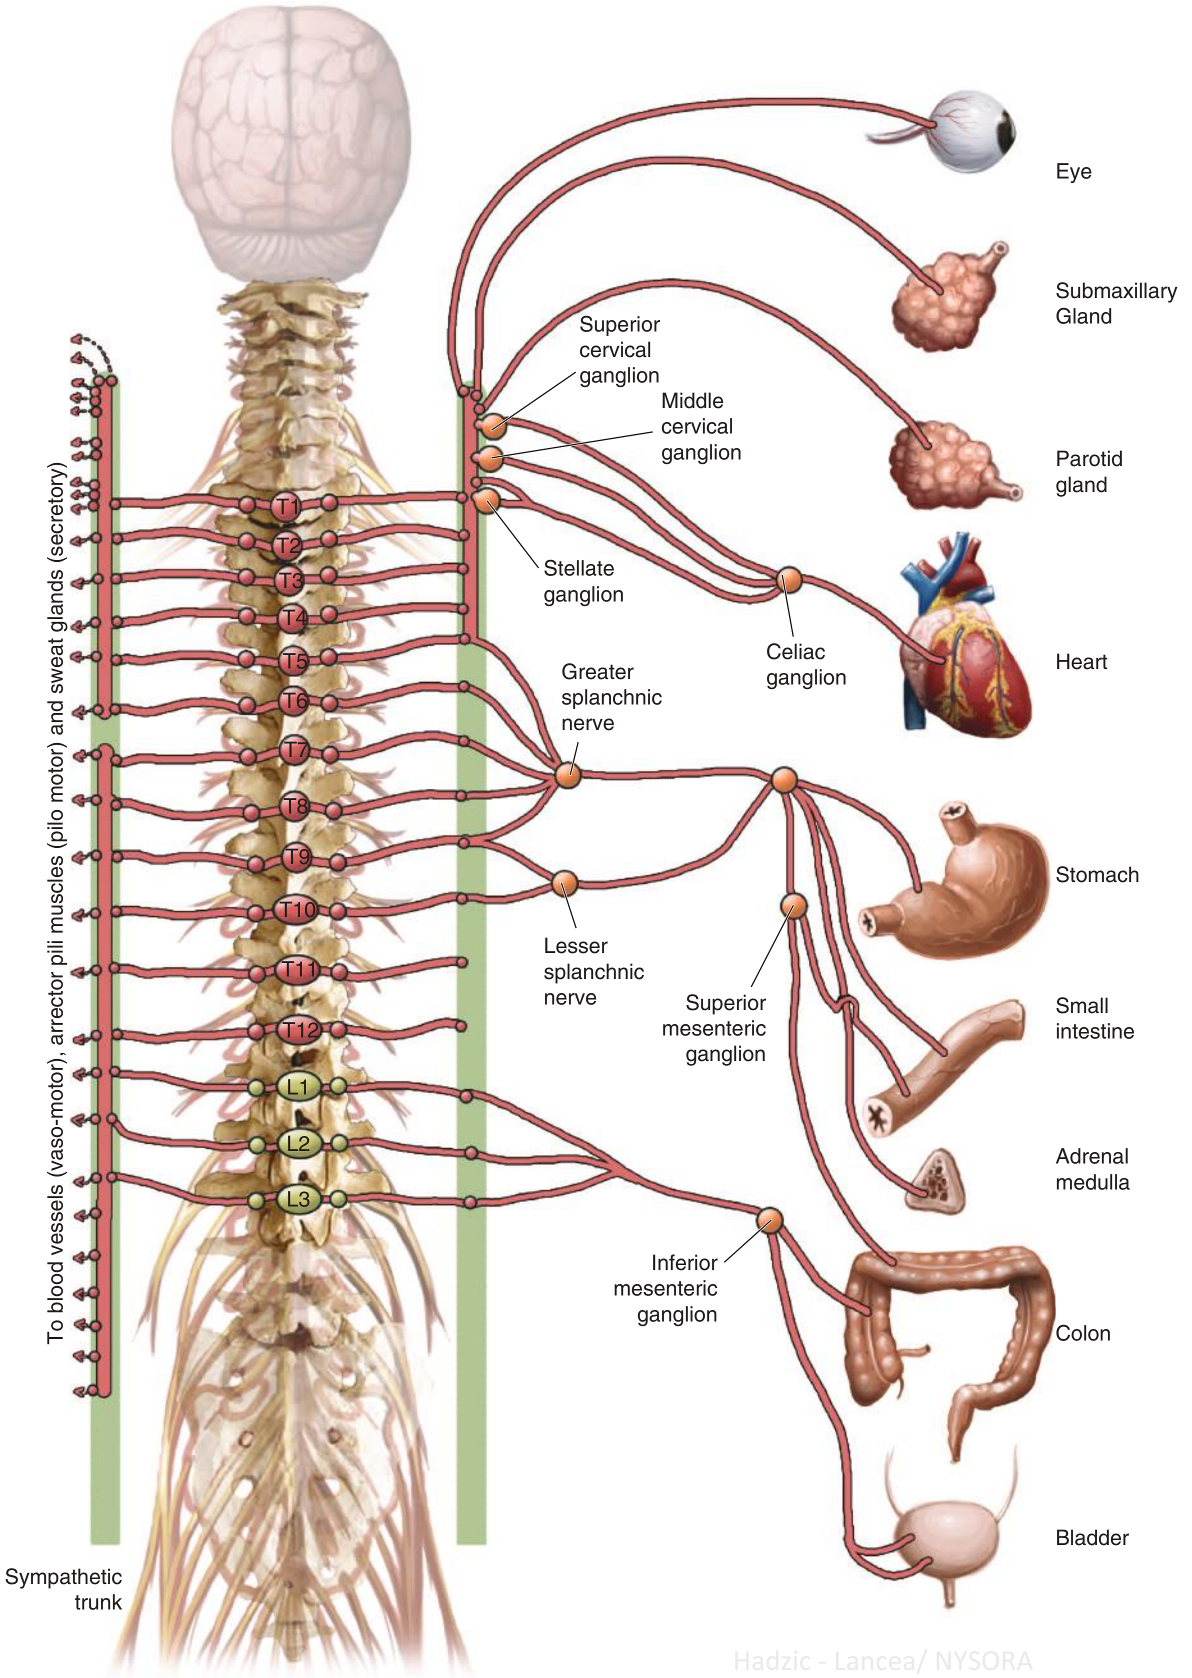

FIGURE 24–10. Sympathetic nervous system.

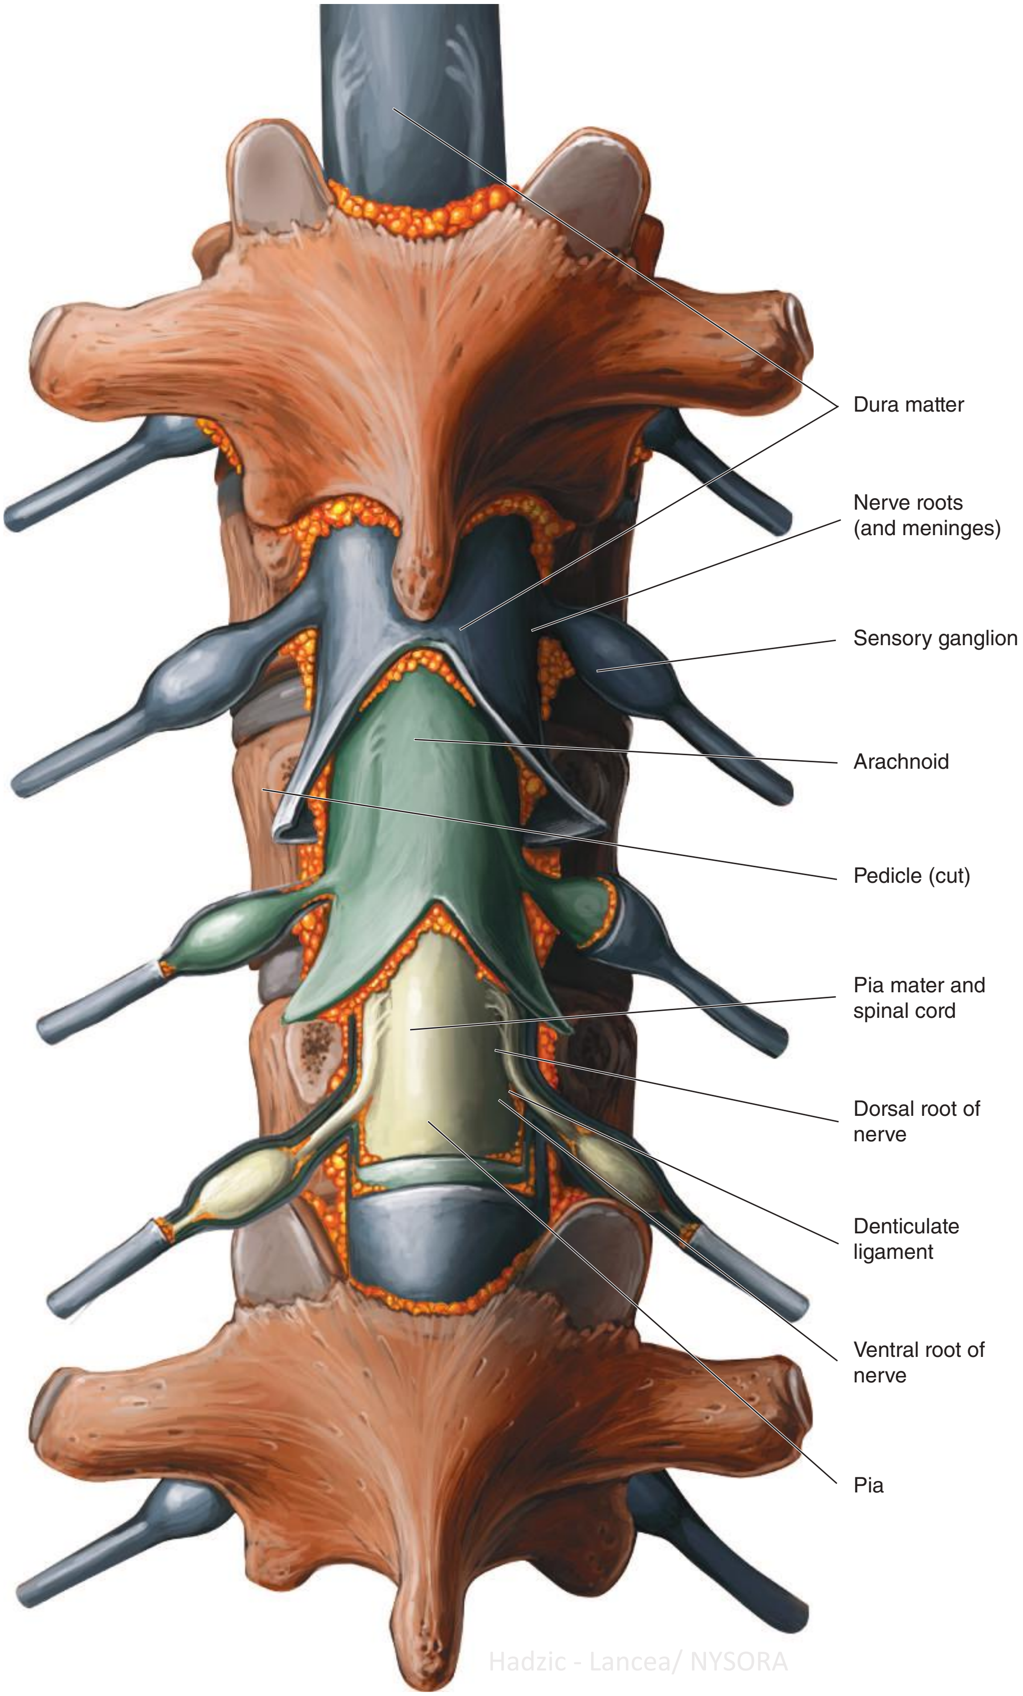

FIGURE 24–11. Spinal meninges.

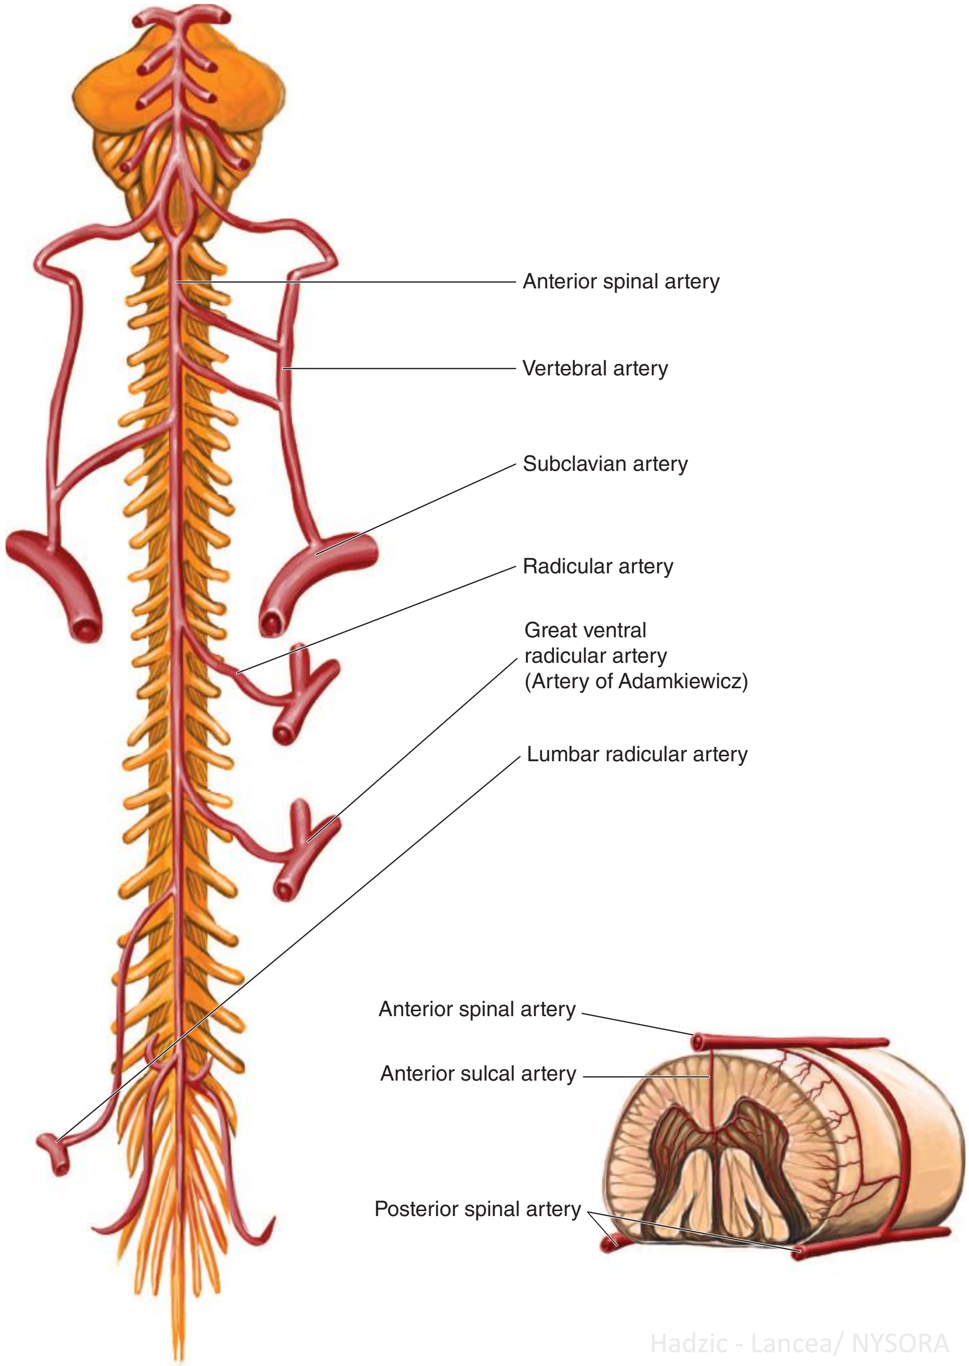

FIGURE 24–12. Blood supply of the spinal cord.

three epidural space compartments (posterior, lateral, and anterior), the posterior epidural space is most relevant clinically. The epidural space in general contains adipose tissue, blood vessels, nerve roots, and loose connective tissue in a nonuniform distribution. The veins in the space are continuous with the iliac vessels in the pelvis and the azygos system in the abdominal and thoracic body walls. Because the plexus is valveless, blood from any of the connected systems can flow into the epidural vessels. In contrast to traditional dogma, these vessels are located primarily in the anterior epidural space, where they are largely confined by the membranous extension of the posterior longitudinal ligament[106] (Figure 24–13). This area is probably a common site of epidural catheter blood vessel puncture. Also of clinical significance, the subatmospheric pressure of the epidural space diminishes significantly in the lumbar region, potentially affecting both the hanging-drop and the epidural pressure waveform techniques of identification of the epidural space.

The contents of the epidural space and their clinical implications have been debated extensively in the literature. The amount of adipose tissue in the epidural space appears to affect the spread of LA, but it remains unclear whether epidural fat prolongs block duration by serving as a reservoir or decreases the amount of available drug, thereby slowing onset, or both.[107] The reduction of adipose tissue with age is speculated to

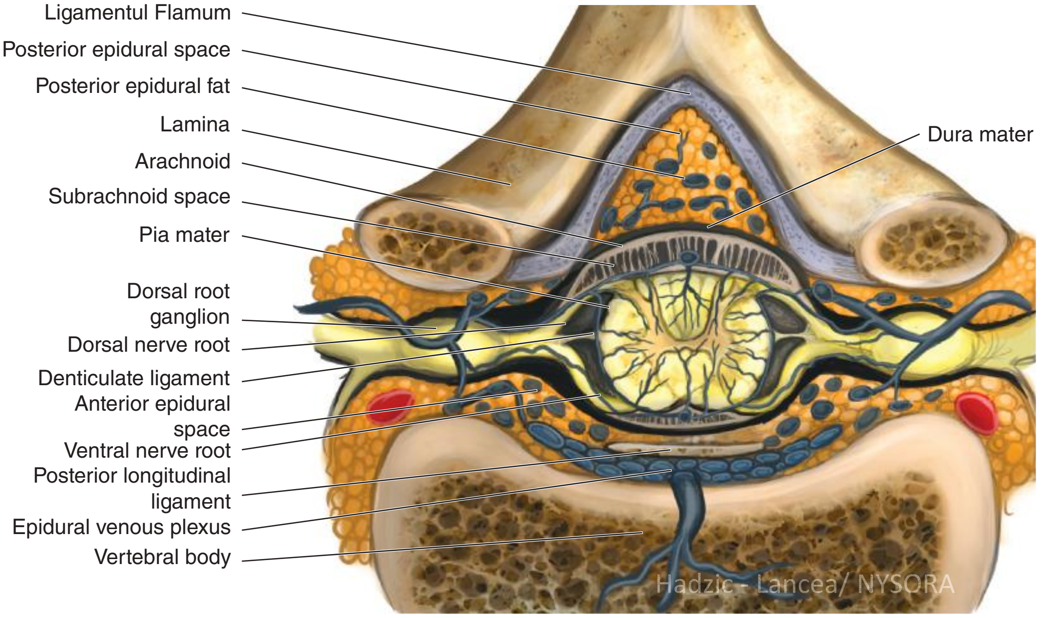

FIGURE 24–13. Epidural vein distribution in the lumbar region.

account in part for the higher levels and faster onset of epidural anesthesia in the elderly.[108] Similarly, the increase in adipose tissue in the lower lumbar area where the dural sac tapers may contribute to the variable effects of LA injections below L4–L5. Finally, adipose tissue in the midline gap, where the ligamentum flava fuse, may alter the tactile sensation that is normally appreciated during the LOR technique.

Another anatomic controversy of the epidural space concerns whether septae, alternately described as sparse strands and as a continuous membrane that attaches the dura to the ligamentum flavum,[109] obstruct catheter advancement, affect the spread and onset of LAs, and contribute to unilateral blocks and unintentional dural punctures. However, these septae have more recently been identified as an artifact of the midline posterior epidural fat pad.[110] These fatty midline attachments do not appear to have a clinically significant effect on the spread of LAs.[106] Rather, Hogan has postulated that the distribution of solution is nonuniform and directed among paths between structures in the epidural space according to differential pressures.[111]

Distance From Skin to Epidural Space

The distance from the skin to the epidural space varies at different levels of the vertebral column. In the cervical region, Han and colleagues found that the average skin-to-epidural space depth (via the midline approach) was shallowest at C5 and C6 and increased in the caudal direction.[92] Fujinaka et al noted that it is difficult to predict the actual depth of the cervical epidural space based on clinical characteristics.[112] In contrast, Aldrete and coworkers, using magnetic resonance imaging (MRI) to measure the depth from the skin to the inner ligamentum flavum, noted the greatest depth at the C6-to-T1 levels, with a mean of 5.7 cm, possibly due to the presence of fatty tissue (the so-called hump pad) in the area.[113] The depth to space in the midthoracic region from midline is influenced primarily by the sharp caudal angle of the spinous processes. As a result of the steep angle and bony impediments in this region, the paramedian approach is often preferred for midthoracic epidural placement.

Several studies have sought to measure the depth to the epidural space at the lumbar level. Studies of parturients show a range of depth from skin to space of 2 to 9 cm, with 89% in the range of 3.5–7.5 cm.[114] In their search for a multivariate model to predict the distance in an obstetric population, Segal and colleagues confirmed previously reported associations between increased weight and increased depth, as well as between oriental race and shallower spaces, with no independent association between race and depth after controlling for weight.[114] In an earlier study, Sutton and Linter recorded that the skin to extradural space in 3011 parturients was 4 to 6 cm in 76% of the study participants.[115] Patients with a shallow depth of 2 to 4 cm, comprising 16% of the study population, were found to be at a threefold higher risk of unintentional dural puncture. Of note, the shallow depth falls within the range of length of the LA infiltration needle. Overall, estimates of the depth to epidural space cannot be applied to the population at large, as independent variables, such as degree of flexion, patient positioning, dimpling and edema at the skin and subcutaneous tissue, and the angle of needle insertion, among other things, are difficult to quantitate and control. In the near future, routine ultrasound determination of depth to space on an individual basis prior to or during epidural needle placement might provide the most reliable means of diminishing the risk of inadvertent dural puncture and other complications of epidural anesthesia. Fluoroscopy is most appropriate in the cervical region, where spinal cord injury, total spinal anesthesia, and intra-arterial injection are among the possible complications.

The variable depth of the posterior epidural space is another clinically relevant measure that may influence the incidence of inadvertent dural puncture. The posterior epidural space viewed in the midline sagittal plane has been described as saw-toothed, characterizing its segmented shape.[116] While studies are conflicting, at each segmental level, the depth of the posterior epidural space appears shallower at the caudal end. These variations notwithstanding, the distance between the ligamentum flavum and the dura is typically estimated as 7 mm, with a broad range from 2 mm to 2.5 cm.[106] This anterior-posterior distance is largest in the lumbar region, at L3–L4, decreases in the thoracic region, and is absent in the cervical region.[117]

PHYSIOLOGIC EFFECTS OF EPIDURAL BLOCKADE

Epidural blockade provides surgical anesthesia, intraoperative muscle relaxation, and intrapartum and postoperative pain relief with widespread direct and indirect effects on several physiologic systems. The extent of these physiologic effects depends on the level of placement and the number of spinal segments blocked. In general, high thoracic epidural blocks (ie, above T5) and extensive epidural blocks are associated with more profound physiologic changes than blocks with low sensory levels (ie, below T10). This section reviews the physiologic alterations related to epidural anesthesia and analgesia.

Differential Blockade

Differential blockade occurs when sensory, motor, and sympathetic nerve functions are obtunded at different rates and to different degrees. It may be observed at both onset and regression of the block. In general, sympathetic blockade, which is not uncommonly incomplete, extends two to six dermatomes higher than sensory blockade, which in turn is higher than the motor blockade. Sensory blockade also occurs with a lower concentration or total dose of LA and develops faster than motor blockade. Among sensory functions, temperature is blocked first, followed by pinprick and, finally, touch.

Although the mechanism of differential blockade has not been fully elucidated, it may be attributed to anatomic features of blocked nerves (eg, diameter and presence or absence of myelin), the length of blocked nervous tissue (a minimal length of blocked nerve is required for effective neuronal blockade), differences in nerve lipid membrane and ion channel composition, concurrent axonal activity during block onset, and LA type and concentration. These and several other mechanisms may collectively contribute to differential blockade.

Central Nervous System Effects

Cerebral blood flow (CBF) is autoregulated and is not affected by epidural blockade unless the patient experiences pronounced hypotension. However, neuraxial anesthesia does appear to have a sedative effect and to reduce anesthetic requirements for several agents, including midazolam, propofol, thiopental, fentanyl, and volatile agents. The degree of sedation and minimum alveolar concentration (MAC) sparing effect appear to correlate with the height and level of the sensory block; blockade of the middle thoracic dermatomes is associated with greater sedative effects than blockade of the lower lumbar segments.[118] Although data are conflicting, higher-concentration LAs may contribute to a greater MAC-sparing effect.[119] The addition of opioid adjuvants, such as morphine, to the epidural LA solution does not appear to reduce volatile agent requirements any further, although it does contribute to better postoperative pain scores.[120] Overall, decreased anesthetic requirements have most commonly been attributed to decreased afferent input induced by the neuraxial block rather than to systemic effects of LAs, altered pharmacokinetics, or direct action of LAs on the brain.[121]

Several studies have demonstrated reduced hypnotic and anesthetic requirements after central neuraxial blockade. In an early study of 53 American Society of Anesthesiologists (ASA) physical status I and II adult males, Tverskoy and colleagues determined that subarachnoid bupivacaine blockade decreased hypnotic requirements for both midazolam and thiopental.[122] A study that followed, also in ASA physical status I and II patients, determined that epidural bupivacaine profoundly decreased midazolam hypnotic requirements.[123] Similarly, in a small prospective, randomized, double-blind, placebo-controlled trial, Hodgson and colleagues found that lidocaine epidural anesthesia reduced the MAC of sevoflurane by up to 50%.[124] More recently, epidural bupivacaine administered via the caudal route has been shown to have a sparing effect on both intravenous fentanyl and sevoflurane requirements during orthopedic surgery in children.[125]

Cardiovascular and Hemodynamic Effects

Cardiovascular changes associated with epidural anesthesia and analgesia result primarily from blockade of sympathetic nerve fiber conduction. These changes include venous and arterial vasodilation, reduced SVR, changes in chronotropy and inotropy, and associated alterations in blood pressure and CO. The type and intensity of these changes are related to the level of block, the total number of dermatomes blocked, and, relatedly, the type and dose of LA administered. In general, lumbar epidural or low thoracic blocks are not associated with significant hemodynamic changes, while higher thoracic blocks (particularly those involving the T1–T4 sympathetic fibers) can cause more marked changes, not all of which are detrimental. However, factors such as pregnancy, age, comorbidities, patient positioning, and hypovolemia can complicate the clinical scenario and the anticipated cardiovascular effects.

Hypotension

Hypotension associated with neuraxial blockade results primarily from vasodilation and increased vascular bed capacitance.[126] Both direct inhibition of the sympathetic outflow to the nerves innervating the blood vessels and a decrease in endogenous catecholamine release from the adrenal glands contribute to arterial and venous vasodilation. In general, arteriolar smooth muscle maintains autonomous tone, even in the setting of complete sympathectomy, while veins and venules dilate maximally. However, a degree of arteriolar vasodilation does occur. The venodilatory effect also predominates because of the large amount of blood in the venous system compared to the arterial system.

The degree of hypotension associated with epidural blockade correlates with the sensory level. For example, a more marked increase in venous capacitance occurs with blockade of the sympathetic outflow to the splanchnic veins (T6 to L1) due to dilation of the extensive splanchnic bed. With low epidural blocks, vasoconstriction of unblocked areas and release of catecholamines from the adrenal medullary system partially compensate for venous and arteriolar pooling and reductions in mean arterial pressure.[127] Overall, healthy, normovolemic patients experience a nominal decrease in peripheral resistance and blood pressure during initiation and maintenance of epidural blockade.

Risk factors for appreciable hypotension during neuraxial anesthesia include sensory level above T5, low baseline pressure, increasing age, and combined general-neuraxial anesthesia. Severely hypovolemic patients and cardiac-compromised patients are also more likely to experience significant hypotension requiring vasopressor and inotropic support. Hypotension occurs more commonly with spinals than with epidurals, despite equivalent degrees of sympathetic blockade.

Heart Rate and Cardiac Function

In general, changes in heart rate and ventricular function vary with level of blockade, with more pronounced changes as the level increases. When the cardiac sympathetic fibers from T1 to T4 are blocked, decreased cardiac contractility and bradycardia ensue, resulting in decreased CO. Bradycardia also results from the decreased atrial stretch receptor activity attributed to decreased right atrial pressure. Venous pooling also contributes to the reduction in CO, particularly with higher blocks. Missant et al studied the effects of epidural anesthesia on left and right ventricular function in a pig model and found that lumbar epidural anesthesia reduced SVR without affecting left or right ventricular function.[128] However, TEA reduced left ventricular contractility and minimally reduced SVR, while preserving right ventricular function.

Neuraxial blockade appears to have certain beneficial effects on the cardiovascular system, such as improved myocardial blood flow and myocardial oxygen balance. Tissue oxygenation has been observed to improve with high TEA under certain circumstances, particularly with intravenous fluid administration.[129,130] TEA also appears to have antianginal effects,[131,132] improve coronary perfusion,[20] and improve recovery from reversible myocardial ischemia.[133,134] Whether this results in improved perioperative cardiac outcome following major cardiac or thoracic surgery, however, is the subject of ongoing debate.[135] Several authors have hypothesized that TEA may also protect against postoperative arrhythmias and atrial fibrillation after major cardiac and thoracic surgeries. However, data are conflicting. Svircevic et al performed a meta-analysis comparing GA and TEA for cardiac surgery and noted fewer postoperative supraventricular arrhythmias.[136] However, Gu et al, in another recent meta-analysis, could not support such an effect.[137]

Pulmonary Effects

The motor and sympathetic changes associated with epidural anesthesia may affect lung function, depending on the level of blockade. In general, tidal volume remains unchanged even during high neuraxial blocks, while vital capacity may be reduced due to the decrease in expiratory reserve volume that occurs as accessory muscles involved in expiration are blocked. The ability to cough and clear respiratory secretions may also be impaired, particularly in patients with severely compromised respiratory function at baseline. However, inspiratory muscle function is unaffected and should remain sufficient to provide adequate ventilatory function.

Higher sensory levels may result in more marked changes in lung function. In a sentinel study, Freund et al inserted a lumbar epidural catheter and administered a mean volume of 20 mL of 2% lidocaine.[138] An extensive block to T4 was achieved, but the decrease in vital capacity was minimal. However, catheter insertion at higher levels, with concomitant higher spread of LA, results in more pronounced pulmonary derangement.[139] In contrast, when TEA is used postoperatively, a net positive effect on lung function can be observed, most likely because the enhanced pain relief prevents splinting. In a recent review article, Lirk and Hollmann determined the role of TEA and confirmed the benefits in major abdominal and thoracic surgery.[140]

The rare occurrence of respiratory arrest after high epidural or spinal blockade can be attributed to hypoperfusion of the respiratory center in the brainstem rather than to direct LA effects on either the phrenic nerve or the CNS.

Gastrointestinal Effects

The sympathetic outflow to the GI tract arises from T5 to T12, while parasympathetic innervation is supplied by the vagus nerve. Sympathectomy associated with epidural blockade in the mid- to low-thoracic levels results in unopposed vagal tone, which manifests clinically with increased peristalsis, relaxed sphincters, an increase in GI secretions, and, likely, more rapid restoration of GI motility in the postoperative phase. Nausea and vomiting commonly accompany hyperperistalsis and can be treated effectively with intravenous atropine. Theoretically, increased intestinal motility could contribute to breakdown of surgical anastomoses, but this has not been demonstrated in the literature. Rather, TEA may decrease the risk of anastomotic leakage and improve perioperative intestinal perfusion, although the data are somewhat conflicting. Numerous experimental and clinical studies have demonstrated that TEA protects against splanchnic hypoperfusion and reduces postoperative ileus.[141] However, similar benefits are not seen with lumbar epidural anesthesia.[141]

Renal/Genitourinary Effects

Because renal blood flow (RBF) is maintained through autoregulation, epidural anesthesia has little effect on renal function in healthy individuals. Compensatory and feedback mechanisms (afferent arteriolar dilation and efferent arteriolar vasoconstriction) ensure constant RBF over a broad range of pressures (50–150 mm Hg). During transient periods of hypotension below 50 mm Hg, oxygen delivery to the kidneys is adequately maintained.

Neuraxial blockade at the lumbar level has been postulated to impair control of bladder function secondary to blockade of the S2–S4 nerve roots, which carry the sympathetic and parasympathetic nerves that innervate the bladder. Urinary retention may occur until the block wears off. The clinician should avoid administering an excessive volume of intravenous fluids if a urinary catheter is not in place.

Neuroendocrine Effects

Surgical stress produces a variety of changes in the host's humoral and immune response. Increased protein catabolism and oxygen consumption are common. Increased plasma concentrations of catecholamines, vasopressin, growth hormone, renin, angiotensin, cortisol, glucose, antidiuretic hormone, and thyroid-stimulating hormone have been documented after sympathetic stimulation associated with both minimally invasive and major open surgery. Perioperative manifestations of the surgical stress response may include HTN, tachycardia, hyperglycemia, suppressed immune function, and altered renal function. Increased catecholamine levels can also cause increased left ventricular afterload and, in combination with other pathologic responses to stress (eg, proinflammatory responses that may lead to plaque instability via activation of matrix metalloproteinase; raised corticotropin-releasing hormone levels that reduce cardiac nitric oxide release, increase endothelin production, and aggravate coronary endothelial dysfunction), trigger acute coronary syndromes and myocardial infarctions in patients with coexisting cardiac disease. Afferent sensory information from the surgical site is thought to play a pivotal role in this response.

The surgical stress response can be influenced by sympathetic blockade during epidural anesthesia and analgesia. The mechanisms involved are unresolved but most likely include both direct blockade of afferent and efferent signals during surgical stress and direct effects of LA agents. Brodner et al demonstrated that TEA combined with GA resulted in a reduced surgical stress response when compared to GA alone.[142]

The most critical effect of neuroendocrine activation in the perioperative period is the increase in plasma norepinephrine, which peaks roughly 18 hours after the surgical stimulus is initiated. The increase in plasma norepinephrine is associated with activation of nitric oxide in the endothelium of patients with atherosclerotic disease, producing paradoxical vasospasm. Thus, in patients with significant atherosclerotic disease, the combination of vasospasm and a hypercoagulable state may be the factors modulated by the cardioprotective effects of TEA. Indeed, studies indicated that coronary artery blood flow is improved with TEA.[20]

Thermoregulation

Hypothermia has significant side effects, such as increased cardiac morbidity, impaired coagulation, increased blood loss, and increased risk for infection. The rate and severity of hypothermia associated with epidural anesthesia is similar to that observed during cases under GA.[143] Hypothermia associated with neuraxial anesthesia is primarily due to peripheral vasodilation resulting in heat redistribution from the core to the periphery.[144] In addition, reduced heat production (due to reduced metabolic activity) results in a negative heat balance due to unchanged heat loss. Finally, thermoregulatory control is impaired. Of note, rewarming with forced air warming devices occurs more rapidly with neuraxial anesthesia as compared to GA due to peripheral vasodilation.[145]

Coagulation System

The postoperative period is a marked hypercoagulable state. Neuraxial blockade is associated with a decreased risk of DVT and pulmonary embolism, as well as a decreased risk of arterial and venous thrombosis.

PHARMACOLOGY OF EPIDURAL BLOCKADE

An understanding of the physiology of nerve conduction and the pharmacology of LAs is essential for successful epidural blockade. Potency and duration of LAs, preferential blockade of sensory and motor fibers, and the anticipated duration of surgery or need for postoperative analgesia are factors that should be considered before initiating epidural blockade. This section covers several practical aspects of attaining effective epidural anesthesia and analgesia.

Epidural solutions may contain an LA with or without an adjuvant drug. Dose, volume, and concentration, as well as site of injection, of the LA solution vary, resulting in different pharmacodynamic effects. A, B, and C nerve fibers vary in size and in the presence of a myelin sheath. A-delta and C fibers are responsible for temperature and pain transmission. B fibers are autonomic fibers. The larger A fibers (especially A-alpha fibers) are motor fibers. C fibers are unmyelinated and smallest in size. Because they lack a protective myelin sheath and diffusion barrier, they are blocked rapidly. A and B fibers are myelinated and larger in size than C fibers. B fibers are responsible for autonomic nervous system transmission. They are smaller in size than A-delta fibers, but larger than C fibers. It is widely accepted that autonomic fibers are more susceptible to LA block than sensory fibers. Epidurally administered LA preferentially blocks sympathetic neural function; this explains the more extensive sympathetic dermatomal blockade when compared with sensory and motor blocks.[146–149] However, Ginosar et al recently suggested that sensory function was more susceptible to blockade than sympathetic function.[150] Several other studies concurred.[151,152] The dose and concentration of LA used may account for the different findings in these studies. Because of their thick myelin sheath, motor fibers require much more LA and much more time before an adequate block is achieved.

Local anesthetics produce reversible nerve blockade by blocking sodium passage through the nerve membrane. When LA is injected into the epidural space, several things occur. Most of the injected LA is absorbed into the venous blood, and a large part is retained in epidural fatty tissue. The primary sites of action of an epidurally administered LA are the ventral and dorsal nerve roots that pass through the epidural space. However, based on studies using labeled LAs, LAs can cross the dura and penetrate the spinal cord, but to a lesser extent than their penetration into the spinal nerve roots.[153] The segmental nerve roots are mixed sensory, motor, and sympathetic nerve fibers. Hence, all three types of fibers will be affected (to varying degrees).

Choice of Local Anesthetics

Drugs used for epidural blockade can be categorized into short-, intermediate-, and long-acting LAs. Onset of epidural blockade in the dermatomes immediately surrounding the site of injection can usually be detected within 5 or 10 minutes, if not sooner. The time to peak effect varies with the type of LA and the dose/volume administered (Table 24–19).

PART 3

TABLE 24–19. Commonly used local anesthetics for epidural anesthesia and analgesia.

Drug	Concentration (%)	Onset Time (min)	Duration (min)
2-Chloroprocaine	3	5–15	30–90
Lidocaine	2	10–20	60–120
Bupivacaine	0.0625–0.5	15–20	160–220
Ropivacaine	0.1–0.75	15–20	140–220
Levobupivacaine	0.0625–0.5	15–20	150–225

Duration of blockade can be prolonged by addition of epinephrine, typically 1:200:000 to 1:400:000.

The shortest-acting LA for neuraxial blockade is chloroprocaine, an ester. In the past, chloroprocaine was associated with adhesive arachnoiditis when large volumes were accidentally administered into the subarachnoid space.[154] In addition, severe back pain was not uncommonly reported when large volumes were administered in the epidural space, most likely due to the ethylenediaminetetraacetic acid (EDTA) and bisulfite preservatives in the solution. Since 1996, preservative-free chloroprocaine has been available and has not been associated with either neurotoxic effects or back pain. In ambulatory settings and for emergency cesarean deliveries with in situ epidurals, chloroprocaine can provide excellent surgical anesthesia quickly, without delaying recovery room discharge.

Delivered via the epidural route, 2% lidocaine is an intermediate-acting LA commonly used for surgical anesthesia. When epinephrine is added to the solution (1:200,000), it prolongs the duration of action by up to 60%.

Long-acting LAs used for epidural blockade are bupivacaine, levobupivacaine (no longer available in the United States), and ropivacaine. Dilute concentrations (eg, 0.1% to 0.25%) can be used for analgesia, while higher concentrations (eg, 0.5%) may be more appropriate for surgical anesthesia. The addition of epinephrine to these solutions can prolong the duration of action, although this effect is less reliable with long- versus intermediate-acting agents. Severe cardiotoxic reactions (hypotension, atrioventricular block, ventricular fibrillation, and torsades de pointes) refractory to usual resuscitation methods can result from accidental intravascular injection of bupivacaine. The rationale for the resistance to resuscitative measures lies in its high degree of protein binding and more pronounced effect on cardiac sodium channel blockade.[155,156] Levobupivacaine, the *S*-enantiomer of bupivacaine, has a similar profile to bupivacaine but with less-pronounced cardiotoxic effects. Ropivacaine, a mepivacaine analogue, has a similar profile of action to bupivacaine. In most studies, ropivacaine has demonstrated a slightly shorter duration of action than bupivacaine, potentially with a less-dense motor block at equipotent doses. A deterrent to the broader use of ropivacaine in clinical practice is its higher cost.[157,158]

Onset and Duration of Local Anesthetics

Alkalinization of the LAs, which are marketed in a water-soluble, ionized state, hastens onset. By increasing the concentration of the nonionized form, more lipid-soluble LA is available to penetrate the neural sheath and nerve membrane. Adding sodium bicarbonate immediately before injection of lidocaine, mepivacaine, or chloroprocaine produces a clinically significant faster onset of anesthesia and may also contribute to a denser block.[159] However, ropivacaine and bupivacaine will precipitate with the addition of bicarbonate unless a very low concentration is used. Combining short- and long-acting drugs for rapid onset and a prolonged sensory block has not been proven to be effective. For example, mixing 2-chloroprocaine with bupivacaine for the rapid onset of the former and long duration of the latter results in shortening the duration and effectiveness of the bupivacaine.[160] Continuous drug administration and the use of additives obviate the need for mixing LAs.

Clinical Pearl

- Combining short- and intermediate- or long-acting LAs for rapid onset with prolonged duration of action has not been proven to be effective. Continuous drug administration and the use of additives obviate the need for mixing LAs.

Adding epinephrine to certain LAs can increase the duration of action, most likely by decreasing vascular absorption. The effect is greatest with 2-chloroprocaine, lidocaine, and mepivacaine and is less effective with the longer-acting agents. Other vasoconstrictors, such as phenylephrine, have not been proven to be as effective in reducing the peak blood levels of LAs as epinephrine.[161]

Adjuvants to Local Anesthetics in the Epidural Space

A variety of other classes of drugs have been studied more recently to try to improve the quality of neuraxial blockade. In addition to several opioids (eg, fentanyl, sufentanil, and preparations of morphine); α-adrenergic agonists; cholinesterase inhibitors; semisynthetic opioid agonist-antagonists; ketamine; and midazolam have been studied, with mixed results.

The administration of clonidine in the epidural space has been studied extensively. An α_2-adrenergic agonist, clonidine appears to prolong the duration of action of LAs, although the mechanism remains unclear. Animal studies have shown that clonidine reduces regional spinal cord blood flow, therefore slowing the rate of drug elimination.[162] Kroin and colleagues demonstrated that the mechanism by which clonidine prolongs the duration of a block when mixed with LAs is not mediated by α-adrenoreceptors; rather, it is more likely related to the hyperpolarization-activated cation current I_h.[163]

Some of the potential benefits of the administration of clonidine in the epidural space may include the following:

1. Prolongation and enhancement of the effects of epidural LAs without an additional risk of hypotension
2. Reduction in LA dose requirements for labor epidural analgesia[164,165]
3. Effective analgesia without motor impairment[162]
4. Synergistic effect with opioids and opioid agonist-antagonists
5. Modulation of the stress response to thoracic surgery[166]
6. Preservation of lung function after thoracotomy[167]
7. Possible reduction in cytokine response, further reducing pain sensitivity[168]

Side effects that are commonly associated with epidural clonidine include dose-independent hypotension, bradycardia, sedation, and dry mouth. Combining clonidine with other agents, such as opioids, anticholinergics, opioid agonist-antagonists, and ketamine, may enhance the beneficial effects of these drugs while minimizing adverse side effects.[169,170]

Neostigmine, a cholinesterase inhibitor, is a more recent addition to the list of epidural additives for selective analgesia. The mechanism of action for its analgesic effect appears to be the inhibition of the breakdown of acetylcholine and the indirect stimulation of muscarinic and nicotinic receptors in the spinal cord. Although experience with epidural neostigmine is limited, it has been reported to provide postoperative pain relief without inducing respiratory depression, motor impairment, or hypotension.[169] When combined with other opioids, clonidine, and LAs, it may provide benefits similar to clonidine without the side-effect profile of any of these drugs given alone.[171–173] Observations in patients with cancer pain showed promise that its use might be associated with less nausea and vomiting than the intrathecal application.[174] In an investigation randomizing 48 patients to receive 0, 1, 2, or 4 μg/kg of epidural neostigmine in addition to a bupivacaine spinal anesthetic for minor knee surgery, no case of intraoperative nausea or vomiting was observed, and postoperative nausea scores did not differ between groups.[175] These results need to be corroborated by further studies before epidural neostigmine can be recommended for daily practice.

Other agents, such as ketamine, tramadol, droperidol, and midazolam, have been considered for epidural administration, with mixed results. Considerable controversy surrounds the use of midazolam intrathecally. Despite multiple publications recommending its use,[176–178] recent studies have demonstrated that even a single dose of intrathecal midazolam may have neurotoxic effects.[179] Until its safety profile can be ensured in human subjects, it is not recommended for neuraxial use at this time.[180]

One agent that shows promise is the extended-release formulation of one of the oldest opioids, morphine. DepoDur®, the brand name for extended-release epidural morphine, uses a drug-release delivery system called DepoFoam®. DepoFoam is composed of microscopic lipid-based particles with internal vesicles that contain the active drug and slowly release it. Recent studies have demonstrated effective pain relief with relatively minor side effects for up to 48 hours when appropriately dosed.[181–183] However, concerns about delayed respiratory depression have limited its clinical use in this early stage of its clinical use.

Other Factors Affecting Epidural Blockade

Injection Site

The epidural blockade is most effective when the block or the catheter is inserted in a location that corresponds to the dermatomes covered by the surgical incision. The most rapid onset and the densest block occur at the site of injection. By inserting the catheter closer to the dermatomal distribution of the surgical site, a lower dose of drug can be given, thereby reducing side effects.[184,185] This concept is especially important when thoracic epidural analgesia is used for postoperative analgesia.

After lumbar epidural injection, the analgesic and anesthetic effects spread to a greater degree cranially then caudally. Of note, there is a delay in onset of anesthesia at the L5–S1 segments secondary to the larger size of these nerve roots.[186] With thoracic injection, the LA spreads evenly from the site of injection, but meets resistance to blockade in the lumbar region because of the larger nerve roots. By controlling the dose in the thoracic region, a true segmental blockade affecting only the thoracic region can be established. Lumbar and sacral regions will be spared, thereby avoiding more extensive sympathetic blockade and subsequent associated hypotension and bladder dysfunction, as well as lower limb motor blockade.

Dose, Volume, and Concentration

The dose of LAs necessary for epidural anesthesia or analgesia is a function of the concentration of the solution and the volume injected. Concentration of the drug affects the density of the block; the higher the concentration, the more profound the motor and sensory block. Lower concentrations can selectively produce a sensory block.[187]

Volume and total LA dose are the variables that affect the degree of spread of the block. A larger volume of the same concentration of LA will block a greater number of segments. However, if the total dose of LA is unchanged but the concentration is doubled, the volume can be halved to achieve similar spread of LA.[188] A generally accepted guideline for dosing epidural anesthesia in adults is 1–2 mL per segment to be blocked. This guideline should be adjusted for shorter patients and for very tall patients. For example, to achieve a T10 sensory level from an L3–L4 injection, approximately 8 mL of LA should be administered. Below concentrations of the equivalent of 1% lidocaine, motor block is minimal, regardless of the volume of the LA injected, unless doses are given at repeating intervals.

Time to repeat a dose of LAs depends on the duration of the drug. Doses should be administered before the block regresses to the point the patient experiences pain, commonly referred to as "time to two-segment regression." This is defined as the time it takes for the sensory block to regress by two dermatome levels. When two-segment regression has occurred, one-third to one-half of the initial loading dose can safely be administered

TABLE 24–20. Redosing local anesthetics.

Drug	Concentration (%)	Time to Two-Segment Regression (min)	Recommended Time for "Top-Up" Dose From Initial Dose (min)
2-Chloroprocaine	3	45–75	45
Lidocaine	2	60–140	60
Bupivacaine	0.10	180–260	120
Ropivacaine	0.10	180–260	120

to maintain the block. For example, the time to two-segment regression of lidocaine is 60–140 minutes (Table 24–20).

Patient Positioning

Patient positioning during initiation of epidural blockade does not appear to affect the resultant spread of analgesia or anesthesia. The patient may be placed in either the lateral or sitting position. The midline of the spine is easier to palpate when the patient is sitting, especially in the obese patient, therefore making the block technically easier. Whether the patient is in the sitting or the lateral position, there is no significant difference in block height.[189] It has been suggested in a study by Seow and associates that there is slightly faster onset time, duration, and density of motor block on the dependent side when the epidural is placed with the patient in the lateral position.[190]

Patient Characteristics: Age, Weight, Height, and Pregnancy

With advancing age, the LA dose required to attain a specific block is reduced. Some studies have observed a nonclinically significant difference in block height (between one and four segments higher) with a fixed volume and concentration of LA in patients older than age 50.[191–193] Greater spread in the elderly may be related to the reduced size of the intervertebral foramina, which theoretically limits the egress of LAs from the epidural space. Decreased epidural fat, which allows more of the drug to bathe the nerves, and changes in the compliance of the epidural space, which may lead to enhanced cephalad spread, have also been proposed.[194]

There is little correlation between the spread of analgesia and the weight of the patient. However, in morbidly obese patients, there may be compression of the epidural space related to increased intra-abdominal pressure; a higher block may be attained with a given dose of LA.

Height appears to play little role in LA requirements. For short patients (≤5 ft 2 in.), the common practice has been to reduce the dose to 1 mL per segment to be blocked (instead of 2 mL per segment). Bromage suggested a more precise dosing regimen of increasing the dose of LA by 0.1 mL per segment for every 2 in. above 5 ft of height.[195] The safest practice is to use incremental dosing and monitor the effect to avoid excessively high anesthetic levels.

Pregnancy causes an increased sensitivity to both LAs and general anesthetics, although the studies regarding the causes are conflicting. Elevated levels of progesterone and endogenous endorphins may contribute. Conflicting evidence regarding the spread of LA in pregnant versus nonpregnant individuals has been published.[196,197]

Intermittent Versus Continuous Epidural Block

The decision whether to use intermittent dosing after the initial loading dose, a continuous infusion, or patient-controlled or programmed intermittent bolus dosing may be influenced by the nature of the surgery or procedure, staffing, and equipment. All of these options can provide safe and effective epidural analgesia or anesthesia. Advantages of continuous infusion include greater cardiovascular stability, fewer labor requirements, decreased incidence of tachyphylaxis, decreased frequency and severity of side effects related to bolus injections, less rostral spread, decreased risk of the potential for contamination, and the ability to achieve a steady state of anesthesia. Intermittent manual bolus dosing, on the other hand, is simple and does not require additional equipment (eg, infusion devices).

EPIDURAL TECHNIQUE

Several factors influence the success of epidural blockade, including the clinician's experience and knowledge of anatomy, patient preparation and positioning, the level of epidural catheter insertion, and the technique used to initiate the procedure. This section reviews factors that contribute to successful epidural placement, starting with patient selection and preparation, equipment requirements, and current recommendations for the prevention of infectious complications associated with neuraxial techniques. It then presents technical aspects of cervical, thoracic, and lumbar epidural placement and addresses various controversies related to the technique of neuraxial blockade, such as the optimal method to identify the epidural space and the efficacy of the epidural test dose.

Patient Evaluation

As in the case with any anesthetic, the risks and benefits of epidural placement should be discussed with the patient in a manner consistent with informed consent. Any concerns and questions should be addressed prior to the administration of premedication. When a language barrier exists, trained interpreters or telephone translation services should be utilized.

The patient's medical history and active medication list should be reviewed prior to the initiation of epidural blockade, with particular emphasis on the presence of conditions that may predispose the patient to serious complications. Drug therapy that influences the patient's clotting function or physiologic response to blockade of the sympathetic preganglionic fibers should be taken into consideration, including when the last dose was administered. The patient's last oral intake should also be documented. For those patients receiving epidural blockade as the sole anesthetic or as an adjuvant to GA for elective surgical procedures, the ASA guidelines for nothing by mouth should be enforced. Patients with medical conditions that worsen with reduced afterload or preload (eg, severe AS, mitral stenosis, hypertrophic cardiomyopathy) and patients who may experience worsening shortness of breath, such as those with restrictive lung disease or severe COPD, may require additional testing. Clinical conditions that predispose patients to neuraxial infections, such as immunosuppression, DM, pancreatitis, and alcohol or drug abuse, may require further evaluation or laboratory studies. Preexisting neurologic deficits or CNS disorders should be assessed and documented. History of sensitivity or adverse reaction to opioids or LAs and complications related to prior epidural procedures require further investigation.

Physical examination should include an evaluation of the spine for evidence of scoliosis or prior back surgery, focal infection, severely limited range of motion, or other findings that may make epidural placement more challenging or impossible. Obesity, especially central obesity, may obscure surface landmarks.

Routine laboratory studies are not required for epidural placement in healthy patients for routine procedures. Many clinicians may choose to obtain a complete blood cell count (CBC), particularly when appreciable blood loss is expected or when the patient is known to be anemic. Baseline assessment of the patient's coagulation status or platelet count should be obtained in patients with known or suspected coagulation disorders, bleeding diatheses, and thrombocytopenia, as well as in patients receiving antithrombotic or thrombolytic therapy or any medications known to affect platelet quality or function (besides routine NSAIDs).

Clinical Pearls

- Routine laboratory studies are not required for initiation of epidural blockade in healthy patients for routine procedures.
- Patients with known or suspected bleeding disorders and those receiving antithrombotic or thrombolytic therapy require assessment of baseline coagulation status or platelet count (and possibly platelet function).
- Patients undergoing surgeries with anticipated blood loss or hemodynamic changes may require additional workup, including a CBC.

Preparation

A large-bore intravenous catheter for fluid or emergency drug administration must be secured prior to initiation of epidural blockade. Fluid preloading is not required and may be harmful in certain subsets of patients with decreased serum colloid oncotic pressure (eg, those with burns, preeclamptic patients).[198] However, reversible conditions, such as severe hypovolemia, should be managed prior to block placement and dosing.

	Endotracheal tubes
	Eschmann stylet/bougie
	Syringes and needles
Emergency drugs	Ephedrine
	Phenylephrine
	Epinephrine
	Atropine
	Sedative/hypnotic
	20% lipid emulsion
	Succinylcholine

Appropriate monitoring during performance of epidural blockade depends on the purpose of the epidural block and when and where the epidural is to be dosed. Epidural blocks for analgesia, such as for labor analgesia, require intermittent blood pressure monitoring during placement and for the duration of the epidural infusion, as well as continuous pulse oximetry with heart rate monitoring during placement and block initiation. Electrocardiogram (ECG) monitoring should be available. In laboring patients, fetal heart rate monitoring before and after placement is recommended if continuous monitoring is not feasible.

Sedatives or analgesics are not uncommonly administered to alleviate patient stress and discomfort during epidural placement and may require additional monitors and equipment, such as a nasal cannula. If premedications are administered, medical personnel who can provide continuous monitoring should be present. Of note, excessive sedation should be avoided to ensure patient cooperation during positioning, to detect the presence of paresthesias during placement, and to evaluate the level of sensory blockade and the effect of the test dose (if administered). Standard ASA monitors are required for initiation and intraoperative management of epidural anesthesia. Emergency drugs and equipment must be readily available during initiation of all central neuraxial procedures (Table 24–21).

Communication With Surgical Staff

A discussion with the surgical staff regarding the operative approach, the desired positioning of the patient, the estimated length of the surgical procedure, the anesthetic or analgesic goals of the blockade, and postoperative analgesic requirements can help to determine whether a continuous epidural, a single-shot epidural, or a CSE is preferable. The surgical staff can also share information about the patient that is not readily available in the chart or immediately apparent during the preoperative interview.

When feasible, to minimize unnecessary delays the block can be initiated in the preoperative area or in the operating room while the nursing staff is setting up the surgical equipment. Wherever the block is performed, sufficient space for the anesthesiologist and, optimally, an assistant, as well as adequate lighting, monitoring, and resuscitation equipment are essential.

Equipment

Commercially prepared, sterile, disposable epidural trays are available from several manufacturers. A standard kit typically includes the following: a sterile drape; prep swabs; 4 × 4 gauze sponges; a paper towel; povidone-iodine solution; an ampoule of 0.9% preservative-free sodium chloride; a 5-mL ampoule of 1.5% lidocaine with epinephrine 1:200,000; a 5-mL ampoule of 1% lidocaine for skin infiltration; a filtering device (needle or straw); a bacterial filter; needles and syringes of various sizes; a styletted epidural needle with cm markings; a 5- or 10-mL glass or plastic LOR syringe (either Luer lock or Luer slip); a catheter connector securing device; an epidural catheter with centimeter gradations and a connector/adapter; a thread assist device (TAD); a needle guard for sharps disposal; and labels.

In an adult epidural kit, the epidural needle is typically 17 or 18 gauge and 9 cm (roughly 3.5 in.) in length, with surface markings at 1-cm intervals. Longer needles up to 15 cm (6 in.) in length are available for obese patients. The Tuohy needle, which is commonly supplied in noncustom kits, has a curved tip with a blunt bevel designed to permit easier identification of tissue as the needle advances and facilitate passage of the epidural catheter. Wings at the junction of the needle shaft and hub may allow for better control as the needle is passed through tissue, particularly when using the "hanging drop" technique for epidural space identification, although some practitioners may prefer epidural needles without wings or with attachable wings (Figure 24–14). Epidural needles with a back-eye opening for exit of a spinal needle (for CSEs) and double-lumen needles with separate openings for the spinal needle and catheter are also available.

Epidural catheters vary in diameter, materials, and tip design. In commercially prepared kits, 19-gauge catheters are usually paired with 17-gauge epidural needles; 20-gauge catheters are paired with 18-gauge needles. Many currently available epidural catheters are nylon blends with varying degrees of stiffness to facilitate threading. Some stiff nylon catheters have specially designed flexible tips intended to veer away from veins, nerves, and other obstacles encountered in the epidural space. Wire-reinforced catheters embedded in either a

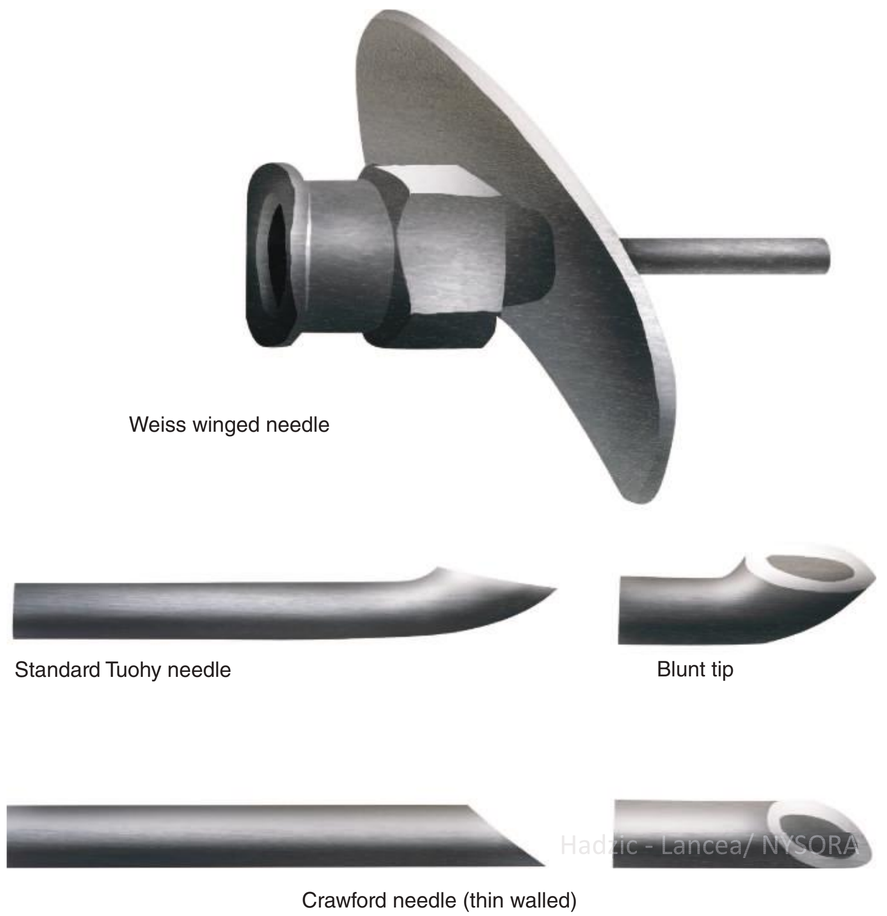

FIGURE 24–14. Epidural needles: bevel and wing configuration.

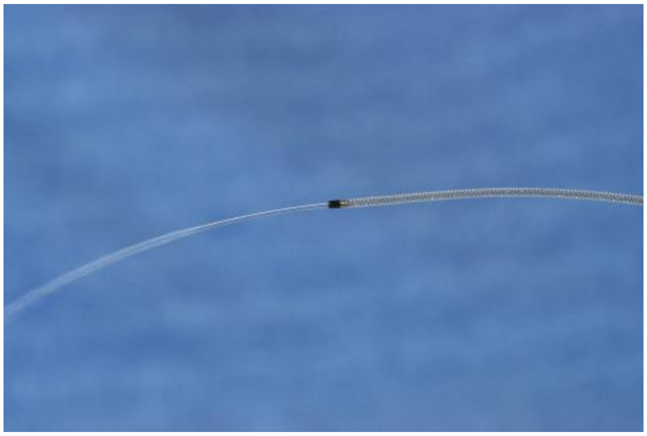

FIGURE 24–15. Single end-hole wire-reinforced catheter. (Used with permission from Epimed International.)

polyurethane or nylon-blend catheter represent a more recent technological advance and are becoming increasingly popular (Figure 24–15). Adult versions are 19 gauge in diameter and designed for use with a 17-gauge epidural needle; pediatric versions are available from some manufacturers.

Many commercially available nylon and wire-reinforced catheters are manufactured in both single end-hole and multiorifice versions (Figure 24–16). A lack of robust data precludes a full assessment of whether clinical outcomes, such as the incidence of paresthesias, epidural vein cannulation, intrathecal migration, and adequate analgesia, are improved with the uniport or multiport design. However, a 2009 prospective, single-blind, randomized controlled trial by Spiegel et al investigated the success of labor analgesia, the number of episodes of breakthrough pain requiring supplemental medicine, and the occurrence of complications, such as paresthesias and intravascular and intrathecal catheter placement, in 493 parturients who received either a single end-hole, wire-reinforced polyurethane catheter or a multiorifice, wire-reinforced nylon catheter.[199] The authors found no statistically significant difference in outcomes between the two groups and postulated that the flexibility afforded by the wire coil may eliminate any of the potential advantages of the multiport design.

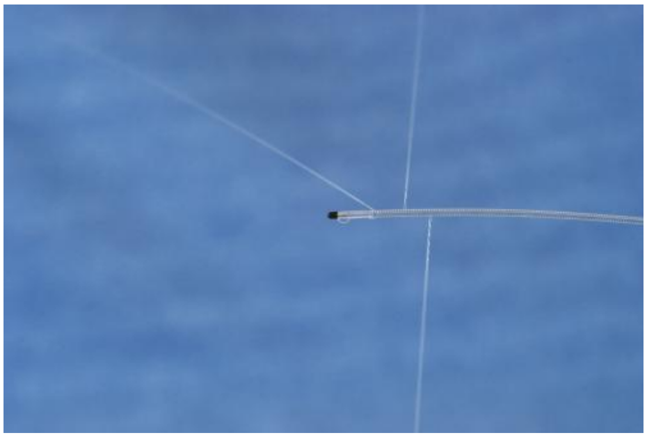

FIGURE 24–16. Multiorifice wire-reinforced catheter. (Used with permission from Epimed International.)

Clinical Pearls

- The use of wire-reinforced epidural catheters appears to reduce the incidence of complications associated with epidural techniques, including epidural vein cannulation, paresthesias, and inadequate analgesia.
- Current data suggest that clinical outcomes are similar with the use of uniport and multiport spring-wound catheters; the flexibility afforded by the stainless steel coil appears to negate any potential benefits of a multiport design.

Additional equipment that may be needed for initiation of epidural procedures includes 0.5% chlorhexidine with ethanol (Hydrex®) or 2% chlorhexidine with 70% isopropyl alcohol (ChloraPrep®), which is not supplied in epidural trays; a transparent sterile, occlusive dressing for the puncture site; and tape to secure the catheter. To minimize the remote risk of chemical arachnoiditis, the skin disinfection solution should not make contact with the epidural drugs or equipment and should be given adequate time to dry. Usually a large clear dressing (eg, Tegaderm") and adhesive tape are sufficient to prevent catheter dislodgement and to keep the epidural insertion site visible and clean. A sterile pen to label medications and a 25- or 27-gauge spinal needle (for CSEs) can be dropped onto the sterile field.

Clinical Pearls

- A clear sterile occlusive dressing is recommended to prevent catheter dislodgement.
- The catheter and its centimeter markings should be visible to the anesthesia provider to ensure that the catheter remains at the original insertion site and that CSF and heme return are absent prior to dosing.

Analgesia and Sedation During Block Initiation

Analgesia or sedation can be provided to improve patient comfort during neuraxial blockade. However, there is emerging evidence that intravenous sedatives may increase pain perception in an agent-type- and pain-type-specific manner.[200] Light sedation with a benzodiazepine (most commonly midazolam) or a short-acting opioid prior to epidural placement is usually sufficient. This may also be appropriate for obstetric patients. In a small, double-blind randomized study, Frölich and colleagues found that maternal analgesia and sedation with fentanyl and midazolam prior to spinal placement was not associated with adverse neonatal effects.[201] Importantly, mothers in both the group that received premedication and the control group showed no difference in their ability to recall the births of their babies.

For those who prefer to be "asleep" during epidural placement, a propofol infusion can be titrated to maintain sedation without respiratory impairment in selected clinical settings.

However, it is preferable to have adult patients awake and cooperative enough to alert the anesthesia provider to the presence of paresthesias during initiation of neuraxial blockade and to participate in assessment of the sensory level. In clinical scenarios in which the administration of premedication prior to epidural placement may not be appropriate, there appears to be a placebo effect from the use of gentler, more reassuring words during lidocaine skin wheal administration, which is often considered the most painful part of the procedure.[202] Studies suggest that the following tips may also serve to reduce pain on injection of LA: Chloroprocaine (with or without sodium bicarbonate) may be less painful than lidocaine for skin infiltration[203]; adjusting the pH of lidocaine to approximate physiologic pH reduces pain on injection[204]; and cryoanalgesia (skin cooling) may be as effective as buffering the LA solution with sodium bicarbonate.[205]

Clinical Pearls

The following tips may serve to reduce pain on injection of LA for skin infiltration:

- Communication with the patient during the procedure and verbal reassurance
- Adjusting the pH of lidocaine with the addition of sodium bicarbonate to more closely approximate physiologic pH
- Skin cooling (cryoanalgesia) or topical anesthetic before skin puncture

Patient Positioning

Optimal patient positioning is essential for successful epidural placement. Depending on the patient's medical status (eg, body habitus and ability to cooperate), the planned procedure, the anesthesia provider's experience, the baricity of the intrathecal solution (for CSE placement), and several other factors, the sitting, lateral decubitus, jackknife, or prone position can be used. Each position has advantages and disadvantages. Regardless of which position is selected for the initiation of neuraxial procedures, it is useful to have an assistant to help maintain the position until the procedure is complete. Overall, while epidural block can be initiated with the patient in any position that permits access to the back, improper positioning can turn an otherwise-easy epidural placement into a needlessly challenging one. Several positioning devices are available commercially to facilitate patient positioning without the aid of nursing personnel.

Sitting Position

In general, it is technically easier to identify the midline in the sitting position, particularly in obese and scoliotic patients. Anesthesia providers may also be more experienced and more comfortable performing neuraxial procedures in the sitting position. The sitting position has also been observed to provide the most direct route to the epidural space, with shorter distance from skin to space[206] and, in the case of CSEs with dextrose-free LA and hypobaric intrathecal opioids, greater cephalad spread of the sensory block.[207] However, elderly patients, parturients in advanced stages of labor, patients with hip fractures, heavily sedated patients, and uncooperative patients may not be able to assume or maintain the sitting position (Table 24–22).

TABLE 24–22. Advantages of sitting position for initiation of neuraxial blockade.

Easier to identify midline, particularly in obese and scoliotic patients
Practitioners more experienced in sitting position
Shorter procedure time
Shorter distance from skin to epidural space
Greater cephalad spread of hypobaric solutions

If the sitting position is chosen, the patient should be assisted to sit on the operating room table or bed with the backs of the knees touching the edge of the bed and the feet resting on a stool or hanging over the bed. The patient should relax the shoulders and curve the back out toward the clinician, assuming a "slouched" or "mad-cat" position. It is useful to have an assistant stand in front of the patient and help the patient attain maximal spinal flexion (Figure 24–17). Flexing the neck should help to flex the lower spine and open the vertebral spaces (Figure 24–18). Asking the patient to hug a pillow may also help with positioning.

Lateral Decubitus Position

The lateral decubitus position may be more appropriate for patients who cannot comfortably assume the sitting position. Additional benefits include the following: Sedation can be used more liberally; vagal reflexes can be minimized; hemodynamic changes may be better tolerated; there may be less need for a well-trained assistant to help maintain positioning; and there appears to be a reduced incidence of unintentional epidural vein cannulation and dural puncture (Table 24–23).[208] Finally, in the case of CSEs with hyperbaric LAs, unilateral blocks for certain orthopedic procedures may be more easily attained in the lateral position.

In the lateral decubitus position, the patient's back should be fully aligned with the edge of the table or bed (Figure 24–19). The left lateral recumbent position may be preferable for right-handed physicians and may provide improved hemodynamic stability for parturients. The coronal plane of the patient should be perpendicular to the floor, with the tips of the spinous processes pointing toward the wall. The thighs should be flexed toward the abdomen and the knees drawn to the chest; the neck should be in a neutral position or flexed so that the chin rests on the chest. Asking the patient to "assume the fetal position" may help maximally flex the spine. The hips should be aligned one above the other, and the nondependent arm should extend toward and rest on the nondependent hip. The patient's head may need to be elevated with a pillow to avoid rotation of the spine. Obese patients or those with larger hips may require additional pillows to maintain proper alignment. Directing the needle toward an imaginary line that extends cephalad and

FIGURE 24–17. **A, B:** Epidural placement in the sitting position with assistant helping to position the patient.

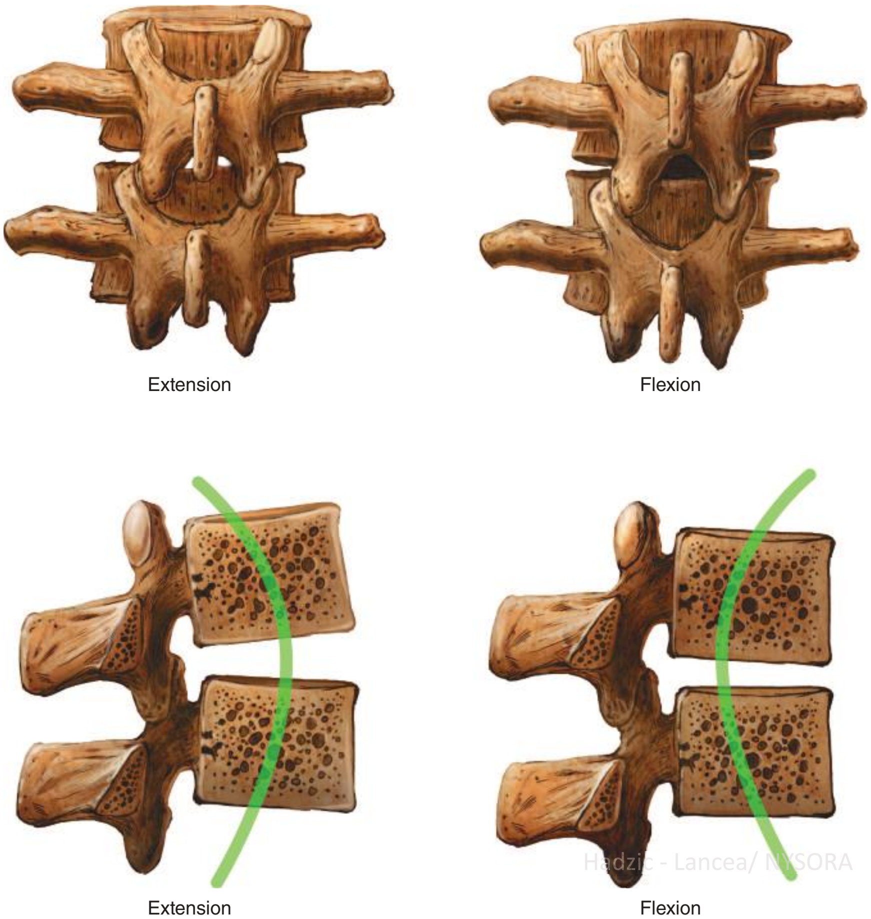

FIGURE 24–18. Flexion versus extension during epidural placement.

TABLE 24–23. Advantages of lateral position for initiation of neuraxial blockade.

Sedation can be used more liberally
Reduced patient movement
Increased patient comfort
Improved patient cooperation
Improved patient satisfaction
Reduced catheter displacement
Decreased incidence of epidural vein cannulation
Attenuation of vagal reflexes
Hemodynamic changes better tolerated
Bedside assistance may not be required
Intentional unilateral block for surgical procedures feasible

caudad from the umbilicus may optimize chances of midline insertion, which is particularly important during initiation of CSEs (Table 24–24). The bevel of the epidural needle is directed toward the patient's head.

Infection Control

Adherence to strict aseptic techniques is essential during initiation and maintenance of neuraxial blockade. The ASA Task Force on Infectious Complications Associated With Neuraxial Techniques advises the following measures: remove jewelry on fingers and wrists; use careful hand washing before gloving; use caps, masks (changed with each new patient encounter), and sterile gloves; use chlorhexidine with alcohol for skin preparation; drape the patient under sterile conditions; and cover the catheter insertion site with a sterile occlusive dressing.[209] A single application of chlorhexidine with alcohol appears as efficacious as two applications for skin disinfection.[210] When chlorhexidine, which is not supplied in epidural kits, is not available, the use of povidone-iodine with alcohol is preferable to povidone-iodine alone. All antiseptic solutions are considered neurotoxic if they come into direct contact with the meninges[211]; care should be taken to keep needles and drugs in the epidural tray separate from the skin disinfectants. Bacterial filters may be helpful for patients with chronic or extended continuous epidural infusions, but there are no data to support that they decrease the incidence of catheter-related infections. The catheter should remain in place no longer than necessary, and catheter disconnects and filter changes should be kept to a minimum. The data are insufficient to support wearing a surgical gown during initiation of epidural procedures (Table 24–25).

Techniques to Identify the Epidural Space

Three techniques can be used to identify the epidural space: LOR, hanging drop, and ultrasonography. Despite increasing interest in ultrasound-assisted neuraxial procedures, the LOR technique, which relies on the different tissue densities as the needle passes through ligaments into the epidural space, is the most commonly used technique. Both LOR to fluid, with or without an air bubble, and air are recognized as acceptable means of identifying the epidural space. Randomized trials comparing saline to air for LOR have suggested that saline is superior. However, these trials may overstate the difference between the two media by forcing the anesthesia provider to use a less-preferred technique.[212] Regardless of which technique is used during routine epidural placement, it is important to bear in mind that LOR to air is not recommended for EBP procedures.

Evidence in the literature is lacking concerning the best method to identify the epidural space in children, who are commonly anesthetized during placement. Recently, the use of ultrasound has been advocated. However, the technique can be cumbersome and requires experience with ultrasound imaging. With refinements in technology and expanding practitioner experience, ultrasound guidance may facilitate placement of epidural catheters in this patient population.

Loss of Resistance to Air

The LOR to air technique is associated with several complications (Table 24–26). Air is compressible and may result in a false LOR and, relatedly, an increased incidence of ADP. ADP in the setting of LOR to air may result in pneumocephalus, a severe headache that develops immediately after injection of air into the subarachnoid space.[213] Pneumocephalus, in turn, can result in serious neurologic injury, such as hemiparesis and generalized convulsions, as well as nausea and vomiting and delayed recovery

FIGURE 24–19. Epidural placement in the lateral position.

TABLE 24–24. Tips for attaining optimal lateral position.

Align patient's back with edge of table or bed
Align coronal plane perpendicular to floor
Flex thighs toward abdomen
Neck should be neutral or flexed
Align hips one above the other
Rest nondependent arm on nondependent hip
Elevate head with pillow to avoid rotation of the spine

from GA.[214] The incidence of PDPH and the onset of symptoms may also be higher when the LOR to air technique is used to identify the epidural space. In addition, the LOR to air technique has been associated with a higher incidence of unblocked segments or patchy pain relief and neurologic deficits related to compression of nerve roots or the spinal cord by air bubbles.[215] Venous air embolism (VAE) in the presence of tears in the epidural venous plexus or if the pressure from the air source is higher than the venous pressure has been reported.[216] Finally, both an increased incidence of epidural venous cannulation and difficult catheter insertion have been associated with LOR to air, particularly in the absence of fluid predistension of the epidural space, although the data are conflicting.[217]

Advocates of LOR to air feel that it is easier to detect ADP if air alone is used, as any fluid return is undeniably CSF in the absence of saline injection. In the event of an equivocal ADP, CSF can be distinguished from saline with the use of a urine reagent strip to check for glucose and protein; if positive, the diagnosis of CSF can be made. CSF can also be distinguished from saline or LA by the temperature differential; CSF is expected to be body temperature. Advocates of the LOR to air approach also point to the inadequate sensory block and delay in block onset that may occur if large volumes of saline are injected into the epidural space, presumably due to a dilutional effect. This, however, can be avoided by limiting the amount of saline injected. For practitioners who routinely perform CSEs, an argument could also be made that injecting saline complicates the identification of CSF prior to the administration of intrathecal medications.

TABLE 24–25. Aseptic technique during epidural blockade initiation and maintenance.

Remove jewelry on fingers and wrists
Perform careful hand washing before gloving
Use cap, mask, and sterile gloves
Use chlorhexidine with alcohol for skin preparation
Drape the patient under sterile conditions
Cover catheter insertion site with sterile, occlusive dressing
Keep catheter in place no longer than necessary
Keep catheter disconnection and filter changes to a minimum

TABLE 24–26. Complications associated with loss of resistance to air.

Pneumocephalus
Increased risk of accidental dural puncture
Faster onset of signs and symptoms of PDPH
Higher incidence of PDPH
Incomplete/patchy block
Spinal cord or nerve root compression by air
Venous air embolism
Subcutaneous emphysema
Increased incidence of epidural vein cannulation
Difficult catheter insertion

PDPH = postdural puncture headache.

To identify the epidural space with the LOR to air technique, advance the needle slowly, exerting either continuous or intermittent pressure on the LOR syringe. As the needle enters the ligamentum flavum, there is usually a distinct sensation of increased resistance followed by a subtle "give" when light pressure is exerted on the plunger. Avoid injecting air on identifying the epidural space due to concerns for pneumocephalus (in the event of ADP) and patchy, inadequate analgesia.

Loss of Resistance to Saline With or Without an Air Bubble

The syringe is filled with 2–3 mL of saline or saline with a clearly visible air bubble. The bubble provides a gauge of the appropriate pressure to be applied on the LOR syringe; it will compress and provide some resistance if the epidural needle tip is engaged in ligament but will dissipate effortlessly with only light pressure once the needle enters the epidural space. The saline can be injected directly for fluid predistension. The small air bubble should not result in complications associated with LOR to air if it also is injected. Omit the air bubble when performing an EBP due to the remote possibility that the air could be introduced into the subarachnoid space via the meningeal breach.

With LOR to saline with or without air, the needle is advanced in the same fashion as with air. Continuous or intermittent pressure can be exerted on the plunger of the needle.

The Hanging Drop Technique

The hanging drop technique relies on the subatmospheric pressure of the epidural space, which is more pronounced and reliable in the cervical and thoracic regions than in the lumbar segments. Dural tenting from the advancing epidural needle also contributes to the pressure that appears to "suck in" the drop of fluid. To identify the epidural space with this approach, an epidural needle with wings is required. A drop of saline is placed at the hub of the needle once the needle is engaged in ligament. The needle is advanced continuously with the thumb and index fingers firmly grasping the wings and the third through fifth fingers of both hands positioned against the patient's back. Entry into the epidural space is signaled by entry of the drop into the hub of the needle.

The hanging drop technique is most effective in the thoracic region, where the subatmospheric pressure is more notable. However, this technique carries a higher risk of meningeal tear, in part because of the epidural needle's proximity to the dura. Also, patients with severe obstructive lung disease may have attenuated subatmospheric pressure, even in the thoracic region; the hanging drop technique may not be appropriate in this setting.

Ultrasonography

Ultrasound technology is being used increasingly to aid in the identification of the epidural space. Studies suggest that the use of ultrasonography to identify the anticipated depth to space, particularly in obese parturients,[218] and to identify the midline prior to placement reduces the number of attempts, minimizes the risk of complications, and facilitates the procedure without significantly prolonging the procedure. Ultrasound guidance also serves to help identify the correct interspace, which may be difficult based on anatomic landmarks alone. See Chapter 40 for more detailed information about ultrasound-guided neuraxial techniques.

Technique of Epidural Blockade

There are four common approaches to the epidural space: midline, paramedian, Taylor (modified paramedian), and caudal. Clinical expertise in each of these techniques gives the anesthesiologist more flexibility when performing epidural blockade. For all approaches, monitors should be in place and the skin should be prepped and draped in a sterile fashion before initiation of the procedure. Emergency equipment and medication must be immediately available. Sedation may be used, as appropriate. In general, the epidural needle bevel should be facing cephalad regardless of the approach used to access the epidural space unless an intentional unilateral block is desired (eg, for lower extremity orthopedic procedures performed under CSE).

Midline Approach

This approach is most commonly used for epidural placement in the sitting position and for epidural procedures in the lumbar, low thoracic, and cervical spine region.

1. An epidural tray can be placed to the anesthesiologist's right for right-handed and left for left-handed clinicians.
2. Identify the desired interspace by surface anatomic landmarks and palpation or with ultrasonography. The needle used to anesthetize the skin can also be used as a "finder needle" to help identify bony landmarks, particularly in obese patients.
3. Infiltrate the skin and subcutaneous tissue with LA (most commonly 1% lidocaine) along the intended path of the epidural needle between adjacent spinous processes. A large skin wheal with a smaller volume of LA in the subcutaneous tissue will serve to anesthetize the skin adequately without obscuring landmarks.
4. Insert the styletted epidural needle along the same track with the bevel oriented cephalad. During needle insertion, the dorsum of the anesthesiologist's noninjecting hand can rest on the patient's back with the thumb and index finger holding the hub of the epidural needle. A modified approach is to advance with the dominant hand firmly wrapped around the hub of the epidural needle while the index finger and thumb of the nondominant hand grasp and guide the needle shaft. Placing the tips of the middle fingers on the patient's back and grasping the needle wings with both thumbs and forefingers is an alternative method to engage the needle.

   To engage the epidural needle properly, advance through the skin, subcutaneous tissue, fatty tissue, supraspinous ligament, interspinous ligament, and, possibly, into the ligamentum flavum; at that point, the needle should sit firmly in the midline (Figure 24–20). If the needle shaft wobbles or deviates sideways, it is not properly anchored in ligament. The epidural needle can be engaged in the interspinous ligament or the ligamentum flavum.

Clinical Pearls

- The epidural needle advances through skin, subcutaneous tissue, supraspinous ligament, interspinous ligament, and ligamentum flavum before reaching the epidural space.
- The needle can be engaged in either the interspinous ligament or the ligamentum flavum during initiation of epidural blockade.
- Lateral deviation or a "wobbly" needle indicates that the needle is not properly engaged in ligament, necessitating withdrawal and re-direction toward midline.

   Determining which ligaments are traversed is an acquired skill. The interspinous ligament may feel "gritty" against the advancing needle, while the ligamentum flavum offers more resistance. However, midline gaps in the ligamentum flavum are not uncommon, and obstetric patients may have softer ligaments. The depth from the skin to the ligamentum flavum generally ranges from 4 to 6 cm in normal-size adults, although there is a great deal of variability.

   After the ligaments are penetrated, it is no longer advisable to change the direction of the needle tip without withdrawing the needle several centimeters or to the skin level. The stylet should be placed in the epidural needle while redirecting to avoid the accumulation of bony debris or soft tissue plugs that may hinder the flow of CSF in the event of an ADP.
5. Remove the stylet from the epidural needle and attach the LOR syringe with air or saline (with or without an air bubble) firmly to the hub of the needle. Glass or low-resistance plastic LOR syringes are appropriate. Care should be taken to ensure that glass syringes are not "sticky."

FIGURE 24–20. Epidural needle engaged in midline ligament.

FIGURE 24–21. Advancing epidural needle: nondominant hand on patient's back with thumb and forefinger on needle hub.

Multiple hand positions are appropriate to advance the epidural needle into the epidural space: The back of the nondominant hand can rest firmly on the patient's back, with the thumb and forefinger grasping the needle shaft, while pressure is exerted on the LOR plunger either continuously or intermittently by the thumb of the dominant hand. The nondominant hand can rest on the patient's back with the thumb and forefinger extending to and stabilizing the needle hub, while the thumb of the dominant hand applies pressure (Figure 24–21). Or, the middle through fourth or fifth fingers of the nondominant hands can rest on the back, with both thumbs and forefingers grasping the wings of the epidural needle and the dominant hand intermittently releasing its position and exerting pressure on the LOR syringe plunger (Figure 24–22).

As the needle enters the epidural space, the plunger of the LOR syringe suddenly "gives." Avoid injecting the full contents of the syringe, particularly with LOR to air, if possible. For continuous epidurals, a small volume of saline can be injected into the epidural space to dilate the space, thereby reducing the risk of epidural vein cannulation and facilitating catheter insertion. Note the depth of the needle at the skin. The marking on the needle at the skin represents the depth from the skin to the epidural space. Because the centimeter markings are not numbered, it may help to count the number of centimeter markings between the skin and the epidural needle hub and subtract that number from the length of the needle. For example, if 4 markings remain visible between the skin and the needle hub, subtract 4 from 9 (the common length of an epidural needle) to determine that the depth to epidural space is 5 cm.

6. Insert the catheter with the assistance of the insertion device that fits into the epidural needle hub until the 15-cm mark is visualized entering the needle hub; then, remove the needle without dislodging the catheter (Figure 24–23). The catheter should be threaded no more than 5–6 cm into the epidural space; 2–3 cm is appropriate for short surgical procedures. To determine where the catheter should be secured at the skin, add 2–6 cm, depending on the distance the catheter is to be threaded, to the previously calculated depth to epidural space. For example, if the needle entered the epidural space at 7 cm, the catheter should be secured at the 12-cm mark at the skin to ensure that 5 cm of the catheter rests in the epidural space.

Clinical Pearl

- An easy way to measure depth to epidural space when using the LOR technique is to count the number of centimeter markings that are visible between the skin and the needle hub. Subtract that number from the length of the needle. For example, most epidural needles are 9 cm in length. If 4 centimeter markings are visible after epidural space identification, subtract 4 from 9 to conclude that the depth to space is 5 cm. The epidural catheter should be inserted no more than 5 or 6 cm beyond that distance (ie, taped at 10–11 cm at the skin).

FIGURE 24–22. Advancing epidural needle: thumbs and index fingers grasping wings.

For the less-common single-shot epidural technique, the LA may be administered directly through the needle in divided doses over several minutes. This technique, however, requires that the patient remain immobile during dosing and may result in painful pressure with large volumes. For the continuous catheter technique, administering LA through the needle is not recommended, as correct catheter placement cannot be verified.

7. A clear occlusive dressing should be applied over the insertion site to allow inspection of the catheter. The catheter should be secured to the patient's back with the connector at the patient's shoulder. Using clear tape has the advantage of permitting the practitioner to visualize the proximal and distal "flashback" windows of the catheter prior to administering boluses of LA.

FIGURE 24–23. Inserting the epidural catheter.

Paramedian Approach

The paramedian approach offers a larger opening into the epidural space than the midline approach and is particularly useful for patients who cannot be positioned easily or who cannot flex the spine during epidural placement; for patients with calcified ligaments or spinal deformities (eg, kyphoscoliosis, prior lumbar surgery); and for epidural techniques in the low- to midthoracic area. The spinous processes from T4–T9 are sharply angled and have tips that point caudally, making midline insertion of the epidural needle more difficult.

The "feel" of the paramedian approach is different from that of the midline approach because different tissues are penetrated. The supraspinous and interspinous ligaments are midline structures that are not traversed in the paramedian approach. Instead, the epidural needle penetrates paraspinous tissue with little resistance before entering the ligamentum flavum. Several approaches to the paramedian technique have been described. Essentially, needle entry is directed caudal and lateral to the inferior aspect of the superior spinous process of the desired interspace and walked off the lamina in a cephalad direction (Figure 24–24).

1. Identify the intended interspace with surface landmarks, palpation, or ultrasound guidance. Raise a skin wheal roughly 1 cm lateral and 1 cm caudad to the inferior aspect of the superior spinous process of the desired spinal level.
2. The epidural needle is inserted 15° off the sagittal plane, angled toward midline with a cephalad tilt.

FIGURE 24–24. Paramedian epidural technique.

3. If bone (most likely lamina, if depth and angle of approach are appropriate) is encountered, the needle is redirected in a cephalad and medial direction (See Part VI, Pediatric Anesthesia). If the lateral aspect of the spinous process is encountered, the needle should be redirected laterally and cephalad.

Taylor Approach

The Taylor approach is a modified paramedian approach utilizing the large L5–S1 interspace. It is an excellent approach for hip surgery or for any lower extremity surgery in trauma patients who cannot tolerate the sitting position. This approach may provide the only available access to the epidural space in patients with ossified ligaments.

1. With the patient in the sitting or lateral position, a skin wheal is placed 1 cm medial and 1 cm caudad to the posterior superior iliac spine.
2. The epidural needle is inserted into this site in a medial and cephalad direction at a 45° to 55° angle.
3. As in the classic paramedian approach, the first resistance felt before entry to the epidural space is on entry into the ligamentum flavum.
4. If the needle contacts bone (usually the sacrum), the needle should be walked off the bone into the ligament and then into the epidural space in progressively more medial and cephalad directions.

Caudal Approach

The caudal approach is commonly used in pediatrics for single-shot or continuous epidural catheter placement for intraoperative and postoperative analgesia (see Chapter 25). In adults, it is usually reserved for procedures requiring blockade of the sacral and lumbar nerves (eg, anal and vaginal surgeries, inguinal herniorrhaphy, cystoscopy); epidurography; and lysis of adhesions in patients with low-back pain with radiculopathy after spinal surgery.

The sacrum is a triangular-shaped bone formed by the fusion of the sacral vertebrae. Nonfusion of the fifth sacral vertebral arch creates the structure known as the sacral hiatus, which is covered by the sacrococcygeal ligament (an extension of the ligamentum flavum) and bordered by bony prominences known as the sacral cornua. The sacral hiatus is the point of access into the sacral epidural space. It is usually identified as a groove above the coccyx (Figure 24–25). If fluoroscopy is not used, there are two methods to identify the hiatus:(1) The sacral hiatus lies at the apex of an equilateral triangle connecting the posterior superior iliac spines and pointing caudad. (2) The bony protuberances (the sacral cornua) that surround the sacral hiatus can be palpated by applying firm pressure with the index finger as it moves cephalad from the coccyx.

1. Place the patient in a lateral or prone position (with pillow under pelvis and hips internally rotated, if prone). In the lateral position, the dependent leg is flexed slightly, while the nondependent leg is flexed to a greater degree (until the knee contacts the bed).
2. Advance the needle at a 45° tilt (relative to the skin surface).
3. A distinct "pop" or "snap" is felt when the needle pierces the sacrococcygeal membrane.
4. If the dorsal aspect of the ventral plate of the sacrum is encountered, withdraw the needle slightly, decrease the

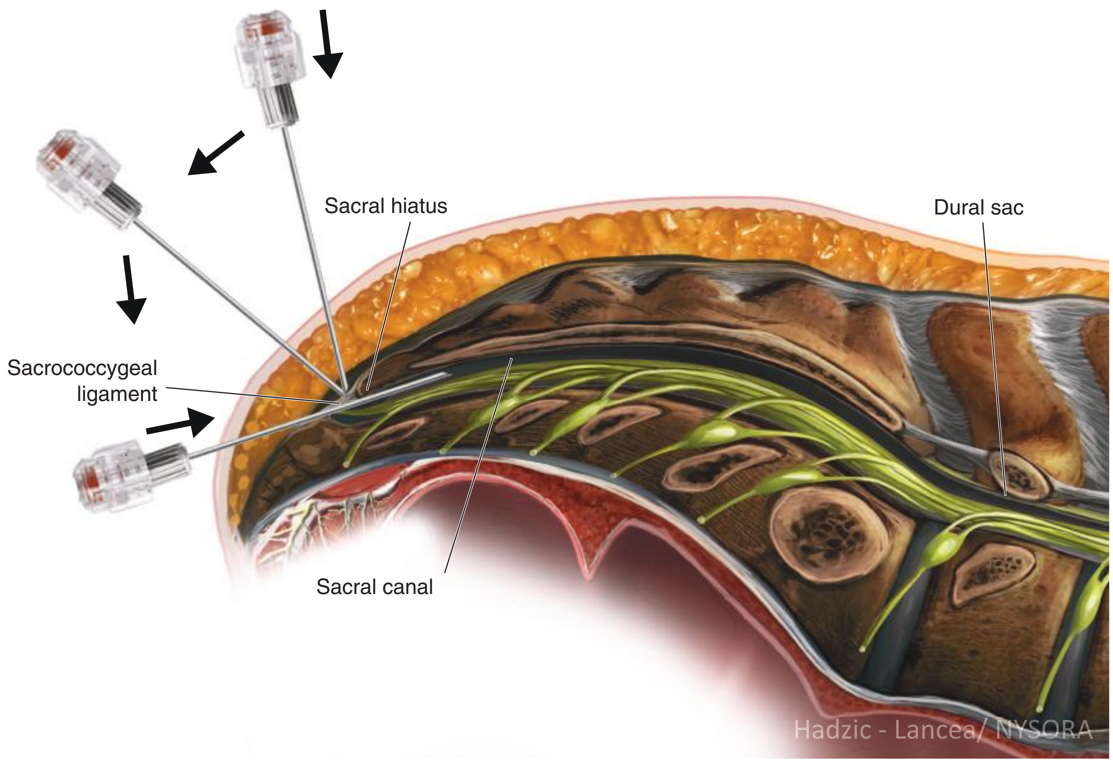

FIGURE 24–25. Caudal approach for epidural catheter placement.

angle of insertion, and advance again. The needle angle is lowered until it is almost flat against the skin (ie, parallel to the coronal plane) for male patients. Female patients may require a 15° tilt.

5. After LOR is encountered, advance the needle slightly into the caudal canal. Advancing too far may lead to ADP or unintended intravascular injection or epidural vein cannulation during catheter placement. If LOR is equivocal, several milliliters of saline can be injected through the caudal needle while palpating the skin overlying the sacrum. The needle is likely positioned correctly if a skin bulge does not develop.
6. Aspirate for blood or CSF before injecting LA.
7. An epidural catheter can be inserted through the needle and advanced to the desired level.

Cervical Epidural Blockade

Single-shot or continuous cervical epidural techniques are used for a variety of surgical and pain procedures, including carotid endarterectomy, thyroidectomy, and chronic neck pain conditions. Both the midline and paramedian approaches are used to perform cervical procedures, although fluoroscopic guidance is becoming increasingly common. Cervical epidural blockade can be initiated in the prone, lateral, or sitting position. The prone position is used most commonly for fluoroscopic-assisted procedures, although the sitting position can be used. Whichever position is used, flexion of the neck serves to increase the distance from the ligamentum flavum to the dura mater, increasing the margin of safety for these procedures, and to expand the interlaminar space.

As in the case of lumbar and thoracic epidural procedures, both the LOR and the hanging drop techniques are suitable methods to identify the epidural space. Either air (preferably a small volume) or saline (with or without an air bubble) can be used for LOR. However, the ligamentum flavum is discontinuous at midline in the cervical region in a large percentage of patients, contributing to a false LOR. Also, it is important to bear in mind that the ligamentum flavum is thinner at this level (1.5–3 mm) than at the lumbar and thoracic levels.

In the cervical region, the C7–T1 interspace is widest and easiest to access. In addition, the depth from the skin to the epidural space is larger at this interspace, and the distance from the epidural space to the dural sac is greater than at other cervical levels. However, using palpation and surface landmarks to identify the C7–T1 level is not always reliable; the vertebra prominens (presumed to be C7) is not uncommonly confused with C6 and T1 in certain patient populations. Single-shot injections at this level should be administered slowly. For continuous catheter techniques, the catheter is usually threaded no more than 2–3 cm.

Initiation and Management of Epidural Blockade

Test Dose

Before administering medications through the epidural catheter, subarachnoid, intravascular, and subdural placement should be ruled out. Although rare, catheter migration may occur after initial confirmation that the catheter is in the epidural space; each bolus should be preceded by confirmation of proper catheter location.

Although the efficacy of LA with epinephrine in detecting misplaced catheters has been questioned, many clinicians still routinely rely on the pharmacologic test dose. The classical dose combines 3 mL of 1.5% lidocaine with 15 µg of epinephrine. The intrathecal injection of 45 mg of lidocaine should produce a significant motor block if the catheter is in the subarachnoid space, although recent evidence suggests that this is not always reliable.[219] A change in heart rate of 20% or greater (or, alternatively, an increase in heart rate of 10 to 25 beats per minute) within 1 minute suggests that the catheter has been placed in (or has migrated into) a vessel and should be replaced. If the heart rate does not increase by 20% or greater or if a significant motor block does not develop within 5 minutes, the test dose is considered negative. Exceptions to this rule have been observed in laboring patients, anesthetized patients, and patients receiving β-adrenergic blocking agents. Relying on ECG changes after the test dose and the use of nerve stimulators[220] have been advocated as alternative methods to confirm epidural placement, although these methods also have shortcomings.

The safety and efficacy of the traditional test dose is debated in the literature. In laboring patients, a change in heart rate attributed to the epinephrine may in fact be due to a painful contraction, contributing to a false-positive interpretation. Alternatively, a true-positive test result in this patient population can result in an epinephrine-induced decrease in uterine blood flow. Patients with HTN, including women with preeclampsia, can experience a severe increase in blood pressure that may not be well tolerated after an intravenous dose of 15 µg of epinephrine. Volatile general anesthetics may interfere with the response to epinephrine and contribute to a high percentage of false-negative results in children, who are most commonly anesthetized during epidural placement. In patients on β-adrenergic blocking agents, heart rate changes may not be reliable. An increase in systolic blood pressure greater than 20 mm Hg has been used as an indicator of intravascular injection in this patient population.

Additional studies are needed to determine the optimal strategy to detect intrathecal and intravascular catheter placement. Fortunately, with the widespread use of low-concentration LA infusions for epidural analgesia, the risk of systemic LA toxicity is vastly reduced; the utility of a traditional test dose to evaluate for intravascular cannulation in this setting is limited. In addition, epidural catheter design innovations over the past several decades, particularly the introduction of flexible catheters, have contributed to a marked decrease in the incidence of both intrathecal catheter migration and epidural venous cannulation or migration. Nonetheless, incremental dosing of LA (ie, 3- to 5-mL aliquots), with simultaneous aspiration for blood and CSF and careful observation, is required when dosing an epidural. In the future, new methods of detecting misplaced catheters, such as acoustic signal guidance, nerve stimulation, and ultrasound-guided insertion, may replace the classical test dose.

Dosing Regimen

After the epidural catheter has been aspirated to check for blood or CSF or after a negative test dose, the catheter can be dosed to provide analgesia or anesthesia. As mentioned, LA concentration determines the density of block, while the volume and total dose of LA determine the spread. As a general guideline, the initial loading dose can be determined as follows: 1–2 mL of LA per segment to be blocked in a lumbar epidural, 0.7 mL per segment for a thoracic epidural, and 3 mL per segment for a caudal epidural. The loading dose should be administered through the catheter in 3- to 5-mL aliquots at 3- to 5-minute intervals, permitting time to assess the patient's response to dosing and to avoid systemic toxicity. Appropriate loading doses for postoperative analgesia include 10 mL of 0.2%–0.25% bupivacaine, levobupivacaine, or ropivacaine with or without adjuvants; however, patients may experience varying degrees of motor block. Recent evidence suggests that higher volumes of lower-concentration LAs may provide better spread and improved analgesia.[221] Up to 20 mL of 0.0625%–0.125% bupivacaine or the equipotent dose of ropivacaine may be administered incrementally as a loading dose. Higher-concentration LAs are required for surgical anesthesia. Up to 20 mL of 2% lidocaine, with or without epinephrine 1:200,000 and sodium bicarbonate, or 15 mL of 0.5% bupivacaine or ropivacaine may be used to initiate epidural anesthesia in the lumbar region.

Maintenance of the desired level of anesthesia can be accomplished through intermittent or continuous dosing after the initial loading dose. With manual boluses, one-quarter to one-third of the initial amount can be administered at timed intervals, depending on duration of action of the initial LA (ie, short, intermediate, or long acting), although several maintenance regimens are appropriate. Manual boluses are usually given during prolonged surgery; a continuous infusion, however, can be started after the initial bolus to maintain surgical anesthesia. Continuous infusions require the same diligent attention to the patient as any other anesthetic. The usual infusion rate is between 4 and 15 mL/h. The wide range is usually dependent on the age, weight, extent of sensory or motor blockade desired in a particular patient; site of catheter insertion; and the type and dose of LA. Thus, individualization is necessary, and a fixed rule cannot be applied for this purpose.

Patient-controlled epidural analgesia (PCEA), most commonly with infusions of low-concentration LAs and opioid adjuncts, are increasingly used for postoperative analgesia and for laboring patients. A demand bolus at timed intervals, with or without a loading dose and a background infusion, can be programmed to optimize patient comfort with less LA consumption.[222] Pumps that deliver automated mandatory boluses at timed intervals, with or without a basal infusion, have been developed, although they are not yet widely available.

For thoracic epidural blockade, several dosing regimens can be used to minimize hemodynamic changes and respiratory impairment (in awake patients). An initial dose of 3 to 6 mL of dilute bupivacaine 0.125%–0.25% or 0.1%–0.2% ropivacaine with or without fentanyl, hydromorphone, or preservative-free morphine can be followed by 3 mL of 0.25%–0.5% bupivacaine every 30 min. An alternative regimen is as follows: Administer a loading dose with 3–6 mL of 0.125% bupivacaine or 0.1%–0.2% ropivacaine with an opioid (fentanyl 2 μg/mL or hydromorphone 20 μg/mL) at least 30 minutes before the end of the case, as tolerated. Start an infusion of bupivacaine 0.0625% or 0.1% ropivacaine with fentanyl or hydromorphone at 3–5 mL/h before the patient leaves the operating room.

The level and duration of epidural anesthesia depends primarily on the injection site and the volume and concentration of the drug. Other factors such as age, pregnancy, and sex are less important factors but need to be considered. The addition of fresh epinephrine and 8.4% sodium bicarbonate to lidocaine, mepivacaine, and chloroprocaine will decrease the latency, improve the quality, and prolong the duration of the block. Epinephrine is less effective with the long-acting LAs. Adding bicarbonate to ropivacaine and bupivacaine can cause precipitation. The addition of opioids (eg, fentanyl) has been shown to improve the quality of the block without any effect on duration.

Top-Up Dosing

Repeat doses, commonly referred to as "top-ups," should be administered before the level of the block has receded more than two dermatomes. One-quarter to one-third or more of the original loading dose of LA can be administered for each repeat dose, although different top-up doses may be required for different clinical scenarios. For example, if the patient is comfortable but the sensory level is not adequate, a high-volume, low-concentration LA top-up may be appropriate. This may also be the case if the blockade is unilateral or patchy but the patient desires to maintain motor strength. However, if the patient requires a denser block for surgical anesthesia or for the second stage of labor, for example, less volume of a higher-concentration LA may be a better choice. Overall, the anesthesiologist must have a working knowledge of the characteristics of the LA used to properly implement a redosing protocol.

Problem Solving

Epidural placement presents unique challenges that are directly related to practitioner experience, the clinical scenario, and patient characteristics, among other things. Most of these problems can be overcome if the clinician recognizes the problem, is familiar with vertebral column anatomy, and knows how to make adjustments in technique (Table 24–27).

Difficulty Identifying the Epidural Space

Several troubleshooting measures may help if equivocal LOR occurs while trying to identify the epidural space. First, ensure that the LOR syringe is tightly connected to the epidural needle. If using the LOR to air technique, next put 2–3 mL of saline into the LOR syringe and push gently (ie, with the little finger). If using LOR to saline, omit the bubble for this step. The saline will flow easily if the tip of the epidural needle is in

TABLE 24–27. Problem solving during initiation of epidural blockade.

Problem	Possible Explanation	Action
Needle floppy; needle angles laterally	Entry off midline; missed supraspinous ligament	Reassess midline; redirect needle
Bone contact at < 2 cm	Contacted spinous process; spinal flexion inadequate	Reidentify interspace; place needle in caudal region of interspace
Bone contact at ≥ 4 cm	Needle entry too lateral; contacted lamina	Redirect needle toward midline
Bony resistance throughout	Ossified ligaments; arthritic spine	Consider paramedian approach
Inability to advance catheter	False loss of resistance; narrow epidural space; needle too close to dura mater; obstructed needle orifice	Fluid predistention; rotate needle bevel; use stiffer catheter; advance epidural needle slightly; attempt new placement at different interspace; withdraw needle to ligamentum flavum and readvance
Heme in catheter	Epidural vein cannulation; needle entry too lateral; engorged epidural veins	Withdraw catheter 1–2 cm and flush with saline; perform new placement if heme persists; consider initiating epidural procedure in lateral position
Warm, clear fluid return in needle or catheter	Accidental dural puncture; intrathecal placement	Distinguish cerebrospinal fluid from saline or local anesthetic; if cerebrospinal fluid, consider continuous spinal or new placement at different interspace
Pain/paresthesia on catheter insertion	Catheter advanced > 6 cm into epidural space; catheter near nerve root	Withdraw catheter to < 6 cm in epidural space (2–3 cm for short surgical procedures); perform new placement if pain persists
Inability to palpate spinous processes	Obesity; severe arthritis; patient with previous back surgery	Optimize patient position; consider midline approach for obese patients; use long finder needle to help identify bony landmarks; consider placement in lateral position if patient unable to flex spine; use ultrasonography
Inability to flex spine	Elderly; arthritis; patient with previous spinal instrumentation	Consider paramedian approach; consider placement in lateral position
Curvature of spine	Scoliosis	Use ultrasonography; if possible, perform procedure below level of curvature (otherwise direct needle into curve)

the epidural space but will encounter resistance if the needle tip is in soft tissue. If resistance is met, continue injecting the saline into the soft tissue and then resume the original LOR technique. Often, the familiar feedback from the LOR syringe returns after saline has dissipated throughout the soft tissue planes.

Another method to distinguish between soft tissue and the epidural space during the LOR to saline technique is to place a small bubble in the LOR syringe. The bubble should compress to varying degrees when the epidural needle is in soft tissue or ligament but will inject effortlessly if the needle is in the epidural space.

If LOR is still equivocal, insert a 25- or 27-gauge spinal needle through the epidural needle to puncture the dura. If CSF is visible in the spinal needle, the epidural needle is properly placed. The absence of CSF indicates that the epidural space has not yet been encountered or that the epidural needle is off midline, in the lateral epidural space.

If LOR remains equivocal, attempt to thread the catheter. Many catheters, particularly flexible or wire-reinforced versions, will not advance if the epidural needle is not fully in the epidural space.

Paresthesias During Epidural Needle or Catheter Placement

Patients not uncommonly report paresthesias during epidural procedures, particularly on direct questioning by the clinician. Because a paresthesia indicates that the needle or catheter is near a nerve, the needle should be withdrawn and redirected if the sensation persists. Alternatively, the epidural procedure can be initiated at another interspace. Most often, however, the needle can simply be redirected away from the side where the paresthesia was detected. During catheter placement, fluid predistention may help to reduce the incidence of paresthesias, although the data are conflicting. Threading the catheter no more than 5–6 cm appears to reduce the risk of paresthesias. The use of flexible catheters and, in particular, wire-reinforced catheters also appears to reduce the incidence of paresthesias. If a paresthesia is transient, it is acceptable to continue advancing the needle or threading the catheter.

Accidental Dural Puncture

Accidental dural puncture complicates an estimated 1% of epidural procedures, although the reported incidence varies substantially in the literature. Management options include placing a continuous spinal catheter or withdrawing the epidural needle and repeating the epidural procedure at a different interspace. Whether a spinal catheter is placed or a new epidural placement is performed, the choice should be made quickly to avoid excessive egress of CSF through the large-bore epidural needle. A continuous spinal technique may have the slight advantage of reducing the incidence of PDPH and the need for an EBP (see discussion that follows), although the data are limited and conflicting.[223,224] In cases in which identification of the epidural space was difficult or with high-risk patients (eg, obese parturients with a high likelihood of conversion to cesarean delivery and surgical patients with anticipated difficult airways), placing a continuous spinal catheter may also be advantageous. This option avoids the risk of a second dural puncture and has been reported to provide reliable analgesia and anesthesia, although the data are conflicting. Disadvantages of threading a continuous spinal catheter include the risk of an accidental injection of large doses of LA intended for the epidural space and, possibly, an increased risk of infection. Protocols should be in place to alert all providers when a spinal catheter has been placed.

If the practitioner elects to place the epidural at another interspace, he or she incurs the risk of a second ADP. Also, there is a concern for LA passage from the epidural to the subarachnoid space via the dural breach, resulting in a higher-than-anticipated block. Although it may not be necessary, it is reasonable to reduce the basal rate for continuous or PCEA pumps; as always, use caution when injecting boluses of LA or epidural morphine. The evidence does not support the use of the epidural catheter for a prophylactic EBP,[225] although more recent studies may demonstrate some benefit. More elaborate considerations of the anatomy, pathophysiology, and treatment of PDPH are discussed in Chapter 27.

Difficulty Threading the Catheter

Difficulty threading the catheter is not uncommon, even if the needle is properly engaged in the epidural space. This problem is more common with flexible, soft-tipped catheters. Troubleshooting measures include confirming that the epidural needle is properly positioned in the epidural space (see previous discussion); injecting several milliliters of saline to "open" the epidural space; advancing the epidural needle slightly so that the entire bevel is engaged in the epidural space (the LOR syringe with saline without an air bubble should be attached during this step); rotating the bevel of the epidural needle; inserting a different, less-flexible catheter; retracting the needle to the ligament and identifying the epidural space again; and repeating the epidural procedure at a different spinal level. Occasionally, the epidural needle is plugged with tissue debris that blocks the passage of the catheter. Replacing and then removing the stylet may serve to remove the obstructing debris. The subatmospheric pressure is variable in the lumbar region; asking the patient to take a deep breath is unlikely to facilitate catheter threading, particularly when with flexible, wire-reinforced catheters. Overall, performing a new placement at another interspace appears to confer less risk of ADP than rotating the needle or cautiously advancing the epidural needle. If electing to start over at another interspace, withdraw the needle and the catheter simultaneously to avoid shearing of the catheter.

Unilateral Block

After an epidural has been dosed adequately, the patient may complain that one side is densely blocked, while the opposite side has intact pain and motor function. The most common explanation for a unilateral block is that the catheter has advanced too far into the epidural space, permitting the tip of the catheter to enter the intervertebral foramen or be in close proximity to a nerve. Current data suggest that there is no indication to advance a catheter (either single end hole or multiorifice) more than 6 cm into the epidural space. If a unilateral block persists despite appropriate depth of insertion, consider pulling the catheter back 1–2 cm, leaving 3–4 cm (2–3 cm for short procedures) in the epidural space. If the patient remains uncomfortable despite catheter manipulation, place the patient in the lateral position with the unblocked side down and administer several milliliters of dilute LA. If these maneuvers have no effect, replace the catheter.

Blood in the Epidural Needle or Catheter

Epidural vein cannulation is not uncommon, although the incidence has declined substantially with the widespread use of flexible catheters. The epidural veins lie primarily in the anterior epidural space, cordoned off by the posterior longitudinal ligament and its fascia. A bloody tap may be an indication that needle or catheter insertion is too lateral and should be redirected toward midline. Other measures to minimize the risk of epidural vein cannulation during catheter insertion include the use of wire-reinforced catheters, the administration of fluid to open the epidural space prior to threading the catheter, and avoiding catheter insertion beyond 5–6 cm, among others (see Local Anesthetic Systemic Toxicity). If blood returns through the catheter despite these measures, the catheter can be withdrawn slightly and flushed with saline. This can be repeated until either the blood ceases to return or there is insufficient length of catheter in the epidural space, at which point the catheter must be replaced.

Pain Despite Adequate Block Height and Density

Persistent pain despite adequate block height and density may be a result of incomplete blockade ("window" of pain), "patchy" blockade, or poor sacral spread. A window of pain in which a distinct, small area remains unblocked despite an otherwise dense block may be difficult to troubleshoot. It is reasonable to administer top-ups and turn the patient with the window side of the catheter down. Injecting opioids into the epidural space may also help. However, performing a CSE technique that provides density from the spinal portion or replacing the epidural at another interspace may be required. Extreme caution should be exercised when deciding to perform CSE anesthetic in case of failed epidural anesthesia as there may be a higher risk of high spinal anesthesia. Wherever possible, a continuous spinal catheter with gradual dosing of the spinal anesthetic should be considered.

A "spotty" or "patchy" block may result from the injection of air when using the LOR to air technique, from individual anatomic variations that contribute to "missed" dermatomes, or from catheter migration. Administering additional LA, with or without an opioid, after a sufficient amount of time has elapsed since the initial dose is appropriate. It may also help to withdraw the catheter 1–2 cm and place the patient with the less-blocked side in the dependent position. However, it is also reasonable to replace the catheter, particularly if multiple top-ups have been administered and if there is a high likelihood of conversion to surgical anesthesia.

In the case of poor sacral spread, the following measures may help: Raise the head of the bed and redose the catheter with a more highly concentrated LA; administer 100 µg of epidural fentanyl to improve the quality of the block; or inject preservative-free neostigmine 500–750 µg or clonidine 75 µg epidurally. Replacing a stand-alone epidural with a CSE also improves sacral analgesia, as the sacral nerve is large and occasionally difficult to block with LAs administered in the epidural space.

Inadequate Analgesia Despite Fully Dosed Epidural Catheter

Most often, the best strategy is to replace the epidural catheter. To assess whether an epidural is functioning properly, feel whether both legs are warm to touch (LA-induced vasodilation should make the lower extremities warm if the epidural is properly placed and fully functioning). Assess also whether the patient has decreased temperature perception and decreased response to pinprick in the dermatomes that correspond to the expected sensory blockade. Consider administering a definitive dose of LA (eg, 5–10 mL of 2% lidocaine with or without epinephrine in incremental doses) to determine whether the catheter is functioning, provided that the resulting motor blockade is not contraindicated. Evaluate the patient's motor strength and temperature and pain perception after each dose. Monitor vital signs for any indication of sympathectomy-induced hypotension. It is advisable not to administer more than 10 mL of LA if the catheter remains equivocal; removing the catheter and performing a spinal anesthetic incurs the risk of a high or total spinal if an excessive amount of LA has already been administered epidurally. Recent evidence suggests that the number of top-ups is a reliable indicator of whether an epidural used for analgesia can be successfully used for surgical anesthesia.[226] If several top-ups have been administered and the degree of analgesia remains equivocal, the catheter should be removed and replaced.

Dissipating Block Requiring Larger Doses

This problem occurs for several possible reasons. Patients who received CSEs with either spinal fentanyl or a combination of opioid and LA may experience an abrupt transition from relief to an inadequate epidural block, particularly if the spinal anesthetic has resolved before a sufficient volume of the epidural infusion has accumulated. Increasingly larger doses of LA per epidural may be required to compensate for the inadequate epidural loading dose and to meet high patient expectations after experiencing the comfort of the spinal portion. Alternatively, if the epidural catheter has been used for analgesia and has been dosed frequently, tachyphylaxis to the LA can occur. Another possibility is that the catheter has migrated into a vessel (see previous discussion) or become completely dislodged from the epidural space. If the catheter remains in its initial insertion site, administer a bolus of higher-concentration LA and increase the infusion rate (if continuous). Consider adding an opioid or clonidine to enhance the quality of the block.

Failed Epidural Analgesia

The problem of failed epidural analgesia is often seen in obstetrics. An epidural catheter is placed and dosed, but the patient remains uncomfortable. More LA is administered, with subjective improvement. Subsequently, the patient is taken to the operating room for cesarean delivery, which requires a dense T4 sensory level, and the block is inadequate.

Several options exist if an epidural fails despite troubleshooting measures. In elective situations, the epidural catheter can be replaced, preferably at a different interspace, and cautiously redosed to decrease the risk of high epidural blockade. For more urgent procedures, a CSE can be performed. A reduced dose of spinal medication is necessary if a large volume of epidural LA was administered while troubleshooting or if the patient has a partial block. With a CSE, the sensory level can be raised as necessary with supplemental epidural dosing. A reduced dose single-shot spinal may also be appropriate if speed of onset is a concern. However, replacing a failed epidural with a spinal technique incurs the risk of high or total spinal anesthesia. Infiltrating the skin and subcutaneous tissue with LA or performing a peripheral nerve block, depending on the time remaining in the surgery and the type of surgery, may provide alternatives. Conversion to GA is appropriate if there is insufficient time to repeat the neuraxial technique or to place a peripheral block or if performing another neuraxial procedure presents undue risk.

Optimally, a nonfunctioning epidural will be recognized and replaced before large doses of LA have been administered and before alternative anesthetic techniques are required. The number of boluses required to maintain adequate analgesia is a reliable indicator that an epidural used for analgesia may fail on conversion to surgical anesthesia. As a general rule, if catheter function remains equivocal during dosing, stop injecting after a predetermined volume (eg, 10 mL) to ensure that performing another regional technique does not lead to high or total spinal anesthesia or to LA systemic toxicity (LAST).

Difficulty Removing the Epidural Catheter

Occasionally, resistance is met on attempted removal of the epidural catheter. Using excessive force may lead to catheter breakage and retained catheter fragments. In the event of catheter entrapment, placing the patient in the lateral decubitus position or in the original insertion position and applying continuous, gentle traction may facilitate removal. Sometimes, positioning the patient in the identical position in which the catheter was inserted may be necessary. Taping the catheter to the skin under traction and reattempting removal later, threading a stylet, and injecting saline into a wire-reinforced catheter have also been observed to assist in removal. Reports of neurologic sequelae from retained fragments are rare, suggesting that surgical removal is unwarranted in the asymptomatic patient.

COMPLICATIONS AND COMMON SIDE EFFECTS

Complications of epidural blockade can be classified broadly as either drug or procedure related. Potential drug-related complications include LAST, allergy to LAs, direct LA-induced nervous tissue injury, and drug or mode of delivery errors. Procedure-related complications may be mild to moderate or transient, such as back pain, pneumocephalus, and PDPH. Potentially life-threatening complications include subdural injection of LAs, total or high spinal, infectious or aseptic meningitis, cardiac arrest, SEA, epidural hematoma formation, and permanent neurologic injuries. In contrast to complications, several known or expected side effects accompany initiation and maintenance of epidural blockade without adversely affecting long-term patient outcomes. This section reviews both the complications and the common side effects associated with epidural blockade, with emphasis on risk factors, preventive measures, and treatment. Several of the complications are covered in greater detail elsewhere in this textbook.

Local Anesthetic Systemic Toxicity

Local anesthetic systemic toxicity results from excessive plasma concentration in the blood due to unintentional intravascular injection or, less commonly, systemic absorption from the injection site.[227] Direct intravascular injection can occur with unintentional epidural vein cannulation during catheter placement or subsequent catheter migration into a vessel. Risk factors for intravascular cannulation include trauma to the epidural vessels during block initiation, the use of stiff catheters, pregnancy, and patient positioning during epidural placement, among others (Table 24–28). The risk of epidural vein cannulation in obstetric patients may be reduced with initiation of epidural blockade in the lateral position, the use of wire-reinforced catheters, the use of a single end-hole (versus multiorifice) catheters, fluid predistention with normal saline prior to threading the catheter, and limiting the depth of catheter insertion to 6 cm or less (Table 24–29).[228] Limiting the number of attempts at epidural placement; avoiding the lateral epidural space, where vessel puncture is more likely; and avoiding direct administration of LAs through the epidural needle may also reduce the risk of direct intravascular injection.

TABLE 24–28. Risk factors for epidural vein cannulation.

Trauma to epidural vessels during block initiation
Multiple attempts at placement
Stiff, nonflexible catheter
Engorged epidural veins (eg, pregnancy)
Sitting position

Although the data are inconclusive regarding the role of catheter material and tip configuration, the use of flexible catheters may reduce the risk of subsequent catheter migration into a vessel. Because of preferential efflux from the proximal port of multiport catheters during continuous infusion techniques, there remains a remote possibility that a distal port may migrate into a vessel unnoticed until a manual bolus is administered. This can be avoided with the use of a single-orifice catheter.

Dosing the epidural catheter in 3- to 5-mL increments with frequent negative aspiration for blood and CSF is recommended to detect misplaced catheters. Most commercially available epidural catheters have distal and proximal "flashback" windows to facilitate visualization of blood or CSF on aspiration. The use of a transparent dressing and tape improves visualization of these windows. Although the use of the traditional epinephrine test dose is controversial, a test dose may be used to assess whether the catheter tip is in a blood vessel.

The degree of systemic absorption is determined in part by the site of injection, the dose and concentration of LA injected, properties of the LA administered, the vascularity of the injection site, and the presence or absence of epinephrine in the solution. Certain conditions and comorbidities, such as advanced age, liver failure, low plasma protein concentration, severe cardiac dysfunction, ischemic heart disease, cardiac conduction abnormalities, and metabolic and respiratory acidosis, may also predispose patients to systemic toxicity.[229] In general, systemic absorption from the epidural space is less likely to

occur than from areas of higher vascularity. The areas of highest plasma concentration from absorption in descending order are as follows: intercostal, caudal, paracervical, epidural, brachial plexus, and sciatic/femoral (Table 24–30). However, trauma to the vessels during initiation of the epidural procedure may lead to more rapid intravascular absorption from the epidural space than anticipated. The addition of epinephrine to the LA solution diminishes systemic absorption but may not be appropriate in highly vascular areas, where systemic absorption is likely, or for all patient populations. Epinephrine may also unnecessarily prolong the duration of action of LAs. Toxicity associated with systemic absorption of LAs can be reduced by careful patient selection, remaining vigilant for signs and symptoms of toxicity, limiting the total dose of LA administered, use of appropriate LA concentrations, and, possibly, by using the newer amide LAs, such as ropivacaine and levobupivacaine. Racemic bupivacaine has been associated with greater cardiotoxicity due to enhanced binding to and slower dissociation from ion channels in the myocardium.

Early CNS signs and symptoms of LA toxicity include lightheadedness, dizziness, tinnitus, perioral numbness and tingling, slurred speech, diplopia or blurred vision, restlessness, and confusion. Muscle twitching, tremors of the facial muscles and extremities, shivering, and generalized seizures occur at higher plasma concentrations, followed by global CNS depression, as manifested by drowsiness, unconsciousness, and respiratory arrest. Acidosis, hypercarbia, and hypoxia both predispose to and exacerbate CNS toxicity. Cardiovascular manifestations at high plasma concentrations include hypotension, bradycardia and other arrhythmias, and cardiac arrest (Table 24–31).

When LAST is recognized or suspected, refrain from administering additional LA and call for assistance. Treatment requires immediate attention to airway support, suppression of seizure activity, and preparedness for cardiopulmonary resuscitation and, possibly, CPB. Current guidelines recommend limiting individual epinephrine doses to less than 1 μg/kg during resuscitative efforts. Lipid emulsion (20%) therapy should be commenced with an initial loading dose of 1.5 mL/kg, followed by a continuous infusion of 0.25 mL/kg/min for a minimum of 10 minutes after circulatory stability has been restored.[229] Refer to Chapter 65 for a more detailed discussion of LAST.

Allergy to Local Anesthetics

True allergic reactions to LAs can occur, but fortunately are rare. Most documented reactions are not mediated by immunoglobulin E (IgE) and can be attributed to reactions to other agents administered concomitantly (eg, additives, epinephrine, preservatives, antibiotics) or to a delayed type IV hypersensitivity reaction (ie, mild contact dermatitis). Alternatively, reported reactions may be due to anxiety, a vasovagal episode, endogenous sympathetic stimulation, or an adverse patient response to the surgical, dental, ophthalmic, or obstetric procedure itself. Based on an extensive review of the literature, Bhole and colleagues estimated the prevalence of true IgE-mediated allergy to be less than 1%.[230] An immune complex–mediated reaction associated with reduced or depleted serum complement levels is even rarer.

When a patient reports a history of allergy to LAs, it is important to elicit a detailed history, including which LA was implicated, the dose and route of administration, the reaction that occurred, and the clinical setting. True allergic reactions may present with a range of dermatologic, cardiac, or respiratory signs and symptoms, such as hives, pruritus, angioedema, hypotension, shock, and bronchospasm. Although the current literature suggests that allergic reactions to amide LAs are more common than reactions to ester-linkage-type LAs, this may reflect the current preferential use of the former. Historically, adverse reactions, especially contact dermatitis, have been reported more often with ester agents, such as procaine, benzocaine, tetracaine, and chloroprocaine. This may be partly attributable to the fact that ester compounds are derivatives of para-aminobenzoic acid (PABA), an additive found in many household items (eg, lotion, sunscreen, cosmetics); previous exposure to PABA has been hypothesized to sensitize individuals to ester LAs. Alternatively, methylparaben, a preservative in both amide and ester LAs that is metabolized to

PABA, may account for many of the reported allergic reactions. Cross-reactivity between the amide and ester groups has been reported, but is exceedingly rare and likely attributable to a common preservative. Cross-reactivity can occur between ester LAs and, less commonly, between amide LAs.

Reliable tests to identify sensitivity to LAs are currently lacking. The presence of serum mast cell tryptase can confirm an anaphylactic reaction in the immediate aftermath, while skin prick testing, intradermal testing, and subcutaneous challenge tests may help identify the causative agent. Management of an allergic reaction to LAs includes removing the offending agent; early administration of intravenous epinephrine to treat hypotension and cardiovascular collapse; airway support, if necessary; and, possibly, intravenous administration of histamine-1 and -2 receptor blockers, bronchodilators, and corticosteroids.

Arachnoiditis

Arachnoiditis is a rare disorder marked by inflammatory changes in the arachnoid mater. Although the precise mechanism remains unclear, fibrosis develops and adhesions form between the nerve roots and the membranes that surround the brain, spinal cord, and cauda equina. In chronic, adhesive cases, collagen deposits ultimately encapsulate the nerve roots, creating nerve root atrophy as a result of an interruption to the blood supply.[231] Trauma, surgery, infections, contaminants, disinfectants, contrast media, tumors, subarachnoid hemorrhage, and the subarachnoid administration of irritants (eg, steroids) can precipitate these inflammatory changes. Accidental intrathecal administration of large volumes of chloroprocaine containing the preservative sodium bisulfite has also been linked to arachnoiditis, although the role of the preservative has been called into question in recent studies.[232]

A link between epidural block or catheter placement and arachnoiditis has not been clearly established in the literature. No data exist on the risk of arachnoiditis with the use of the antiseptic solution chlorhexidine in humans[233]; nonetheless, it is prudent to keep the solution away from all drugs and equipment in the spinal and epidural kits and to permit it to dry before initiating neuraxial procedures. Chlorhexidine in alcohol remains the solution of choice for skin disinfection prior to initiation of central neuraxial blockade.

The clinical presentation of arachnoiditis is complex, with varied symptomatology, and may be delayed for several months. The most common clinical features are back pain that radiates to the lower extremities and increases on exertion; buttocks pain; muscle spasms; decreased range of motion of the trunk; sensory abnormalities; motor weakness or paralysis below the level of injury that does not typically progress; and urinary sphincter dysfunction (Table 24–32).[234]

Unfortunately, the mixed clinical presentation can lead to misdiagnosis, and arachnoiditis may be attributed incorrectly to spinal stenosis, lumbar disk disease, spinal tumors, or other compressive lesions of the spine. Diagnosis can be confirmed by myelography, computed tomography (CT), or MRI. Characteristic MRI findings show conglomerations of roots residing centrally in the dural sac, adhesions tethering the nerve roots peripherally, and soft tissue replacing the subarachnoid space.[235]

TABLE 24–32. Clinical presentation of arachnoiditis.

Back pain radiating to lower extremities, worsens with activity
Buttocks pain
Muscle spasms
Motor weakness/paralysis
Decreased range of motion of trunk
Urinary sphincter dysfunction

Unfortunately, significant neurologic improvement is unlikely with current therapies, including intravenous corticosteroids, NSAIDs, and antibiotic therapy. Deficits may progress to severe and permanent disability.

Backache

Back pain is a common postoperative complaint, with an incidence that ranges from 3% to 31% after nonobstetric surgery, regardless of the anesthetic technique.[236] Although the etiology is multifactorial, both postoperative and peripartum back pain are often attributed to neuraxial techniques when a temporal association exists.

Backache after epidural blockade is more common, more severe, and longer lasting than after spinal procedures. Local trauma, inflammation of the ligaments, needle puncture of an intervertebral disk, stretching of the joint capsules and ligaments beyond their physiologic range, and muscle spasm may account for some of the reported postepidural back pain. The use of larger needles, the insertion of catheters, and the increased volume of LAs, when compared with spinal techniques, may also play a role. Large epidural doses of 2-chloroprocaine containing the preservative EDTA have also been associated with back pain[237]; similar complications have not been observed with preservative-free 2-chloroprocaine. In a recent study, Hakim and colleagues identified the following independent risk factors for persistent (ie, ≥3 months) low-back pain after nonobstetric surgery with epidural anesthesia: multiple attempts at epidural placement, higher body mass index (BMI), surgery in the lithotomy position, and surgical time exceeding 2.5 hours.[238]

Back pain after epidural blockade is usually self-limiting and should resolve within 7–10 days. Patients should be encouraged to refrain from bed rest. NSAIDs, acetaminophen, or heat may provide symptomatic relief. If pain persists, progresses, or is out of proportion to what might be expected, other etiologies, such as TNS, herniated disk, spinal stenosis, arachnoiditis, sacroiliitis, musculoskeletal injury, nerve injury, epidural abscess, and epidural hematoma, should be considered. Prophylactic interventions that may help prevent back pain associated with epidural procedures include performing a field block to anesthetize the recurrent spinal nerves that innervate the interspinous ligaments and muscles prior to initiating epidural blockade[239]; adding NSAIDs to the LA used for skin infiltration[236]; and administering epidural dexamethasone.[240]

Despite the widespread association between musculoskeletal back pain and neuraxial procedures, studies of pregnant women who have received epidural analgesia for labor pain provide compelling evidence that back pain is unrelated to neuraxial techniques. Several randomized controlled trials and prospective cohort studies have shown that new, long-term postpartum back pain is not caused by intrapartum epidural analgesia.[241]

Postdural Puncture Headache

Postdural puncture headache is a common complication of spinal anesthesia, lumbar punctures ("spinal taps"), and epidural procedures complicated by ADP or unrecognized dural tear. The incidence of ADP is generally accepted to be at or below 1%; up to 80% of patients may experience PDPH following ADP. Although the precise mechanism remains poorly understood, signs and symptoms of PDPH appear to result from CSF leakage through the dural hole. In the upright position, the brain tissue sags in the cranial vault, creating painful traction on the dura, falx cerebri, cerebral blood vessels, tentorium, cranial nerves, and nerve roots.[242] This traction also contributes to the cranial nerve palsies that are not uncommonly seen in patients with PDPH.[243] Compensatory cerebral vasodilation in response to the decrease in CSF also appears to play a role in the genesis and severity of PDPH.

A universally accepted definition of PDPH is lacking in the literature. According to the International Headache Society, a PDPH develops within 5 days of a lumbar puncture, is usually accompanied by neck stiffness or subjective hearing symptoms, and resolves spontaneously within 2 weeks or after effective treatment with an EBP.[244] Clinically, patients commonly complain of a fronto-occipital headache that is mild or absent in the supine position and intensifies when the head is elevated. The pain may extend into the neck, shoulders, and upper extremities and may be accompanied by nausea and vomiting, dizziness, diplopia, tinnitus, blurred vision, nystagmus, and hearing loss. Cranial nerve involvement should prompt expeditious evaluation and treatment. The headache develops within 48 hours in the vast majority of cases (most commonly in the first 24 hours) (Table 24–33). Headaches that occur during or immediately after epidural procedures are more likely due to accidental injection of air during identification of the epidural space with the LOR to air technique (pneumocephalus). PDPH typically resolves spontaneously within 1 to 2 weeks but may last months or even years; a substantial percentage of patients may develop chronic headaches after ADP with a large-bore Tuohy needle.[245]

Risk factors for PDPH include younger age, female gender, lower BMI, pregnancy, pushing during the second stage of labor, the use of cutting versus atraumatic spinal needles, and the use of larger-gauge needles (Table 24–34). There is less-compelling evidence regarding the role of needle bevel orientation, the number of dural punctures, the approach used to enter the epidural space (paramedian vs. midline), patient positioning during initiation of the epidural procedure, and the technique used to identify the epidural space (LOR to air versus saline with or without an air bubble).

Several interventions for the prevention or treatment of PDPH have been proposed. There appears to be little benefit from conservative measures, such as bed rest and aggressive fluid administration. However, symptomatic relief may be obtained with analgesics, pharmacologic agents with vasoconstricting properties (caffeine, theophylline, sumatriptan), and, possibly, corticotropin (ACTH). In a quantitative systematic review of available evidence for measures to prevent PDPH, Apfel et al found that the administration of epidural morphine prior to removal of the catheter may confer some advantage, but this conclusion was based on one small randomized controlled trial.[246] In a recent meta-analysis, Heesen et al. suggested that insertion of an intrathecal catheter following ADP may protect against PDPH and may reduce the need for an EBP, but additional studies are warranted.[223] The evidence to date regarding the routine use of prophylactic EBP is not conclusive.[225] There are limited data to support epidural patching with normal saline, dextran 40, and gelatin and fibrin glue.

Epidural blood patch, preferably early in the course of the headache, remains the gold standard for treatment. Observational studies reported rapid recovery in over 90% of patients after EBP, although relief may be transient in a small percentage of these patients.[247] A well-designed, randomized controlled trial in neurology patients demonstrated that EBP offers complete resolution of symptoms in a large percentage of patients and reduces the severity of symptoms in those who do not experience complete resolution.[248] In addition, early treatment with an EBP

TABLE 24–33. Signs and symptoms of postdural puncture headache.

Use of larger-gauge needle

decreases the length of hospital stay and emergency room visits and permits patients to resume their activities of daily living sooner than otherwise feasible with expectant management.[249]

Prior to performing an EBP, other causes of headache, such as preeclampsia/eclampsia and meningitis, should be ruled out. In certain clinical scenarios, it may also be necessary to rule out elevated ICP. Using sterile techniques, the epidural space at or below the level of prior ADP is identified using LOR to normal saline. The air bubble is omitted due to the concern that air may enter the dural breach, leading to pneumocephalus. Up to 20 mL of the patient's blood (drawn aseptically) is slowly injected into the space; the clinician should stop injecting blood if the patient experiences moderate-to-severe pain or pressure in the lower back or neck region. Although the optimal volume of blood remains to be determined, injection of more than 20 mL appears to confer no additional benefit.[250] The patient typically remains supine for at least 1 hour after the EBP. Back pain and, less frequently, neck pain are commonly experienced during the procedure and, when severe, may alert the clinician to stop injecting blood. To minimize the risk of infections and related sequelae, both the acquisition of autologous blood and identification of the epidural space should be performed using strict aseptic techniques. For a more in-depth discussion of PDPH, refer to Chapter 27.

Subdural Injection

The subdural space has been described historically as a potential space between the normally closely adherent arachnoid mater and the overlying dura mater, although it may represent a cleft along the dural border cell layer that results only from direct tissue damage.[251] Injection of a small dose of LA into the area can have profound hemodynamic and sympatholytic effects.

Subdural injection is a relatively rare occurrence, with an estimated incidence of 0.1%–0.82% of epidural injections.[252] Clinical features that may help to distinguish subdural from epidural or spinal anesthesia include a higher-than-expected sensory blockade with poor caudal spread and sacral sparing; a higher-than-anticipated level of motor blockade of variable density; and a speed of onset that more closely resembles epidural anesthesia (10–20 minutes). Subdural injections commonly result in bilateral blockade, although unilateral or patchy blocks can occur, with more notable sensory and motor changes in the upper extremities and inadequate analgesia and anesthesia in the lower extremities. Patients may develop Horner syndrome (ptosis, miosis, and anhidrosis), facial and corneal anesthesia, and dyspnea. In addition, mild-to-moderate hypotension may develop (Table 24–35). Treatment may require cardiovascular and respiratory support, including the administration of intravenous fluid and vasopressors and, possibly, endotracheal intubation with mechanical ventilation. However, case reports have described the use of subdural catheters to attain surgical anesthesia.

TABLE 24–35. Clinical presentation of a subdural block.

Higher-than-expected sensory blockade
Poor caudal spread, sacral sparing
Higher-than-expected motor blockade of variable density
Blockade usually bilateral, but may be unilateral or asymmetric
Horner syndrome (ptosis, miosis, anhidrosis)
Facial and corneal anesthesia
Dyspnea
Hypotension

Total Spinal Anesthesia

Total spinal blockade, which complicates an estimated 1 in 1400 attempted epidural procedures[253] may result from unrecognized ADP with unintentional injection of an epidural dose of LA, the administration of a large dose of LA into the subdural compartment, and undetected migration of the epidural catheter tip into the subarachnoid space. It has also been observed when one hole of a multiorifice catheter is lodged in the subarachnoid space; with translocation of LA through an accidental or intentional dural breach; after CSE techniques; and after a failed epidural blockade is replaced with a spinal technique.[254]

Total spinal anesthesia usually develops within minutes of LA administration, although it may occur unexpectedly later with changes in patient positioning or after a previously functioning epidural catheter has migrated into the subarachnoid space. During total spinal blockade, the LA spreads high enough to block the entire spinal cord and, occasionally, the brainstem. Ascending sensory and motor changes develop rapidly, followed by profound hypotension, bradycardia, dyspnea, and difficulty phonating and swallowing. Unconsciousness and apnea may result from direct LA action on the brainstem, respiratory muscle paralysis, and cerebral hypoperfusion. Treatment includes airway support and, if necessary, endotracheal intubation; the administration of 100% oxygen; and hemodynamic support with intravenous fluids and vasopressors. Epinephrine should be used early and in escalating doses to stabilize the heart rate and blood pressure in unstable patients. As the block recedes, the patient will regain consciousness and control of breathing followed by recovery of motor and sensory function. The administration of sedation until the block regresses may be appropriate once the patient is stable.

Total spinal anesthesia can usually be avoided during continuous epidural catheter techniques by careful administration of LA in small, divided doses, with frequent aspiration and, possibly, the use of an epidural test dose. Patients should be monitored during top-ups, during incremental dosing to attain surgical anesthesia, and while on PCEAs. Unusual patient complaints and unexpected hemodynamic changes may warrant immediate removal and replacement of the catheter. If unintentional dural puncture is recognized during needle placement, the needle can be removed and placed at another interspace or a spinal catheter can be inserted. If ADP is recognized after catheter insertion, either proceeding with a continuous spinal technique or repeating the epidural procedure at another interspace is appropriate. A reduced dose of LA may be required if a catheter is successfully placed at a different spinal level after a prior dural puncture. If a spinal catheter is placed, the catheter should be clearly labeled, the infusion pump should be labeled and configured at a reduced dose, and all practitioners involved should be informed. Optimally, procedures and policies should be in place regarding management of spinal catheters.

Spinal Epidural Abscess

Spinal epidural abscess is a rare disorder that affects elderly and immunocompromised patients disproportionately.[255] Individuals with prolonged intensive care unit stays, intravenous drug users, and patients with bacteremia, DM, alcohol dependence, cancer, HIV, and end-stage renal disease are at increased risk compared with the general population (Table 24–36). In recent decades, the incidence of SEA has increased, in part due to the increase in spinal instrumentation, the rise of illicit drug use, and the aging population.[256,257]

An estimated 5% of SEAs are associated with epidural procedures.[258] Risk factors for this rare complication include extended epidural catheter infusions and localized or systemic infection at the time of initiation of the block. The site of epidural placement also appears to place some patients at higher risk for SEA formation, with thoracic and lumbar catheters implicated more often than cervical catheters.[256] Poor adherence to sterile technique and, possibly, multiple attempts at epidural placement may place patients at additional risk.

Bacteria gain access to the epidural space through either hematogenous spread (most commonly) or contiguous spread; the source of access is not identified in the remainder of the cases. *Staphylococcus aureus* and, increasingly, methicillin-resistant *S. aureus* (MRSA) account for the vast majority of the SEA cases. Pathogens that are less commonly involved include *Escherichia coli*, *Pseudomonas aeruginosa*, and *Staphylococcus epidermidis*, with the last more commonly associated with neuraxial procedures, including epidural blockade and epidural steroid injections. The infection appears to injure the spinal cord via direct mechanical compression or thrombosis (vascular occlusion from septic thrombophlebitis) or a combination of the two, although the precise mechanism has not been elucidated.

TABLE 24–36. Predisposing conditions for spinal epidural abscess.

Elderly	Steroid injection
Diabetes mellitus	Alcoholism
HIV/AIDS	Liver disease
Chronic steroid use	Renal failure
Adrenal insufficiency	Rheumatoid arthritis
Chronic epidural catheter	Cellulitis
Prolonged urinary catheterization	Psoas abscess
Indwelling vascular device	Intravenous drug use
Recent spinal instrumentation	Osteomyelitis

Early diagnosis, prompt treatment, and consistent follow-up are essential to avoid irreversible neurologic damage from SEA. The most common clinical symptoms are back pain, fever, and neurologic changes, such as leg weakness or sensory deficits, but a majority of patients do not present with this triad. Instead, patients may present with bladder dysfunction, sepsis, meningitis, paraplegia or quadriplegia, urinary tract infection (UTI), mental status changes, inflammation at the catheter site, headache, neck stiffness, or nausea and vomiting. Symptoms most commonly present within 7 days but may be delayed for 60 days or more.[259] Elevated white blood cell (WBC) count and elevated erythrocyte sedimentation rate (ESR) or C-reactive protein may also be present, but these laboratory findings are nonspecific. If SEA is suspected, gadolinium-enhanced MRI is the diagnostic tool of choice. Some investigators have proposed that MRI scanning be considered in patients who have received epidural catheters if systemic and local signs of infection (eg, pus or erythema at the epidural insertion site) develop, even in the absence of neurologic deficits.

Broad-spectrum intravenous antibiotic administration, ultimately tailored to blood or tissue cultures, without surgical drainage may be appropriate treatment for SEA in the absence of neurologic symptoms. However, prompt surgical intervention (decompressive laminectomy, debridement of infected tissue, and abscess drainage) may be required, depending on the clinical presentation. Most likely owing to a delay in diagnosis or an initial misdiagnosis, morbidity associated with SEA remains high at 33%–47%, while mortality is estimated to be 5%.[257] Neurologic status prior to intervention is the strongest predictor of final outcome.[260] There is also a strong association between poor outcome and age greater than 70 years, MRSA strain infection, and the presence of DM or adrenal insufficiency.[261]

The risk and long-term sequelae of SEA can be reduced with careful patient selection, maintenance of strict sterile techniques during initiation of epidural procedures, the administration of antibiotics prior to initiation of neuraxial blockade in patients with fever or localized infection, removal of indwelling catheters at the earliest sign of infection at the puncture site, and maintenance of a high index of suspicion in patients with risk factors who present with nonspecific neurologic complaints or local and systemic signs of infection, possibly several weeks after an epidural procedure.

Meningitis

Bacterial meningitis following epidural anesthesia is a rare event. Microorganisms can be transmitted via syringes, catheters, needles, infusion tubing, and medications injected into the epidural space, as well as from the clinician or patient. Similar infectious complications can occur with nonanesthetic procedures, such as EBP, myelography, epidural steroid injection, and diagnostic lumbar puncture. Most cases appear to be caused by contamination of the puncture site by organisms from the naso- or oropharynx of the health care provider. Less commonly, contaminants from incompletely sterilized skin and direct or hematogenous spread from an endogenous infectious site are implicated.[262] A dural puncture, such as in the setting of a CSE, spinal, or an ADP, is believed to place patients at higher risk by allowing transfer of blood-borne pathogens across the blood-brain barrier.[263] However, the incidence of bacterial meningitis remains low despite the increasing use of CSE and spinal techniques. Also, diagnostic lumbar puncture in the setting of bacteremia is rarely associated with meningitis. Additional risk factors include breaches in aseptic technique, reinsertion of the stylet that has been exposed to ambient air, difficulty performing the neuraxial procedure, and, relatedly, multiple attempts at spinal or epidural placement.

Signs and symptoms of meningitis include fever, headache, lethargy, confusion, nuchal rigidity, nausea/vomiting, photophobia, and Kernig sign (Table 24–37). Symptoms usually present within 6 to 36 hours after the anesthetic procedure. Because the initial clinical presentation is similar to that of a PDPH, the diagnosis of meningitis can be delayed. Meningitis can be distinguished from PDPH by the presence of a fever, mental status changes (ie, lethargy and confusion), and a headache that is not positional in nature. The diagnosis is confirmed with CSF analysis and culture with or without prior head CT. The CSF is often cloudy, with leukocytosis (predominantly neutrophils), elevated protein content, and low glucose concentration. Early diagnosis is essential. Common pathogens include *Streptococcus salivarius* and other strains of viridans streptococci, *S. aureus*, *P. aeruginosa*, *Neisseria meningitidis*, and *Enterococcus faecalis*. In many cases, no organism is isolated. Treatment of bacterial meningitis includes immediate empiric broad-spectrum antibiotic therapy, such as vancomycin with a third-generation cephalosporin, ultimately tailored to blood or CSF culture results. Neurologic sequelae may include cranial nerve palsies, hemiparesis, quadriparesis, and aphasia. If diagnosis and treatment are delayed, death may result. Adherence to full aseptic precautions, including removal of jewelry, hand washing, appropriate skin preparation with individual packets of antiseptic solution (preferably chlorhexidine with alcohol), the use of a sterile drape and dressing, and, at a minimum, the use of caps, sterile gloves, and face masks (changed between each patient encounter), is critical to minimize the risk of bacterial meningitis associated with neuraxial instrumentation. Alternatives to neuraxial techniques should be offered to patients at high risk for infectious complications, and patients with known or suspected bacteremia should be started on antibiotic therapy prior to neuraxial instrumentation.

Seizures
Focal neurologic deficits
Kernig sign
Brudzinski sign

Spinal Cord and Nerve Root Injury

Neurologic deficits can be caused by direct trauma to the spinal cord or spinal nerves, from spinal cord ischemia, from accidental injection of neurotoxic drugs or chemicals, or from hematomas or abscesses.[264] Fortunately, serious neurologic injury is an extremely rare complication of neuraxial anesthesia, with an estimated incidence of 0.03%–0.1%. Horlocker and colleagues evaluated the records of over 4000 patients who had received lumbar epidurals for thoracic surgery while under GA and found no cases of neurologic complications. In another extensive review of 45,000 patients undergoing epidural placement, 40 cases of neurologic injuries were reported. Of note, 22 of these patients experienced paresthesias during the epidural procedure.[265] There have been a few case reports of myelopathy and paraplegia occurring with thoracic epidurals placed in anesthetized patients, but these complications are exceedingly rare.[266] Most peripheral neuropathies associated with neuraxial techniques resolve spontaneously. Those that become permanent are usually limited to persistent paresthesias and limited motor weakness.

Cauda Equina Syndrome

Cauda equina syndrome (CES), a rare state of neurologic compromise due to lumbosacral root compression, is characterized by bowel and bladder dysfunction, low-back pain, perineal sensory loss and other patchy sensory deficits, unilateral or bilateral sciatica, and lower extremity motor weakness. It has been associated with trauma, infection, lithotomy position, and ischemic compression by a hematoma, abscess, tumor, prolapsed intervertebral disk, or spondylolisthesis.[267] CES has also been linked to direct neurotoxicity from large volumes or high concentrations of hyperbaric LAs in the sacral CSF. The nerve roots of the cauda equina have a poorly developed epineurium and limited blood flow and appear to be particularly susceptible to the pooling of LAs that may accompany continuous spinal infusions with microbore catheters, accidental intrathecal injection of large doses of LA intended for epidural anesthesia, and repeat intrathecal injections after failed spinal block.[268] Cases of CES have also been reported after single-shot spinals.[269]

Whether intrinsic neurotoxicity of LAs, microenvironmental factors, excessively large doses of LAs, the microbore catheter used for continuous spinal anesthesia, patient positioning, the surgical procedure, or a combination of these factors is primarily responsible for CES has not been fully elucidated in the literature. The US Food and Drug Administration (FDA) removed small-bore continuous spinal catheters from the market in the early 1990s after a series of reports of CES in association with their use.[270] However, continuous spinal anesthesia remains a useful technique. The use of lower concentrations of LAs, limiting the total dose of LA, limiting the depth of insertion of the spinal catheter, and using maneuvers to increase the spread of LA if maldistribution is suspected may minimize the risk of CES.[271] Some investigators have also advocated using alternatives to hyperbaric 5% lidocaine given that safe alternatives exist.[272] Unfortunately, CES is a permanent disability. Symptoms consistent with this syndrome should prompt an early neurology consult and imaging studies. High-dose corticosteroids; surgical decompression (eg, in the case of a lumbar synovial cyst, hemangioma, or metastatic tumors); and treatment of the underlying disorder with chemotherapeutic agents or antibiotics (eg, in the case of malignancy or abscess formation) have been used, but limited data are available on optimal therapies and the course of recovery.

Epidural Hematoma

Epidural hematoma is a rare occurrence that can lead to cord compression, cord ischemia, or myelopathy similar to that caused by a space-occupying tumor. The incidence of hematoma associated with epidural blockade is estimated at 1:150,000, somewhat higher than that of spinal anesthetics (1:220,000). However, the incidence varies dramatically with the patient population and may be significantly higher in a subset of patients with a less-compliant epidural space and a greater likelihood of coagulation disorders. Indeed, hemostatic abnormalities during either initiation of epidural blockade or removal of the epidural catheter are present in the majority of reported cases, although a large proportion of the documented cases also occur spontaneously, with no predisposing factors. Complicated epidural needle or catheter placement also appears to place the patient at risk for epidural hematoma formation.

Coagulation disturbances that predispose patients to the development of epidural hematoma may be iatrogenic or secondary to underlying disease. Iatrogenic disturbances that may predispose patients to epidural hematoma formation are often associated with antithrombotic or thrombolytic therapy. The most recent American Society of Regional Anesthesia and Pain Medicine guidelines can be used to assist the anesthesiologist in determining the most appropriate and safest period for initiating epidural blockade in anticoagulated patients (see Chapter 52). Thrombocytopenia is a relatively common cause of coagulopathy and may be related to pregnancy (gestational thrombocytopenia, HELLP syndrome, or preeclampsia/eclampsia), immune disorders (eg, ITP), or hepatic dysfunction, among other things. Unfortunately, there is no universally accepted platelet count that can be considered safe for performance of neuraxial blockade, and there is no widely available bedside test to assess platelet function. The nature of the underlying disorder must be taken into account (eg, Is the process dynamic, with rapidly dropping platelets? Is platelet function intact despite a low number? Is the patient on concomitant antiplatelet therapy? Does he or she have another disorder affecting coagulation? and so on), and patients with thrombocytopenia should be approached with caution prior to initiation of neuraxial blockade.

Signs and symptoms of epidural hematoma may progress rapidly from mild sensory or motor deficits to devastating paraplegia and incontinence. Early signs include back pain and pressure, with motor and sensory deficits. The back pain associated with epidural hematoma may be severe and persistent. Bowel and bladder incontinence, radicular pain, and worsening lower extremity neurologic deficits ensue. The onset of symptoms is usually within 12 hours to 2 days of initiation of neuraxial blockade or removal of an epidural catheter. Unfortunately, motor and sensory deficits within this timeframe may be mistaken for residual epidural blockade. Recurrence of motor and sensory blockade after partial or total resolution or, alternatively, prolonged block should raise concerns for an epidural hematoma and prompt immediate consultation with a neurologist or neurosurgeon, as well as prompt MRI scanning. A negative MRI cannot rule out a developing hematoma, which may not be recognized by an inexperienced radiologist.[273] Surgical decompression within 8 hours is advocated to minimize the risk of permanent neurologic injury.

Anterior Spinal Artery Syndrome

Anterior spinal artery syndrome (ASAS) occurs most commonly in patients with vascular disease and concomitant decreased spinal blood flow due to obstruction, compression, or hypotension. However, it has also been described in the setting of acute thoracic disk herniation, spondylosis, arteriovenous malformation, and similar pathologic conditions that can disrupt the tenuous blood flow in the anterior spinal artery distribution. ASAS is the most common neurologic complication after abdominal aortic surgery but has also been reported after surgery on the thoracic spine. Massive blood loss and persistent hypotension induced by neuraxial anesthesia have been implicated in the intraoperative development of this potentially life-threatening syndrome. ASAS presents with immediate, painless paraplegia and loss of lower extremity sensory function. Proprioception and vibration sense are spared. Prognosis is poor, with permanent and disabling neurologic deficits. Correction of intraoperative hypotension is essential in patients at high risk for ASAS.

Cardiac Arrest

Cardiac arrest resulting in death or brain damage is a rare complication of epidural blockade.[274] Causes include unintentional total spinal anesthesia, LAST, myocardial ischemia, respiratory compromise, or any of several circulatory events that do not fall within these categories, such as complete blockade of the preganglionic cardiac accelerator fibers or vagal predominance in the setting of sympathetic blockade.[275] Although the mechanism of increased vagal tone has not been fully elucidated, blockade of the sympathetic efferents results in vasodilation and a decrease in venous return. Decreased preload, in turn, may enhance cardiac vagal tone. Bradycardia, reduced CO, and cardiac arrest may result and can be attributed in part to reflex activity. The paradoxical Bezold-Jarisch reflex, for example, triggers slowing of the heart rate in response to decreased ventricular volume to permit more time for complete filling of the heart.

To minimize the risk of cardiac arrest associated with vagal predominance after neuraxial procedures, Pollard and colleagues proposed maintenance of adequate preload, the use of vagolytic drugs and pressor agents, if necessary, appropriate patient selection, and caution when changing patient positioning.[276] Early epinephrine administration is recommended if bradycardia is marked. Vasopressin may be more effective than epinephrine for cardiopulmonary resuscitation during epidural anesthesia due to its longer-lasting effect and the improved acid-base profile after multiple doses,[277] although adherence to the most current advanced cardiovascular life support (ACLS) protocol is recommended. Patient-related risk factors for cardiac arrest after neuraxial anesthesia include male gender, ASA I physical status, a low baseline heart rate (below 60), a sensory level above T6, age below 50, the use of β-adrenergic blocking agents, and prolonged PR interval. Rapid onset of action of LAs, the use of LAs that cause a more profound sympathetic block, and a broader spread of block have also been associated with hypotension and bradycardia after epidural blockade.[278] Ligouri and colleagues have identified the following secondary factors that may precipitate or contribute to the severity of the increased vagal tone associated with bradycardia and asystole during epidural anesthesia: opioid administration, hypoxemia, sedation, hypercarbia, chronic medication use, and coexisting medical disease.[279]

Side Effects

Several common side effects accompany epidural procedures, including transient fever in obstetric patients, nausea and vomiting, pruritus associated with neuraxial opioids, shivering, and urinary retention. Numerous studies have found an association between epidural labor analgesia and new-onset maternal intrapartum fever, although the relationship may not be causal. The increase in maternal temperature is often subclinical and self-limited and does not appear to have an adverse effect on the fetus.[281]

Nausea and vomiting are common after both GA and neuraxial blockade. In the setting of epidural anesthesia and analgesia, nausea and vomiting may be attributed to hypotension or to the epidural adjuvants, such as opioids. Lipophilic opioids, such as fentanyl and sufentanil, administered epidurally appear to confer some decreased risk of nausea and vomiting when compared to epidural morphine.[281] The administration of intravenous ondansetron (possibly in combination with other antiemetic agents), supplemental oxygen, and anxiolytics, as well as prompt correction of hypotension and hypovolemia, is recommended in the multimodal approach to therapy. Intravenous dexamethasone also appears to be effective in reducing nausea and vomiting associated with epidural morphine.[282] Ephedrine, which is thought to have antiemetic effects unrelated to its hemodynamic effects, antihistamines, and anticholinergics also show promise.

Pruritus, a common side effect of neuraxial opioids, is observed more often during spinals than epidurals. It is usually transient and most commonly affects the nose and other areas of the face. The pure opioid antagonist naloxone effectively reverses opioid-induced pruritus, but at the cost of reversing the analgesia. The partial agonist-antagonist nalbuphine appears to be the most effective treatment of opioid-induced pruritus. A single 5-mg dose is often sufficient; a second 5-mg dose is occasionally necessary. Antihistamines are ineffective; opioid-induced pruritus is not a histamine-mediated reaction.

Shivering is another common side effect of neuraxial analgesia and anesthesia, occurring more quickly and more intensely in spinal versus epidural anesthesia. The mechanism remains unclear but may be related in part to impairment of central thermoregulatory control and redistribution of body heat.

Hypotension, as defined by a greater than 20% reduction in systolic, diastolic, or mean blood pressure, is common following epidural blockade. High thoracic blocks, obesity, concurrent general and neuraxial anesthesia, hypovolemia, and excessive intraoperative blood loss are among the risk factors. Patients may present with nausea, vomiting, light-headedness, mental status changes, shortness of breath, difficulty breathing, and cardiac arrhythmias. Cardiovascular collapse may accompany severe cases. Optimally, the blood pressure should be maintained within 20% of the patient's resting baseline. Proposed methods to reduce the incidence of hypotension after neuraxial blockade include the judicious administration of vasopressors (most commonly, ephedrine or phenylephrine); volume expansion with a crystalloid or colloid solution at the time of initiation of the block (ie, a coload); maintenance of left uterine displacement after 18 to 20 weeks' gestation in obstetric patients; changing patient positioning (eg, from supine to sitting) gradually; placing the block at a lower spinal segment, when feasible; slow titration of epidural LAs; and reducing the dose of intrathecal or epidural LA. In cases of severe hypotension, elevating the lower extremities or placing military antishock trousers will reduce venous pooling. Alternative α- and β-adrenergic pressor agents, such as norepinephrine and epinephrine, should also be considered. Positioning the patient in reverse Trendelenburg in an attempt to limit the spread of the LA should be avoided; Trendelenburg will serve to alleviate venous pooling in the lower extremities and improve blood flow to the heart and brain (Table 24–38). Many of these measures to reduce the incidence and severity of hypotension following neuraxial blockade remain under debate in the literature and are beyond the purview of this chapter.

SUMMARY

Both the indications for neuraxial techniques and the patient population that is considered appropriate for these procedures have expanded over the past several decades. Epidural blockade is currently being advocated as an adjuvant to GA for cardiothoracic, major vascular, and other high-risk surgeries; as the sole anesthetic in surgeries that were previously performed exclusively under GA; and for acute and chronic pain management. Neuraxial techniques are also increasingly being used in the ambulatory setting, where the decrease in PONV and

TABLE 24–38. Treatment of hypotension following neuraxial blockade.

Discontinue epidural infusion, if applicable
Volume expansion with intravenous fluid administration
Intravenous vasopressor administration (phenylephrine and/or ephedrine)
Place patient in Trendelenburg position
Ensure uterine displacement after 18–20 weeks' gestation
Elevate lower extremities
Administer atropine 0.4–0.5 mg IV with concurrent bradycardia
Wrap legs with thromboembolic deterrent stockings/ pneumatic compression hose; place military antishock trousers
Norepinephrine or epinephrine administration as needed

improved pain relief permit earlier discharge; for a variety of diagnostic procedures; and to alleviate pain in adults and children in the end-of-life setting.

The benefits of epidural blockade are well established. Epidural techniques provide optimal pain relief following major surgeries and have been associated with fewer cardiovascular, respiratory, GI, and hematologic complications when compared with GA.[283] The incidence of perioperative thromboembolic events, the time to return of GI function, and length of intensive care stay, among other things, appear to be reduced with epidural blockade. In addition, epidural anesthesia has been associated with prolonged survival and decreased cancer recurrence rates in patients with breast, localized colon, prostate, and ovarian cancers.[284] However, the potential role of epidural blockade in reducing mortality after major surgery is still debated in the literature.

Despite the many potential advantages of epidural blockade, neuraxial techniques are not without risks, although major complications are rare. A risk-benefit analysis on a case-by-case basis and informed patient consent are warranted prior to initiation of epidural blockade.

SECTION 3 Caudal Anesthesia

CHAPTER 25

Caudal Anesthesia

Kenneth D. Candido, Anthony R. Tharian, and Alon P. Winnie

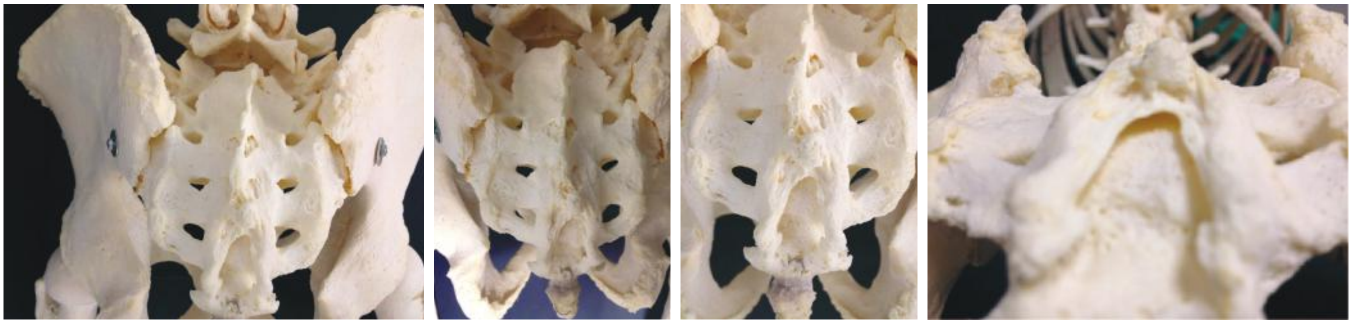
INTRODUCTION

Caudal anesthesia was described at the turn of last century by two French physicians, Fernand Cathelin and Jean-Anthanase Sicard. The technique pre-dated the lumbar approach to epidural block by several years.[1] Caudal anesthesia, however, did not gain in popularity immediately following its inception. One of the major reasons caudal anesthesia was not embraced is the wide anatomical variations of sacral bones and the consequent failure rate associated with attempts to locate the sacral hiatus. The failure rate of 5% to 10% made caudal epidural anesthesia unpopular until a resurgence of interest in the 1940s, led by Hingson and colleagues, who used it in obstetrical anesthesia. Caudal epidural anesthesia has many applications, including surgical anesthesia in children and adults, as well as the management of acute and chronic pain conditions. Success rates of 98%–100% can be achieved in infants and young children before the age of puberty, as well as in lean adults.[1] The technique of caudal epidural block in pain management has been greatly enhanced by the use of fluoroscopic guidance and epidurography, in which high success rates can be attained.

Unfortunately, clinical indications, and especially therapeutic interventions for the relief of chronic pain in individuals with failed back surgery syndrome, are often most prevalent in patients with difficult caudal landmarks. It has been suggested that traditional lumbar peridural block should not be attempted employing an approach requiring needle placement through a spinal surgery scar due to the likelihood of tearing the dura and the possibility of inducing hematoma formation over the cauda equina when blood from the procedure becomes trapped between the layers of scar and connective tissues.[2] Under these circumstances, it is recommended that fluoroscopically guided caudal epidural block be performed in lieu of the traditional palpation approach. Alternatively, the use of ultrasound may be appropriate to identify the sacral hiatus, and this technique has recently been described. The second resurgence in popularity of caudal anesthesia has paralleled the increasing need to find safe alternatives to conventional lumbar epidural block in selected patient populations, such as individuals with failed back surgery syndrome.

ANATOMIC CONSIDERATIONS

The sacrum is a large triangularly shaped bone formed by the fusion of the five sacral vertebrae. It has a blunted, caudal apex that articulates with the coccyx. Its superior, wide base articulates with the fifth lumbar vertebra at the lumbosacral angle (see Figure 25–1A). Its dorsal surface is convex and has a raised interrupted median crest with four (sometimes three) spinous tubercles representing fused sacral spines. Flanking the median crest, the posterior surface is formed by fused laminae. Lateral to the median crest, four pairs of dorsal foramina lead into the sacral canal through intervertebral foramina, each of which transmits the dorsal ramus of a sacral spinal nerve (see Figure 25–1A). Below the fourth (or third) spinous tubercle, an arched sacral hiatus is identified in the posterior wall of the sacral canal due to the failure of the fifth pair of laminae to meet, exposing the dorsal surface of the fifth sacral vertebral body. The caudal opening of the canal is the sacral hiatus (see Figures 25–1B and 25–1C) roofed by the firm elastic membrane, the sacrococcygeal ligament, which is



A B C D

FIGURE 25–1. A: Skeletal specimen of the sacrum viewed from craniad to caudad demonstrating the four pairs of dorsal foramina, situated bilaterally. **B:** Skeletal model demonstrating the sacral hiatus and its relationship to the coccyx and the sacrum. The fifth inferior articular processes project caudally and flank the sacral hiatus as sacral cornua. **C:** Skeletal model showing the sacral hiatus with the exposed dorsal surface of the fifth sacral vertebral body. **D:** Skeletal specimen viewed from inferior to the sacral hiatus.

an extension of the ligamentum flavum. The fifth inferior articular processes project caudally and flank the sacral hiatus as sacral cornua, connected to the coccygeal cornua by intercornual ligaments.

The sacral canal is triangular in shape. It is a continuation of the lumbar spinal canal. Each lateral wall presents four intervertebral foramina, through which the canal is in contiguous with the pelvic and dorsal sacral foramina. The posterior sacral foramina are smaller than their anterior counterparts. The sacral canal contains the cauda equina (including the filum terminale) and the spinal meninges. Near its midlevel (typically the middle one-third of S2, but varying from the midpoint of S1 to the midpoint of S3), the subarachnoid and subdural spaces cease to exist, and the lower sacral spinal roots and filum terminale pierce the arachnoid and dura maters.[3,4] However, variations in the termination of the dural sac as well as pathologic conditions like sacral meningocele or sacral perineural cysts can increase the chances of inadvertent dural puncture when performing caudal block in such patients with abnormal anatomy.[5]

The lowest margin of the filum terminale emerges at the sacral hiatus and traverses the dorsal surface of the fifth sacral vertebra and sacrococcygeal joint to reach the coccyx. The fifth sacral nerve roots also emerge through the hiatus medial to each of the sacral cornua. The sacral canal contains the epidural venous plexus, which generally terminates at S4 but which may continue more caudally. Most of these vessels are concentrated in the anterolateral portion of the canal. The remainder of the sacral canal is filled with adipose tissue, which is subject to an age-related decrease in its density. This change may be responsible for the transition from the predictable spread of local anesthetics administered for caudal anesthesia in children to the limited and unpredictable segmental spread seen in adults.[6]

Considerable variability occurs in sacral hiatus anatomy among individuals of seemingly similar backgrounds, race, and stature.[1] As individuals age, the overlying ligaments and the cornua thicken significantly. The hiatal margins often defy recognition by even skilled fingertips. The practical problems related to caudal anesthesia are mainly attributable to wide anatomical variations in size, shape, and orientation of the sacrum. Trotter[3] summarized the major anatomical variations of the sacrum. The sacral hiatus may be almost closed, asymmetrically open, or widely open secondary to anomalies in the pattern of fusion of the laminae of the sacral arches. Sacral spina bifida was noted in about 2% of males and in 0.3% of females. The anteroposterior depth of the sacral canal may vary from less than 2 mm to greater than 1 cm. Individuals with sacral canals having anterior-posterior (A-P) diameters less than about 3 mm may not be able to accommodate anything larger than a 21-gauge needle (5% of the population).[1]

In addition, the lateral width of the sacral canal varies significantly. Because the depth and width may vary, the volume of the canal itself may also vary. Trotter found that sacral volumes varied between 12 and 65 mL, with a mean volume of 33 mL.[3] A magnetic resonance imaging (MRI) study in 37 adult patients found the volume (excluding the foramina and dural sac) was 14.4 mL, with a range of 9.5 to 26.6 mL.[7] Patients with smaller capacities may not be able to accommodate the typical volumes of local anesthetics administered for epidural anesthesia via the caudal route.

In a cadaver study of 53 specimens, the mean distance between the tip of the dural sac and the upper edge of the sacral hiatus as denoted by the sacrococcygeal membrane was 45 mm, with a range of 16–75 mm[3]. In the MRI study mentioned, the mean distance was found to be 60.5 mm, with a range of 34–80 mm.[7]

The sacrococcygeal membrane could not be identified in 10.8% of subjects using MRI.[7] An anatomical evaluation of 92 isolated sacra found that 42% of cases had both a hiatus and cornua; 4% of the cases showed an absent hiatus. The apex of the sacral hiatus, in that study, was noted in 64% of cases to exist at the S4 level. The hiatus was closed in 3% of cases.[8]

The sacral foramina afford anatomical passages that permit the spread of injected solutions, such as local anesthetics and adjuvants (see Figure 25–1A). The posterior sacral foramina are essentially sealed by the multifidus and sacrospinalis muscles, but the anterior foramina are unobstructed by muscles and ligaments, permitting ready egress of solutions through them.[9] The sacral curvature varies substantially.[10] In a cadaver study, looking at the anatomy of caudal epidural space, the sacral cornua were not palpable bilaterally in 14.3% and palpable unilaterally in 24.5% of specimens. The level of maximum curvature of the sacrum was at S3 in 69.4% of cases.[11] This variability tends to be more severe in males than in females.

The clinical significance of this finding is that a noncurving epidural needle will more likely pass easily into the canal of females than males. The angle between the axis of the lumbar canal and the sacral canal varies between 7° and 70° in subjects with marked lordosis. The clinical implication of this finding is that the cephalad flow of caudally injected solutions may be more limited in lordotic patients with exaggerated lumbosacral angles than in those with flatter lumbosacral angles, in whom the axes of the lumbar and sacral canals are more closely aligned.

Clinical Pearls

- Considerable variability occurs in sacral hiatus anatomy.
- With advancing age, the overlying ligaments and the cornua thicken; consequently, identification of the sacral hiatal margins becomes more challenging.
- The success rate of caudal anesthesia is largely dependent on anatomic variations in size, shape, and orientation of the sacrum.

INDICATIONS FOR CAUDAL EPIDURAL BLOCK

The indications for caudal epidural block are essentially the same as for lumbar epidural block, but its use may be preferred when sacral nerve spread of anesthetics and adjuvants is preferred over lumbar nerve spread. The unpredictability cephalad spread of anesthetics administered into the caudal canal limits the use of this technique in situations where it is essential to provide lower thoracic and upper abdominal neuraxial blockade. Although this modality is described for perioperative use (diminishing role) and for managing chronic pain scenarios in adults (increasing role), caudal block has a wide range of indications[12–15] (Table 25–1). Successful treatment of postdural puncture headache by performing an epidural blood patch through a caudally placed needle has been reported.[16]

Clinical Pearls

- The indications for caudal epidural block are essentially the same as those for lumbar epidural block.
- Caudal block may be preferred over lumbar epidural block when sacral nerve spread of anesthetics and adjuvants is preferred over lumbar nerve spread.
- The unpredictability of ascertaining consistent cephalad spread of anesthetics administered through the caudal canal limits the usefulness of this technique when it is essential to provide lower thoracic and upper abdominal neuraxial blockade.

TABLE 25–1. Indications for caudal epidural block.

Surgical, Obstetric, Diagnostic, and Prognostic
1. Surgical anesthesia
2. Obstetric anesthesia
3. Differential neural blockade to evaluate pelvic, bladder, perineal, genital, rectal, anal, and lower extremity pain
4. Prognostic indicator before destruction of sacral nerves
Acute Pain
1. Acute low back pain
2. Acute lumbar radiculopathy
3. Palliation in acute pain emergencies
4. Postoperative pain
5. Pelvic and lower extremity pain secondary to trauma
6. Pain of acute herpes zoster
7. Acute vascular insufficiency of the lower extremities
8. Hidradenitis suppurativa
Chronic Benign Pain
1. Lumbar radiculopathy
2. Spinal stenosis
3. Low back syndrome
4. Vertebral compression fractures
5. Diabetic polyneuropathy
6. Postherpetic neuralgia
7. Reflex sympathetic dystrophy
8. Orchialgia
9. Proctalgia
10. Pelvic pain syndromes
Cancer Pain
1. Pain secondary to pelvic, perineal, genital, or rectal malignancy
2. Bony metastases to pelvis
3. Chemotherapy-related peripheral neuropathy
Special Situations
Patients with previous lumbar spine surgery
Patients who are "anticoagulated" or have coagulopathy

Other, newer indications in adults deserve mention and are described further in this chapter, including the performance of percutaneous epidural neuroplasty[17,18]; the use of caudal analgesia following lumbar spinal surgery[19]; caudal analgesia after orthopedic lower extremity surgery[20]; local anesthetic adjuvants for postoperative analgesia[21]; and caudal block for performing neurolysis for treatment intractable cancer pain.[22]

THE TECHNIQUE OF CAUDAL EPIDURAL BLOCK

The classical technique of caudal epidural block involves palpation, identification, and puncture.[1] Patients are evaluated as for any epidural block, and the indications and relative and absolute contraindications to its performance are identical. A full complement of noninvasive monitors is applied, and baseline vital signs are assessed. One must decide whether a continuous or single-shot technique will be employed. For continuous techniques, a Tuohy-type needle with a lateral-facing orifice is preferred.

Patient Positioning

Several positions can be used in adults, compared with the lateral decubitus position in neonates and children. The lateral position is often preferred in pediatrics because it permits easy access to the airway when general anesthesia or heavy sedation has been administered prior to performing the block. In pediatric patients, blocks may be performed with the patient fully anesthetized; this is not recommended for older children and adults. In adults, the prone position is the most frequently utilized, but the lateral decubitus position or the knee-chest (also known as "knee-elbow") position may be employed. In the prone position, the procedure table or operating room table should be flexed, or a pillow may be placed beneath the symphysis pubis and iliac crests to produce slight flexion of the hips. This maneuver makes palpation of the caudal canal easier. The legs are separated with the heels rotated outward to smooth out the upper part of the anal cleft, while simultaneously relaxing the gluteal muscles. For placement of caudal epidural block in the parturient, the lateral (Sim's position) and the knee-elbow position are most commonly used.

Anatomical Landmarks

A dry gauze swab is placed in the intergluteal cleft to protect the anal area and genitalia from povidone iodine or other disinfectants (especially alcohol) used to desinfect the skin. Anatomical landmarks are next assessed. The skinfolds of the buttocks are useful guides in locating the underlying sacral hiatus. Alternatively, a triangle may be marked on the skin over the sacrum, using the posterior superior iliac spines (PSISs) as the base, with the apex pointing inferiorly (caudally). Normally, this apex sits over or immediately adjacent to the sacral hiatus. However, a recent study indicated that identification of the sacral hiatus using this method may be inaccurate because the actual triangle formed by the sacral hiatus and PSISs is not equiangular.[23] Once the hiatus is marked, the tip of the index finger is placed on the tip of the coccyx in the intergluteal cleft while the thumb of the same hand palpates the two sacral cornua located 3–4 cm more rostrally at the upper end of the intergluteal cleft. The sacral cornua may be identified by gently moving the palpating index finger from side to side (Figure 25–2). The palpating thumb should sink into the hollow between the two cornua, as if between two knuckles of a fist.[1] Sterile skin preparation and draping of the entire region are performed in the usual fashion.

Technique Using Fluoroscopy

A small-gauge 1.5-inch needle is then utilized to infiltrate the skin over the sacral hiatus using 3–5 mL of 1%–1.5% plain lidocaine HCl (Figure 25–3). If fluoroscopy is utilized, a lateral view is obtained to demonstrate the anatomic boundaries of the sacral canal. We routinely leave the local anesthetic infiltration needle in situ for this view because it demonstrates whether the approach is at the appropriate level for subsequent advancement of the epidural needle. With fluoroscopy, the caudal canal appears as a translucent layer posterior to the sacral segments. The median sacral crest is visualized as an opaque line posterior to the caudal canal. The sacral hiatus is usually visualized as a translucent opening at the base of the caudal canal. The coccyx may be seen articulating with the inferior surface of the sacrum (Figure 25–4).

Once the tissues overlying the hiatus have been anesthetized, a 17- or 18-gauge Tuohy-type needle is inserted either in the midline or, using a lateral approach, into the caudal canal (Figure 25–5, Figure 25–6). A feeling of a slight "snap" may be

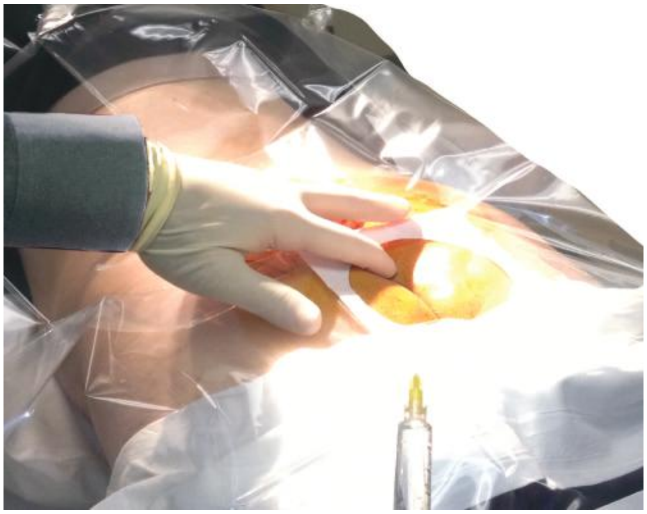

FIGURE 25–2. Technique of palpating the midline over the sacral hiatus. The palpating index and middle fingers are spread over the fifth sacral vertebral body. The sacrococcygeal ligament lies directly beneath the palpating finger.

FIGURE 25–3. Technique of skin infiltration with local anesthetic. The needle is inserted first above and then into the substance of the sacrococcygeal ligament.

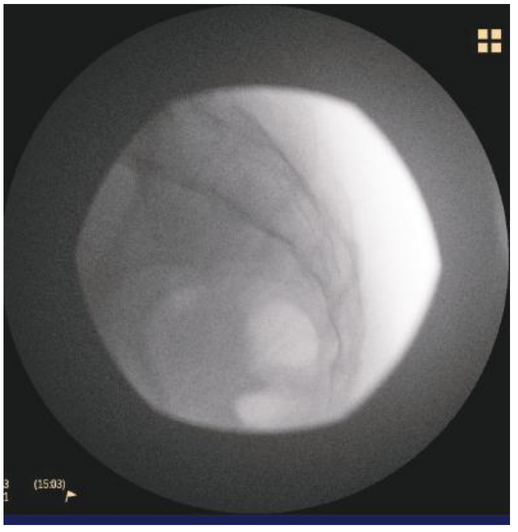

FIGURE 25–4. Lateral fluoroscopic image demonstrating the boundaries of the caudal canal.

appreciated when the advancing needle pierces the sacrococcygeal ligament. Once the needle reaches the ventral wall of the sacral canal, it is slowly withdrawn and reoriented, directing it more cranially (by depressing hub and advancing) for further insertion into the canal. We utilize the anteroposterior view once the epidural needle is safely situated within the canal, and the epidural catheter is advanced cephalad (Figure 25–7, Figure 25–8). In this projection, the intermediate sacral crests appear as opaque vertical lines on either side of the midline. The sacral foramina are visualized as translucent and nearly circular areas lateral to the intermediate sacral crests. The presence of intestinal gas may obscure the recognition of these structures. A syringe loaded with either air or saline containing a small air bubble is then attached to the needle, and the loss-of-resistance technique is used to establish entry into the epidural space.

Clinical Pearls

- The needle tip should stay below the S2 level to avoid tearing the dura.
- The needle should never be advanced in the space too deep.
- The skin corresponding to about 1 cm inferior to the PSISs indicates the S2 level (caudal-most extension of the dura mater).
- The dural sac extends lower in children than in adults, and epidural needles should be carefully advanced no deeper than the S3 or S4 level.

An acoustic test, also called the "whoosh" test has been described for identifying correct needle placement in the caudal canal. This characteristic sound has been noted during auscultation of the thoracolumbar region during the injection of 2–3 mL of air into the caudal epidural space.[24] The "swoosh test," described by Orme and Berg, substitutes saline or local anesthetic instead of air as the injectate. Of the 108 patients with a successful block in one study, 98 had a positive test, with no false-positive results.[25] Once the correct placement of the needle is confirmed, a catheter is inserted into the desired location (depth) and its position confirmed fluoroscopically when desired (Figure 25–9). Color Doppler ultrasonography has also been described for guiding the needle insertion into the epidural space and to confirm any intravascular injection.[26]

ULTRASOUND-GUIDED CAUDAL BLOCK

Ultrasound has played an increasing role in regional anesthesia and pain management, ultrasound guidance can be utilized to identify the sacral hiatus, thereby facilitating needle entry into the hiatus, as well as to visualize the advancing needle in the caudal canal. Because caudal blocks are relatively easy to perform in the pediatric population, ultrasound may not be

Usually, when fluoroscopy is not available to verify correct needle placement, a syringe loaded with air or saline is attached to the needle, and the loss-of-resistance technique is employed to identify the epidural space.

significantly advantageous over landmark-based techniques. However, in adult patients, for whom the anatomy of the sacral hiatus, caudal canal, and dural sac are variable, ultrasound guidance may prove to be helpful in reducing the risk of complications such as tissue trauma, dural puncture, local anesthetic toxicity, and vascular compromise.

Technique

With the patient in the prone position, the sacral cornua are identified by palpation using the technique described in the section on anatomic landmarks. Sterile skin preparation and draping of the entire region are performed. A low-frequency curvilinear probe, is placed in the transverse plane across the two sacral cornua (Figure 25–10). The sacral cornua can be visualized as two symmetric hyperechoic arches, with a hypoechoic shade underneath both lines, bridging these two structures. Traversing this hypoechoic area are two hyperechoic lines, the superficial one being the sacrococcygeal ligament and the deeper one line being the dorsal bony surface of the sacrum (Figure 25–11). A 22-gauge needle is inserted into the space between the two cornua. A distinct "pop" is felt as the needle tip penetrates the sacrococcygeal ligament.

At this point, the orientation of the probe is changed into the sagittal plane (Figure 25–12), and the caudal canal is identified as a hypoechoic canal tapering off caudally and bordered by dorsal and ventral hyperechoic bands. The dorsal band is formed by the dorsal bony aspect of the caudal canal cranially and the sacrococcygeal ligament caudally. The ventral band is formed by the ventral bony surface of the caudal canal (Figure 25–13).

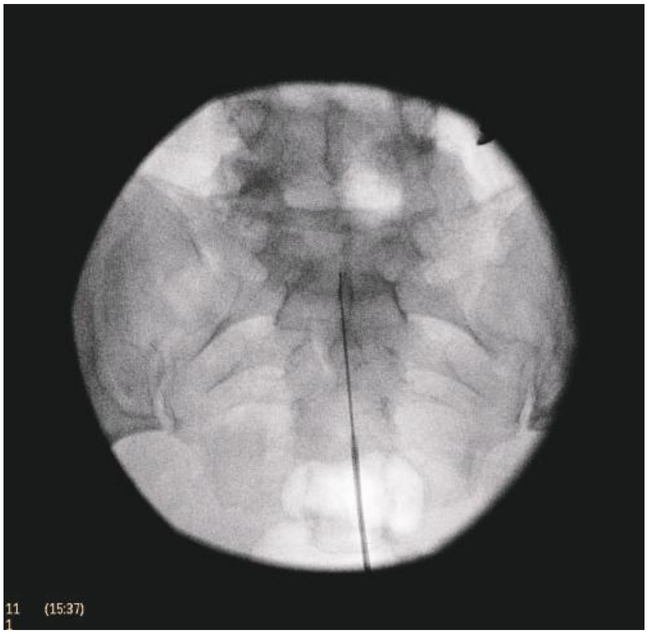

FIGURE 25–8. Anteroposterior fluoroscopic imaging depicting proper placement of the needle.

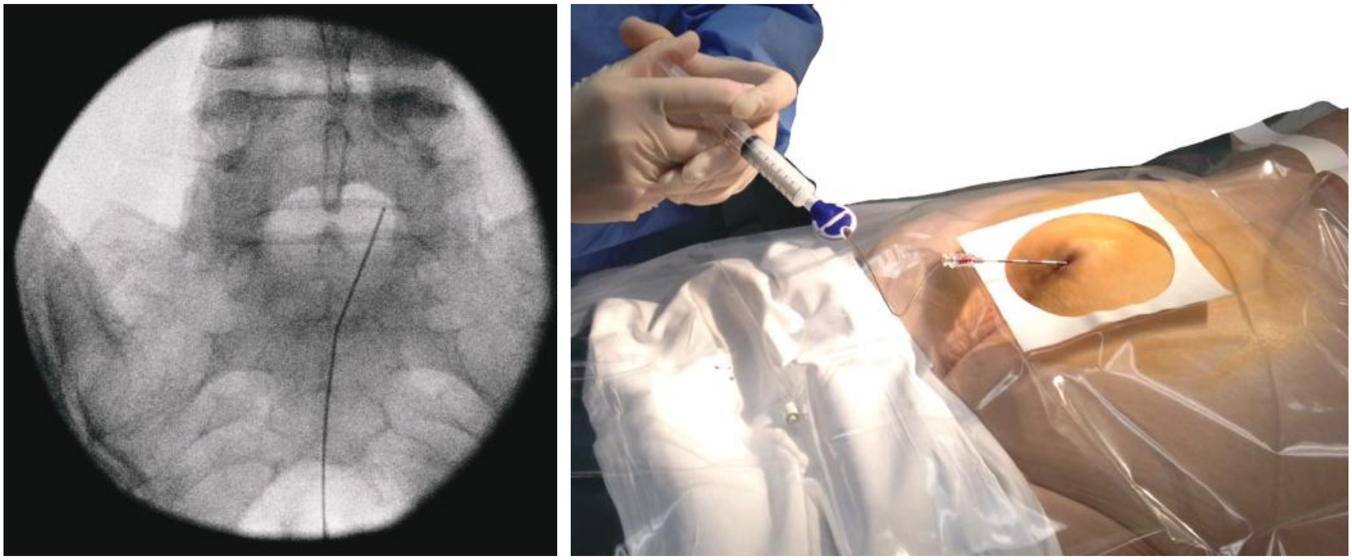

A B

FIGURE 25–9. Anteroposterior fluoroscopic image depicting the catheter advanced to the L5–S1 interspace.

Once the needle is within the caudal canal, aspiration is undertaken to ensure there is no CSF or blood. Once negative aspiration is confirmed, injection is carried out under real-time ultrasonography. The spread of the injectate can be visualized as turbulence within the caudal canal.[27]

The major limitation of the ultrasound-guided caudal block is the difficulty in identifying intrathecal or intravascular injection. Although color Doppler has been described[26] to detect intrathecal or intravascular injection, the turbulence created by the injectate in the caudal canal produces variable color patterns, which makes interpretation unreliable. Contrast fluoroscopy is still the best technique to rule out inadvertent intrathecal or intravascular injection.

Clinical Pearls

- In pediatric patients, electrical stimulation has been used to ascertain correct needle placement in the caudal canal. Anal sphincter contraction (corresponding to stimulation of S2–S4) is sought with 1- to 10-mA currents.[28]
- If the needle has been inserted correctly, moving the hub from side to side, while the shaft is held at the sacrococcygeal membrane will allow the tip swinging freely in the sacral canal like a fulcrum.

FIGURE 25–10. A low-frequency curvilinear ultrasound probe ensheathed in a sterile probe cover containing gel being placed in the transverse plane across the two sacral cornua.

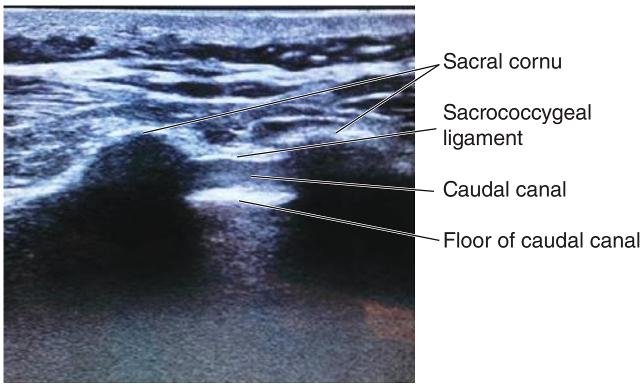

FIGURE 25–11. Ultrasound image along the short axis of the caudal canal, depicting the sacral cornua, sacrococcygeal ligament, and the caudal canal.

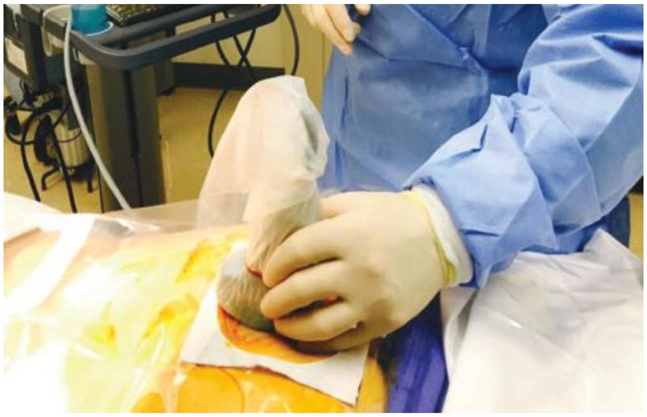

FIGURE 25–12. The low-frequency curvilinear probe placed in the sagittal plane along the long axis of the caudal canal.

- If cerebrospinal fluid (CSF) is obtained after aspiration, the needle should be withdrawn and injection should not be undertaken.
- If blood is aspirated, the needle should be withdrawn and reinserted until no blood is apparent at the hub.
- When injection of air (or saline) for the loss-of-resistance technique results in bulging over the sacrum, the needle tip most probably lies dorsal to the sacrum in the subcutaneous tissues.
- If the needle tip is subperiosteal, the injection will meet with significant resistance, resulting is significant patient discomfort. The cortical layer of the sacral bone is often thin, particularly in infants and older subjects, and its penetration can easily occur especially if force is exerted while advancing the needle. The sensation of entering cancellous bone is not unlike penetrating the sacrococcygeal membrane; there is a feeling of resistance that is suddenly overcome, and the needle advances more freely and subsequent injection is unhampered.

Several complications related to the technique procedure have been described. Injected solutions may be absorbed rapidly from bone marrow, and toxic drug reactions result. In this situation, pain is typically noted over the caudal part of the sacrum during the injection. If this occurs, the needle should be withdrawn slightly and rotated on its axis until it can be reinserted in a slightly different direction.[29–31]

If injection is made anterior to the sacrum, it is possible to perforate the rectum, or, in parturients, the baby's head may be injured. This limits the use of caudal block in laboring women once the presenting part has descended into the perineum. Inadvertent venous puncture may also occur, and the incidence of this has been reported to be about 0.6%.[32]

Caudal block may be used with a single-shot or continuous catheter technique. For continuous block, the catheter may be advanced anterograde (conventionally) or retrograde. Continuous caudal block may be performed in retrograde fashion using needle insertion into the lumbar epidural space, but directed inferiorly instead of superiorly. In one study of 10 patients, epidural catheters were advanced through 18-gauge Tuohy-type epidural needles in retrograde fashion from the L4–L5 interspace. This technique was associated with a 20% failure rate, with the catheter going into the paravertebral or retrorectal spaces, despite easy epidural space entry.[33] Using the conventional approach, a Huber-tipped Tuohy needle is used as a conduit to pass the epidural catheter into the canal. This needle has a curved bevel tip that limits it being caught or snagged on the sacral periosteum. The needle is inserted with its shoulder facing anteriorly and its orifice dorsally. Alternatively, a standard 16- or 17-gauge catheter-over-needle assemblage (angiocatheter) may serve as the introducing needle for subsequent catheter placement. The catheter is advanced under fluoroscopic guidance, especially when it is performed for chronic pain management in failed back surgery syndrome. The catheters should be advanced gently because there have been reports of dural puncture with rapid or aggressive advancement. A lateral and anteroposterior fluoroscopic views should be obtained

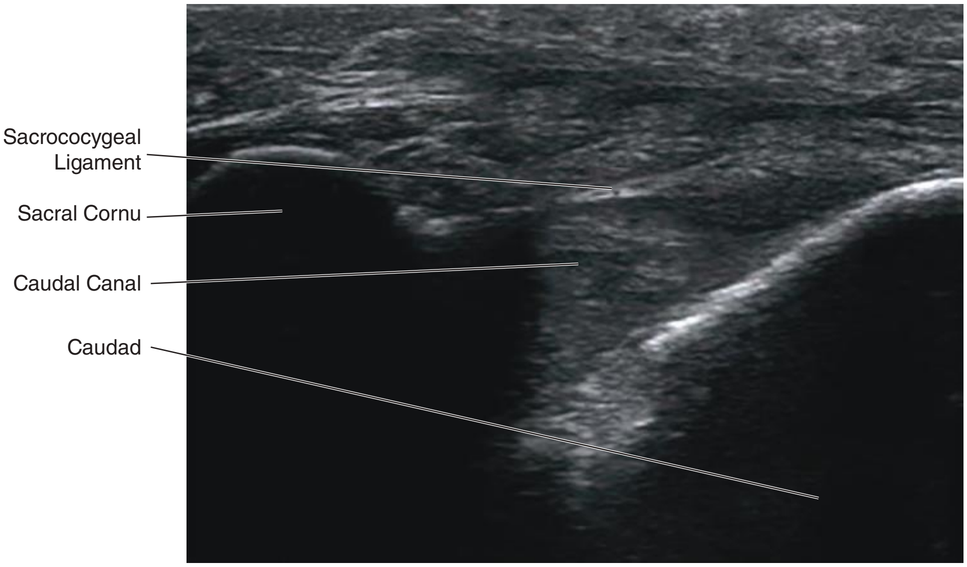

FIGURE 25–13. Ultrasonographic image along the long axis of the caudal canal depicting the long-axis view of the caudal canal.

to demonstrate placement of the catheter in the epidural space (Figures 25–14 and 25-9) and to follow its path in a cephalad or cephalolateral direction. When the desired level is attained, iodinated nonionic contrast media may be injected, followed by the injection of local anesthetics, corticosteroids, or adjuncts (Figure 25–15). Usually, the catheter is not advanced higher than the level of L4 vertebral body, although it could be advanced to the L1 or L2 levels for specific indications. Some authors recommend not to advance the catheter more than 8–12 cm cephalad.

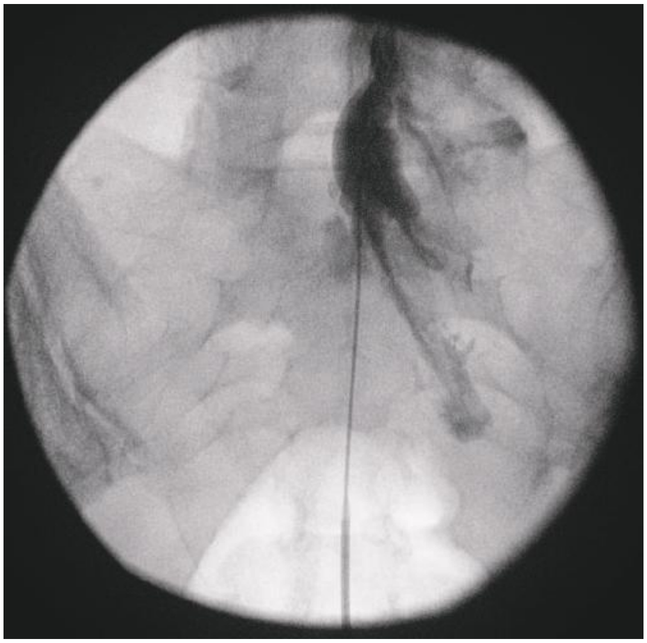

FIGURE 25–15. Anteroposterior fluoroscopic image depicting radiopaque contrast medium in the epidural space.

Clinical Pearls

- Spread of the local anesthetic solutions injected into the caudal epidural space in adults is influenced by injected volume, speed of injection, and patient positioning.
- There is no correlation between the speed of injection and spread of the local anesthetic in children undergoing caudal anesthesia.[34]

CHARACTERISTICS OF CAUDAL EPIDURAL BLOCK IN ADULTS

Caudal epidural block results in sensory and motor block of the sacral roots and limited autonomic block. The sacral contribution of the parasympathetic nervous system is blocked causing loss of visceromotor function of the bladder and intestines distal to the colonic splenic flexure. Sympathetic block, although limited compared to the lumbar or thoracic epidural block, does occur. However, the sympathetic outflow from the preganglionic sympathetic fibers of the spinal cord ends at the L2 level; therefore, caudal block should not routinely result in peripheral vasodilatation of the lower extremities to the degree witnessed with lumbar epidural blockade. Caudal epidural local anesthetic block in adults may be chosen for surgeries of the lower abdomen, perineum, or lower extremities. The local anesthetic mixtures and doses are similar to those for lumbar epidural block (Table 25–2). One recent study looking at the effect of gender on the minimal local anesthetic concentrations (MLACs) of ropivacaine for caudal anesthesia in patients undergoing anorectal surgery found that the MLAC for caudal anesthesia in female patients is 31% higher than in male patients.[35]

Spread of Local Anesthetic Solutions

The large capacity of the sacral canal accommodates correspondingly large volumes of solution; significant volumes may be lost through the wide anterior sacral foramina. Therefore, the caudal dose requirements of local anesthetics to achieve the same segmental spread are significantly larger than are the corresponding lumbar doses. Roughly twice the lumbar epidural local anesthetic dose is needed for caudal blockade to attain similar levels of analgesia and anesthesia, and solutions injected in the caudal space take longer to spread (Table 25–2). Bromage noted that age is not correlated with caudal segmental spread in adults, and the upper level of analgesia resulting from 20-mL doses of local anesthetic solution varies widely between S2 and T8.[1] This unpredictability limits the usefulness of applying caudal anesthesia for surgical procedures that require cephalad analgesia levels above the pelvic level or the umbilicus. A more recent study confirmed Bromage's findings. In 172 women undergoing minor gynecologic surgery using caudal anesthesia with 20 mL of 1.5% lidocaine,[36] the highest sensory dermatome level reached was below T10.

TABLE 25–2. Local anesthetics commonly used for caudal anesthesia in adults

Agent	Concentration	Dose (mg)	Sensory Onset (4-Segment Spread)	Duration (2-Segment Regression)
Lidocaine	1.5%–2%	300–600	10–20 min	90–150 min
Chloroprocaine	2%–3%	400–900	8–15 min	45–80 min
Mepivacaine	2%%	400–600	10–20 min	90–240 min
Ropivacaine	0.75%–1%	150–300	15–25 min	120–210 min
Bupivacaine/ levobupivacaine	0.5%–0.75%	100–225	10–25 min	180–270 min

All solutions with epinephrine 1:200,000, except ropivacaine.

Clinical Pearls

- The sacral canal contains the cauda equina (including the filum terminale), the spinal meninges, adipose tissue, and sacral venous plexus.
- The volume of the sacral canal averages 14.4 mL.
- The indications for caudal epidural block are the same as for a lumbar epidural block.
- Percutaneous epidural neuroplasty is a technique of administering local anesthetics, corticosteroids, hyaluronidase, and hypertonic saline through a caudal catheter for the purpose of lysing epidural adhesions.
- Adult patients are typically placed prone for the block, whereas the lateral decubitus position is preferred for pediatrics.
- Caudal blockade in pediatrics is used primarily for perioperative pain control, whereas in adults it is primarily for chronic pain management.
- In adults, roughly twice the local anesthetic dose is required to attain the same segmental spread with caudal block compared with the dose used for lumbar epidural block.

Indications for Caudal Epidural Analgesia in Adults

A caudal epidural block is indicated whenever the area of surgery involves the sacral and lower lumbar nerve roots. The technique is suitable for anal surgery (hemorrhoidectomy and anal dilation), gynecologic procedures, surgery on the penis or scrotum, and lower limb surgeries. Using a catheter technique, it is possible to use the caudal epidural block for cesarean section, vaginal hysterectomy, and inguinal herniorrhaphy.

A caudal epidural block is used less frequently than the lumbar or thoracic epidural block for perioperative analgesia in adults. The pelvis enlarges markedly in puberty, while the epidural fat in the lumbosacral region undergoes compaction and increased fibrous content. This hinders cephalad spread of solutions, particularly when compared with the spread in children.

As an alternative to the caudal epidural block in adults, one might consider a median approach to transsacral epidural block. In the original description of that technique, 87% of blocks were successful for transurethral resection of bladder tumors versus 100% success for sacral procedures. Anesthesia level, side effects, and hemodynamics were similar between the two groups studied in the initial report.[37]

CAUDAL BLOCK FOR LABOR ANALGESIA

The sacral canal shares in the general engorgement of extradural veins that occurs in late pregnancy or in any clinical condition in which the inferior vena cava (IVC) is partially obstructed. Because the effective volume of the caudal canal is markedly diminished during the latter part pregnancy, the caudal dosage should be reduced proportionately in women at term. The segmental spread of local anesthetics may increase substantially in pregnant women at term, necessitating a 28% to 33% decrease of dose requirement in this patient population.[1] The choice of a continuous catheter or a single-shot technique during active labor is limited by the relative lack of sterility at the sacral hiatus, which may be contaminated by feces and meconium.

Rare cases of Horner syndrome have been reported when large doses of local anesthetics are injected caudally during labor analgesia administration.[1] This is most likely to occur if injection is made with the patient on her back (engorgement of epidural venous plexus and IVC compression are maximal).

The so-called dual technique (lumbar and caudal) of epidural block for labor is no longer widely used. Because the pain of uterine contractions is mediated by sympathetic nervous system fibers originating from the T10 to L2 spinal segments, a lumbar epidural catheter suffices for both stage I and stage II of parturition, with dosage adjustments made depending on the exact circumstances and requirements (see Chapter 41, Obstetric Regional Anesthesia).

INDICATIONS FOR CAUDAL EPIDURAL ANALGESIA IN CHILDREN

Characteristics of the Blockade

The sacral hiatus is usually easy to palpate in infants and children, which makes this technique much easier and predictable. Consequently, in many institutions with large numbers of pediatric patients, caudal epidural block is an integral part of the intra- and postoperative pain management for children undergoing a wide range of surgical procedures both below and above the diaphragm. The technique is easily learned; one study demonstrated an 80% success rate in resident trainees after completing 32 procedures performed without fluoroscopic guidance.[38] In infants and small children, a 21-gauge, short-bevel, 1-inch needle may be used for single-injection techniques. For continuous blocks, a standard epidural catheter may be advanced through an 18-gauge angiocatheter or through a thin-wall 18-gauge epidural needle. It has been noted that by 4 or 5 years of age the sacral canal is usually large enough to accept such a needle for passage of a catheter.[1] The electrocardiogram has been used to verify appropriate thoracic catheter tip placement (epidural electrocardiography).[39]

Spread of Local Anesthetic Solutions

The segmental spread of analgesia following caudal administration is more predictable in children up to about 12 years of age.[40] Some studies suggested that the cephalad spread of caudal solutions in children is not hampered by the same anatomical constraints that develop from puberty onward. Before puberty, anatomical barriers at the lumbosacral junction have not yet developed to a marked degree, and caudal solutions can flow freely upward into the higher recesses of the spinal canal. As a consequence, the rostral spread of caudal anesthesia is more extensive and more predictable in children than in adults.

Indications in Children

In children, caudal block is usually combined with light general anesthesia with spontaneous ventilation. During lower abdominal and genitourinary surgery in children, caudal block with 0.25% bupivacaine (2 mg/kg) was shown to lower the metabolic and endocrine responses to stress, as measured by glucose concentrations; mean prolactin levels; insulin; and cortisol concentrations, as compared with general anesthesia alone.[41] Thoracic placement of catheters is possible in neonates and small children. However, one radiographic study of 115 infants found 10 caudally placed catheters to be in the high thoracic or low cervical region, when their intended site was in the lower thoracic segments.[42]

The three groups of indications for caudal epidural block in children are the following:

1. Patients requiring sacral block (circumcision, anal surgery)
2. Patients requiring lower thoracic block (inguinal herniorrhaphy)
3. Patients requiring analgesia of the upper thoracic dermatomes (thoracic surgery)

Pharmacologic Considerations for Caudal Epidural Anesthesia in Children

Caudal block with bupivacaine (4 mg/kg) and morphine (150 μg/kg) was found to lower fentanyl requirements during cardiac surgery and shorten extubation times in a group of 30 pediatric patients randomized to receive general anesthesia alone or a combination of general or caudal block.[43]

Anesthetic dose requirements are about 0.1 mL/segment per year for 1% lidocaine or 0.25% bupivacaine.[1] The dose may also be calculated based on body weight. The relationship between age and dose requirements is strictly linear, with a high degree of correlation up to 12 years old.[1] A recent study using fluoroscopy with 0.2% ropivacaine containing radiopaque dye at a ratio of 1:4 showed that the weight-based doses for caudally administered 0.2% bupivacaine were applicable to 0.2% ropivacaine as well.[44] Plasma bupivacaine concentrations in children receiving caudal block with 0.2% of the local anesthetic (2 mg/kg) were less than equivalent doses administered via ilioinguinal-iliohypogastric block for pain control following herniotomy or orchidopexy. In addition, the times to peak plasma concentrations were faster in the peripheral nerve block group, indicating that caudal block is a safe alternative to local infiltration techniques in inguinal surgery.[45]

In a study of children 1 to 6 years of age who underwent orchidopexy, a caudal block using larger volumes of dilute bupivacaine (0.2%) was shown to be more effective than a smaller volume of the standard (0.25%) concentration for blocking the peritoneal response to spermatic cord traction, with no change in the quality of postoperative analgesia. In that study, the total bupivacaine dose was identical in both groups (20 mg).[46] Ropivacaine 0.5% was shown to provide a significantly longer duration of analgesia following inguinal herniorrhaphy in children aged 1.5–7 years when compared to 0.25% ropivacaine or 0.25% bupivacaine.[47] All children received 0.75 mL/kg of the local anesthetic. However, the times to first voiding and to standing were significantly delayed in the group receiving 0.5% ropivacaine, and there was one case of motor block of the lower extremities.

Another study compared high-volume/low-concentration (1.5 mL/kg of 0.15% solution) and low-volume/high-concentration ropivacaine (1.0 mL/kg 0.225% solution) for caudal analgesia in children aged 1–5 years of age undergoing orchiopexy. This study showed that a larger volume of diluted ropivacaine provided better quality and longer duration of analgesia after discharge than a smaller volume of more concentrated ropivacaine.[48]

Ropivacaine has also been used for caudal block for hypospadias repair in a double-blind, randomized study in 26 children. The minimal effective local anesthetic concentration of ropivacaine was found to be 0.11%, to provide effective caudal analgesia in children under general anesthesia with 0.5 minimum alveolar concentration of enflurane.[49]

Plasma concentrations of ropivacaine after caudal block in 20 children 1 to 8 years of age, using 2 mg/mL, 1 mL/kg, demonstrated free fractions of 5%, clearance of 7.4 mL/kg/min, and terminal half-life of 3.2 hours, well below those associated with toxic symptoms in adults.[50] Another study looking at the minimum local analgesic concentration of ropivacaine for intraoperative caudal analgesia in preschool and school-age children undergoing hypospadias repair found that a higher concentration of ropivacaine was needed for school-age children than preschool age children to provide intraoperative caudal analgesia when combined with general anesthesia.[51] Of the three commonly used local anesthetics for single-shot caudal anesthesia (bupivacaine, ropivacaine, and levobupivacaine), no superiority in terms of clinical efficacy was found for any of these drugs in a meta-analysis of 17 randomized controlled trials that concerned single-shot pediatric caudal anesthesia with at least two of the three drugs in question. Bupivacaine and ropivacaine showed the highest and lowest incidence of motor block, respectively.[52]

A quantitative systematic review of randomized controlled trials looking at the safety and efficacy of clonidine as an additive for caudal regional anesthesia suggested that clonidine may provide extended duration of analgesia with a decreased incidence for analgesic rescue requirements and few adverse effects compared to caudal local anesthetics alone. Data from 20 randomized controlled trials were used in this meta-analysis to assess the safety and efficacy of caudal clonidine added to local anesthetics versus local anesthetics alone in children undergoing urological, lower abdominal, or lower limb surgery.[53] Dexmedetomidine (1 μg/kg) was shown to provide extended duration of pain relief when added to bupivacaine 2.5 mg/mL, 1 mL/kg, when compared to an identical dose of bupivacaine alone in children aged 1–6 years undergoing unilateral inguinal hernia repair/orchidopexy.[54] Another study compared the analgesic effects and side effects of dexmedetomidine and clonidine added to bupivacaine in pediatric patients undergoing lower abdominal surgeries. Sixty patients aged 6 months to 6 years were evenly and randomly assigned into three groups in a double-blinded manner. Each patient received a single caudal dose of bupivacaine 0.25% (1 mL/kg) combined with dexmedetomidine 2 μg/kg in normal saline 1 mL, clonidine 2 μg/kg in normal saline 1 mL, or a corresponding volume of normal saline.[55] The results demonstrated that while both additives increased the period of analgesia, there was no significant advantage of selecting dexmedetomidine over clonidine.

The local anesthetics typically administered for single-shot caudal blocks in pediatric patients are listed in Table 25–3.

Clinical Pearls

- Relaxation of the anal sphincter following local anesthetic injection may predict the success for a caudal block.
- This is particularly useful in children because most caudal blocks are performed while the child is anesthetized, and it is not possible to assess the effectiveness of the block by testing for sensory analgesia levels.
- One study demonstrated that the presence of a lax anal sphincter at the termination of surgery correlated with the reduced need to administer opioids perioperatively.[56]

Other Considerations for Use of Caudal Epidural Anesthesia in Children

Although the caudal block is a mainstay of perioperative pain management in pediatric surgery and represents probably 60% of all regional anesthetic techniques performed in this patient population, not all studies have demonstrated a marked benefit of caudal block for postoperative analgesia when compared with other modalities. Following unilateral inguinal herniorrhaphy, the caudal block was shown to provide effective, but not superior, pain management when compared with local wound infiltration in 54 children. The side effects and rescue analgesia requirements did not differ between the two groups.[57]

Caudal epidural block in children may induce significant changes in descending aortic blood flow while maintaining heart rate and mean arterial blood pressure. In a study of 10 children aged 2 months to 5 years, a transesophageal Doppler probe was used to calculate hemodynamic variables after the injection of 1 mL/kg of 0.25% bupivacaine with epinephrine 5 μg/mL. The aortic ejection volume increased, and aortic vascular resistance decreased by about 40%.[58] Another study that looked at peripheral hemodynamics using Doppler ultrasonography in sevoflurane-anesthetized children before and after a caudal block showed significantly altered flow patterns after the block. The peak velocity increased by 24%; volume flow increased by 76%; and the diameter of the dorsalis pedis

TABLE 25–3. Typical local anesthetics for caudal block in pediatrics (single shot).

Agent	Concentration (%)	Dose	Onset (minutes)	Duration of Action (minutes)
Ropivacaine[74]	0.2	2 mg/kg	9	520
Bupivacaine[74]	0.25	2 mg/kg	12	253
Ropivacaine[75]	0.2	0.7 mg/kg	11.7	491
Bupivacaine[75]	0.25	0.7 mg/kg	13.1	457
Ropivacaine[76]	0.2	1 mL/kg	8.4	Not available
Levobupivacaine[76]	0.25	1 mL/kg	8.8	Not available
Bupivacaine[76]	0.25	1 mL/kg	8.8	Not available

artery increased by 20%. However, blood pressures and heart rates were not significantly affected by caudal block.[59] These data suggest that caudal block results in vasodilatation secondary to sympathetic nervous system blockade.

APPLICATIONS OF CAUDAL EPIDURAL BLOCK IN ACUTE AND CHRONIC PAIN MANAGEMENT

Radiculopathy Refractory to Conventional Therapy

In cases of radiculopathy refractory to conventional analgesic therapies, caudal epidural analgesic techniques can significantly and reliably reduce pain. One such technique is percutaneous epidural neuroplasty: A caudal catheter is left in place for up to 3 days for the purpose of injecting hypertonic solutions into the epidural space to treat radiculopathy with low back pain and associated epidural scarring, typically from previous lumbar spinal surgery. In addition to local anesthetics and corticosteroids, hypertonic saline and hyaluronidase are added to the injectate. The technique requires use of fluoroscopic guidance and caudal epidurography because of its efficacy in correlating a filling defect of injected iodinated nonionic contrast medium with a patient's reported level of pain.[18]

Injection of solutions into the epidural space of a patient with meningeal adhesions is usually painful because of stretching of affected nerve roots.[14] Dexamethasone or betamethasone have been recommended instead of methylprednisolone or triamcinolone because particulate steroids may occlude an epidural catheter or possibly cause spinal ischemia following unintentional intravascular injection.

Hypertonic saline is used to prolong pain relief due to its local anesthetic effects and its ability to reduce edema in previously scarred or inflamed nerve roots.[17] A lateral needle approach is recommended into the caudal canal, directing the needle and catheter toward the affected side. Lateral placement tends to minimize the likelihood of penetrating the dural sac or injecting subdural. When 5–10 mL of contrast media are injected into the caudal canal through an epidural catheter, a "Christmas tree" appearance develops as dye spreads into the perineural structures inside the bony canal and along the nerves as they exit the vertebral column.[17] Epidural adhesions prevent the spread of the dye, so the involved nerves are not outlined by the contrast. Once correct catheter placement in the epidural space is ensured, 1500 units of hyaluronidase in 10 mL of preservative-free saline is injected rapidly. This is followed by an injection of 10 mL of 0.2% ropivacaine and 40 mg of triamcinolone. After these two injections, an additional volume of 9 mL of 10% hypertonic saline is infused over 20–30 minutes. On the second and third days, the local anesthetic (ropivacaine) injection is followed by the hypertonic saline solution.

A study compared the effectiveness of percutaneous epidural adhesiolysis utilizing an injection of 5 mL of preservative-free 2% lidocaine, followed by 6 mL of 10% sodium chloride solution and 6 mg of nonparticulate betamethasone via a fluoroscopically guided, targeted placement of a caudal catheter (group 1) versus an injection of the same solution with 6 mL of 0.9% sodium chloride solution instead of the hypertonic saline via a catheter placed in the caudal canal with its tip at the S3 level (group 2). The study found significant pain relief (76%) in the hypertonic saline group at 1-year follow-up, compared to 4% of patients in the normal saline group.[60]

A prospective, double-blind, randomized study looking at the role of adding hyaluronidase to fluoroscopically guided caudal epidural steroid and hypertonic saline injections in patients with failed back surgery syndrome showed a significant improvement in long-term pain relief in patients who received hyaluronidase. A total of 38 patients were enrolled in the study. Twenty patients received fluoroscopically guided caudal injections of 10 mL of 0.25% bupivacaine solution containing 80 mg of methylprednisolone and 30 mL of 3% hypertonic saline (group 1). Eighteen patients received the same amount of local anesthetic and steroids, followed by 1500 IU of hyaluronidase (which was replaced by an equivalent volume of normal saline in group 1 patients) and 30 mL of 3% hypertonic saline (group 2).[61]

Another randomized, controlled, double-blind trial of fluoroscopically guided caudal epidural injections compared 10 mL of lidocaine 0.5% and 9 mL of lidocaine 0.5% mixed with either 6 mg of betamethasone or 40 mg of methylprednisolone (total volume 10 mL). This study showed a potential superiority of steroids when compared with local anesthetic alone at 1-year follow-up.[62]

Postoperative Analgesia in Patients Undergoing Lumbar Spine Surgery

Another unique application of caudal block is the provision of postoperative analgesia in patients undergoing lumbar spine surgeries. In one case series, patients received 20 mL of 0.25% bupivacaine with 0.1 mg buprenorphine via the caudal epidural approach, performed prior to surgical incision. The patients underwent posterior interbody fusion and laminotomy for spinal stenosis, and postoperative pain control was compared in the caudal group with a group treated with conventional parenteral opioids. The caudal group required fewer rescue analgesic medication doses for the first 12 hours following surgery.[19] A reduction in blood pressure in the caudal group patients undergoing laminotomy, but not fusion, was noted in the patients with prolonged duration (24 hours) of postoperative analgesia.

Other Applications

Caudal epidural block has also been compared with intramuscular opioids in the treatment of pain after emergency lower extremity orthopedic surgery. The caudal group who received 20 mL of 0.5% bupivacaine had 8 hours of superior analgesia and also had a significant reduction in the need for rescue opioid medications.[20]

Caudal injection of clonidine (75 μg with 7 mL bupivacaine 0.5% and 7 mL lidocaine 2% with epinephrine 5 μg/mL) has been used for postoperative analgesia after elective hemorrhoidectomy. Thirty-two adults received the clonidine-local combination, while a control group received local anesthetic alone.

Analgesia averaged 12 hours in the clonidine group, compared to less than 5 hours in the group receiving only local anesthetic. Bradycardia occurred in about 22% of patients in the clonidine group.[18] This contrasts with the results of an evaluation of clonidine used as an adjunct for pediatric caudal anesthesia as noted previously.[63]

Caudal injections of alcohol or phenol have been used to treat intractable pain due to cancer. In a study of 67 blocks, it was found that the lower sacral roots were easily reached with the caudal injection, and that the S1 and S2 roots (contribution from the lumbosacral plexus) were spared.[22]

COMPLICATIONS ASSOCIATED WITH CAUDAL EPIDURAL BLOCK

The complications of caudal block are the same as those occurring following lumbar epidural block and may include those related to the technique itself and those related to the injectate (local anesthetic or other injected substance). Fortunately, serious complications occur infrequently. The list of potential complications includes epidural abscess, meningitis, epidural hematoma, dural puncture and postdural puncture headache, subdural injection, pneumocephalus and air embolism, back pain,[64] and broken or knotted epidural catheters. Other rare complications that have been reported with caudal anesthesia include unilateral parotid swelling,[65] persistent hiccups following continuous caudal infusion of 0.1% ropivacaine,[66] and intracranial hypotension headache after uncomplicated caudal epidural injection.[67]

Systemic Toxicity of Local Anesthetics

The incidence of local anesthetic–induced seizures following caudal block seems to be higher that of lumbar or thoracic approaches. In a retrospective study of 25,697 patients who received brachial plexus blocks, caudal epidural blocks, or lumbar epidural blocks from 1985 to 1992, Brown noted 26 seizure episodes.[68] The frequency of seizures in adults by decreasing order was caudal, brachial plexus block, lumbar, or thoracic epidural block. Nine cases were attributed to caudal blocks, eight occurring with chloroprocaine and one with lidocaine. There was a 70-fold increased incidence of local anesthetic toxic reactions with caudal epidural anesthesia (0.69%) than with lumbar or thoracic epidural anesthesia in adults.

Clinical Pearls

- The incidence of local anesthetic–induced seizures following caudal epidural block is higher than following lumbar or thoracic approaches.
- The relative risk of local anesthetic toxicity follows this order: caudal > brachial plexus block > lumbar or thoracic epidural block.
- Elevation of heart rate by more than 10 beats per minute or an increase in systolic blood pressure of more than 15 mm Hg after injection of epinephrine-containing local anesthetic is suggestive of intravascular injection.

In children, however, one retrospective review identified only two toxic reactions (ie, local anesthetic–induced seizures) in 15,000 caudal blocks.[69] Dalens's group found that unintentional intravascular injection occurs in up to 0.4% of pediatric caudal blocks,[70] demonstrating the importance of performing epinephrine-containing test dosing in this age group. It has been suggested that an elevation of heart rate by more than 10 beats per minute or an increase in systolic blood pressure of more than 15 mm Hg should be taken as indicative of systemic injection. T-wave changes on the ECG occur earliest following intravascular injection, followed by heart rate changes and finally by blood pressure changes. These changes may be delayed for up to 90 seconds following the injection.[70]

Occurrence of Total Spinal Anesthesia

Total spinal anesthesia can occur when an injected dose of local anesthetic intended for the epidural space gains access to the subarachnoid space. In the case report of an 18-month-old child weighing 10 kg who received a caudal block postoperatively after undergoing emergency repair of a recurrent diaphragmatic hernia, 4 mL of 0.5% bupivacaine and 2.5 μg/kg of buprenorphine were injected in a total volume of 10 mL. Eye opening and hand movement were delayed for 3 hours following this complication.[71] In another infant undergoing revision of a Nissen fundoplication, a caudally placed catheter was unintentionally advanced to the cervical spinal region. Electrical stimulation of the catheter (Tsui test) resulted in phrenic nerve stimulation. The catheter was successfully repositioned and further care was uncomplicated. This case report illustrates the relative ease of passing the catheter to high vertebral levels in infants as opposed to adults.[72]

Infection

One case report documented the rare occurrence of distant diskitis and vertebral osteomyelitis involving skip levels and without the development of epidural abscess formation in an elderly woman who received caudal epidural steroid and local anesthetic for degenerative spondylolisthesis. One month later, she developed an L2–L3 and L4–L5 infective diskitis, together with adjacent vertebral osteomyelitis. Cultures demonstrated *Pseudomonas aeruginosa* growth, which was treated with antibiotics.[73]

SUMMARY

Caudal epidural block is a technique of providing analgesia and anesthesia of the lumbosacral nerve roots that pre-dates conventional lumbar approaches. The block has undergone several periods of acceptability, and although it is infrequently applied to routine surgical cases in adults, it is the most commonly performed regional anesthetic technique in infants and children. Caudal block in adult patients has enjoyed a resurgence lately, mainly because it provides an alternative route to the lumbar epidural space when direct access is limited by previous surgeries and for performing epiduroscopy. Clinicians who routinely utilize fluoroscopy and ultrasound imaging will find that it has many applications, for both routine and complicated cases.

Combined Spinal-Epidural Anesthesia

J. Sudharma Ranasinghe, Elyad Davidson, and David J. Birnbach

INTRODUCTION

In recent years, regional anesthesia techniques for surgery, obstetrics, and postoperative pain management have been used with increasing frequency.[1–3] The combined spinal-epidural (CSE) technique, a comparatively new anesthetic choice, includes an initial subarachnoid injection followed by epidural catheter placement and subsequent administration of epidural medications. This allows for rapid relief of pain or induction of regional anesthesia by the rapid onset of the spinal drugs and subsequent administration of medications for prolonged anesthesia. In addition, postoperative analgesia via the epidural catheter can be delivered for extended periods.

Clinical studies have demonstrated that the CSE technique provides excellent surgical conditions as quickly as the single-shot subarachnoid block and with advantages in comparison to the conventional epidural block.[4–6] The advantage lies in the fact that CSE anesthesia offers benefits of both spinal and epidural anesthesia.

Although the CSE technique has become increasingly popular over the past two decades, it is a more complex technique that requires comprehensive understanding of epidural and spinal physiology and pharmacology.

This chapter discusses the technical aspects, advantages, potential complications, and limitations of the CSE technique for surgery, postoperative pain management, and labor analgesia.

CLINICAL APPLICATIONS OF CSE

The results of a survey conducted by Blanshard and Cook demonstrated wide variation in CSE anesthesia use and practice among experienced anesthesiologists,[7] reflecting concern over the frequency of CSE-related complications,[8,9] controversy over the technique,[10,11] and the potential for higher failure rates with the CSE technique compared with individual spinal or other anesthetic techniques.[12]

General Surgery

The CSE technique has been described in the medical literature for use in general surgery, orthopedics, trauma surgery of a lower limb, and urological and gynecological surgery. Clinical studies have demonstrated that the CSE technique provides excellent surgical conditions as quickly as with single-shot subarachnoid block—conditions that are better than with epidural block alone.[4,13] With the CSE technique, surgical anesthesia is established rapidly, saving 15–20 minutes compared with epidural anesthesia. Furthermore, epidural catheterization provides the possibility of supplementing the subarachnoid anesthesia, which may be insufficient when used alone.

This was recently illustrated by Mane et al,[14] who presented a case series of laparoscopic appendectomy successfully performed under CSE anesthesia. CSE anesthesia in their series was performed using separate needles at two different interspaces. Spinal anesthesia was performed at the L2–L3 interspace using 2 mL 0.5% (10 mg) hyperbaric bupivacaine mixed with 25 μg fentanyl. The epidural catheter was inserted at the T10–T11 interspace to supplement spinal anesthesia and for postoperative pain relief. In an obstetrics-related article, it was also observed that various needles can be used in different combinations when performing the CSE technique and may have different advantages and disadvantages for different patients and situations.[15] This is discussed further in the chapter.

Labor Analgesia

The CSE technique is widely used in obstetric practice to provide optimal analgesia for parturients. It offers effective, rapid-onset analgesia with minimal risk of toxicity or motor block.[16] In addition, this technique provides the ability to prolong the duration of analgesia, as often is required in labor, through the use of an epidural catheter. Furthermore, should an operative delivery become necessary, that same epidural catheter can be used to provide operative anesthesia. The onset of spinal analgesia is almost immediate, and the duration is between 2 and 3 hours, depending on which agent or agents are chosen.

The duration of spinal analgesia, however, has been found to be decreased when administered to a woman in advanced labor versus one in early labor.[17] Laboring patients may have greater satisfaction with CSE anesthesia than with standard epidurals, perhaps because of a greater feeling of self-control.[18] The original descriptions of spinal labor analgesia utilized sufentanil or fentanyl,[19] but the addition of isobaric bupivacaine to the opioid produces a greater density of sensory blockade while still minimizing motor blockade.[20] Originally, 25 μg of fentanyl or 10 μg of sufentanil were advocated, but subsequent studies suggested the use of smaller doses of opioid combined with a local anesthetic.[21] For example, many clinicians are now routinely using 10–15 μg of intrathecal fentanyl. Several studies have suggested that ropivacaine and levobupivacaine can be substituted for intrathecal bupivacaine, especially when added to an opioid, to provide labor analgesia.[22–24] The CSE technique has also made ambulation possible for many women receiving neuraxial analgesia, although ambulation may also be possible with other techniques. Wilson et al[25] showed that significantly more women maintained superior leg power for a longer period with CSE anesthesia than with low-dose infusion of standard epidural. In addition to the advantage of rapid onset of pain relief, the CSE technique may reduce the incidence of several potential problems associated with the conventional epidural technique, including incomplete (patchy) blockade, motor block, and poor sacral spread.

Another potential advantage of the CSE technique is that it may be associated with a significant reduction in the duration of the first stage of labor in primiparous parturients.[26,27] However, according to a more recent study by Pascual-Ramirez et al,[28] when compared with conventional epidural analgesia, the CSE technique did not shorten total labor duration but did reduce local anesthetic requirement and motor weakness. Reduction of motor blockade is advantageous for parturients, even those who will not ambulate.

Combined Spinal-Epidural Technique for Cesarean Delivery

The CSE technique, first reported as an option for cesarean delivery in 1984,[29] has recently increased dramatically in popularity. The advantage of this technique is that it provides rapid onset of dense surgical anesthesia while allowing the ability to prolong the block with an epidural catheter. In addition, because the block can be supplemented at any time, the CSE technique allows the initial use of smaller doses of spinal local anesthetics, which may in turn reduce the incidence of high spinal block or prolonged hypotension.[30] It may also reduce the duration of postanesthesia care unit (PACU) stay. Potential problems of the CSE technique for cesarean delivery include an inability to test the catheter, the possibility of a failed epidural catheter after spinal injection, and the risk of enhanced spread of previously injected spinal drug after use of the epidural catheter.[31]

Combined Spinal-Epidural Technique for External Cephalic Version of Breech Presentation

Neuraxial analgesia has been used to reduce the maternal pain during external cephalic version (ECV) for breech presentation. A potential benefit of the CSE technique is the ability to provide fast and effective pain relief for ECV and convert to neuraxial anesthesia for emergency delivery, if required. Kawase et al[32] reported a successful case of ECV under CSE technique followed by vaginal delivery. Sullivan and collegues[33] studied the effect of the CSE technique on the success of ECV when compared with systemic opioid analgesia and found no difference; however, the pain scores were lower and satisfaction was higher with CSE analgesia.

ADVANTAGES OF THE COMBINED SPINAL-EPIDURAL TECHNIQUE

Onset of the Block

When CSE block was compared with either epidural or subarachnoid block for hip or knee arthroplasty, CSE anesthesia was found to be superior to epidural anesthesia. With the CSE technique, surgical anesthesia was rapidly established, saving 15–20 minutes compared with epidural anesthesia. Furthermore, the epidural catheter provided the possibility of supplementing insufficient subarachnoid anesthesia. Patients who received the CSE technique had more intense motor blockade than those who received epidural anesthesia alone.[4]

Failure Rate

It has been reported that the CSE technique decreases the failure rate and incidence of several other adverse events associated with neuraxial analgesia.[34] In a retrospective analysis of almost 20,000 deliveries (75% neuraxial labor analgesia rate), the overall failure rate with this technique was 12%. The patients had adequate analgesia from initial placement, but 6.8% of patients had subsequent inadequate analgesia during labor and required epidural catheter replacement. Ultimately, 98.8% of all patients in Pan's report received adequate analgesia, even though 1.5% of patients had one or more epidural catheter replacements.[34] However, when compared with epidural analgesia alone for labor, the incidents of overall failure, accidental intravascular epidural catheters, accidental dural punctures, inadequate epidural analgesia, and catheter replacements were repeatedly shown to be significantly lower in patients receiving CSE analgesia.[16,34,35] In addition, Eappen et al reported that CSE had a higher success rate compared to the conventional epidural technique.[35] This difference may be due to the ability to confirm questionable epidural location by successful spinal placement and observation of cerebrospinal fluid (CSF).

Local Anesthetic Requirement

During Surgery CSE enables low-dose spinal anesthesia for cesarean delivery.[36–40] When using single-shot spinal (SSS) anesthesia for ambulatory surgery, many anesthesiologists tend to administer more medication than is needed because there is only one chance to ensure an effective spinal block. The presence of an epidural catheter as a "safety net" allows the anesthesiologist to use the lowest effective dose of local anesthetic. Urmey et al used the CSE technique to investigate the appropriate dose of intrathecal isobaric lidocaine 2% for day case arthroscopy.[41] The CSE technique provided excellent anesthesia for all 90 patients in his study. Patients receiving the smallest dose (40 mg) had a significantly shorter duration of anesthesia, which allowed quicker discharge than for the patients receiving 60 or 80 mg of intrathecal lidocaine.

Norris et al suggested the use of a CSE technique with intrathecal sufentanil alone for outpatient shock-wave lithotripsy, reserving the use of epidural catheter for patients who did not achieve adequate analgesia.[42]

During Labor Analgesia Patel et al[43] studied the impact of spinal medication administered as part of a CSE technique on the subsequent epidural bupivacaine requirement. In a prospective, randomized, double-blind study, the MLAC (minimum local analgesic concentration) of epidural bupivacaine for labor analgesia was assessed following initial intrathecal (CSE) or epidural medication (standard epidural). They reported that the MLAC of epidural bupivacaine was not reduced by the use of intrathecal medication, but actually increased by a factor of 1.45. (MLAC in the standard epidural group was 0.032% wt/vol and for the CSE group was 0.047% wt/vol.) This suggests that CSE analgesia may not offer a quantitative analgesia advantage over standard epidural analgesia beyond the initial dose.

Epidural Volume Extension: A Modification of the CSE

During CSE anesthesia, it has been shown that supplementation of the epidural space with epidural saline ("epidural volume extension," EVE) may influence the anesthetic level and quality of spinal anesthesia. The proposed mechanism for this augmentation is a compressive effect on the subarachnoid space that promotes the cephalad spread of local anesthetic.

Takiguschi et al,[44] in a study using myelography on human volunteers, demonstrated that the contrast medium in the subarachnoid space was displaced cranially after lumbar epidural saline injection and the diameter of the subarachnoid space was narrowed due to the volume effect. This is a time-dependent phenomenon with maximum benefit if performed early.

Similarly, Blumgart et al showed that EVE with 10 mL of normal saline resulted in an increase in sensory block height of four segments following the administration of 8–9 mg of subarachnoid hyperbaric bupivacaine in women undergoing cesarean delivery.[45] However, a more recent study by Loubert et al failed to show a difference in sensory block height after EVE with 5 mL of normal saline.[46] It is possible that the 5-mL volume was insufficient in this patient population, although the volume of normal saline that has been previously shown to be effective for EVE is approximately 5–10 mL.[47]

The results may also be due to a positional effect; in both studies, the CSE technique was performed in the sitting position. However, Blumgart injected 10 mL of saline epidurally through the catheter within 5 minutes of hyperbaric spinal medication only after the patient was turned supine with a 15° left lateral tilt. In Loubert's study, 5 mL of normal saline were injected through the Tuohy needle immediately after the spinal hyperbaric medication while the patients were still in the sitting position. Finally, the epidural catheter was threaded and the patients were helped into the supine 15° left lateral tilt.

Is the baricity of the local anesthetic a factor? A study by Tyagi et al demonstrated (in nonobstetric patients) that EVE was more effective with plain bupivacaine compared to hyperbaric bupivacaine, requiring a smaller dose while producing a higher sensory block with an earlier onset.[48] They attributed this difference to the restricted spread of hyperbaric local anesthetics in the subarachnoid space compared to the plain solution. Another study by Tyagi et al found that the intrathecal block level was similar in duration and extent with hyperbaric bupivacaine whether given as a SSS or a CSE administration with or without EVE on parturients undergoing elective cesarean delivery.[49]

Many factors seem to affect EVE. These include timing, volume of saline, features of the local anesthetic (hyperbaric vs. hypobaric), position during or after spinal anesthesia, and obstetric versus nonobstetric patients. Although it has been proposed that EVE may allow a reduced subarachnoid dose of local anesthetic for surgery and consequently reduce the incidence of hemodynamic effects associated with spinal block, there is a lack of uniformity between protocols and study results. Therefore, the influence of epidural saline injection on the quality of spinal anesthesia remains unclear.

Sequential CSE

In a study by Fan et al, four different intrathecal doses of hyperbaric bupivacaine (2.5, 5, 7.5, and 10 mg) were compared in patients undergoing cesarean delivery under sequential CSE block, a technique that involves administration of a relatively small subarachnoid block that may be supplemented as needed by epidural local anesthetics. The authors demonstrated that 5 mg intrathecal bupivacaine combined with an appropriate dose of epidural lidocaine provided adequate surgical analgesia while maintaining optimal hemodynamic stability. Higher doses of intrathecal bupivacaine were associated with typical adverse effects of high subarachnoid block, such as nausea, vomiting, and dyspnea.[50]

Macfarlane et al demonstrated that CSE anesthesia appears to offer no hemodynamic benefits compared with SSS anesthesia during cesarean delivery when the same dose of local anesthetic is administered. Hemodynamic stability was studied directly by measuring noninvasive blood pressure and indirectly by the ephedrine requirement, systemic vascular resistance index, and cardiac index using thoracic impedance cardiography.[51]

Combined Spinal-Epidural for High-Risk Patients

The sequential CSE technique may be particularly advantageous in high-risk patients, such as those with cardiac disease, when slower onset of sympathetic blockade is desirable.[52,53] Most spinal anesthetics are administered as a single-injection procedure, and rapid onset of sympathetic blockade may result in abrupt, severe hypotension. Traditionally, high-risk patients are managed with the slow onset of controlled epidural anesthesia, which requires much higher total dosages of local anesthetic than is the case with sequential CSE. With careful positioning of the patient prior to induction of the subarachnoid block, and by allowing titration with small incremental epidural doses to the precise level of anesthesia desired, the sequential CSE technique may enhance the safety of the neuraxial block.

Agarwal et al reported successful management of hysterectomy in a patient with ventricular septal defect and pulmonary atresia (VSD-PA) using CSE with the EVE technique.[54] Along similar high-risk lines, Month et al presented two parturients with idiopathic intracranial hypertension who achieved both labor analgesia and symptomatic relief using the CSE technique with small-volume CSF withdrawal.[55]

In summary, CSE can reduce or eliminate many of the disadvantages of subarachnoid or epidural anesthesia alone while preserving their respective advantages. The CSE block offers the speed of onset, efficacy, and minimal toxicity of a subarachnoid block combined with the potential of improving an inadequate block or prolonging the duration of anesthesia with epidural supplements; with the epidural, one may extend the analgesia well into the postoperative period. Although the sequential CSE technique will take somewhat longer than the standard CSE technique, the use of minimal doses of local anesthetics has been shown to reduce the frequency and severity of hypotension when compared with epidural or spinal techniques.[56]

Despite numerous studies advocating CSE, a 2007 Cochrane review of 19 randomized trials involving 2658 laboring women concluded that CSE offers little benefit when compared to conventional epidural analgesia, and there was no difference in the overall satisfaction of the women between the two techniques.[57] However, the authors did acknowledge that CSE produced slightly faster onset of effective pain relief and less need for rescue analgesia and was associated with less urinary retention. Later, Van de Velde[58] criticized this Cochrane review, stating that a number of well-performed studies were excluded from analysis. He wrote, "With conventional epidural analgesia, a wider inter-patient variability exists with respect to onset time of analgesia. With CSE, onset time is short in all patients irrespective of the other factors."

FUNCTIONAL ANATOMY RELATED TO CSE

When performing an epidural block, skin-to-epidural space distance (SED) and the posterior epidural space distance (PED) are measures that can help reduce the inadvertent penetration of the dura and injury to neural structures.[59,60] The knowledge of these distances is also important in the success rate of epidural blocks. The PED, a measure of the epidural space depth, is particularly important with the CSE needle-through-needle (NTN) technique. Underestimation of this distance (short protrusion of the spinal needle through the epidural needle) will result in a higher incidence of spinal block failure. Any nonmidline approach also would increase the risk of not reaching the subarachnoid space because the dural sac has a triangular shape with the top pointing dorsally. Overestimation of PED will cause over protrusion of the spinal needle, which may increase the risk of neural damage.[61] These distances have been measured using various methods,[62] including magnetic resonance imaging (MRI), computed tomography (CT), ultrasound, and measurement of CSE tip-to-tip distance or the amount of protrusion of the spinal needle beyond the Tuohy needle.

The distance from the SED is most commonly 4 cm (50%) and is 4–6 cm in 80% of the population according to detailed records of 3200 cases.[62] The width of the PED varies with vertebral level, being the widest in the midlumbar region (5–6 mm) and decreasing toward the cervical vertebral column. In the midthoracic region, it is 3–5 mm in the midline and narrows laterally. In the lower cervical region, it is only 1.5–2 mm in the midline.[63] These spaces also correlate with the weight/height ratio and body mass index (BMI).[64] Based on these measures, the present design of spinal needle protrusion varies between 10 and 15 mm beyond the epidural needle.

Epidural Space and Ligament Flavum

The thickness of the ligamentum flavum, distance to dura, and skin-to-dura distance vary with the area of vertebral canal (see Table 26–1).

The two ligamenta flava are variably joined (fused) in the midline, and this fusion or lack of fusion of the ligamenta flavum occurs at different vertebral levels in individual patients. Lirk et al investigated the incidence of lumbar ligamentum flavum midline gaps in embalmed cadavers.[65] Vertebral column specimens were obtained from 45 human cadavers. The gaps in the lumbar ligamentum flavum are most frequent between L1 and L2 (22.2%) but are rare below this level (L2–L3 = 11.4%, L3–L4 = 11.1%, L4–L5 = 9.3%, L5–S1 = 0). Therefore, when using a midline approach, one

TABLE 26–1. Characteristics of ligamentum flavum at different vertebral levels.

Site	Skin to Ligament (cm)	Thickness of Ligament (mm)
Cervical	—	1.5–3.0
Thoracic	—	3.0–5.0
Lumbar	3.0–8.0	5.0–6.0
Caudal	Variable	2.0–6.0

cannot rely on the ligamentum flavum to impede entering the epidural space in all patients.

TECHNIQUE

A number of reviews have discussed the technical factors related to the performance and success of CSE.[66–68] Although CSE is considered a relatively new technique, in 1937 Soresi actually described the intentional injection of anesthetic agents outside and within the subarachnoid space.[69] Somewhat different from current practice, Soresi intentionally used a single needle. He first injected some local anesthetic into the epidural space and then advanced the needle and injected the rest of the medication to cause a subarachnoid block. Although this technique included both spinal and epidural anesthesia, no catheter was used.

In 1979, Curelaru[70] reported the first CSE with an introduction of an epidural catheter through a Tuohy needle. Catheter insertion was followed by a test dose and then a traditional dural puncture, which was performed at a different interspace using a 26-gauge spinal needle. That same year, Brownridge suggested the use of CSE for obstetrics. He described successful use of CSE for elective cesarean section in 1981.[71,72]

In 1982, the NTN CSE technique was first described independently by Coates and Mumtaz, and its active use in obstetric practice was first published in 1984 by Carrie.[73–75] Popularity of the technique began in the late 1990s. Several approaches for Initiation of CSE have been described in the recent literature.

Needle-Through-Needle Technique

In contrast to Soresi's initial description of CSE, in which a single needle was introduced into the epidural space and then advanced into the subarachnoid space, the currently preferred NTN technique includes use of separate epidural and spinal needles. Typically, the epidural space is located with a conventional epidural needle and technique, and then a long spinal needle is passed through the epidural needle until CSF appears in the hub of the spinal needle. Drug is administered via the spinal needle into the subarachnoid space, the spinal needle is removed, and finally an epidural catheter is inserted into the epidural space. Although several different CSE techniques are used in clinical practice (including the two-needle, two-interspace technique), NTN is the most widely used CSE technique in the United States.

Separate Needle Technique

The CSE technique may be performed using two separate needles with the separate needle technique (SNT), with spinal block and epidural catheter placement at either a single[76,77] or two different interspaces.[78–80] If the epidural catheter is placed first, proper placement can be tested before administration of spinal medications, potentially decreasing the risk of accidental intravascular or intrathecal catheter migration. Placing the epidural catheter first may also reduce the risk of neural damage, which may occur when the catheter is inserted after subarachnoid block, because paresthesia and other warning signs of improper needle placement may be absent after administration of spinal medications. However, there is also the risk of striking the epidural catheter with the spinal needle.[81–83] Some authors consider this to be a purely hypothetical risk and have demonstrated that it is not possible to perforate an epidural catheter with commonly used spinal needles.[84,85]

Cook et al[86] reported a series of 201 consecutive CSEs performed with a novel SNT. The study was designed to avoid potential and actual problems associated with the CSE technique. Cook et al placed the spinal needle in the subarachnoid space and then replaced the spinal needle stylet to stop the CSF leak. Next, the epidural catheter was placed through a different interspace and then returned to the spinal needle to inject the subarachnoid drug, thus avoiding epidural catheter insertion in an anesthetized patient. This method of CSE anesthesia, although much more work, may be associated with high success and low complication rates.

Regardless of which component is performed first, the major disadvantage of the two-needle, two-interspace technique is that it takes longer to perform and requires two separate injections.

Comparison of Techniques

The SNT technique has a few theoretical advantages compared to the NTN technique. It enables placement of the epidural catheter prior to initiation of the spinal block. The SNT may thus theoretically reduce the risk for neurological injury because paresthesia and other symptoms are not masked. Because the epidural catheter is placed early, problems that may occur due to delayed catheter placement (technical problems) after the injection of a hyperbaric spinal solution (such as unilateral, sacral, or low lumbar regional neuraxial block) are avoided.[87–89]

Several studies have compared NTN and SNT techniques.[90–93] Some have reported better success and lower failure rates with the SNT. However, these studies also reported greater patient acceptance and less discomfort with the NTN technique. Backe et al, in a prospective randomized study,[94] compared the outcomes and techniques of NTN and SNT (double space) CSE in 200 elective cesarean delivery patients. Successful blocks to T5 with the double-space and the NTN techniques were 80 versus 54, respectively, odds ratio 0.29. SNT had a greater success rate than the NTN technique; the T5 dermatome was reached with fewer corrective manipulations (epidural augmentation or repeated blocks). Failure to enter the intrathecal space once the epidural space had been located occurred in 29 patients in the NTN group. Time to readiness for surgery, however, was slightly increased with SNT (15 minutes with SNT vs. 12.9 minutes with NTN).

Sadashivaiah et al[95] retrospectively analyzed data from 3519 elective cesarean deliveries performed under the SNT technique. They reported a lower rate of conversion to general anesthetic due to failed neuraxial block (0.23%) than previously reported (0.8%–1.3%).

One of the problems with the NTN technique is that many patients complain of paresthesia/dysesthesia or respond (movement, grimacing, vocalization) to dural puncture during insertion of a pencil-point needle. Van den Berg et al[96] compared the effects of saline versus air for loss of resistance (LOR) on the occurrence of this discomfort and reported that use of saline is associated with fewer patient (18% vs. 44%) responses at the moment of thecal penetration. Although the mechanism of this reduced response with saline for LOR is not clear, the authors postulated that perhaps the placement of saline in the epidural space modulated dural sensitivity.

Techniques to Improve the Success and Safety of Combined Spinal-Epidural

The success of a CSE block is heavily dependent on accurate cannulation of the epidural space. The identification of the epidural space is traditionally achieved by a blind LOR technique. With this handling of the needles, where the feedback to the operator is merely tactile, deviation of the axis of the needle trajectory may occur. Because of the triangular form of the dural sac, deviation of the spinal needle from the midline will cause the dural sac to be missed, leading to spinal component failure or unsuccessful dural puncture.

Grau et al performed real-time ultrasound scanning of the lumbar spine to provide accurate reading of the location of the needle tip and to facilitate the performance of CSE anesthesia.[97] Their aim was to establish a less-invasive method to monitor the advancement of the needle in real time. Thirty parturients scheduled for cesarean delivery were randomized to three equal groups. Ten control patients received CSE anesthesia performed in a conventional manner. Ten received ultrasound scans by an off-line technique. The remaining 10 received online imaging of the lumbar region during puncture. The Tuohy needle was inserted using the midline approach in all three groups. In the control group, CSE was performed using A single-space NTN technique with the standard LOR to saline method.

In the off-line group, ultrasound images were taken just before the puncture to improve needle trajectory. In the online group, ultrasonic images were taken to monitor and identify needle trajectory in real time.

The authors reported that in both ultrasound groups, a significant reduction in the number of necessary puncture attempts was found ($p < .036$); the number of interspaces necessary for puncture was reduced ($p < .036$); and the number of spinal needle manipulations was significantly reduced ($p < .036$). Dural tenting was observed in 9 of 10 of the online group (tenting length 2.4 mm). Asymmetric block was observed in 10% of those in the control group, but not in any of those in the ultrasound groups. The authors concluded that the use of ultrasound imaging was obviously helpful in finding the ideal needle trajectory and to improve puncture conditions by demonstration of the relevant anatomy.

In the CSE NTN technique, there is no practical test to confirm correct epidural catheter placement. Tsui and colleagues proposed the use of nerve stimulators to confirm the proper placement of epidural catheter.[98] They studied 39 obstetric patients in labor, receiving epidural catheters (not CSE) for analgesia. A low-current (1- to 10-mA) electrical stimulation was used to confirm the correct placement of the epidural catheter (19-gauge Arrow Flextip plus). A positive motor response (truncal or limb) indicated that the catheter was in the epidural space. They reported that the sensitivity and specificity of this test were 100% and 100%, respectively, with 38 true positive tests and 1 true negative test. A case of intravascular epidural catheter migration was detected using this new test and was subsequently confirmed by a positive epinephrine test. If the motor response only occurs with larger currents (>10 mA) or does not respond at all (before receiving any local anesthetics), the catheter is most likely outside the epidural space. If a positive response occurs at an unusually low milliamperage (<1 mA), intrathecal placement is likely.

The electrical stimulation test may not be applicable when the CSE technique is used for surgery, where anesthetic doses of local anesthetics are administered intrathecally prior to the placement of the epidural catheter. When using the CSE technique for labor analgesia, this test may be utilized as a simple and practical method to determine the epidural catheter placement. The standard test dose utilized in the United States (3 mL of 1.5% lidocaine with 1:200,000 epinephrine) may help to identify intravascular and intrathecal placement, but it does not verify appropriate epidural placement or function.

DRUGS FOR COMBINED SPINAL-EPIDURAL

Sufentanil and fentanyl, with or without local anesthetics, are most often administered intrathecally to provide analgesia for the laboring woman receiving CSE. The usual doses of sufentanil are 2.5–10 μg; however, most practitioners are now using 2.5 or 5 μg. The ED_{50} and ED_{95} for laboring patients were found to be 2.6 and 8.9 μg respectively.[99] The doses of fentanyl used are typically10–25 μg. The median effective dose (ED_{50}) and effective dose in 95% of the population (ED_{95}) for laboring patients have been reported to be 5.5 and 17.4 μg, respectively.[100] Although the original studies used much higher doses of intrathecal opioids (10 μg sufentanil and 25–50 μg of fentanyl), subsequent studies have suggested the use of smaller doses, with reduced side effects and similar analgesic effect.[101]

Morphine, a highly ionized, water-soluble opioid, produces analgesia of long duration but slow onset (approximately 60 minutes between neuraxial injection and onset). In addition, it may be associated with an unacceptably high incidence of side effects, such as nausea, vomiting, pruritus, as well as the potential for delayed respiratory depression. These side effects, coupled with the slow onset of pain relief, limit the usefulness of intrathecal morphine for labor analgesia. Intrathecal meperidine (10 mg) may provide reliable analgesia in advanced labor[102] but has been associated with a high incidence of nausea, vomiting, hypotension, and need for low blood pressure management. In addition, it is the only opioid that has intrinsic local anesthetic properties at clinically appropriate doses[102] by blocking nerve conduction at the proximal end of the dorsal root[103] via a mechanism other than sodium channel blockade.[104] This nerve conduction blockade is not reversible with naloxone.[103]

In many patients, a single intrathecal injection of a lipid-soluble opioid is insufficient to produce analgesia for the entire duration of labor. If the second stage of labor is imminent, to achieve a greater depth of pain relief, the subarachnoid administration of local anesthetic plus opioid should be considered.

The combination of 2.5–5 μg sufentanil plus 2.5 mg bupivacaine provides rapid analgesia without motor block, alleviates the pain of the second stage of labor, and lasts longer than sufentanil alone.[105] Although the original reports[106] recommended the use of 10 μg of sufentanil, Sia and colleagues showed that adequate labor pain relief could be safely provided by administering half that dose of intrathecal sufentanil plus bupivacaine.[107]

Previous studies[108] have attempted to determine the ED_{50} of intrathecal bupivacaine, defined as minimum local anesthetic dose (MLAD) or ED_{50} and then use this to assess the effect of different doses of fentanyl. The MLAD of intrathecal bupivacaine has been found to be 1.99 mg, and the addition of 5 μg intrathecal fentanyl offered a similar significant sparing effect to 15 or 25 μg of fentanyl, resulting in less pruritus but with a shortened duration of action. ED_{95} was estimated from those studies.

Whitty et al[109] performed an up-down dose-finding study to determine the ED_{95} for intrathecal bupivacaine (more clinically relevant than that calculated from ED_{50}) when combined with a fixed amount of fentanyl. They recommended 1.75 mg of bupivacaine with 15 μg of fentanyl to reliably and rapidly relieve pain of parturients in the active phase of labor. At Jackson Memorial Hospital (Miami, FL), we currently use 1.25 mg bupivacaine plus 15 μg fentanyl as our spinal drug.

Levin et al compared a standard dose of intrathecal bupivacaine with sufentanil for CSE analgesia using two doses of ropivacaine (2 and 4 mg) with sufentanil. They concluded that both local anesthetics provided similar labor analgesia duration with equivalent side effects.[110]

COMPLICATIONS AND CONCERNS OF THE CSE TECHNIQUE

Failure of the Spinal Component

The most common method of performing a CSE is the single-interspace NTN technique. Failure to achieve a spinal block with this technique has been reported in 10%–15% of cases in the past,[111,112] although in experienced hands this risk may be as low as 2%–5%.[113]

Possible causes for failure of CSE include the following:

1. *Spinal needle too short.* The needle does not extend far enough beyond the epidural tip or tents the dura.[111] Holloway and Telford observed the distance from identification of the epidural space to penetration of the dura in 31 patients during the use of a Tuohy needle to perform deliberate dural puncture for the insertion of lumbar drains.[114] Although many reference textbooks indicate lesser distances[115] from location of the epidural spaces to dural puncture, these authors found an unexpectedly large distance of up to 2.25 cm[114] and postulated that tenting of the dura by the blunt atraumatic spinal needle might be the cause of this finding.
2. *Failure to enter the dura.* This may occur with very small caliber needles that lack the rigidity to puncture the dura.[116] As postulated by Holloway and Telford,[114] the absence of negative epidural space pressure limits the transdural pressure gradient and minimizes the reactive forces across the dura. Therefore, penetration of the dura (a relatively tough membrane) requires a substantial reactive force.[117]
3. *Divergence from the midline.* This may cause the spinal needle to pass by the dura,[92,97] despite the fact the epidural space has been identified.
4. *Use of a long small-gauge spinal needle.* A long small-gauge spinal needle may penetrate the dura and then be advanced too far (to the anterior epidural space) due to the delay in the reflux of CSF.[118–120]
5. *Use of a long pencil-point spinal needle.* Another potential problem may occur with the long pencil-point spinal needles currently being used. The spinal needle may be poorly anchored because it is located in the epidural needle and not held firmly in tissue. Therefore, with the spinal needle likely to move during injection, the medication may be only partially administered to the subarachnoid space.[121–123] The ability to hold the spinal needle steadily takes practice but is easily learned.
6. *Delay while placing the epidural catheter.* After subarachnoid drug has been administered, there can be a delay while placing the epidural catheter. This is usually brief and without consequences, but according to some authors,[124,125] it may alter the final characteristics of the block. This complication is of greater clinical significance when performing CSE for cesarean delivery. However, should a delay occur and the block not reach optimum height, the epidural catheter can be used to supplement the block.

Most current needle designs allow extension of the spinal needle 12–15 mm beyond the tip of the Tuohy needle. Excessively long needles, however, pose problems of handling and depth of placement. Deviation from midline will lengthen the epidural-dural distance and may also cause the spinal needle to miss the spinal space laterally (Figures 26–1 and 26–2). In addition, preservative-free normal saline used to identify the epidural space may be misinterpreted as CSF.

Complications Associated With Spinal Migration of the Epidural Catheter or Intrathecal Administration of Epidural Drugs

Subarachnoid Placement of Intended Epidural Catheter

One of the concerns with the CSE technique is that the epidural catheter may unintentionally pass through the dural puncture hole into the subarachnoid space during the CSE technique. This seems more likely with the NTN CSE technique than the SNT or with epidural needles with back holes (Figure 26–3). Although this may seem a rare theoretical problem, several publications have reported its occurrence.[126–129]

Angle et al[130] studied factors contributing to unintentional subarachnoid catheter passage after epidural placement with an in vitro model using human dural tissue. In that study, the dura was punctured with 25-gauge Whitacre® spinal needles. The likelihood of the catheter to enter into the subarachnoidal space was compared between the intact dura, versus the dura with obvious epidural needle punctures, and single 25-gauge

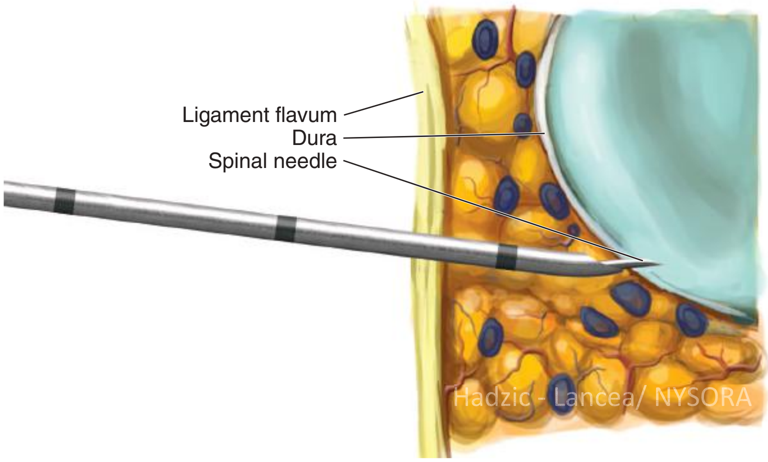

FIGURE 26–1. Deviation of the epidural needle laterally.

Whitacre spinal needle punctures after a CSE technique. Their conclusion was that the catheter passage is unlikely to occur in the presence of an intact dura or after an uncomplicated CSE technique. Therefore, unintentional subarachnoid passage of the epidural catheter suggests dural damage with the epidural needle.

Holtz et al investigated the possible passage of the epidural catheter into the subarachnoid space in an anatomical preparation.[131] In 10 series of experiments, the epidural compartment was entered with an 18-gauge Tuohy needle. The spinal puncture (27- or 29- gauge Quincke needle) was performed with the NTN technique. Subsequently, the internal side of the intrathecal compartment was examined endoscopically for penetration of the epidural catheter. In a similar way, the endoscope was inserted epidurally to visualize the movements of the epidural catheter in the epidural compartment. In this model of simulated physiologic intrathecal conditions, using one space NTN technique, they could not detect intrathecal passage of the epidural catheter.

Holmstrom and colleagues, in a percutaneous epiduroscopy study using fresh cadavers, also reported that it was impossible to force an epidural catheter into the subarachnoid space after a single perforation of the dura with a small-gauge spinal needle. However, they found that the risk of intrathecal catheter migration increased to approximately 5% after multiple dural punctures with the spinal needle. Dural penetration of the epidural catheter after a dural puncture with a Tuohy needle was clearly demonstrated in the same study.[132]

Whether the incidence of an unintentional passage of the epidural catheter into the subarachnoid space is increased with CSE as compared to standard epidural technique alone is controversial. Therefore, regardless of technique used, all epidural medications should be given in incremental doses.

Subarachnoid Spread of Epidurally Administered Drugs

Leighton and colleagues reported that, following a CSE, a dose of epidural local anesthetic will produce a higher dermatomal level than expected, presumably due to subarachnoid flux of the drug.[133] However, when used for labor analgesia, unless the dura is breached with the epidural needle or large bolus volumes are administered,[134] flux should not be clinically significant. Suzuki et al found, in nonpregnant patients, that dural puncture using a 26-gauge Whitacre spinal needle before the epidural injection increased caudal spread of analgesia induced by epidural local anesthetics with no change in the cephalad spread.[135]

Holtz et al endoscopically investigated the possible passage of epidural anesthetic through the dural puncture hole into the CSF compartment in an anatomical preparation.[131] Even 1 hour after epidural administration of 20 mL of methylene blue–dyed local anesthetic (bupivacaine 0.5%, isobaric), no passage of local anesthetic into the intrathecal compartment could be detected under continuous endoscopic monitoring.

A study by Kamiya et al[136] measured the lidocaine concentration in CSF after epidural administration at different interspaces with or without preceding spinal anesthesia. They concluded that there was no difference in the lidocaine concentrations in CSF with or without a meningeal hole. The authors explained the possible reason for the lack of difference in lidocaine concentration as follows: Lidocaine readily penetrates through meningeal tissue, and this transfer efficiency was most likely not affected by the presence of a small meningeal hole. The equilibrium of the lidocaine concentration in CSF, close to the administration site, would be attained within a few minutes

FIGURE 26–2. Spinal needle threaded into epidural needle.

FIGURE 26–3. Epidural needle with back hole.

due to this rapid penetration. Stated differently, the amount of local anesthetic that crosses through the small hole in the dura is trivial when compared with the amount that crosses through the meninges. This study confirmed that CSE is safe, and that the dural holes have no clinically significant influence on duration or extent of the spinal blocks in patients undergoing cesarean delivery. The data from several clinical studies of the CSE technique have not indicated an increase in spread of sensory block due to subarachnoid leakage of epidurally administered medications.[131,137–139]

However, the magnitude of flux is a function of the diameter of the spinal needle, and the risk may be increased by using a larger spinal needle or in the presence of a hole made with a Tuohy needle. The possibility of this hazard is supported by reports of high or total spinal block during epidural anesthesia administered following unintentional dural perforation with the epidural needle.[140,141]

The administration of a test dose for spinal placement of an epidural catheter may be problematic and aspiration may fail, but test doses have been found to detect more intrathecal catheters than aspiration alone during labor analgesia.[142] Despite studies that have reported that intrathecal migration is very rare and that the flux should not produce clinically relevant complications, the reader is cautioned that epidural drugs or catheters may migrate into the spinal space following CSE. Therefore, all epidural doses should be incremental, and patients receiving continuous epidural infusions for analgesia should be checked approximately every hour to rule out excessive motor or sensory block that may be indicative of unintentional intrathecal administration of drugs.

Hypotension

Does subarachnoid block induced by CSE (using LOR to air) render a higher level of sensory anesthesia than SSS when an identical mass of intrathecal anesthetic was injected? Goy et al performed a prospective randomized study comparing CSE (using LOR to air) versus SSS on 60 patients who were undergoing minor gynecological procedures and concluded that subarachnoid block induced by CSE produces greater sensorimotor anesthesia ($p < .01$) and prolonged recovery ($p < .05$) than SSS.[143] They also found a more frequent incidence of hypotension and vasopressor use in the CSE group ($p < .05$), despite using identical doses of intrathecal medications.[143]

Another study reported similar findings when only 4 mL of air were used as part of the LOR technique.[144] The objective of that study was to determine the ED_{50} of intrathecal hyperbaric bupivacaine for CSE and SSS by using the up-down sequential allocation technique. Sixty participants were allocated into two groups in a double-blind, randomized, prospective study design. They concluded that, under similar clinical conditions, the ED_{50} of intrathecal hyperbaric bupivacaine in CSE was 20% less than that in SSS. Although the mechanism that accounts for this finding has not been determined, one possible explanation is that the LOR to air technique in CSE could introduce air pockets within the epidural space. MRI has demonstrated residual air pockets to extend up to three lumbar vertebral segments and compress the lumbar thecal sac dorsally and laterally.[145] This could potentially result in a reduction of the lumbosacral CSF volume and enhance the extent of sensory anesthesia.[146]

Epidural administration of drugs seems to affect the thecal contents and therefore influence the spread of earlier induced subarachnoid block.[147,148] The magnitude of this effect depends on the time interval between the injections and the volume of the epidural injectate. Initially, the proposed mechanism for this effect was the subarachnoid leak of epidurally administered medications.

Hypotension can occur following the administration of intrathecal fentanyl or sufentanil, even if sympathetic blockade does not occur. However, the hemodynamic effects of intrathecal fentanyl are usually benign in nature and may actually be due to a decrease in catecholamines secondary to pain relief. Vasodilation due to sympathectomy, however, causes a decrease in preload, end diastolic index, and stroke index and an increase in heart rate. Because the end diastolic index and stroke index remained relatively stable and the heart rate decreased in a study by Mandell and colleagues, these authors concluded that the observed hypotension was not due to vasodilation.[149] The hypotensive episodes following administration of neuraxial opioids for labor are transient, easily treated, and not necessarily associated with adverse fetal heart rate changes.

Neurological injury

Neurological complications directly related to spinal anesthesia may be caused by trauma, cord ischemia, infection, and neurotoxicity.

Needle Trauma

Needle- or catheter-induced trauma rarely results in permanent neurological injury. However, Horlocker et al, in a retrospective review of 4767 consecutive spinal anesthetics for central nervous system complications, concluded that the presence of a paresthesia during needle placement significantly increased the risk of persistent paresthesia ($p < .001$). In that review, paresthesia was elicited during needle placement in 298 (6.3%) cases. Six patients reported pain (persistent paresthesia) on resolution of the spinal anesthetic; four of these individuals had pain that resolved within 1 week, and the pain of the remaining two resolved in 18–24 months.[150] According to a more recent study by Bigeleisen on peripheral nerve blockade, nerve puncture and intraneural injection did not invariably lead to neurological injury.[151]

There are a few reasons for a possible increase in the risk of neurological sequelae following the CSE technique. In the single-space, NTN technique of CSE, the insertion of the epidural needle and catheter after administration of spinal local anesthetics may prevent identification of paresthesias that may warn the anesthesiologist about needle misplacement. Higher incidence of paresthesia during CSE is a recognized factor. In fact, it has been reported that paresthesias occur in up to 11% of patients undergoing CSE.[152] Browne et al reported a 14% incidence of paresthesias with the Espocan needle (18-gauge Tuohy epidural needle with an extra lumen in the needle bevel) and a 42% incidence with a conventional Tuohy epidural needle.[15]

In a randomized prospective study, McAndrew et al similarly reported that 37% (17 of 46) of women in the NTN CSE group and only 9% (4 of 43) in the SSS group had paresthesia on spinal needle insertion ($p < 0.05$). The equipment used was a 16-gauge/26-gauge CSE kit and a 26-gauge pencil-point spinal needle with introducer (both Sims Portex, Australia). They postulated that the higher incidence of paresthesias may be related to deeper penetration of the subarachnoid space with the CSE technique. Interestingly, in that study, none of the patients had persistent neurological symptoms on examination at postoperative day 1.[153]

Holloway et al conducted a pilot survey of anesthetists' experiences of neurological sequelae following spinal and CSE anesthesia in the obstetric units in the United Kingdom.[154] Because of the retrospective nature of the survey, many neurological problems that were reported lacked detail. However, there were no obvious differences in incidence of problems associated with CSE versus the SSS techniques.

Turner and Shaw suggested the possibility that painful insertion and subsequent root damage might be increased by the use of atraumatic pencil-point spinal needles.[155] In that survey, problems were reported with both Whitacre and Sprotte needles, but none with Quincke needles. However, the numbers using Quincke needles were too small to allow statistical analysis.

More dangerous than root damage is damage to the spinal cord itself, and in that survey,[155] there were two cases of conus damage, one with CSE and one with SSS. This complication is not a fault of atraumatic needles, but rather of the technique. It is important to remember that in 19% of patients, the spinal cord terminates below L1. Even more worrisome, in more than 50% of cases, the chosen space is incorrectly identified.[156] Therefore, a space L3/L4 or below should be selected for CSE or SSS.

Risk of Metal Toxicity in CSE

It has been alleged that during the NTN CSE technique, tiny metal particles abraded by the spinal needle from the inner edge of the Tuohy needle may be introduced into the epidural or spinal compartment.[157] To examine this concern, Holst and colleagues simulated the NTN technique in an in vitro model.[131] They used atomic absorption spectrography (AAS) to identify abraded metal particles. The needles were then examined under an electron microscope. They reported no increased alloy components detected in the rinse solution after either twofold or fivefold puncture compared with the control measurements. After five punctures and handling the needle as in normal practice, no traces of use could be detected by electron microscopy on the inner ground edge of the Tuohy needle.[131]

Tissue Coring

Tissue coring is a phenomenon that may occur during lumbar puncture, in which pieces of tissue are removed by the needle as it passes through the tissue and deposits the pieces in the subarachnoid space. Although rare, adverse outcomes such as intraspinal iatrogenic epidermoid tumors may be associated with this phenomenon. Sharma et al[158] postulated that the CSE technique introduces fewer epithelial cells in the subarachnoid space when compared with the SSS without the use of an introducer. However, this study did not support the hypothesis. Significant tissue coring occurred with both techniques (CSE 88% and SSS 96%).

Infectious Neurological Complications

Although overall incidence of infections and their sequelae following placement of CSE is perceived to be extremely low, the relative risk compared to either a spinal or epidural techniques alone is not known. In a classic study, Dripps and Vandam prospectively reported no cases of meningitis after 10,098 spinal anesthetics.[159] Phillips et al also reported no cases after a prospective review of 10,440 such cases.[160] These studies included patients undergoing obstetric and urological operations, which are known to be associated with perioperative bacteremia. However, case reports of meningitis following CSEs appeared in the journals beginning mid1990s.[161,162]

Theoretically, CSE is thought to be associated with an increased risk of meningitis compared to epidural alone because the dura (protective barrier for the central nervous system) is punctured deliberately during CSE, and then a foreign body, an epidural catheter, is placed nearby. The epidural catheter can lie close to the dural hole and is a potential focus of infection, especially following bacteremia.[163] Contamination of the subarachnoid space may occur from bleeding due to needle trauma in a bacteremic patient or from failure of aseptic technique.

Several studies have shown that face masks prevent forward dispersal of organisms from the upper airway and downward dispersal during talking and head turning.[164,165] Despite this, in 1996 a postal survey of members of the Obstetric Anaesthetists Association in the United Kingdom found that over half those surveyed did not routinely wear face masks when performing neuraxial anesthesia.[166]

In 2007, for the first time, the Healthcare Infection Control Practices Advisory Committee (HICPAC) recommended that surgical masks be worn during spinal procedures to prevent infections.[167] This recommendation was made in response to several reports of meningitis following myelography procedures. In 2008, three bacterial meningitis cases in postpartum women were reported to the New York State Department of Health. All three women received CSE for labor. *Streptococcus salivarius* (a normal commensal of oral flora) was cultured from the CSF of two patients. The anesthesiologist responsible for all three cases reported routine use of masks during neuraxial procedures. However, the staff reported that it was common to have unmasked visitors present in the room during these procedures. The hospital instituted new policies to minimize visitors and to require masks for all persons in the room during neuraxial labor analgesia procedures. In 2009, two similar cases were reported to the Ohio Department of Health. The anesthesiologist responsible for these two cases did not wear a mask. CSF cultures from both patients revealed *S. salivarius*, and one of them died from suppurative meningoencephalitis.[168] In 2009, Sankovsky et al[169] also reported a case of *S. salivarius* meningitis subsequent to CSE for labor in a healthy primigravid patient. The anesthesiologist was wearing sterile gloves and a mask, but the mask had been worn during prior procedures.

These cases highlight the importance of adhering to established infection control recommendations during neuraxial procedures, which include the use of masks, washing hands, and adherence to aseptic technique. It is important that the face mask be tightly attached to cover the mouth and nose and not be reused.

Headache and neck pain or neck stiffness in a patient who recently received spinal anesthesia is often attributed to postdural puncture headache (PDPH). One case report highlighted the dangers associated with missed diagnosis of meningitis. The patient was misdiagnosed as having endometritis when presenting with headache, vomiting, and fever for 2 days after uncomplicated epidural analgesia for labor. Her condition rapidly deteriorated, and meningitis was not considered as a diagnosis until it was too late. She subsequently died in intensive care.[170]

Cauda Equina Syndrome

Hyperbaric bupivacaine is frequently administered intrathecally during CSE anesthesia. Although neurological problems are mostly reported following administration of lidocaine or mepivacaine, a few cases of cauda equina syndrome following ordinary doses of intrathecal bupivacaine in a CSE technique have been reported.

Tariq[171] reported a case of an 83-year-old man who developed cauda equina syndrome after uneventful CSE anesthesia for elective knee arthroplasty. Takasu et al[172] reported a 29-year-old parturient who developed cauda equina syndrome following uneventful CSE with hyperbaric bupivacaine for cesarean delivery. Kubina et al[173] also described two cases of cauda equina following uneventful CSE with hyperbaric bupivacaine. One of the patients, however, suffered from spinal stenosis, which could explain this complication. Kato et al described a case of cauda equina syndrome following CSE with an ordinary dose of hyperbaric bupivacaine in an older patient without spinal stenosis.[174] It is thought that the lack of a protective sheath in the cauda equina as the spinal nerves and roots pass through the dura makes them particularly prone to injury from high concentration of local anesthetics.

Postdural Puncture Headache

The incidence of PDPH after CSE technique is controversial; some authors have reported decreased incidence when compared with epidural technique alone,[175] while others report an increased incidence.[176] Balestrieri reported that the patients who received conventional epidural analgesia were more likely to suffer an accidental dural puncture (twofold increase; epidural vs. CSE = 4.2% vs. 1.7%). They offered two possible explanations for this result. The first reason was that they usually chose CSE for women who were most often in early labor and reserved epidural analgesia for patients in the more painful active phase of labor. Therefore, the patients in the epidural group were more likely to move during the procedure and thus cause a "wet tap." Second, during CSE if uncertain of the location of the epidural needle, the spinal needle could be inserted to look for CSF[177] and the epidural needle advanced no further after seeing CSF in the spinal needle.

There are other factors that may also decrease the incidence of PDPH following the CSE technique. Administration of intrathecal opioids has been shown to decrease the incidence of PDPH.[178] Subsequent infusion of epidural local anesthetic increases the subarachnoid pressure and may help to decrease the incidence of PDPH following CSE. Dunn et al. argued that the intentional dural puncture involved in the CSE technique would increase the risk of PDPH in obstetric patients compared to epidural analgesia alone.[176] The use of small-gauge atraumatic pencil-point spinal needles (such as Whitacre, Pencan, Sprotte, and Gertie Marx) will greatly reduce the incidence of PDPH in patients receiving CSE.[175,179]

Chan and Paech reported three cases of persistent CSF leak following uneventful CSE analgesia for labor.[180] It was confirmed that the leaking fluid was CSF in two cases by β_2-trasferrin immunofixation assay.[181] None of the patients developed PDPH or any other complications. Howes and Lenz also reported a CSF cutaneous fistula in two patients following epidural anesthesia (not CSE) for postoperative pain relief. Both patients developed PDPH only after removal of the catheters and were treated successfully with autologous blood patch.[182]

Complications Related to Labor Analgesia

Fetal Bradycardia

Reports in the literature suggested an increased frequency of nonreassuring fetal heart rate (FHR) tracings and fetal bradycardia associated with CSE.[183–185] The etiology of fetal bradycardia after CSE remains elusive but may be related to an acute reduction in circulating maternal catecholamine levels after the almost-immediate onset of analgesia. In addition, it has been postulated that an imbalance between epinephrine and norepinephrine levels (decreased epinephrine levels in the continuing presence of high norepinephrine levels) causes unopposed α-adrenoceptor effects on uterine tone with increased uterine vascular resistance leading to decreased uterine blood flow.

A meta-analysis by Mardirosoff and colleagues found a relative risk of 1.81 of having FHR abnormalities when intrathecal opioids were used. However, the risk of subsequent cesarean delivery was not increased.[186] There is evidence of a dose relationship and greater occurrence of worrisome FHR abnormalities with higher doses of opioids.[187] Nicolet et al performed a prospective study to identify maternal factors implicated in fetal bradycardia after CSE for labor pain. They found that the level of maternal pain scores at the time of labor analgesia request and maternal age were independent predictors of fetal bradycardia after neuraxial analgesia for labor.[188]

The resulting fetal bradycardia was usually short lived and typically resolved within 5–8 minutes.[189] A retrospective study of 1240 patients who received regional labor analgesia (mostly CSE) and 1140 patients who received systemic medication or no analgesia demonstrated no significant difference in the rate of cesarean delivery, with rates of 1.3% and 1.4%, respectively. That study also reported that no emergency cesarean deliveries for acute fetal "distress" were necessary in the absence of obstetric indications up to 90 minutes after intrathecal sufentanil administration.[190] A prospective randomized study by Skupski et al[191] also found no difference in the rate of prolonged deceleration between labor epidural versus CSE for labor (3.2% vs. 6.2%, respectively; $p = 0.43$).

EQUIPMENT

The CSE technique has gained popularity and acceptance, especially in obstetrics. Special kits have been produced for CSE (eg, B Braun Medical Ltd. comprising the standard 16-gauge, 8-cm Tuohy needle with a 26-gauge Quincke spinal needle). Various concerns of the CSE technique have led to some modification of the needles used.

To direct the epidural catheter away from the dural puncture site, Rawal et al recommended rotation of the epidural needle 180° following dural puncture. This maneuver directs the epidural catheter 2–2.5 mm away from the dural puncture site.[192] However, Meikljohn, using postmortem dura mater, demonstrated that rotation of the epidural needle significantly decreased the force required to puncture the dura[117] and thus might result in a wet tap.

Recently, CSE kits designed with an orifice in the back curve (back hole) of the epidural needle for separate spinal needle passage have been made available[15] (Figure 26–4). This needle and others like it may reduce the likelihood of dural passage of the epidural catheter by directing the catheter away from the dural puncture site. However, the spinal needle may not always go through the spinal needle orifice and may exit through the Huber tip, thus losing the advantage of the back hole[15] (Figure 26–5).

Joshi and McCarroll suggested a technique to enhance the spinal needle exit through the spinal needle orifice.[111,193] The modified technique consisted of first aligning the bevel orifice of the spinal needle to the same direction as the Tuohy bevel and then bending the spinal needle 10° toward the Tuohy bevel while advancing through the Tuohy needle. This technique guides the spinal needle tip to exit through the back hole. Pan, in a prospective randomized study, evaluated the success rate of the spinal needle exiting through the spinal needle orifice in two commonly available single-lumen, dual-orifice, CSE needle kits.[194] The CSE kits studies were first the Espocan CSE kit (Braun Medical Ltd.) that consists of a standard 18-gauge Tuohy needle with a 26-gauge sleeved Quincke spinal needle that extends 12 mm beyond the tip of the Tuohy needle through the back hole. The sleeve on the spinal needle was designed to guide the spinal needle to exit through the back hole. Second was the Espocan CSE kit (Braun Medical Ltd.), which consists of the same epidural needle with a 27-gauge nonsleeved Sprotte spinal needle that extends 13 mm beyond the tip of the Tuohy needle through the back hole. They performed 1600 attempts, which included the modified technique described by Joshi and McCarroll. The modified technique improved the success rate of spinal needle exiting through the back hole from 67% to 94% for the first kit and 50% to 81% for the second kit; cephalad orientation of the Tuohy needle bevel further improved the success rate to 96% and 91%, respectively. Overall, the sleeved spinal needle had a better success rate than the unsleeved spinal needle.

The failure of the spinal needle to exit through the back hole may also result in bending of the spinal needle and less protrusion beyond the tip of the Tuohy needle. This may contribute to the increased failure rate of dural puncture. The ideal length of spinal needle protrusion is reported to be at least 12–13 mm. In a prospective randomized study of 40 patients, Joshi and McCarroll reported a 15% failure rate of CSF return when the spinal needle protruded only 10 mm beyond the tip of the Tuohy needle and 0% with a 13-mm protrusion.[111] Riley et al reported[195] similar results comparing 24-gauge Sprotte (9-mm protrusion past the tip of the Tuhoy and 17% failure to obtain CSF) and Gertie Marx (protrusion 17 mm and 0% failure rate). The number of patients developing PDPH and requiring blood

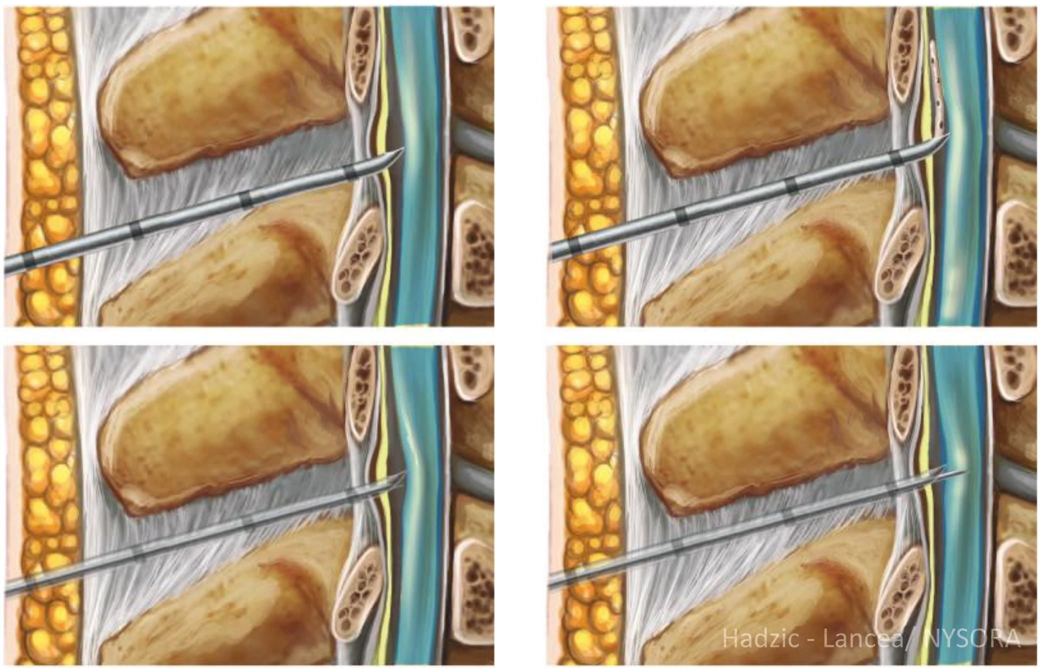

FIGURE 26–4. Combined spinal-epidural kit with an orifice in the back curve for separate spinal needle passage.

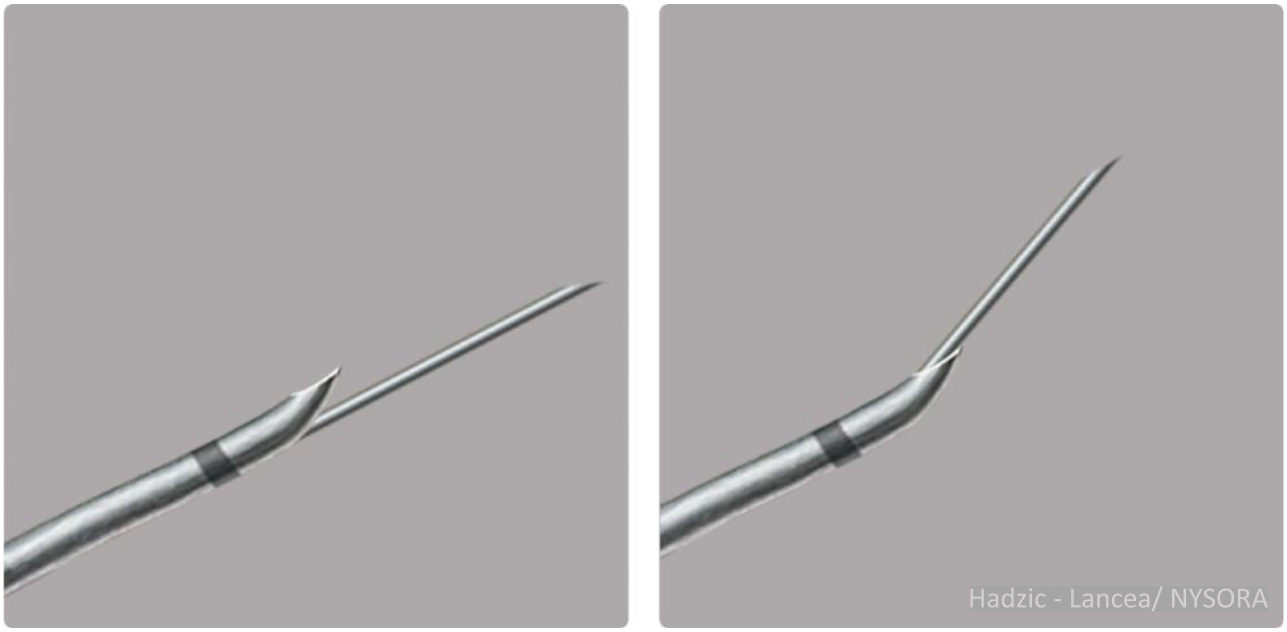

FIGURE 26–5. Combined spinal-epidural kit with spinal needle exiting the back hole and the Huber tip.

patch was greater with Gertie Marx than the Sprotte needle. However, this difference was not statistically significant. It is possible that the longer spinal needle also punctured the anterior aspect of the dura and thus might have caused a greater CSF leak. Greater rates of paresthesia were also noted (anecdotal) with the 127-mm needle, and the 124-mm Gertie Marx needle was suggested as an excellent compromise.

Herbstman et al compared four pencil-point spinal needles commonly used in the CSE technique and reported that longer spinal needles were associated with significantly more transient paresthesias (Gertie Marx 15-mm protrusion with 29% incidence; Whitacre 10-mm protrusion with 17% incidence). Success in obtaining CSF and the incidence of PDPH did not differ among the four needles.[196]

The conventional spinal needle in the CSE kit, which does not lock within the epidural needle, may be difficult to handle and stabilize during injection of spinal medication. The displacement of the spinal needle during aspiration of the CSF and injection may result in failed anesthesia or may push the spinal needle deeper, leading to nerve damage or anterior dural perforation. To overcome this problem, Simsa suggested an external fixation device.[197] This device, however, is somewhat complicated to handle.

Recently, spinal needles with an adjustable locking device have been introduced (CSEcure and Adjustable Durasafe CSE needle). Studies of the lockable extensions reported them to provide safe and stable conditions during placement of the syringe and injection.[62,198] However, both studies reported frequent inability to feel dural perforation with the locking needles (15.3% with CSFcure and 25% with Adjustable Durasafe). There was no clear explanation for this.

In a CSE technique, sometimes the epidural catheter cannot be threaded or threaded intravascularly after the intrathecal drugs have been injected. To overcome this problem, a dual-lumen, dual-orifice CSE kit was developed in which an epidural catheter can be inserted in place prior to inserting the spinal needle and medication.[199,200] This is possible because there are two separate lumens for the catheter and the spinal needle (Figure 26–6).

Recently, a dual-lumen CSE needle was commercialized in Europe (Epistar; Medimex, Germany).

CONTROVERSIAL TOPICS IN CSE TECHNIQUE

Test Dose

The issue of whether a test dose is needed when administering labor epidural analgesia is controversial.[201,202] Because very dilute solutions of LAs are commonly used and aspiration is often diagnostic, some authors believe that a conventional test dose is unnecessary.[203] However, because catheter aspiration is not always predictive (especially when using a single-orifice epidural catheter), others maintain the importance of a test dose to improve detection of intrathecal or intravascular placement of an epidural catheter.[204]

Part of the controversy surrounding the testing of epidural catheters involves the use of epinephrine. Epinephrine has been shown to produce a reliable increase in heart rate in volunteers and surgical patients when the epidural has been sited in a blood vessel.[204] However, in laboring women, maternal heart rate variability from the pain of uterine contractions may confuse interpretation of the heart rate response, and intravenous epinephrine may have deleterious effects on uterine blood flow.[205]

FIGURE 26–6. Dual-lumen, dual-orifice CSE kit.

Means to improve the reliability of an epinephrine test dose include injecting the dose between uterine contractions and repeating the test dose when the response is equivocal. However, the lack of sensitivity and specificity of the test dose calls into question its usefulness as a diagnostic tool.

Leighton and colleagues have described an alternative means of testing an epidural catheter for intravascular placement. They advocated the injection of 1–2 mL of air into the epidural catheter while listening over the precordium with the maternal external Doppler monitor for evidence of air.[206]

With reports of subarachnoid administration of chloroprocaine,[207] it is possible that in the future this agent will be utilized for testing epidural catheters. Caution, however, is necessary because preservative-containing chloroprocaine is also commercially available. If continuous infusion of dilute local anesthetic is administered and the patient remains comfortable without a motor block, proper epidural catheter placement is highly likely. That is, if the epidural catheter were intravascular, the patient should have inadequate pain relief, and if the catheter were subarachnoid, a solid motor block would develop. Although infusions of ultradilute local anesthetics do not pose a serious threat, such is not true of concentrated local anesthetics used for operative delivery. Some authors have suggested that a test dose is essential for any parturient receiving epidural anesthesia.[204] Regardless of the technique used, the safe practice of administering labor epidural analgesia dictates initial catheter aspiration, incremental injections, and continuous monitoring for evidence of local anesthetic toxicity.

Positioning for CSE

Neuraxial blocks are often performed with the patients in the sitting position, especially obese individuals, because the midline is easily recognized. The sitting position has been shown to allow better spinal flexion in the parturients.[208] In addition, the distance from the skin to the epidural space was shown to be significantly greater when epidural puncture was performed in the lateral position as compared with the sitting position. This change in distance may cause catheter dislodgment when the patient is turned from the sitting position to lateral, with consequent inadequate analgesia.

Yun et al compared the effects of induction of CSE anesthesia in the sitting versus lateral position in healthy women undergoing elective cesarean delivery.[209] The severity of hypotension, measured by the maximal percentage decrease in systolic blood pressure from control, as well as its duration were significantly greater in the sitting group ($p < 0.05$). Patients in the sitting group required twice as much ephedrine to treat hypotension than those in the lateral recumbent group. The reason for the difference in the severity of hypotension was not clear. They postulated it to be related to a slower recovery from venous pooling in the lower extremities when assuming a supine position from the initial sitting position. These authors concluded that the position used for induction of CSE should be considered in cases associated with greater maternal or fetal risk from hypotension.

Traditional teaching is that the spread of hyperbaric intrathecal solutions follows gravity. Lewis et al compared the development of spinal blocks in the left lateral position versus a supine wedge position after performing the CSE in the sitting position.[210] The intrathecal medications consisted of 2 mL of 0.5% hyperbaric bupivacaine with 15 μg fentanyl. The left lateral position did not produce unilateral blockade. The left lateral position was associated with slower block onset ($p = .004$) but eventually produced a spinal block similar in characteristics to that obtained in the supine wedge position. The left lateral position is known to improve maternal cardiac output, and slower onset may be outweighed by the possible benefit to the fetus.

SUMMARY

The CSE technique is well established method[10,58] for various types of surgery, particularly in obstetrics. In our institution, the CSE technique is the most commonly performed regional technique for labor analgesia (97%) as well as cesarean delivery (54%). CSE offers many advantages; it provides a method to administer neuraxial anesthesia and analgesia in numerous clinical situations.

The CSE technique offers the advantages of both spinal and epidural techniques and therefore has a high success rate in providing regional anesthesia. CSE provides rapid onset and the ability to titrate to a desired sensory level, control the duration of the block, and deliver postoperative analgesia. Another advantage of CSE is the facilitation of the spinal needle entrance into the subarachnoid space. The Tuohy needle serves as a guide for the spinal needle almost to the subarachnoid space. This allows for use of the smaller-gauge atraumatic spinal needles, with which the PDPH is absent or rare.[179]

The disadvantages of the CSE are that, the combined technique introduces potential side effects such as PDPH, the increased risk of catheter migration into the subarachnoid space, and transient paresthesias from the spinal needle. Although the risk is low, a number of equipment modifications have been suggested and developed to avoid penetration of the epidural catheter through the dural hole made by the spinal needle.

The ideal length of spinal needle protrusion beyond the tip of the epidural needle is reported to be at least 12–13 mm. Longer spinal needles were shown to be associated with significantly higher incidence of transient paresthesias. Inability to obtain CSF through the spinal needle may occur with shorter needles (<10 mm of protrusion) and result in failure of the spinal component of the technique. CSE failure is also related to a faulty puncture site or axis deviation during needle advancement. The risk of infection, hematoma, and neurological damage increases with multiple attempts and multiple manipulations of the needles, but it is not clear if the CSE technique increases these risks.

SECTION 5 Postdural Puncture Headache

CHAPTER 27

Postdural Puncture Headache

Brian E. Harrington and Miguel Angel Reina

INTRODUCTION

Postural headaches following interventions that disrupt meningeal integrity are most commonly labeled *postdural puncture headaches* (PDPHs). This terminology has been officially adopted in the International Classification of Headache Disorders[1] and is used in this chapter. However, use of the word *postdural* has been criticized as confusing[2] and probably inaccurate,[3] resulting in the proposal of an alternate term, *meningeal puncture headache* (MPH), which readers may increasingly encounter.[4,5] It is also important to acknowledge that references to "dural puncture" throughout the medical literature (including this chapter) actually describe puncture of the dura-arachnoid and are more correctly termed and thought of as "meningeal puncture."

Regardless of terminology, the PDPH is well known to the many clinicians whose practice includes procedures that access the subarachnoid space. Yet, our understanding of this serious complication remains surprisingly incomplete. This chapter summarizes the current state of knowledge regarding this familiar iatrogenic problem as well as the closely related topics of accidental, or unintentional, dural puncture (ADP or UDP, respectively), and the epidural blood patch (EBP).

HISTORY AND CURRENT RELEVANCE

As one of the earliest recognized complications of regional anesthesia, PDPH has a long and colorful history.[6] Dr. August Bier noted this adverse effect in the first patient to undergo successful spinal anesthesia on August 16, 1898 (Figure 27–1). Bier observed: "Two hours after the operation his back and left leg became painful and the patient vomited and complained of severe headache. The pain and vomiting soon ceased, but *headache was still present the next day*" (italics added).[7] The following week, Bier and his assistant, Dr. August Hildebrandt, performed experiments with cocainization of the spinal cord on themselves. In a description of PDPH scarcely improved on in an intervening century, Bier later reported firsthand his experience in the days to follow: "I had a feeling of very strong pressure on my skull and became rather dizzy when I stood up rapidly from my chair. All these symptoms vanished at once when I lay down flat, but returned when I stood up. … I was forced to take to bed and remained there for nine days, because all the manifestations recurred as soon as I got up. … The symptoms finally resolved nine days after the lumbar puncture."[7] In medical history, few complications have come to be associated as closely to a specific technique as PDPH with spinal anesthesia.

Employing the methods of the early 20th century, spinal anesthesia was frequently followed by severe and prolonged headache, casting a long shadow over the development and acceptance of this modality. Investigations into the cause of these troubling symptoms eventually led to the conclusion that they were due to persistent cerebrospinal fluid (CSF) loss through the rent created in the meninges. The most notable successful efforts to minimize the loss of CSF were through the use of smaller-gauge and "noncutting" needles (as convincingly demonstrated in the 1950s by Vandam and Dripps[8] and Hart and Whitacre,[9] respectively). Despite these significant advances in prevention, PDPH remained a frustratingly common occurrence.

FIGURE 27–1. Dr. August Bier.

The extensive search for effective treatments for PDPH dates to Bier's time. Yet, efforts through the first half of the 20th century, while often intensive and creative, were questionably worthwhile. In a monograph intended to be a comprehensive review of PDPH from the 1890s through 1960, Dr. Wallace Tourette and colleagues cited dozens of separate and far-ranging treatment recommendations, including such interventions as intravenous ethanol, x-rays to the skull, sympathetic blocks, and manipulation of the spine.[10] Unfortunately, prior to the introduction of the EBP there were no treatment measures that could be described as significant improvements over the simple passage of time. In his 1955 textbook, *Complications of Regional Anesthesia*, Dr. Daniel C. Moore described in detail a full 3-day treatment protocol for PDPH. He concluded by noting that 3 days was the usual duration of untreated mild-to-moderate headaches, but that, "Nevertheless, the patient feels an attempt to help his problem is being made."[11]

The EBP, a startlingly unique medical procedure, proved to be the major breakthrough in the treatment of PDPH. The concept of using autologous blood to "patch" a hole in the meninges was introduced in late 1960 by Dr. James Gormley, a general surgeon.[12] Yet, Gormley's brief report went largely unnoticed for nearly a decade because, to the practitioners of the day, an iatrogenic epidural hematoma raised serious concerns of scarring, infection, and nerve damage. The procedure was only later popularized in anesthesiology circles, and performed as a true epidural injection, largely through the work of Drs. Anthony DiGiovanni and Burdett Dunbar.[13] The EBP procedure was further refined through the 1970s as the volume of blood commonly utilized increased to 20 mL.[14] Today, the EBP is nearly universally employed as the cornerstone for treatment for severe PDPH.[15]
