Postdural puncture headache remains a prominent clinical concern to the present day. Largely due to modifications in practice that followed the identification of risk factors, rates of PDPH following spinal anesthesia have steadily declined, from an incidence exceeding 50% in Bier's time, to around 10% in the 1950s,[8] until currently a rate of 1% or less can be reasonably expected. However, as perhaps the highest-risk group, an unfortunate 1.7% of obstetric patients continue to experience PDPH after spinal anesthesia using 27-gauge Whitacre needles.[16] Intending to avoid meningeal puncture, epidural techniques are an attractive alternative to spinal anesthesia. Yet, occasional ADP, with either the needle or the catheter, is unavoidable (and may be unrecognized at the time in over 25% of patients who eventually develop PDPH[17]). In nonobstetric situations (eg, interlaminar epidural steroid injections), the rate of ADP should be less than 0.5%. However, ADP is of greatest concern in the obstetric anesthesia setting, where the incidence of this adverse event is around 1.5%.[16] Over half of all patients who experience ADP with epidural needles will eventually develop headache symptoms, with many studies in obstetric populations reporting PDPH rates of 75% or greater. Of further concern, ADP in parturients has also been noted to be associated with chronic headache and back pain that is reduced, but not entirely eliminated, by EBP.[18] In addition to anesthesia interventions, PDPH remains a too-common iatrogenic complication following myelography and diagnostic/therapeutic lumbar puncture (LP). In these situations, rates of MPH of around 10% are still commonly cited as practitioners often continue to use large-gauge Quincke needles—considered necessary due to the viscosity of contrast material and to facilitate the timely collection of CSF.[19] Consequently, there is evidence to suggest that the majority of instances of PDPH now have a non-anesthesia-related origin.[20]

Clinical Pearls

- PDPH may carry a risk of medicolegal liability.
- ADP may result in chronic headache and back pain.
- Anesthetic procedures with risk of PDPH require proper informed consent.

The practical significance of PDPH is illustrated by notation in the American Society of Anesthesiologists Closed Claims Project database as one of the most frequent claims for malpractice involving obstetric anesthesia,[21] regional anesthesia,[22] and chronic pain management.[23] Justifiably, headache is the most commonly disclosed risk when obtaining consent for spinal and epidural anesthesia.[24] The potentially serious nature of this complication necessitates inclusion in informed consent involving any procedure that may result in PDPH. As part of this discussion, patients should also be apprised of the normal delayed onset of symptoms and be given clear instructions for the timely provision of advice or management should they experience adverse effects.

PATHOPHYSIOLOGY

It has long been accepted that PDPH results from a disruption of normal CSF homeostasis. However, despite a great deal of research and observational data, the pathophysiology of PDPH remains incompletely understood.[25] Cerebrospinal fluid is produced primarily in the choroid plexus at a rate of approximately 0.35 mL/min and reabsorbed through the arachnoid villa. The total CSF volume in adults is maintained around 150 mL, of which approximately half is extracranial, and gives rise to normal lumbar opening pressures of 5–15 cm H_2O in the horizontal position (40–50 cm H_2O in the upright position). It has been shown experimentally that the loss of approximately 10% of total CSF volume predictably results in the development of typical PDPH symptoms, which resolve promptly with reconstitution of this deficit.[26] It is generally agreed that PDPH is due to the loss of CSF through a persistent leak in the meninges. In this regard, it has been postulated that the cellular arachnoid mater (containing frequent tight junctions and occluding junctions) is perhaps more important than the more permeable and acellular dura mater in the generation of symptoms.[3] In fresh cadavers, Reina et al studied lesions of the human dural sac produced by different spinal needles and different bevel orientations. The dura mater has a thickness around 400 μm, and it is formed by randomly distributed fibers, arranged around 80 concentric layers, known as dural laminas, while the arachnoid layer has a thickness around 40 μm[1–9] (Figure 27–2).

Recently, these authors reported on the possible importance of the arachnoid layer in the closure of dural and arachnoid

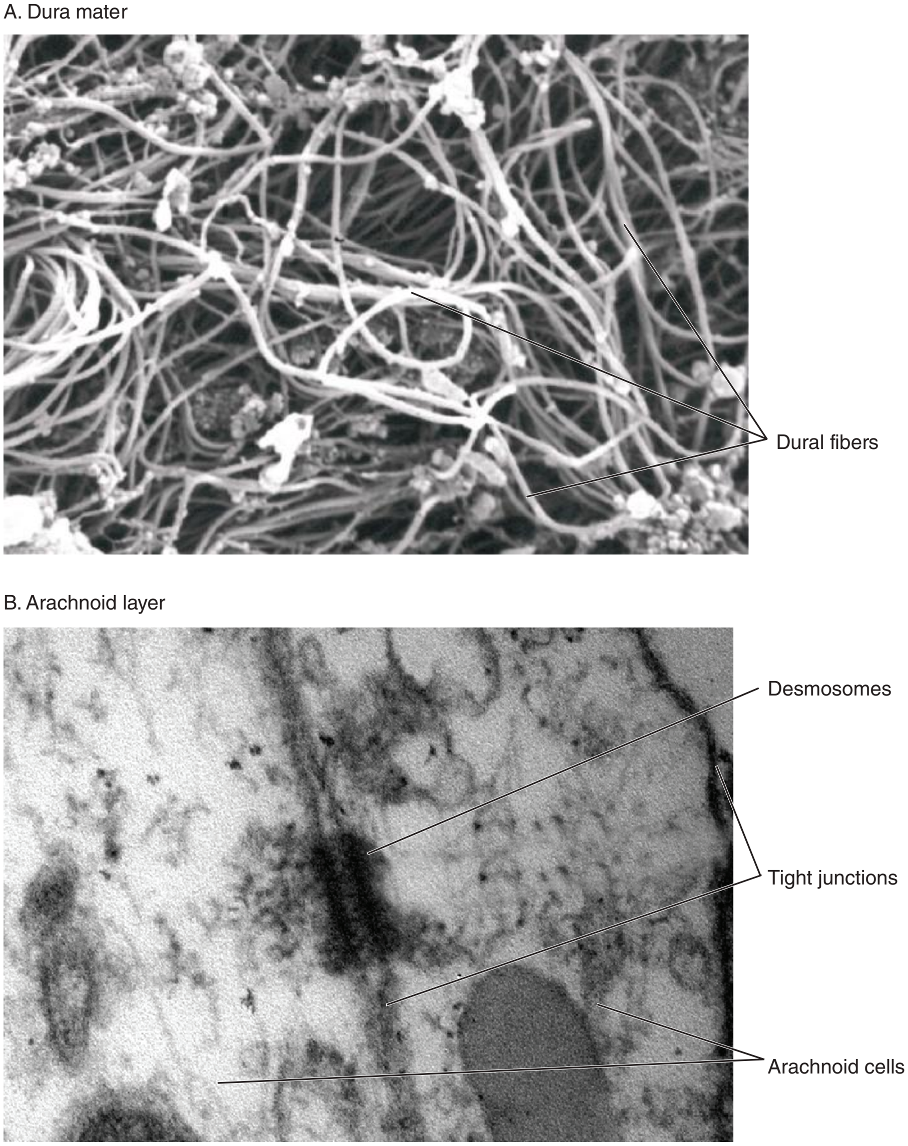

FIGURE 27–2. A: Human spinal dura mater. Collagen fibers in random direction. Scanning electron microscopy. Magnification x6500. lesions.[1,2] The arachnoid membrane may exhibit tissue closure in relation to the dura because its main function is to act as a barrier; therefore, it may lack the elastic properties of the dural layer. The arachnoid layer limits the escape of fluid, so the amount of CSF lost through the punctured orifice is likely related to the speed of closure of the arachnoid lesion (Figures 27–3 to 27–6).

Thus, the anatomically supported term *meningeal puncture headache* (MPH) has been proposed as an alternative to the rather ambiguous *postdural puncture headache* (PDPH). The apparent role of the arachnoid mater in this disorder further calls into question the significance of many published studies that involve isolated dura mater in vitro.

The actual means by which CSF hypotension generates headache is somewhat controversial and currently ascribed to a bimodal mechanism involving both loss of intracranial support and cerebral vasodilation (predominantly venous). Diminished buoyant support is thought to allow the brain to sag in the upright position, resulting in traction and pressure on pain-sensitive structures within the cranium (dura, cranial nerves, bridging veins, and venous sinuses). Adenosine-mediated vasodilation may occur secondary to diminished intracranial CSF (in accordance with the Monro-Kellie hypothesis, which states that intracranial volume must remain constant) and reflexively secondary to traction on intracranial vessels.

Multiple neural pathways are involved in generating the symptoms of PDPH. These include the ophthalmic branch of the trigeminal nerve (cranial nerve [CN] V_1) in frontal head pain, cranial nerves IX and X in occipital pain, and cervical nerves C1–C3 in neck and shoulder pain.[27] Nausea is attributed to vagal stimulation (CN X). Auditory and vestibular symptoms are secondary to the direct communication between the CSF and the perilymph via the cochlear aqueduct, which results in decreased perilymphatic pressures in the inner ear and an imbalance between the endolymph and perilymph.[28,29] Significant visual disturbances are thought to represent a transient palsy of the nerves supplying the extraocular muscles of the eye (CN III, IV, and VI). Here, the lateral rectus muscle is most often involved, which is attributed to the long, vulnerable intracranial course of the abducens nerve (CN VI).[30,31] Other, much

less-frequent cranial nerve palsies of the trigeminal (CN V), facial (CN VII), and auditory (CN VIII) nerves have also been reported.[32]

CLINICAL PRESENTATION AND CHARACTERISTICS

Although many clinical variations have been described, most cases of PDPH are characterized by their typical onset, presentation, and associated symptoms.

Clinical Pearls

Most cases of PDPH will be typical (see text for details) in

- Onset—often delayed, but within 48 hours
- Presentation—symmetric, bilateral headache
- Associated symptoms—more likely with severe headache

Onset

Onset of symptoms is generally delayed, with headache usually beginning 12–48 hours and rarely more than 5 days following meningeal puncture. In their landmark observational study, Vandam and Dripps reported onset of headache symptoms within 3 days of spinal anesthesia in 84.8% of patients for whom such data were available.[8] More recently, Lybecker and colleagues performed a detailed analysis of 75 consecutive patients with PDPH following spinal anesthesia (primarily using 25-gauge cutting-point needles). While none of their patients noted the onset of symptoms during the first hour following meningeal puncture, 65% experienced symptoms within 24 hours and 92% within 48 hours.[33] An onset of symptoms within 1 hour of neuraxial procedures is suspicious for pneumocephalus, especially in the setting of an epidural loss-of-resistance technique using air.[34] Occasional reports of unusually delayed onset of PDPH highlight the importance of seeking a history of central neuraxial instrumentation whenever positional headaches are evaluated.[35]

Presentation

The cardinal feature of PDPH is its postural nature, with headache symptoms worsening in the upright position and relieved, or at least improved, with recumbency. The International Headache Society (IHS) diagnostic criteria further describe this positional quality as worsening within 15 minutes of sitting or standing and improving within 15 minutes after lying.[1] Headache is always bilateral, with a distribution that is frontal (25%), occipital (27%), or both (45%).[33] Headaches are typically described as "dull/aching," "throbbing," or "pressure type."

The severity of headache symptoms, a feature with important ramifications for treatment, varies considerably among patients. Although there is no universally accepted severity scale, one practical approach is to have patients simply rate their headache intensity using a 10-point analog scale, with 1–3 classified as "mild," 4–6 "moderate," and 7–10 "severe." Lybecker et al further categorized patients according to restriction in physical activity, degree of confinement to bed, and presence of associated symptoms.[33] Using this classification system, they prospectively determined that 11% of their PDPH cases after spinal anesthesia were mild, 23% moderate, and 67% severe.

Associated Symptoms

The IHS criteria for PDPH require that headache be accompanied by at least one of the following symptoms: neck stiffness, tinnitus, hypoacusia, photophobia, and nausea. However, these criteria may need to be revisited as many patients (29% in one recent study)[36] have been noted to suffer from PDPH in the absence of any symptoms apart from the headache itself. It can be said that the more severe the headache, the more likely it is to be accompanied by associated symptoms.

Clinical Pearl

The IHS criteria for PDPH are as follows:

- Headache accompanied by at least one of these symptoms:
  - neck stiffness
  - tinnitus
  - hypoacusia
  - photophobia
  - nausea

The most common associated symptom is nausea, which may be reported by a majority of patients (especially if questioned specifically) and can lead to vomiting.[33] Pain and stiffness in the neck and shoulders are also common and are seen in nearly half of all patients experiencing PDPH.[37] Uncommonly, patients may experience auditory or visual symptoms, and the risk for either appears to be directly related to needle size.[30,38]

In Vandam and Dripps's large observational study of PDPH, auditory and visual symptoms were each seen in 0.4% of patients.[8] Auditory symptoms include hearing loss, tinnitus, and even hyperacusis, and can be unilateral. It is interesting to note that subclinical hearing loss, especially in the lower frequencies, has been found to be common following spinal anesthesia, even in the absence of PDPH.[38] Closely associated with auditory function, vestibular disturbances (dizziness or vertigo) may also occur. Visual problems include blurred vision, difficulties with accommodation, mild photophobia, and diplopia.[30] In contrast to headache complaints, which are consistently bilateral, nearly 80% of episodes of diplopia secondary to meningeal puncture involve unilateral cranial nerve palsies.

RISK FACTORS

Risk factors for PDPH can be broadly categorized into patient characteristics and procedural details.

Patient Characteristics

The patient characteristic having the greatest impact on risk of PDPH is age. Uncommonly reported in children less than 10 years of age, PDPH has a peak incidence in the teens and early 20s.[39] The incidence then declines over time, becoming much less frequent in patients over 50 years of age.

Gender is also a significant risk factor, with nonpregnant females having approximately twice the risk for PDPH when compared with age-matched male subjects.[40] While the etiology behind this gender difference has not been convincingly elucidated, a number of physiological, anatomical, social, perceptual, and behavioral explanations have been proposed.[36]

Clinical Pearl

Major patient related risk factors for PDPH include:

- Age: It is uncommon in patients less than 10 years of age; peak incidence is in the teens and early 20s.
- Gender: Nonpregnant females have twice the risk compared to age-matched men.

Pregnancy has traditionally been regarded as a risk factor for PDPH,[8] but this consideration largely reflects a young female cohort as well as the high incidence of ADP in the gravid population. Although controversial, pushing during the second stage of labor, thought to promote the loss of CSF through a hole in the meninges, has been reported to influence the risk of PDPH following ADP. Angle and colleagues noted that the cumulative duration of bearing down correlated with the risk of developing PDPH in patients who had experienced ADP.[41] They also found that patients who avoided pushing altogether (proceeded to cesarean delivery prior to reaching second-stage labor) had a much lower incidence of PDPH (10%) than those who pushed (74%). Furthermore, they noted a marked difference in the requirement for EBP to treat PDPH between those who pushed and those who did not (81% vs. 0%).

Body mass index (BMI) appears to be a mixed-risk factor. Morbid obesity presents obvious technical difficulties for central neuraxial procedures, increasing the likelihood of multiple needle passes and ADP.[42] Yet, low BMI has been reported to be an independent risk factor for PDPH,[43] and high BMI (ie, obesity) may actually decrease risk, possibly secondary to a beneficial effect of increased intra-abdominal pressure.[44]

Recently, a retrospective analysis reported cigarette smoking to be associated with a lower risk of PDPH.[45] It can be hoped that this observation will promote further insights into the mechanism of PDPH symptoms and pharmacologic treatment options.

Postdural puncture headaches appear to have an interesting association with other headaches. Patients who report having had a headache within the week prior to LP have been observed to have a higher incidence of PDPH.[43] On further analysis, only those with chronic bilateral tension-type headaches were found to be at increased risk.[46] A history of unilateral headache[46] or migraine[47] has not been linked to an increased risk of PDPH. Menstrual cycle, a factor in migraine headaches, did not influence the rate of PDPH in one small pilot study.[48] Patients with a history of previous PDPH, particularly women, appear to have an increased risk for new PDPH after spinal anesthesia.[36] With epidural procedures, patients with a history of ADP have been shown to be at slightly increased risk for another ADP (and subsequent PDPH).[49]

Procedural Details

Needle size and tip design are the most important procedural factors related to PDPH.[50] Needle size is directly related to the risk of PDPH. Meningeal puncture with larger needles is associated with a higher incidence of PDPH,[8] more severe headaches, more associated symptoms,[50] a longer duration of symptoms,[51] and a greater need for definitive treatment measures.[52] Needle tip design is also a major influence, with "noncutting" needles clearly associated with a reduced incidence of PDPH when compared with "cutting" (usually Quincke) needles of the same gauge (Figure 27–7). In general, noncutting needles have an opening set back from a tapered ("pencil-point") tip and include the Whitacre, Sprotte, European, Pencan, and Gertie Marx needles. Adding to this somewhat-confusing terminology, noncutting needles are sometimes still incorrectly referred to as "atraumatic" needles, this despite being shown with electron microscopy to produce a more traumatic rent in the dura than cutting needles (perhaps resulting in a better inflammatory healing response).[53] The influence of needle size on risk of PDPH appears to be greatest for cutting needles (in other words, the reduction seen in the incidence of PDPH between 22- and 26-gauge sizes is greater for cutting than noncutting needles). Insertion of cutting needles with the bevel parallel to the long axis of the spine significantly reduces the incidence of PDPH.[54] This observation was for many years attributed to spreading rather than cutting of longitudinally oriented dural fibers. However, scanning electron microscopy revealed the dura to be made of many layers of concentrically

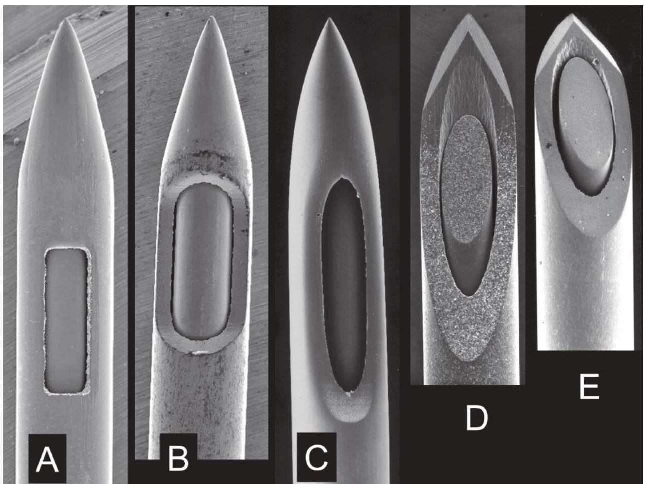

FIGURE 27–7. Spinal needles of different manufacturers with same external diameter. **A:** Whitacre type. **B:** Spinal type. **C:** Sprotte type. **D, E:** Quincke type. directed fibers,[55] and the importance of needle bevel insertion is now thought to be due to longitudinal tension on the meninges, particularly in the upright position, and its influence on CSF leakage through holes having differing orientations.

Clinical Pearl

- The most important equipment-related details for risk of PDPH are needle gauge (larger > smaller) and needle tip design (cutting > noncutting).

Not surprisingly, the experience/comfort/skill of the operator appear to be significant factors in the development of PDPH. A larger number of meningeal punctures, frequently associated with inexperience, have been shown to increase the rate of PDPH.[56] De Almeida et al noted higher rates of PDPH when LP was performed by inexperienced providers.[57] Higher rates of ADP have been consistently reported when epidural procedures are performed by residents.[58,59] The risk of ADP also appears to be higher for procedures done at night, strongly suggesting a significant contribution of operator fatigue.[60]

A number of procedural details do not appear to influence the rate of development of PDPH, including patient position at the time of meningeal puncture, "bloody tap" during spinal anesthesia, addition of opiates to the spinal block, and volume of CSF removed (for diagnostic purposes).[6]

PREVENTION

Although prophylaxis is most simply thought of as preventing any symptoms of PDPH, in the clinical context this issue is deceptively complex. It is important to appreciate that significant "prevention" may encompass a number of other endpoints, such as a reduced incidence of severe PDPH, a shorter duration of symptoms, or decreased need for EBP. Unfortunately, despite the clear relevance of this issue, the overall quality of evidence for preventive measures is generally weak.[61–63]

General Measures

As with all regional techniques, appropriate patient selection is crucial in minimizing complications. As age is a major risk factor, indications for spinal anesthesia should be weighed against the risks of PDPH in patients under 40 years of age unless the benefits are sufficiently compelling (such as in the obstetric population). Practitioners (and patients alike) may also wish to carefully consider central neuraxial techniques in those with a previous history of ADP or PDPH (particularly females). Other patient-related factors (eg, obesity) should be considered on a case-by-case basis, weighing the risks of PDPH with the benefits of regional anesthesia.

While only recently utilized for neuraxial techniques, the use of ultrasound for regional anesthesia holds some promise in reducing the risk of PDPH. Ultrasound can decrease the number of needle passes required for regional procedures and has been shown to accurately predict the depth of the epidural space.[64] Further study is ongoing to define this potential for ultrasound to reduce the incidence of ADP and PDPH.

While multiple pharmacologic agents have been tried and investigated for prevention of PDPH, the efficacy of various strategies remains unclear. As an example, intravenous dexamethasone has recently been shown in randomized controlled trials (RCTs) to decrease,[65] but not influence,[66] and even increase the risk of PDPH.[67]

A recent review of drug therapy for preventing PDPH identified only 10 RCTs for review.[68] The primary outcome, a reduction in the number of patients affected by PDPH of any severity, was affected by administration of intrathecal morphine sulfate or fentanyl, oral caffeine, rectal indomethacin, or intravenous dexamethasone. Although a reduction in the incidence of PDPH was seen with epidurally administered morphine (relative risk [RR] 0.25),[69] intravenous cosyntropin (RR 0.49),[70] and intravenous aminophylline (RR 0.21 at 48 hours),[71] the benefit of each was only demonstrated in a single study.

Regardless, despite the paucity of evidence, pharmacologic measures—particularly caffeine—continue to be widely used in hopes of decreasing the incidence or severity of PDPH following meningeal puncture.[15] However, no pharmacologic prophylaxis for PDPH has been independently confirmed, and various regimens used have been associated with adverse events.

A recent survey of US anesthesiologists reported that bed rest and aggressive oral and intravenous hydration continue to be suggested by a sizable majority as prophylactic measures against PDPH.[15] However, a systematic review of the literature regarding bed rest versus early mobilization after dural puncture failed to show any evidence of benefit from bed rest and suggested that the risk of PDPH may actually be decreased by early mobilization.[72] It is notable that the practice of US anesthesiologists regarding bed rest is in contrast to that in UK maternity units, where a survey indicated that 75% of UK consultants encourage mobilization as early as possible following ADP as prophylaxis against PDPH.[73] Likewise, in a randomized prospective trial, increased oral hydration following LP failed to decrease the incidence or duration of PDPH.[74] In summary, at this time there is no evidence to support the common practice of recommending bed rest and aggressive hydration in the prevention of PDPH.

Clinical Pearl

- There is no evidence to support the common practice of recommending bed rest and aggressive hydration in the prevention of PDPH.

Spinal Technique

Needle selection is critical for reducing the incidence of PDPH. Given the strong association between needle gauge and PDPH, spinal procedures should be performed with needles having the smallest gauge reasonably possible. However, it should be acknowledged that needles of extremely small gauge can be more difficult to place, have a slow return of CSF, may be associated with multiple unrecognized punctures of the dura, and can result in a higher rate of failed block. Attention to needle tip design is another important technical means of reducing the risk of PDPH with spinal anesthesia. If available, noncutting needles should routinely be employed as they appear to be associated with fewer adverse events at a lower overall cost.[75] These factors generally make a 24- to 27-gauge noncutting needle the ideal choice for spinal anesthesia. If cutting-tip needles are used, the bevel should be directed parallel to the long axis of the spine (Figure 27–7).

Replacing the stylet after CSF collection but prior to needle withdrawal has been shown to be an effective means of lowering the incidence of PDPH after LP. In a prospective, randomized study of 600 patients with procedures using 21-gauge Sprotte needles, replacing the stylet reduced the incidence of PDPH from 16.3% to 5.0% ($p < .005$).[76] This safe-and-simple maneuver is theorized to decrease the possibility of a wicking strand of arachnoid mater from extending across the dura. However, in a more recent study of 630 patients having spinal anesthesia using 25-gauge Quincke needles, replacing the stylet did not affect the incidence of PDPH.[77] The disparity in these results may be related to the needle gauges used as well as fundamental differences between the techniques of lumbar puncture (drainage of CSF) and spinal anesthesia (injection of anesthetic agent).

Continuous spinal anesthesia (CSA) has been reported by some to be associated with surprisingly low incidences of PDPH compared with single-dose spinal techniques using similar-gauge needles.[78] This observation has been attributed to reaction to the catheter, which may promote better sealing of a breach in the meninges. CSA with small-gauge needles and catheters ("microcatheters") is an appealing option when titration of spinal drug is desirable and duration of surgery is uncertain, but microcatheters are currently unavailable in the United States, where the risk of PDPH with CSA remains concerning when using about 20-gauge "macrocatheters." For this reason, although the technique may have clinical advantages, deliberate CSA has been investigated almost exclusively in low-risk populations.

As mentioned, aminophylline has been demonstrated in one RCT to reduce the incidence of PDPH.[71] Patients undergoing cesarean delivery under spinal anesthesia were randomized to receive intravenous aminophylline (1 mg/kg) or placebo after cord clamping. At 48 hours after surgery, 3 of 60 patients (5%) receiving aminophylline versus 14 of 60 patients (23.3%) in the control group experienced PDPH. No patients in either group required EBP.

Epidural Technique

Although epidural options are limited, especially with catheter techniques, the risk of PDPH following ADP can be reduced by using the smallest feasible epidural needles. Simply decreasing the size of epidural needles from 16 to 18 gauge has been reported to reduce the incidence of PDPH from 88% to 64%.[79]

The issue of air versus liquid for identification of the epidural space with the loss-of-resistance technique has long been a source of controversy. Each method has acknowledged advantages and disadvantages, but neither has been shown convincingly to result in a lower risk of ADP.[80] In this case, operator preference and experience would be expected to strongly influence performance, and the overriding significance of this factor is illustrated in fewer instances of ADP noted when the medium is chosen at the anesthesiologist's discretion.[81]

Bevel orientation for epidural needle insertion remains a matter of debate. Norris et al found the incidence of moderate-to-severe PDPH after ADP was only 24% when the needle bevel was oriented parallel to the long axis of the spine (compared to 70% with perpendicular insertion).[82] This resulted in fewer therapeutic EBPs administered to patients in the parallel group ($p < .05$). However, this technique necessitates a controversial 90° rotation of the needle for catheter placement.[83] It appears that a number of concerns regarding parallel needle insertion (lateral needle deviation, difficulties with catheter insertion, and dural trauma with needle rotation) are of greater concern to practitioners. Most respondents (71.3%) to a survey of US anesthesiologists preferred to insert epidural needles with the bevel perpendicular to the long axis of the spine (consistent with the intended direction of catheter travel).[15]

Combined spinal-epidural (CSE) techniques have been reported to be associated with a low incidence of PDPH. While providing the advantages of a spinal anesthetic, CSE appears to have no increased incidence of PDPH or need for EBP when compared to conventional epidural analgesia.[84] This observation may be due to several factors, including the ability to successfully use extremely small (eg, 27-gauge) noncutting spinal needles and tamponade provided by epidural infusions.

Measures to Reduce the Risk of PDPH After ADP

The risk-to-benefit ratio of prophylaxis should be most favorable in situations having the greatest likelihood of developing severe PDPH. Therefore, most efforts to reduce the risk of PDPH after ADP have been in the obstetric patient population. Several prophylactic measures, discussed in the material that follows, are worthy of consideration and have been utilized alone or in combination.[85] However, because not all patients who experience ADP will develop PDPH, and only a portion of those who do will require definitive treatment with an EBP, a cautious approach in this regard is still generally warranted. It should be acknowledged that the efficacy of all the measures discussed next is debatable. Therefore, it is critical that in the event of recognized ADP, these patients at the very least be clearly informed of the high risk of PDPH development and be followed daily until discharge (or called at home if discharged within 48 hours).

Stylet Replacement

Although there have not been any studies to support the use of the stylet replacement technique in the setting of ADP, replacing the stylet is a simple and effective means of lowering the incidence of PDPH after LP.[76] Given the innocuous nature of this maneuver, if no other prophylactic measures are taken, there appears to be little reason not to replace the stylet prior to epidural needle removal in the event of ADP.

Subarachnoid Saline

Limited evidence indicates that the subarachnoid injection of sterile preservative-free saline following ADP may be associated with a significant reduction in the incidence of PDPH and need for EBP. In one small study (n = 43), immediate injection of 10 mL saline through the epidural needle substantially reduced the incidence of PDPH (32%, compared with 62% in a matched control group) and resulted in a significant reduction in the need for EBP (p = 0.004).[86] The injection of saline and the reinjection of CSF have been speculated as important in the prevention of PDPH by maintaining CSF volume.[85] However, given the relatively rapid rate of CSF regeneration, it may be that the benefit of fluid injection following ADP is actually in preventing a wicking strand of arachnoid (as proposed for stylet replacement after LP). Further investigation into this issue is needed.

Intravenous Cosyntropin

As mentioned, there is no convincing evidence that systemic pharmacologic measures are beneficial in the prevention of PDPH. However, based on a number of theoretical mechanisms, corticotropin (adrenocorticotrophic hormone, ACTH) and its analogues have long been used in the treatment of PDPH.[87] Hakim recently reported randomizing 90 parturients experiencing ADP to receive either 1 mg cosyntropin or saline intravenously 30 minutes after delivery.[70] The incidence of PDPH and EBP was 33% and 11% in the cosyntropin group versus 69% and 30% in the saline group. No serious reactions were associated with cosyntropin use. These limited data are encouraging but will need to be supported through further study.

Limiting/Avoiding Pushing

In the event of ADP, limiting the duration of the second stage of labor (usually to 30–60 minutes) and avoiding pushing at that time may reduce the risk of PDPH. While these measures are not uncommonly recommended in UK maternity units,[73] such management is rare in US practice.[15]

Intrathecal Catheters

Following ADP in an obstetric setting, Russell noted a 41% incidence of at least two additional attempts at epidural placement and a 9% risk of a second dural puncture.[88] Immediately placing an intrathecal catheter (ITC) after ADP has the advantages of being able to rapidly provide spinal analgesia as well as eliminate the possibility of another ADP under challenging clinical circumstances. However, the potential benefits of ITC use must be weighed against the readily appreciated risks involved (accidental use, misuse, and infection).

Although evidence is extremely limited, ITC use has also been proposed to reduce the risk of PDPH after ADP.[62] The mechanism of benefit from ITCs is unclear but may be due to reaction to the catheter, with inflammation or edema preventing further CSF loss after removal. Ayad and colleagues placed and maintained an ITC for 24 hours following ADP.[89] In their obstetric population, catheter placement resulted in a PDPH rate of only 6.2%, with an expected incidence of greater than 50% in this setting. However, this impressive reduction in the incidence of PDPH has generally not been duplicated. A recent meta-analysis of nine studies concluded that ITC insertion following ADP failed to statistically decrease the incidence of PDPH (RR = 0.82, 95% CI 0.67–1.01, p = .06) but did, however, significantly reduce the need for EBP (RR = 0.64, 95% CI 0.49-0.84, p = 0.001).[90] It should be noted that benefits have often not been reported in studies where catheters have been left in situ for less than 24 hours. There are also preliminary data to suggest that the incidence of PDPH may be further reduced by the injection of preservative-free saline through an ITC immediately prior to removal.[86] With some accepted and other possible benefits, rates of ITC use following ADP have clearly increased during the past decade. Recent surveys of US, UK, and Australian practice have noted rates of routine intrathecal catheterization following ADP in obstetric patients of 18%, 28%, and 35%, respectively.[15,73,91]

Although ITC use has become more common, reattempting an epidural at an adjacent interspace remains the preferred action following ADP.[15] Provided an epidural catheter can be successfully placed, several epidural approaches have been used in hope of reducing the incidence and severity of PDPH.

Epidural Saline

Efforts regarding epidural saline have included both bolus (usually around 50 mL as a single or repeated injection) and continuous infusion techniques (commonly 600–1000 mL over 24 hours). As these measures are resource intensive and may only serve to delay the inevitable onset of symptoms, they have generally not been continued beyond 36 hours. In one large analysis (n = 241), Stride and Cooper reported a reduction in the incidence of PDPH from 86% in a conservatively treated control group to 70% with epidural saline infusion.[92] Trivedi and colleagues noted a similar reduction in PDPH (from 87% to 67%) in 30 patients who received a single prophylactic "saline patch" (40–60 mL) following completion of an obstetric procedure.[93] Other studies of epidural saline have noted this modest decrease in the incidence of PDPH. Stride and Cooper also reported a lower incidence of severe headache (from 64% to 47%), but this effect has been inconsistently seen by other investigators, and there is no convincing evidence that epidural saline reduces the eventual need for EBP.

Epidural Opiates

Epidural opiates (especially morphine), while long utilized for the treatment of PDPH, have been thought unlikely to influence the natural history of the disorder. However, recently revisiting the issue of opiates as prophylaxis after ADP, Al-metwalli found two epidural injections of morphine (3 mg in 10 mL), compared with epidural injections of an equal volume of saline, resulted in fewer episodes of PDPH (p = 0.014) and decreased the need for EBP (p = 0.022).[69] Due to the small number of patients involved (n = 25), further prospective investigation is warranted.

Prophylactic Epidural Blood Patch

The impressive efficacy of the EBP when used as treatment for PDPH has fueled interest in the technique for prophylaxis. Research into the efficacy of the EBP for prophylaxis has yielded mixed results, and closer scrutiny indicates that optimism should be guarded. The strongest investigation to date has been by Scavone and colleagues, who performed a prospective, randomized, double-blind study in 64 parturients comparing the prophylactic EBP (PEBP) to a sham EBP.[94] In this study, an identical 56% of patients in each group went on to develop PDPH. Although there was a trend toward fewer therapeutic EBPs recommended and performed in the prophylactic group, the difference was not statistically significant ($p = 0.08$). The primary benefit of the PEBP was a shorter total duration of symptoms (from a median of approximately 5 days to 2 days) and, consequently, a reduction in the overall pain burden.

While there are studies that have shown greater benefit from PEBP, systematic reviews of the evidence have repeatedly noted the inferior methodology of these other studies when compared with that of Scavone et al.[63,95,96] With such inconclusive support, the PEBP is not currently recommended as a routine measure based on available evidence.[62,97] Due to concerns of exposing patients to a potentially unnecessary and marginally beneficial procedure, prophylactic application of the EBP has declined substantially in recent years.[15,73,98] If used for prophylaxis, the EBP should be performed only after any spinal or epidural local anesthetic has worn off, as premature administration has been associated with excessive cephalad displacement of local anesthetic.[99] Residual epidural local anesthetic may also inhibit coagulation of blood, further decreasing the efficacy of the EBP.[100]

DIAGNOSTIC EVALUATION

Postdural puncture headache remains a diagnosis of exclusion. Although headache following meningeal puncture will naturally be suspected to be PDPH, it remains critical to rule out other etiologies (Table 27–1). Fortunately, a careful history with a brief consideration of other possible diagnoses is usually all that is necessary to differentiate PDPH from other causes of headache. While numerous clinical variations have been reported, most cases of PDPH will have (a) a history of known or possible meningeal puncture, (b) delayed onset of symptoms (but within 48 hours), and (c) bilateral postural headache (possibly accompanied by associated symptoms if moderate or severe). Importantly, most non-MPHs will not have a strong positional nature. Laboratory studies are usually not necessary for the diagnosis of PDPH and, if obtained, are generally unremarkable (most commonly, MRI may show meningeal enhancement and LP may reveal low opening pressures and increased CSF protein).

Physical examination plays a limited role in the diagnosis of PDPH. Vital signs (normal blood pressure and absence of fever) and a basic neurologic exam (gross motor and sensory function plus ocular and facial movements) should be documented. Firm bilateral jugular venous pressure, applied briefly (10–15 seconds), tends to worsen headaches secondary to intracranial hypotension.[26] Conversely, the "sitting epigastric pressure test" may result in transient relief of PDPH symptoms.[101] For this test, the patient is placed in a sitting position until headache symptoms become manifest. Firm, continuous abdominal pressure is applied with one hand, while the other hand is secure against the patient's back. In cases of PDPH, some improvement is usually noted within 15–30 seconds with prompt return of symptoms on release of abdominal pressure.

It must be appreciated that benign headaches are frequently encountered in the perioperative setting, even in the absence of meningeal puncture, but have generally been noted to be less severe than PDPH (common etiologies include dehydration, hypoglycemia, anxiety, and caffeine withdrawal). With spinal anesthesia, the specific local anesthetic used and the addition of dextrose or epinephrine may influence the occurrence of nonspecific headache but do not affect the rate of true PDPH.[102] The majority of headaches following meningeal puncture will be benign, nonspecific headaches. In a careful analysis of headache following spinal anesthesia for ambulatory surgery in the general population using strict criteria for PDPH, Santanen and colleagues found an incidence of non-MPH of 18.5%, with an incidence of true PDPH of only 1.5%.[103] Headaches and neck/shoulder pain are also common in the postpartum period.[37] In one study, 39% of postpartum patients were noted to be symptomatic, but over 75% of these issues were determined to be primary headaches (migraine, tension type, cervicogenic, and cluster).[59] In this analysis, while 89% of patients received neuraxial anesthesia, only 4.7% of postpartum headaches were PDPH.

Benign headaches can often be differentiated from PDPH by their characteristic features. Exacerbation of chronic headache (eg, tension type, cluster, or migraine) is usually notable for a history of similar headaches. In the study cited immediately in the preceding paragraph, a previous headache history was a significant risk factor for postpartum headache (adjusted odds ratio = 2.25, if > 12 episodes per year).[59] Significant hypertension may cause headaches and should be detected through routine vital sign assessment.

Stella et al studied severe and unrelenting postpartum headaches with onset more than 24 hours from the time of delivery and found that 39% were tension-type headaches, 24% were due to preeclampsia/eclampsia, and only 16% were PDPHs (despite neuraxial anesthesia in 88% of patients).[104] Based on

this observation, they recommended treatment of tension/migraine headache prior to consideration of PDPH.

Pneumocephalus can produce a positional headache that can be difficult to distinguish from PDPH and does not respond to EBP but is readily diagnosed with computerized tomography (CT).[105] Sinusitis may be associated with purulent nasal discharge and tenderness over the affected sinus and is often improved with assuming an upright position. It should be kept in mind that headache is also a side effect of some commonly utilized pharmacologic agents, such as ondansetron.[106] Although certainly unusual, classic PDPH symptoms may even conceivably represent a coincidental case of spontaneous intracranial hypotension (SIH).[107] A number of other benign etiologies are possible.

Serious causes of headache will be rare but must be excluded. It is important to remember that lateralizing neurologic signs (with the exception of cranial nerve palsies), fever/chills, seizures, or changes in mental status are not consistent with a diagnosis of PDPH. Meningitis tends to be associated with fever, leukocytosis, changes in mental status, and meningeal signs (such as nuchal rigidity).[108]

Subdural hematoma (SDH) is a recognized complication of dural puncture and is believed under these circumstances to be due to intracranial hypotension resulting in excessive traction on cerebral vessels, leading to their disruption. Practitioners must maintain a high index of suspicion for SDH, which is often preceded by typical PDPH symptoms but progresses to lose its postural component and may evolve to include disturbances in mentation and focal neurologic signs. It has been proposed that early definitive treatment of severe PDPH may serve to prevent SDH.[109]

Subarachnoid hemorrhage, most commonly due to rupture of a cerebral aneurysm or arteriovenous malformation, is usually associated with the sudden onset of excruciating headache followed by a decreased level of consciousness or coma.[110] Preeclampsia/eclampsia often presents with headache and may only become evident in the postpartum period.[111] Intracranial venous thrombosis (ICVT) is most often seen in the postpartum obstetric population, where headache symptoms are easily confused with PDPH but may progress to seizures, focal neurologic signs, and coma.[112,113] Predisposing factors for ICVT include hypercoagulability, dehydration, and inflammatory and infectious diseases. Reports of other intracranial pathology (intracranial tumor, intracerebral hemorrhage, etc.) misdiagnosed as PDPH are extremely uncommon and will be detected with a thorough neurological evaluation.[114]

Diagnosis of PDPH can be particularly challenging in patients who have undergone LP as part of a diagnostic workup for headache. In these situations, a change in the quality of headache, most commonly a new postural nature, points toward PDPH. Occasionally, if the benign diagnostic possibilities cannot be narrowed down with certainty, a favorable response to EBP can provide definitive evidence for a diagnosis of PDPH.

TREATMENT

Once a diagnosis of PDPH has been made, patients should be provided a straightforward explanation of the presumed etiology, anticipated natural course (factoring in the time from meningeal puncture), and a realistic assessment of treatment options (with consideration of needle gauge). Treatment considerations are presented individually next. Although surveys indicate that formal protocols for management of PDPH are common practice in the United Kingdom, such plans remain the exception in North American practice.[98] A treatment algorithm, based primarily on the severity of symptoms, can serve as a useful guide for management (Figure 27–8).

Time

Because PDPH is a complication that tends to resolve spontaneously, the simple passage of time plays an important role in the appropriate management of this disorder. Prior to the introduction of the EBP as definitive therapy, the natural history of PDPH was documented by Vandam and Dripps as they followed 1011 episodes of PDPH after spinal anesthesia using cutting needles of various sizes.[8] While their analysis was flawed by a lack of information regarding duration in 9% of patients, if one considers their observed data, spontaneous resolution of PDPH was seen in 59% of cases within 4 days and 80% within 1 week.

More recently, Lybecker et al closely followed 75 episodes of PDPH after spinal anesthesia and, while providing an EBP to 40% of their patients (generally to those having the most severe symptoms), observed in the untreated patients a median duration of symptoms of 5 days with a range of 1–12 days.[33] van Kooten et al, in a small but prospective, randomized, blinded study of patients with moderate or severe PDPH following LP primarily using 20 gauge needles, noted 18 of 21 patients (86%) in the control treatment group (24-hour bed rest, at least 2 L of fluids by mouth daily, and analgesics as needed) still having headache symptoms at 7 days, with over half of these still rating symptoms as moderate or severe[115] (Figure 27–9).

These data serve to illustrate the unpredictable and occasionally prolonged duration of untreated PDPH. Indeed, Vandam and Dripps reported 4% of patients still experiencing symptoms 7–12 months after spinal anesthesia.[8] Given this reality, it is not surprising that there are a number of case reports of successful treatment of PDPH months and even years after known or occult meningeal puncture.

Largely due to the self-limited nature of PDPH, the optimal time course of treatment has not been well defined. Clinically, the practical issue is how long definitive therapy (ie, the EBP) can appropriately be delayed. Many practitioners currently advocate a trial, most commonly 24–48 hours, of conservative management.[15] However, the rationale behind this approach is questionable given the often severely disabling nature of symptoms, particularly in the postpartum period when newborn care may be significantly impaired.

Supportive Measures

Reassurance and measures directed toward minimizing symptoms, while not expected to alter the natural course of the disorder, are advised for all patients. By definition, the majority of patients with moderate-to-severe PDPH will naturally seek a recumbent position for symptomatic relief. Despite a lack of

supportive evidence, aggressive hydration continues to be the most frequently recommended practice utilized in treatment of PDPH.[15] Although aggressive hydration does not appear to influence the duration of symptoms,[74] patients should and often must be encouraged to avoid dehydration.

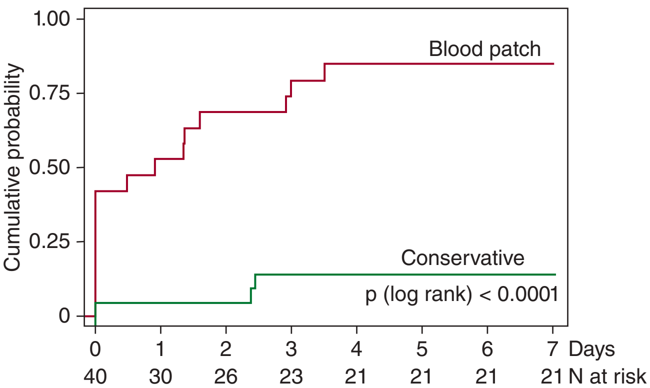

FIGURE 27–9. Cumulative probability of recovery from PDPH. Recovery from moderate-to-severe PDPH after diagnostic LP in 40 patients. At 7 days, only 3 of 21 conservatively treated patients had fully recovered (no headache symptoms) versus 16 of 19 patients treated with EBP ($p < .0001$). (Reproduced with permission from van Kooten F, Oedit R, Bakker SL, et al: Epidural blood patch in post dural puncture headache: a randomised, observer-blind, controlled clinical trial. *Neurol Neurosurg Psychiatry*. 2008 May;79(5):553–558.)

Analgesics (acetaminophen, nonsteroidal anti-inflammatory drugs [NSAIDs], opiates, etc.) may be administered by a number of different routes and are commonly used, yet the relief obtained is often unimpressive, especially with severe headaches. Antiemetics and stool softeners should be prescribed when indicated. Abdominal binders have been advocated but are uncomfortable and seldom used in modern practice. Alternative measures that have been suggested in the management of PDPH include acupuncture[116] and bilateral greater occipital nerve block.[117,118]

Pharmacologic Therapies

Many pharmacologic agents have been advocated as treatments for PDPH. Reports of successful use of pharmacologic agents for treatment of PDPH are intriguing, but their proper place in the management of PDPH awaits further study of efficacy and safety. While appealing, these options have generally been poorly studied and are of questionable value due to the small number of patients treated, methodological flaws in published reports, publication bias, and the self-limited nature of the disorder.

A recent review of RCTs assessing the effectiveness of any pharmacological drug used for treating PDPH only included[118] seven studies with a total of 200 participants (primarily parturients).[119] Given the initial optimistic but eventually disproven role for so many treatments through the years, practitioners are advised to have guarded expectations in this regard, especially when dealing with severe PDPH. A detailed review of pharmacologic therapies for PDPH is beyond the scope of this chapter, but some popular or recently investigated options include the following:

1. *Methylxanthines.* Due to known cerebral vasoconstrictive effects, this class of drugs has become the most commonly used pharmacologic approach to PDPH. These agents include aminophylline, theophylline, and—the most familiar—caffeine. Experimentally, caffeine has been used intravenously (usually 500 mg caffeine sodium benzoate, which contains 250 mg caffeine) and orally (eg, 300 mg). Published studies of caffeine for PDPH consistently demonstrated improvement at 1–4 hours in over 70% of patients treated.[120] However, a single oral dose of 300 mg caffeine for treatment of PDPH is statistically no better than placebo at 24 hours.[121] With a terminal half-life usually less than 6 hours, repeated doses of caffeine would seem necessary for treatment of PDPH, yet few studies have evaluated more than 2 doses for efficacy or safety (of particular concern in the nursing parturient). Furthermore, there is no convincing evidence that caffeine, or any pharmacologic agents, reduce the eventual need for EBP. Overall, the use of caffeine for PDPH does not appear to be supported by the available literature.[122] Nevertheless, surveys indicated that it continues to be widely used in the treatment of PDPH.[15,73,98] Clinically, encouraging unmonitored caffeine intake is of extremely uncertain value, especially considering the widespread lack of awareness of caffeine content in readily available beverages and medications. The temporary benefit often observed with caffeine would indicate that, if used, it is perhaps most appropriate for the treatment of PDPH of moderate (and possibly mild or severe) intensity while awaiting spontaneous resolution of the condition. While the familiarity of caffeine for nonmedical purposes would argue for its general safety, practitioners should note that its use is contraindicated in patients with seizure disorders, pregnancy-induced hypertension, or a history of supraventricular tachyarrhythmias.
2. *Serotonin type 1d receptor agonists.* These agents cause cerebral vasoconstriction and are commonly used for migraine headache. Despite anecdotal reports of success, sumatriptan was ineffective for treatment of severe PDPH in a small randomized, prospective study.[123]
3. *Ergot alkaloids.* These cerebral vasoconstrictive agents are also commonly used for migraine headache. A small, uncontrolled pilot study suggested that methylergonovine (0.25 mg orally three times daily for 24–48 hours) may hasten resolution of PDPH.[124]
4. *Corticosteroidogenics (corticotropin [ACTH] and its synthetic analogues [ie, cosyntropin/tetracosactin]).* Although the mechanism of action remains speculative, ACTH is known to have multiple physiologic effects that could theoretically improve symptoms of PDPH.[87] However, a synthetic ACTH analogue was ineffective for treatment of severe PDPH in a small randomized, prospective study.[125]
5. *Corticosteroids.* Similar to corticosteroidogenics, corticosteroids have multiple physiologic effects that could theoretically improve symptoms of PDPH. In a randomized, prospective study of 60 patients with severe PDPH after spinal anesthesia using 25-gauge Quincke needles for cesarean delivery, addition of hydrocortisone (200 mg IV initially, followed by 100 mg every 8 hours for 6 doses) resulted in significantly lower headache intensity.[126] Only one patient in this study (in the conventionally treated group) required EBP. A similar randomized study in 60 nonobstetric surgery patients experiencing PDPH after spinal anesthesia showed significant reductions in headache intensity in the hydrocortisone group.[127]
6. *Anticonvulsants.* Several membrane-stabilizing agents are widely used for various pain syndromes. Some reports have suggested that gabapentin may be useful in the setting of PDPH. In an uncontrolled case series of 17 postpartum patients with severe PDPH, 9 (53%) experienced "excellent" (visual analog scale [VAS] < 2 of 10 plus resumption of normal activity) relief with gabapentin (200 mg initially, followed by 100–300 mg three times daily, with dose adjusted to tolerance and efficacy).[128] In a randomized, placebo-controlled study, pregabalin (75 mg twice a day for 2 days, then 150 mg twice a day for 2 days) was demonstrated to result in lower pain scores and analgesic consumption in patients with PDPH following spinal anesthesia or LP.[129] It is interesting to note that, despite starting with mean VAS scores of greater than 8 of 10, none of the 40 patients in this study required EBP.

Epidural Therapies

While not a contraindication to epidural treatments, a history of significant technical difficulties with attempted neuraxial techniques should naturally encourage a trial of less-invasive measures. However, the appeal of epidural approaches is evident if access to the epidural space is deemed reasonable or if the patient already has a correctly placed catheter in situ.

Epidural Saline

Epidural saline, as bolus and infusion, has a long history of use for treatment of PDPH. Bolus injections of epidural saline (usually 20–30 ml, repeated as necessary if a catheter is present) have been reported to produce prompt and virtually universal relief of PDPH, yet the practice is plagued by an extremely high rate of headache recurrence. This transient effect is not surprising as increases in epidural pressure following bolus administration of saline have been demonstrated to return to baseline within 10 minutes.[130] Favorable results achieved with this approach have been speculated to represent the mechanical reapproximation of a dural flap (the "tin-lid" phenomenon).[6] However, bolus administration of saline for treatment of PDPH has been convincingly shown to be inferior to the EBP, especially when headaches are secondary to large-bore needle punctures.[131] Overall, epidural saline appears to be of limited value for established PDPH.[62] Nevertheless, the successful use of epidural saline, administered as bolus or infusion, continues to be reported occasionally under exceptional circumstances.[132,133]

Epidural Blood Patch

During the past several decades, the EBP has emerged as the "gold standard" for treatment of PDPH (Figure 27–10).[6] A Cochrane review (a systematic assessment of the evidence) regarding the EBP concluded that the procedure now has proven benefit over more conservative treatment.[97] The mechanism of action of the EBP, while not entirely elucidated, appears to be related to the ability to stop further CSF loss by the formation of clot over the defect in the meninges as well as a tamponade effect with cephalad displacement of CSF (the "epidural pressure patch").[134]

The appropriate role of the EBP in individual situations will depend on multiple factors, including the duration and severity of headache and associated symptoms, type and gauge of original needle used, and patient wishes. The EBP should be encouraged in patients experiencing ADP with an epidural needle and those whose symptoms are categorized as severe (ie, pain score > 6 on a 1–10 scale). Informed consent for the EBP should include a discussion with the patient regarding the common as well as serious risks involved, true success rate, and anticipated side effects. Finally, patients should be provided clear instructions for the provision of timely medical attention should they experience a recurrence of symptoms.

A number of controversies surround the EBP, reflecting the scarcity of adequately powered, randomized trials. The procedure itself has been well described and consists of the sterile injection of fresh autologous blood near the previous dural puncture (Table 27–2). An MRI study of the EBP in 5 young patients (ages 31–44) using 20 mL blood noted a spread of 4.6 ± 0.9 intervertebral spaces (mean ± SD), averaging 3.5 levels above and 1 level below the site of injection.[134] This and other observations of a preferential cephalad spread of blood in the lumbar epidural space has led to the common recommendation to perform the EBP "at or below" the meningeal puncture level. However, the influence of the level of placement and use of an epidural catheter (often situated considerably cephalad to a meningeal puncture) on efficacy for EBP has never been clinically evaluated.

FIGURE 27–10. Blood patch. Administration of an epidural blood patch using 20 mL of freshly drawn blood. The blood is injected until 20 mL are reached or the patient perceives significant pain or pressure in the back, whichever comes first.

TABLE 27–2. Epidural blood patch procedure.

- Obtain written informed consent.
- Establish intravenous access. An 18-gauge or larger saline lock is sufficient.
- Position the patient for epidural needle placement (mindful that a lateral decubitus position may be more comfortable than sitting for the patient).
- Using standard sterile technique, place an epidural needle into the epidural space at or below the level of previous meningeal puncture.
- Collect 20 mL fresh autologous venous blood using strict sterile technique (this is usually readily accomplished using the previously placed saline lock).
- Without delay, steadily inject blood through the epidural needle until the patient reports fullness or discomfort in the back, buttocks, or neck.
- Maintain the patient in a recumbent position for a period of time (1–2 hours may result in more complete resolution of symptoms). Intravenous infusion of 1 L crystalloid during this interval is often helpful.
- Instructions for discharge:
  - Encourage over-the-counter analgesics (eg, acetaminophen, ibuprofen) as needed for any mild residual discomfort.
  - Prescribe stool softeners or cough suppressants if indicated.
  - Avoid lifting, straining, or air travel for 24 hours.
  - Provide clear instructions on how to contact anesthesia personnel for inadequate relief or recurrence of symptoms.

The optimal timing of the EBP is a matter of debate. After diagnosis, most practitioners prefer to delay performing the EBP, possibly to further confirm the diagnosis as well as to allow an opportunity for spontaneous resolution. A 1996 survey of UK neurological departments found that only 8% would consider the EBP before 72 hours had passed following LP.[135] A recent survey of UK maternity units reported that 71% would perform the EBP only "after the failure of conservative measures."[73] Likewise, the majority of respondents to recent surveys of practice in the United States and Nordic countries usually waited at least 24 hours from the onset of symptoms before performing the EBP.[15,136]

Several studies have suggested that the EBP procedure may become more effective with the passage of time.[137,138] Safa-Tisseront et al. found a delay of less than 4 days from meningeal puncture before performing an EBP to be an independent risk factor for failure of the procedure.[138] Yet, these authors were careful to state that failure of the EBP may be primarily related to the severity of the CSF leak (with larger, harder-to-treat situations demanding earlier attention), and that their study should not be grounds for delaying the EBP.

Sandesc and colleagues performed a prospective, randomized, double-blind study of the EBP versus conservative management (intravenous or oral fluids up to 3 L/d, NSAIDS, and caffeine sodium benzoate 500 mg IV every 6 hours) in 32 patients with severe PDPH symptoms (mean pain intensity = 8.1).[139] At the time treatment was initiated, none of these patients had experienced symptoms for longer than 24 hours. While all patients in the EBP group had satisfactory resolution of symptoms at 24-hour follow-up, the control group was essentially unchanged (mean pain intensity = 7.8). Notably, 14 of 16 patients in the conservatively treated group then elected for EBP treatment. These investigators concluded that there was no reason to delay the EBP for more than 24 hours after making a diagnosis of severe PDPH. This recommendation was further supported by a prospective analysis of 79 patients with PDPH that determined early EBP in those with moderate-to-severe symptoms minimized overall patient suffering.[140]

The ideal volume of blood for EBP has been an evolving issue that is becoming more clearly understood. Conceptually, the volume of blood used should be sufficient to form an organized clot over the meningeal defect as well as produce some degree of epidural tamponade.[134] When performing the EBP, anesthesiologists commonly inject as much blood as was drawn (usually around 20 mL), stopping when the patient complains of discomfort or fullness in the back, buttocks, or neck.

There appear to be geographic preferences regarding blood volume. The largest analysis of the EBP to date (n = 504) utilized a blood volume of 23 ± 5 ml (mean ± SD).[137] Importantly, this French study found no significant difference in blood volumes between successful and failed EBP. Notably, they reported "discomfort" in 78% of injections with 19 ± 5 mL and "pain" in 54% with 21 ± 5 mL, with the only independent risk factor for pain during EBP being age less than 35 years. A recent survey of US anesthesiologists reported general unanimity for a smaller blood volume, with two-thirds (66.8%) most commonly using between 16 and 20 mL.[15]

As previously mentioned, there may be some experimental support for using a blood volume of 15–20 mL, as early studies of CSF drainage in volunteers reported consistently producing positional headache symptoms with loss of 10% of total CSF volume (approximately 15 mL).[26] Furthermore, the reduction in CSF pressures produced by this degree of fluid loss would be expected to reduce or eliminate transmeningeal driving pressure, resulting at that point in a relative CSF volume homeostasis (in the supine position).

Two RCTs have been performed to determine the optimum volume of blood for EBP in obstetric patients with PDPH following ADP. The first, which compared 7.5 to 15 mL in 33 Taiwanese women, reported similar efficacy with the two volumes and failed to find any advantage with the larger volume.[142] The second was a larger, multicenter study that looked at three volumes of blood for EBP (15, 20, and 30 mL).[143] This trial found that patients receiving 15 mL had less-complete relief of symptoms than those receiving 20 or 30 mL, with no difference in efficacy between 20 and 30 mL. These investigators also found that only 54% of patients randomized to the highest volume were able to tolerate the full 30 mL (compared with 81% in the 20-mL group).

While these two studies failed to definitively determine the ideal volume of blood for EBP, they both indicated that it does not appear necessary to use volumes greater than 20 mL. It is notable that although the utility of the EBP in the treatment of SIH is uncertain,[62] much larger blood volumes (up to 100 mL) are commonly recommended for this indication.[143] However, recent case reports highlighted some potential complications, such as severe radiculopathy, from large-volume EBP,[144,145] and practitioners are therefore generally encouraged to use the smallest effective blood volume.

To allow for clot organization and regeneration of CSF (approximately 0.35 mL/minute), it is common practice to have patients remain recumbent for a period of time following the EBP. While the optimal duration of bed rest immediately following an EBP remains unknown, one small study suggested that maintaining the decubitus position for at least 1 and preferably 2 hours may result in a more complete resolution of symptoms.[146] Patients are also usually advised to avoid lifting, Valsalva maneuvers (eg, straining with bowel movement), and air travel for 24–48 hours after EBP to minimize the risk of patch disruption.

Modifications have been made to the standard EBP technique in special circumstances. To accommodate the religious beliefs of Jehovah's Witness patients, techniques have been described that keep autologous blood within a continuous circuit.[147] The EBP has been repeatedly demonstrated to be safe and effective for treatment of PDPH in the pediatric population.[148,149] A blood volume of 0.2–0.3 mL/kg appears appropriate for young children as well as adolescents. The EBP is also performed with decreased blood volumes at extralumbar sites (eg, cervical spine).[150]

Contraindications to the EBP are similar to those of any epidural needle placement: coagulopathy, systemic sepsis, fever, infection at the site, and patient refusal. Theoretical concerns have been expressed regarding the possibility of neoplastic seeding of the central nervous system in patients with cancer.[151] It has been suggested that special care, in the form of slower injections of smaller blood volumes, may be prudent in patients whose central nervous system may be vulnerable to injury produced by increased epidural pressures generated with EBP, such as those with multiple sclerosis.[152] Although not free from concern and controversy, the EBP has been safely provided to patients with HIV infection[153] and acute varicella.[154]

Minor side effects are common following the EBP. Patients should be warned to expect aching in the back, buttocks, or legs (seen in approximately 25% of patients).[137] While usually short-lived, backache was noted to be persistent in 16% of patients following EBP and lasted 3–100 days (with a mean duration in this subgroup of 27.7 days).[155] Despite these lingering symptoms, patient satisfaction with the EBP is high. Other frequent but benign aftereffects of the EBP include transient neckache,[155] bradycardia,[156] and modest temperature elevation.[155]

Largely through extensive clinical experience, the EBP has been sufficiently proven to be safe. Risks are essentially the same as with other epidural procedures (infection, bleeding, nerve damage, and ADP). Although some patients may develop temporary back and lower extremity radicular pain as mentioned, such complications are uncommon. With proper technique, infectious complications are vanishingly rare. In general, a previous EBP does not appear to significantly influence the success of future epidural interventions,[157] but case reports suggest that the EBP may occasionally result in clinically significant scarring.[158] Serious complications secondary to the EBP do occur but have usually consisted of isolated case reports and have often been associated with significant deviations from standard practice.[6]

Alternative Treatment Options to EBP

A number of alternatives to blood have been promoted as patch materials. The various rationales for using alternative agents include situations for which the use of blood has been ineffective or is contraindicated.[159] The most commonly proposed materials (dextran 40, hydroxyethylstarch, gelatin, and fibrin glue) have been adapted for a perceived ability to provide prolonged epidural tamponade or result in sealing of a meningeal rent. In a rat model, experimental support for a "blood-like" effect was best shown for fibrin glue.[130] Yet, clinical use of these alternatives is limited to case reports and small series, and their use is uncommon in the United States.[15] While not necessarily without merit, these options remain poorly defined and are not without potential for serious risk (eg, allergic reactions to dextran), and reports of their use should still be considered preliminary.

PERSISTENT OR RECURRENT PDPH

Early reports of the EBP frequently cited success rates between 90% and 100% but often did not include a strict definition of "success," had little or no follow-up, and failed to consider the influence of such confounding factors as needle size and tip design, severity of symptoms, or natural history of PDPH. The true efficacy of the EBP procedure is now known to be significantly lower than once thought. Persistent or recurrent headaches following the EBP, while not necessarily requiring consultation, warrant follow-up and thoughtful reevaluation.

The EBP is associated with nearly immediate symptomatic relief in greater than 90% of cases, but appropriate follow-up reveals a number of patients experiencing incomplete relief, failure, or recurrence of symptoms. In an uncontrolled, prospective, observational study of 504 consecutive patients treated with EBP following meningeal puncture with needles of various sizes, Safa-Tisseront et al reported that some relief of symptoms occurs in 93% of patients.[138] On closer analysis, however, complete relief of symptoms was seen in only 75% of patients, with 18% experiencing incomplete relief. They also found that the EBP was more likely to fail if the original meningeal puncture was made with needles larger than 20 gauge. For needles larger than 20 gauge, the unqualified success rate of the EBP was only 62%, with 17% of patients reporting incomplete relief of symptoms and 21% experiencing failure. Not surprisingly, the majority of these large needles were Tuohy epidural needles.

Expectations of success with the EBP must be further tempered in obstetric patients (all young and female) following ADP with epidural needles. Under these circumstances, Williams et al noted complete relief of symptoms with EBP in only 34% of patients, partial relief in 54%, and no relief in 7% (results unknown in 5%).[160] If performed, a second EBP resulted in complete relief in 50%, partial relief in 36%, and no relief in 14%. In a similar patient population, Banks and colleagues, despite initially observing complete or partial relief with EBP in 95% of patients, reported the return of moderate-to-severe symptoms in 31%, with a mean time to development of recurrent headache of 31.8 hours (range 12–96 hours).[137] The rates of repeat EBP for the Williams and Banks studies were 27% and 19%, respectively. These studies clearly demonstrated the reduced efficacy of the EBP following meningeal punctures made with large needles, which not uncommonly make it necessary to consider repeating the procedure.

Overall, success rates of a second EBP appear to be approximately equal to that of a first. The ideal timing and blood volume for repeat EBP are even more uncertain than for a primary procedure. A majority of US anesthesiologists would wait at least 24 hours after recurrence of PDPH symptoms before performing a second EBP.[15] If more than one EBP is performed within a short period of time, practitioners should remain cognizant of the cumulative amount of blood used as excessive volumes under these circumstances have been implicated in adverse outcomes.[144,145]

Insufficient evidence exists to guide management following a second failed EBP. Given the frequency of PDPH and significant failure rate of the EBP, instances of sequential EBP failure are not unheard of, especially following large-gauge meningeal punctures. In an analysis of outcomes following ADP with 18-gauge Tuohy needles in an obstetric unit, Sadashivaiah reported 3 of 48 patients (6.25%) requiring a third EBP to relieve the headache.[161] Obviously, each failure of the EBP necessitates an even more critical reconsideration of the diagnosis.

While experiences with managing repeated EBP failure have been published,[162] such sporadic case reports are insufficient to guide others. However, one frequently cited and logical recommendation regarding repeat EBP, and particularly a third EBP, is to use some form of radiologic guidance to ensure accurate epidural blood placement (eg, fluoroscopy). Other measures under these difficult circumstances may include any of the aforementioned "treatments," with open surgical repair constituting a last resort.

WHEN TO SEEK FURTHER CONSULTATION

Because PDPH tends to improve even without specific treatment and the EBP has a relatively high rate of success, many practitioners reasonably seek neurological consultation if symptoms have failed to resolve after an arbitrary duration (eg, 7–10 days) or number of EBPs (usually two or three).

Consultation is always indicated if serious non-PDPH is suspected or cannot reasonably be ruled out. As previously mentioned, lateralizing neurologic signs, fever/chills, seizures, or change in mental status are not consistent with a diagnosis of PDPH or benign headache. Consultation is also appropriate for any headaches with atypical features. Proceeding with treatment measures directed toward PDPH under uncertain circumstances may hinder a correct diagnosis, cause critical delays in proper treatment, and can prove harmful. The EBP, for example, has occasionally been reported to produce detrimental increases in intracranial pressure.

Because PDPH can be anticipated to resolve spontaneously, headaches that worsen over time and no longer have a positional nature should be strongly suspected to be secondary to SDH (especially if there are focal neurologic signs or decreases in mental status). Under these circumstances, a neurological consultation should be obtained and diagnostic radiologic studies performed.

Although headache and most associated symptoms, including auditory symptoms,[38] resolve quickly following EBP, cranial nerve palsies generally resolve slowly (within 6 months) and may appropriately prompt a neurology consult for ongoing management and reassurance.[30] Although there are no accepted treatments for cranial nerve palsy associated with PDPH, it seems reasonable to treat these conditions similar to idiopathic facial nerve (CN VII) palsy ("Bell's palsy"). There is some evidence, for example, to suggest that corticosteroids administered early (within 72 hours of onset) may hasten resolution of symptoms from Bell's palsy,[163] and similar treatment has been suggested for cranial nerve palsy following meningeal puncture.[32]

SUMMARY

Over a century after being first described, PDPH remains a significant clinical concern for a number of medical specialties. As with any complication, prevention is preferable to treatment. Identification and consideration of the risk factors for PDPH have resulted in an impressive reduction in the incidence of this persistent iatrogenic problem.

Accidental meningeal puncture with epidural needles continues to be a major concern and challenge. The consequent PDPH symptoms tend to be more severe, of longer duration, and more difficult to treat than those seen with smaller-gauge needles. It should be noted that there is no evidence to support the two most commonly practiced prophylactic measures in this setting: aggressive hydration and encouraging bed rest. Although some prophylactic measures have shown promise, none to this point appears to be a definitive measure.

Many episodes of PDPH, especially those of mild-to-moderate severity, will resolve in a timely manner without specific treatment. Despite being commonly advised, hydration, bed rest, and caffeine are all of questionable value in the treatment of established PDPH. Although alternatives have been proposed, the EBP remains the only proven treatment for PDPH and therefore can be encouraged and performed early (within 24 hours of diagnosis) if symptoms are severe.

Unfortunately, the published literature concerning PDPH has generally been of poor quality.[62,97,164] Many questions remain regarding the optimal means of preventing and treating this troublesome complication. Even much of what is "known" to this point has not been confirmed in follow-up studies. It is anticipated that these issues will be resolved in the future through well-designed clinical investigations.

PART 3-D

ULTRASOUND-GUIDED NERVE BLOCKS

SECTION 1 Fundamentals of Ultrasound-Guided Regional Anesthesia

CHAPTER 28

Physics of Ultrasound

Daquan Xu

INTRODUCTION

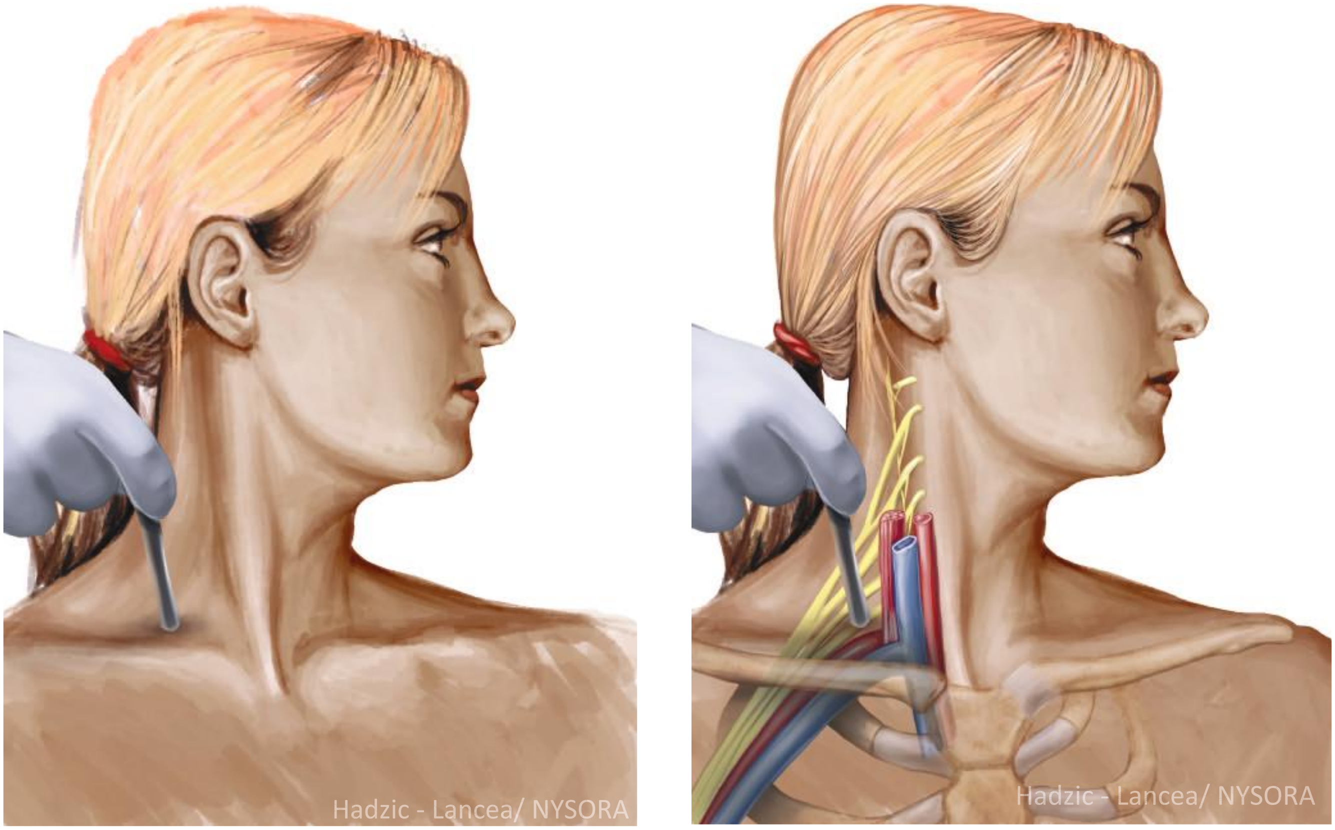
Ultrasound application allows for noninvasive visualization of tissue structures. Real-time ultrasound images are integrated images resulting from reflection of organ surfaces and scattering within heterogeneous tissues. Ultrasound scanning is an interactive procedure involving the operator, patient, and ultrasound instruments. Although the physics behind ultrasound generation, propagation, detection, and transformation into practical information is rather complex, its clinical application is much simpler. Because ultrasound imaging has improved tremendously over last decade, it can provide anesthesiologists opportunity to directly visualize target nerve and relevant anatomical structures. Ultrasound-guided nerve block is a critical growth area for new applications of ultrasound technology and become an essential part of regional anesthesia. Understanding the basic ultrasound physics presented in this chapter will be helpful for anesthesiologists to appropriately select the transducer, to set the ultrasound system, and then to obtain a pleasing imaging.

HISTORY OF ULTRASOUND

In 1880, French physicists Pierre Curie and his elder brother, Paul-Jacques Curie, discovered the piezoelectric effect in certain crystals.[1] Paul Langevin, a student of Pierre Curie, developed piezoelectric materials, which can generate and receive mechanical vibrations with high frequency (therefore *ultra*sound).[2] During World War I, ultrasound was introduced in the navy as a means to detect enemy submarines.[3] In the medical field, however, ultrasound was initially used for therapeutic rather than diagnostic purposes. In the late 1920s, Paul Langevin discovered that high-power ultrasound could generate heat in bone and disrupt animal tissues.[4] As a result, throughout the early 1950s ultrasound was used to treat patients with Ménière disease, Parkinson disease, and rheumatic arthritis.[5]

Diagnostic applications of ultrasound began through the collaboration of physicians and sonar (sound navigation ranging) engineers. In 1942, Karl Dussik, a neuropsychiatrist, and his brother, Friederich Dussik, a physicist, described ultrasound as a medical diagnostic tool to visualize neoplastic tissues in the brain and the cerebral ventricles.[6,7] However, limitations of ultrasound instrumentation at the time prevented further development of clinical applications until the mid-1960s. The real-time B-scanner was developed in 1965 and was first introduced in obstetrics.[8,9] In 1976, the first ultrasound machines coupled with Doppler measurements were commercially available.[10]

With regard to regional anesthesia, as early as 1978, La Grange and his colleagues were the first anesthesiologists to publish a case series report of ultrasound application for peripheral nerve blockade.[11] They simply used a Doppler transducer to locate the subclavian artery and performed supraclavicular brachial plexus block in 61 patients (Figures 28–1A and 28–1B). Reportedly, Doppler guidance led to a high block success rate (98%) and absence of complications such as pneumothorax, phrenic nerve palsy, hematoma, convulsion, recurrent laryngeal nerve block, and spinal anesthesia. In 1989, Ting and Sivagnanaratnam reported the use of B-mode ultrasonography to demonstrate the anatomy of the axilla and to observe the spread of local anesthetics during axillary brachial plexus block.[12]



A

B

FIGURE 28–1. **A:** Early application of Doppler ultrasound by LaGrange to perform supraclavicular brachial block. **B:** Relationship of the brachial plexus of nerves and the subclavian artery.

In 1994, Stephan Kapral and colleagues systematically explored brachial plexus with B-mode ultrasound. Since that time, multiple teams worldwide have worked tirelessly to define and improve the application of ultrasound imaging in regional anesthesia.[13] Ultrasound-guided nerve blockade is currently used routinely in the practice of regional anesthesia in many centers worldwide.

Here is a summary of ultrasound quick facts:

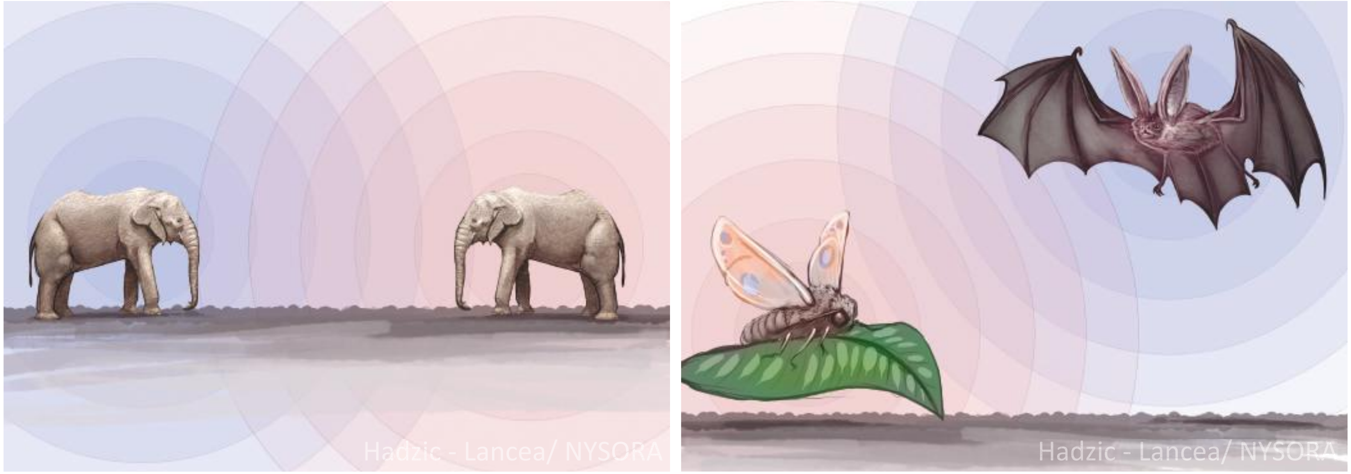
- 1880: Pierre and Jacques Curie discovered the piezoelectric effect in crystals.
- 1915: Ultrasound was used by the navy for detecting submarines.
- 1920s: Paul Langevin discovered that high-power ultrasound can generate heat in osseous tissues and disrupt animal tissues.
- 1942: The Dussik brothers described ultrasound use as a diagnostic tool.
- 1950s: Ultrasound was used to treat patients with Ménière disease, Parkinson disease, and rheumatic arthritis.
- 1965: The real-time B-scan was developed and was introduced in obstetrics.
- 1978: La Grange published the first case series of ultrasound application for placement of needles for nerve blocks.
- 1989: Ting and Sivagnanaratnam used ultrasonography to demonstrate the anatomy of the axilla and to observe the spread of local anesthetics during axillary block.
- 1994: Steven Kapral and colleagues explored brachial plexus blockade using B-mode ultrasound.

Definition of Ultrasound

Sound travels as a mechanical longitudinal wave in which back-and-forth particle motion is parallel to the direction of wave travel. Ultrasound is high-frequency sound and refers to mechanical vibrations above 20 kHz. Human ears can hear sounds with frequencies between 20 Hz and 20 kHz. Elephants can generate and detect sound with frequencies less than 20 Hz for long-distance communication; bats and dolphins produce sounds in the range of 20 to 100 kHz for precise navigation (Figures 28–2A and 28–2B). Ultrasound frequencies commonly used for medical diagnosis are between 2 and 15 MHz. However, sounds with frequencies above 100 kHz do not occur naturally; only human-developed devices can both generate and detect these frequencies, or ultrasounds.

Piezoelectric Effect

Ultrasound waves can be generated by material with a piezoelectric effect. The piezoelectric effect is a phenomenon exhibited by the generation of an electric charge in response to a mechanical force (squeeze or stretch) applied on certain materials. Conversely, mechanical deformation can be produced when an electric field is applied to such material, also known as the piezoelectric effect (Figure 28–3). Both natural and human-made materials, including quartz crystals and ceramic materials, can demonstrate piezoelectric properties. Recently, lead zirconate titanate has been used as piezoelectric material for



A B

FIGURE 28–2. A: Elephants can generate and detect the sound of frequencies less than 20 Hz for long-distance communication. **B:** Bats and dolphins produce sounds in the range of 20–100 kHz for navigation and spatial orientation.

medical imaging. Lead-free piezoelectric materials are also under development. Individual piezoelectric materials produce a small amount of energy. However, by stacking piezoelectric elements into layers in a transducer, the transducer can convert electric energy into mechanical oscillations more efficiently. These mechanical oscillations are then converted into electric energy.

Ultrasound Terminology

Period is the time for a sound wave to complete one cycle; the period unit of measure is the microsecond (μs).

Wavelength is the length of space over which one cycle occurs; it is equal to the travel distance from the beginning to the end of one cycle.

Frequency is the number of cycles repeated per second and measured in hertz (Hz).

Acoustic velocity is the speed at which a sound wave travels through a medium. It is equal to the frequency times the wavelength. Speed c is determined by the density ρ and stiffness κ of the medium ($c = (\kappa/\rho)^{1/2}$). *Density* is the concentration of a medium. *Stiffness* is the resistance of a material to compression. Propagation speed increases if the stiffness is increased or the density is decreased.

The average propagation speed in soft tissues is 1540 m/s (ranges from 1400 to 1640 m/s). However, ultrasound cannot penetrate lung or bone tissues.

Acoustic impedance z is the degree of difficulty demonstrated by a sound wave being transmitted through a medium; it is equal to density ρ multiplied by acoustic velocity c ($z = \rho c$). It increases if the propagation speed or the density of the medium is increased.

Attenuation coefficient is the parameter used to estimate the decrement of ultrasound amplitude in certain media as a function of ultrasound frequency. The attenuation coefficient increases with increasing frequency; therefore, a practical consequence of attenuation is that the penetration decreases as frequency increases (Figure 28–4).

Ultrasound waves have a self-focusing effect, which refers to the natural narrowing of the ultrasound beam at a certain travel distance in the ultrasonic field. It is a transition level between *near field* and *far field*. The beam width at the transition level is equal to half the diameter of the transducer. At the distance of two times the near-field length, the beam width reaches the transducer diameter. The self-focusing effect amplifies ultrasound signals by increasing acoustic pressure.

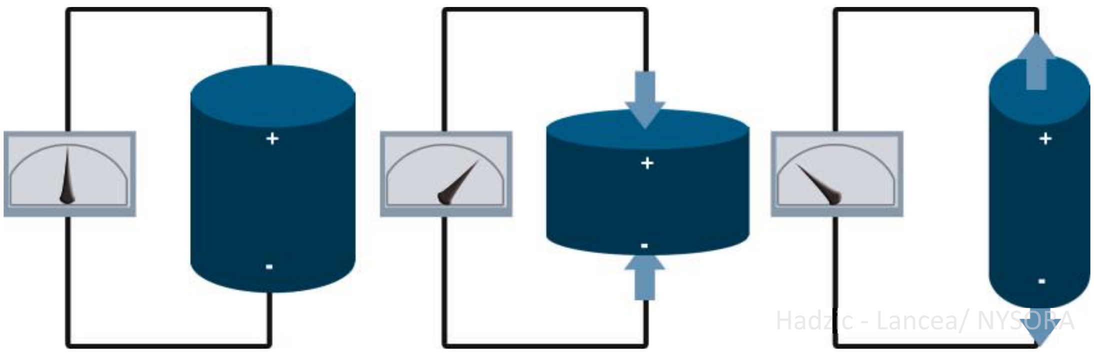


FIGURE 28–3. The piezoelectric effect. Mechanical deformation and consequent oscillation caused by an electrical field applied to certain material can produce a sound of high frequency.

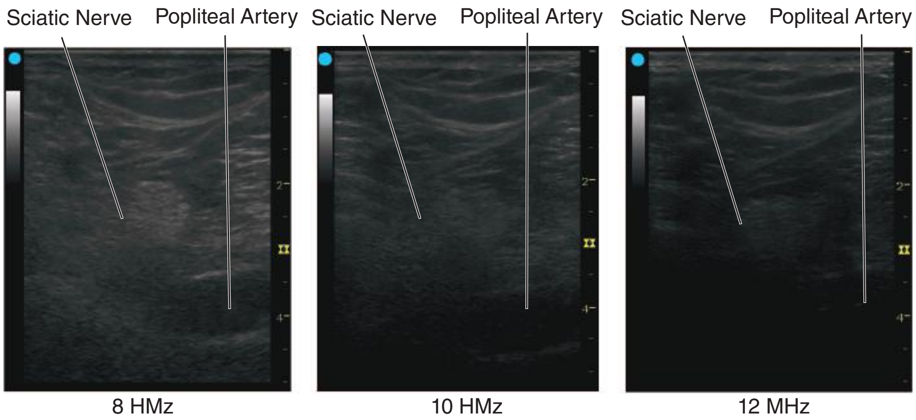

FIGURE 28–4. The ultrasound amplitude decreases in certain media as a function of ultrasound frequency, a phenomenon known as the attenuation coefficient. (Adapted with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc; 2011.)

In ultrasound imaging, there are two aspects of spatial resolution: axial and lateral. *Axial resolution* is the minimum separation of above-below planes along the beam axis. It is determined by spatial pulse length, which is equal to the product of wavelength and the number of cycles within a pulse. It can be presented in the following formula:

$$\text{Axial resolution} = \text{Wavelength } \lambda \times \text{Number of cycles per pulse } n \div 2$$

The number of cycles within a pulse is determined by the damping characteristics of the transducer. The number of cycles within a pulse is usually set between 2 and 4 by the manufacturer of the ultrasound machines. As an example, if a 2-MHz ultrasound transducer is theoretically used to do the scanning, the axial resolution would be between 0.8 and 1.6 mm, making it impossible to visualize a 21-gauge needle. For a constant acoustic velocity, higher-frequency ultrasound can detect smaller objects and provide an image with better resolution. The axial resolution of current ultrasound systems is between 0.05 and 0.5 mm. Figure 28–5 shows images at different resolutions when a 0.5-mm diameter object is visualized with three different frequency settings.

Lateral resolution is another parameter of sharpness to describe the minimum side-by-side distance between two objects. It is determined by both ultrasound frequency and beam width. The higher frequencies have narrower focus and provide better axial and lateral resolution. Lateral resolution can also be improved by adjusting focus to reduce the beam width.

Temporal resolution is also important for observing a moving object such as blood vessels and heart. Like a movie or cartoon video, the human eye requires that the image be updated at a rate of approximately 25 times a second or higher for an ultrasound image to appear continuous. However, imaging resolution will be compromised by increasing the frame rate. Optimizing the ratio of resolution to the frame rate is essential for providing the best possible image.

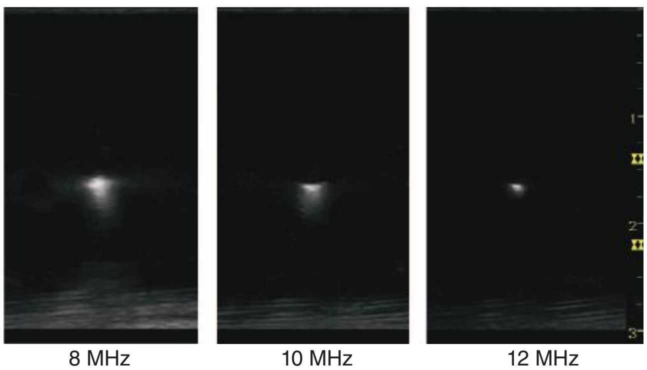

FIGURE 28–5. Ultrasound frequency affects the resolution of the imaged object. Resolution can be improved by increasing frequency and reducing the beam width by focusing. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc; 2011.)

INTERACTIONS OF ULTRASOUND WITH TISSUES

As the ultrasound wave travels through tissues, it is subject to a number of interactions. The most important features are as follows:

- Reflection
- Scatter
- Absorption

When ultrasound encounters boundaries between different media, part of the ultrasound is reflected and the other part is transmitted. The reflected and transmitted directions are given by the reflection angle θ_r and transmission angle θ_t, respectively (Figure 28–6).

Refection of sound waves is similar to optical refection. Some of its energy is sent back into the medium from which it came. In a true reflection, the reflection angle θ_r must equal the incidence angle θ_i. The strength of the reflection from an interface is variable and depends on the difference of impedances

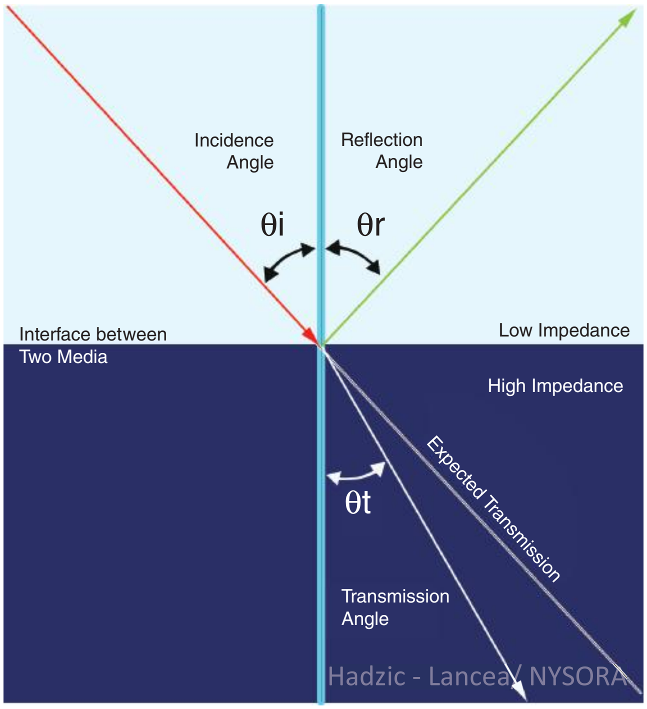

FIGURE 28–6. The interaction of ultrasound waves through the media in which they travel is complex. When ultrasound encounters boundaries between different media, part of the ultrasound is reflected and part is transmitted. The reflected and transmitted directions depend on the respective angles of reflection and transmission. (Adapted with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc; 2011.)

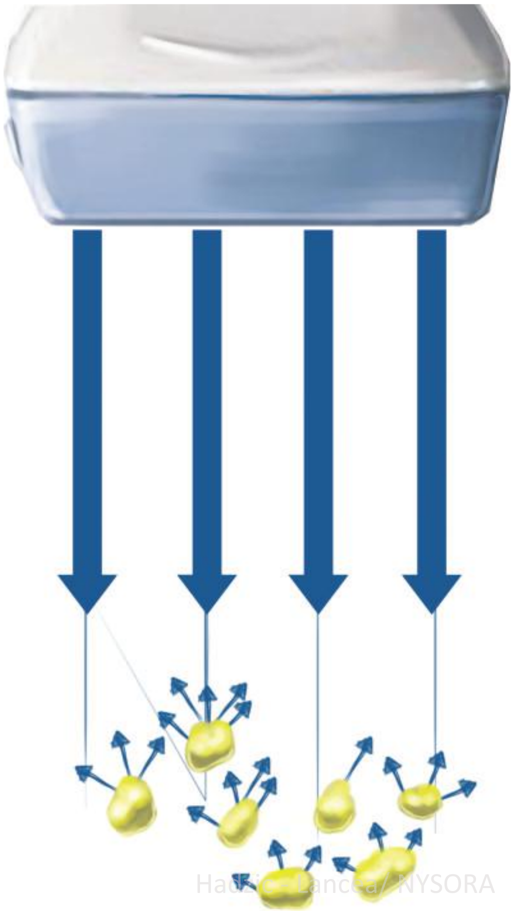

FIGURE 28–7. Scattering is the redirection of ultrasound in any direction caused by rough surfaces or by heterogeneous media. (Adapted with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc; 2011.)

between two affinitive media and the incident angle at the boundary. If the media impedances are equal, there is no reflection (no echo). If there is a significant difference between media impedances, there will be nearly complete reflection. For example, an interface between soft tissues and either lung or bone involves a considerable change in acoustic impedance and creates strong echoes. This reflection intensity is also highly angle dependent. In practical terms, it means that the ultrasound transducer must be placed perpendicular to the target nerve to visualize it clearly. A change in sound direction when crossing the boundary between two media is called *refraction*. If the propagation speed through the second medium is slower than that through the first medium, the refraction angle is smaller than the incident angle. Refraction can cause the artifact that occurs beneath large vessels on the image.

During ultrasound scanning, a coupling medium must be used between the transducer and the skin to displace air from the transducer-skin interface. A variety of gels and oils are applied for this purpose. Moreover, they can act as lubricants, making a smooth scanning performance possible. Most scanned interfaces are somewhat irregular and curved. If the boundary dimensions are significantly less than the wavelength or not smooth, the reflected waves will be diffused.

Scattering is the redirection of sound in any directions by rough surfaces or by heterogeneous media (Figure 28–7). Normally, scattering intensity is much less than mirror-like reflection intensities and is relatively independent of the direction of the incident sound wave; therefore, the visualization of the target nerve is not significantly influenced by other nearby scattering.

Absorption is defined as the direct conversion of the sound energy into heat. In other words, ultrasound scanning generates heat in the tissue. Higher frequencies are absorbed at a greater rate than lower frequencies. However, a higher scanning frequency gives better axial resolution. If the ultrasound penetration is not sufficient to visualize the structures of interest, a lower frequency is selected to increase the penetration. The use of longer wavelengths (lower frequency) results in lower resolution because the resolution of ultrasound imaging is proportional to the wavelength of the imaging wave. Frequencies between 6 and 12 MHz typically yield adequate resolution for imaging in peripheral nerve blockade, whereas frequencies between 2 and 5 MHz are usually needed for imaging of neuraxial structures. Frequencies of less than 2 MHz or higher than 15 MHz are rarely used because of insufficient resolution or the insufficient penetration depth in most clinical applications.

PART 3

ULTRASOUND IMAGE MODES

A-Mode

The A-mode is the oldest ultrasound technique and was invented in 1930.[14] The transducer sends a single pulse of ultrasound into the medium. Consequently, a one-dimensional simplest ultrasound image is created on which a series of vertical peaks is generated after ultrasound beams encounter the boundary of the different tissue. The distance between the echoed spikes (Figure 28–8) can be calculated by dividing the speed of ultrasound in the tissue (1540 m/s) by half the elapsed time, but it provides little information on the spatial relationship of imaged structures. Therefore, A-mode ultrasound is not applicable in regional anesthesia.

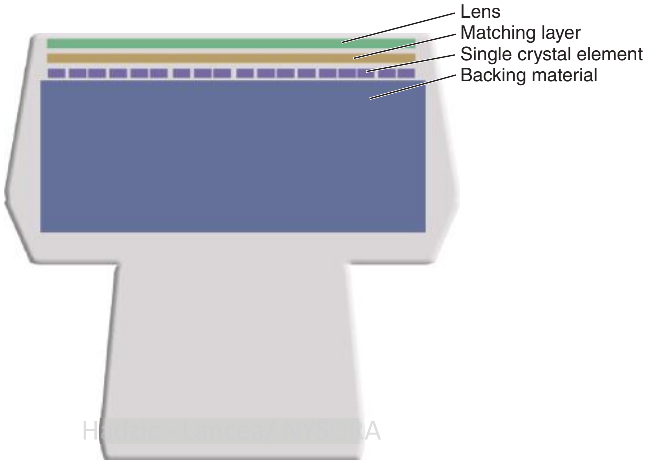

FIGURE 28–9. The B-mode transducer incorporates numeric piezoelectric elements that are electrically connected in parallel.

B-Mode

The B-mode is a two-dimensional (2D) image of the area that is simultaneously scanned by a linear array of 100–300 piezoelectric elements rather than a single one as in A-mode (Figure 28–9). The amplitude of the echo from a series of A-scans is converted into dots of different brightness in B-mode imaging. The horizontal and vertical directions represent real distances in tissue, whereas the intensity of the grayscale indicates echo strength (Figure 28–10). B-mode can provide an image of a cross section through the area of interest, and it is the primary mode currently used in regional anesthesia.

Doppler Mode

The Doppler effect is based on the work of Austrian physicist Johann Christian Doppler.[15] The term describes a change in the frequency or wavelength of a sound wave resulting from relative motion between the sound source and the sound receiver. In other words, at a stationary position, the sound frequency is constant. If the sound source moves toward the sound receiver, the sound waves have to be squeezed, and a higher-pitch sound occurs (positive Doppler shift); if the sound source moves away from the receiver, the sound waves have to be stretched, and the received sound has a lower pitch (negative Doppler shift) (Figure 28–11). The magnitude of Doppler shift depends on the incident angle between the directions of emitted ultrasound beam and moving reflectors. With a 90° angle there is no Doppler shift. If the angle is 0° or 180°, the largest Doppler shift can be detected. In medical settings, the Doppler shifts usually fall in the audible range.

Color Doppler produces a color-coded map of Doppler shifts superimposed onto a B-mode ultrasound image. Blood flow direction depends on whether the motion is toward or away from the transducer. Selected by convention, red and blue colors provide information about the direction and velocity of the blood flow. According to the color map (color bar) in the upper left-hand corner of the figure (Figure 28–12), the red color on the top of the bar denotes the flow coming toward the ultrasound probe, and the blue color on the bottom of the bar indicates the flow away from the probe.

FIGURE 28–8. The A-mode of ultrasound consists of a one-dimensional ultrasound image displayed as a series of vertical peaks corresponding to the depth of structures the ultrasound encounters in different tissues. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc; 2011.)

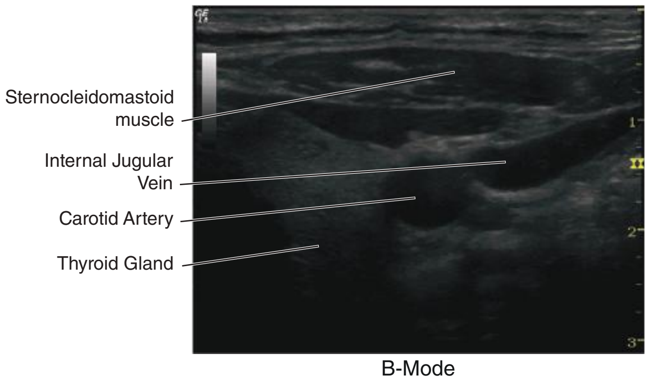

FIGURE 28–10. An example of B-mode imaging. The horizontal and vertical directions represent distances and tissues, whereas the intensity of the grayscale indicates echo strength. (Adapted with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc; 2011.)

FIGURE 28–11. The Doppler effect. When a sound source moves away from the receiver, the received sound has a lower pitch and vice versa. (Adapted with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc; 2011.)

In ultrasound-guided peripheral nerve blocks, color Doppler mode is used to detect the presence and nature of the blood vessels (artery vs. vein) in the area of interest. When the direction of the ultrasound beam changes, the color of the arterial flow switches from blue to red, or vice versa, depending on the convention used (Figures 28–13, 28–14A, 28–14B, and 28–14C). Power Doppler is up to five times more sensitive in detecting blood flow than color Doppler, and it is less dependent on the scanning angle. Thus, power Doppler can be used to identify the smaller blood vessels more reliably. The drawback is that power Doppler does not provide any information on the direction and speed of blood flow (Figure 28–15).

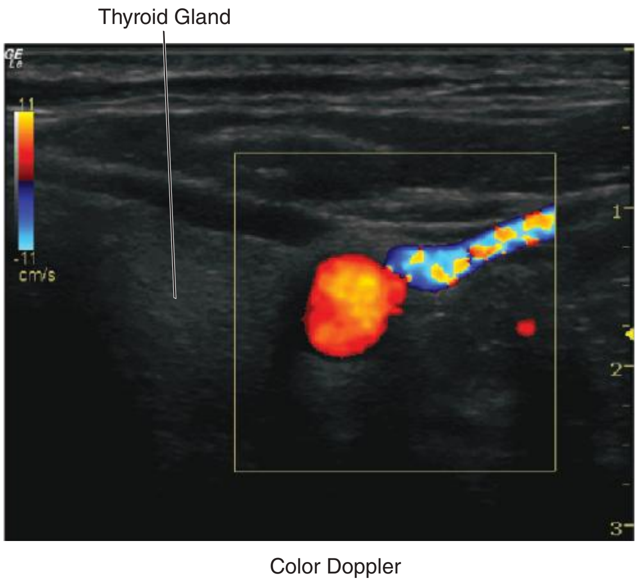

FIGURE 28–12. Color Doppler produces a color-coded map of Doppler shapes superimposed onto a B-mode ultrasound image. Selected by convention, red and blue colors provide information about the direction and velocity of the blood flow. (Adapted with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc; 2011.)

M-Mode

A single beam in an ultrasound scan can be used to produce a picture with a motion signal, where movement of a structure such as a heart valve can be depicted in a wave-like manner. M-mode is used extensively in cardiac and fetal cardiac imaging; however, its present use in regional anesthesia is negligible (Figure 28–16).

ULTRASOUND INSTRUMENTS

Ultrasound machines convert the echoes received by the transducer into visible dots, which form the anatomic image on an ultrasound screen. The brightness of each dot corresponds to the echo strength, producing what is known as a grayscale image.

Two types of scan transducers are used in regional anesthesia: linear and curved. A linear transducer can produce parallel scan lines and a rectangular display, called a linear scan, whereas a curved transducer yields a curvilinear scan and an arc-shaped image (Figures 28–17A and 28–17B). In clinical scanning, even a very thin layer of air between the transducer and skin

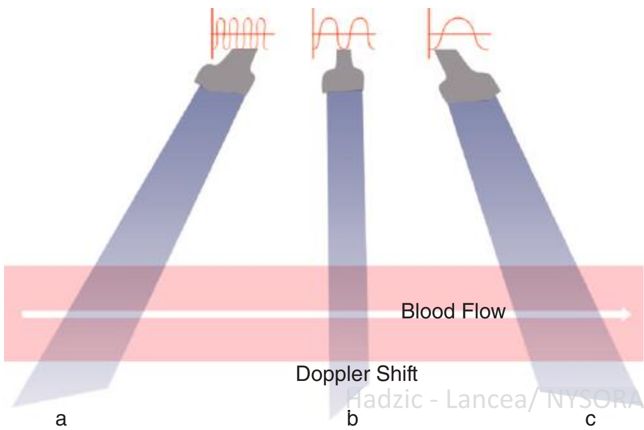

FIGURE 28–13. Color Doppler mode is used to detect the direction of the blood vessel.

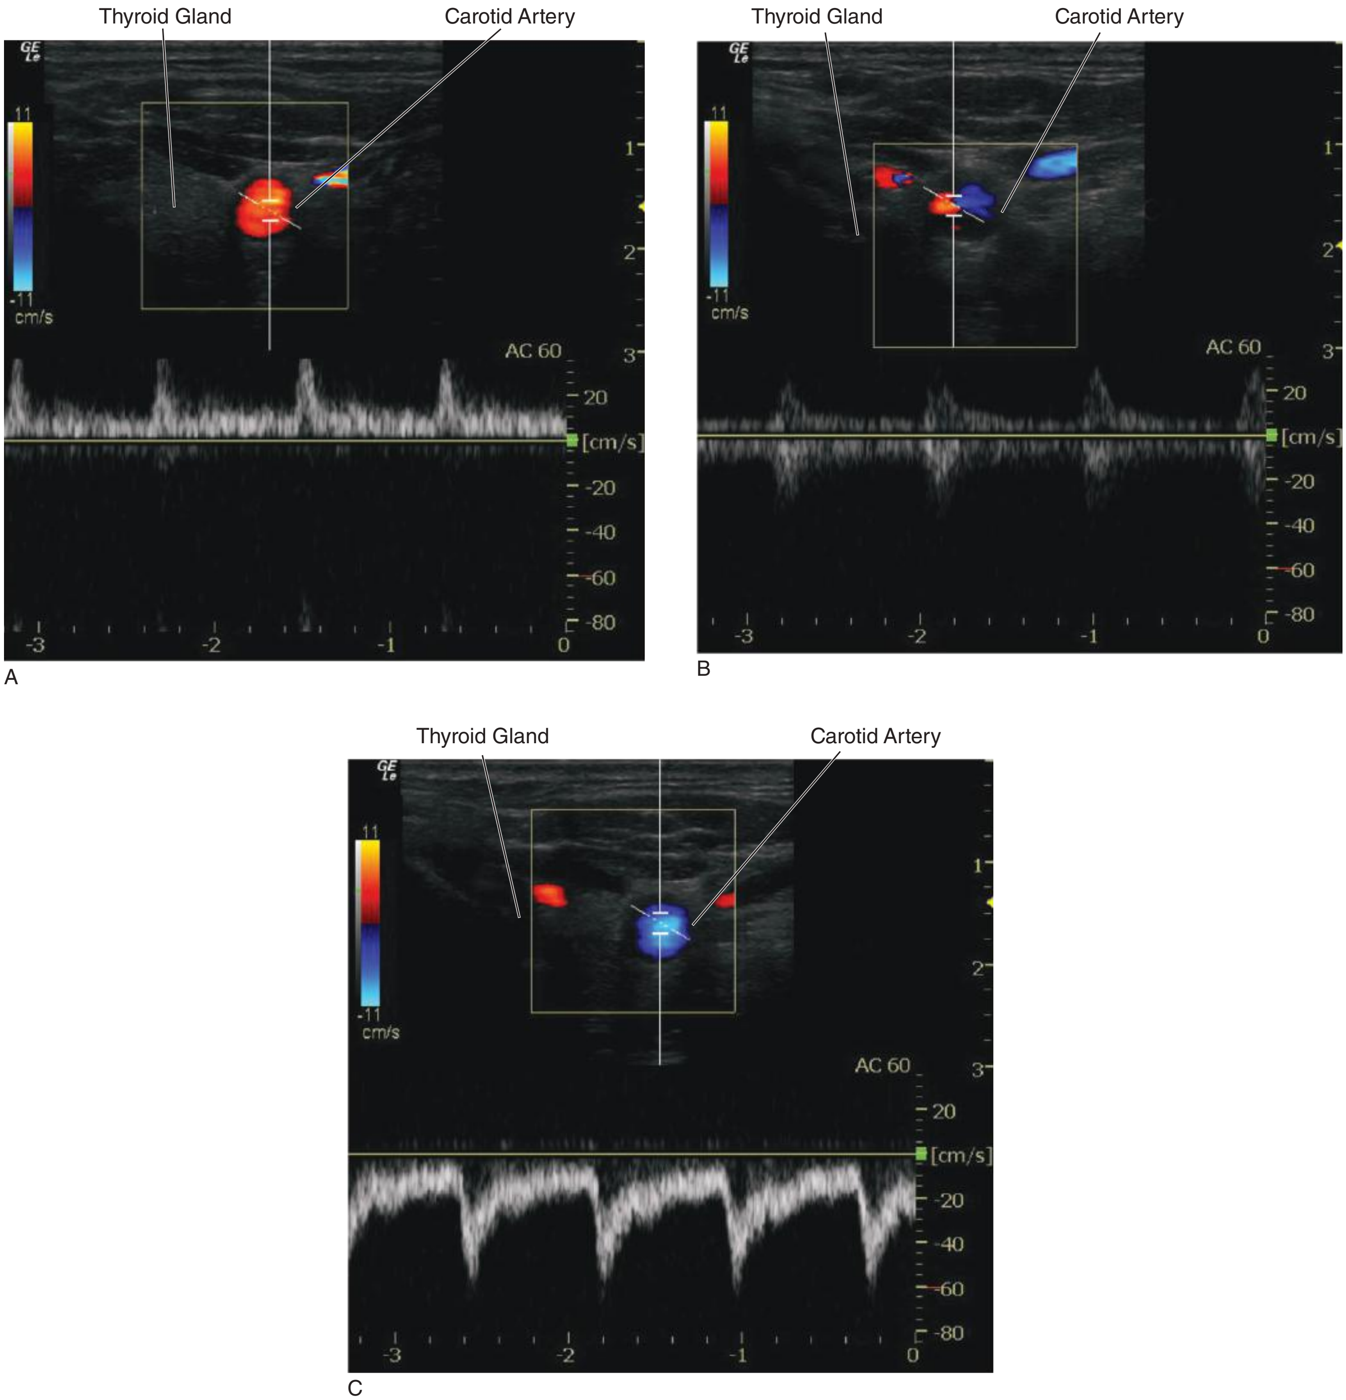

FIGURE 28–14. A: Carotid artery displays red color when the blood flows toward the transducer. **B:** Carotid artery displays ambiguous color at a 90° Doppler angle; the equal waveform can be seen on both sides of the baseline. **C:** Carotid artery displays blue color when the blood flows away from the transducer.

may reflect virtually all the ultrasound, hindering any penetration into the tissue. Therefore, a coupling medium, usually an aqueous gel, is applied between surfaces of the transducer and skin to eliminate the air layer. The ultrasound machines currently used in regional anesthesia provide a 2D image, or "slice." Machines capable of producing three-dimensional (3D) images have recently been developed. Theoretically, 3D imaging should help in understanding the relationship of anatomic structures and spread of local anesthetics. There are three major types of 3D ultrasound imaging: (1) Freehand 3D is based on a set of 2D cross-sectional ultrasound images acquired from a sonographer sweeping the transducer over a region of interest (Figures 28–18A and 28–18B). (2) Volume 3D provides 3D volumetric images using a dedicated 3D transducer. The transducer elements automatically sweep through the region of interest during the scanning; the sonographer is not required to

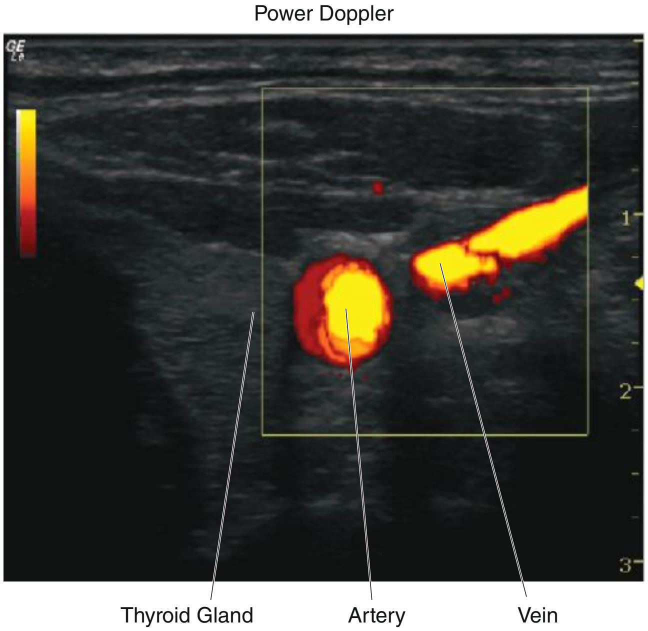

FIGURE 28–15. Although the power Doppler may be useful in identifying smaller blood vessels, the drawback is that it does not provide information on the direction and speed of blood flow. perform hand motions (Figure 28–18C). (3) Real-time 3D takes multiple images at different angles, allowing the sonographer to see the 3D model moving in real time. However, typical spatial resolution of 3D imaging is about 0.34–0.5 mm. At present, 3D imaging systems still lack the resolution and simplicity of 2D images, so their practical use in regional anesthesia is limited.

TIME-GAIN COMPENSATION

The echoes exhibit a steady decline in amplitude with increasing depth. This occurs for two reasons: First, each successive reflection removes a certain amount of energy from the pulse, decreasing the generation of later echoes. Second, tissue absorbs ultrasound, so there is a steady loss of energy as the ultrasound pulse travels through the tissues. This can be corrected by manipulating time-gain compensation (TGC) and compression functions. *Gain* is the ratio of output to input electric power; it controls the brightness of the image. The gain is usually measured in decibels (dB). Increasing the gain amplifies not only the returning signals, but also the background noise within the system in the same manner. TGC is time-dependent amplification. TGC function can be used to increase the amplitude of incoming signals from various tissue depths.

The layout of the TGC controls varies from one machine to another. A popular design is a set of slider knobs. Each knob in the slider set controls the gain for a specific depth, which allows for a well-balanced gain scale on the image (Figures 28–19A, 28–19B, and 28–19C).

Amplification is the conversion of the small voltages received from the transducer into larger ones that are suitable for further processing and storage. There are two amplification processes considered to increase the magnitude of ultrasound echoes: linear and nonlinear amplification. Currently, the ultrasonic imaging system with linear amplifiers is commonly used in medical diagnostic applications. However, strength of echoes attenuates exponentially as the distance between the transducer and the reflector increases. Ultrasonic imaging instruments equipped with logarithmic amplifiers can display echo signals with a wider dynamic range than a linear amplifier and remarkably improve the sensitivity for a small magnitude of echoes on the screen.

Dynamic range is the range of amplitudes from largest to the smallest echo signals that an ultrasound system can detect. The wider/higher dynamic range presents a larger number of grayscale levels, and it creates a softer image; the image with a narrower/lower dynamic range appears with more contrast (Figures 28–20A and 28–20B). Dynamic range less than 50 dB or greater than 100 dB is probably too low or too high in terms of visualization of peripheral nerve. *Compression* is the process of decreasing the differences between the smallest and largest echo-voltage amplitudes; the optimal compression is between 2 and 4 for a maximal scale equal to 6.

FOCUSING

As previously discussed, it is common to use electronic means to narrow the width of the beam at some depth and achieve a focusing effect similar to that obtained using a convex lens (Figure 28–21). There are two types of focusing: annular and linear. These are illustrated in Figures 28–22A and 28–22B, respectively.

Adjusting focus improves the spatial resolution on the plane of interest because the beam width is converged. However, the reduction in beam width at the selected depth is achieved at the expense of degradation in beam width at other depths, resulting in poorer images below the focal zone.

BIOEFFECT AND SAFETY

The mechanisms of action by which an ultrasound application could produce a biologic effect can be conceptually categorized into two aspects: heating and mechanical. In reality, these two

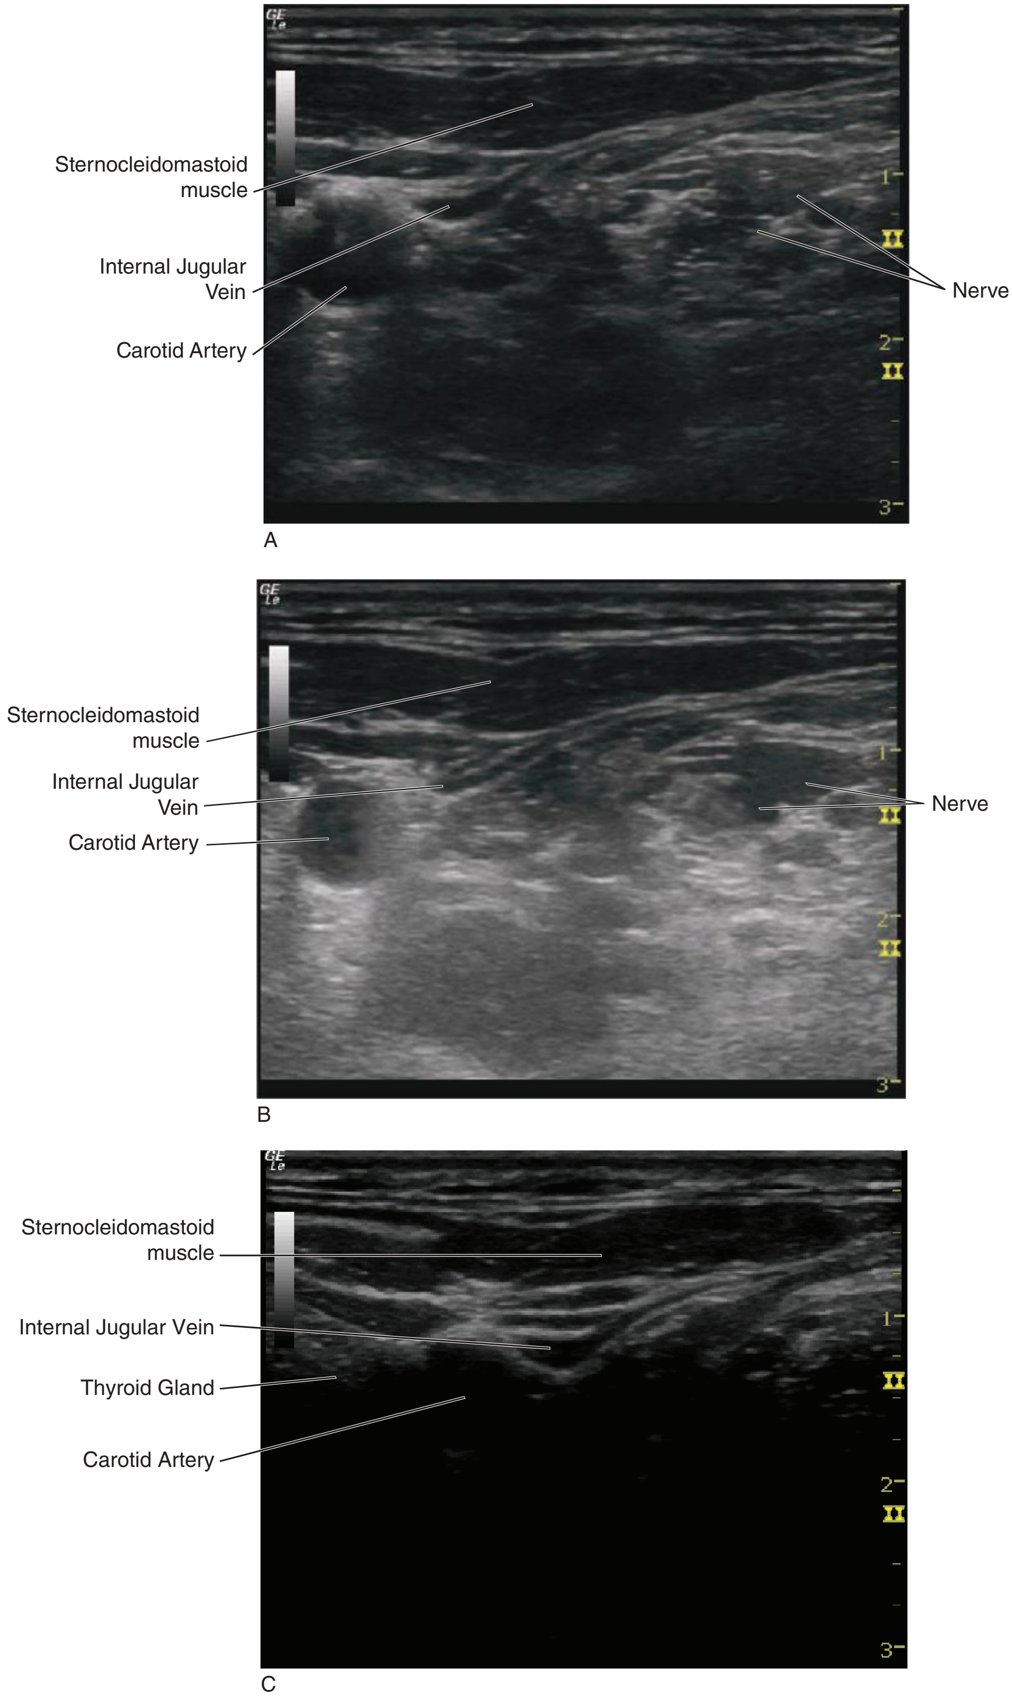

FIGURE 28–19. A, B, and **C:** The effect of the time-gain compensation settings. Time-gain compensation is a function that allows time-(depth) dependent amplification of signals returning from different depths. (Adapted with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc; 2011.)

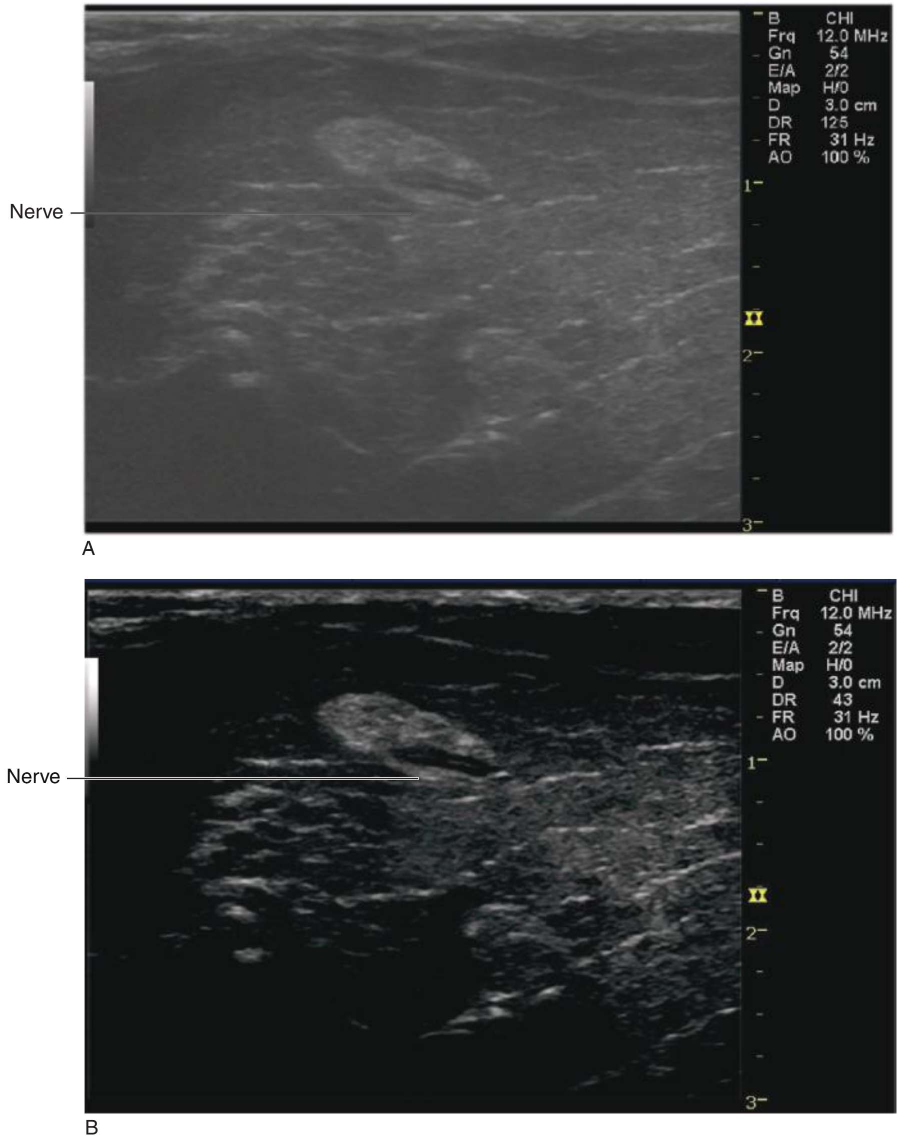

FIGURE 28–20. **A:** A softer image provided by a higher dynamic range. **B:** An image with more contrast provided by a lower dynamic range.

effects are rarely separable except for extracorporeal lithotripsy, the therapeutic application of mechanical bioeffects alone. The generation of heat increases as ultrasound intensity or frequency is increased. For similar exposure conditions, the expected temperature increase in bone is significantly greater than in soft tissues. In in vivo experiments, high-intensity ultrasound (usually > 2 W/cm^2) is used to evaluate harmful biological effect; it is 5 to 20 times larger than therapeutic intensities (0.08–0.5 W/cm^2) and 8 to 100 times larger than diagnostic intensities (color flow mode 0.25 W/cm^2, B-mode scan 0.02 W/cm^2). Reports in animal models (mice and rats) suggest that application of ultrasound may result in a number of undesired effects, such as fetal weight reduction, postpartum mortality, fetal abnormalities, tissue lesions, hind limb paralysis, blood flow stasis, and tumor regression. Other reported undesired effects in mice are abnormalities in B-cell development and ovulatory response and teratogenicity.[16,17]

In general, adult tissues are more tolerant of rising temperature than fetal and neonatal tissues. A modern ultrasound machine displays two standard indices: thermal and mechanical. The thermal index (TI) is defined as the transducer acoustic output power divided by the estimated power required to raise tissue temperature by 1°C. The mechanical index (MI) is equal to the peak rarefactional pressure divided by the square root of the center frequency of the pulse bandwidth. TI and MI indicate the relative likelihood of thermal and mechanical hazard in vivo, respectively. Either TI or MI greater than 1.0 is hazardous.[18,19]

Biologic effect due to ultrasound also depends on tissue exposure time. The researchers usually use pregnant mice to expose to ultrasound with a minimum intensity of 1 W/cm^2 for 60 to 420 minutes to evaluate the time-dependent adverse events that happen in rodent fetuses.[20] Fortunately, ultrasound-guided nerve block requires the use of only low TI and MI values on the patient for a short period of time. Based on in vitro and in vivo experimental study results to date, there is no evidence that the use of diagnostic ultrasound in routine clinical practice is associated with any biologic risks.

CHAPTER 29

Optimizing an Ultrasound Image

Daquan Xu, Shaun De Meirsman, and Ruben Schreurs

INTRODUCTION

Optimizing an ultrasound image is an essential skill during ultrasound-guided nerve blockade. Anatomically, a peripheral nerve is always located in the vicinity of an artery between fascial layers. The echotexture of normal nerve shows a hyperechoic, hypoechoic, or honeycomb pattern (Figure 29–1).[1,2] There are several scanning steps to obtain adequate nerve imaging, including the selection of sonographic modes, adjustment of function keys, needle visualization, and interpretation of image artifacts.

Clinical Pearl

- It is often easier to identify easily recognizable structures in the vicinity of the nerve, then to look for the nerve structures upfront.

Common sonographic imaging modes used for medical diagnostics, such as, conventional imaging, compound imaging, and tissue harmonic imaging (THI) can all be utilized in imaging of peripheral nerves. Conventional imaging is generated from a single-element angle beam at a primary frequency designated by the transducer. Compound imaging is implemented by acquiring several (usually three to nine) overlapping frames from different frequencies or from different angles.[3] THI acquires the information from harmonic frequencies generated by ultrasound beam transmission through tissue. Harmonic frequencies are multiples of the primary frequency. THI improves axial resolution and boundary detection by suppression of scattering signals from tissue interfaces, especially for obese patients.

Currently, THI has been set as the default mode by many, if not most, US manufacturers. Compound imaging with THI can provide images with better resolution, penetration, and interfaces and margin enhancement compared with conventional sonography. In Figure 29–2, both compound imaging and conventional imaging were employed to visualize an interscalene brachial plexus. There is clear margin definition of two hypoechoic oval-shaped nerve structures in compound imaging; the contrast resolution between anterior scalene muscle and surrounding adipose tissue is increased in comparison with conventional imaging.

Five function keys on an ultrasound machine are of crucial importance to achieve an optimal image during the performance of peripheral nerve imaging (Figure 29–3).[4]

1. *Depth*: The depth of the nerve is the first consideration when an ultrasound-guided nerve block is performed. Peripheral nerve branches have a great variation of depth, which depends on patients' habitus; the optimal depth setting can provide good focusing properties for imaging. Table 29–1 recommends the initial depth and frequency settings for common peripheral nerve blockades. The target nerve should be at the center of ultrasound imaging because it not only has the best resolution of the nerve but also reveals the other anatomical structures in the vicinity of the nerve. For example, ultrasound imaging during supraclavicular or infraclavicular brachial plexus blockade must require that the first rib and pleura are observed simultaneously to avoid lung puncture with the needle.
2. *Frequency*: The ultrasound transducer with the optimal frequency range should be selected to best visualize the target nerves. Ultrasound energy is absorbed gradually by the transmitted tissue; the higher the frequency of ultrasound, the more rapid the absorption and the less distance propagation. Therefore, a low-frequency transducer is used to scan structures at a deeper location; unfortunately, this is at the expense of reduced image resolution. In some particular cases, like lumbar plexus block, a lower-frequency transducer with a Doppler setting is useful for identifying the vasculature close to the lumbar plexus in obese patients.

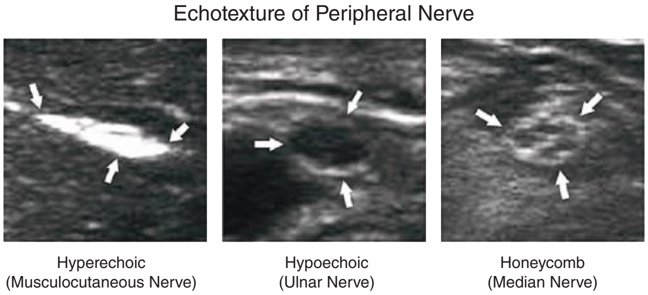

FIGURE 29–1. Echotexture of peripheral nerves. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc.; 2011.)

3. *Focusing*: Lateral resolution can be improved by choosing a higher frequency as well as by focusing the ultrasound beam. In clinical practice, the focus is adjusted at the level of the target nerve; the best image quality for a given nerve is obtained by choosing an appropriate frequency transducer and the focal zone (Figure 29–4A). Furthermore, when possible, selecting no more than two focus zones yields better image because multiple focal zones can slow the frame rate and decrease the temporal resolution.
4. *Gain*: Screen brightness can be adjusted manually by two function buttons—gain and time-gain compensation (TGC)—on ultrasound machines that have TGC built in. Excessive or inadequate gain can cause blurring of tissue boundaries and loss of information. Optimal gain for scanning peripheral nerves is typically the gain at which the best contrast is obtained between the muscles and the adjacent connective tissue. This is because muscles are well-vascularized tissue invested with connective tissue fibers, whereas the echo texture of connective tissue is similar to that of nerves. In addition, increasing gain below the focus works well with the TGC control to visualize both the target nerve and the structures below it. Figure 29–4B shows the same section with both correct and incorrect gain and TGC settings. TGC sliders aligned in a curve can lead to a desirable image with appropriate gain.
5. *Doppler*: In regional anesthesia, Doppler ultrasound is used to detect vascular structures or the location of the spread of the local anesthetic injection. Doppler velocity scale is best set between 15 and 35 cm/s to reduce aliasing of color Doppler imaging and artifacts of color (Figure 29–5). Of note, power Doppler is more sensitive for detecting blood flow than color Doppler. The gate size is another common setting when color Doppler is used. It should be as small as possible to overlay the area of interest. An appropriate small gate not only can exclude distractive signals from adjacent tissues but also can improve temporal resolution by increasing the frame rate.

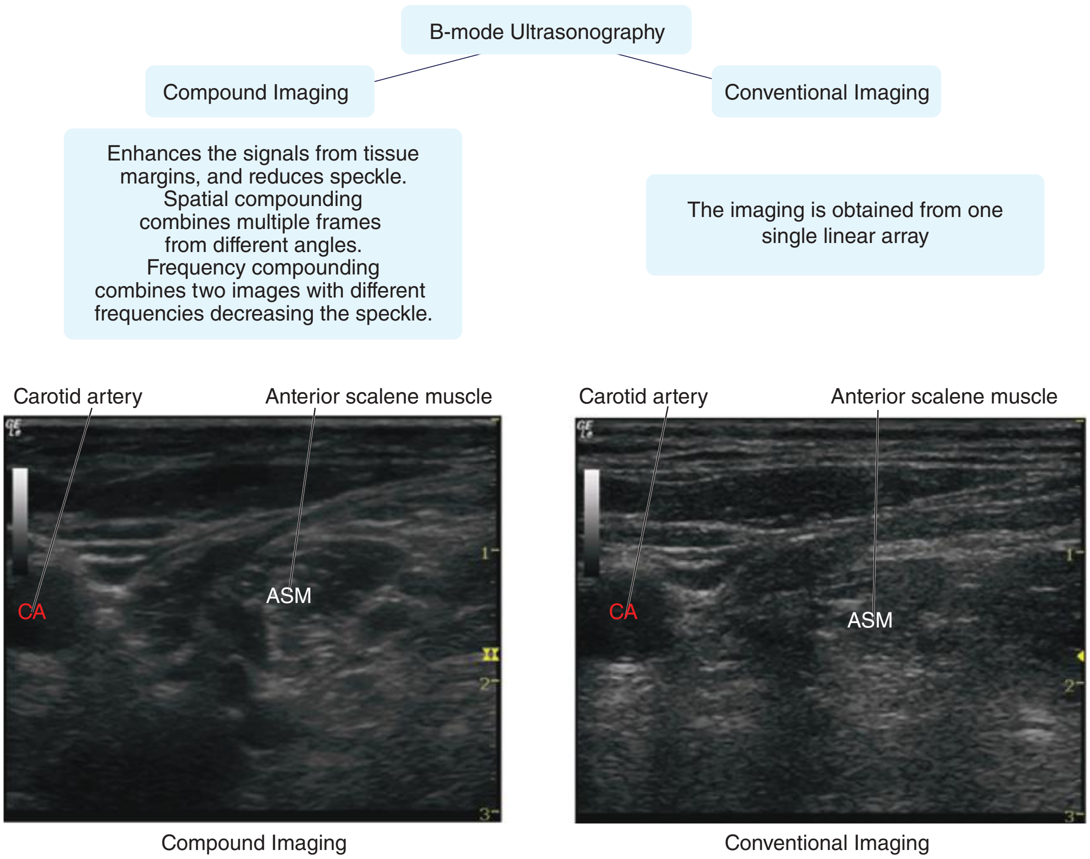

FIGURE 29–2. Examples of image quality typically obtained with conventional versus compound imaging. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc.; 2011.)

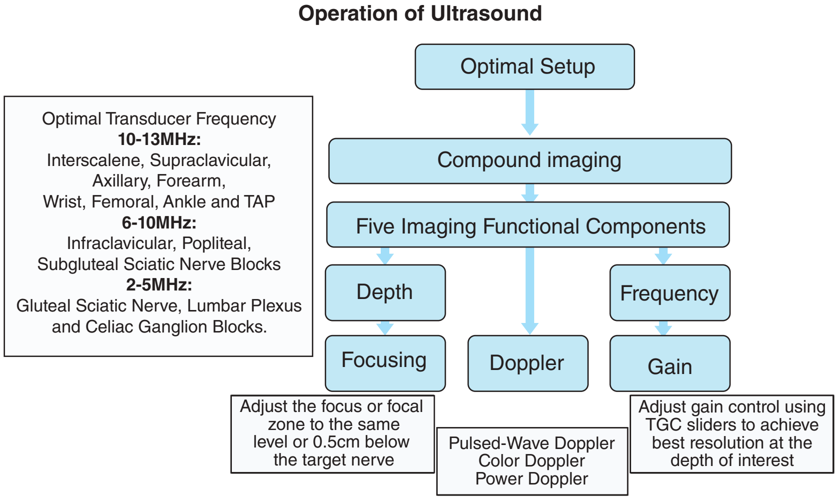

FIGURE 29–3. Optimizing an ultrasound image using five key functional adjustments and specific tips on adjusting the focus and gain. Some ultrasound models are specifically optimized for regional anesthesia application and may not incorporate user-adjustable focus or time-gain compensation (TGC). (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc.; 2011.)

Clinical Pearl

- When excessive pressure is applied on the transducer during imaging, small- and medium-size vessels may collapse and not be detected with Doppler.

Two needle insertion techniques with relevance to the needle-transducer relationship are commonly used in ultrasound-guided nerve block: the in-plane and out-of-plane techniques (Figure 29–6). An in-plane technique means the needle is placed in the plane of the ultrasound beam; as a result, the needle shaft and the tip can be observed in the longitudinal view in real time as the needle is advanced toward the target nerve. When the needle path is not seen on the image, the needle advancement should be paused; tilting, sliding or rotating the transducer can bring the ultrasound beam into alignment with the needle. In addition, a subtle, fast needle shake and or injection of a small amount of injectate may help depict the needle location.

The out-of-plane technique involves needle insertion perpendicular or any other angle to the transducer to the transducer. The needle shaft is imaged in a cross-sectional plane and often can be identified as a bright dot in the image. Visualization of the tip of the needle, however, requires higher degree of skill. The method used to visualize the tip of the needle is as follows: Once a bright dot (shaft) is seen in the image, the needle can be shaken slightly or the transducer can be tilted toward the direction of needle insertion simultaneously until the dot disappears. Shaking the needle helps differentiate the echo as emanating from the needle or from the surrounding tissue. The last capture of the hyperechoic dot is its tip. A small amount of injectate can be used to confirm the location of the needle tip. Whenever injectate is used to visualize the needle tip, attention must be paid to avoid resistance (pressure) to injection because when the needle-nerve interface is not well seen, there is a risk for the needle to be against the nerve or to inject intrafascicularly.[5]

TABLE 29–1. Suggested optimal imaging depth and frequency for common peripheral nerve blocks.

Field Depth (cm)	Frequency (MHz)	Peripheral Blockades
<2.0	12–15	Wrist, ankle block
2.0–3.0	10–12	Interscalene, supraclavicular, axillary brachial plexus block
3.0–4.0	10–12	Femoral nerve block, TAP block
4.0–7.0	5–10	Infraclavicular, popliteal, subgluteal sciatic nerve blocks
7.0–10.0	5–10	Pudendal, gluteal sciatic nerve, lumbar plexus block
>10.0	3–5	Anterior approach to sciatic nerve, celiac ganglion block

Source: Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc.; 2011.

Clinical Pearls

- If the needle trajectory is lost visually, the operator should stop advancing the needle and then tilt the transducer to visualize the needle.
- When the spread of the local anesthetic is not seen during the injection process, the operator should stop the injection, tilt the transducer, and inject a tiny amount of local anesthetic (or air) to locate the needle tip and spread of injectate.

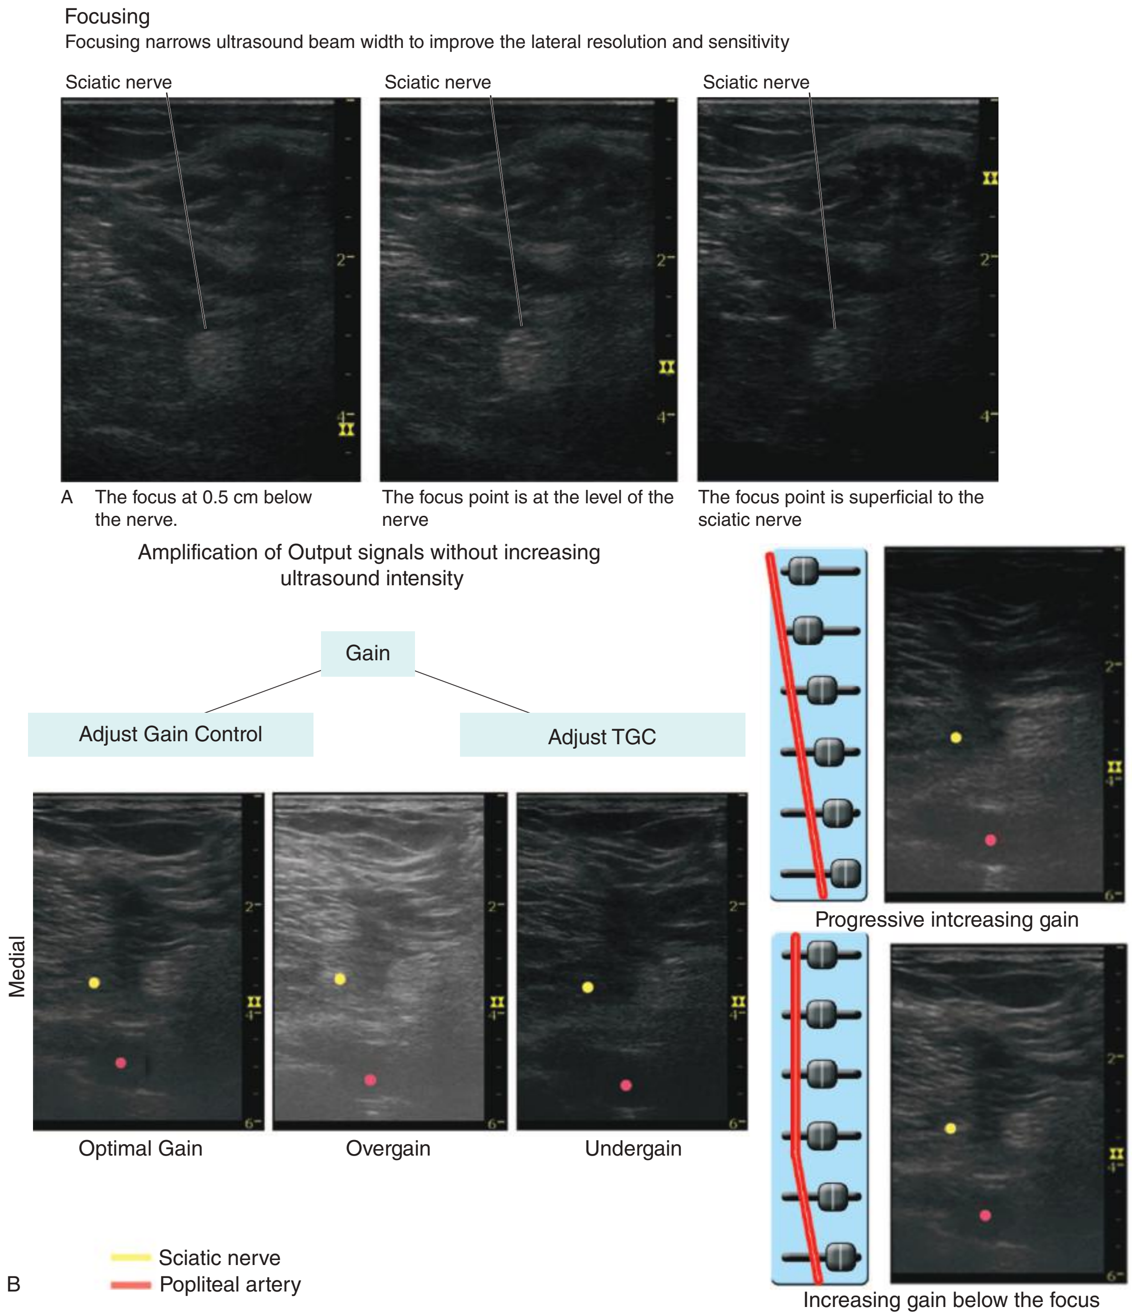

FIGURE 29–4. A: Focusing narrows ultrasound beam width to improve the lateral resolution and sensitivity. Shown are three examples of focusing when imaging the sciatic nerve: below the nerve, at the level of the nerve, and superficial to the nerve. **B:** Optimal and incorrect gain and TGC settings. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc.; 2011.)

Continuous peripheral nerve blocks (CPNBs) have become a common practice; however, the visualization of the catheter tip can be challenging. Direct visualization of the catheter tip can be obtained when the catheter is introduced at a short distance from the needle tip (eg, 2 cm past the needle tip) (Figure 29–7). However, when the catheter is inserted 3–5 cm past the needle tip, the needle, nerve, and catheter are never in the same plane of the ultrasound beam, therefore becoming challenging to image. There are two ways to confirm the catheter tip: (1) The operator can tilt or slightly slide the transducer to see a "bright dot," which is the transverse view of the catheter. The position of the catheter tip can be detected by observing the spread of 1–2 mL injectate through the catheter, and the use of color Doppler may help visualize the spread more significantly (Figures 29–8A and 29–8B). (2) In some cases, the bright dot may not be obviously visualized or ensured; the operator has to slide the transducer within a certain distance away from the needle tip, with the distance based on the length of catheter threaded past the needle tip. Injection of 0.5 mL air can be beneficial to ascertain the position of the catheter tip with a

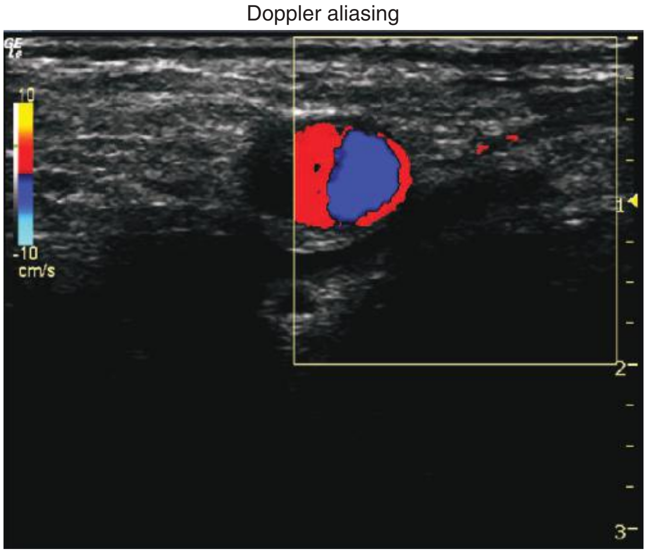

FIGURE 29–5. Color Doppler aliasing occurs when the velocity scale for color Doppler is set too low.

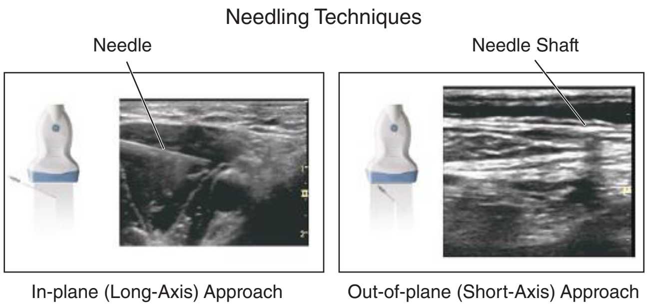

FIGURE 29–6. In-plane and out-of-plane needle insertion and the appearance in a corresponding ultrasound image.

sharp echoic contrast on the ultrasound image (Figures 29–9A and 29–9B). The obvious drawback is that injection of air may degrade the image for other purposes.

Clinical Pearl

- Catheters often cannot be visualized by ultrasound because they coil within the tissue sheaths. Visualization of the spread of injectate is the most convenient and important method to ascertain the position of the catheter tip in the desired tissue plane.

Ultrasound artifacts occur commonly and, in fact, are an intrinsic part of ultrasound imaging. By definition, an ultrasound artifact is any image aberration that does not represent the correct anatomic structures. Most artifacts are undesirable, and operators must learn how to recognize them during nerve blockade. The five artifacts most commonly seen in regional anesthesia practice (Figure 29–10) are the following[6–8]:

1. *Shadowing* is a significant attenuation of ultrasound signal deep to tissues and structures that absorb or reflect most of the ultrasound waves, as bones, calcifications or air. This is manifested by a weak or absent echo area which appears as a shadow on the imaging behind a bright, hyperechoic interface. Acoustic shadowing has a favorable diagnostic value for detection of calcified lesions, such as gallstones, scar tissue, and the like. However, the shadowing may interfere with nerve visualization in regional anesthesia. Changing the scanning plane to find the best acoustic window is the best strategy to avoid shadowing when necessary.
2. *Enhancement* manifests as overly intense echogenicity behind an object (a fluid-filled structure, such as a vessel or cyst)

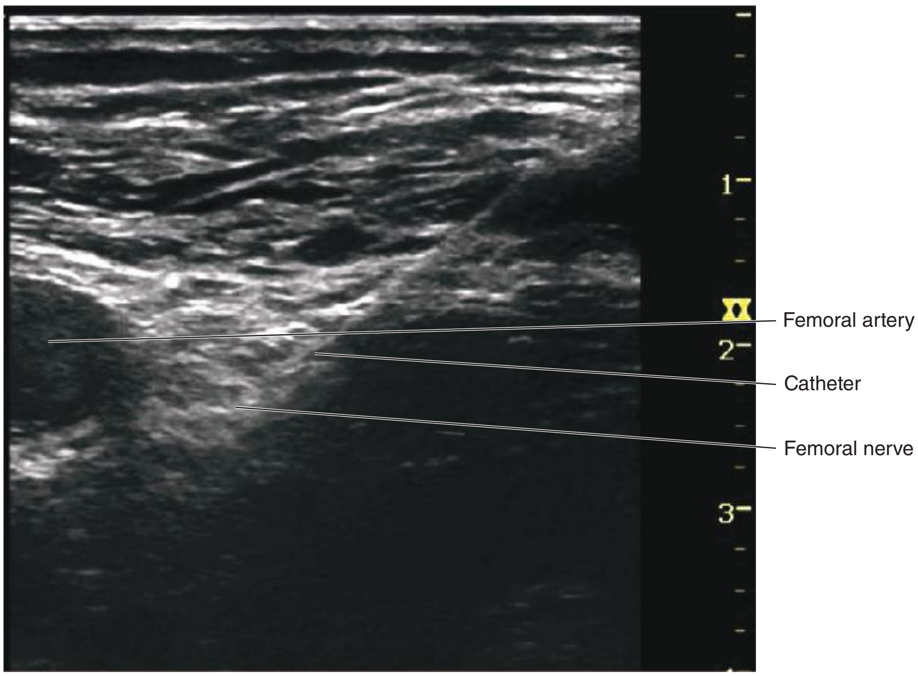

FIGURE 29–7. The catheter tip can be directly seen just beneath femoral nerve.

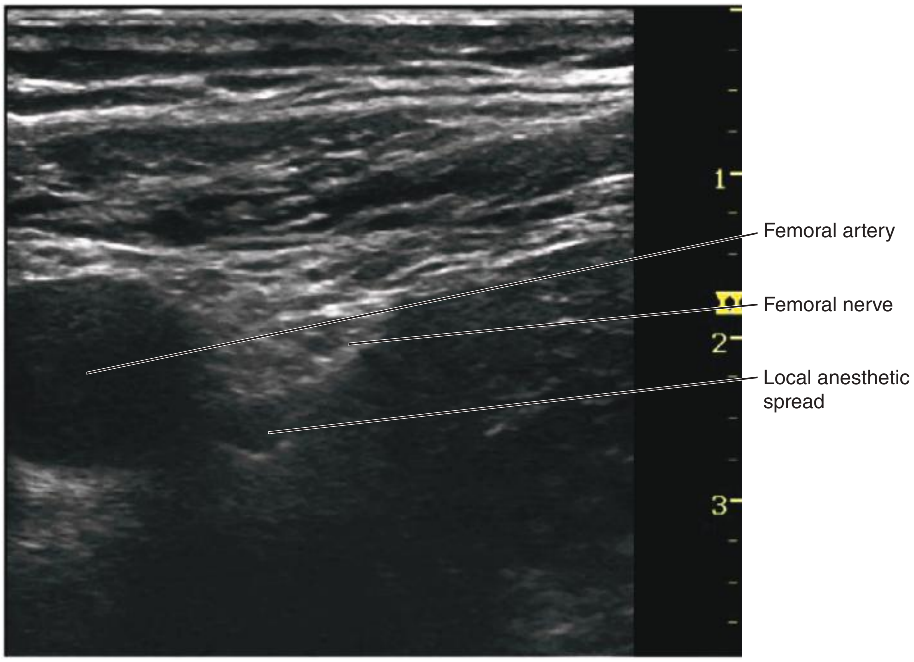
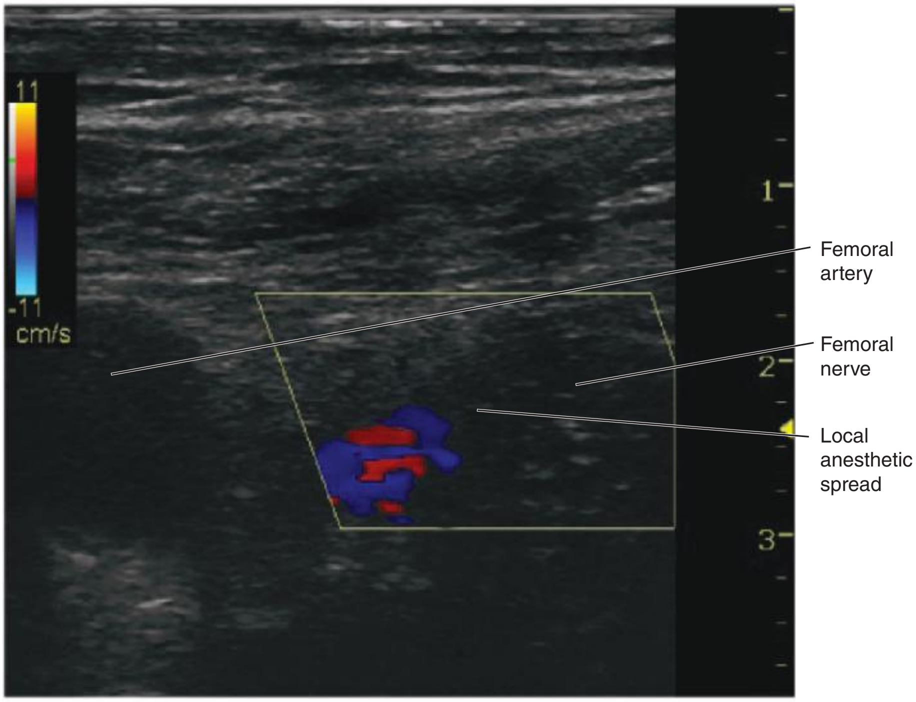


A

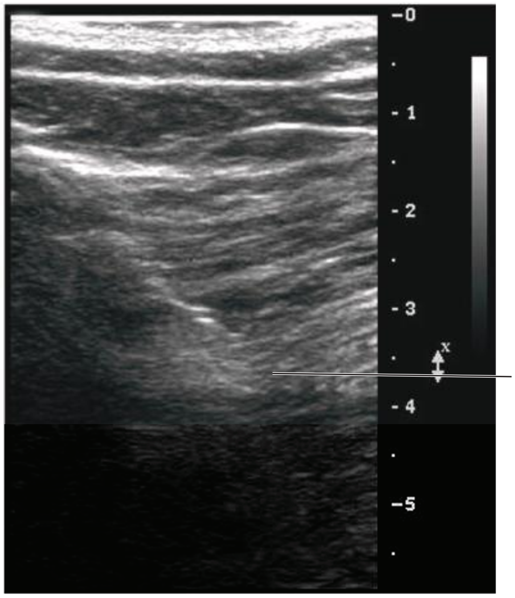


B

FIGURE 29–8. **A:** The position of catheter tip can be estimated by observing the spread of injectate. **B:** Doppler can be used to confirm the location of the spread.

that is less attenuating than the surrounding soft tissues. Enhancement occurs when the echo signals are overamplified in brightness disproportional to the echo strength at the same depth. Scanning from different angles or from different planes may help to decrease shadowing/enhancement artifacts and to visualize the target nerve; using automatic TGC may make enhancement artifact less apparent as well.

3. *Reverberation* displays in the form of parallel, equally spaced bright linear echoes behind the reflectors in the near field of the image. The multiple echoes occur when the ultrasound beam bounces repeatedly between the interfaces of the transducer and a strong reflector, especially when these two interfaces are parallel to each other. It may be attenuated or eliminated when the scanning direction is changed slightly or the ultrasound frequency is decreased.



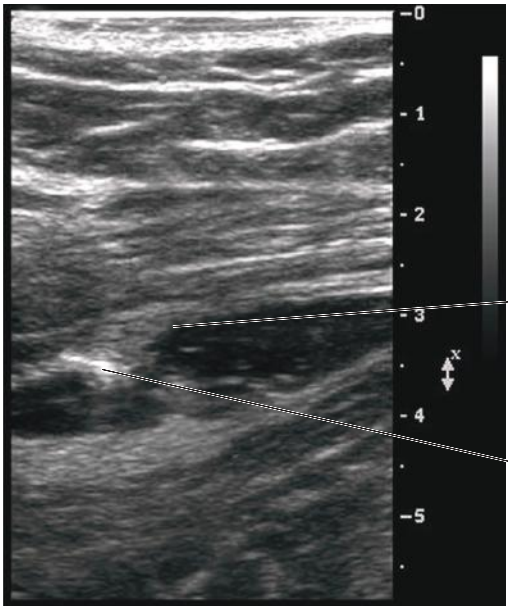


FIGURE 29–9. **A:** The location of the catheter tip cannot be visualized before a small amount of air is injected. **B:** The discernable brightness indicates the location of the catheter tip when 0.3–0.5 mL air is injected.

4. *Mirror* image artifact results from an object located on one side of a highly reflective linear boundary that acts like an acoustic "mirror," appearing on the other side as well. The transducer receives both direct echoes from the object and indirect echoes from the mirror (Figure 29–11). Both virtual and artifactual images have an equal distance to the mirror from opposite directions. The duplicated artifactual image is always less bright and deeper than the real image because indirect echoes transmit a longer distance and attenuate more wave energy. Changing the scanning direction may decrease the artifact.

Velocity error is the displacement of the interface, which is caused by the difference of actual velocity of ultrasound in human soft tissue, compared with the calibrated speed, which is assumed to be a constant velocity of 1540 m/s set by the ultrasound system. Consequently, a reflector is displaced toward the transducer by a significant error in distance calculations. The inherent artifact in the process of scanning cannot be completely eliminated in all cases by manipulating ultrasound devices or changing the settings. However, recognizing and understanding ultrasound artifacts help the operator avoid misinterpretation of images.

PREPARING TO SCAN

An acronym, SCANNING, can be used by operators to prepare for scanning:

S: Supplies
C: Comfortable positioning
A: Ambiance
N: Name and procedure
N: Nominate transducer
I: Infection control
N: Note lateral/medial/superior/inferior orientation on screen
G: Gain depth

1. Gather supplies: All equipment necessary for ultrasound scanning should be prepared. Equipment may differ slightly depending on the area to be scanned; however, some necessary equipment includes the following:
   a. Ultrasound machine
   b. Transducer covers
   c. Nerve block kit, nerve stimulator
   d. Sterile work trolley
   e. Local anesthetic drawn up and labeled
   f. Whenever possible, connect the ultrasound machine to the power outlet to prevent the machine from powering down during a procedure. Although many point-of-care ultrasound machines are equipped with batteries, these run out of power during the most importunate part of the procedure.
2. Comfortable patient position: The patient should be positioned in such a way that the patient, the anesthesiologist, the ultrasound machine, and the sterile block tray are all arranged ergonomically to allow for time-efficient performance of the procedure.
   a. The ultrasound machine should be set up on the opposite side of the patient from the operator with the screen at the operator's eye level.
   b. The block tray should be positioned close enough to the operator can easily reach for needle, gel, and other supplies without interference with the scanning procedure.

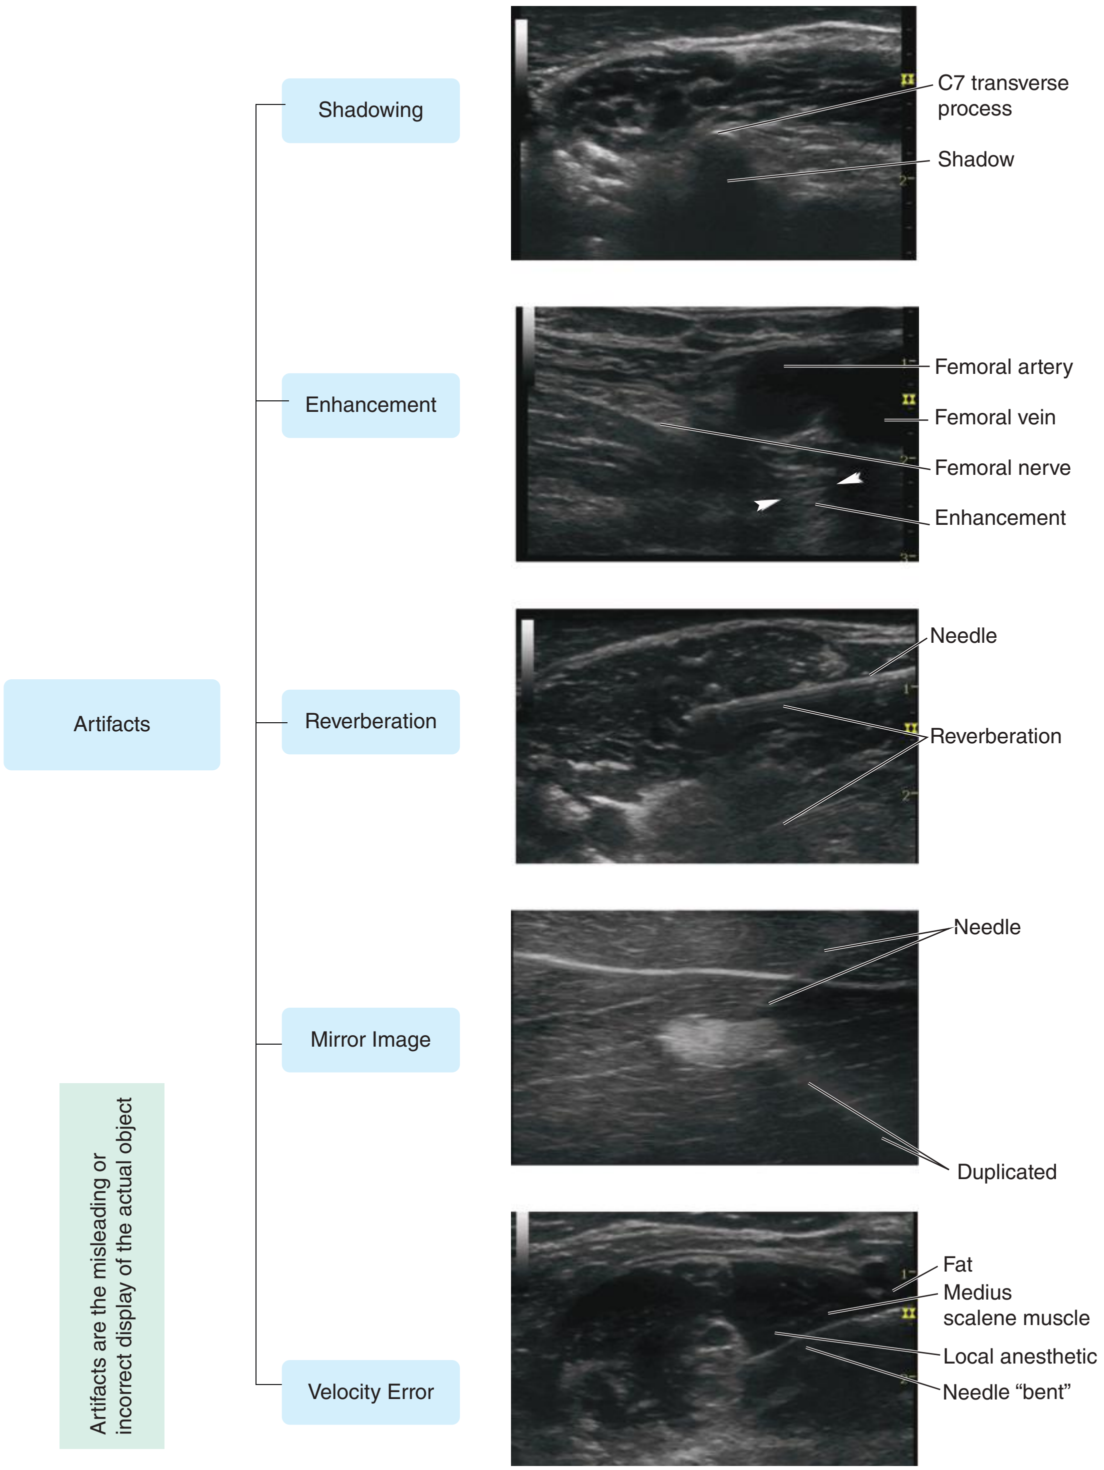

FIGURE 29–10. Five common ultrasound artifacts during ultrasound-guided peripheral nerve block. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc.; 2011.)

3. Ambiance set room settings: Adjust the lights in the room to view the ultrasound machine and procedural site adequately.
   a. Dim lighting optimizes visualization of the image on the screen; more lighting may be needed for the procedural site.
   b. Adjust the room light settings to allow for proper lighting to both areas, as well as for safe monitoring of the patient.
4. Name of patient, procedure, and site of procedure: Before performing a scan take a "time-out" to ensure patient information is correct, the operation being done is confirmed, and the side in which the procedure is being done is validated. The New York School of Regional Anesthesia (NYSORA) team uses the acronym ECT for the time-out procedure: E for equipment for patient monitoring and needle-nerve monitoring; C for the

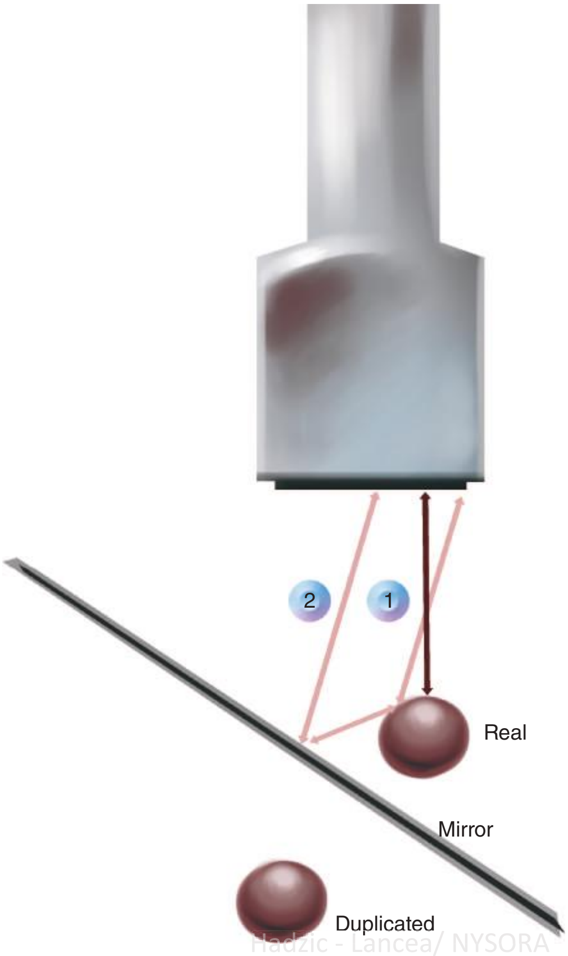

FIGURE 29–11. Mirror image artifact: Transducer receives both direct echoes from the object (1) and indirect echoes from the "mirror" (2).

patient's consent for the procedure; and T for the time for the time-out to identify the patient and ensure correct laterality. Checking that patient information is entered into the ultrasound machine and matches the information on the patient's wristband not only confirms identity but also allows for images to be saved during the scanning process for documentation.

5. Select transducer: Select the transducer that best fits the scheduled procedure. A linear transducer is best for scanning superficial anatomic structures; a curved (phased-array) transducer displays a sector image and is typically better for deeper-positioned structures. A hockey stick ultrasound transducer is an ideal choice for vascular access or a superficial block with limited space, such as an ankle block.
6. Disinfection: Disinfect the patient's skin using a disinfectant solution to reduce the risk of contamination and infection.
7. Orient transducer and apply gel: The operator should orient the transducer to match the medial-lateral orientation of the patient. This is conventionally not done by radiologists/sonographers, but it is useful for intervention-oriented regional anesthesia procedures.
   a. Touch one edge of the transducer to orient the side of the transducer so the medial-lateral orientation on the patient corresponds to that on the screen.
   b. A sufficient amount of gel is applied to either the transducer or the patient's skin to allow for transmission of the ultrasound. A copious amount of disinfectant solution can be used instead of gel in many instances.
   c. Insufficient quality of gel will decrease reflection-absorption rates and may result in unclear/blurry images on the ultrasound image being displayed.
8. Place the transducer on the patient's skin and adjust the ultrasound machine settings:
   a. The gain should be adjusted with the general gain setting or by using TGC.
   b. The depth is adjusted to optimize imaging of the structures of interest.
   c. Where available, focus point level.
   d. Scanning mode can be switched to assist in the recognition of the structures as necessary. Power Doppler can help depict blood vessels; color mode can distinguish between arteries and veins.

CHAPTER 30

Introduction to Ultrasound-Guided Regional Anesthesia

Steven L. Orebaugh and Kyle R. Kirkham

INTRODUCTION

Ultrasonography (US) as a means to guide peripheral nerve blockade (PNB) was first explored by anesthesiologists at the University of Vienna in the mid-1990s.[1] Although radiologists had made use of ultrasound technology to guide needles for biopsy, the application of this imaging modality for PNB was novel at that time.[2] The utility of ultrasound to facilitate a range regional anesthesia techniques including brachial plexus and femoral blocks was demonstrated.[1,3] A decade later, colleagues from the University of Toronto, Canada, began to embrace this technology, further demonstrating its utility and describing in detail the sonoanatomy of the brachial plexus.[4] A number of advances in technology took place in the meantime, including smaller and more mobile ultrasound platforms, improved resolution, and needle recognition software, all cumulatively leading to increased bedside utility of ultrasound by anesthesiologists.[5]

ADVANTAGES OF ULTRASOUND GUIDANCE

The previously used surface anatomy-based techniques, such as nerve stimulation, palpation of landmarks, fascial "clicks," paresthesias, and transarterial approaches, did not allow for the monitoring of the disposition of the local anesthetic injectate. Ultrasound guidance, however, offers a number of important practical advantages for nerve blockade. Ultrasound allows visualization of the anatomy of the region of interest. This allows more informed guidance for the needle pathway to the target while avoiding structures that might be damaged by the needle.[6] Ultrasound also allows visualization of the needle tip as it is passed through the tissues, confirming alignment with the intended path, again reducing the likelihood of inadvertent needle trauma to unintended structures. Perhaps most important, real-time ultrasound imaging permits continual visualization of local anesthetic solution delivery to ensure proper distribution, with the potential for adjustment of the needle tip position as necessary to optimize local anesthetic distribution.[7]

Introduction of ultrasound guidance in regional anesthesia has led to refinement of many nerve block techniques, expanded use of PNB, and greater acceptance by surgical colleagues and patients.

ULTRASOUND AND SONOANATOMY

Ultrasound-guided PNB may be broken down into two fundamental aspects: imaging structures in the plane of section, including the target nerve, and guiding the needle. Understanding and recognition of three-dimensional anatomic structures on a two-dimensional image requires training in the technology and sonoanatomy pattern recognition (Table 30–1). As anatomic recognition remains essential to placing blocks, even with real-time visual guidance, specialty society guidelines for training residents and fellows continue to stress the importance of anatomical dissection and gross anatomy training as an inherent component of learning ultrasound-guided regional anesthesia (UGRA).[8] In a study conducted over a 1-month regional anesthesia rotation, residents demonstrated markedly improved recognition of relevant structures at the sites of several different PNBs, using ultrasound imaging.[9] In an evaluation of ultrasound-guided interscalene block instruction, residents demonstrated increasing efficiency of sonoanatomy recognition as their experience over the course of the rotation increased.[10]

More innovative methods of training have shown promise as well.[11] Integrating an anatomic program into the software of a bedside ultrasound machine has been shown to improve scores on a written test of anatomy.[12] After exposure to a multimedia anatomy presentation, residents and community anesthesiologists demonstrated increased knowledge of ultrasound anatomy on a posttest, although they were not able to improve scores on a practical examination of sonoanatomy on live models.[13] However, the optimal link between anatomic knowledge and recognition of two-dimensional anatomic patterns on ultrasound has not yet been adequately explored.

TABLE 30–1. Optimizing sonoanatomy visualization.

Choose appropriate transducer/frequency
Understand underlying anatomic relationships
Apply varying degree of pressure with transducer
Align transducer with underlying nerve target
Rotate transducer to fine-tune image
Tilt the transducer to optimize image

Certain basic tenets of optimizing an ultrasound image are applicable to all nerve blocks. For instance, sonography requires an understanding of mechanics and ergonomics. Novices are subject to errors such as probe fatigue, reversing probe orientation, and inadequate equipment preparation.[14] To optimize the ultrasound image, the mnemonic PART (pressure, alignment, rotation, tilting) has been recommended.[8] Pressure is necessary to minimize the distance to the target and compress underlying subcutaneous adipose tissues. Alignment refers to placing the transducer in a position over the extremity (or trunk) at which the underlying nerve is expected to be in the field of view. Rotation allows fine-tuning of the view of the target structure. Tilting helps to bring the face of the probe into a perpendicular arrangement with the underlying target to maximize the number of returning echoes and thus provide the best image (Figure 30–1). In-depth discussion on optimizing ultrasound imaging is discussed in Chapter 29.

Clinical Pearl

- To optimize the ultrasound image, the mnemonic PART has been recommended: pressure, alignment, rotation, tilting.

Clinical Pearls

- Recognition and understanding of sonoanatomy requires knowledge of the underlying three-dimensional anatomy.
- Optimum visualization of the target nerve requires appropriate transducer pressure, alignment with nerve, and rotation and tilting of the probe to fine-tune the image.

OPTIMIZING NERVE AND NEEDLE IMAGING WITH ULTRASOUND-CLINICAL SCENARIOS

Nerve imaging may be performed in either short-axis (probe face perpendicular to axis of nerve) or long-axis (probe face parallel to axis of nerve) position (Figure 30–2). It is frequently easier to recognize the round, often-hyperechoic, neural element with short-axis imaging, especially for a beginner. Because most nerve blocks are conducted in the extremities, this orientation results in a transducer position that is transverse, across the long axis of the arm or leg. In general, understanding the course of the nerves, based on knowledge of gross anatomy, allows one to align and rotate the transducer perpendicular to the course of the nerve subsequently adjusting the tilt as described previously to optimize the image.

Once the nerve and surrounding anatomy are identified, a needle path may be chosen so that it is imaged either in plane (needle parallel to long axis of probe) or out of plane (needle perpendicular to long axis of probe) to the ultrasound beam. While neither method has been shown superior for either block success or patient safety, the preferred approach may vary with anatomic or technical considerations. However, with in-plane imaging, it is possible to maintain an image of the entire needle, including the tip, although it can be challenging to keep the needle entirely in the viewing plane of the transducer.[15] This method is especially beneficial during instruction, as the supervisor has continual visualization of the needle tip as it is advanced through the tissues. During out-of-plane imaging, the observer is able to see only the cross section of the needle, which appears as a small hyperechoic dot, at any plane along its entire length, so that distinguishing the tip from the shaft is much more difficult.[15]

Guiding the needle tip to the target while maintaining the entire needle in the plane of imaging, however, can be challenging (Table 30–2). Appropriate adjustment of the bed height and ergonomic placement of the ultrasound so that operator's eyes can easily and rapidly shift from the image to the field (Figure 30–3), where needle alignment with the long axis of the probe can be ensured, is beneficial. It is surprisingly easy for the transducer to wander away from the plane of the needle while one's vision is fixed on the ultrasound screen. This is more likely if the operator has the probe and needle aligned perpendicular to his or her own axis of viewing, as opposed to aligning the needle and probe with the viewing axis.

In a study of novice medical students learning the basics of UGRA, Speer et al found that the subjects required less time to locate the target, and were better able to keep the needle visualized in plane on the ultrasound image, when eyes, needle, probe, and viewing screen were aligned.[16] Needle guides may also permit improved imaging of the needle during approach to the target, although more work has been done in vascular access.[17] One disadvantage of needle guides is that they restrict needle motion to one plane, which may not be always desirable.

Nerves in short axis have an appearance that is to some extent determined by their proximity to the neuraxis. Although in most areas nerves are round, they may appear fusiform, such as the musculocutaneous nerve in the proximal arm,[18] or oval-shaped, such as the sciatic nerve in the infragluteal region.[19] In close association with the spine, nerves and nerve roots are comprised primarily of neural tissue, with minimal connective tissue.[20] Because neural tissue appears hypoechoic on ultrasound imaging, while the connective tissue between fascicles is hyperechoic, nerves near the neuraxis appear as dark nodules.[21] As nerves course peripherally, the number of fascicles increases, although they diminish in size, while the amount of connective tissue also increases.[22] These changes lead to an increasingly complex "honeycomb" appearance on ultrasound in short-axis viewing[21] (Figure 30–4). Unfortunately, because of the technology limitations of the current ultrasound machines, the number

FIGURE 30–1. Fine adjustment of the probe tilt is necessary to optimize echo return from the target structure and enhance image resolution (yellow arrowheads indicate sciatic nerve at the popliteal fossa).

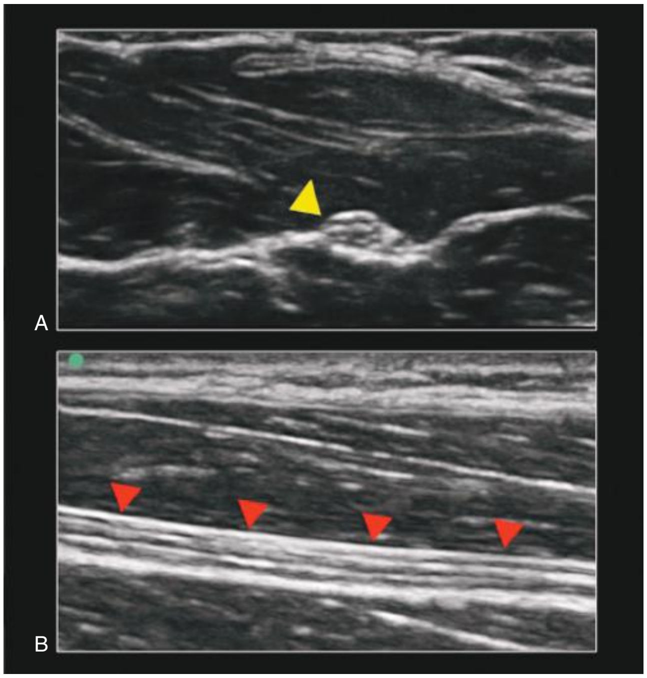

FIGURE 30–2. The median nerve. **A:** Cross-section (target structure out of plane to ultrasound beam; yellow arrowhead). **B:** Longitudinal section (target structure in plane to ultrasound beam; red arrowheads).

FIGURE 30–3. Ergonomic positioning for bed height and ultrasound position.

and arrangement of fascicles within a peripheral nerve may not be accurately portrayed.[23]

While different tissues have characteristic appearances on ultrasound, nerve may not be easily be distinguished from tendon when both are viewed in short axis. However, using knowledge of anatomy, the operator can follow the course of the structure caudad-cephalad to determine the nature of the structure imaged. The tendons will eventually disappear into the muscle of origin or insert into bones. A good example is the median nerve at the wrist, where it is difficult to discern the neural structure from the many tendons in the carpal tunnel, versus at the midforearm, where the nerve is much more visually distinct, as it is situated between two layers of muscle, with no surrounding tendons[24] (Figure 30–5).

An important aspect of preparing for a block is to obtain the preferred imaging plane while planning the route for needle path. The operator should make certain that no vulnerable structures are in the projected course, such as a blood vessel, the pleura, or sensitive structures such as periosteum. This process is referred to as a "preblock scan," which can contribute to patient safety and block success.[6] In addition to two-dimensional imaging, the color Doppler setting should be utilized to identify small vessels, which may readily be confused with nerve structures (particularly roots) when viewed in short axis[25] (Figure 30–6).

To maintain the view of the needle tip and shaft, several techniques can be used. The more parallel the needle is to the face of the probe, the more echoes are transmitted back to the transducer, resulting in a superior image. This can be accomplished by gently indenting the skin at the needle insertion site or by moving the insertion site further away from the probe, resulting in a less-acute angle of insertion (Figure 30–7). The limitation of this approach is that a longer needle may be required, and more tissue is traversed en route to the target.[26]

Another technique, referred to as *heeling*, involves pressing in on the edge of the transducer opposite the side of needle insertion, which results in a more parallel alignment of the probe face with the needle. In addition, the needle itself may be structurally altered to increase its echogenicity; commercially available versions of these "echogenic needles" usually have been etched on the surface of the shaft with crosshatches to create a greater degree of scatter of the ultrasound beam.[27]

As noted, needle guides may be utilized to improve needle imaging, though at the cost of constraint of movement.[28] Laser guidance systems have also been created to improve alignment, with some success.[29] One novel, alternative method of targeted needle placement and local anesthetic delivery utilizes a GPS guidance system, which may be especially useful when imaging is made difficult by steep needle angles.[30] Proprietary software for needle localization at steep angles makes use of spatial compound imaging, which combines images of different angles of insonation. This results in enhanced needle imaging with both standard and echogenic block needles.[31] Finally, localization of the needle tip may be accomplished with "hydrolocation," in which small volumes of either dextrose solution or local anesthetic are injected to visualize spread within tissues, which typically reveals the position of the needle tip.[26]

TABLE 30–2. Optimizing needle imaging with ultrasound.

Utilize a shallow angle of approach, if possible
"Heel" the transducer to make the face more parallel to the needle
Rotate the transducer to ensure the entire needle is seen
Tilt the transducer as necessary
Choose an "echogenic" needle
Apply needle recognition software, if available
"Hydrolocation" may help ascertain needle tip location

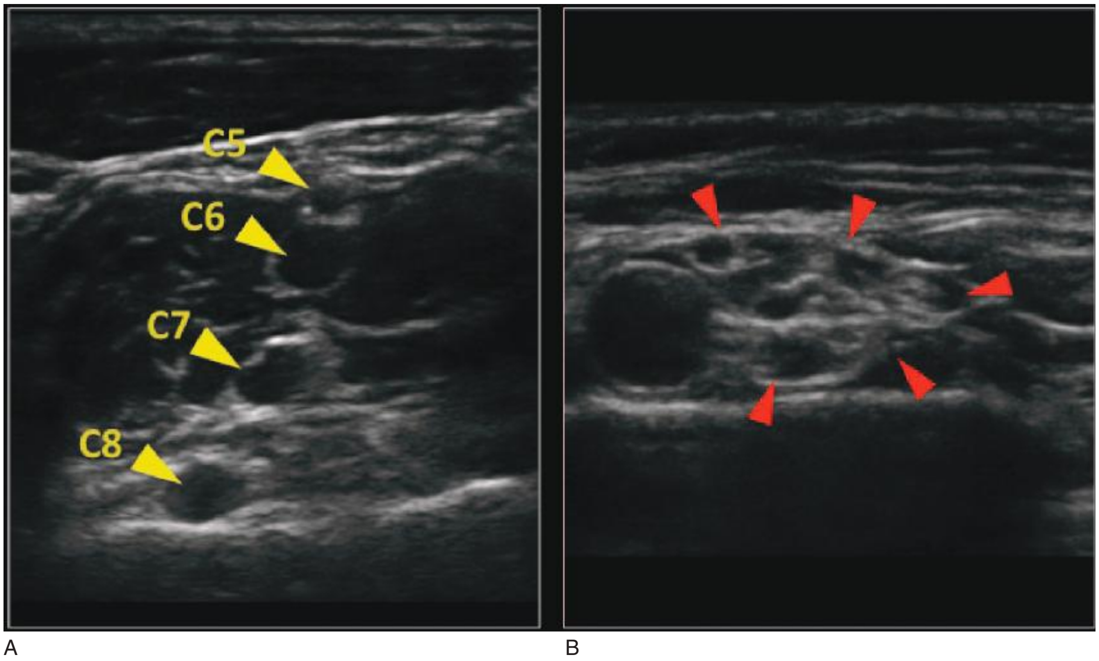

FIGURE 30–4. A: Proximal nerve appearance in the interscalene groove (yellow arrows indicate nerve roots) with little echogenic connective tissue. **B:** More distal in the supraclavicular fossa (red arrows indicate brachial plexus trunks) with "honeycomb" appearance.

Clinical Pearls

- Several different techniques are useful to maintain visualization of the needle with ultrasound imaging, including use of a shallow angle of approach, "heeling" the transducer, commercially available echogenic needles, and physical measures such as rotation and tilting of the transducer.
- In addition, hydrolocation with a small injection of fluid can be utilized to facilitate localization of the needle in difficult situations.

Clinical Pearls

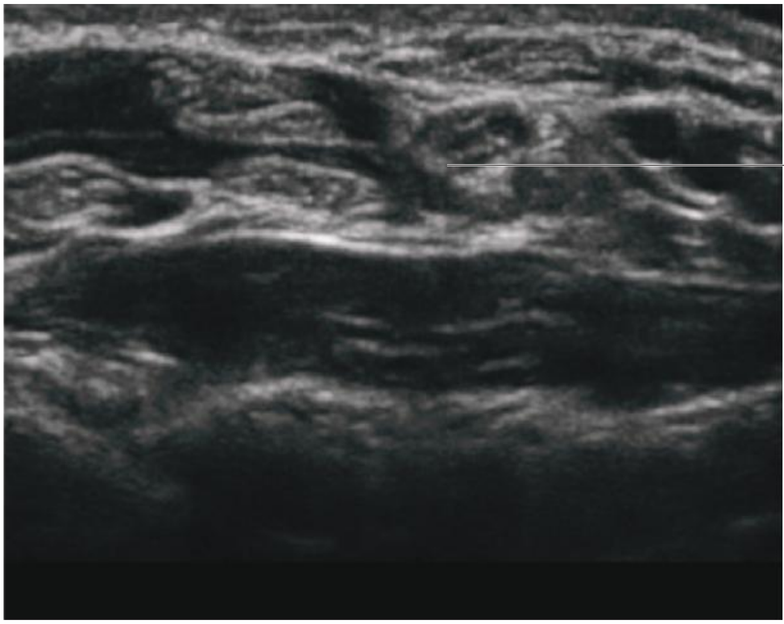
- The needle should be advanced with continuous visualization to avoid injury to anatomic structures.
- A preblock scan, including use of the color Doppler function, helps plan the course of the needle.
- Passage of the needle tip through fascial planes that abut a nerve should be conducted in a tangential fashion to avoid impaling the nerve when the fascia "releases" the needle.

SAFE NEEDLE GUIDANCE WITH ULTRASOUND

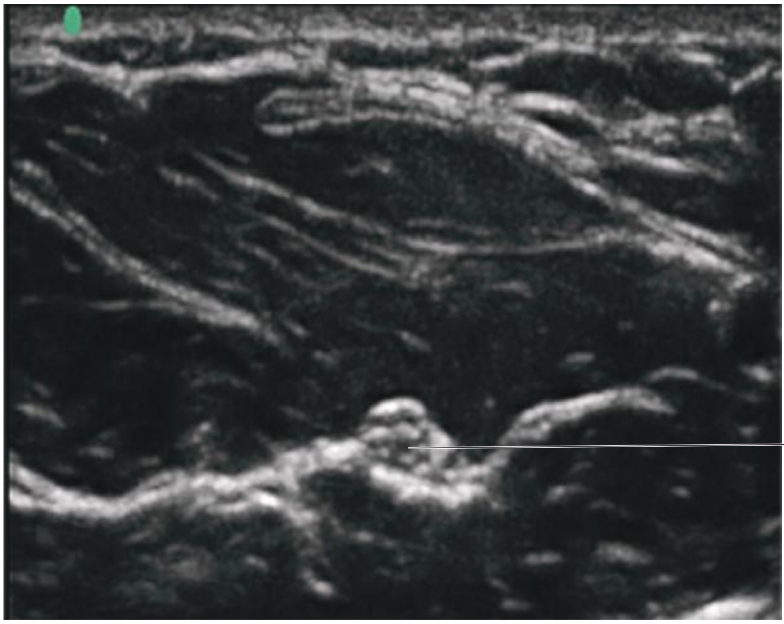
In advancing the needle tip toward the targeted nerve with in-plane imaging, one should be cautious and deliberate, attempting to maintain the needle in plane at all times (Table 30–3). The in-plane needle tip is characterized by a double-echo return generated from the beveled surface. Ultrasound is reflected from both the superficial and the deep walls of the needle, resulting in a step appearance that can be distinguished from the single return of the needle shaft. A subtle sliding motion of the ultrasound probe can aid in confirming the location of the tip as the beam walks up and down the needle shaft.

Commonly, fascial planes will be encountered that resist advance of the needle. These tough layers of connective tissue may be seen to "tent" as the tip pushes against them, suddenly giving way and snapping back to their original position. This abrupt change may have two consequences: First, the needle may advance quickly and inadvertently beyond the intent of the operator (unless this is anticipated); second, the needle may move out of plane. At this point, the forward motion of the needle should be stopped until the in-plane image is once again optimized. It is common for such fascial planes to lie just superficial or adjacent to the nerve target, as at the interscalene groove, the axillary neurovascular bundle, or the femoral nerve.[22,32] This motion may actually result in the needle thrusting forward and encountering the nerve if the sudden give of the fascial plane is not anticipated. For this reason, it is recommended to approach nerves tangentially, projecting the advance of the needle so that its tip will lie adjacent to the nerve, but not aiming for its center.[33]

The resistance encountered by these tough facial planes may also inadvertently redirect a needle when approached at a shallow angle. Temporarily steepening the needle angle may permit an easier and more controlled passage. Unfortunately, ultrasound guidance does not always produce clear images that allow one to distinguish the nerve tissue from surrounding tissue. In such situations, as the needle is advanced,



A



B

FIGURE 30–5. A: The median nerve at the wrist among many tendons within the carpal tunnel. **B:** The median nerve more proximal in the forearm surrounded by muscle.

"hydrodissection" (deliberate injection of fluid into tissue planes) can be utilized to separate structures, allowing better clarity in imaging, with either dextrose or local anesthetic solution. In addition, the behavior of tissues can be observed as the needle is advanced to help localize the needle tip in relation to neural tissue.

While it was once held that contacting a nerve with a needle tip would likely result in paresthesia, and, indeed, this was considered an appropriate nerve localization technique, we now know that paresthesia is not consistently elicited with needle-nerve contact. This emphasizes the need to accurately localize the needle tip with ultrasound imaging as well as using additional monitoring during PNBs to detect hazardous needle-nerve relationships, such as nerve stimulation and injection pressure monitoring.[34,35]

Clinical Pearls

- Deposition of local anesthetic solution should be optimized by taking advantage of fascial planes or sheaths that can contain or channel the drug around the nerve and longitudinally along its course.
- For nerves without such local fascial containment, the solution should be injected in a circumferential manner to hasten onset of the block.

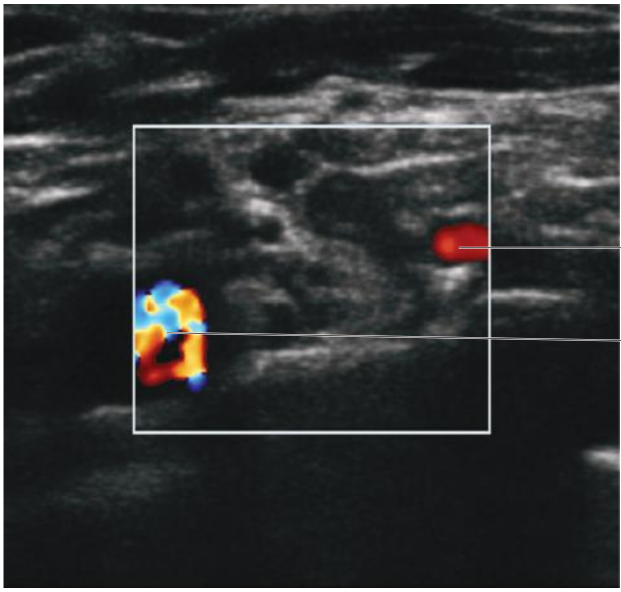


FIGURE 30–6. The supraclavicular brachial plexus with surrounding vasculature. The subclavian artery is indicated by the multicolor area, with the transverse cervical artery indicated by the red area.

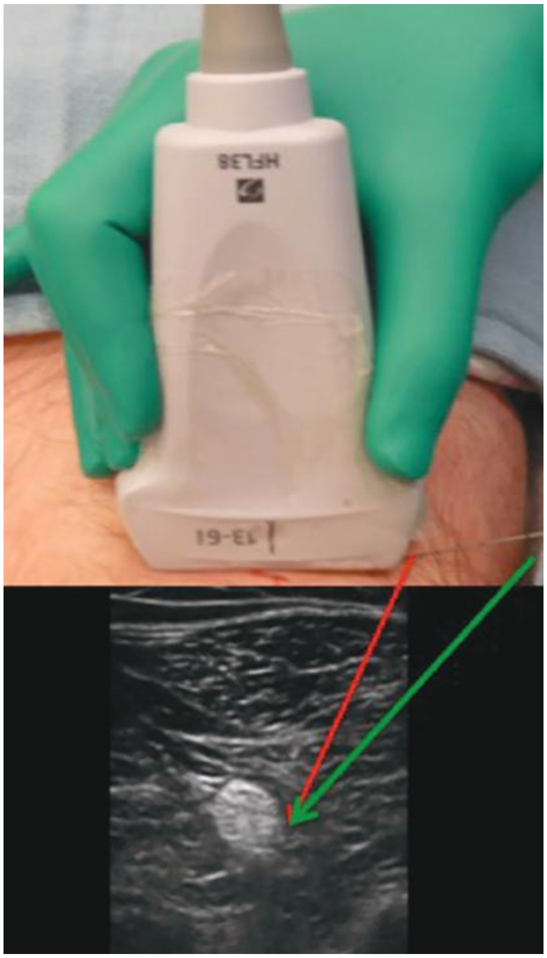

FIGURE 30–7. Needle insertion directly beside the ultrasound probe may result in difficult visualization. Insertion at a distance from the probe permits a shallower approach, allowing for stronger echo return and better visualization of the needle (green arrow) although traversing a longer tissue path.

USE OF PERIPHERAL NERVE STIMULATION WITH ULTRASOUND

The peripheral nerve stimulator (PNS) has been a standard tool in nerve localization during PNBs for several decades, with a high degree of success and low complication rate.[36] However, the widespread adoption of ultrasound imaging has called into question its ongoing role in PNB. Over a decade ago, Perlas et al evaluated the sensitivity of upper extremity peripheral nerves to peripheral nerve stimulation during ultrasound imaging of needle to nerve contact.[37] The authors reported that, despite visualizing the needle tip indenting the surface of the nerve, with the stimulator set to deliver a current of 0.5 mA or less, no motor stimulation occurred over 25% of the time.

Several studies, with a variety of different blocks, have been performed to assess the utility of this localization tool in

TABLE 30–3. Safety tips during ultrasound-guided nerve blocks.

Perform a "preblock scan" to ascertain anatomy
Utilize the color Doppler setting to identify blood vessels
Do not advance needle if tip is not localized
"Hydrodissection" can be utilized to delineate anatomy
When pushing through fascia toward a nerve, approach tangentially
Pass through fascia slowly, awaiting a "pop" or sudden release
Reoptimize image of needle tip after passing through fascia
When in doubt about needle-nerve interface, gently move needle to ascertain that the nerve does not move with it (indicating that tip is embedded within epineurium)

association with UGRA. Whether for supraclavicular block,[38] for axillary block,[39] or for femoral block[40] authors have shown that addition of the nerve stimulator as a nerve localization tool during ultrasound-guided PNB was not contributory to success. Moreover, Robards et al found that absence of a motor response to PNS between 0.2 and 0.5 mA during popliteal block did not always exclude placement of the needle within the nerve, and that stimulation might actually lead to unnecessary manipulation of the needle into the nerve.[41]

However, the stimulator may be useful as an adjunct to UGRA for reasons other than ensuring block efficacy. Because it has been well established that a threshold of nerve stimulation lower than 0.2 mA indicates high likelihood of needle tip placement within the nerve, the stimulator may be employed during UGRA as a safety monitor.[34] The nerve stimulator is particularly necessary during US-guided block of the deep nerves, or when the ultrasound image is less precise than desired. In this setting, an evoked motor response could warn against intrafascicular injection of local anesthetic.

Moreover, in some circumstances, it may be desirable to identify different nerves with more precision, as during axillary block, for which the PNS serves to delineate the nerves by their specific motor response to electrical stimulation. There may be, in some anatomic locations, neural structures that can be challenging to identify by visualization alone, whether they are the target of blockade[42] or one simply wishes to avoid them with the needle[43]; in these cases, a PNS may be invaluable to provide this identification.

Finally, there are nerves that do not lend themselves readily to ultrasound visualization, primarily because of depth or osseous interference with ultrasound transmission. The most common example of this is the posterior approach to the lumbar plexus, in which ultrasound can be used to identify local osseous structures to guide the block, but for which the PNS remains a valuable tool for guidance of the needle tip into proximity with the nerves of the plexus.[44]

Taken overall, a plethora of data indicate that routine use of a nerve stimulator during ultrasound-guided nerve blocks yields clinically relevant safety information that can influence the clinical decision making and positively affect patient safety. However, the primary purpose of the suggested *routine* use of nerve stimulation with UGRA is for safety monitoring, rather nerve localization (Figure 30–8). In this capacity, the nerve stimulator can be simply set at 0.5 mA (0.1 ms), 2 Hz, without changing the current intensity throughout the procedure. While the motor response is not sought, occurrence of the motor response should necessitate cessation of the needle advancement and slight withdrawal of the needle as a motor response at this current delivery setting almost always indicates needle-nerve contact or intraneural needle placement.[45,46]

OPTIMIZING THE DELIVERY OF LOCAL ANESTHETIC NEAR THE TARGET NERVE

After accurate needle placement near the target nerve, and after ascertaining that aspiration is negative for intravascular needle placement, injection of the local anesthetic is made in the tissue plane that contains the nerve(s) to be anesthetized (Table 30–4). Brull et al evaluated the long-held notion that the local anesthetic solution should be directed in a circumferential manner around the visible nerve, with change of needle position if

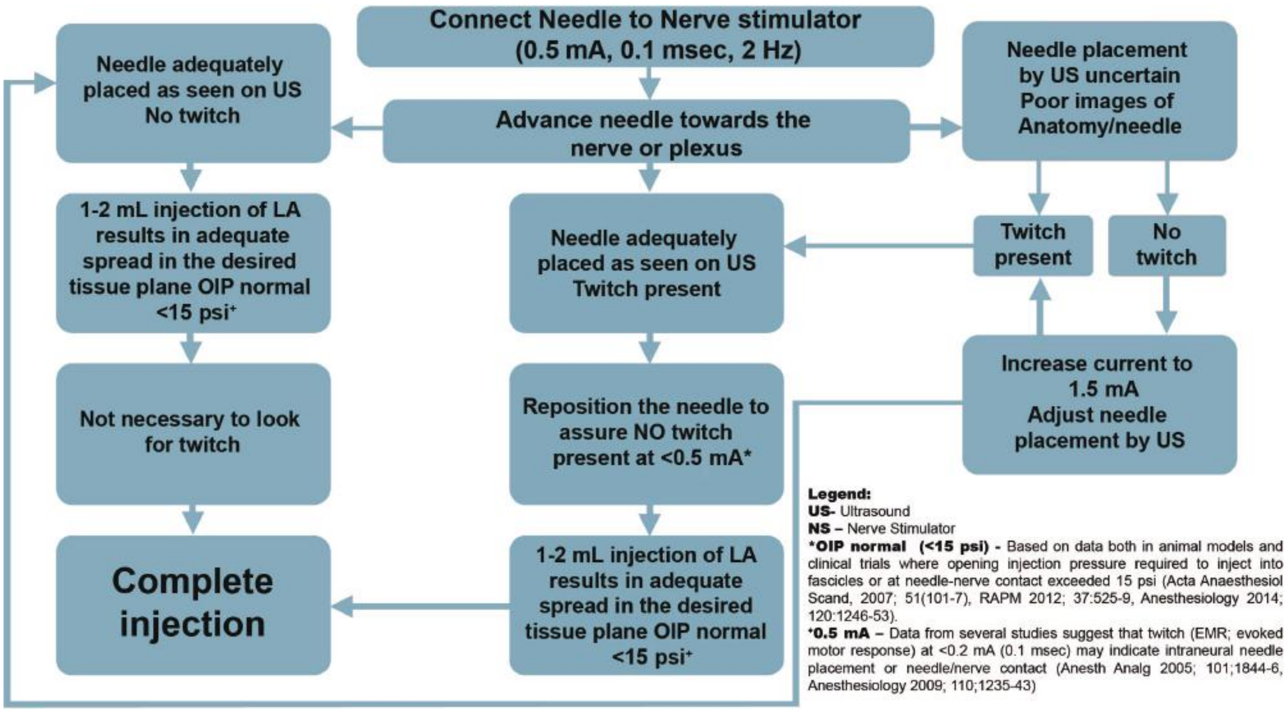

FIGURE 30–8. Algorithm: The primary purpose of the suggested *routine* use of nerve stimulation with UGRA is for the purpose of safety monitoring, rather than nerve localization.

TABLE 30–4. Optimizing local anesthetic deposition.

Inject local anesthetic solution in small aliquots
Observe for pain or high pressure during injection
Make certain that spread of fluid is observed at needle tip during injection
Aspirate between injections
Be aware of intervening fascial planes that may sequester or channel the solution
Avoid deposition of local anesthetic into muscle
For solitary nerves in extremities, seek to create a "donut" or "halo" around nerve
For nerves within a fascial enclosure, seek to "fill" the fascial confines with solution[a]

[a]Specific situations are discussed in chapters covering individual nerve blocks.

necessary, in comparison to simply allowing the solution to accumulate along one aspect of the nerve with one needle position.[47] They found that the resultant block set up 33% more rapidly with the former than with the latter. While the creation of a "donut" or "halo" around the nerve may be suggested as a general recommendation, some nerves, by virtue of their anatomical situation, may not require such deliberate circumferential placement. This is typically dictated by the location and configuration of overlying or surrounding fascial planes, such as in the interscalene groove[48] and at the femoral triangle.[32] Optimal delivery of local anesthetic around each nerve is described in subsequent specific UGRA chapters.

Real-time imaging of local anesthetic injection permits assessment of correct disposition of the fluid. The injection phase should be carried out with small aliquots of local anesthetic (3–5 mL), with a short period allowed to elapse between each, to allow evidence of any symptoms of local anesthetic systemic toxicity (LAST) to be manifest before continuing to administer the drug, as recommended by the American Society of Regional Anesthesia and Pain Medicine (ASRA) guidelines.[49] In addition, delivery of each aliquot should be preceded by aspiration and should progress with attention to opening injection pressures or complaints of pain or paresthesia in the distribution of the target nerve.

While ultrasound has been shown to produce a lower likelihood of intravascular needle placement,[50] intravascular injection with LAST may still occur.[51] It is thus imperative to be aware of the location of vessels, which have a distending pressure so low that ordinary pressure at the body surface with a transducer obliterates their lumen entirely.[4] Therefore, it is helpful to screen for the presence of vessels using color Doppler during the preblock scan. However, small vessels may be missed, and Doppler function deteriorates at greater depths. Thus, it is imperative to observe the ultrasound image throughout the injection for evidence of tissue spread by the local anesthetic solution at the tip of the needle. Failure to visualize such spread suggests that the tip of the needle either is out of plane or is in the lumen of a vessel.

Errant needle placement has been described both into vessels[52] and into nerves.[53,54] Moayeri et al in a cadaver-based study, have shown that ultrasound imaging is sensitive to injection into peripheral nerve, with as little as 0.5 mL causing visible evidence of nerve distension.[55] Such visualization allows immediate withdrawal of the needle, which may reduce the chance for nerve injury, compared to injection of a large volume of local anesthetic.

CONCLUSION

Ultrasonography has revolutionized the field of regional anesthesia. The effective application of this technology requires understanding of two-dimensional anatomy, optimal imaging of the nerves and anatomical structures, accurate real-time needle guidance, and precise local anesthetic delivery. The combination of these elements ensures that the most benefit can be derived from this powerful imaging modality, ensuring high nerve block success and improved patient safety, particularly with regard to LAST. Individual ultrasound-guided blocks are discussed in detail in Chapters 31 through 35.

SECTION 2 Ultrasound-Guided Head and Neck Nerve Blocks

CHAPTER 31

Nerve Blocks of the Face

Chrystelle Sola, Christophe Dadure, Olivier Choquet, and Xavier Capdevila

INTRODUCTION

Regional anesthesia is commonly used for postoperative pain management to decrease postoperative pain and opioid consumption following head and neck surgery. Myriad techniques can be used for both acute and chronic pain management either diagnostic or therapeutic procedures. Because of the vicinity of cranial and cervical nerves to many vital structures in a compact area, the efficacy and safety of cephalic blocks are based on precise and detailed knowledge of the anatomical relationships of the selected nerve, its deep and superficial courses, and the final sensory territories.

Sensory innervation of the face and neck is supplied by the trigeminal nerve (fifth cranial or V) and the C2–C4 cervical nerve roots that constitute the superficial cervical plexus (Figure 31–1A).

This chapter outlines clinically applicable regional blocks of the face that for perioperative and chronic pain management. For each block, practical anatomy, indications, technique, and type of complications are specifically described.

TRIGEMINAL NERVE

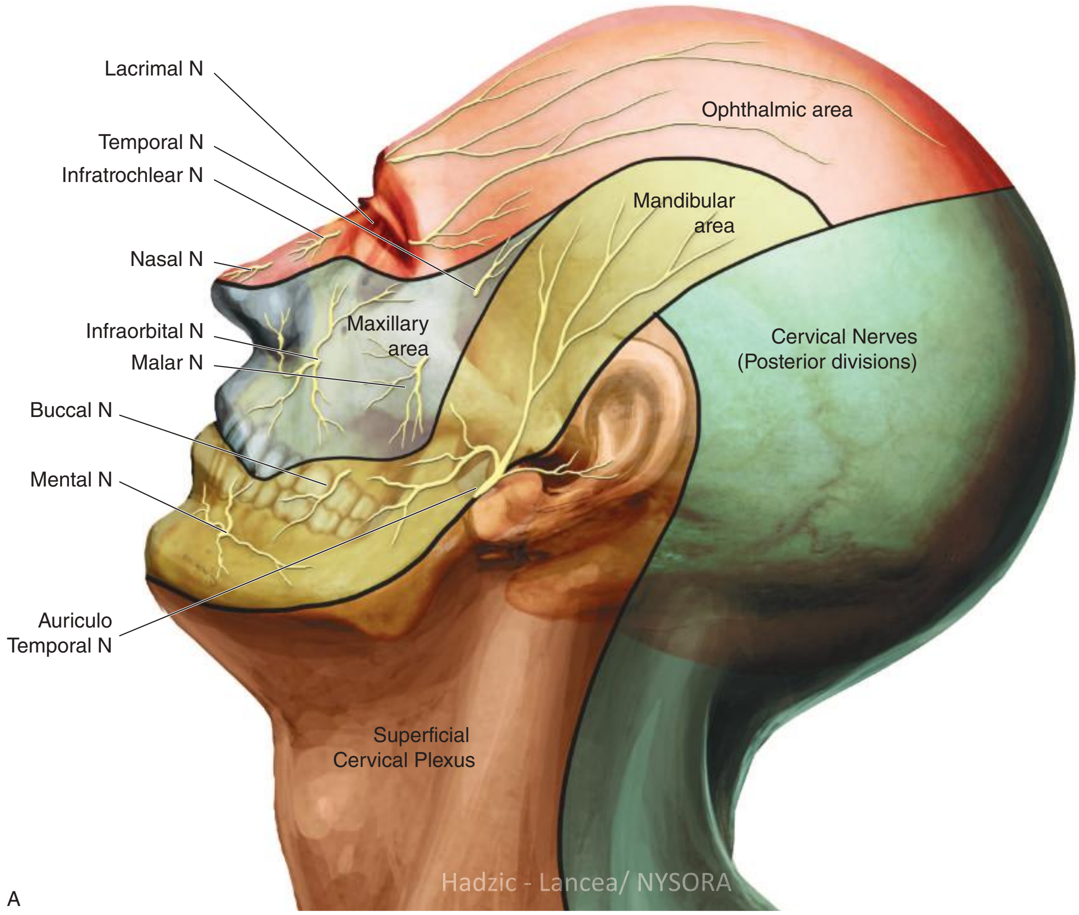
The fifth cranial nerve carries both sensory and motor components. The trigeminal ganglion (semilunar or Gasserian ganglion) lies in Meckel's cave, an invagination of the dura mater near the apex of the petrous part of the temporal bone in the posterior cranial fossa. Postganglionic fibers exit the ganglion to form three nerves:

- The ophthalmic nerve (V1), a sensory nerve, divides into three branches (lacrimal, frontal, and nasociliary nerves) before entering the orbit through the superior orbital fissure. It innervates the forehead, eyebrows, upper eyelids, and anterior area of the nose (Figure 31–1B).
- The maxillary nerve (V2), a purely sensory nerve, exits the middle cranial fossa via the foramen rotundum, passes forward and laterally through the pterygopalatine fossa, and reaches the floor of the orbit by the infraorbital foramen. It innervates the lower eyelid, the upper lip, the lateral portion of the nose and nasal septum, cheek, roof of the mouth, bone, teeth and sinus of the maxilla, and the soft and hard palates (Figure 31–1B).
- The mandibular nerve (V3) is a mixed sensory and motor (for the mastication muscles) nerve. After exiting the cranium through the foramen ovale, it delivers sensory branches that supply the front of the ear, the temporal area, the anterior two-thirds of the tongue and the skin, mucosa, and teeth and bone of the mandible (Figure 31–1B).

These sensory nerves can be blocked either at their emergence point from the cranium (V2 and V3) or, more distally and superficially, at their exit from the facial bones (V1, V2, V3) (Figure 31–1).

Clinical Pearls

- Neural blockade of the trigeminal ganglion is reserved for patients with trigeminal neuralgia who do not respond to pharmacologic therapy.
- Block of the trigeminal ganglion and its primary divisions is often used as a diagnostic test to predict response to neural blockade prior to proceeding with neurolysis.



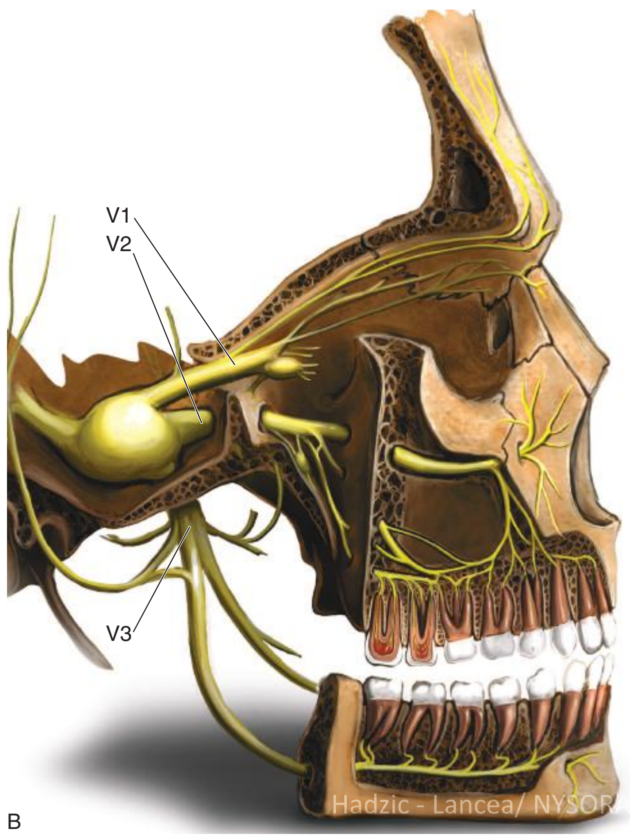


FIGURE 31–1. Innervation of the face. **A:** Dermatomes of the head, neck, and face. **B:** Distribution of the three branches of the trigeminal nerve.

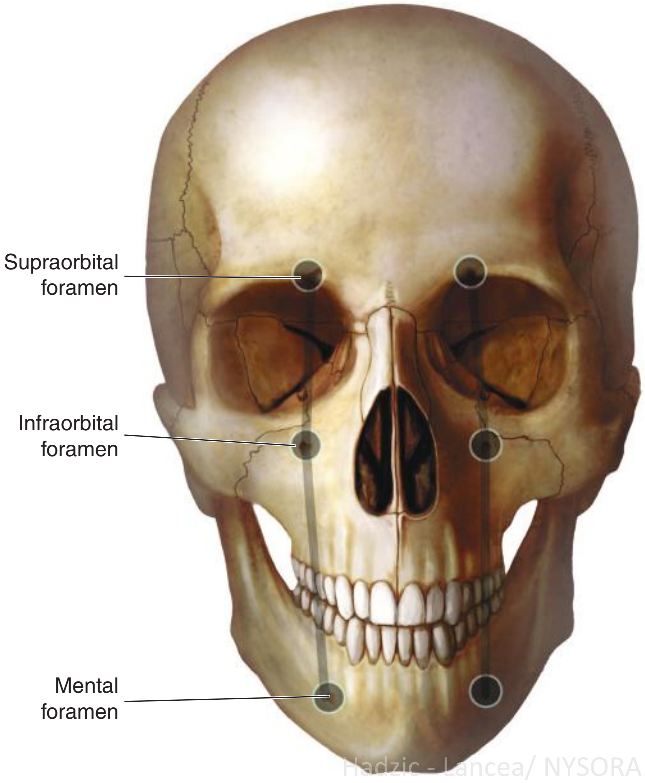

FIGURE 31–2. Terminal sensory branches of the trigeminal nerve exit the facial bone through the supraorbital, infraorbital, and mental foramen, which are at the intersection with the vertical line passing over the ipsilateral centered pupil.

The Superficial Trigeminal Nerve Blocks

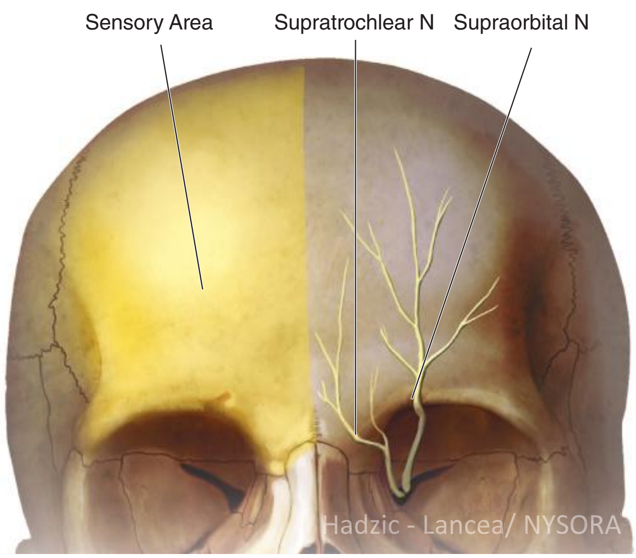
For superficial trigeminal nerve blocks, the local anesthetic solution should be injected in close proximity to the three individual terminal superficial branches of the trigeminal nerve divisions: frontal nerve (of the ophthalmic nerve, V1 division); infraorbital nerve (of the maxillary nerve, V2 division); and mental nerve (sensory terminal branch of the mandibular nerve, V3 division). Each nerve is anatomically close to its respective foramen, usually located on a line drawn sagittally through the pupil (Figure 31–2).

Block of the Frontal Nerve (Supraorbital and Supratrochlear Branches)

Anatomy The frontal nerve enters the orbit at the superior orbital fissure and divides into the supraorbital and supratrochlear branches. The supraorbital nerve exits with its vessels through the supraorbital foramen and continues superiorly between the elevator palpebrae superioris and the periosteum. The supratrochlear nerve appears more medial through the supraorbital notch. These two branches supply the sensory innervation to the frontal scalp and forehead, the medial part of the upper eyelid, and the root of the nose (Figures 31–3A and 31–3B).

Indication The block of the frontal nerve is useful for lower forehead and upper eyelid surgery such as repair of a laceration, frontal craniotomies, frontal ventriculoperitoneal shunt placement, Ommaya reservoir placement,[1] and plastic surgical

A



B

FIGURE 31–3. A: Supraorbital and supratrochlear block. **B:** Sensory area of the supraorbital and supratrochlear nerves.

procedures, including excision of anterior scalp pigmented nevus, benign tumor with skin grafting, or dermoid cyst excision.[2] Frequently, surgery on one side of the forehead requires a supplemental block of the contralateral supratrochlear nerve because of overlapping distributions of the nerves.

Block of branches of the ophthalmic nerve has been described for the management of acute migraine headache attacks localized to the ocular and retro-ocular region[3] and in the treatment of pain related to acute zherpesoster.[4]

Classical Landmark Technique The supraorbital foramen can easily be palpated by following the orbit rim 2 cm from the midline in adults (intersection of the medial one-third and the lateral two-thirds). It is located approximately at the same sagittal plane as the pupil in most patients. The needle (25-gauge intradermal needle in adults, 30 gauge in children) is introduced 0.5 cm under the inferior edge of the eyebrow and is directed medially and cephalad. When the needle tip is near the supraorbital notch, after test aspiration, and with caution not to penetrate the foramen, local anesthetic solution (0.5–1 mL) can be injected, creating a subcutaneous wheal. For a supratrochlear block, the landmark is at the top of the angle formed by the eyebrow and the nasal spine where the nerve is in contact with the bone. The supratrochlear nerve can be blocked immediately following supraorbital nerve block, without removing the needle, by directing the needle about 1 cm toward the midline and injecting an additional 0.5 mL of local anesthetic.

After the injection, firm pressure is applied for better anesthetic spread and prevention of ecchymosis.

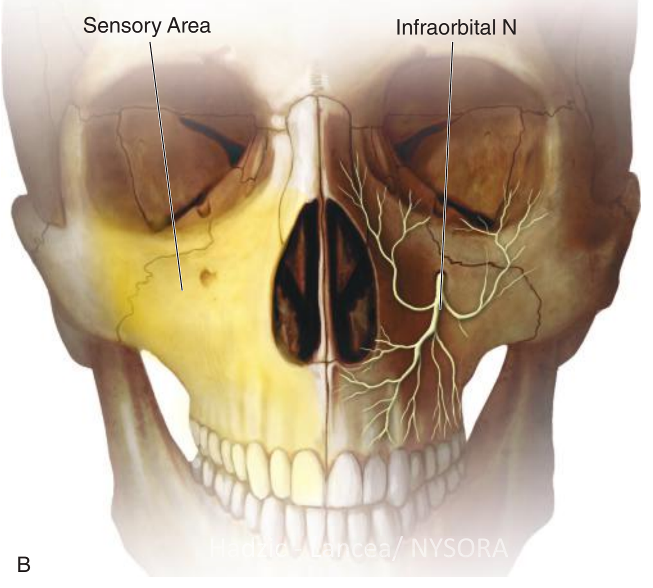
Complications Complications are rarely reported during the performance of this block, and may include hematoma, intravascular injection, and eye globe damage.

Clinical Pearls

The following are specific complications associated with head and neck blocks:

- Subarachnoid or epidural placement of local anesthetic may lead to high spinal and brainstem anesthesia.
- Generalized seizures may occur with the injection of even small intra-arterial volumes of local anesthetic (0.5 mL or less) as the arterial blood flow continues directly from the arteries in the head and neck to the brain.
- Hematoma formation.
- Respiratory distress may result from block of the phrenic or recurrent laryngeal nerves, pneumothorax, or loss of sensory or motor function of the nerves to the airway.

A



B

FIGURE 31–4. **A:** Infraorbital nerve block. **B:** Sensory area of the infraorbital nerve.

Block of the Infraorbital Nerve

Anatomy The terminal branch of the maxillary nerve (V2, the second division of the trigeminal nerve) is called the infraorbital nerve when it reaches the infraorbital fossa. It exits the cranium through the infraorbital foramen in a caudad and medial direction and divides into several sensory branches: the inferior palpebral, the lateral nasal, and the superior labial nerves. The infraorbital artery and vein run parallel in close proximity to the nerve. Territories of the infraorbital nerve include the skin and mucous membrane of the upper lip and lower eyelid and the cheek between them and to the lateral side of the nose (Figures 31–4A and 31–4B).

Indications Infraorbital nerve block is commonly used in neonates, infants, and older children undergoing cleft lip repair to provide early postoperative analgesia without the potential risk of respiratory depression that may occur when opioid analgesics are used.[5–7] The other main indications are surgeries of the lower eyelid, the upper lip, the median cheek, endoscopic sinus surgery,[8] rhinoplasty or nasal septal repair, and transsphenoidal hypophysectomy.[9]

Clinical Pearls

- The infraorbital nerve is sensory nerve. As the nerve exits the infraorbital foramen, it supplies the skin of the lower eyelid, nose, cheek, and upper lip.
- It is accompanied by the infraorbital artery and vein.

Classical Landmark Techniques For the classical landmark techniques, two approaches can be used to perform this block: the intraoral and extraoral approaches. Regardless of the chosen technique, it is necessary to prevent the penetration of the foramen to prevent damage to the eyeball. This can be done by keeping a finger on the foramen throughout the procedure.

- For the intraoral approach, the first landmark is the infraorbital foramen, which is localized just below the orbital rim, at the intersection of a vertical line drawn caudally through the center of the pupil and a horizontal line through the nasal alae. The incisor and the first premolar are then palpated. A 25- to 27-gauge needle is inserted into the buccal mucosa in the subsulcal groove at the level of the canine or the first premolar and directed upward and outward into the canine fossa. A finger is kept over the infraorbital foramen to assess the proper location of the needle tip and to avoid damage of the eyeball by accidental cephalad advancement of the needle into the orbit. Then, 1–3 mL of local anesthetic is injected after negative aspiration.
- For the extraoral approach, the infraorbital foramen is palpated (see preceding discussion). A 25- to 27-gauge needle is advanced perpendicularly with a cephalic and medial direction toward the foramen until bony resistance is appreciated. Because the axis of the infraorbital foramen is oriented caudally and medially, a lateral-to-medial approach reduces the risk of penetration of the foramen. A finger is always placed at the level of the infraorbital foramen to avoid further cephalad advancement of the needle, and gentle pressure is recommended to prevent hematoma formation.

Complications Hematoma formation, persistent paresthesia of the upper lip, prolonged numbness of the upper lip, and intravascular placement are possible. A serious (but rare) risk is penetration of the foramen, which may result in nerve damage by compression in the narrow infraorbital canal, or needle penetration of the flimsy orbital floor and damage to the orbital contents. The intraoral approach is not advised in neonates and small infants because of the proximity of the orbit.

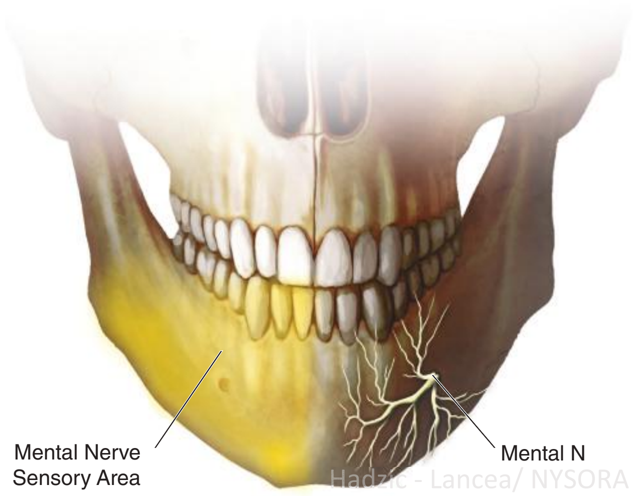
Block of the Mental Nerve

Anatomy The mental nerve is the terminal branch of the alveolar nerve (the largest branch of the mandibular nerve, V3). It emerges at the mental foramen and divides into three branches: a descending branch to the skin of the chin and two ascending branches to the skin, labial mucosae of the lower lip, as well as the anterior teeth (Figures 31–5A and 31–5B).

Indications Procedures involving hemangiomata, laceration repair, and other surgery involving the lower lip, skin of the chin, and the incisive and canine teeth.

Classical Landmark Technique For the classical landmark technique, the mental foramen is located in line with the pupil on the mental process of the mandible, in regard to the inferior premolar tooth. Puncture with a 25- to 27-gauge needle is performed 1 cm lateral to the foramen palpated. The needle is directed with a lateral-to-medial direction to avoid foramen penetration.

A



B

FIGURE 31–5. **A:** Mental nerve block. **B:** Sensory area of the mental nerve.

Similar to the infraorbital nerve block, an intraoral route can be utilized: The lower lip is retracted, and the needle is introduced through the mucosa in front of the first inferior premolar tooth. The needle is directed downward and outward toward the mental foramen palpated with the finger.

Complications Hematoma formation and persistent paresthesia have been reported. Less commonly, penetration of the foramen occurs, which may result in permanent nerve damage or vascular injection.

Ultrasound Guidance Technique for Superficial Trigeminal Nerve Blocks

The ultrasound-guided approach to locate the landmark foramina for superficial trigeminal nerve block is feasible.[10] Using a high-frequency linear transducer, bone appears as a hyperechoic linear edge (white line) with an underlying anechoic (dark) shadow. At the foramina of these three nerves, disruption within the hyperechoic line indicates a discontinuity in the bone ("bone gap"). In addition, ultrasound can visualize satellite vessels close to each nerve using the color Doppler function. The real-time view of the injection spread can help avoid intravascular injection, nerve injury by the needle, or injection into the foramen.

To localize the supraorbital notch (foramen), the probe is located transversely above the orbital rim (Figure 31–6A).

The infraorbital foramen can be visualized by positioning the ultrasound probe horizontally or vertically in the sagittal plane. Fine translational movements from medial to lateral along the lower orbital margin are performed to highlight the disruption of the bone table (Figure 31–6B).

Finally, the mental foramen is localized using a transverse or sagittal plane with dynamic scanning between the upper and lower borders of the mandible (Figure 31–6C).

Clinical Pearls

The following are specific complications associated with Superficial Nerves Blocks of the face:

- Facial artery vasospasm.
- Nerve injury is rare and most cases are transient and resolve completely. However, careful attention is needed to avoid injection into foramina whose consequences could lead to permanent neurological damage.
- Intravascular injection and systemic toxicity: Generalized seizures may occur with the injection of even small intraarterial volumes of local anesthetic (0.5 mL or less) as the arterial blood flow continues directly from the face arteries to the brain.
- Ecchymosis and Hematoma formation. This complication can be decreased after superficial nerves blocks techniques by using a 25- or 27- gauge needle and applying a manual pressure immediately after injection.
- Needle tract infection is very infrequent complication.

The Maxillary Nerve Block

Anatomy

The maxillary nerve exits the skull through the foramen rotundum before dividing into terminal branches (Table 31–1 and

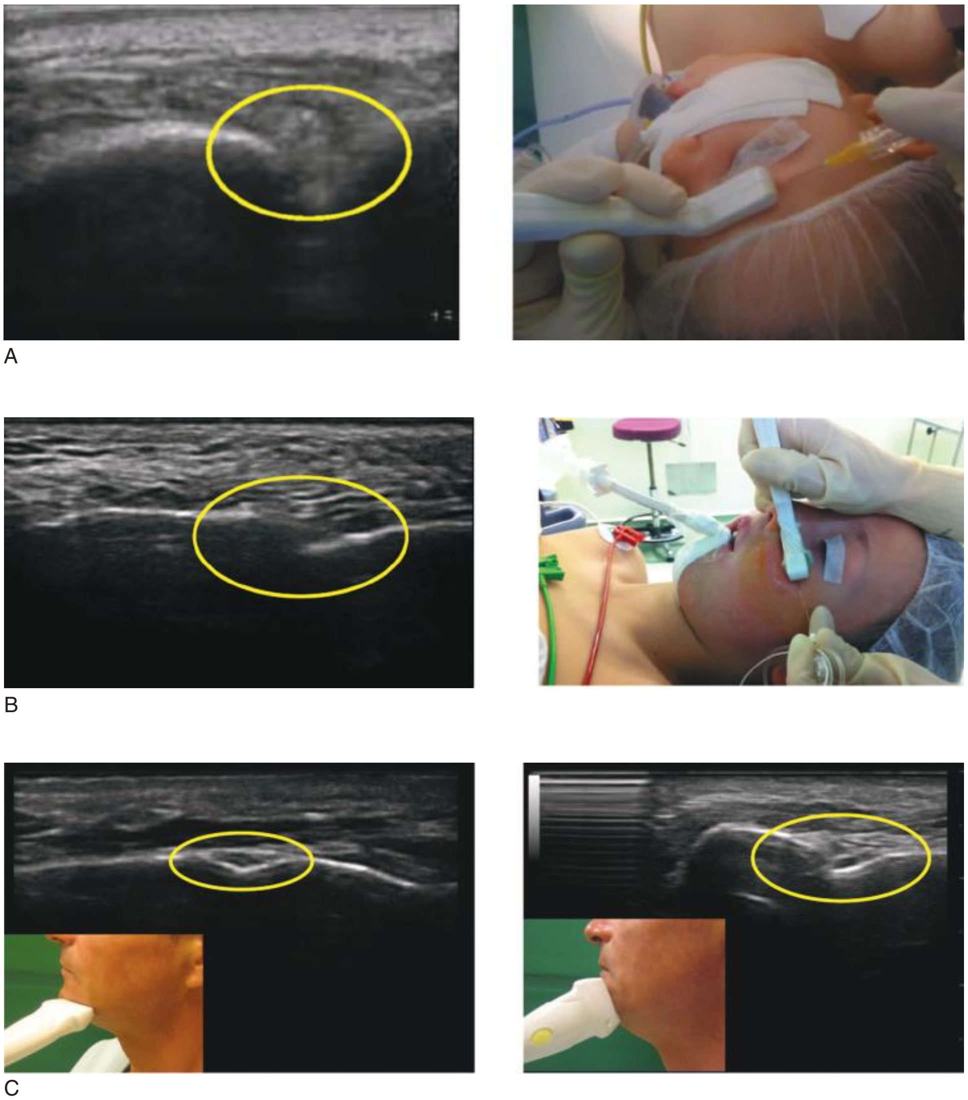


FIGURE 31–6. Ultrasound imaging for superficial trigeminal nerve block. **A:** The supraorbital nerve block under ultrasound guidance. **B:** The infraorbital nerve block under ultrasound guidance. **C:** The mental nerve block under ultrasound guidance.

    - Nasal branches
    - Nasopalatine nerve
    - Greater palatine nerve
    - Lesser palatine nerve
    - Pharyngeal branch
3. **Zygomatic nerves**
    - Zygomaticofacial
    - Zygomaticotemporal
4. **Posterior superior alveolar nerve**
5. **Infraorbital nerve**
    - Before exits infraorbital canal
        - Middle superior alveolar
        - Anterior superior alveolar
    - After exits infraorbital canal
        - Inferior palpebral
        - Lateral (external) nasal
        - Superior labial

Figure 31–7). Except for the middle meningeal nerve (the intracranial branch that innervates the dura mater), all branches (zygomatic branches, superior alveolar nerve, pterygopalatine and parasympathetic branches, palatine and pharyngeal branches) arise in the pterygopalatine fossa.

Outside the cranial vault, the maxillary nerve supplies sensory branches to

- the skin of the temple and cheek
- the nasal septum and the lateral nasal wall
- the soft and bone palates
- upper teeth and maxillary sinus
- the territory of the infraorbital nerve (previously described)

At the upper part of the pterygopalatine fossa, the maxillary nerve is accessible for a complete maxillary block. The territories supplied by this complete block are the following:

- superficial: lower eyelid, ala of the nose, cheek, upper lip, cutaneous zygomatic, and temporal zone
- deep: superior teeth, palatine zone, maxillary bone

Indications

This block is mainly offered as an adjunct to general anesthesia for major cancer surgery of the maxilla, the ethmoidal sinus, and the pterigomaxillary or infratemporal fossa. In children, bilateral maxillary nerve blocks improve perioperative analgesia and favor the early resumption of feeding following repair of congenital cleft palate.[11] Many other procedures may benefit from a maxillary nerve block, such as maxillary trauma (Lefort I), maxillary osteotomy, or the diagnostic and therapeutic management of trigeminal neuralgias.[12]

Classical Landmark Technique

Many approaches to the classical landmark technique (Figure 31–8) have been described.

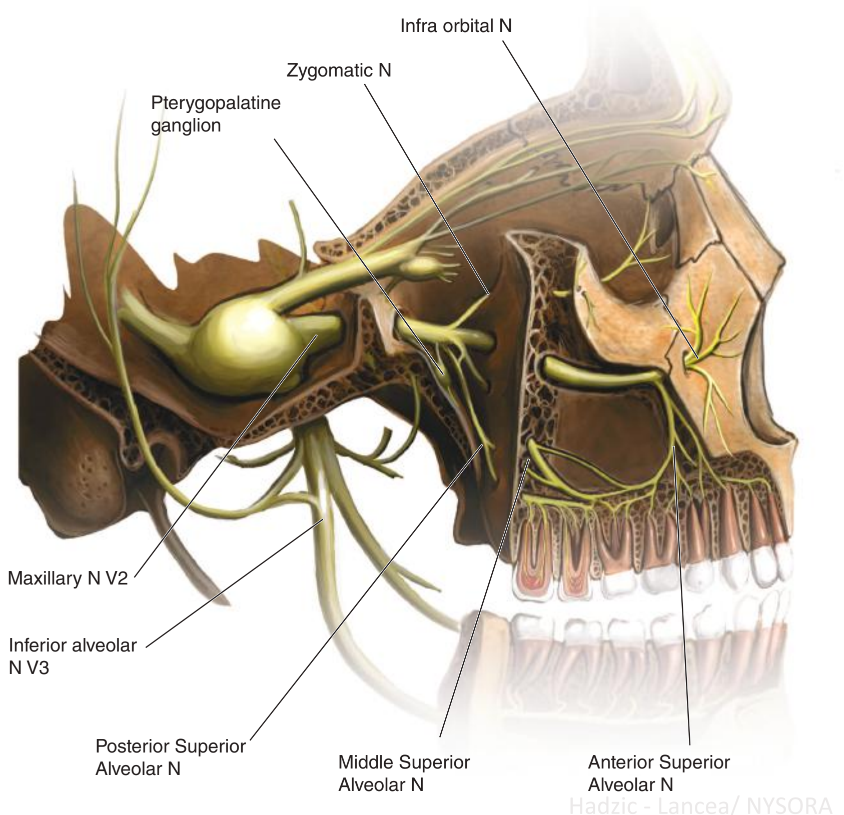

FIGURE 31–7. The maxillary nerve.

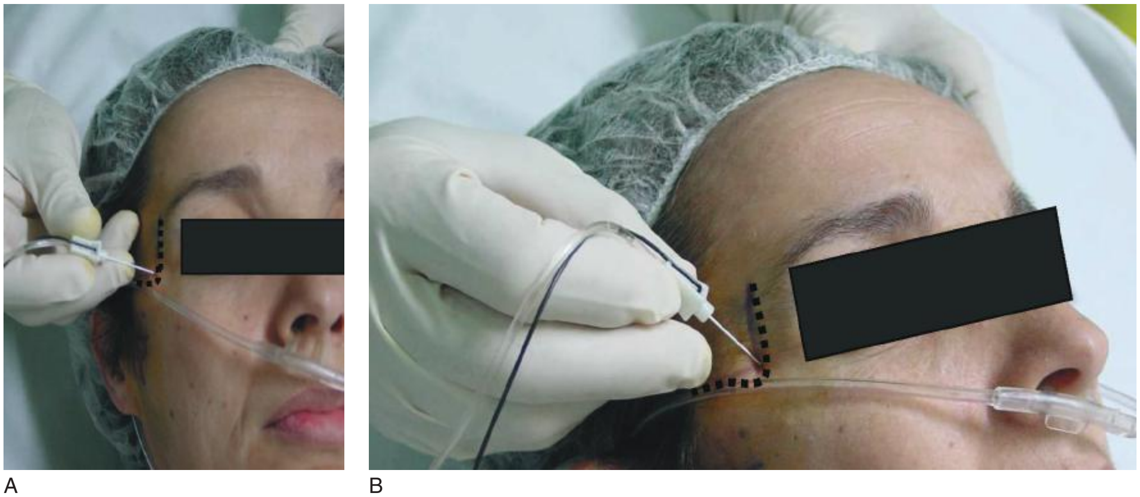

FIGURE 31–8. **A** and **B:** Suprazygomatic maxillary nerve block.

- The anterior infrazygomatic approach presents significant risks, including puncture of the maxillary artery, puncture of the posterior pharyngeal wall, submucosal abscess, or intraorbital injection through the superior orbital fissure.
- The suprazygomatic approach seems to be the safest and is easily reproducible in either children or adult patients. The patient is placed supine with the head in a neutral position. The needle entry point is found at the angle formed by the superior edge of the zygomatic arch below and the posterior orbital rim forward. The needle (22 to 25 gauge) is inserted perpendicular to the skin and advanced to reach the greater wing of the sphenoid at a depth of approximately 10–15 mm (Figure 31–8A). The needle is then reoriented in a caudal and posterior direction (Figure 31–8B) and advanced a further 35–45 mm to reach the pterygopalatine fossa. After a negative aspiration test for blood, 0.1 mL kg^{-1} up to maximum of 5 mL of local anesthetic solution is slowly injected.

Nerve stimulation may help locate the pterygopalatine fossa: Nerve stimulation is associated with paresthesia coinciding with the stimulating frequency of the nerve stimulator. In anesthetized children, stimulation of the temporal muscle that results in a mandibular contraction may be noted. The disappearance of the muscle contraction heralds the passage through the temporal muscle and entrance into the pterygomaxillary fossa.

Ultrasound Guidance Technique

The (Figure 31–9), ultrasound transducer is placed in the infrazygomatic area, over the maxilla, with an inclination of 45° in both the frontal and the horizontal planes. The probe location allows visualization of the pterygopalatine fossa, limited anteriorly by the maxilla and posteriorly by the greater wing of the sphenoid. The needle is advanced using an out-of-plane approach. Real-time ultrasound guidance allows direct localization of the internal maxillary artery, identification of the needle tip, and spread of local anesthetic solution within the pterygopalatine fossa.[13]

Complications

Block failure can occur due to inadequate bony landmarks or inadequate needle tip position external to the pterygomaxillary fossa. Complications include cephalgia, facial paralysis, trismus, and hematoma.

The Mandibular Nerve Block

Anatomy

The mandibular nerve, the largest branch of the trigeminal nerve, exits from the cranium through the foramen ovale of the greater wing of the sphenoid. It divides into an anterior branch, which supplies motor innervation to temporalis, masseter, pterygoids, mylohyoid, tensor tympani, and palati muscles, as well as a sensory branch, the buccal nerve. The large posterior trunk divides into auriculotemporal, lingual, and inferior alveolar nerves (which reach the mental foramen, becoming the mental nerve) (Table 31–2 and Figure 31–10).

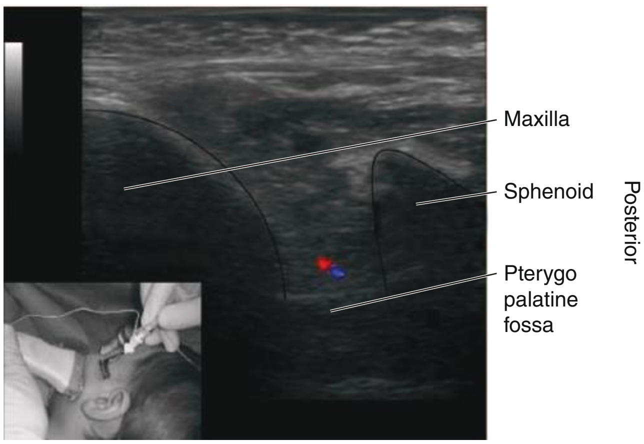

FIGURE 31–9. Ultrasound imaging for the pterygopalatine fossa limited by the maxilla (anterior) and the greater wing of the sphenoid (posterior). The maxillary vessels lie ventral and inferior to the maxillary nerve in the bottom of the pterygopalatine fossa.

   - Via chorda tympani (VII)
     Taste sensations to the anterior third of tongue
6. **Inferior alveolar nerve**
   - Dental
   - Incisive
   - Mental

Mandibular nerve is blocked where the nerve emerges through the foramen ovale. Complete block results in anesthesia of the ipsilateral mandibular bone, lower teeth up to the midline, buccal and lingual hard and soft tissue, anterior two-thirds of the tongue, floor of the mouth, the external acoustic meatus and auricle of the ear in its anterior zone, the skin over the jaw, the posterior part of the cheek, and the temporal area (except the area of the angle of the mandible, which is supplied by the superficial cervical plexus).

Indications

Surgery on the lower lip, the mandible skin or bone (including the lower teeth), and the anterior two-thirds of the tongue can be accomplished with this technique. This block could be useful in patients with cancer or trauma. Nonmalignant chronic pain conditions such as trigeminal, vascular, or postherpetic neuralgia are also good indications for the mandibular block.

Classical Landmark Technique

In the classical landmark technique, the puncture area is bound by the zygomatic arch at the top and the mandibular notch just anterior and below the tragus of the ear. The needle entry point is located between the coronoid and condylar processes of the ramus of the mandible. To avoid the risk of arterial puncture, it is recommended to insert the needle as high as possible in the space between the zygomatic arch and the center of the mandibular notch (Figure 31–11). After perpendicular skin penetration and advancement of 2–4 cm toward the lateral pterygoid plate, the 22- to 25-gauge needle is advanced posteriorly and inferiorly, guided by mandible elevation twitch. Depth required to contact the mandible should not be more than 5–6 cm. The minimal intensity of stimulation (around 0.5 mA)

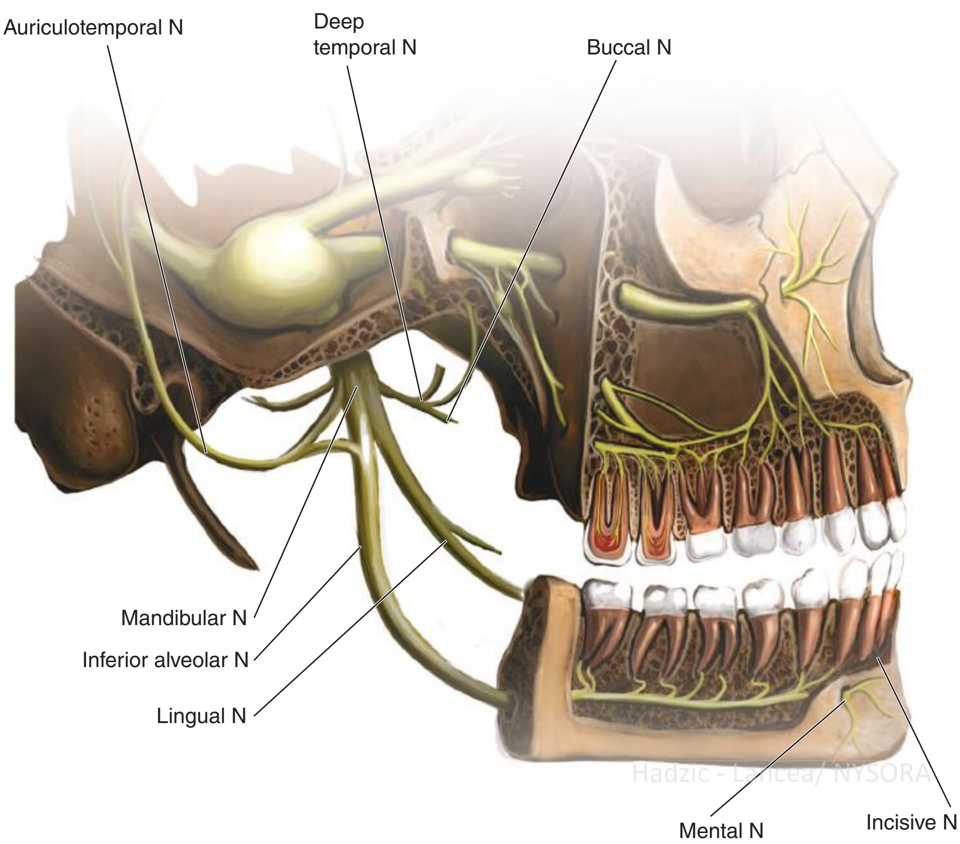

FIGURE 31–10. Mandibular nerve division and its relationship with vascular structures close.

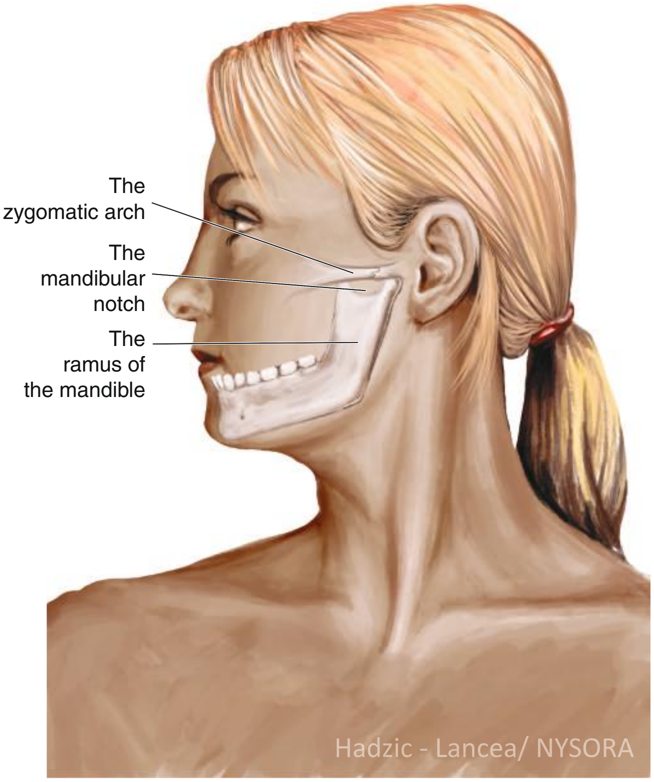

FIGURE 31–11. The mandibular nerve block: classical anatomic landmark.

is determined, and 0.1 mL kg^{-1} to a maximal of 5 mL of local anesthetic solution is slowly injected after negative blood aspiration. This transcutaneous procedure with neurostimulation is associated with a high success rate.

Complications

The risk of puncture of the internal maxillary or middle meningeal arteries (Figure 31–10) can be high when the needle inserted too high in the space between the coronoid and condylar processes. After an injection of a large volume of local anesthetic solution, transient facial nerve block has been reported, which resolved spontaneously without sequelae.

Regional Block of the Nose

Anatomy

The innervation of the nose and nasal cavity is complex and involves both the ophthalmic (V1) and maxillary (V2) branches of the trigeminal nerve (Figures 31–12A and 31–12B)

- The nasociliary nerve (a branch of the ophthalmic nerve, V1) gives off, within the orbital cavity, the following branches: the posterior ethmoidal nerve, long ciliary nerves, communicating branches to the ciliary ganglion, the anterior ethmoidal nerve, and the infratrochlear nerve. The ethmoidal branches supply the superior and anterior half of the nasal cavity and the sphenoidal, ethmoidal, and frontal sinuses. Internal and external nasal branches of the anterior ethmoidal nerve supply the anterior part of the septum, the lateral wall of the nasal cavity, the nasal bone, and skin to the tip of the nose.
- The supratrochlear nerve (terminal branch of the frontal nerve, V1) supplies the root of the nose.
- Nasal and nasopalatine divisions of the maxillary nerve (V2) supply the posterior aspect of the septum and nasal cavity.
- The infraorbital nerve (terminal branch of V2) supplies the wings of the nose and the mobile septum.

Indications

Bilateral nerve blocks are often required. In most cases of intranasal surgery and septoplasty, topical anesthesia or infiltration by surgeons is needed to compliment analgesia and decrease bleeding by vasoconstriction using epinephrine.

Current indications for "nasal" block include rhinoplasty, polyp removal, repair of nasal fracture, and repair of nasal skin laceration.

Classical Technique

In the classical technique, the nasociliary nerve is blocked prior to its division into nasal branches of the anterior ethmoidal nerve and the infratrochlear nerve, close to the ethmoidal foramen. At this location, epinephrine-free solutions should be used to avoid the risk of retinal artery spasm. An intradermal (15–30 mm; 25–27 gauge) needle is inserted 1 cm above the medial canthus, halfway between the posterior palpebral fold and the eyebrow. It is then directed medially and backward to contact the bony roof of the orbit. At a depth of 1.5 cm, the needle should be at the anterior ethmoidal foramen; a maximum of 2 mL of local anesthetic solution is then slowly injected after a negative aspiration test. Continuous injection while removing the needle allows for blockade of the external nasal nerve. Compression of the interior angle of the eye by the finger promotes the diffusion of the solution to the foramen.

The infratrochlear nerve can be blocked by infiltrating at the superomedial border of the orbit and along its medial wall. The external nasal branch of the anterior ethmoidal nerve can also be blocked by infiltration at the junction of the nasal bone and the nasal cartilage.

Accompanied with an infraorbital nerve block and a pterygopalatine ganglion block by topical application of local anesthetic, complete anesthesia of the nasal cavity, septum, and lateral wall of the nose appears effective.

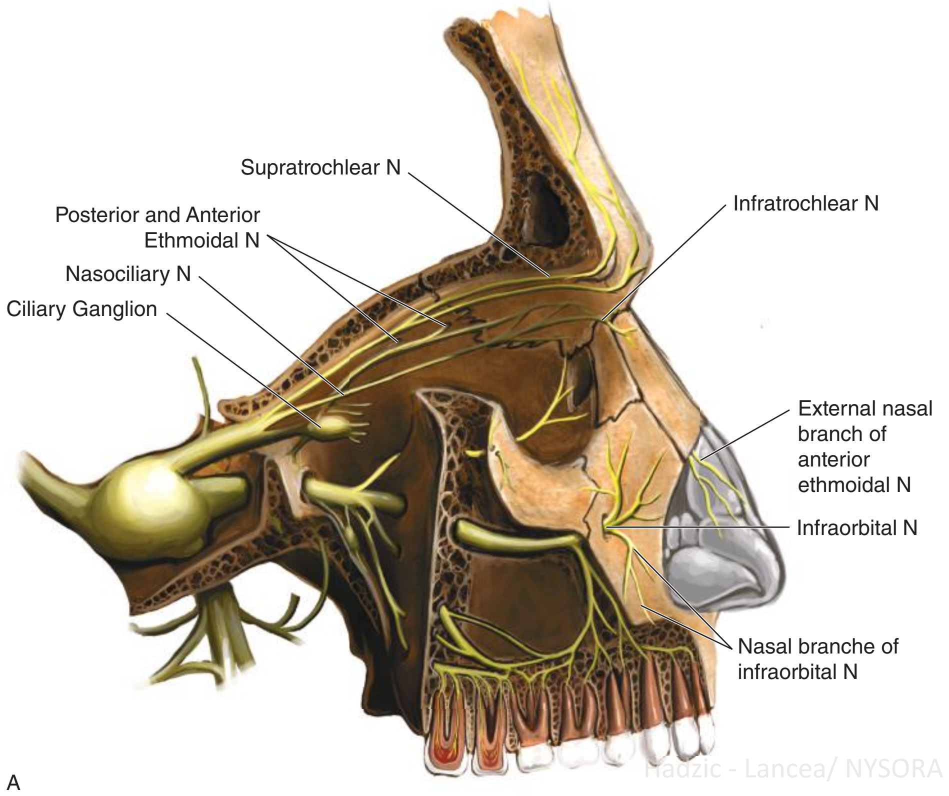
Complications

Most reported complications are minor and transient: palpebral edema, diplopia due to paralysis of the superior obliquus muscle of the eye, ptosis, and ecchymosis at the puncture site or hematoma secondary to ethmoidal vessel puncture. Rare cases of retrobulbar hemorrhage have been described.

REGIONAL BLOCKS OF THE EXTERNAL EAR

Anatomy

The innervation of the pinna of the ear is mainly provided by the trigeminal nerve and the cervical plexus (Figures 31–13A and 31–13B).



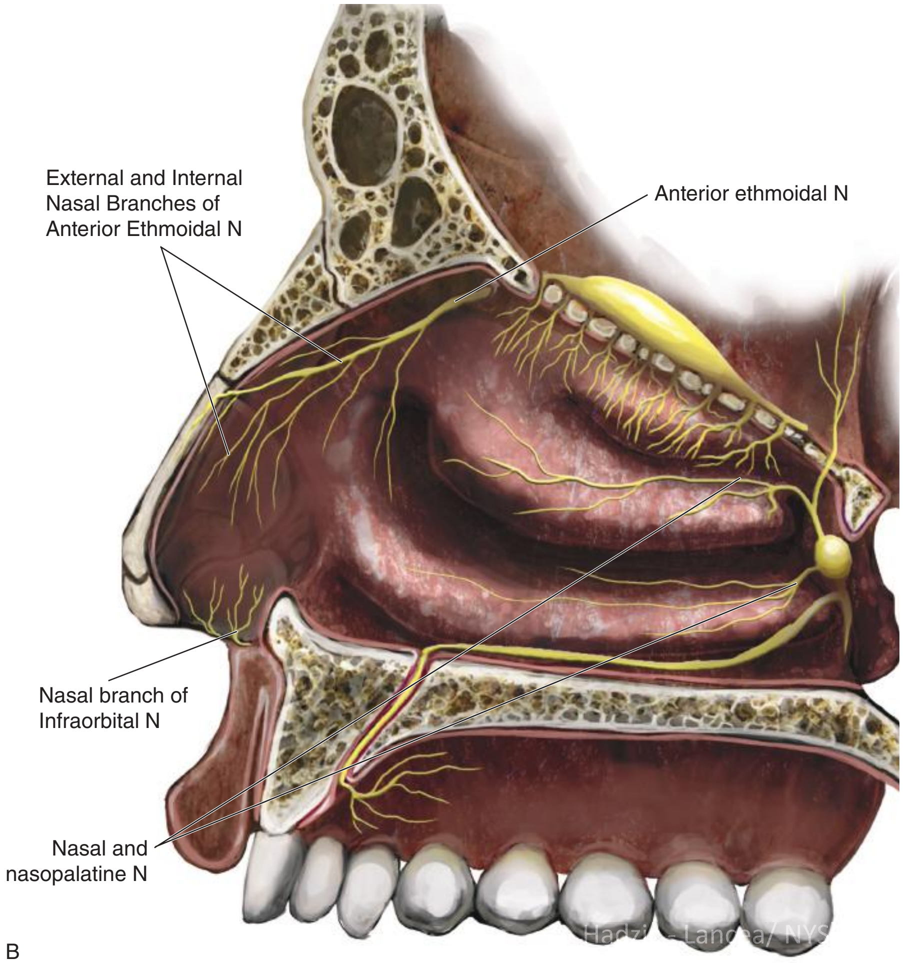


FIGURE 31–12. Innervation of the nose and nasal cavity. **A:** External nose. **B:** Septum and nasal cavity.

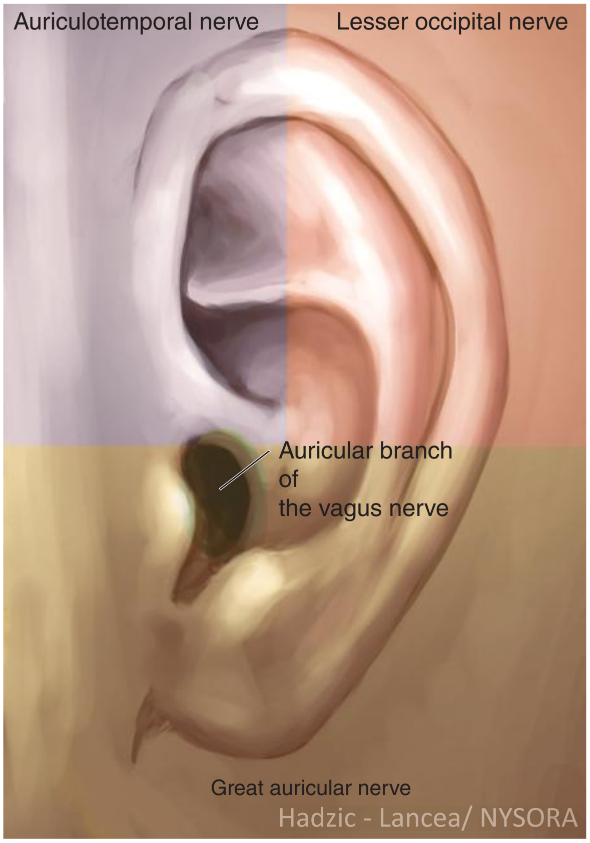
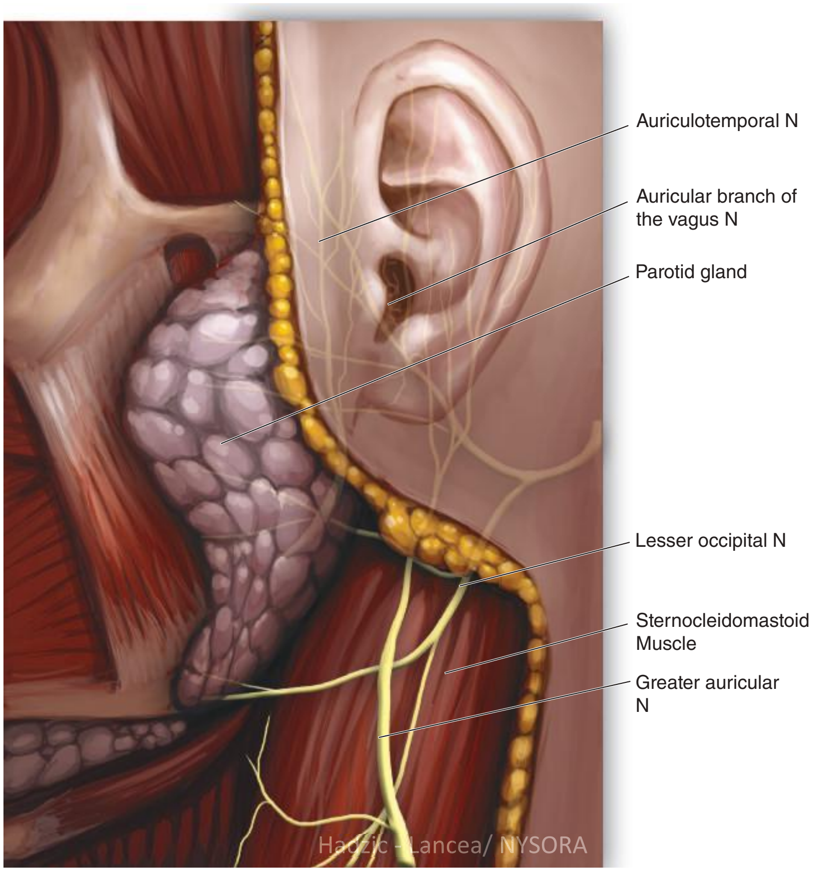


A



B

FIGURE 31–13. A and **B:** The innervation of the external ear.

- The superior two-thirds of the anterior surface are supplied by the *auriculotemporal branch* of the mandibular division of the trigeminal nerve. The auriculotemporal nerve passes through the parotid gland to ascend anterior to the auditory canal with the superficial temporal artery and passing superiorly superficial to the zygomatic arch.
- The posterior surface of the ear and the lower third of its anterior surface depend on the great auricular nerve and the lesser occipital nerve, two branches of the cervical plexus.
- The *great auricular nerve* arises from the second and third cervical nerve roots, emerges from the posterior border of the sternocleidomastoid muscle, and ascends (dividing into anterior and posterior branches) to the mandible, the parotid gland, and the pinna. It supplies the lower posterior aspect of the auricle, the lobule, and the skin of the angle of the mandible.
- The *lesser occipital nerve* arises from the ventral primary rami of the second and third cervical roots and gives innervation to the upper part of the earlobe and lateral occipital zone.
- The *auricular branch of the vagus nerve* (nerve of Arnold) innervates the concha and most of the posterior wall of the external auditory meatus (zona of Ramsay Hunt) as well as the inferior portion of the tympanic membrane.

Indication

This block is useful for analgesia after several painful procedures such as incision and drainage of an abscess or hematoma,[14] suture of lacerations of the ear or the skin surrounding the ear,[15] postauricular incisions such as tympanomastoid surgery and cochlear implants,[16] otoplasty,[17] or surgical correction of “bat ears.”[5]

In children having tympanomastoid surgery, greater auricular nerve block provides analgesia, with lower incidence of postoperative nausea and vomiting secondary to avoidance or reduction in the need for opioids.[16]

Classical Techniques

For classical techniques, regional field block around the auricle allows anesthesia of each nerve branch involved in external ear sensory innervation except the Ramsay Hunt area (Figure 31–14A).

- The auriculotemporal nerve can be blocked by injecting local anesthetic solution above the posterior portion of the zygoma, anterior to the ear and behind the superficial temporal artery. The needle (27 gauge) is inserted anterior and superior to the tragus. Caution is necessary due to the vicinity of the temporal artery.
- The greater auricular nerve and the lesser occipital nerves can be blocked distally over the mastoid process posterior to the ear. The needle is inserted behind the lower lobe of the ear and advanced following the curve of the posterior sulcus.
- Infiltration with the ring block technique also provides additional efficient analgesia of the external ear (Figure 31–14B).

The superficial cervical plexus block is anesthetizes the lesser occipital nerve and the greater auricular nerve, two of its terminal branches. This technique is described elsewhere in this volume.

Recently, a block of the auricular branch of the vagus nerve has been described for pain control following myringotomy and tube placement, tympanoplasty, and paper patch for ruptured tympanic membrane.[14] To perform this block, the tragus is everted, a 30-gauge needle is inserted into the tragus, and after aspiration, 0.2 mL of local anesthetic solution is injected (Figure 31–14C).

Complications

Intravascular injections, hematoma, deep cervical nerve block, potential phrenic nerve block, and transient inability to shrug the shoulder are potential adverse effects of the superficial plexus cervical approach behind the sternocleidomastoid muscle.

Bleeding from the needle entry site is rare, and intravascular injection should be avoided by careful aspiration.

HEAD BLOCKS

Greater Occipital Nerve Block

Anatomy

The greater occipital nerve (GON) arises from the second cervical nerve root that emerges between the atlas and the axis. It ascends between the obliquus capitis inferior and semispinalis capitis before piercing the latter muscle. It then becomes subcutaneous by piercing the trapezius aponeurosis, slightly inferior to the superior nuchal line. At this point, the GON is most often located immediately medial to the occipital artery.

The GON provides cutaneous innervation to the major portion of the posterior scalp from the level of the external occipital protuberance to the vertex.

Indications

This block is useful for pain relief after posterior craniotomies, revision or insertion of a ventriculoperitoneal shunt, as well as for diagnosis and pain treatment secondary to various headache syndromes, such as primary headache, cervicogenic headache, migraine, occipital neuralgia, and tension headache.[18]

Classical Landmark Technique

The GON is located at approximately two-thirds the distance on a line drawn from the center of the mastoid to the external occipital protuberance along the superior nuchal line, where it lies medial to the occipital artery. The pulsation of the occipital artery is easy to palpate. Palpation in this area may elicit a paresthesia or uncomfortable feeling in the distribution of the nerve. A 25- or 27-gauge needle can be used depending on the size of the patient.

The needle is directed at 90° toward the occiput; after aspiration, 1–3 mL of local anesthetic is injected. When the needle is withdrawn, pressure should be maintained over the site of injection to promote soaking the nerve with local anesthetic

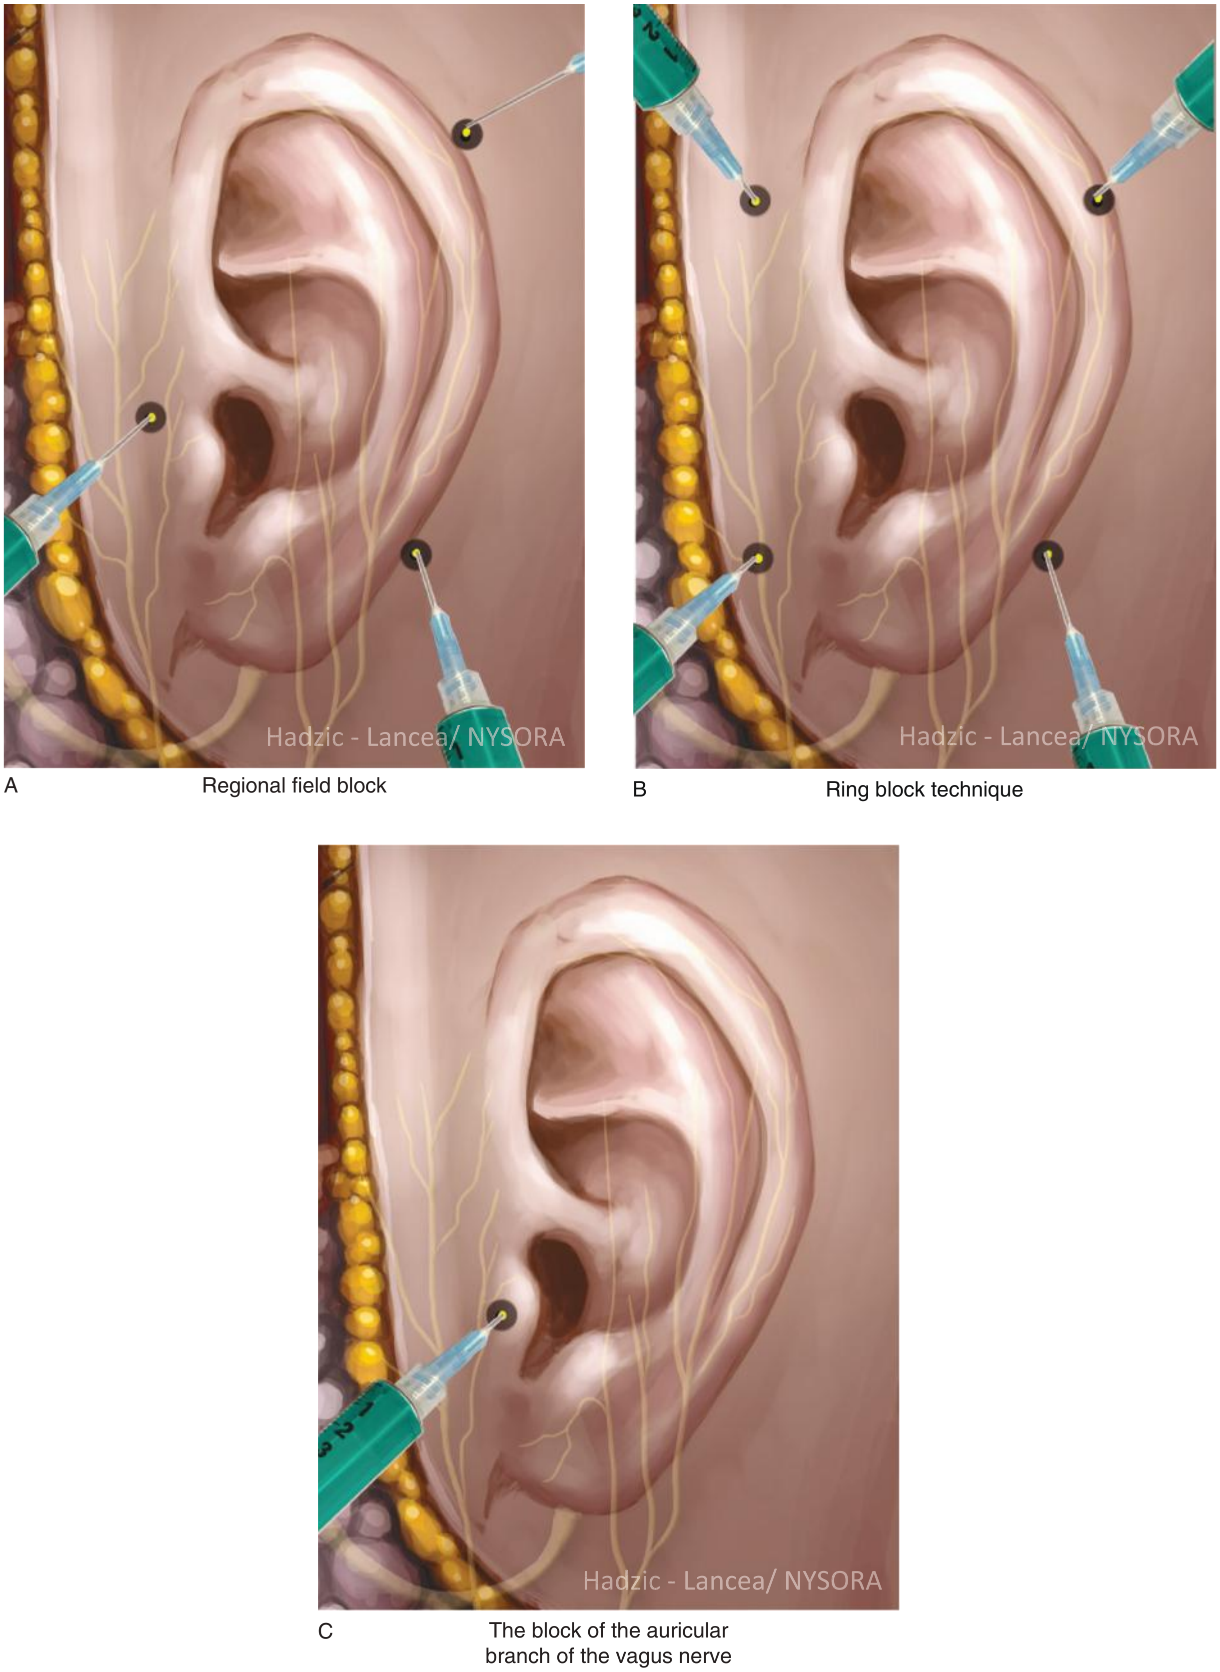


FIGURE 31–14. External ear block techniques. **A:** Regional field block. **B:** Ring block technique. **C:** Auricular block.

and to achieve hemostasis. Numbness over the top of the head is a sign of a successful block.

There is considerable interpatient variability in the nerve location, with high variability (1.5–7.5 cm) of the distance of the GON to the midline at a horizontal level between the external occipital protuberance and the mastoid process.[19] More recently, ultrasound guidance has been described to perform this block.

Ultrasound Guidance Technique

In classical distal block technique, at the level of the superior nuchal line, the ultrasound probe was initially placed in a transverse plane with the center of the probe lateral to the external occipital protuberance (Figure 31–15, area 1).

A more proximal approach at the level of the second cervical vertebra (C2), was developed by Greher and al.[20] At this new site, the GON lies superficial to the obliquus capitis inferior muscle; the relationship of the GON to this muscle appears constant and reliable. The ultrasound transducer is moved down over the atlas (C1) to the location of the spinous process of C2 (that is always bifid). The probe is then moved laterally to identify the obliquus capitis inferior muscle of the neck (Figure 31–15, area 2). The GON can be easily visualized at this level, crossing the obliquus capitis inferior muscle from caudal to rostral and lateral to medial (Figure 31–16).

Complications

There are relatively few complications because of the superficial location of the nerve. Intravascular injection is always possible and prevented by performing careful aspiration prior to injection. Caution needs to be taken because the vertebral artery and the spinal cord are close proximity to the GON. The vertebral artery is lateral to the GON deep to the obliquus capitis inferior muscle and the lamina of the atlas, while the spinal cord is medial and again deep to the muscle.

Scalp Block

Anatomy

The "scalp block" is classically described with potential blockade of seven nerves, including branches from cervical spinal rami and from the trigeminal division (Figure 31–17).

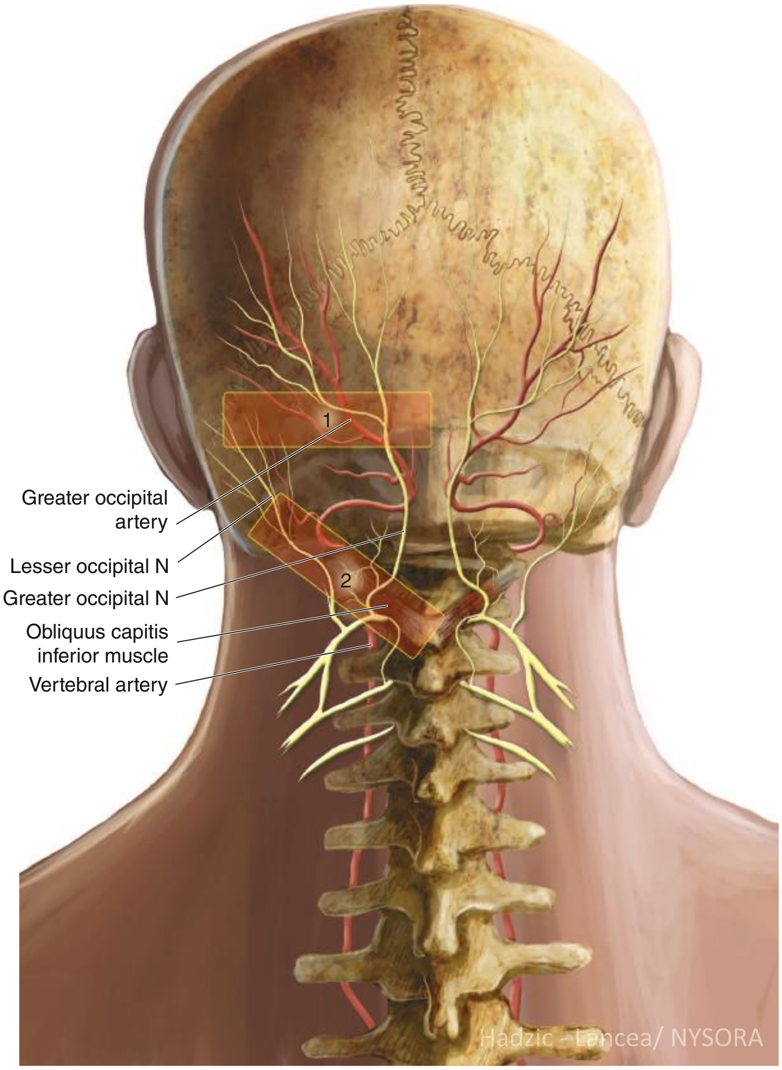

FIGURE 31–15. Transducer positions for ultrasound-guided blocks of the GON. **1,** Classic block site at the superior nuchal line; **2,** new block site at C2, over the obliquus capitis inferior muscle.

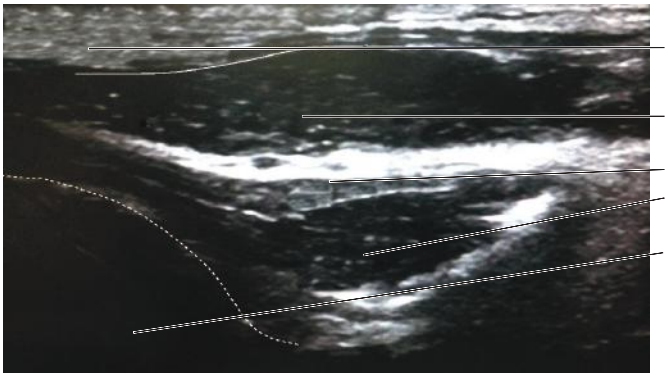

FIGURE 31–16. Sonogram of greater occipital nerve. The probe is placed along the long axis of the obliquus capitis inferior muscle (Figure 31–15, 2).

- Greater occipital, lesser occipital, and great auricular nerves originate from the ventral and the dorsal rami of C2 and C3 spinal nerves. The GON travels up to the vertex, and the lesser occipital nerve innervates skin behind the ear.
- The ophthalmic division of the trigeminal nerve gives off, via the frontal nerve, supraorbital and supratrochlear nerves, which innervate the skin from the forehead to the lamboidal suture.
- The zygomaticotemporal nerve is one of the two branches of the zygomatic nerve that arise from the maxillary division of the trigeminal nerve. It innervates a small area of the forehead and temporal area.
- The auriculotemporal nerve arises from the mandibular division of the trigeminal nerve. It innervates the posterior portion of the skin of the temple.

Indication

Scalp blocks are used in adults and children for a variety of head and neck procedures as well as in neurosurgery or in diagnostic

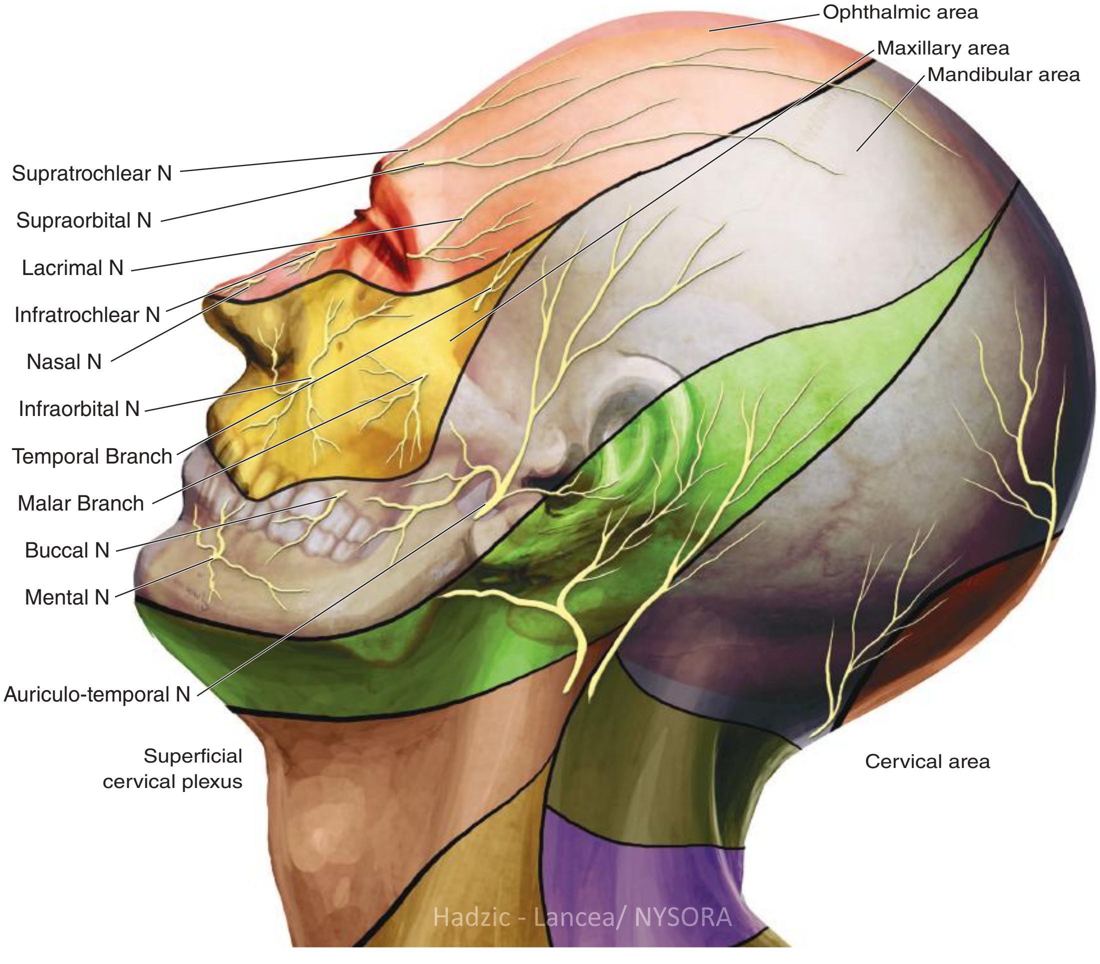

FIGURE 31–17. Innervation of the scalp.

and therapeutic management of chronic pain (eg, headache disorders of muscular and nervous etiology).

Common reasons for providing anesthesia to the scalp are repair of a laceration, foreign body removal, or exploration of scalp wounds and drainage of abscesses or subdural hematomas.

In neurosurgery, adverse hemodynamic reactions can occur during a craniotomy due to algogenic or reflexogenic events (insertion of the cranial pins of the Mayfield head holder, incision of the scalp, craniotomy, and dural incision). These reactions can be modulated by local or regional anesthesia,[21] with the additional benefit of postoperative analgesia.[22]

Local anesthesia for scalp blockad is essential in intraoperative anesthetic management of patients undergoing awake craniotomy Local scalp blocks are particularly useful when the patient's cooperation is needed for functional testing during the neurosurgical procedure, such as during epilepsy surgery and deep brain stimulation for Parkinson's disease, resections of lesions located close to or within functionally essential motor, cognitive, or sensory cortical areas.[23,24]

Infiltrational Anesthesia

All the nerves involved in the sensitivity of the scalp become superficial and accessible to anesthetic. To block the entire scalp, a circumferential infiltration of local anesthetic solution (with 1:200,000 epinephrine) above an imaginary line drawn from the occipital protuberance to the eyebrows, passing along the upper border of the ear, is necessary. Approximately 30 mL are required to perform this ring block around the scalp.

"Regional Blocks" Technique

For the "regional blocks" technique,[21] the supraorbital and supratrochlear nerves are blocked with an intradermic needle as they emerge from the orbit.

- The auriculotemporal nerves are blocked 1.5 cm anterior to the ear at the level of the tragus (see the section on regional blocks of the external ear).
- The postauricular branches of the greater auricular nerves are blocked 1.5 cm posterior to the ear at the level of the tragus (see the section on regional blocks of the external ear).
- Great and lesser occipital nerves are blocked by infiltrating along the superior nuchal line, approximately halfway between the occipital protuberance and the mastoid process (see the section on GON block).

Complications

The most common complication associated with scalp anesthesia is hematoma formation at the site of injection. Careful aspiration is suggested to avoid a potentially intravascular injection; because of the high vascularity of the scalp, the use of a diluted anesthetic solution with 1:100,000 or 1:200,000 epinephrine is usually considered safe to prevent toxic plasma drug levels.

CONCLUSION

A number of nerve block procedures can be used for surgical procedures performed on the face and scalp. The entire face area can be anesthetized using five simple nerve blocks, providing adequate anesthesia for skin procedures as well as perioperative pain management of orthopedic, craniofacial, and cancer surgery.

CHAPTER 32A

Ultrasound-Guided Cervical Plexus Block

Thomas F. Bendtsen, Sherif Abbas, and Vincent Chan

CERVICAL PLEXUS BLOCK AT A GLANCE

- Indications: carotid endarterectomy, superficial neck surgery (Figure 32A–1)
- Transducer position: transverse over the midpoint of the sternocleidomastoid muscle (posterior border)
- Goal: local anesthetic spread around the superficial cervical plexus *or* deep to the sternocleidomastoid muscle
- Local anesthetic: 5–15 mL

GENERAL CONSIDERATIONS

The goal of the ultrasound (US)-guided technique of superficial cervical plexus block is to deposit local anesthetic within the vicinity of the sensory branches of the nerve roots C2, C3, and C4 (Figures 32A–2 and 32A–3). Advantages over the landmark-based technique include the ability to visualize the spread of local anesthetic in the correct plane, which therefore increases the success rate, and to avoid a needle insertion that is too deep and the inadvertent puncture of neighboring structures.

Both US-guided superficial and deep cervical plexus blocks have been well described.[1–8] The deep cervical plexus block is an advanced block with a risk of potentially serious complications, such as intrathecal injection or injection into the vertebral artery. For this reason, we will focus primarily on the superficial cervical plexus block technique. It is simpler, safer, and, for most indications, it is equally as suitable as the deep cervical plexus block. An understanding of the fascial planes of the neck and the location of each of these blocks is necessary (see Figure 32A–2). For the superficial cervical plexus block, local anesthetic is injected superficially to the deep cervical fascia. For the superficial (intermediate) cervical plexus block, the injection is made between the investing layer of the deep cervical fascia and the prevertebral fascia, whereas for the deep cervical plexus block, local anesthetic is deposited deep to the prevertebral fascia.

ULTRASOUND ANATOMY

The sternocleidomastoid muscle (SCM) forms a "roof" over the nerves of the superficial cervical plexus (C2–4) (see Figure 32A–2). The roots combine to form the four terminal branches (the lesser occipital, greater auricular, transverse cervical, and supraclavicular nerves) and emerge from behind the posterior border of the SCM (Figures 32A–3, 32A–4, and 32A–5). The plexus can be visualized as a small collection of hypoechoic nodules (honeycomb appearance or hypoechoic [dark] oval structures) immediately deep or lateral to the posterior border of the SCM (see Figure 32A–5), but this is not always apparent. Occasionally, the greater auricular nerve is visualized on the superficial surface of the SCM as a small, round, hypoechoic

FIGURE 32A–1. Expected sensory distribution of cervical plexus blockade.

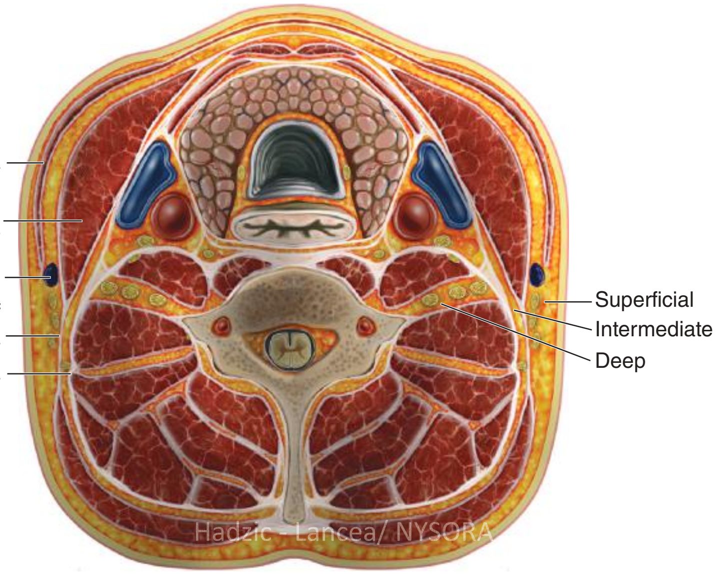

FIGURE 32A–2. Site of injection of local anesthetic for superficial, intermediate, and deep cervical plexus blocks.

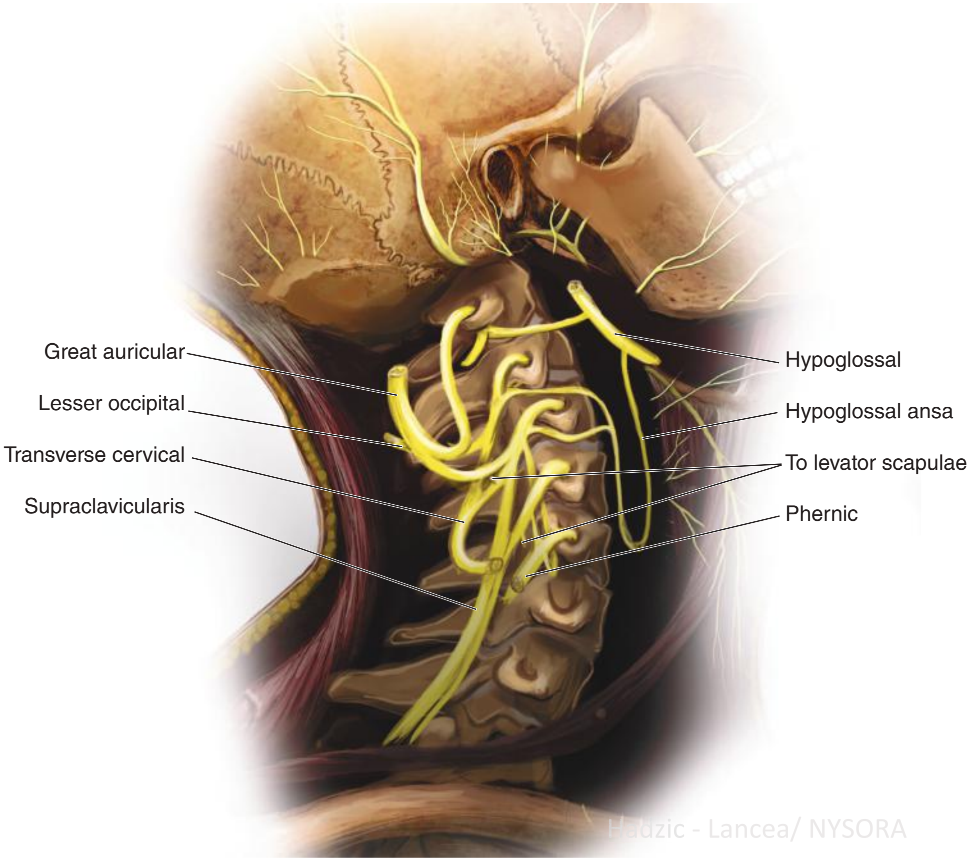

FIGURE 32A–3. Anatomy of the deep cervical plexus and its main branches and anastomoses.

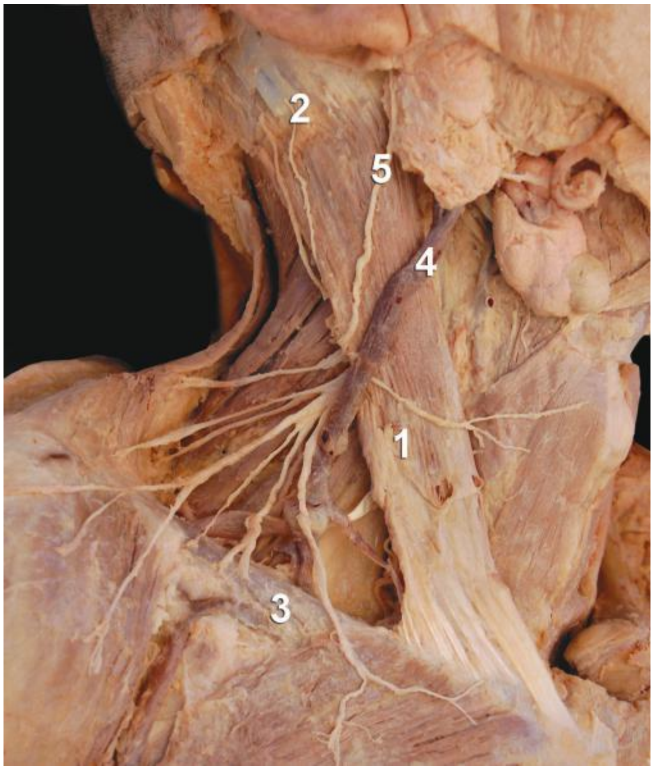

FIGURE 32A–4. Anatomy of the cervical plexus. The cervical plexus is seen emerging behind the posterior border of the sternocleidomastoid muscle at the intersection of the muscle with the external jugular vein. **1:** Sternocleidomastoid muscle. **2:** Mastoid process. **3:** Clavicle. **4:** External jugular vein. **5:** Greater auricular nerve. Supraclavicular nerves are seen crossing the clavicle.

structure. The SCM is separated from the brachial plexus and the scalene muscles by the prevertebral fascia, which can be seen as a hyperechoic linear structure. The cervical plexus lies posterior to the SCM and immediately superficial to the

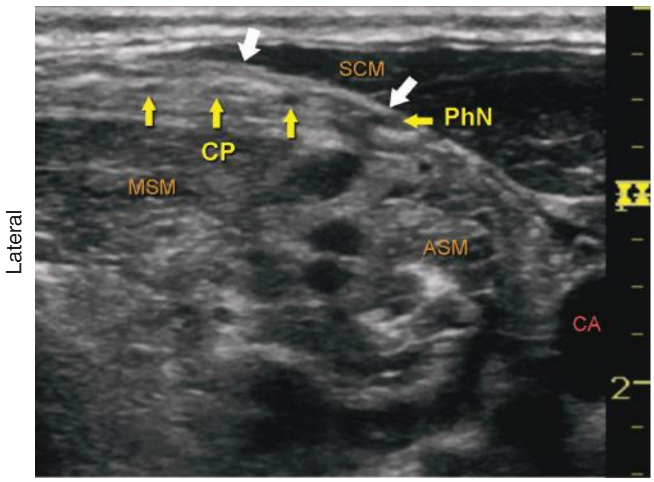

FIGURE 32A–5. Cervical plexus (transverse view). Branches of the cervical plexus (CP) are seen superficial to the prevertebral fascia, which covers the middle (MSM) and anterior (ASM) scalene muscles, and posterior to the sternocleidomastoid muscle (SCM). White arrows, investing fascia of deep cervical fascia; CA, carotid artery; PhN, phrenic nerve.

prevertebral fascia overlying the interscalene groove (see Figure 32A–5). Strictly speaking, the technique we describe, with an injection between the investing layer of the deep cervical fascia and the prevertebral fascia, is thus an intermediate cervical plexus block.

DISTRIBUTION OF ANESTHESIA

The superficial cervical plexus block results in anesthesia of the skin of the anterolateral neck and the ante-auricular and retro-auricular areas, as well as the skin overlying and immediately inferior to the clavicle on the chest wall (Figures 32A-1 and 32A-6). The mental, infraorbital, and supraorbital nerves are branches of the trigeminal nerve and are not blocked with cervical plexus block.

EQUIPMENT

The equipment needed for a cervical plexus block includes the following:

- Ultrasound machine with a linear transducer (8–18 MHz), sterile sleeve, and gel
- Standard nerve block tray
- A 10-mL syringe containing local anesthetic
- A 5 cm, 23- to 25-gauge needle attached to low-volume extension tubing
- Sterile gloves

LANDMARKS AND PATIENT POSITIONING

Any patient position that allows for comfortable placement of the ultrasound transducer and needle advancement is appropriate. This block is typically performed in the supine or semi-sitting position, with the head turned slightly away from the side to be blocked to facilitate operator access (Figure 32A–7). The patient's neck and upper chest should be exposed so that the relative length and position of the SCM can be assessed. The posterior border of the SCM can be difficult to locate, especially in obese patients. Asking the patient to lift his or her head off the bed can facilitate palpation of the posterior border of the SCM.

GOAL

The goal of this block is to place the needle tip in the fascial layer underneath the SCM adjacent to the cervical plexus, which is contained within the tissue space between the cervical fascia and posterior sheath of the SCM. If the elements of the cervical plexus are not easily visualized, the local anesthetic can be deposited in the plane immediately deep to the SCM and superficial investing layer of deep cervical fascia and superficial to the prevertebral fascia. A volume of 5-10 mL of local anesthetic usually suffices.

TECHNIQUE

With the patient in the proper position, the skin is disinfected and the transducer is placed on the lateral neck, overlying the

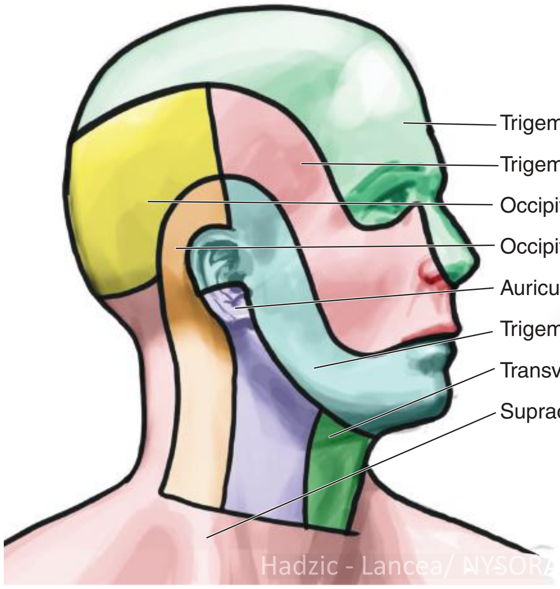

FIGURE 32A–6. Innervation of the lateral aspect of the face and neck.

FIGURE 32A–7. Cervical plexus block. (**A**) Transverse approach. (**B**) Longitudinal approach.

SCM at the level of its midpoint (approximately the level of the cricoid cartilage). Once the SCM has been identified, the transducer is moved posteriorly until the tapering posterior edge is positioned in the middle of the screen. At this point, an attempt should be made to identify the brachial plexus and/or the interscalene groove between the anterior and middle scalene muscles. The cervical plexus is visible as a small collection of hypoechoic nodules (honeycomb appearance) immediately superficial to the prevertebral fascia that overlies the interscalene groove (see Figures 32A–2 and 32A–5).

Once the plexus has been identified, the needle is passed through the skin, platysma, and investing layer of the deep cervical fascia, and the tip is placed adjacent to the plexus (Figure 32A–8). Because of the relatively shallow position of the target, both in-plane (from the medial or lateral sides) and out-of-plane approaches may be used. Following negative aspiration, 1–2 mL of local anesthetic is injected to confirm the proper injection site. The remainder of the local anesthetic (5–15 mL) is administered to envelop the plexus (Figure 32A–9).

If the plexus is not visualized, an alternative substernocleidomastoid approach may be used. In this case, the needle is passed behind the SCM, and the tip is directed to lie in the space between the SCM and the prevertebral fascia, close to the posterior border of the SCM (Figures 32A–7b, 32A–10, and 32A–11). Local anesthetic (5–15 mL) is administered and should be visualized layering out between the SCM and the underlying prevertebral fascia (Figure 32A–12). If the injection of local anesthetic does not appear to result in an appropriate spread, needle repositioning and further injections may be necessary. Because the cervical plexus is made up of purely sensory nerves, high concentrations of local anesthetic are usually not required; ropivacaine 0.25–0.5%, bupivacaine 0.25%, or lidocaine 1% is a sufficient.

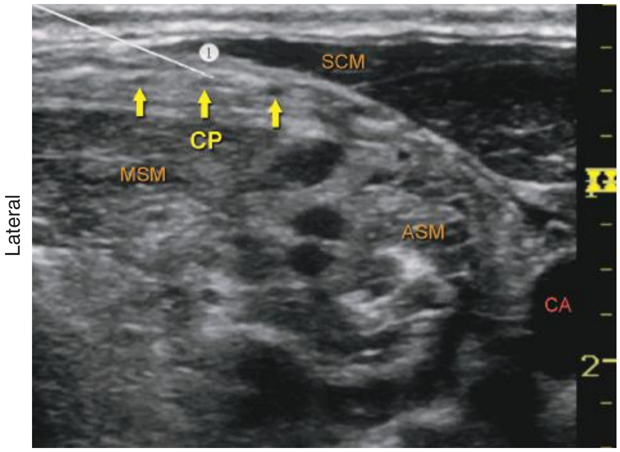

FIGURE 32A–8. Superficial cervical plexus (transverse view): needle path (1) and position to block the cervical plexus (CP). The needle is seen positioned underneath the lateral border of the sternocleidomastoid muscle (SCM) and superficial to the prevertebral fascia with the transducer in a transverse position (see Figure 32A–7a). ASM, anterior scalene muscle; CA, carotid artery; MSM, middle scalene muscle.

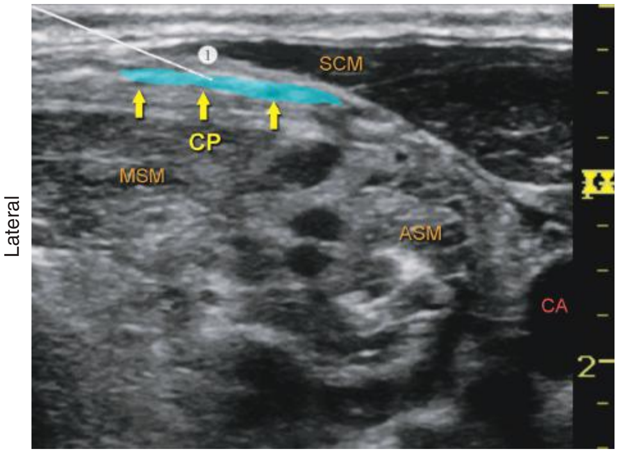

FIGURE 32A–9. Cervical plexus (transverse view): desired distribution of local anesthetic (blue-shaded area) to block the cervical plexus. Needle path: 1. ASM, anterior scalene muscle; CA, carotid artery; CP, cervical plexus; MSM, middle scalene muscle; SCM, sternocleidomastoid muscle.

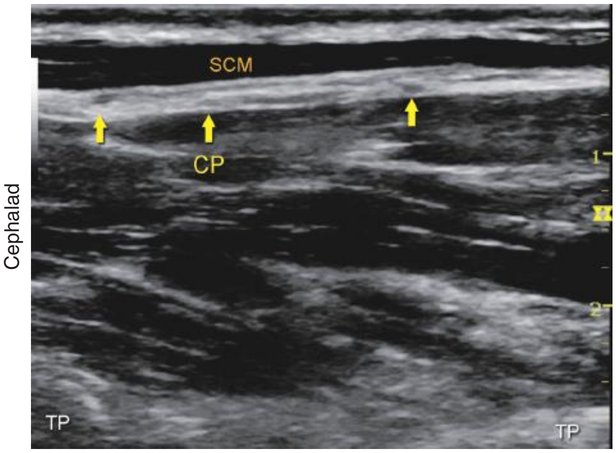

FIGURE 32A–10. Cervical plexus (longitudinal view): Elements of the cervical plexus (CP) underneath the lateral border of the sternocleidomastoid muscle (SCM).

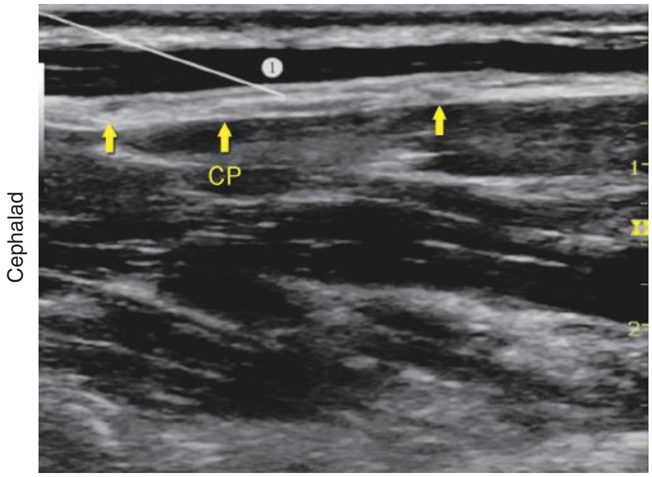

FIGURE 32A–11. Cervical plexus (longitudinal view): needle position to block the cervical plexus (CP).

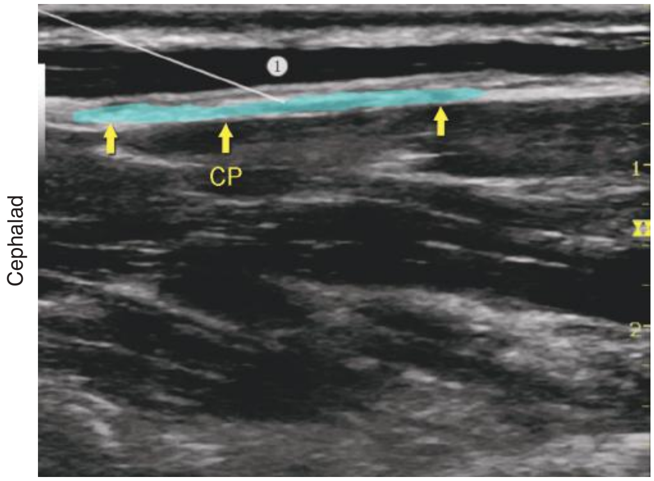

FIGURE 32A–12. Cervical plexus (longitudinal view): desired spread of local anesthetic under the deep cervical fascia to block the cervical plexus (CP).

TIPS

- Visualization of the plexus is *not* necessary to perform this block because the plexus may not always be readily apparent. Administration of 10 mL of local anesthetic deep to the SCM provides a reliable block without the position of the plexus needing to be confirmed.

CHAPTER 32A

CHAPTER 32B

Ultrasound-Guided Interscalene Brachial Plexus Block

Philippe E. Gautier, Catherine Vandepitte, and Jeff Gadsden

INTERSCALENE BRACHIAL PLEXUS BLOCK AT A GLANCE

- Indications: shoulder and upper arm surgery, surgery of the clavicle (combined with cervical plexus block)
- Transducer position: transverse on neck, 3–4 cm superior to clavicle, over external jugular vein (Figure 32B–1)
- Goal: local anesthetic spread around superior and middle trunks of brachial plexus, between the anterior and middle scalene muscles
- Local anesthetic: 7–15 mL

GENERAL CONSIDERATIONS

US guidance allows for visualization of the spread of the LA and additional injections around the brachial plexus if needed to ensure adequate spread of local anesthetic, improving block success. The ability to visualize local anesthetic spread and to inject multiple aliquots also allows for a reduction in the volume of local anesthetic required to accomplish the block.[1,2]

ULTRASOUND ANATOMY

The brachial plexus at the interscalene level is seen lateral to the carotid artery and internal jugular vein, between the anterior and middle scalene muscles (Figures 32B–2 and 32B–3). The prevertebral fascia, superficial cervical plexus, and sternocleidomastoid muscle are seen superficial to the plexus. The transducer is moved in the proximal-distal direction until two or more of the brachial plexus elements are seen in the space between the scalene muscles. Depending on the depth of field selected and the level at which scanning is performed, the first rib and/or the apex of the lung may be seen. The brachial plexus is typically visualized at a depth of 1–3 cm.

BLOCKADE DISTRIBUTION

The interscalene approach to brachial plexus blockade results in reliable anesthesia of the shoulder and upper arm (Figure 32B–4). The supraclavicular branches of the cervical plexus, supplying the skin over the acromion and clavicle, are also blocked due to the proximal and superficial spread of local anesthetic. The inferior trunk (C8-T1) is usually spared, unless the injection occurs at a more distal level of the brachial plexus.

EQUIPMENT

The equipment needed for an interscalene brachial plexus block includes the following:

- Ultrasound machine with linear transducer (8–14 MHz), sterile sleeve, and gel
- Standard nerve block tray
- A 20-mL syringe containing local anesthetic
- A 5-cm, 22-gauge, short-bevel, insulated stimulating needle
- Peripheral nerve stimulator
- Opening injection pressure monitoring system
- Sterile gloves

LANDMARKS AND PATIENT POSITIONING

Any position that allows for comfortable placement of the ultrasound transducer and needle advancement is appropriate. The block is typically performed with the patient in a supine, beach

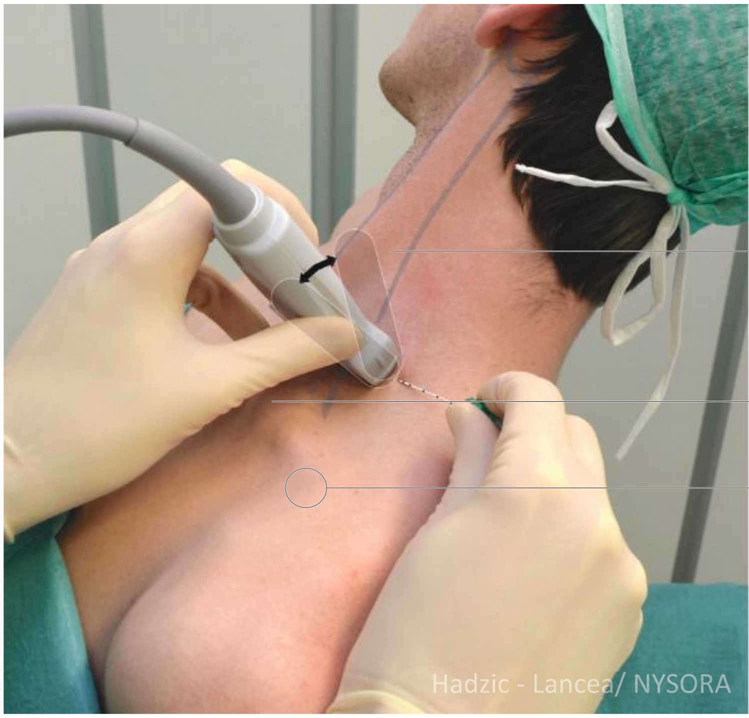

FIGURE 32B–1. Ultrasound-guided interscalene brachial plexus block: transducer and needle position to obtain the desired ultrasound image for an in-plane approach. The knowledge of external landmarks substantially facilitates and shortens the time to obtain the view necessary for block performance. The transducer is positioned behind the clavicular head of the sternocleidomastoid muscle (SCM) and over the external jugular vein (not seen). The patient is in a semi-sitting position. Tilting the transducer in the caudad direction can facilitate recognition of the brachial plexus (arrow).

chair, or semilateral decubitus position, with the patient's head facing away from the side to be blocked. The latter position may prove more ergonomic, especially during an in-plane approach from the lateral side, in which the needle enters the skin at the posterolateral aspect of the neck. A slight elevation of the head of the bed is often more comfortable for the patient and allows for better drainage and less prominence of the neck veins. The patient should be asked to reach for the ipsilateral knee in order to lower the shoulder and provide more space for the block performance.

Knowledge of the underlying anatomy and the position of the brachial plexus is important to facilitate recognition of the ultrasound anatomy. Scanning usually begins just below the level of the cricoid cartilage and medial to the sternocleidomastoid muscle with the goal of identifying the carotid artery.

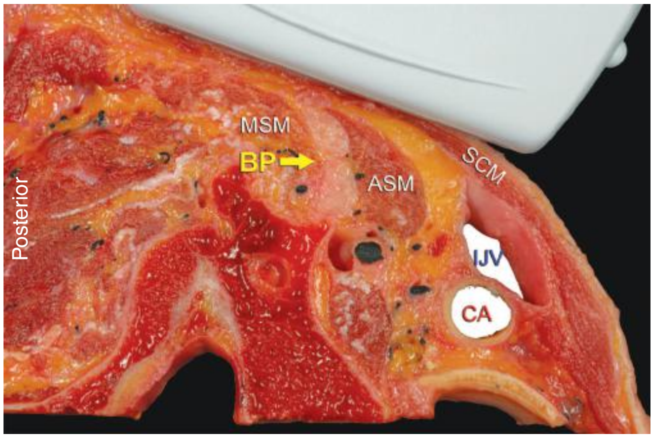

FIGURE 32B–2. Relevant anatomy for interscalene brachial block and transducer position to obtain the desired views. The brachial plexus (BP) is seen between middle scalene muscle (MSM) laterally and the anterior scalene muscle (ASM) medially. The ultrasound image often includes a partial view of the lateral border of the sternocleidomastoid muscle (SCM) as well as the internal jugular vein (IJV) and carotid artery (CA). The transverse process of one of the cervical vertebrae is also often seen.

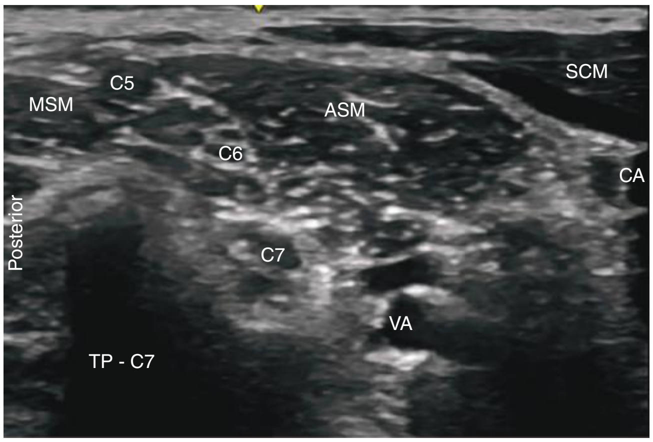

FIGURE 32B–3. Ultrasound image of the brachial plexus at the interscalene groove. The BP is seen positioned between the anterior scalene muscle (ASM) and the middle scalene muscle (MSM). In this particular image, the vertebral artery (VA), carotid artery (CA), and the transverse process of C7 (TP-C7) are also seen.

FIGURE 32B–4. Sensory distribution of the interscalene brachial plexus block (in red). Ulnar nerve distribution area (C8-T1) can also be accomplished by using larger volume (e.g. 15-20 ml) and using low interscalene block where the injection occurs between the ISB and supraclavicular block.

GOAL

The goal of this block is to place the needle in the tissue space between the anterior and middle scalene muscles and inject local anesthetic until the spread around the brachial plexus is documented by ultrasound. The volume of the local anesthetic and number of needle insertions are determined during the procedure and depend on the adequacy of the observed spread of local anesthetic.

TECHNIQUE

With the patient in the proper position, the skin is disinfected and the transducer is positioned in the transverse plane to identify the carotid artery (Figure 32B–5). Once the artery has been identified, the transducer is moved slightly laterally across the neck. The goal is to identify the anterior and middle scalene muscles and the elements of the brachial plexus that is located between them.

Clinical Pearl

- When visualization of the brachial plexus between the scalene muscles proves difficult, a "traceback" technique can be used.[3] The transducer is lowered to the supraclavicular fossa. At this position, the brachial plexus is identified posterior and superficial to the subclavian artery (Figure 32B–6). From here, the brachial plexus is traced cranially to the desired level.

It is recommended to use the color Doppler to identify vascular structures and avoid them. The needle is then inserted in plane toward the brachial plexus, typically in a lateral-to-medial direction (Figure 32B–7), although a medial-to-lateral needle orientation can also be used if there is no room for the former. The needle should always be aimed in between the roots instead of directly at them in order to minimize the risk of accidental nerve injury.

As the needle passes through the prevertebral fascia, a certain "pop" is often appreciated. When nerve stimulation is used (0.5 mA, 0.1 msec), the entrance of the needle in the interscalene groove is often associated with a motor response of the shoulder, arm, or forearm as another confirmation of proper needle placement. After careful aspiration to rule out intravascular needle placement, 1–2 mL of local anesthetic is injected to verify proper needle placement (Figure 32B–8a). It is necessary to ensure that high resistance to injection is absent to decrease the risk of intrafascicular injection. Injection of several milliliters of local anesthetic often displaces the brachial plexus away from the needle. An additional advancement of the needle 1–2 mm toward the brachial plexus may be beneficial to ensure proper spread of the local anesthetic (Figure 32B–8b). When injection of the local anesthetic does not appear to result in a spread around the brachial plexus, additional needle repositioning and injections may be necessary.

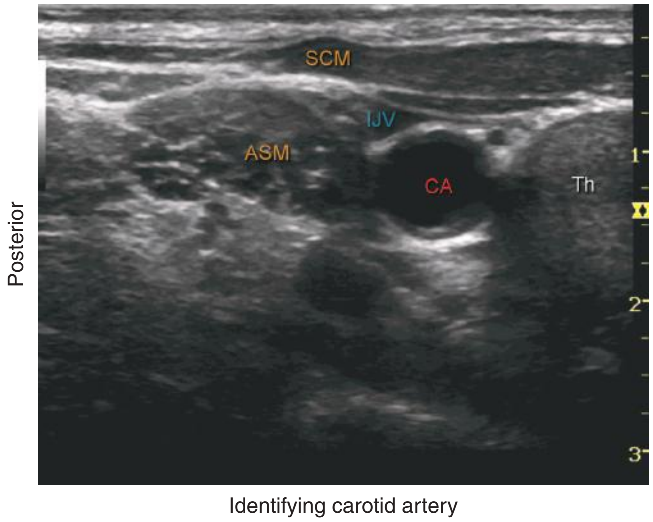

FIGURE 32B–5. Ultrasound image just below the level of the cricoid cartilage and medial to the sternocleidomastoid muscle (SCM). ASM, anterior scalene muscle; CA, carotid artery; IJV, internal jugular vein; SCM, sternocleidomastoid muscle; Th, thyroid gland.

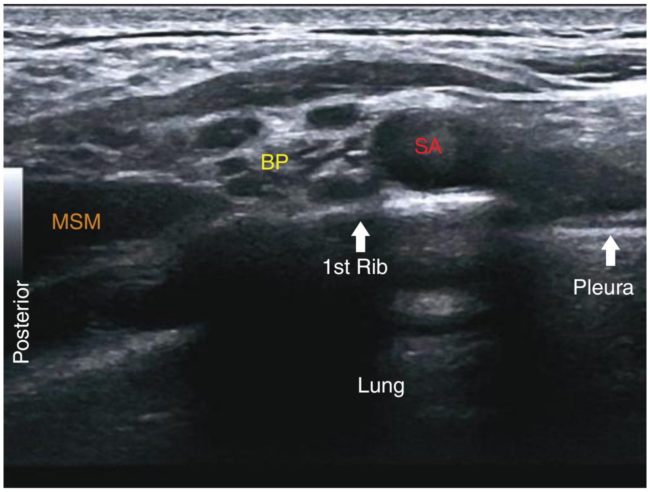

FIGURE 32B–6. View of the brachial plexus (BP) at the supraclavicular fossa. When identification of the brachial plexus at the interscalene level proves difficult, the transducer is positioned at the supraclavicular fossa to identify the BP superficial and posterior to the subclavian artery (SA). The transducer is then slowly moved cephalad while continuously visualizing the brachial plexus until the desired level is reached.

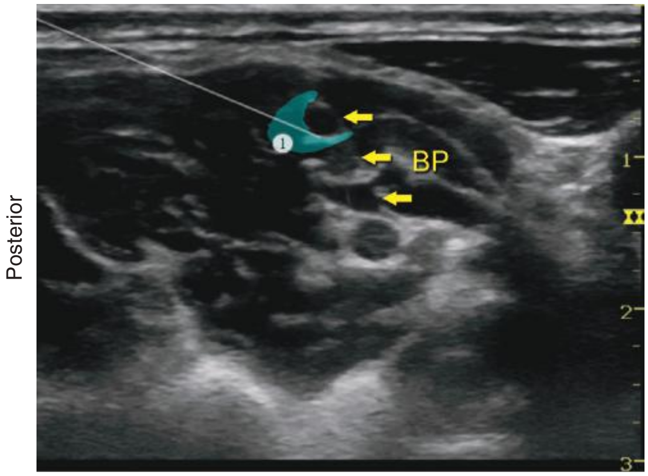
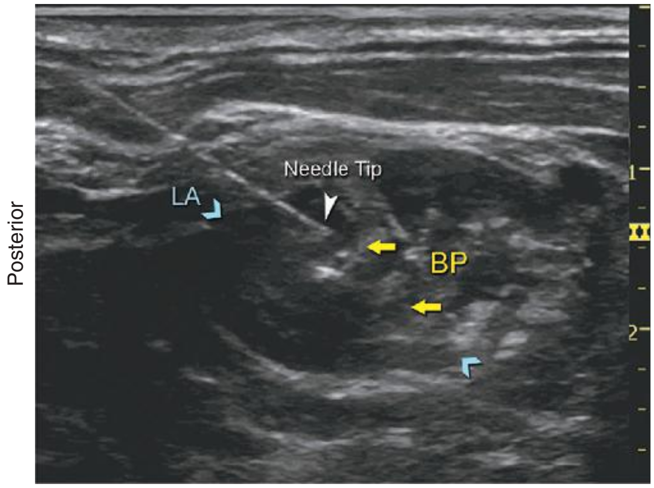
B

FIGURE 32B–7. (**A**) Transducer placement and needle insertion. (**B**) Position of the needle (1) for the interscalene brachial plexus block using an in-plane approach. The needle tip is seen in contact with the elements of the brachial plexus (yellow arrows); this always results in high injection pressure (> 15 psi)—indicating that the needle should be withdrawn slightly away from the trunk.



A



B

FIGURE 32B–8. (**A**) A small volume of local anesthetic (blue-shaded area) is injected through the needle to confirm proper needle placement. A properly placed needle tip will result in distribution of local anesthetic between and/or alongside roots of the brachial plexus (BP). (**B**) An actual needle (white arrowhead) placement in the interscalene groove, with dispersion of local anesthetic (LA) (blue-shaded area or arrows) surrounding the BP.

TIPS

- It is not necessary to elicit a motor response to nerve stimulation; however, when it occurs at intensities < 0.5 mA, the needle should be slightly withdrawn before injecting as it may be intraneural.
- The neck is a highly vascular area, and care must be exercised to avoid needle placement or injection into the vascular structures. Of particular importance is to avoid the vertebral artery and branches of the thyrocervical trunk: the inferior thyroid artery, suprascapular artery, and transverse cervical artery. Use color Doppler imaging at least once before inserting the needle to locate any vessel that might be in the path of the needle. Anatomical variations are common.[4]

- Never inject against high resistance because such resistance may indicate needle–nerve contact or an intrafascicular injection. A high opening injection pressure (> 15 psi) is always present with needle–root contact.[5] Thus, a seemingly extraneural injection may in fact be subepineural.[6] An intraneural injection may spread proximally into the spinal canal.[7]
- One useful maneuver to ensure injection into the proper compartment, after injecting 5–7 mL, is to trace the plexus down to the supraclavicular fossa (while keeping the needle steady to avoid injury). If the injection is performed insede the brachial plexus "sheath," the correct spread can be seen very clearly (Figure 33B–9). The probe can then be moved back until the needle is visualized in order to complete the injection. If the brachial plexus appears unchanged in the supraclavicular area, one must question whether the injection was done outside the correct compartment (see Figure 32B–9).
- The lateral-to-medial insertion is often chosen to prevent injury to the phrenic nerve, which is typically located anteriorly to the anterior scalene, although one should be aware that the dorsal scapular nerve and the long thoracic nerve usually course through the middle scalene and could potentially be injured as well (Figure 32B–10).[8–10]
- It is common for C6 and C7 to split proximally. It is prudent to avoid injecting between the nerves coming from a single root, as this may result in an intraneural injection. Instead, it is safer to inject between C5 and C6, superficial to C5, or deep to C6 (Figure 32B–11).[11]
- Another relatively common anatomical variation involves the C5 root travelling through the anterior scalene for part of its course (Figure 32B–12). To block this anatomical variant, the root should be traced distally until it enters the interscalene groove.
- Multiple injections are best avoided as they are not usually needed to successfully block the brachial plexus and may carry higher risk of nerve injury.
- In an adult patient, 7–15 mL of local anesthetic is usually adequate for a successful and rapid onset of blockade. Smaller volumes of local anesthetic may also be effective;[12,13] however, the rate of success of smaller volumes

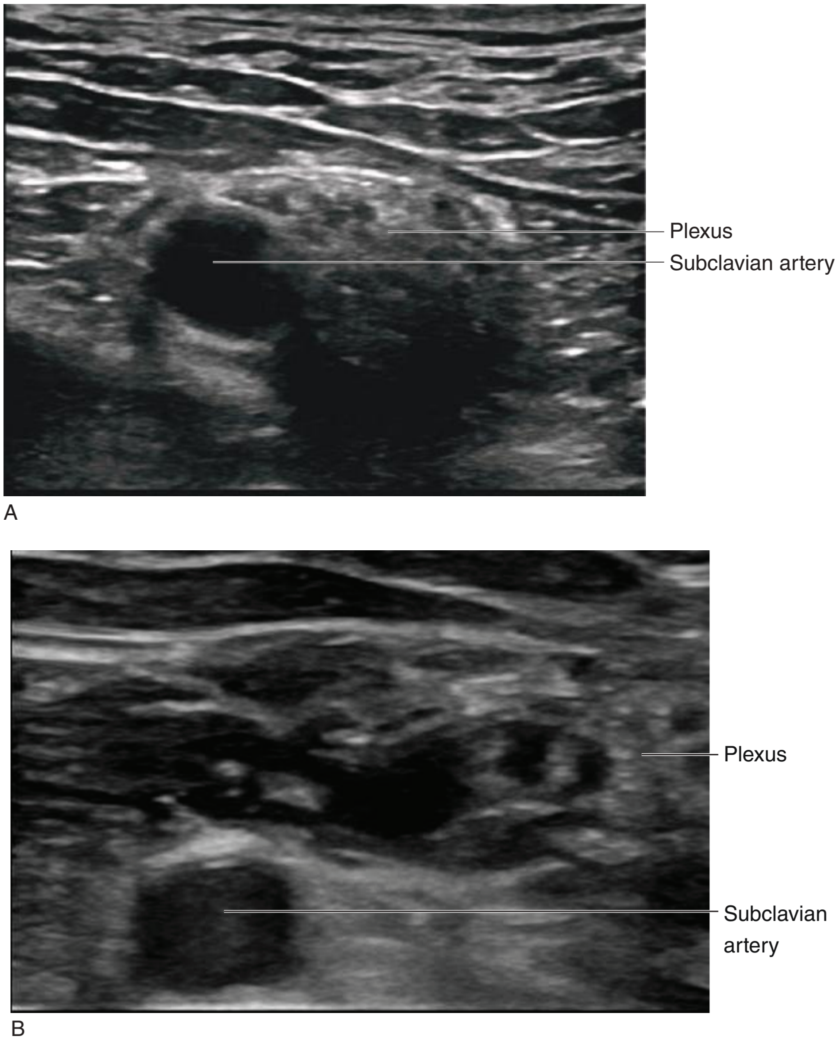


FIGURE 32B–9. Diffusion of local anesthetic solution to the supraclavicular area during interscalene block performance. (**A**) Before injection. (**B**) After injection of 10 mL at the interscalene level. The nerves lateral to the subclavian artery are surrounded by local anesthetic and appear deeper. This confirms that the injection was performed in the correct space.

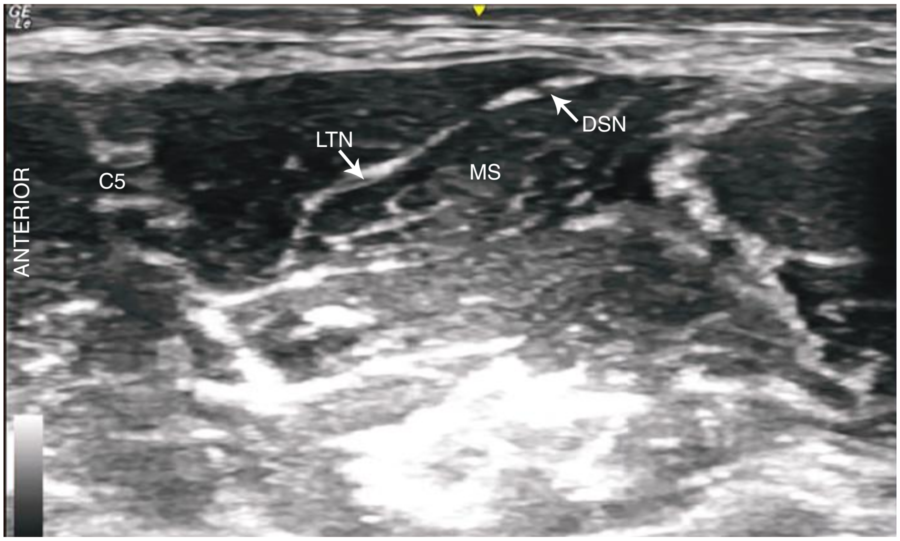

FIGURE 32B–10. Dorsal scapular nerve (DSN) and long thoracic nerve (LTN) visible in the middle scalene muscle (MS).

in everyday clinical practice may be inferior to those reported in meticulously conducted clinical trials.

PHRENIC NERVE BLOCKADE

Phrenic nerve blockade is common following ISB and may compromise respiratory function in patients with pre-existing pulmonary pathology. Four main strategies[14] can be used in such patients to provide analgesia after shoulder surgery while avoiding phrenic blockade: (1) decreasing local anesthetic volume; (2) performing the ISB more caudad in the neck, around C7; (3) using a supraclavicular block;[15] and (4) using a suprascapular nerve block (possibly in association with an axillary nerve block).

The phrenic nerve lies just superficially to the interscalene groove at the level of the cricoid cartilage and courses caudad and anteriorly and distally along the superficial aspect of the anterior scalene muscle along the neck.[16]

The use of a low volume of local anesthetic (eg, 5 mL) reduces the incidence of phrenic nerve blockade[17–19] but may also reduce the duration of analgesia[20] and possibly decreases the success rate. Higher volumes (10 mL) injected at the level of the cricoid would cause phrenic nerve blockade.[21]

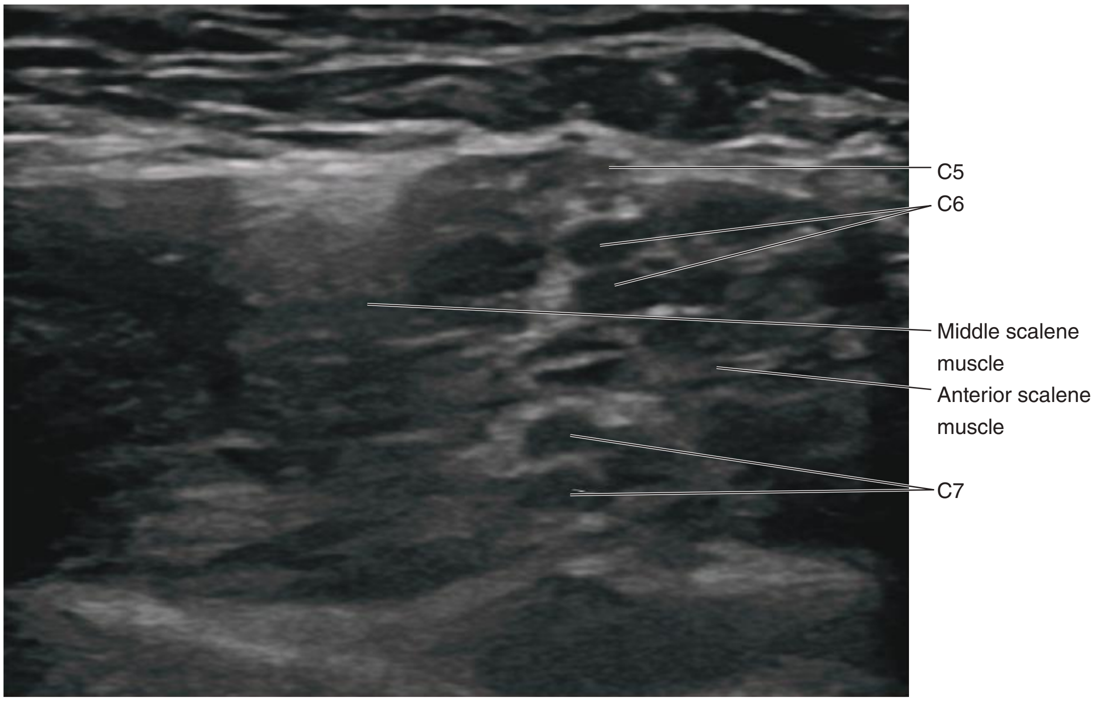

FIGURE 32B–11. Split C6 and C7 roots in the interscalene groove.

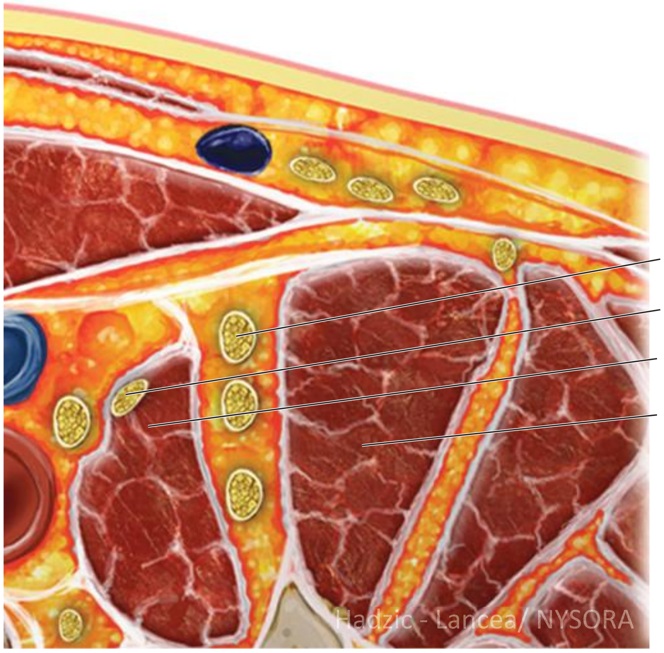

FIGURE 32B–12. Anatomic variation showing the C5 root located in the anterior scalene muscle. To block this anatomical variant, the root should be traced distally until it enters the interscalene groove.

The function of the phrenic nerve can be assessed using ultrasound in M-mode[22] during which a low-frequency curvilinear probe is positioned under the rib cage on the anterior axillary line to evaluate the hemidiaphragm motion (Figure 32B–13).

Of note, some authors have recommended using a combination of suprascapular nerve and axillary nerve blockade to provide postoperative analgesia with minimal motor blockade distal to the shoulder with a lower risk of phrenic nerve blockade and other complications of interscalene block.[23–27] The targeted nerves are small, and may prove difficult to find in obese patient. Moreover, these blocks will not provide surgical anesthesia.

Another issue that must be considered is persistent phrenic nerve palsy. There is little agreement as to what causes persistent phrenic nerve palsy, but it seems to be at least in part related to inflammation and nerve entrapment rather than direct needle trauma.[28] A contribution of cervical spine disease has been suggested.[29] Other factors may be involved, as most patients in published series have been male, overweight or obese, and middle-aged.[30]

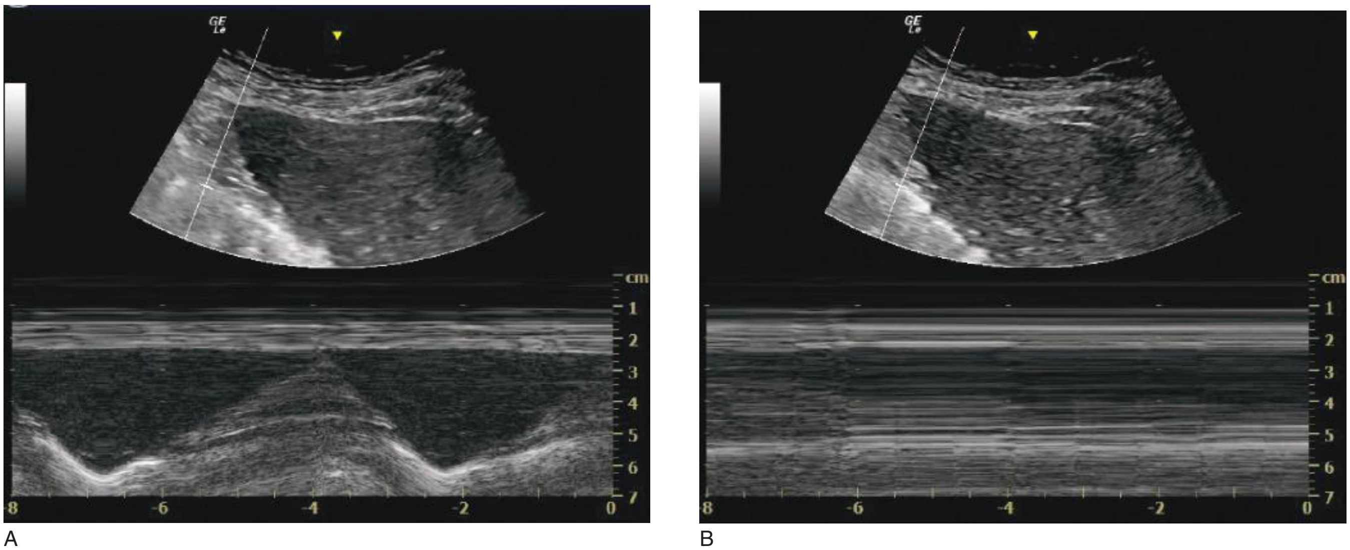

FIGURE 32B–13. Imaging of the right hemidiaphragm under the ribcage on the anterior line. (**A**) Before interscalene block. (**B**) After interscalene block with phrenic nerve block.

CONTINUOUS ULTRASOUND-GUIDED INTERSCALENE BLOCK

The goal of the continuous interscalene block is to place the catheter in the vicinity of the elements of the brachial plexus between the scalene muscles. The procedure consists of: (1) needle placement; (2) LA injection to assure the proper needle tip position and "open up the space" for catheter (3) catheter advancement; (4) Injection through the catheter while monitoring on US to verify its therapeutic position and (5) securing the catheter. For the first two phases of the procedure, ultrasound can be used to ensure accuracy. The needle is typically inserted in plane from the lateral-to-medial direction and underneath the prevertebral fascia to enter the interscalene space (Figure 32B–14), although other needle orientations, such as out-of-plane or aiming caudad, may also be used.

Proper needle placement can also be confirmed by obtaining a motor response of the deltoid muscle, arm, or forearm (0.5 mA, 0.1 msec), at which point 4–5 mL of local anesthetic can be injected. This small dose of local anesthetic serves to ensure adequate distribution of local anesthetic as well as to make the advancement of the catheter more comfortable to the patient. This first phase of the procedure does not significantly differ from the single-injection technique. The second phase of the procedure involves maintaining the needle in the proper position and inserting the catheter 2–3 cm into the interscalene space within the vicinity of the brachial plexus (Figure 32B–15). Catheter insertion can be accomplished by a single operator or with an assistant. Proper catheter location can be confirmed either by visualizing the course of the catheter or by an injection of local anesthetic through the catheter. When this proves difficult, an alternative is to inject a small amount of air (1 mL) to confirm the catheter tip location.

The catheter is secured either by taping to the skin with or without tunneling. Some clinicians prefer one over the other. However, the decision about which method to use can be based on patient age, duration of catheter therapy, and/or anatomy.

FIGURE 32B–14. Continuous brachial plexus block. The needle is inserted in the interscalene space using an in-plane approach. Note that for didactic purposes, neither sterile drapes nor ultrasound transducer cover are used in this figure.

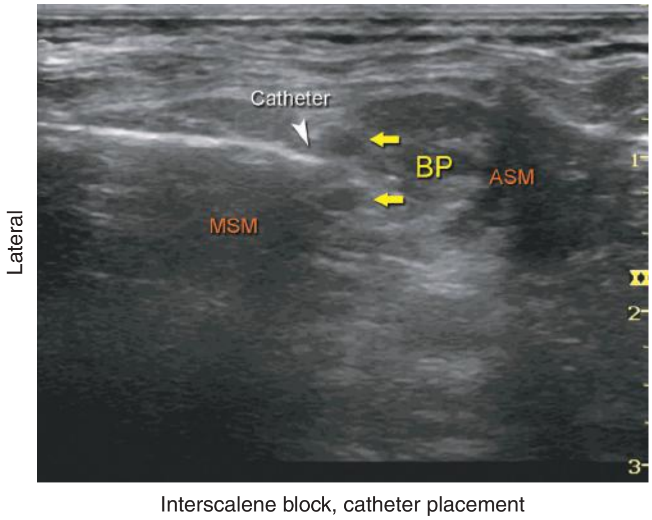

FIGURE 32B–15. An ultrasound image demonstrating needle and catheter (white arrowhead) inserted in the interscalene space between the anterior (ASM) and middle (MSM) scalene muscles. BP, brachial plexus.

Tunneling may be preferred in older patients with obesity or sagging skin over the neck or when a longer duration of catheter infusion is expected. Two main disadvantages of tunneling are the risk of catheter dislodgement during tunneling and the potential for scar formation. A number of catheter-securing devices are available to help stabilize the catheter.

TIPS

- Both stimulating and nonstimulating catheters can be used. Because motor response on catheter stimulation may be absent even with ideal catheter placement, the use of stimulating catheters may lead to unnecessary needle and catheter manipulation to obtain evoked motor responses.[31]
- The catheter-over-needle technique has recently been reintroduced as an alternative to accomplishing continuous interscalene blockade.[32]

CHAPTER 32C

Ultrasound-Guided Supraclavicular Brachial Plexus Block

Thomas F. Bendtsen, Ana M. Lopez, and Catherine Vandepitte

SUPRACLAVICULAR BRACHIAL PLEXUS BLOCK AT A GLANCE

- Indications: arm, elbow, forearm, hand surgery; anesthesia for shoulder surgery is also possible (Figure 32C–1).[1]
- Transducer position: transverse on neck, just superior to the clavicle at the midpoint (Figure 32C–1)
- Goal: local anesthetic spread around the brachial plexus, posterior and superficial to the subclavian artery
- Local anesthetic: 20–25 mL

GENERAL CONSIDERATIONS

At this location, the proximity of the brachial plexus to the chest cavity and pleura had been of concern (Figure 32C–2) until ultrasound (US) guidance renewed interest in the supraclavicular approach to the brachial plexus block. The ability to image the plexus, rib, pleura, and subclavian artery with US has increased safety due to improved monitoring of anatomy and needle placement. Because the trunks and divisions of the brachial plexus are relatively close as they pass over the first rib, the extension and quality of anesthesia are favorable. For these reasons, the supraclavicular block has become a commonly used technique for surgery of the upper limb distal to the shoulder.

ULTRASOUND ANATOMY

The subclavian artery crosses over the first rib between the insertions of the anterior and middle scalene muscles, posterior to the midpoint of the clavicle. The subclavian artery is readily apparent as an anechoic round structure, whereas the parietal pleura and the first rib can be seen as a linear hyperechoic structure immediately lateral and deep to the subclavian artery (Figure 32C–3). The rib casts an acoustic shadow so that the image field deep to the rib appears anechoic.[2] The brachial plexus can be seen as a bundle of hypoechoic round nodules just posterior and superficial to the artery (Figures 32C–3 and 32C–4). It is often possible to see the fascial sheath of the muscles surrounding the brachial plexus. Adjusting the transducer orientation, the upper, middle and lower trunks of the brachial plexus can be individually identified, as they join together at the costoclavicular space. To visualize the lower trunk, the transducer is oriented in the sagittal plane, until the first rib is seen deep to the plexus and the artery. (Figure 32C-4). Anterior or posterior to the first rib is the hyperechoic pleura, with lung tissue deep to it. This structure can be confirmed by observing a “sliding” motion of the viscera l pleura in synchrony with the patient’s respiration. The brachial plexus is typically visualized at a 1- to 2-cm depth at this location.

The presence of two separate clusters of elements of the brachial plexus may be more or less obvious, sometimes with a separation by a blood vessel[3] (Figure 32C-4). The dorsal scapular artery commonly passes through or within the vicinity of the brachial plexus. It is important to recognize that the more superficial and lateral branches come from C5–C7 (shoulder, lateral aspect of arm, and forearm) and can be tracked up to the interscalene area, whereas the deeper and more medial contingent are branches of C8 and T1 (hand and medial aspect of forearm). Adequate spread of local anesthetic in both areas is necessary for successful block of the arm and hand.

DISTRIBUTION OF ANESTHESIA

The supraclavicular approach to the brachial plexus blockade results in anesthesia of the upper limb including often the shoulder because all trunks and divisions can be anesthetized from this location. The skin of the proximal part of the medial side of the arm (intercostobrachial nerve, T2), however, is never anesthetized by any technique of the brachial plexus block and, when necessary, can be blocked by an additional subcutaneous injection just distal to the axilla (Figure 32C-1). (For a more

FIGURE 32C–1. Expected sensory distribution of the supraclavicular brachial plexus block.

comprehensive review of the brachial plexus anatomy and distribution, see Chapter 3.)

EQUIPMENT

The equipment needed for a supraclavicular brachial plexus block includes the following:

- Ultrasound machine with linear transducer (8–18 MHz), sterile sleeve, and gel (or other acoustic coupling agent; eg, saline)
- Standard nerve block tray
- 20–25 mL local anesthetic
- 5-cm, 22-gauge, short-bevel, insulated stimulating needle
- Peripheral nerve stimulator
- Opening injection pressure monitoring system
- Sterile gloves

LANDMARKS AND PATIENT POSITIONING

Any position that allows for comfortable placement of the ultrasound transducer and needle advancement is appropriate. This block can be performed with the patient in the supine, semi-sitting, or slight lateral position, with the patient's head turned away from the side to be blocked. When possible, asking the patient to reach for the ipsilateral knee will depress the clavicle slightly and allow better access to the structures of the anterolateral neck.

Knowledge of the underlying anatomy and the position of the brachial plexus in relation to the subclavian artery, first rib, and pleura is important for the success and safety of the technique. Scanning is usually started just above the clavicle, approximately at its midpoint.

GOAL

The goal of this block is to place the needle within the brachial plexus sheath posterior to the subclavian artery and inject local anesthetic to surround the trunks and divisions of the brachial plexus at this level.

TECHNIQUE

With the patient in the proper position, the skin is disinfected and the transducer is positioned in the transverse plane immediately proximal to the clavicle, slightly posterior to at its midpoint. The transducer is tilted caudally, as if to image the chest contents, to obtain a cross-sectional view of the subclavian artery (Figure 32C–5). The brachial plexus is seen as a collection of hypoechoic oval structures posterior and superficial to the artery. Color Doppler should be routinely used prior to needle insertion to rule out the passage of large vessels (ie, dorsal scapular artery, transverse cervical artery, suprascapular artery) in the anticipated trajectory of the needle.[4]

Clinical Pearl

- To achieve the best possible view, the transducer often must be tilted slightly inferiorly (see arrows in Figure 32C–5). The goal is to see the subclavian artery in the transverse view and the brachial plexus just superficial and posterior to the subclavian artery, enclosed within the brachial plexus sheath. Transducer rotation clockwise often facilitate best imaging of the tissue space (sheath) containing the plexus.

Using a 25- to 27-gauge needle, 1–2 mL of local anesthetic is injected into the skin 1 cm lateral to the transducer to decrease discomfort during needle insertion. To avoid inadvertent puncture of and injection into the brachial plexus, the needle should not be initially inserted deeper than 1 cm. The distribution of local anesthetic via small-volume injections is observed as the needle advances through tissue layers (hydrolocalization); small-volume injections are used to avoid inadvertent needle insertion into the brachial plexus. The block needle is then inserted in plane toward the brachial plexus, in a lateral-to-medial direction (Figures 33C–5 and 33C–6). Nerve stimulation (0.5 mA, 0.1 msec), is often associated with a motor

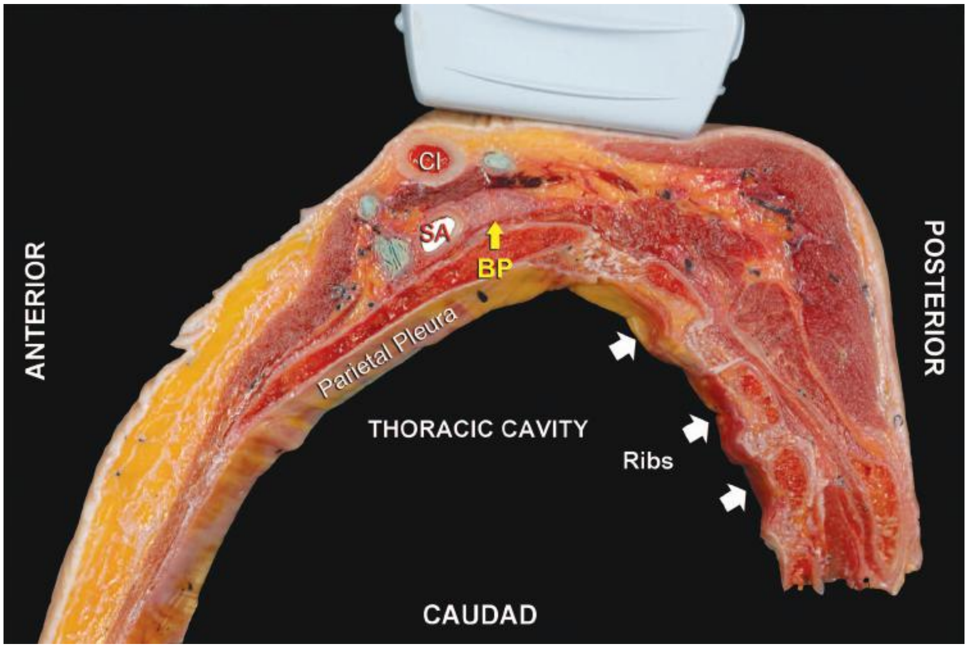

FIGURE 32C–2. Anatomy of the supraclavicular brachial plexus with proper transducer placement slightly oblique above the clavicle (Cl). Yellow arrow: brachial plexus (BP). SA, subclavian artery.

response of the arm, forearm, or hand. Note, however, that motor response may be absent despite accurate needle placement. Insertion of the needle into the sheath is often associated with a palpable "pop." After careful aspiration, 1–2 mL of local anesthetic is injected to confirm proper needle placement. When the injection displaces the brachial plexus away from the needle, an additional advancement of the needle 1–2 mm closer to the plexus may be required to accomplish adequate local anesthetic spread (Figures 32C–7, 32C–8, and 32C–9). When the injection of local anesthetic does not appear to result in a spread around the brachial plexus, needle repositioning may be necessary. Typically, 20–25 mL of local anesthetic is required for adequate block.

It has been suggested that lower volumes can be used in older patients.[5] (see Figure 32C–7).

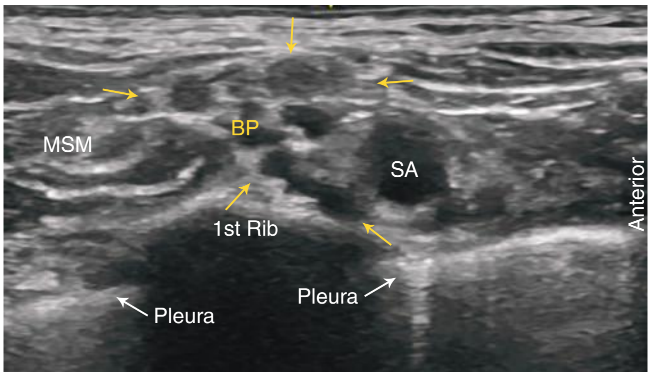

FIGURE 32C–3. Supraclavicular brachial plexus (BP; yellow arrows) seen slightly superficial and posterolateral to the subclavian artery (SA). The brachial plexus is enveloped by a connective tissue sheath. Note the intimate location of the pleura and lung to the brachial plexus and subclavian artery. MSM, middle scalene muscle.

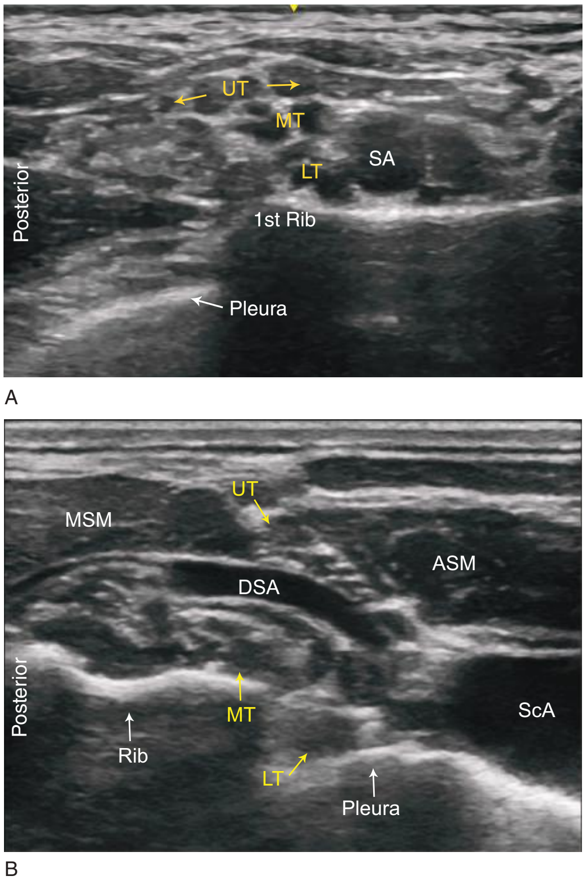

FIGURE 32C–4. Ultrasound images of the brachial plexus cephalad to the clavicle. (**A**) Sagittal view: The upper (UT), Middle (MT) and lower (LT) trunks of the brachial plexus are seen posterior to the subclavian artery (SA) and superficial to the first rib. (**B**) Oblique view: The upper trunk (UT) is positioned between the anterior (ASM) and middle (MSM) scalene muscles. The lower trunk (LT) and the subclavian artery are superficial to the pleura.

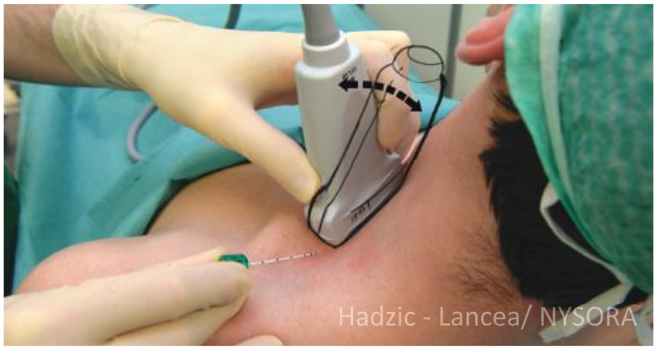

FIGURE 32C–5. Supraclavicular brachial plexus block: transducer position just proximal the clavicle and needle insertion. The brachial plexus is very shallow at this location, typically 1–3 cm; therefore, inclination of the needle should be equally shallow. The image also shows the caudal tilt that is useful in obtaining best image of the plexus.

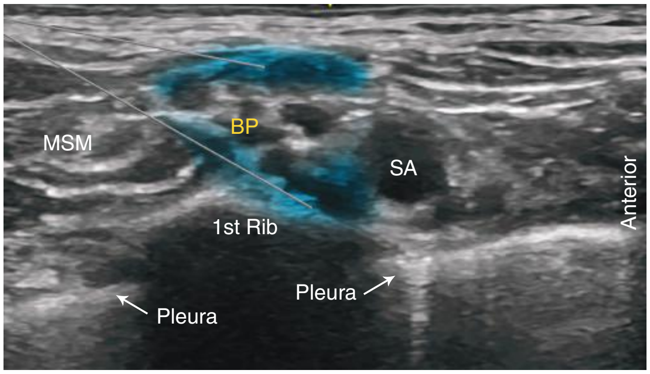

FIGURE 32C–7. The desired spread of local anesthetic (blue-shaded areas) in two different needle positions to accomplish brachial plexus (BP) block. Local anesthetic should spread within the connective tissue sheath resulting in separation of the brachial plexus trunks posterior to the subclavian artery (SCA).

TIPS

- A motor response to nerve stimulation is not necessary if the plexus, needle, and local anesthetic spread are well visualized.
- The neck is a highly vascular area, and care must be exercised to avoid needle placement or injection into the vascular structures. Of particular importance is to note the intimately located subclavian artery and dorsal scapular artery, which often cross the brachial plexus at this level.[4,6] Other vessels can be found within the vicinity of the brachial plexus, such as the suprascapular artery and the transverse cervical artery.[7] The use of color Doppler before needle placement and injection is highly recommended.
- Pneumothorax is also a rare but possible complication,[9–13] typically delayed rather than immediate, therefore, it is paramount to keep the needle tip visible at all times.
- Never inject against high resistance to injection. The inability to initiate injection with an opening injection pressure of less than 15 psi may signal an intrafascicular injection.

- Multiple injections
  - May increase the speed of onset and the success rate.[14–16]
  - May allow for a reduction in the required volume of local anesthetic.
  - May carry a higher risk of nerve injury.

CONTINUOUS ULTRASOUND-GUIDED SUPRACLAVICULAR BLOCK

The ultrasound-guided continuous supraclavicular block is in many ways similar to the technique used for interscalene catheter placement. The goal is to place the catheter within the vicinity of the trunks and divisions of the brachial plexus adjacent to the subclavian artery. The procedure consists of three phases: (1) needle placement; (2) catheter advancement; and (3) securing the catheter. For the first two steps of the procedure, ultrasound can be used to ensure accuracy in most patients. The needle is typically inserted in plane from the lateral-to-medial direction so that the tip is just posterior to the brachial plexus sheath. The needle is then advanced to pierce the sheath, followed by catheter placement.

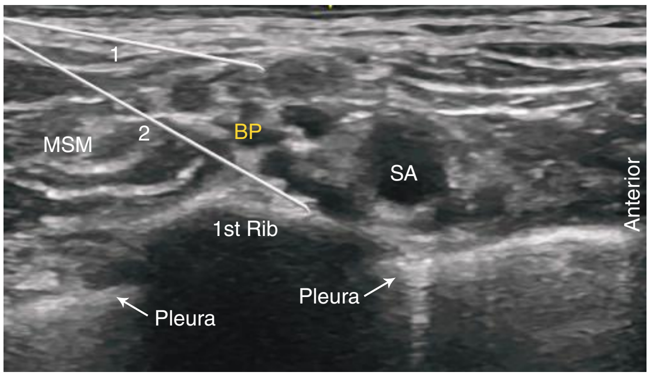

FIGURE 32C–6. Supraclavicular brachial plexus block: needle path and two separate injections required for block of the brachial plexus. Two needle positions (1 and 2) are used to inject local anesthetic within the connective tissue sheath (arrows) containing the brachial plexus (BP).

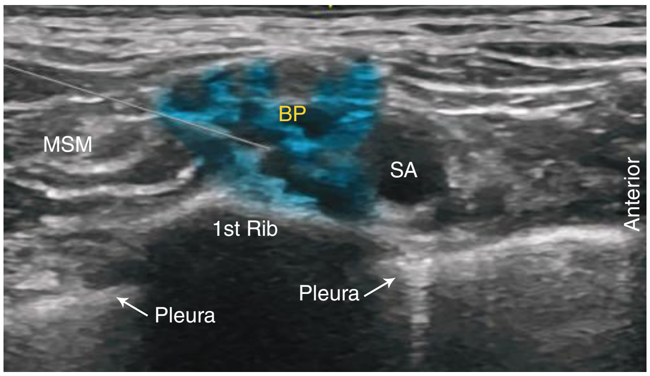

FIGURE 32C–8. Ultrasound image simulating needle path and expected local anesthetic spread after a single injection within the connective tissue sheath surrounding the brachial plexus. Additional monitoring (eg, nerve stimulation and injection pressure) is recommended to decrease the risk of intrafascicular injection.

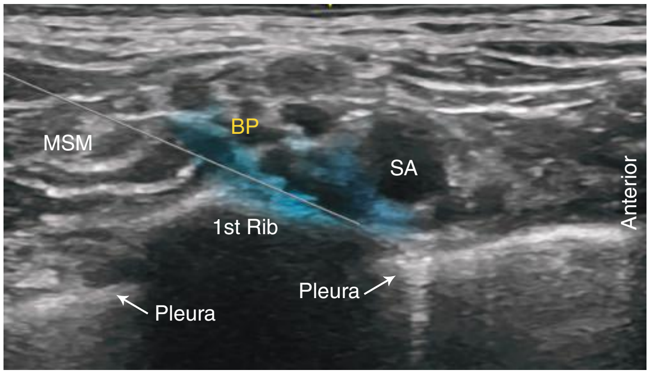

FIGURE 32C–9. Ultrasound-guided supraclavicular brachial plexus block simulating a single injection between the subclavian artery (SA) and the first rib.

Clinical Pearl

- The risk of phrenic nerve palsy is lower than with the interscalene block but cannot be reliably avoided.[8] Therefore, in patients who cannot tolerate a 27–30% decrease in respiratory function with phrenic blockade, an axillary or infraclavicular block is a better choice of anesthesia for upper extremity surgery.

Two main disadvantages of tunneling are the risk of catheter dislodgement during the tunneling and the potential for scar formation. A number of devices are commercially available to help secure the catheter. The starting infusion regimen is typically 5-8 mL/h of 0.2% ropivacaine of bupivacaine 0.125% with 3-5 mL patient-controlled boluses hourly. A catheter-over-needle technique has also been described.[17]

CHAPTER 32D

Ultrasound-Guided Infraclavicular Brachial Plexus Block

Arthur Atchabahian, Catherine Vandepitte, and Ana M. Lopez

INFRACLAVICULAR BRACHIAL PLEXUS BLOCK AT A GLANCE

- Indications: arm, elbow, forearm, and hand surgery (Figure 32D-1)
- Transducer position: approximately parasagittal, just medial to the coracoid process, inferior to the clavicle
- Goal: local anesthetic spread around axillary artery
- Local anesthetic volume: 20–30 mL

GENERAL CONSIDERATIONS

The ultrasound (US)-guided infraclavicular brachial plexus block is in some ways both simple and challenging. It is simple in that identification of the arterial pulse on the sonographic image is an easy primary goal in establishing the landmark. However, the plexus at this level is situated deeper, and the angle of approach is more acute, making simultaneous visualization of the needle and the relevant anatomy more challenging. Fortunately, although it is not always possible to reliably identify the three cords of the plexus, adequate block can be achieved by simply depositing the local anesthetic in a U shape around the artery. The infraclavicular brachial plexus block is well suited for the catheter technique because the musculature of the chest wall helps stabilize the catheter and prevents its dislodgement compared with the more superficial location used with the interscalene and supraclavicular approaches to brachial plexus blockade.

ULTRASOUND ANATOMY

The axillary artery can be identified deep to the pectoralis major and minor muscles. An effort needs to be made to obtain clear views of both pectoralis muscles and their respective fasciae. This is important because the area of interest lies underneath the fascia of the pectoralis minor muscle. Surrounding the artery are the three cords of the brachial plexus: the lateral, posterior, and medial cords. These are named for their usual position relative to the axillary artery, although there is a great deal of anatomical variation. With the left side of the screen corresponding to the cephalad aspect, the cords can often be seen as round hyperechoic structures at the positions of approximately 9 o'clock (lateral cord), 7 o'clock (posterior cord), and 5 o'clock (medial cord) (Figures 32D–2 and 32D–3). The axillary vein is seen as a compressible hypoechoic structure that lies medially to the axillary artery. Multiple other, smaller vessels (eg, the cephalic vein) are often present as well. The transducer is moved in the cephalad-caudad and medial-lateral direction until the artery is identified in cross-section. Depending on the depth selected and the level at which the scanning is performed, the chest wall and the pleura may be seen in the medial and more caudal aspect of the image. The axillary artery and/or brachial plexus are typically identified at a depth of 3–5 cm in average-size patients.

DISTRIBUTION OF ANESTHESIA

The infraclavicular approach to brachial plexus blockade results in anesthesia of the upper limb below the shoulder. If required, the skin of the medial aspect of the upper arm (intercostobrachial nerve, T2) can be blocked by an additional subcutaneous injection on the medial aspect of the arm just distal to the axilla. A simpler approach is for surgeons to infiltrate the skin with the local anesthetic directly over the incision line as needed. For a more comprehensive review of the brachial plexus distribution, see Chapter 3.

FIGURE 32D–1. Distribution of sensory blockade of the infraclavicular brachial plexus block.

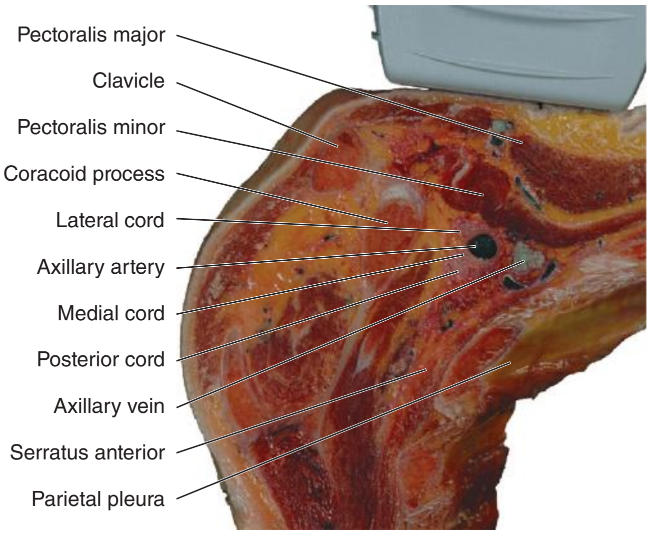

FIGURE 32D–2. Anatomy of the infraclavicular brachial plexus (BP) and the position of the transducer. Paramedian sagittal plane at the level of the coracoid process. The BP is seen surrounding the axillary artery (AA) underneath the coracoid process and pectoralis minor muscle (PMiM). Note that the injection of local anesthetic should take place below the fascia of the PMiM to spread around the AA.

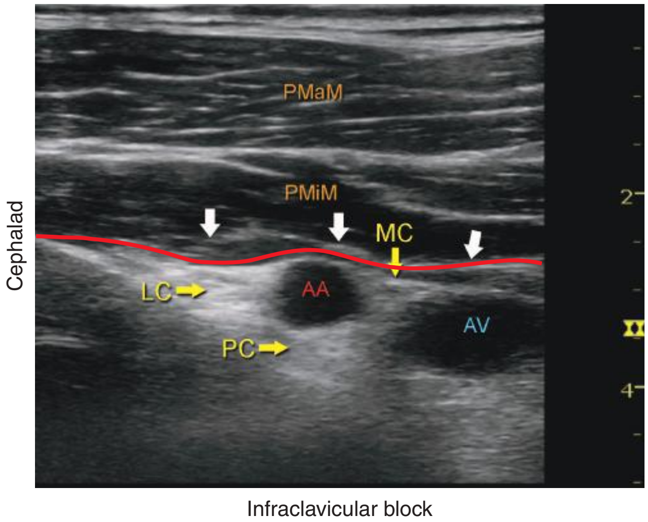

FIGURE 32D–3. Ultrasound image of the brachial plexus (BP) distal to the clavicle. Note that the BP, axillary artery (AA) and axillary vein (AV) are located below the fascia (red line) of the pectoralis minor muscle (PMiM). LC, lateral cord; MC, medial cord; PC, posterior cord; PMaM, pectoralis major muscle.

EQUIPMENT

The equipment recommended for an infraclavicular brachial plexus block includes the following:

- Ultrasound machine with linear transducer (8–14 MHz), sterile sleeve, and gel
- Standard nerve block tray
- 20–30 mL of local anesthetic drawn up in syringes
- 8- to 10-cm, 21- to 22-gauge, short-bevel, insulated stimulating needle
- Peripheral nerve stimulator
- Opening injection pressure monitoring system
- Sterile gloves

LANDMARKS AND PATIENT POSITIONING

Any position that allows for the comfortable placement of the ultrasound transducer and needle advancement is appropriate. The block is typically performed with the patient in the supine position with the head turned away from the side to be blocked (Figure 32D–4). The arm is abducted to 90 degrees and the elbow flexed. This maneuver raises the clavicle, reduces the depth from the skin to the plexus,[1] and substantially facilitates visualization of the pectoralis muscles as well as the cords of the brachial plexus and the needle.[2]

The coracoid process is an important landmark and can be easily identified by palpating the bony prominence just medial to the shoulder while the arm is elevated and lowered. As the arm is lowered, the coracoid process meets the fingers of the palpating hand. Scanning usually begins just medial to the coracoid process and inferior to the clavicle.

Keeping the probe in a parasagittal plane, scanning medially and laterally allows the chest wall and pleura to be located (Figure 32D–5). The block should be performed with the

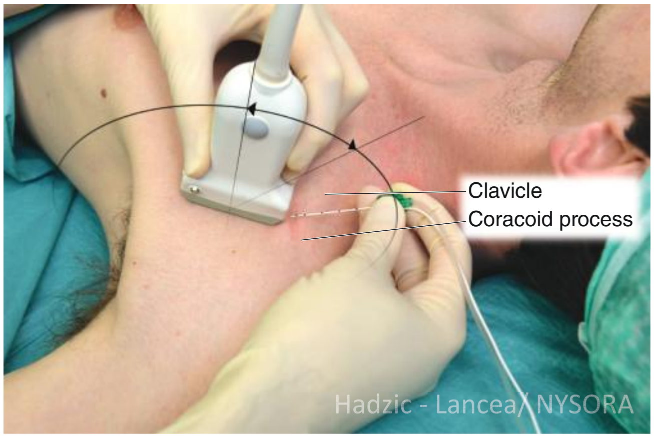

FIGURE 32D–4. Patient position for infraclavicular brachial plexus block needle insertion. The transducer is positioned parasagittally just medial to the coracoid process and inferior to the clavicle.

probe lateral to the pleura in order to minimize the risk of pneumothorax.

GOAL

The goal of the technique is to inject local anesthetic until the spread around the artery is verified by ultrasound. It is not necessary to identify and target individual cords. Instead, injection of local anesthetic to surround the artery in an U-shaped pattern (cephalad, caudad, and posterior) suffices for the block of all three cords.

TECHNIQUE

With the patient in the proper position, the skin is disinfected and the transducer is positioned in the parasagittal plane to identify the axillary artery (see Figures 33D–3 and 33D–4). This may require adjustment of the depth, depending on the thickness of the patient's chest wall musculature. The axillary artery is typically seen between 3 and 5 cm. Once the artery has been identified, an attempt is made to identify the hyperechoic cords of the brachial plexus and their corresponding positions relative to the artery, although these may not always be identifiable. Fortunately, visualization of the cords are not necessary for successful blockade.

The needle is inserted in plane from the cephalad end of the probe, with the insertion point just inferior to the clavicle (see Figure 32D–4). The needle is aimed toward the posterior aspect of the axillary artery and passes through the pectoralis major and minor muscles. If nerve stimulation is used concurrently (0.5–0.8 mA, 0.1 msec), the first motor response is often from the lateral cord (either elbow flexion or finger flexion). As the needle is advanced farther beneath the artery, a posterior cord motor response may appear (finger and wrist extension). After careful aspiration, 1–2 mL of local anesthetic is injected to confirm proper needle placement and spread. The injectate should spread cephalad and caudad to cover the lateral and medial cords, respectively (Figure 32D–6). When a single injection of local anesthetic does not appear to result in adequate spread, additional needle repositioning and injections around the axillary artery may be necessary.

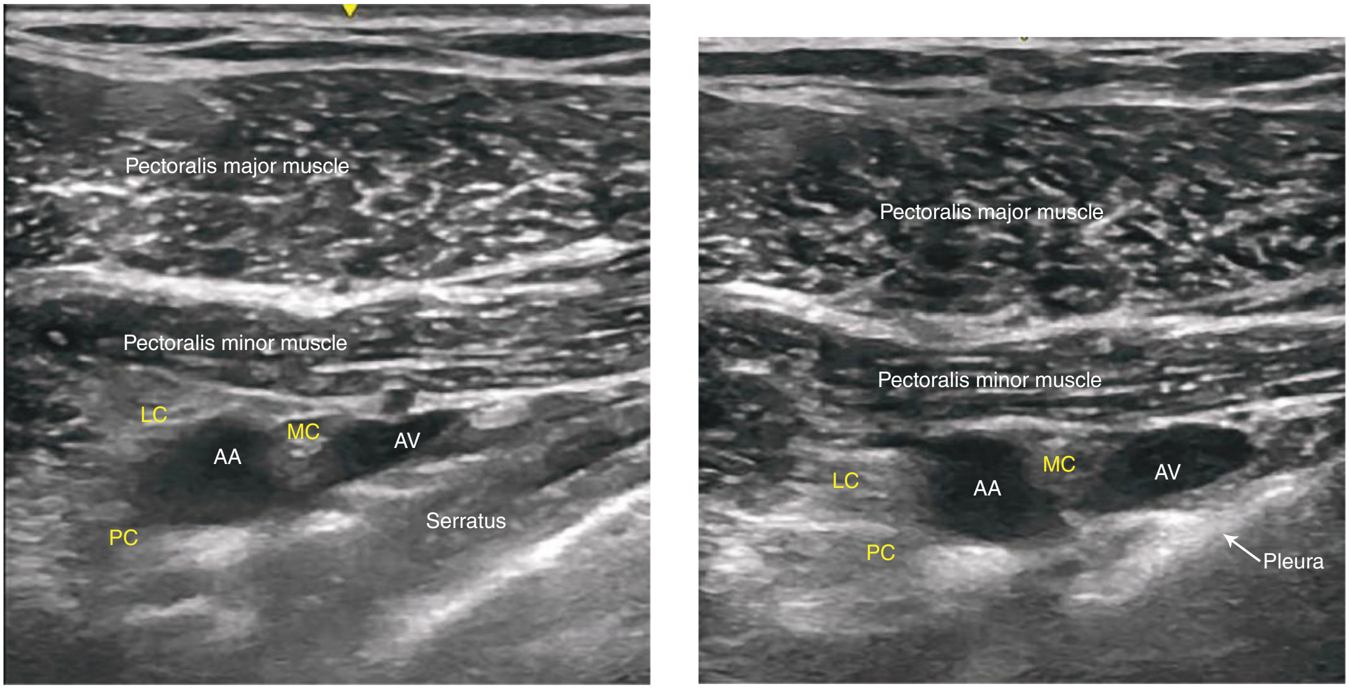

FIGURE 32D–5. Ultrasound-guided infraclavicular block: a medial-to-lateral probe movement is used to avoid the area where the needle advanced in the parasagittal plane could enter the pleura. (**A**) Parasagittal lateral view: the serratus anterior is seen between the neurovascular bundle and the pleura. (**B**) In this probe position, the pleura lies closer to the brachial plexus.

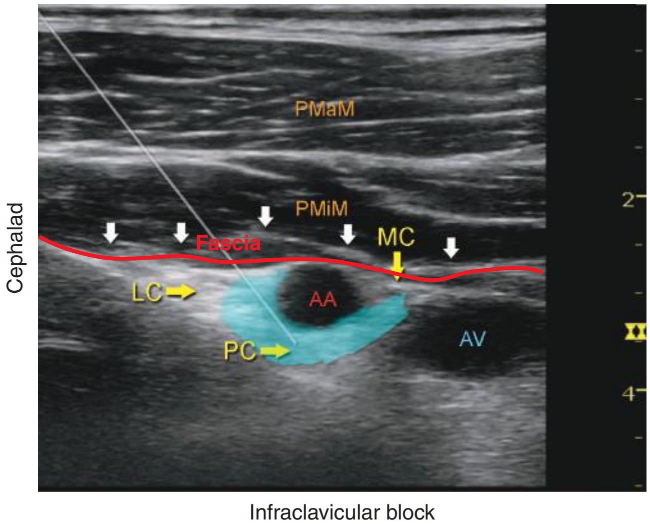

FIGURE 32D–6. Ultrasound image demonstrating an ideal needle path for the infraclavicular brachial plexus block. The blue-shaded area mimics an ideal spread of local anesthetic around the axillary artery (AA) and reaches all three cords of the brachial plexus (the lateral cord [LC], posterior cord [PC], and medial cord [MC]) below the fascia (red line) of the pectoralis minor muscle (PMiM), pectoralis major muscle (PMaM), and axillary vein (AV).

In an adult patient, 20–30 mL of local anesthetic is usually adequate for successful blockade. Although a single injection of such a large volume of local anesthetic often suffices,[3–5] it may be beneficial to inject two to three smaller aliquots at different locations to ensure local anesthetic spread in all planes containing the brachial plexus. There have been reports of septa hindering the diffusion of local anesthetic around the artery,[6,7] and when that appears to be the case, repositioning the needle tip to achieve a U-shaped spread will ensure block success. Alternative approaches to block the brachial plexus distal to the clavicle have been described. A Single injection in between the cords at a more cephalad level (the coscoclavicular space), where the branchial plexus can be visualized lateral to the artery (Figure 32D-7).

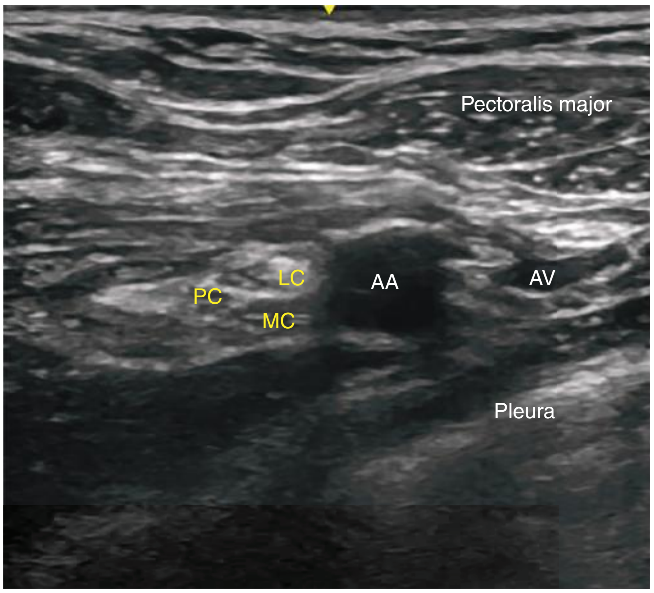

FIGURE 32D–7. Ultrasound view of the brachial plexus at the costoclavicular space. The lateral (LC), medial (MC) and posterior (PC) cords are clustered together lateral to the axillary artery lying more superficial. At this level, the pectoralis minor is not seen deep to the pectoralis mayor.

TIPS

- An artifact posterior to the artery is often misinterpreted as the posterior cord. Figure 32D–6.
- A "heel-up" maneuver (rocking the probe toward the patient's head in a parasagittal plane, depressing the tissues caudad to the probe) makes it easier to change the needle's angle as needed (see Figure 32D–4).
- To decrease the risk of complications, adhere to the following guidelines:
  - Aspirate intermittently every 5 mL to decrease the risk of intravascular injection.
  - Do not inject if the injection resistance is high (> 15 psi).

CONTINUOUS ULTRASOUND-GUIDED INFRACLAVICULAR BLOCK

The goal of the continuous infraclavicular block is similar to the non–ultrasound-based techniques: to place the catheter within the vicinity of the cords of the brachial plexus beneath the pectoral muscles. The procedure consists of three phases: (1) needle placement; (2) catheter advancement; and (3) securing the catheter. For the first two phases of the procedure, ultrasound can be used to ensure accuracy in most patients. The needle is typically inserted in plane from the cephalad-to-caudad direction, similar to the single-injection technique (Figure 32D–8).

FIGURE 32D–8. The patient position, imaging, and needle placement for continuous infraclavicular brachial plexus block are similar to those for a single-injection technique. Once proper needle tip placement is determined by the injection of a small volume of local anesthetic, the catheter is inserted 2–4 cm beyond the needle tip.

As with the single-injection technique, the needle tip should be placed posterior to the axillary artery prior to injection and catheter advancement. Proper needle placement can also be confirmed by obtaining a motor response of the posterior cord (finger or wrist extension), at which point 1–2 mL of local anesthetic is injected. The rest of the technique, advancing and securing the catheter is the same as previously described (continuous block section, Chapter 32B).

A typical starting infusion regimen is 5 mL/h, followed by 8-mL patient-controlled boluses every hour. The larger bolus volume is necessary for the adequate spread of the injectate around the artery so that all cords of the brachial plexus are reached.

CHAPTER 32E

Ultrasound-Guided Axillary Brachial Plexus Block

Catherine Vandepitte, Ana M. Lopez, and Hassanin Jalil

AXILLARY BRACHIAL PLEXUS BLOCK AT A GLANCE

- Indications: elbow, forearm and hand surgery (Figure 32E–1)
- Transducer position: short axis to arm, just distal to the pectoralis major insertion
- Goal: local anesthetic spread around axillary artery
- Local anesthetic: 15–20 mL

GENERAL CONSIDERATIONS

The axillary brachial plexus block is relatively simple to perform and may be associated with a lower risk of complications compared with interscalene (eg, spinal cord or vertebral artery puncture) and supraclavicular brachial plexus blocks (eg, pneumothorax). In clinical scenarios in which access to the upper parts of the brachial plexus is difficult or impossible (eg, local infection, burns, indwelling venous catheters), the ability to anesthetize the plexus at a more distal level may be important. Although individual nerves can usually be identified this is not absolutely necessary because the deposition of local anesthetic around the axillary artery is sufficient for an effective block.

ULTRASOUND ANATOMY

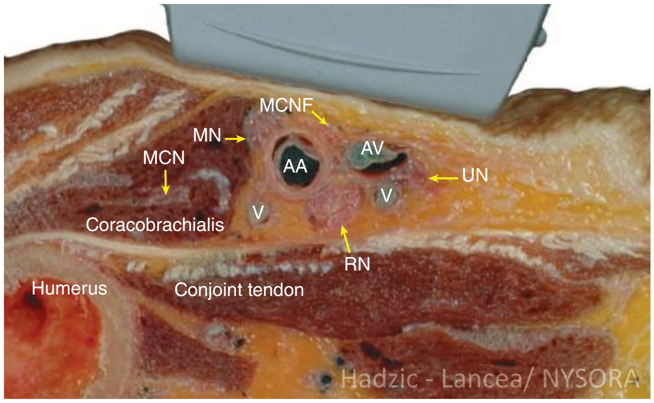
The structures of interest are superficial (1–3 cm below the skin), and the axillary artery is readily identified within a centimeter of the skin surface on the medial aspect of the proximal arm (Figure 32E–2). The artery is accompanied by one or more axillary veins, often located medially to the artery. Importantly, excessive pressure with the transducer during imaging may compress the veins, rendering veins invisible and prone to puncture with the needle. Surrounding the axillary artery, three of the four principal branches of the brachial plexus can be seen: the median (superficial and lateral to the artery), the ulnar (superficial and medial to the artery), and the radial (posterior and lateral or medial to the artery) nerves (see Figure 32E–2). The nerves appear as round hyperechoic structures. Several authors have reported the anatomical variations of the nerves relative to the axillary artery;[1–4] Figure 32E–3 illustrates the most common patterns.

Three muscles surround the neurovascular bundle: the biceps (anterior and superficial), the wedge-shaped coracobrachialis (anterior and deep), and the conjoined tendon of the teres major and latissimus dorsi (medial and posterior). The musculocutaneous nerve is located in the fascial layers between the biceps and coracobrachialis muscles, though its location is variable and can be seen within either muscle. It is usually seen as a hypoechoic flattened oval structure with a bright hyperechoic rim. Moving the transducer proximally and distally along the long axis of the arm, the musculocutaneous nerve appears to move toward or away from the neurovascular bundle in the fascial plane between the two muscles. Variations are determined by the position of the musculocutaneous nerve relative to the median nerve and by the position of the ulnar nerve relative to the axillary vein.

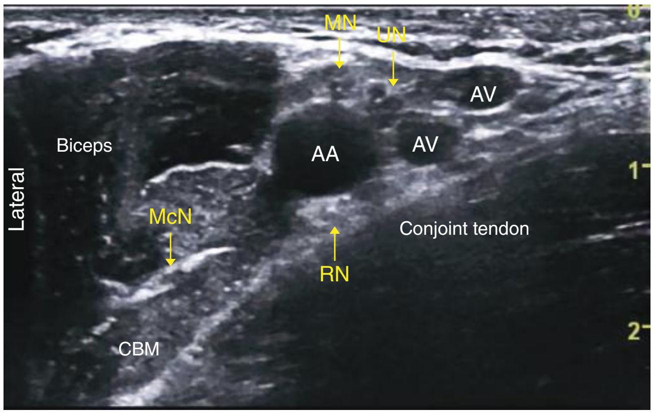
DISTRIBUTION OF ANESTHESIA

The axillary brachial plexus block (including the musculocutaneous nerve) results in anesthesia of the upper limb from the mid-arm down to and including the hand. Importantly, the block lends its name from the approach and not from the

FIGURE 32E–1. Sensory distribution after axillary brachial plexus block.



A



B

FIGURE 32E–2. (**A**) Cross-sectional anatomy of the axillary fossa and ultrasound image (**B**) of the terminal nerves of brachial plexus. The BP is seen scattered around the axillary artery and enclosed within the adipose tissue compartment containing the axillary artery (AA), and axillary veins (AV). MCN, musculocutaneous nerve. MN, median nerve; RN, radial nerve; UN, ulnar nerve; MACN, median antebrachial cutaneous nerve; CBM, corachobrachialis muscle.

axillary nerve, which itself is not blocked because it departs from the posterior cord more proximally in the axilla. Therefore, the skin over the deltoid muscle is not anesthetized. With nerve stimulator and landmark-based techniques, the blockade of the musculocutaneous nerve is often unreliable. However, the musculocutaneous nerve is readily visualized and reliably anesthetized by a separate injection using ultrasound guidance. When required, the medial skin of the upper arm (intercostobrachial nerve, T2) can be blocked by an additional subcutaneous injection just distal to the axilla.

EQUIPMENT

- Ultrasound machine with linear transducer (8–14 MHz), sterile sleeve, and gel
- Standard nerve block tray
- Syringes with local anesthetic (20 mL)
- 5-cm, 22-gauge, short-bevel, insulated stimulating needle
- Peripheral nerve stimulator
- Opening injection pressure monitoring system
- Sterile gloves

LANDMARKS AND PATIENT POSITIONING

Abduction of the arm to 90 degrees is necessary to allow for transducer placement and needle advancement, (Figure 32E–4). Care should be taken not to over-abduct the arm, as this may cause patient discomfort as well as traction on the brachial plexus, making it theoretically more vulnerable to injury by needle or injection.

The pectoralis major muscle is palpated as it inserts onto the humerus, and the transducer is placed on the skin immediately distal to that point, perpendicular to the axis of the arm. The starting point should have the transducer overlying both the biceps and triceps muscles (ie, on the medial aspect of the arm). Sliding the transducer proximally will bring the axillary artery, the conjoint tendon and the terminal branches of the brachial plexus into view, if not readily apparent.

GOAL

The goal is to deposit local anesthetic around the axillary artery. Typically, two or three injections are required. In addition,

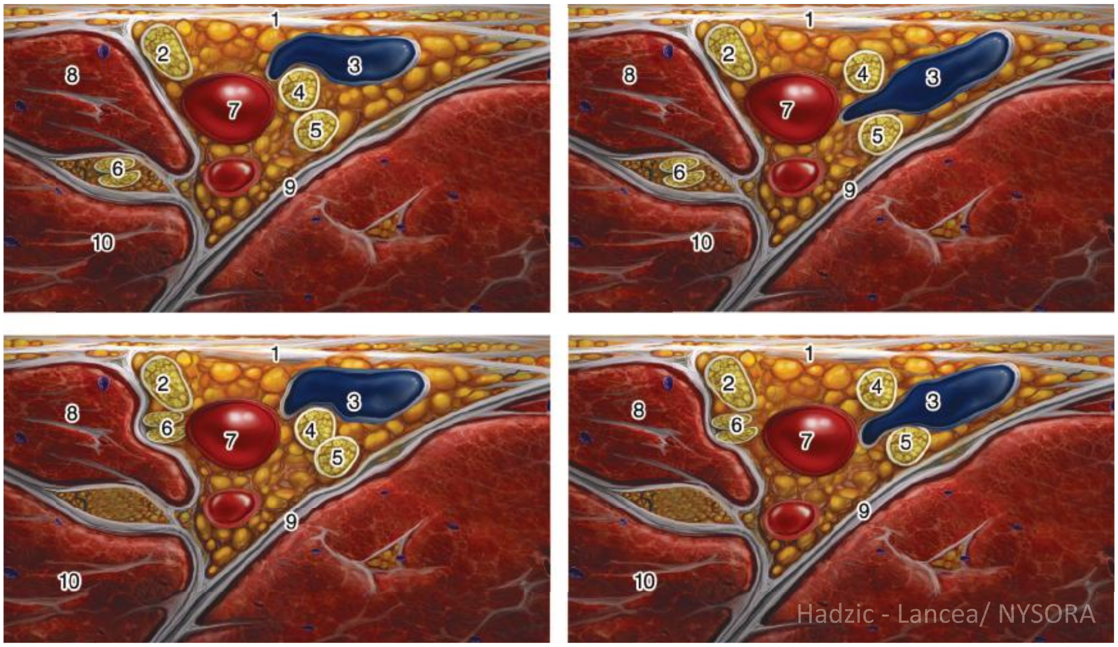


FIGURE 32E–3. Most common patterns of nerve location around the axillary artery in ultrasound-guided axillary brachial plexus block.[4]

an aliquot of local anesthetic should be injected around the musculocutaneous nerve.

TECHNIQUE

The skin is disinfected and the transducer is positioned in the short axis orientation to identify the axillary artery about 1–3 cm from the skin surface. Once the artery is identified, an attempt is made to identify the hyperechoic median, ulnar, and radial nerves (Figure 32E–5). However, these may not always be well visualized with ultrasound. Frequently present, an acoustic enhancement artifact deep to the artery is often misinterpreted as the radial nerve. Prescanning should also reveal the position of the musculocutaneous nerve, in the plane between the coracobrachialis and biceps muscles or within either of the muscles (a slight proximal-distal movement of the transducer is often required to bring this nerve into view) (Figure 32E–6). The needle is inserted in plane from the anterior aspect and directed toward the posterior aspect of the axillary artery (Figure 32E–7).

Because nerves and vessels are positioned closely together in the neurovascular bundle by adjacent musculature, advancement of the needle may require careful hydrodissection with a small amount of local anesthetic or other injectate. This technique involves the injection of 0.5–2 mL, indicating the plane in which the needle tip is located. The needle is then carefully advanced stepwise few millimeters at a time. The use of nerve stimulation is recommended to decrease the risk of needle-nerve injury during needle advancement.

Local anesthetic should be deposited posterior to the artery first, to avoid displacing the structures of interest deeper and obscuring the nerves, which may occur if injections for the median or ulnar nerves are carried out first. The posteriorly

FIGURE 32E–4. Patient position and needle insertion for ultrasound-guided (in-plane) axillary brachial plexus block. All needle redirections are done through the same needle insertion site.

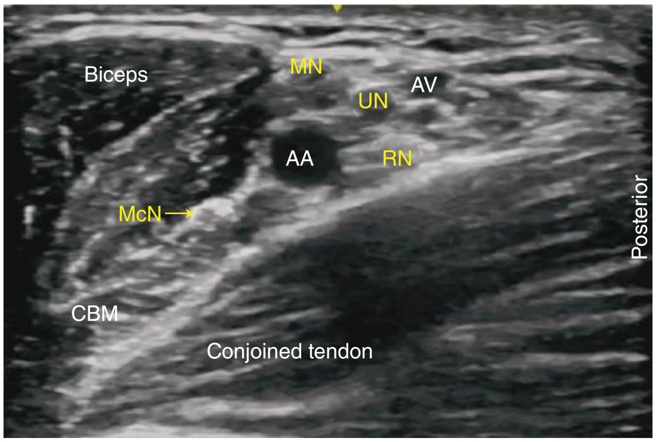

FIGURE 32E–5. The median (MN), ulnar (UN), and radial (RN) nerves are seen scattered around the axillary artery (AA). The musculocutaneous nerve (MCN) is seen between the biceps and coracobrachialis muscle (CBM), away from the rest of the brachial plexus. AV, axillary vein.

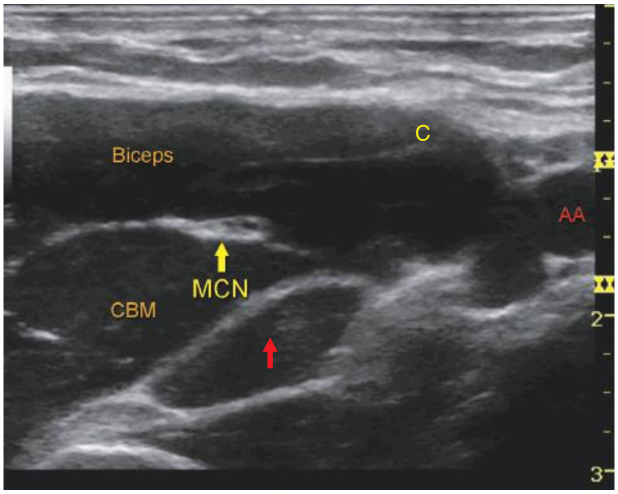

Musculocutaneous nerve at

FIGURE 32E–6. The musculocutaneous nerve (MCN) is located few cm away from the axillary artery (AA) between the biceps and the coracobrachialis muscle. The course of the MCN along the upper arm display frequent anatomic variations. Systematic scanning to identify the nerve and a separate injection of local anesthetic are usually required for a successful axillary brachial plexus block.

located radial nerve is often visualized more clearly once surrounded by local anesthetic. Once 5–7 mL has been administered, the needle is withdrawn almost to the level of the skin, redirected toward the median and ulnar nerves, and a further 7–10 mL is injected in these areas to complete the spread around the nerves. The described sequence of injection is demonstrated in Figure 32E–8.

An alternative, perivascular approach is to simply inject local anesthetic deep to the artery, at the 6 o'clock position, instead of targeting the three nerves individually. This technique may shorten the duration of the block procedure, but also delay onset time, resulting in no difference in total time from skin puncture to onset of the surgical block.[5]

The last step in the procedure, the needle is withdrawn and redirected toward the musculocutaneous nerve. Once adjacent to the nerve (stimulation will result in elbow flexion), 5–7 mL of local anesthetic is deposited. Occasionally, the musculocutaneous nerve will lie in close proximity to the median nerve, rendering a separate injection unnecessary.

In an adult patient, 20 mL of local anesthetic is usually adequate for successful blockade, although successful blocks have been described with smaller volumes.[6] Adequate spread within the axillary brachial plexus sheath is necessary for success but infrequently seen with a single injection. This is accomplished with two to three redirections and injections of 5-7 mL are usually necessary for reliable blockade, as well as a separate injection to block the musculocutaneous nerve.

TIPS

- Frequent aspiration and slow administration of local anesthetic are critical for decreasing the risk of intravascular injection. Cases of systemic toxicity have been reported after apparently straightforward ultrasound-guided axillary brachial plexus blocks.
- If no spread is seen on the ultrasound image despite local anesthetic injection, the tip of the needle may be located in a vein.[7] If this occurs, injection should be halted immediately and the needle withdrawn slightly. Pressure on the transducer should be eased before reassessing the ultrasound image for the presence of vascular structures.
- Anatomic variations in the position of the musculocutaneous nerve have been described.[8] In 16% of cases, the musculocutaneous nerve splits off of the median nerve distally to the axilla. In this case, a separate injection is not needed to block the musculocutaneous nerve as it will be blocked by the local anesthetic injected around the median nerve.[9]

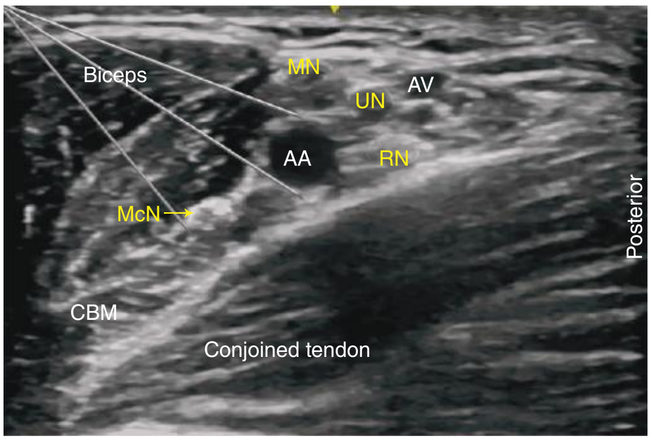

FIGURE 32E–7. Needle insertions for axillary brachial plexus block. Axillary block can be accomplished by two to four separate injections, depending on the disposition of the nerves around the axillary artery (AA) and the quality of the image. MCN, musculocutaneous nerve; MN, median nerve; RN, radial nerve; UN, ulnar nerve. AA, axilary vein, AV, axillary vein.

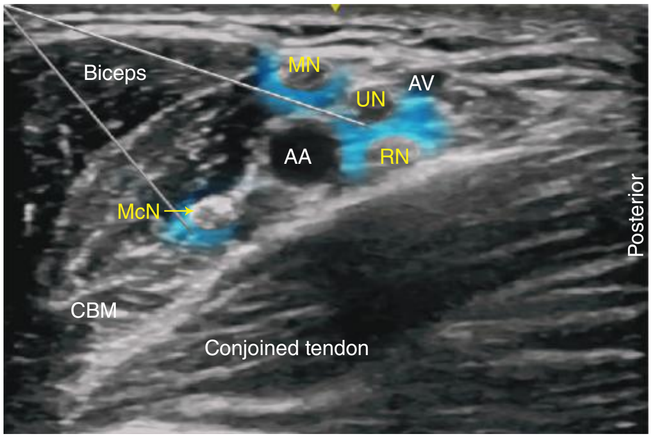

FIGURE 32E–8. This image demonstrates the ideal distribution pattern of local anesthetic. In this particular disposition of nerves, a single needle pass superficially to the artery allows for two injections: one for the median (MN) and a second one between the ulnar (UN) and radial (RN). The musculocutaneous (MCN) requires a separate injection.

PART 3

CONTINUOUS ULTRASOUND-GUIDED AXILLARY BLOCK

The indwelling axillary catheter is a useful technique for analgesia and sympathetic block. The goal of the continuous axillary block is to place the catheter within the vicinity of the branches of the brachial plexus (ie, within the "sheath" of the brachial plexus). The procedure is similar to that previously described in Chapter 32B. The needle is typically inserted in plane from the anterior to posterior direction, just as in the single-injection technique).

After an initial injection of local anesthetic to confirm proper needle tip position posterior to the axillary artery, the catheter is inserted 3–5 cm beyond the needle tip. Injection is then repeated through the catheter to document adequate spread of local anesthetic, wrapping the axillary artery. Alternatively, the axillary artery can be visualized in the longitudinal view with the catheter being inserted in the longitudinal plane alongside the axillary artery. The longitudinal approach requires a significantly greater degree of ultrasonographic skill; no data suggesting that one approach is more effective than the other currently exist.

CHAPTER 32F

Ultrasound-Guided Blocks at the Elbow

Jui-An Lin, Thomas F. Bendtsen, Ana M. Lopez, and Hassanin Jalil

FOREARM BLOCKS AT A GLANCE

- Indications: hand and wrist surgery (Figure 32F-1)
- Transducer position: transverse on the elbow
- Goal: injection of local anesthetic within the vicinity of individual nerves (radial, median, and ulnar)
- Local anesthetic: 4–5 mL per nerve

GENERAL CONSIDERATIONS

Ultrasound imaging of individual nerves in the distal upper limb allows for reliable nerve blockade. The two main indications for a forearm block are a standalone technique for hand and/or wrist surgery and as a means of rescuing or supplementing an incomplete or failed proximal brachial plexus block. Advantages of rescue block are the reduction of the risk of vascular puncture and in the overall volume of local anesthetic used. There are a variety of locations where a practitioner could approach each of these nerves, most of which are similar in efficacy. In this chapter, we present the approach for each nerve at the level of the elbow.

Ultrasonographic assessment shows that a median nerve block using nerve stimulation alone is commonly associated with intraneural injection.[1]

Some authors have suggested additional indications for forearm blocks, in combination with a proximal brachial plexus block. Combining proximal and distal blocks allows for a decrease in onset time and improved block consistency.[2] It is possible to use these blocks in the setting of wrist or hand surgery involving the bone to provide long-lasting analgesia without blocking the whole limb for many hours; this is done by combining a short-acting brachial plexus block with distal blocks around the elbow, according to the surgical procedure.[3] If distal blocks are to be performed after a proximal brachial plexus block, it is of paramount importance to clearly visualize the needle tip at all times in order to avoid intraneural injection.

ULTRASOUND ANATOMY

The Radial Nerve

The radial nerve is best visualized above the lateral aspect of the elbow, lying in the interfascial plane between the brachioradialis and the brachialis muscles (Figure 32F–2). The transducer is placed transversely on the anterolateral aspect of the distal arm, 3–4 cm above the elbow crease. The nerve appears as a hyperechoic, triangular or oval structure with the characteristic honeycomb appearance of a distal peripheral nerve. The nerve divides just distal to the elbow crease into the superficial (sensory) and deep (motor) branches. These smaller divisions of the radial nerve are more challenging to identify in the forearm; therefore, a single injection above the elbow is favored because it ensures blockade of both. The transducer can be slid up and down the arm to better visualize the nerve and the musculature surrounding it. As the transducer is moved proximally, the nerve will be seen to travel posteriorly and closer to the humerus, to lie deep to the triceps muscle in the spiral groove (Figure 32F–3).

The Median Nerve

The median nerve is imaged at the level of the elbow crease, as it is located superficially. The transducer is placed just above the crease and adjusted to obtain a clear view of the brachial artery. The median nerve lies on the medial side in close contact to the artery as a hyperechoic oval shaped structure of about the same size of the artery (Figure 32F-4). Scanning proximally, both the nerve and the artery can be easily followed up to the axilla as they course together, although changing the relative position to one another. Scanning distally to the elbow crease, the median

(**B**) Sonoanatomy of the radial nerve at the distal arm. The RN is located between the brachioradialis and the brachialis muscles.

nerve separates from the artery and lies deep to the pronator teres muscle and the flexor digitorum superficialis as it reaches the midforearm.

The Ulnar Nerve

The ulnar nerve is identified at the postero medial aspect of the elbow, few centimeters proximally to the crease, as a hyperechoic oval "honeycomb" structure immediately underneath the brachial fascia and superficial to the triceps muscle (Figure 32F-5). The ulnar nerve can be traced distally toward the ulnar notch, where it appears as a round hypoechoic structure diving into the bony ulnar sulcus before entering the forearm underneath the flexor carpi ulnaris muscle. Sliding the transducer proximally, the nerve can be easily traced back to the axilla along the medial aspect of the arm.

DISTRIBUTION OF ANESTHESIA

Anesthetizing the radial, median, and/or ulnar nerves provides sensory anesthesia and analgesia to the respective territories of the hand, forearm, and wrist. Note that the lateral cutaneous nerve of the forearm (a branch of the musculocutaneous nerve) supplies the lateral aspect of the forearm, and it may need to be blocked separately by a subcutaneous wheal distal to the elbow if lateral wrist surgery is planned. The same applies for the median cutaneous nerve of the forearm (Figure 32E-1). The use of a tourniquet, either on the arm or forearm, usually requires sedation and/or additional analgesia. (For a more

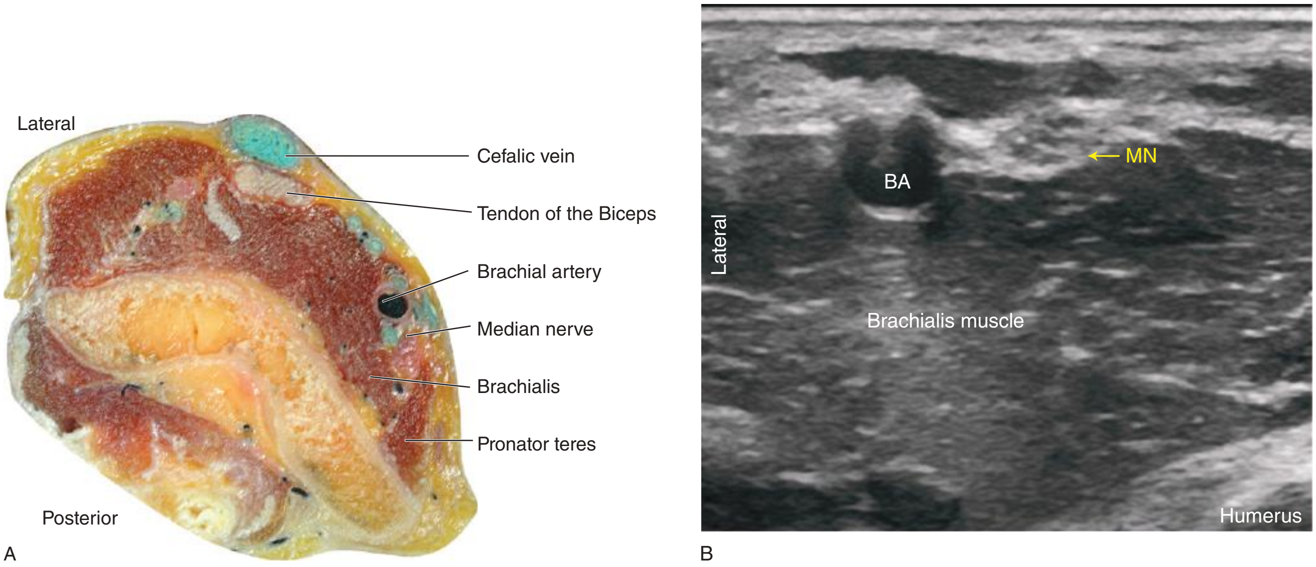

FIGURE 32F–4. (**A**) Anatomy section of the distal arm at the level of the elbow. (**B**) Sonoanatomy of the median nerve proximally to the elbow crease.

comprehensive review of the innervation of the hand, see Chapter 3.)

EQUIPMENT

The equipment recommended for a forearm block includes the following:

- Ultrasound machine with linear transducer (8–14 MHz), sterile sleeve, and gel
- Standard nerve block tray
- Three 5 mL syringes containing local anesthetic
- A 2-in, 22- to 25-gauge, short-bevel, insulated stimulating needle (optional)
- Peripheral nerve stimulator (optional)
- Sterile gloves
- Pressure monitoring

Clinical Pearl

- Because these are superficial blocks of the distal peripheral nerves, some practitioners choose to use a small-gauge (eg, 25-gauge) needle. When using a small-gauge needle, however, meticulous attention should be paid in order to avoid an intraneural injection, which is more likely with a smaller-diameter and sharp-tip design.

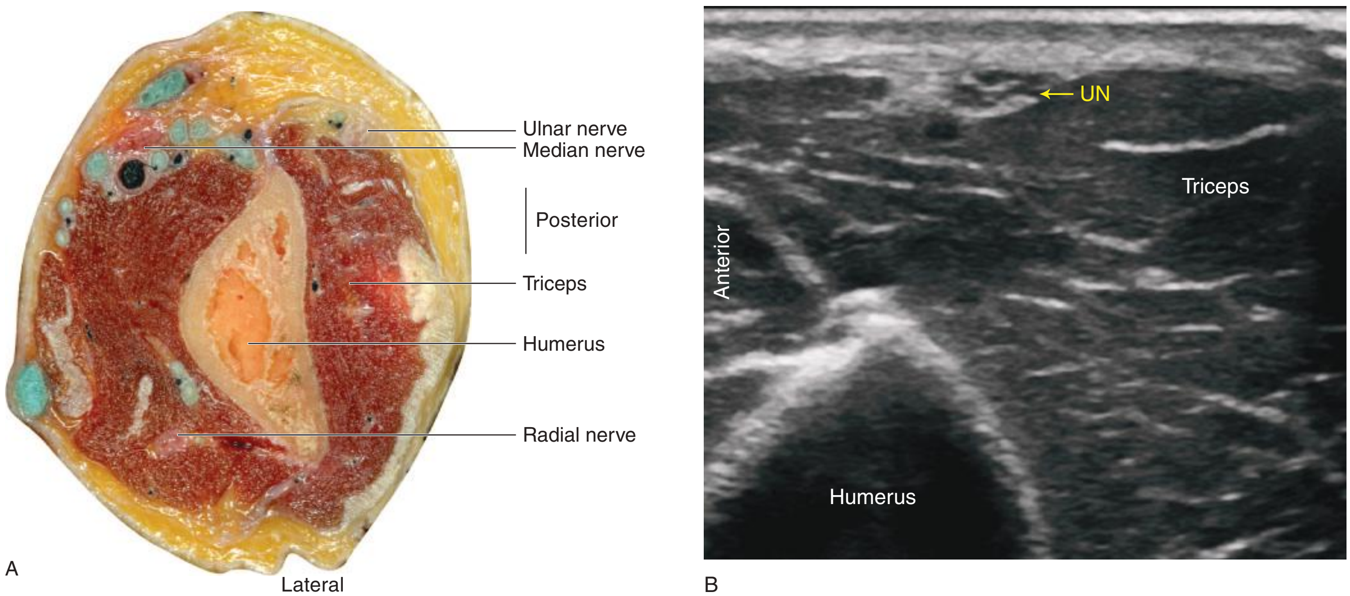

FIGURE 32F–5. (**A**) Anatomy section of the distal arm at the level of the elbow. (**B**) Sonoanatomy of the ulnar nerve proximally to the elbow crease.

LANDMARKS AND PATIENT POSITIONING

Typically, the block is performed with the patient in the supine position. For the radial nerve block, the arm could also be flexed at the elbow, and the hand is placed on the patient's abdomen (see Figure 32F–6a). This position allows for the most practical application of the transducer. The median and ulnar nerves are blocked with the arm abducted. (see Figures 32F-7a and 32F-8a).

GOAL

The goal of a forearm block is to place the needle tip adjacent to the nerve(s) of choice and to deposit 4–5 mL of local anesthetic within the fascial sheath enclosing the nerve. It is unnecessary to completely surround the entire nerve in a circumferencial pattern, although this can enhance the speed of block onset. As with all peripheral blocks, it is imperative to avoid high opening injection pressure in order to decrease the risk of intrafascicular injection.

TECHNIQUE

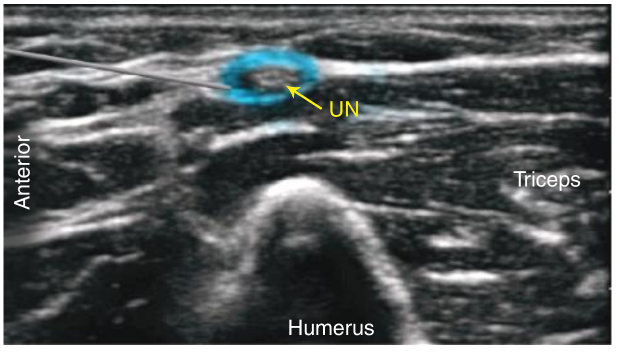
The Radial Nerve

The skin is disinfected and the transducer positioned so as to identify the radial nerve. The needle is inserted in plane, with the goal of traversing the brachioradialis muscle and placing the tip next to the radial nerve (Figure 33F–6a). If nerve stimulation is used, a wrist or finger extension response should be elicited when the needle is within proximity of the nerve. After negative aspiration, 4–5 mL of local anesthetic is injected (Figure 32F–6b). If the spread is inadequate, slight adjustments can be made and a further 2–3 mL of local anesthetic administered.

It is also possible to block the branches of the radial nerve in the forearm. Anterior to the elbow joint, the radial nerve can be visualized between the extensor carpi radialis muscles (longus and brevis) and brachioradialis. The superficial branch can then be seen clearly at the proximal forearm covered by the brachioradialis. The deep branch is more difficult to image, as it emerges at the level of the radial neck and passes into the posterior compartment by passing between the two heads of the supinator muscle.[4]

PART 3

A



B

FIGURE 32F–8. (**A**) Position of the arm, probe and needle for ulnar nerve block proximal to the elbow. (**B**) Distribution of local anesthetic (blue-shaded area) for UN block.

The Median Nerve

With the arm abducted and the palm facing up, the skin of the anterior and medial side of the elbow is disinfected and the transducer positioned transversely on the antecubital fossa. The median nerve should be identified on the medial side of the artery. If it is not immediately visualized, the transducer should be positioned slightly more medially and the brachial artery identified using color Doppler ultrasound. The needle is inserted in plane from either side of the transducer, although a medial to lateral approach is usually more convenient to avoid the artery that lies lateral to the nerve. (Figure 32F–7a). After negative aspiration, 4–5 mL of local anesthetic is injected (Figure 32F–7b). If the spread is inadequate, slight adjustments can be made and a further 2–3 mL of local anesthetic administered.

The Ulnar Nerve

The transducer is then positioned more medially until the ulnar nerve is identified. The needle is inserted in plane from either side of the transducer (the anterior to posterior side is often more ergonomic) (Figure 32F–8a). After negative aspiration, 4–5 mL of local anesthetic is injected (Figure 32F–8b). If the spread of local anesthetic is inadequate, slight adjustments can be made and a further 2–3 mL administered.

TIPS

- When in doubt, nerve stimulation (0.5–1.0 mA) can be used to confirm localization of the correct nerve.
- The out-of-plane approach can also be used for all three blocks.

CHAPTER 32G

Ultrasound-Guided Wrist Block

Ine Leunen, Sofie Louage, Hassanin Jalil, and Xavier Sala-Blanch

WRIST BLOCK AT A GLANCE

- Indications: hand and finger surgery
- Transducer position: transverse at wrist crease or distal third of the forearm (Figure 32G–1)
- Goal: local anesthetic injection next to the median and ulnar nerves and the sensory branch of the radial nerve
- Local anesthetic: 10–15 mL (total volume)

GENERAL CONSIDERATIONS

The wrist block is an effective method to provide anesthesia of the hand and fingers without the arm immobility that occurs with more proximal brachial plexus blocks. Traditional wrist block technique involves advancing needles using surface landmarks toward the three nerves that supply the hand: the median, ulnar, and radial nerves. Since the nerves are located relatively close to the surface, this is a technically easy block to perform, but knowledge of the anatomy of the soft tissues of the wrist is essential for successful blockade with minimum patient discomfort. In addition to providing anesthesia and analgesia, wrist blocks using botulinum toxin to treat hyperhidrosis have been described.[1]

ULTRASOUND ANATOMY

Three individual nerves are involved in a wrist block: the median, ulnar, and radial nerves.

The Median Nerve

The median nerve crosses the elbow medial to the brachial artery and courses toward the wrist deep to the flexor digitorum superficialis in the center of the forearm. As the muscles taper toward tendons near the wrist, the nerve assumes an increasingly superficial position until it is located beneath the flexor retinaculum in the carpal tunnel with the tendons of the flexor digitorum profundus, flexor digitorum superficialis, and flexor pollicis longus. A linear transducer placed transversely at the level of the wrist crease will reveal a cluster of oval hyperechoic structures, one of which is the median nerve. At this location, it is easy to confuse the tendons for the nerve and vice versa; for this reason, it is recommended to slide the transducer 5–10 cm proximally the volar side of the forearm, to confirm the location of the nerve. The tendons will have disappeared on the image, leaving just muscle and the solitary median nerve (Figures 32G-2 and 32G-3), which then can be carefully traced back to the wrist, if desired. In many instances, however, it is much simpler to perform a median nerve block at the midforearm, where the nerve is easier to recognize.

Clinical Pearl

- The median nerve exhibits pronounced anisotropy. Tilting the transducer slightly will make the nerve appear alternately brighter (more contrast) or darker (less contrast) with respect to the background.

The Ulnar Nerve

The ulnar nerve is located medially (ulnar side) to the ulnar artery from the level of the midforearm to the wrist; this provides a useful landmark. A linear transducer placed at the level of the wrist crease will show the hyperechoic anterior surface of the ulna with shadowing behind; just lateral to the bone and very superficial will be the triangular or oval hyperechoic ulnar nerve, with the pulsating ulnar artery immediately next to it

FIGURE 32G–1. Ultrasound-guided wrist block. Transducer and needle positions for (**A**) median nerve block; (**B**) ulnar nerve block; (**C**) radial nerve block.

(Figures 32G–4 and 32G–5). At this location, the tendon of the flexor carpis ulnaris muscle can be seen superficial to the ulnar nerve. Scanning proximally, these two structures can be easily differentiated. Sliding the transducer up and down the forearm helps verify that the structure is the ulnar nerve by following the course of the ulnar artery and looking for the nerve on its ulnar side.

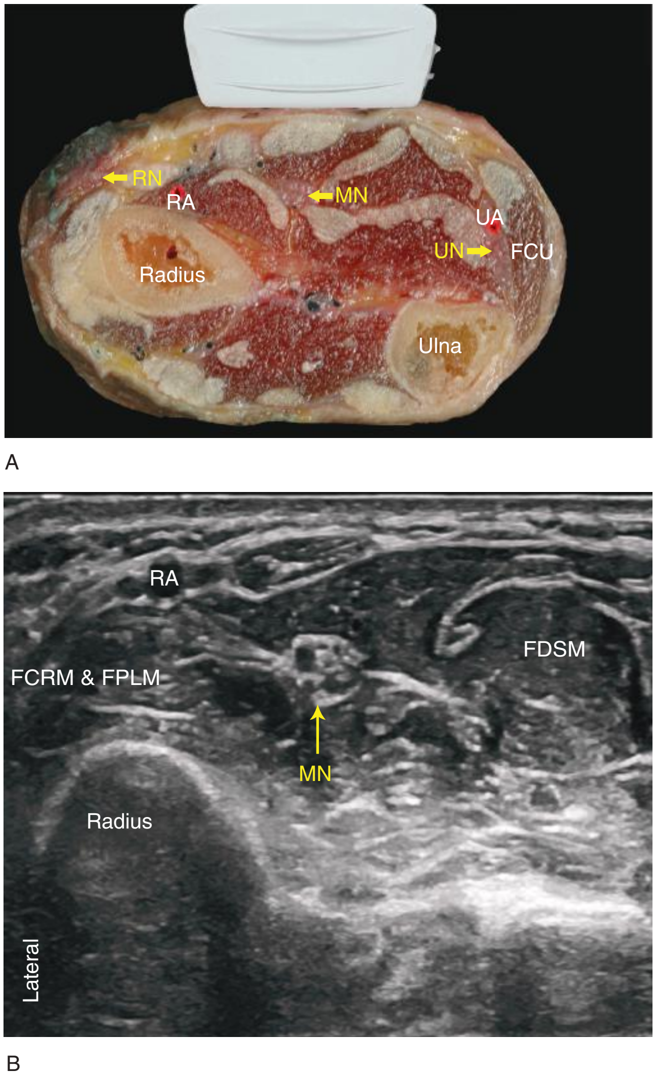

FIGURE 32G–2. (**A**) Cross-sectional anatomy of the distal forearm. (**B**) Sonoanatomy of the median nerve (MN) at the forearm. RA, radial artery; FCRM, flexor carpi radialis muscle; FPLM, flexor pollicis longus muscle; FDSM, flexor digitorum superficialis muscle.

The Radial Nerve

The superficial branch of the radial nerve divides into terminal branches at the level of the wrist; for this reason, ultrasonography is not very useful for block placement guidance at the level of the wrist. A subcutaneous field block around the area of the styloid process of the radius remains an easy method to perform an effective radial nerve block at the level of the wrist. However, ultrasonography can be used at the level of the elbow or in the midforearm. At this level, the nerve is identified as a thin hyperechoic structure lateral to the radial artery and superficial to the radius. The nerve exits the antebrachial fascia between the tendons of the brachioradialis and the extensor carpi radialis muscles (Figures 32–6 and 32–7).

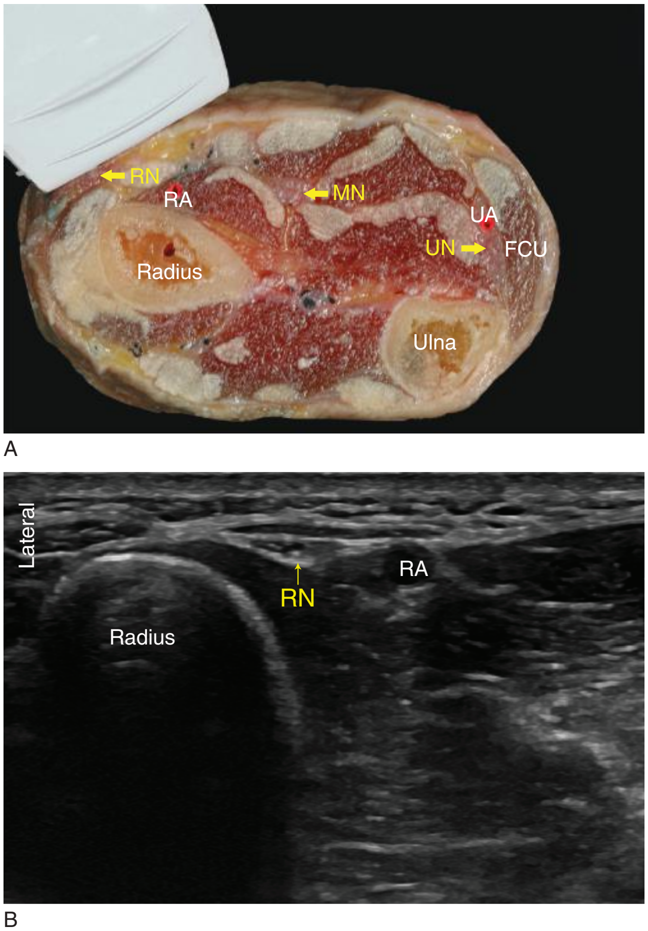

FIGURE 32G–6. (**A**) Cross-sectional anatomy of the distal forearm. (**B**) Sonoanatomy of the radial nerve (RN) at the forearm. RA, radial artery.

DISTRIBUTION OF ANESTHESIA

A wrist block results in anesthesia of the entire hand, except the territory of the deep branch of the radial nerve. For a more comprehensive review of the distribution of each terminal nerve, see Chapter 3.

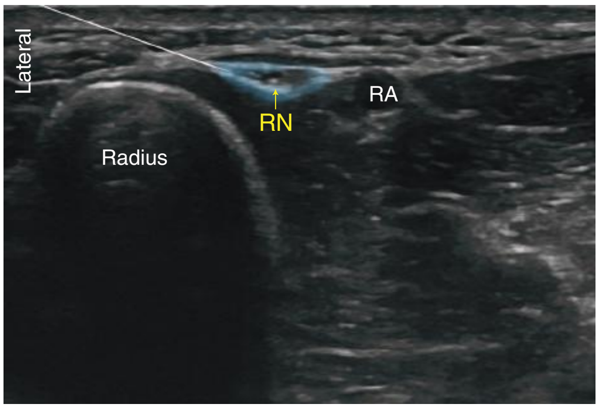

FIGURE 32G–7. Sonoanatomy of the radial nerve (RN) at the level of the wrist. The superficial branch of the RN at the wrist is shown lateral to the radial artery (RA), and the approximate needle path to reach the branch of the radial nerve is shown with an approximate spread of local anesthetic (blue-shaded area) to anesthetize it.

PART 3

EQUIPMENT

The equipment needed for a wrist block includes the following:

- Ultrasound machine with linear transducer (8–14 MHz), sterile sleeve, and gel
- Standard nerve block tray
- 5 mL syringes containing local anesthetic
- A 2-3 mm 22- to 25-gauge needle with low-volume extension tubing
- Sterile gloves

LANDMARKS AND PATIENT POSITIONING

The wrist block is most easily performed with the patient in the supine position to allow for the volar surface of the wrist to be exposed (Figure 32G-1). It is useful to remove splints and/or bandages on the hand to facilitate placement of the transducer and sterile preparation of the skin surface.

GOAL

The goal of this block is to place the needle tip immediately adjacent to each of the nerves to deposit local anesthetic until its spread around the nerve is documented with ultrasound visualization.

TECHNIQUE

With the arm in the volar side up position, the skin is disinfected. The wrist is a "tightly packed" area that is bounded on three sides by bones. For this reason, a US-guided "wrist" block is often performed 5–10 cm proximally to the wrist crease, where there is more room to maneuver. This location also ensures the blockade of the palmar branches of the median and ulnar nerves, which take off few centimeters proximaly to the wrist crease. For each of the blocks, the needle may be inserted either in plane or out of plane. Ergonomics often dictates which is most effective. Care must be taken when performing the ulnar and radial nerve blocks since these nerves are intimately associated with arteries. Inadvertent arterial puncture can lead to hematoma. Successful block is predicted by the spread of local anesthetic immediately adjacent to the nerve. Multiple injections to achieve circumferential spread are usually not necessary because these nerves are small and the local anesthetic diffuses quickly into the neural tissue due to the lack of thick epineural tissues. Assuming deposition immediately adjacent to the nerve, 3–4 mL/nerve of local anesthetic is sufficient to ensure an effective block.

SECTION 4 Ultrasound-Guided Nerve Blocks for the Lower Extremity

CHAPTER 33A

Ultrasound-Guided Femoral Nerve Block

Arthur Atchabahian, Ine Leunen, Catherine Vandepitte, and Ana M. Lopez

BLOCK AT A GLANCE

- Indications: femur, patella, quadriceps tendon, and knee sugery; analgesia for hip fracture (Figure 33A–1)
- Transducer position: transverse, femoral crease
- Goal: local anesthetic spread adjacent to the femoral nerve
- Local anesthetic: 10–15 mL

GENERAL CONSIDERATIONS

The ultrasound (US)-guided technique of femoral nerve blockade allows the practitioner to monitor the spread of local anesthetic and needle placement and make appropriate adjustments to accomplish the desirable disposition of the local anesthetic. US also may reduce the risk of femoral artery puncture. Although nerve stimulation is not required for success, motor response observed during nerve stimulation often provides contributory safety information should the needle–nerve relationship be missed by US alone.

ULTRASOUND ANATOMY

Orientation begins with the identification of the femoral artery at the level of the femoral crease. Commonly, the femoral artery and the deep artery of the thigh are both seen. In this case, the transducer should be moved proximal until only the femoral artery is seen (Figure 33A–2a, b). The femoral nerve is lateral to the vessel and covered by the fascia iliaca; it is typically hyperechoic and roughly triangular or oval in shape (Figure 33A–3a, b). The nerve is enveloped within two layers of the fascia iliaca. The femoral nerve typically is visualized at a depth of 2–4 cm.

FIGURE 33A–1. Expected distribution of femorar nerve blockade. Left - Osteotomal distribution, Right - Dermatomal distribution.

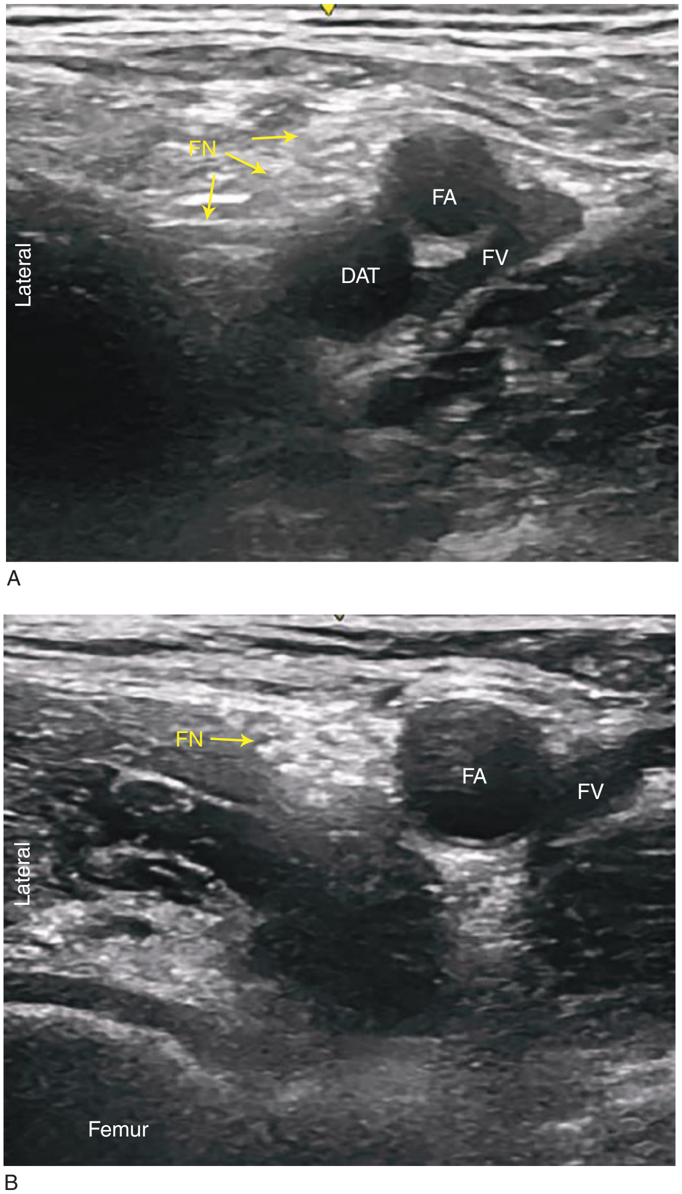

FIGURE 33A–2. Femoral nerve (FN) as seen distally (**A**) and at the femoral crease (**B**). Note that FN is better visualized at B, before the take off the deep artery of the thigh (DAT). Femoral vein (FV) is medial to the artery.

TIPS

- Identification of the femoral nerve often is made easier by slightly tilting the transducer cranially or caudally. This adjustment helps bring out the image of the nerve, making it distinct from the background.
- Applying pressure to the transducer often optimizes the image of the femoral nerve but may collapse veins, obscuring them from the examiner's eye.
  The transducer pressure also may compress the interfascial space and interfere with the adequate spread of the local anesthetic. Therefore, the transducer pressure should be released and vasculature re-ascertained before injection.

DISTRIBUTION OF ANESTHESIA

Femoral nerve block results in anesthesia of the anterior and medial thigh down to and including the knee, as well as a variable strip of skin on the medial leg and foot. It also innervates the hip, knee, and ankle joints.

EQUIPMENT

The equipment recommended for a femoral nerve block includes the following:

- Ultrasound machine with linear transducer (8–18 MHz), sterile sleeve, and gel
- Standard nerve block tray
- One 20-mL syringe containing local anesthetic

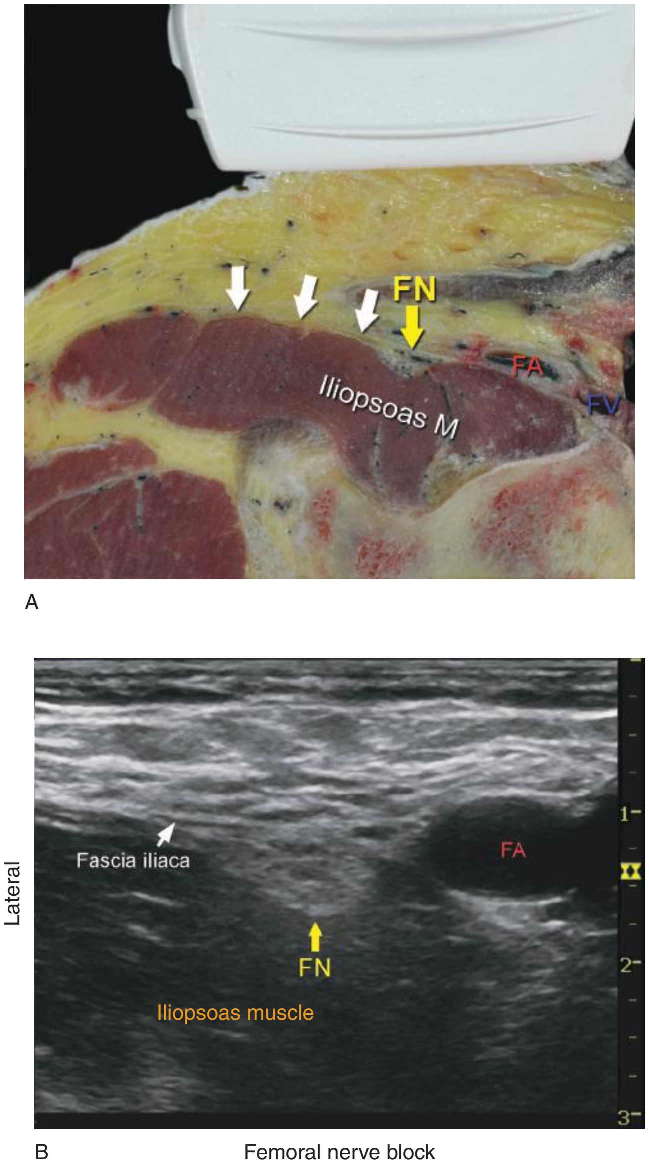

FIGURE 33A–3. (**A**) Cross-sectional anatomy of the femoral nerve (FN) at the level of the femoral crease. The FN is seen on the surface of the iliopsoas muscle covered by fascia iliaca (white arrows). The femoral artery (FA) and femoral vein (FV) are seen enveloped within their own vascular fascial sheath created by one of the layers of fascia lata. (**B**) Sonoanatomy of the FN at the femoral triangle. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc.; 2011.)

- A 50- to 100-mm, 22-gauge, short-bevel, insulated stimulating needle
- Peripheral nerve stimulator
- Injection pressure monitor
- Sterile gloves

LANDMARKS AND PATIENT POSITIONING

This block typically is performed with the patient in the supine position, with the bed or table flattened to maximize operator access to the inguinal area. The transducer is placed transversely on the femoral crease, over the pulse of the femoral artery, and moved slowly in a lateral-to-medial direction to identify the artery.

FIGURE 33A–4. Obesity is common in patients who present with an indication for femoral nerve block. Taping the adipose tissue away helps optimize exposure to the femoral crease in patients with morbid obesity.

Clinical Pearl

- In such cases, using a wide silk tape to retract the abdomen is a useful maneuver prior to skin preparation and scanning (Figure 33A–4).

GOAL

The goal is to place the needle tip immediately adjacent to the lateral aspect of the femoral nerve, below the fascia iliaca or between the two layers of the fascia iliaca, that surround the femoral nerve. Proper deposition of local anesthetic is confirmed either by observation of the femoral nerve being displaced by the injectate or by the spread of the local anesthetic above or below the nerve, surrounding and separating it from the fascia iliaca layers.

TECHNIQUE

With the patient in the supine position, the skin over the femoral crease is disinfected and the transducer is positioned to identify the femoral artery and nerve. If the nerve is not immediately apparent lateral to the artery, tilting the transducer proximally or distally often helps to image and highlight the nerve from the iliacus muscle and the more superficial adipose tissue. In doing so, an effort should be made to identify the iliacus muscle and its fascia, as well as the fascia lata, because injection underneath a wrong fascial sheath may result in block failure.

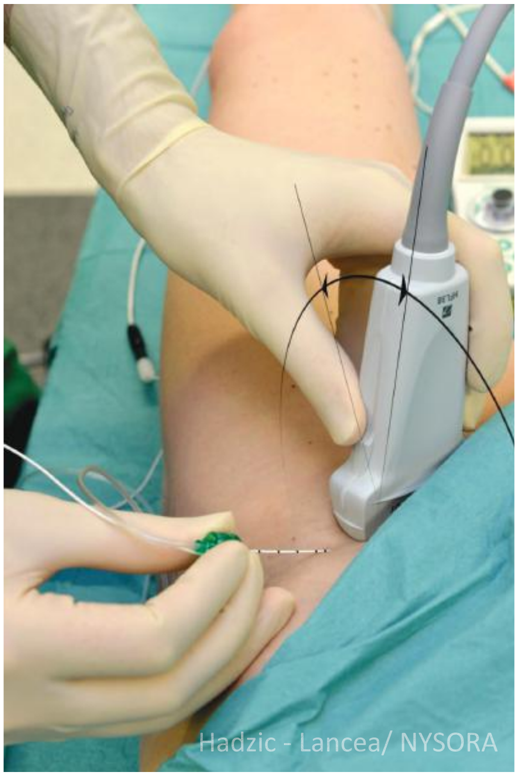

FIGURE 33A–5. Transducer position and needle insertion using an in-plane technique to block the femoral nerve at the femoral crease.

Once the femoral nerve is identified, a skin wheal of local anesthetic is made 1 cm away from the lateral edge of the transducer. The needle is inserted in plane in a lateral-to-medial orientation and advanced toward the femoral nerve (Figure 33A–5). If nerve stimulation is used (0.5 mA, 0.1 msec), the passage of the needle through the fascia iliaca and contact of the needle tip with the femoral nerve usually is associated with a motor response of the quadriceps muscle group. In addition, a needle passage through the fascia iliaca is often felt. Once the needle tip is adjacent (either above, below, or lateral) to the nerve (Figure 33A–6), and after careful aspiration, 1–2 mL of local anesthetic is injected to confirm proper needle placement (Figures 33A–7 and 33A-8). Proper injection will push the femoral nerve away from the injection. Additional needle repositions and injections are done only when necessary. Anatomic variations have been described with aberrant positions of the femoral nerve.[1,2] In an adult patient, 10–15 mL of local anesthetic is adequate for a successful block.

TIPS

- Never inject against high resistance to injection because this may signal an intrafascicular needle placement or needle tip position in a wrong fascial plane.
- Circumferential spread of local anesthetic around the nerve is not necessary for this block. A pool of local anesthetic immediately adjacent to either the posterolateral or the anterior aspects is sufficient.[3]

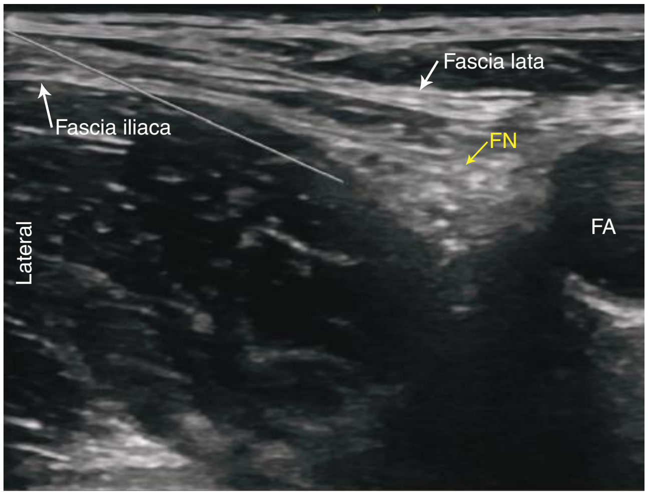

FIGURE 33A–6. Ultrasound image of the needle path to block the femoral nerve. The needle pierces the fascia iliaca lateral to the femoral nerve (FN) and the needle tip is advanced along the deep border of the nerve. FA, femoral artery.

- Locate the femoral vein, releasing pressure on the transducer, using color Doppler if needed. The femoral vein is typically medial to the artery, but it can occasionally lie deep or even lateral to it.[4,5] It is often compressed by the probe during block performance; being aware of the position of the vein helps decrease the risk of inadvertent intravascular injection.[4,5]
- Applying forceful pressure to the transducer will compress the tissue below it, making injection more difficult and possibly interfering with spread between the fascial layers.
- Following hip arthroscopy, landmarks might be displaced by fluid extravasation, with the artery and the nerve significantly deeper than their preoperative position.[6]

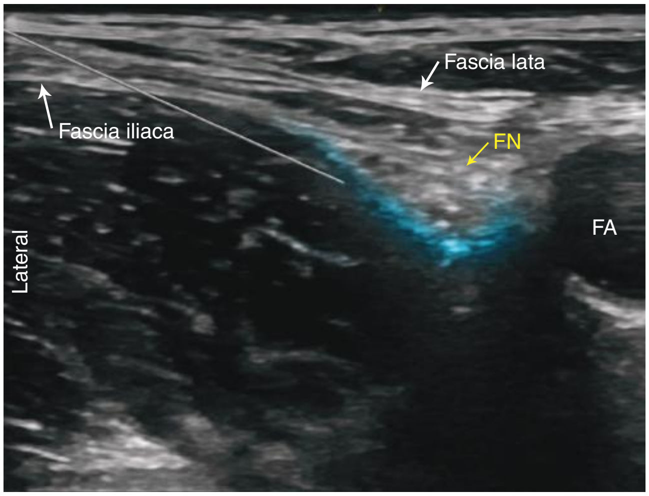

FIGURE 33A–7. Simulated needle path and spread of local anesthetic (blue-shaded area) to block the femoral nerve (FN). FA, femoral artery.

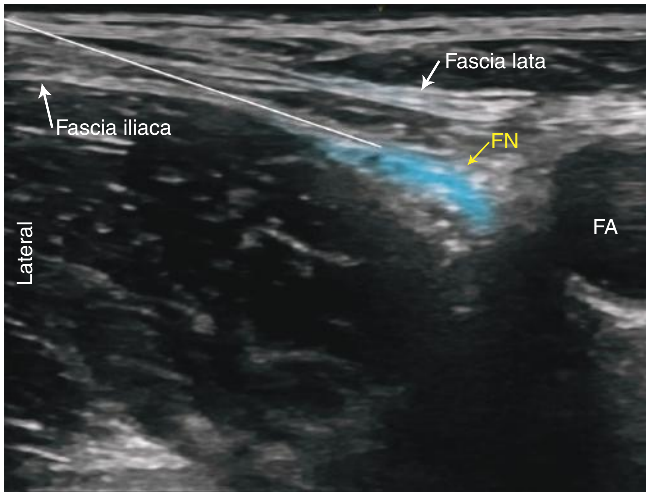
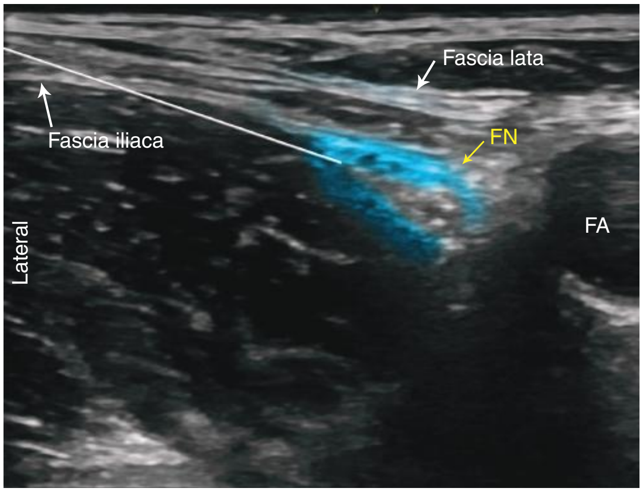


A



B

FIGURE 33A–8. Simulated needle paths and local anesthetic spread to block the femoral nerve (FN). (**A**) The needle tip is advanced in between the fascia iliaca and the nerve and the local anesthetic deposited superficially to the nerve. (**B**) The tip is located just lateral to the femoral nerve nerve, in between the two layers surrounding the nerve. FA, femoral artery.

CONTINUOUS ULTRASOUND-GUIDED FEMORAL NERVE BLOCK

The goal of the continuous femoral nerve block is placement of the catheter within the vicinity of the femoral nerve just deep to the fascia iliaca. The procedure consists of five steps: (1) needle placement; (2) injection through the needle to confirm needle placement in the proper tissue plane; (3) catheter advancement; (4) injection through the catheter to assure its therapeutic position; (5) securing the catheter. For the first two phases of the procedure, US can be used to ensure accuracy in most patients. The in-line approach from the lateral-to-medial direction is the most common method because the out-of-plane approach holds greater risk for puncture of the femoral nerve if the needle is introduced directly above the nerve (Figure 33A-9).[7,8,9] Alternative approaches, such as the oblique approach, have also been suggested.[10]

Clinical Pearls

- With US guidance, nonstimulating catheters are used for continuous femoral block. Stimulating catheters require a longer insertion time, without improvement in analgesia.[11,12] Stimulating catheters also may lead to unnecessary needle and catheter manipulation to obtain the motor response, when in fact the catheter is often in the proper place even when there is no motor response.
- Adequate catheter placement with US guidance is confirmed by disposition of the local anesthetic in the proper anatomical space rather than by motor stimulation.[13]

For detailed description, please refer to “Continuous US-guided nerve block” in Chapter 32B. In general, the inguinal area is quite mobile, and the femoral nerve is shallow, both of which predispose to catheter dislodgment. The more lateral the starting point for needle insertion for continuous femoral nerve block, the longer the catheter would be within the iliacus muscle, which may help prevent dislodgment because muscle tends to stabilize a catheter better than adipose tissue. A common empirical infusion regimen for femoral nerve block in an adult patient is ropivacaine 0.2% at an infusion rate of 5 mL/h with a 5 mL/h patient-controlled bolus.

FIGURE 33A–9. Continuous femoral nerve block. The needle is seen inserted in plane approaching the nerve in a lateral-to-medial direction. Although it would seem intuitive that a longitudinal needle insertion would have advantages, the technique demonstrated here is simpler and commonly used. The catheter should be inserted 2–4 cm past the needle tip.

CHAPTER 33B

Ultrasound-Guided Fascia Iliaca Block

Arthur Atchabahian, Ine Leunen, Catherine Vandepitte, and Ana M. Lopez

FASCIA ILIACA BLOCK AT A GLANCE

- Indications: anterior thigh and knee surgery, analgesia following hip and knee procedures
- Transducer position: transverse, close to the femoral crease and lateral to the femoral artery (Figure 33B–1)
- Goal: medial–lateral spread of local anesthetic underneath the fascia iliaca
- Local anesthetic: 20–40 mL of dilute local anesthetic (eg, 0.2% ropivacaine)

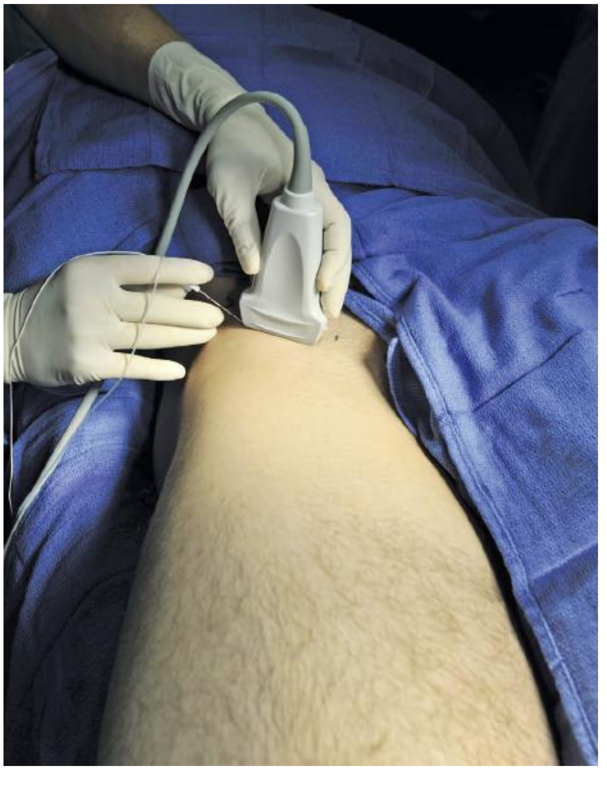

FIGURE 33B–1. Needle insertion for the fascia iliaca block. The blue dot indicates the position of the femoral artery. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

GENERAL CONSIDERATIONS

The fascia iliaca block (also called the fascia iliaca compartment block) is considered an alternative to a femoral nerve or a lumbar plexus block. Since the femoral nerve and lateral femoral cutaneous nerve (LFCN) lie under the fascia of the iliacus muscle, a sufficient volume of local anesthetic deposited deep to the fascia iliaca may spread underneath the fascia in a medial and lateral direction to reach the femoral nerve and sometimes the LFCN.

Although some authors suggest that the local anesthetic may also spread underneath fascia iliaca proximally toward the lumbosacral plexus, this has not been demonstrated consistently. Before ultrasound (US), the technique involved needle placement at the lateral third of the distance from the anterior superior iliac spine to the pubic tubercle, using a "double-pop" technique as the needle passes through the fascia lata and fascia iliaca. However, block success with this "feel" technique is sporadic because false "pops" can occur. In contrast, the US-guided technique allows monitoring of the needle placement and local anesthetic delivery and ensures delivery of the local anesthetic into the correct plane.[1]

ULTRASOUND ANATOMY

The fascia iliaca is located anterior to the iliacus muscle (on its surface) within the pelvis. It is bound superolaterally by the iliac crest and merges medially with the fascia overlying the psoas muscle. Both the femoral and lateral cutaneous nerves of the thigh lie under the fascia iliaca in their intrapelvic course. Anatomical orientation begins in the same manner as

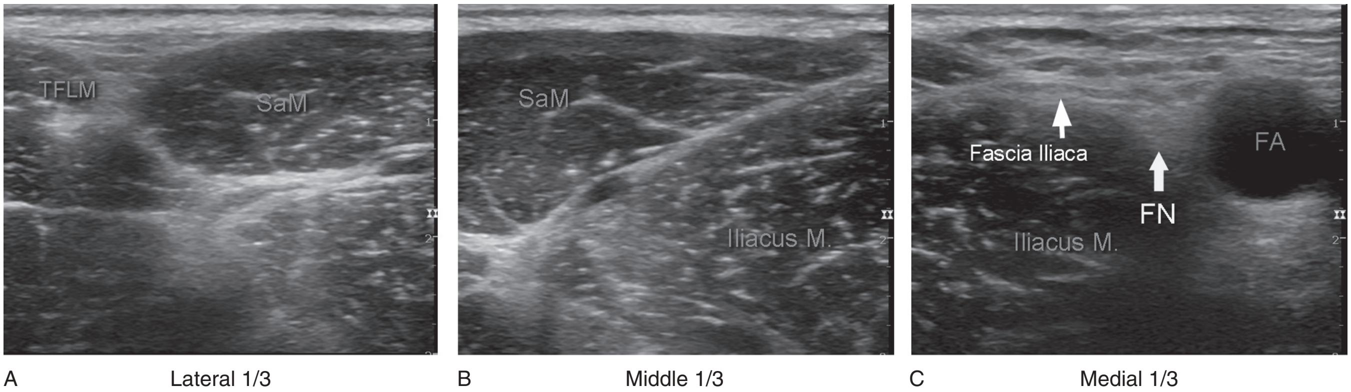

FIGURE 33B–2. A panoramic view of the US anatomy of the femoral (inguinal) crease area. From lateral to medial, shown are the tensor fasciae latae muscle (TFLM), sartorius muscle (SaM), iliac muscle, fascia iliaca, femoral nerve (FN), and femoral artery (FA). The (**A**) lateral, (**B**) middle, and (**C**) medial thirds are derived by dividing the line between the FA and the anterior superior iliac spine in three equal sections. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

the femoral block: identifying the femoral artery at the level of the inguinal crease. If it is not immediately visible, sliding the transducer medially and laterally will eventually bring the vessel into view. Immediately lateral and deep to the femoral artery and vein is a large hypoechoic structure, the iliopsoas muscle (Figure 33B–2). It is covered by a hyperechoic fascia, which can be seen separating the muscle from the subcutaneous tissue superficial to it.

The hyperechoic femoral nerve should be seen wedged between the iliopsoas muscle and the fascia iliaca, lateral to the femoral artery. The fascia lata (superficial in the subcutaneous layer) is more superficial and may have more than one layer. Moving the transducer laterally several centimeters brings into view the sartorius muscle covered by its own fascia as well as the fascia iliaca. Further lateral movement of the transducer reveals the anterior superior iliac spine (see Figure 33B–2). Additional anatomical detail can be seen in the cross-sectional anatomy presented in Chapter 33A. Since the anatomy is essentially identical to that described for the femoral nerve block, it is not repeated here.

Clinical Pearl

- The transducer can be placed anywhere between the level of the femoral crease and inguinal ligament.

DISTRIBUTION OF ANESTHESIA

The distribution of anesthesia and analgesia depends on the extent of local anesthetic spread and the nerves blocked. Blockade of the femoral nerve results in anesthesia of the anterior and medial thigh (down to and including the knee) and anesthesia of the variable strip of skin on the medial leg and foot (saphenous nerve). The femoral nerve also contributes to articular fibers to both the hip and knee. The lateral femoral cutaneous nerve confers cutaneous innervation to the anterolateral thigh (Figure 33B-3). For a more comprehensive review of the femoral and lateral femoral cutaneous nerves and lumbar plexus nerve distribution, see Chapter 3.

EQUIPMENT

The equipment needed for a fascia iliaca block includes the following:

- Ultrasound machine with linear transducer (6–14 MHz), sterile sleeve, and gel
- Standard nerve block tray

FIGURE 33B–3. Expected distribution of fascia iliaca sensory block (lateral femorocutaneous and femoral nerves blocks).

- Two 20-mL syringes containing local anesthetic
- 80- to 100-mm, 22-gauge needle (a short bevel aids in eliciting the fascial "pop" if desired)
- Sterile gloves

LANDMARKS AND PATIENT POSITIONING

This block is typically performed with the patient in the supine position, with the bed or table flattened to maximize access to the inguinal area (Figure 33B–1). Although palpation of a femoral pulse is a useful landmark, it is not required because the artery is quickly visualized by placement of the transducer transversely on the inguinal crease, followed by slow movement laterally or medially. Tilting the probe while pressing helps to identify the hyperchoic fascia iliaca superficial to the hypoechoic iliopsoas muscle. Medially, the Femoral nerve is visualized deep to the fascia and lateral to the artery (Figure 33B-4). Laterally, the sartorious muscle is identified by its typical triangular shape when compressed by the transducer.

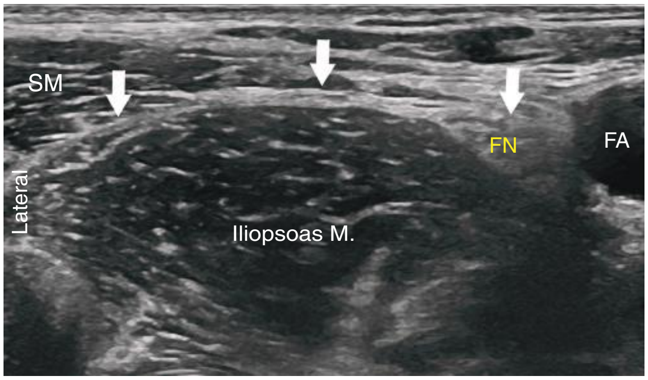

FIGURE 33B–4. Ultrasound image of the fascia iliaca (white line and arrows) at the level of the inguinal ligament. The femoral nerve (FN) and femoral artery (FA) are visualized on the medial side and the sartorious muscle (SM) on the lateral side.

GOAL

The goal is to place the needle tip under the fascia iliaca approximately at a lateral third of the line connecting the anterior superior iliac spine to the pubic tubercle (the injection is made several centimeters lateral to the femoral artery) and to deposit a relatively large volume (20–40 mL) of local anesthetic until its spread laterally toward the iliac spine and medially toward the femoral nerve is observed with US visualization.

TECHNIQUE

With the patient in the proper position, the skin is disinfected and the transducer positioned to identify the femoral artery and the iliopsoas muscle and fascia iliaca. The transducer is moved laterally until the sartorius muscle is identified. After a skin wheal is made, the needle is inserted in plane (see Figure 33B–1). As the needle passes through fascia iliaca, the fascia is first seen indented by the needle. As the needle eventually pierces the fascia, a "pop" may be felt, and the fascia may be seen to "snap" back on the US image. After negative aspiration, 1–2 mL of local anesthetic is injected to confirm the proper injection plane between the fascia and the iliopsoas muscle (Figure 33B–5a, b). If local anesthetic spread occurs above the fascia or within the substance of the muscle itself, additional needle repositions and injections may be necessary. A proper injection will result in the separation of the fascia iliaca by the local anesthetic in the medial–lateral direction from the point of injection as described. Releasing the pressure of the transducer may reduce the resistance to injection and improve the distribution of local anesthetic. If the spread is deemed inadequate, additional injections laterally or medially to the original needle insertion or injection can be made to facilitate the medial–lateral spread.

In an adult patient, 20–40 mL of local anesthetic is usually required for successful blockade. In children, 0.7 mL/kg is commonly used. The success of the block is best predicted by documenting the spread of local anesthetic toward the femoral nerve medially and underneath the sartorius muscle laterally (Figure 33B-5b). In obese patients, an out-of-plane technique

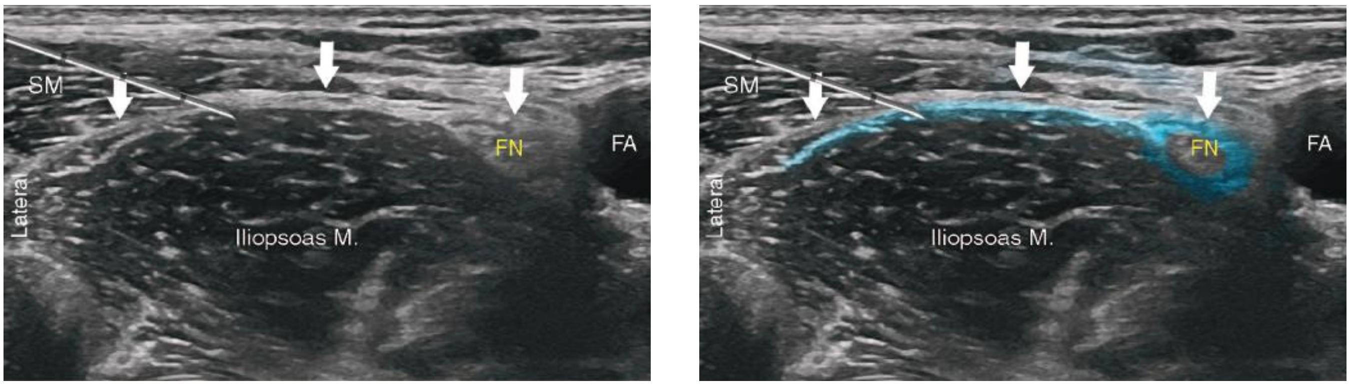

FIGURE 33B–5. (**A**) Position of the needle tip for the fascia iliaca block. The needle is shown underneath the fascia iliaca lateral to the femoral artery but not deep enough to be lodged in the iliac muscle. (**B**) A simulated spread (blue-shaded area) of local anesthetic to accomplish a fascia iliaca block.

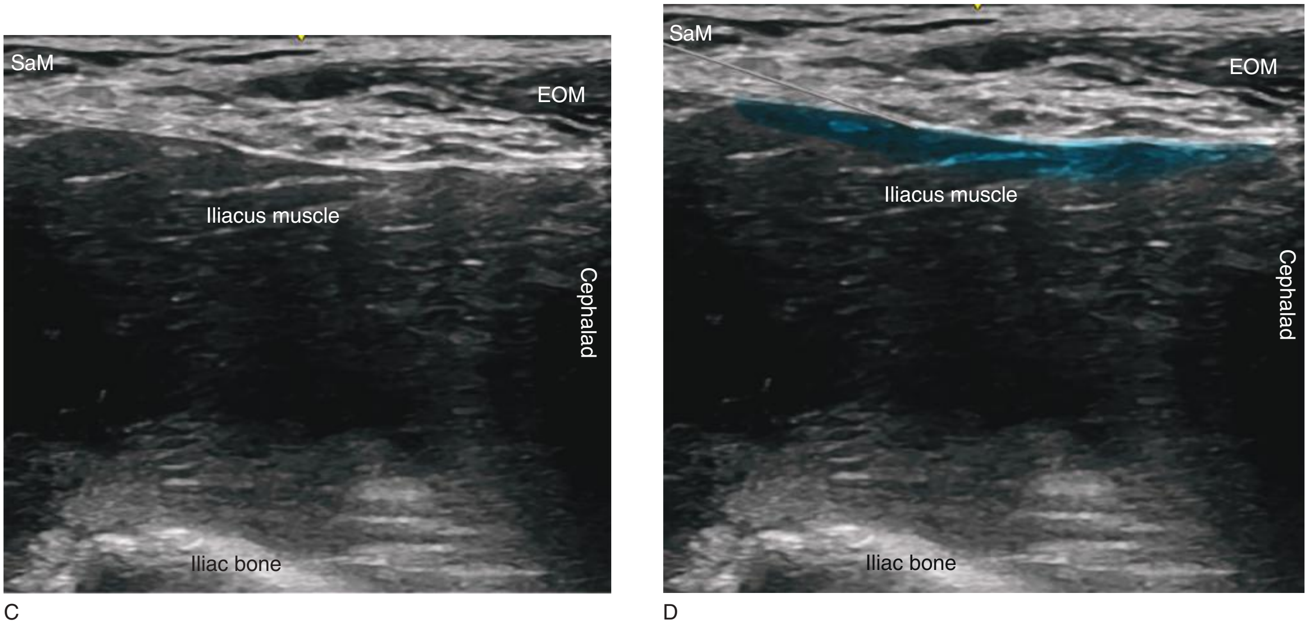

FIGURE 33B–5. (*Continued*) (**C**) Ultrasound view of the suprainguinal approach with the probe oriented in a sagittal plane along the iliacus muscle. (**D**) Needle path and simulated local anesthetic spread (blue-shaded area) just deep to the fascia iliaca and the external oblique muscle (EOM). SaM, sartorius muscle.

may be favored. The block should result in blockade of the femoral nerve in all instances (100%) and the lateral femoral nerve in most instances (80–100%). Blockade of the anterior branch of the obturator nerve does not occur with the fascia iliaca block.[2,3] When required, this nerve should be blocked as described in Chapter 33D.

An alternative suprainguinal technique may result in a more proximal spread and possibly more efficacious analgesia after hip surgery (Figures 33B-5c, 33B-5d, and 33B-6),[4,5] although there are no data published to support these claims. Likewise, there are no data supporting the use of continuous fascia iliaca block at this time.

TIPS

- The fascia iliaca block is a large-volume block. Its success depends on the spread of local anesthetic underneath the fascia iliaca. A volume of 30–40 mL of injectate is necessary to accomplish the block.
- The spread of local anesthetic is monitored with ultrasonography. If the pattern of spread is not adequate (eg, the local anesthetic is collecting in one location and not "layering out"), the injection is stopped and the needle repositioned before continuing. Additional injections may be made to ensure adequate spread.

CHAPTER 33C

Ultrasound-Guided Lateral Femoral Cutaneous Nerve Block

Thomas B. Clark, Ana M. Lopez, Daquan Xu, and Catherine Vandepitte

LATERAL FEMORAL CUTANEOUS NERVE BLOCK AT A GLANCE

- Indications: postoperative analgesia for hip surgery, meralgia paresthetica, and muscle biopsy of the proximal lateral thigh
- Transducer position: transverse, inferior to the anterior superior iliac spine; the lateral edge of the sartorius muscle should be visualized with ultrasound
- Goal: local anesthetic spread around LFCN between the tensor fasciae latae and sartorius muscles
- Local anesthetic: 5 mL (adults)

GENERAL CONSIDERATIONS

The lateral femoral cutaneous nerve (LFCN) divides into several branches innervating the lateral and anterior aspects of the thigh. Of note, in 45% of patients, innervation of the LFCN extends even to the anterior thigh.[1] The variable anatomy of the lateral femoral cutaneous nerve makes it challenging to perform an effective landmark-based block. US guidance, however, allows for more accurate needle insertion into the appropriate fascial plane through which the LFCN passes.

ULTRASOUND ANATOMY

The LFCN typically is visualized between the tensor fasciae latae muscle (TFLM) and the sartorius muscle (SaM), 1–2 cm medial and inferior to the anterior superior iliac spine (ASIS) and 0.5–1.0 cm deep to the skin surface (Figure 33C–1). Ultrasound (US) imaging of the LFCN yields an oval hypoechoic small structure with a hyperechoic rim that can be easily seen in the hypoechoic background. The LFCN can be traced proximally, as it runs from the lateral to the medial edge of the superficial fascia of the SaM. The lateral edge of the SaM is a useful landmark, and as such, it can be relied on throughout the procedure. The posterior branch of the LFCN may sometimes be seen across the anterior margin of the TFLM.

DITRIBUTION OF ANESTHESIA

Block of the LFCN provides anesthesia or analgesia in the anterolateral thigh. There is a large variation in the area of sensory coverage among individuals because of the highly variable course of the LFCN and its branches (Figure 33C-2).

EQUIPMENT

The equipment recommended for an LFCN block is as follows:

- Ultrasound machine with linear transducer (18-6 MHz), sterile sleeve, and gel
- Standard nerve block tray
- Syringe(s) with 10 mL of local anesthetic
- 3–5 cm, 22- to 24-gauge needle
- Sterile gloves

LANDMARKS AND PATIENT POSITIONING

Block of the LFCN is performed with the patient in the supine or lateral position. Palpation of the anterior superior spine provides the initial landmark for transducer placement; the transducer is first positioned at 2 cm inferior and medial to the ASIS and adjusted accordingly. Typically, the nerve is identified slightly more distally in its course. Additional confirmation of

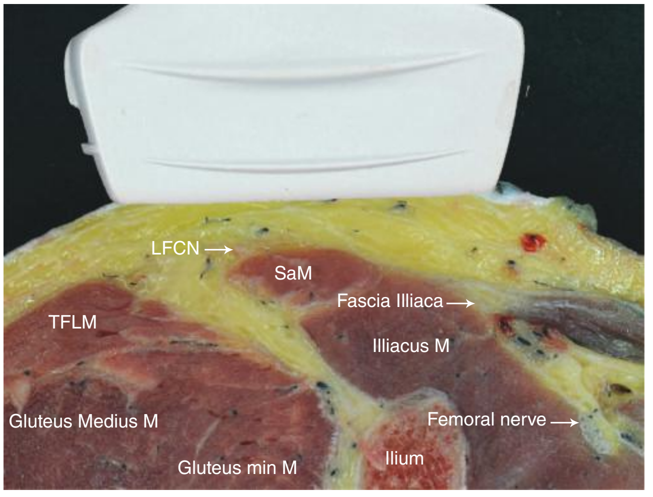

FIGURE 33C–1. Cross-sectional anatomy of the lateral femoral cutaneous nerve (LFCN). Shown are the LFCN, sartorius muscle (SaM), and tensor fasciae latae muscle (TFLM). (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

the correct identification of the LFCN may be made by eliciting a tingling sensation on the lateral side of the thigh using a nerve stimulator.

GOAL

The goal is to inject local anesthetic in the plane between the TFLM and the SaM, typically 1–2 cm medial and inferior to the ASIS.

FIGURE 33C–2. Expected distribution of lateral femorocutaneous nerve sensory block.

FIGURE 33C–3. Transducer position to accomplish a lateral femoral cutaneous nerve (LFCN) block.

TECHNIQUE

With the patient supine, the skin is disinfected and the transducer placed immediately inferior to the ASIS, parallel to the inguinal ligament (Figure 33C–3). The TFLM and SaM are then identified. The nerve should appear as a small hypoechoic oval structure with a hyperechoic rim between the TFLM and SaM in a short-axis view or superficial to the SaM (Figure 33C-4a).

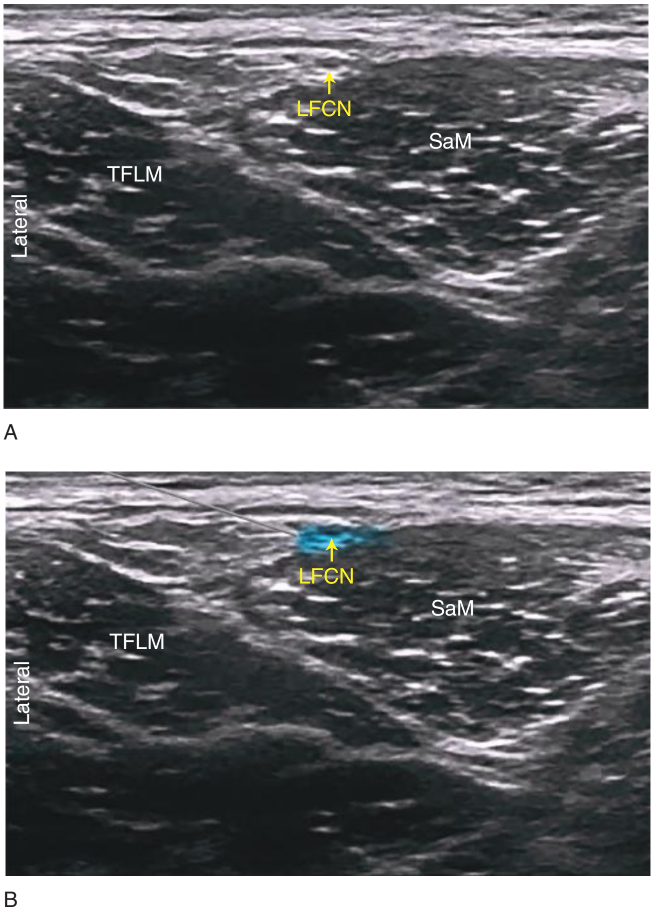

FIGURE 33C–4. (**A**) Ultrasound anatomy of the lateral femoral cutaneous nerve (LCFN). (**B**) Simulated needle path and local anesthetic spread (blue-shaded area) to anesthetize the LFCN.

The needle is inserted in plane in a lateral-to-medial orientation, through the subcutaneous tissue. A fascial "pop" or "click" may be felt as the needle tip enters the plane between the TFLM and SaM. A volume of 1–2 mL of local anesthetic is injected to verify the needle tip position. The correct position is achieved by visualizing the spread of local anesthetic in the described plane between the TFLM and SaM or around the LFCN superficial to the SaM (Figure 33C–4b).

TIPS

- A "subinguinal" technique has also been described, in which the US probe straddles the ASIS and the anterior inferior iliac spine (AIIS). Local anesthetic is injected under the inguinal ligament, 1–2 cm medial to the ASIS, without necessarily attempting to visualize the nerve.[3]
- In an adult patient, 5 mL of local anesthetic is usually sufficient. In children, a volume of 0.15 mL/kg per side is adequate for effective analgesia.

CHAPTER 33D

Ultrasound-Guided Obturator Nerve Block

Sam Van Boxstael, Catherine Vandepitte, Philippe E. Gautier, and Hassanin Jalil

OBTURATOR NERVE BLOCK AT A GLANCE

- Indications: Relief of painful adductor muscle contractions, to prevent adduction of the thigh during transurethral bladder surgery, additional analgesia after major knee surgery, and may provide postoperative analgesia after hamstring tendon harvest for anterior cruciate ligament (ACL) reconstruction (Figure 33D–1).[1,2]
- Transducer position: medial aspect of the proximal thigh.
- Goal: Local anesthetic spread in the interfascial plane in which the nerves lie or around the anterior and posterior branches of the obturator nerve.
- Local anesthetic: 5 mL into each interfascial space or around the branches of the obturator nerve.

GENERAL CONSIDERATIONS

Ultrasound (US)-guided obturator nerve block is simpler to perform and more reliable than surface landmark–based techniques. There are two approaches to performing a US-guided obturator nerve block. The interfascial injection technique relies on injecting local anesthetic solution into the fascial planes that contain the branches of the obturator nerve. With this technique, it is not important to identify the branches of the obturator nerve on the sonogram, but rather to identify the adductor muscles and the fascial boundaries within which the nerves lie. This is similar in concept to other fascial plane blocks (eg, the transversus abdominis plane [TAP] block in which local anesthetic solution is injected between the internal oblique and transverse abdominis muscles without the need to identify the nerves). Alternatively, the branches of the obturator nerve can be visualized with US imaging and blocked after eliciting a motor response.

ULTRASOUND ANATOMY

The obturator nerve forms in the lumbar plexus from the anterior primary rami of the L2–L4 roots and descends to the pelvis on the medial side of the psoas muscle. In most individuals, the nerve divides into an anterior branch and posterior branch before exiting the pelvis through the obturator foramen. In the thigh, at the level of the femoral crease, the **anterior branch** is located between the fascia of the pectineus and adductor brevis muscles. The anterior branch lies further caudad between the adductor longus and adductor brevis muscles. The anterior branch provides motor fibers to the adductor longus, brevis and gracilis muscles; and cutaneous branches to the medial aspect of the thigh. The anterior branch has a great variability in the extent of sensory innervation of the medial thigh.

The **posterior branch** lies between the fascial planes of the adductor brevis and adductor magnus muscles (Figures 33D–2 and 33D–3). The posterior branch is primarily a motor nerve for the adductors of the thigh; however, it also may provide articular branches to the medial aspect of the knee joint. The articular branches to the hip joint usually arise from the obturator nerve, proximal to its division and only occasionally from the individual branches (Figure 33D–4). In 8–30% of patients, an accessory obturator nerve arises from L3 and L4, travels with the femoral nerve, and gives branches to the hip joint.[2]

A helpful mnemonic to remember the order of the adductor muscles, from anterior to posterior, is as follows: Alabama: Adductor Longus, Adductor Brevis, Adductor MAgnus.

Clinical Pearl

- A psoas compartment (lumbar plexus) block is required to reliably block the articular branches of the obturator nerve to the hip joint because they usually depart proximal to the level at which the obturator nerve block is performed in the proximal thigh.

DISTRIBUTION OF ANESTHESIA

Because there is great variability in the cutaneous innervation to the medial thigh, demonstrated weakness of adductor muscle

FIGURE 33D–1. Expected distribution of obturator nerve sensory and motor blockade.

strength is the only reliable method of documenting a successful obturator nerve block (Figure 33D-1). However, the adductor muscles of the thigh may have co-innervation from the femoral nerve (pectineus) and the sciatic nerve (adductor magnus). Adductor motor strength is decreased by about 25% following femoral nerve blockade and 11% following sciatic nerve blockade. For this reason, complete loss of adductor muscle strength is uncommon despite a successful obturator nerve block.

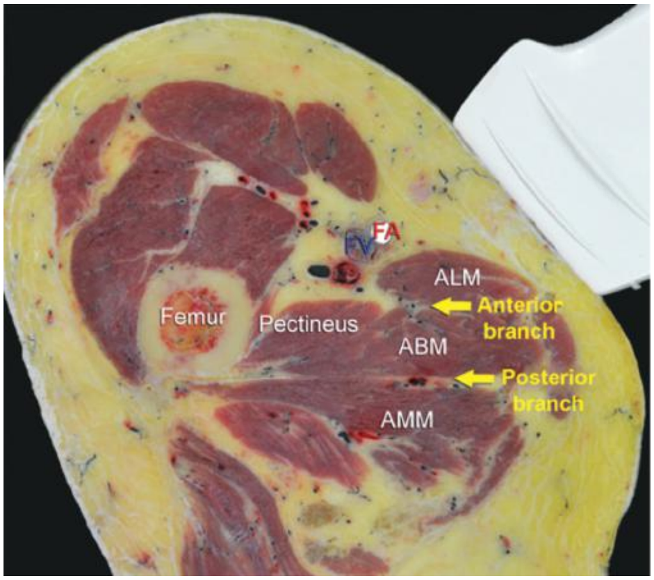

FIGURE 33D–2. Cross-sectional anatomy of relevance to the obturator nerve block. Shown are the femoral vessels (the femoral vein [FV] and femoral artery [FA]), pectineus muscle, adductor longus muscle (ALM), adductor brevis muscle (ABM), and adductor magnus muscle (AMM). The anterior branch of the obturator nerve is seen between the ALM and ABM, whereas the posterior branch is seen between the ABM and AMM. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

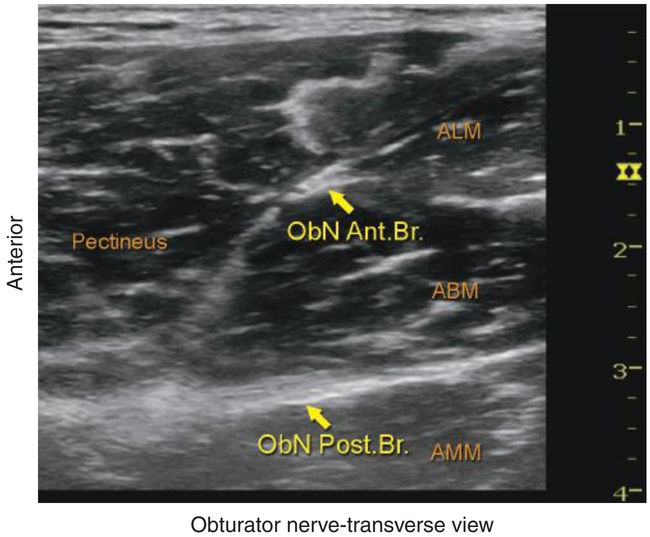

FIGURE 33D–3. The anterior branch (ant. br.) of the obturator nerve (ObN) is seen between the adductor longus muscle (ALM) and the adductor brevis muscle (ABM), whereas the posterior branch (post. br.) is seen between the ABM and the adductor magnus muscle (AMM). (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, Inc.; 2011.)

Clinical Pearl

- A simple method of assessing adductor muscle strength (motor block) is to instruct the patient to adduct the blocked leg from an abducted position against resistance. Weakness or inability to adduct the leg indicates a successful obturator nerve block.

EQUIPMENT

The equipment recommended for an obturator nerve block includes the following:

- Ultrasound machine with linear (or curved) transducer (5–13 MHz), sterile sleeve, and gel
- Standard block tray
- A 10-mL syringe containing local anesthetic solution
- A 10-cm, 21- to 22-gauge, short-bevel, insulated needle
- Peripheral nerve stimulator (optional)
- Sterile gloves

LANDMARKS AND PATIENT POSITIONING

With the patient supine, the thigh is slightly abducted and laterally rotated. The block can be performed either at the level of femoral (inguinal) crease medial to the femoral vein or 1–3 cm

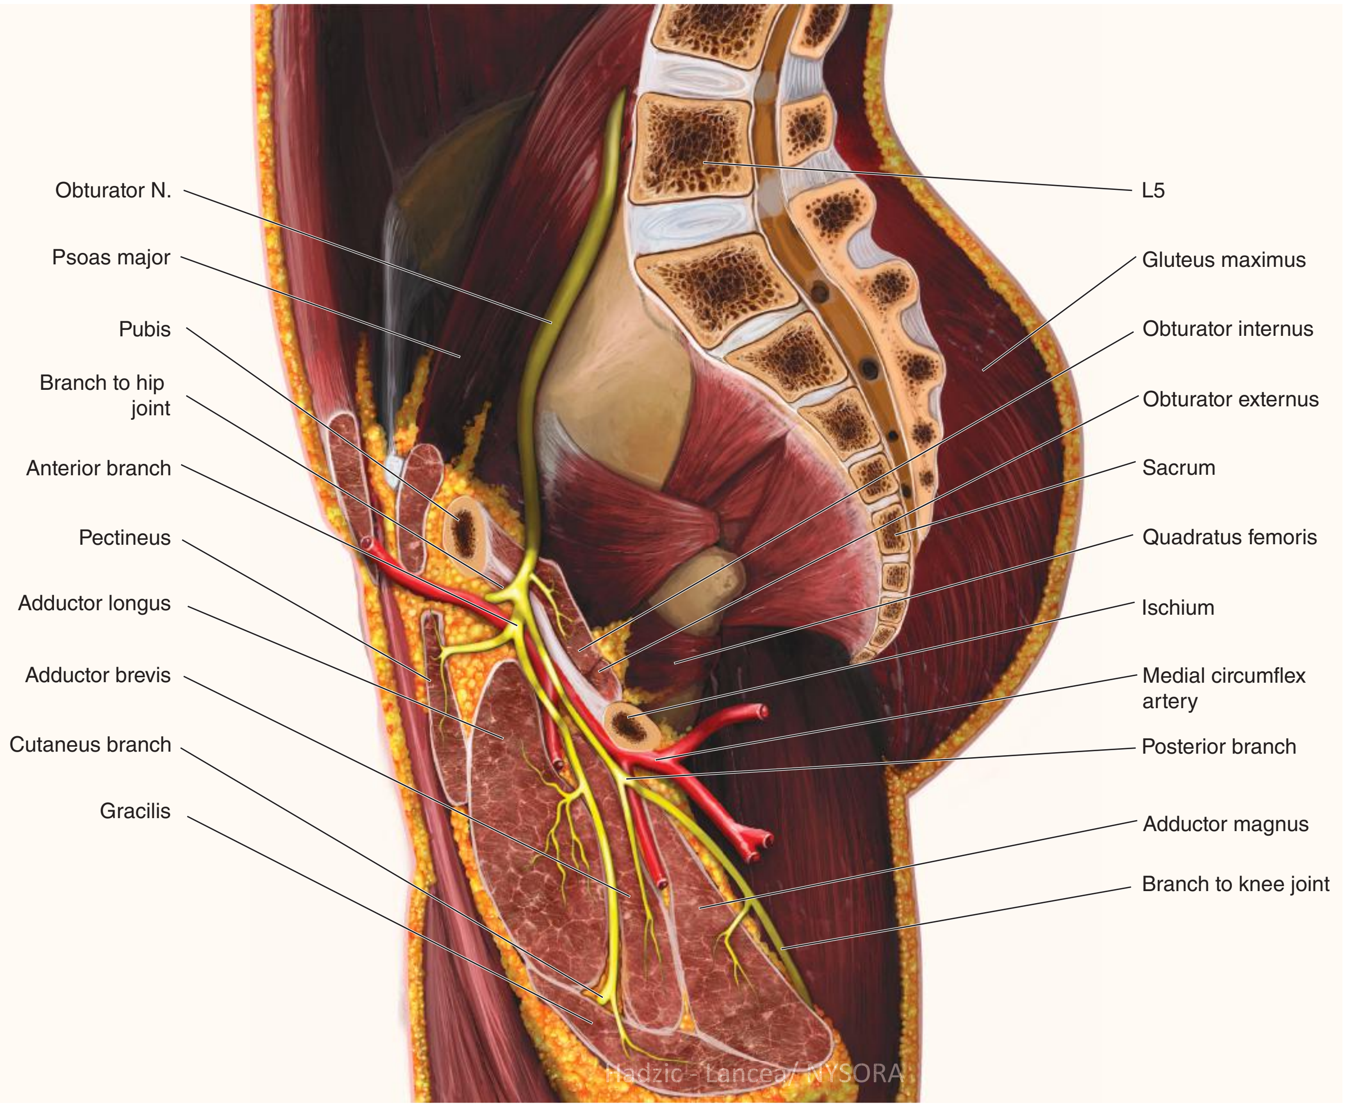

FIGURE 33D–4. The course and divisions of the obturator nerve and its relationship to the adductor muscles.

inferior to the inguinal crease on the medial aspect (adductor compartment) of the thigh (Figure 33D–5).

GOAL

The goal of the interfascial injection technique for blocking the obturator nerve is to inject local anesthetic solution into the interfascial space between the pectineus and adductor brevis muscles to block the *anterior* branch and the adductor brevis and adductor magnus muscles to block the *posterior* branch. When using US guidance with nerve stimulation, the anterior and posterior branches of the obturator nerve are identified and stimulated to elicit a motor response prior to injecting local anesthetic solution around each branch.

TECHNIQUE

The **interfascial approach** is performed at the level of the femoral crease. With this technique, it is important to identify the adductor muscles and the fascial planes in which the individual nerves are enveloped. Color Doppler can be used to visualize the obturator arteries located near the nerve branches in order to avoid puncturing them, although they are not always visible.

The US transducer is placed to visualize the femoral vessels. The transducer is advanced medially along the crease to identify the adductor muscles and their fasciae. The anterior branch is sandwiched between the pectineus and adductor brevis muscles, whereas the posterior branch is located in the fascial plane between the adductor brevis and adductor magnus muscles. The block needle is advanced to initially position the needle tip between the pectineus and adductor brevis (Figure 33D–6a). At this point, 5–10 mL of local anesthetic solution is injected. The needle is advanced farther to position the needle tip between the adductor brevis and adductor magnus muscles, and another 5–10 mL of local anesthetic solution is injected (Figure 33D–6b). It is important for the local anesthetic solution to spread into the interfascial space and not be injected into the muscles. Correct injection of local anesthetic solution into the interfascial space results in an accumulation of the injectate between the

target muscles. The needle may have to be repositioned to allow for precise interfascial injection.

Alternatively, the cross-sectional image of obturator nerve branches can be obtained by scanning 1–3 cm distal to the inguinal crease on the medial aspect of thigh. The nerves appear as hyperechoic, flat, thin, fusiform-shaped structures invested in the fascia of the adductor muscles. The anterior branch is located between the adductor longus and adductor brevis muscles, whereas the posterior branch is located between the adductor brevis and adductor magnus muscles. An insulated block needle attached to the nerve stimulator is advanced toward the nerve with either an out-of-plane or in-plane trajectory. After eliciting contraction of the adductor muscles, 5–7 mL of local anesthetic is injected around each branch of the obturator nerve (see Figure 33D–6b).

CHAPTER 33E

Ultrasound-Guided Saphenous (Subsartorius/Adductor Canal) Nerve Block

Thomas F. Bendtsen, Ana M. Lopez, and Thomas B. Clark

SAPHENOUS NERVE BLOCK AT A GLANCE

- Indications: saphenous vein stripping or harvesting; supplementation for medial foot/ankle surgery in combination with a sciatic nerve block, and analgesia for knee surgery in combination with multimodal analgesia.
- Transducer position: transverse on anteromedial thigh at the junction between the middle and distal third of the thigh or below the knee at the level of the tibial tuberosity, depending on the approach chosen (proximal or distal) (Figure 33E–1)
- Goal: local anesthetic spread lateral to the femoral artery and deep to the sartorius muscle or more distal, below the knee, adjacent to the saphenous vein.
- Local anesthetic: 5–10 mL

GENERAL CONSIDERATIONS

The saphenous nerve is a terminal sensory branch of the femoral nerve. It supplies innervation to the medial aspect of the leg down to the ankle and foot. It also sends infrapatellar branches to the knee joint. A saphenous nerve block is useful as a supplement to sciatic block for foot and ankle procedures that involve the medial aspect of the malleolus and the foot. The block has also been reported as a supplement to multimodal analgesia protocols in patients having knee arthroplasty. Typically, a more proximal (mid-thigh) approach and a larger volume of local anesthetic is used for this "adductor canal block". Several approaches have been described to block the saphenous nerve along its route from the inguinal area to the medial malleolus (Figure 33E–2). The use of ultrasound (US) guidance has improved the success rates of the saphenous blocks compared with field blocks below the knee and blind transsartorial approaches.

ULTRASOUND ANATOMY

The sartorius muscle descends in a lateral to medial direction across the anterior thigh and forms a "roof" over the adductor canal in the lower half of the thigh. The muscle appears as a trapezoid shape beneath the subcutaneous layer of adipose tissue. The sides of the triangular canal are formed by the vastus medialis laterally and the adductor longus or magnus medially (depending on how proximal or distal the scan is). The saphenous nerve is typically imaged by ultrasound as a small, round, hyperechoic structure anterior to the artery. The femoral vein accompanies the artery and saphenous nerve, which all can be identified at a depth of 2–3 cm (Figure 33E-3). When attempting to identify the saphenous nerve on US image, the following anatomical considerations should be kept in mind:

- Above the knee: The saphenous nerve pierces the fascia lata between the tendons of the sartorius and gracilis muscles before becoming a subcutaneous nerve.
- The saphenous nerve lies in close proximity to several vessels along its trajectory: the femoral artery above the knee, the descending genicular artery and its saphenous branch at the knee, and the great saphenous vein in the lower leg and ankle.
- Below the knee, the saphenous nerve passes along the tibial side of the leg, adjacent to the great saphenous vein subcutaneously (Figure 33E–4).

A

B

FIGURE 33E–1. Transducer position and needle insertion to block the saphenous nerve (**A**) at the level of the lower third of the thigh and (**B**) below the knee.

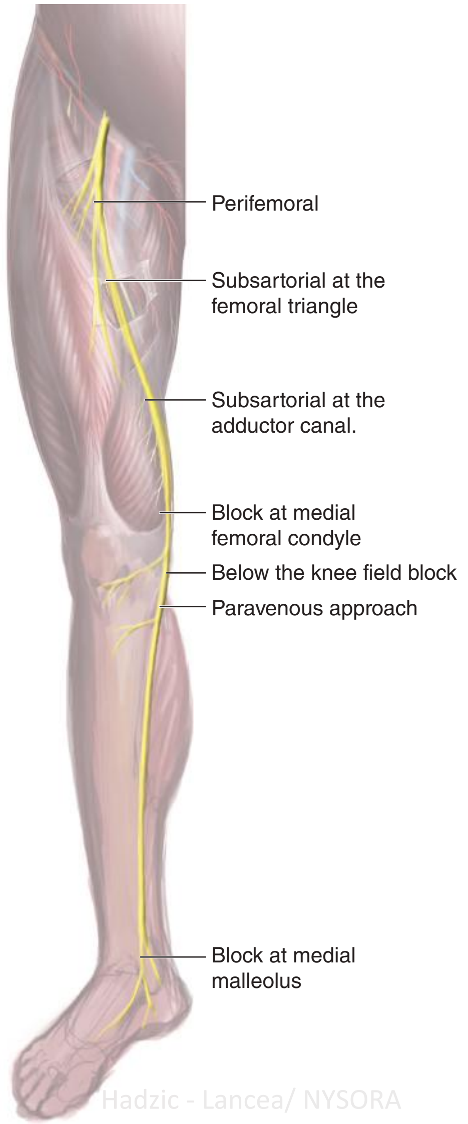

FIGURE 33E–2. Various approaches to the saphenous nerve block: the perifemoral typically targets the nerve to the vastus medialis muscle with nerve stimulation; the subsartorial at the femoral riangle; subsartorial at the adductor canal; at the medial femoral condyle, between the tendons of the sartorius and the gracilis muscle; once the femoral vessels have crossed the adductor hiatus to become the popliteal vessels; the paravenous approach using the saphenous vein as a landmark at the level of the tibial tuberosity; and at the level of the medial malleolus.[1]

- At the ankle, branches of the saphenous nerve are located medially, next to the subcutaneously positioned saphenous vein.

DISTRIBUTION OF ANESTHESIA

The saphenous nerve block results in anesthesia of the skin on the medial leg and foot (Figure 33E-5). For a more comprehensive review of the femoral and saphenous nerve distributions, see Chapter 3. Of note, although the saphenous nerve block is a sensory block, an injection of a large volume of local anesthetic into the subsartorial space can result in a partial motor block of the vastus medialis due to the block of the femoral nerve branch to this muscle, often contain in the canal. For this reason, caution must be taken when advising patients regarding the safety of unsupported ambulation after undergoing a proximal saphenous block.

EQUIPMENT

- Ultrasound machine with linear transducer (8–14 MHz), sterile sleeve, and gel
- Standard nerve block tray

FIGURE 33E–4. (**A**) Cross-sectional anatomy of the saphenous nerve (SaN) at the level of the tibial tuberosity. (**B**) US image of the SaN below the knee. The SaN is seen within the immediate vicinity of the great saphenous vein (SV). The transducer should be applied lightly to avoid compression of the SV because the vein serves as an important landmark for the technique.

- One 10-mL syringe containing local anesthetic
- A 80 mm 22-25 gauge needle
- Peripheral nerve stimulator to elicit paresthesia
- Sterile gloves

LANDMARKS AND PATIENT POSITIONING FOR THE PROXIMAL APPROACH

The patient is placed in any position that allows for comfortable placement of the US transducer and needle advancement. This block typically is performed with the patient in the supine position, with the thigh abducted and externally rotated to allow access to the medial thigh (see Figure 33E–1a).

GOAL

The goal is to place the needle tip just anterior to the femoral artery, deep to the sartorius muscle, and to deposit 5–10 mL (or up to 20 mL for the adductor canal block) of local anesthetic until its spread around the artery is confirmed with US visualization. Block of the nerve at other, more distal and superficial locations consists of a simple subcutaneous infiltration of the tissues within the immediate vicinity of the nerve under US guidance.

TECHNIQUE

The skin is disinfected and the transducer is placed anteromedially, approximately at the junction between the middle and distal third of the thigh or somewhat lower. If the artery is not immediately obvious, several maneuvers can be used to identify it, including color Doppler scanning to trace the femoral artery caudally from the inguinal crease. Once the femoral artery has been identified, the probe is moved distally to trace the artery until it passes through the adductor hiatus to become the popliteal artery.

The saphenous nerve block should be performed at the most distal level where the artery still lies immediately deep to the sartorius muscle, thus minimizing the amount of motor block of the vastus medialis; an adductor canal block is typically performed more proximally, around the mid-thigh level. The needle is inserted in plane in a lateral-to-medial orientation and advanced toward the femoral artery (Figure 33E-1a and 33E-6). If nerve stimulation is used (1 mA, 1 msec), the passage of the needle through the sartorius and/or adductor muscles and into the adductor canal is usually associated with a paresthesia in the saphenous nerve distribution. Once the needle tip is visualized anterior to the artery and after careful aspiration, 1–2 mL of local anesthetic is injected to confirm the proper injection site (Figure 33E–6). When injection of local anesthetic does not appear to result in its spread around the femoral artery, additional needle repositions and injections may be necessary.

Color Doppler can be used to locate the perisaphenous branch of the descending geniculate artery in order to avoid puncturing it.

Because the saphenous nerve is a purely sensory nerve, high concentrations of local anesthetic are not required and in fact may delay patient ambulation should local anesthetic spread to one of the motor branches of the femoral nerve innervating the quadriceps muscle.

FIGURE 33E–5. Expected distribution of analgesia after saphenous nerve block at the level of midthigh.

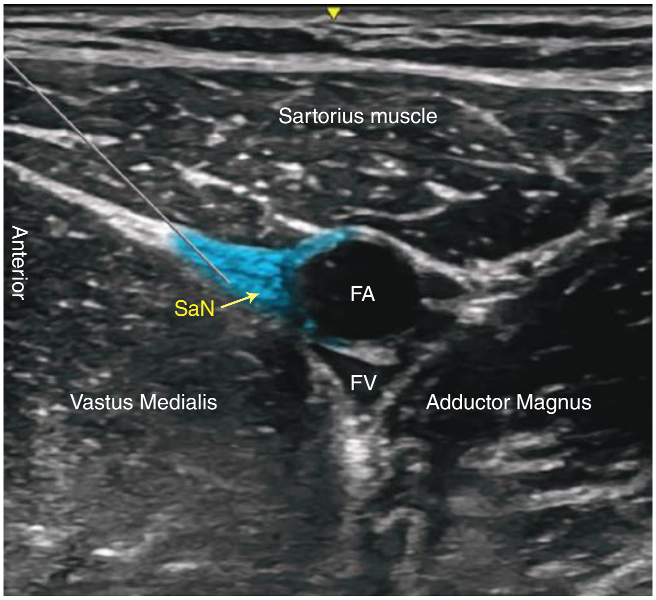

FIGURE 33E-6. Simulated needle path, needle tip position and local anesthetic initial distribution (blue-shaded area) to anesthetize the Saphenous nerve (SaN) at the level of the thigh. FA, femoral artery: FV, femoral vein.

TIPS

- An out-of-plane technique can also be used through the belly of the sartorius muscle. Because the needle tip may not be seen throughout the procedure, small boluses of local anesthetic are administered (0.5–1 mL) as the needle is advanced toward the adductor canal to confirm the location of the needle tip.
- Visualization of the nerve is *not* necessary for this block, as the saphenous nerve is not always well imaged. Administration of 5–10 mL of local anesthetic next to the artery in the plane between the sartorius and vastus medialis muscles should suffice without confirming nerve position.
- Practitioners should be aware of the potential for partial quadriceps weakness following a more proximal approach along the subsartorial space and/or njection of a large volume (20-30 mL) of local anesthetic. Patient education and assistance with ambulation should be encouraged. For that reason, it is recommended to perform this block as distally as practically possible.

CHAPTER 33F

Ultrasound-Guided Sciatic Nerve Block

Arthur Atchabahian, Catherine Vandepitte, Ana M. Lopez, and Jui-An Lin

SCIATIC NERVE BLOCK AT A GLANCE

- Indications: foot and ankle surgery, below-knee amputation, analgesia following knee surgery involving the posterior compartment (Figure 33F–1)
- Transducer position:
  - Anterior approach: transverse on the proximal medial thigh
  - Transgluteal approach: transverse on the posterior buttock, between the ischial tuberosity and greater trochanter
  - Subgluteal approach: transverse on the gluteal crease
  - Other approaches (eg, parasacral, lateral) have been described but will not be detailed here.
- Goal: local anesthetic spread within the sciatic nerve sheath
- Local anesthetic: 10–20 mL

FIGURE 33F–1. Distribution of sensory and motor after sciatic nerve blockade at gluteal and subgluteal level.

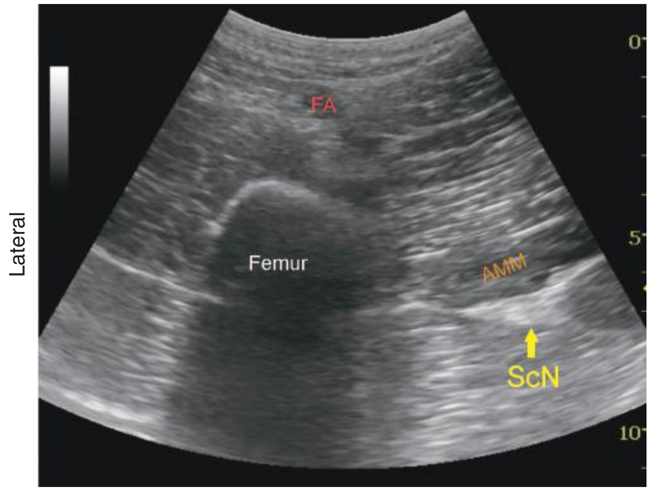
PART I: ANTERIOR APPROACH

GENERAL CONSIDERATIONS

The anterior approach to the sciatic nerve block can be useful in patients who cannot be positioned in the lateral position due to pain, trauma, the presence of external fixation devices that interfere with positioning, or other issues. The ultrasound (US)-guided approach may reduce the risk of femoral artery puncture compared with the landmark-based approach. The actual scanning and needle insertion are performed on the anteromedial aspect of the proximal thigh, rather than the anterior surface, and may require a slight abduction and external rotation of the thigh. This block is not well-suited to catheter insertion because a large needle must traverse several muscles (discomfort during procedure and risk of hematoma), it is an awkward catheter location (medial thigh), and catheter insertion at an approximately perpendicular angle to the sciatic nerve is difficult.

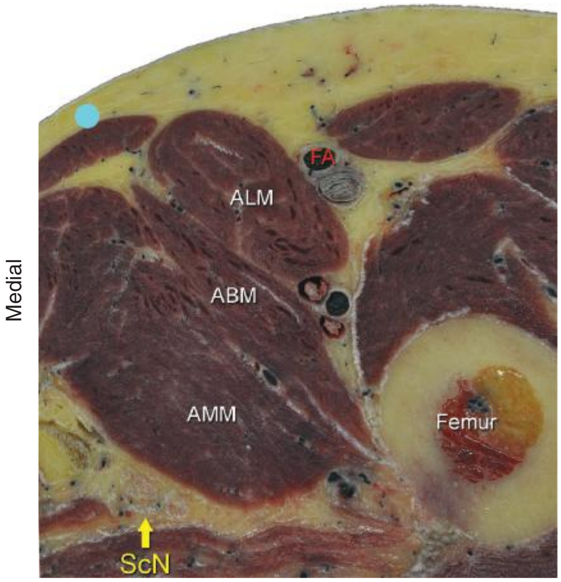
ULTRASOUND ANATOMY

The sciatic nerve is imaged approximately at the level of the minor trochanter. At this location, a curved transducer placed over the anteromedial aspect of the thigh will reveal the musculature of all three fascial compartments of the thigh: anterior, medial, and posterior (Figures 33F–2 and 33F–3). Beneath the sartorius muscle is the femoral artery, and deep and medial to this vessel is the deep artery of the thigh. Both can be identified with color Doppler US for orientation. The femur is seen as a hyperechoic rim with a corresponding shadow beneath the vastus intermedius. Medial to the femur is the adductor magnus muscle, anterior to the hamstring muscles. The sciatic nerve is visualized as a hyperechoic oval structure sandwiched between these two muscle. The nerve is typically visualized at a depth of 6–8 cm (see Figure 33F–3).



Sciatic nerve block-anterior approach

FIGURE 33F–3. Ultrasound anatomy of the sciatic nerve. From superficial to deep, visualized laterally: femoral artery (FA), femur, adductor magnus muscle (AMM), and sciatic nerve (ScN) laterally. The sciatic nerve is typically located at a depth of 6–8 cm. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)



Sciatic Nerve - Anterior Approach, Transverse View

FIGURE 33F–2. Cross-sectional anatomy of the sciatic nerve (ScN). Shown are the femoral artery (FA), adductor longus muscle (ALM), adductor magnus muscle (AMM), adductor brevis muscle (ABM), and femur. The sciatic nerve is seen posterior to the AMM.

DISTRIBUTION OF ANESTHESIA

The sciatic nerve block results in anesthesia of the posterior aspect of the knee, hamstring muscles, and entire lower limb below the knee, both motor and sensory blockade, with the exception of skin on the medial leg and foot (supplied by the saphenous nerve) (Figure 33F-1). The skin of the posterior aspect of the thigh is supplied by the posterior femoro cutaneous nerve, which deviates away from in the sciatic nerve proximal to the level of the anterior approach, and is therefore not blocked. Unless the surgical incision involves the posterior thigh, the lack of anesthesia in its distribution is of little clinical consequence, as pain caused by a thigh tourniquet, for example, is due more to muscle ischemia than to pressure on the skin.

EQUIPMENT

The equipment recommended for a sciatic nerve block using the anterior approach is as follows:

- Ultrasound machine with curved (phased array) transducer (2–8 MHz), sterile sleeve, and gel
- Standard nerve block tray

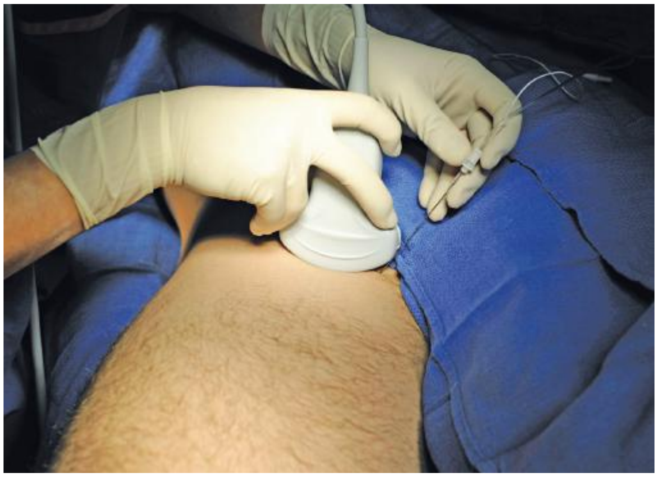


FIGURE 33F–4. Transducer position to visualize the sciatic nerve using the anterior approach. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

- One 20-mL syringe containing local anesthetic
- A 100- or 120-mm, 21-gauge, short-bevel, insulated stimulating needle
- Peripheral nerve stimulator
- Sterile gloves
- Injection pressure monitor

LANDMARKS AND PATIENT POSITIONING

The anterior approach to the sciatic nerve block is performed with the patient in the supine position. The hip is abducted to facilitate transducer and needle placement (Figures 33F–4 and 33F–5). When feasible, the hip and knee should be somewhat flexed to facilitate exposure. If nerve stimulation is to be used at the same time (this is recommended), exposure of the calf and foot are required to observe motor responses. In either case, it is useful to expose the entire thigh to appreciate the distance from the groin to the knee.

GOAL

The goal is to place the needle tip immediately adjacent to the sciatic nerve, between the adductor magnus muscle and biceps femoris muscle.

TECHNIQUE

With the patient in the proper position, the skin is disinfected and the transducer positioned to identify the sciatic nerve. If the nerve is not immediately apparent, sliding and tilting the transducer proximally or distally can be useful to improve the contrast and bring the nerve "out of the background" from the musculature. If the patient is able to dorsiflex and/or plantar flex the ankle, this maneuver often causes the nerve to move within the intermuscular plane, facilitating identification. The needle is inserted in plane from the medial aspect of the thigh, or out of plane, and advanced toward the sciatic nerve (see Figure 33F–5). An in-plane approach may prove less practical due to the steep angle of the needle and the use of a curved (nonlinear) probe. If nerve stimulation is used (1.0 mA, 0.1 msec), the contact of the needle tip with the sciatic nerve is usually associated with a motor response of the calf or foot. Once the needle tip is in the proper position, 1–2 mL of local anesthetic is injected to confirm the adequate distribution of injectate. Such injection helps delineate the sciatic nerve within its muscular tunnel, and it should displace the sciatic nerve away from the needle. Improper spread of local anesthetic or nerve displacement may require an adjustment of the needle tip position.

In an adult patient, 10–15 mL of local anesthetic is usually adequate for successful blockade (Figure 33F–6). Although a

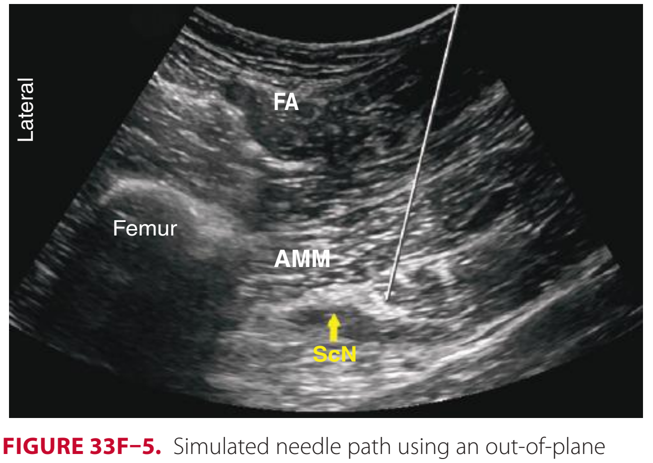

FIGURE 33F–5. Simulated needle path using an out-of-plane technique to reach the sciatic nerve (ScN) using the anterior approach. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

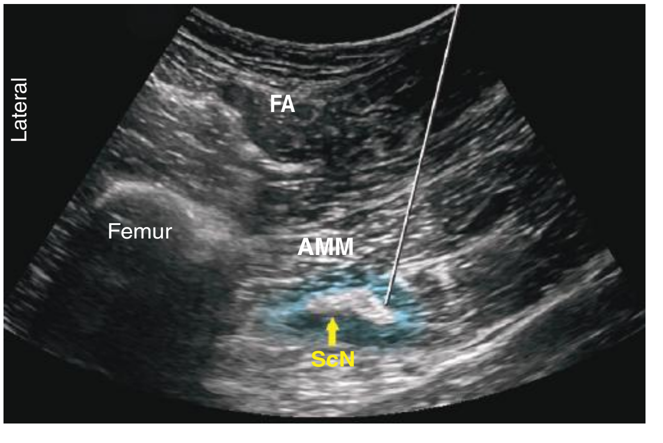

FIGURE 33F–6. Simulated needle path (1) using an out-of-plane technique with proper local anesthetic distribution (blue-shaded area) to anesthetize the sciatic nerve (ScN). (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

single injection of such volume of local anesthetic suffices, it may be beneficial to inject two to three smaller aliquots at different locations to ensure the spread of local anesthetic around the sciatic nerve. The block dynamics and perioperative management are similar to those described in the nerve stimulator technique section.

Clinical Pearl

- Insertion of the needle in an out-of-plane manner using hydrodissection is often a more practical way to accomplish this block compared to an in-plane approach.

PART II: POSTERIOR APPROACH

GENERAL CONSIDERATIONS

With the transgluteal approach, the sciatic nerve is approached deep to the gluteus maximus muscle, where it is identified between two osseous landmarks (the **ischial tuberosity** and the **greater trochanter**). To obtain view of the sciatic nerve and the osseous structures at this level, the curvilinear probe is typically needed.

With the subgluteal approach, the nerve is just below the level of the gluteal crease where the nerve lies more superficial and can be imaged even with a linear probe. The preference of one approach over the other is based on the patient's anatomical characteristics and the operator's personal preference. The subgluteal approach may be a better choice for most patients and indications, including the obese patients.[1]

ULTRASOUND ANATOMY

At the transgluteal level, the sciatic nerve is visualized in the short axis between the two hyperechoic bony prominences of the ischial tuberosity and the greater trochanter of the femur (Figures 33F–7 and 33F–8). The gluteus maximus muscle is seen as the most superficial muscular layer bridging the two osseous structures, typically several centimeters thick. The sciatic nerve is located immediately deep to the gluteus maximus muscle and superficial to the quadratus femoris muscle. Often, it is slightly closer to the ischial tuberosity than to the greater trochanter. At this location in the thigh, it is seen as an oval or roughly triangular hyperechoic structure. At the subgluteal level, the sciatic nerve is positioned between the long head of the biceps femoris muscle and the posterior surface of the adductor magnus.

DISTRIBUTION OF ANESTHESIA

Sciatic nerve block results in anesthesia of the entire lower limb below the knee (both motor and sensory blockade), with the exception of the skin on the medial leg and foot, which is innervated by the saphenous nerve. Both the transgluteal and subgluteal approaches provide motor blockade of the hamstring muscles. The skin of the posterior aspect of the thigh, supplied by the posterior femorocutaneous nerve, is not

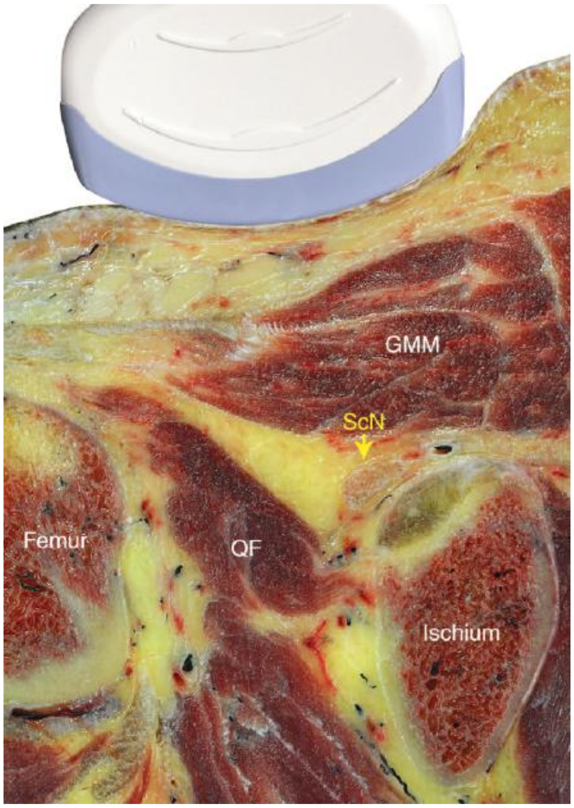

FIGURE 33F–7. Cross-sectional anatomy of the sciatic nerve at the transgluteal level. The sciatic nerve (ScN) is seen between the greater trochanter of the femur and the ischial tuberosity, just deep to the gluteus maximus (GMM) and superficial to the quadratus fermoris (QF) muscles. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

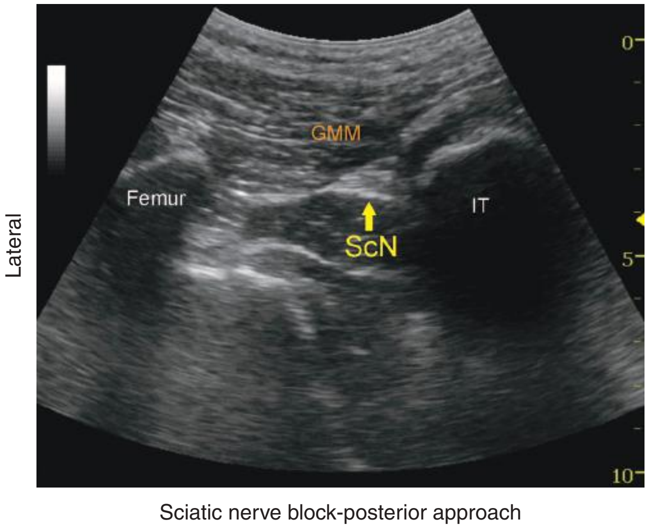

FIGURE 33F–8. Ultrasound image demonstrating the sonoanatomy of the sciatic nerve (ScN). The ScN often assumes an ovoid or triangular shape and is positioned deep to the gluteus maximus muscle (GMM) between the ischial tuberosity (IT) and femur. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

anesthetized by the subgluteal, and when indicated, the posterior femoro cutaneous nerve can be anesthetized separately.[2] For a more comprehensive review of the sciatic nerve distribution, see Chapter 3.

EQUIPMENT

The equipment recommended for a sciatic nerve block using the transgluteal or subgluteal approach is as follows:

- Ultrasound machine with curved (phase array) transducer (2–8 MHz), sterile sleeve, and gel
- Standard nerve block tray
- One 20-mL syringe containing local anesthetic
- A 100-mm, 21- to 22-gauge, short-bevel, insulated stimulating needle
- Peripheral nerve stimulator
- Sterile gloves

Clinical Pearl

- Although a linear transducer occasionally can be used for smaller-size patients undergoing transgluteal approach, a curved transducer permits the operator to visualize a wider field, including the osseous landmarks. The ischial tuberosity and greater trochanter are not seen on the same image when using a linear transducer.

LANDMARKS AND PATIENT POSITIONING

For either the transgluteal or subgluteal approach, the patient is placed in a lateral decubitus position (Figures 33F–9 and 33F–10). The limbs are flexed at the hip and knee. When nerve stimulation is used simultaneously (recommended),

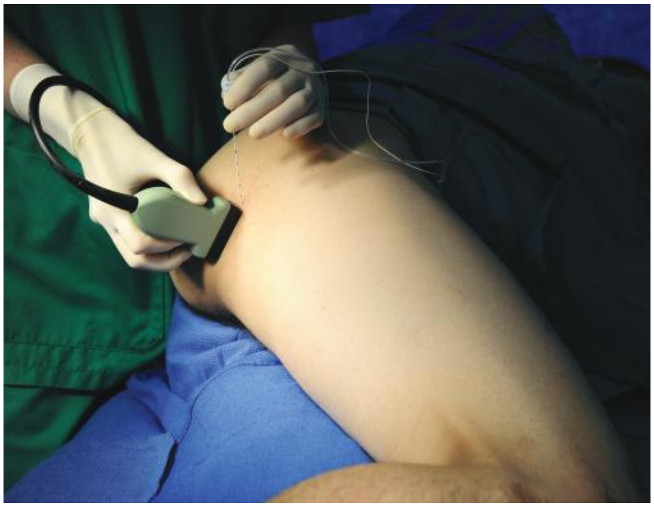

FIGURE 33F–9. Transducer position and needle insertion for subgluteal approach to sciatic nerve block.

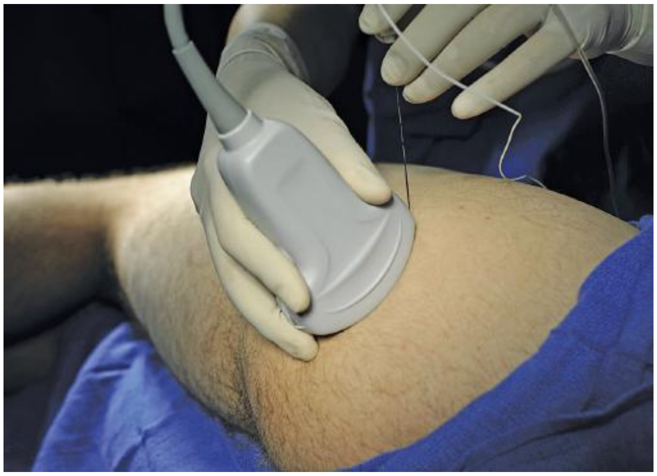

FIGURE 33F–10. Transgluteal approach to sciatic block: patient position, transducer (curved) placement, and needle insertion. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

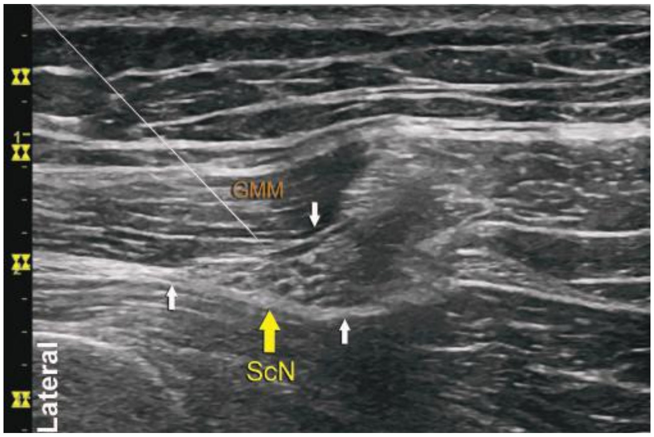

FIGURE 33F–11. The sciatic nerve (ScN) as seen in the subgluteal position (using a linear transducer) and simulated needle path to the interfacial plane (white arrows) between the gluteus maximus muscle (GMM) and the adductor magnus. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

exposure of the hamstrings, calf, and foot is required to detect and interpret motor responses. The osseous prominences of the greater trochanter and ischial tuberosity are palpated and, if desired, marked with a skin marker. The initial transducer position is in the depression between the two bony structures.

GOAL

The goal is to place the needle tip adjacent to the sciatic nerve, deep to the gluteus maximus muscle (the transgluteal technique) and to deposit 15–20 mL of local anesthetic until adequate spread adjacent to the nerve is visualized.

TECHNIQUE

The description of the technique in this chapter will focus primarily on the transgluteal approach. However, since the subgluteal approach is performed just a few centimeters more distally and is technically simpler to perform, the block can be accomplished using either approach by following the general guidelines provided here and by referring to Figures 33F–9 and Figure 33F-11.

The skin is disinfected and the transducer is positioned to identify the sciatic nerve (see Figure 33F–10). Tilting the transducer proximally or distally can help improve the contrast and bring the nerve "out of the background" of the musculature. Often, the nerve is better imaged after the injection of local anesthetic. Alternatively, sliding the transducer slightly proximal or distal can improve the quality of the image and allow for better visualization.

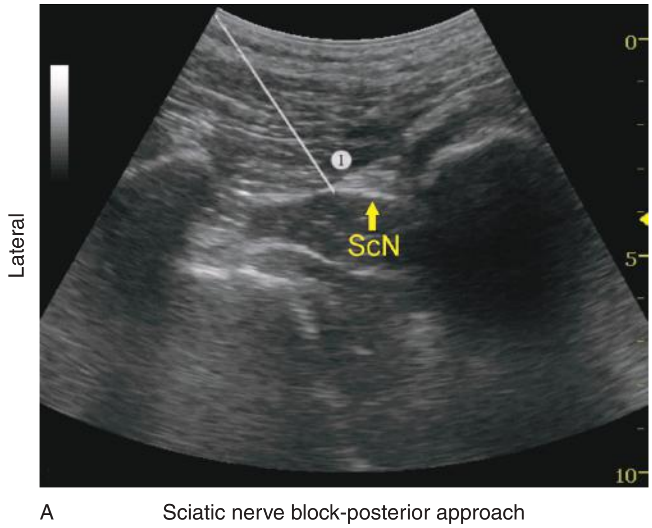
Once identified, the needle is inserted in plane, typically from the lateral aspect of the transducer, and advanced toward the sciatic nerve. If nerve stimulation is used (1.0 mA, 0.1 msec), the passage of the needle through the fascia on the anterior aspect of the gluteus maximus muscle often is associated with a motor response of the calf or foot. Once the needle tip is positioned adjacent to the nerve (Figure 33F–12), and after careful aspiration to rule out an intravascular needle placement, 1–2 mL of local anesthetic is injected to visualize the proper injection site. Such injection often displaces the sciatic nerve away from the needle; therefore, an additional advancement of the needle 1–2 mm toward the nerve may be necessary to ensure proper local anesthetic spread.

Additional needle repositions and injections may be necessary. Ensuring the absence of high resistance to injection to reduce the risk of intrafascicular injection is of utmost importance because the needle tip is difficult to visualize due to the steep angle and depth of the needle placement.

Although a single injection of 15-20 mL of local anesthetic typically suffices, it may be beneficial to inject two to three smaller aliquots at different locations to ensure the spread of local anesthetic solution around the sciatic nerve.

TIPS

- Never inject against high resistance (> 15 psi) because this may signal an intraneural injection. Even experts may miss signs of intraneural injection.[3]
- While some authors have suggested that intraneural injection is safe for the sciatic nerve, given the high proportion of connective tissue relative to the fascicles,[4,5] it is best avoided since reliable blockade can be obtained by injecting around the nerve. The ability to distinguish the sciatic nerve from its soft tissue surroundings often is improved after the injection of local anesthetic; doing so can be used as a marker to identify the nerve when injection begins.



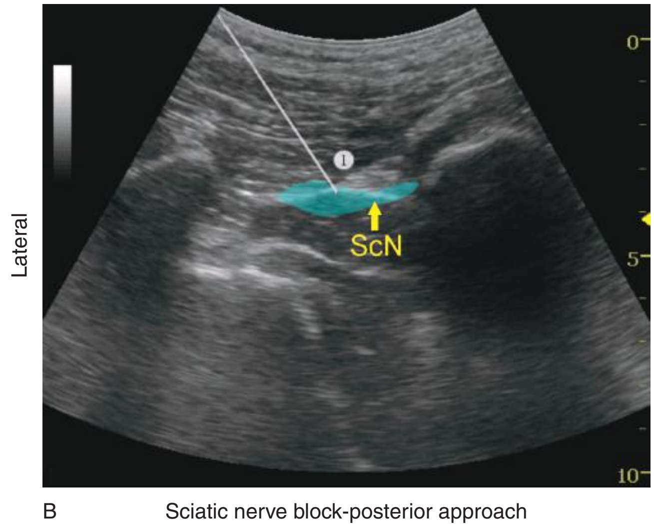


FIGURE 33F–12. (a) Simulated needle path (1) to reach the sciatic nerve (ScN) using an in-plane technique and transgluteal approach. The needle is shown passing through the gluteus muscle with its tip positioned at the lateral aspect of the sciatic nerve. (b) Simulated needle path (1) and local anesthetic distribution (blue-shaded area) to block the ScN with the transgluteal approach. CONTINUOUS ULTRASOUND-GUIDED SUBGLUTEAL SCIATIC BLOCK

The goal of the continuous sciatic nerve block is similar to that of the non–US-based techniques: to place the catheter within the vicinity of the sciatic nerve between the gluteus maximus and quadratus femoris muscles. The procedure is similar to the previously described in the continuous ultrasound-guided block section in Chapter 32A.

Advancement of the needle in plane in a lateral-to- medial direction until the tip is adjacent to the nerve and deep to the gluteus maximus fascia should ensure appropriate catheter location. Proper placement of the needle also can be confirmed by obtaining a motor response of the calf or foot, at which point 4–5 mL of local anesthetic is injected. This small dose of local anesthetic serves to ensure adequate local anesthetic distribution as well as to make the catheter advancement easier. This first phase of the procedure does not significantly differ from the single-injection technique.

Alternatively, the catheter can be inserted using a longitudinal view. With this approach, after successful imaging of the sciatic nerve in the cross-sectional view, the transducer is rotated 90 degrees so that the sciatic nerve is visualized in the longitudinal view. However, this approach requires significantly greater US imaging skills.

The catheter is secured by either taping it to the skin or tunneling. A common infusion strategy consists of ropivacaine 0.2% at a rate of 5 mL/minute with a patient-controlled bolus of 5 mL/h.

CHAPTER 33G

Ultrasound-Guided Popliteal Sciatic Block

Admir Hadzic, Ana M. Lopez, Catherine Vandepitte, and Xavier Sala-Blanch

POPLITEAL SCIATIC BLOCK AT A GLANCE

- Indications: foot, ankle and Achilles tendon surgery
- Transducer position: transverse over the popliteal fossa
- Goal: local anesthetic spread surrounding the sciatic nerve within the epineural sheath
- Local anesthetic: 15–20 mL

GENERAL CONSIDERATIONS

The anatomy of the sciatic nerve in the popliteal fossa is variable, and the division into the tibial nerve (TN) and common peroneal nerve (CPN) occurs at an inconstant distance from the popliteal crease (Figure 33G–1). With nerve stimulator–based techniques, larger volumes (eg, > 40 mL) of local anesthetic have been used to increase the chance of block success. However, US guidance reduces the volume required for reliable block because the injection can be halted once adequate spread is observed.

The most common approaches to the popliteal sciatic block are the lateral approach, with the patient in the supine or lateral position, and the posterior approach in the prone or lateral position (Figure 33G–2). While the patient position and needle path differ between the two approaches, the rest of the technique details are similar.

The injection of local anesthetic must occur within the sciatic nerve sheath that contains both components of the nerve.[1–14] The injection is ideally accomplished at the position where both components of the nerve are within the sheath but slightly separated by adipose tissue, allowing for safe placement of the needle between them.[15] Although the sciatic nerve block can be

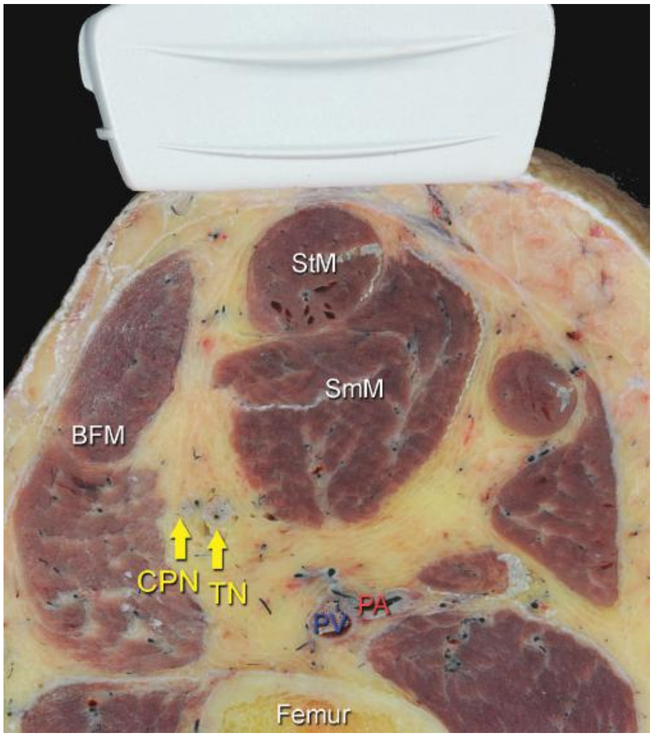

FIGURE 33G–1. Cross-sectional anatomy of the sciatic nerve in the popliteal fossa. Shown are the common peroneal nerve (CPN), tibial nerve (TN), popliteal artery (PA), popliteal vein (PV), femur, biceps femoris muscle (BFM), semimembranosus muscle (SmM), and semitendinosus (StM) muscle. accomplished with an injection around either nerve component, injecting into the space between both is more common in clinical practice.[16,17]

ULTRASOUND ANATOMY

Beginning with the transducer in the transverse position at the popliteal crease, the popliteal artery is identified, aided with color Doppler US when necessary, at a depth of approximately 3–4 cm. The popliteal vein accompanies the artery at it is positioned just superficial (posterior) to it. On either side of the artery are the biceps femoris muscles (laterally) and the semimembranosus and semitendinosus muscles (medially). The tibial nerve is positioned superficial and lateral to the vein and is seen as a hyperechoic, oval or round structure with a honeycomb pattern (Figure 33G–3). Asking the patient to dorsiflex and plantar flex the ankle makes the two sciatic nerve branches twist or move in relation to each other. Usually, tilting the transducer caudally is necessary to bring out the nerve from the neighboring adipose tissue.

Once the tibial nerve has been identified, the CPN is visualized slightly more superficial and lateral to the tibial nerve. The transducer should be slid proximally until the tibial and peroneal nerves are visualized coming together to form the sciatic nerve before its division (Figure 33G-4). This junction usually occurs at

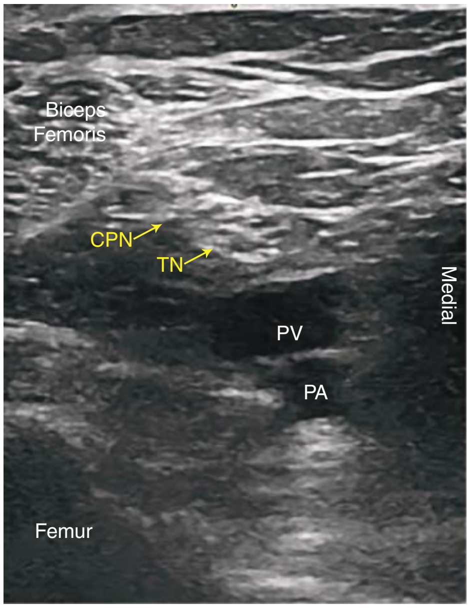

FIGURE 33G–3. Sonoanatomy of the sciatic nerve at the popliteal fossa. The two main divisions of the sciatic nerve, the tibial nerve (TN) and the common peroneal nerve (CPN), are seen immediately lateral and superficial to the popliteal vein (PV) and artery (PA). This image was taken at 5 cm above the popliteal fossa crease, where the TN and CPN have just started diverging.

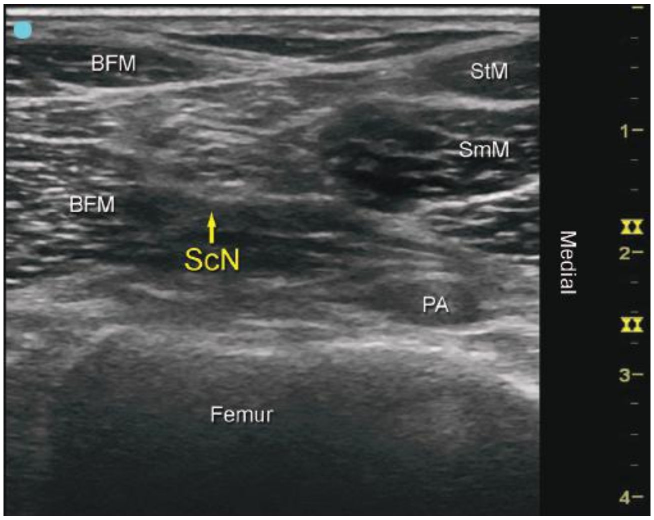

FIGURE 33G–4 Sonoanatomy of the sciatic nerve (ScN) before its division. Shown are the ScN, superior and lateral to the popliteal artery (PA), positioned between the biceps femoris muscle (BFM) the semimembranosus muscle (SmM), and the semitendinosus muscle (StM).

FIGURE 33G–5. Expected distribution of the sciatic nerve sensory blockade at the level of popliteal fossa.

a distance 5–10 cm from the popliteal crease but may occur very close to the crease or, less commonly, more proximally in the thigh. As the transducer is moved proximally, the popliteal vessels move deeper and become more challenging to image. Adjustments in depth, gain, focus, and direction of the US beam should be made to keep the nerve visible at all times. At the popliteal fossa, the sciatic nerve typically is visualized at a depth of 2–4 cm.

Clinical Pearl

- Ultrasound imaging should specifically focus on identifying the sciatic nerve sheath (Vloka's sheath) containing both components of the sciatic nerve (tibial and common peroneal nerves). Successful injection will deposit local anesthetic within the Vloka's sheath

BLOCKADE DISTRIBUTION

Sciatic nerve block results in anesthesia of the lower limb below the knee, both motor and sensory, with the exception of the medial leg and foot, which is the territory of the saphenous nerve, a branch of the femoral nerve. The motor fibers to the hamstring muscles are spared; however, fibers to the posterior aspect of the knee joint are blocked (Figure 33G-5). For a more comprehensive review of the sciatic nerve distribution, see Chapter 3.

EQUIPMENT

The equipment recommended for a popliteal sciatic block includes the following:

- Ultrasound machine with linear transducer (8–12 MHz), sterile sleeve, and gel
- Standard nerve block tray
- A 20-mL syringe containing local anesthetic
- 50- to 100-mm, 21- to 22-gauge, short-bevel, insulated stimulating needle
- Peripheral nerve stimulator
- Injection pressure monitor
- Sterile gloves

LANDMARKS AND PATIENT POSITIONING: LATERAL APPROACH

This block is performed with the patient in the supine or lateral position. This can be accomplished either by resting the foot on an elevated footrest or flexing the knee while an assistant stabilizes the foot and ankle on the bed (Figure 33G–6). If nerve stimulation is used, exposure of the calf and foot is required to observe motor responses.

LANDMARKS AND PATIENT POSITIONING: POSTERIOR APPROACH

This block is performed with the patient in the prone or lateral position (Figure 33G-2). A small footrest is useful to facilitate identification of a motor response if nerve stimulation is used. A footrest also relaxes the hamstring tendons, making transducer placement and manipulation easier.

GOAL

The goal is to inject the local anesthetic within the common connective tissue (Vloka's) sheath that envelops the TN and CPN. Alternatively, separate blocks of TN and CPN can be performed.

FIGURE 33G–6. Needle insertion technique to block the sciatic nerve in the popliteal fossa using the lateral approach with the patient in the supine position. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

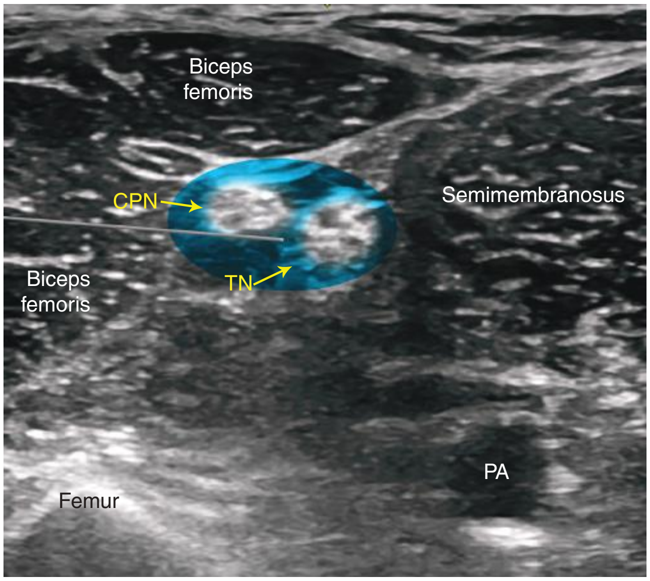

FIGURE 33G–8. Simulated needle path and local anesthetic distribution to block the sciatic nerve (TN and CPN) in the popliteal fossa using the lateral approach. PA, popliteal artery.

TECHNIQUE

The skin is disinfected and the transducer positioned to identify the sciatic nerve. If the nerve is not immediately apparent, tilting the transducer toward the feet can help improve the contrast and bring the nerve "out of the background". Sliding the transducer slightly proximal or distal may improve the quality of the image and allow for better visualization.

It is recommended to perform the block at the level where TN and CPN start diverging but are still in the common sciatic nerve (Vloka's) sheath. For the lateral approach, a skin wheal is made on the lateral aspect of the thigh 2–3 cm above the lateral edge of the transducer, and the needle is inserted in plane in a horizontal orientation from the lateral aspect of the thigh and advanced toward the sciatic nerve (Figures 33G–7 and 33G-8). For the posterior approach, the needle is inserted in plane from lateral to medial (Figure 33G-9) or out of plane (Figure 33G–10). If nerve stimulation is used (0.5 mA, 0.1 msec), the contact of the needle tip with either branch of the nerve usually is associated with a motor response of the calf or foot. Once the needle tip is placed within the common sciatic nerve sheath, 1–2 mL of local anesthetic is injected to confirm the proper injection site. Such injection should result in a distribution of local anesthetic within the sheath, and separation of the TN and CPN within Vloka's sheath (Figure 33G-11).

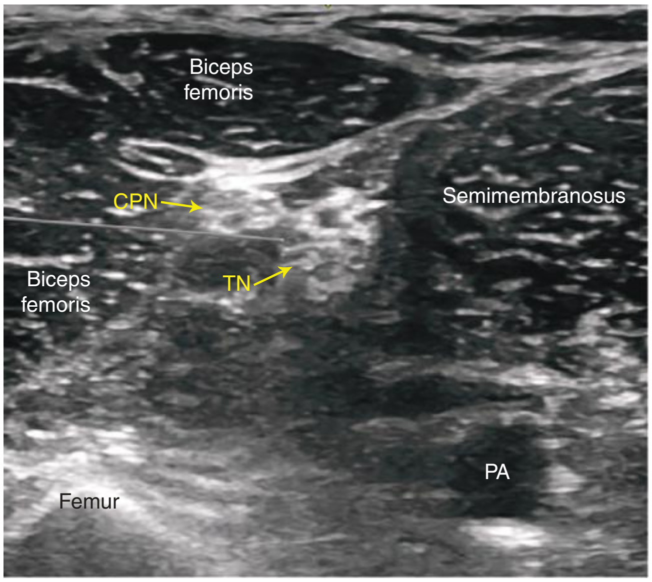

FIGURE 33G–7. Simulated needle path and needle tip placement to block the sciatic nerve (TN and CPN) using the lateral approach. PA, popliteal artery.

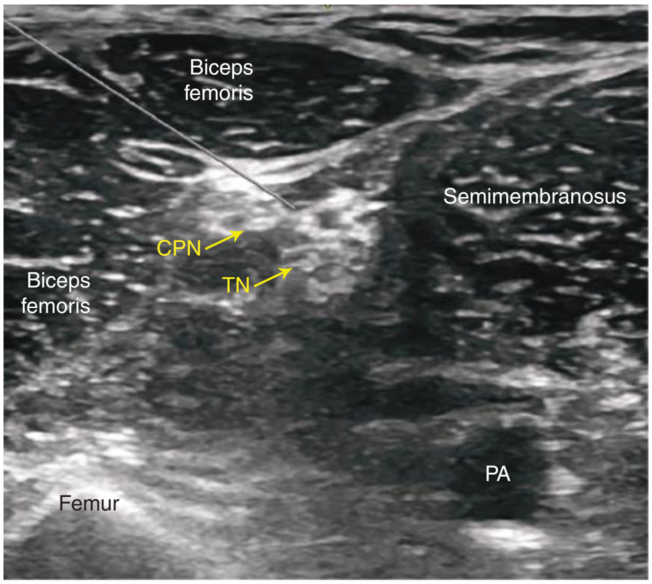

FIGURE 33G–9. Simulated needle path and needle tip placement to block the sciatic nerve (TN and CPN) through the posterior approach, in plane from lateral to medial. PA, popliteal artery.

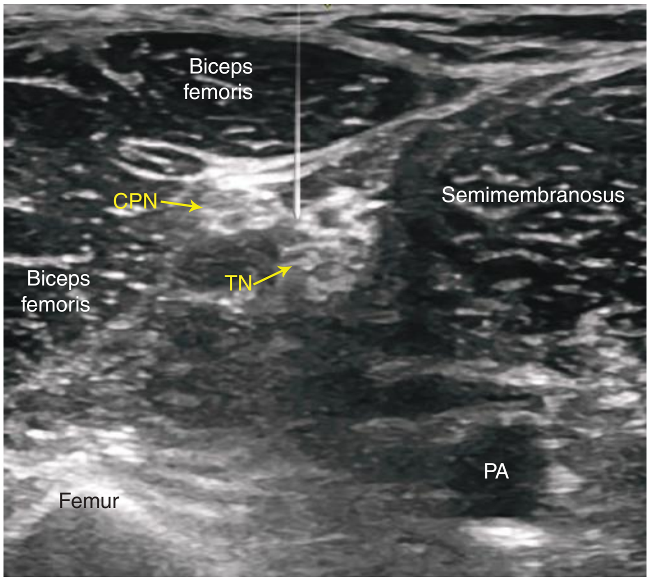

FIGURE 33G–10. Simulated needle path and proper needle tip placement to block the sciatic nerve (TN and CPN) through the posterior approach out of plane. PA, popliteal artery.

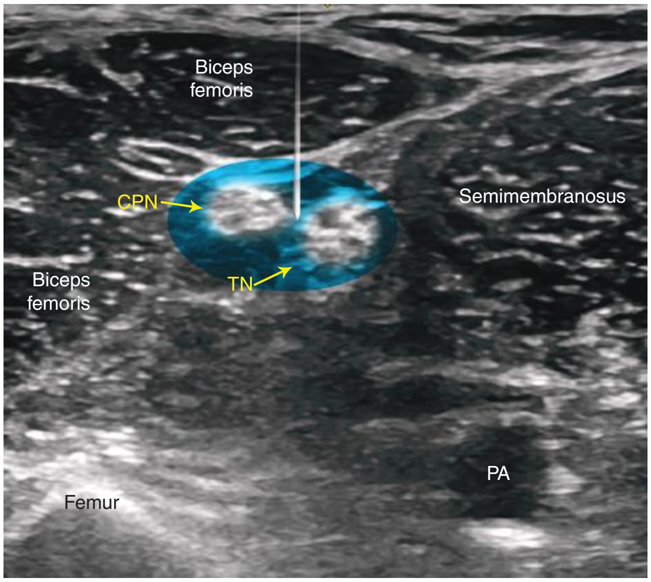

FIGURE 33G–11. Simulated needle path, needle tip position and local anesthetic spread (blue-shaded area) to block the sciatic nerve (TN and CPN) through the posterior approach out of plane. PA, popliteal artery.

When local anesthetic injection does not appear to result in a spread inside the sciatic nerve sheath and around the sciatic nerve components, additional needle repositions and injections may be necessary. Correct injection is recognized when local anesthetic spreads proximally and distally to the site of the injection around both divisions of the nerve, which can be documented by observing the spread of the local anesthetic within Vloka's sheath proximal to the site of injection.

A single injection of local anesthetic typically suffices.

TIPS

- To improve needle visualization, a skin puncture site 2–3 cm lateral to the transducer will reduce the angle between the needle and the footprint of the transducer (see Figure 33G–6).
- The presence of a motor response to nerve stimulation is useful but not necessary if the nerve, needle, and local anesthetic spread are well visualized.
- Never inject against high resistance because this may signal an intraneural injection (injection pressure must be < 15 psi).
- In the posterior approach to the popliteal block, either an in-plane (lateral or medial) or out-of-plane technique can be used (Figures 33G-9 through 33G-12). While the in-plane lateral approach is commonly used, the advantage of the out-of-plane approach is that the needle path is through skin and adipose tissue rather than the muscles and thus, less painful.

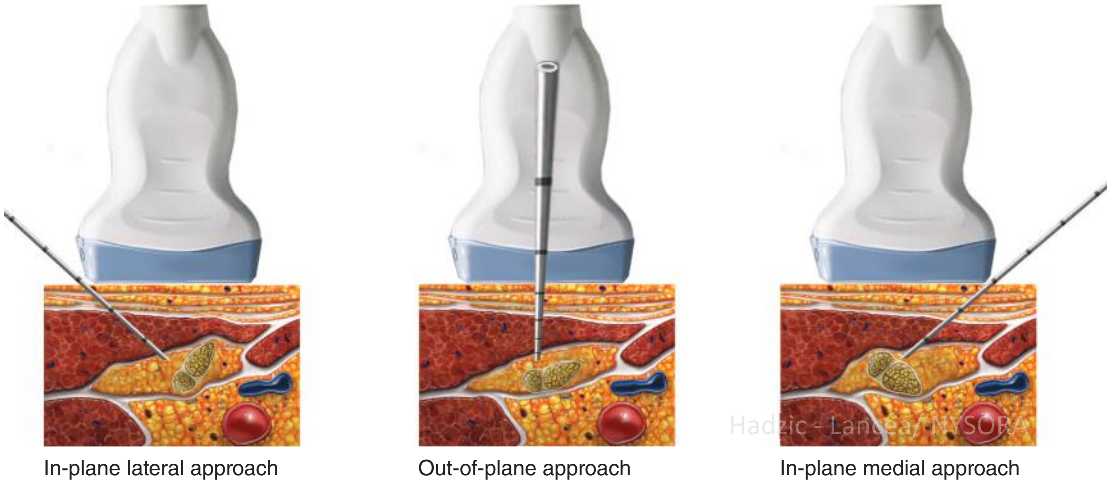

FIGURE 33G–12. In-plane (lateral or medial) or out-of-plane approach are shown - the operator should be able to pick and choose any of these needle orientations, depending on the configuration of tibial and common peroneal branches at the site of injection.

FIGURE 33G–13. Continuous sciatic block in the popliteal fossa using a lateral approach with the patient in the supine position. The needle is positioned within the epineural sheath of the sciatic nerve. After an injection of a small volume of local anesthetic to confirm correct needle position, a catheter is inserted 2–4 cm past the needle tip. Preloading the catheter is useful in facilitating the procedure. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

CONTINUOUS ULTRASOUND-GUIDED POPLITEAL SCIATIC BLOCK

The goal of the continuous popliteal sciatic block is to place the catheter within the sciatic nerve sheath in the popliteal fossa (Figure 33G-13).

The catheter is inserted 4-5 cm beyond needle tip and its correct placement is documented by observing injection of LA within the sciatic nerve sheath. The catheter is secured either by taping it to the skin or tunneling.

The lateral approach may have some advantage over the prone approach with regard to catheter placement. First, the biceps femoris muscle tends to stabilize the catheter and decrease the chance of dislodgement, compared with the subcutaneous tissue of the popliteal fossa in the prone approach. Second, if the knee is to be flexed and extended, the side of the thigh is less mobile than the back of the knee. Finally, access to the catheter site is more convenient with the lateral approach compared with the prone approach.

A common starting infusion regimen is ropivacaine 0.2% at 5 mL/h with a patient-administered bolus of 5 mL every 60 minutes.

CHAPTER 33H

Ultrasound-Guided Ankle Block

Catherine Vandepitte, Ana M. Lopez, Sam Van Boxstael, and Hassanin Jalil

ANKLE BLOCK AT A GLANCE

- Indications: Distal foot and toe surgery
- Transducer position: about the ankle; depends on the nerve to be blocked
- Goal: local anesthetic spread surrounding each individual nerve
- Local anesthetic: 3–5 mL per nerve

GENERAL CONSIDERATIONS

Using an ultrasound (US)-guided technique affords a practitioner the ability to reduce the volume of local anesthetic required for ankle blockade. Because the nerves involved are located relatively close to the surface, ankle blocks are easy to perform; however, knowledge of the anatomy of the ankle is essential to ensure success.[1]

ULTRASOUND ANATOMY

Ankle block involves anesthetizing five separate nerves: two deep nerves and three superficial nerves. The two deep nerves are the tibial nerve and the deep peroneal nerve. The three superficial nerves are the superficial peroneal, sural, and saphenous nerves. All nerves, except the saphenous, are terminal branches of the sciatic nerve; the saphenous nerve is a sensory branch of the femoral nerve.

Tibial Nerve

The tibial nerve is the largest of the five nerves at the ankle level and provides innervation to the heel and sole of the foot. With the linear transducer placed transversely at (or just proximal to) the level of the medial malleolus, the nerve can be seen immediately posterior to the posterior tibial artery (Figures 33H–1, 33H–2, and 33H–3). Color Doppler can be very useful in locating the posterior tibial artery when it is not readily apparent. The nerve typically appears hyperechoic with honeycomb pattern. A useful mnemonic for the relevant structures in the vicinity is **T**om, **D**ick **AN**d **H**arry, which refers to, from anterior to posterior, the **t**ibialis posterior tendon, flexor **d**igitorum longus tendon, **a**rtery/**n**erve/vein, and flexor **h**allucis longus tendon. These tendons can resemble the nerve in appearance, which can be confusing. The nerve's intimate relationship with the artery should be kept in mind to avoid misidentification. If in doubt, track the structure proximally: tendons will turn into muscle bellies, whereas the nerve will not change in appearance.

Deep Peroneal Nerve

This branch of the common peroneal nerve innervates the ankle extensor muscles, the ankle joint and the web space between the first and second toes. As it approaches the ankle, the nerve crosses the anterior tibial artery from a medial to lateral position. A transducer placed in the transverse orientation at the level of the extensor retinaculum will show the nerve lying immediately lateral to the artery, on the surface of the tibia (Figures 33H–4, 33H–5, and 33H–6). In some individuals the nerve courses along the medial side of the artery. The nerve usually appears hypoechoic with a hyperechoic rim, but it is small and often difficult to distinguish from the surrounding tissue.

Clinical Pearl

- When the deep peroneal nerve is difficult to identify on US, an injection around the artery may help with visualization.

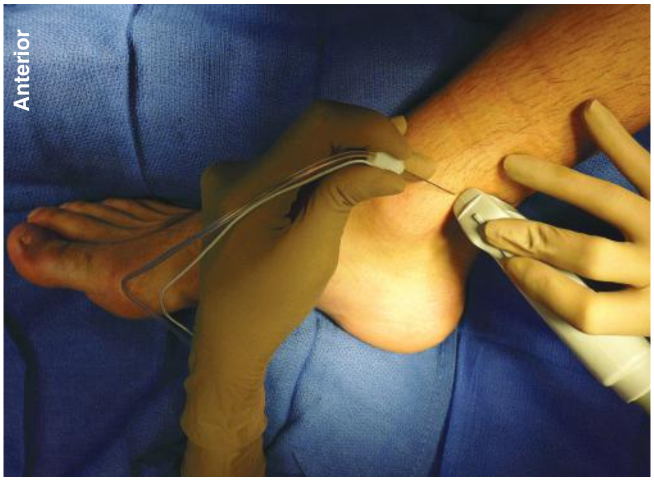

FIGURE 33H–1. Transducer position and needle insertion for a block of the tibial nerve using an in-plane technique.

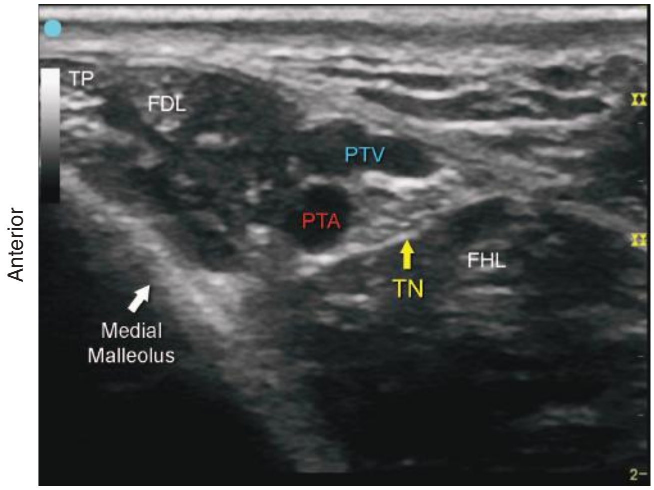

FIGURE 33H–3. The tibial nerve (TN) is seen posterior and deep to the posterior tibial artery (PTA). TP, tibialis posterior; FDL, flexor digitorum longus; FHL, flexor hallucis longus; PTV, posterior tibial vein.

Superficial Peroneal Nerve

The superficial peroneal nerve innervates the dorsum of the foot. It emerges to lie superficial to the fascia 10–20 cm above the ankle joint on the anterolateral surface of the leg and divides into two or three small branches. A transducer placed transversely on the leg, approximately 5-10 cm proximal and anterior to the lateral malleolus, will identify the hyperechoic nerve branches lying in the subcutaneous tissue immediately superficial to the fascia (Figures 33H–7, 33H–8, and 33H–9). To identify the nerve proximal to its division, the transducer can be traced proximally until, at the lateral aspect, the extensor digitorum longus and peroneus brevis muscle can be seen with a prominent groove between them leading to the fibula (Figure 33H–10). The superficial peroneal nerve is located in this groove, just deep to the fascia. Once it has been identified at this more proximal location, the nerve can be traced distally to the ankle or it can be blocked at this level. Because the superficial nerves are rather small, their identification with US is not always possible.

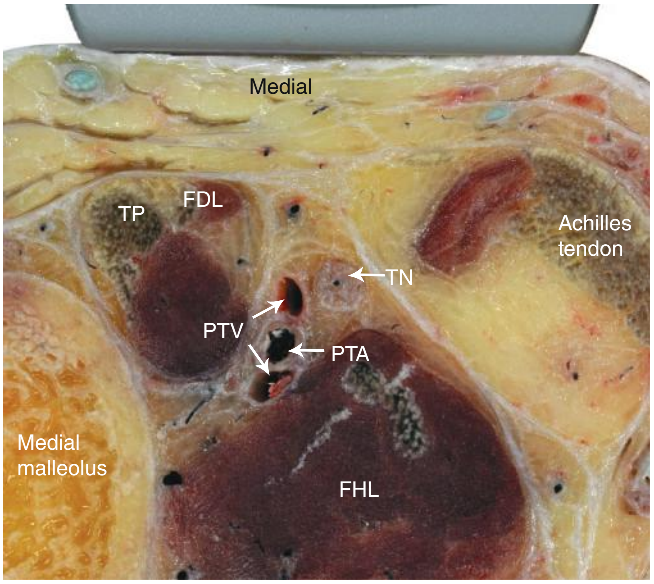

FIGURE 33H–2. Cross-sectional anatomy of the tibial nerve at the level of the ankle. Shown are the posterior tibial artery (PTA) and vein (PTV) behind the medial malleolus , the tibialis posterior (TP) and the flexor digitorum longus (FDL). The tibial nerve (TN) is just posterior to the posterior tibial vessels and superficial to the flexor hallucis longus muscle (FHL). (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

Clinical Pearl

- The use of a small-gauge needle (25-gauge) is recommended to decrease patient discomfort as needle insertion in this area can be painful.

FIGURE 33H–4. Transducer position and needle insertion to block the deep peroneal nerve at the level of the ankle. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

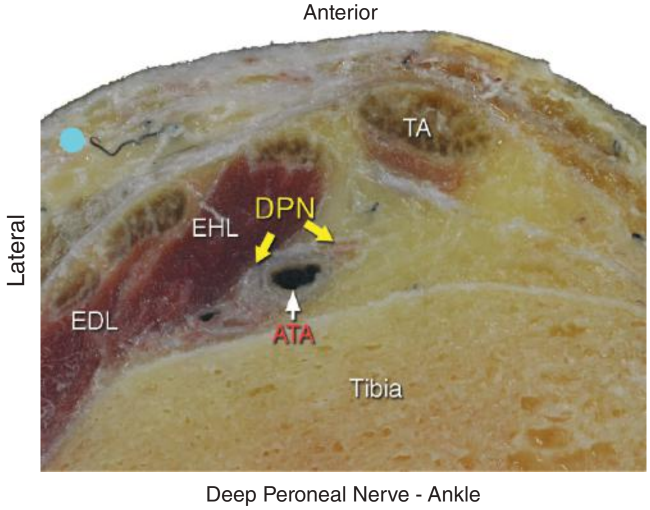

FIGURE 33H–5. Cross-sectional anatomy of the deep peroneal nerve at the level of the ankle. The deep peroneal nerve (DPN) is located just lateral to anterior tibial artery (ATA) and between extensor hallucis longus (EHL) and tibia. Note the proximity of the extensor digitorum longus (EDL) and the tibialis anterior (TA), which can serve as an important landmark; to locate it, flex and extend the patient's great toe manually. The deep peroneal nerve appears divided in this section. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

FIGURE 33H–7. Transducer position and needle insertion to block the superficial peroneal nerve.

Sural Nerve

The sural nerve innervates the lateral margin of the foot and ankle. Proximal to the lateral malleolus, the sural nerve can be visualized as a small hyperechoic structure that is intimately associated with the small saphenous vein superficial to the deep fascia. The sural nerve, can be traced back along the posterior aspect of the leg, running in the midline superficial to the achiles tendon and gastronemious muscles (Figures 33H–11, 33H–12, and 33H–13). A calf tourniquet can be used to increase the size of the vein and facilitate its imaging; the nerve is often found in the immediate vicinity of the vein.

Saphenous Nerve

The saphenous nerve innervates the medial malleolus and a variable portion of the medial aspect of the leg below the knee. The nerve travels down the medial leg alongside the great saphenous vein. Because it is a small nerve, it is best visualized 10–15 cm proximal to the medial malleolus, using the great saphenous vein as a landmark (Figures 33H–14, 33H–15, and 33H–16). A proximal calf tourniquet can be used to assist in

increasing the size of the vein. The nerve appears as a small hyperechoic structure, next to the vein. At this level the nerve often has several branches.

Clinical Pearl

- When using veins as landmarks, use as little pressure as possible on the transducer in order to permit the veins to fill.

DISTRIBUTION OF ANESTHESIA

An ankle block results in anesthesia of the entire foot. For a more comprehensive review of the distribution of each nerve, see Chapter 3.

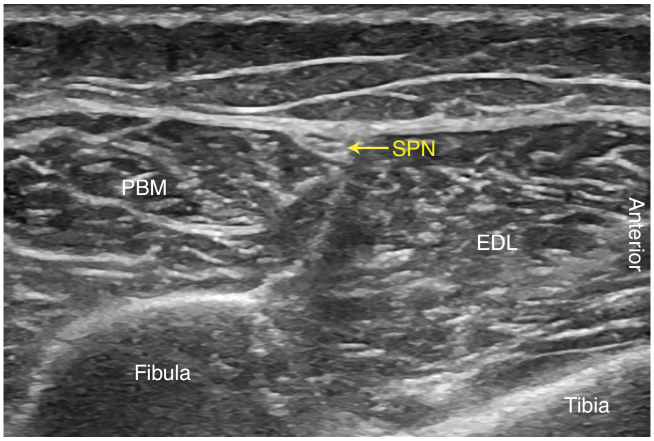

FIGURE 33H–10. US anatomy of the superficial peroneal nerve with structures labeled. EDL, extensor digitorum longus muscle; PBM, peroneus brevis muscle; SPN, superficial peroneal nerve.

EQUIPMENT

The equipment recommended for an ankle block is as follows:

- Ultrasound machine with linear transducer (8–18 MHz), sterile sleeve, and gel

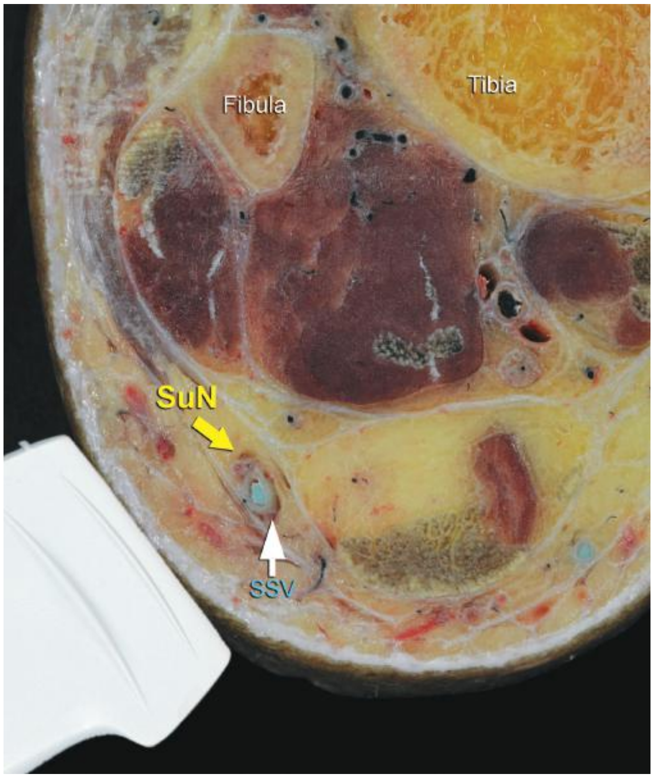

FIGURE 33H–12. Cross-sectional anatomy of the sural nerve at the level of the ankle. Shown is the sural nerve (SuN) in the immediate vicinity of the small saphenous vein (SSV). (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

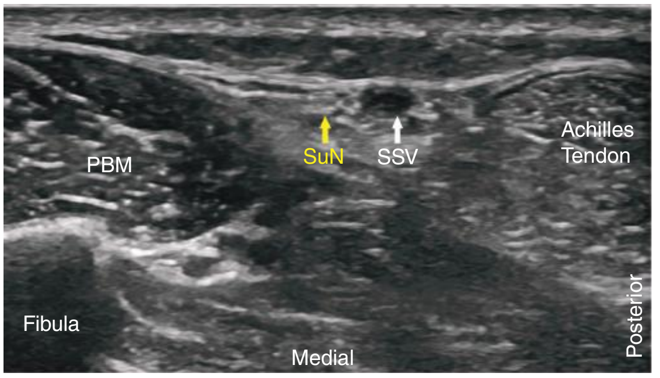

FIGURE 33H–13. US anatomy of the sural nerve (SuN). Shown are the peroneus brevis muscle (PBM) and small saphenous vein (SSV).

- Standard nerve block tray
- Three 10-mL syringes containing local anesthetic
- A 1.5-inch, 22- to 25-gauge needle with low-volume extension tubing
- Sterile gloves

LANDMARKS AND PATIENT POSITIONING

This block is usually performed with the patient in the supine position. A footrest underneath the calf facilitates access to the ankle, especially for the tibial and sural nerve blocks. An assistant is helpful to maintain internal or external rotation of the leg as needed.

GOAL

The goal is to place the needle tip immediately adjacent to each of the five nerves and deposit local anesthetic until the spread around each nerve is accomplished.

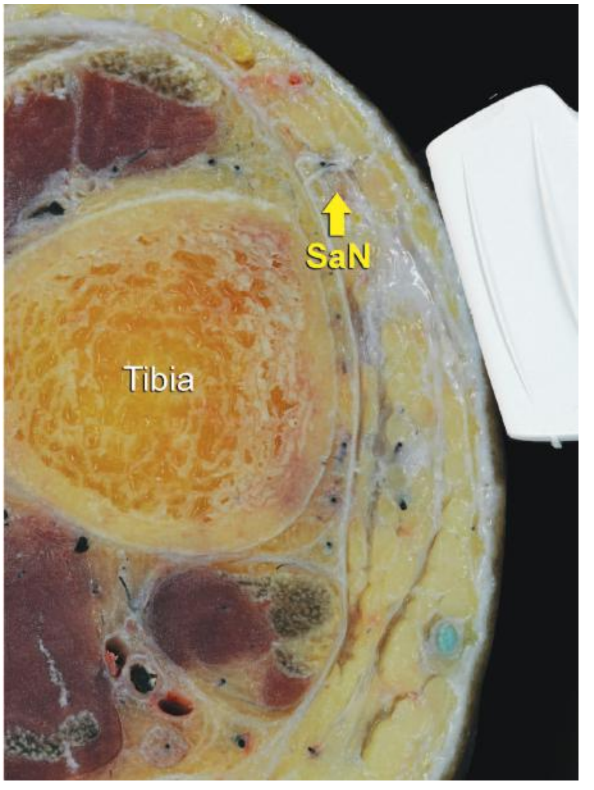

FIGURE 33H–15. Cross-sectional anatomy of the saphenous nerve (SaN) at the level of the ankle. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

TECHNIQUE

With the patient in the proper position, the skin is disinfected. For each of the blocks, the needle can be inserted either in plane or out of plane. Ergonomics often dictate which approach is

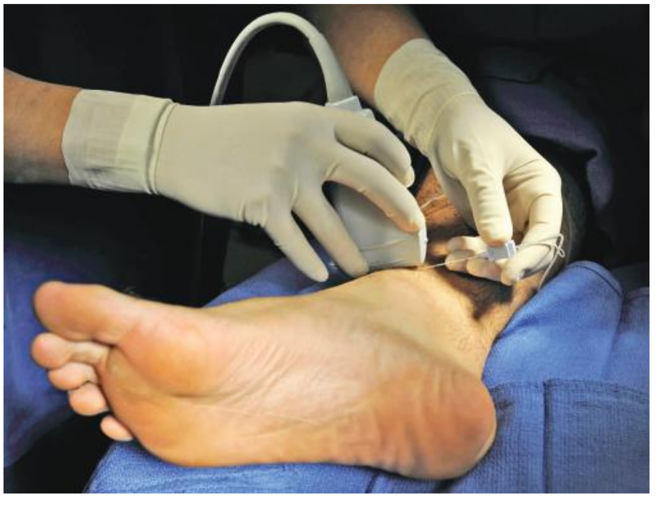

FIGURE 33H–14. Transducer position and needle insertion to block the saphenous nerve. (Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

(Reproduced with permission from Hadzic A: *Hadzic's Peripheral Nerve Blocks and Anatomy for Ultrasound-Guided Regional Anesthesia*, 2nd ed. New York: McGraw-Hill, 2011.)

most effective. A successful block is predicted by the spread of local anesthetic immediately adjacent to the nerve; redirection to achieve circumferential spread is not necessary because these nerves are small, and the local anesthetic diffuses quickly into the neural tissue. A 3–5 mL of local anesthetic per nerve is typically sufficient for an effective block.

TIPS

- If the smaller superficial nerves (sural, saphenous and superficial peroneal) are not seen, these nerves can be blocked simply by injecting local anesthetic into the subcutaneous tissue as a "skin wheal"; for the sural nerve, inject from the Achilles tendon to the lateral malleolus; for the superficial peroneal and the saphenous, inject anteriorly from one malleolus to the other, taking care to avoid injuring the great saphenous vein.
- For surgery on the forefoot and toes, the saphenous nerve block may be omitted, as in 97% of patients, the saphenous nerve innervation does not extend beyond the midfoot. However, an anatomical study found branches of the saphenous nerve reaching the first metatarsal in 28% of specimens.[2,3]

SECTION 5 Ultrasound-Guided Nerve Blocks for Abdominal & Thoracic Wall

CHAPTER 34

Ultrasound-Guided Transversus Abdominis Plane and Quadratus Lumborum Blocks

Hesham Elsharkawy and Thomas F. Bendtsen

INTRODUCTION

Ultrasound-guided transversus abdominis plane (TAP) block has become a common analgesic method after surgery involving the abdominal wall. Because TAP blockade is limited to somatic anesthesia of the abdominal wall and highly dependent on interfascial spread, various newer techniques have been proposed to enhance analgesia, either in addition to TAP block or as a single modality. In particular, variants of quadratus lumborum blocks (QLBs) have been proposed as more consistent methods with an aim to accomplish somatic as well as visceral analgesia of the abdomen. The present evidence, mainly case reports, suggests that different variants of QLB have different analgesic effects and mechanisms of action, although this has not been formally validated. In particular, transmuscular QLB and the so-called QLB2 may result in wider and longer sensory blockade compared to TAP block (T4–L1 for QL block vs. T6–T12 for the TAP blocks) (Figures 34–1 and 34–2). This chapter focuses on underlying principles for TAP blockade and the newer QLB techniques, with an understanding that the information about the latter is based on sparse evidence of limited quality as outcome-based studies are not yet available.

ANATOMY

The **transversus abdominis plane** is the fascial plane superficial to the transversus abdominis muscle, the innermost muscular layer of the anterolateral abdominal wall. The upper fibrous anterior part of the muscle lies posterior to the rectus abdominis muscle and reaches the xiphoid process. The posterior aponeuroses of the transversus abdominis and internal oblique muscles fuse and attach to the thoracolumbar fascia (TLF). In the TAP, the intercostal, subcostal, and L1 segmental nerves communicate to form the upper and lower TAP plexuses, which innervate the anterolateral abdominal wall, including the parietal peritoneum. Therefore, TAP blockade requires anesthesia of the upper (also known as the subcostal or intercostal) TAP plexus, as well as the lower TAP plexus, located in the vicinity of the deep circumflex iliac artery.

The subcostal approach to the TAP block ideally anesthetizes the intercostal nerves T6–T9 between the rectus abdominis sheath and the transversus abdominis muscle. The lateral TAP block in the midaxillary line between the thoracic cage and iliac crest as well as between the internal oblique and transversus abdominis muscles ideally should reach intercostal nerves T10–T11 and the subcostal nerve T12. Of note, the umbilicus is innervated by intercostal nerve T10. The L1 segmental nerves in the TAP are not covered by the lateral TAP block and require an anterior TAP block medial to the anterior superior iliac spine. A posterior approach to block the TAP plexuses via the triangle of Petit has also been described. TAP blocks provide somatic analgesia of the abdominal wall including the parietal peritoneum.

The **quadratus lumborum (QL) muscle** lies in the posterior abdominal wall dorsolateral to the psoas major muscle (Figure 34–3). The QL muscle originates from the posterior part of the iliac crest and the iliolumbar ligament and inserts on the 12th rib and the transverse processes of vertebrae L1–L5. The QL muscle assists in lateral flexion of the lumbar spine.

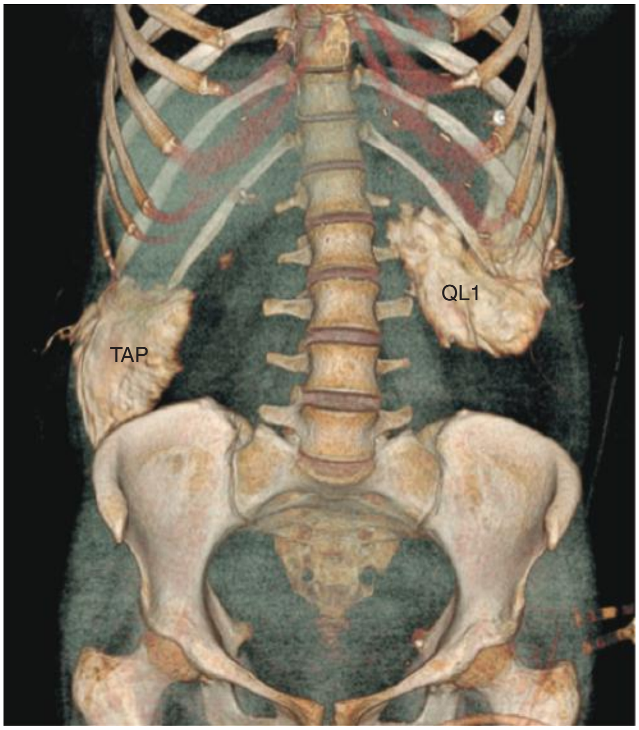

FIGURE 34–1. The transverse abdominis plane (TAP) and quadratus lumborum 1 (QL1) blocks: anterior view. Injection of 20 mL of contrast in the TAP block resulted in the posterolateral spread from the 12th rib to the iliac crest. The QL1 block after injection of 20 mL of contrast resulted in the spread of the contrast toward the transverse process cephalad alongside the thoracolumbar fascia to the 11th and 10th intercostal spaces.

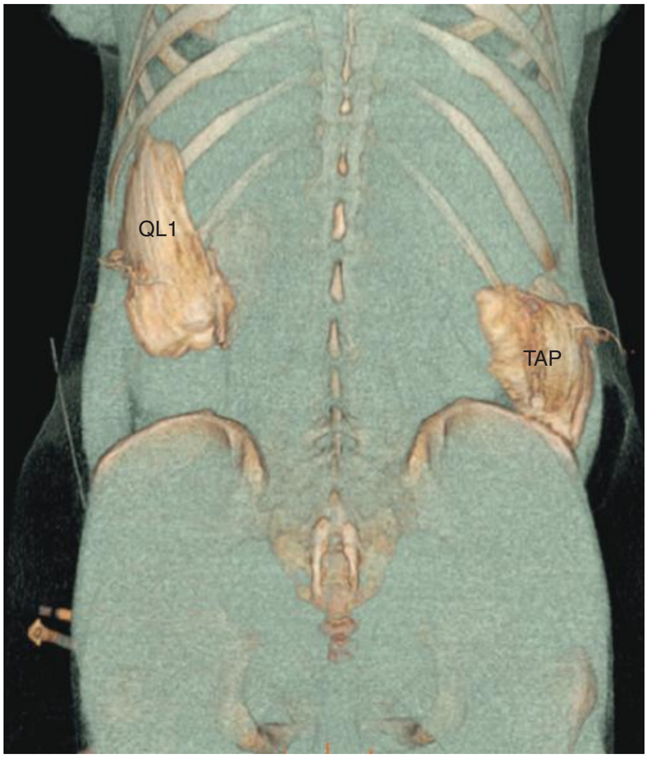

FIGURE 34–2. Transverse abdominis plane (TAP) and quadratus lumborum 1 (QL1) blocks: posterior view. Injection of 20 mL of contrast in the TAP block resulted in the posterolateral spread from the 12th rib to the iliac crest. After injection of 20 mL of contrast, the QL1 block resulted in the spread of the contrast toward the transverse process cephalad alongside the thoracolumbar fascia to the 11th and 10th intercostal spaces.

The **thoracolumbar fascia** consists of anterior, middle, and posterior layers (Figure 34–4). The posterior layer of the TLF forms an attachment to the strong membranous aponeurosis of the latissimus dorsi. The three layers of the TLF are continuous with the fused posterior aponeurosis of the internal oblique and transversus abdominis muscles.

The posterior layer of the TLF covers the superficial side of the erector spinae. In the lumbar region, the posterior layer extends from the spinous processes medially to the lateral margin of the erector spinae, where it fuses with the middle layer of the TLF and forms the so-called lateral raphe, which is a dense connective pillar that extends from the iliac crest to the 12th rib. The deepest lamina of the posterior layer is called the *paraspinal retinacular sheath* (PRS), which encapsulates the erector spinae muscles.[1] The *lateral interfascial triangle* (LIFT)s is made by the lateral margin of the erector spinae muscle (base), the PRS with overlying posterior and middle layers of the TLF (sides), and the lateral raphe (apex). The middle layer of the TLF separates the QL and erector spinae muscles. The anterior layer of the TLF covers the anterior aspect of the QL muscle.

The **transversalis fascia (TF)** invests the parietal subperitoneal areolar tissue in the abdominal cavity. The outer surface of the TF lines the deep side of the transversus abdominis, QL, and psoas major muscles. The TF communicates with the endothoracic fascia posterior to the diaphragm where the TF is thickened as the medial and lateral arcuate ligaments, with possibility of spread of injectate from the QL and psoas major muscle compartments to the thoracic paravertebral space (Figure 34–5).[2] Consequently, when local anesthetic is injected into the fascial plane between these muscles in the lumbar region, it could spread cranially to the thoracic paravertebral space. The anterior layer of the TLF is fused with the TF. The iliohypogastric, ilioinguinal, and subcostal nerves that cross the QL muscle lie between this muscle and the TF. The **four lumbar arteries** on each side pass posterior to the psoas major and QL muscles, pierce the aponeurosis of the transversus abdominis muscle, and end up inside the TAP (Figure 34–6).

The lower pole of the kidney lies anterior to the QL muscle and can reach the L4 level with deep inspiration. Therefore, this should be checked when performing QL block as the kidney may be separated from the QL muscle only by perinephric fat, the posterior layer of renal fascia, the TF, and the anterior layer of the TLF. In summary, the kidney should always be visualized with QL blocks to avoid kidney injury.

PATIENT POSITIONING AND EQUIPMENT SELECTION

For QL blocks, the lateral decubitus position is preferred over the supine position as it provides better ergonomics and relevant sono-images of the neuroaxial structures. A low-frequency (5- to 2-MHz) curved array ultrasound transducer in transverse

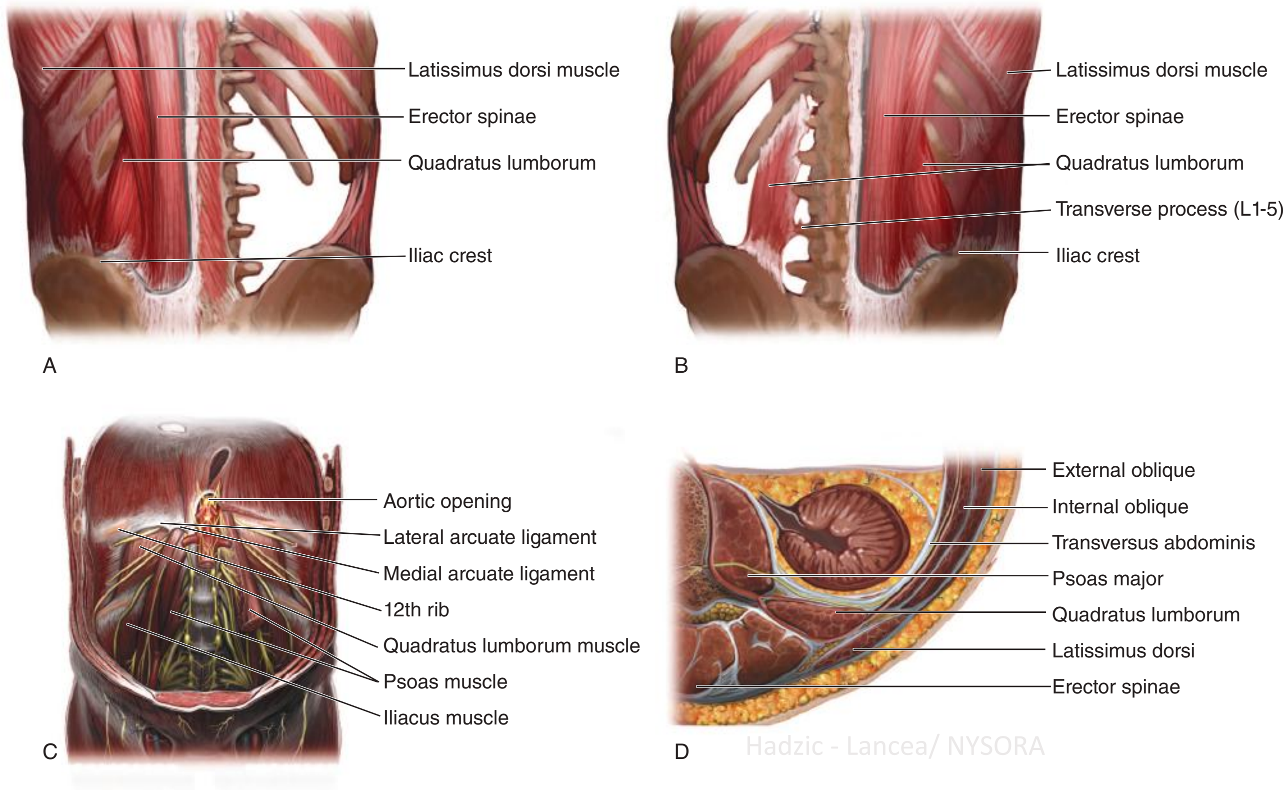

FIGURE 34–3. The quadratus lumborum (QL) muscle in four views: **A:** QL muscle from the back covered by the erector spinae and latissimus dorsi muscles. **B:** QL muscle from the back, with ES and LD muscles removed to show the origin and insertion of the QL muscle. **C:** QL muscle from the front, on the left side the psoas muscle is cut, showing the ventral rami of the spinal nerve roots pass in front of the QL. **D:** QL muscle cross section showing the surrounding muscles and the QL relation to the kidney.

axis is preferred to visualize the three lateral abdominal wall muscle layers and the QL muscle. A 22-gauge, short-bevel needle is recommended for the single-injection technique, whereas an 18- to 21-gauge, 10-cm Tuohy needle with extension tubing is used for catheters. A peripheral nerve stimulator may be useful as a warning sign to prevent further needle advancement should the needle be mistakenly placed too deep and next to the lumbar plexus.

SCANNING AND BLOCK TECHNIQUES

Subcostal TAP Block

A linear transducer is placed alongside the lower margin of the rib cage as medial and cranial as possible for the subcostal TAP block (Figure 34-7a). The rectus abdominis muscle and its posterior rectus sheath are visualized along with the transversus

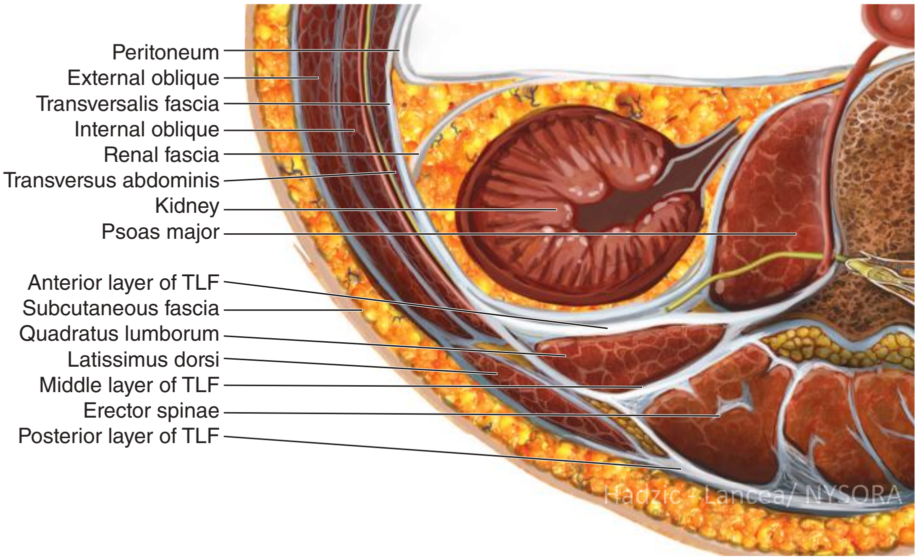

FIGURE 34–4. The different layers of the thoracolumbar fascia (TLF).

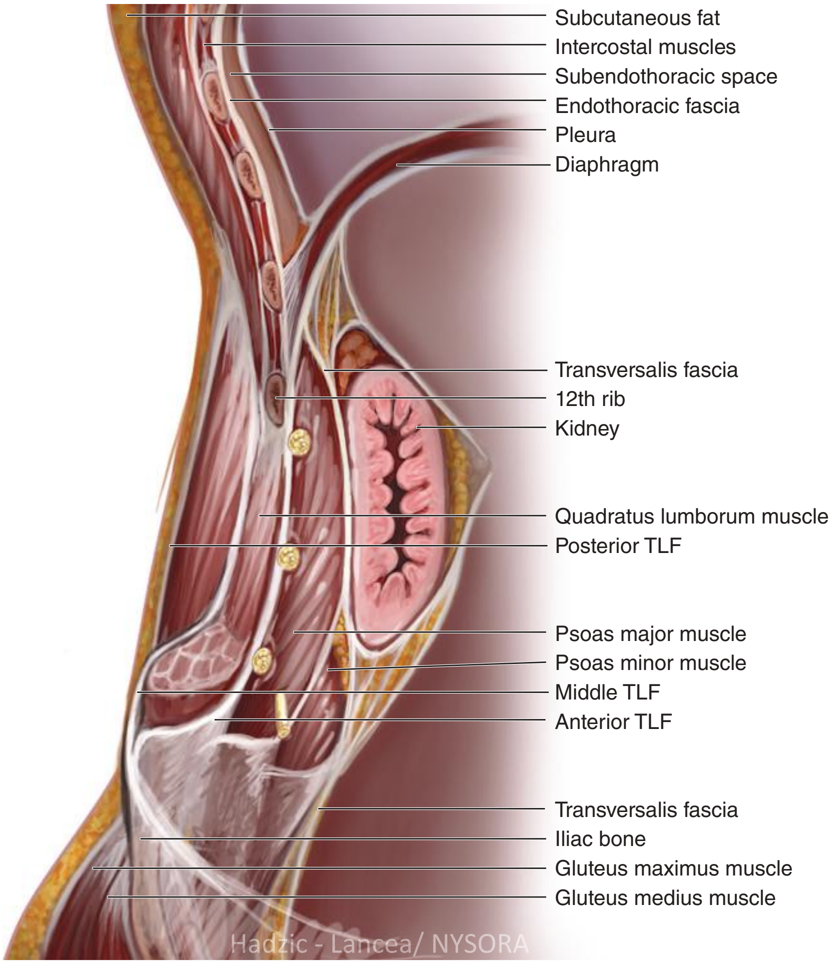

FIGURE 34–5. A sagittal section showing the fascial relations of the lower thoracic subendothoracic paravertebral space and the retroperitoneal space.

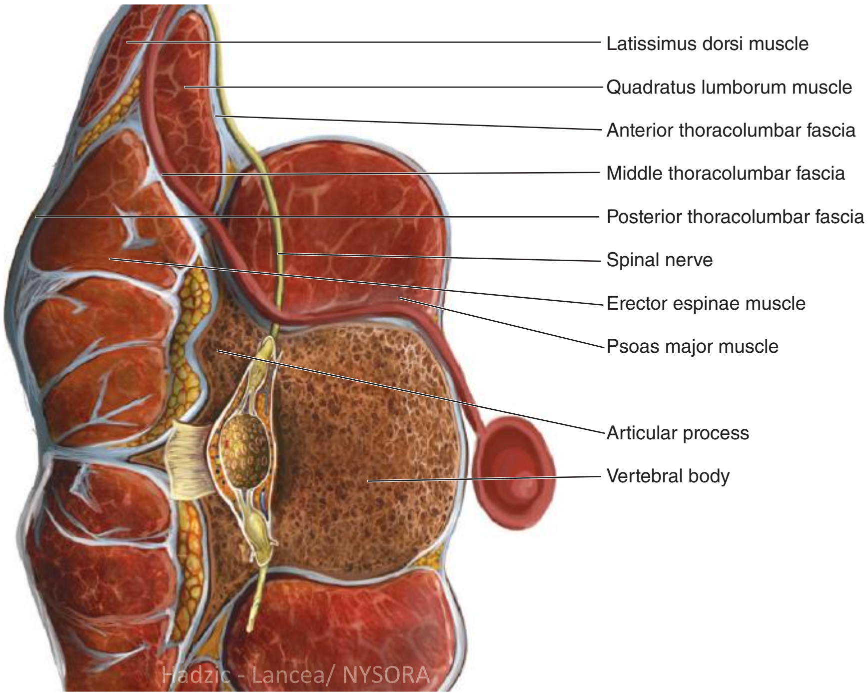

FIGURE 34–6. Cross section of the quadratus lumborum (QL) muscle and its relation the ventral rami of the spinal nerve roots (yellow) and the abdominal branches of the lumbar arteries (red).

abdominis muscle deep to the posterior rectus sheath. The target is the fascial plane between the posterior rectus sheath and the transversus abdominis muscle. The needle is inserted above the rectus abdominis close to the midline and advanced from medial to lateral (alternatively, lateral to medial). The end point of injection is the spread of local anesthetic between the posterior rectus sheath and the anterior margin of the transversus abdominis muscle.

Lateral TAP Block

For the lateral TAP block, a linear transducer is placed in the axial plane on the midaxillary line between the subcostal margin and the iliac crest (Figure 34-7b). The three layers of abdominal wall muscles are visualized: external and internal oblique as well as the transversus abdominis muscles. The target is the fascial plane between the internal oblique and the transversus abdominis muscles. The needle is inserted in the anterior axillary line, and the needle tip is advanced until it reaches the fascial plane between the internal oblique and transversus abdominis muscles approximately in the midaxillary line.

Anterior TAP Block

A linear transducer is placed medial to the anterior superior iliac spine pointing toward the umbilicus with a caudad tilt for the anterior TAP block (Figure 34-7c). The three abdominal wall muscles are visualized (see discussion for the lateral TAP block). The target is the same fascial plane at the level of the deep circumflex iliac artery. The needle is inserted medial to the anterior superior iliac spine. The needle tip is advanced until it is placed between the internal oblique and transversus abdominis muscles adjacent to the deep circumflex iliac artery.

Posterior TAP Block

For the posterior TAP block, the linear transducer is placed in the axial plane in the midaxillary line and moved posteriorly to the most posterior limit of the TAP between the internal oblique and transversus abdominis muscles (Figure 34-7d). The target is the most posterior end of the TAP. The needle is inserted in the midaxillary line and advanced posteriorly until it reaches the posterior end of the TAP.

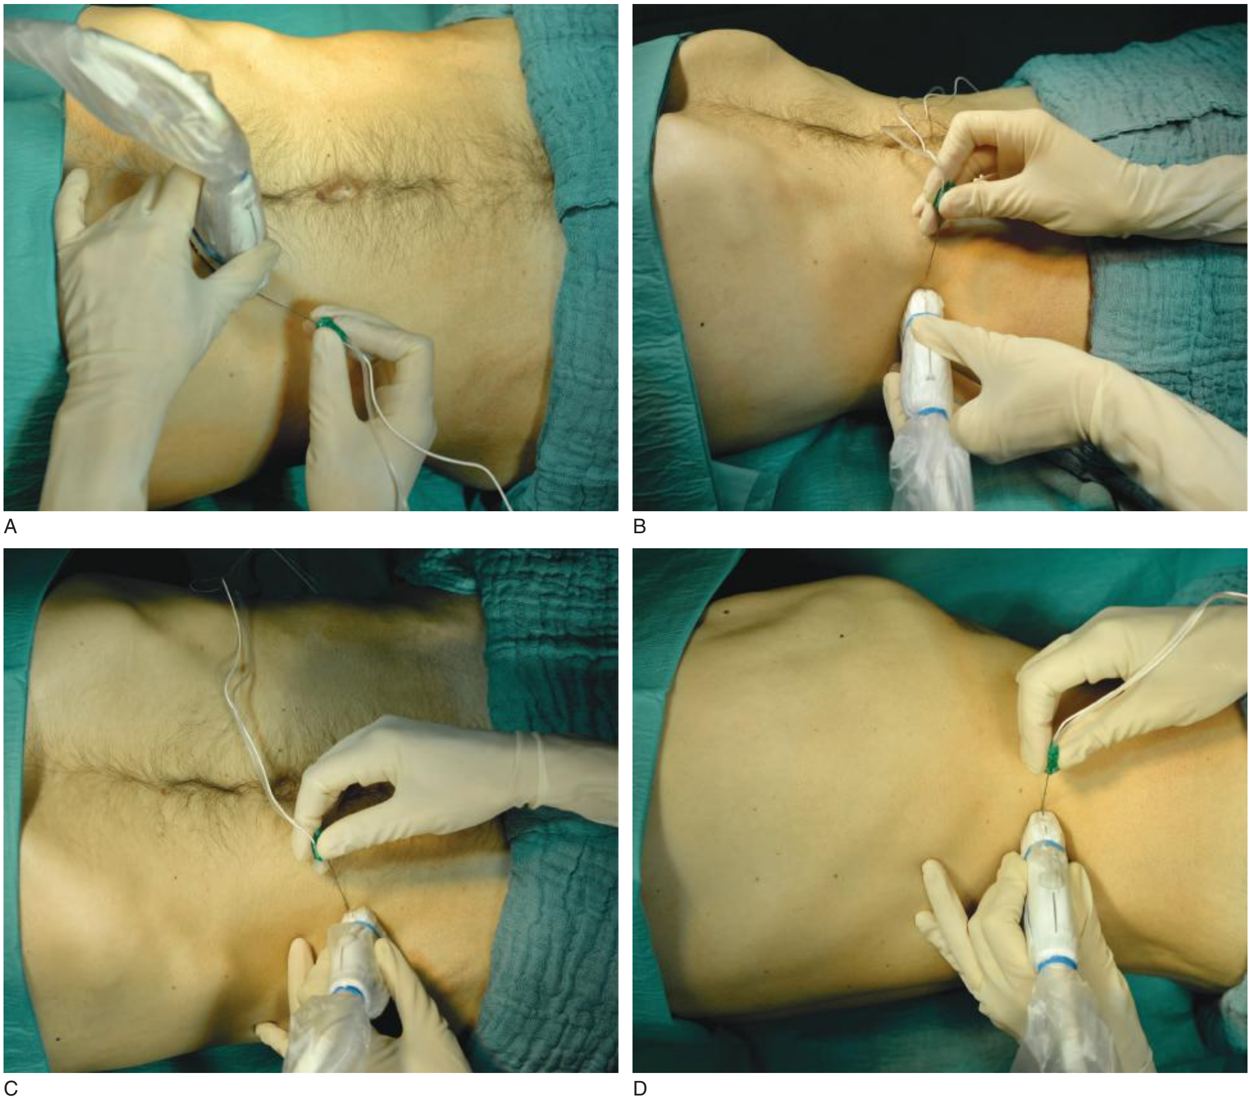

FIGURE 34–7. Patient and transducer position for different TAP block approaches: subcostal (**A**), lateral (**B**), anterior (**C**), and posterior (**D**).

A B

FIGURE 34–8. Cross section with the ultrasound probe location. B: Ultrasound image of the lateral abdominal wall. QL = quadratus lumborum; PM = psoas major; ES = erector spinae; TP = transverse process; VB = vertebral body (L4); TA = transverse abdominis; IO = internal oblique; EO = external oblique; LD = latissimus dorsi; RP = retroperitoneal space; P = peritoneal space; A = aorta; arrows = lumbar plexus; arrow heads = transversus abdominis aponeurosis.

Transmuscular QL Block

A curved array transducer for the transmuscular QL (TQL) block is placed in the axial plane on the patient's flank just cranial to the iliac crest. The "shamrock sign" is visualized: The transverse process of vertebra L4 is the stem, whereas the erector spinae posteriorly, QL laterally, and psoas major anteriorly represent the three leaves of the trefoil. The target for injection is the fascial plane between the QL and psoas major muscles (Figure 34–8).[3] The needle is inserted using an in-plane technique from the posterior end of the transducer through the QL muscle (Figure 34-9). The injectate should ideally spread from the injection site inside the fascial plane between the QL and psoas major muscles to the thoracic paravertebral space with a goal to accomplish segmental somatic and visceral analgesia from T4 to L1. The needle approaches of the QLBs are shown in Figure 34–10.

Type 1 QL Block

For the type 1 QL (QL1) block, a linear transducer is placed in the axial plane in the midaxillary line and moved posteriorly until the posterior aponeurosis of the transversus abdominis muscle becomes visible as a strong specular reflector. The target is just deep to the aponeurosis but superficial to the TF at the lateral margin of the QL muscle. This is just lateral to the pararenal fat compartment. The QL1 block is identical to the *fascia transversalis plane block*.[4] The needle is inserted from either the anterior or the posterior end of the transducer and advanced until the needle tip just penetrates the posterior aponeurosis of the transversus abdominis muscle. Local anesthetic is injected between the aponeurosis and the TF at the lateral margin of the QL muscle. The main effect is anesthesia of the lateral cutaneous branches of the iliohypogastric, ilioinguinal, and subcostal nerves (T12–L1).

Type 2 QL Block

In the type 2 QL (QL2) block, a linear transducer is placed in the axial plane in the midaxillary line and moved posteriorly as in the QL1 block, until the LIFT, which encapsulates the paraspinal muscles, becomes visible between the latissimus dorsi and QL muscles. The target is the deep layer (the PRS) of the

FIGURE 34–9. Patient and transducer position for Transmuscular QLB.

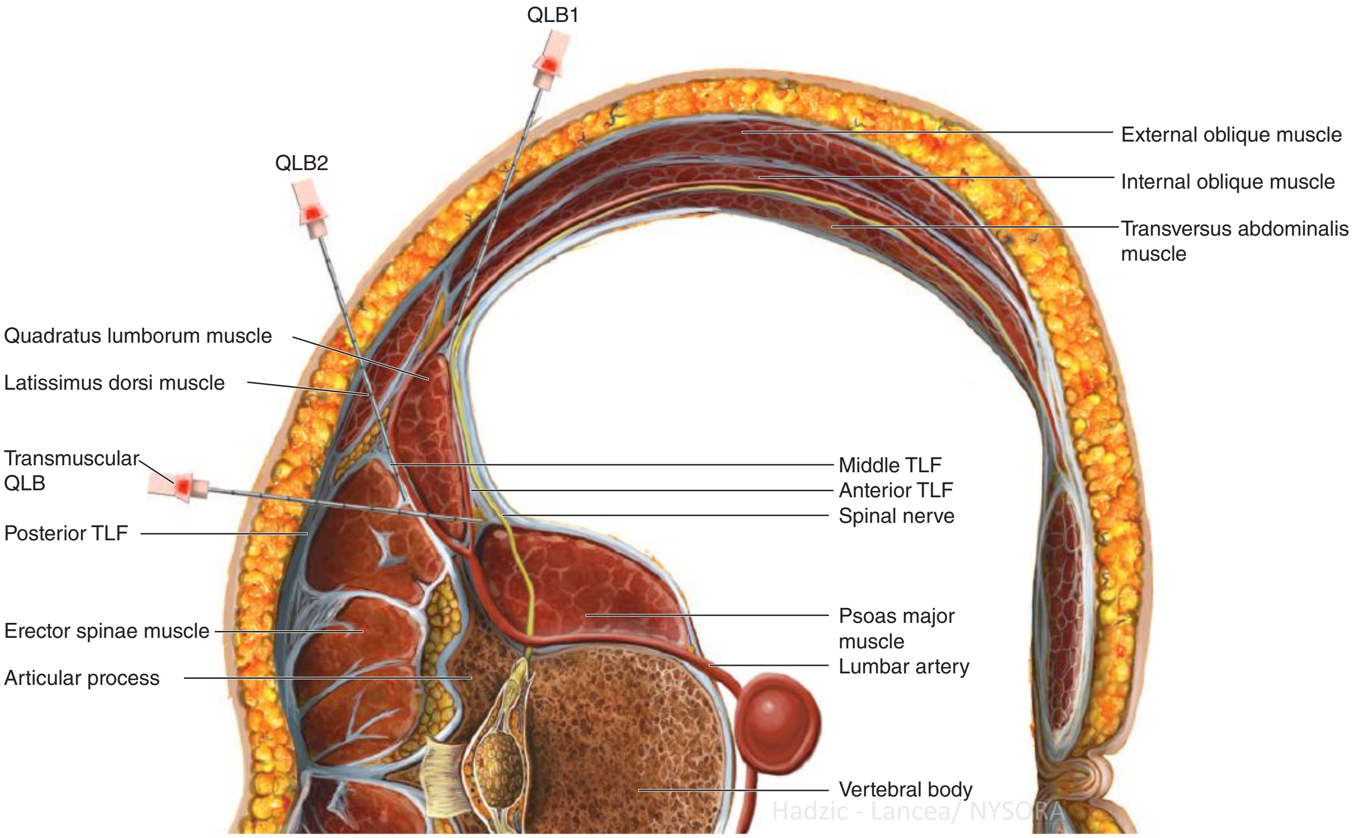

FIGURE 34–10. Trajectory of the needle for all three approaches of the quadratus lumborum (QL) block (QLB1, QLB2, and QLB3).

middle layer of the TLF. The needle is inserted from the lateral end of the transducer. The needle tip is advanced until it is inside the middle layer of the TLF close to the LIFT. The local anesthetic is injected intrafascially and apparently provides analgesia equivalent to TQL block but with faster onset. The mechanism of action is not well understood.

DOSE AND VOLUME OF LOCAL ANESTHETIC

The TAP blocks as well as the TQL block and QLB1 are "tissue plane" blocks and thus require large volumes of local anesthetic to obtain reliable blockade. For each of the TAP blocks, a minimum volume of 15 mL is recommended. The local anesthetic dose needs to be considered for the size of the patient to ensure that a maximum safe dose is not exceeded, especially with dual bilateral TAP blocks. The QL region is relatively vascular as the lumbar arteries lie posterior to the muscle. Absorption of the local anesthetic into the circulation depends primarily on the vascularity of the site of deposition.[14] As the QL muscle is well vascularized and a large volume of local anesthetic is needed, the dose should be calculated accurately to prevent high peak plasma concentrations of local anesthetics in this type of block.

INDICATIONS

Most of the indications for QL blocks are based on case reports and clinical anecdotal experience. There are no studies comparing the safety and efficacy of the three types of QL block. Table 34–1 compares and summarizes the three types of QL blocks. The various QL blocks share the same indications as the TAP block.[8-13] Some examples are as follows:

- Large-bowel resection, open/laparoscopic appendectomy, and cholecystectomy
- Cesarean section, total abdominal hysterectomy
- Open prostatectomy, renal transplant surgery, nephrectomy, abdominoplasty, iliac crest bone graft
- Ileostomy
- Exploratory laparotomy, bilateral blocks for midline incisions

Clinical Pearls

- Close to the transverse process, the QL muscle appears thin as it is visualized anterior-posterior; visualized from the flank, the muscle looks much broader.
- Use color Doppler before insertion of the needle to detect the lumbar arteries on the posterior aspect of the QL muscle or any other large vessels.
- The QL is identified medial to the transversus abdominis muscle. The latissimus dorsi and erector spinae muscles are superficial and more hyperechoic.

SUMMARY

The various TAP blocks can provide somatic analgesia for abdominal wall surgery. QL blocks can provide somatic as well as visceral analgesia of both the abdominal wall and the lower

TABLE 34–1. Main features of QL blocks.

	QLB1	QLB2	TQLB
Clinical indications	Abdominal surgery below the umbilicus.	Abdominal surgery either above or below the umbilicus (any type of operation that requires intra-abdominal visceral pain coverage and abdominal wall incisions as high as T6)	
Dermatomes covered	L1	T4 to T12-L1; blocks the anterior and the lateral cutaneous branches of the nerves	
Lower extremity weakness	Not reported	Not reported	Potential
Spread to lumbar plexus	Not reported	Not reported	Potential
Needle entry and approach	Lateral abdomen near the posterior axillary line, below the costal margin and above the iliac crest and inserting the needle inplane with the curved array probe oriented axially.		
Potential complications	Complications are related to the lack of anatomical understanding and needle expertise. It is possible to puncture intra-abdominal structures such as the kidney, liver, and spleen.		
Injection site	Potential space medial to the abdominal wall muscles and lateral to QL muscle, anterolateral border of the QL muscle, at the junction with the transversalis fascia, outside the anterior layer of the TLF and fascia transversalis	Posterior to the QL muscle, outside the middle layer of the TLF	Anterior to the QL muscle, between the QL and the psoas major muscles, outside the anterior layer of the TLF and fascia transversalis, close to the intervertebral foramen
Level of difficulty	Intermediate	Intermediate	Advanced

segments of the thoracic wall and therefore could be a useful analgesic modality for selected abdominal surgeries. QL blocks may provide visceral analgesia due to their paravertebral and possibly epidural spread. The information in this chapter is based on the current knowledge, with an understanding that more specific recommendations are pending a stronger evidence base.

CHAPTER 35

Pectoralis and Serratus Plane Blocks

Rafael Blanco and Michael J. Barrington

INTRODUCTION

Pectoralis nerve (Pecs) and serratus plane blocks are newer ultrasound (US)-guided regional anesthesia techniques of the thorax.[1] The increasing use of ultrasonography to identify tissue layers and, particularly, fascial layers has led to the development of several newer interfascial injection techniques for analgesia of the chest and abdominal wall. For instance, the Pecs I block was devised to anesthetize the medial and lateral pectoral nerves, which innervate the pectoralis muscles.[1] This is accomplished by an injection of local anesthetic in the fascial plane between the pectoralis major and minor muscles. The Pecs II block (which also includes the Pecs I block) is an extension that involves a second injection lateral to the Pecs I injection point in the plane between the pectoralis minor and serratus anterior muscles with the intention of providing blockade of the upper intercostal nerves.[2] A further modification is the serratus plane block, in which local anesthetic is injected between the serratus anterior and latissimus dorsi muscles.[3] These interfascial injections were developed as alternatives to thoracic epidural, paravertebral, intercostal, and intrapleural blocks, primarily for analgesia after surgery on the hemithorax. Initially, Pecs blocks were intended for analgesia after breast surgery; however, case reports have also described the use of Pecs and serratus plane blocks for analgesia following thoracotomy[4] and rib fracture.[5]

Information from the currently published literature on Pecs and serratus plane blocks in peer-reviewed journals is summarized in Table 35–1.[3–8] Pecs blocks have also been proposed in letters to the editor as alternative techniques to anesthetize operative regions such as the axilla, proximal medial upper arm, and posterior shoulder, which are not innervated by the brachial plexus (Figure 35–1).[9–11]

ANATOMY OF THE PECTORAL AND AXILLARY REGIONS

Pecs blocks are applied in the pectoral and axillary regions, with the muscles in both regions innervated by the brachial plexus. The pectoral region overlies the pectoralis major muscle and is limited by the axillary, mammary, and inframammary regions (Figure 35–2). The axillary region is lateral to the pectoral region and consists of the area of the upper chest that surrounds the axilla. In both regions, there are muscles, nerves, and vessels within the fascial layers (Figure 35–3). In the pectoral region, there are four muscles relevant to Pecs blocks: the pectoralis major, pectoralis minor, serratus anterior, and subclavius muscles. The pectoralis major and minor muscles are innervated by the lateral and medial pectoral nerves; the serratus anterior is innervated by the long thoracic nerve (C5, C6, and C7); and the subclavius is innervated by the upper trunk of the brachial plexus (C5 and C6).

The axillary region is a pyramidal structure with four borders:

1. The apex or axillary inlet, formed by a lateral border of the first rib, superior border of the scapula, and the posterior border of the clavicle
2. The anterior border, formed by the pectoralis major and minor muscles
3. The lateral border, formed by the humerus
4. The posterior border, formed by the teres major, latissimus dorsi, and subscapularis muscles.

TABLE 35–1. Summary of published controlled clinical trials and case reports.

Author, Year	Study Type	Surgery/Indication	Block Type	N	Injectate	Outcome
Blanco et al., 2013	Volunteer study	–	Serratus plane	4	0.4 mL/kg levobupivacaine 0.125% and gadolinium	Mean duration of paresthesia in the intercostal nerve distribution T2–T9, was 752 minutes (injection superficial to serratus anterior)
Wahba and Kamal, 2014	Randomized controlled trial	Mastectomy	Pecs II versus PVB	60	0.25% levobupivacaine: 15–20 mL T4 PVB, 10 mL Pecs I block	Pecs blocks reduced postoperative morphine consumption (first 24 h) and pain scores (first 12 h) in comparison with PVB following mastectomy
Fujiwara et al., 2014	Case report	Insertion of cardiac resynchronization device	Intercostal at first and second interspace, Pecs I block	1	0.375% ropivacaine: 4 mL intercostal block, 10 mL Pecs I block	Surgery performed under intercostal/ Pecs I blocks and dexmedetomidine
Kunhabdulla et al., 2014	Case report	Analgesia for rib fracture	Serratus plane	1	20 mL bolus 0.125% bupivacaine, then infusion of 0.0625% bupivacaine at 7–12 mL/h	Effective analgesia to enable physiotherapy and ambulation
Madabushi et al., 2015	Case report	Analgesia for thoracotomy	Serratus plane	1	6 mL bolus 1% lignocaine, then infusion of bupivacaine 0.1% at 7 mL/h	Improvement in pain and ventilation
Murata et al., 2015	Case report	Breast surgery	Pecs II	2	35 mL 0.2% ropivacaine (mastectomy); 45 mL 0.2% ropivacaine (lumpectomy)	Mastectomy performed under Pecs II block and supplemental infiltration
Ueshima, 2015	Case report	Segmental breast resection	TTP combined with Pecs II	1	0.15% levobupivacaine: 15 mL TTP, 10 mL Pecs I, 20 mL Pecs II	Surgery performed under TTP and Pecs II blocks
Bashandy and Abbas, 2015	Randomized controlled trial	Mastectomy	Pecs II	120	0.25% bupivacaine: 10 mL Pecs I, 20 mL Pecs II	Lower visual analog scale pain scores and opioid requirements in the Pecs group compared to control group
Kulhari, 2016	Randomized controlled trial	Radical mastectomy	Pecs II versus PVB	40	25 mL 0.5 % ropivacaine	Duration of analgesia increased in Pec's block compared to PVB group (4.9 versus 3.3 hours)
Hetta, 2016	Randomized controlled trial	Radical mastectomy	Serratus plane	64	30 mL 0.25 % bupivacaine, Serratus plane; 15 mL 0.25% bupivacaine, PVB	Increased opioid consumption in the serratus plane compared to the PVB group

PVB, paravertebral block; TTP, transversus thoracic muscle plane.

FIGURE 35–1. Transducer position for Pecs blocks. Also refer to Figures 35-9 and 35-11.

Figure 35-2, the muscles, nerves and vessels relevant to Pecs and serratus plane blocks are summarized in Tables 35-2, 35-3 and 35-4 respectively.

The pectoral and axillary regions are separated by fascias. In the pectoral region, there are two main fascias: the superficial fascia and the deep thoracic fascia. The deep thoracic fascia divides into three separate fascias: the pectoral (superficial), clavipectoral (intermediate), and exothoracic (deep). The clavipectoral fascia stretches between the clavicle and the pectoralis minor (Figure 35–4) and encloses the pectoralis minor with a thin layer of fascia. Between the pectoralis minor and subclavius muscles, the two layers of the clavipectoral fascia fuse.

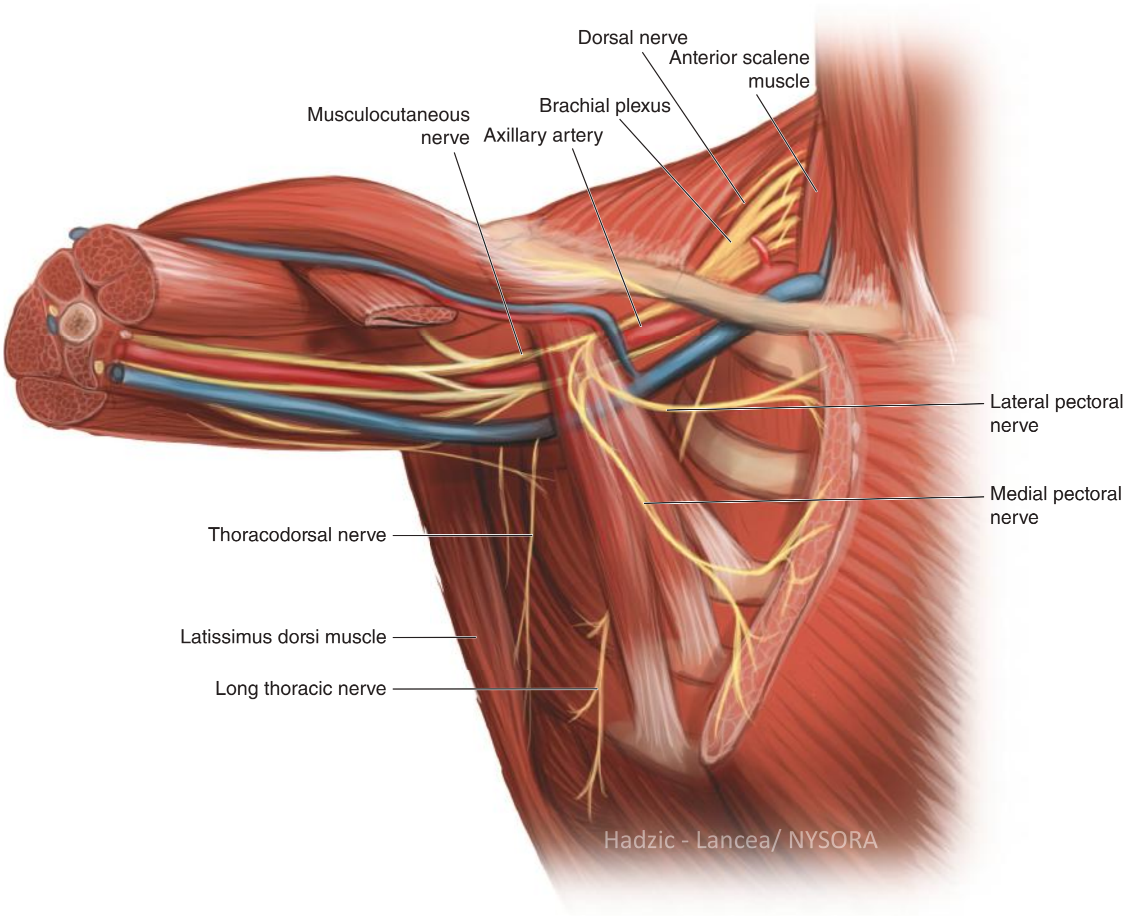

FIGURE 35–2. Pectoral region.

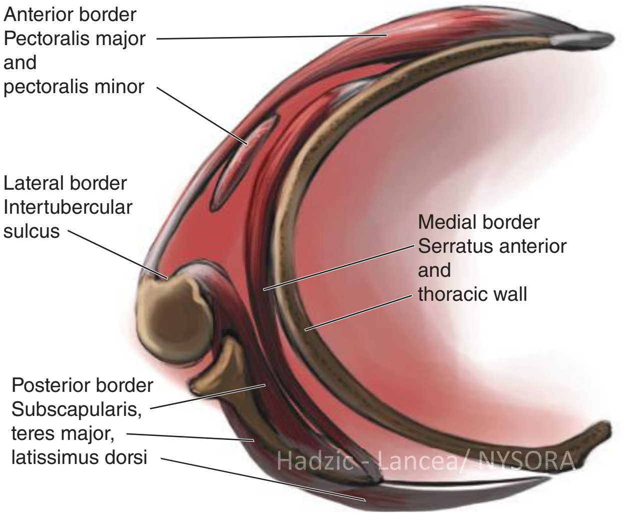

FIGURE 35–3. Axillary region.

Caudal to the pectoralis minor, the clavipectoral fascial layers rejoin to form the suspensory ligament of the axilla, which is joined to the axillary fascia (Figure 35–5).

At the pectoral level, the fascias create four potential compartments for the injection of local anesthetic:

1. Between the superficial and deep pectoral fascial layers
2. Between the pectoral fascia and the clavipectoral fascia
3. Between the clavipectoral fascia and the superficial border of the serratus anterior muscle
4. Between the serratus anterior muscle and the exothoracic fascia

The first two compartments are in the pectoral region, but the third and fourth communicate with the axillary region. The nerves and vessels in this region create communications by crossing the compartments. The nerves of the pectoral region are mainly the lateral and medial pectoral nerves, but there is also an important innervation from the supraclavicular nerve and from the lateral and anterior branches of the intercostal nerves. The lateral pectoral nerve crosses the axillary artery anteriorly and pierces the clavipectoral fascia in close relationship with the thoracoacromial artery on the undersurface of the upper portion of the pectoralis major muscle, which it supplies with lateral cord fibers from C5–C7 (Figure 35–6). The lateral pectoral nerve is medial to the pectoralis minor before entering the pectoralis major muscle; it communicates across the axillary artery with the medial pectoral nerve and, through this communication (via ansa pectoralis), supplies the pectoralis minor. The medial pectoral nerve arises from the medial cord fibers from C8–T1, behind the axillary artery at the level below the clavicle, and passes through the deep surface of the pectoralis minor, which is perforates and then enters and innervates pectoralis major. Both pectoral nerves enter the deep surface of the pectoralis major, and neither has a cutaneous branch.

The nerves of the axillary region are the intercostobrachialis, intercostal T3–T9, long thoracic, and thoracodorsal. The intercostobrachialis nerve is the lateral cutaneous brnach of the second and third intercostal nerves in 67% and 33% of cases, respectively. It crosses the serratus anterior muscle in the midaxillary line to innervate the axilla. The intercostobrachialis nerve is a vital nerve if regional anesthesia of the axilla is required.

TABLE 35–2. Nerves relevant to pecs and serratus plane blocks.

Nerve	Origin	Innervation	Relevance
Long thoracic	Roots (C5, C6, C7)	Serratus anterior muscle	Known as the nerve to the serratus anterior.
Lateral pectoral	Lateral cord (C5, C6, C7)	Pectoralis major and pectoralis minor muscles	Penetrates the clavipectoral fascia to supply the pectoralis major directly and, through communication with the medial pectoral nerve, the pectoralis minor. There is no cutaneous branch. Can be located on the deep surface of the pectoralis major.
Medial pectoral	Medial cord (C8, T1)	Pectoralis major and pectoralis minor muscles	Penetrates the deep surface of the pectoralis minor to innervate this muscle before penetrating it to supply the pectoralis major muscle.
Intercostal	Anterior rami of thoracic spinal nerves	Segmental somatic sensory innervation to skin	Lateral cutaneous branches of T2-T6 innervate the lateral breast. Accessible in the mid-axillary line.
Thoracodorsal	Posterior cord (C6, C7, C8)	Latissimus dorsi muscle	Large nerve from the posterior cord, which has a course in the posterior axillary wall, crosses the lower border of the teres major to enter the deep surface of the latissimus dorsi muscle. The thoracodorsal nerve is adjacent to the thoracodorsal artery.

TABLE 35–3. Muscles relevant to pecs and serratus plane blocks.

Muscle	Innervation	Relevance
Pectoralis major	Medial (C8, T1) and lateral (C5–C7) pectoral nerves	Sonographic landmark.
Pectoralis minor	Both pectoral nerves (C5–C8)	Sonographic landmark.
Serratus anterior	Long thoracic nerve (C5–C7)	Sonographic landmark for Pecs II and serratus plane blocks. The intercostobrachial, long thoracic, and thoracodorsal nerves lie on this muscle. The thoracodorsal artery is superficial to this muscle.
Teres major	Subscapular nerve (C5–C6) (offspring of subscapularis muscle)	Contributes to the posterior wall of the axilla.
Subscapularis	Upper and lower subscapular nerves (C5–C8)	Contributes to the posterior wall of the axilla.
Latissimus dorsi	Thoracodorsal nerve (C6–C8)	Contributes to the posterior wall of the axilla; sonographic landmark for serratus plane blocks.

The intercostal nerves (T3–T9) provide motor supply to the intercostal muscles and receive sensory information from the skin and parietal pleura. The intercostal nerves have posterior, lateral, and anterior branches and an anterior accessory branch that innervates the sternum. The lateral branches innervate most of the pectoral and axillary regions, together with the posterior hemithorax, back to the scapula. They pierce the external intercostal muscle and exit between the serratus anterior digitations at the level of the midaxillary line. The long thoracic nerve is in the axillary compartment close to the lateral thoracic branch of the thoracoacromial artery and travels down the lateral aspect of the serratus anterior muscle, which it innervates. Arising from the posterior cord, the thoracodorsal nerve, C6–C8 (nerve to the latissimus dorsi), has a course posteriorly in the axillary compartment, in close relationship with the thoracodorsal artery (Tables 35-2 through 35-4). The thoracodorsal nerve becomes prominent when the humerus is abducted and laterally rotated. It is an important and large nerve in danger during reconstructive surgery and other operations involving the lower axilla (see Table 35–2).

THORACIC WALL BLOCKS

Pecs I Block

The Pecs I block involves a hydrodissection of the plane between the pectoral muscles with local anesthetic to block the lateral and medial pectoral nerves.

The main landmarks to identify the point of injection under US guidance are the pectoralis major and pectoralis minor muscles and the pectoral branch of the thoracoacromial artery. The block is performed with the patient supine, either with the arm next to the chest or abducted 90 degrees. With standard American Society of Anesthesiology (ASA) monitoring and supplemental oxygen, the operator locates the coracoid process on US in the paramedian sagittal plane. The transducer is rotated slightly to

TABLE 35–4. Vessels relevant to pecs and serratus plane blocks.

Vessel	Relevance
Axillary	Is the continuation of the subclavian artery after it passes the lateral border of the first rib. It lies lateral to the axillary vein. It gives of the branches listed below.
Superior thoracic	Branch of the first part of the axillary artery; supplies both pectoral muscles.
Thoracoacromial	Arises from the second part (deep to the pectoralis minor) of the axillary artery, close to the upper border of the pectoralis minor; pierces the clavipectoral fascia in the infraclavicular fossa; has four branches that may arise deep or superficial to the clavipectoral fascia.
Lateral thoracic	Follows the lower border of the pectoralis minor; supplies both pectoral muscles.
Thoracodorsal	Arises from the third part (distal to the pectoralis minor) of the axillary artery; initially known as the subscapular artery, located in the posterior axillary wall (largest branch of the axillary artery), before becoming the thoracodorsal artery; has a course with the thoracodorsal nerve, which innervates the latissimus dorsi.

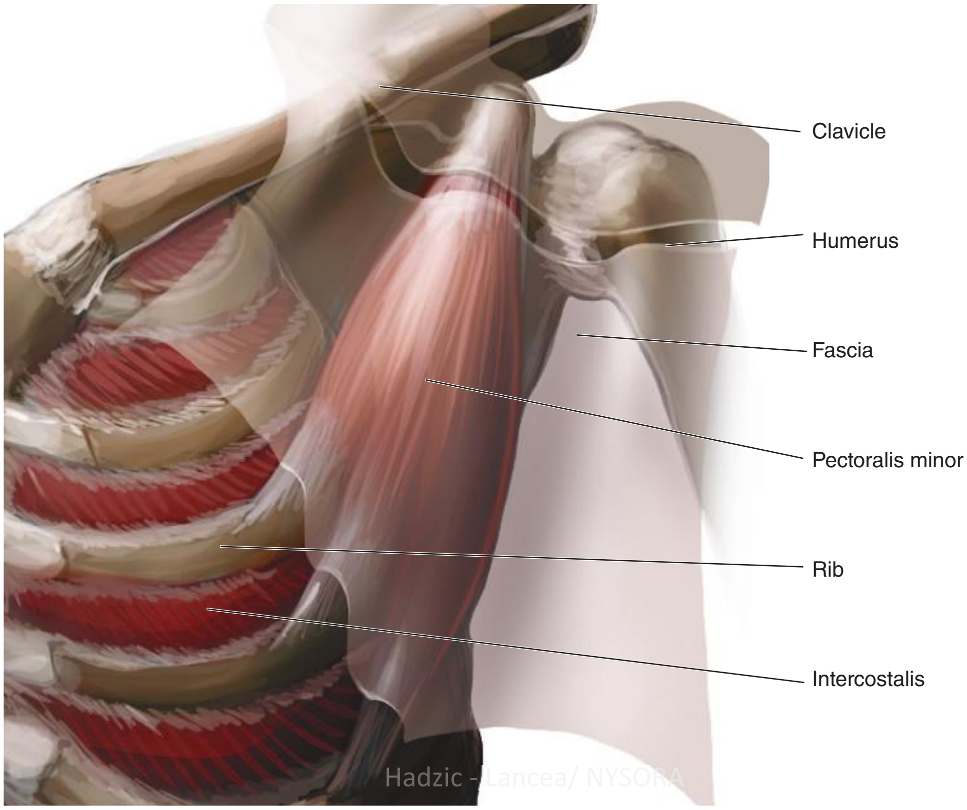

FIGURE 35–4. The clavipectoral fascia and its continuation into the axillary fascia.

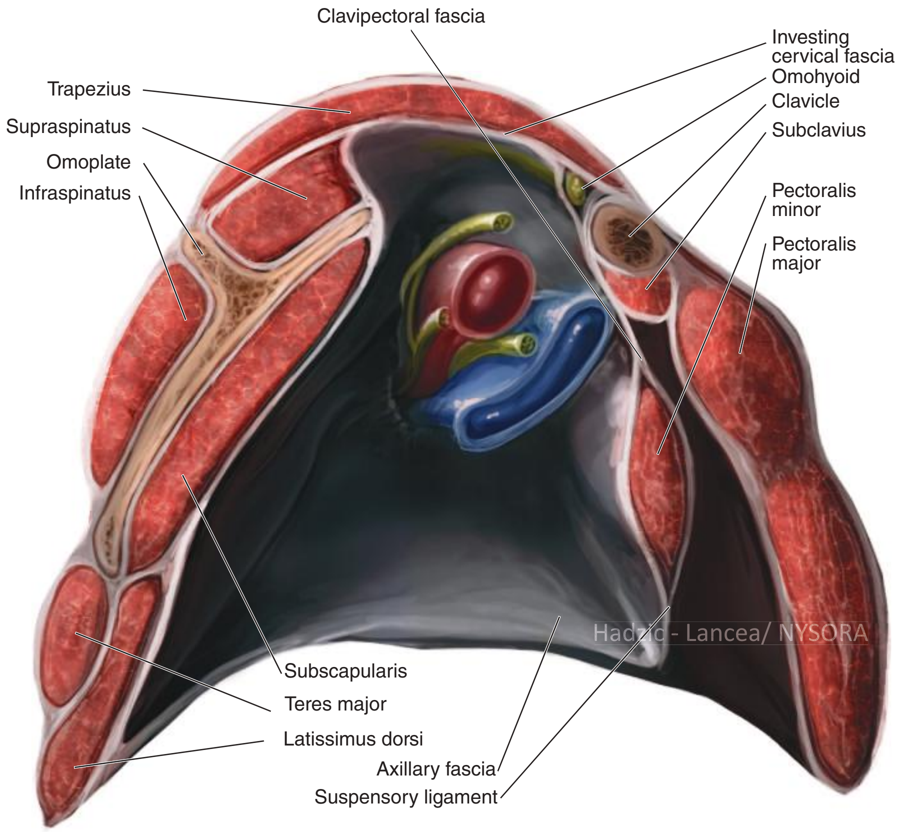

FIGURE 35–5. Section of the axilla showing the clavipectoral fascia enclosing the subclavius and the pectoralis minor muscles. Inferior to the pectoralis minor muscle, the clavipectoral fascia becomes the suspensory ligament.

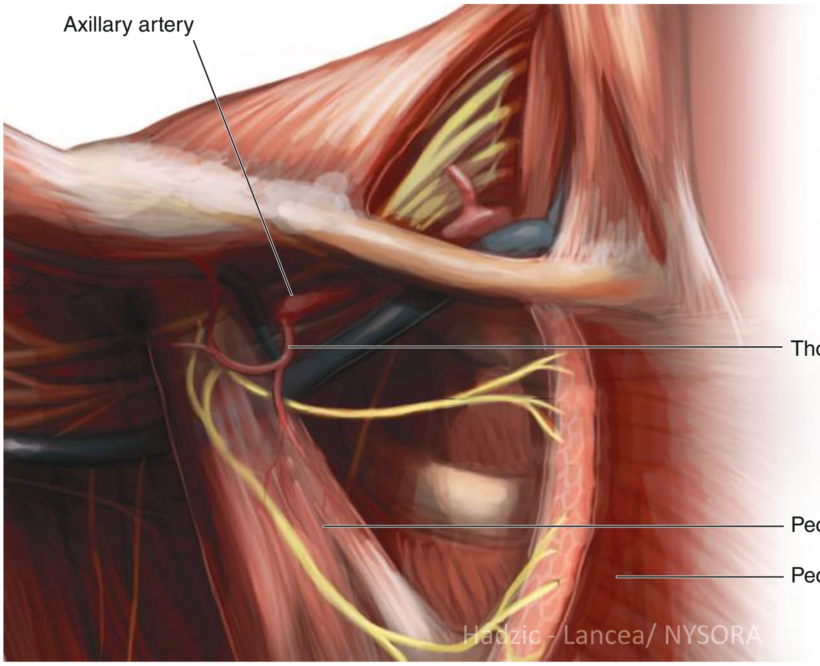

FIGURE 35–6. Relationship of the lateral pectoral nerve to the acromiothoracic artery.

allow an in-plane needle trajectory from the proximal and medial side toward the lateral side (ie, the caudal border of the transducer is moved laterally, while the proximal border remains unchanged) (Figure 35–7). This rotation helps image the pectoral branch of the thoracoacromial artery. The proper fascial plane is confirmed by hydrodissection to open the space between the pectoralis muscles. The suggested volume is 0.2 mL/kg of a long-acting local anesthetic (Figure 35–8); however, the reader should be informed that dose-ranging studies have not been conducted at the time of publication, and, therefore, there are no evidence-based recommendations currently available.

Pecs II Block

The goal of the Pecs II block is to infiltrate two fascial compartments by dividing the dose of local anesthetic between the pectoral nerves (the pectoral fascia and clavipectoral fascia) and under the pectoralis minor muscle (between the clavipectoral fascia and the superficial border of the serratus muscle). The local anesthetic should cover two important compartments of the fascias involved: The pectoral compartment with the pectoral nerves and the intercostal branches for the axilla and chest. The block is performed with the patient supine, either with the arm abducted 90 degrees or by his or her side. The first injection is similar to Pecs I, whereas the second is made at the anterior axillary line at the level of the fourth rib. The depth is usually 1–3 cm for the first injection and 3–6 cm for the second injection. With the transducer at the midclavicular level and angled inferolaterally, the axillary artery and vein and the second rib can be identified (Figure 35–9). The transducer is then moved laterally until the pectoralis minor and serratus anterior are identified. With further lateral transducer movement, the third and fourth rib can then be identified. The local anesthetic is injected at two points: A first injection of approximately 0.2 mL/kg long-acting local anesthetic is made between the pectoral major and minor muscles, and a second injection of 0.2 mL/kg is made between the pectoralis minor and serratus anterior muscles. Figure 35–10 illustrates the sonographic anatomy, needle trajectory, and desired spread of injectate.

Serratus Anterior Plane Block

The serratus plane block is performed in the axillary region, at a more lateral and posterior location than the Pecs I and II blocks.[3,4] At the axillary fossa, the intercostobrachialis nerve, lateral cutaneous branches of the intercostal nerves (T3–T9), long thoracic nerve, and thoracodorsal nerve are located in a compartment between the serratus anterior and the latissimus dorsi muscles, between the posterior and midaxillary lines.

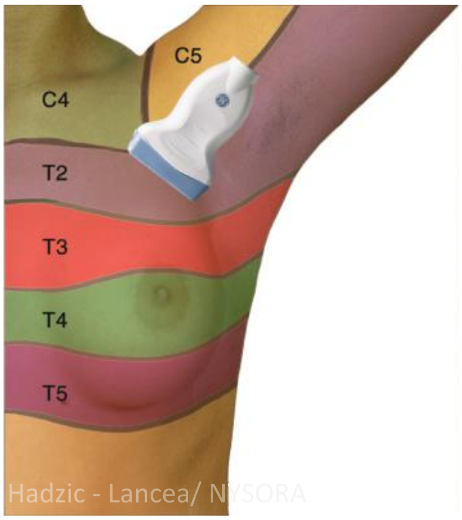

FIGURE 35–7. Transducer position for the Pecs I block.

FIGURE 35–8. Sonogram of the Pecs I injection. Left: needle placement; right: desired spread of local anesthetic.

The two main anatomical landmarks are the latissimus dorsi and the serratus anterior muscles. The thoracodorsal artery runs in the fascial plane between the two. The ribs, pleura, and intercostal muscles can also be seen during the procedure.

Lying on the side or supine with the arm brought forward is the preferable patient position. There are two main methods for identifying the plane for the serratus block. The first method requires counting the ribs from the clavicle while moving the transducer laterally and distally until the fourth and fifth ribs are identified (Figure 35–10). The transducer is orientated in the coronal plane and then tilted posteriorly until the latissimus dorsi (a superficial thick muscle) is identified (Figure 35–11). The serratus muscle, a thick, hypoechoic muscle deep to the latissimus dorsi is imaged over the ribs. Translating the transducer posteriorly

Pecs II sonogram: steps to locate points of injection. **A:** Left: Start from the clavicle; right: Count ribs down to the axilla. **B:** Left: First injection between the pectoralis major and pectoralis minor; right: Angle probe to locate Gilbert's ligament. **C:** Left: Above the serratus muscle; right: Underneath the serratus muscle; cl, clavicle; scm, subclavius muscle; pM, pectoralis major; pm, pectoralis minor; av, axillary vein; aa, axillary artery; pl, pleura; sm, serratus muscle.

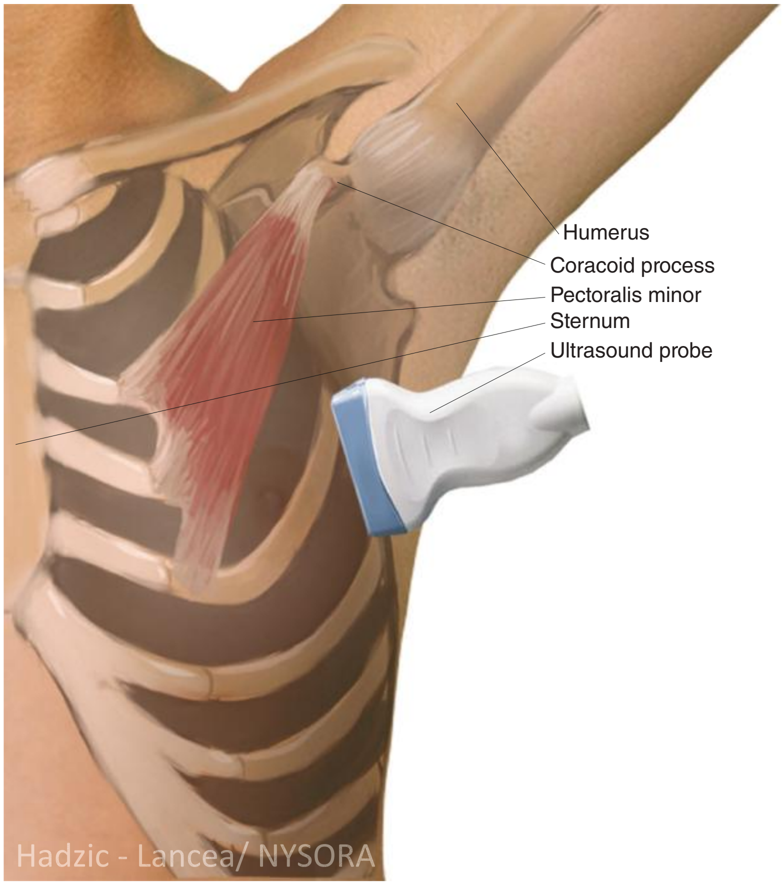

FIGURE 35–11. Transducer position required for the serratus plane block.

facilitates identification of the plane between the serratus anterior and latissimus dorsi muscles. An alternative method is to place the transducer across the axilla, where the latissimus dorsi will appear more prominent (Figure 35–12). The location of the thoracodorsal artery is easier to identify this way. Both in-plane and out-of-plane approaches are appropriate.

Following the identification of sonographic landmarks, regional anesthesia can be achieved using a 38-mm, 6–13-MHz, linear transducer set for small parts and a depth of 1–4 cm; a 50–100-mm, 22-gauge regional block needle; and an injectate of 0.4 mL/kg of long-acting local anesthetic.

THE ANALGESIC POTENTIAL OF PECS BLOCKS

A summary of published studies is given in Table 35–1. At the time of writing, there were two randomized controlled trials (180 patients), five case reports (6 patients), and one

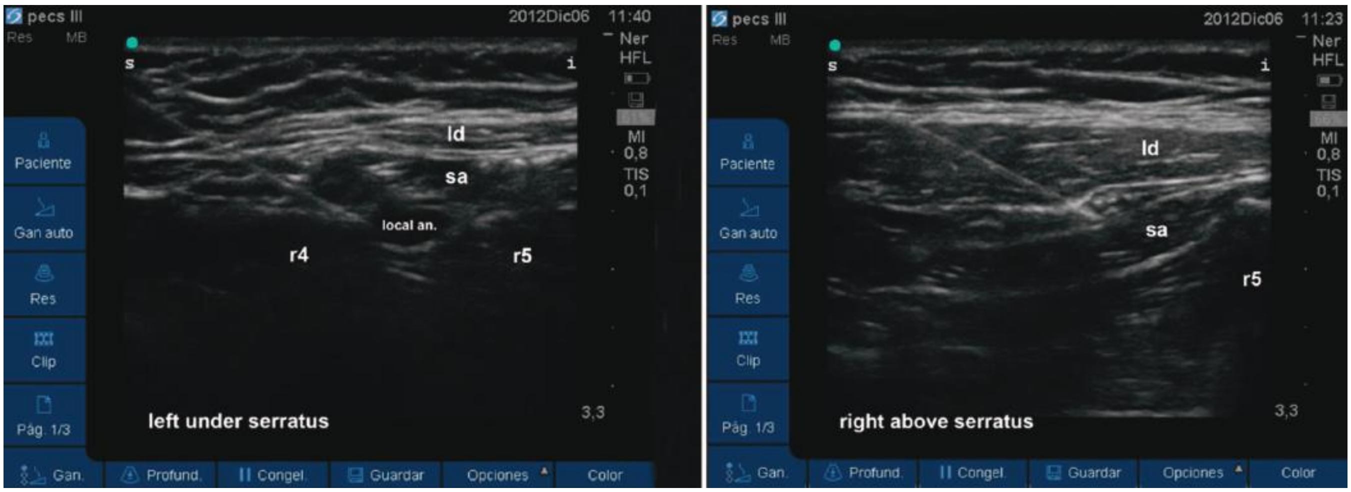

FIGURE 35–12. Sonogram of two possible levels for the serratus plane block below (left) or above the muscle (right).

volunteer study (4 patients, 8 hemithoraces). Bashandy and Abbas reported lower visual analog scale pain scores and opioid requirements in the Pecs group compared to a control group of patients following mastectomy.[12] In this study there was an inadequate description of allocation concealment and blinding of operating room personnel. Wahba and Kamal compared Pecs blocks to paravertebral blocks in 60 patients undergoing mastectomy. They found that Pecs blocks reduced postoperative morphine consumption (in the first 24 hours) and pain scores (in the first 12 hours) in comparison with paravertebral blockade following mastectomy.[13] Pecs blocks have also been used for the insertion of a cardiac resynchronization device.[7] The few remaining reports describe the utility of serratus plane blocks for analgesia following rib fracture[5] and thoracotomy.[4]

SUMMARY

Pecs and serratus plane blocks are newer US-guided blocks for analgesia after breast and lateral thoracic wall surgery. The key sonographic landmarks are the pectoralis major, pectoralis minor, and serratus anterior muscles and the pectoral branch of the acromiothoracic artery. As there are currently few reports on the utility of these US-guided interventional analgesia modalities, data from the imminent randomized controlled trials will be necessary to establish the analgesic benefit, indications, and safety of the Pecs and serratus plane blocks.

PART 3-E

LOCAL AND REGIONAL ANESTHESIA FOR ORAL AND MAXILLOFACIAL SURGERY

CHAPTER 36

Oral & Maxillofacial Regional Anesthesia

Benaifer D. Preziosi, Adam T. Hershkin, Paul J. Seider, and Gregory M. Casey

INTRODUCTION

Oral surgical and dental procedures are often performed in an outpatient setting. Regional anesthesia is the most common method of anesthetizing the patient before office-based procedures. Several highly efficacious and practical techniques can be used to achieve anesthesia of the dentition and surrounding the hard and soft tissues of the maxilla and mandible. The type of procedure to be performed as well as the location of the procedure determine the technique of anesthesia to be used. Orofacial anesthetic techniques can be classified into three main categories: local infiltration, field block, and nerve block.

The local infiltration technique anesthetizes the terminal nerve endings of the dental plexus (Figure 36–1). This technique is indicated when an individual tooth or a specific isolated area requires anesthesia. The procedure is performed within the direct vicinity of the site of infiltration.

The field block anesthetizes the terminal nerve branches in the area of treatment. Treatment can then be performed in an area slightly distal to the site of injection. The deposition of local anesthetic at the apex of a tooth for the purposes of achieving pulpal and soft tissue anesthesia is often used by dental and maxillofacial practitioners. Although this is commonly termed "local infiltration," since the terminal. Terminal nerve branches are anesthetized in this technique, such infiltration is more correctly termed as **field block**. In contrast, the nerve block anesthetizes the main branch of a specific nerve, allowing treatment to be performed in the region innervated by the nerve.[1]

This chapter reviews the essential anatomy of orofacial nerves and details the practical approaches to performing nerve blocks and infiltrational anesthesia for a variety of surgical procedures in this region.

ANATOMY OF THE TRIGEMINAL NERVE

General Considerations

Anesthesia of the teeth and the soft and hard tissues of the oral cavity can be achieved with block of the branches of the trigeminal nerve (fifth cranial nerve). In fact, regional, field, and local anesthesia of the maxilla and mandible is accomplished by the deposition of anesthetic solution near terminal nerve branches or a main nerve trunk of the trigeminal nerve.

The largest of all the cranial nerves, the trigeminal nerve gives rise to a small motor root, originating in the motor nucleus within the pons and medulla oblongata, and a larger sensory root, which finds its origin in the anterior aspect of the pons (see Figure 36–1). The nerve travels forward from the posterior cranial fossa to the petrous portion of the temporal bone within the middle cranial fossa. Here, the sensory root forms the trigeminal (semilunar or gasserian) ganglion, situated within Meckel's cavity on the anterior surface of the petrous portion of the temporal bone. The ganglia are paired, with one innervating each side of the face. The sensory root of the trigeminal nerve gives rise to the ophthalmic division (V_1), the maxillary division (V_2), and the mandibular division (V_3) from the trigeminal ganglion (see Figure 36–1).

The motor root travels from the brainstem along with, but separate from, the sensory root. It then leaves the middle cranial fossa through the foramen ovale after passing underneath the trigeminal ganglion in a lateral and inferior direction. The motor root exits the middle cranial fossa along with the third division of the sensory root: the mandibular nerve. It then unites with the mandibular nerve to form a single nerve trunk after exiting the skull. The motor fibers supply the muscles of mastication (masseter, temporalis, medial pterygoid, and lateral pterygoid) and the mylohyoid, anterior belly of the digastric, tensor veli palatine, and tensor tympani muscles.

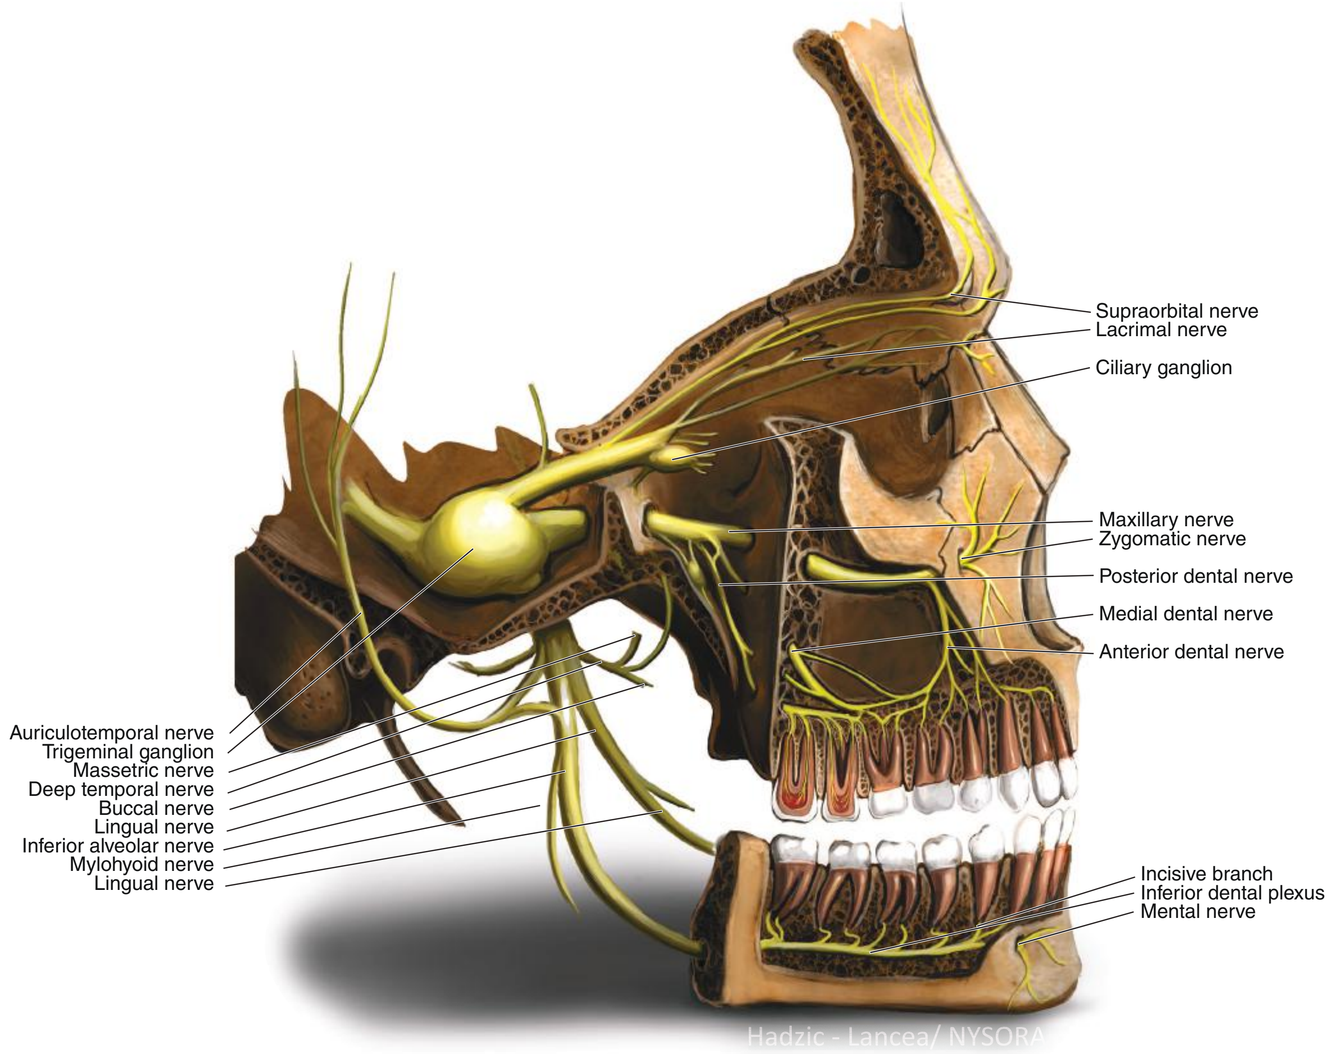

FIGURE 36–1. Anatomy of the trigeminal nerve. The sensory root of the trigeminal nerve gives rise to the ophthalmic division (V_1), maxillary division (V_2), and mandibular division (V_3) from the trigeminal ganglion.

The Ophthalmic Division

The smallest of the three divisions, the ophthalmic division (V_1) is purely sensory and travels anteriorly in the lateral wall of the cavernous sinus in the middle cranial fossa to the medial part of the superior orbital fissure. Before its entrance into the orbit through the superior orbital fissure, the ophthalmic nerve divides into three branches: the frontal, nasociliary, and lacrimal.

The **frontal nerve** is the largest branch of the ophthalmic division and travels anteriorly in the orbit, terminating as the supratrochlear and supraorbital nerves. The supratrochlear nerve lies medial to the supraorbital nerve and supplies the skin and conjunctiva of the medial portion of the upper eyelid and skin over the lower forehead close to the midline. The supraorbital nerve supplies the skin and conjunctiva of the central portion of the upper eyelid, the skin of the forehead, and the scalp as far back as the parietal bone and lambdoid suture.

The **nasociliary branch** travels along the medial aspect of the orbital roof, giving off various branches. The nasal cavity and the skin at the apex and ala of the nose are innervated by the anterior ethmoid and external nasal nerves. The mucous membrane of the anterior portion of the nasal septum and lateral wall of the nasal cavity are innervated by the internal nasal nerve. The skin of the lacrimal sac, lacrimal caruncle, and adjoining portion of the side of the nose are innervated by the infratrochlear branch. The ethmoid and sphenoid sinuses are supplied by the posterior ethmoidal nerve. The eyeball is innervated by the short and long ciliary nerves.

The **lacrimal nerve** supplies the skin and conjunctiva of the lateral portion of the upper eyelid and is the smallest branch of the ophthalmic division.

The Maxillary Division

The maxillary division (V_2) of the trigeminal nerve is also a purely sensory division. Arising from the trigeminal ganglion in the middle cranial fossa, the maxillary nerve travels forward along the lateral wall of the cavernous sinus. Shortly after stemming from the trigeminal ganglion, the maxillary nerve gives off the only branch within the cranium: the middle meningeal nerve. It then leaves the cranium through the foramen rotundum, located in the greater wing of the sphenoid bone. After exiting the foramen rotundum, the nerve enters a space located behind and below the orbital cavity known as the pterygopalatine fossa. After giving off several branches within the fossa, the nerve enters the orbit through the inferior orbital fissure, at which point it becomes the infraorbital nerve. Coursing along the floor of the orbit in the infraorbital groove, the nerve enters the infraorbital canal and emerges onto the face through the infraorbital foramen.

The **middle meningeal nerve** is the only branch of the maxillary division within the cranium; it provides sensory innervation to the dura mater in the middle cranial fossa.

Within the pterygopalatine fossa, several branches are given off, including the pterygopalatine, zygomatic, and posterior superior alveolar nerves. The **pterygopalatine nerves** are two short nerves that merge within the pterygopalatine ganglion and then give rise to several branches. They contain postganglionic parasympathetic fibers, which pass along the zygomatic nerve to the lacrimal nerve innervating the lacrimal gland, as well as sensory fibers to the orbit, nose, palate, and pharynx. The sensory fibers to the orbit innervate the orbital periosteum.

The posterior aspect of the nasal septum, mucous membrane of the superior and middle conchae, and the posterior ethmoid sinus are innervated by the nasal branches. The anterior nasal septum, floor of the nose, and premaxilla from canine to canine are innervated by a branch known as the nasopalatine nerve. The **nasopalatine nerve** courses downward and forward from the roof of the nasal cavity to the floor to enter the incisive canal. It then enters the oral cavity through the incisive foramen to supply the palatal mucosa of the premaxilla.

The hard and soft palate are innervated by the palatine branches: the greater (anterior) and lesser (middle and posterior) palatine nerves. After descending through the pterygopalatine canal, the greater palatine nerve exits the greater palatine foramen onto the hard palate. The nerve provides sensory innervation to the palatal mucosa and bone of the hard and soft palate. The lesser palatine nerves emerge from the lesser palatine foramen to innervate the soft palate and tonsillar region.

The pharyngeal branch leaves the pterygopalatine ganglion from its posterior aspect to innervate the nasopharynx.

The **zygomatic nerve** gives rise to two branches after passing anteriorly from the pterygopalatine fossa to the orbit. The nerve passes through the inferior orbital fissure and divides into the zygomaticofacial and zygomaticotemporal nerves, supplying the skin over the malar prominence and skin over the side of the forehead, respectively. The zygomatic nerve also communicates with the ophthalmic division via the lacrimal nerve, sending fibers to the lacrimal gland.

The **posterior superior alveolar (PSA) nerve** branches off within the pterygopalatine fossa before the maxillary nerve enters the orbit. The PSA travels downward along the posterior aspect of the maxilla to supply the maxillary molar dentition, including the periodontal ligament and pulpal tissues, as well as the adjacent gingiva and alveolar process. The mucous membrane of the maxillary sinus is also innervated by the PSA. It is of clinical significance to note that the PSA does not always innervate the mesiobuccal root of the first molar.[1,2] Several dissection studies have been performed tracing the innervation of the first molar back to the parent trunk. These studies have demonstrated the variations in innervation patterns of the first molar, and this is of clinical significance when anesthesia of this tooth is desired.

In a study by Loetscher and Walton,[3] 29 human maxillae were dissected to observe innervation patterns of the first molar. The study evaluated the innervation patterns by the posterior, middle, and anterior superior alveolar nerves on the first molar. The posterior and anterior superior alveolar nerves were found to be present in 100% (29/29) of specimens. The middle superior alveolar (MSA) nerve was found to be present 72% of the time (21/29 specimens). Nerves were traced from the first molar to the parent branches in 18 of the specimens. The PSA nerve was found to provide innervation in 72% (13/18) of specimens. The MSA nerve provided innervation in 28% (5/18) specimens, whereas the anterior superior alveolar nerve did not provide innervation to the first molar in any of the specimens. In the absence of the MSA nerve, the PSA nerve may provide innervation to the premolar region. In a study by McDaniel,[4] 50 maxillae were decalcified and dissected to demonstrate the innervation patterns of maxillary teeth. The PSA nerve was found to innervate the premolar region in 26% of dissections when the MSA nerve was not present. Table 36–1 lists the branches of the ophthalmic, maxillary, and mandibular divisions.

Within the infraorbital canal, the maxillary division is known as the **infraorbital nerve** and gives off the middle and anterior superior alveolar nerves. When present, the MSA nerve descends along the lateral wall of the maxillary sinus to innervate the first and second premolar teeth. It provides sensation to the periodontal ligament, pulpal tissues, gingiva and alveolar process of the premolar region, as well as the mesiobuccal root of the first molar in some cases.[1,2] In a study by Heasman,[5] dissections of 19 human cadaver heads were performed, and the MSA was found to be present in seven specimens. Loetscher and Walton[3] found that the mesial or distal position at which the MSA nerve joins the dental plexus (an anastomosis of the posterior, middle, and anterior superior alveolar nerves described below) determines its contribution to the innervation of the first molar. Specimens in which the MSA joined the plexus mesial to the first molar were found to have innervation of the first molar by the PSA and the premolars by the MSA. Specimens in which the MSA joined the plexus distal to the first molar demonstrated innervation of the first molar by the MSA. In its absence, the premolar region derives its innervation from the PSA and anterior superior alveolar nerves.[4] The anterior superior alveolar nerve descends within the anterior wall of the maxillary sinus. A small terminal branch of the anterior superior alveolar nerve communicates with the MSA to supply a small area of the lateral wall and floor of the nose. It also provides sensory innervation to the periodontal ligament, pulpal tissue, gingiva, and alveolar process of the central and lateral incisor and canine teeth. In the absence of the MSA, the anterior superior alveolar nerve has been shown to provide innervation to the premolar teeth. In the previously mentioned

TABLE 36–1. Branches of three major divisions.

study by McDaniel, the anterior superior alveolar nerve was shown to provide innervation to the premolar region in 36% of specimens in which no MSA nerve was found.[4]

The three superior alveolar nerves anastomose to form a network known as the dental plexus, which comprises terminal branches coming off the larger nerve trunks. These terminal branches are known as the dental, interdental, and interradicular nerves. The dental nerves innervate each root of each individual tooth in the maxilla by entering the root through the apical foramen and supplying sensation to the pulp. Interdental and interradicular branches provide sensation to the periodontal ligaments, interdental papillae, and buccal gingiva of adjacent teeth.

The infraorbital nerve divides into three terminal branches after emerging through the infraorbital foramen onto the face. The inferior palpebral, external nasal, and superior labial nerves supply sensory innervation to the skin of the lower eyelid, lateral aspect of the nose, and skin and mucous membranes of the upper lip, respectively.

The Mandibular Division

The largest branch of the trigeminal nerve, the mandibular branch (V_3), is both sensory and motor (Figure 36–2). The sensory root arises from the trigeminal ganglion, whereas the motor root arises from the motor nucleus of the pons and medulla oblongata. The sensory root passes through the foramen ovale almost immediately after coming off the trigeminal ganglion. The motor root passes underneath the ganglion and through the foramen ovale to unite with the sensory root just outside the cranium, forming the main trunk of the mandibular nerve. The nerve then divides into anterior and posterior divisions. The mandibular nerve gives off branches from its main trunk as well as from the anterior and posterior divisions.

The main trunk gives off two branches known as the **nervus spinosus** (meningeal branch) and the **nerve to the medial pterygoid**. After branching off the main trunk, the nervus spinosus reenters the cranium, along with the middle meningeal artery, through the foramen spinosum. The nervus spinosus supplies the meninges of the middle cranial fossa as well as the mastoid air cells. The nerve to the medial pterygoid is a small motor branch that supplies the medial (internal) pterygoid muscle. It gives off two branches that supply the tensor tympani and tensor veli palatini muscles.

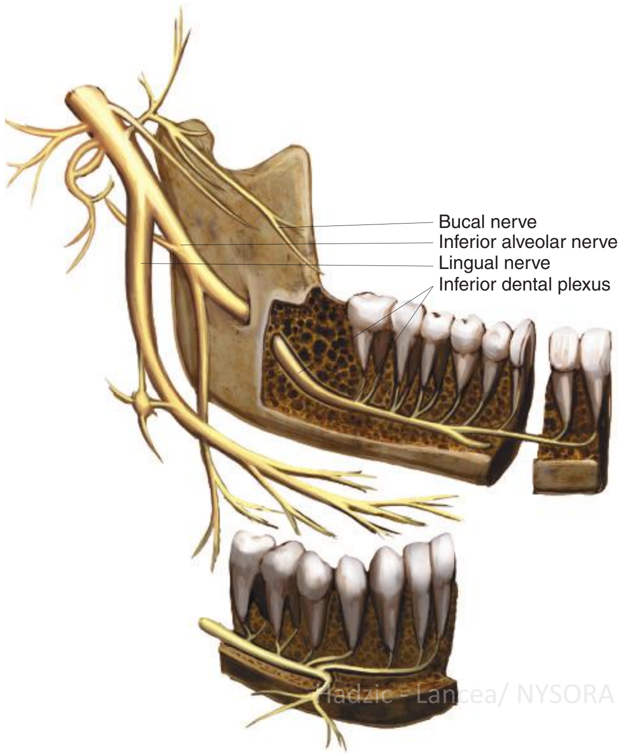

FIGURE 36–2. Anatomy of the mandibular nerve.

Three motor branches and one sensory branch are given off by the anterior division of the mandibular nerve. The **masseteric, deep temporal, and lateral pterygoid nerves** supply the masseter, temporalis, and lateral (external) pterygoid muscles, respectively. The sensory division known as the **buccal (buccinator or long buccal) nerve**, runs forward between the two heads of the lateral pterygoid muscle, along the inferior aspect of the temporalis muscle to the anterior border of the masseter muscle. Here, it passes anterolaterally to enter the buccinator muscle; however, *it does not innervate this muscle*. The buccinator muscle is innervated by the buccal branch of the facial nerve. The buccal nerve provides sensory innervation to the skin of the cheek, buccal mucosa, and buccal gingiva in the mandibular molar region.

The posterior division of the mandibular branch gives off two sensory branches (the auriculotemporal and lingual nerves) and one branch made up of both sensory and motor fibers (the inferior alveolar nerve).

The **auriculotemporal nerve** crosses the superior portion of the parotid gland, ascending behind the temporomandibular joint and giving off several sensory branches to the skin of the auricle, external auditory meatus, tympanic membrane, temporal region, temporomandibular joint, and parotid gland via postganglionic parasympathetic secretomotor fibers from the otic ganglion.

The **lingual nerve** travels inferiorly in the pterygomandibular space between the medial aspect of the ramus of the mandible and the lateral aspect of the medial pterygoid muscle. It then travels anteromedially below the inferior border of the superior pharyngeal constrictor muscle deep to the pterygomandibular raphae. The lingual nerve then continues anteriorly in the submandibular region along the hyoglossus muscle, crossing the submandibular duct inferiorly and medially to terminate deep to the sublingual gland. The lingual nerve provides sensory innervation to the anterior two-thirds of the tongue, mucosa of the floor of the mouth, and lingual gingiva.

The **inferior alveolar branch** of the mandibular nerve descends in the region between the lateral aspect of the sphenomandibular ligament and the medial aspect of the ramus of the mandible. It travels along with, but lateral and posterior to, the lingual nerve. While the lingual nerve continues to descend within the pterygomandibular space, the inferior alveolar nerve enters the mandibular canal through the mandibular foramen. Just before entering the mandibular canal, the inferior alveolar nerve gives off a motor branch known as the mylohyoid nerve (discussed below). The nerve accompanies the inferior alveolar artery and vein within the mandibular canal and divides into the mental and incisive nerve branches at the mental foramen. The inferior alveolar nerve provides sensation to the mandibular posterior teeth.

The **incisive nerve** is a branch of the inferior alveolar nerve that continues within the mandibular canal to provide sensory innervation to the mandibular anterior teeth.

The **mental nerve** emerges from the mental foramen to provide sensory innervation to the mucosa in the premolar/canine region, as well as to the skin of the chin and lower lip.

The **mylohyoid nerve** branches off the inferior alveolar nerve before its entry into the mandibular canal. It travels within the mylohyoid groove and along the medial aspect of the body of the mandible to supply the mylohyoid muscle as well as the anterior belly of the digastric muscle.[1,2]

FIGURE 36–3. Breech-loading, metallic, cartridge-type, aspirating syringe.

EQUIPMENT FOR REGIONAL MAXILLARY & MANDIBULAR ANESTHESIA

Administration of regional anesthesia of the maxilla and mandible is achieved via the use of a dental syringe, needle, and anesthetic cartridge. Several types of dental syringes are available for use. However, the most common is the breech-loading, metallic, cartridge-type, aspirating syringe. The syringe comprises a thumb ring, finger grip, barrel containing the piston with a harpoon, and needle adaptor (Figure 36–3). A needle is attached to the needle adaptor, which engages the rubber diaphragm of the dental cartridge (Figure 36–4). The anesthetic cartridge is placed into the barrel of the syringe from the side (breech-loading). The barrel contains a piston with a harpoon that engages the rubber stopper at the end of the anesthetic cartridge (Figure 36–5). After the needle and cartridge have been attached, a brisk tap is given to the back of the thumb ring to ensure that the harpoon has engaged the rubber stopper at the end of the anesthetic cartridge (Figure 36–6).

Dental needles are referred to in terms of their gauge, which corresponds to the diameter of the lumen of the needle. Increasing gauge corresponds to a smaller lumen diameter. Needles of 25 and 27 gauge are most commonly used for maxillary and mandibular regional anesthesia and are available in long and short lengths. The length of the needle is measured from the tip of the needle to the hub. The conventional long needle is approximately 40 mm in length, whereas the short

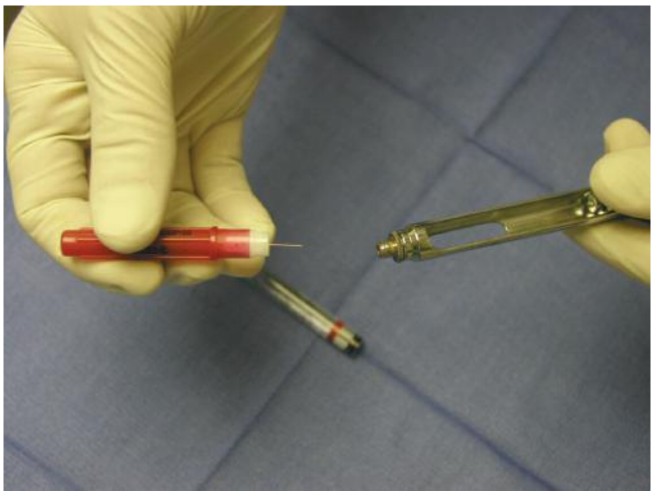

FIGURE 36–4. Needle–syringe assembling. A needle is attached to the needle adaptor.

FIGURE 36–5. **A:** Needle–syringe assembling. The anesthetic cartridge is placed into the barrel of the syringe from the side (breech loading). **B:** A piston with a harpoon engages the rubber stopper at the end of the anesthetic cartridge while the needle adaptor engages the rubber diaphragm of the dental cartridge.

needle is approximately 25 mm. Variations in needle length do exist, depending on the manufacturer.

Anesthetic cartridges are prefilled, 1.8-mL glass cylinders with a rubber stopper at one end and an aluminum cap with a diaphragm at the other end (Figure 36–7). The contents of an anesthetic cartridge are the local anesthetic, vasoconstrictor (anesthetic without vasoconstrictor is also available), preservative for the vasoconstrictor (sodium bisulfite), sodium chloride, and distilled water. The most common anesthetics used in clinical practice are the amide anesthetics: lidocaine and mepivacaine. Other amide anesthetics available for use are prilocaine, articaine, bupivacaine, and etidocaine. Esther anesthetics are not as commonly used but remain available. Procaine, procaine plus propoxycaine, chloroprocaine, and tetracaine are some common esther anesthetics (Table 36-2). Additional armamentaria include dry gauze, topical antiseptic, and anesthetic. The site of injection should be made dry with gauze, and a topical antiseptic should be used to clean

the area. Topical anesthetic is applied to the area of injection to minimize discomfort during insertion of the needle into the mucous membrane (Figure 36–8). Common topical preparations include benzocaine, butacaine sulfate, cocaine hydrochloride, dyclonine hydrochloride, lidocaine, and tetracaine hydrochloride.

Universal precautions should always be observed by the clinician; these include the use of protective gloves, mask, and eye protection. After withdrawing the needle when a block has been completed, the needle should always be carefully recapped to avoid accidental needle stick injury to the operator.[1]

Retraction of the soft tissue for visualization of the injection site should be performed with the use of a dental mirror or retraction instrument. This is recommended for all maxillary and mandibular regional techniques discussed below. Use of an instrument rather than one's fingers helps to prevent accidental needle-stick injury to the operator.

TECHNIQUES OF REGIONAL MAXILLARY ANESTHESIA

The techniques most commonly used in maxillary anesthesia include supraperiosteal (local) infiltration, periodontal ligament (intraligamentary) injection, PSA nerve block, MSA nerve block, anterior superior alveolar nerve block, greater palatine nerve block, nasopalatine nerve block, local infiltration of the palate, and intrapulpal injection (Table 36–3). Of less clinical application are the maxillary nerve block and intraseptal injection.

Supraperiosteal (Local) Infiltration

The supraperiosteal, or local, infiltration is one of the simplest and most commonly used techniques for achieving anesthesia of the maxillary dentition. This technique is indicated when any individual tooth or soft tissue in a localized area is to be treated. Contraindications to this technique are the need to anesthetize multiple teeth adjacent to one another (in which case a nerve block is the preferred technique), acute inflammation and infection in the area to be anesthetized, and, less significantly, the density of bone overlying the apices of the teeth. A 25- or 27-gauge short needle is preferred for this technique.

Procedure

Identify the tooth to be anesthetized and the height of the mucobuccal fold over the tooth. This will be the injection site. The right-handed operator should stand at the 9 o'clock to 10 o'clock position, whereas the left-handed operator should stand at the 2 o'clock to 3 o'clock position. Retract the lip, and orient the syringe with the bevel toward bone. This prevents discomfort from the needle coming into contact with the bone and minimizes the risk of tearing the periosteum with the needle tip. Insert the needle at the height of the mucobuccal fold above the tooth to a depth of no more than a few millimeters, and aspirate (Figure 36–9). If aspiration is negative, slowly inject one-third to one-half (0.6–1.2 mL) of a cartridge of anesthetic solution over the course of 30 seconds. Withdraw the syringe, and recap the needle. Successful administration provides anesthesia to the tooth and associated soft tissue within 2–4 minutes. If adequate anesthesia has not been achieved, repeat the procedure, and deposit another one-third to one-half of the cartridge of anesthetic solution.[1]

Periodontal Ligament (Intraligamentary) Injection

The periodontal ligament, or intraligamentary, injection is a useful adjunct to the supraperiosteal injection or a nerve block. Often, it is used to supplement these techniques to achieve profound anesthesia of the area to be treated. Indications for the use of the intraligamentary injection technique are the need to anesthetize an individual tooth or teeth, need for soft tissue anesthesia within the immediate vicinity of a tooth, and partial anesthesia after a field block or nerve block. A 25- or 27-gauge short needle is preferred for this technique.

Procedure

Identify the tooth or area of soft tissue to be anesthetized. The sulcus between the gingiva and the tooth is the injection site for the periodontal ligament injection. Position the patient in the supine position. For the right-handed operator, retract the lip with a retraction instrument held in the left hand, and stand where the tooth and gingiva are clearly visible. The same applies

TABLE 36–2. Commonly used local anesthetics in maxillofacial anesthesia[12,13].

Name	Chemical Structure	Class	Max Adult Dosage (mg/kg)	Max Pediatric Dosage (mg/kg)	Onset of Action (min)	pKa
Articaine *(with vasoconstrictor)*		Amide	7.0	7.0	1.0–3.0	7.8
Benzocaine		Esther	–	–	0.3–0.5	3.5
Bupivacaine		Amide	1.3	Use not recommended for patients under 12 years of age	6.0–10.0	8.1

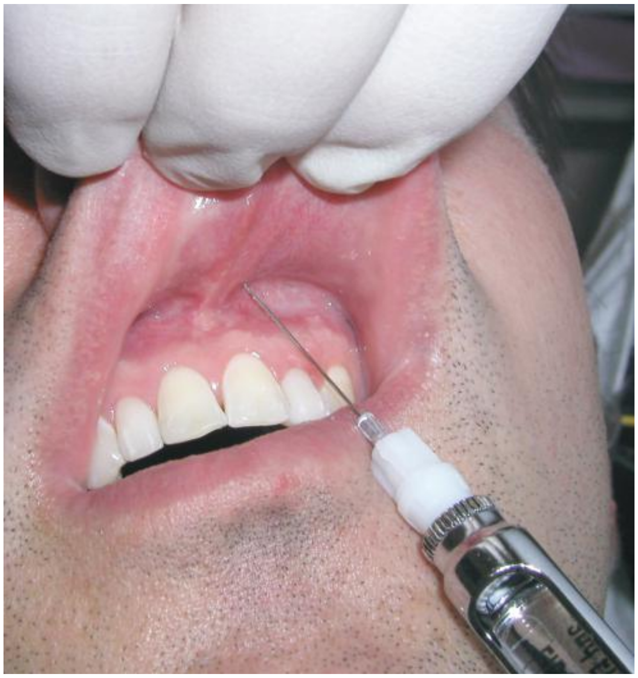
for the left-handed operator, except that the retraction instrument is held in the right hand. Hold the syringe parallel with the long axis of the tooth on the mesial or distal aspect. Insert the needle (bevel facing the root) to the depth of the gingival sulcus (Figure 36–10). Advance the needle until resistance is met. Then, administer a small amount of anesthetic (0.2 mL) slowly over the course of 20–30 seconds. It is normal to experience resistance to the flow of anesthetic. Successful execution of this technique provides pulpal and soft tissue anesthesia to the individual tooth or teeth to be treated.[1]

Posterior Superior Alveolar Nerve Block

The PSA nerve block, otherwise known as the tuberosity block or the zygomatic block, is used to achieve anesthesia of the maxillary molar teeth up to the first molar, with the exception of its mesiobuccal root in some cases. A possible complication of this technique is the risk of hematoma formation from injection of anesthetic into the pterygoid plexus of veins or from accidental puncture of the maxillary artery. Aspiration before injection is indicated when the PSA block is given. The indications for this technique are the need to anesthetize multiple molar teeth. Anesthesia can be achieved with fewer needle penetrations than with the supraperiosteal technique, providing greater comfort to the patient. The PSA block can be given to provide anesthesia of the maxillary molars when acute inflammation and infection are present. If inadequate anesthesia is achieved via the supraperiosteal technique, the PSA block can be used to achieve more profound anesthesia of a longer duration. The PSA block also provides anesthesia to the premolar region in a certain percentage of patients in whom the MSA is absent.

Contraindications to the procedure are related to the risk of hematoma formation. In individuals with coagulation disorders, care must be taken to avoid injection into the pterygoid

A



B

FIGURE 36–9. A: Locate the height of the mucobuccal fold over the tooth to be anesthetized. **B:** Clinical picture depicting a local infiltration of the maxillary left central incisor tooth. plexus or puncture of the maxillary artery. A short 25- or 27-gauge needle is preferred for this technique.

Procedure

Identify the height of the mucobuccal fold over the second molar. This is the injection site. The right-handed operator should stand at the 9 o'clock to 10 o'clock position, whereas the left-handed operator should stand at the 2 o'clock to 3 o'clock position. Retract the lip with a retraction instrument. Hold the syringe with the bevel toward the bone. Insert the needle at the height of the mucobuccal fold above the maxillary second molar at a 45-degree angle directed superiorly, medially, and posteriorly (one continuous movement). Advance the needle to a depth of three-fourths of its total length (Figure 36–11). No resistance should be felt while advancing the needle through the soft tissue. If contact is made with bone, the medial angulation is too great. Slowly retract the needle (without removing it), and bring the syringe barrel toward the occlusal plane. This allows the needle to be angulated slightly more laterally to the posterior aspect of the maxilla. Advance the needle, aspirate, and inject one cartridge of anesthetic solution slowly over the course of 1 minute, aspirating frequently during the administration. Before injecting, one should aspirate in two planes to avoid accidental injection into the pterygoid plexus. After the first aspiration, the needle should be rotated one quarter turn. The operator should then reaspirate. If positive aspiration occurs, slowly retract the needle and re-aspirate in two planes. A successful injection technique results in anesthesia of the maxillary molars (with the exception of the mesiobuccal root of the first molar in some cases) and associated soft tissue on the buccal aspect.[1]

Middle Superior Alveolar Nerve Block

The MSA nerve block is useful for procedures in which the maxillary premolar teeth or the mesiobuccal root of the first molar requires anesthesia. Although not always present it is useful if the posterior or anterior superior alveolar nerve blocks or supraperiosteal infiltration fails to achieve adequate anesthesia. For individuals in whom the MSA nerve is absent, the PSA and anterior superior alveolar nerves provide innervation to the maxillary premolar teeth and the mesiobuccal root of the first molar.

Contraindications to the procedure include acute inflammation and infection in the area of injection or a procedure involving one tooth in which local infiltration will be sufficient. A 25- or 27-gauge short needle is preferred for this technique.

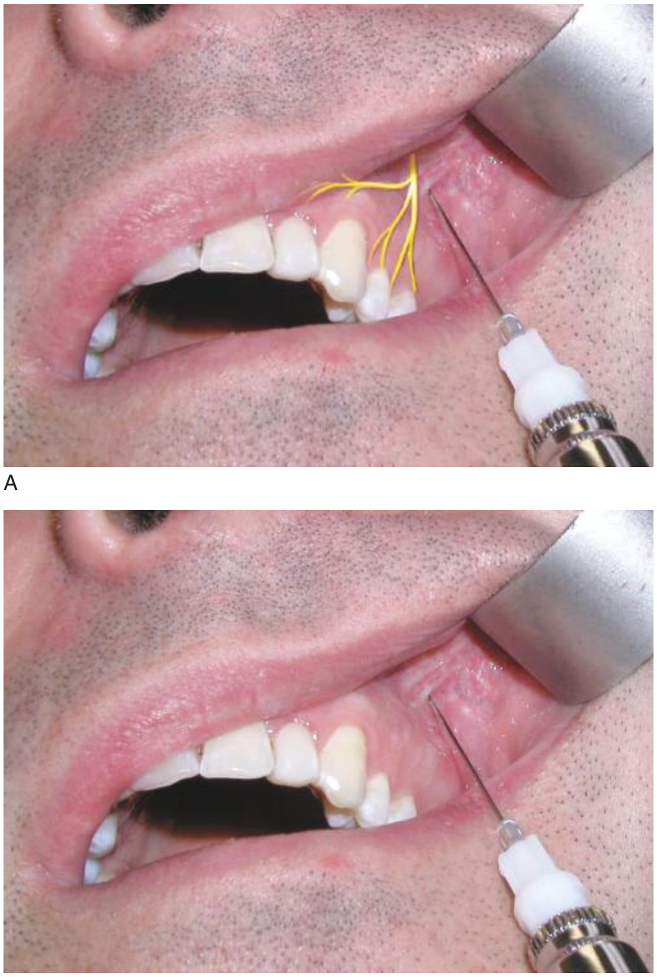
Procedure

Identify the height of the mucobuccal fold above the maxillary second premolar. This is the injection site. The right-handed operator should stand at the 9 o'clock to 10 o'clock position, whereas the left-handed operator should stand at the 2 o'clock

A

B

FIGURE 36–11. A: Location of the posterior superior alveolar (PSA) nerve. **B:** Position of the needle during the PSA nerve block. The needle is inserted at the height of the mucobuccal fold above the maxillary second molar at a 45-degree angle aimed superiorly, medially, and posteriorly.



A

B

FIGURE 36–12. A: Location of the middle superior alveolar nerve. **B:** The needle is inserted at the height of the mucobuccal fold above the maxillary second premolar.

to 3 o'clock position. Retract the lip with a retraction instrument, and insert the needle until the tip is above the apex of the second premolar tooth (Figure 36–12). Aspirate, and inject two-thirds to one cartridge of anesthetic solution slowly over the course of 1 minute. Successful execution of this technique provides anesthesia to the pulp, surrounding soft tissue, and bone of the first and second premolar teeth and the mesiobuccal root of the first molar.[1]

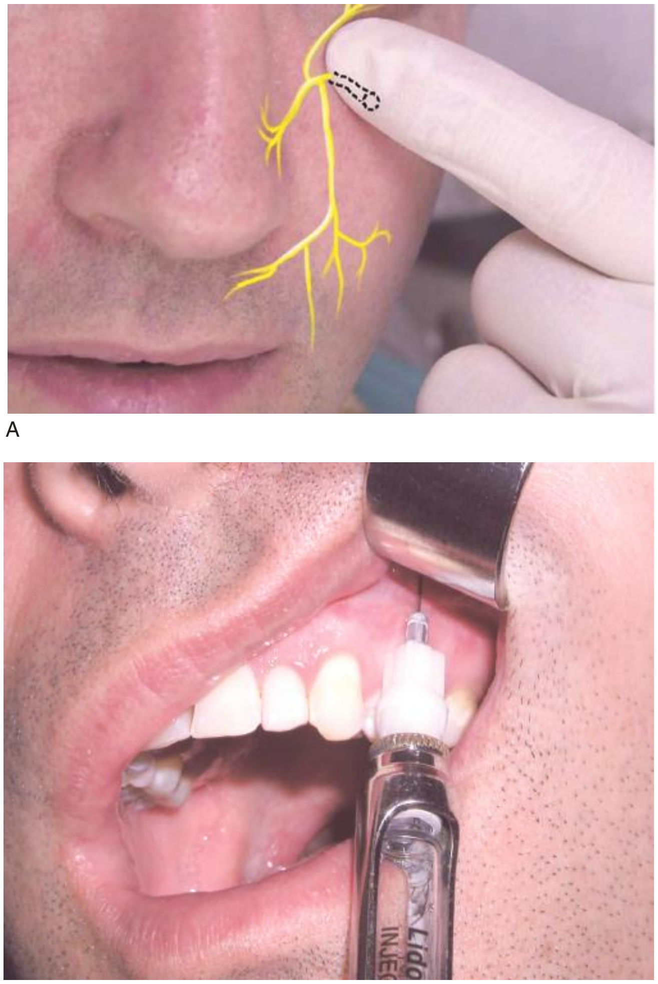
Anterior Superior Alveolar (Infraorbital) Nerve Block

The anterior superior alveolar, or infraorbital, nerve block, is a useful technique for achieving anesthesia of the maxillary central and lateral incisors and canine as well as the surrounding soft tissue on the buccal aspect. In patients who do not have an MSA nerve, the anterior superior alveolar nerve may also innervate the premolar teeth and mesiobuccal root of the first molar. Indications for the use of this technique include procedures involving multiple teeth and inadequate anesthesia from the supraperiosteal technique. A 25-gauge long needle is preferred for this technique.

Procedure

Place the patient in the supine position. Identify the height of the mucobuccal fold above the maxillary first premolar. This is the injection site. The right-handed operator should stand at the 10 o'clock position, whereas the left-handed operator should stand at the 2 o'clock position. Identify the infraorbital notch on the inferior orbital rim (Figure 36–13a). The infraorbital foramen lies just inferior to the notch, usually in line with the second premolar. Slight discomfort is felt by the patient when digital pressure is placed on the foramen. It is helpful but not necessary to mark the position of the infraorbital foramen. Retract the lip with a retraction instrument while noting the location of the foramen. Orient the bevel of the needle toward bone, and insert the needle at the height of the mucobuccal fold above the first premolar (Figure 36–13b).

The syringe should be angled toward the infraorbital foramen and kept parallel with the long axis of the first premolar to avoid hitting the maxillary bone prematurely. The needle is advanced into the soft tissue until contact is made with the bone over the roof of the foramen. This is approximately half the length of the



A

B

FIGURE 36–13. A: Location of the infraorbital nerve. **B:** The needle is kept parallel to the long axis of the maxillary first premolar and inserted at the height of the mucobuccal fold above the first premolar.

needle; however, length varies from individual to individual. After aspiration, approximately one-half to two-thirds (0.9–1.2 mL) of the anesthetic cartridge is deposited slowly over the course of 1 minute. It is recommended that pressure be kept over the site of injection to facilitate the diffusion of anesthetic solution into the foramen. Successful execution of this technique results in anesthesia of the lower eyelid, lateral aspect of the nose, and upper lip. Pulpal anesthesia of the maxillary central and lateral incisors, canine, buccal soft tissue, and bone is also achieved. In a certain percentage of people, the premolar teeth and the mesiobuccal root of the first molar are also anesthetized.[1]

Greater Palatine Nerve Block

The greater palatine nerve block is useful when treatment is necessary on the palatal aspect of the maxillary premolar and molar dentition. This technique targets the area just anterior to the greater palatine canal. The greater palatine nerve exits the canal and travels forward between the bone and soft tissue of the palate.

Contraindications to this technique are acute inflammation and infection at the injection site. A 25- or 27-gauge long needle is preferred for this technique.

Procedure

The patient should be in the supine position with the chin tilted upward for visibility of the area to be anesthetized. The right-handed operator should stand at the 8 o'clock position, whereas the left-handed operator should stand at the 4 o'clock position. Using a cotton swab, locate the greater palatine foramen by placing it on the palatal tissue approximately 1 cm medial to the junction of the second and third molars (Figure 36–14). Although this is the usual position for the foramen, it may be located slightly anterior or posterior to this location. Gently press the swab into the tissue until the depression created by the foramen is felt.

Malamed and Trieger[6] found that the foramen is found medial to the anterior half of the third molar approximately 50% of the time, medial to the posterior half of the second molar approximately 39% of the time, and medial to the posterior half of the third molar approximately 9% of the time. The area approximately 1–2 mm anterior to the foramen is the target injection site. Using the cotton swab, apply pressure to the area of the foramen until the tissue blanches. Aim the syringe perpendicular to the injection site, which is 1–2 mm anterior to the foramen. While keeping pressure on the foramen, inject small volumes of anesthetic solution as the needle is advanced through the tissue until contact is made with bone. The tissue will blanch in the area surrounding the injection site. Depth of penetration is usually no more than a few millimeters. Once contact is made with bone, aspirate and inject approximately one-fourth (0.45 mL) of the anesthetic solution. Resistance to deposition of anesthetic solution is normally felt by the operator. This technique provides anesthesia to the palatal mucosa and hard palate from the first premolar anteriorly to the posterior aspect of the hard palate and to the midline medially.[1,6]

Nasopalatine Nerve Block

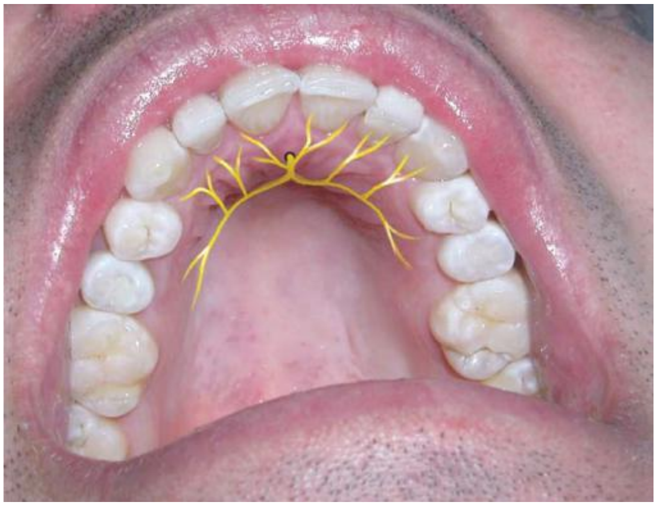
The nasopalatine nerve block, otherwise known as the incisive nerve block or sphenopalatine nerve block, anesthetizes the nasopalatine nerves bilaterally. In this technique, anesthetic solution is deposited in the area of the incisive foramen. This technique is indicated when treatment requires anesthesia of the lingual aspect of multiple anterior teeth. A 25- or 27-gauge short needle is preferred for this technique.

Procedure

The patient should be in the supine position with the chin tilted upward for visibility of the area to be anesthetized. The right-handed operator should be at the 9 o'clock position, whereas the left-handed operator should be at the 3 o'clock position. Identify the incisive papillae. The area directly lateral to the incisive papilla is the injection site. With a cotton swab, hold pressure over the incisive papilla. Insert the needle just lateral to the papilla with the bevel against the tissue

A B

FIGURE 36–14. **A:** Location of the greater palatine nerve. **B:** The area of insertion for the greater palatine nerve block is 1 cm medial to the junction of the maxillary second and third molars.



A

B

FIGURE 36–15. **A:** Location of the nasopalatine nerve. **B:** Needle insertion is just lateral to the incisive papilla for the nasopalatine nerve block.

(Figure 36–15). Advance the needle slowly toward the incisive foramen while depositing small volumes of anesthetic and maintaining pressure on the papilla. Once contact is made with bone, retract the needle approximately 1 mm, aspirate, and inject one-fourth (0.45 mL) of a cartridge of anesthetic solution over the course of 30 seconds. Blanching of surrounding tissues and resistance to the deposition of anesthetic solution are normal. Anesthesia is provided to the soft and hard tissue of the lingual aspect of the anterior teeth from the distal of the canine on one side to the distal of the canine on the opposite side.[1]

Local Palatal Infiltration

The administration of local anesthetic for the palatal anesthesia of just one or two teeth is common in clinical practice. When a block is undesirable, local infiltration provides effective palatal anesthesia of the individual teeth to be treated. Contraindications include acute inflammation and infection over the area to be anesthetized. A 25- or 27-gauge short needle is preferred for this technique.

FIGURE 36–16. Local infiltration on the palatal aspect of the maxillary right first premolar. The needle is inserted approximately 5–10 mm palatal to the center of the crown.

Procedure

The patient should be in the supine position with the chin tilted upward for visibility of the area to be anesthetized. Identify the area to be anesthetized. The right-handed operator should be at the 10 o'clock position, whereas the left-handed operator should be at the 2 o'clock position. The area of needle penetration is 5–10 mm palatal to the center of the crown. Apply pressure directly behind the injection site with a cotton swab. Insert the needle at a 45-degree angle to the injection site with the bevel angled toward the soft tissue (Figure 36–16). While maintaining pressure behind the injection site, advance the needle, and slowly deposit anesthetic solution as the soft tissue is penetrated. Advance the needle until contact is made with bone. Depth of penetration is usually no more than a few millimeters. The tissue is very firmly adherent to the underlying periosteum in this region, causing resistance to the deposition of local anesthetic. No more than 0.2–0.4 mL of anesthetic solution is necessary to provide adequate palatal anesthesia. Blanching of the tissue at the injection site immediately follows deposition of local anesthetic. Successful administration of anesthetic using this technique results in hemostasis and anesthesia of the palatal tissue in the area of injection.[1]

Intrapulpal Injection

Intrapulpal injection involves anesthesia of the nerve within the pulp canal of the individual tooth to be treated. When pain control cannot be achieved by any of the aforementioned methods, the intrapulpal method may be used once the pulp chamber is open. There are no contraindications to the use of this technique as it is at times the only effective method of pain control. A 25- or 27-gauge short needle is preferred for this technique.

Procedure

The patient should be in the supine position with the chin tilted upward for visibility of the area to be anesthetized. Identify the tooth to be anesthetized. The right-handed operator should be at the 10 o'clock position, whereas the left-handed operator should be at the 2 o'clock position. Assuming that the pulp chamber has been opened by an experienced dental professional, place the needle into the pulp chamber, and deposit one drop of anesthetic. Advance the needle into the pulp canal, and deposit another 0.2 mL of local anesthetic solution. It may be necessary to bend the needle in order to gain access to the chamber, especially with posterior teeth. The patient usually experiences a brief period of significant pain as the solution enters the canal, followed by immediate pain relief.[1]

Maxillary Nerve Block

Less often used in clinical practice, the maxillary nerve block (second division block) provides anesthesia of a hemimaxilla. This technique is useful for procedures that require anesthesia of multiple teeth and surrounding buccal and palatal soft tissue in one quadrant or when acute inflammation and infection preclude successful administration of anesthesia by the aforementioned methods. There are two techniques one can use to achieve the maxillary nerve block: the high tuberosity approach and the greater palatine canal approach.

The high tuberosity approach carries with it the risk of hematoma formation and is therefore contraindicated in patients with coagulation disorders. The maxillary artery is the vessel of primary concern with the high tuberosity approach. Both techniques are contraindicated when acute inflammation and infection are present over the injection site.

High Tuberosity Approach

A 25-gauge long needle is preferred for this technique. The patient should be in the supine position with the chin tilted upward for visibility of the area to be anesthetized. Identify the area to be anesthetized. The right-handed operator should be at the 10 o'clock position, whereas the left-handed operator should be at the 2 o'clock position. This technique anesthetizes the maxillary nerve as it travels through the pterygopalatine fossa. Identify the height of the mucobuccal fold just distal to the maxillary second molar. This is the injection site. The needle should enter the tissue at a 45-degree angle aimed posteriorly, superiorly, and medially, as in the PSA nerve block (see Figure 36–11b). The bevel should be oriented toward the bone. The needle is advanced to a depth of approximately 30 mm or a few millimeters shy of the hub. At this depth, the needle lies within the pterygopalatine fossa. The operator should then aspirate, rotate the needle one quarter turn, and aspirate again. After negative aspiration in two planes has been established, slowly inject one cartridge of anesthetic solution over the course of 1 minute. The needle is then slowly withdrawn and recapped.

Successful administration of anesthetic using the high tuberosity approach provides anesthesia to the entire hemimaxilla on the ipsilateral side of the block. This includes pulpal anesthesia to the maxillary teeth; the buccal and palatal soft tissue as far medially as the midline; and the skin of the upper lip, lateral aspect of the nose, and lower eyelid.

Greater Palatine Canal Approach

A 25-gauge long needle is preferred for this technique. Place the patient in the supine position. The right-handed operator should be at the 10 o'clock position, whereas the left-handed operator should be at the 2 o'clock position. Identify the greater palatine foramen as described in the technique for the greater palatine nerve block. The tissue directly over the greater palatine foramen is the target for injection. This technique anesthetizes the maxillary nerve as it travels through the pterygopalatine fossa via the greater palatine canal. Apply pressure to the area over the greater palatine foramen with a cotton-tipped applicator. Administer a greater palatine nerve block using the aforementioned technique (see Figure 36–14b). When adequate palatal anesthesia is achieved, gently probe for the greater palatine foramen with the tip of the needle. For this technique, the syringe should be held so that the needle is aimed posteriorly. It may be necessary to change the angulation of the needle to locate the foramen.

In a case study performed by Malamed and Trieger, the majority of canals were angled 45–50 degrees. Once the foramen has been located, advance the needle to a depth of 30 mm. If resistance is met, withdraw the needle a few millimeters, and reenter at a different angle. Malamed and Trieger found bony obstructions preventing needle passage in approximately 5–15% of canals. If resistance is met early and the operator is unable to advance the needle into the canal more than a few millimeters, the procedure should be aborted and the high tuberosity approach should be considered. If no resistance is met and penetration of the canal is successful, aspirate in two planes as described above, and slowly deposit one cartridge of local anesthetic solution. As with the high tuberosity approach, the hemimaxilla on the ipsilateral side as the injection becomes anesthetized with successful execution of this technique.[1,6,7]

Intraseptal Injection

The intraseptal technique is a useful adjunct to the aforementioned techniques (supraperiosteal, PSA, MSA, and anterior superior alveolar). Although not used as often in clinical practice, the technique offers the added advantage of hemostasis in the area of injection. Terminal nerve endings in the surrounding hard and soft tissue of individual teeth are anesthetized with this technique. Contraindications to the procedure include acute inflammation and infection over the site of injection. A 27-gauge short needle is preferred for this technique.

Procedure

Place the patient in the supine position. The target area is the interdental palpillae 2–3 mm apical to the apex of the papillary triangle (Figure 36–17). The right-handed operator should be at the 10 o'clock position, whereas the left-handed operator should be at the 2 o'clock position. The operator may ask the patient to turn his or her head for optimum visibility. The syringe is held at a 45-degree angle to the long axis of the tooth with the bevel facing the apex of the root. The needle is inserted into the soft tissue and is advanced until contact is made with

FIGURE 36–17. Intraseptal technique. Note the position of the needle 3 mm apical to the apex of the papillary triangle.

bone. A few drops of anesthetic should be administered at this time. The needle is then advanced into the interdental septum, and 0.2 mL of anesthetic solution is deposited. Resistance to the flow of anesthetic solution is expected, and ischemia of the soft tissue surrounding the injection site ensues shortly after anesthetic solution is administered.[1]

Table 36–4 lists maxillary and mandibular anesthesia techniques for the treatment of a quadrant or multiple teeth.

TECHNIQUES OF MANDIBULAR REGIONAL ANESTHESIA

Techniques used in clinical practice for the anesthesia of the hard and soft tissues of the mandible include the supraperiosteal technique, periodontal ligament injection, intrapulpal anesthesia, intraseptal injection, inferior alveolar nerve block, long buccal nerve block, Gow-Gates technique, Vazirani-Akinosi closed-mouth mandibular block, mental nerve block, and incisive nerve block.

TABLE 36–4. Techniques of anesthesia for treatment of a quadrant or multiple teeth.

Technique	Area Anesthetized
Maxillary	
Posterior superior alveolar nerve block	Maxillary molars (except the mesiobuccal root of the maxillary first molar in some cases), hard and soft tissue on buccal aspect
Middle superior alveolar nerve block	Mesiobuccal root of maxillary first molar (in some cases), premolars, and surrounding hard and soft tissue on buccal aspect
Anterior superior alveolar (infraorbital) nerve block	Maxillary central and lateral incisors and canine, surrounding hard and soft tissue on buccal aspect, mesiobuccal root of maxillary first molar (in some cases)
Greater palatine nerve block	Palatal mucosa and hard palate from first premolar anteriorly to posterior aspect of the hard palate and to midline medially
Nasopalatine nerve block	Hard and soft tissue of lingual aspect of maxillary anterior teeth from distal of canine on one side to distal of canine on the contralateral side
Maxillary nerve block	Hemimaxilla on side of injection (teeth; hard and soft, buccal, and lingual tissue)
Mandibular	
Inferior alveolar nerve block	Mandibular teeth on side of injection, buccal and lingual hard and soft tissue, lower lip
Buccal nerve block	Buccal soft tissue of molar region
Gow-Gates mandibular nerve block	Mandibular teeth to midline; hard and soft tissue of buccal and lingual aspect; anterior two-thirds of tongue; floor of mouth; skin over zygoma, posterior aspect of cheek, and temporal region on side of injection
Vazirani-Akinosi closed-mouth	Mandibular teeth to midline, hard and soft tissue of buccal aspect, anterior two-thirds of tongue, floor of mouth
Mental nerve block	Buccal soft tissue anterior to mental foramen, lower lip, chin
Incisive nerve block	Premolars, canine, incisors, lower lip, skin over chin, buccal soft tissue anterior to mental foramen

The supraperiosteal, periodontal ligament, intrapulpal, and intraseptal techniques are executed in the same manner as described for maxillary anesthesia. When anesthetizing the mandible, the patient should be in the semisupine or reclined position. The right-handed operator should stand at the 9 o'clock to 10 o'clock position, whereas the left-handed operator should stand at the 3 o'clock to 4 o'clock position.

Inferior Alveolar Nerve Block

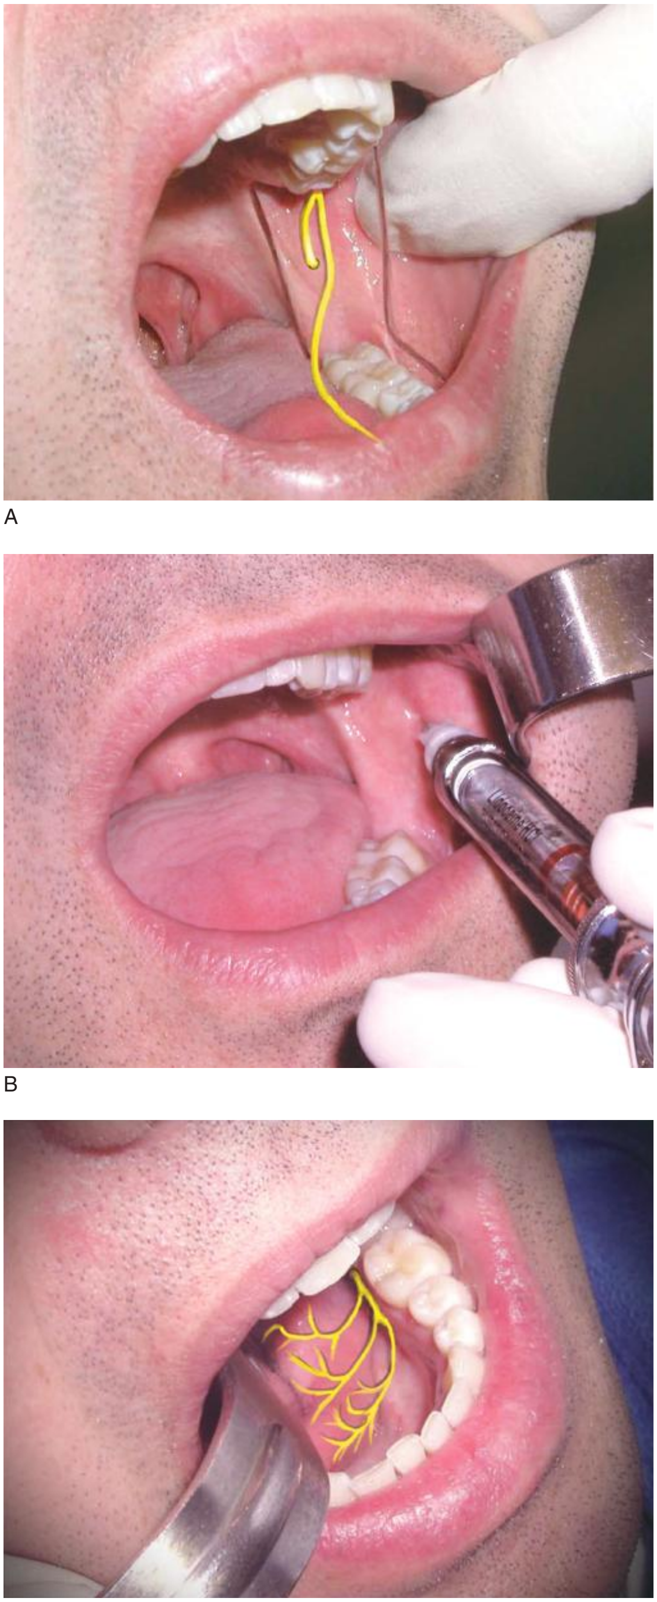
The inferior alveolar nerve block is one of the most commonly used techniques in mandibular regional anesthesia. It is extremely useful when multiple teeth in one quadrant require treatment. While effective, this technique carries a high failure rate even when strict adherence to protocol is maintained. The target for this technique is the mandibular nerve as it travels along the medial aspect of the ramus before its entry into the mandibular foramen. The lingual, mental, and incisive nerves are also anesthetized. A 25-gauge long needle is preferred for this technique.

Procedure

The patient should be in the semisupine position. The right-handed operator should be in the 8 o'clock position, whereas the left-handed operator should be in the 4 o'clock position. With the patient's mouth open maximally, identify the coronoid notch and the pterygomandibular raphae. Three-fourths of the anteroposterior distance between these two landmarks and approximately 6–10 mm above the occlusal plane is the injection site. Use a retraction instrument to retract the cheek, and bring the needle to the injection site from the contralateral premolar region. As the needle passes through the soft tissue, deposit 1 or 2 drops of anesthetic solution. Advance the needle until contact is made with bone. Then, withdraw the needle 1 mm, and redirect the needle posteriorly by bringing the barrel of the syringe toward the occlusal plane (Figures 36–18a and 36–18b). Advance the needle to three-fourths of its depth, aspirate, and inject three-fourths of a cartridge of anesthetic solution slowly over the course of 1 minute. As the needle is withdrawn, continue to deposit the remaining one-fourth of anesthetic solution so as to anesthetize the lingual nerve (Figure 36–18c). Successful execution of this technique results in anesthesia of the mandibular teeth on the ipsilateral side to the midline, the associated buccal and lingual soft tissue, the lateral aspect of the tongue on the ipsilateral side, and the lower lip on the ipsilateral side.[1]

Buccal Nerve Block

The buccal nerve block, otherwise known as the long buccal or buccinator block, is a useful adjunct to the inferior alveolar nerve block when manipulation of the buccal soft tissue in the mandibular molar region is indicated. The target for this technique is the buccal nerve as it passes over the anterior aspect of the ramus. Contraindications to the procedure include acute inflammation and infection over the site of injection. A 25-gauge long needle is preferred for this technique.



A B C

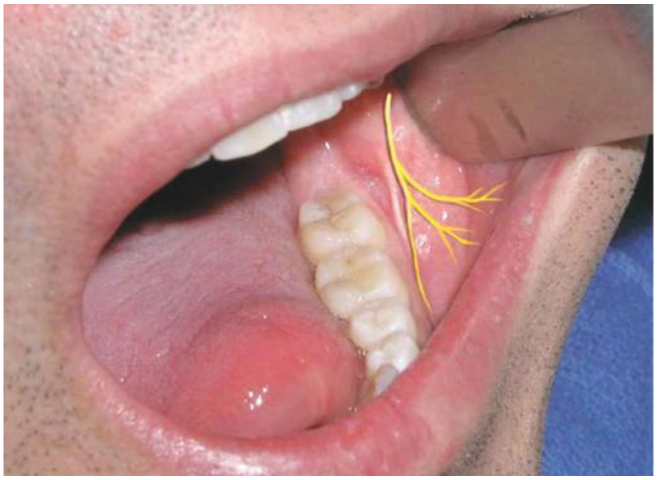
FIGURE 36–18. A: Location of the inferior alveolar nerve. **B:** After making contact with bone, the needle is redirected posteriorly by bringing the barrel of the syringe toward the occlusal plane. The needle is then advanced to three-fourths of its depth. **C:** Location of the lingual nerve, which is anesthetized during the administration of an inferior alveolar nerve block.

Procedure

The patient should be in the semisupine position. The right-handed operator should be in the 8 o'clock position, whereas the left-handed operator should be in the 4 o'clock position. Identify the most distal molar tooth on the side to be treated. The tissue just distal and buccal to the last molar tooth is the target area for injection (Figure 36–19). Use a retraction instrument to retract the cheek. The bevel of the needle should be toward bone, and the syringe should be held parallel with the occlusal plane on the side of the injection. The needle is inserted into the soft tissue, and a few drops of anesthetic solution are administered. The needle is advanced approximately 1–2 mm until contact is made with bone. Once contact is made with bone and aspiration is negative, 0.2 mL of local anesthetic solution is deposited. The needle is withdrawn and recapped. Successful execution of this technique results in anesthesia of the buccal soft tissue of the mandibular molar region.[1]

Gow-Gates Technique

The Gow-Gates technique, or third division nerve block, is a useful alternative to the inferior alveolar nerve block and is often used when the latter fails to provide adequate anesthesia. Advantages of this technique compared with the inferior alveolar technique are its low failure rate and its low incidence of positive aspiration. The Gow-Gates technique anesthetizes the auriculotemporal, inferior alveolar, buccal, mental, incisive, mylohyoid, and lingual nerves. Contraindications include acute inflammation and infection over the site of injection and trismatic patients. A 25-gauge long needle is preferred for this technique.



A

B

FIGURE 36–19. **A:** Location of the buccal nerve. **B:** The tissue just distal and buccal to the last molar tooth is the target area for injection.

Procedure

The patient should be in the semisupine position. The right-handed operator should be in the 8 o'clock position, whereas the left-handed operator should be in the 4 o'clock position. The target area for this technique is the neck of the condyle below the area of insertion of the lateral pterygoid muscle. A retraction instrument is used to retract the cheek. The patient is asked to open maximally, and the mesiolingual cusp of the maxillary second molar on the side of desired anesthesia is identified. The insertion site of the needle should be just distal to the maxillary second molar at the level of the mesiolingual cusp. Bring the needle to the insertion site in a plane that is parallel with an imaginary line drawn from the intertragic notch to the corner of the mouth on the same side as the injection (Figure 36–20). The orientation of the bevel of the needle is not important in this technique. Advance the needle through soft tissue approximately 25 mm until contact is made with bone. This is the neck of the condyle. Once contact is made with bone, withdraw the needle 1 mm, and aspirate. Redirect the needle superiorly, and reaspirate. If aspiration in two planes is negative, slowly inject one cartridge of local anesthetic solution over the course of 1 minute. Successful execution of this technique provides anesthesia to the ipsilateral mandibular teeth up to the midline and the associated buccal and lingual hard and soft tissue. The anterior two-thirds of the tongue; the floor of the mouth; and the skin over the zygoma, posterior aspect of the cheek, and temporal region on the ipsilateral side of injection are also anesthetized.[1,8]

Vazirani-Akinosi Closed-Mouth Mandibular Block

The Vazirani-Akinosi closed-mouth mandibular block is a useful technique for patients with limited opening due to trismus or ankylosis of the temporomandibular joint. Limited mandibular opening precludes the administration of the inferior alveolar nerve block or use of the Gow-Gates technique, both of which require the patient to open maximally. Other advantages to this technique are the minimal risk of trauma to the inferior alveolar nerve, artery, and vein and the pterygoid muscle; a low complication rate; and minimal discomfort upon injection. Contraindications to this technique are acute inflammation and infection in the pterygomandibular space, deformity or tumor in the maxillary tuberosity region, and an inability to visualize the medial aspect of the ramus. A 25-gauge long needle is preferred for this technique.

Procedure

The patient should be in the semisupine position. The right-handed operator should be in the 8 o'clock position, whereas

A

B

FIGURE 36–20. **A:** The patient is asked to open his or her mouth maximally. The mesiolingual cusp of the maxillary second molar is the reference point for the height of the injection. **B:** The needle is then moved distally and is held parallel to an imaginary line drawn from the intertragic notch to the corner of the mouth.

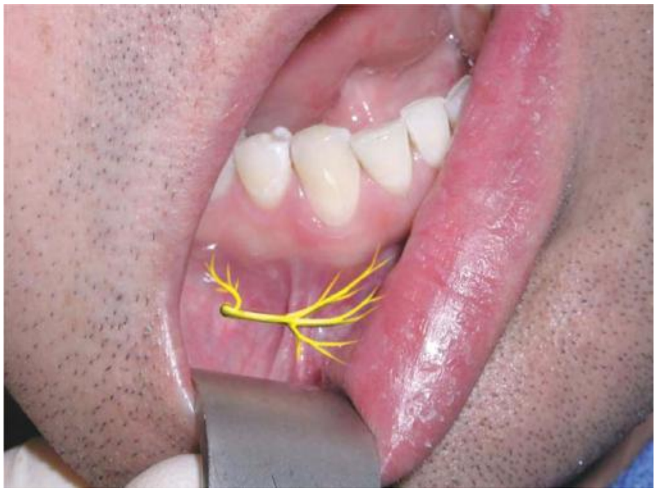
the left-handed operator should be in the 4 o'clock position. The gingival margin above the maxillary second and third molars and the pterygomandibular raphae serve as landmarks for this technique. A retraction instrument is used to stretch the cheek laterally. The patient should occlude gently on the posterior teeth. The needle is held parallel with the occlusal plane at the level of the gingival margin of the maxillary second and third molars. The bevel is directed away from the bone facing the midline. The needle is advanced through the mucous membrane and buccinator muscle to enter the pterygomandibular space. The needle is inserted to approximately one-half to three-fourths of its length. At this point, the needle will be in the midsection of the ptyerygomandibular space. Aspirate; if negative, one cartridge of local anesthetic solution is deposited over the course of 1 minute. Diffusion and gravitation of the local anesthetic solution anesthetizes the lingual and long buccal nerves in addition to the inferior alveolar nerve. Successful execution of this technique provides anesthesia of the ipsilateral mandibular teeth up to the midline and the associated buccal and lingual hard and soft tissue. The anterior two-thirds of the tongue and floor of the mouth are also anesthetized.[9,10]

Mental Nerve Block

The mental nerve block is indicated for procedures in which manipulation of buccal soft tissue anterior to the mental foramen is necessary. Contraindications to this technique are acute inflammation and infection over the injection site. A 25- or 27-gauge short needle is preferred for this technique.

Procedure

The patient should be in the semisupine position. The right-handed operator should be in the 8 o'clock position, whereas the left-handed operator should be in the 4 o'clock position. The target area is the height of the mucobuccal fold over the mental foramen (Figures 36–21a and 36–21b). The foramen



A

B

FIGURE 36–21. **A:** Location of the mental and incisive nerves. **B:** Block of the mental and incisive nerves. The needle is inserted at the height of the mucobuccal fold over the mental foramen for both the mental nerve block and the incisive nerve block.

can be manually palpated by applying gentle finger pressure to the body of the mandible in the area of the premolar apices. The patient will feel slight discomfort upon palpation of the foramen. Use a retraction instrument to retract the soft tissue. The needle is directed toward the mental foramen with the bevel facing the bone. Penetrate the soft tissue to a depth of 5 mm, aspirate, and inject approximately 0.6 mL of anesthetic solution. Successful execution of this technique results in anesthesia of the buccal soft tissue anterior to the foramen, lower lip, and chin on the side of the injection.[1]

Incisive Nerve Block

The incisive nerve block is not as frequently used in clinical practice; however, it proves very useful when treatment is limited to mandibular anterior teeth and full quadrant anesthesia is not necessary. The technique is almost identical to the mental nerve block but with one additional step. Both the mental and incisive nerves are anesthetized using this technique. Contraindications to this technique are acute inflammation and infection at the site of injection. A 25- or 27-gauge short needle is preferred for this technique.

Procedure

The patient should be in the semisupine position. The right-handed operator should be in the 8 o'clock position, whereas the left-handed operator should be in the 4 o'clock position. The target area is the height of the mucobuccal fold over the mental foramen (see Figure 36–21b). Identify the mental foramen as previously described. Give the patient a mental nerve block as described above, and apply digital pressure at the site of injection during administration of anesthetic solution. Continue to apply digital pressure at the site of injection 2–3 minutes after the injection is complete to aid the anesthetic in diffusing into the foramen. Successful implementation of this technique provides anesthesia to the premolars, canine, incisor teeth, lower lip, skin of the chin, and buccal soft tissue anterior to the mental foramen.[1]

PART 3-F

LOCAL AND REGIONAL ANESTHESIA FOR THE EYE

CHAPTER 37

Local and Regional Anesthesia for Ophthalmic Surgery

Stavros Prineas

INTRODUCTION

Ophthalmic surgery is one of the most common surgical procedures requiring anesthesia in developed countries.[1] Ophthalmic anesthesia offers insights into some fundamental principles of good anesthetic practice, especially in the conduct of local and regional blocks.

LOCAL ANESTHESIA IN EYE SURGERY

Clinical strategies to minimize patient movement during eye surgery are essential. Historically, eye surgeons favored general anesthesia (GA), which usually provided akinesia (through neuromuscular blockade) and low intraocular pressure. However, these conditions are not always achieved under GA. A closed-claims analysis by Gild and coworkers[2] found that 30% of eye injury claims associated with anesthesia involved the patient moving during ophthalmic surgery, with most incidents occurring under GA. While perioperative morbidity and mortality rates associated with eye surgery (eg, cataract extraction) are low,[3,4] patients having cataract surgery tend to be older and to have significant comorbidities.[5–10] For this reason, systematic preoperative evaluation should be performed to consider whether a patient is eligible for a GA and surgery.[10]

Appropriate anesthetic management contributes to the success or failure of ophthalmic surgery. Quicker patient rehabilitation and fewer complications in this patient population are the main reasons why many ophthalmic surgeons are now choosing local anesthesia (LA) over GA.[11–13]

Traditionally, the gold standard of eye blocks was retrobulbar anesthesia (RBA), with the surgeon performing the block. However, advances in technology and surgical technique, particularly in cataract surgery, have led to the replacement of the older wide-incision techniques (eg, extra-capsular cataract extraction) with minimally invasive phacoemulsification (PhE) techniques. Consequently, for new generation of cataract surgeons, total akinesia is no longer necessary for PhE.

Clinical Pearls

- Twenty-first century innovations and trends have revolutionized eye surgery.
- Local and regional anesthetic techniques has largely replaced general anesthesia.
- Understanding functional anatomy and surgical techniques is essential for selection of regional techniques.
- Sub-Tenon's block is one of the most common choices for anesthesia as it can generally achieve akinesia with the favorable safety profile.
- Topical anesthesia, is increasingly becoming most prevalent for cataract surgery.
- Complications of eye blocks are uncommon but can be life- or sight-threatening, emphasizing the need of adequate training.

Innovation has also broadened the anesthetic options for eye surgery. As the conventional RBA carries a greater risk of complications, less invasive techniques have increasingly been used, with a substantial diversity in practice styles around the world. For instance, one Australian study from 2002 reported that peribulbar block was the most popular among an international sample of ophthalmic surgeons.[14] However, a 2006 survey found that 64% of a sample of UK anesthetists favored the sub-Tenon's technique,[15] and, by 2008, a survey of the British Ophthalmic Anaesthesia Society found that over 87% of anesthesiologist members regularly performed sub-Tenon's blocks.[16] On the other hand, an annual survey of the American Society of Cataract and Refractive Surgery reported that its members' preference for using topical anesthesia had risen steadily from 11% in 1995 to 76% in 2012.[17,18] In the same survey, the use of sub-Tenon's blocks appeared to be consistently low over the years (around 1%–3%) despite its growing popularity elsewhere, with the use of retrobulbar and peribulbar blocks seemingly in gradual but sustained decline.

Each anesthetic technique has its strengths and limitations. Knowledge of the relevant anatomy for the various anesthetic techniques is essential to determine the appropriate block for specific clinical situations and to best avoid life- and sight-threatening complications. This chapter reviews the relevant anatomy of the eye, classical needle and non-needle block techniques, and choice of LA and adjuvant agents. With a wider range of options comes a greater burden on the anesthesiologist to discuss individual anesthetic requirements with the surgeon, to be adaptable, and to have excellent communication and team-working skills.

FUNCTIONAL ANATOMY[19]

Orbit

The **orbits** (Figures 37–1 and 37–2) are two symmetrical bony enclosures in the front of the skull, each containing an eyeball (or **globe**) and its associated structures. The cavity of each orbit is a truncated pyramid, with a flattened apex posteriorly and a trapezoidal base facing anterolaterally. The medial (nasal) walls of each orbit are parallel to each other, while the lateral (temporal) walls are perpendicular to each other. The volume of each adult orbit is approximately 30 mL.

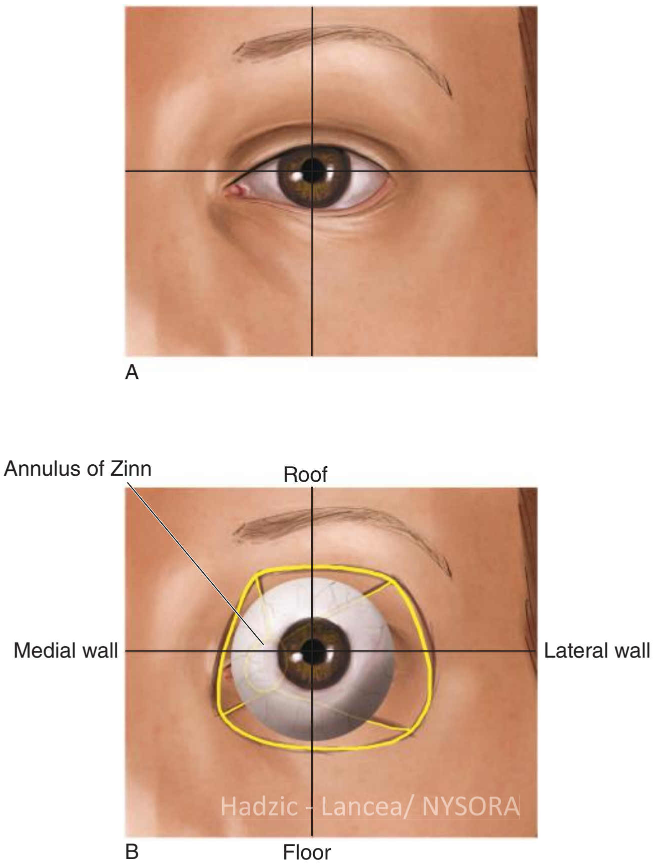

FIGURE 37–1. (**A**) The eye. (**B**) Surface anatomy.

Globe

The globe (Figure 37–3) is suspended in the anterosuperior part of the orbit. It is roughly spherical, its contents contained within three outer layers or **tunics**:

- A **fibrous tunic** comprising the translucent **cornea** in front and the opaque **sclera** peripherally and behind
- Deep to the fibrous tunic, a **vascular, pigmented tunic** comprising the **iris** and **ciliary body** in front and the **choroid** peripherally and behind
- Deep to this again, a **neural tunic** overlying the posterior part of the other two tunics internally, comprising the **retina**.

The globe has a large **posterior segment** (comprising the **vitreous humor**, the **retina**, the **macula**, and the root of the **optic nerve**) and a small convex **anterior segment** comprising two **chambers**. The **anterior chamber** immediately behind the cornea is filled with **aqueous humor** produced by the **ciliary body**. The **posterior chamber** contains the **lens**. The two chambers are separated by the **iris** and communicate via the **pupil** of the eye. Externally, the circumferential junction of cornea and sclera (with its overlying **conjunctiva**) is called the **limbus**.

The volume of the globe is approximately 7 mL. The axial (anteroposterior) length of the adult globe is on average about 24 mm; however, this can be considerably longer in myopic individuals (> 26 mm) and shorter in hypermetropia (down to 20 mm). As a rule of thumb, the distance from the front of the globe to its equator is about 12–15 mm, but, where possible, it is better to know the measured axial length of the eye before attempting to inject behind the equator (eg, for patients undergoing cataract surgery, biometric data are routinely found in the surgeon's clinical notes).

The sclera is thinnest at the equator and at the insertion points of the extraocular muscles. However, more myopic eyes (with a longer axial length) have a markedly increased prevalence of posterior staphyloma, an otherwise rare "blow-out" weakness in the fibrous tunic, which poses a major risk for globe perforation with blind needle techniques (see "Complications of Eye Blocks" later).

Muscles of the Eye

The four rectus and two oblique muscles of the eye insert anteriorly near the equator of the globe (see Figure 37–3). Posteriorly, they originate together at the apex from the tendinous **annulus communis of Zinn**. The four rectus muscles, running posteriorly from the equator to the annulus of Zinn, delineate the **retrobulbar cone**. The optic nerve traverses the cone from the posterior part of the globe and enters the orbit through the annulus of Zinn.

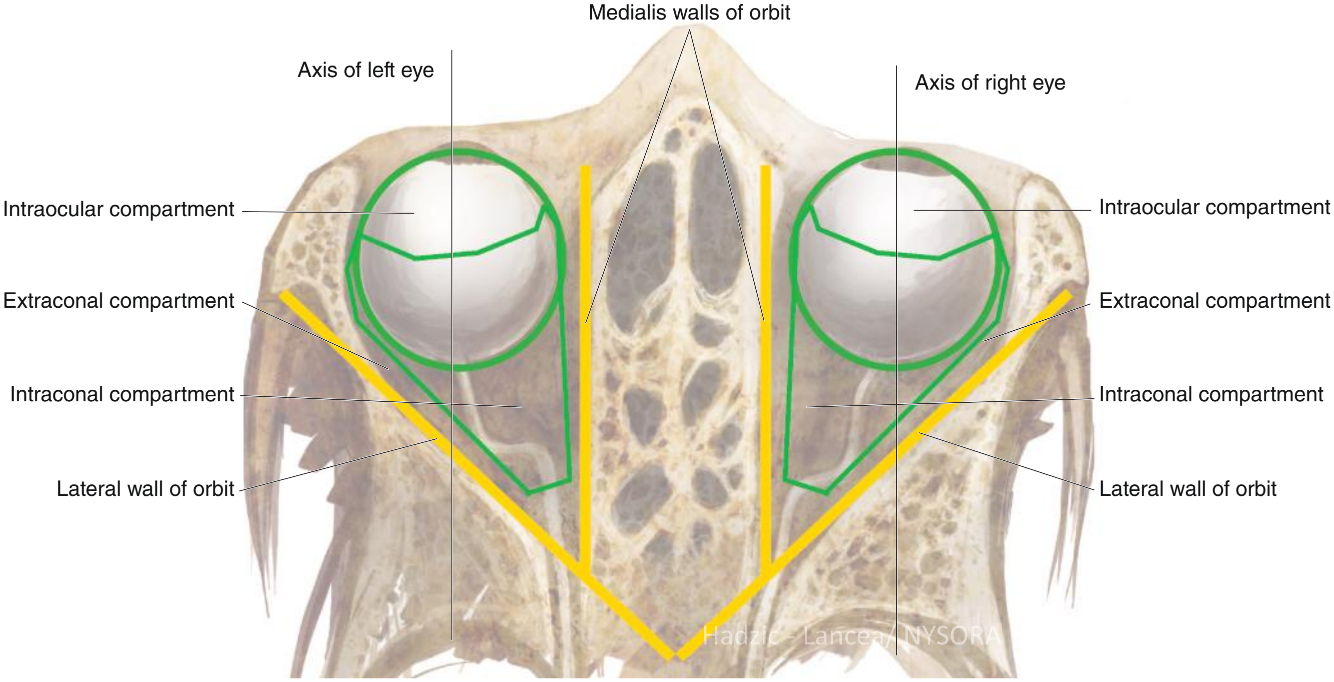

FIGURE 37–2. The orbit: diagrammatic superior view.

Three Intraorbital Compartments

The globe and muscular retrobulbar cone define the three classical anatomical compartments of the orbital cavity: the **intraocular**, **intraconal**, and **extraconal** (see Figure 37–2). However the retrobulbar cone is not sealed by any intermuscular membrane,[20–23] and, in fact, there is free communication between the intraconal and extraconal spaces. Thus, a large-volume peribulbar (extraconal) block can theoretically provide as effective anesthesia and akinesia as a targeted small-volume retrobulbar block.

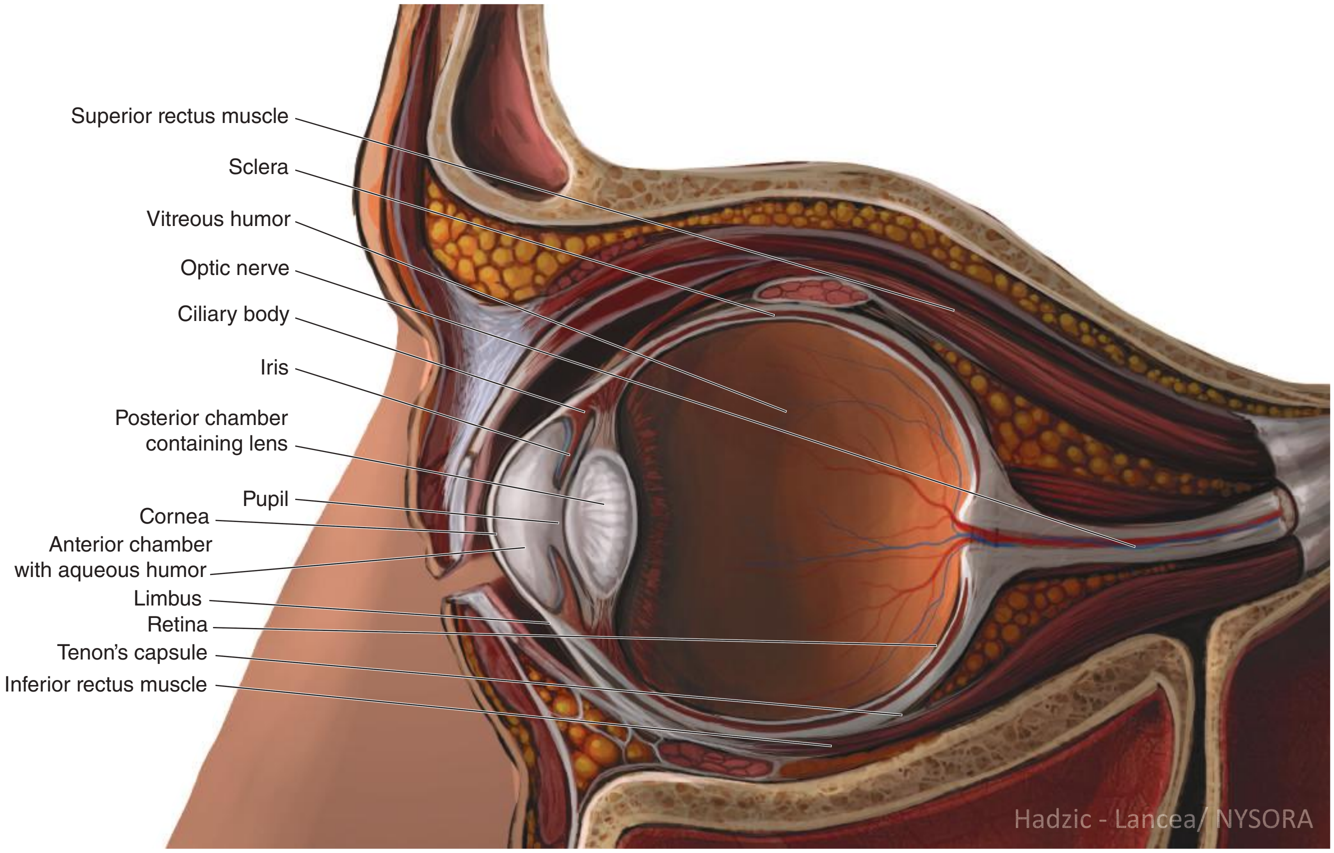

FIGURE 37–3. The globe: sagittal section.

Innervation of the Orbit

Sensory innervation of the orbit and globe is provided mostly by the frontal and nasociliary branches of the ophthalmic nerve (first branch of the trigeminal nerve, V), which pass through the muscular cone (Figures 37–4 and 37–5), while some of the floor of the orbit is supplied by the infraorbital branch of the maxillary nerve (the second branch of the trigeminal nerve). The trochlear nerve (IV) provides motor control to the superior oblique muscles, the abducens nerve (VI) to the lateral rectus muscle, and the oculomotor nerve (III) to all other extraocular muscles, including the levator muscle. All except the trochlear nerve pass through the muscular conus.

Anatomical Quadrants of the Globe and Orbit

The sphere of the globe can be divided in the three standard perpendicular anatomical planes into eight "quadrants": anterior superomedial, posterior superomedial, and so on. Looking from the front, the corresponding anterior extraocular quadrants of the orbit are often referred to as the superonasal, supro-temporal, inferonasal, and inferotemporal, where *nasal* has the same meaning as *medial*, and *temporal* has the same meaning as *lateral* (Figure 37–6). The inferotemporal (or inferolateral) space is usually the largest and least vascular and the preferred quadrant of approach for modern retrobulbar and single-shot peribulbar blocks. The inferonasal (or inferomedial) quadrant is most popular for sub-Tenon's blocks. The superonasal (or superomedial) quadrant is quite vascular but contains the anterior ethmoidal nerve, a useful nerve to block for some oculoplastic procedures (see "Oculoplastic Blocks" below).

Tenon's Capsule and Sub-Tenon's Space

The scleral portion of the globe is surrounded by Tenon's capsule (also known as the fascial sheath of the eyeball), a fibroelastic layer stretching from the corneal limbus anteriorly to the optic nerve posteriorly.[24] Tenon's capsule generally becomes thinner and less adherent to the sclera with age. It delimits a potential space referred to as the episcleral space (sub-Tenon's space), which expands when fluid is injected into it. The conjunctiva overlies the sclera in the anterior part of the eye until it is reflected at the **fornices** of the eye to continue as the mucosal lining of the underside of the eyelids. Note that Tenon's capsule fuses with the sclera about 2 mm from the limbus. Where the sclera is visible, the two layers are easier to pick up

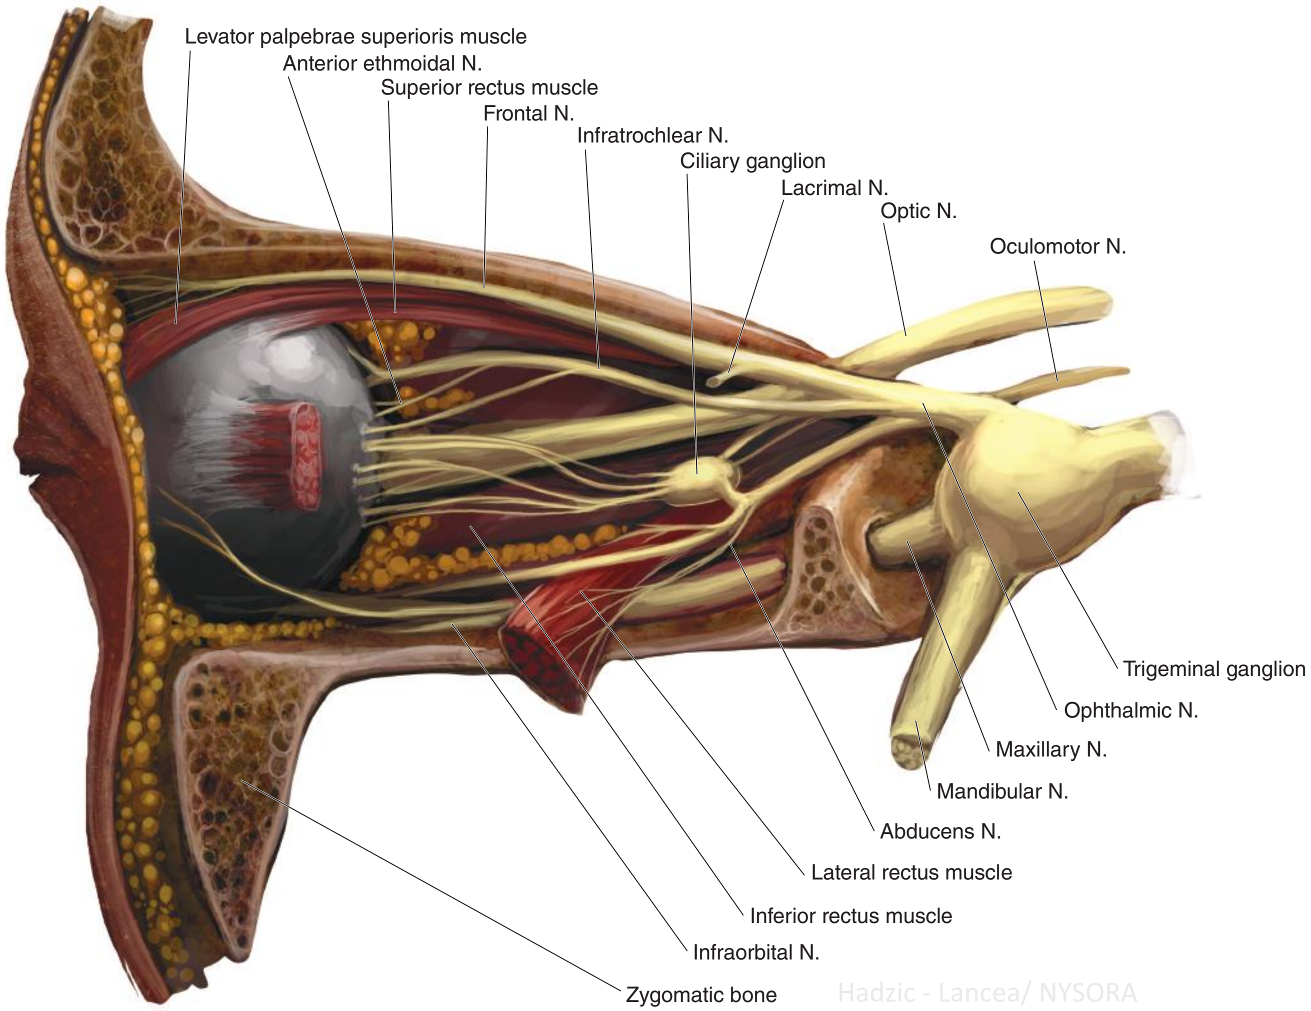

FIGURE 37–4. Left orbit: lateral prosected view. Lateral wall and lacrimal gland removed.

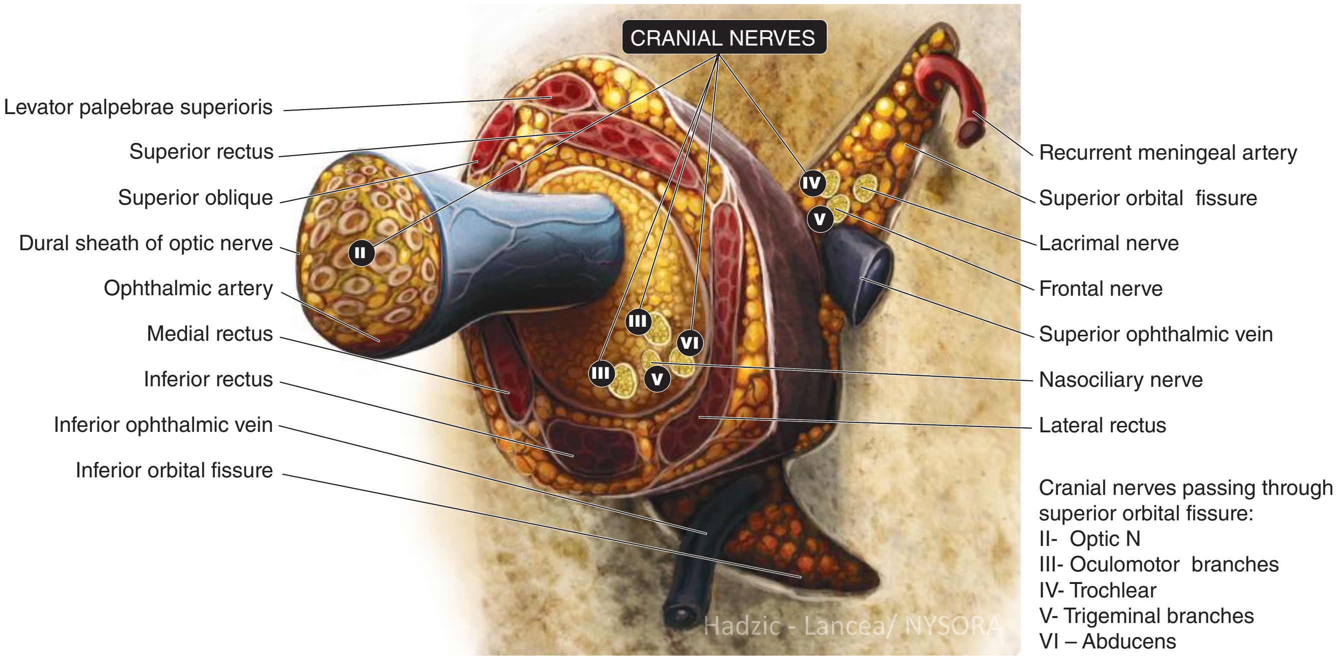

FIGURE 37–5. Extraocular muscles and innervation of the orbit at the level of the annulus of Zinn. Cranial nerves indicated by Roman numerals.

as one; closer to the fornix, the conjunctivum becomes fleshier and more distinct from the sub-Tenon's layer. This helps identify the ideal breach point for the sub-Tenon's technique (q.v.)

Spread of Local Anesthetic Within the Orbit

Injection of LA solution inside the cone will provide anesthesia and akinesia of the globe and (usually) all extraocular muscles. Only the motor nerve to the orbicularis muscle of the eyelids has an extraorbital course, coming from the superior branch of the facial nerve (VII). Many major structures are located within the muscular conus and are therefore at risk of needle and injection injury. These include the optic nerve with its meningeal coverings, the blood vessels of the orbit, and the nerves supplying the globe. For this reason, some authors advise that introduction of the needle into the muscular cone be avoided and suggest that needle insertion be limited to the extraconal space.[25,26]

KEY SURGICAL CONSIDERATIONS[27]

It is important to get to know your surgeon. Choosing an appropriate local anesthetic technique requires an understanding

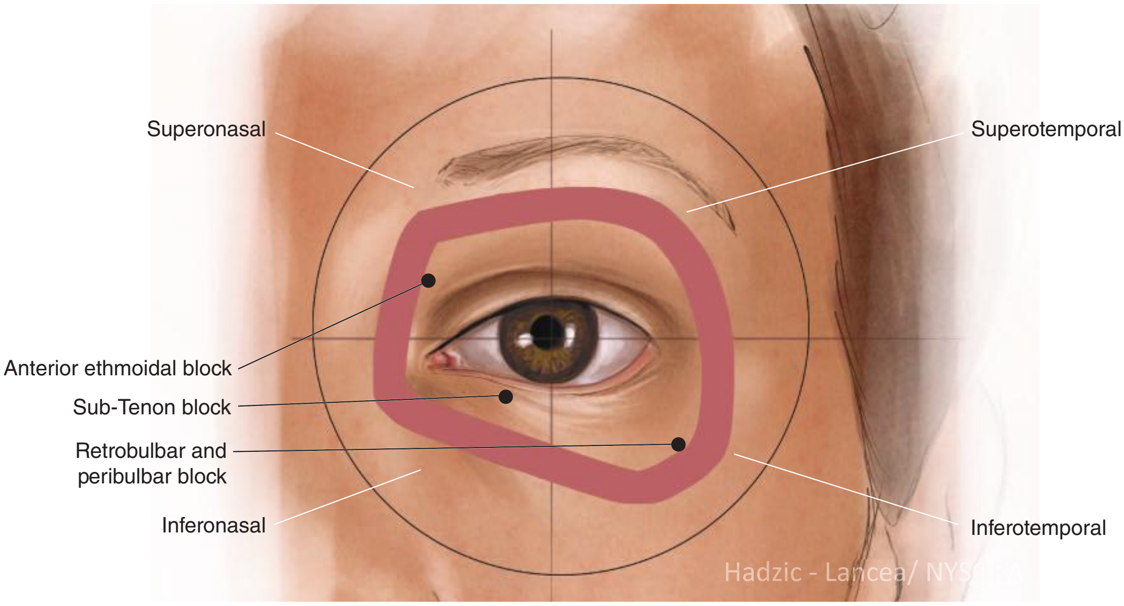

FIGURE 37–6. The anterior orbital quadrants.

not only of surgical procedures but also the surgeon's personal preferences.

Akinesia

The requirement for akinesia varies with the procedure (see below) and the surgeon. With blocks behind the equator of the eye, improving the likelihood of akinesia generally requires more volume,[28] more time,[29] or the addition of hyaluronidase [30] (see "Choice of Local Anesthetic and Adjuvant Agents" below).

Primary Position Versus "On-Axis" Position

Complete paresis of all extraocular muscles renders the eye in the "primary" or "neutral" position. Usually, this corresponds with the surgeon having the pupil aligned with the axis of the surgical microscope (ie, the surgeon has an ideal "on-axis" view of the operative field). However, in cases of incomplete motor block, or in patients who have significant spinal curvature or who are unable to lie flat, the "resting" position of the blocked eye may not correspond to an on-axis view. For this reason, many surgeons actually prefer to have a fully mobile eye for certain patients or certain procedures (eg, trabeculectomy, pterygium removal) so that they can ask the patient to look at the light of the microscope, thereby bringing the eye "on axis," or to look away, allowing greater access to more peripheral parts of the globe.

The Volume Effect of Injections Behind the Eye

Any substantial injection (> 3 mL) behind the equator of the eye (a peribulbar, retrobulbar, or posterior sub-Tenon injection) can significantly raise intraocular pressure and push the posterior segment forward, resulting in a crescent-shaped anterior chamber with decreased volume (Figure 37–7). This can make surgical conditions more challenging, and while this can mostly be offset by counter-pressure (through gentle digital pressure or application of a weight or balloon), some surgeons prefer techniques that retain a "physiological" anterior segment, and most surgeons prefer techniques that avoid large volumes of injectate (> 10 mL) in the orbit. On the other hand, in patients with significant enophthalmos, bringing the globe forward can improve surgical exposure.

"The Only Eye"

In patients who have vision in only one eye—the eye being operated upon—surgeons and anesthetists alike tend to be risk averse and steer away from sharp needle blocks. Techniques that do not involve loss of vision (ie, topical, subconjunctival, "superficial" sub-Tenon's) may be preferable. Techniques that better guarantee akinesia usually cause temporary loss of vision due to anesthesia of the optic nerve. In day-case settings, it may be preferable to use a shorter-duration LA (eg, lidocaine, articaine) over longer-acting agents.

Cataract Surgery

The minimally invasive PhE technique was popularized in the 1990s. The PhE probe is inserted via a small superior, three-plane (self-sealing) incision. The contents of the posterior chamber are manipulated using a needle-width stay probe inserted laterally. After the posterior chamber is voided and cleaned, a foldable or injectable artificial intraocular lens is inserted via the same incision. Anesthesia of the anterior segment is all that is required. Some surgeons require akinesia; others (notably high-turnover surgeons) do not.

Corneal Surgery

The most common operations on the cornea involve trauma, removal of foreign bodies, conjunctival flap and pterygium surgery, corneal transplant surgery, and, increasingly, keratoprosthesis. For these procedures, anesthesia of the anterior segment is typically all that is required. Most surgeons require akinesia for

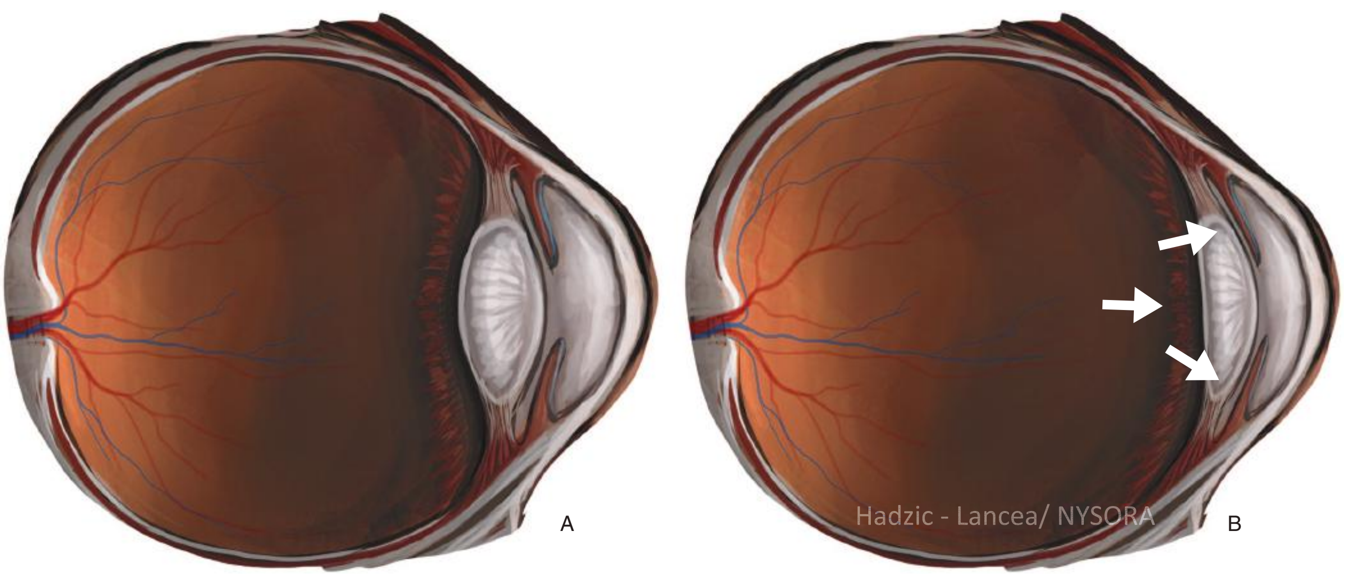

FIGURE 37–7. (**A**) "Physiological" anterior segment. (**B**) The effect of increased retrobulbar volume.

penetrating corneal surgery (eg, trauma, transplant, prosthetic surgery, re-do procedures), while many do not for pterygium surgery, where the fibrous tunic remains essentially intact. Some surgeons find subconjunctival anesthesia useful for separating the conjunctiva from the sclera in pterygium surgery.

Refractive Surgery

Corneal surface ablation, incisional refractive surgery, and intracorneal ring insertion are usually performed under topical anesthesia. Refractive procedures involving the anterior chamber (eg, phakic intraocular lens insertion) are done in a manner similar to cataract surgery.

Glaucoma Surgery

Glaucoma filtration surgery and trabeculectomy both involve creating a fistula between the anterior chamber and the subconjunctival space. Again, anesthesia of only the anterior segment is needed. Depending on the surgeon, there may or may not be a need for akinesia. Some surgeons do not like the disruption of integrity of the conjunctiva that often accompanies the surgical sub-Tenon's (or "snip") technique, particularly in inexperienced hands. Furthermore, conjunctival hematoma can introduce reticuloendothelial cells that interfere with trabeculectomy flaps; consequently, some glaucoma surgeons prefer peribulbar anesthesia for these procedures. Topical anesthesia (with or without intracameral lidocaine) and subconjunctival anesthesia both avoid the potential effect of volume injections behind or around the orbit on pulsatile ocular blood flow in patients with advanced glaucoma. Paradoxically, nonpenetrative glaucoma surgery (eg, deep sclerotomy), being a longer and more difficult procedure, generally requires a technique that guarantees a longer block with akinesia. Procedures involving aqueous tube shunts can be done under topical anesthesia but tend to be more uncomfortable for the patient.

Cyclophotocoagulation is the circumferential ablation of the ciliary body deep to the limbus. Akinesia is not essential for this procedure but may be preferred by some surgeons; however, good analgesia is essential, as the procedure can be very painful. Subconjunctival anesthesia works but needs time; sub-Tenon's or needle blocks usually provide acceptable anesthesia more quickly.

Oculoplastic Surgery

Procedures of the soft tissues of the eye include correction of eyelid malpositions such as entropion and ectropion, eyelash malpositions (districhiasis), ptosis surgery, eyelid tumor surgery, eyelid reconstruction, blepharoplasty, tear duct surgery, orbital decompression (eg, for Grave's disease), and enucleation and evisceration. While many of these procedures can be performed under local infiltration, specific anesthetic techniques are described later in this chapter.

Extraocular Muscle Surgery

Strabismus surgery is most commonly performed in children under general anesthesia. In adults, squint surgery is usually performed in persons under the age of 30, a group which can often be less than stoic, so again GA is usually preferred. However, this surgery can be performed under regional anesthesia. While akinesia is helpful, the main requirement is for deep anesthesia of the muscle cone, as pulling on extraocular muscles is usually quite painful and can induce an oculocardic reflex. Simple suture adjustments can be done under topical anesthesia.[31]

Vitreoretinal Surgery

Vitrectomy and retinal detachment repairs (including scleral buckling) require both anesthesia of the posterior segment and akinesia of the eye; topical and subconjunctival techniques are inadequate for this. Thus, a sub-Tenon's, retrobulbar, or peribulbar block is more appropriate. Prior buckling surgery is a relative contraindication to any regional technique, as both the buckle and scar tissue around it will hamper the spread of local anesthetic. However, if the position of the buckle is known, a deep sub-Tenon's block may be possible via one of the unaffected quadrants. The "tap-and-inject" treatment for endophthalmitis is usually performed using a retrobulbar or peribulbar block.

Open-Globe Injuries

Patients with a known or suspected open-globe injury are most frequently managed under general anesthesia to avoid the risks of infection, retrobulbar hemorrhage, and raised intraocular pressure, which can cause further damage. There are authors who advocate repair under local anesthesia and sedation, arguing that this method avoids the dilemma of using succinylcholine, which can markedly increase intraocular pressure, in patients with both a penetrating eye injury and a full stomach.[32] Rapid-onset nondepolarizing muscle relaxants (NDMRs), such as rocuronium, and the wider availability of the NDMR reversal agent, sugammadex, have largely mitigated this problem. Nevertheless, recent literature appears to suggest that the risk of vitreous extrusion remains very real,[33] and, perhaps in carefully selected situations, local anesthesia should not be discounted as an alternative in cases of eye trauma.

Ophthalmic Oncology

Most procedures for the removal of eye tumors can be performed under local or general anesthesia, according to surgeon and/or patient preference. However, procedures that require stereotactic immobilization or deliberate hypotension should be performed under general anesthesia.

ANESTHETIC TECHNIQUES

Sub-Tenon's (Episcleral) Block

Common Principles

Sub-Tenon's anesthesia, first described in 1884, places the local anesthetic into the potential space between Tenon's capsule and the sclera (Figure 37–8). While this space can theoretically be accessed from any quadrant of the globe, the inferonasal conjunctival fornix is most popular, at approximately the

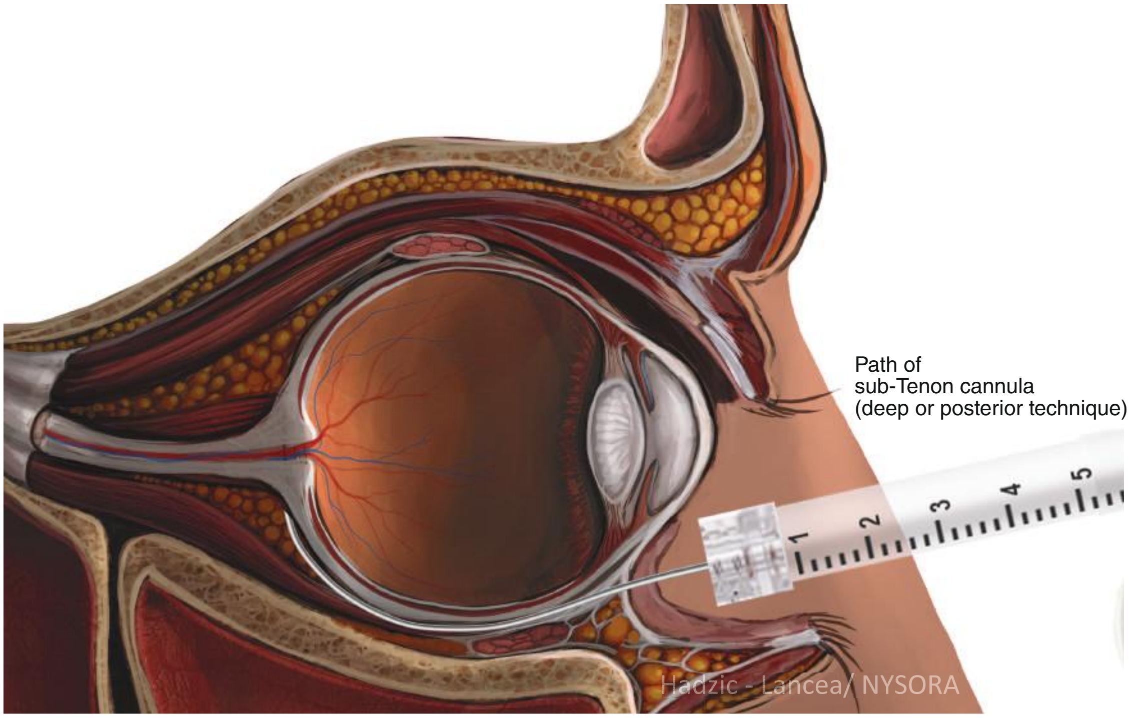

FIGURE 37–8. Sub-Tenon block.

4:30 (right eye) or 7:30 (left eye) position to avoid encountering the insertions of the medial rectus and inferior oblique muscles at the equator.

Using either a surgical or nonsurgical approach (see below), a purpose-specific needle or cannula is directed posteriorly following the curve of the globe. A superficial or deep injection of LA solution can then be performed. "Superficial" or more anterior injections (immediately beyond the equator) allow the LA to spread circularly around the scleral portion of the globe, ensuring high-quality analgesia of the whole globe with relatively low injection volumes (usually 3–5 mL).[34,35] Injection of a larger volume (up to 8–11 mL) causes the LA to spread to the extraocular muscle sheaths, ensuring reproducible akinesia.[34–37] However, larger volumes often cause chemosis (a subconjunctival spread of LA), which requires compression to resolve, as well as a significant increase in intraocular pressure.

On the other hand, "deep" or posterior injections direct more injectate into the posterior intra- and extraconal spaces and are more likely to achieve anesthesia at lower volumes and without chemosis, without akinesia (2–3 mL) or with full akinesia (3–5 mL). While the "surgical" deep injection technique is currently the most popular, several approaches have been described.

Surgical ("Snip") Technique with a Blunt Cannula

This technique, first proposed as a supplement to (or rescue block from) retrobulbar anesthesia, [38,39] is probably the most popular variation of the sub-Tenon's approach. After topical anesthesia, the bulbar conjunctiva is grasped with small forceps in the inferonasal quadrant near the fornix. Small scissors are used to create a small opening into the conjunctiva and Tenon's capsule to gain access to the episcleral space. The same scissors are used to blunt-dissect a passage to the posterior sub-Tenon's space. A blunt metal (eg, Stevens) or plastic (eg, Helica) cannula is then inserted into this space to allow for the injection.[40,41] Some practitioners opt for a superficial passage and then "hydro-dissect" using the local anesthetic injectate; others (particularly for posterior segment surgery) prefer to probe-dissect as close to the intraconal space as possible using closed scissors. It is also possible, particularly in the elderly, to gently push the cannula posteriorly without dissection. The usual LA injection volume is 3–5 mL. Increasing the injection volume (up to 11 mL) results in an increased likelihood of akinesia but is rarely necessary.[37] The main advantage of this technique is its safety, as it avoids the blind introduction of a sharp needle into the orbit. In 6000 cases, no serious complications were reported, with only a 7% rate of subconjunctival hematoma and a 6% rate of subconjunctival edema. Surgery was cancelled because of subconjunctival hematoma in only one patient out of the 6000.[42]

Nonsurgical Technique with a Blunt Cannula

Cutting the conjunctiva can result in long-term scarring and creates a portal for bacteria and occasionally other foreign bodies to enter.[43,44] With practice, a round-tipped blunt cannula (such as a 21-gauge Eagle Laboratories "Tri-Port" sub-Tenon cannula or even a Stevens cannula) can be introduced through the conjunctiva and Tenon's layers without prior incision.[45] This causes less trauma, reduces bleeding, and is preferred particularly where conjunctival damage needs to be minimized (eg, glaucoma surgery).

Nonsurgical Technique with a Sharp Needle

A 25-gauge, 25-mm, short-bevel sharp needle is introduced into the fornix between the semilunaris fold of the conjunctiva and the globe, tangentially to the globe.[34,35] The needle is shifted slightly medially and advanced posteriorly. After a small loss of resistance (click) at 10–15 mm, LA is injected. Using a large volume with this technique (6–11 mL) results in good globe and eyelid akinesia that is more reproducible than classic peribulbar anesthesia;[36] however, note that these are large volumes compared to other techniques, and, as for all sharp-needle techniques, the risk of needle misplacement and its subsequent complications must always be kept in mind. Nevertheless, this technique is associated with a low risk of complications, and it is simple to learn and use. In a series of 2000 cases, no serious complications occurred.[46]

Improvised Cannula Technique

This historical technique was briefly popular before specialized cannulae became widely available. A short intravenous (IV) cannula (18- or 20-gauge) was typically used to inject low volumes of LA (3–5 mL). It provides good globe analgesia but only partial akinesia of the globe and lids.[42] The injection causes only a minor increase in intraocular pressure, and preoperative compression of the globe is typically unnecessary. However, given that it requires introduction of the cannula by piercing the Tenon's capsule, not unlike the technique of IV cannulation, the risk of needle misplacement has reduced the popularity of this technique.

Limitations of the Sub-Tenon's Technique

The sub-Tenon's technique may not be possible where the conjunctival fornices have been obliterated, such as in chronic ocular pemphigus. It should also be avoided where the sclera is known to be thin or frail (eg, the "blue sclerae" of osteogenesis imperfecta or an anterior staphyloma).

Access may be challenging in patients whose inferonasal space is already scarred by multiple previous blocks or in those with a scleral buckle in place, particularly one that is circumferential. In most of these situations, access is possible via an alternative quadrant (most commonly the inferotemporal). Chronic eye inflammation can cause the conjunctiva to become fleshy and painful to touch and to bleed easily. Access through a pterygium should be avoided for the same reasons.

Clinical Pearls

The Surgical "Snip" Technique of the Sub-Tenon's Block According to Guise[47]

- Use half-strength iodine: A substantial body of evidence suggests that this reduces the risk of bacterial endophthalmitis.[48]
- Stay in the "line of longitude" from pole to pole: Keep equally between the medial and inferior recti.
- Keep the Westcott scissors closed: Only one snip at the start is needed.
- Keep the tip of the cannula tight against the sclera: It's easy to overshoot.
- Inject in different directions: Rotating the syringe slightly will aid spread behind the eye.
- Avoid the pterygia: They make access to the sub-Tenon's space more difficult, and they bleed.
- Keep the local anesthetic posterior to the equator: Keep the channel created by the Westcott scissors as narrow as possible to minimize reflux.
- Reduce the rate and force of injection: Too fast and hard is painful for the patient and more likely to cause chemosis.
- Use less than 5mL to minimize chemosis and the increase in intraocular pressure.
- Avoid ocular massage, which can cause dramatic peaks in intraocular pressure and may even cause anterior chamber bleeding. Gentle, steady pressure, if anything, is better.
- Take care with scleral buckles: The inferotemporal quadrant is usually clear, but ask your surgeon. If it is not clear, and you are not comfortable trying a different quadrant, or if you expect or encounter significant scarring, try a different technique.

RETROBULBAR ANESTHESIA

Historically, retrobulbar anesthesia (RBA) was the gold standard for anesthesia of the eye and orbit. This technique generally consists of injecting a small volume of LA solution (3–5 mL) inside the muscular cone (see Figure 38–3). A facial nerve block is occasionally required to prevent blinking (see "Oculoplastic Blocks" below). Because of its extraconal motor control, the superior oblique muscle frequently may remain functional, precluding total akinesia of the globe. The main hazard of RBA is the risk of injury to the globe or to one of the anatomical structures in the muscular cone. Near the apex, these structures are packed in a very small space and are fixed by the tendon of Zinn, which prevents them from moving away from a needle.

Classical Technique (Now Obsolete)

In Atkinson's classical 1936 description,[49] the patient is asked to look in the "up-and-in" direction. The needle is introduced through the skin below the inferior lid at the junction between the lateral third and the medial two-thirds of the inferior orbital edge. The needle is directed toward the apex of the orbit (slightly medially and cephalad) and advanced to a depth of 25–35 mm. A volume of 2–4 mL of LA solution is then injected. An additional facial nerve block may be needed to prevent blinking; the technique most frequently used is the Van Lint block (see "Oculoplastic Blocks").

Modern Techniques

Modern retrobulbar blocks are performed with the eye in the neutral position (Figure 37–9). The Atkinson "up-and-in" gaze position was abandoned when Liu et al.[49] and Unsöld et al.[50] warned that it increased the risk of optic nerve injury, since this

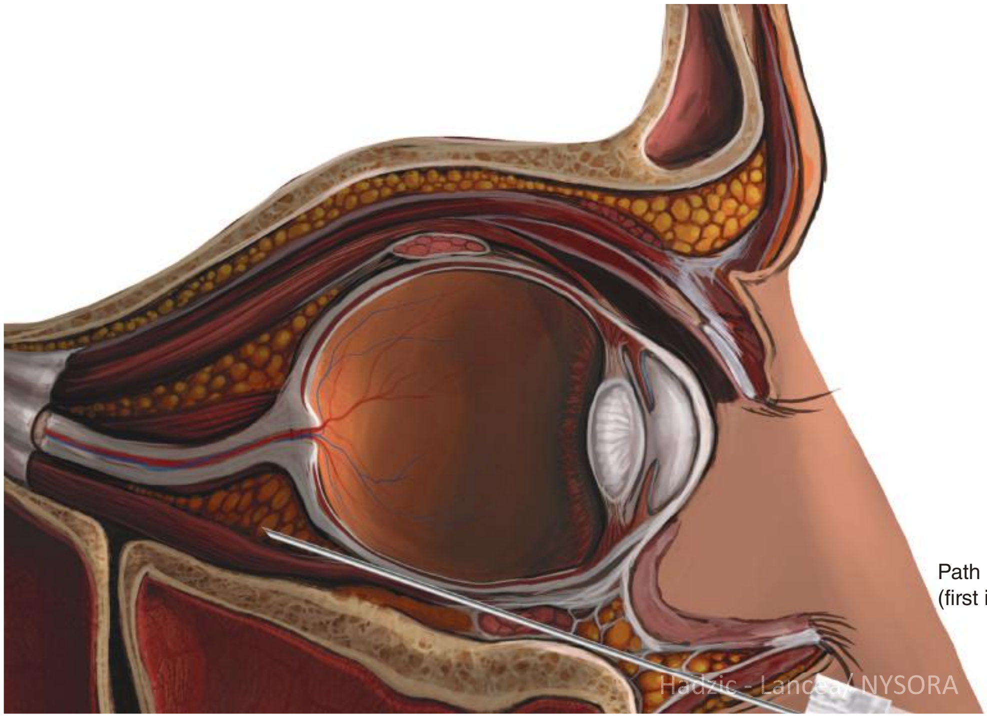

FIGURE 37–9. Retrobulbar block.

position places the optic nerve near the path of the needle. Moreover, the optic nerve is stretched and can be injured easily by the needle, rather than being pushed aside. Alternative puncture sites and specially designed bent or curved needles have been proposed but have not gained popularity.[52,53]

RBA: Is There a Future?

Recently, there has been a growing literature on ultrasound-guided retrobulbar block. The original work in this area was done in human cadavers,[54,55] but there have since been pilot studies in humans.[56] However, concerns have been raised about the ease with which the block may compromise sterility, and questions about the need for this technique have also been asked, given the now-established utility and safety profile of sub-Tenon's blocks, which do not require ultrasonic guidance.[57] It is possible that with future advances in ultrasonic technology this situation may well change. Meanwhile, given the versatility and rising popularity of sub-Tenon's blocks, and given that there is no situation in which a retrobulbar block would be preferred over a peribulbar block, it seems unlikely that retrobulbar blocks will remain part of the repertoire of the modern anesthesiologist.

PERIBULBAR ANESTHESIA

With peribulbar anesthesia (PBA), the needle is introduced into the extraconal space (Figure 37–10).[25,26,58,59] The classical technique involves two injections. The first injection is inferior and temporal, the needle being introduced at the same site as for an RBA injection, but with a lesser up-and-in angle. The second injection is superior and nasal, between the medial third and lateral two-thirds of the orbital roof edge (see Figure 37–10).

The injected volume of LA (6–12 mL) is larger than that for a retrobulbar injection. This larger volume allows the LA to spread into the whole corpus adiposum of the orbit, including the intraconal space, where the nerves to be blocked are located. Additionally, such a large volume allows for the anterior spread of LA to the lids to provide a block of the orbicularis muscle and to avoid the need for an additional lid block.

Several variations on PBA have been described (Figure 37–11). The most common are (1) medial canthus injection,[60] (2) lacrimal caruncle injection[61,62] and (3) inferior and temporal injections.[25,26]

Principles of Peribulbar Anesthesia

- *Single-injection versus multiple-injection technique:* Increasing the injected volume of LA provides sufficient anesthesia. Additional injections are not needed.[63] In addition, anatomic distortion following the first injection may increase the risk of complications associated with consecutive injections.[64] As a rule of thumb, a second injection should be performed only as a supplement when the first injection has failed to provide effective anesthesia.
- *Needle insertion sites:* Needle insertion through the superior nasal site should be avoided. At this level, the distance between the orbital roof and the globe is reduced, theoretically increasing the risk of globe perforation. Additionally, the needle may injure the superior oblique muscle. The inferonasal approach or an approach through the medial canthus should be used instead.[60] The needle is

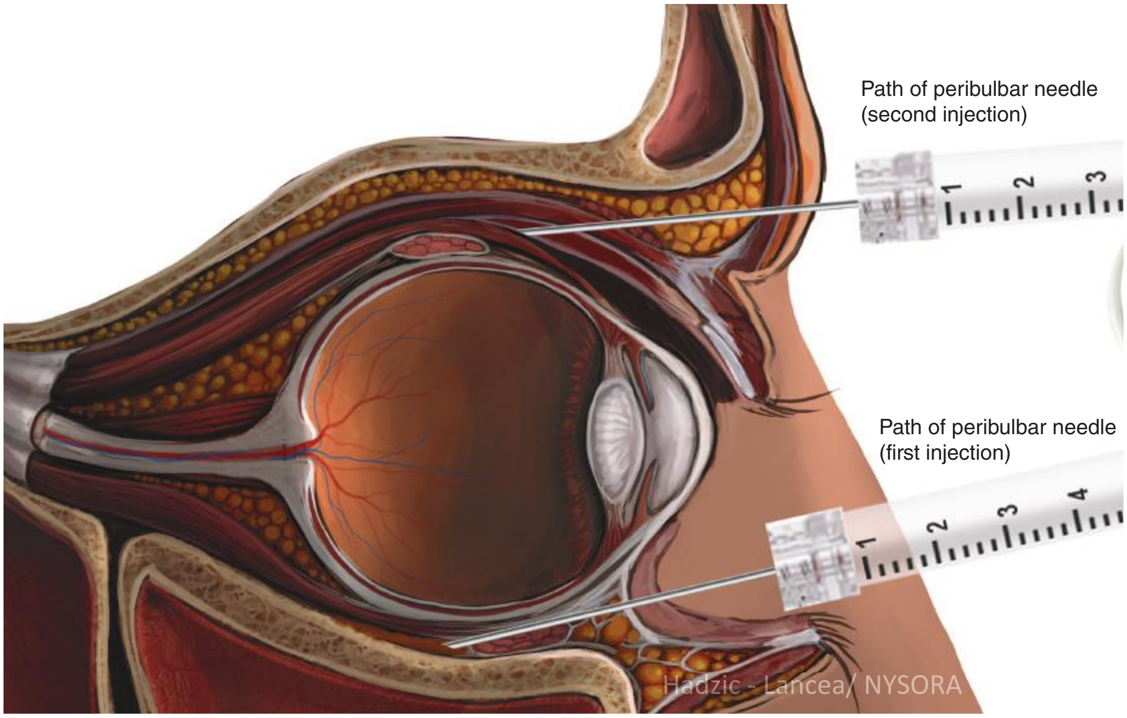

FIGURE 37–10. Peribulbar block: superior second injection technique.

introduced at the medial junction of the lids, nasal to the lacrimal caruncle, in a strictly posterior direction to a depth of 15 mm or less. At this level, the space between the orbital wall and the globe is similar in size to that of the inferior and temporal approach and is free of blood vessels. Moreover, myopic staphyloma, an anatomical anomaly that represents a risk factor for perforation, is infrequently encountered on the nasal side of the globe.

- *Needle insertion depth:* Limit the needle insertion depth to 25 mm. Posterior to the globe, the rectus muscles are in contact with the orbital walls, so that the extraconal space entirely disappears and becomes virtual. Increasing the needle insertion depth would be expected to cause a peribulbar injection to become a retrobulbar injection.[65] Some posterior peribulbar blocks are in fact unintentional retrobulbar injections. This is a plausible explanation for optic nerve injury after an attempted peribulbar injection. Moreover, a long needle fully introduced into the orbit may reach the apex of the orbit, another hazardous area.[66] Inserting the needle to a depth of 40 mm has led to

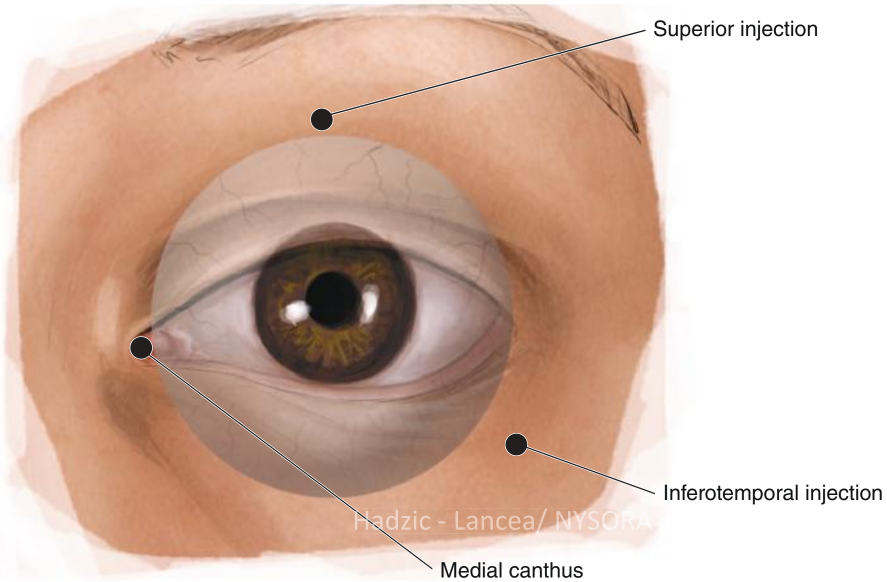

FIGURE 37–11. Peribulbar block: alternative injection sites.

performing the injection directly through the optical foramen in 11% of cases.[67]

- *Fine needles (25-gauge) are suggested for reducing pain on needle insertion:* The use of short-bevel needles may be safer because they may enhance the tactile perception of resistance during needle insertion (intraneural or intramuscular placement). Indeed, on cadavers, more pressure is required with short-bevel needles to perforate the sclera.[68] Nevertheless, these are only theoretical considerations, since the complication rate with peribulbar blocks is low.
- *Use compression to lower intraocular pressure, which increases after injection:* Compression has not been shown to enhance the quality of the block. Applying a pressure of 30 mm Hg for 5–10 minutes is usually sufficient.
- *In all cases, the spread of LA within the corpus adiposum of the orbit remains somewhat unpredictable, leading to the need for more anesthetic to prevent an imperfect block:* Depending on the surgeon's request for akinesia, additional anesthetic is required in up to half of all cases.[58,59] The poor reproducibility in block efficacy is the main disadvantage of peribulbar anesthesia.[26]

Retrobulbar Versus Peribulbar Versus Sub-Tenon's Blocks

RBA has been traditionally assumed to be more effective than PBA. However, when a sufficient volume of LA is injected, both blocks appear to have similar success rates.[69] This is explained by the absence of an intermuscular membrane to separate extra- from intraconal compartments, resulting in a favorable spread of LA (see "Functional Anatomy"). Therefore, if the effectiveness is similar, one should prefer to use the technique with a lower risk of complications. Since RBA theoretically carries a higher risk of complications (eg, optic nerve injury, brainstem anesthesia, retrobulbar hemorrhage; see "Complications of Eye Blocks" below), PBA is deemed preferable to RBA.

However, all other requirements being equal, the sub-Tenon's block offers the best safety profile of the three blocks and can reliably deliver both surgical anesthesia and akinesia if performed by an experienced practitioner with an appropriate volume (with or without adjuvants). However, where chemosis, conjunctival hematoma, or the disruption of the conjunctiva are undesirable, or where the posterior anatomy is seriously abnormal, this technique may not be appropriate.

The diversity of opinion and data suggest, to this author at least, that the individual efficacy of any of these blocks is heavily operator dependent. To a significant extent, the same is true in regard to their safety profiles.

COMPLICATIONS OF EYE BLOCKS

The primary cause of serious complications is needle misplacement. Although some anatomical features may increase the risk of complications, the main risk factor is inadequate knowledge and limited experience on the part of the operator. However, it should be noted that complications such as **retrobulbar hemorrhage** and **oculocardic reflex** may occur with even the most experienced practitioners. Presenting signs, symptoms, and mechanisms of common complications are summarized in Tables 37–1 and 37–2).

TABLE 37–1. Signs, symptoms, and mechanisms of complications of retrobulbar anesthesia.

Complication	Signs and Symptoms	Mechanism of Complication
Ocular		
Globe perforation	Ocular pain, intraocular hemorrhage, restlessness	Direct trauma: myopic eye, posterior staphyloma, repeated injections
Retrobulbar hemorrhage	Subconjunctival or eyelid ecchymosis, increasing proptosis pain, and/or increased intraocular pressure	Direct trauma (artery or vein)
Optic nerve damage	Visual loss, possible early optic disc swelling, late optic disc pallor	Direct injury to nerve or blood vessels, vascular occlusion
Systemic		
Intra-arterial injection	Cardiopulmonary arrest, convulsions	Retrograde flow to internal carotid and access to midbrain structures
Optic nerve sheath injection	Brainstem anesthesia: agitation, ptosis, mydriasis dysphagia, dizziness, confusion, contralateral ophthalmoplegia, loss of consciousness, respiratory depression/arrest, cardiac arrest	Subdural or subarachnoid injection
Oculocardiac reflex	Bradycardia, other arrhythmias, asystole	Trigeminal nerve (afferent, arc) to floor of fourth ventricle with efferent arc via vagus nerve

TABLE 37–2. Other complications of retrobulbar anesthesia.

Complication	Comment
Chemosis (subconjunctival edema)	Usually of minimal concern; disappears with pressure.
Venous hemorrhage	Usually mild and, while unsightly, is easily controlled.
Arterial hemorrhage	Can be dramatic, causing proptosis, extensive subconjunctival and lid hematoma, and a dramatic increase in intraocular pressure. This is a sight-threatening complication: inform surgeon immediately, as orbital decompression (eg, lateral canthotomy/cantholysis) may be necessary to prevent blindness. Usually causes postponement of surgery.
Globe perforation	Likely more common to occur in long, myopic eyes. A long eye has thinner sclera and may have an irregular outline (staphylomata). The needle should be inserted tangentially to the globe and move freely in the orbital fat without rotating the globe.
Damage to the optic nerve	A result of direct trauma, injection into the nerve sheath, or the ischemic consequences of the pressure on injection.
Decreased visual acuity	Usually resolves with resolution of the block, but beware "wipe-out", especially in patients with advanced glaucoma (see "Choice of Local Anesthetic and Adjuvant Agents").
Myotoxicity	May follow direct injection into a muscle or the use of high concentrations of LA (probably more common than currently recognized; usually resolves during surgical convalescence).
Systemic complications	Subarachnoid injection during retrobulbar block is a possible cause of respiratory arrest.
Grand mal seizures, loss of consciousness, and respiratory depression or cardiac arrest	These complications can result from systemic LA toxicity, injection of LA into the optic nerve sheath (and thence to the brainstem), or retrograde arterial flow.
Pulmonary edema	Rare; mechanism is poorly understood.
Reaction to epinephrine	Often inappropriately referred to as "epinephrine toxicity"; in patients with hypertension, angina, or arrhythmias, the amount of epinephrine injected with the LA should be reduced.
Oculocardiac reflex, vasovagal reaction	See text for presentation and management.
Allergic reactions	Extremely rare with amide-type LAs; more common with animal-derived hyaluronidase.

Central Nervous System Complications

Central nervous system eye block complications may occur following a needle block by two different mechanisms:

1. An unintentional **intra-arterial injection** may reverse the blood flow in the ophthalmic artery up to the anterior cerebral or internal carotid artery,[70] so that an injected volume as small as 4 mL may cause seizures. Symptomatic treatment by maintaining a patent airway; providing oxygenation; and abolishing seizure activity with small doses of benzodiazepam, propofol, or a barbiturate is usually adequate and results in a rapid recovery without sequelae.
2. An unintentional **subarachnoid injection** via puncture of the dura mater sheath of the optic nerve or directly through the optic foramen results in partial or total brainstem anesthesia.[71–73] Katsev et al. have shown that the apex of the orbit may be reached with a 40-mm needle in up to 11% of patients.[67] Depending on the dose and volume of LA spreading toward the brainstem, subarachnoid injection can lead to bilateral block; cranial nerve palsy with sympathetic activation, confusion, and restlessness; or total spinal anesthesia with tetraparesis, arterial hypotension, bradycardia, and eventually respiratory arrest. Symptomatic treatment (oxygen, vasopressors, and, if required, tracheal intubation and ventilation) should permit complete recovery after the spinal block wears off (a few hours).

Unintentional **globe perforation** and rupture is the most devastating complication of eye blocks. It has a poor prognosis, especially when the diagnosis is delayed. The incidence is between 1 in 350 and 7 in 50,000 cases.[74,75] Main risk factors include inadequate experience of the operator and a highly myopic eye (ie, a long eyeball).[76] In a study of 50,000 cases, Edge and Navon observed that **myopic staphyloma** was a significant risk factor. This suggests that isolated high myopia may not be a risk factor per se but acts as a confounding factor, as staphyloma seems to occur only in myopic eyes.[75] Vohra and

Good[76] observed with B-mode ultrasound that the probability of staphyloma is greater in highly myopic than in slightly myopic eyes. Moreover, staphyloma was more frequently found at the posterior pole of the globe (accounting for perforations after RBA) or in the inferior area of the globe (accounting for perforations after inferior and temporal punctures, both peri- and retrobulbar). As a result, at least in myopic patients, and at best in all patients, ultrasound measurement of the axial length of the globe (biometry) should be available. In cases of a highly myopic eye (axial length greater than 26 mm), a needle block can carry an increased risk of globe perforation, and a sub-Tenon's or topical block is preferable. Unusual causes of globe perforation include misplaced infraorbital nerve blocks (see "Oculoplastic Blocks") and patients sneezing under propofol sedation (see "Sedation").

Extraocular Muscle Injury

Injury to an extraocular muscle may cause diplopia and ptosis. Several mechanisms can be involved, including direct injury by the needle resulting in intramuscular hematoma, high pressure as a result of injection into the muscle sheath, or direct LA myotoxicity.[77]

Direct Extraocular Myotoxicity

It has been known for some time that high concentrations of amide-type local anesthetics, particularly bupivacaine, cause myotoxic changes in skeletal muscle.[78] The extraocular muscles seem particularly susceptible, and numerous case reports of persistent diplopia after cataract surgery have been attributed to this.[79–81] However, to date, no formal clinical evaluation of skeletal muscle function after eye block has been performed. In monkeys, a 0.75% bupivacaine retrobulbar block typically causes a myopathic response that peaks at 14 days and is largely resolved by 27 days.[78] In rabbits, bupivacaine myotoxicity appears to be concentration dependent, with 0.75% solutions producing extensive and longer-lasting damage, whereas 0.19% produces little sign of short- or long-term damage.[82] Lidocaine solutions containing epinephrine cause substantially more damage to skeletal muscle than does plain lidocaine, both in rats and humans.[83] Indeed in humans, bupivicaine toxicity of eye muscles is deliberately induced to treat strabismus.[84] The injury progresses in three steps: first, the muscle is paralyzed; second, the muscle seems to recover; and third, retractile hyperplasia develops.

Given the case reports and the impressive and consistent pathological evidence across species, and with the many thousands of eye blocks being performed each year, it is surprising that the phenomenon is not more clinically apparent. It has been proposed that postoperative pain may mask myopathic changes and that any eye discomfort or dysfunction is readily attributed to the operation rather than other causes.[85] Furthermore, the animal evidence suggests that in most cases there is likely to be rapid recovery with complete tissue regeneration. In another animal study, skeletal muscle damage induced by femoral nerve block was more severe in younger rats than older rats,[86] so perhaps older humans, too, are less susceptible.

Based on the limited available evidence, it would seem that extraocular myotoxicity is probably a more frequent concomitant of volume blocks behind the equator of the eye than is generally recognized and that it is concentration dependent and more likely to occur with bupivacaine, but that any clinically significant adverse effects in the relevant patient population *usually* (but not always) resolve completely within the time frame of healing of the operation.

Clinical Pearls

Retrobulbar Hemorrhage

- Retrobulbar hemorrhage is typically caused by an inadvertent arterial puncture. It may lead to a compressive hematoma, which can threaten retinal perfusion.
- At the time of hemorrhage, it is imperative to have an ophthalmologist present who can monitor intraocular pressure and take the appropriate steps to preserve central retinal artery perfusion. Lack of perfusion for even short periods can lead to permanent, devastating loss of vision.
- Surgical decompression may be required, but in most cases surgery has only to be postponed.[87]
- Venous puncture may occur after both retrobulbar and peribulbar injection. It leads to noncompressive hematoma, the consequences of which are much less severe, so that in most cases surgery can be continued.
- For patients on anticoagulants (including even aspirin and similar medications), consider sub-Tenon's or topical anesthesia to minimize the risk of hemorrhage.

Optic Nerve Trauma

Direct optic nerve trauma by the needle is rare but serious, as it causes blindness. Computed tomography imaging usually shows optic nerve enlargement caused by intraneural hematoma.[88]

Summary

Overall, there is a 1%–3% chance of complications, often necessitating postponement of the planned surgery. Since some complications may be life threatening if patients are not immediately resuscitated, it is recommended that an anesthesiologist be present to monitor the patient perioperatively.[89]

Clinical Pearls

Oculocardiac Reflex

- Bradycardia due to a range of stimuli in or around the orbit, such as traction on the extraocular muscles, pressure on the globe, retrobulbar block, ocular trauma or pressure on residual tissues after enucleation.
- Also causes other arrhythmias including ventricular tachycardia and (rarely) asystole.

- The relevant neural pathways are branches of the trigeminal nerve (afferent) and vagus nerve (efferent). While mainly associated with stimulation of the ophthalmic nerve, it can occur with any branch of the trigeminal nerve.
- The incidence is highest in children (up to 90% without pre-treatment with atropine).
- For prophylaxis in children, atropine 0.02 mg/kg or glycopyrrolate 0.01 mg/kg prior to surgery is indicated.
- Intramuscular atropine is not useful due to delayed onset.
- Prophylaxis in adults is not indicated.
- Treatment of bradycardia includes removal of stimulus or asking the surgeon to stop the stimulation, initiation of intravenous anticholinergics (eg atropine 5-10 mcg/kg or glycopyrrolate 2.5-5 mcg/kg), and checking depth of anaesthesia (where GA is used).

TOPICAL ANESTHESIA

Instillation of LA eye drops provides corneal anesthesia, thus allowing for cataract surgery by PhE (Figure 37–12). This technique is quick and simple to perform and avoids the potential hazards of needle techniques. It has been suggested that the lack of akinesia and intraocular pressure control, associated with the short duration of this technique, may make surgery hazardous;[90] however, this observation does not appear to have dented the growing popularity of the technique. Many US surgeons appear to prefer topical anesthesia for routine PhE in more than 90% of their cases.

Nevertheless, use of topical anesthesia should be limited to uncomplicated procedures performed by experienced surgeons in cooperative patients. In parts of the world where PhE is not technically available, and in some specific indications where PhE is not feasible, total akinesia is still required, and the use of topical anesthesia may be questionable.[91,92]

As to what patients actually prefer, there are conflicting reports. Boezaart has reported that because anesthesia may be incomplete in topical approaches, patients randomly subjected to one of these techniques for one eye and another technique for the other eye preferred the retrobulbar to the topical technique (71% versus 10%).[93] Patients consistently report less intraoperative discomfort under retrobulbar[94,95] or sub-Tenon's [95,96] anesthesia compared to topical anesthesia. On the other hand, a meta-analysis by Zhao et al.[96] reported that patients overwhelmingly preferred topical anesthesia over needle blocks, citing "fear of needles" as a key reason, despite finding that the same population of patients reported more intraoperative discomfort under topical anesthesia compared to needle blocks. In some experienced hands, no anesthesia at all appears to be as effective as topical anesthesia in selected cases.[97]

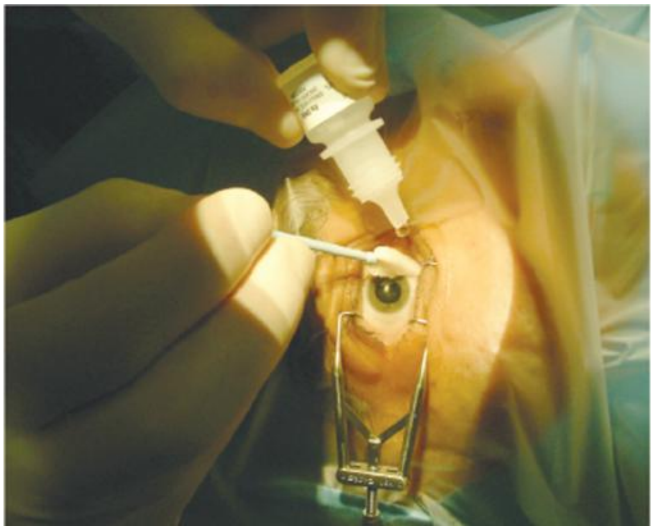

FIGURE 37–12. Topical anesthesia.

An intracameral injection of LA appears to substantially enhance analgesia with a topical approach.[98] This consists of injecting small amounts (0.1 mL) of LA into the anterior chamber at the beginning of or during surgery. Intracameral anesthetic agents must be preservative free. Some concerns have been expressed about the toxicity effects of LA on the corneal endothelium, which is unable to regenerate; however, the safety of intracameral injection now seems well established.[99] Some authors have questioned its analgesic benefit when compared with simple topical anesthesia,[98,100,101] and indeed the degree of analgesia does not seem to correlate with intracameral LA concentration.[102] Nevertheless, the combination of topical plus intracameral anesthesia is currently the technique most preferred by US ophthalmic surgeons.

The insertion of sponges soaked in LA into the conjunctival fornices has been proposed.[103] The use of lidocaine jelly instead of eye drops seems to enhance the quality of analgesia of the anterior segment [94,103,104] and is becoming very popular for improving patient comfort under topical anesthesia.

Direct Corneal Epithelial Toxicity of Topical Anesthetics

From animal studies, it has been known for some time that repeated applications of virtually all topical anesthetic agents cause some degree of transient corneal epithelial toxicity that is macroscopically apparent, including reversible corneal thickening and opacification.[105,106] Changes may be evident with even a single topical application, and these may take more than an hour or more to recover.[107] In humans, topical anesthetic abuse is a known cause of severe keratopathy among arc welders and metalworkers,[108] and even in patients who overuse their "comfort drops" after refractive keratectomy.[109,110]

Transient corneal edema has been noted in patients undergoing cataract surgery under topical ropivacaine or lidocaine.[111] Fernandez et al. reviewed the condition of corneal epithelia by slit-lamp examination the day after cataract surgery under topical levobupivacaine or lidocaine.[112] They found mild epithelial changes in 17–22% of patients and signs of significant epithelial damage (punctates) in 2.4–5.8%, respectively; however, no data were provided on how, when, or whether these changes resolved.

Nevertheless, to date, no cases of severe keratopathy associated with the routine administration of topical anesthesia for eye surgery have been reported. The current relative paucity of hard clinical data may in part explain the diversity of practice

PART 3

across continents, as practitioners may interpret what data there are to affirm their own preferences. Given the growing popularity of the technique (especially in the US), one might assume that, as for extraocular myotoxicity, any clinically significant effect is transient and may be masked by and/or attributed to the effects of surgery during convalescence.

SUBCONJUNCTIVAL ANESTHESIA

Subconjunctival injection of LA, a technique relatively unfamiliar to many anesthesiologists, provides anesthesia of the anterior segment without akinesia.[113] Also known as "perilimbal" anesthesia, it is, in effect, a form of episcleral injection and can also be thought of as a "very anterior" or "very superficial" Sub-tenon's block. This block is useful for cataract, pterygium, and superficial glaucoma surgery. After pretreatment with one drop of topical anesthetic, a fine-bore (27- to 30-gauge) needle is used to lift the superotemporal or inferotemporal conjunctiva at least 5–8 mm from the limbus (Figure 37–13). A surgical microscope or loupes can be used to avoid conjunctival vessels and hematoma. Once the needle is under the conjunctiva, 0.5–0.8 mL of local anesthetic solution will cause chemosis, which is dispersed with gentle, constant pressure, either using fingers or a purpose-specific weight or balloon. Hyaluronidase can be added to assist with the spread of solution and dispersal of chemosis. Compared to retrobulbar injection, this technique is less painful and reduces the need for supplemental anesthesia during cataract surgery.[114] Injection at the superotemporal conjunctiva appears to be less painful than injection at the inferotemporal conjunctiva.[115] Subconjunctival injection results in reliable and substantial concentrations of local anesthetic in the aqueous humor.[116]

FIGURE 37–13. Subconjunctival block.

OCULOPLASTIC BLOCKS

Many oculoplastic procedures (Figure 37–14) can be performed under local anesthetic. However, given the sensitive innervation of the face, these blocks are best performed under some form of transient, deep sedation (eg, a small IV dose of propofol), except in the very stoic patient. Note also that, while targeted blockade of individual nerves is useful, there is often significant overlap of sensory supply. Depending on the site and extent of the proposed operative wound, more than one type of block may be required, and supplemental local infiltration may be necessary. Most oculoplastic surgeons are quite accustomed to this.

Upper and Lower Lid blocks

Procedures such as upper and lower blepharoplasty and ectropion repair can be performed under gentle subcutaneous local infiltration of the base of the operative lid. Certain procedures require the surgeon to evert the eyelid under deep sedation and infiltrate distal to the semilunar fold.

Facial Nerve Block

Occasionally, a block of the periocular branches of the facial nerve is required to prevent excessive blinking during eye surgery. Classical approaches include the Van Lint[117] and O'Brien[118] techniques; Atkinson has described a modified technique,[119] variants of which are probably most popular today. A bleb of local anesthetic is raised about 2–3 cm lateral to the lateral rim of the orbit at the level of the lateral canthus, which is somewhere between the locations of the more distal Van Lint and the more proximal O'Brien approaches. Two radii of local infiltration are then injected superiorly and inferiorly from this point forming a "V" that catches the fibers of the facial nerve. A total of 5 mL is typically more than sufficient.

Supratrochlear/Supraorbital Nerve Block

Blocks of the supraorbital and supratrochlear nerves, branches of the ophthalmic nerve, are useful for procedures that involve the upper eyelid area immediately at or above the eyebrow. The supraorbital notch can usually be felt about 2–3 cm from the midline along the medial part of the superior rim of the orbit, usually in line with the patient's pupil. Paresthesia can often be elicited by pressing on this notch. A volume of 2 mL of local anesthetic here should provide some anesthesia to the area immediately around the eyebrow, the upper eyelid, and the lower forehead; however, it is usually also necessary to block the supratrochlear nerve by running a medial band of infiltration (an additional 2–3 mL) from the notch to the midline and approximately 1–2 cm laterally to catch lateral supraorbital fibers that can arise through a separate foramen.

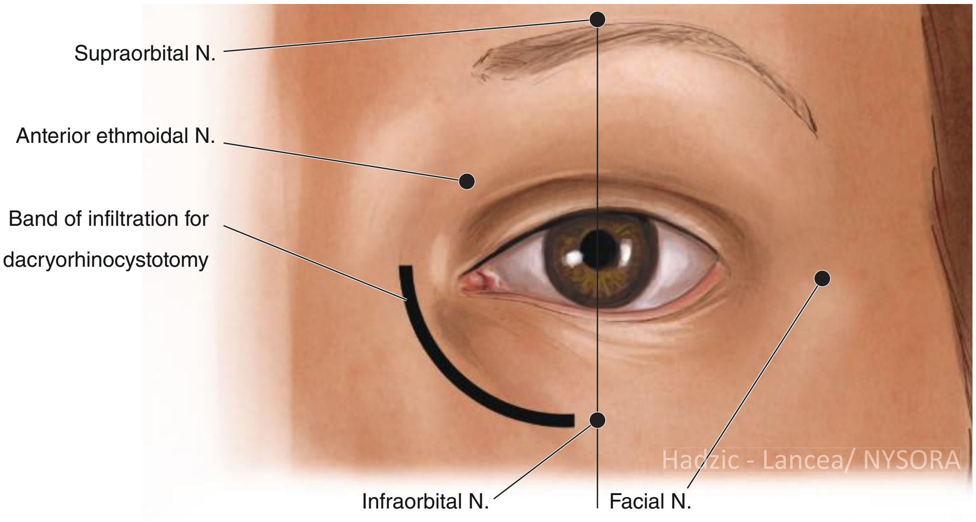

FIGURE 37–14. Landmarks for oculoplastic blocks.

Infraorbital Nerve Block

The infraorbital nerve, a major branch of the maxillary nerve, supplies sensation to the lower eyelid and the floor of the orbit. It emerges onto the face through the infraorbital foramen, which is reliably found just below the inferior orbital rim, in line with both the pupil and the supraorbital notch. A volume of 2–3 mL of local anesthetic at this point is usually more than enough. In the traditional approach to this block, the needle is directed slightly upward to align with the orientation of the infraorbital canal; however, note that at least two cases of inadvertent globe penetration have been reported with this technique.[120,121]

Nasocilary/Infratrochlear/Anterior Ethmoidal Nerve Block

The nasocilary nerve is a branch of the ophthalmic nerve and supplies, via its intratrochlear and anterior ethmoidal branches, sensation to the medial wall of the orbit, the proximal lacrimal sac, the proximal nasolacrimal duct, the mucosa of the nasal cavity, and much of the skin of the nose. This nerve is blocked via an injection of 2–3 mL of local anesthetic by a vertical insertion of a fine-gauge needle parallel to the medial wall of the orbit approximately in line with the bridge of the nose to a depth of about 25 mm. This corresponds with the foramen through which the anterior ethmoidal nerve exits the orbit. It is important that the needle descend freely to the point of injection, as the orbital wall is thin at this level, and perforation of the ethmoidal and even sphenoidal sinuses is quite possible.

Local Anesthesia for Tear Duct Surgery

Local anesthesia for dacryorhinocystostomy and other procedures involving the lacrimal apparatus is possible using a combination of topical anesthesia of the nasal cavity (for the nasal branches of the anterior and posterior ethmoid, sphenopalatine, and nasopalatine nerves), a nasociliary block, an infraorbital block, and a short band of subcutaneous infiltration along the base of the nose from the level of the medial canthus to the level of the infraorbital foramen.

USE OF EYE BLOCK FOR POSTOPERATIVE ANALGESIA

Regional anesthesia, especially the sub-Tenon's block, has been proposed as a treatment for postoperative pain.[122] However, this is not required for anterior segment surgery, which usually results in minimal or no discomfort postoperatively.

Clinical Pearls

Postoperative Pain

- Significant pain occurring after cataract surgery is unusual and should raise suspicion for increased intraocular pressure, severe inflammation, or infection; the eye should be examined by an ophthalmologist.
- Postoperative pain is more likely after posterior segment surgery. The use of an indwelling retrobulbar, peribulbar, or sub-Tenon's catheter has been proposed to improve intraoperative anesthesia, prolong postoperative regional analgesia, and treat intractable eye pain.[123]

CHOICE OF LOCAL ANESTHETIC AND ADJUVANT AGENTS

All available LAs have been used for eye block, either alone or as a combination of two agents. The injected LAs used most often are lidocaine, bupivacaine, ropivacaine, mepivacaine, or a combination of two of these. The choice of LAs should be based on the pharmacologic properties and availability of the drugs, with the primary consideration being the requirement for quick onset (lidocaine, mepivacaine), prolonged effect, or postoperative residual block for analgesia (ropivacaine, bupivacaine) or akinesia (higher concentration). Because the amount of LA injected is usually small (3–11 mL), systemic toxicity is not a major concern.

Septocaine (articaine) is a relatively novel amide-type LA, commonly used in dentistry, with an emergent use in eye blocks. It has a faster onset than bupivacaine/lidocaine preparations in peribulbar[124] and sub-Tenon's blocks[125] and, because it appears to diffuse through tissues more readily than other LAs, often results in a denser block. There appears to be no clinical advantage of 4% over 2% articaine, at least in dental anesthesia.[126] Despite concerns about its neurotoxic potential in animal studies,[127] there does not seem to any conclusive evidence that it is more toxic than other high-concentration LAs.[128]

Hyaluronidase is an enzyme that has been widely used to facilitate the spread of local anesthetic through connective tissue, thereby improving both the onset and success rate of regional anesthesia for the eye.[129] Another benefit is a reduced incidence of postoperative strabismus connected with its use, possibly by limiting LA myotoxicity owing to its faster spread.[130,131]

Some authors are less confident about the real benefit of hyaluronidase in improving akinesia.[132,133] There are also significant concerns about its allergenic potential;[134–136] however, these may be due to the impurities intrinsic to traditional animal-derived hyaluronidase; newer human recombinant products have been shown to be not only more potent but also to have higher enzyme purity and to be virtually free of hypersensitivity reactions.[137] It would appear that, as the requirement for akinesia relaxes, adjuvants such as hyaluronidase are becoming less popular. Nevertheless, in situations where akinesia is required, hyaluronidase may still have an important role.

α2-adrenergic agonists are well known to ophthalmologists as topical agents that reduce intraocular pressure in glaucoma. **Clonidine** has been shown to enhance intraoperative anesthesia and postoperative analgesia when added to the LA in a range of eye blocks.[138–142] At a dose of 1 mcg/kg, clonidine does not increase the incidence of systemic adverse events such as hypotension or excessive sedation.[143] Moreover, it may help to prevent intraoperative arterial hypertension and lower intraocular pressure. **Dexmedetomidine**, a more highly selective α2 agonist, has been used increasingly as an effective adjuvant in peripheral nerve blocks, including the sub-Tenon's block.[144] It has been proposed that the addition of α2 agonists may allow for surgical anesthesia at lower concentrations of LA, thereby limiting LA-induced myotoxicity. It should be noted that all studies on α2 adjuvants to date have been relatively low-powered, and, while this is a promising area of study, substantially higher sample sizes are required. **Epinephrine** is sometimes used to increase the duration of eye block. However, the availability of long-acting LAs and the fear of vasospasm with subsequent retinal ischemia have decreased its use. "Wipe-out" (a sudden total sight loss not overtly related to ocular pathology) is a rare but serious risk, particularly in glaucoma patients. LA solutions containing epinephrine have been implicated as a contributing factor.[145]

Alkalinization of local anesthetic solutions has been proposed for decreasing pain during injection and accelerating block onset; however, its efficacy remains unproven. Other adjuvant agents have been proposed but have not gained popularity. Small doses of muscle relaxant may enhance akinesia, but concern has been expressed about their potential risk for systemic effects.[146] Opioids do not appear to be more efficient via a regional ophthalmic route than via systemic administration.[147]

Warming the LA may decrease pain on injection and enhance block efficacy, although these benefits do not appear to be clinically relevant.[148]

WHO SHOULD PERFORM EYE BLOCKS?

Since the 1980s, anesthesiologists have become increasingly involved in eye blocks that previously were performed by surgeons. However, in some countries, anesthesiologists are not available, and surgeons have to manage the block themselves.[149] In other countries, anesthesiologists monitor only the anesthesia care, as the surgeon performs the block.

In many developed countries (eg, France and Australia), anesthesiologists are often responsible for administering eye blocks. The same was true in the United Kingdom; however, recent cost constraints have forced managers to reconsider the role of the anesthesiologist in elective ophthalmic procedures that do not require a general anesthetic. There are currently no hard data to support or refute the idea that having the *anesthesiologist* performing eye blocks, rather than the surgeon, or even having the anesthesiologist in attendance, is *safer* for this patient population. However the available literature does suggest that with proper training, anesthesiologists can perform eye blocks with the same degree of safety as in other regional anesthesia techniques.[42,46,52,60] Having one experienced person performing blocks while another operates is more time efficient, and there is a theoretical benefit to having a person skilled in resuscitation present in the unlikely event of a life-threatening complication[89] (which, unsurprisingly, materializes into an *actual* benefit whenever such a complication occurs).

PERIOPERATIVE MANAGEMENT OF PATIENTS UNDERGOING EYE BLOCK

Patient Selection and Assessment

Older patients undergoing eye surgery frequently have coexisting diseases such as diabetes mellitus, hypertension, coronary artery disease, or cardiac insufficiency. A preoperative assessment should be routinely done to ensure that coexisting medical conditions are reasonably well controlled. Despite the low morbidity and mortality associated with local ophthalmic anesthesia, patients should be carefully screened for their eligibility for surgery. Patients with severe kyphosis or scoliosis pose obvious practical problems for microscopic surgery. Patients who may not be able to lie flat for the requisite period, due to cardiac or respiratory insufficiency, neurological disease, or dementia, are also challenging. Once draped, patients with profound deafness may be unable to respond to intraoperative commands unless carefully briefed preoperatively.

Briefing Patients

Given the potential problems of excessive sedation (see below), an empathic and interactive preoperative briefing is a useful tool for both reducing anxiety and optimizing cooperation during eye surgery. Patients should be given a clear explanation of what will be done to them, what they are likely to experience, and what they may be asked to do during the operation, in language appropriate to their level of understanding.

Monitoring

Intraoperative monitoring should include basic monitoring (ie, electrocardiogram, pulse oximetry, and automated noninvasive blood pressure measurement). Intravascular access is required for any invasive anesthetic technique.

Sedation

Eye surgery (eg, cataract surgery) carries a low risk of perioperative morbidity and mortality. Eye block is associated with lower perioperative morbidity than is general anesthesia used for ophthalmic surgery, provided that heavy sedation is avoided.[150–152] Anxiety and residual pain frequently occur during eye surgery under LA. Perfect immobility is required, and the presence of drapes over the head increases patient anxiety and impairs access to the airway. The patient should be positioned as comfortably as possible, with sufficient space to allow free breathing. Intraoperative sedation with judicious doses of sedatives may be used to limit anxiety and pain. However, an excess of sedation may lead to restlessness, sleeping, snoring, or respiratory depression, which, in the absence of any airway access, pose a significant intraoperative challenge. Maintenance of meaningful patient contact is of paramount importance to avoid disasters that can occur with disoriented or combative patients while the surgery is underway.

Another interesting and dangerous phenomenon associated with ophthalmic needle blocks performed under propofol sedation is involuntary sneezing,[153,154] which may occur in up to one-fifth of patients during injection;[155,156] this reaction is sight threatening, as it can lead to accidental globe perforation.[157] It is more likely to occur in patients who are male, have a history of photic sneezing (sneezing with sudden exposure to bright light or sunshine), are under deeper sedation, or who are given concurrent midazolam.[156] It does not appear to occur in patients undergoing blocks with remifentanil sedation[155] or with no sedation at all.[154] Awareness of this phenomenon should better prepare operators to withdraw the block needle immediately if a sneeze is imminent and possibly reconsider their current sedation practice. Dexmedetomidine, a highly selective α-agonist, is gaining some popularity as a sedative agent in a range of clinical settings, including eye surgery.

Do Patients Undergoing Eye Block Need to Fast?

Fasting practices for patients having procedures under topical, local, or regional block have undergone an evolution in recent years.[158] In the complex machine of public-sector medical practice, the well-intentioned and traditional "NPO from midnight" doctrine often leads to patients fasting well in excess of 12 hours.[159] In addition to an increased likelihood of postoperative nausea and vomiting, inappropriately prolonged fasting can cause discomfort and distress, as well as dehydration and metabolic derangements, all of which can make patients (especially children and the elderly) restless and uncooperative. Moreover, while there is an obvious theoretical case for fasting prior to any surgical procedure, there have been no reported cases of aspiration under local anesthesia during cataract operations.[160] The joint view of the learned colleges in the United Kingdom is that fasting is generally not required for patients undergoing eye surgery without sedation.[161] Moreover, at least one experienced ophthalmic center has performed blocks under "judicious doses" (0.5–2 mg) of IV midazolam in over 5000 unfasted patients without untoward incident.[162] Nevertheless, where it is anticipated that deep sedation or general anesthesia, however brief, will be needed either to perform the block or during the operation, then standard preoperative fasting remains a sensible prerequisite, and, where needed, systemic measures should be explored to minimize inappropriately prolonged fasting. Where fasting is not routinely required, a small proportion of problematic patients will present for surgery unfasted but for whom the need for deep sedation becomes obvious once they are in the operating room. Individual institutions need to audit the prevalence of this phenomenon and to make cost and risk–benefit decisions accordingly. A comprehensive and compassionate preoperative patient briefing may have an important role in minimizing this issue.

Is Intravenous Access Required in Patients Undergoing Eye Block?

In recent years, many centers, particularly those performing office-based eye procedures, have abandoned the traditional requirement of securing IV access for all surgical procedures, provided that procedures are performed under "needleless" anesthesia (ie, topical anesthesia or sub-Tenon's block). According to a joint statement of the Royal College of Anaesthetists and the Royal College of Ophthalmologists in the UK, "Intravenous access … is essential with peribulbar and retrobulbar blocks and when intraoperative sedation is used" and "recommended for long/complex cases, sub-Tenon's blocks, and patients with poor general health."[161] In relation to this, the author is in agreement with Guise[163] in making the following observations: (1) Sedation may occasionally be required at very short notice by patients even under topical anesthesia, and prior IV access makes timely sedation easier and less stressful; (2) vasovagal and other dysrhythmic reactions, while uncommon, may also occur, in which case IV access already in situ is beneficial for both patient and resuscitator; and (3) it is a prudent clinical precaution, and no real trouble, if a person experienced in IV cannulation (such as an anesthesiologist) is in attendance.

Eye Blocks and the Anticoagulated Patient

Traditionally, anesthesiologists would often make a formulaic decision whether to perform an ophthalmic regional block (which was usually a retrobulbar or peribulbar block) based on results of a blood-clotting profile and by nominating an arbitrary cut-off point (eg, an international normalized ratio [INR] of 1.5–2.0 or a platelet count of 50–100). Nowadays, however, there is not only a diversity of anticoagulant therapies (several of which defy easy assessment), but also a range of anesthetic management options. Moreover, the risks of discontinuing anticoagulant therapy in some patients may outweigh the risks of perioperative bleeding on full anticoagulation. Consequently, there is no clear algorithm for managing “patients undergoing eye surgery who are on anticoagulants.”[161,164] It is best to make a balanced benefit-versus-risk decision in each case based on a number of fundamental questions:

- *Which anticogulant(s) is the patient taking?* A variety of agents are now available. While there are established management strategies for drugs such as warfarin and heparin, strategies for others are less straightforward. Dabigatran, for example, is a novel long-acting oral anticoagulant with no direct antidote. The perioperative management of potential bleeding in patients on this drug is currently a matter of much concern, including those undergoing eye surgery. Since there are currently no data on patients on dabigatran undergoing eye block, including sub-Tenon’s block, current recommendations are to withhold the drug for two to five days prior to performing the block and surgery.[47,165]
- *Why is the patient being anticoagulated?* Occasionally, patients self-initiate aspirin intake (eg, because they have read about it in a magazine). It is common for patients to be treated with warfarin for acute-onset atrial fibrillation that spontaneously reverts. Such situations make it easier to consider withholding the drug rather than choosing not to perform the block.
- *Is the patient in a high-risk group (eg, with a documented history of thromboembolism)?* Often, there is not only a clear clinical indication for anticoagulation, but also a clear increased risk if perioperative anticoagulation is not managed correctly, and therefore a greater imperative to use a technique that does not require the patient’s anticoagulant therapy to be modified. When in doubt, consult with the medical team that started the patient on anticoagulant therapy.
- *What are the relative bleeding risks of the procedure proposed?* Here, the team should consider both the surgical and anesthetic procedures. Oculoplastic and glaucoma surgeries tends to carry a higher bleeding risk, whereas most PhE and vitreoretinal procedures can be done on full anticoagulation (however, discuss individual cases with the surgeon, as the decision is ultimately his or hers). Generally, topical, subconjunctival, and sub-Tenon’s blocks are considered low risk, and the limited evidence to date supports going ahead with these techniques without altering the patient’s routine anticoagulant therapy. Low-powered studies suggest that, while minor bleeding complications such as subconjunctival hematoma are more frequent with sub-Tenon’s blocks performed in patients on aspirin, warfarin, or clopidogrel, major complications such as sight-threatening bleeding are not.[166,167] Retrobulbar and peribulbar blocks are considered high risk.
- *What are the surgical requirements for anesthesia?* Where akinesia is not required for anterior segment surgery, topical or subconjunctival techniques are more attractive. If posterior segment anesthesia and/or akinesia are needed and there are no other contraindications, sub-Tenon’s block is now seen to be the safest option.
- *Is it an elective case or a true emergency?* Where there is time to take a more gradual approach that avoids the use of antidotes and prothrombotic agents, this opportunity should be taken.

Working with High-Volume Surgeons

Running a high-turnover cataract list (20 or more patients a day) safely and efficiently is both a science and an art form requiring not only consummate individual technical skill but also good teamwork and communication skills, as well as attention to ergonomic detail. A good surgeon will include all members of his or her theater team in the planning and execution of the list. The anesthesiologist’s role is to support the team both technically and tactfully, monitoring the whole team and signaling when the team should slow down or even stop. Standardization wherever possible—from role allocation and patient trolley positioning to the vocabulary used to describe equipment and procedures—helps to streamline activities and to make deviations from routine more salient. The use of a modified World Health Organization (WHO) surgical safety checklist in a fast-paced eye theater[168,169] may also help to detect anomalies and reduce errors. Regular feedback and discussion of individual and team performance helps to promote *kaizen*: the approximation of perfection through small, continuous, incremental improvements over time.

SUMMARY

In developed countries, eye surgery is among the most frequently performed surgical procedures requiring anesthesia. During the past 20 years, anesthesiologists have assumed a growing role in performing eye blocks. The requirement for a deep anesthetic block with total akinesia has been greatly lessened through the use of PhE for cataract surgery, giving a more prominent role to topical anesthesia.

Needle blocks carry a low but real risk of serious complications, mainly the result of needle misplacement. Training and practice are required to minimize such problems. The use of the sub-Tenon’s block reduces the risks of needle blocks and is now an established and popular technique, although it does not completely prevent complications. The right anesthetic technique is informed by the anesthesiologist’s skill, experience, and understanding of the surgical procedure and the individual surgeon’s preferences.

ACKNOWLEDGEMENTS

The author would like to thank Jacques Ripart, Kenneth Mehbridge, and Robert Della Rocca for their first-edition version of this chapter and without whom this revision would not have been possible. Thanks with deep gratitude also to Keith Allman, Tom Eke, Phil Guise, and Chandra Kumar, all of whom devoted substantial time and effort to offer invaluable suggestions and additional references.

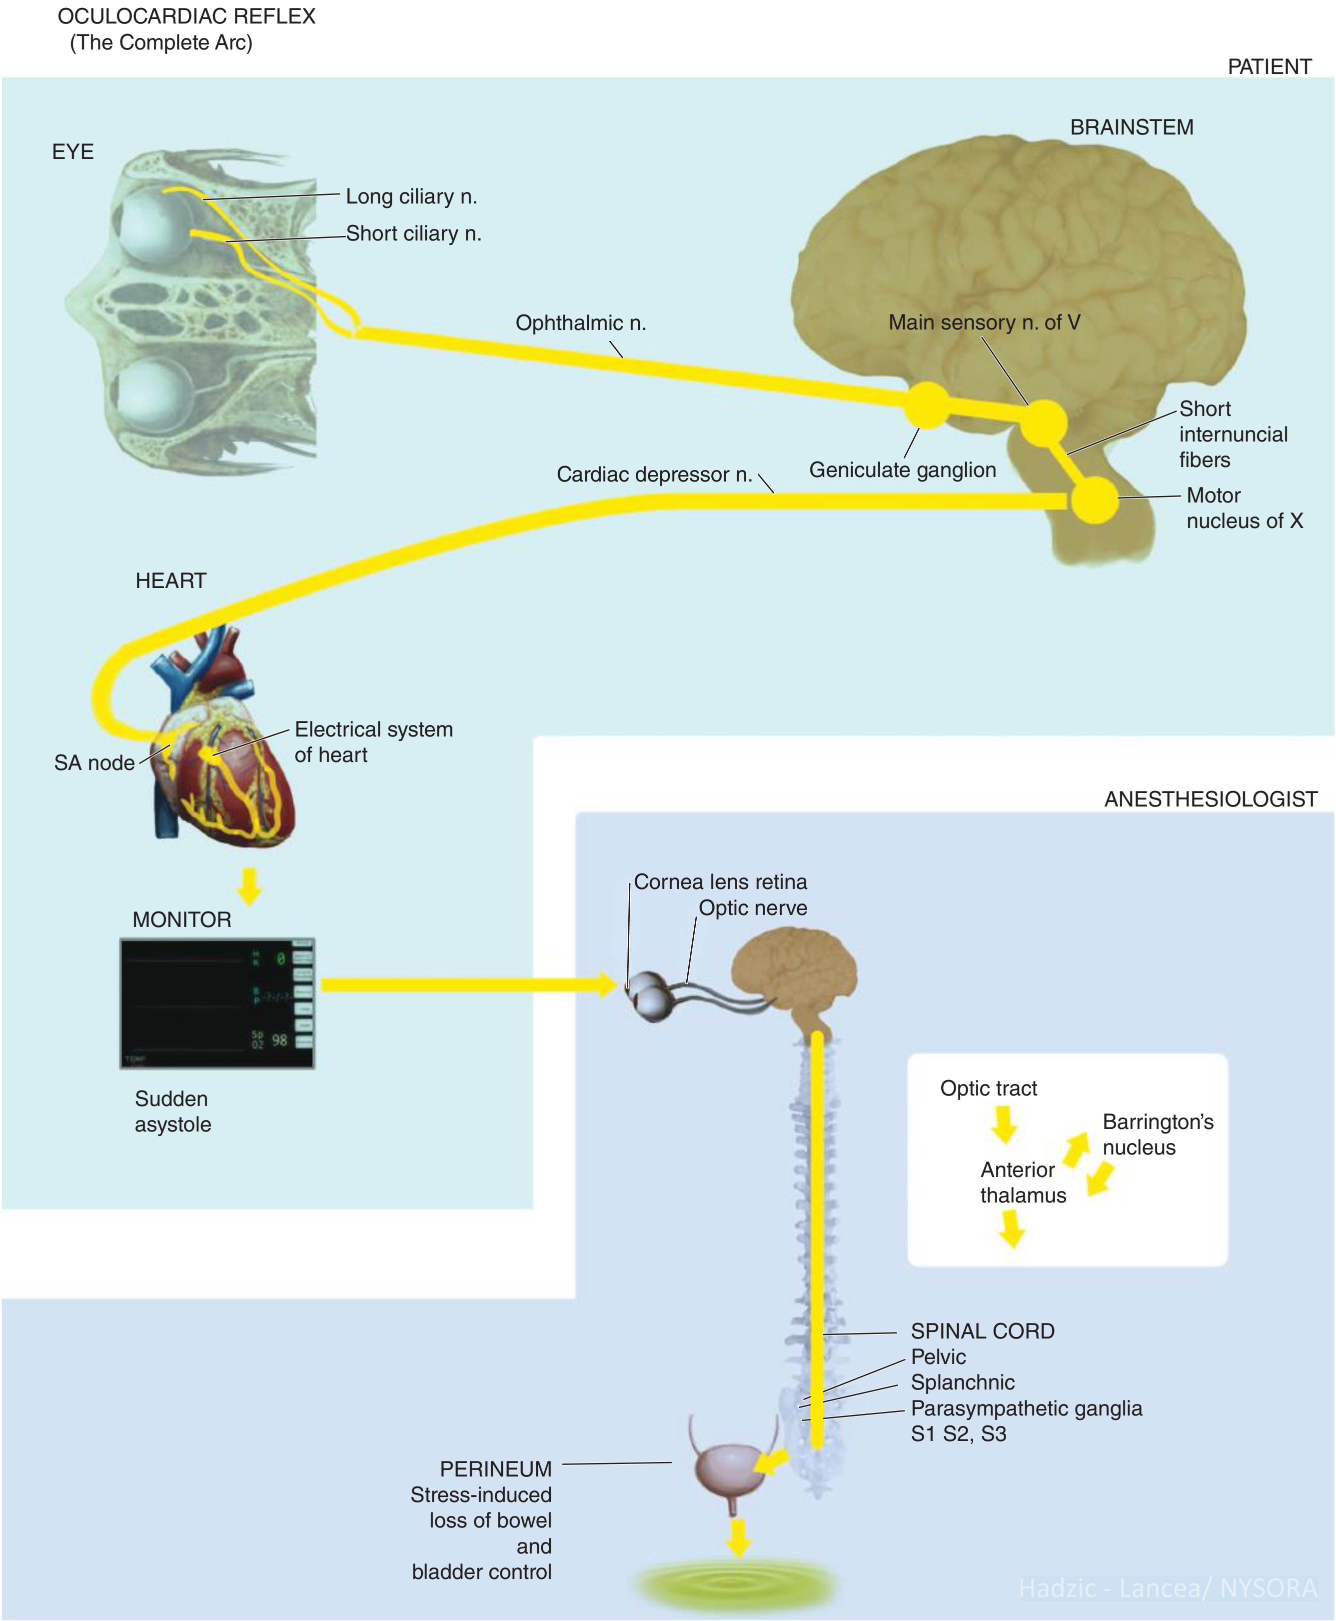

FIGURE 37–15. Oculocardiac reflex arc.

APPENDIX: THE OCULOCARDIAC REFLEX

The **oculocardiac reflex**, first described in 1908; is a decrease in heart rate over 20% below baseline values often seen during traction on the extrinsic muscles of the eye, particularly during strabismus surgery. However, it can also occur during the administration of eye blocks, particularly retrobulbar block. Other triggers include ocular trauma, intraorbital hematoma, acute glaucoma, a sudden increase in intraocular pressure, stretching of the eyelid muscles, and conjunctiva. In unprepared subjects, bradycardia can be quite dramatic, and occasionally leading to asystole in the patient (and tachycardia in the anesthesiologist), which lasts as long as the triggering stimulation is applied. While sinus slowing of the heart is classical, any arrhythmia including ventricular fibrillation may occur. The reflex is exaggerated in children (in up to 90% without pretreatment) and in the presence of hypoventilation, hypoxemia, and acidosis.

The reflex arc has been well described (Figure 37–15), the afferent limb consisting of the long and short branches of the ciliary nerves, the ophthalmic nerve, the geniculate ganglion, and the main sensory nucleus of the trigeminal nerve. Short internuncial fibers then convey the reflex to the efferent limb, consisting of the motor nucleus of the vagus, the vagus nerve, and the cardiac depressor nerve. The oculocardiac reflex is a specific variant of the **trigeminocardiac reflex**, a wider constellation of brainstem-mediated reactions—bradycardia, sweating, breath holding, yawning, sneezing, and so on—triggered by stimulation of any of the sensory branches of the trigeminal nerve (primarily the ophthalmic nerve).

The best treatment in children is prophylaxis: IV atropine 10–20 mcg/kg or glycopyrrolate 5–10 mcg/kg on induction. Intramuscular agents are less useful due to their delayed onset. Prophylaxis in adults is usually not indicated; however, it is prudent to have an IV anticholinergic predrawn and available.

Acute treatment consists of removing the stimulus: Ask the surgeon to stop whatever they are doing. If the pulse does not improve, give an anticholinergic (eg, IV atropine 5–10 mcg/kg or glycopyrrolate 2.5–5 mcg/kg). Check the depth of anesthesia in cases of GA.

CHAPTER 38

Sonography of the Lumbar Paravertebral Space and Considerations for Ultrasound-Guided Lumbar Plexus Block

Hiroaki Murata, Tatsuo Nakamoto, Takayuki Yoshida, and Manoj K. Karmakar

INTRODUCTION

Traditionally, lumbar plexus block (LPB) is performed using surface anatomical landmarks to identify the site for needle insertion and eliciting quadriceps muscle contraction in response to nerve electrolocalization, as described in the nerve stimulator-guided chapter. The main challenges in accomplishing LPB relate to the depth at which the lumbar plexus is located and the size of the plexus, which requires a large volume of local anesthetic for success.[1] Due to the deep anatomical location of the lumbar plexus, small errors in landmark estimation or angle miscalculations during needle advancement can result in needle placement away from the plexus or at unwanted locations. Therefore, monitoring the needle path and final needle tip placement should increase the precision of the needle placement and the delivery of local anesthetic. Although computed tomography and fluoroscopy can be used to increase precision during LPB, these technologies are impractical in the busy operating room environment, costly, and associated with radiation exposure. It is only logical, then, that ultrasound (US)-guided LPB be of interest because of the ever-increasing availability of portable machines and the improvement in the quality of the images obtained.[2,3]

ANATOMY AND GENERAL CONSIDERATIONS

LPB, also known as psoas compartment block, comprises an injection of local anesthetic in the fascial plane within the posterior aspect of the psoas major muscle, usually at the L3–4 level (occasionally at the L2–3 or L4–5 levels). Because the roots of the lumbar plexus are located in this plane, an injection of a sufficient volume of local anesthetic in the posteromedial compartment of the psoas muscle results in a block of the majority of the plexus (the femoral nerve, lateral femoral cutaneous nerve, and obturator nerve).[1] The anterior boundary of the fascial plane that contains the lumbar plexus is formed by the fascia between the anterior two-thirds of the compartment of the psoas muscle that originates from the anterolateral aspect of the vertebral body and the posterior one-third of the muscle that originates from the anterior aspect of the transverse processes. The lateral and dorsal borders of the psoas major muscle consist of the quadratus lumborum muscle and the erector spinae muscle, respectively. Considering the rich vascularity of the lumbar paravertebral area, such as the dorsal branch of the lumbar artery, the use of smaller-gauge needles and the avoidance of this block in patients on anticoagulants are prudent.[4,5] LPB in patients with obesity can be challenging.

TRANSVERSE IN-PLANE TECHNIQUE

Regardless of technique, the patient is placed in the lateral decubitus position with the side to be blocked uppermost. The operator should identify the transverse processes on a longitudinal sonogram (Figure 38–1a, b, c). One technique involves identifying the flat surface of the sacrum and then scanning proximally until the intervertebral space between L5 and S1 is recognized as an interruption of the sacral line continuity (Figure 38–1b). Once the operator identifies the L5 transverse process, the transverse processes of the other lumbar vertebrae

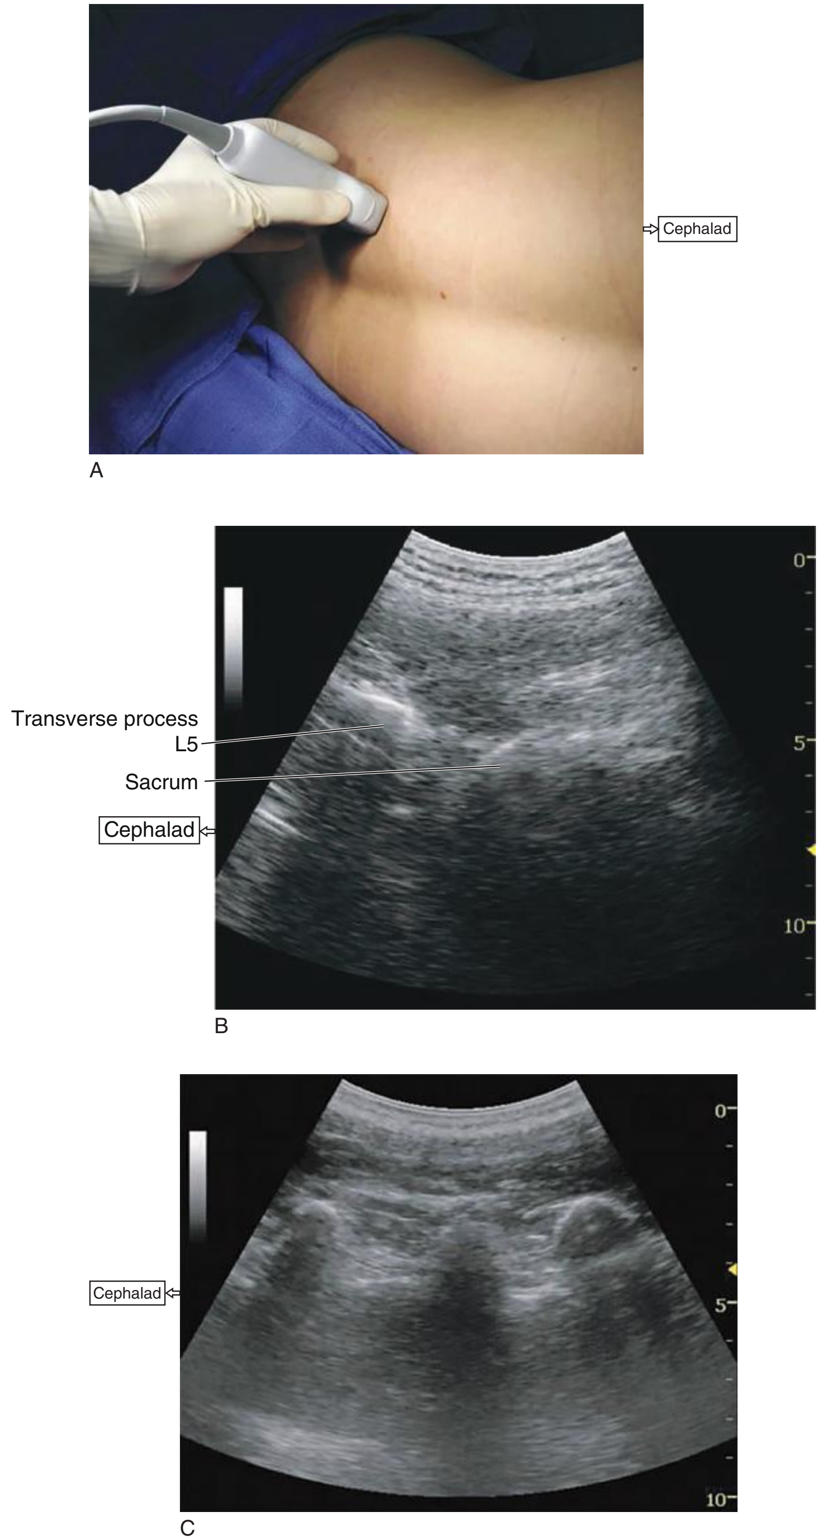

FIGURE 38–1. (**A**) Transducer position to image the longitudinal lumbar paravertebral space including the transverse processes. Lumbar plexus block can be performed with this transducer position using both out-of-plane and in-plane approaches (see also Figure 38–4a). (**B**) Longitudinal US image of the lumbar paravertebral space demonstrating the sacrum and L5 transverse process. When the surface of the sacrum disappears, the next osseous structure is the L5 transverse process. (**C**) US anatomy of the lumbar paravertebral space demonstrating transverse processes at a depth of approximately 3 cm. The acoustic shadows of the transverse processes look like a trident. A lower-frequency, curved array transducer is used to optimize imaging at this deep location and obtain a greater angular view.

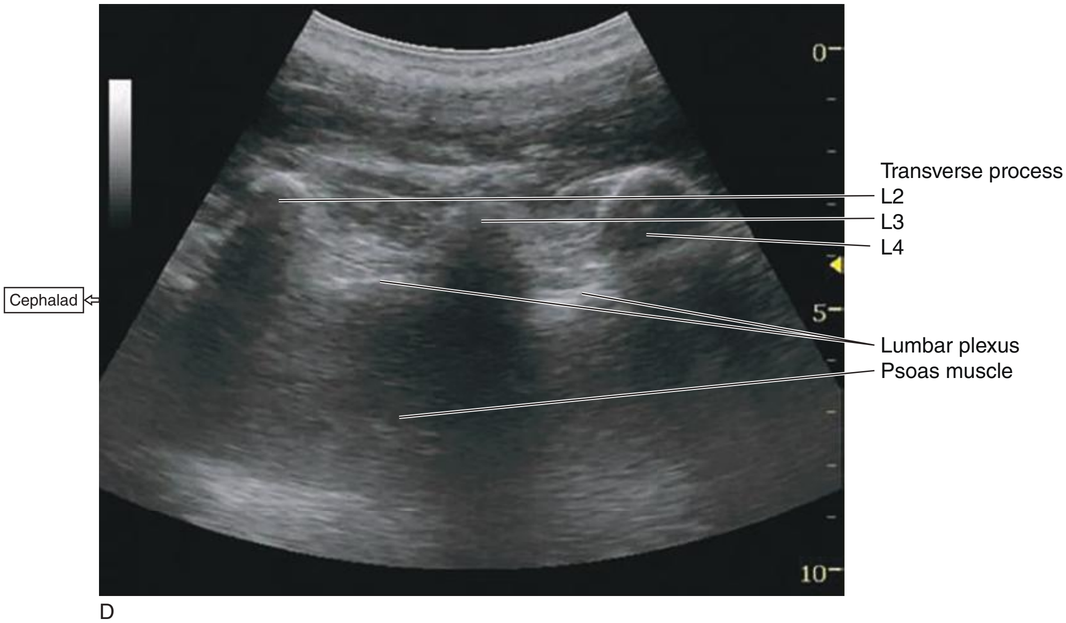

FIGURE 38–1. (*Continued*) (**D**) Labeled US image of Figure 38–1C.

are easily identified by a dynamic cephalad scan in ascending order (Figure 38–1c, d). The following settings are typically used to start the scanning:

- Abdominal preset or nerve preset if available
- Depth: 9–12 cm
- Curved array transducer (4–8 MHz)
- Tissue harmonic imaging and compound imaging functions engaged when available
- Adjustment of the overall gain and time-gain compensation

The transducer is positioned approximately 4 cm lateral from the midline at the level just cephalad to the iliac crest and directed slightly medially to assume a transverse oblique orientation (Figure 38–2a).[6,7] This approach allows imaging of the lumbar paravertebral region with the psoas major, erector spinae, and quadratus lumborum muscles; the vertebral lamina; and the anterolateral surface of the vertebral body (Figure 38–2b, c, d). In this view, the psoas major muscle appears slightly hypoechoic with multiple hyperechoic striations within. The inferior vena cava on the right-sided scan (Figure 38–2e) or the abdominal aorta on the left-sided scan can be seen deep to the psoas major muscle, providing additional information regarding the location of the psoas major muscle, which is positioned superficial to these vessels. When scanning at the L2–L4 level, the lower pole of the kidney can

PART 4

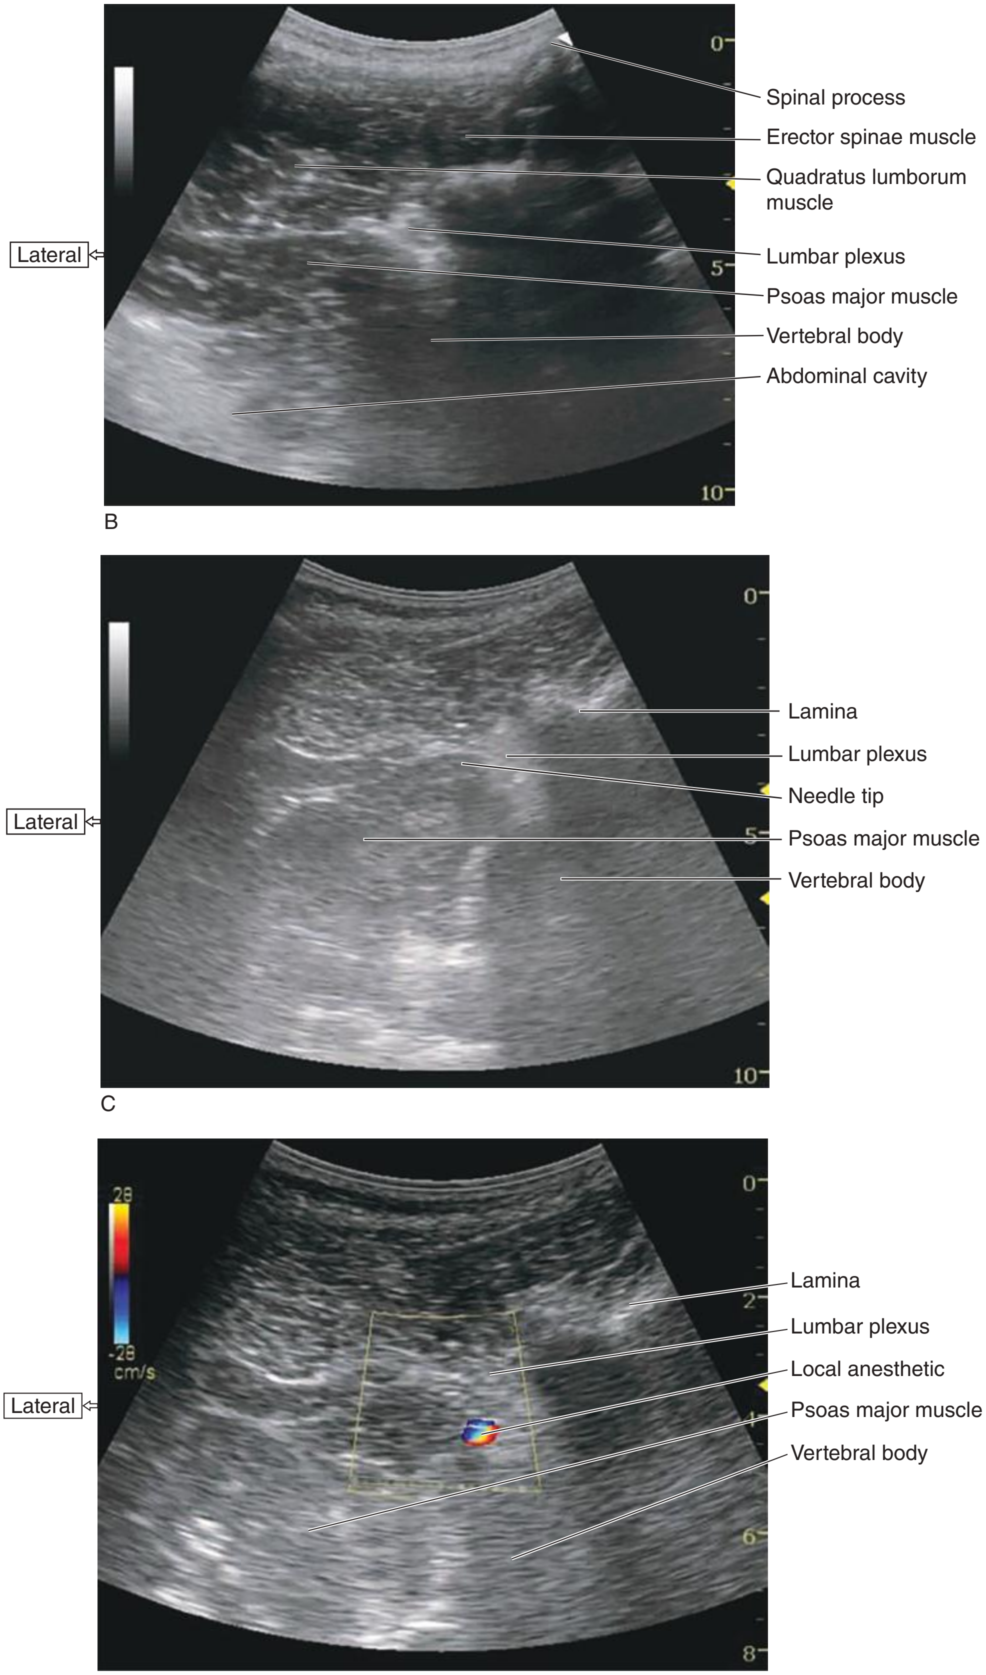

FIGURE 38–2. (*Continued*) (**B**) US anatomy of the lumbar paravertebral space in the transverse oblique view. The lumbar plexus root is seen just below the lamina as it exits the interlaminar space and enters into the posteromedial aspect of the psoas major muscle. (**C**) Needle path in US-guided lumbar plexus block using a transverse oblique view and in-plane approach from the lateral to medial direction. (**D**) Spread of local anesthetic solution with lumbar plexus block injection. Due to the deep location of the plexus, local anesthetic spread may not always be well seen. Color Doppler imaging can be used to help determine the location of the injectate.

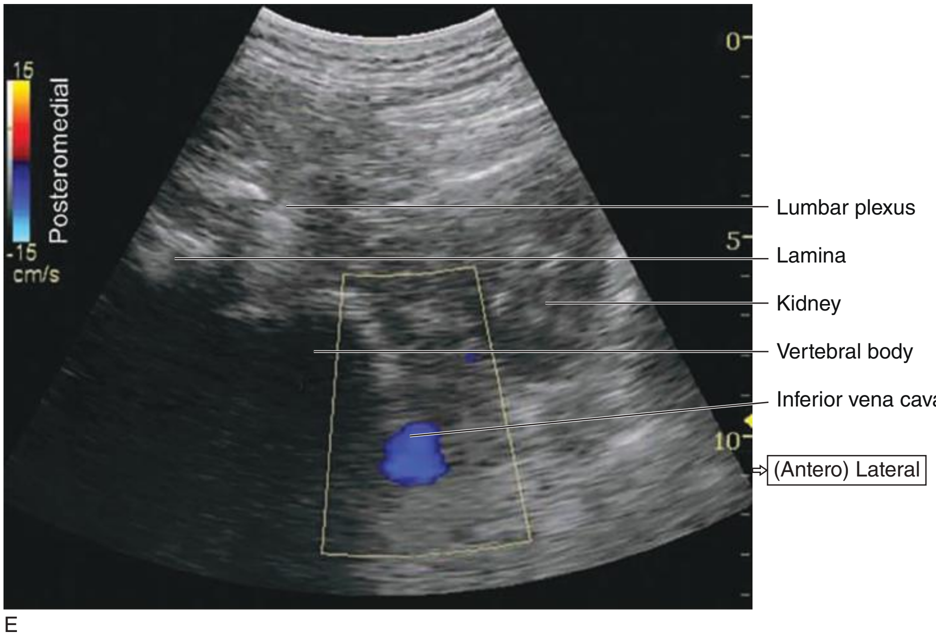

FIGURE 38–2. (*Continued*) (**E**) Transverse image of the right-side lumbar paravertebral space. Color Doppler US captures the flow in the inferior vena cava. The right kidney is also seen.

be seen as an oval structure that ascends and descends with respirations (see Figure 38–2e). The key to obtaining adequate images of the psoas major muscle and lumbar plexus with the transverse oblique scan is to insonate between two adjacent transverse processes (the lumbar intertransverse space).[7] This scanning method avoids the acoustic shadow of the transverse processes, which obscures the underlying psoas major muscle and the intervertebral foramen (angle between the transverse process and vertebral body), and also allows visualization of the articular process of the facet joint. Because the intervertebral foramen is located at the angle between the articular process of the facet joint and vertebral body, lumbar nerve roots can be depicted. The needle can be inserted laterally or medially to the transducer and advanced toward the posterior aspect of the psoas major muscle until either contact of the needle with the lumbar plexus is seen or an ipsilateral quadriceps muscle contraction is elicited.[6] Local anesthetic injection into the lumbar paravertebral area should be performed without excessive force because high injection pressure can lead to unwanted epidural spread and/or rapid intravascular injection.[8]

Recently, the "shamrock method" has become considered one of the standard approaches for US-guided LPB.[9–11] In this method, the transducer is placed transversely in the abdominal flank adjacent to the iliac crest (Figure 38–3a). A shape like a shamrock with three leaves can be seen with the psoas major muscle anteriorly, the erector spinae muscle posteriorly, and the quadratus lumborum muscle at the apex of the transverse process (Figure 38–3b). The lumber plexus can be identified as a hyperechoic oval structure in the posteromedial compartment of the psoas major muscle near the transverse process. By tilting the transducer caudally, the L3 transverse process disappears from the US image, which permits an in-plane posteroanterior needle approach (Figure 38–3c). The needle insertion point is based on the landmark-guided method; that is, approximately 4 cm lateral to the midline[12] or at the junction of the lateral third and medial two-thirds of a line between the spinous process of L4 and a line parallel to the spinal column passing through the posterior superior iliac spine.[13] The needle insertion point can be decided by an ultrasonographical estimation of the distance from the bottom of the transducer to the posteromedial quadrant of the psoas major muscle, where the lumbar plexus is expected to locate.[10] Then, the needle is advanced anteriorly under US guidance until the needle tip reaches to the lumbar plexus or an appropriate muscle twitch is observed. In this view, the inferior vena cava and abdominal aorta can be seen simultaneously anterior to the vertebral body (Figure 38–3d).

The shamrock method has been reported to have several advantages over US-guided LPB using paramedian transverse scan.[9] First, the needle trajectory is almost the same as in the traditional landmark-guided LPB, which means that this method simply adds ultrasonographical information to the landmark-guided LPB approach. Second, needle can be advanced perpendicularly to the US beam, which allows for a clearer visualization of the needle.

LONGITUDINAL OUT-OF-PLANE AND IN-PLANE TECHNIQUES

In the parasagittal longitudinal US image, the acoustic shadow of the transverse process has a characteristic appearance, referred to as the "trident sign" (see Figure 38–1c, d).[14] Once the transverse processes are recognized at approximately 4 cm lateral and parallel to the lumbar spine, to produce a

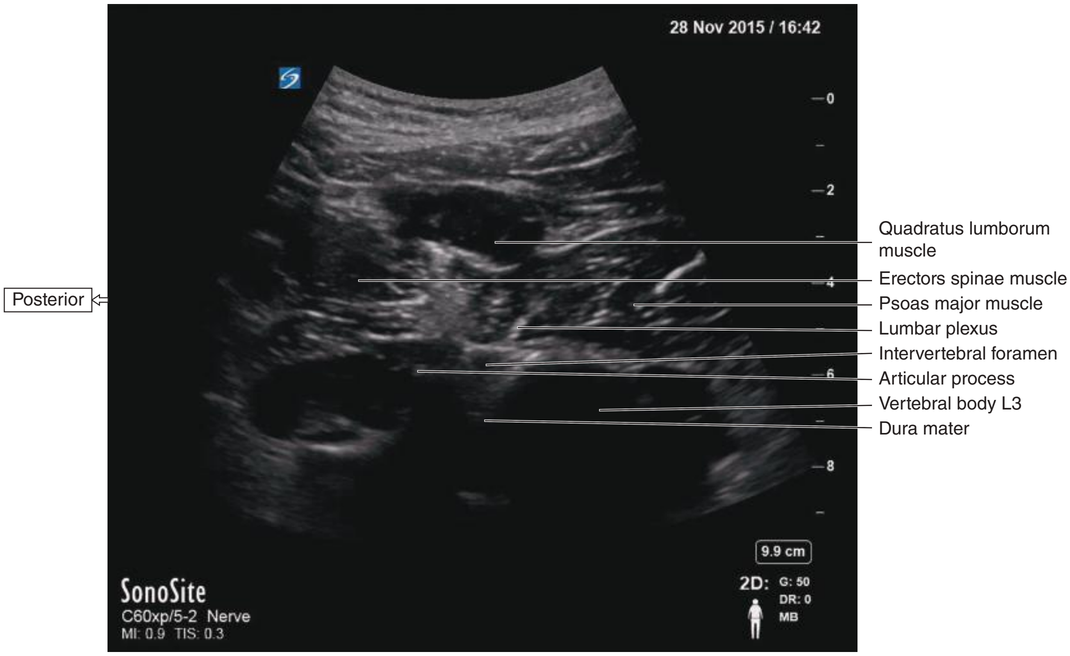
The transducer is placed transversely in the left side of the abdominal flank adjacent to the iliac crest to image the "shamrock" with the transverse process (1). By tilting the transducer (2), the transverse process disappears from the US image, which permits an in-plane posteroanterior needle approach. (**B**) US anatomy of the right lumbar paravertebral region at the level of the L3 transverse process in the shamrock view. A shape that looks like a shamrock with three leaves consists of the erector spinae, quadratus lumborum, and psoas major muscles and the transverse process.



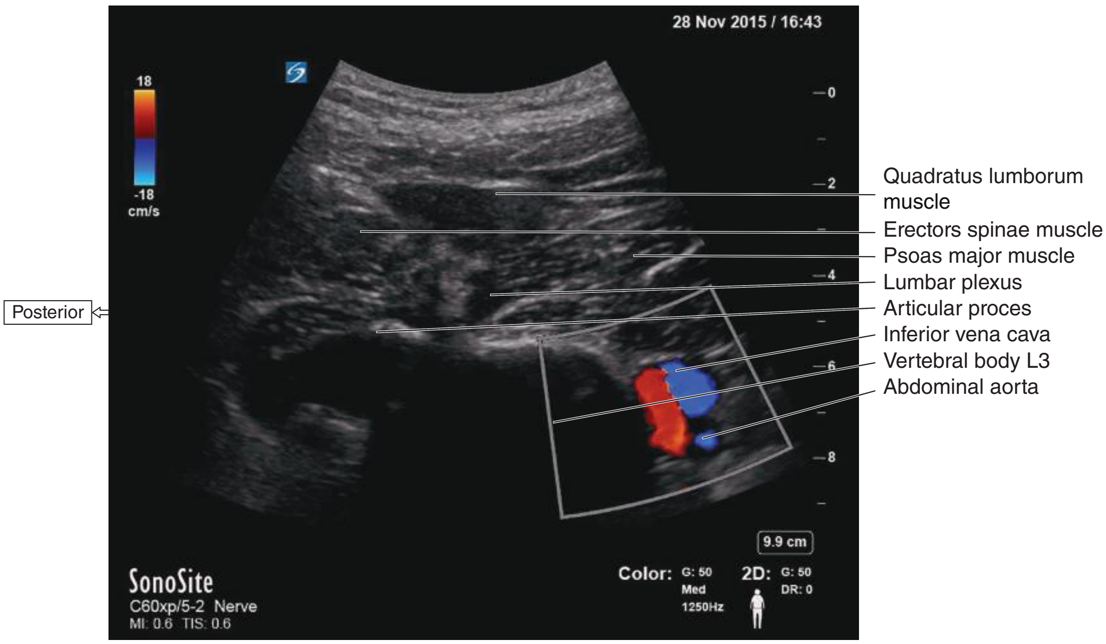


FIGURE 38–3. (*Continued*) (**C**) US anatomy of the right lumbar paravertebral region just caudal to the L3 transvers process (lumbar intertransverse space in the shamrock view). The lumbar plexus root is seen just lateral to the intervertebral foramen. The dura mater is confirmed as a hyperechoic line in the spinal canal through the intervertebral foramen. (**D**) The abdominal aorta and inferior vena cava are confirmed by color Doppler anterior to the vertebral body at the lumbar intertransverse space in the right-side shamrock view.

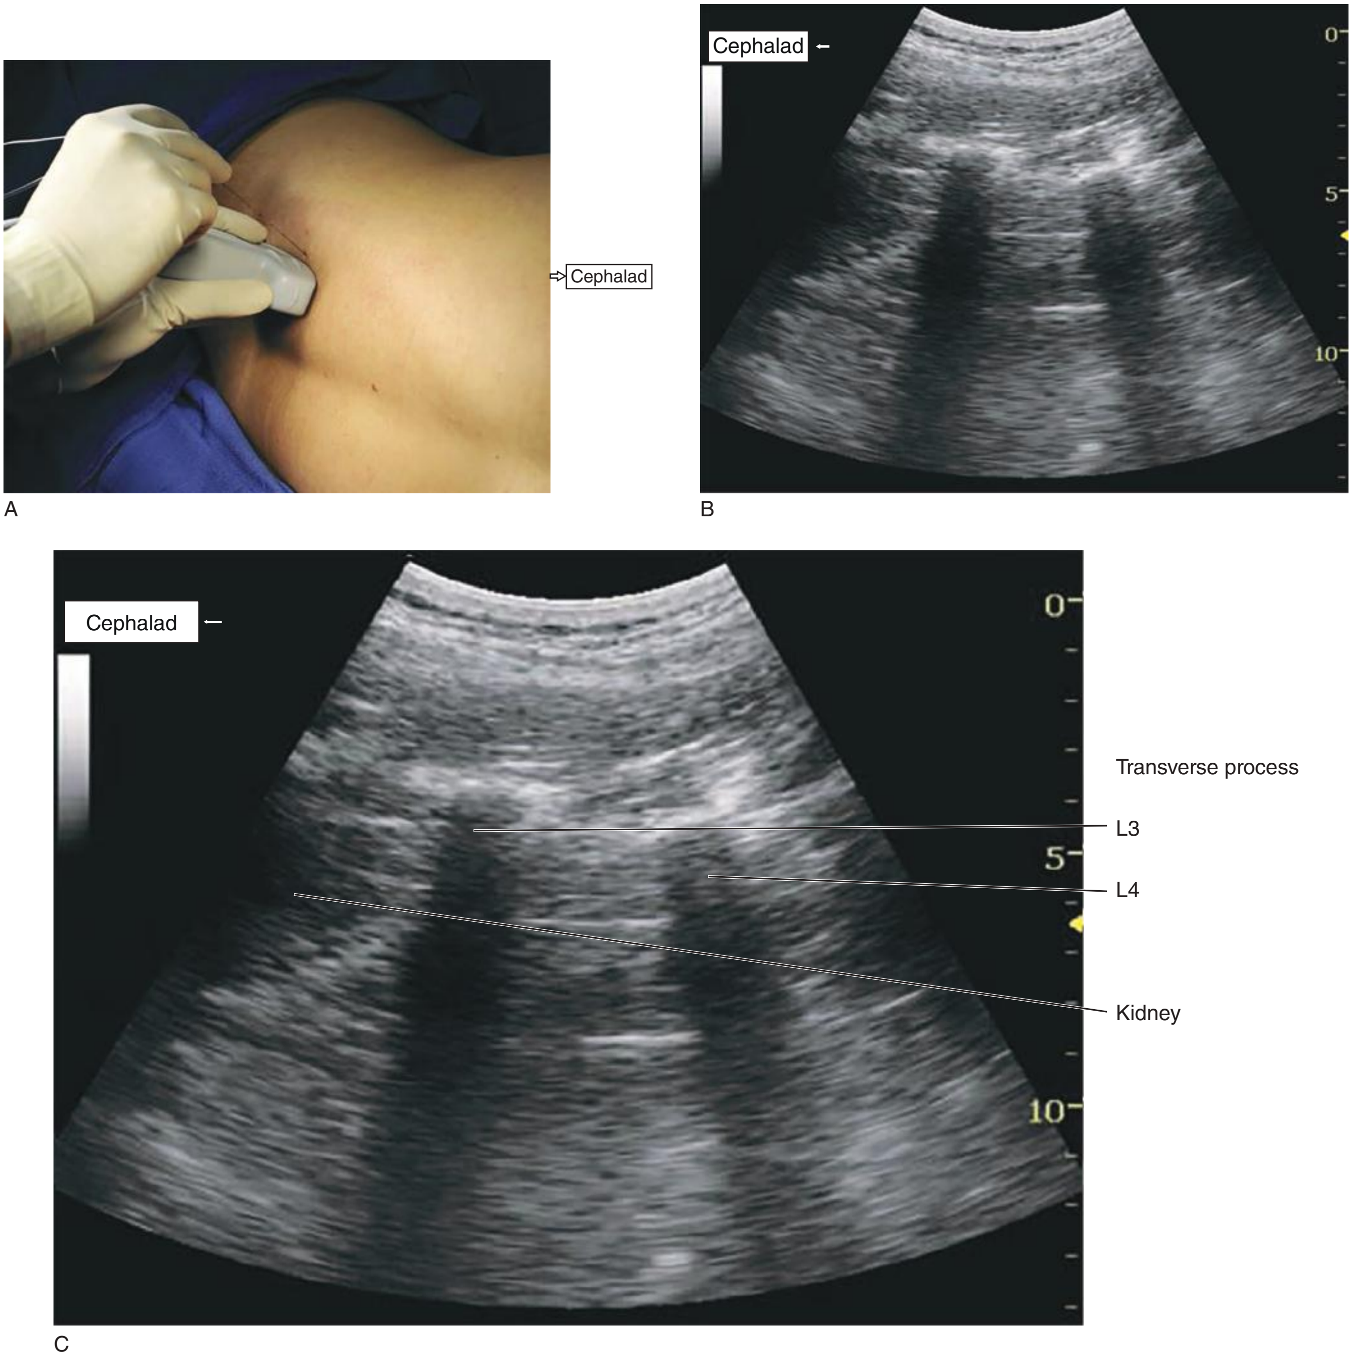

FIGURE 38–4. (**A**) Transducer position and needle insertion point to accomplish US-guided lumbar plexus block in the longitudinal parasagittal view using an out-of-plane approach. (**B**) US anatomy of the longitudinal lumbar paravertebral space at the L2–L3 and L3–L4 levels demonstrating the lower pole of the kidney on the left side of the image at a depth of approximately 5 cm. (**C**) Labeled US image of Figure 38–4b.

longitudinal scan of the lumbar paravertebral region (Figure 38–4a), the psoas major muscle is imaged through the acoustic window of the transverse processes. The psoas muscle appears as a combination of longitudinal hyperechoic striations within a typical hypoechoic muscle appearance just deep to the transverse processes (see Figure 38–1c, d). Some hyperechoic striations may appear particularly intense and may mislead the operator to interpret them as roots of the lumbar plexus; therefore, the identification of the roots in a longitudinal scan is not reliable without nerve stimulation. This unreliability is partly because intramuscular connective tissues (eg, septa, tendons) within the psoas muscle are thick and may be indistinguishable from the nerve roots at such a deep location. As the transducer is moved progressively cephalad, the lower pole of the kidney often comes into view as low as the level of L2–L4 (Figure 38–4b, c). The goal of the technique

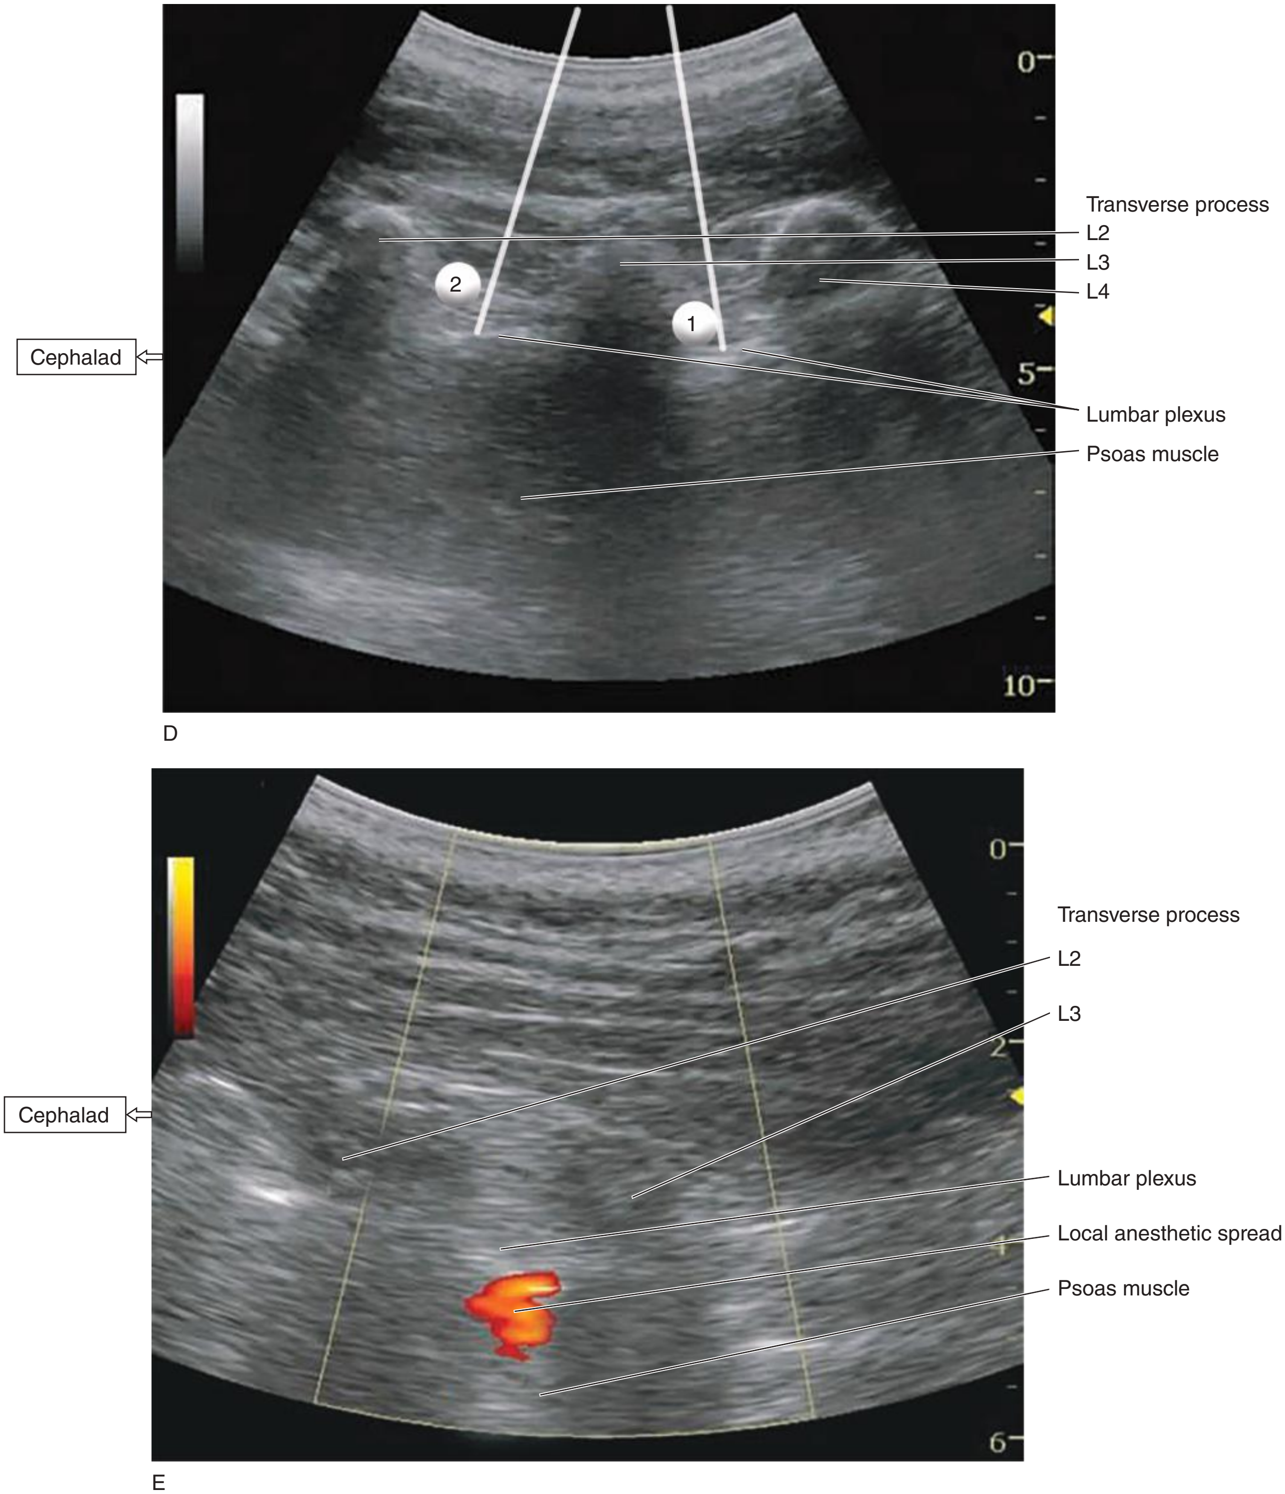

FIGURE 38–4. (*Continued*) (**D**) Simulated needle insertion paths (1, 2) to inject local anesthetic at two different levels to accomplish a lumbar plexus block using an out-of-plane technique. (**E**) Local anesthetic disposition during injection into the psoas muscle and the L2–L3 level. The spread of local anesthetic is often not well visualized using two-dimensional imaging.

is to guide the needle through the acoustic window between the transverse processes (between the "teeth" of the "trident") of L3–L4 or L2–L3 into the posterior part of the psoas major muscle containing the roots of the lumbar plexus. Both out-of-plane (see Figure 38–4a) and in-plane approaches can be employed with the parasagittal longitudinal technique. After obtaining ipsilateral quadriceps muscle contractions, local anesthetic is injected (Figures 38–4d) with a real-time visualization of the injection into the posterior part of the psoas major muscle (Figure 38–4e).

CHAPTER 39

Lumbar Paravertebral Sonography and Considerations for Ultrasound-Guided Lumbar Plexus Block

Manoj K. Karmakar

INTRODUCTION

Lumbar plexus block (LPB) produces anesthesia of the major components of the ipsilateral lumbar plexus, the femoral nerve (FN), lateral femoral cutaneous nerve (LFCN), and the obturator nerve (OBN)[1] LPB is used as a sole technique[2–4] or in combination with a sciatic nerve[5] block for anesthesia or analgesia in patients having hip[2–4] or lower extremity surgery.[2] It is also referred to as psoas compartment block (PCB)[2,6,7] or posterior lumbar plexus block (PLB).[3,7] The term PCB was originally coined by Chayen and colleagues.[6] They believed that branches of the lumbar plexus and parts of the sacral plexus were located close to each other in a "compartment" between the psoas major and quadratus lumborum muscles at the level of the L4 vertebra[6] and could be identified using "loss of resistance."[6] However, the lumbar plexus is located within the substance of the psoas muscle[8–11] and local anesthetic is injected into a fascial plane within the posterior aspect of the psoas muscle during an LPB.[9,10]

LPB is traditionally performed using surface anatomical landmarks and peripheral nerve stimulation.[12] The main challenges with accomplishing LPB with anatomical landmarks and peripheral nerve stimulation relate to the depth at which the lumbar plexus is located.[13] Small errors in estimation of landmark or angle of needle insertion can lead to the block needle being directed away from the plexus, resulting in inadvertent deep needle insertion or renal[12,14] or vascular injury.[12,14–16] Therefore, real-time monitoring of the needle and local anesthetic injection during an LPB is desirable and may improve the accuracy and safety of the technique. While fluoroscopy and computed tomography can be used to improve precision during an LPB, they are impractical in a busy operating room environment, costly, and, more importantly, associated with exposure to radiation. Ultrasound (US) is increasingly being used to guide peripheral nerve blocks, and it is only logical that ultrasound-guided (USG) LPB is of interest because of the ever-increasing availability of US machines, which produce high-quality images, in the operating room. US has been used to preview the relevant anatomy,[7,9,10,13,17] measure the depth to the transverse process, guide the block needle to the posterior aspect of the psoas muscle or the lumbar plexus in real time,[10,13,17–19] and monitor needle–nerve contact[10] or spread of local anesthetic[10,17,19] during an LPB. Understanding of the sonoanatomy of the lumbar paravertebral region is a prerequisite to using US for LPB. This chapter briefly describes the techniques used to perform lumbar paravertebral sonography, the relevant sonoanatomy, and the practical considerations for using US for LPB.

GROSS ANATOMY

The lumbar plexus is formed by the union of the anterior primary rami of L1, L2, and L3 and the greater part of L4 (Figure 39–1) within the substance of the psoas muscle (Figures 39–2, 39–3, 39–4, and 39–5).[8] It also receives variable contribution from T12 (subcostal nerve) and L5 (see Figure 39–1). The lumbar plexus is located in an intramuscular fascial plane or "compartment," also referred to as the psoas compartment, within the posterior one-third of the psoas muscle (Figure 39–6)[8,9] and is very closely related to the lumbar

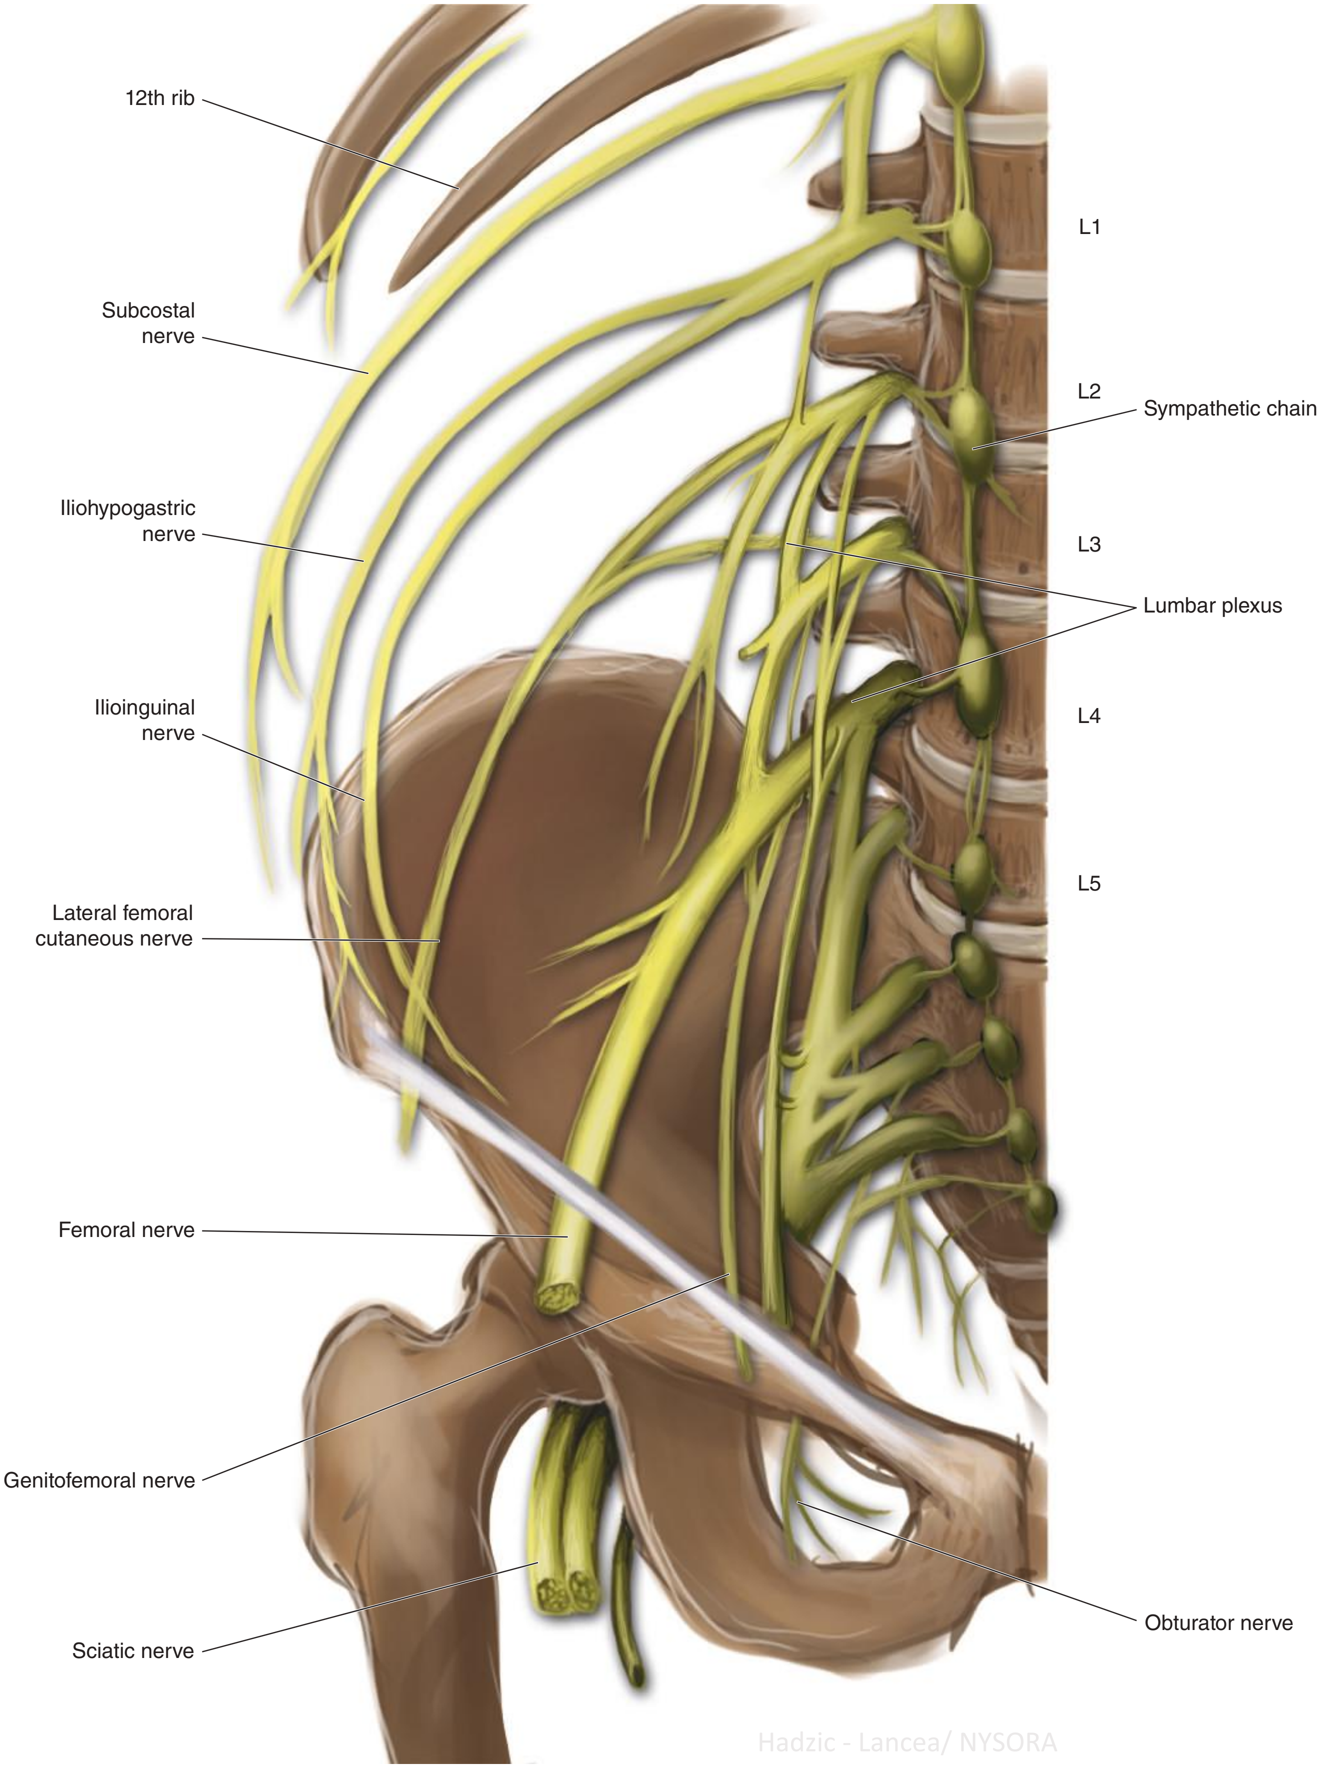

FIGURE 39–1. Lumbar plexus and its three major components: the lateral femoral cutaneous, obturator, and femoral nerves. Note the close anatomical relation of the lumbar plexus to the transverse processes of the vertebra and the lumbar sympathetic chain.

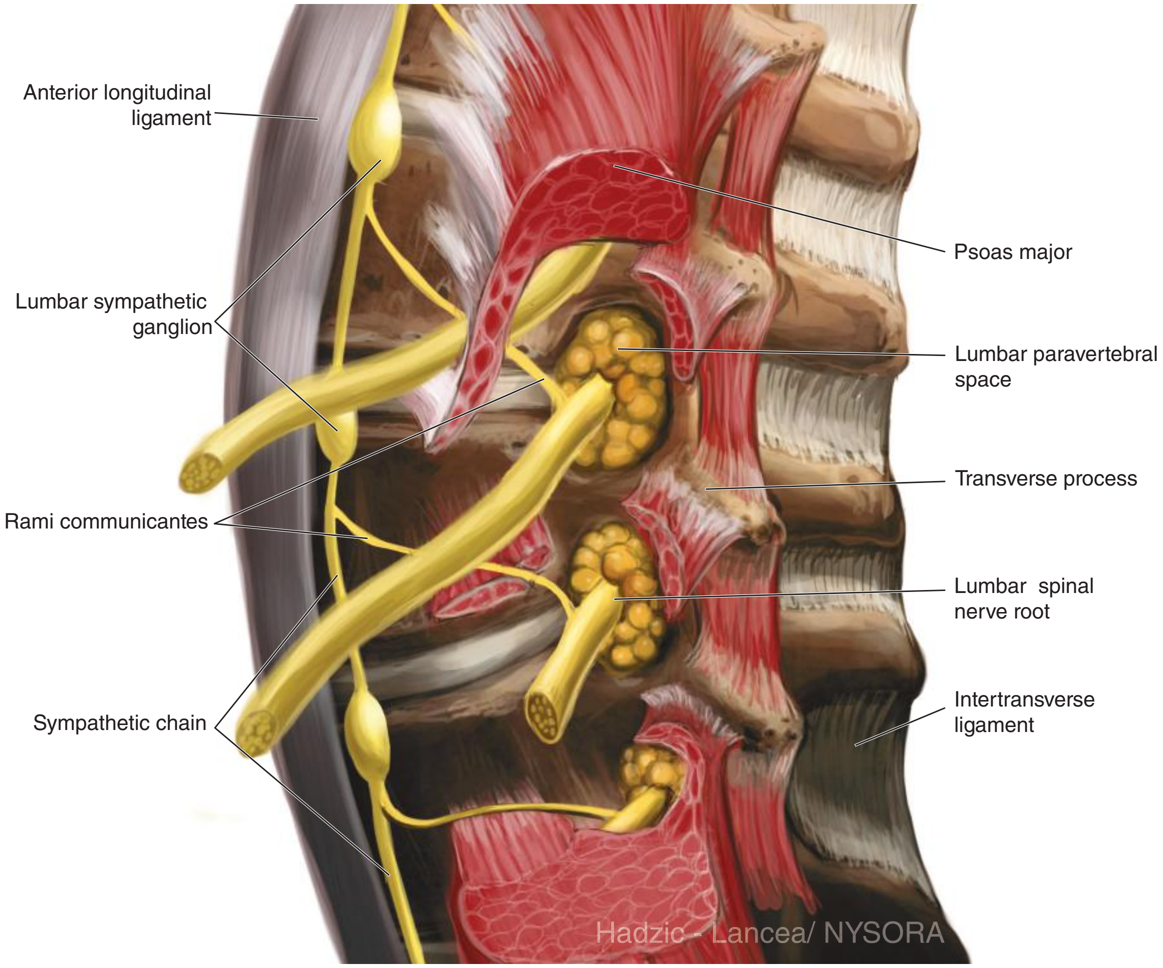

FIGURE 39–2. Location of the lumbar nerve roots within the substance of the psoas muscle and its relation to the transverse process of the lumbar vertebrae. Also note the formation of the lumbar paravertebral space between the larger (fleshy) anterior part of the psoas muscle, which originates from the anterolateral surface of the vertebral body, and the thinner (accessory) posterior part of the muscle, which originates from the anterior aspect of the transverse processes.

FIGURE 39–3. Human cadaver dissection image showing the lumbar plexus nerves within the substance of the psoas muscle. The psoas muscle has been split longitudinally to expose the lumbar plexus nerves within the posterior aspect of the muscle.

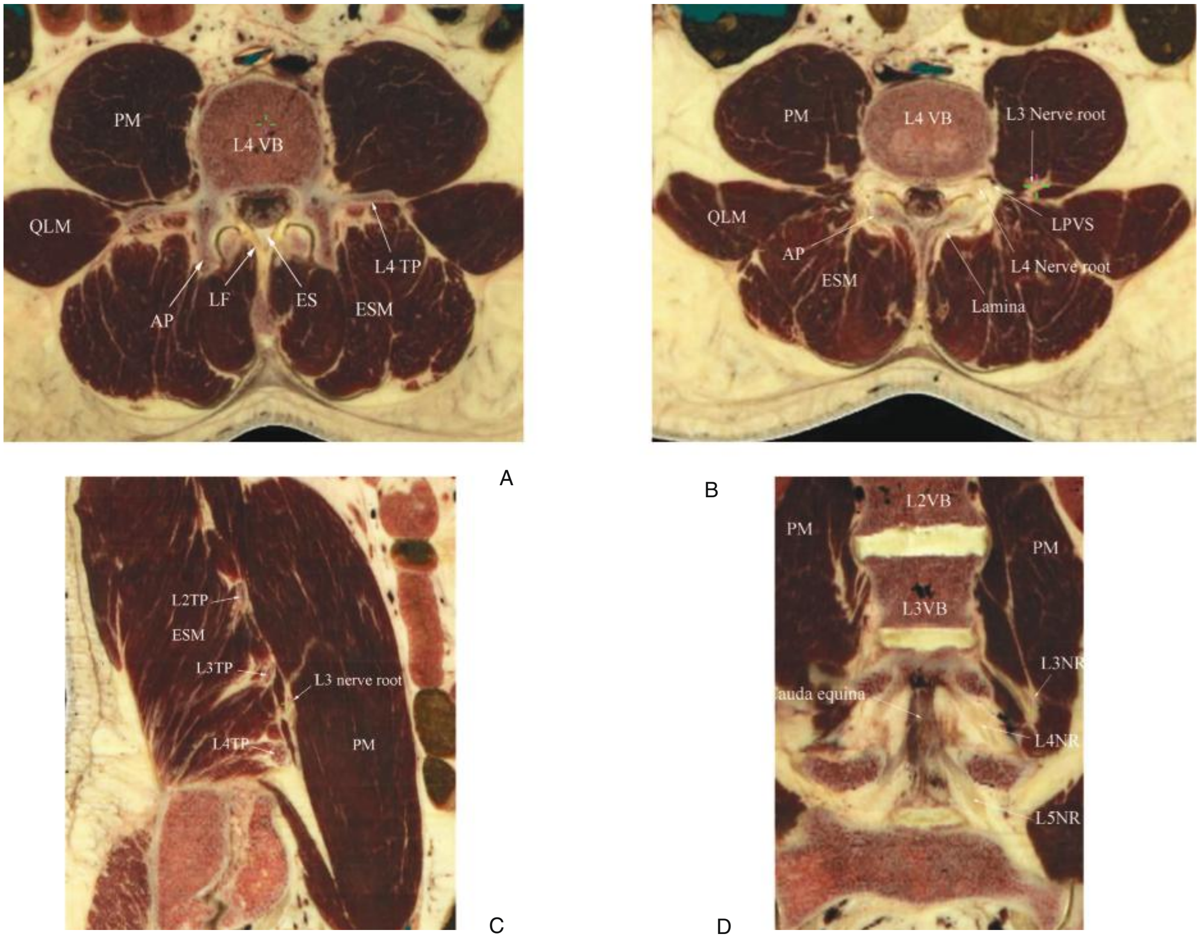

FIGURE 39–4. Multiplanar cadaver anatomical sections showing the anatomical relation of the lumbar nerve root and lumbar plexus to the psoas muscle (PM). (**A**) Cross-section through the L4 vertebral body and transverse process, corresponding to the level at which the paramedian transverse oblique scan at the level of the transverse process (PMOTS-TP) is performed. (**B**) Cross-sectional cadaver anatomical section from just inferior to the L4 transverse process and through the lower part of the L4 vertebral body, corresponding to the level at which the paramedian transverse oblique scan through the intertransverse space and at the level of the articular process (PMOTS-AP) is performed. (**C**) Sagittal cadaver anatomical section showing the relation of the lumbar plexus to the transverse process (TP) and PM. (**D**) Coronal cadaver anatomical section showing how the lumbar nerve roots, after they exit the intervertebral foramen, take a steep caudal course and enter the substance of the PM more caudally. The "reference-marker" of the Java application is seen as a "green cross-hair," which represents the same anatomical point in the multiplanar cadaver anatomical sections. AP, articular process; ES, epidural space; ESM, erector spinae muscle; LF, ligamentum flavum; LPVS, lumbar paravertebral space; NR, nerve root; QLM, quadratus lumborum muscle; TP, transverse process; VB, vertebral body.

transverse processes. The larger anterior (fleshy) part of the psoas muscle originates from the anterolateral surface of the vertebral body and the intervertebral disc, while the thinner posterior (accessory) part of the psoas muscle originates from the anterior aspect of the transverse processes[8] (see Figure 39–2). The two parts of the muscle fuse to form the main bulk of the psoas muscle, but close to the vertebral bodies, they are separated by a fascia or space (see Figure 39–2)[8,9] that contains the lumbar nerve root, branches of the lumbar artery (Figures 39–6 and 39–7), and the ascending lumbar vein.[8,9] This wedge-shaped space close to the intervertebral foramen is called the lumbar paravertebral space (LPVS) (see Figures 39–4, 39–5, and 39–6).[9] After it exits the intervertebral foramen, the lumbar nerve root enters the LPVS (see Figures 39–4, 39–5, and 39–6),[9] after which, instead of entering the psoas muscle at the same vertebral level, it takes a steep caudal course (see Figures 39–4, 39–5, and 39–6) and enters the psoas compartment at the vertebral level below (see Figures 39–4, 39–5, and 39–6). This explains why the L3 contribution to the lumbar plexus lies opposite the L4 intervertebral foramen and the L4 nerve root (see Figures 39–4 and 39–5). It is not known if the LPVS is continuous with the psoas compartment at the same vertebral level, but the occurrence of epidural spread after a lumbar plexus block[20] suggests that it is. Once the plexus is formed, it is visualized as a triangular shape, narrow cranially and wider at its caudal portion (see Figure 39–5).[8] The nerves that originate from the plexus also exhibit a fanned-out distribution, with the LFC being outermost, the OBN innermost, and the FN in between.[8] The positions of the LFC and FN within the psoas compartment are relatively consistent,[8] but the position of the OBN is variable and may even lie in a fold of the psoas muscle separate from that enclosing the other two

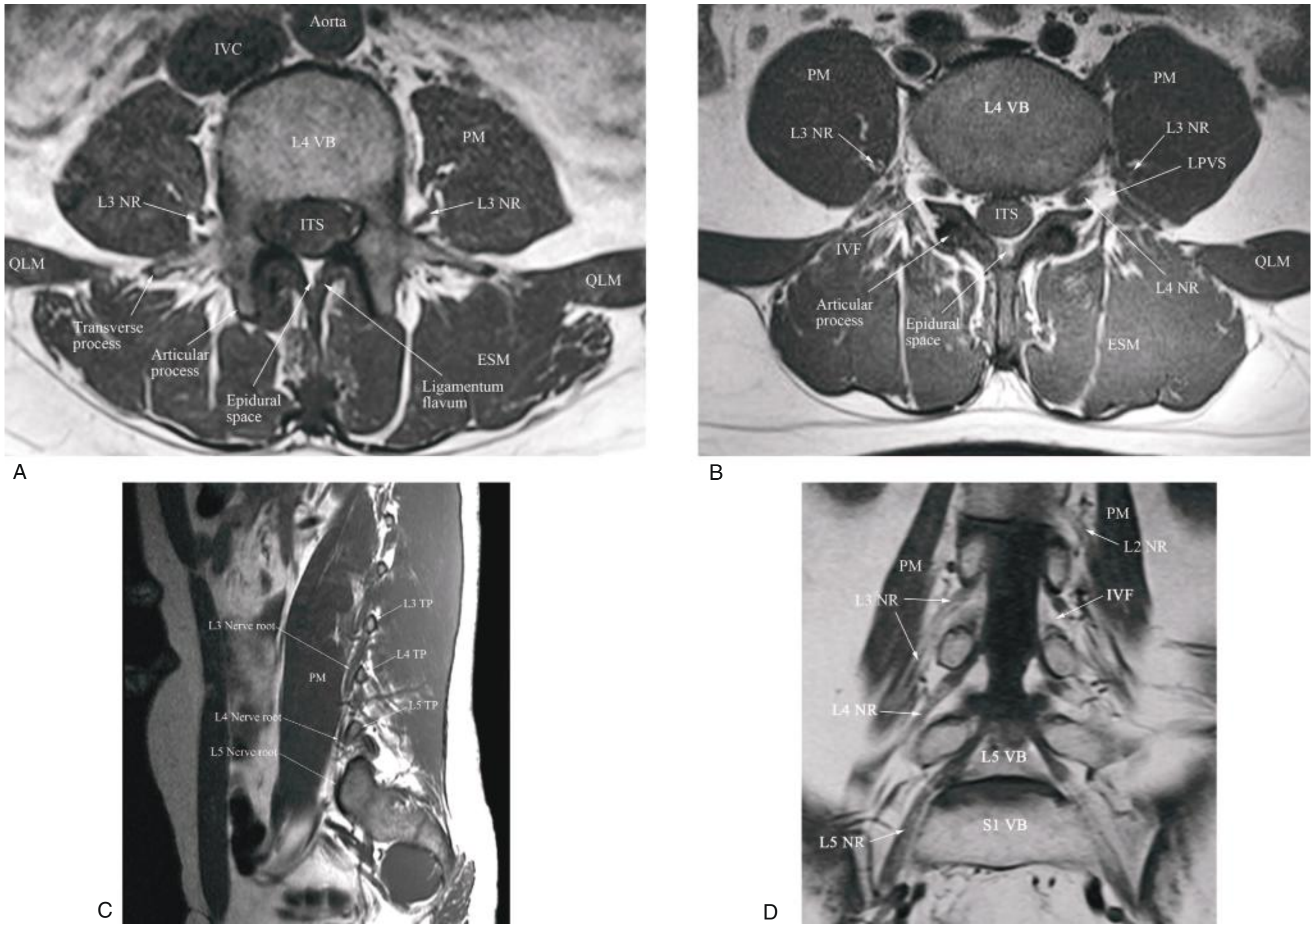

FIGURE 39–5. Multiplanar T1-weighted magnetic resonance imaging (MRI) images showing the anatomical relation of the lumbar nerve root and lumbar plexus to the psoas muscle (PM). (**A**) Transverse view at the level of the L4 vertebral body and the transverse process, corresponding to the level at which the paramedian transverse oblique scan at the level of the transverse process (PMOTS-TP) is performed. (**B**) Transverse view from just below the L4 transverse process and through the lower half of the body of the L4 vertebra and the articular process (inferior), corresponding to the level at which the paramedian transverse oblique scan at the level of the articular process (PMOTS-AP) is performed. Note the hypointense L4 nerve root as it exits the intervertebral foramen (IVF) and enters the hyperintense fat-filled lumbar paravertebral space (LPVS). Also seen in the posterior aspect of the psoas muscle is the L3 nerve of the lumbar plexus, which is surrounded by a layer or hyperintense fat and situated within an intramuscular compartment (the "psoas compartment"). (**C**) Sagittal view of the lumbar paravertebral region at the L3–L5 vertebral level showing the steep caudal course of the lumbar nerve roots. (**D**) Coronal view at the L3–L5 vertebral level showing the steep caudal course of the lumbar spinal nerves after they emerge from the IVF. nerves (Figure 39–8).[8] The depth from the skin to the lumbar plexus also varies with gender and body mass index (BMI).

SONOANATOMY FOR LUMBAR PLEXUS BLOCK

General Considerations

The depth of the lumbar plexus necessitates the use of low-frequency US (5–10 MHz) and curved array transducers to image the lumbar paravertebral anatomy. Low-frequency US provides good penetration but lacks spatial resolution at the depths (5–9 cm) at which the anatomy relevant for LPB is located. The lack of spatial resolution often compromises the ability to locate the lumbar plexus nerves within the psoas muscle. However, recent improvements in US technology, the image processing capabilities of US machines, the availability of compound imaging and tissue harmonic imaging (THI), and the use of new US scan protocols[9,10,19,20] have all contributed to improved imaging of the lumbar paravertebral region.

Ultrasound Scan Techniques

Ultrasound scan for LPB can be performed in the transverse[7,10,13,18,19] or sagittal[17] axis (Figures 39–9 and 39–10) and with the patient in the lateral,[10,17–19,21] sitting, or prone[22] position. A disadvantage of performing LPB with the patient in the prone position is that this position impairs visualization of the quadriceps muscle contraction that is used as an end point for needle placement. The author prefers to perform the US scan with the patient in the lateral decubitus position with the side to be blocked uppermost (see Figure 39–9).[10,17] The following anatomical landmarks are identified and marked on the

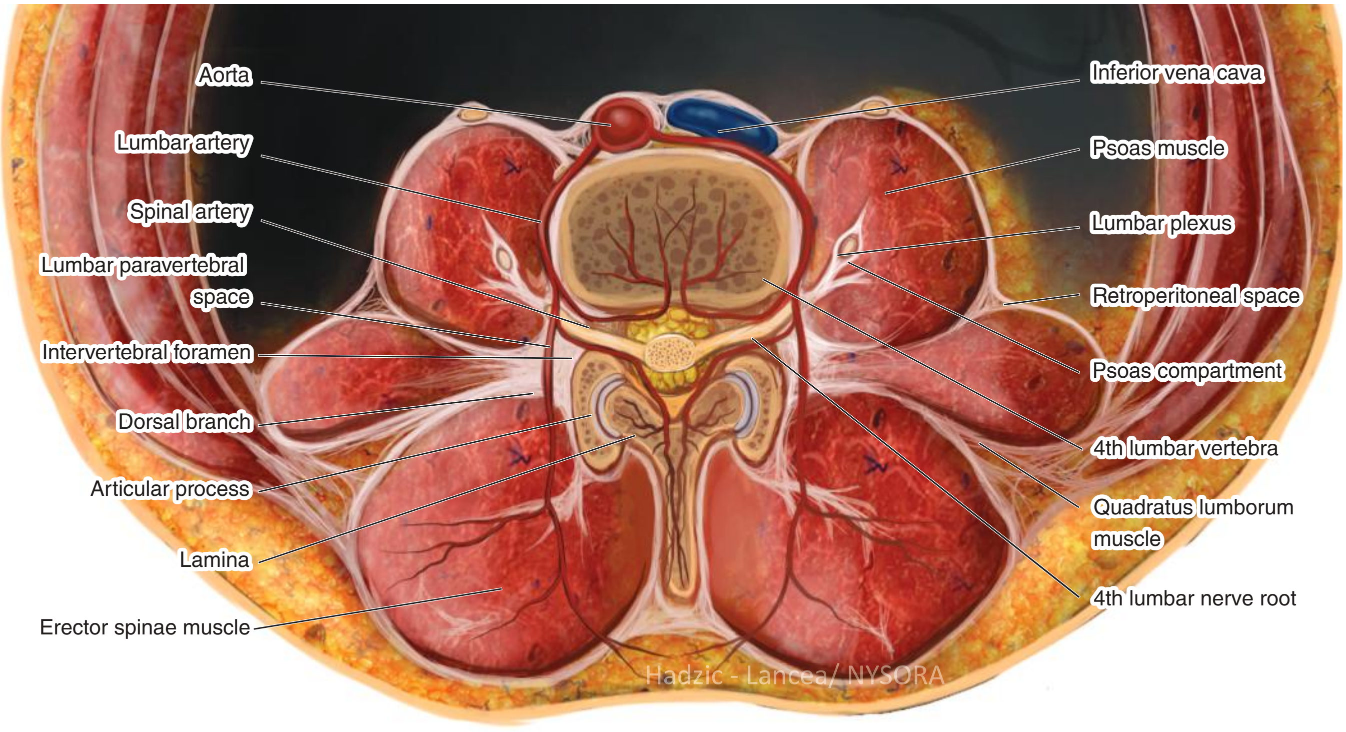

FIGURE 39–6. Transverse anatomy of the lumbar paravertebral region at the L4 vertebral level. Note the origin and branching of the lumbar artery.

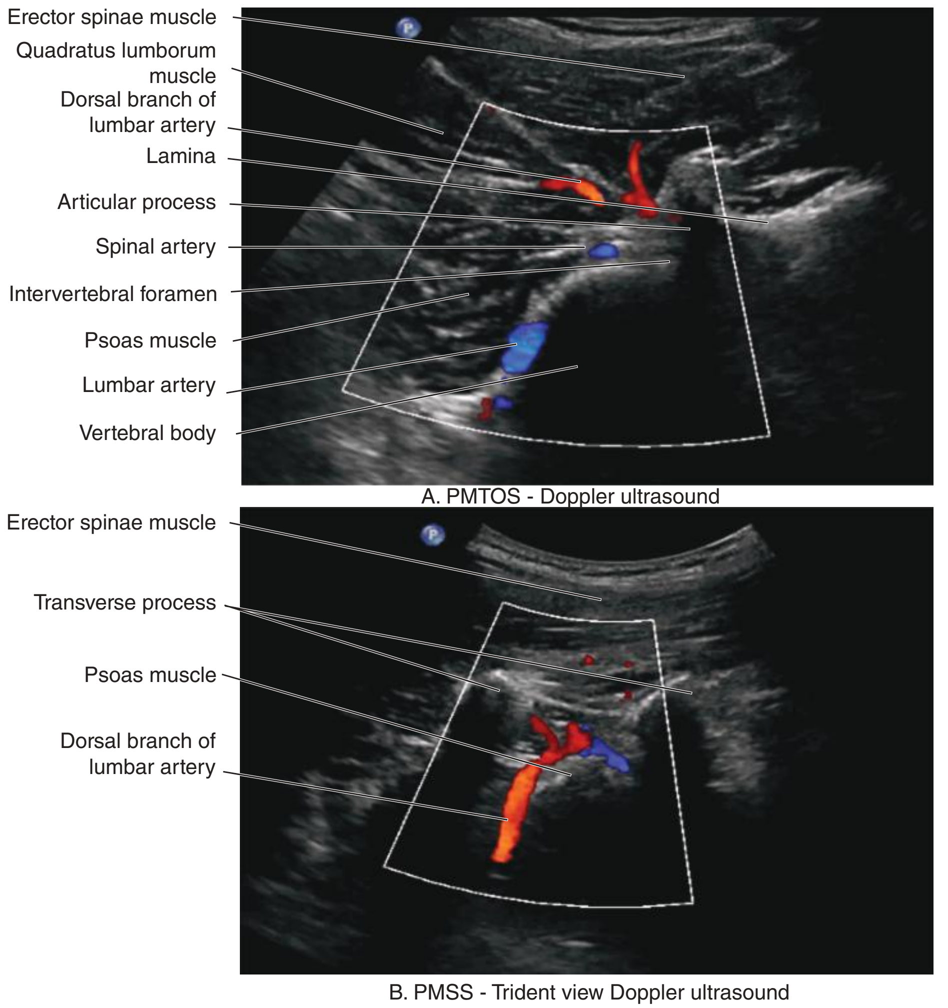

FIGURE 39–7. Color Doppler US images of the lumbar paravertebral region in the (**A**) transverse and (**B**) sagittal scan planes. Note the dorsal branch of the lumbar artery on the posterior aspect of the psoas muscle in both the transverse and sagittal sonograms and the spinal artery in the transverse sonogram. PMSS, paramedian sagittal scan; PMTOS, paramedian transverse oblique scan.

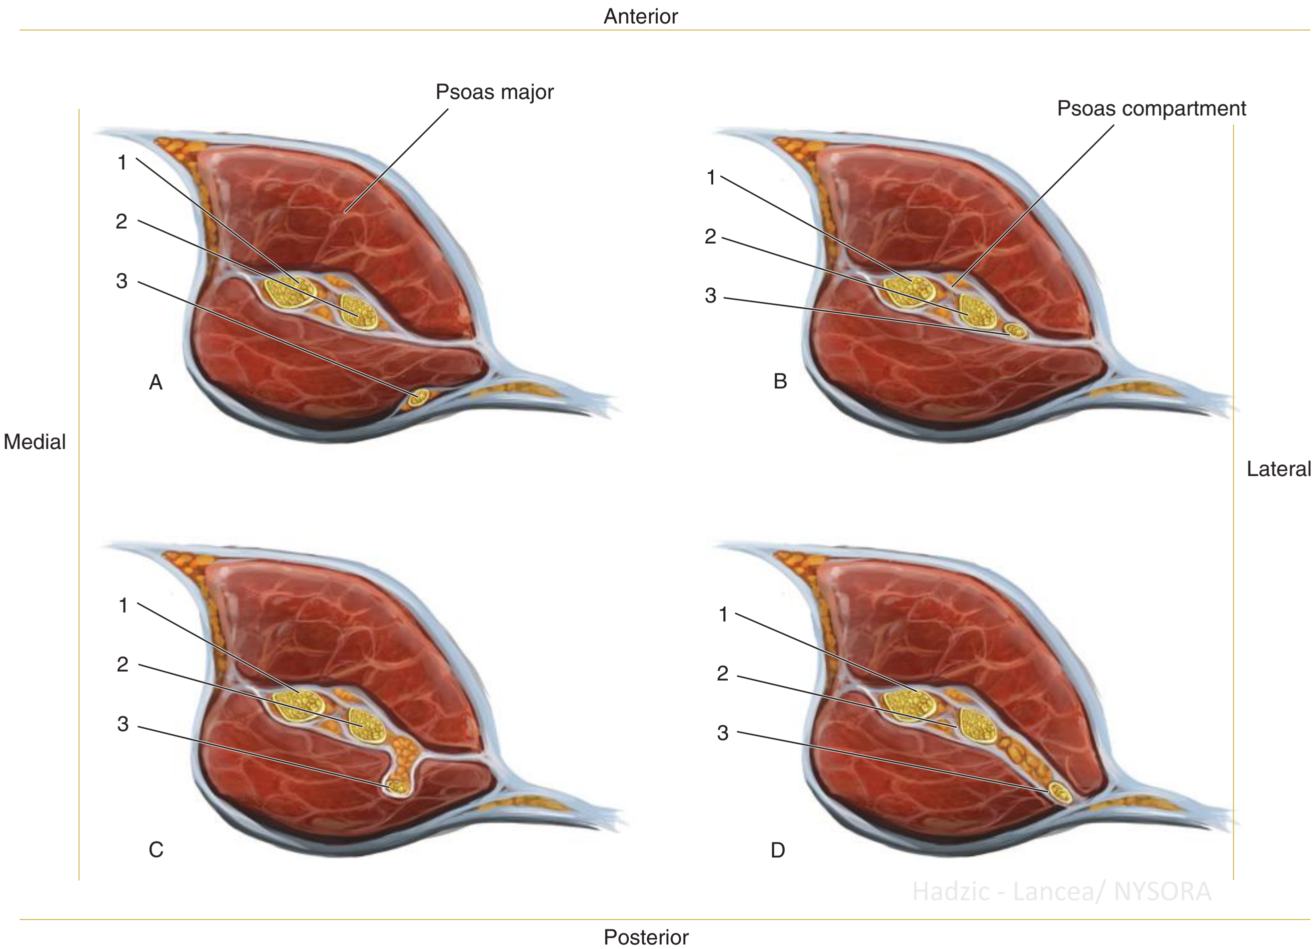

FIGURE 39–8. Position of the (1) lateral femoral cutaneous nerve; (2) femoral nerve; and (3) obturator nerve in the psoas compartment. Note that while the positions of 1 and 2 are fairly consistent, the position of 3 can vary and may even lie in a separate intramuscular fold (c) or compartment separate from the psoas compartment.

skin of the nondependent side of the back: the posterior superior iliac spine, iliac crest, lumbar spinous processes (midline; see Figure 39–9) and intercristal line (see Figure 39–9). Thereafter, a line parallel to the midline, which intersects the intercristal line at a point 4 cm lateral to the midline (paramedian), corresponding to the point at which the block needle is inserted during a landmark-based LPB, is also marked (sagittal scan line; see Figure 39–9). The target vertebral level for the US scan (L3/4/5) is then identified as previously described.[23,24] This involves visualizing the lumbosacral junction (L5–S1 gap) on a sagittal sonogram and then counting cranially to locate the lamina and transverse processes of the L3, L4, and L5 vertebrae.[23,24]

A liberal amount of ultrasound gel is applied to the skin over the lumbar paravertebral region for acoustic coupling. To simplify image orientation, irrespective of the side imaged, the orientation marker of the US transducer is directed cranially during a sagittal scan and laterally (outward) during a transverse scan. For a sagittal scan (Figures 39–9, 39–10, 39–11, and 39–12), the US transducer is positioned over the sagittal scan line (see Figure 39–9a) with its orientation marker directed cranially. For a transverse scan (Figures 39–9, 39–10, 39–13, and 39–14), the US transducer is positioned 4 cm laterally to the midline along the intercristal line and just above the iliac crest (see Figure 39–9b). The transducer is also directed slightly medially (paramedian transverse oblique scan [PMTOS]; see Figure 39–9b) so as to produce a transverse oblique view of the lumbar paravertebral region (see Figures 39–13 and 39–14).[9] During a PMTOS, the US beam can be insonated either at the level of the transverse process (PMTOS-TP; see Figures 39–10b and 39–13) or through the intertransverse space at the level of the articular process (PMTOS-AP: see Figures 39–10c and 39–14).[9,10] Alternatively, a transverse scan can be performed by placing the US transducer more anteriorly in the flank and above the iliac crest (Figures 39–15, 39–16, 39–17, 39–18, and 39–19), as described by Sauter and colleagues with the "shamrock method."[19]

Sagittal Sonoanatomy

On a sagittal sonogram, the lumbar transverse processes are identified by their hyperechoic reflection and an anterior acoustic shadow (see Figures 39–11 and 39–12), which is typical of bone. The acoustic shadow of the transverse processes produces a sonographic pattern referred to as the "trident sign"[17,25] (see Figures 39–11 and 39–12) because of its similarity in shape to

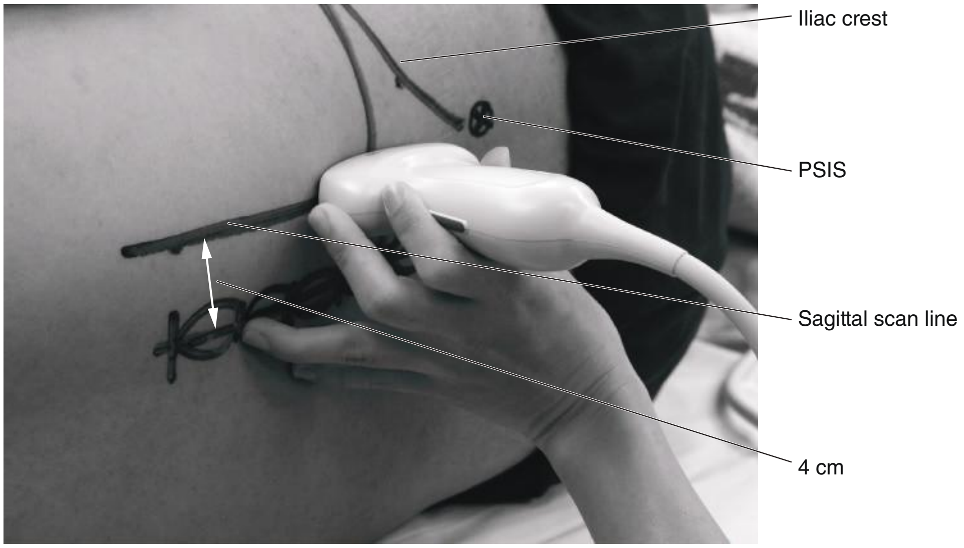

FIGURE 39–9. Position of the patient and US transducer during (**A**) a paramedian sagittal (PMSS) and (**B**) a paramedian transverse oblique (PMTOS) scan of the lumbar paravertebral region. For the PMSS, the US transducer is placed over the "sagittal scan" line, which is a line 4 cm lateral and parallel to the midline (paramedian), at the level of the iliac crest. For the PMTOS, the US transducer is placed laterally to the sagittal scan line and over the intercristal line. Note how the transducer is angled medially for the PMTOS. PSIS, posterior superior iliac spine.

a trident (in Latin, *tridens* or *tridentis*). The psoas muscle is visualized through the acoustic window (see Figures 39–11 and 39–12) of the trident as multiple longitudinal hyperechoic striations against a hypoechoic background typical of muscle (see Figure 39–11). The lumbar plexus nerves are seen as longitudinal hyperechoic structures in the posterior aspect of the psoas muscle (see Figure 39–11) One should note that not all hyperechoic shadows or striations within the psoas muscle are nerves because the psoas muscle contains intramuscular tendons, which also produce hyperechoic shadows (Figure 39–20). Nevertheless, the nerves of the lumbar plexus can be differentiated from the intramuscular tendons as they are thicker than the muscle fibers, take an oblique course through the psoas muscle (see Figure 39–11), and are better visualized after local anesthetic injection.[17] A laterally positioned US transducer will produce a "suboptimal" sagittal sonogram without the US "trident," but with the lower pole of the kidney, which lies anterior to the quadratus lumborum muscle and can reach the L3–L4 level in some patients.

Transverse Sonoanatomy

Kirchmair and colleagues were the first to describe the detailed transverse sonoanatomy of the lumbar paravertebral region relevant for LPB.[7] However, they were unable to delineate the lumbar plexus in the cadavers and volunteers they examined, which they attributed to a loss of spatial resolution due to the use of low-frequency US.[7] The author's group has recently demonstrated that it is possible to accurately delineate the lumbar nerve root, lumbar paravertebral space, lumbar plexus, and

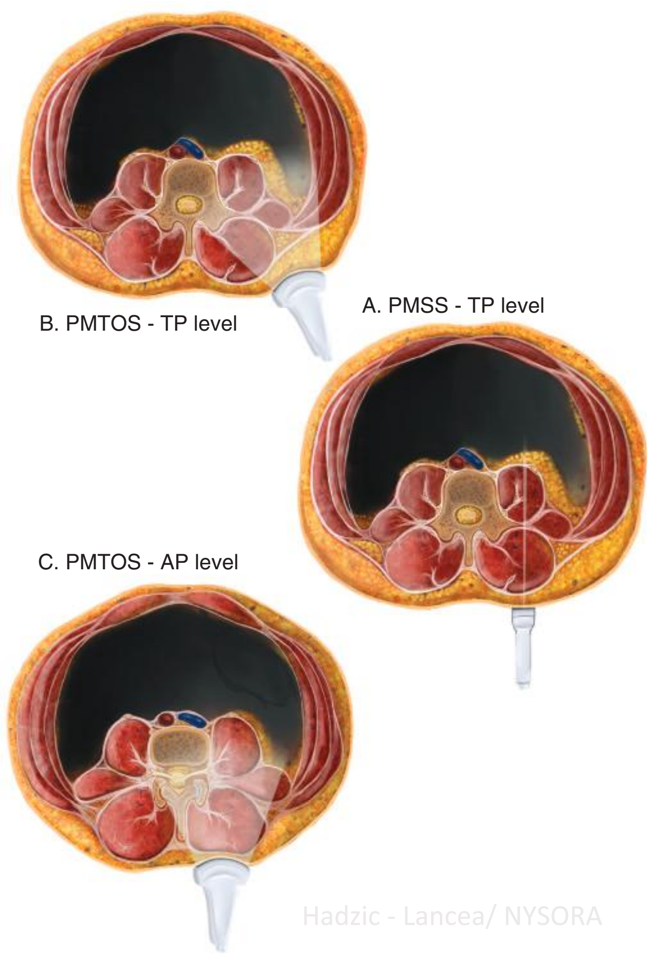

FIGURE 39–10. Plane of US imaging during a sagittal and transverse scan of the lumbar paravertebral region for lumbar plexus block. An image of a US transducer and the plane of the US beam has been superimposed onto transverse anatomical sections of the lumbar paravertebral region to illustrate how the US beam is insonated during (**A**) paramedian sagittal scan at the level of the transverse process (PMSS-TP); (**B**) paramedian transverse oblique scan at the level of the transverse process (PMTOS-TP); and (**C**) paramedian transverse oblique scan at the level of the articular process (PMTOS-AP).

psoas compartment using a paramedian transverse oblique scan (describe earlier).[9] On a typical PMTOS-TP (see Figure 39–10b), the erector spinae muscle, transverse process, psoas major muscle, quadratus lumborum muscle, and anterolateral surface of the vertebral body are clearly visualized (see Figure 39–13). The psoas muscle appears hypoechoic, but multiple areas of hyperechogenicity are also interspersed within the central part of the muscle (see Figure 39–13). These hyperechoic speckles represent the intramuscular tendon fibers of the psoas muscle and are more pronounced below the level of the iliac crest. The inferior vena cava (IVC; on the right side) and the aorta (on the left side) are also identified anterior to the vertebral body (see Figure 39–13) and are useful landmarks to look out for while performing a PMTOS. The lower pole of the kidney, which can extend to the L3–L4 level, is closely related to the anterior surfaces of the quadratus lumborum and psoas muscles and frequently seen as an oval structure that moves synchronously with respiration in the retroperitoneal space (Figure 39–21). The acoustic shadow of the transverse process obscures the posterior aspect of the psoas muscle during a PMTOS-TP (see Figure 39–13). Therefore, the lumbar nerve root and lumbar plexus are rarely visualized through the PMTOS-TP scan window. However, the spinal canal, with the dura and the intrathecal space, may be visualized during a PMTOS-TP (see Figure 39–13) due to the US signal entering the spinal canal through the interlaminar space (see Figure 39–13). Being able to visualize the neuraxial structures during a lumbar paravertebral scan may be useful in documenting epidural spread after an LPB.

In contrast, during a PMTOS through the lumbar intertransverse space and at the level of the articular process (PMTOS-AP) (see Figure 39–10c), apart from the erector spinae, psoas, and quadratus lumborum muscles, the intervertebral foramen, articular process, and lumbar nerve root are clearly delineated (see Figure 39–14).[9] The LPVS is also seen as a hypoechoic space adjacent to the intervertebral foramen (see Figure 39–14),[9] and the lumbar nerve root can be seen exiting the foramen to enter the paravertebral space (see Figure 39–14).[9] After it exits the intervertebral foramen, the lumbar nerve root

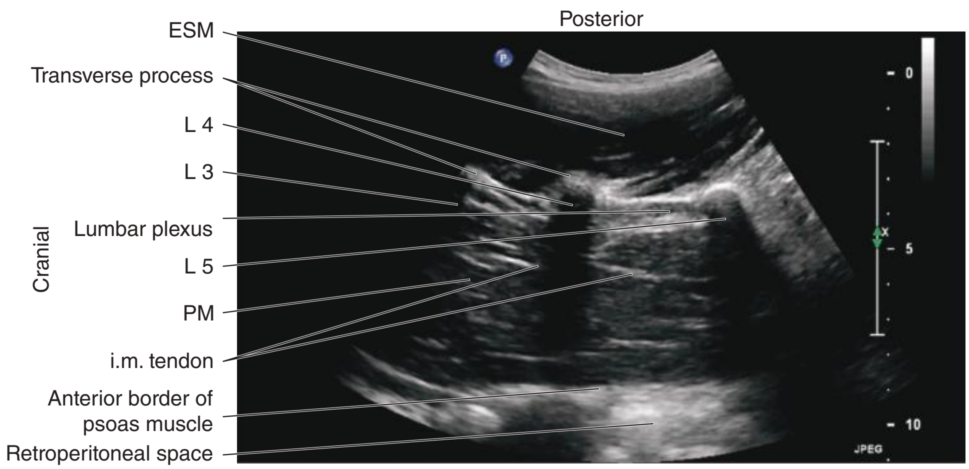

FIGURE 39–11. Sagittal sonogram of the lumbar paravertebral region showing the lumbar plexus as a hyperechoic structure in the posterior aspect of the psoas muscle (PM) between the L4 and L5 transverse processes. Also note the hyperechoic intramuscular tendons within the bulk of the psoas muscle. ESM, erector spinae muscle; i.m. tendon = intramuscular tendon.

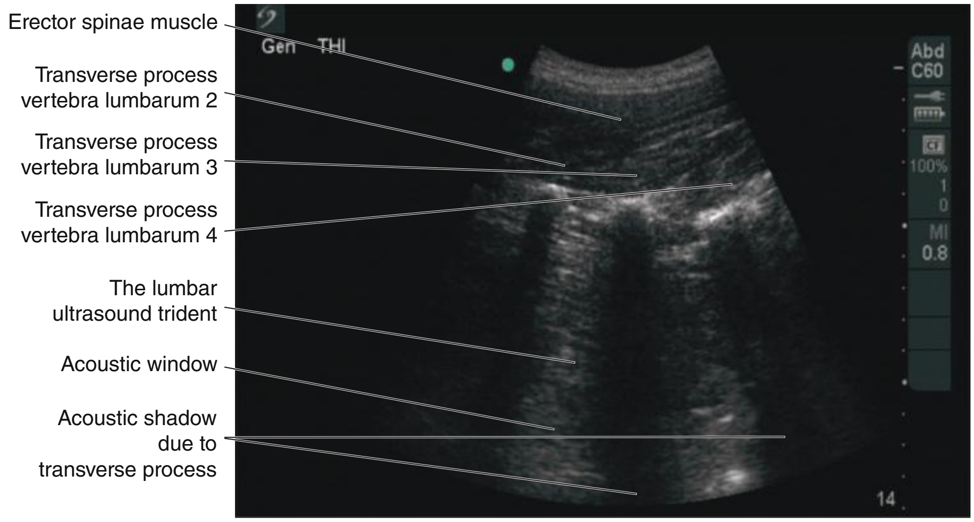

FIGURE 39–12. Sagittal sonogram of the lumbar paravertebral region showing the acoustic shadows of the lumbar transverse processes (L3, L4, and L5), which produce a sonographic pattern called the "trident sign." The psoas muscle is seen in the intervening acoustic window.

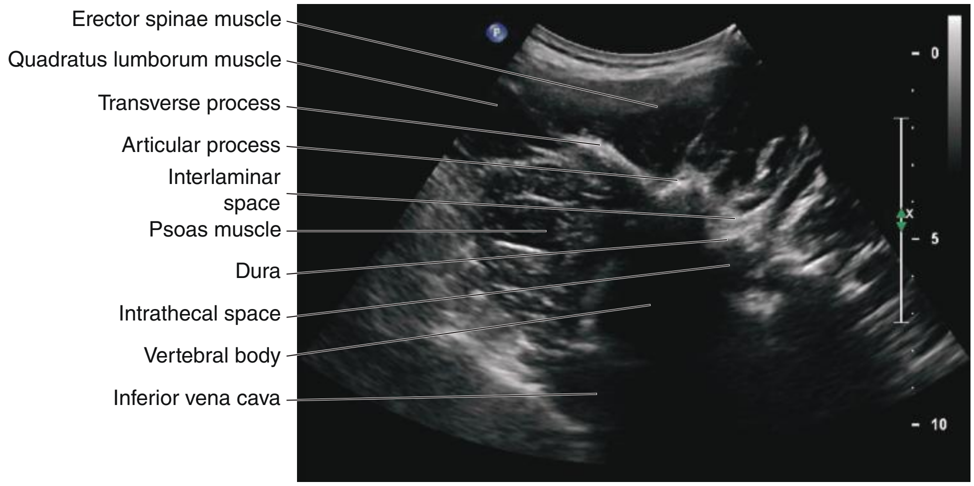

FIGURE 39–13. Paramedian transverse oblique scan of the lumbar paravertebral region at the level of the transverse process (PMTOS-TP). Note how the acoustic shadow of the transverse process obscures the posterior part of the psoas muscle and the intervertebral foramen and how parts of the spinal canal and neuraxial structures (dura and intrathecal space) are seen through the interlaminar space.

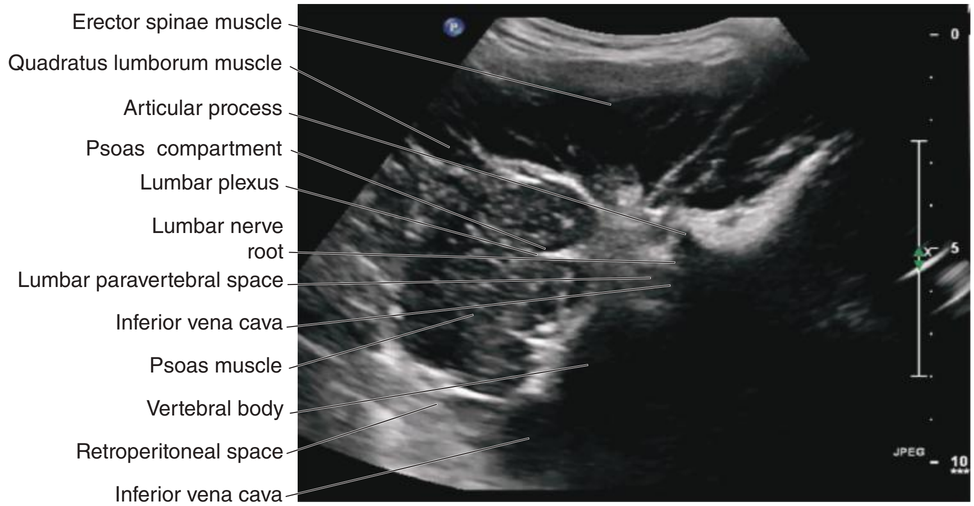

FIGURE 39–14. Paramedian transverse oblique scan of the right lumbar paravertebral region through the lumbar intertransverse space and at the level of the articular process, showing the lumbar plexus as a discrete hyperechoic structure within a hypoechoic intramuscular space (the psoas compartment) in the posteromedial aspect of the psoas muscle.

Note that the transverse axis (**A**) is the primary data acquisition plane and that the corresponding orthogonal image along the secondary data acquisition plane (dotted line with blue arrowhead in [a]) is a coronal view (**B**) showing the lumbar plexus nerves within the psoas muscle.

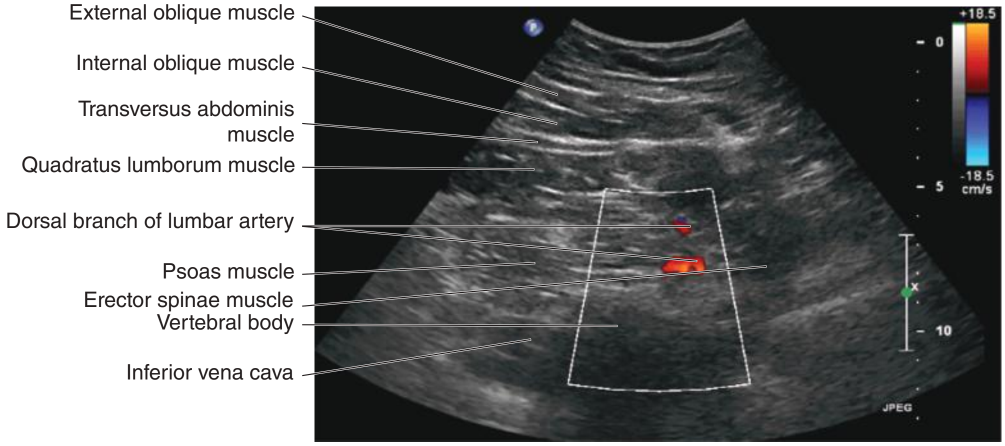

FIGURE 39–19. Color Doppler image of the lumbar paravertebral region obtained with the shamrock method. Note the Doppler signal in the posterior aspect of the psoas muscle from the dorsal branch of the lumbar artery.

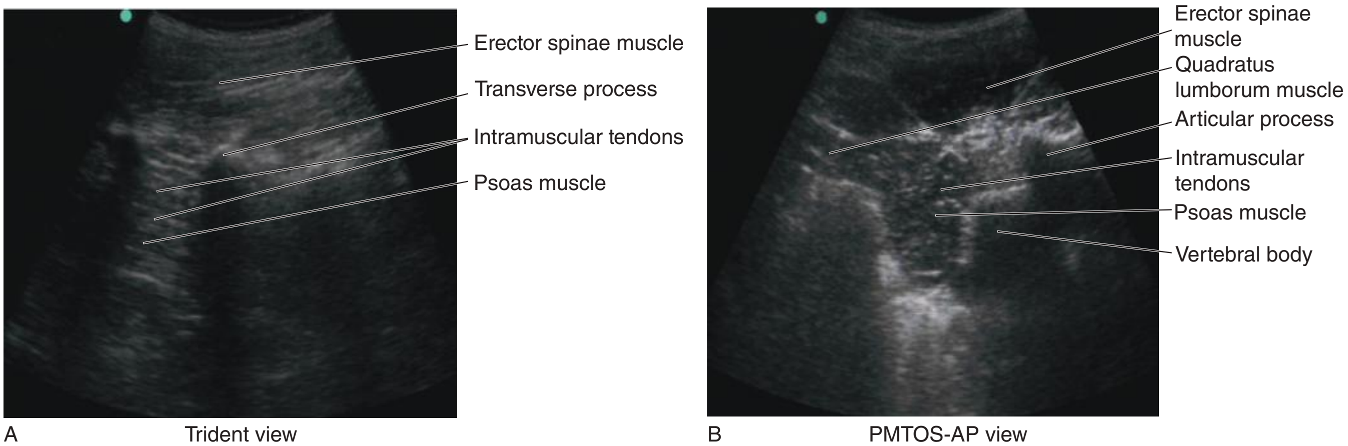

FIGURE 39–20. Sonograms showing intramuscular tendons within the psoas muscle. They are seen as (**A**) hyperechoic striations in a sagittal sonogram or (**B**) as multiple hyperechoic speckles in a transverse sonogram. PMTOS-AP, paramedian transverse oblique scan at the level of the articular process.

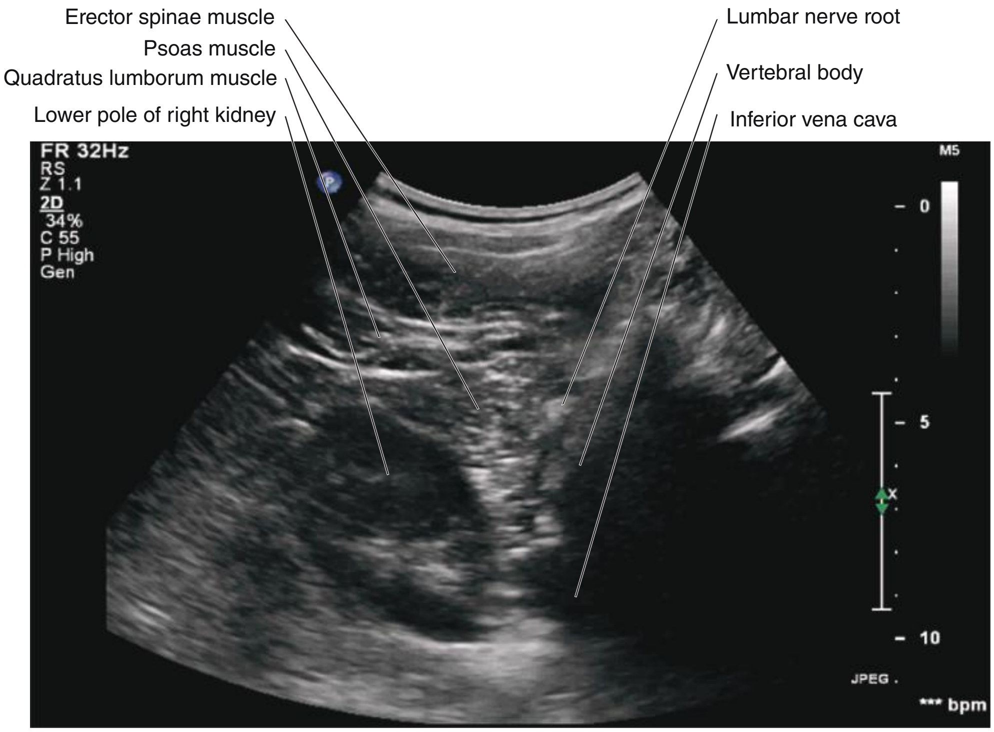

FIGURE 39–21. Paramedian transverse oblique scan of the right lumbar paravertebral region through the intertransverse space and at the level of the articular process (PMTOS-AP). The lumbar nerve root is seen emerging from the intervertebral foramen. Also note that the lower pole of the right kidney is seen anterior to the psoas muscle in this sonogram.

does not enter the psoas muscle directly opposite the intervertebral foramen from which it emerges (see Figure 39–14), but takes a steep caudal course (see Figure 39–14), entering the psoas muscle at the vertebral level below to join the lumbar plexus. The lumbar plexus is seen as a separate hyperechoic structure within a hypoechoic space, the psoas compartment,[9] in the posterior aspect of the psoas muscle (see Figure 39–14).

In a transverse sonogram produced by the shamrock method (see Figure 39–15), the psoas, erector spinae, and quadratus lumborum muscles are also clearly visualized (see Figures 39–16, 39–17, 39–18, and 39–19). The anatomical arrangement of the three muscles around the transverse process—that is, the psoas muscle lying anteriorly, the erector spinae muscle lying posteriorly, and the quadratus lumborum muscle lying at the apex (see Figure 39–16)—produces a sonographic pattern that has been likened to the shape of a "shamrock," with the muscles representing its three leaves.[19] The lumbar nerve root may also be visualized close to the angle between the vertebral body and the transverse process (see Figure 39–16) and the lumbar plexus within the posterior aspect of the psoas muscle, typically about 2 cm anterior to the transverse process (see Figures 39–17 and 39–18).[19] From this position, if the transducer is gently tilted caudally, the acoustic shadow of the L4 transverse process disappears, and the US beam is now insonated through the intertransverse space and at the level of the articular process of the L4 vertebra, similar to that seen with a PMTOS-AP (see Figure 39–17).[9,10,19] As a result, apart from the psoas, erector spinae, and quadratus lumborum muscles, the intervertebral foramen and lumbar plexus may also be visualized (see Figure 39–17).

ULTRASOUND-GUIDED LUMBAR PLEXUS BLOCK

Although it is possible to define the anatomy relevant for LPB with both sagittal[17] and transverse[9] scans, it is not known which approach is best for USG LPB. Therefore, it is not possible to make recommendations of an optimal technique to use for USG LPB. The author believes that the paucity of data on USG LPB reflects only the greater degree of skill required to perform the US scan, interpret the sonograms, and perform the intervention, which is at a depth. Therefore, USG LPB should be considered an advanced-skill-level block and performed only after one has acquired the appropriate level of training and skill. Furthermore, since it is not always possible to accurately delineate the lumbar plexus nerves within the psoas muscle in the US scans, it is prudent to use peripheral nerve stimulation in conjunction with US (dual guidance) for nerve localization during a USG LPB.

Ultrasound-Guided Lumbar Plexus Block Techniques

The following section briefly describes the various techniques used for USG LPB.

1. USG LPB Using the Trident View

As described above, a paramedian sagittal scan is performed with the patient in the lateral decubitus position, with the side to be blocked uppermost (see Figures 39–9 and 39–10). Once an optimal view of the lumbar US trident is obtained

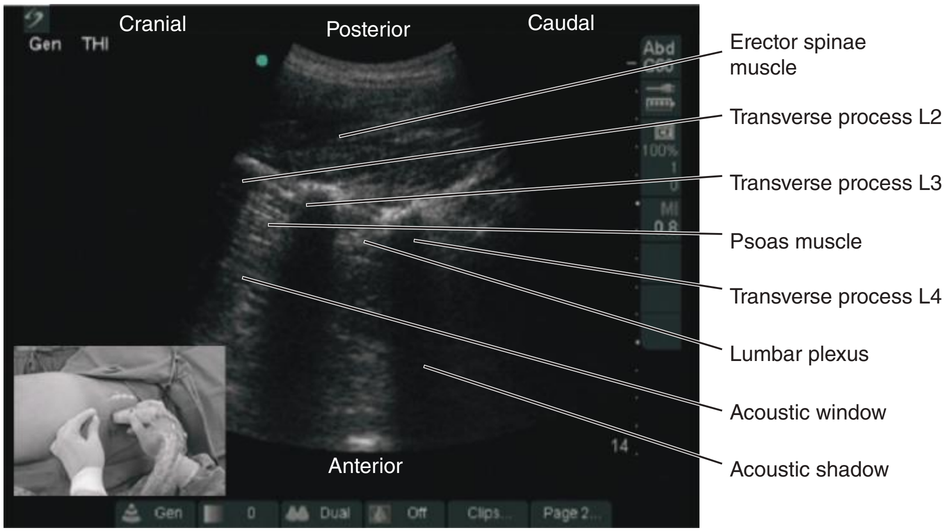

FIGURE 39–22. Sagittal sonogram of the lumbar paravertebral region showing the "trident" view. The psoas muscle is seen in the acoustic window between the transverse processes and is recognized by its typical striated appearance. Part of the lumbar plexus is also seen as a hyperechoic shadow in the posterior aspect of the psoas muscle between the transverse processes of the L3 and L4 vertebrae. The inset photograph shows the orientation of the US transducer and the direction in which the block needle is introduced (in plane) during a USG LPB via the trident view.

(Figure 39–22), an insulated nerve block needle, connected to a nerve stimulator, is inserted in plane from the caudal end of the US transducer (see Figure 39–22).[17] The aim is to guide the block needle through the acoustic window of the lumbar US trident; that is, through the space between the transverse process of L3 and L4 into the posterior aspect of the psoas major muscle until either needle–nerve contact is visualized or an ipsilateral quadriceps muscle contraction is elicited.[17] After negative aspiration, an appropriate dose of local anesthetic (20–25 mL of 0.5% ropivacaine or levobupivacaine) is injected in aliquots over 2–3 minutes and the patient is closely monitored. Spread of local anesthetic within the posterior aspect of the psoas muscle can be visualized in real time, and the nerves of the lumbar plexus are better visualized after the local anesthetic injection (see Figure 39–22).

2. USG LPB Using a Paramedian Transverse Scan

Originally described by Kirchmair and colleagues[13] in cadavers, this technique involves performing a transverse scan of the lumbar paravertebral region to delineate the psoas major muscle (as described above) at the L3–L4 or L4–L5 level. It may be difficult to locate the psoas muscle at the L4–L5 level as the iliac crest interferes with transducer placement, particularly curved array transducers with a large footprint (60 mm). As described above, the author prefers to perform a PMTOS-AP with the patient positioned in the lateral position (Figure 39–23) since it provides better visualization of the anatomy relevant for LPB.[10] Once an optimal PMTOS-AP view is obtained (see Figure 39–14), an insulated block needle, connected to a nerve stimulator, is inserted medially to the US transducer and in the plane of the US beam (in-plane technique) (Figure 23–24a).[10] The point of needle insertion corresponds to a point 4 cm lateral to the midline and at the same location where one would insert the block needle during a landmark-based LPB (see Figure 39–23).[10] The block needle is slowly advanced under real-time US guidance to the posterior aspect of the psoas muscle, and correct needle tip position is confirmed by observing needle–nerve contact (Figure 39–25) and/or an ipsilateral quadriceps muscle contraction (mostly the latter).[10] There are also reports of the block needle being inserted from the lateral border of the US transducer and being advanced anteromedially in plane toward the psoas muscle from a lateral to medial direction.[18,22] As described above, the lumbar plexus is not sonographically visualized in all patients but, when visualized, is seen as a hyperechoic structure in the posterior part of the psoas muscle (see Figure 39–25). Since the block needle is inserted in the plane of the US beam, it can be visualized and tracked in real time (see Figure 39–25). After negative aspiration, an appropriate dose of local anesthetic (20–25 mL of 0.5% ropivacaine or levobupivacaine) is injected in aliquots over 2–3 minutes and the patient is closely monitored (Figure 39–26). Occasionally, needle–nerve contact can be visualized on the US image during needle insertion or after the local anesthetic injection (see Figure 39–25).[10] Also, the lumbar plexus is better visualized after the local anesthetic injection,[10,17] as the hypoechoic local anesthetic surrounds the lumbar plexus nerves (Figures 39–26 and 39–27).

3. The Shamrock Method

Sauter and colleagues recently described an alternative approach for USG LPB,[19] which they refer to as the "shamrock method (Figure 39-24b)."[19] As described above, a transverse scan is performed at the flank and immediately above the iliac crest, with the patient in the lateral position and with the side to be blocked uppermost (see Figures 39–15a, b and 39-24b). Once the sonographic pattern of the "shamrock" is obtained at the level of the L4 transverse process (see Figure 39–16),[19] the US transducer is tilted slightly caudally until the

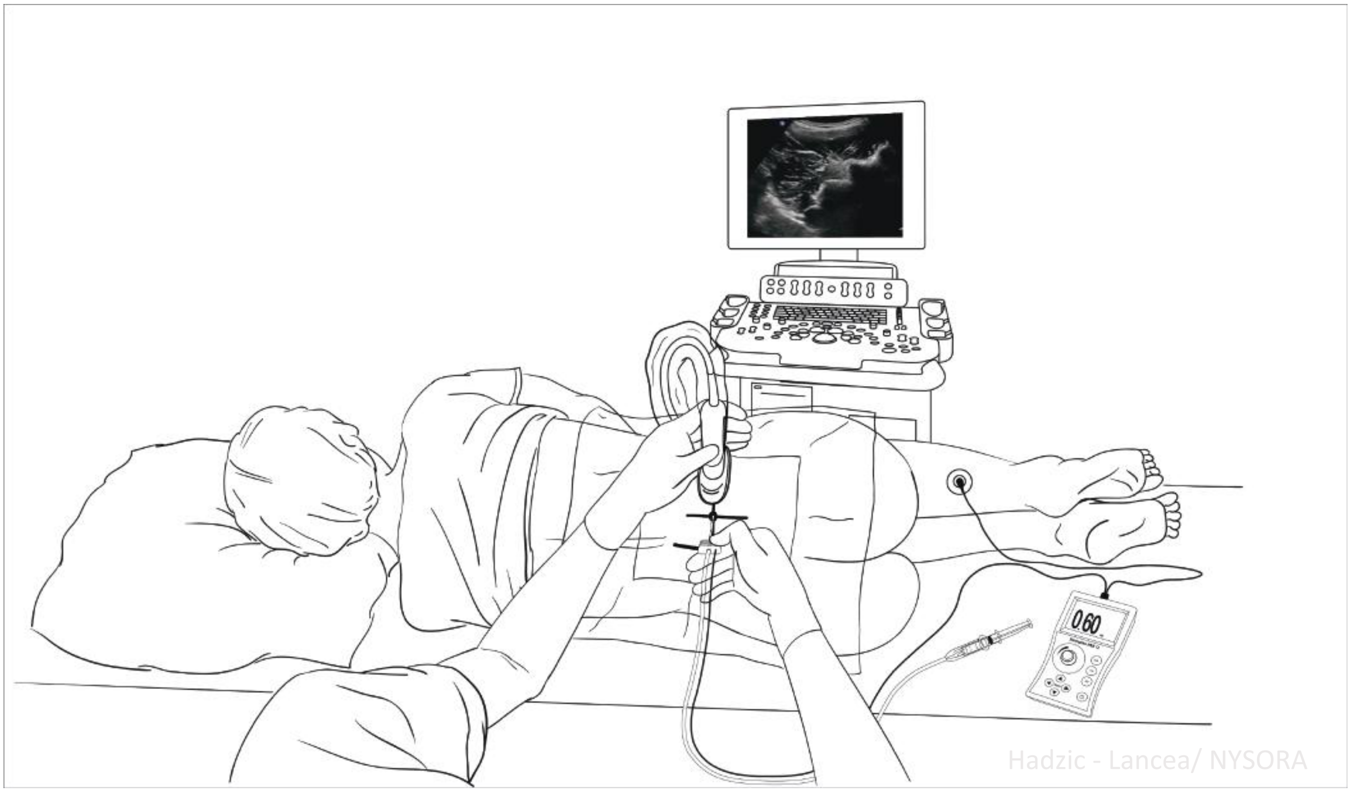

FIGURE 39–23. Position of the patient, anesthesiologist, US system, and US transducer orientation during a paramedian transverse oblique scan through the lumbar intertransverse space and at the level of the articular process.

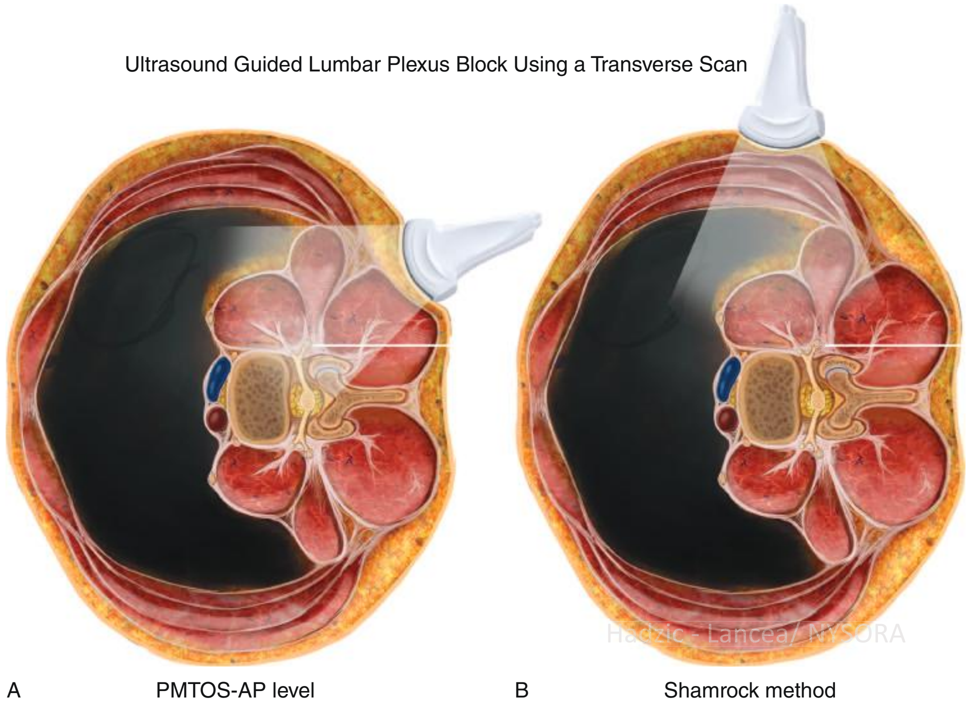

FIGURE 39–24. Position of the US transducer and the plane of the US beam, which has been superimposed on a transverse anatomical section (L4 vertebral level), rendered from the Visible Human Project® male dataset, illustrating the relevant lumbar paravertebral anatomy and how the US beam is insonated during (**A**) the paramedian transverse oblique scan at the level of the articular process (PMTOS-AP) and (**B**) the shamrock method. Note the relationship (in plane) of the nerve block needle to the US beam in both methods.

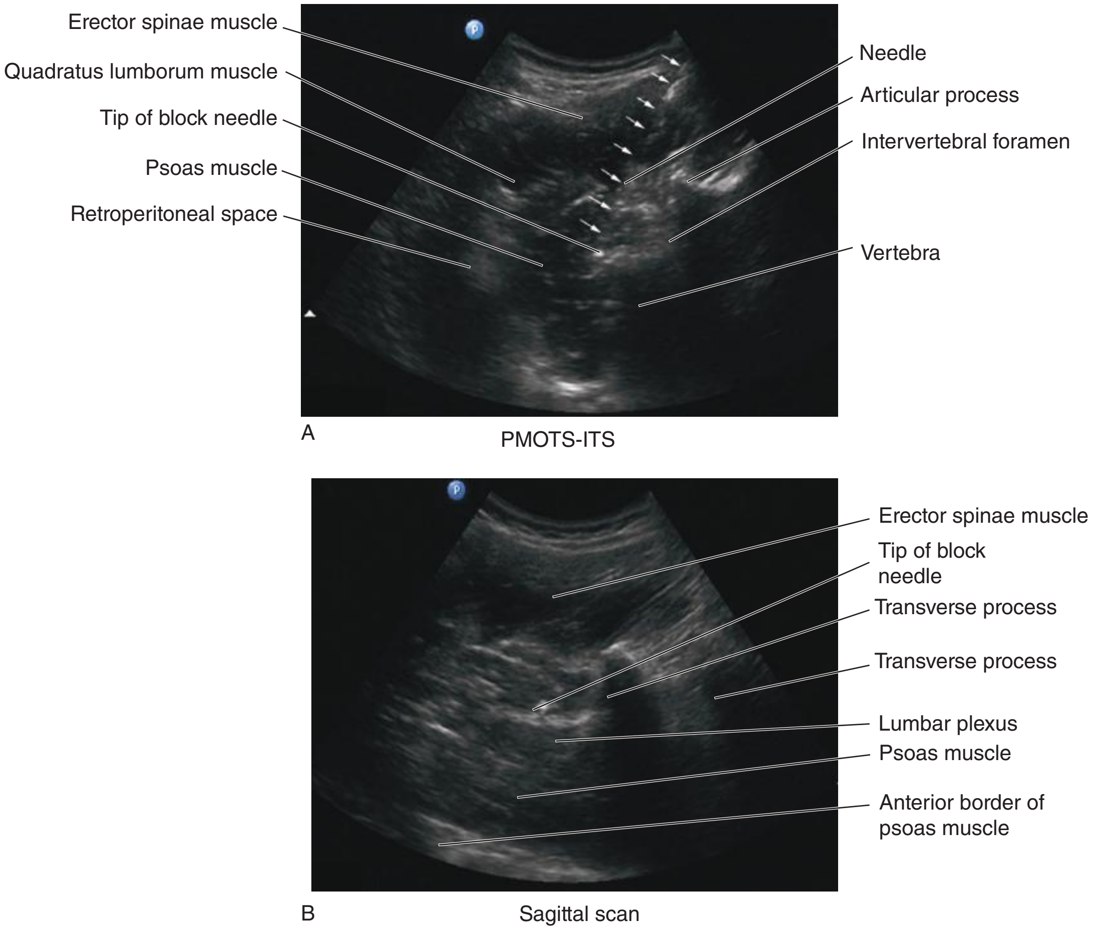

FIGURE 39–25. Sonograms of the lumbar paravertebral region showing the needle–lumbar plexus relationship when an ipsilateral quadriceps muscle contraction is elicited during a USG LPB. (**A**) Paramedian transverse oblique scan at the level of the articular process (PMTS-AP). (**B**) Sagittal sonogram in the same patient, validating the accuracy of the observation. Also note the direction of the in-plane needle insertion.

acoustic shadow of the transverse process is no longer visualized (see Figure 39–17).[19] This view represents the transverse view of the anatomy relevant for LPB through the L4–5 intertransverse space.[19] A line is then drawn on the patient's back extending from the center of the medial end of the IS transducer to the midline (back). A nerve block needle is inserted 4 cm from the midline along this line (Figure 39–28) and gradually advanced anteriorly under real-time US guidance (in-plane needle insertion; Figure 39–29a) until the needle tip is close to the L3 nerve root.[19] Nerve stimulation

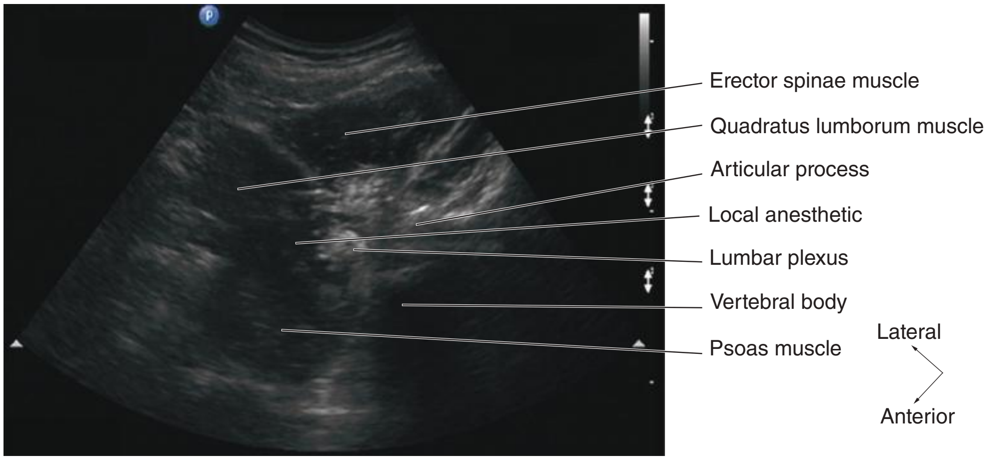

FIGURE 39–26. Transverse sonogram of the lumbar paravertebral region during a USG LPB and after local anesthetic (LA) injection. Note the spread of the LA relative to the lumbar plexus and the distention of the psoas compartment (short white arrows) by the LA.

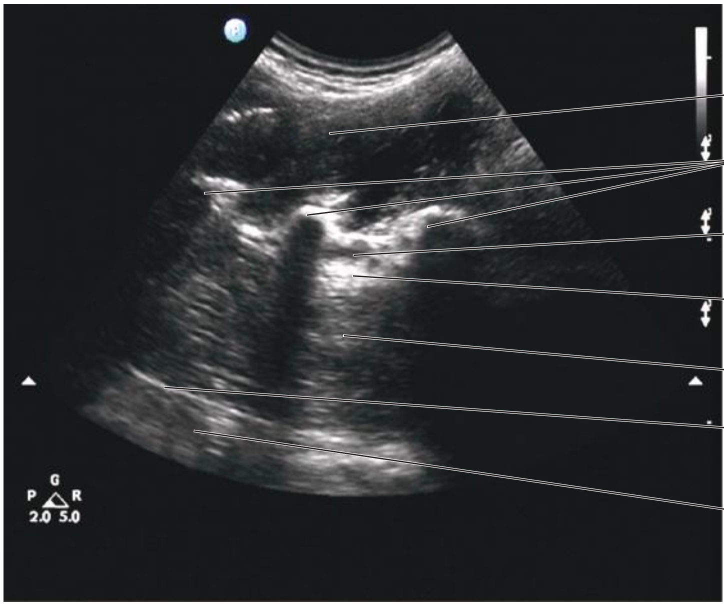

FIGURE 39–27. Sagittal sonogram of the lumbar paravertebral region during a USG LPB using the paramedian transverse oblique scan at the level of the articular process (PMTOS-AP) and after local anesthetic injection. Note the hyperechoic lumbar plexus nerve in the posterior aspect of the psoas muscle and the distribution of LA relative to the nerve (in front, behind, and in a craniocaudal direction) within the psoas compartment.

should be used in conjunction with US to confirm correct needle placement, after which 20–30 mL of ropivacaine or levobupivacaine 0.5% is injected slowly while visualizing the perineural spread of the drug in the posterior aspect of the psoas muscle (Figure 39–29b).[19] The technical challenge with this approach is that although the block needle is inserted in plane, visualizing the needle initially can be very challenging, since the sites for the US scan and needle insertion are separated by a considerable distance (see Figure 39–28).[19] Nevertheless, with experience, needle visualization can be easily accomplished.

THE PEARLS AND PITFALLS OF ULTRASOUND-GUIDED LUMBAR PLEXUS BLOCK

The lumbar paravertebral region is highly vascular and contains the ascending lumbar veins and lumbar arteries, which can be visualized using color and power Doppler US (see Figures 39–7 and 39–19). There is also a rich network of blood vessels (arteries and veins) within the substance of the psoas major muscle including the psoas compartment. The dorsal branch of the lumbar artery is also closely related to the

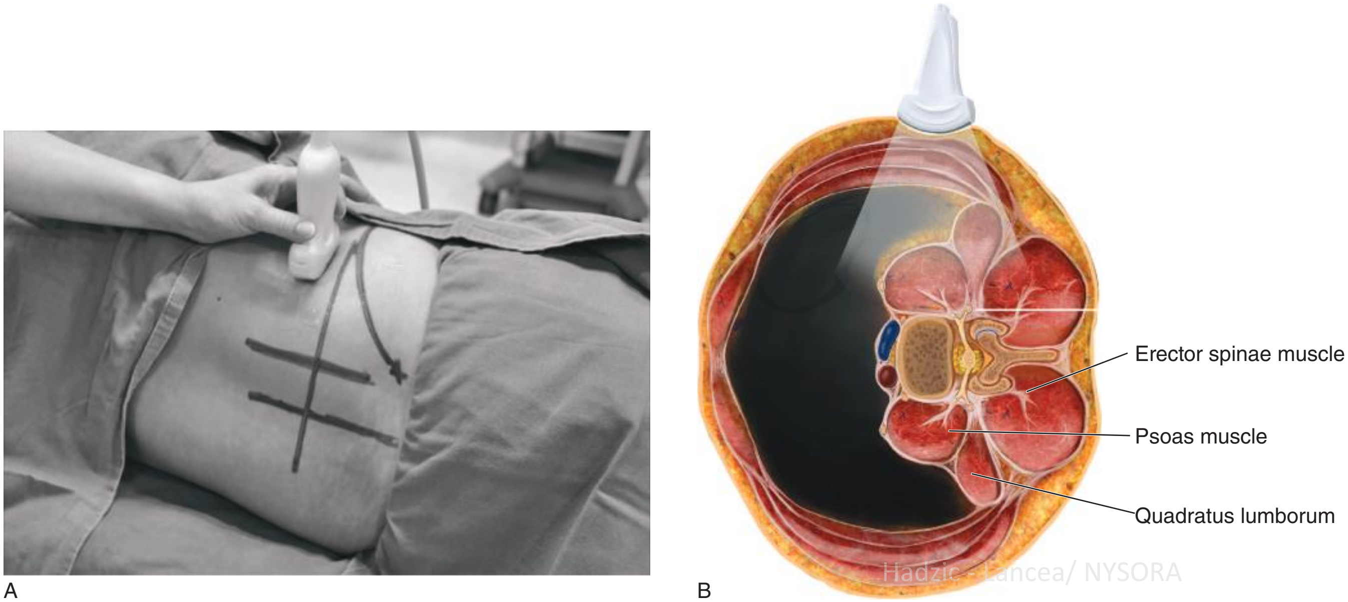

FIGURE 39–28. The shamrock method of US LPB. (**A**) Position of the patient (lateral decubitus), anesthesiologist, and US transducer and site and direction of needle insertion. (**B**) Simulated path of the block needle relative to the plane of the US beam (in plane) and paravertebral anatomy.

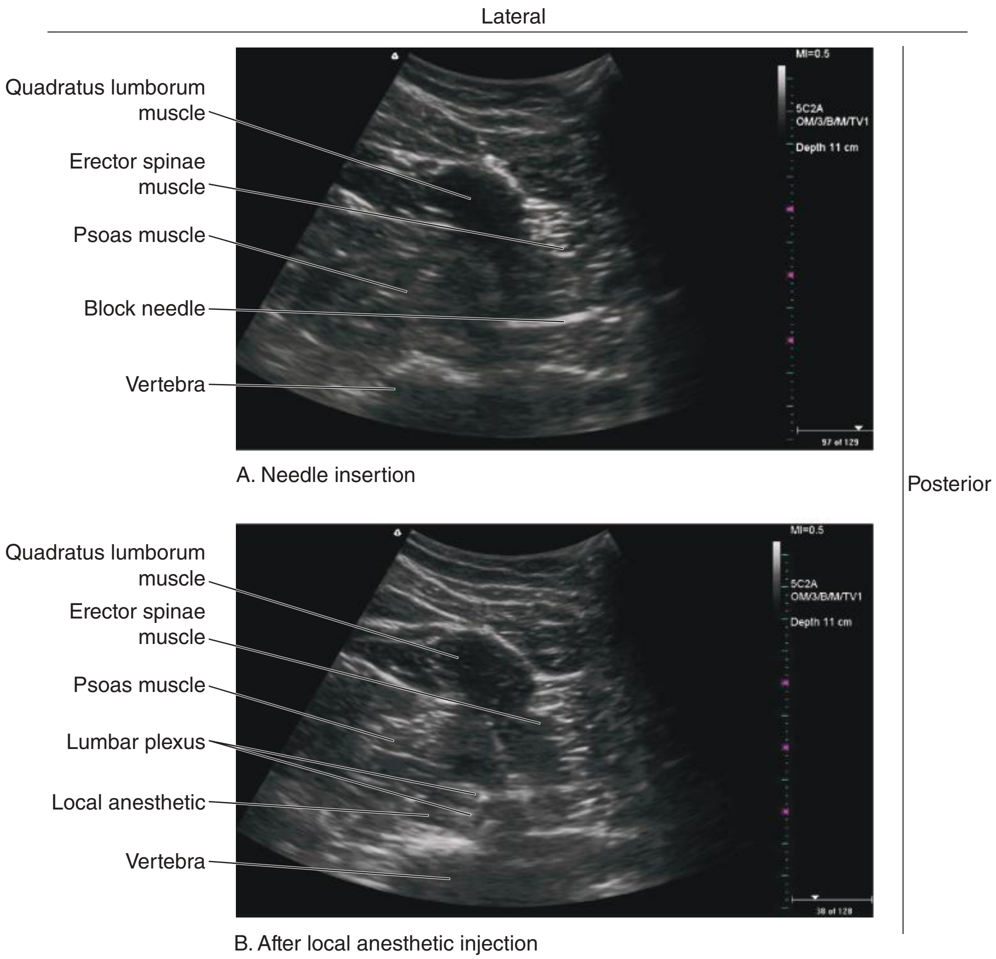

FIGURE 39–29. Transverse sonograms showing (**A**) the direction of needle insertion relative to the lumbar paravertebral anatomy and (**B**) the local anesthetic (LA) spread during a USG LPB using the shamrock method.

transverse processes and the posterior aspect of the psoas muscle (see Figure 39–7b), where the lumbar plexus is located. Therefore, this blood vessel may be at risk of needle-related injury during LPB because it is directly in the path of the advancing needle (see Figure 39–7). Considering the vascularity of the lumbar paravertebral region, it is not surprising that inadvertent intravascular injection of local anesthetic and psoas hematoma[26] have been described after LPB. It is for the same reason that one must exercise caution when considering an LPB in patients with mild to moderate coagulopathy or in patients receiving thromboprophylaxis; based on our current understanding, such conditions may be considered a relative contraindication for LPB. That said, there are reports of the safe use of LPB (both the single-injection and continuous techniques) before the initiation of postoperative thromboprophylaxis[27] and the removal of catheters in patients receiving thromboprophylaxis and/or aspirin[27] with an international normalized ratio (INR) of equal to or greater than 1.5.[28] One must exercise caution in interpreting such results, however, because the site at which an LPB is performed is noncompressible, and there are previous reports of retroperitoneal hematoma complicating LPB.[16,26] Moreover, there are currently very few evidence-based indications for LPB.

The echo intensity (EI) of skeletal muscles is significantly increased in the elderly,[29] and there is a strong correlation between the EI of muscles and age. Therefore, in US images, the lumbar paravertebral region in the elderly appears whiter and brighter than in younger patients, and there is also a loss of contrast between the muscle and the adjoining structures, making it more difficult to delineate the lumbar plexus. Therefore, USG LPB in the elderly can be very challenging. The same is also true in the obese, as excessive fat can make US imaging of the lumbar paravertebral anatomy and US guidance during LPB difficult. Gadsden and colleagues[30] have also recently demonstrated that injection of local anesthetic under high pressure (> 20 psi) during a lumbar plexus block results in unwanted bilateral sensory motor blockade and a high incidence of neuraxial block.[30] Therefore, one must ensure that the injection pressure is low (< 15 psi) during USG LPB. Occasionally, one may also find that during USG LPB, the needle tip is in the posterior aspect of the psoas muscle but no motor response is elicited. This may not be an uncommon phenomenon, considering that it is commonly seen during upper extremity blocks. However, one must ensure that the block needle has not been inadvertently inserted in the upper lumbar region because the upper lumbar nerves (L1 and L2) contribute predominantly to sensory nerves, and stimulating these nerves may not elicit a motor response.

SUMMARY

Recent advances in US technology, the image processing capabilities of US machines, and the development of new US scan protocols to image the lumbar paravertebral region have made it possible to image the anatomy relevant for lumbar plexus block. With US, one is able to preview the paravertebral anatomy, determine the safe depth for needle insertion, accurately guide the block needle to the target in real time, and visualize the distribution of the injected local anesthetic. These advantages may translate into improved accuracy, reduced needle-related complications, and improved success. It is also an excellent teaching tool for demonstrating the anatomy of the lumbar paravertebral region. However, the use of US for LPB is still in its infancy, and it is the author's opinion that USG LPB is an advanced-skill-level block that should be performed only after one has acquired the necessary imaging and interventional skills. Published data suggest that it is possible to image the anatomy relevant for LPB, and several USG LPB techniques have been described. Future research is warranted to define the role of US for LPB and to establish evidence-based indications for LPB.

CHAPTER 40

Spinal Sonography and Applications of Ultrasound for Central Neuraxial Blocks

Manoj K. Karmakar and Ki Jinn Chin

INTRODUCTION

Central neuraxial blocks (CNBs), which include spinal, epidural, combined spinal epidural (CSE), and caudal epidural injections, are commonly practiced regional anesthesia techniques and frequently used in the perioperative period for anesthesia and analgesia and for managing chronic pain.[1] Traditionally, CNBs are performed using a combination of surface anatomical landmarks, the operator's perception of tactile sensation (loss of resistance) during needle advancement, and/or visualizing the free flow of cerebrospinal fluid. Although the spinous processes are relatively reliable surface anatomical landmarks in many patients, they are not always easily recognizable in patients with obesity,[2] edema, underlying spinal deformity, or previous back surgery. Tuffier's line, which connects the highest points of the iliac crests, is another surface anatomical landmark that is widely used to estimate the location of the L3–L4 interspace; however, the correlation is inconsistent.[3] Even in the absence of spine abnormalities, estimation of a specific intervertebral level may not be accurate in many patients[4,5] and may result in needle placement one or two spinal levels higher than intended.[4,6,7] The difficulty in identifying the correct spinal level is exaggerated in patients with obesity and in the upper spinal levels.[4,6,8] This inaccuracy has been implicated in cases of injury to the conus medullaris after spinal anesthesia.[6,8] Moreover, surface landmarks alone do not allow the operator to reliably predict the ease or difficulty of needle placement prior to skin puncture. Unanticipated technical difficulty, multiple attempts at needle placement, and failure of CNB are therefore not uncommon.[9,10] Recently, however, ultrasound (US) imaging of the spine has emerged as a useful method of overcoming many of these shortcomings of the surface landmark–guided approach to CNBs.

US imaging offers several advantages when used to guide needle placement during CNBs. It is noninvasive, safe, simple to use, can be performed expeditiously at the point of care, provides real-time images, is devoid of significant adverse effects, and is particularly helpful in delineating abnormal or variant spinal anatomy. When used for chronic pain interventions of the spine, US can reduce or eliminate exposure to ionizing radiation. Presently, US is most frequently used as a preprocedural tool,[11] but it can also be used for real-time needle guidance during CNBs.[12] During the preprocedural scan, one can accurately locate the midline,[13] identify a given lumbar interspace, predict the depth to the epidural space, and identify patients in whom a CNB may be difficult.[11,14] In expert hands, the use of US for epidural needle insertion reduces the number of puncture attempts,[15–20] improves the success rate of epidural access on the first attempt,[16] reduces the need to puncture multiple levels,[16–18] and improves patient comfort during the procedure.[17] However, despite its advantages, the integration of US into clinical practice for CNBs is still in its infancy. A recent survey of anesthesiologists in the United Kingdom showed that more than 90% of respondents were not trained to image the epidural space using US despite national guidelines advocating its use.[21] In this chapter, we describe techniques of spinal sonography, the relevant sonoanatomy, and practical considerations for using US for CNBs.

HISTORICAL BACKGROUND

Bogin and Stulin were probably the first to report the use of US for central neuraxial interventional procedures.[22] In 1971, they described using US for lumbar puncture.[7] Porter and colleagues, in 1978, used US to image the lumbar spine and measure the diameter of the spinal canal in diagnostic radiology.[23] Cork and colleagues were the first group of anesthesiologists to use US to locate the landmarks relevant for epidural anesthesia.[24] Thereafter, US was used mostly to preview the spinal anatomy and measure the distances from the skin to the lamina and epidural space before epidural puncture.[25,26] Between 2001 and 2004, Grau and colleagues, from Heidelberg, Germany, published a series of studies that formed the foundation of the clinical application of US for CNB.[15–18,27–30] Subsequent improvements in US technology and image processing software have allowed for greater image clarity of the spine and neuraxial structures.[12,31,32] Also, the increasing availability of point-of-care US systems has led to further research by other investigators, which has established our current understanding of spinal sonoanatomy.[11]

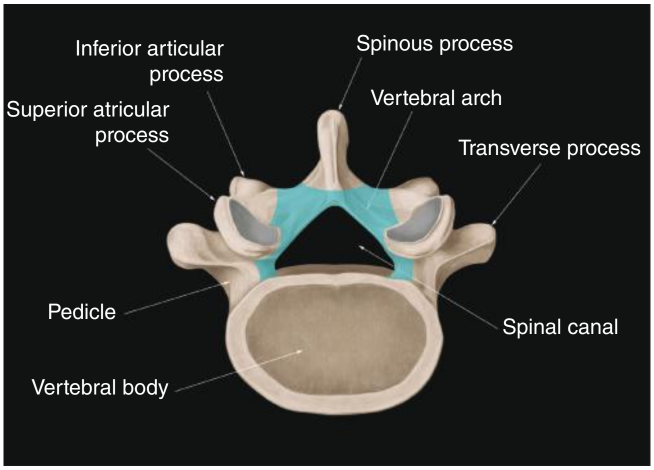

FIGURE 40–2. Vertebral arch of a typical lumbar vertebra. The vertebral arch surrounds the spinal canal and is made up of the posterior surface of the vertebral body, the pedicles, and the laminae.

GROSS ANATOMY OF THE SPINE

The gross anatomy of the spine has been discussed in detail in Chapters 6 and 22. In this section, the anatomy relevant for US imaging of the spine is briefly reviewed. A vertebra is made up of two components: the vertebral body and the vertebral arch (Figure 40–1). The vertebral arch is formed by the supporting pedicles and laminae (Figure 40–2). Seven processes arise from the vertebral arch: one spinous process, two transverse processes, two superior articular processes, and two inferior articular processes (see Figures 40–1 and 40–2). Adjacent vertebrae articulate with each other at the facet joints between the superior and inferior articular processes and the intervertebral disc between the vertebral bodies. This produces two gaps: one between the spinous processes, the "interspinous space" (Figure 40–3), and one between the laminae, the "interlaminar space" (Figure 40–4). It is through these spaces that the US energy enters the spinal canal and makes spinal sonography and CNBs possible.

The three major ligaments of the spine are the ligamentum flavum (Figures 40–3, 40–4, and 40–5), the anterior longitudinal ligament, and the posterior longitudinal ligament (see Figure 40–3). The posterior longitudinal ligament is attached along the length of the anterior wall of the vertebral canal (see Figures 40–3, 40–4, and 40–5). The ligamentum flavum, also referred to as the yellow ligament, is a dense layer of connective tissue that bridges the interlaminar spaces (see Figure 40–4) and connects the laminae of adjacent vertebrae. It is arch-like on cross-section and is widest posteriorly in the midline and in the lumbar region (see Figure 40–5). The ligamentum flavum is attached to the anterior surface of the inferior margin of the lamina above but splits inferiorly to attach to both the posterior surface (superficial component) and anterior surface (deep component) of the lamina below. The spinous processes are attached at their tips by the supraspinous ligament, which is thick and cord-like, and along their length by the interspinous ligament, which is thin and membranous (see Figure 40–3).

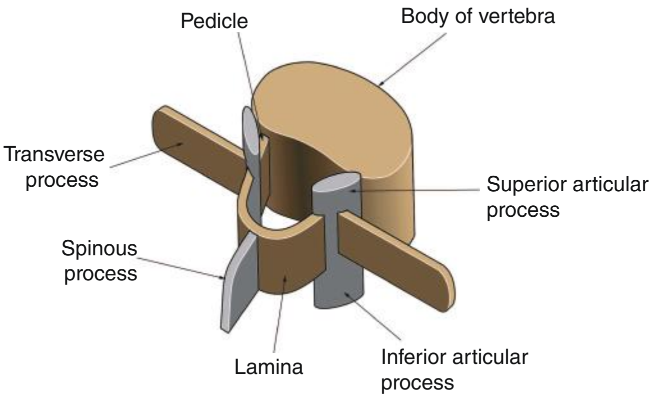

FIGURE 40–1. The components of a typical lumbar vertebra.

The spinal (vertebral) canal is formed by the vertebral arch and the posterior surface of the vertebral body (see Figures 40–2 and 40–5). The openings into the spinal canal are through the intervertebral foramen along its lateral wall and the interlaminar space on its posterolateral wall. Within the spinal canal lies the thecal sac (formed by the dura mater and arachnoid mater; see Figure 40–5) and its contents (the spinal cord, cauda equina, and cerebrospinal fluid; see Figures 40–3 and 40–5). The spinal cord extends from the foramen magnum to the conus medullaris, near the lower border of the first lumbar vertebra (see Figure 40–3), finally terminating as the filum terminale. However, there is normal variation in the position of the conus medullaris, and it may extend anywhere from T12 to the upper third of L3.[33] The cauda equina, named after its resemblance to a horse's tail, is made up of lumbar, sacral, and coccygeal nerves that originate in the conus medullaris and descend caudally to exit the spinal canal through their respective intervertebral foramina. Similarly, the dural sac is classically described as ending at the level of the second sacral vertebra (S2) (see Figure 40–3), but this can vary from the upper border of S1 to the lower border of S4.[34] The epidural space is an anatomical space within the spinal canal but outside the dura mater (referred to as extradural; see Figures 40-3 and 40-5). It extends form the level of the foramen magnum cranially to the tip of the sacrum at the sacrococcygeal ligament (see Figure 40–3). The posterior epidural space is of importance for CNBs. The only structure of importance in the anterior epidural space for neuraxial blocks is the internal vertebral venous plexus.

ULTRASOUND IMAGING OF THE SPINE

Foundation

Located at a depth of several centimeters or more in adults, US imaging of the spine typically requires the use of

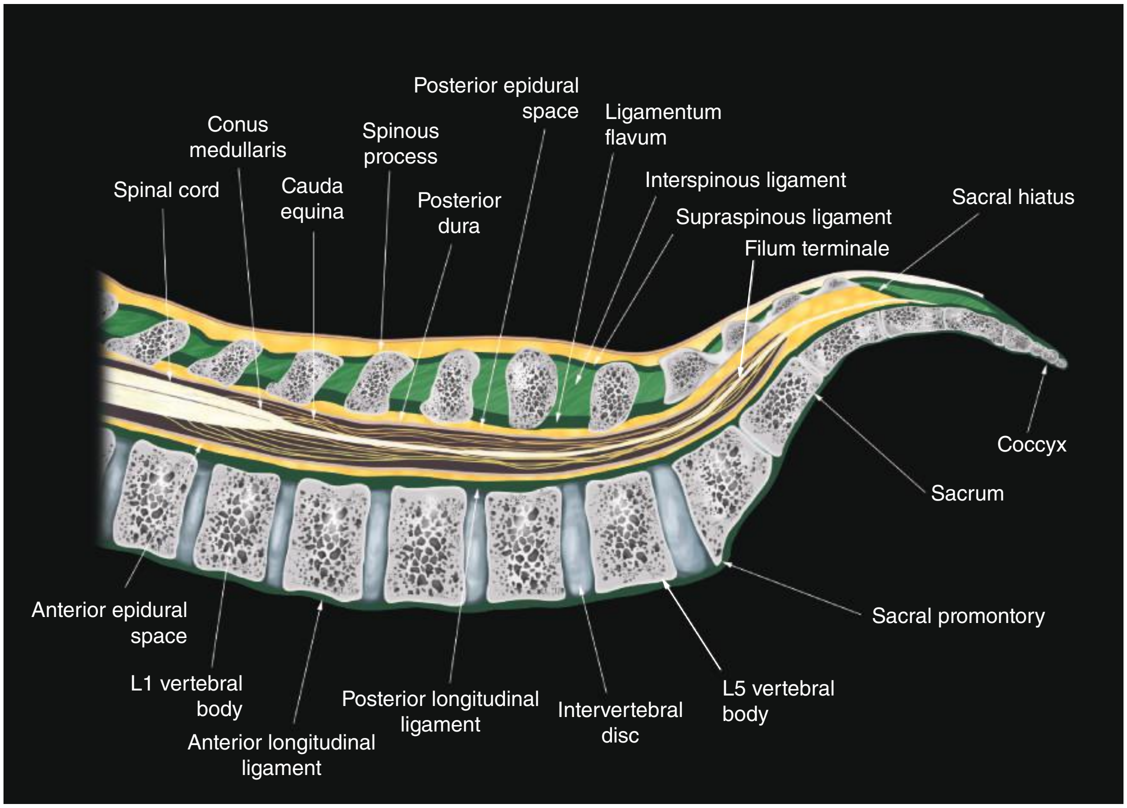

FIGURE 40–3. Sagittal anatomy of the lumbosacral spine in the median plane.

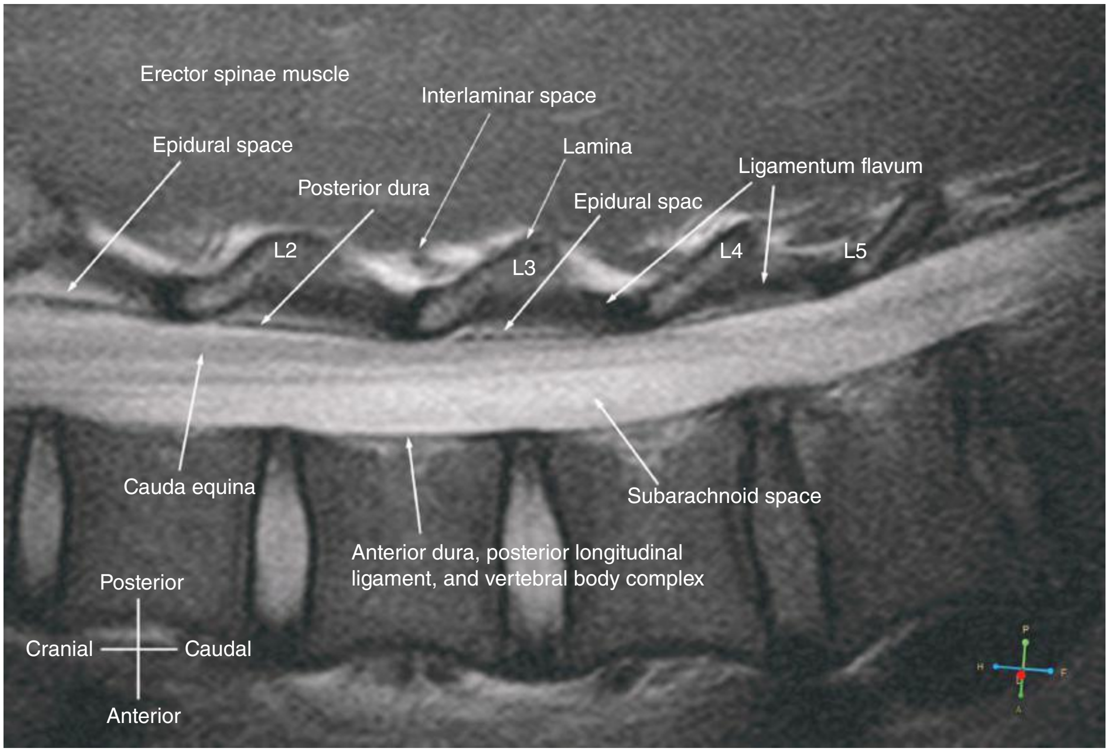

FIGURE 40–4. Paramedian sagittal MRI section of the lumbar spine at the level of the lamina.

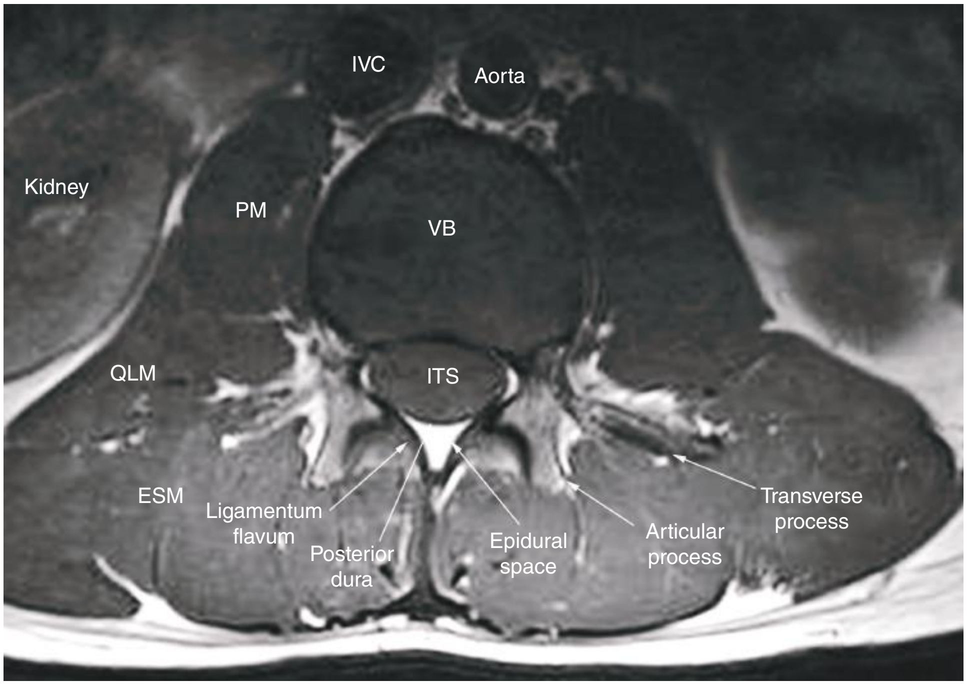

FIGURE 40–5. Transverse MRI section of the lower lumbar spine through the interspinous space. Note the relationship of the articular process to the transverse process and the attachment of the ligamentum flavum to the lamina on either side. Also note that the anterior epidural space is barely seen and that the anterior dura is very closely apposed to the posterior longitudinal ligament of the vertebra. ESM, erector spinae muscle; ITS, intrathecal space; IVC, inferior vena cava; PM, psoas major muscle; QLM, quadratus lumborum muscle; VB, vertebral body.

low-frequency US (2–5 MHz) and curved array transducers. Because of the divergent nature of their US beam, curved array transducers also produce a wide field of view, particularly in the deeper areas, which is useful when using US for CNB. Low-frequency US provides adequate penetration, but unfortunately lacks spatial resolution at the depth (5–7 cm) at which the neuraxial structures are located. The osseous framework of the spine, which envelops the neuraxial structures, reflects much of the incident US signal before it even reaches the spinal canal, presenting additional challenges in acquiring good-quality images. However, this challenge is often offset by improved image processing and advanced image optimization modes in modern US systems, and thus high-quality images of the neuraxis can still be obtained with low-frequency transducers.[32] Also of note is that technology once only available in the high-end cart-based US systems is now available in portable US devices, making US systems even more practical for spinal sonography and US-guided (USG) CNB applications.

Scanning Planes

Although anatomical planes have already been described elsewhere in this text, the importance of understanding them for imaging of the spine dictates a further, more detailed review. There are three anatomical planes: median, transverse, and coronal (Figure 40–6). The **median plane** is a longitudinal plane that passes through the midline, bisecting the body into two equal right and left halves. The **sagittal plane** is a longitudinal plane that is parallel to the median plane and perpendicular to the ground. Therefore, the median plane can also be defined as the sagittal plane that is exactly in the middle of the body (median sagittal plane). The **transverse plane**, also known as the axial or horizontal plane, is parallel to the ground.

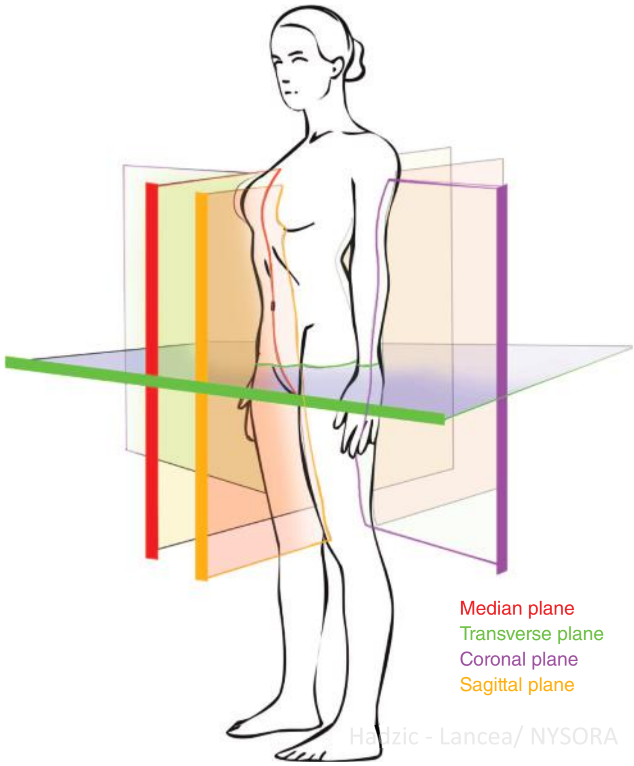

FIGURE 40–6. Anatomical planes of the body.

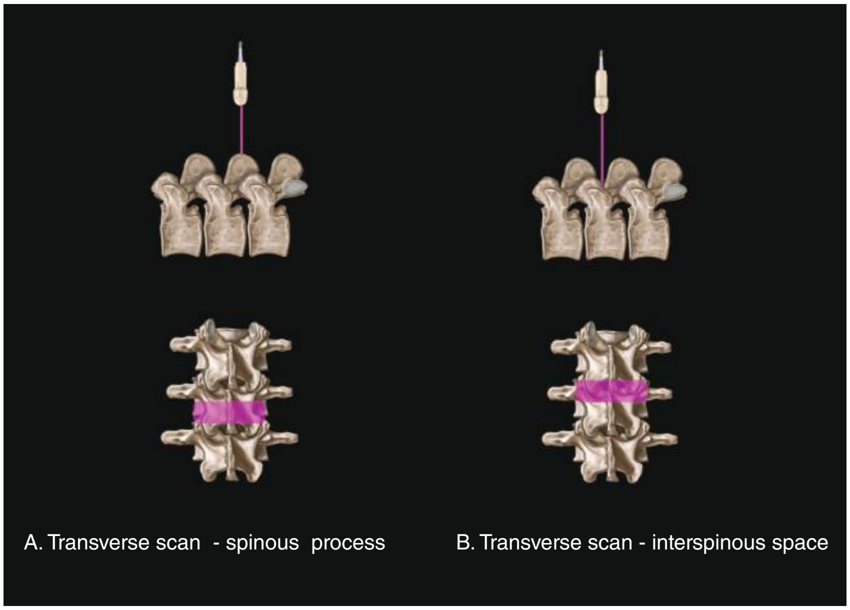

FIGURE 40–7. Axis of scan: transverse scan (**A**) at the level of the spinous process; and (**B**) at the level of the interspinous space.

The **coronal plane**, also known as the frontal plane, is a vertical plane that is perpendicular to the ground and at right angles to the sagittal plane dividing the body into an anterior and a posterior part.

Axis of Scan

US imaging of the spine can be performed in the transverse axis (transverse scan; Figure 40–7) or the longitudinal axis (sagittal scan; Figure 40–8) with the patient in the sitting, lateral decubitus, or prone position. The anatomical information obtained from these two scan planes complement each other during a US examination of the spine. A transverse scan can be performed over the spinous process (see Figure 40–7a) or through the interspinous/interlaminar space (see Figure 40–7b). The former produces the **transverse spinous process view**, whereas the latter produces the **transverse interspinous view** of the spine.[11] Transverse views are relatively easy to acquire in the lumbar region, but the transverse interspinous view is challenging in the midthoracic region (T4–8) due to the acute

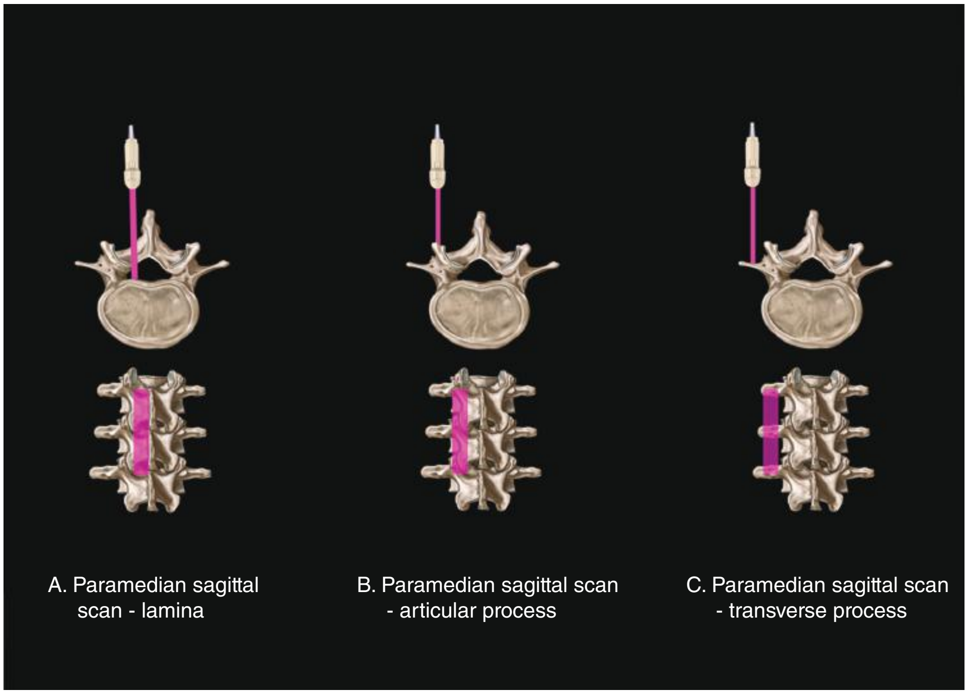

FIGURE 40–8. Axis of scan: paramedian sagittal scan (**A**) at the level of the lamina; (**B**) at the level of the articular process; and (**C**) at the level of the transverse process.

caudal angulation of the spinous processes. Depending on the angle of the spinous processes, the transducer may have to be tilted to produce an optimal interspinous view of the neuraxial structures. A sagittal scan can be performed through the midline (**median sagittal spinous process view**) or through a paramedian plane (Figure 40–8). Overall, three paramedian sagittal views of the spine can be obtained (from medial to lateral): (1) a **paramedian sagittal lamina view** (see Figure 40–8a); (2) a **paramedian sagittal articular process view** (see Figure 40–8b); and (3) a **paramedian sagittal transverse process view** (see Figure 40–8c). Grau et al. have suggested using a paramedian sagittal scan to visualize the neuraxial structures.[27] We have found that the US visibility of neuraxial structures can be further improved when the spine is imaged in the paramedian sagittal oblique plane (Figure 40–9).[12,31] During a paramedian sagittal oblique scan (PMSOS), the transducer is positioned 2–3 cm lateral to the midline (paramedian) and over the laminae in the sagittal axis, tilted slightly medially toward the midline (see Figure 40–9).[12,31] The purpose of the medial tilt is to ensure that the US signal enters the spinal canal through the widest part of the interlaminar space and not the lateral sulcus of the spinal canal.

Sonoanatomy of the Spine

Detailed knowledge of the vertebral anatomy is essential to understand the sonoanatomy of the spine. Unfortunately, cross-sectional anatomy texts describe the anatomy of the spine in traditional orthogonal planes; that is, the transverse, sagittal, and coronal planes. This often results in difficulty interpreting the spinal sonoanatomy because US imaging is generally performed in an arbitrary or intermediary plane by tilting, sliding, and rotating the transducer. Several anatomical models have recently been developed to teach musculoskeletal US imaging techniques (in human volunteers), the sonoanatomy relevant for peripheral nerve blocks (in human volunteers and cadavers), and the required interventional skills (in tissue-mimicking phantoms and fresh cadavers). However, few models or tools are available to learn and practice spinal sonoanatomy or the interventional skills required for USG CNB. Karmakar and colleagues recently described the use of a "water-based spine phantom" (Figure 40–10) to study the osseous anatomy of the lumbosacral spine.[32,35] A gelatin lumbosacral spine phantom,[36] gelatin–agar spine phantom (Figure 40–11), "pig-carcass phantom"[37] (Figure 40–12), and lumbar training phantom (Figure 40–13a; CIRS model 034, CIRS, Inc., Norfolk, VA) have also been described to practice the basic hand–eye coordination skills required to perform USG CNBs. Since three-dimensional (3D) reconstructions of high-definition CT scan data (3D volume datasets) can also be used to study the osseous anatomy (Figure 40–13b, c, d) and validate the structure visualized in multiplanar 3D images (Figure 40–14). Computer-generated anatomical reconstructions from the Visible Human Project dataset that correspond to the US scan planes provide another useful way of studying the sonoanatomy of the spine in vivo[32] (Figure 40–15). Multiplanar 3D reconstructions from archived high-resolution 3D CT datasets of the spine can also be used to study and validate the sonographic appearance of the various osseous elements and neuraxial structures of the spine.

Water-Based Spine Phantom

The **water-based spine phantom**[37] simplifies the process of learning the sonoanatomy of the spine in two easy steps: (1) learning the sonoanatomy of the osseous elements of the spine; and (2) learning the sonoanatomy of the soft-tissue structures that make up the spine. The water-based spine phantom[37] is an excellent model to define the osseous anatomy of the spine[32,37] and is based on a model described previously by Greher and colleagues to study the osseous anatomy of relevance to USG lumbar facet nerve block.[38] The model is prepared by immersing a commercially available lumbosacral spine model in a water bath (see Figure 40–10a). A low-frequency curved array transducer is then used to scan the model through the water in the transverse and sagittal axes as one would do in vivo. Each osseous element of the spine produces a characteristic sonographic pattern.[37] The ability to recognize these sonographic patterns is an important step toward understanding the sonoanatomy of the spine. Representative US images of the spinous process, lamina, articular processes, and transverse process from the water-based spine phantom are presented in Figures 10b, c, d and 16a, b, c. The advantage of this water-based spine phantom is that water produces an anechoic (black) background against which the hyperechoic reflections from the bone are clearly visualized. The water-based spine phantom allows a see-through, real-time visual validation of the sonographic appearance of a given osseous element by performing the scan with a marker (eg, a needle) in contact with it (see Figure 40–16a). The described model is also inexpensive, easily prepared, requires little time to set up, and can be used repeatedly without deteriorating or decomposing, as animal tissue-based phantoms do. Once the novice learns to identify the individual osseous elements of the spine in the various US scan planes, it becomes easy to define the gaps between these elements: the interspinous (see Figure 40–10c) and interlaminar spaces (see Figure 40–16a), through which the US energy enters the spinal canal to produce the acoustic window seen on a spinal sonogram. The same gaps or spaces also permit passage of the needle to the neuraxis during USG CNB.

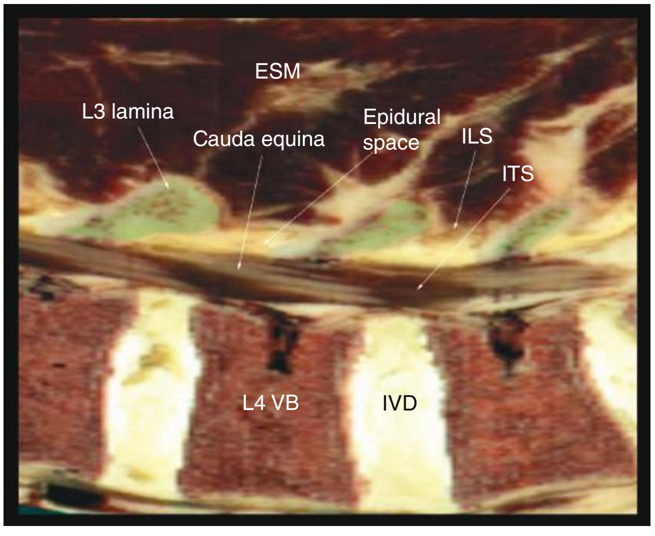

FIGURE 40–15. Sagittal cadaver anatomical section of the lumbar spine through the lamina of the lumbar spine, rendered from the Visible Human Server male dataset. ESM, erector spinae muscle; ILS, interlaminar space; ITS, intrathecal space; IVD, intervertebral disc; VB, vertebral body.

Note the needle in contact with the lamina in (a), a method that was used to validate the sonographic appearance of the osseous elements in the phantom. The inset image in (a) illustrates the horse-head–like appearance of the laminae, and the inset image in (b) illustrates the camel-hump–like appearance of the articular processes. AP, articular process; SS, sagittal scan; TP, transverse process.

ULTRASOUND IMAGING OF THE LUMBAR SPINE

Sagittal Scan

The patient is positioned in the sitting, lateral, or prone position, with the lumbosacral spine maximally flexed. The transducer is placed 1–2 cm lateral to the spinous process (ie, in the paramedian sagittal plane) at the lower back with its orientation marker directed cranially. A slight medial tilt during the scan insonates the spine in a **paramedian sagittal oblique (PMSO)** plane. First, the sacrum is identified as a flat, hyperechoic structure with a large acoustic shadow anteriorly (Figure 40–17). When the transducer is slid in a cranial direction, a gap is seen between the sacrum and the lamina of the L5 vertebra, which is the L5–S1 interlaminar space, also referred to as the L5–S1gap (Figures 40–17 and 40–18).[32,39] The L3–4 and L4–5 interlaminar spaces can now be located by counting upward (Figure 40–19).[12,32] The erector spinae muscles are hypoechoic and lie superficial to the laminae. The lamina appears hyperechoic and is the first osseous structure visualized (see Figure 40–19). Because bone impedes US penetration, there is an acoustic shadow anterior to each lamina. The sonographic appearance of the lamina produces a pattern that resembles the head and neck of a horse (the "horse head sign") (see Figures 40–16a and 40–19).[32] The interlaminar space is the gap between the adjoining laminae (Figure 40–20) and is the "acoustic window" through which the neuraxial structures are visualized within the spinal canal.

The ligamentum flavum appears as a hyperechoic band across the adjacent laminae (see Figure 40–19). The posterior dura is the next hyperechoic structure anterior to the ligamentum flavum, and the epidural space is the hypoechoic area (a few millimeters wide) between the ligamentum flavum and the posterior dura (see Figure 40–19). The ligamentum flavum and posterior dura may also be seen as a single linear hyperechoic structure, which is referred to as the "posterior complex"[11] or "ligamentum flavum–posterior dura complex."[40] The posterior dura is generally more hyperechoeic than the ligamentum flavum.[32] The thecal sac with the cerebrospinal fluid is the anechoic space anterior to the posterior dura (see Figure 40–19). The cauda equina, which is located within the thecal sac, is often seen as multiple horizontal, hyperechoic shadows within the anechoic thecal sac. Pulsations of the cauda equina are identified in some patients.[12,32] The anterior dura is also hyperechoic, but it is not always easy to differentiate it from the posterior longitudinal ligament and the posterior surface of the vertebral body because they are of similar echogenicity (isoechoic) and closely apposed to each other. What results is a single, composite, hyperechoic reflection anteriorly, which is referred to as the "anterior complex" (see Figures 40–17 and 40–19).[12,32]

If the transducer slides medially, that is, to the median sagittal plane, the **median sagittal spinous process view** is obtained, and the tips of the spinous processes of the L3–L5 vertebrae, which appear as superficial, hyperechoic crescent-shaped structures, are seen (Figures 40–10c, 40–21, and 40–22).[31,32] The acoustic window between the spinous processes in the median plane is narrow and often prevents clear visualization of the neuraxial structures within the spinal canal.

If the transducer is moved laterally from the paramedian sagittal plane at the level of the lamina, the **paramedian**

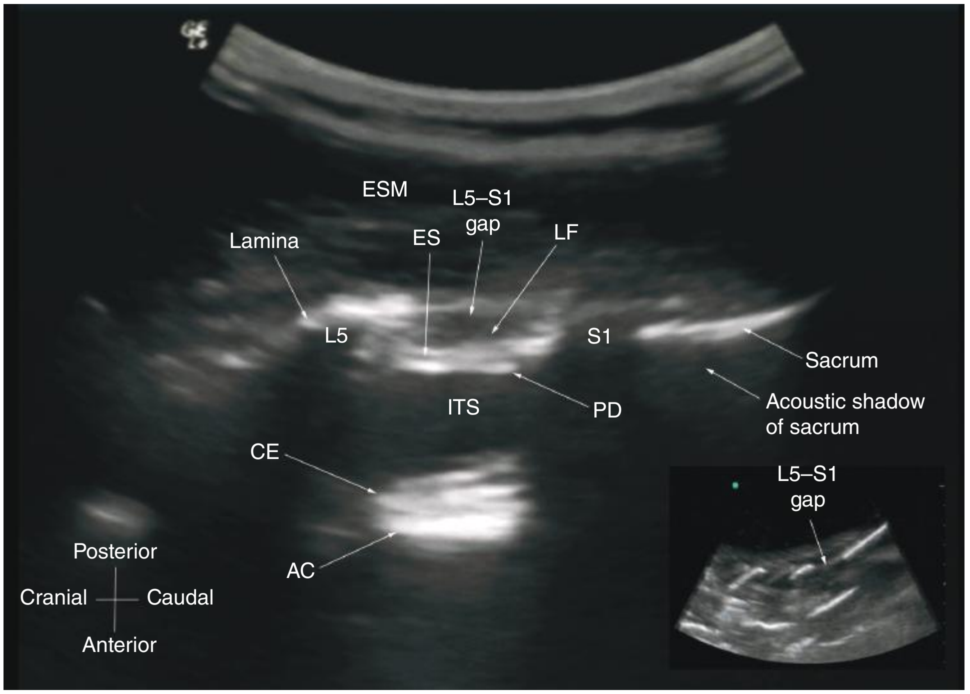

FIGURE 40–17. Paramedian sagittal sonogram of the lumbosacral junction. The posterior surface of the sacrum is identified as a flat hyperechoic structure with a large acoustic shadow anteriorly. The dip or gap between the sacrum and the lamina of L5 is the L5–S1 intervertebral space, or the L5–S1 gap. The inset image is a matching sonogram from a water-based spine phantom showing the L5–S1 gap. AC, anterior complex; CE, cauda equina; ES, epidural space; ESM, erector spinae muscle; ITS, intrathecal space; LF, ligamentum flavum; PD, posterior dura.

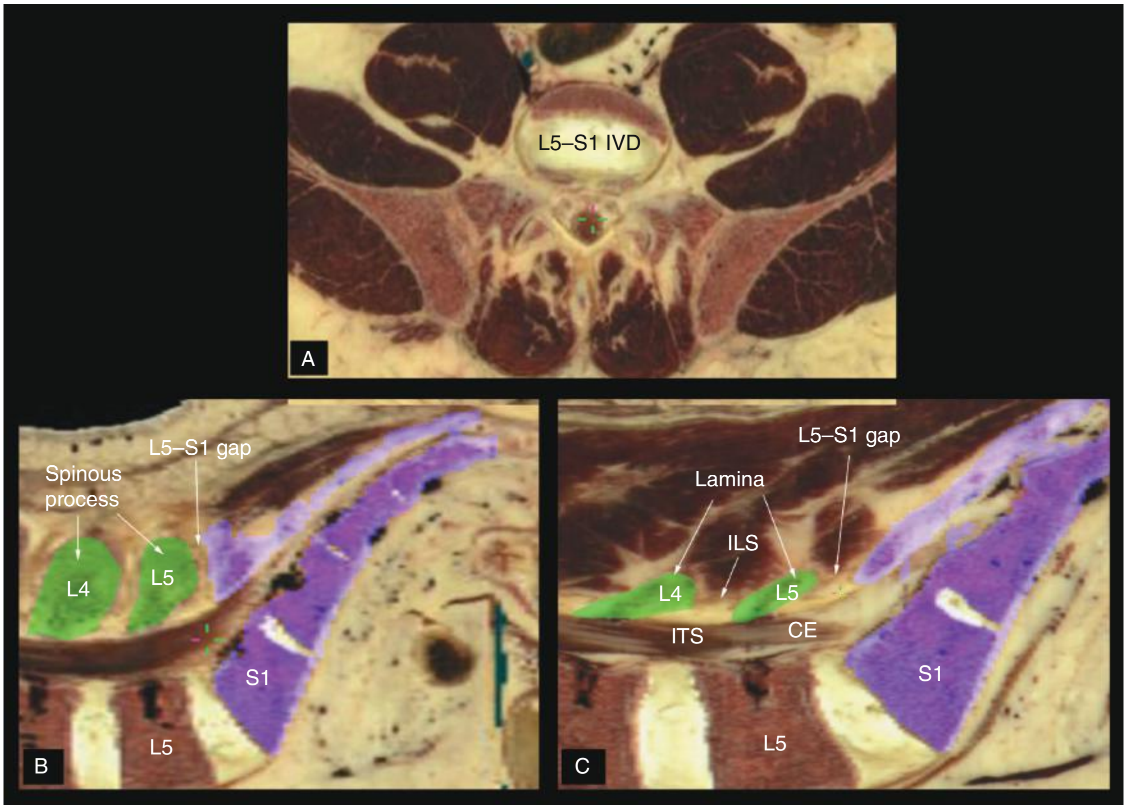

FIGURE 40–18. Cadaver anatomical section showing the lumbosacral junction (L5–S1 gap) in the (**A**) transverse axis; (**B**) median (sagittal) axis and (**C**) paramedian sagittal axis. CE, cauda equina; ILS, interlaminar space; ITS, intrathecal space; IVD, intervertebral disc.

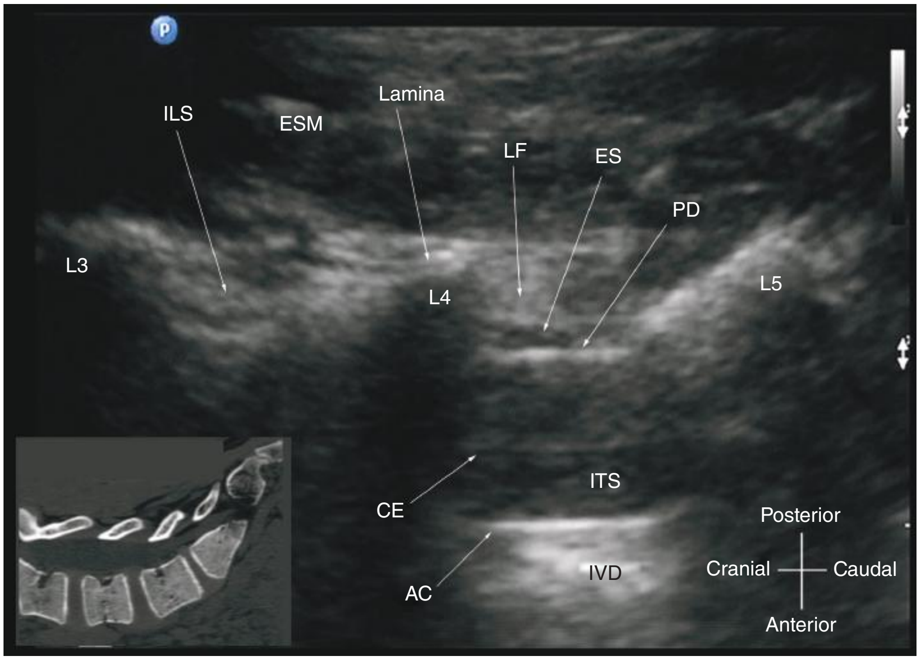

FIGURE 40–19. Paramedian sagittal oblique sonogram of the lumbar spine at the level of the lamina showing the L3–4 and L4–5 interlaminar spaces. Note the hypoechoic epidural space (a few millimeters wide) between the hyperechoic ligamentum flavum and the posterior dura. The intrathecal space is the anechoic space between the posterior dura and the anterior complex. The cauda equina nerve fibers are also seen as hyperechoic longitudinal structures within the thecal sac. The hyperechoic reflections seen in front of the anterior complex are from the intervertebral disc (IVD). The inset image shows a matching computed tomography (CT) scan of the lumbosacral spine in the same anatomical plane as the US scan. The CT slice was reconstructed from a three-dimensional CT dataset from the author's archive. AC, anterior complex; CE, cauda equina; ES, epidural space; ESM, erector spinae muscle; ILS, interlaminar space; ITS, intrathecal space; IVD, intervertebral disc; L3, lamina of L3 vertebra; L4, lamina of L4 vertebra; L5, lamina of L5 vertebra; LF, ligamentum flavum; PD, posterior dura.

The inset image shows a corresponding computed tomography (CT) scan of the lumbosacral spine through the median plane. The CT slice was reconstructed from a three-dimensional CT dataset from the author's archive.

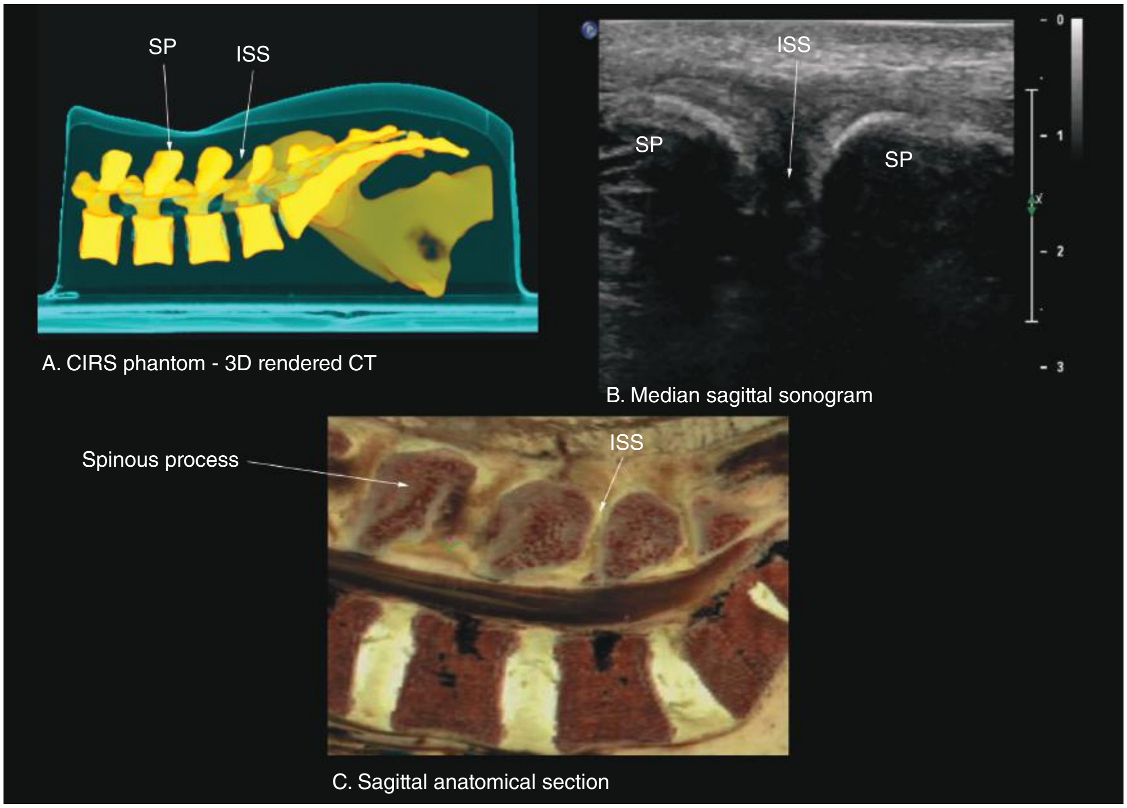

FIGURE 40–22. Median sagittal sections of the lumbosacral spine. (**A**) Three-dimensional (3D) reconstruction of high-resolution computed tomography (CT) scan dataset from the CIRS phantom. (**B**) Median sagittal sonogram showing the spinous process (SP) and interspinous space (ISS). (**C**) Median sagittal cadaver anatomical section.

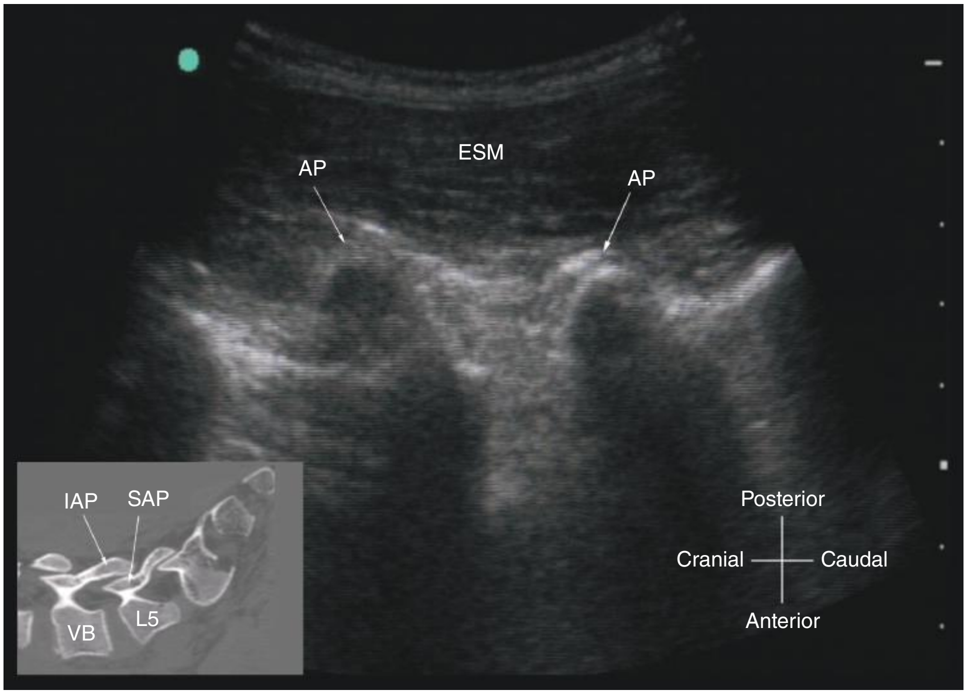

FIGURE 40–23. Paramedian sagittal sonogram of the lumbar spine at the level of the articular processes (APs) of the vertebrae. Note the "camel hump" appearance of the APs. The inset image shows a corresponding computed tomography (CT) scan of the lumbosacral spine at the level of the APs. The CT slice was reconstructed from a three-dimensional CT dataset from the author's archive. ESM, erector spinae muscle; IAP, inferior articular process; SAP, superior articular process; VB, vertebral body.

sagittal articular process view (Figures 40–23 and 40–24) is seen. The articular processes of the vertebrae appear as one continuous, hyperechoic wavy line with no intervening gaps (see Figure 40–23).[31,32] This produces a sonographic pattern that resembles multiple camel humps, which is therefore referred to as the "camel hump sign" (see Figures 40–16b, 40–23, and 40–24).[31,32]

A sagittal scan lateral to the articular processes brings the transverse processes of the L3–L5 vertebrae into view and produces the **paramedian sagittal transverse process view** (Figures 40–25 and 40–26). The transverse processes are recognized by their crescent-shaped, hyperechoic reflections and finger-like acoustic shadows anteriorly (see Figures 40–16c, 40–25, and 40–26).[32,41] These characteristics produce a sonographic pattern that is referred to as the "trident sign" because of its resemblance to the trident (Latin *tridens* or *tridentis*) that is often associated with Poseidon, the god of the sea in Greek mythology, and the trishula of the Hindu god Shiva (Figure 40–25).[41]

Transverse Scan

For a transverse scan of the lumbar spine, the US transducer is positioned over the spinous process (**transverse spinous process view**; see Figure 40–7a), with the patient in the sitting or lateral position. On a transverse sonogram, the spinous process and the lamina on either side are seen as a hyperechoic reflection anterior to which there is a dark acoustic shadow that completely obscures the underlying spinal canal and thus the neuraxial structures (Figures 40–27 and 40–28). Therefore, this view is not suitable for imaging the neuraxial structures but can be useful for identifying the midline when the spinous processes cannot be palpated (eg, in obese patients).

However, by sliding the transducer slightly cranially or caudally, it is possible to perform a transverse scan through the interspinous or interlaminar space (**transverse interspinous view**; Figures 40–7b, 40–29, and 40–30).[13,31] A slight tilt of the transducer cranially or caudally may be needed to align the US beam with the interspinous space and optimize the US image. In the transverse interspinous view, the posterior dura, thecal sac, and anterior complex are visualized (from a posterior to anterior direction) within the spinal canal in the midline and the articular processes, and the transverse processes are visualized laterally (see Figures 40–29 and 40–30).[13,31] The osseous elements produce a sonographic pattern that resembles a cat's head, with the spinal canal representing the head, the articular processes representing the ears, and the transverse processes representing the whiskers (the "cat's head sign") (see Figure 40–10d).

The ligamentum flavum is rarely visualized in the transverse interspinous view, possibly due to anisotropy caused by the arch-like attachment of the ligamentum flavum to the lamina. The epidural space is also less frequently visualized in the transverse interspinous view than in the PMSOS. The transverse interspinous view can be used to examine for rotational deformities of the vertebrae, such as in scoliosis. Normally, both the laminae and the articular processes on either side should be symmetrically located (see Figures 40–10d, 40–13b, and 40–29). However, if there is asymmetry, a rotational deformity of the vertebral column[42] should be suspected and the needle trajectory altered accordingly.

ULTRASOUND IMAGING OF THE THORACIC SPINE

US imaging of the thoracic spine is more challenging than the lumbar spine. The ability to visualize the neuraxial structures with US may vary with the level at which the imaging is performed, with poorer visibility of the neuraxis in the upper thoracic levels.[40] Regardless of the level at which the scan is performed, the thoracic spine is probably best imaged with the patient in the sitting position. In the lower thoracic region (T9–T12), the sonographic appearance of the neuraxial structures (Figure 40–31) is comparable to that in the lumbar region because of comparable vertebral anatomy. However, the acute caudal angulation of the spinous processes and the narrow interspinous and interlaminar spaces in the midthoracic region (T4–T8) results in a narrow acoustic window with limited visibility of the underlying neuraxial anatomy (Figures 40–32 and 40–33).

Grau and colleagues[28] performed US imaging of the thoracic spine at the T5–T6 level in young volunteers and correlated findings with matching magnetic resonance imaging (MRI) images.[28] They found that the transverse axis produced the best images of the neuraxial structures.[28] However, the epidural space was best visualized in the paramedian sagittal scans.[28] Regardless, US was limited in its ability to delineate the epidural space or the spinal cord but was better than MRI in demonstrating the posterior dura.[28] The transverse interspinous view, however, is almost impossible to obtain in the midthoracic region (see Figure 40–33), and, therefore, the transverse scan provides little useful information for CNB other than to help identify the midline.

In contrast, the PMSOS (see Figure 40–32), despite the narrow acoustic window, provides more useful information relevant for CNB.[11,28] The laminae are seen as flat hyperechoic structures with acoustic shadowing anteriorly, and the posterior dura is consistently visualized in the acoustic window (see Figure 40–32). However, the epidural space, spinal cord, central canal, and anterior complex are difficult to delineate and only rarely visualized in the midthoracic region (see Figure 40–32). CNBs are rarely performed in the upper thoracic spine (T1–T4), but US imaging is possible despite the narrow acoustic window (Figures 40–34 and 40–35).

ULTRASOUND IMAGING OF THE SACRUM

US imaging of the sacrum is most commonly performed to identify the sonoanatomy relevant for a caudal epidural injection.[43] Because the sacrum is a superficial structure, a high-frequency linear array transducer can be used for the scan.[43] The patient is positioned in the lateral or prone position, with a pillow under the abdomen to flex the lumbosacral spine. The caudal epidural space is the continuation of the lumbar epidural space and commonly accessed via the sacral hiatus. The sacral hiatus is located at the distal end of the sacrum and is covered by the

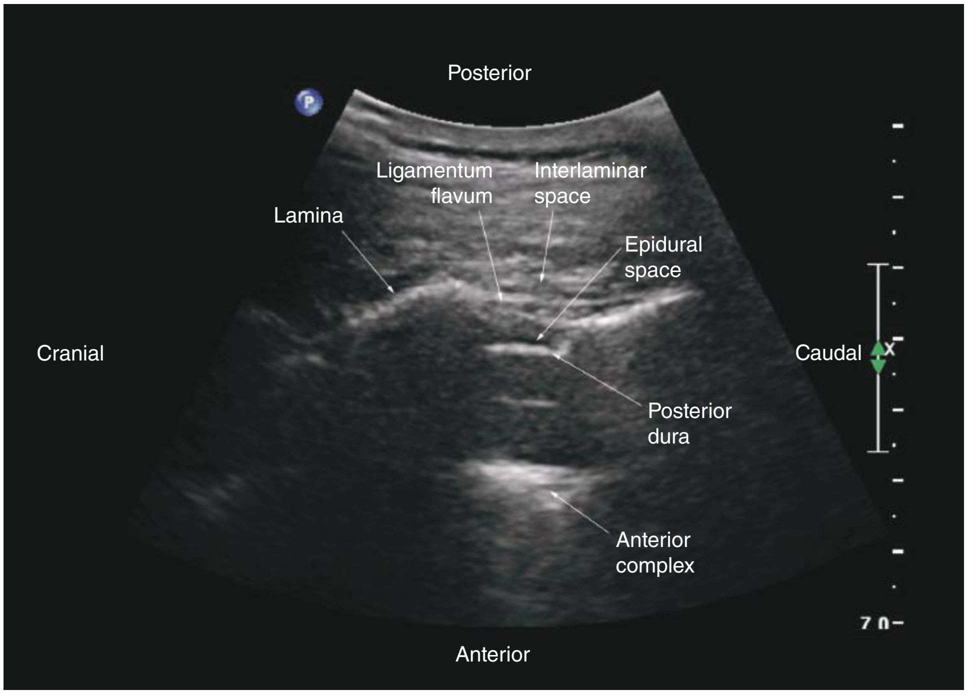

FIGURE 40–31. Paramedian sagittal oblique sonogram of the lower thoracic spine. The acoustic window is relatively large; through it, the ligamentum flavum, posterior dura, epidural space, and anterior complex are clearly visible.

sacrococcygeal ligament. Its lateral margins are formed by the two sacral cornua. On a transverse sonogram of the sacrum at the level of the sacral hiatus, the sacral cornua are seen as two hyperechoic reversed U-shaped structures, one on either side of the midline (Figure 40–36).[43] Connecting the two sacral cornua, and deep to the skin and subcutaneous tissue, is a hyperechoic band: the sacrococcygeal ligament (see Figure 40–36).[43]

Anterior to the sacrococcygeal ligament is another hyperechoic linear structure, which represents the posterior surface of

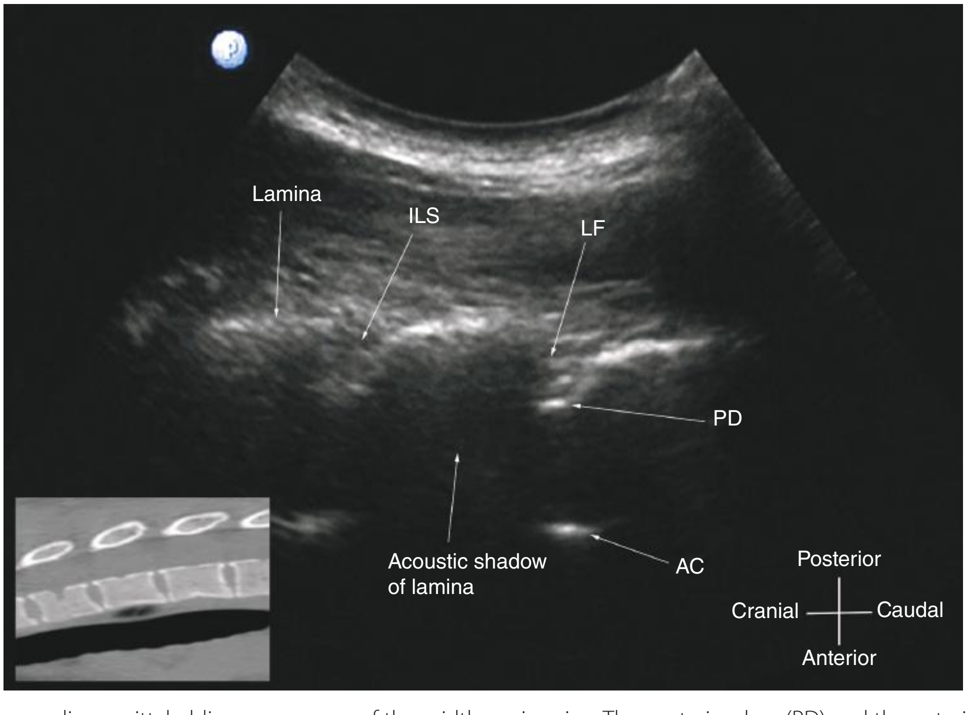

FIGURE 40–32. Paramedian sagittal oblique sonogram of the midthoracic spine. The posterior dura (PD) and the anterior complex (AC) are visible through the narrow acoustic window. The inset image shows a corresponding computed tomography (CT) scan of the midthoracic spine. The CT slice was reconstructed from a three-dimensional CT dataset from the author's archive. ILS, interlaminar space; LF, ligamentum flavum.

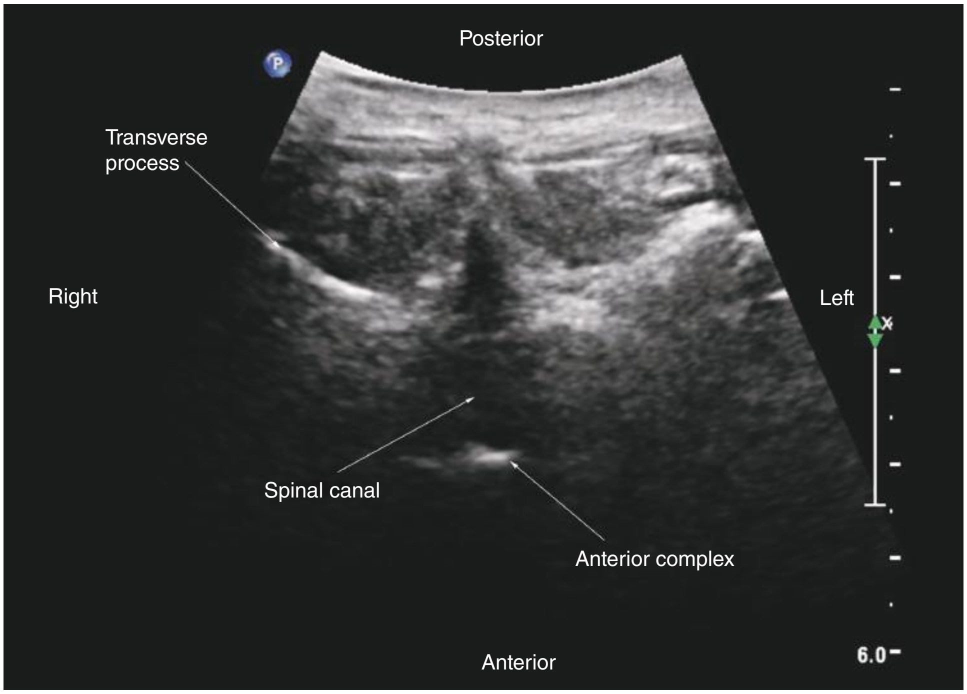

FIGURE 40–33. Transverse interspinous sonogram of the midthoracic region. Visualization of the posterior dura and anterior complex can be very challenging in the midthoracic region due to the acute angulation of the spinous processes and requires cranial angulation of the US transducer.

the sacrum. The hypoechoic space between the sacrococcygeal ligament and the bony posterior surface of the sacrum is the caudal epidural space (see Figure 40–36). The two sacral cornua and the posterior surface of the sacrum produce a pattern on the sonogram that is referred to as the "frog eye sign" because of its resemblance to the eyes of a frog (see Figure 40–36).[31]

On a sagittal sonogram of the sacrum at the level of the sacral cornua, the sacrococcygeal ligament, the base of sacrum, and the caudal canal are also clearly visualized (Figure 40–37).[31] However, due to the acoustic shadow of the posterior surface of the sacrum, only the lower part of the caudal epidural space is seen (see Figure 40–37).

TECHNICAL ASPECTS OF ULTRASOUND-GUIDED CENTRAL NEURAXIAL BLOCKS

During CNBs, US can be used either as a preprocedural tool or to guide needle insertion in real time. The former involves performing a preprocedural scan (or scout scan) to preview the spinal anatomy and determine the optimal site, depth, and trajectory for needle insertion before performing a traditional spinal or epidural injection.[44,45] In contrast, the latter technique involves performing a real-time USG CNB by one[12] or two[18] operators. Real-time USG CNB demands a high degree of manual dexterity and hand–eye coordination. Therefore, the

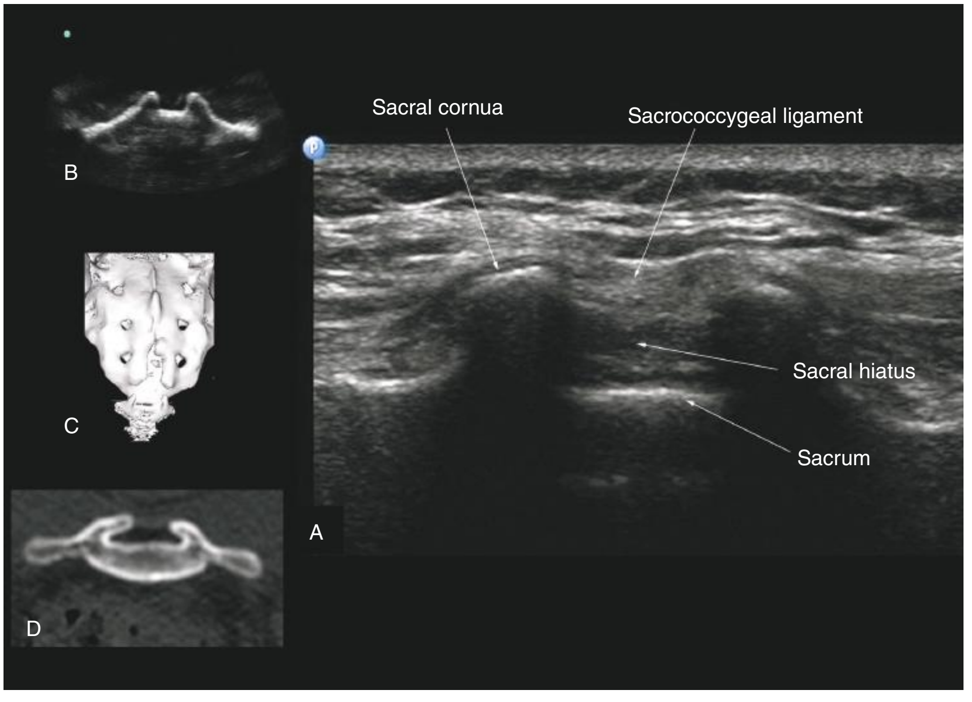

FIGURE 40–36. Transverse sonogram of the sacrum at the level of the sacral hiatus. Note the two sacral cornua and the hyperechoic sacrococcygeal ligament that extends between the two sacral cornua. (**A**) The hypoechoic space between the sacrococcygeal ligament and the posterior surface of the sacrum is the sacral hiatus. The image in (**B**) shows the sacral cornua from the water-based spine phantom; the image in (**C**) shows a three-dimensional (3D) reconstructed image of the sacrum at the level of the sacral hiatus from a 3D CT dataset from the author's archive; and the image in (**D**) shows a transverse CT slice of the sacrum at the level of the sacral cornua.

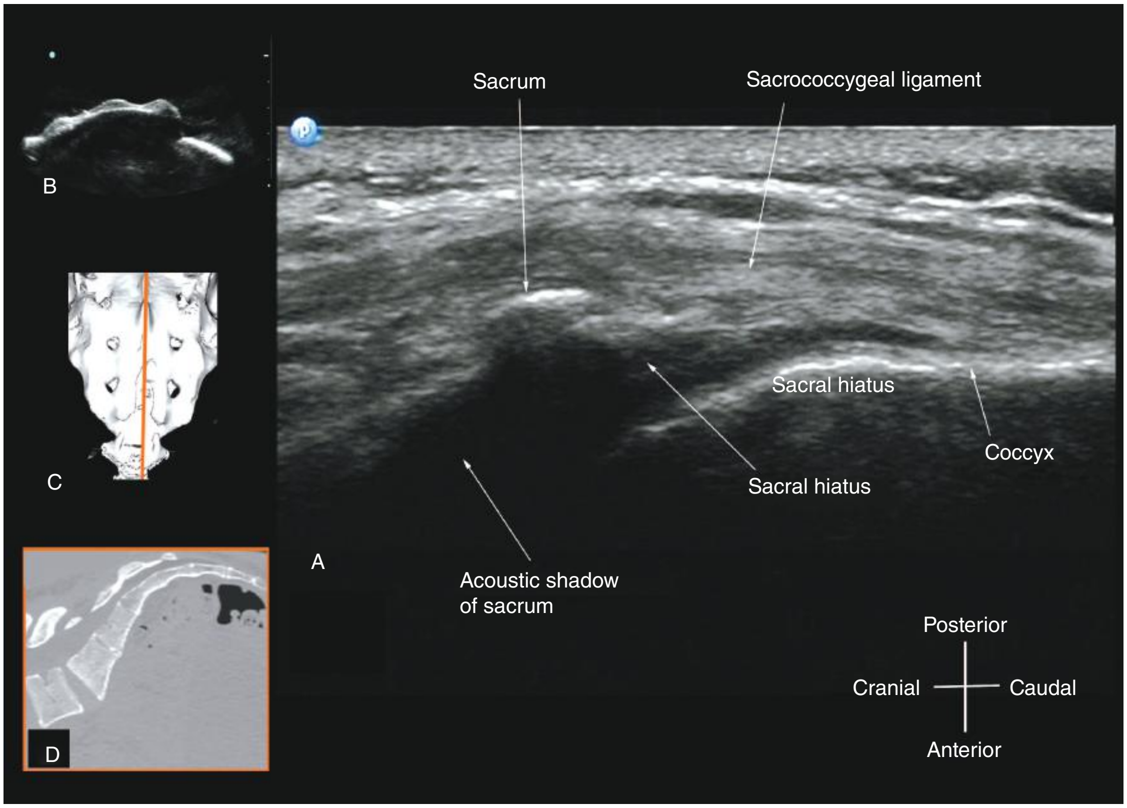

FIGURE 40–37. Sagittal sonogram of the sacrum at the level of the sacral hiatus. operator should have a sound knowledge of the basics of US, be familiar with the sonoanatomy of the spine and scanning techniques, and have the necessary interventional skills before attempting a real-time USG CNB.

At this time, there are no data on the safety of the US gel if it is introduced into the meninges, subarachnoid space, or nervous tissues during USG CNB. However, data from animal studies in pigs suggests that this results in an inflammatory response within the neuraxial space.[46] Due to the paucity of published data, it is not possible to make recommendations, although some clinicians have resorted to using sterile normal saline solution as an alternative coupling agent to keep the skin moist under the footprint of the transducer during the scan.[12] As a result, there is some degradation in the quality of the US image, but this can be overcome by minor changes in the settings of the US system.

KEY PRINCIPLES

1. The use of US to assist or guide CNBs is an advanced technique that can be helpful in patients with difficult spinal anatomy. It is necessary to gain experience with the use of US for neuraxial blockade before attempting it in patients with difficult anatomy.
2. If the posterior or anterior complex cannot be clearly visualized, the articular and transverse processes identified in a transverse scan can serve as surrogate markers of the interlaminar space.
3. Asymmetry in the position of the articular processes in a transverse interspinous view of the lumbar spine suggests a rotational defect in the vertebra; for example, as seen in scoliosis.
4. The angle of insonation that provides the best visualization of the posterior dura during a transverse interspinous scan usually reflects the angle (trajectory) at which the needle should be inserted during a midline CNB.
5. When performing a preprocedural scan, meticulous skin marking and keeping the skin from shifting are important.
6. In older patients, the failure to visualize the anterior or posterior complex may indicate narrowed interspaces from degenerative disease. Neuraxial block may still be possible, but difficulty should be anticipated, and there should be a lower threshold for proceeding to alternative methods of anesthesia or analgesia.
7. Strict asepsis must be maintained, and we recommend local protocols be established for USG CNB.
8. Attention to detail with positioning of the patient and ergonomics go a long way in ensuring success during a USG CNB.
9. Needle deviation during insertion may occur, especially with long, thin (25-gauge or less) needles in obese

subjects. This can be avoided by careful needle handling and the use of introducer needles or larger-gauge needles (22-gauge or larger) for the CNB.

10. If bone is encountered during needle insertion, subsequent alterations in trajectory should be small and gradual to avoid overshooting the interlaminar space.
11. The lumbosacral junction (L5–S1 gap) is the largest interlaminar space and must not be overlooked in patients with difficult spines, as it may provide a safe route for access to the neuraxis for CNBs.

TYPES OF INJECTION

Spinal Injection

There are limited data in the published medical literature on the use of US for spinal (intrathecal) injections,[47,48] although US has been reported to guide lumbar punctures by radiologists[49] and emergency physicians.[50] Most available data are anecdotal case reports.[47,48,51–53] Yeo and French, in 1999, were the first to describe the successful use of US to assist spinal injection in a patient with abnormal spinal anatomy.[53] They used US to locate the vertebral midline in a parturient with severe scoliosis with Harrington rods in situ.[53] Yamauchi and colleagues have described using US to preview the neuraxial anatomy and measure the distance from the skin to the dura in a post-laminectomy patient before the intrathecal injection was performed under X-ray guidance.[52] Costello and Balki have described using US to facilitate spinal injection by locating the L5–LS1 gap in a parturient with poliomyelitis and previous Harrington rod instrumentation of the spine.[47] Prasad and colleagues have reported using US to assist spinal injection in a patient with obesity, scoliosis, and multiple previous back surgeries with instrumentation.[48] More recently, Chin and colleagues[51] have described real-time USG spinal anesthesia in two patients with abnormal spinal anatomy (one had lumbar scoliosis, and the other had undergone spinal fusion surgery at the L2–L3 level).

Lumbar Epidural Injection

US imaging can be used to preview the underlying spinal anatomy[16–18] or to guide the Tuohy needle in real time[12] during a lumbar epidural access. Moreover, real-time US guidance for epidural access can be performed by one[12] or two[18] operators. In the latter technique, described by Grau and colleagues[18] for combined spinal epidural anesthesia, one operator performs the US scan via the paramedian axis, while the other carries out the needle insertion through the midline approach using a "loss-of-resistance" technique.[18] Using this approach, Grau and colleagues reported being able to visualize the advancing epidural needle despite different axes of US scan and needle insertion.[18] They were able to visualize the dural puncture in all patients, as well as dural tenting in a few cases, during the needle-through-needle spinal puncture.[18]

Karmakar and colleagues recently described a technique of real-time USG epidural injection in conjunction with loss of resistance (LOR) to saline.[12] The epidural access was performed by a single operator, and the epidural needle was inserted in the plane of the US beam via the paramedian axis.[12] Generally, it is possible to visualize the advancing epidural needle in real time until it engages in the ligamentum flavum.[12] The need for a second operator to perform the LOR can be circumvented by using a spring-loaded syringe (eg, Episure AutoDetect syringe, Indigo Orb, Inc., Irvine, CA) with an internal compression spring that applies constant pressure on the plunger (Figure 40–38).[12] Anterior displacement of the posterior dura and widening of the posterior epidural space are the most frequently visualized changes within the spinal canal. Compression of the thecal sac can be seen occasionally.[12] These ultrasonographic signs (Figure 40–39) of a correct epidural injection were previously described in children.[54] The neuraxial changes that occur within the spinal canal following the "loss of resistance" to saline may have clinical significance.[12]

Despite the ability to use real-time US for establishing epidural access, visualization of an indwelling epidural catheter in adults has proved more challenging. Occasionally, anterior displacement of the posterior dura and widening of the posterior epidural space after an epidural bolus injection via the catheter can be observed and therefore used as a surrogate marker of the location of the catheter tip. Grau and colleagues postulated that this may be related to the small diameter and poor echogenicity of conventional epidural catheters.[30] It remains to be seen whether the imminent development of echogenic epidural needles and catheters will have an impact on the ability to visualize epidurally placed catheters.

Thoracic Epidural Injection

There are limited published data on the use of US for thoracic epidural blocks.[55] This lack may be due to the poor US visibility of the neuraxial structures in the thoracic region compared with the lumbar region (see above) and the associated technical difficulties. However, despite the narrow acoustic window, the lamina, interlaminar space, and posterior dura are visualized consistently when using the paramedian axis (see Figures 40–31, 40–32, 40–33, 40–34, and 40–35). The epidural space is more difficult to delineate, but it also is best visualized in a paramedian sagittal scan (see Figures 40–31 and 40-32).[28] As a result, US can be used to perform a preprocedural scan[55] or, as we have used it, to assist epidural access via the paramedian window. In the latter approach, the patient is positioned in the sitting position, and a PMSOS is performed at the desired thoracic level with the orientation marker of the transducer directed cranially. Under strict aseptic precautions (described previously), the Tuohy needle is inserted via the paramedian axis in real time and in the plane of the US beam. The needle is advanced steadily until it makes contact with the lamina or enters the interlaminar space. At this point, the US transducer is removed, and a traditional loss-of-resistance-to-saline technique is used to access the epidural space. Because the lamina is relatively superficial in the thoracic region, it is possible to visualize the advancing Tuohy needle in real time. Preliminary experience with this approach indicates that US may improve the likelihood of thoracic epidural access on the first attempt. However, more research to compare the utility of a

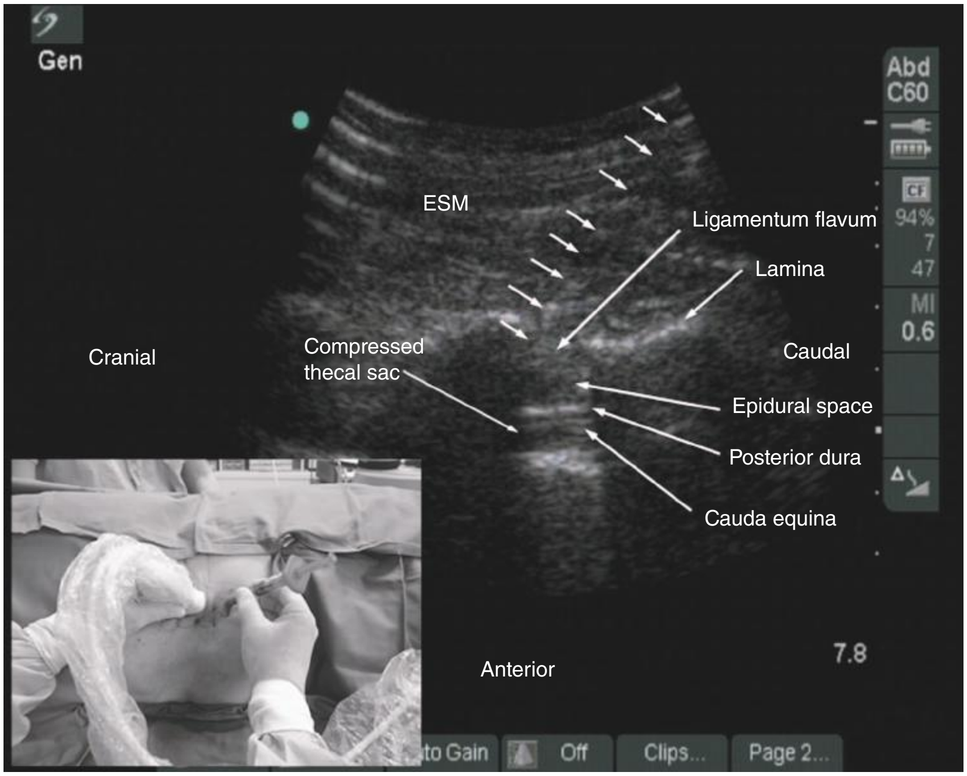

FIGURE 40–38. Paramedian oblique sagittal sonogram of the lumbar spine showing the sonographic changes within the spinal canal after the "loss of resistance" to saline. Note the anterior displacement of the posterior dura, the widening of the posterior epidural space, and the compression of the thecal sac. The cauda equina nerve roots are also now better visualized within the compressed thecal sac in this patient. The inset image shows how the Episure AutoDetect syringe was used to circumvent the need for a third hand for the "loss of resistance."

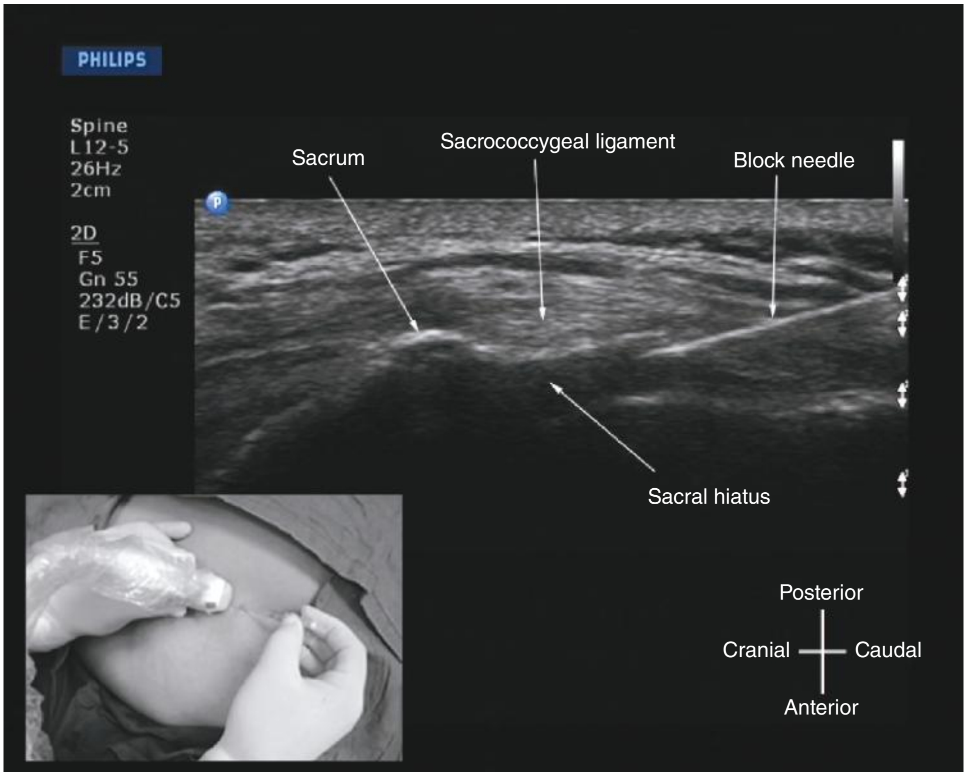

FIGURE 40–39. Sagittal sonogram of the sacrum at the level of the sacral hiatus during a real-time US-guided caudal epidural injection. Note the hyperechoic sacrococcygeal ligament and the block needle that has been inserted in the plane (in-plane) of the US beam. The inset image shows the position and orientation of the transducer and the direction in which the block needle was inserted.

preprocedural scan or the US-assisted technique described above with the traditional approach is necessary before more definitive recommendations on the utility and safety of US for thoracic epidural injections can be made.

Caudal Epidural Injection

For a USG caudal epidural injection, a transverse (see Figure 40–36) or sagittal (see Figure 40–37) scan is performed at the level of the sacral hiatus. Because the sacral hiatus is a superficial structure, a high-frequency (13-6 MHz) linear array transducer is used for the scan as described previously. The needle can be inserted in the short (out-of-plane) or long (in-plane) axis. For a long-axis needle insertion, a sagittal scan is performed, and the passage of the block needle through the sacrococcygeal ligament into the sacral canal is visualized in real time (see Figure 40–39). However, because the sacrum impedes the passage of the US, there is a large acoustic shadow anteriorly, which makes it impossible to visualize the tip of the needle or the spread of the injectate within the sacral canal. An inadvertent intravascular injection, which reportedly occurs in 5%–9% of procedures, may not be detected using US. As a result, the clinician should still factor in traditional clinical signs such as the "pop" or "give" as the needle traverses the sacrococcygeal ligament, ease of injection, absence of subcutaneous swelling, "whoosh test," nerve stimulation, or assessment of the clinical effects of the injected drug to confirm correct needle placement.

Color Doppler US can also be used to confirm spread of the injectate inside the caudal epidural space.[56] This is done by placing the color Doppler interrogation box over the acoustic window of the caudal canal in the sagittal sonogram while the injection is performed. Yoon and colleagues have reported that a correct injection deep to the sacrococcygeal ligament with unidirectional flow produces, in real time, a positive color spectrum change with one predominant color.[56] In contrast, an inadvertent intravascular injection is seen as multicolored spectrum.[56] Chen and colleagues reported a 100% success rate in placing a caudal needle under US guidance as confirmed by contrast fluoroscopy.[43] This report is encouraging, considering that, even in experienced hands, failure to place a needle in the caudal epidural space successfully is as high as 25%.[43,57]

More recently, Chen and colleagues[58] have described using US imaging as a screening tool during caudal epidural injections.[58] In their cohort of patients, the mean diameter of the sacral canal at the sacral hiatus was 5.3 ± 2 mm, and the distance between the sacral cornua (bilateral) was 9.7 ± 1.9 mm.[58] These researchers also identified that the presence of sonographic features such as a closed sacral hiatus and a sacral canal diameter of around 1.5 mm are associated with a greater probability of failure.[58]

Based on the published data, it can be concluded that US guidance, despite its limitation, can be useful as an adjunct tool for caudal epidural needle placement and has the potential to improve technical outcomes, reduce failure rates and accidental intravascular injection, and minimize exposure to radiation in the chronic pain setting and therefore deserves further investigation.

CLINICAL UTILITY OF ULTRASOUND FOR CENTRAL NEURAXIAL BLOCKS

Outcome data on the use of US for CNB have primarily focused on the lumbar region. Most studies to date have evaluated the utility of a preprocedural US scan. A preprocedural scan allows the operator to identify the midline[13] and accurately determine the interspace for needle insertion,[11,12,39] which are useful in patients in whom anatomical landmarks are difficult to palpate, such as in those with obesity,[2,15] edema of the back, or abnormal anatomy (eg, scoliosis,[15,59] postlaminectomy surgery,[52] or spinal instrumentation[47,48,53]). It also allows the operator to preview the neuraxial anatomy,[12,16–18,55,60] identify asymptomatic spinal abnormalities, such as in spina bifida,[61] predict the depth to the epidural space,[16,17,24,25] particularly in obese patients,[44] identify ligamentum flavum defects,[62] and determine the optimal site and trajectory for needle insertion.[17,30] Cumulative evidence suggests that a US examination performed before the epidural puncture improves the success rate of epidural access on the first attempt,[16] reduces the number of puncture attempts[15–20] or the need to puncture multiple levels,[16–18] and also improves patient comfort during the procedure.[17] A preprocedural scan can also be useful in patients presumed to have difficult epidural access, such as those with a history of difficult epidural access, obesity, or kyphosis or scoliosis of the lumbar spine.[15,63] When used for obstetric epidural anesthesia, US guidance was reported to improve the quality of analgesia, reduce side effects, and improve patient satisfaction.[15,18] A preprocedural scan may also improve the learning curve of students for epidural blocks in parturients.[29] Currently, there are limited data on the utility of real-time US guidance for epidural access,[12,18] although preliminary reports indicate that it may improve technical outcomes.[18]

APPLICATIONS IN THE LUMBAR SPINE

Identification of Specific Lumbar Intervertebral Levels

The identification of lumbar intervertebral levels based on surface anatomical landmarks is often imprecise. In one study using MRI as the gold standard, the correct intervertebral level was identified in as few as 29% of patients.[4] Other studies have repeatedly shown significant discordance between US and clinical determinations of lumbar intervertebral level. In an orthopedic population of 50 patients undergoing total joint arthroplasty, the palpated intercristal line corresponded to the L3–L4 level identified by US in 72%, to the L2–L3 level in 26%, and to the L4–L5 level in 2% of patients.[45] In a similar study of 90 parturients, identification of the L3–L4 intervertebral space was concordant in only 53% of nonobese and 49% of obese patients.[64] Of more concern was the fact that in 93% of the cases where there was disagreement, the clinically identified L3–L4 level corresponded to a higher (L1–L2 or L2–L3) level as identified by US. This tendency was confirmed by two other studies of women who had received epidural anesthesia for labor analgesia.[65,66] Both compared the documented epidural insertion level with a postpartum US assessment of the intervertebral level corresponding to the needle insertion scar. Once again, a high rate of discordance (45–63%) was observed between the two assessment methods, and the level of insertion according to US was more likely to be higher (72–76%) than that noted in the clinical record.

The available evidence indicates that US is more accurate than clinical assessment of intervertebral level. In one study comparing clinical assessment, US, and the gold standard of lateral spine X-ray examination,[39] clinical assessment accurately identified the L2–L3 interspace only 30% of the time, with an additional 7% of markings placed over the immediately adjacent spinous processes. US correctly identified the L2–L3 interspace in 60% of cases, with a further 24% of markings placed over the immediately adjacent spinous processes. It should be noted that the margin of error with US was at most either one space above (9%) or below (7%) the intended target. In contrast, clinical assessment showed greater variability, with margins of error up to two spaces higher (9%) or lower (18%). Furthermore, clinical assessment of intervertebral level was deemed impossible in 4% of cases compared to none when US was used.

FACILITATING THE TECHNICAL PERFORMANCE OF SPINAL AND EPIDURAL ANESTHESIA

Measuring Depth to the Epidural and Intrathecal Spaces

Cork et al. provided one of the first reports of the use of US to assist in epidural anesthesia. Despite relatively primitive US equipment, they were able to identify and measure the depth to the ligamentum flavum using a longitudinal neuraxial scan in 33 of 36 patients.[24] They found a high correlation ($r = 0.98$) between measured depth by US and needle depth to the epidural space. In a subsequent study, Currie et al. also found a high correlation ($r = 0.96$) between US-measured depth to the lamina in the PMSO view and needle insertion depth to the epidural space.[25] The transverse interspinous view may also be used to measure the depth to the epidural space.

A high correlation between the measured depth to the posterior complex and needle insertion depth has been observed in both obese and nonobese parturients undergoing labor epidural analgesia ($r = 0.85$–0.88)[44,60] and has been consistently demonstrated in a large number of studies.[15,16,26,67–70] A recent meta-analysis[19] identified 13 studies, involving 875 patients, that specifically addressed the correlation between US-measured depth and actual needle insertion depth. They confirmed that the correlation was high, regardless of which US view was used, with a pooled correlation coefficient of 0.91. The difference between US-measured depth and needle insertion depth in most trials is quite small (approximately 0.5 cm or less), with US usually underestimating needle depth. This difference is commonly attributed to soft-tissue compression by the US transducer during the scan.

Reducing the Number of Needle Passes Required for Block Success

In an early 2001 study of preprocedural US, Grau et al.[15] randomized 72 parturients with difficult anatomy to surface landmark–guided or US-assisted epidural placement. Patients had either a history of difficult epidural, kyphoscoliosis, or a body mass index (BMI) of more than 33 kg/m^2. In this population, needle entry into the epidural space in the surface landmark–guided group required a mean of 2.6 puncture attempts compared to 1.5 in the US-assisted group ($p < 0.001$).

More recently, Chin et al. evaluated an older population of 120 orthopedic patients with clinical predictors of difficult neuraxial block, including a BMI of more than 35 kg/m^2, scoliosis, and prior lumbar surgery.[63] Patients were randomized to either surface landmark–guided or US-assisted spinal anesthesia. US halved the median number of needle insertions from 2 to 1 and significantly reduced the need for additional needle passes (6 vs. 13).[63]

Improved performance of neuraxial blockade after preprocedural ultrasound imaging is seen even in patients without predictors of technical difficulty. In a randomized controlled trial by Grau et al. of epidural analgesia in 300 parturients, the mean number of needle passes was significantly lower with the use of US compared to surface landmarks alone (1.3 vs. 2.2).[17] These findings were validated in a later study by Vallejo et al., who randomized 15 first-year anesthesia trainees to perform 370 labor epidurals with or without the assistance of preprocedural US imaging.[70] Once again, fewer insertion attempts were required in the US-guided group of patients (median of 1 vs. 2).[70]

Most recently, two separate systematic reviews of the available literature have confirmed these findings. Shaikh et al.[20] compared US-guided and non–US-guided neuraxial procedures, including diagnostic lumbar punctures as well as epidural and spinal anesthetics. They identified 14 publications, involving 1334 patients, that met their inclusion criteria. They found that the use of US significantly reduced both skin punctures and needle redirections required for successful CNB. Perlas et al.[19] performed a similar systematic review of studies involving the use of US for lumbar CNB and lumbar puncture in adults. They identified 14 randomized controlled trials that met inclusion criteria, six of which were newer and had not been included in the previous systematic review. Once again, they found that US significantly reduced the overall number of needle passes required for procedural success.

Improved Block Success and Epidural Efficacy

In addition to reducing the technical difficulty of epidural needle insertion, US may also increase the efficacy of labor epidural analgesia. In two separate randomized controlled trials by Grau et al.,[15,17] there was a significant reduction in the rate of incomplete analgesia (2% vs. 8%) in one study[17] and epidural failure (0% vs. 5.6%) in the other.[15] In addition, a small but statistically significant decrease in post-block pain scores was noted in the US-assisted groups compared to the surface landmark–guided groups. These findings may be partially explained by observed reductions in the incidences of asymmetric and patchy blocks. It is notable that the more recent study by Vallejo et al., involving multiple operators, observed a similarly impressive reduction in the epidural failure rate in the US-assisted group (1.6% vs. 5.5%).[70] Systematic reviews have provided further evidence that US increases block success.[19,20] Shaikh et al. found that the use of US reduced the risk of procedural failure by 79%, with a number needed to treat (NNT) to avoid one failure of 16. A subgroup analysis of intrathecal (relative risk [RR] = 0.19) and epidural (RR = 0.23) procedures confirmed that this effect is similar for both.[20] The findings of Perlas et al. were similar, although more modest in magnitude, with a risk reduction of 49% and an NNT of 34 for procedural failure.[19]

Effect on Procedure Time

In their early evaluations of US-assisted lumbar epidural insertion, Grau et al. reported that US scanning added only 60–75 seconds to the preparation time.[16,17] Similarly, in their large randomized controlled trial of labor epidural insertion by trainees, Vallejo et al. reported that the use of US increased average total procedure time by 60 seconds.[70] The caveat here is that these studies involved a single experienced sonographer and a cohort of healthy obstetric patients with normal anatomy. More time may be required in less-experienced hands or in patients with difficult spinal anatomy. Chin et al.[63] found that in patients with scoliosis, prior lumbar surgery, or a BMI of more than 35 kg/m^2, preprocedural scanning took 6.7 minutes on average to complete compared to 0.6 minutes for palpation of surface landmarks alone. However, this difference was partially offset by a decrease in time taken to perform the spinal anesthetic (5.0 vs. 7.3 minutes).[63]

Reducing the Risk of Complications

US may potentially reduce adverse effects related to neuraxial anesthesia. Grau et al.[17] observed a significant reduction in the rate of postpartum headache (4.7% vs. 18.7%) and backache (14.7% vs. 22.0%) with US-assisted epidural insertion. The risk of inadvertent dural puncture may also be reduced by the ability to measure the depth to the epidural space.

With regard to more serious complications, although there is no direct supporting evidence, the decreased technical difficulty associated with US suggests that it may theoretically reduce risk in a number of ways. Conus medullaris injuries from spinal needles inserted at a level much higher than intended by the anesthesiologist have been reported.[7,8] Improved accuracy of intervertebral level identification could reduce the risk of this rare but potentially devastating outcome. Spinal hematoma and persistent neurological deficit are similarly rare but important complications. Technical difficulty in performing the block has been identified as an associated risk factor for both these complications;[71,72] thus, preprocedural US has the potential to reduce their incidence. This is supported by the recent meta-analysis by Shaikh et al.[20] of US-guided versus non–US-guided procedures, which found a 73% reduction in the risk of traumatic procedures with the use of US.[20]

Predicting the Feasibility and Ease of Performing Neuraxial Blockade

In addition to assisting the technical performance of neuraxial blockade, US may also be used as a preoperative assessment tool to guide decision making. This has been illustrated in two case reports. The first involved a patient who had a history of L3–L5 spinal decompression and fusion with corresponding hardware in situ and who had experienced two previous failed attempts at a spinal anesthetic. Preprocedural US determined that there was in fact a patent acoustic window at the L3–L4 level, which, due to dense overlying scar tissue, could be penetrated only by a larger-gauge (22-gauge) Quincke-tip spinal needle.[51] The second involved a patient with severe ankylosing spondylitis and a history of failed spinal anesthesia despite persistent efforts by multiple experienced operators. Here, a US scan in the preanesthetic clinic identified an acoustic window at L4–L5, which allowed planning for a spinal anesthetic that was successfully performed at that level on the day of surgery.[73]

The potential of using US to predict the ease of performing spinal anesthesia has been evaluated in two cohort studies. These were based on the premise that the ability to visualize the vertebral canal should correspond to the size of the interlaminar space, thus reflecting the ease with which it may be penetrated. Weed et al.[74] performed preprocedural US scans using the PMSO view in 60 orthopedic patients and documented the quality of the images obtained. Clinicians blinded to the results of the imaging performed spinal anesthesia using a surface landmark–guided approach. There was a remarkable difference in block performance between patients in whom the anterior complex was visible on US (a good image) and those in whom it was not (a poor image).[74] When images were poor, the median number of needle passes required was 10 compared to 4 in patients with good images. Spinal anesthesia was classified as difficult by the operator in 9% of patients with good images compared to 50% of patients with poor images of the anterior complex. The positive predictive value of a poor image in the PMSO view for difficult spinal anesthesia was calculated to be 82.3%, with the negative predictive value 67.4%.[74]

In the second study, Chin et al. studied the ability of both the PMSO and transverse interspinous views to predict difficult spinal anesthesia in a cohort of 100 orthopedic patients.[14] As in the study by Weed et al., the anesthesiologists performing the spinal anesthetic were blinded to the results of imaging. If both posterior and anterior complexes were visible (a good-quality view) in the transverse interspinous view, the positive predictive value for absence of technical difficulty at that level was 85%.[14] This discriminative ability was not present, however, with the PMSO view, which may be explained by the fact that a midline needle approach was used in all cases. There were a small number of patients in whom spinal anesthesia was challenging despite a good-quality transverse median (TM) view of the vertebral canal. The authors hypothesized that this could have been avoided if the preprocedure US scan had been used to guide the spinal procedure, as would be the case in the clinical setting.

APPLICATIONS IN THE THORACIC SPINE

Identification of Thoracic Intervertebral Levels

As in the lumbar spine, clinical methods of identifying thoracic intervertebral levels based on surface anatomical landmarks have been shown to be inaccurate when referenced to the gold standard of MRI or X-ray imaging.[6,75,76] In one study, the T7 spinous process was accurately identified only 29% of the time by counting down from the vertebra prominens (C7) and only 10% of the time when the inferior tip of the scapula was used as the primary landmark.[76] The majority of errors tended to be in the caudad direction.[6,76] The accuracy of US in identifying thoracic intervertebral levels has not been verified against a gold-standard imaging modality; however, Arzola et al.[77] have demonstrated a similar lack of agreement between US identification of thoracic intervertebral level (using a counting-up method from the sacrum and twelfth rib) and surface anatomical landmarks. As with the earlier studies, the vertebra prominens was a more accurate landmark for C7 (58% agreement) than the inferior angle of the scapula was for T7 (36% agreement). Errors in identifying T7 were most often in a caudad direction (83% of errors), whereas the errors in identifying C7 were equally distributed in a cephalad and caudad direction.

Determining the Depth to the Thoracic Epidural Space

Rasoulian et al. compared US measurement of the depth to the ligamentum flavum in the PMSO view to actual needle insertion depth in a small cohort of 20 patients receiving thoracic epidural analgesia.[78] There was moderately good correlation (r^2 = 0.65) observed between the two measurements, with US tending to underestimate needle insertion depth by a mean of 4.68 mm. It is notable that this correlation was similar to that obtained when CT measurement of the depth to the epidural space was compared to needle insertion depth (r^2 = 0.69, mean difference of 4.49 mm). Similar results were reported by Salman et al. in another study of mid-to-lower thoracic epidural insertion in 35 adult patients using a paramedian approach.[55] Correlation between US-measured depth and needle insertion depth was good (r^2 = 0.75), and the mean difference was 7.1 mm, with US tending to underestimate the depth. These findings suggest that US is a useful tool for estimating depth to the thoracic epidural space.

Improving the Technical Performance of Thoracic Epidurals

The ability to delineate the underlying anatomy of the thoracic spine can potentially improve the technical performance of thoracic epidurals. However, unlike in the lumbar spine, there is presently limited evidence supporting the benefit of preprocedural US imaging in this regard. In the aforementioned study by Salman et al.,[55] the PMSO view on US was used to determine the optimal needle insertion point for a paramedian approach to mid-to-lower thoracic epidural insertion.[55] Successful insertion was achieved with only one skin puncture on average and within two or fewer redirections in 88% of cases. In addition, case reports suggest that US is useful in evaluating abnormal anatomy and determining the optimal needle insertion site and trajectory in scoliotic patients.[59,79]

EDUCATION AND TRAINING

Learning USG CNB techniques takes time and patience. Regardless of the technique used, USG CNB and, in particular, real-time USG CNB are advanced techniques and are by far the most difficult USG interventions. They demand a high degree of manual dexterity, hand–eye coordination, and an ability to conceptualize two-dimensional information into a 3D image. Therefore, before attempting to perform a USG CNB, the operator should have a sound knowledge of the basics of US, be familiar with image optimization, understand the sonoanatomy of the spine, and have the necessary interventional skills. It is advisable to start by attending a course or workshop tailored to this purpose where the operator can learn the basic scanning techniques, spinal sonoanatomy, and relevant interventional skills. Further experience in spinal sonography can also be acquired by scanning human volunteers.[80] Currently, there is paucity of data[80,81] on what the minimum training requirement is to attain competence in spinal sonography or USG CNB. Preliminary data suggest that once the basic knowledge on US of the lumbar spine is attained, experience with 40 or more cases may be necessary to attain competence in scanning.

Today, there are several models (phantoms) for learning spinal sonoanatomy and practicing USG central neuraxial interventions. The water-based spine phantom[35] is useful for learning the osseous anatomy of the spine, but it is not a good model for learning USG spinal interventions because it lacks tissue-mimicking properties. Spinal sonography is often taught at workshops, but such workshops are not suitable for practicing actual techniques. Fresh cadaver courses are available, which allow participants to study neuraxial sonoanatomy and practice USG CNB with realistic haptic feedback, but they may be limited by the quality of the US images. Further, such courses are uncommon and conducted in anatomy departments with the cadavers in a position that rarely mimics what is practiced in the operating room. Anesthetized pigs can also be used, but animal ethics approval is required and, for the organizers, a license from the local health department to conduct such workshops. This method entails infectious precautions, and religious beliefs may preclude its use as a model for some. Moreover, such workshops are conducted in designated animal laboratories that are typically small and not suited to accommodate large groups of participants. To circumvent some of these problems, the group at the Chinese University of Hong Kong recently introduced the pig carcass spine phantom (see Figure 40–12),[37] an excellent model that can be used in conference venues and provides excellent tactile and visual feedback.[37] The limitation of the pig carcass spine phantom is that it is a decapitated model, and there is loss of cerebrospinal fluid during the preparation process. This presentation results in air artifacts and loss of contrast within the spinal canal during spinal sonography unless the thecal sac is cannulated at its cranial end and continuously irrigated with fluid (normal saline), a process that requires surgical dissection to isolate the thecal sac.[82]

Therefore, an "in vitro" model that can facilitate the learning of the scanning techniques and the hand–eye coordination skills required for real-time USG CNB is highly desirable. A low-cost gelatin-based US phantom of the lumbosacral spine has been recently proposed.[36] However, the gelatin phantom is soft in consistency, lacks tissue-mimicking echogenic properties, does not provide haptic feedback, is easily contaminated with mold and bacteria, and is limited in its usefulness by needle track marks,[36] all of which preclude its extended use.

Karmakar and colleagues have recently developed a gelatin–agar spine phantom[83] (see Figure 40–11) that overcomes some of the drawbacks of the gelatin-based spine phantom. It is mechanically stable, has a tissue-like texture and echogenicity, needle track marks are less of a problem, and it can be used over extended periods of time to study the osseous anatomy of the lumbosacral spine and to practice the hand–eye coordination skills required to perform USG CNB.[83] Although a variety of spine phantoms have been described to learn the scanning and needle insertion techniques in the workshop setting, none of these have undergone scrutiny to determine how effective they are for transferring the knowledge and skills necessary for USG CNB.

Once the basic knowledge and skills are attained, it is best to start by performing USG spinal injections, under supervision, before progressing to performing epidural blocks. Real-time USG epidurals can be technically challenging, even for an experienced operator, and it is our opinion that it is not practical in the clinical setting or for everyday use. In contrast, a preprocedural scan is simple to perform and provides valuable information that can translate into improved technical outcomes during a CNB and may be the prudent approach to using US for CNBs. That said, real-time US guidance might be the only way out, for safety, in patients with difficult backs (eg, those with scoliosis, ankylosing spondylitis, or instrumented or operated backs). Therefore, the skills necessary to perform real-time USG CNBs must be developed as part of one's ongoing skill development. If it is not possible to gain experience in USG CNB locally, it is advisable to visit a center where such interventions are practiced.

SUMMARY

USG CNB is a rapidly developing alternative to traditional landmark-based techniques. It is noninvasive, safe, can be quickly performed, does not involve exposure to radiation, provides real-time images, and is free from adverse effects. Experienced sonographers can visualize neuraxial structures with satisfactory clarity using US. A preprocedural scan allows the operator to preview the spinal anatomy, identify the midline, locate a given intervertebral level, accurately predict the depth to the epidural space, and determine the optimal site and trajectory for needle insertion. A preprocedural scan may also be used to predict the feasibility and ease of performing CNBs. The use of US also improves the success rate of epidural access on the first attempt, reduces the number of puncture attempts or the need to puncture multiple levels, and improves patient comfort during the procedure. US is an excellent teaching tool for demonstrating the anatomy of the spine and improves the learning curve for the performance of epidural blocks in parturients. US guidance also may allow the use of CNB in patients who in the past may have been considered unsuitable for such procedures due to abnormal spinal anatomy.

However, US guidance for CNB is still in its early stages of development; the evidence to support its use is sparse but in favor of its use as a preprocedural imaging tool. Furthermore, initial experience with real-time USG CNB indicates that it is technically demanding and, therefore, unlikely to replace traditional methods of performing CNB in the near future because traditional methods are well established as safe, simple, and effective in most patients. As US technology continues to improve and as skills necessary to perform USG interventions become more widely available, the use of US for CNB may become the standard of care in the future.

PART 5

OBSTETRIC ANESTHESIA

This page intentionally left blank

CHAPTER 41

Obstetric Regional Anesthesia

Jason Choi, Liane Germond, and Alan C. Santos

INTRODUCTION

Most women experience moderate to severe pain during labor and delivery, often requiring some form of pharmacologic analgesia.[1] The lack of proper psychological preparation combined with fear and anxiety can greatly enhance the patient's sensitivity to pain and further add to the discomfort during labor and delivery. However, skillfully conducted obstetric analgesia, in addition to relieving pain and anxiety, may benefit the mother in many other ways. This chapter focuses on the management of obstetric patients with a primary focus on regional anesthesia techniques.

Physiologic Changes of Pregnancy

Pregnancy results in significant changes affecting most maternal organ systems (Table 41–1). These changes are initiated by hormones secreted by the corpus luteum and the placenta. Such changes have important implications for the anesthesiologist caring for the pregnant patient. This chapter reviews the most relevant physiologic changes of pregnancy and discusses the approach to obstetric management using regional anesthesia.

Changes in the Cardiovascular System

Oxygen consumption increases during pregnancy, as the maternal cardiovascular system is required to meet the increasing metabolic demands of a growing fetus. The end result of these changes is an increase in heart rate (15%–25%) and cardiac output (up to 50%) compared with values before pregnancy. In addition, lower vascular resistance is found in the uterine, renal, and other vascular beds. These changes result in a lower arterial blood pressure because of a decrease in peripheral resistance, which exceeds the increase in cardiac output. Decreased vascular resistance is mostly due to the secretion of estrogens, progesterone, and prostacyclin.[2] Particularly significant increases in cardiac output occur during labor and in the immediate postpartum period owing to added blood volume from the contracted uterus.

Clinical Pearls

- Cardiovascular changes and pitfalls in advanced pregnancy include the following:
- Increase in heart rate (15%–25%) and cardiac output (up to 50%).
- Decrease in vascular resistance in the uterine, renal, and other vascular beds.
- Compression of the lower aorta in the supine position may further decrease uteroplacental perfusion and result in fetal asphyxia.
- Significant hypotension is more likely to occur in pregnant versus nonpregnant women undergoing regional anesthesia, necessitating uterine displacement or lateral pelvic tilt maneuvers, intravascular preloading, and vasopressors.

From the second trimester onward, aortocaval compression by the enlarged uterus becomes progressively more important, reaching its maximum effect at 36–38 weeks, after which it may be relieved some as the fetal head descends into the pelvis.[3] Cardiac output may decrease when patients are in the supine position but not in the lateral decubitus position. Venous occlusion by the growing fetus causes supine hypotensive syndrome in 10% of pregnant women and manifests as maternal tachycardia, arterial hypotension, faintness, and pallor.[4]

Compression of the lower aorta in this position may further decrease uteroplacental perfusion and result in fetal asphyxia. Uterine displacement or lateral pelvic tilt should be applied routinely during the anesthetic management of the pregnant

TABLE 41–1. Summary of physiologic changes of pregnancy at term.

Variable	Change	Amount
Total blood volume	Increase	25%–40%
Plasma volume	Increase	40%–50%
Fibrinogen	Increase	50%
Serum cholinesterase activity	Decrease	20%–30%
Cardiac output	Increase	30%–50%
Minute ventilation	Increase	50%
Alveolar ventilation	Increase	70%
Functional residual capacity	Decrease	20%
Oxygen consumption	Increase	20%
Arterial carbon dioxide tension	Decrease	10 mm Hg
Arterial oxygen tension	Increase	10 mm Hg
Minimum alveolar concentration	Decrease	32%–40%

patient. Uterine displacement is best achieved by placing the patient in the left lateral decubitus position. In this position, cardiac vagal activity will be augmented as compared to the supine position.[5] Placing a wedge under the bony pelvis has been used to achieve uterine tilt. However, it has recently been demonstrated that uterine tilt is more effective when the mother is placed in the full left lateral decubitus position and then is turned supine onto the pelvic wedge.[6]

Changes in the electrocardiogram are common in late pregnancy. The QRS axis may initially shift to the right during the first trimester, rotating to left axis by the third trimester as a result of the expanding uterus.[7] A shortening of the PR and QT intervals and an increase in heart rate are also present. The QT interval shortening may have implications for women with long QT syndrome.[8] Indeed, Seth et al. found a reduced risk (risk ratio [RR] = 0.38) of cardiac events during pregnancy in woman with prolonged QT syndrome. However, an increased risk of postpartum cardiac events in the first nine months after delivery was also found, which suggests that the QT interval becomes prolonged again in the early post-delivery period. There is also a tendency toward premature atrial contractions, sinus tachycardia, and paroxysmal supraventricular tachycardia.

Changes in the Respiratory System

Minute ventilation increases from the beginning of pregnancy to a maximum of 50% above normal by term.[9] This is mostly a result of a 40% increase in tidal volume and a small increase in respiratory rate. Dead space does not change significantly during pregnancy; thus, alveolar ventilation is increased by 70% at term. After delivery, as blood progesterone levels decline, ventilation returns to normal within 1–3 weeks.[10]

Elevation of the diaphragm occurs with an increase in the size of the uterus. Expiratory reserve volume, residual volume, and functional residual capacity (FRC) decrease by the third trimester of pregnancy.[9] However, because there is also an increase in inspiratory reserve volume, total lung capacity remains unchanged. A decreased FRC is typically asymptomatic in healthy parturients. Those with preexisting alterations in closing volume as a result of smoking, obesity, scoliosis, or other pulmonary disease may experience early airway closure with advancing pregnancy, leading to hypoxemia. The Trendelenburg and supine positions also exacerbate the abnormal relationship between closing volume and FRC. The residual volume and FRC return to normal shortly after delivery.

Pregnant women often have difficulty with nasal breathing. Friability of the mucous membranes during pregnancy can cause severe bleeding, especially on airway instrumentation. These changes are caused by increased extracellular fluid and vascular engorgement. It may also be difficult to perform laryngoscopy in obese, short-necked parturients with enlarged breasts. Use of a short-handled laryngoscope has proved helpful.

Clinical Pearl

- Airway edema may be severe in pregnant women, particularly in those with preeclampsia, those in whom the Trendelenburg position is used for prolonged periods, and those in whom tocolytic agents are used.

Metabolic Changes

Oxygen consumption increases during early pregnancy, with an overall increase of 20% by term. Regardless, increased alveolar ventilation occurring during pregnancy actually leads to a reduction in the partial pressure of carbon dioxide in arterial blood ($PaCO_2$) to 32 mm Hg and an increase in the partial pressure of oxygen in arterial blood (PaO_2) to 106 mm Hg. The plasma buffer base decreases from 47 to 42 mEq; consequently, the pH remains practically unchanged. The maternal uptake and elimination of inhalational anesthetics are enhanced because of the increased alveolar ventilation and decreased FRC. However, the decreased FRC and increased metabolic rate predispose the mother to the development of hypoxemia during periods of apnea or hypoventilation.[11]

Changes in the Gastrointestinal System

The effects of pregnancy on the gastrointestinal system are controversial. It has been proposed that enhanced progesterone production causes decreased gastrointestinal motility and slower absorption of food. Gastric secretions are more acidic, and lower esophageal sphincter tone is decreased. However, more recent studies using radiographic, ultrasound, and dye dilution techniques have demonstrated that gastric emptying of liquid and solid materials does not decrease at any time during pregnancy.[12–15]

The risk of regurgitation on induction of general anesthesia depends, in part, on the gradient between the lower esophageal sphincter and intragastric pressures. In parturients with "heartburn," the lower esophageal sphincter tone is greatly reduced.[16] No single routine prophylactic regimen can be recommended with certainty. The efficacy of prophylactic nonparticulate antacids is diminished by inadequate mixing with gastric contents, improper timing of administration, and the tendency for antacids to increase gastric volume. The administration of histamine (H2)-receptor antagonists, such as cimetidine and ranitidine, requires anticipation and careful timing since their onset of action is relatively slow. In those women at greatest risk, an argument can be made for the administration of intravenous (IV) metoclopramide before elective cesarean section delivery. This dopamine antagonist hastens gastric emptying and increases resting lower esophageal sphincter tone in both nonpregnant and pregnant women.[17] However, there have been conflicting data on its efficacy (perhaps due to timing of administration) and the frequency of side effects, such as extrapyramidal reactions and transient neurologic dysfunction.[18,19]

Endocrine Changes Influencing Plasma Volume, Blood Composition, and Glucose Metabolism

Plasma volume and total blood volume begin to increase in early gestation, resulting in an increase of 40%–50% and 25%–40%, respectively, at term. These changes are due to an increased mineralocorticoid activity during pregnancy, which results in sodium retention and increased body water content.[20] The relatively smaller increase in red blood cell volume (20%) accounts for a relative reduction in hemoglobin (to 11–12 g/L) and hematocrit (to 35%); the platelet count, however, remains unchanged. Plasma fibrinogen concentrations increase during normal pregnancy by approximately 50%, whereas clotting factor activity is variable.[21] Coagulation factors I, VII, VIII, IX, X, and XII increase during pregnancy,[22] whereas factor XI and XIII concentrations decrease and factor II and V concentrations remain unchanged during pregnancy.

Serum cholinesterase activity declines to a level of 20% below normal by term and reaches a nadir in the puerperium. The net effect of these changes in the serum cholinesterase is of negligible relevance to the metabolism of clinically used doses of succinylcholine or ester-type local anesthetics (2-choloroprocaine).[23,24] The albumin–globulin ratio declines because of the relatively greater reduction in albumin concentration. A decrease in serum protein concentration may be clinically significant in that the free fractions of protein-bound drugs can be expected to increase.

Human placental lactogen and cortisol increase the tendency toward hyperglycemia and ketosis, which may exacerbate preexisting diabetes mellitus. The patient's ability to handle a glucose load is decreased, and the transplacental passage of glucose may stimulate fetal secretion of insulin, leading, in turn, to neonatal hypoglycemia in the immediate postpartum period.[25]

Altered Drug Responses in Pregnancy

Pregnancy results in a progesterone-mediated increase in neural sensitivity to local anesthetics.[26] Lower doses of local anesthetic are needed per dermatomal segment of epidural or spinal block. This has been attributed to an increased spread of local anesthetic in the epidural and subarachnoid spaces as a result of epidural venous engorgement and enhanced sensitivity to local anesthetic block due to progesterone. The minimum alveolar concentration for inhalational agents is decreased by 8–12 weeks of gestation and may be related to an increase in progesterone levels.[27]

Clinical Pearls

- During pregnancy, there is a progesterone-mediated increase in neural sensitivity to local anesthetics.
- Doses of local anesthetic need to be lowered per dermatomal segment of epidural or spinal block.

PLACENTAL TRANSFER OF LOCAL ANESTHETICS

Local anesthetics readily cross the placenta by simple diffusion. Several factors influence the placental transfer of drugs, including the physicochemical characteristics of the drug itself, maternal drug concentrations in the plasma, properties of the placenta, and hemodynamic events within the fetomaternal unit.

Highly lipid-soluble drugs, such as local anesthetics, cross biologic membranes more readily, and the degree of ionization is important because the nonionized moiety of a drug is more lipophilic than the ionized drug. Local anesthetics are weak bases, with a relatively low degree of ionization and considerable lipid solubility. The relative concentrations of drug existing in the nonionized and ionized forms can be estimated from the Henderson–Hasselbalch equation:

$$\text{pH} = \text{p}K_a + \log (\text{base})/(\text{cation})$$

The ratio of base to cation becomes particularly important with local anesthetics because the nonionized form penetrates tissue barriers, whereas the ionized form is pharmacologically active in blocking nerve conduction. The pK_a (acid dissociation constant) is the pH at which the concentrations of free base and cation are equal. For the amide local anesthetics, the pK_a values (7.7–8.1) are sufficiently close to physiologic pH so that changes in maternal or fetal biochemical status may significantly alter the proportion of ionized and nonionized drug (Figure 41–1). At steady state, the concentrations of nonionized local anesthetics in the fetal and maternal plasma are equal. With fetal acidosis, there is a greater tendency for drug to exist in the ionized form, which cannot diffuse back across the placenta. This causes a larger total amount of local anesthetic to accumulate in the fetal plasma and tissues. This is called ion trapping.[28]

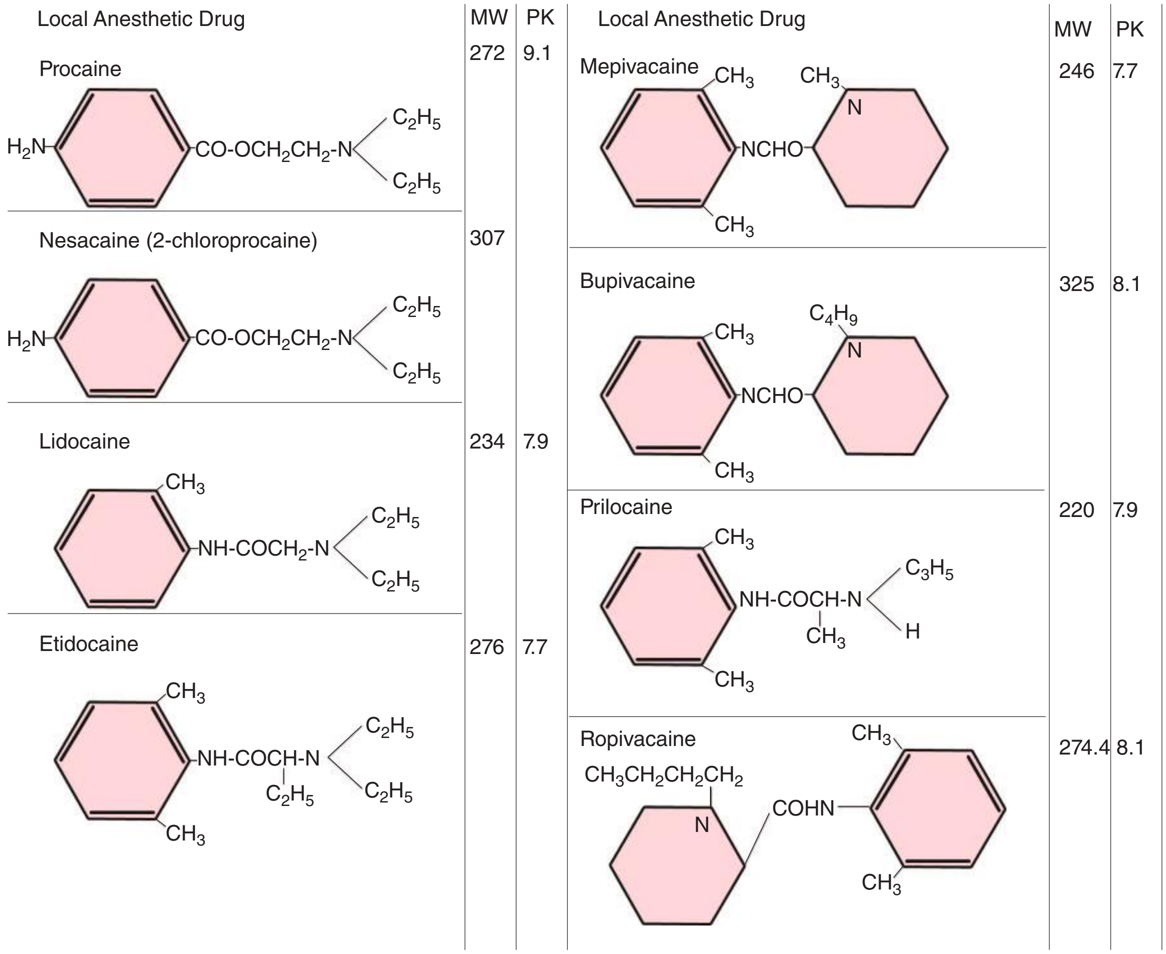

FIGURE 41–1. Chemical structures of local anesthetics. MW = molecular weight; PK = ionizing constant.

Clinical Pearl

- The prolonged administration of highly protein-bound drugs (eg, bupivacaine) may lead to substantial fetal accumulation of the drugs.

The effects of maternal plasma protein binding on the rate and amount of local anesthetic accumulating in the fetus are inadequately understood. Animal studies have shown that the transfer rate is slower for drugs that are extensively bound to maternal plasma proteins, such as bupivacaine.[29,30] However, with the prolonged administration of highly protein-bound drugs, such as bupivacaine, substantial accumulation of drug can occur in the fetus.[31]

The concentration gradient of free drug between the maternal and fetal blood is a significant factor. On the maternal side, the dose administered, the mode and site of administration, and the use of vasoconstrictors can influence fetal exposure. The rates of distribution, metabolism, and excretion of the drug, which may vary, are equally important. Higher doses result in higher maternal blood concentrations. The absorption rate can vary with the site of injection. For instance, an IV bolus results in the highest blood concentration. It was once believed that intrathecal administration resulted in negligible plasma concentrations of local anesthetics. However, we now know that spinal anesthesia induced with 75 mg lidocaine results in maternal plasma concentrations that are similar to those reported by others after epidural anesthesia.[32] Furthermore, significant levels of the drug can be found in the umbilical vein at birth.

Repeated administration can result in high maternal blood concentrations, depending on the dose and frequency of reinjection, in addition to the kinetic characteristics of the drug. The half-life of amide local anesthetic agents is relatively long, so that repeated injection may lead to accumulation in the maternal plasma (Figure 41–2).[33] In contrast, 2-chloroprocaine, an ester local anesthetic, undergoes rapid enzymatic hydrolysis in the presence of pseudo-cholinesterase. After epidural injection, the mean half-life in the mother is approximately 3 minutes; after reinjection, 2-chloroprocaine can be detected in the maternal plasma for only 5–10 minutes, and no accumulation of this drug has occurred.[34]

Pregnancy is associated with physiologic changes that also may influence maternal pharmacokinetics and the action of anesthetic drugs. These changes may be progressive during the course of gestation and are often difficult to predict for an individual drug. Nonetheless, the elimination half-life of bupivacaine after epidural injection has been shown to be similar in pregnant and nonpregnant women.[35]

Fetal regional blood flow changes can also affect the amount of drug taken up by individual organs. For example, during asphyxia and acidosis, a greater proportion of the fetal cardiac

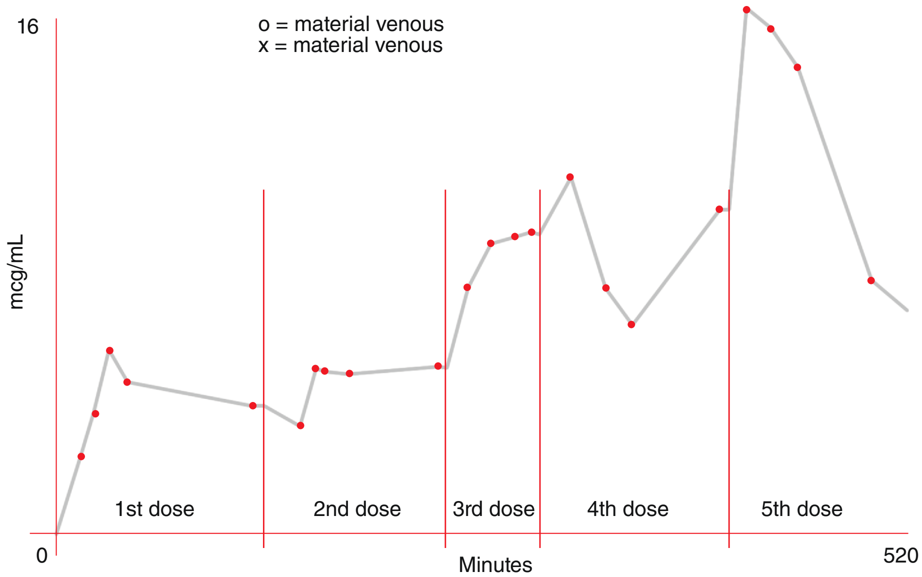

FIGURE 41–2. Increased maternal blood concentration of local anesthetic after repeated doses (300 mg) of mepivacaine.

output perfuses the fetal brain, heart, and placenta. Infusion of lidocaine resulted in increased drug uptake in the heart, brain, and liver of asphyxiated baboon fetuses compared with nonasphyxiated control fetuses.[36]

Risk of Drug Exposure: Fetus Versus Newborn

The fetus can excrete local anesthetics back into the maternal circulation after the concentration gradient of the free drug across the placenta has been reversed. This may occur even if the total plasma drug concentration in the mother exceeds that in the fetus, because there is lower protein binding in fetal plasma.[30] 2-chloroprocaine is the only drug that is metabolized in the fetal blood so quickly that even with acidosis, substantial exposure in the fetus is avoided.[34]

Both term and preterm infants have the hepatic enzymes necessary for the biotransformation of amide local anesthetics. In a comparative study, the pharmacokinetics of lidocaine among adult ewes and fetal/neonatal lambs indicated that the metabolic clearance in the newborn was similar to, and renal clearance greater than, that in the adult.[37] However, the half-life was longer in the newborn; this is related to a greater volume of distribution and tissue uptake, so that, at any given moment, the neonate's liver and kidneys are exposed to a smaller fraction of lidocaine accumulated in the body. Similar results have been reported in another study involving lidocaine administration to human infants in a neonatal intensive care unit.[38]

Neonatal depression occurs at blood concentrations of mepivacaine or lidocaine that are approximately 50% less than those producing systemic toxicity in the adult. However, infants accidentally injected in utero with mepivacaine (intended for maternal caudal anesthesia) stopped convulsing when the mepivacaine level decreased below the threshold for convulsions in the adult.[39] The relative central nervous toxicity and cardiorespiratory toxicity of local anesthetics have been studied in sheep.[40] The doses required to produce toxicity in the fetal and newborn lamb were greater than those required in the ewe. In the fetus, this difference was attributed to placental clearance of drug into the mother and better maintenance of blood gas tensions during convulsions, whereas in the newborn lamb, a larger volume of distribution was probably responsible for the higher doses needed to induce toxic effects.

It has been suggested that bupivacaine may be implicated as a possible cause of neonatal jaundice because of its high affinity for fetal erythrocyte membranes, resulting in a decrease in filterability and deformability rendering subjects more prone to hemolysis. However, a more recent study has failed to show demonstrable bilirubin production in newborns whose mothers were given bupivacaine for epidural anesthesia during labor and delivery.[41]

Neurobehavioral studies have revealed subtle changes in newborn neurologic and adaptive function with regional anesthesia. In the case of most anesthetic agents, these changes are minor and transient, lasting for only 24–48 hours.[42]

ANESTHESIA FOR LABOR & VAGINAL DELIVERY

In the first stage of labor, pain is caused by uterine contractions related to dilation of the cervix and distention of the lower uterine segment. Pain impulses are carried in visceral afferent type C fibers, which accompany the sympathetic nerves. In early labor, only the lower thoracic dermatomes (T11–T12) are affected. However, with progressive cervical dilation during the transition phase, adjacent dermatomes may be involved and pain referred from T10 to L1. During the second stage, additional pain impulses due to distention of the vaginal vault and perineum are carried in the pudendal nerve, which is composed of lower sacral fibers (S2–S4).

Regional analgesia may benefit the mother in other ways beyond relieving pain and anxiety. In animal studies, pain may cause maternal hypertension and reduced uterine blood flow.[43] Epidural analgesia blunts the increases in maternal cardiac output, heart rate, and blood pressure that occur with painful uterine contractions and "bearing-down" efforts.[44] By reducing the maternal secretion of catecholamines, epidural analgesia may convert a previously dysfunctional labor pattern to a normal one.[45] Regional analgesia can benefit the fetus by eliminating maternal hyperventilation with pain, which often leads to a reduced fetal arterial oxygen tension owing to a leftward shift of the maternal oxygen–hemoglobin dissociation curve.[46]

The most frequently chosen methods for relieving the pain of parturition are psychoprophylaxis, systemic medication, and regional analgesia. Inhalational analgesia, conventional spinal analgesia, and paracervical blockade are less commonly used. General anesthesia is rarely necessary but may be indicated for uterine relaxation in some complicated deliveries.

Systemic Analgesia

The advantages of systemic analgesics include ease of administration and patient acceptability. However, the drug, dose, timing, and method of administration must be chosen carefully to avoid maternal and neonatal depression. Drugs used for systemic analgesia are opioids, tranquilizers, and occasionally ketamine.

Systemic Opioids

In the past, meperidine was the most commonly used systemic analgesic to ameliorate pain during the first stage of labor. It can be administered by IV injection (effective analgesia in 5–10 minutes) or intramuscularly (peak effect in 40–50 minutes). It was also commonly used for postoperative pain in the general population. But with the popularity of its administration, disturbing side effects began to emerge. One of the most serious side effects was the occurrence of seizures both from the primary drug effect and from the drug's metabolite, normeperidine. In the pregnant patient at risk for seizures—that is, with pregnancy-induced hypertension or preeclampsia—confusing the picture by the administration of a drug known to cause seizures complicates patient care.[47,48] Other side effects are nausea and vomiting, dose-related depression of ventilation, orthostatic hypotension, the potential for neonatal depression, and euphoria out of proportion to the analgesic effect, leading to misuse of the drug.[49] Meperidine may also cause transient alterations of the fetal heart rate, such as decreased beat-to-beat variability and tachycardia. Among other factors, the risk of neonatal depression is related to the interval between the last drug injection and delivery.[50] The placental transfer of an active metabolite, normeperidine, which has a long elimination half-life in the neonate (62 hours), has also been implicated in contributing to neonatal depression and subtle neonatal neurobehavioral dysfunction. The effects of systemically administered meperidine on the course of labor are controversial. It has been suggested that meperidine administration may prolong the latent phase of labor but shorten the cumulative length of the first stage of labor. However, a recent study showed no benefit to the administration of meperidine in order to possibly shorten the first stage of labor in women having dystocia.[51]

Experience with the newer synthetic opioids, such as fentanyl and alfentanil, has been limited. Although they are potent, their usefulness during labor is limited by their short duration of action. However, these drugs offer an advantage when analgesia of rapid onset but short duration is necessary (eg, with forceps application). For example, a single IV injection of fentanyl, up to 1 mcg/kg, results in prompt pain relief without severe neonatal depression but for a short period of time.[52] Alfentanil may be associated with greater neonatal depression than equivalent meperidine patient-controlled analgesia (PCA).[53] In another study, alfentanil PCA failed to provide adequate analgesia compared to fentanyl PCA.[54] For more prolonged analgesia, fentanyl can be administered with patient-controlled delivery devices.[55] More commonly, fentanyl (15–25 mcg) and sufentanil (5–10 mcg) have been used with local anesthetics in an initial spinal dose with a local anesthetic during the placement of a continuous spinal–epidural for labor with excellent relief of pain.[56,57]

Remifentanil is an opioid that is rapidly metabolized by serum and tissue cholinesterases, and consequently, has a short (3-minute), context-sensitive half-time.[58] When used in bolus dosing (0.3–0.8 mcg/kg per bolus), remifentanil has been found to have an acceptable level of maternal side effects and a minimal effect on the neonate. Remifentanil crosses the placenta and appears to be either rapidly metabolized or redistributed in the neonate.[59] In one study, Apgar and neurobehavioral scores were good in neonates whose mothers were given an IV infusion of remifentanil, 0.1 mcg/kg/min, during cesarean section delivery under epidural anesthesia.[60] When administered by PCA, remifentanil has been found to provide better pain relief, equivalent hemodynamic stability, less sedation, and less oxygen desaturation compared with meperidine.[59,61] In a recent double-blind trial, remifentanil PCA was compared to lumbar epidural for equivalent analgesia. Twenty-six percent of women in the remifentanil group reported acceptable pain scores compared to 56% of women receiving lumbar epidural analgesia.[62] In countries outside the United States, intermittent nitrous oxide has been used for labor analgesia. When comparing remifentanil with nitrous oxide, remifentanil was found to provide better pain relief with fewer side effects. However, remifentanil can result in hypoventilation and hypoxemia, thus oxygen saturation should be routinely monitored during remifentanil IV PCA.[63]

Opioid agonist-antagonists, such as butorphanol and nalbuphine, have also been used for obstetric analgesia. These drugs have the proposed benefits of a lower incidence of nausea, vomiting, and dysphoria, as well as a "ceiling effect" on depression of ventilation.[64] Intramuscular (IM) nalbuphine has been compared to meperidine in a double-blind study. Analgesia was comparable in both groups; however, nalbuphine was associated with increased maternal sedation compared to meperidine.[65] Butorphanol is probably the most popular of the mixed agonist-antagonists; unlike meperidine, it is metabolized into inactive metabolites and has a ceiling effect on depression of ventilation in doses exceeding 2 mg. Butorphanol results in comparable maternal pain relief to meperidine and no difference in Apgar scores. However, butorphanol use was associated with fewer maternal side effects, such as nausea, vomiting, and dizziness, than meperidine.[66] A potential disadvantage is a high incidence of maternal sedation. The recommended dose is 1–2 mg by IV or IM injection. Nalbuphine 10 mg IV or IM is an alternative to butorphanol.

Naloxone, a pure opioid antagonist, should not be administered to the mother shortly before delivery to prevent neonatal ventilatory depression because it reverses maternal analgesia at a time when it is most needed. In some instances, naloxone has been reported to cause maternal pulmonary edema and even cardiac arrest. If necessary, the drug should be given directly to the newborn IM (0.1 mg/kg).

Ketamine

Ketamine is a potent analgesic. However, it may also induce unacceptable amnesia that may interfere with the mother's recollection of the birth. Nonetheless, ketamine is a useful adjuvant to incomplete regional analgesia during vaginal delivery or for obstetric manipulations. In low doses (0.2–0.4 mg/kg), ketamine provides adequate analgesia without causing neonatal depression.

Regional Analgesia Techniques

Regional techniques provide excellent analgesia with minimal depressant effects in mother and fetus. The techniques most commonly used for labor anesthesia include central neuraxial (spinal, epidural, and combined spinal–epidural), paracervical, and pudendal blocks and, less frequently, lumbar sympathetic blocks. Hypotension resulting from sympathectomy is the most common complication that occurs with central neuraxial blockade. Therefore, maternal blood pressure must be monitored at regular intervals, typically every 2–5 minutes for approximately 15–20 minutes after the initiation of the block and at routine intervals thereafter. Regional analgesia may be contraindicated in the presence of severe coagulopathy, acute hypovolemia, or infection at the site of needle insertion. Chorioamnionitis without sepsis is not a contraindication to central neuraxial blockade.

Epidural Analgesia

Effective analgesia for the first stage of labor is achieved by blocking the T10–Ll dermatomes with a low concentration of local anesthetic, often in combination with a lipid-soluble opioid. For the second stage of labor, because of pain due to vaginal distention and perineal pressure, the block should be extended to include the pudendal segments, S2–4 (Figures 41–3 and 41–4).

There has been concern that the early initiation of epidural analgesia during the latent phase of labor (2–4 cm cervical dilation) may result in prolongation of the first stage of labor and a higher incidence of dystocia and cesarean section delivery, particularly in nulliparous women.[66–69] Generally speaking, the first stage of labor is not prolonged by epidural analgesia, provided that aortocaval compression is avoided.[66–68,70,71] Chestnut et al.[70,71] demonstrated that the incidence of cesarean section delivery was no different in nulliparous women having epidural analgesia initiated during the latent phase (at 4 cm dilation) compared with women whose analgesia was initiated during the active phase. Others have shown that epidural analgesia is not associated with an increased incidence of cesarean section delivery compared with IV PCA in nulliparous women.[67,68]

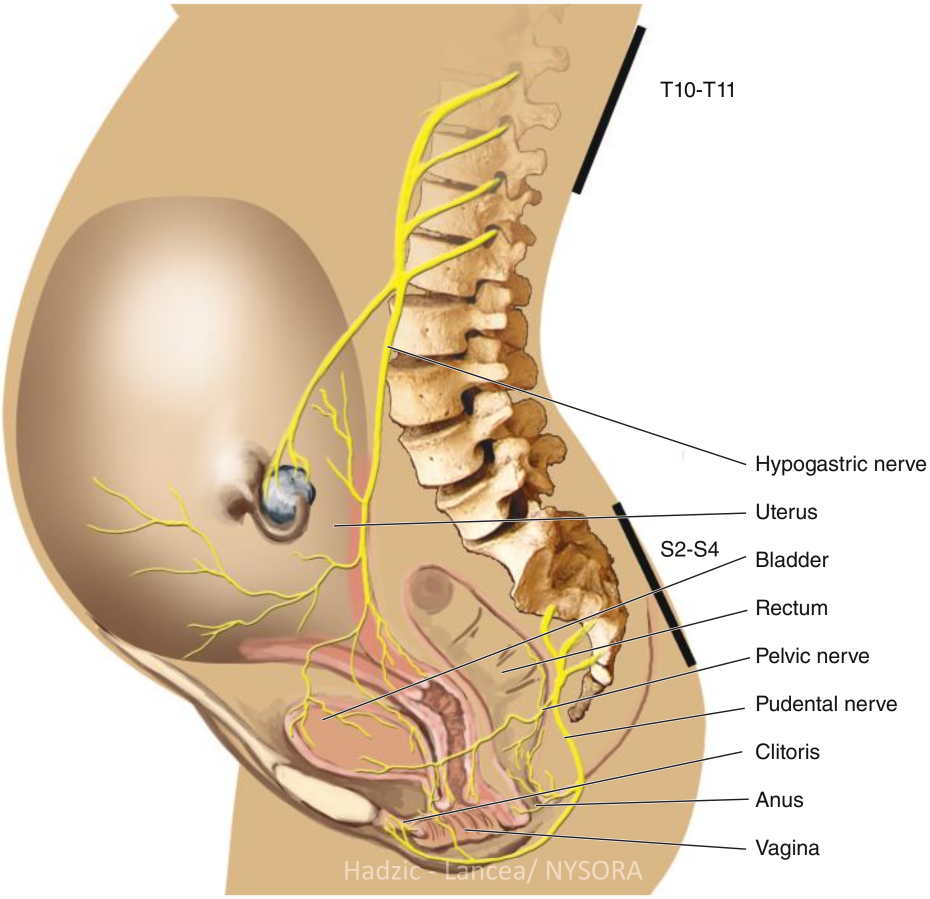

FIGURE 41–3. Pain pathways in a parturient.

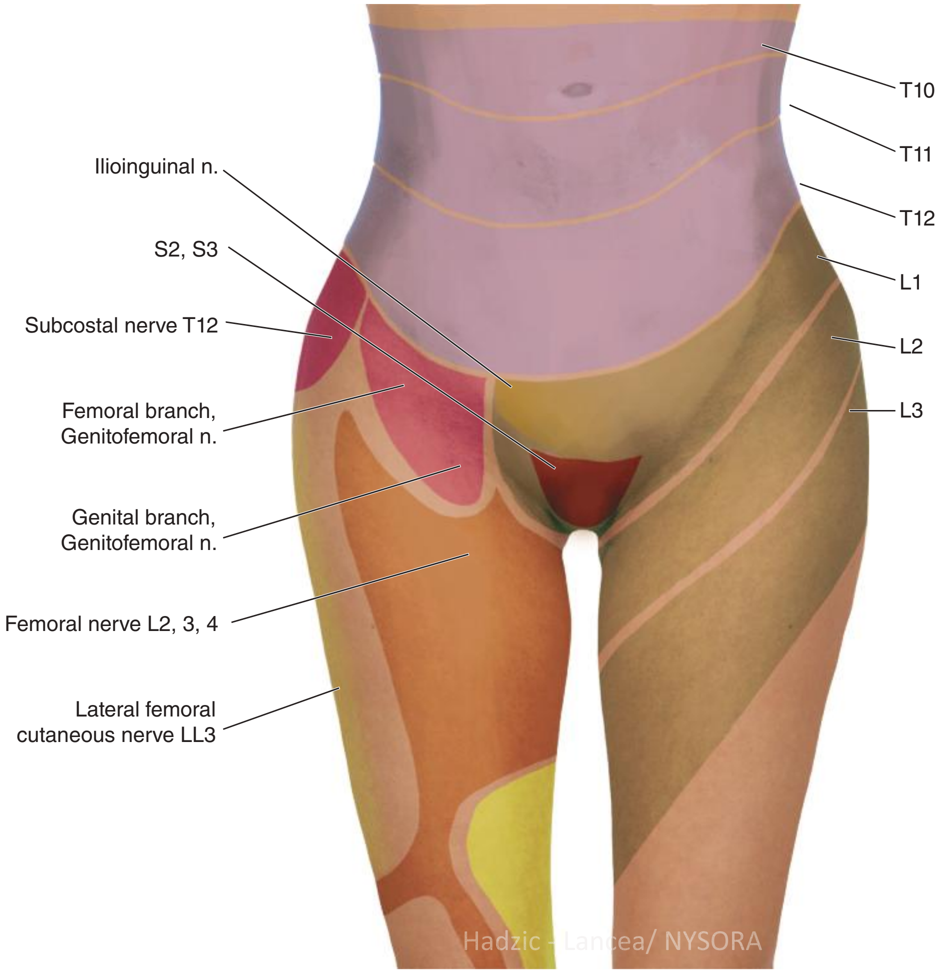

FIGURE 41–4. Dermatomal level of the lower abdomen, perineal area, hip, and thigh.

However, a prolongation of the second stage of labor has been reported in nulliparous women, possibly owing to a decrease in expulsive forces or malposition of the fetus.[66,71,72]

Thus, with the use of epidural analgesia, the American College of Obstetricians and Gynecologists (ACOG) has defined an abnormally prolonged second stage of labor as longer than 3 hours in nulliparous women and longer than 2 hours in multiparous women.[73]

A longer second stage of labor may be minimized by the use of an ultra-dilute local anesthetic solution in combination with an opioid.[74] Long-acting amides, such as bupivacaine, ropivacaine, and levobupivacaine, are most frequently used because they produce excellent sensory analgesia while sparing motor function, particularly at the low concentrations used for epidural analgesia.

Clinical Pearls

- Analgesia during the first stage of labor is achieved by blocking the T10–Ll dermatomes with a low concentration of local anesthetic (see Figure 41–3).
- Analgesia for the second stage of labor and delivery requires the block of the S2–4 segments because of pain due to vaginal distention and perineal pressure.

Analgesia for the first stage of labor may be achieved with 5–10 mL of bupivacaine, ropivacaine, or levobupivacaine (0.125%–0.25%), followed by a continuous infusion (8–12 mL/h) of 0.0625% bupivacaine or levobupivacaine, or 0.1% ropivacaine. Fentanyl 1–2 mcg/mL or sufentanil 0.3–0.5 mcg/mL may be added. During the actual delivery, the perineum may be blocked with 10 mL of 0.5% bupivacaine, 1% lidocaine, or, if a rapid effect is required, 2% chloroprocaine in the semirecumbent position.

There is controversy regarding the need for a test dose when using a dilute solution of local anesthetic.[75,77] Catheter aspiration alone is not always diagnostic. For that reason, some authors believe that a test dose should be administered to improve detection of an intrathecally or intravascularly placed epidural catheter. If injected into a blood vessel, 15 mcg epinephrine results in a change in heart rate of 20–30 bpm with a slight increase in blood pressure within 30 seconds of administration. The duration is approximately 30 seconds. The anesthesiologist should observe the pulse oximeter during the first minute after injection to determine whether an accidental intravascular injection has occurred. However, the tachycardia associated with an intravenous test dose of epinephrine is not a reliable indicator of intravascular injection during labor because it may be confounded coincident with a painful uterine contraction. In addition, epinephrine is not reliable in patients who have received a beta-adrenergic receptor antagonist.[77] Other subtle signs of intravascular injection may include a feeling of apprehension or unease or palpitations. It is important to fractionate the total dose of local anesthetic and observe the patient at one-minute intervals.

Patient-controlled epidural analgesia (PCEA) is a safe and effective alternative to conventional bolus or infusion techniques.[78] Maternal acceptance is excellent, and demands on anesthesia manpower may be reduced. Studies have shown that PCEA with a relatively low continuous epidural infusion and top-ups required fewer anesthetic interventions compared to PCEA without a basal rate epidural infusion.[79] Initial analgesia is achieved with bolus doses of local anesthetic. Once the mother is comfortable, PCEA may then be started with a maintenance infusion (8–12 mL/h) of local anesthetic (bupivacaine, levobupivacaine, or ropivacaine 0.0625%–0.125%) with or without an opioid (fentanyl 1–2 mcg/mL or sufentanil 0.3–0.5 mcg/mL). The machine may be programmed to administer an epidural demand bolus of 8 mL with a lockout period of 10 minutes between doses.[78] The caudal, rather than lumbar, approach may result in a faster onset of perineal analgesia and therefore may be preferable to the lumbar epidural approach when an imminent vaginal delivery is anticipated. However, caudal analgesia is no longer popular because of occasionally painful needle placement, a high failure rate, potential contamination at the injection site, and risks of accidental fetal injection. Before caudal injection, a digital rectal examination must be performed to exclude needle placement in the fetal presenting part. Low spinal "saddle block" has virtually eliminated the need for caudal anesthesia in modern practice.

Spinal Analgesia

A single intrathecal injection, usually of an opioid and a small dose of local anesthetic, for labor analgesia has the benefits of a reliable and rapid onset of analgesia for the first stage of labor. However, repeated intrathecal injections may be required for a long labor, thus increasing the risk of postdural puncture headache. In addition, motor block may be uncomfortable for some women and may prolong the second stage of labor. This technique is most useful for multiparous parturients who are rapidly progressing in labor and require analgesia or anesthesia of short duration before complete cervical dilation and anticipated vaginal delivery or in settings in which continuous epidural analgesia is not possible.[80]

Microcatheters were introduced for continuous spinal anesthesia in the 1980s. They were subsequently withdrawn when found to be associated with neurologic deficits, possibly related to maldistribution of local anesthetic in the cauda equina region.[81] Fortunately, in a recent multi-institutional study, no cases of neurologic symptoms occurred after the use of 28-gauge microcatheters for continuous spinal analgesia in laboring women.[82] Spinal anesthesia is also a safe and effective alternative to general anesthesia for instrumental delivery.

Combined Spinal–Epidural Analgesia

Combined spinal–epidural (CSE) analgesia is an ideal analgesic technique for use during labor. It combines the rapid, reliable onset of profound analgesia resulting from spinal injection with the flexibility and longer duration of epidural techniques. In a recent meta-analysis, the onset of analgesia for CSE was significantly faster than with an epidural technique (2–5 minutes vs. 10–15 minutes).[83]

Technique

After identifying the epidural space using a conventional (or specialized) epidural needle, a longer (127-mm), pencil-point spinal needle is advanced into the subarachnoid space through the epidural needle. After intrathecal injection, the spinal needle is removed, and an epidural catheter inserted. Intrathecal injection of fentanyl 10–25 mcg or sufentanil 2.5–5 mcg, alone or in combination with up to 1 mL of isobaric bupivacaine 0.25%, produces profound analgesia lasting for 60–120 minutes with minimal motor block.[84]

It should be noted that the incidence of pruritus is greater with intrathecal opioid administration than with epidural opioid administration.[85] An opioid alone may provide sufficient relief for the early latent phase, but the addition of bupivacaine is almost always necessary for satisfactory analgesia during advanced labor. Other adjuvants have also been used. The addition of adjuvants, such as clonidine and neostigmine, has been disappointing.[85] An epidural infusion of bupivacaine 0.03%–0.0625% with an opioid may be started within 10 minutes of spinal injection. Alternatively, the epidural component may be activated when necessary. Women with hemodynamic stability and preserved motor function who do not require continuous fetal monitoring may ambulate with assistance.[86,87] Before ambulation, women should be observed for 30 minutes after intrathecal or epidural drug administration to assess maternal and fetal well-being. A recent study indicated that the early administration of CSE analgesia to nulliparous women did not increase the cesarean section delivery rate.[88]

Clinical Pearl

- Intrathecal injection of fentanyl 10–25 mcg or sufentanil 5–10 mcg alone or, more commonly, with 1 mL isobaric bupivacaine 0.25% produces profound analgesia lasting for 90–120 minutes with minimal motor block.

The most common side effects of intrathecal opioids are pruritus, nausea, vomiting, and urinary retention. Rostral spread resulting in delayed respiratory depression is rare with fentanyl and sufentanil and usually occurs within 30 minutes of injection.[89] Transient nonreassuring fetal heart rate patterns may occur because of uterine hyperstimulation, presumably as a result of a rapid decrease in maternal catecholamines resulting in the unopposed effects of oxytocin.[90]

A preliminary study by O'Gorman et al.[91] suggests that fetal bradycardia may occur in the absence of uterine hyperstimulation or hypotension and is unrelated to uteroplacental insufficiency. The incidence of fetal heart rate abnormalities may be greater in multiparous woman with a rapidly progressing, painful labor.[92] Most studies have demonstrated that the incidence of emergency cesarean section delivery is no greater with CSE analgesia than after conventional epidural analgesia.[93,94] Postdural puncture headache is always a risk after intrathecal injection. However, the incidence of headache is no greater with CSE analgesia compared with standard epidural analgesia.[95]

Unintentional intrathecal catheter placement through the dural puncture site is also rare after use of a 27-gauge spinal needle for CSE analgesia. The potential exists for epidurally administered drug to leak intrathecally through the dural puncture, particularly if large volumes of drug are rapidly injected. In fact, epidural drug requirements are approximately 30% less with CSE analgesia than with standard lumbar epidural techniques for cesarean section delivery.[96] Some clinicians do not advocate the CSE analgesia technique for labor because of the concern for an "unproven" epidural catheter that may need to be used emergently for cesarean section delivery. The patient may have a partial block insufficient for surgery with an epidural that may or may not work. An algorithm for patient management in the event of an incomplete epidural is presented in Figure 41–5.

Paracervical Block

As recently as 2001, only 2%–3% of parturients in the United States received paracervical block during labor.[97] Although paracervical block effectively relieves pain during the first stage of labor, it is now rarely used in the United States because of its association with a high incidence of fetal bradycardia, particularly with the use of bupivacaine. This may be related to uterine artery constriction or increased uterine tone.[98]

The use of levobupivacaine compared to racemic bupivacaine has been demonstrated to result in fewer fetal bradycardias.[99] Paracervical block is a useful technique to provide analgesia for uterine curettage. The technique is very simple and involves a submucosal injection of local anesthetic at the vaginal fornix near the neural fibers innervating the uterus (Figure 41–6).

Paravertebral Lumbar Sympathetic Block

Paravertebral lumbar sympathetic block is a reasonable alternative to central neuraxial blockade. Lumbar sympathetic block effectively interrupts the painful transmission of cervical and uterine impulses during the first stage of labor.[100] Leighton et al. showed that women who received lumbar sympathetic blocks had a more rapid rate of cervical dilatation during the first two hours of analgesia and a shorter second stage of labor compared to epidural analgesia. However, there was no difference in the rate of dilatation during the active phase of labor.[100] Although there is less risk of fetal bradycardia with lumbar sympathetic block compared with paracervical blockade, technical difficulties associated with the performance of the block and risks of intravascular injection have hampered its routine use. Hypotension may also occur with lumbar sympathetic blocks.

FIGURE 41–6. (a) and (b): Paracervical block for uterine curettage. The technique involves a submucosal injection of local anesthetic at the vaginal fornix, near the neural fibers innervating the uterus.

Pudendal Nerve Block

The pudendal nerves are derived from the lower sacral nerve roots (S2–4) and supply the vaginal vault, perineum, rectum, and sections of the bladder. The nerves are easily blocked transvaginally where they loop around the ischial spines. A recent study demonstrated that a pudendal nerve block does not provide reliable analgesia for the second stage of labor, probably related to the upper vagina being innervated by lumbar, rather than sacral, fibers. However, the block is useful for episiotomy and repair.[101] There may also be postpartum benefits of pudendal nerve block. For instance, a unilateral nerve stimulator–guided pudendal nerve block with ropivacaine was associated with decreased pain and less need for supplemental analgesia during the first 48 hours after the performance of mediolateral episiotomy at vaginal delivery.[102]

ANESTHESIA FOR CESAREAN SECTION DELIVERY

The most common indications for cesarean section delivery include failure to progress, nonreassuring fetal status, cephalopelvic disproportion, malpresentation, prematurity, and prior uterine surgery involving the corpus. The choice of anesthesia should depend on the urgency of the procedure in addition to the condition of the mother and fetus. After a comprehensive discussion of the risks and benefits of all anesthesia options, the mother's desires should be considered. Before the initiation of any anesthetic technique, resuscitation equipment for mother and neonate should be made available (Table 41–2).

TABLE 41–2. Resuscitation equipment in the delivery room.

Radiant warmer
Suction with manometer and suction trap
Suction catheters
Wall oxygen with flow meter
Resuscitation bag-mask positive pressure ventilation device (≤ 750 mL)
Infant face masks
Infant oropharyngeal airways
Endotracheal tubes: 2.5, 3.0, 3.5, and 4.0 mm
Endotracheal tube stylets
Laryngoscope(s) and blade(s)
Sterile umbilical artery catheterization tray
Needles, syringes, three-way stopcocks
Medications and solutions: • 1:10,000 epinephrine • Naloxone hydrochloride • Sodium bicarbonate • Volume expanders

Advantages of Regional Anesthesia in the Obstetric Patient

Cesarean delivery accounts for more than 30% of all births and is the most common surgical procedure performed in the United States, with more than 1 million performed each year.[103] A 1992 survey of obstetric anesthesia practices in the United States demonstrated that most patients undergoing cesarean section delivery do so under spinal or epidural anesthesia.[104]

Regional techniques have several advantages: They reduce the risk of gastric aspiration, avoid the use of depressant anesthetic drugs, and allow the mother to remain awake during delivery. Operative blood loss may also be reduced with regional compared with general anesthesia. Generally speaking, with regional techniques, the duration of antepartum anesthesia does not affect neonatal outcome, provided that there is no protracted aortocaval compression or hypotension.[105] The risk of hypotension may be greater than during vaginal delivery because the sensory block must extend to at least the T4 dermatome.

Studies have shown preloading with crystalloid does not reliably prevent neuraxial anesthesia–induced hypotension. In fact, recent studies indicate that intravenous co-loading at the time of intrathecal injection is as effective as prehydrating before neuroblockade.[106] If hypotension occurs despite these measures, left uterine displacement should be increased, the rate of IV infusion augmented, and IV ephedrine 5–15 mg (or phenylephrine 25–50 mcg) administered incrementally. The greatest success in preventing hypotension has been found with a continuous low-dose infusion of phenylephrine until delivery.

Spinal Anesthesia

Subarachnoid block is probably the most commonly administered regional anesthetic for cesarean section delivery because of its speed of onset and reliability. It has also become an alternative to general anesthesia for emergency cesarean section.[107]

Hyperbaric solutions of lidocaine 5%, tetracaine 1.0%, or bupivacaine 0.75% have been used. However, bupivacaine has now become the most widely used drug for spinal anesthesia for cesarean delivery. Using 0.75% hyperbaric bupivacaine, Norris[109] has shown that it is not necessary to adjust the dose of drug based on the patient's height. In addition, the patient's age, weight, and vertebral column length do not affect the resulting neuraxial blockade.[109] Recent studies using spinal ropivacaine have shown less hypotension and faster recovery but a slower onset compared to bupivacaine.[110] However, it has been questioned whether ropivacaine produces spinal anesthesia of similar quality to that of bupivacaine. Hemodynamic monitoring during cesarean section should be similar to that used for other surgical procedures, with the exception that blood pressure should be monitored at a minimum of every 3 minutes before the birth of the baby. Before delivery, oxygen should be routinely administered to optimize fetal oxygenation. Reports of transient neurologic syndrome and/or cauda equina syndrome have been associated with lidocaine in doses greater than 60 mg, whether in a 5% or 2% preparation. This has led some clinicians to avoid the use of lidocaine for intrathecal administration (see "Systemic Toxicity of Local Anesthetics" below). Table 41–3 lists local anesthetics and the dosages commonly used for cesarean section delivery with subarachnoid block.

TABLE 41–3. Local anesthetics commonly used for cesarean section delivery with subarachnoid block.

Dosage per Height of Patient (cm)	Bupivacaine 0.75% in 8.25% Dextrose (mg)	Bupivacaine 0.5% (Isobaric) (mg)
150–160 cm	8	8
160–180	10	10–12.5
> 180 cm	12	12.5–15
Onset of action	2–4 min	5–10 min

Despite an adequate dermatomal level, women may experience varying degrees of visceral discomfort, particularly during exteriorization of the uterus and traction on abdominal viscera. Improved perioperative analgesia can be provided by the addition of fentanyl 20 mcg or preservative-free morphine 0.1 mg to the local anesthetic solution.[111] Preservative-free morphine produces significant analgesia in doses ranging from 0.1 to 0.25 mg.[112] Higher doses of spinal morphine result in greater pruritus. Delayed respiratory depression can occur with spinal morphine but is extremely rare and more often associated with comorbid conditions such as obesity. The respiratory depression is due to the rostral spread of subarachnoid morphine. In a retrospective study of 1915 parturients receiving spinal morphine 0.15 mg for cesarean delivery, five patients (0.26%) experienced bradypnea, and one patient required naloxone.[113] In addition, spinal clonidine, in doses of 60 to 150 mcg, improves intraoperative analgesia and decreases shivering in women undergoing cesarean delivery.[114] However, hypotension and sedation have been reported with spinal clonidine and may limit its routine use. Nausea and vomiting may be alleviated by the administration of ondansetron or metoclopramide. Maternal sedation should be avoided if possible. If the initial block is not adequate, concern exists regarding a repeat spinal injection and the potential for inadvertent high spinal anesthetic. See Figure 41–5 for a range of options available in situations in which spinal anesthesia fails to prove adequate for surgery.

Clinical Pearls

- Even with an adequate dermatomal level for surgery, women undergoing cesarean section may experience discomfort, particularly during exteriorization of the uterus and traction on abdominal viscera.
- Perioperative analgesia may be enhanced by the addition of fentanyl 20 mcg or preservative-free morphine 0.1 mg to the local anesthetic solution.

Lumbar Epidural Anesthesia

Epidural anesthesia has a slower onset of action and a larger drug requirement to establish an adequate sensory block compared with spinal anesthesia. The advantages are a perceived reduced risk of postdural puncture headache and the ability to titrate the local anesthetic through the epidural catheter. However, correct placement of the epidural catheter and avoidance of inadvertent intrathecal or intravascular injection are essential.

Aspiration of the epidural catheter for blood or cerebrospinal fluid is not 100% reliable for detecting catheter misplacement. For this reason, a "test dose" is often used to rule out inadvertent intravascular or intrathecal catheter placement. A small dose of local anesthetic, lidocaine 45 mg or bupivacaine 5 mg, produces a readily identifiable sensory and motor block if injected intrathecally. However, a recent study has suggested that ropivacaine 15 mg was not a useful intrathecal test dose because a slow onset of motor blockade may preclude the timely diagnosis of intrathecal injection.[115] The addition of epinephrine 15 mcg with careful continuous heart rate and blood pressure monitoring may herald intravascular injection with a transient increase in heart rate and blood pressure. However, an epinephrine test dose is not reliable because false-positive results do occur in the form of tachycardia related to painful uterine contractions. In addition, epinephrine may potentially reduce uteroplacental perfusion in some patients. Electrocardiography and the application of a peak-to-peak heart rate criterion may improve detection (10 beats over maximum heart rate preceding epinephrine injection). Rapid injection of 1 mL of air with simultaneous precordial Doppler monitoring appears to be a reliable indicator of intravascular catheter placement.[116] Most important, a negative test, although reassuring, does not eliminate the need for the fractional administration of local anesthetic.

Clinical Pearls

- Aspiration of the epidural catheter for blood or cerebrospinal fluid is not absolutely reliable for detecting catheter misplacement.
- A "test dose" is often used to rule out inadvertent intravascular or intrathecal catheter placement.
- A small dose of local anesthetic, lidocaine 45 mg or bupivacaine 5 mg, produces a readily identifiable sensory and motor block if injected intrathecally.
- The addition of epinephrine 15 mcg with careful hemodynamic monitoring may signal intravascular injection when followed by a transient increase in heart rate and blood pressure.
- However, the use of an epinephrine test dose is controversial because false-positive results do occur in the presence of uterine contractions.

Local Anesthetic Choices

The most commonly used local anesthetic agents are 2-chloroprocaine 3%, bupivacaine 0.5%, and lidocaine 2% with epinephrine 1:200,000.

Adequate anesthesia can be usually achieved with 15–25 mL of local anesthetic given in divided doses. The patient should be monitored as with spinal anesthesia. Because of its extremely high rate of metabolism in maternal and fetal plasma, 2-chloroprocaine provides a rapid-onset, reliable block with minimal risk of systemic toxicity.[34] It is the local anesthetic of choice in the presence of fetal acidosis and when a preexisting epidural block is to be rapidly extended for an urgent cesarean section delivery.[107] Neurologic deficits after massive inadvertent intrathecal administration of the drug have occurred with the formulation containing a relatively high concentration of sodium bisulfite at a low pH.[117]

In a new formulation of 2-chloroprocaine (Nesacaine-MPF), ethylenediaminetetraacetic acid (EDTA) has been substituted for sodium bisulfite. However, severe spasmodic back pain has been described after epidural injection of large volumes of Nesacaine-MPF in surgical patients, but not in parturients.[118] This has been attributed to an EDTA-induced leaching of calcium from paravertebral muscles. The most recent formulation of 2-chloroprocaine contains no additives and is packaged in an amber vial to prevent oxidation.

Bupivacaine 0.5% provides profound anesthesia of slower onset for cesarean section delivery but of longer duration of action. Considerable attention has been focused on the drug because it was reported that unintentional intravascular injection could result not only in convulsions but also in almost simultaneous cardiac arrest, with patients often refractory to resuscitation.[119] The greater cardiotoxicity of bupivacaine (and etidocaine) compared with other amide local anesthetics has been well established.

When using potent long-acting amide local anesthetics, fractioning the induction dose is critical. Lidocaine has an onset and duration intermediate to those of 2-chloroprocaine and bupivacaine. The need to include epinephrine in the local anesthetic solution to ensure adequate lumbosacral anesthesia limits the use of lidocaine in women with maternal hypertension and uteroplacental insufficiency.

Prolonged postoperative pain relief can be provided by the epidural administration of an opioid, such as morphine 4 mg, or the use of PCEA. Delayed respiratory depression may occur with the use of morphine; hence, the patient must be monitored carefully in the postoperative period. Recently, a lipid-encapsulated preparation of morphine (DepoDur) has been approved for post–cesarean section delivery analgesia. It can be used only epidurally, can last up to 48 hours, and the patient must be monitored for delayed respiratory depression. A potential limitation in obstetrics is that once the drug is administered, additional local anesthetic cannot be injected epidurally for a period of up to one hour since the local anesthetic may cause an uncontrolled release of morphine from the lipid. Carvalho et al.[120] evaluated the epidural administration of 5, 10, and 15 mg of extended-release morphine for post–cesarean section analgesia and demonstrated that the 10 mg and 15 mg doses provided good analgesia for up to 48 hours after surgery. No significant side effects were observed. Another study showed lower pain scores and fewer supplemental analgesia requirements for patients receiving extended-release morphine compared to preservative-free morphine.[121] No differences in nausea, pruritus, or sedation scores were observed. In addition, the bolus administration of epidural fentanyl (50–100 mcg) has been found to result in activity at both spinal and supraspinal sites of action and to improve the quality of anesthesia.[122]

ANESTHETIC COMPLICATIONS

Maternal Mortality

A study of anesthesia-related deaths in the United States between 1979 and 1990 showed that the case fatality rate with general anesthesia was 16.7 times greater than that with regional anesthesia. Most anesthesia-related deaths were a result of cardiac arrest due to hypoxemia when difficulties securing the airway were encountered.[104] Pregnancy-induced anatomical and physiological changes, such as reduced FRC, increased oxygen consumption, and oropharyngeal edema may expose the patient to serious risks of desaturation during periods of apnea and hypoventilation.

Pulmonary Aspiration

The risk of the inhalation of gastric contents is increased in pregnant women, particularly if difficulty is encountered establishing an airway or if airway reflexes are obtunded. Measures to decrease the risks of aspiration include comprehensive airway evaluation, prophylactic administration of nonparticulate antacids, and the preferred use of regional anesthesia. If aspiration occurs, management includes immediate treatment of hypoxemia with continuous positive airway pressure (CPAP) and possible rigid bronchoscopy. Recent studies do not support the administration of corticosteroids or lung lavage with saline and bicarbonate to neutralize acidity.[123] Prophylactic antibiotics are not recommended because gastric contents are sterile.

Hypotension

Regional anesthesia may be associated with hypotension, which is related to the degree and rapidity of local anesthetic–induced sympatholysis. Thus, greater hemodynamic stability may be observed with epidural anesthesia, where gradual titration of local anesthetic allows for better control of the block level as well as for adequate time for vasopressor administration in anticipation of blood pressure reduction.

The risk of hypotension is lower in laboring women compared with nonlaboring women.[128] Maternal prehydration with 15 mL/kg of lactated Ringer's solution before the initiation of regional anesthesia and the avoidance of aortocaval compression may decrease the incidence of hypotension. It has been demonstrated that for effective prevention of hypotension, the blood volume increase from preloading must be sufficient to result in a significant increase in cardiac output.[125] This was possible only with the administration of hetastarch 0.5–1 L.[125] Nonetheless, controversy exists regarding the efficacy of volume loading in the prevention of hypotension.[104,126] A recent study using a prophylactic phenylephrine infusion combined with a rapid crystalloid co-loading given at the time of intrathecal injection markedly reduced the incidence of spinal anesthesia–induced hypotension.[127] If hypotension does occur despite prehydration, therapeutic measures should include increasing the displacement of the uterus, rapid infusion of IV fluids, titration of IV ephedrine (5–10 mg), and oxygen administration. In the presence of maternal tachycardia, phenylephrine 25–50 mcg may be substituted for ephedrine in women with normal uteroplacental function. Continued vigilance and active management of hypotension can prevent serious sequelae in both mother and neonate.[124,128]

High Spinal Anesthesia

High, or total, spinal anesthesia is a rare complication of intrathecal injection in modern-day practice. It occurs with an excessive cephalad spread of local anesthetic in the subarachnoid space. Unintentional intrathecal administration of epidural medication as a result of dural puncture or catheter migration may also result in this complication. Left uterine displacement and continued fluid and vasopressor administration may be necessary to achieve hemodynamic stability. The reverse Trendelenburg position does not prevent cephalad spread and may cause cardiovascular collapse because of venous pooling related to sympathectomy. Rapid control of the airway is essential, and endotracheal intubation may be necessary to ensure oxygenation without aspiration.

Clinical Pearls

- Obstetric patients often complain of difficulty breathing during cesarean section delivery under neuraxial anesthesia.
- Although most common reasons are inability to feel "breathing" as the abdominal and thoracic segments are anesthetized (including the stretch receptors), practitioners must rule out an impending "high spinal" anesthetic by repetitive examinations.
- The following maneuvers are useful to rule out the possibility of high neuraxial anesthesia:
  - The ability of the patient to phonate
  - The ability of the patient to squeeze the practitioner's hand (indicates that the block level is below the level of the brachial plexus (C6–T1)

Systemic Toxicity of Local Anesthetics

Unintended intravascular injection or drug accumulation after repeated epidural injection can result in high serum levels of local anesthetic. Rapid absorption of local anesthetic from highly vascular sites of injection may also occur after paracervical and pudendal blocks.

Resuscitation equipment should always be available when any major nerve block is undertaken. IV access, airway equipment, emergency drugs, and suction equipment should be immediately accessible. To avoid systemic toxicity of local anesthetic agents, strict adherence to recommended dosages and avoidance of unintentional intravascular injection are essential.

Despite these precautions, life-threatening convulsions and, more rarely, cardiovascular collapse may occur. Seizure activity has been treated with IV thiopental 25–50 mg or diazepam 5–10 mg. In current clinical practice, propofol 20–50 mg or midazolam 2–4 mg is more commonly used.

The airway should be evaluated and oxygenation maintained. If cardiovascular collapse does occur, the Advanced Cardiac Life Support (ACLS) algorithm should be followed. In a 2006 case report, lipid emulsion was used to treat refractory cardiac arrest resulting from bupivacaine toxicity.[129] The mechanism of action is unclear but may result from the greater affinity of bupivacaine for the lipid or because the lipid provides a substrate for a bupivacaine-poisoned mitochondrial energy system. Further study is required to determine the efficacy of this treatment. However, it would seem prudent that treatment of a pregnant woman intoxicated with bupivacaine should include the administration of lipid emulsion early on in the resuscitation. The current recommended protocol for lipid rescue (see http://www.lipidrescue.org) involves a 20% lipid emulsion: a 1.5 mL/kg initial bolus, followed by 0.25 mL/kg/min for 30–60 minutes. The early administration of lipid has also been shown to prevent progression to cardiac arrest when bupivacaine was injected intravascularly.

Whenever there is maternal cardiac arrest, regardless of cause, the fetus should be delivered early on, usually within 5 minutes, if attempts at resuscitation are unsuccessful in relieving aortocaval compression and ensuring the efficiency of cardiac massage.[130]

Postdural Puncture Headache

Pregnant women have a higher risk of developing a postdural puncture headache (PDPH) should an inadvertent dural puncture occur. In a recent meta-analysis, the risk of PDPH was 52.1% (95% confidence interval [CI], 51.4–52.8%) after an accidental dural puncture with an epidural needle.[131] The reduced epidural pressure increases the risk of cerebrospinal fluid leakage through the dural opening. Russell et al. reported that the placement of an intrathecal catheter after an accidental dural puncture did not lower the incidence of headache or the need for blood patch compared to repeating an epidural.[132] The incidence of headache was higher with the use of a 16-gauge compared to an 18-gauge epidural needle. The pathophysiology and management of postdural puncture headache are discussed in greater detail in Chapter 27.

Neurologic Complications

Neurologic sequelae of central neuraxial blockade, although rare, have been reported. Pressure exerted by a needle or catheter on spinal nerve roots produces immediate pain and necessitates repositioning. Infections such as epidural abscess and meningitis are very rare and may be a manifestation of systemic sepsis. In recent years, several cases of epidural abscess have been reported after epidural catheterization in obstetric patients.[133] Potential risk factors identified from these cases are entry-point infections from usual causative organisms (eg, *Staphylococcus aureus*), possible systemic sources of infection, poor aseptic technique, and prolonged catheterization. Epidural hematoma can also occur, usually in association with coagulation defects. However, epidural hematoma may also occur spontaneously, unrelated to instrumentation.[134] The pathogenesis may be due to a weakened epidural vascular architecture. Nerve root irritation may have a protracted recovery, lasting weeks or months. Peripheral nerve injury as a result of instrumentation, lithotomy position, or compression by the fetal head may occur even in the absence of neuraxial technique.

REGIONAL ANESTHESIA IN COMPLICATED PREGNANCY

Pregnancy and parturition are considered high risk when accompanied by conditions unfavorable to the well-being of the mother or fetus, or both. Maternal problems may be related to the pregnancy; that is, preeclampsia-eclampsia, hypertensive disorders of pregnancy, or antepartum hemorrhage resulting from placenta previa or abruptio placentae. Diabetes mellitus; cardiac, chronic renal, and neurologic problems; sickle cell disease; asthma; obesity; and drug abuse are not related to pregnancy but often are affected by it. Prematurity (gestation of less than 37 weeks), postmaturity (gestation of 42 weeks or longer), intrauterine growth retardation, and multiple gestation are fetal conditions associated with risk. During labor and delivery, fetal malpresentation (eg, breech, transverse lie), placental abruption, compression of the umbilical cord (eg, prolapse, nuchal cord), precipitous labor, or intrauterine infection (eg, prolonged rupture of membranes) may increase the risk to the mother or fetus.

In general, the anesthetic management of the high-risk parturient is based on the same maternal and fetal considerations as for the management of healthy mothers and fetuses. However, there is less room for error because many of these functions may be compromised before the induction of anesthesia.

Preeclampsia-Eclampsia

Pathophysiology and Signs and Symptoms

Hypertensive disorders occur in approximately 7% of all pregnancies and are a major cause of maternal mortality. The most recent diagnostic criterion for preeclampsia is referred to as “proteinaceous increase in blood pressure.”[135] The presence or absence of edema is no longer considered one of the required criteria. Rather than a specific blood pressure elevation, a blood pressure that is consistently 15% above baseline is now considered diagnostic. The added appearance of convulsions is diagnostic for eclampsia.[94] Preeclampsia-eclampsia is a disease unique to humans, occurring predominantly in young nulliparous women. Symptoms usually appear after the twentieth week of gestation, occasionally earlier with a hydatidiform mole. Delivery of the infant and placenta is the only effective treatment; as a result, preeclampsia is a leading cause of iatrogenic preterm delivery in developed countries.[136]

The origin of preeclampsia-eclampsia is unknown, but all patients manifest placental ischemia. Decreased placental perfusion occurs in early pregnancy in women destined to become preeclamptic, and there is a failure of the normal trophoblastic invasion.[137] In normal pregnancy, the diameter of spiral arteries increase approximately four-fold to create flaccid tubes that provide a low-resistance pathway to the intervillous space.[138] This angiogenesis is a result of the trophoblast invasion into the decidual and myometrial segments of the spiral arteries. However, in preeclamptic women, the myometrium is not invaded. This causes superficial placental implantation, resulting in decreased placental perfusion and ischemia related to stiff, muscular spiral arteries. Placental ischemia results in a release of uterine renin, an increase in angiotensin activity, and a widespread arteriolar vasoconstriction causing hypertension, tissue hypoxia, and endothelial damage (Figure 41–7). The fixation of platelets at sites of endothelial damage results in coagulopathies, occasionally in disseminated intravascular coagulation. Enhanced angiotensin-mediated aldosterone secretion leads to increased sodium reabsorption and edema. Proteinuria, a sign of preeclampsia, is also attributed to placental ischemia, which leads to local tissue degeneration and a release of thromboplastin with subsequent deposition of fibrin in constricted glomerular vessels. As a result, an increased permeability to albumin and other plasma proteins occurs. Furthermore, there is a decreased production of prostaglandin E, a potent vasodilator secreted in the trophoblast, which normally balances the hypertensive effects of the rennin–angiotensin system.

Many of the symptoms associated with preeclampsia, including placental ischemia, systemic vasoconstriction, and increased platelet aggregation, may result from an imbalance between the placental production of prostacyclin and thromboxane. During normal pregnancy, the placenta produces equal amounts of the two, but in a preeclamptic pregnancy, there is seven times more thromboxane than prostacyclin.[139]

According to the latest theory, endothelial cell injury is central to the development of preeclampsia.[140] This injury occurs as a result of reduced placental perfusion, leading to a production and release of substances (possibly lipid peroxidases) causing endothelial cell injury. Abnormal endothelial cell function contributes to an increase in peripheral resistance and other abnormalities noted in preeclampsia through a release of fibronectin, endothelin, and other substances.

In rodent models, two placental antiangiogenic proteins have been identified and likely play a role in the pathogenesis of preeclampsia.[133] Soluble fms-like tyrosine kinase-1 (sFlt-1) is upregulated in the placenta of preeclamptic women. The elevated sFlt-1 protein levels antagonize and reduce vascular endothelial growth factor (VEGF) and placental growth factor (PlGF).[141] Levine et al. demonstrated that increased sFlt-1 levels and reduced PlGF levels predicted the subsequent development of preeclampsia.[142] Another antiangiogenic protein, soluble endoglin (sEng), is elevated in cases of HELLP syndrome (which consists of hemolysis, elevated liver enzymes, and low platelet count).

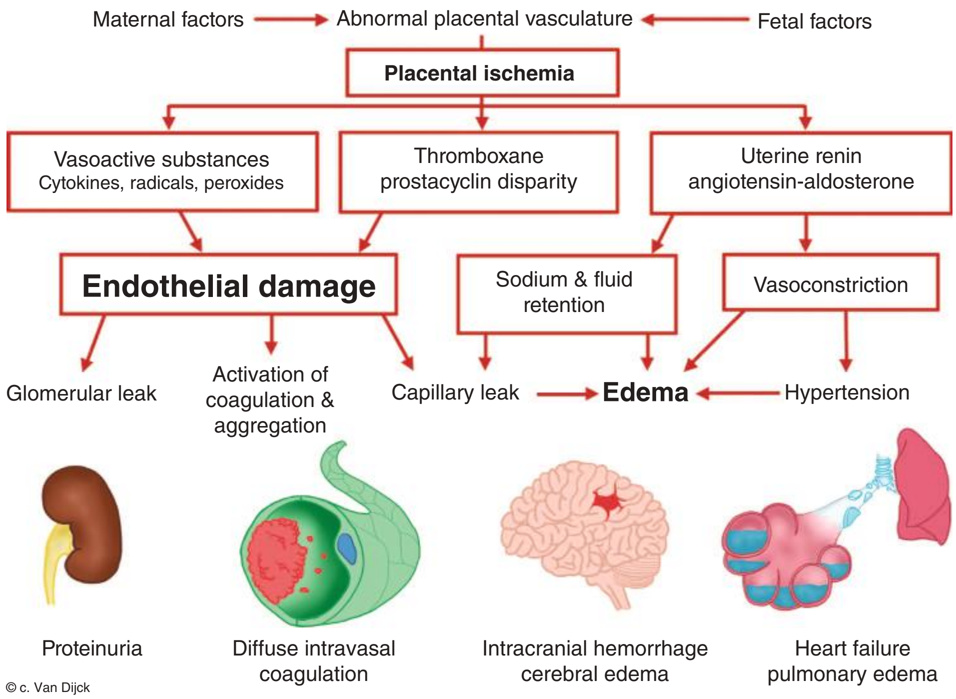

FIGURE 41–7. Pathophysiology of preeclampsia and eclampsia.

Clinical Pearl

Preeclampsia is classified as severe if it is associated with any of the following:

- Systolic blood pressure consistently more than 15% above baseline
- Diastolic blood pressure consistently more than 15% above baseline
- Proteinuria of 5 g/24 h
- Oliguria of 400 mL/24 h
- Cerebrovisual disturbances
- Pulmonary edema or cyanosis
- Epigastric pain
- Intrauterine growth retardation

In severe preeclampsia-eclampsia, all major organ systems are affected because of widespread vasospasm. Global cerebral blood flow is not diminished, but focal hypoperfusion cannot be ruled out. Postmortem examination has revealed hemorrhagic necrosis in the proximity of thrombosed precapillaries, suggesting intense vasoconstriction. Edema and small foci of degeneration have been attributed to hypoxia. Petechial hemorrhages are common after the onset of convulsions. Symptoms related to the above changes include headache, vertigo, cortical blindness, hyperreflexia, and convulsions. Cerebral hemorrhage and edema are the leading causes of death in preeclampsia-eclampsia, which together account for approximately 50% of deaths. Heart failure may occur in severe cases as a result of peripheral vasoconstriction and increased blood viscosity from hemoconcentration. Decreased blood supply to the liver may lead to periportal necrosis of variable extent and severity. Subcapsular hemorrhages account for the epigastric pain encountered in severe cases.

In the kidneys, there is swelling of glomerular endothelial cells and deposition of fibrin, leading to a constriction of the capillary lumina. Renal blood flow and glomerular filtration rate decrease, resulting in reduced uric acid clearance and, in severe cases, increase in creatinine.[143]

Although preeclampsia is accompanied by exaggerated retention of water and sodium, the shift of fluid and proteins from the intravascular into the extravascular compartment may result in hypovolemia, hypoproteinemia, and hemoconcentration, which may be further aggravated by proteinuria. The risk of uteroplacental hypoperfusion and poor fetal outcome correlates with the degree of maternal plasma and protein depletion.

Platelet adherence at sites of endothelial damage may result in consumption coagulopathy, which develops in approximately 20% of patients with preeclampsia. Mild thrombocytopenia, with a platelet count of 100,000–150,000/mm, is the most common finding. The prolongation of prothrombin and partial thromboplastin times indicates a consumption of procoagulants. Bleeding time, prolonged in approximately 25% of patients with normal platelet counts, is no longer considered a reliable test of clotting.[144] The HELLP syndrome is a particular form of severe preeclampsia characterized by hemolysis, elevated liver enzymes, and low platelets.

The goals of the management of the patient with preeclampsia-eclampsia are to prevent or control convulsions, improve organ perfusion, normalize blood pressure, and correct clotting abnormalities. The mainstay of anticonvulsant therapy in the United States is magnesium sulfate. Its efficacy in preventing seizures has been well substantiated, but its mechanism of action remains controversial. The patient usually receives a loading dose of 4 g in a 20% solution, administered over 5 minutes, followed by a continuous infusion of 1–2 g/h.

Antihypertensive therapy in preeclampsia is used to lessen the risk of cerebral hemorrhage in the mother while maintaining, or even improving, tissue perfusion. There is no evidence to suggest that antihypertensive therapy delays disease progression or improves perinatal outcome.[145] Plasma volume expansion combined with vasodilation fulfills these goals.[146] Hydralazine is the most commonly used vasodilator because it increases uteroplacental and renal blood flows. However, side effects include tachycardia, palpitations, headache, and neonatal thrombocytopenia.[147] Nitroprusside is used during laryngoscopy and intubation to prevent dangerous elevations in blood pressure. Trimethaphan, a ganglion blocking agent, is useful in hypertensive emergencies when cerebral edema and increased intracranial pressure are a concern because it does not cause vasodilation in the brain. Other agents that have been used to control maternal blood pressure include α-methyldopa, nitroglycerine, and, now more frequently, labetalol.[148]

Consumption coagulopathy may require infusion of fresh whole blood, platelet concentrates, fresh frozen plasma, and cryoprecipitate. Delivery is indicated in refractory cases or if the pregnancy is close to term. In severe cases, aggressive management should continue for at least 24–48 hours after delivery.

Anesthesia Management

There are very few contraindications for epidural anesthesia in labor and delivery. In the presence of severe clotting abnormalities or severe plasma volume deficit, the risk–benefit ratio favors other forms of anesthesia.[149] In volume-depleted patients positioned with left uterine displacement, epidural anesthesia does not cause an unacceptable reduction in blood pressure and leads to a significant improvement in placental perfusion.[150] With the use of radioactive xenon, it was shown that the intervillous blood flow increased by approximately 75% after the induction of epidural analgesia (10 mL bupivacaine 0.25%).[151] The total maternal body clearance of amide local anesthetics is prolonged in preeclampsia, and repeated administration of these drugs can lead to higher blood concentrations than in normotensive patients.[152]

For cesarean section delivery, the sensory level of regional anesthesia must extend to T3–4, making adequate fluid therapy and left uterine displacement even more vital.

Epidural anesthesia has been preferred to spinal anesthesia in preeclamptic women because of its slower onset of action and controllability. In the past, the rapid onset of sympathectomy related to spinal anesthesia was associated with hypotension, particularly in volume-depleted patients. However, in two recent studies, the incidence of hypotension, perioperative fluid and ephedrine administration, and neonatal conditions were found to be similar in preeclamptic women who received either epidural or spinal anesthesia for cesarean delivery.[153,154] Aya et al. conducted a prospective cohort study that showed the risk of significant spinal anesthesia–induced hypotension was significantly lower in preeclamptic women compared to normotensive pregnant women.[147] There is an increased sensitivity to vasopressors in preeclampsia; therefore, lower doses of ephedrine and phenylephrine are usually required to correct hypotension.

Antepartum Hemorrhage

Antepartum hemorrhage occurs most commonly in association with placenta previa (abnormal placental implantation on the lower uterine segment and partial to total occlusion of the internal cervical os) and abruptio placentae. Placenta previa occurs in 0.11% of all pregnancies, resulting in up to a 0.9% incidence of maternal and a 17–26% incidence of perinatal mortality. It may be associated with abnormal fetal presentation, such as transverse lie or breech. Placenta previa should be suspected whenever a patient presents with painless, bright red vaginal bleeding, usually after the seventh month of pregnancy. The diagnosis is confirmed by ultrasonography. Unless the lowest placental edge is more than 2 cm from the internal cervical os, an abdominal delivery is usually required.[155] If the bleeding is not profuse and the fetus is immature, obstetric management is conservative to prolong the pregnancy. In severe cases or if the fetus is mature at the onset of symptoms, prompt delivery is indicated, usually by cesarean section. An emergency hysterectomy may be required because of severe hemorrhage, even after the delivery of the placenta, because of uterine atony. In patients who have undergone prior uterine surgery, particularly prior cesarean delivery, the risk of severe hemorrhage is even greater, owing to a higher incidence of placenta acreta (penetration of the myometrium by placental villi).

Abruptio placentae occurs in 0.2–2.4% of pregnant women, usually in the final 10 weeks of gestation and in association with hypertensive diseases. Complications include Couvelaire uterus (which occurs when extravasated blood dissects between the myometrial fibers), renal failure, disseminated intravascular coagulation, and anterior pituitary necrosis (ie, Sheehan syndrome). The maternal mortality is high (1.8–11.0%), and the perinatal mortality rate is even higher (in excess of 50%). The diagnosis of abruptio placentae is based on the presence of uterine tenderness, hypertonus, and vaginal bleeding of dark, clotted blood. Bleeding may be concealed if the placental margins have remained attached to the uterine wall. Changes in maternal blood pressure and pulse rate, indicative of hypovolemia, may occur if the blood loss is severe. Fetal movements may increase during acute hypoxia and decrease if hypoxia is gradual. Fetal bradycardia and death may ensue.

Anesthesia Management

The establishment of invasive monitoring (arterial line, central venous catheter) and blood volume replacement via a 14- or 16-gauge catheter is usually required. If clotting abnormalities exist, blood components and fresh frozen plasma, cryoprecipitate, and platelet concentrates may be required. The choice of anesthetic for a woman with placental abruption depends on maternal and fetal condition and how urgently the procedure needs to be performed. General anesthesia is indicated in the presence of uncontrolled hemorrhage and coagulation abnormalities.[106,156]

Epidural anesthesia may be used, particularly if there is a functioning epidural in place during labor at the time of abruption and there is no hemodynamic instability. Vincent et al. observed that epidural anesthesia significantly worsened maternal hypotension, uterine blood flow, and fetal PaO_2 and pH during untreated hemorrhage in gravid ewes.[157] However, this was uncorrected hypotension, which, with intravascular fluid replacement hemodynamics, returned to normal even with epidural anesthesia.

Preterm Delivery

Preterm labor and delivery present a significant challenge to the anesthesiologist because both the mother and the infant may be at risk. The definition of prematurity was altered to distinguish between the preterm infant, born before the thirty-seventh week of gestation, and the small-for-gestational-age infant, who may be born at term but whose weight is more than 2 standard deviations below the mean. Although preterm delivery occurs in 8–10% of all births, it accounts for approximately 80% of early neonatal deaths. Severe complications, such as respiratory distress syndrome, intracranial hemorrhage, hypoglycemia, hypocalcemia, and hyperbilirubinemia, are prone to develop in preterm infants.

Obstetricians frequently try to inhibit preterm labor to obtain time for fetal lung maturity. Delaying delivery by even 24–48 hours may be beneficial if glucocorticoids are administered to the mother to enhance fetal lung maturity. Various agents have been used to suppress uterine activity (tocolysis), such as ethanol, magnesium sulfate, prostaglandin inhibitors, β-sympathomimetics, and calcium channel blockers. β-adrenergic drugs, such as ritodrine and terbutaline, are the most commonly used tocolytics. Their predominant effect is β2 receptor stimulation, which results in myometrial inhibition, vasodilation, and bronchodilation. Numerous maternal complications, including hypotension, hypokalemia, hyperglycemia, myocardial ischemia, pulmonary edema, and death, have been reported as a result of these tocolytics.

Anesthesia Management

Complications may occur because of interactions with anesthetic drugs and techniques. With the use of regional anesthesia, peripheral vasodilation caused by β-adrenergic stimulation increases the risk of hemodynamic instability in the presence of preexisting tachycardia, hypotension, and hypokalemia. The premature infant is known to be more vulnerable than the term newborn to the effects of drugs used in obstetric analgesia and anesthesia. However, there have been few systemic studies to determine the maternal and fetal pharmacokinetics and dynamics of drugs throughout gestation.

There are several postulated causes of enhanced drug sensitivity in the preterm newborn: less protein available for drug binding; higher levels of bilirubin, which may compete with the drug for protein binding; greater drug access to the central nervous system because of a poorly developed blood–brain barrier; greater total body water and lower fat content; and a decreased ability to metabolize and excrete drugs. However, most drugs used in anesthesia exhibit low to moderate degrees of binding in the fetal serum: approximately 50% for bupivacaine, 25% for lidocaine, 52% for meperidine, and 75% for thiopental.

In selecting the anesthetic drugs and techniques for delivering a preterm infant, concerns regarding drug effects on the newborn are far less important than preventing asphyxia and trauma to the fetus. For vaginal delivery, well-conducted epidural anesthesia is advantageous in providing good perineal relaxation. Before induction of epidural blockade, the anesthesiologist should ascertain that the fetus is neither hypoxic nor acidotic. Asphyxia results in a redistribution of fetal cardiac output, which increases oxygen delivery to vital organs such as the brain, heart, and adrenals. Regardless, these changes in the preterm fetus may be better preserved with bupivacaine or chloroprocaine than with lidocaine.[158,159] Preterm infants with breech presentation are usually delivered by cesarean section. Regional anesthesia can be successfully used, with nitroglycerin available for uterine relaxation if needed.

Clinical Pearls

- When delivering a preterm infant, concerns about drug effects on the newborn are far less important than preventing asphyxia and trauma to the fetus.
- Before inducing epidural blockade, it should be ascertained that the fetus is neither hypoxic nor acidotic.

Regional analgesia during labor and vaginal delivery has become the preferred technique of pain relief in selected high-risk patients because it prevents obtundation of the mother and depression of the fetus and reduces many of the potential adverse physiologic effects of labor, such as increased oxygen consumption and hemodynamic alterations. For cesarean section delivery, regional anesthesia has emerged as a safe and effective technique in high-risk parturients, partly because of the added ability to provide prolonged postoperative analgesia.

NONOBSTETRIC SURGERY IN THE PREGNANT WOMAN

Approximately 1.6–2.2% of pregnant women undergo surgery for reasons unrelated to parturition. Apart from trauma, the most common emergencies are abdominal, intracranial aneurysms, cardiac valvular disease, and pheochromocytoma.

When the necessity for surgery arises, anesthetic considerations are related to the alterations in maternal physiologic condition with advancing pregnancy, the teratogenicity of anesthetic drugs, the indirect effects of anesthesia on uteroplacental blood flow, and the potential for abortion or premature delivery. The risks must be balanced to provide the most favorable outcome for mother and child.

Five major studies have attempted to relate surgery and anesthesia during human pregnancy to fetal outcome as determined by anomalies, premature labor, or intrauterine death.[160–162] Although these studies failed to correlate surgery and anesthetic exposure with congenital anomalies, all studies demonstrated an increased incidence of fetal death, particularly after operations performed in the first trimester. No particular anesthetic agent or technique was implicated. The condition that necessitated surgery was the most relevant factor, with fetal mortality greatest following pelvic surgery or procedures performed for obstetric indications; that is, cervical incompetence.

The cytotoxicity of anesthetic agents is closely associated with biodegradation, which, in turn, is influenced by oxygenation and hepatic blood flow. Thus, the complications associated with anesthesia—maternal hypoxia, hypotension, vasopressor administration, hypercarbia, hypocarbia, and electrolyte disturbances—may be greater factors in teratogenesis than the use of the agents themselves.[163–165]

The experimental evidence on exposure to specific drugs and agents is discussed briefly, with the understanding that it is difficult to extrapolate laboratory data to the clinical situation in humans. Very large numbers of patients must be exposed to a suspected teratogen before its safety can be ascertained. Complicating factors include the frequency of maternal exposure to a multiplicity of drugs; the difficulty in separating the effects of the underlying disease process and surgical treatment from those of the drug administered; differing degrees of risk with stage of gestation; and the variety, rather than the consistency, of anomalies that appear in association with one agent. With regard to regional anesthetic agents, local anesthetics have not been shown to be teratogenic in animals or humans.

Caution has been exercised with sedatives before block placement because of several reports describing a specific relationship between diazepam and oral clefts; however, other studies have not confirmed this.[166,167] A prospective study of 854 women who ingested diazepam during the first trimester did not demonstrate a higher risk of cleft palate or cleft lip.[168] Currently, diazepam is not a proven teratogen.[169]

Recently, there has been concern relating to adverse neurocognitive effects in children exposed to anesthetics during fetal life. Indeed, neonatal rats exposed to in utero general anesthesia had a greater degree of neuroadaptive deficits than a control group.[170] Similarly, infants born under general anesthesia for cesarean delivery have also been found to display mild impairment of cognition compared to regional anesthesia.[171] The difficulty with this study is that it was retrospective in nature, and the potential for patient selection bias existed. For instance, the use of general anesthesia is reserved for emergency situations, such as nonreassuring fetal status or placental abruption, which, in our opinion, would affect neurocognition more than the anesthetic. Most worrisome is that infants born via vaginal delivery had similar profiles as children born by cesarean delivery with general anesthesia. Nonetheless, it would seem prudent to avoid general anesthesia in preference for regional techniques during pregnancy because of the maternal and fetal considerations previously discussed. There are few data to guide medical decision making, but altering the type of surgical technique (eg, converting from laparoscopic to open appendectomy) should be entertained in order to facilitate the use of regional anesthesia.[170,171] As maternal pain and apprehension may result in decreased uterine blood flow and deterioration of the fetus (similar to infusions of epinephrine or norepinephrine), early intervention to relieve postoperative pain with regional techniques (ie, peripheral nerve block or epidural infusion) should be considered.[172]

Clinical Pearl

- Local anesthetics have not been shown to be teratogenic in animals or humans.

SUMMARY

Pregnancy results in a number of significant physiologic changes that require adjustment in anesthesia and analgesia techniques for the safe and effective management of the pregnant patient. It is prudent to delay surgery, when possible, until after the birth of the infant. Only emergency surgery should be considered during the first trimester.

Regional techniques have become the most accepted for pain relief during labor and vaginal delivery. Likewise, neuraxial techniques are now the most frequently used techniques to administer anesthetics for cesarean section delivery. Advances in regional anesthesia and its widespread routine use have resulted in significantly enhanced maternal safety compared with that of general anesthesia.

PART 6

PEDIATRIC ANESTHESIA

This page intentionally left blank

CHAPTER 42

Regional Anesthesia in Pediatric Patients: General Considerations

Steve Roberts

INTRODUCTION

Regional anesthesia is an essential part of modern pediatric anesthetic practice, conveying many significant advantages to the patient and to the hospital (Table 42–1). However, despite a strong body of evidence highlighting the advantages of regional anesthesia, it has been only relatively recently that regional anesthesia has begun to become more common place in anesthetic practice. Large prospective studies by the French-Language Society of Pediatric Anesthesiologists (ADARPEF) have demonstrated no increased risk to children having blocks performed under general anesthesia.[1–2] However, complications were four times greater in children aged less than 6 months compared to those older than 6 months.[2]

Historically, it was thought that neonates required little or no analgesia. However, inadequate analgesia in the neonate can cause biobehavioral changes that may modulate future responses to pain in childhood.[3] As a consequence, advanced regional anesthesia techniques (eg, epidural analgesia) have become increasingly utilized in children of all ages. Interestingly, the ADARPEF studies identified that there is a now a trend away from the central neuraxial blocks toward peripheral nerve catheter techniques. This change may have been influenced by advances in minimally invasive surgery and the more predictable administration of peripheral catheter techniques in modern regional anesthesia practice.[1–2]

All regional anesthetic techniques can be safely performed in the pediatric population with the adequate training and modern equipment.

ANATOMICAL DIFFERENCES BETWEEN CHILDREN & ADULTS

With respect to anatomy, physiology, and pharmacology, adolescents may be considered “little adults”; however, neonates and infants need special consideration.[4–5] Anatomically, the major difference lies in the spine and its contents; this topic is described in greater detail in Chapter 43. Physiologically, there are a number of differences found in the developing paediatric nervous system when compared to adults. Myelination is incomplete at birth, and the process can take 12 years to complete; consequently, lower concentrations of local anesthetic may be effectively utilized in the pediatric population, thereby also reducing the risk of toxicity. Although the nociceptive pathways are fundamentally the same in children as in adults, there are differences that may result in children experiencing greater pain than adults.[6] In children, the receptive field of a neuron may be greater, leading to poor pain localization. The descending inhibitory pathways are immature, and this may allow unmodulated nociceptive inputs to the ascending spinal pain pathways. The physiological immaturities of the neonatal liver in association with a relatively high cardiac output produce pharmacological differences that combine to increase the risk of local anesthetic toxicity in neonates.

PHARMACOLOGY OF LOCAL ANESTHETICS IN PEDIATRIC PATIENTS

There are two main groups of local anesthetic drugs used in pediatric regional anesthesia: the amino esters and the amino amides. (A detailed discussion of these drugs can be found in Chapter 7.) There are relatively few local anesthetic pharmacokinetics in children, and especially in neonates, is limited; unfortunately, it is this age group that is at the greatest risk of local anesthetic drug toxicity.[7]

Amino Amide–type Local Anesthetics

The most commonly used group of local anesthetics in pediatric practice are the amino amides: lidocaine, bupivacaine, ropivacaine, and levobupivacaine. The amino amide local anesthetics

TABLE 42–1. Advantages of regional anesthesia in children.

Patient benefits	Superior analgesia: Results in calmer patient and parents/caregivers.
	Reduced MAC: Reduced risk of deeper GA, smoother emergence, earlier return of appetite.
	Neurotoxicity: This potential problem is GA dose–dependent; therefore, a reduced MAC exposure may be beneficial.
	Hemodynamic stability: Up to 8 years of age, CNBs rarely cause significant hypotension.
	Reduced requirement for postoperative ventilator support: Particularly in neonates and infants undergoing upper abdominal and thoracic surgery.
	Obtunds the hormonal stress response.
	Reduced intraoperative blood loss: Demonstrated during hypospadias repair, cleft repair, and tonsillectomy.
	Improved GI function: Peristalsis better maintained; improved splanchnic perfusion in cases of NEC and gastroschisis.
	Avoids the need for GA: Premature infants who undergo GA are at risk of postoperative apnea.
Hospital benefits	Easier to nurse: Pain-free children are less labor intensive to care for.
	Reduced MAC: Rapid discharge from first-stage recovery.
	Reduced requirement for postoperative ventilatory support: This is of particular benefit when there is limited PICU support.
	Reduced length of stay.

CNB, central neuraxial block; GA, general anesthesia; GI, gastrointestinal; MAC, minimum alveolar concentration; NEC, necrotizing enterocolitis; PICU, pediatric intensive care unit.

undergo hepatic metabolism. However, the neonatal liver is immature, with the cytochrome systems maturing at varying rates: the CYP3A4 within the first 9 months of life compared to the CYP1A2, which can take until 8 years of age to mature.[8–9] The volume of distribution at steady state in infants is greater than in adults. Fluid compartments change drastically with age, 80% of body weight consisting of water in a premature neonate, 75% in a term neonate, 65% in an infant, and 60% in older children. As age increases, the intracellular fluid increases from 20% of body weight in premature neonates to the 30% seen in adults; within this time frame, extracellular fluids are halved. Local anesthetics are water soluble; therefore, the age-related changes in fluid compartment composition are significant. Infants have lower levels of local anesthetic–binding proteins (eg, alpha-1-acid glycoprotein and albumin), which leads to an increased fraction of unbound local anesthetic and therefore to a greater risk of toxicity. However, in the first 48 hours postoperatively, there is an increase in alpha-1-acid glycoprotein that may act to protect the neonate. The clearance of these drugs is decreased in those less than 3 months of age, gradually reaching adult levels by 8 months of age.[10] Consequently, elimination half-lives of local anesthetics are longer in neonates and infants compared to adults.

Bupivacaine

Bupivacaine is an isomer with both l- and d-enantiomer, the d-enantiomer causing most of the adverse effects that are seen in humans. Given that bupivacaine is the most toxic of the amino amide local anesthetics, consideration should be given to using a safer alternative, particularly for neonates and when continuous infusion techniques through indwelling catheters are administered. The pharmacokinetics and pharmacodynamics of bupivacaine have been well documented in the literature.[11–12] The preferred concentration for children is 0.25% for peripheral nerve blocks and 0.1% for continuous infusions. Older children can tolerate a higher dose of local anesthetic solution (0.4 mg/kg/h) compared with neonates and infants (0.2 mg/kg/h).[13] The dosage of bupivacaine is limited to 2–4 mg/kg for a single-dose injection and 0.2–0.4 mg/kg for a continuous infusion.

Ropivacaine

Ropivacaine is a newer amide local anesthetic that is being used more frequently in pediatric surgery. It is an l-enantiomer with less cardiovascular and central nervous system side effects compared with bupivacaine. Ropivacaine has slight vasoconstrictive properties that may explain the longer T_{max} when administered caudally compared to bupivacaine. Pharmacokinetic data are available in children on the use of ropivacaine in continuous infusions as well as for single-shot injections.[14–18] Pediatric trials have demonstrated a longer duration of action with ropivacaine than with mepivacaine when used for peripheral nerve blockade.[19] Caution should be exercised while using ropivacaine in children as well, as cases of cardiovascular toxicity has been reported.

Levobupivacaine

Levobupivacaine is a newer l-enantiomer with potentially less risk of severe cardiovascular toxicity. Pharmacokinetic data are available in children, and the dosage interval is similar as that of bupivacaine.[20–23] Animal experiments have shown that levobupivacaine causes less myocardial depression and a decreased incidence of inducing fatal dysrhythmias compared with bupivacaine.[24] Although this drug provides the practitioner with the option of a drug that is less cardiotoxic, caution should still be exercised.

Ester-type Local Anesthetics

Due to their short duration of action and propensity to cause allergic reactions, the amino esters (eg, procaine, 2-chloroprocaine, tetracaine) are the least commonly used group of local anesthetics. Unlike amino amide local anesthetics, the amino esters are metabolized by plasma cholinesterases.[25–27] As a result, the metabolism of ester local anesthetics depends on plasma cholinesterase levels.[28–31] Hence, in populations with decreased plasma cholinesterase levels, such as neonates and infants, the plasma level of these drugs may be increased, potentially leading to toxic drug levels. The presence of plasma cholinesterase also limits the duration of action of these drugs, leading to a shortened activity.

The most common ester local anesthetics used in infants and children are chloroprocaine and tetracaine. These drugs are occasionally used in children as an adjuvant to spinal anesthesia in formerly premature infants undergoing spinal anesthesia or as the sole anesthetic solution for caudal analgesia.[32] Tetracaine has been reported in spinal anesthesia, especially in premature infants, as the sole anesthetic for inguinal hernia repair.[33] 2-chloroprocaine has been used extensively in children for analgesia in the central neuraxial space.[34]

DOSING OF LOCAL ANESTHETICS IN PEDIATRIC PATIENTS

Most drug doses in pediatric patients are based on the weight of the patient (Table 42–2), though it is often debated whether total body weight or lean body mass is more appropriate for drug calculations.[35] However, this may not be applicable to local anesthetic considerations; studies done on infants undergoing spinal anesthesia found a larger requirement of local anesthetic solution (weight-scaled) compared with their adult counterparts using bupivacaine or tetracaine.[36]

The concentration of local anesthetic administered should also be carefully considered. A lower concentration of long-acting local anesthetic (eg, 0.25% levobupivacaine) is often used because the child is also receiving a general anesthetic; therefore, the block is used for analgesia only. However, in certain scenarios, lower or higher concentrations of local anesthetic should be administered. Lower concentrations (eg, 0.125% levobupivacaine) are useful in decreasing the risk of toxicity in neonates and are less likely to mask compartment syndrome or delay ambulation. Higher concentrations of local anesthetic(eg, 0.5% levobupivacaine) should be considered where a profound motor block is desirable (eg, lower limb tendon transfer surgery in children with cerebral palsy.

TOXICITY OF LOCAL ANESTHETIC DRUGS

The toxicity of local anesthetics in children include cardiovascular and central nervous system toxicity (Table 42–3) and allergic reactions to ester local anesthetic solutions.[35] The already discussed pharmacokinetic differences, together with the immaturity of the blood–brain barrier, may make central nervous system toxicity more likely in neonates.[37–41] However, the co-administration of general anesthesia may mask early signs and symptoms of systemic toxicity. The local anesthetic dose for children is always calculated on a milligram-per-kilogram basis, rather than predicted volumes as in adult regional anesthesia. While it is recognized that, of pediatric patients, infants are at a higher risk of systemic toxicity, caution should be the norm for children of all ages, as higher concentrations of some local anesthetics have been recorded in adolescents compared to adults. Toxic plasma levels have also been reported following safe doses of local anesthetic used for caudal and ilioinguinal blocks, so the minimum effective dose is recommended.

Interestingly, Weintraud et al. found that US-guided ilioinguinal blocks resulted in higher plasma concentrations when compared to landmark-based techniques.[42] This may be due to

TABLE 42–2. Maximum recommended doses and approximate duration of action of commonly used local anesthetic agents.

Local Anesthetic	Class	Maximum Dose (mg/kg)[a]	Duration of Action (min)	Infusion (mg/kg/h)
Procaine	Ester	10	60–90	–
2-chloroprocaine	Ester	20	30–60	–
Tetracaine	Ester	1.5	180–600	–
Lidocaine	Amide	5	90–200	–
Bupivacaine	Amide	2.5	180–600	0.2–0.4
Ropivacaine	Amide	2.5	180–600	0.2–0.5
Levobupivacaine	Amide	2.5	180–600	0.2–0.5

[a]In neonates, it may be safer to halve the maximum dose.

TABLE 42–3. Systemic toxicity of local anesthetic solution.

Central nervous system[a]
Dizziness and lightheadedness
Visual and auditory disturbances
Muscle twitching and tremors
Generalized convulsions
Cardiovascular
Direct cardiac effects
Depressed rapid phase of repolarization of Purkinje fibers
Depressed spontaneous firing of the sinoatrial node
Negative inotropic effect on cardiac muscle
Calcium influx altered, leading to decreased myocardial contractility
Effects on vascular tone
Low concentrations: vasoconstriction
High concentrations: vasodilatation
Increased pulmonary vascular resistance

[a] Particularly in infants and children with special needs, early signs of central nervous system toxicity are often misdiagnosed as a result of poor analgesia; therefore, a high level of suspicion must be maintained at all times in these patients.

a greater surface area of absorption created by placing the local anesthetic precisely in a fascial plane compared to the multiple deposits within muscle that often occur with a landmark-based method.

Clinical Pearls

Preventing Systemic Toxicity in the Pediatric Population

- Choose a less toxic drug (eg, levobupivacaine or ropivacaine).
- Do not exceed the maximum dose (in neonates, it may be prudent to halve the maximum dose).
- Inject small aliquots and aspirate repeatedly.
- US allows for lower doses of drugs to be used and for injection visualization.
- Beware of repeated doses, and limit infusions in neonates to 48 hours.
- An epinephrine-containing test dose may be used to identify intravascular injection but is limited by which general anesthetic is administered.
- No matter which technique is used, all children, given any local anesthetic solution, particularly when given as continuous infusions, should be monitored continuously for adverse effects.

Clinical Pearls

Managing Local Anesthetic Toxicity

In pediatric practice, early warning signs and symptoms of toxicity may be masked by the concurrent administration of general anesthesia. This means the first sign may be arrhythmia or cardiovascular collapse. Consider the following when managing local anesthetic toxicity:

- Stop the local anesthetic injection.
- Institute basic life support, and call for assistance.
- Secure the airway, ventilate with 100% oxygen, and gain intravenous access.
- Seizures can be managed with a benzodiazepine or anesthetic induction agent.
- If cardiac arrest has occurred, commence advanced life support.
- Note that arrhythmias are often refractory, and resuscitation should therefore be prolonged.
- Lipid administration.[43] The Association of Anaesthetists of Great Britain and Ireland has published a simple protocol to follow (Figure 42–1).

TOPICAL ANESTHESIA

It is important to discuss the use of topical anesthesia in children because it is commonly used in clinical practice to provide analgesia for intravenous catheter placement, lumbar puncture, and other invasive procedures (eg, circumcision in neonates). The most common preparations include lidocaine, tetracaine, benzocaine, and prilocaine. The topical anesthetic solution permeates through the skin to provide analgesia. The three most common preparations available include eutectic mixture of local and anesthetics (EMLA), LMX-4 (4% liposomal lidocaine solution), and Ametop (4% amethocaine gel).[44–47] EMLA contains lidocaine and prilocaine and must be applied at least one hour before cannulation. Its duration of action is only 30–60 minutes, though it can be left on for 4–5 hours. LMX-4 requires only 30 minutes to take effect and can also be left on for 4–5 hours. Ametop requires 45 minutes to take effect and must be removed within an hour of application; its duration of effect is up to 3 hours, as it binds to proteins in the stratum corneum. Ametop is vasodilatory, which may aid cannulation. However, Ametop can cause erythema and edema, which may obscure veins.[48]

Clinical Pearls

The following are considerations for children undergoing regional anesthesia:

- Regional anesthesia is mostly commonly performed with the patient under general anesthesia.
- The dose of local anesthetic used is much lower than for adults and is calculated in milligrams per kilogram).
- Use a local anesthetic at the lowest effective concentration.

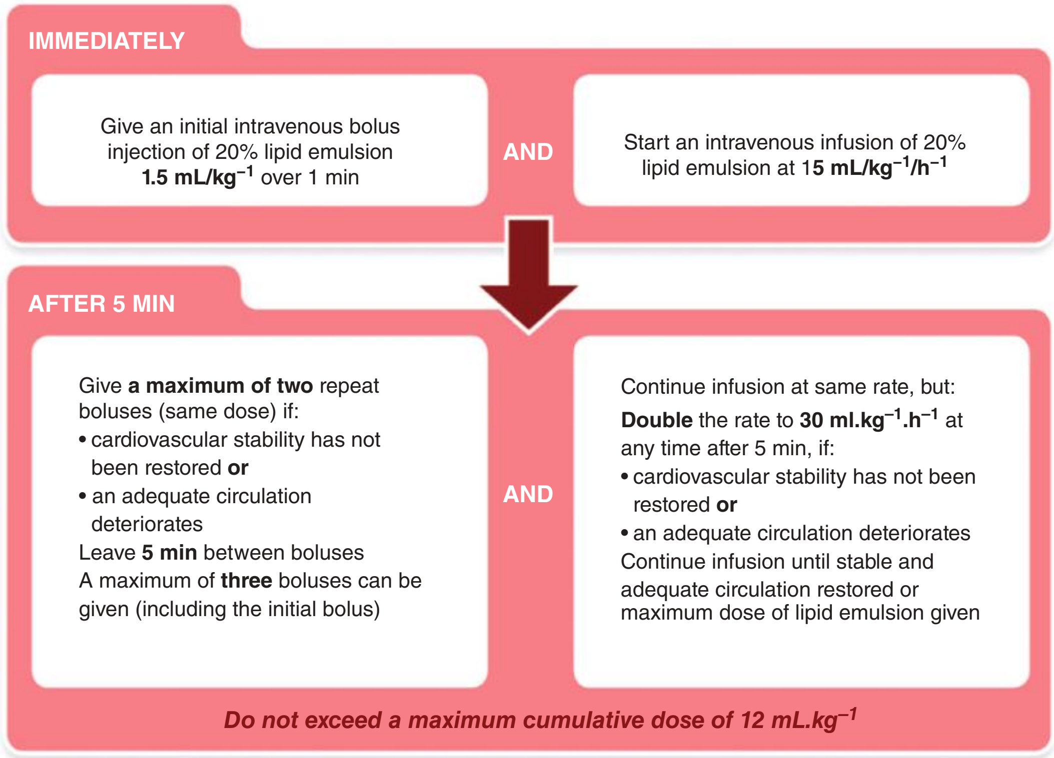

FIGURE 42–1. Association of Anaesthetists of Great Britain and Ireland (AAGBI) Protocol for Local Anesthetic Toxicity.

- If moderate or severe pain is expected, intense physiotherapy required post operatively, or there is a history of chronic pain, consider using a catheter technique.
- Far fewer regional anesthesia complications are reported in children than in adults.
- Always obtain patient assent or consent if the child is older.
- Always explain postoperative paresthesia to patients.

PREOPERATIVE ASSESSMENT

The preoperative visit is an opportunity to assess and prepare the patient and family for the proposed surgery and anesthetic technique. It is important that the anesthesiologist understand the intended surgery so that a decision can be made to perform either a single-injection or continuous regional anesthetic technique. Generally, the more peripheral block should be chosen, as this typically has the lowest risk and fewest side effects and will therefore have greater acceptability to the patient and parents or caregivers alike. A catheter technique is recommended for moderate to major surgery, procedures that will require prolonged postoperative physiotherapy, and for children with chronic pain. It is also important to ensure there will be nursing staff trained to manage continuous regional anesthetic techniques.

The anesthesiologist should seek potential contraindications (eg, comorbidities) to a given regional anesthetic technique. A thorough pain history should be taken, looking specifically for a history of chronic pain or muscle spasticity. Children with special needs can be particularly challenging, and the anesthesiologist needs to know how the child copes with and expresses pain. The standard preoperative anesthetic examination should include an examination of the proposed block insertion site to identify things such as anatomical difficulties (eg, scoliosis) and local infection. In children with neurological disease, their preoperative neurological deficit should be documented.

The anesthesiologist should explain the advantages, side effects, and potential complications of the proposed anesthetic plan to the child and the parents/caregivers; it is prudent also to discuss a "plan B" should the proposed technique fail. Alternative analgesic strategies should be discussed so that informed consent can be given. In particular, the postoperative paresthesiae of the regional technique should be explained to children in terms they can understand, as this is often an experience they find difficult to cope with. If a continuous regional anesthetic technique will be used, reassure the child that removal of the catheter will not be painful. Parents or caregivers typically provide consent for a procedure for their child. However, if the child has the cognitive ability to discern right from wrong, it is suggested that the child's assent for a regional technique be obtained as well.[49] There is debate as to when or what this age may be. If a child refuses to have a regional procedure despite the parents' or caregivers' insistence, it is important for the anesthesiologist to provide an alternative modality of pain relief.

Analgesic premedication with paracetamol (acetaminophen) and a nonsteroidal anti-inflammatory drug (NSAID) should be considered, especially where it is known that the block will not provide total analgesia (eg, a transverse abdominis plane [TAP] block for appendectomy). Postoperative instructions should be given preoperatively and reinforced postoperatively on discharge.

REGIONAL ANESTHESIA: AWAKE OR ASLEEP?

Whether it is best for the patient to be awake or asleep during regional anesthesia has been a controversial issue in adults, and this debate once permeated the realm of pediatric regional anesthesia practice. Placing a regional block in an awake child is difficult due to the inability of the child to cooperate as well as the cognitive inability of the child to relate to symptoms such as paresthesia or pain. Therefore, the child is best provided with a regional technique under deep sedation or after the induction of general anesthesia; this practice has been the consensus of pediatric anesthesiologists in the U.S. as well as abroad for some time.[50]

However, there are two scenarios in which awake regional techniques are used in children. First, it was thought that by avoiding general anesthesia in premature infants undergoing minor surgery, the incidence of postoperative apnea could be reduced. This is probably less of an issue now that premature neonatal lungs are better protected and with the availability of newer inhalational agents that provide a more rapid emergence.

Second, the more mature child may be considered suitable for an awake regional technique when undergoing a minor surgery if they prefer or when a general anesthetic is considered too risky (eg, lymph node biopsy in a teenager with a mediastinal mass). For older patients, it is essential to prepare the child and parents or caregivers for the whole operating room visit, not just the insertion of the block. The block insertion can be made more comfortable by applying a topical anesthetic cream (EMLA has the best penetration) over the proposed injection site. During the operating room visit, the child should be supported and distracted by a nurse or play specialist. The child may also find the use of a DVD or MP3 player a useful distraction. It may be necessary to use nitrous oxide (Entonox) or anxiolytic doses of propofol or remifentanil to ease proceedings. Marhofer et al. have shown that in the pediatric trauma scenario, brachial plexus blocks are more comfortably inserted with US than with nerve stimulation.[51] In pediatric hospitals, the operating room staff and surgeon must be reminded that the patient will be awake, and the drugs and equipment needed to convert to general anesthesia must be ready.

PERIOPERATIVE BLOCK MANAGEMENT

Some simple rules need to be followed when performing any regional anesthetic technique in children. A skilled assistant should be present at all times, and this individual should understand the basic principles of regional anesthesia, in particular the need to aspirate regularly prior to injection, the need to warn the anesthesiologist about injection resistance. Further, the assistant should be able to make basic adjustments to the peripheral nerve stimulator (PNS) and US machines.

The child should have a secure airway, intravenous access, and full monitoring prior to commencing the block. As part of the World Health Organization (WHO) Surgical Safety Checklist, consent and side of surgery are checked, and just before block insertion, the site should again be confirmed with the anesthesiologist's assistant.

The child, US machine (when used), equipment, and anesthesiologist should be positioned ergonomically.

There is some debate as to the minimal standards for asepsis for regional anesthesia. For single-injection techniques, it is sufficient to scrub one's hands, wear sterile gloves, apply an alcoholic solution to the patient's skin, and cover the US probe. For catheter techniques, a more rigorous aseptic technique is advised. When performing any catheter technique, it is useful when draping the child to have a large area of anatomy visible; this allows the anesthesiologist sufficient room to perform a mapping/scout scan and also a better view, and thus appreciation of, the patient's anatomy (particularly important when placing epidurals in children with scoliosis).

It may be beneficial to tunnel the catheter, as this aids fixation, and in some cases may decrease the risk of infection (eg, with a caudal catheter, the catheter can be tunneled away from the diaper area.

There is no ideal test dose; therefore, repeated, frequent aspiration during injection is suggested.

When the block is not expected to cover all aspects of surgical pain (eg, a rectus sheath block for pyloromyotomy), consideration should be given to the administration of paracetamol intravenously and/or an NSAID per rectum to aid analgesia. Other adjuvants may prove beneficial (eg, intraoperative magnesium sulphate 50 mg/kg may decrease postoperative muscle spasms in cerebral palsy patients undergoing lower-limb surgery).

It is the author's opinion that, where possible, the regional anesthetic technique's efficacy should not be obscured by the administration of opioids or nitrous oxide. It is important in the intraoperative assessment of the block that any changes in heart rate and blood pressure are noted and related to the specific surgical proceedings at the time. This allows for the planning of rescue blocks at the end of the procedure. Even with successful blocks, occasional cardiovascular responses to surgical stimuli may occur, as the blocks are generally performed using a lower concentration of local anesthetic (eg, 0.25% levobupivacaine), and, if a tourniquet is used, a gradual increase in heart rate and blood pressure will occur after the first 30–40 minutes.

The degree of intraoperative cardiovascular stability helps the anesthesiologist decide whether any patient distress during the first stage of recovery is due to pain or another cause (eg, emergence delirium).

In first-stage recovery, if there is doubt as to why a child is upset, then it should be assumed that the patient is in pain, and this should swiftly be dealt with by administering a fast-acting opiate (eg, fentanyl).

POSTOPERATIVE CARE

Postoperative advice pertaining to protecting the anesthetized area should be given verbally preoperatively and repeated postoperatively, and written instructions should also be given to the family. The family and child should be warned of muscle weakness and diminished sensation. Slings should be provided to pediatric patients with upper-limb blocks. Ambulatory children with lower-limb blocks should have the means to mobilize and travel home arranged. Every institution must have guidelines for in-patient nursing care and monitoring of regional anesthetic techniques, and the staff must receive regular education on managing regional blocks postoperatively and care of the anesthetized extremity. It is generally more economical and safer to place patients receiving regional anesthesia and analgesia on specific wards. (For more information on this topic, see Chapter 45.)

TRAINING

The training of anesthesiologists in pediatric regional anesthesia and anatomy is essential for its successful and safe implementation. Where possible, each department should provide a structured approach to teaching the common simple blocks: caudal, penile, femoral, axillary, ilioinguinal, and rectus sheath. Training should include US scanning and needling techniques. Once basic US needling skills have been learned on phantoms and scanning skills developed on adult volunteers, these skills can then be transferred to the clinical setting. Generally, these techniques are easier and more safely performed on older patients first.

Clinical Pearl

- Where possible, each department should provide a structured approach to teaching the common blocks: caudal, penile, femoral, axillary, ilioinguinal, and rectus sheath.

SUMMARY

Regional anesthesia improves the postoperative experience of both children and parents or caregivers and facilitates the efficient use of hospital facilities and it is expected that the use of regional anesthesia in children will continue to grow in popularity. Regional anesthetic techniques should provide the correct balance between risks and benefits for the children and surgery of today. US is allowing a greater array of peripheral blocks to be safer and reliably used in children. Technology is important, but is not a replacement for a solid understanding of anatomy and a high standard of general safe practice.

CHAPTER 43

Pediatric Epidural and Spinal Anesthesia & Analgesia

Belen De Jose Maria, Luc Tielens, and Steve Roberts

EPIDURAL ANESTHESIA IN CHILDREN

INTRODUCTION

Epidural analgesia is commonly used in addition to general anesthesia and to manage postoperative pain. Effective postoperative pain relief from epidural analgesia has numerous benefits including earlier ambulation, facilitating weaning from ventilators, reducing time spent in a catabolic state, and lowering circulating stress hormone levels.[1] Precise placement of epidural needles for single-injection techniques and catheters for continuous epidural anesthesia ensures that the dermatomes involved in the surgical procedure are selectively blocked, allowing for lower doses of local anesthetics to be used and sparing unnecessary blockade in nondesired regions. The approach to the epidural space can be at the caudal, lumbar, or thoracic level.

ANATOMY AND PHYSIOLOGICAL IMPLICATIONS

There are significant anatomical differences in children compared with adults that should be considered when using neuraxial anesthesia. For instance, in neonates and infants, the conus medullaris is located lower in the spinal column (at approximately the L3 vertebra) compared with that in adults, in whom it is situated at approximately the L1 vertebra. This is a result of different rates of growth between the spinal cord and the bony vertebral column in infants. However, at approximately 1 year of age, the conus medullaris reaches the L1 level similar to that in an adult.

Clinical Pearls

- In neonates and infants, the conus medullaris ends approximately the L3 level as opposed to adults, where it is located approximately at the L1 vertebra.
- At approximately 1 year of age, the conus medullaris reaches the L1 level, similar to that in an adult.

The sacrum of children is also more flat and narrow compared with the adult population. At birth, the sacral plate, which is formed by five sacral vertebrae, is not completely ossified and continues to fuse until approximately 8 years of age (although it may take until 21 years of age). There is a 6% incidence of sacral atresia. The incomplete fusion of the sacral vertebral arch forms the sacral hiatus. The caudal epidural space can be accessed easily in infants and children through the sacral hiatus. Because of the continuous development of the sacral canal roof, there is considerable variation in the sacral hiatus. In young children, the sacral hiatus is located more cephalad than in older children, and the dural sac may end more caudally: at S4 in infants younger than 1 year and at S2 in older children. Therefore, because of the increased risk of accidental dural puncture, caution is warranted when placing caudal blocks in infants.

Clinical Pearls

- In young children, the sacral hiatus is located more cephalad than in older children, and the dural sac may end more caudally (at S4 in infants younger than 1 year).
- Caution with the use caudal blocks is warranted in infants because of the risk of dural puncture.

Ultrasound (US) assessment of the neuraxial structures is less challenging in younger children because ossification is less developed. In infants, the spinal cord fibers, the cerebrospinal fluid (CSF), and the dura mater are easily identified using linear high-frequency US probes. It has also been suggested that the epidural fat is less densely packed in children than in adults.[2] The loosely packed epidural fat may facilitate the spread of local anesthetic and help achieve a quicker block onset. It may also allow the unimpeded advancement of epidural catheters from the caudal epidural space to the lumbar and thoracic levels. However, the final placement of a catheter's tip is best monitored directly under US guidance or indirectly by identifying the injection of local anesthetic.

The amount of CSF per body weight is higher in neonates and infants (4 mL/kg) compared with adults (2 mL/kg), and the CSF is localized primarily in the spinal canal. In addition, the spinal cord in neonates is still nonmyelinated, meaning that lower concentrations of local anesthetic can be effectively used.

Because children have a higher cardiac output compared to adults, the systemic absorption of local anesthetic occurs faster. This can lead to toxic plasma levels and a shorter duration of block.

Clinical Pearls

- Compared to older children, the sacral hiatus in neonates is located more cephalad, and the dural sac ends lower, increasing the risk of accidental dural puncture.
- US imaging can be used to evaluate the neuraxial anatomy and the approach to the epidural space.

LOCAL ANESTHETICS FOR EPIDURAL ANESTHESIA IN CHILDREN

Since most pediatric patients receive epidural analgesia in conjunction with a general anesthetic, the main purpose of the epidural catheter is to deliver enough local anesthetic solution for effective intraoperative and postoperative analgesia. As with epidural anesthesia in adults, local anesthetic concentration and volume are important factors in determining the density and level of blockade. However, in pediatric patients, knowledge of total drug dose is also important to avoid local anesthetic toxicity. A more detailed description of local anesthetic solutions, their characteristics, and toxicity potential has been described in Chapter 7.

Bupivacaine, ropivacaine, and levobupivacaine are the most commonly used local anesthetics for neuraxial anesthesia in children.[3–5] Lidocaine is not often used because of its excessive motor block. As a general rule, high concentrations of local anesthetics, such as 0.5% bupivacaine or 0.5% ropivacaine, are seldom used in epidural blocks in children. Instead, larger volumes of more dilute local anesthetic are more commonly used to cover multiple dermatomes. Body weight is usually a better correlation than patient age in predicting spread of local anesthetic after a caudal block. The maximal safe dose of bupivacaine is 2.5 mg/kg. For caudal use, the optimum concentration of bupivacaine is 0.125%–0.175%.[6] Compared with the 0.25% preparation, this concentration provides a similar duration of postoperative analgesia (4–8 hours) but with less motor blockade. Some clinicians prefer administering doses on a volume-per-weight basis. A dose of 1.0 mL/kg of a dilute solution, such as 0.125% bupivacaine, to a maximum volume of 20 mL can sometimes provide T10 sensory block without exceeding the maximum levels recommended in the literature.[7] In infants, higher volumes, such as 1.25 mL/kg or even 1.5 mL/kg, may be administered to provide a more cephalad block without the risk of local anesthetic toxicity.[7] For continuous epidural infusion, a commonly accepted dosage guideline for bupivacaine is 0.2 mg/kg/h for neonates and 0.4 mg/kg/h for older children.[8] Cumulative toxicity is a concern even at lower rates of local anesthetic solution infusions.[9] Therefore, duration of neonatal epidural infusions should be limited to 48 hours.

Ropivacaine has a higher therapeutic index than the older local anesthetic bupivacaine.[10–12] At low concentrations, ropivacaine may produce less motor block and equivalent analgesia compared to bupivacaine with a decreased incidence of cardiac and central nervous system toxicity. Because of its possible vasoconstricting properties, ropivacaine may undergo slower systemic absorption than bupivacaine.[13,14] This may have clinical implications when a prolonged local anesthetic infusion is used in children with impaired hepatic function.[15] For a single-injection caudal block, a bolus of 1 mL/kg of 0.2% ropivacaine is recommended.[16,17] An infusion of 0.1% ropivacaine at 0.2 mg/kg/h in infants and 0.4 mg/kg/h in older children, lasting no longer than 48 hours, has also been shown to be effective and safe.

Levobupivacaine, the *S* (–)-isomer of bupivacaine, is less likely to cause myocardial depression and fatal arrhythmias and is also less toxic to the central nervous system than racemic bupivacaine. A dose of 0.8 mL/kg of 0.25% levobupivacaine injected caudally provides analgesia in children having penile or groin surgery.[18] For continuous epidural infusion, the dose for levobupivacaine is similar to that for racemic bupivacaine.

Clinical Pearls

- High concentrations of local anesthetic, such as 0.5% bupivacaine or 0.5% ropivacaine, are not recommended in the pediatric population. As the myelination is not complete, lower concentrations of amino amide local anesthetics are effective (eg, 0.125% levobupivacaine).
- Instead, larger volumes of more dilute local anesthetics are more commonly used to cover several dermatomes of interest.

- In the pediatric patients, body weight provides a better correlation than patient age in predicting spread of local anesthetic after a caudal block.
- A simple rule for a caudal single injection in children under 20 kg is to use bupivacaine 0.125%–0.175% or ropivacaine 0.2% and give a bolus of one of the following:
  - 0.5 ml/kg to achieve a sacral surgical level
  - 1.0 ml/kg to achieve a high lumbar surgical level
  - 1.25 ml/kg to achieve a low thoracic surgical level
- For continuous epidural infusion, bupivacaine 0.125% at a rate of 0.2 mg/kg/h for neonates and 0.4 mg/kg/h for older children is often used. Ropivacaine 0.1% at a rate of 0.2 mg/kg/h for neonates and 0.4 mg/kg/h for older children for 48 hours has been shown to be an effective and safe regimen.

ADJUVANTS FOR EPIDURAL ANESTHESIA IN CHILDREN

A single-injection caudal block with local anesthetic is used primarily for minor surgery because of its limited duration of analgesia. Adjuvants may be used to prolong the duration of blockade, and several drugs have been trialed. The most commonly used adjuvant to local anesthetics has been epinephrine. Epinephrine in a concentration of 1:200,000 is used to decrease the absorption rate of local anesthetic and has the added benefit of serving as a possible marker for an inadvertent intravascular injection. Recent research has focused on the use of a multitude of adjuvants. Midazolam and neostigmine have also been studied; however, there is no evidence that these drugs provide any analgesic benefit when administered epidurally.[19] Opioids, clonidine, and ketamine all deserve more consideration and will therefore discussed in greater detail.

Opioids

Epidural opioids may enhance the effect of local anesthetics and prolong analgesia. However, some opioids may not be advisable in an ambulatory setting because of the potential for respiratory depression and other unacceptable side effects (eg, nausea and vomiting, itching, urinary retention).[20] As a result, the use of caudal epidural opioids in children should be restricted to special clinical situations outside the outpatient setting. A dose of 2 mcg/kg of fentanyl for single-injection caudal anesthesia along with the standard local anesthetic solution has been recommended for more extensive or painful procedures and in patients who have a urinary catheter in the postoperative period. The addition of 1–2 mcg/mL fentanyl to 0.1% bupivacaine for continuous epidural infusions has also been used with success in children in a well-monitored inpatient setting. However, fentanyl should *not* be used in neonatal epidural infusions.

Epidural morphine may also be used for inpatients undergoing major abdominal or thoracic surgery. When added to single-injection caudal epidural blocks, it will enhance the level of blockade because of its rostral dispersion (as morphine is a hydrophilic molecule). Doses of caudal morphine vary from 30–90 mcg/kg depending on the type of surgery. Epidural morphine carries a potential risk for respiratory depression; therefore, continuous pulse oximetry is recommended with lower doses of caudal morphine and is mandatory with medium doses. When higher doses of caudal morphine are used, postoperative admission to intensive care must be planned.[21]

Clonidine

Of the various nonopioid adjuncts used in epidural blocks in children, clonidine offers the best profile.[22] Clonidine is an α_1-agonist and acts by stimulating the descending noradrenergic medullospinal pathways, which inhibits the release of nociceptive neurotransmitters in the dorsal horn of the spinal cord. The addition of clonidine (1–5 mcg/kg) can improve the analgesic effect of local anesthetics for single-injection caudal blockade and prolong the local anesthetic duration of action without the unwanted side effects of epidural opioids. For continuous epidural infusions, clonidine 0.1 mcg/kg/h has been used with good effect.[23] It should be cautioned that higher doses have been associated with sedation and hemodynamic instability in the form of hypotension and bradycardia. With bolus doses of 2 mcg/kg, these side effects are unusual. In addition, epidural clonidine blunts the ventilatory response to increasing levels of end-tidal carbon dioxide (PCO_2). Although respiratory depression does not appear to be a common problem,[24] apnea has been reported in a term neonate who received a caudal block consisting of 1 mL/kg of 0.2% ropivacaine with clonidine 2 mcg/kg.[25] Caution should be exercised when using clonidine in very young infants because of the sedation and hypotension that may ensue.

Ketamine

The addition of *S*-ketamine[23] to a single-injection caudal block prolongs the analgesic effect of local anesthetics. The main disadvantages of ketamine are its psychomimetic effects. However, at small doses (0.25–0.5 mg/kg), ketamine is effective without noticeable behavioral side effects. Ketamine 1 mg/kg can also be used as an effective caudal analgesic solely without the addition of local anesthetic solution.[26] The combination of *S* (+)-ketamine (0.5–1 mg/kg) and clonidine (1 or 2 mcg/kg) has been shown to provide effective analgesia after inguinal herniotomy in children with a prolonged duration of effect (> 20 hours) without any adverse central nervous system (CNS) effects or motor impairment.[27] One concern regarding the use of ketamine in neonates relates to a controversial series of animal studies suggesting that ketamine can produce apoptotic neurodegeneration in the developing brain.[28] Other infant animal studies have demonstrated that ketamine may have a neuroprotective effect.[29] Nevertheless, many anesthesiologists are hesitant to introduce caudal *S*-ketamine into their routine clinical practice, and ketamine is unlikely to be widely adopted in countries where preservative-free formulas are unavailable.

COMPLICATIONS ASSOCIATED WITH EPIDURAL ANESTHESIA

Major complications from either single-injection or continuous epidural blocks are rare if proper technique is used.[30]

Neurologic Injury

A large prospective study, which summarized data from over 15,000 central blocks in children, reported no incidence of permanent neurologic injuries and concluded that the incidence of complications is rare.[31] However, three infant deaths and two other incidences of paraplegia and quadriplegia were reported in another large retrospective report published in 1995 with over 24,000 epidural blocks in children.[32] This study also reported two cases of transient paresthesia. Although the overall risk seems low, devastating complications from direct damage to the spinal cord can occur, particularly with thoracic and high lumbar epidural needle placement. In addition, hypotension can compromise spinal perfusion. Because the placement of epidural needles and catheters is usually performed with the patient under sedation or general anesthesia, the fact that unconscious patients are unable to report pain or paresthesia (the currently accepted warning sign of needle encroachment on the spinal cord) raises concern.[33] Keeping the patient spontaneously breathing while performing the neuraxial block has been suggested as a safety measure. Preprocedural US scanning of the neuraxial anatomy where available is highly recommended to assess depth to the epidural space.

A case report of spinal cord injury after placing a single-injection thoracic epidural under general anesthesia for appendectomy[34] highlights the importance of the routine assessment of the risk–benefit ratio of placing a direct thoracic epidural for less extensive surgery. In particular, the use of thoracic and high lumbar epidural catheter placement should be reserved only for extensive thoracic and abdominal procedures and should be performed by anesthesiologists with experience in thoracic epidural placement.

To minimize the risk of spinal cord injury (and the risk of dural puncture), knowledge of the expected depth of the epidural space is important. As a general rule, the epidural space in children weighing more than 10 kg is found at 1 mm/kg of body weight. There are other formulas based on the patient's body weight or age to calculate this depth. However, the best option is to measure the depth by preprocedural US imaging of the neuraxial anatomy (Table 43–1).

Clinical Pearl

- As a general rule, the epidural space in children weighing more than 10 kg is found at a depth of 1 mm/kg of body weight. However, preprocedural US imaging is useful to determine the depth of the epidural space.

TABLE 43–1. Formulas to determine depth of epidural space from skin.

Note: An individual preprocedural ultrasound assessment is the preferred method of determining the depth of epidural space from the skin.
1. Rough estimate: 1 mm/kg body weight
2. Depth (cm) = 1 + (0.15 × age in years)
3. Depth (cm) = 0.8 + (0.05 × weight in kilograms)

Epidural Hematoma

Epidural hematoma associated with epidural analgesia in children is rare. This may be because anticoagulation protocols are rarely indicated during the perioperative period in pediatric patients. Nonetheless, epidural analgesia should be avoided in patients with clinically significant coagulopathy or thrombocytopenia. Guidelines for the use of epidural anesthesia in adult patients should also be applied in pediatric patients receiving antithrombotic or thrombolytic therapy.[35]

Infection

Although the overall infection rate associated with caudal epidural catheters appears to be low, isolated case reports exist of infection related to epidural catheters in children. Compared with lumbar epidural catheters, there is some concern regarding catheter infection with the prolonged use of caudally placed catheters owing to the proximity of the sacral hiatus to the rectum. Although studies have not found clinical evidence of higher infection rates with the caudal approach, bacterial colonization has been reported to be higher. *Staphylococcus epidermidis* is the predominant microorganism colonized on the skin and catheters of lumbar and caudal epidurals.[36] Gram-negative bacteria have also been found on the tips of caudal catheters. Even with widely used single-injection caudal blocks, infections such as sacral osteomyelitis can still occur.[37] To reduce the risk of contamination by stool and urine, techniques such as catheter tunneling and fixing the catheter with occlusive dressing in a cephalad direction can be used.[38] A strict aseptic technique including the use of a sterile closed-infusion system should also be used, and care should be taken to avoid local tissue trauma. Daily inspection of the dressing and entry site is also important, although the dressing should not be changed unless strictly necessary. If the child develops a persistent fever greater than 38°C of unknown origin, the catheter should be removed and sent for culture.

Dural Puncture and Postdural Puncture Headache

Dural puncture during caudal epidural analgesia is uncommon if caution is taken to avoid advancing the needle too far into the sacral canal. The use of real-time US imaging to control needle position makes this risk extremely low. Treatment for postdural puncture headache (PDPH) includes bed rest, oral or intravenous (IV) hydration, analgesia (eg, regular acetaminophen, nonsteroidal anti-inflammatory drugs [NSAIDs]), and antiemetics. Bed rest, although relieving the severity of the headache, has no effect on the incidence or duration of PDPH.

In adults, caffeine has been used for both the prophylaxis and treatment of PDPH. Caffeine causes cerebral vasoconstriction by blocking adenosine receptors, which dilate vessels when activated. Reducing cerebral blood flow decreases the amount of blood in the brain and may lessen the traction on pain-sensitive intracranial structures, thus relieving PDPH.[39] However, caffeine is not frequently used in children for relief of PDPH, and an optimal dose is unknown.

The use of epidural blood patch to treat PDPH has been used with success in adults since 1960. There are now many reports of its successful use in children as well.[40,41] An epidural blood patch is thought to be effective through the formation of a gelatinous cover over the dural hole by the injected blood. In the short term, the epidural blood patch seals the hole and relieves CSF hypotension both by mass effect from CSF cranial displacement and by increasing intracranial volume and pressure. Actual healing takes place over the longer term. In children, it is recommended that approximately 0.3 mL/kg of autologous blood be injected in the awake or mildly sedated patient, if possible, to detect the appearance of radicular symptoms. A more complete discussion on PDPH is presented in Chapter 27.

Hemodynamic Effects and Total Spinal Anesthesia

Significant changes in blood pressure are uncommon in pediatric patients after the accurate administration of epidural analgesia. A high sympathetic single-injection caudal block to T6 has been found to evoke no significant changes in heart rate, cardiac index, or blood pressure in children.[42] Even when thoracic epidural block is combined with general anesthesia, cardiovascular stability is usually maintained in otherwise healthy pediatric patients. Therefore, hypotension should raise the suspicion of total spinal anesthesia and/or an intravascular injection leading to local anesthetic toxicity. After these complications are ruled out, other causes, such as hydration status, intravascular filling pressure, and inotropic state, and the depth of anesthesia should be assessed.

If total spinal anesthesia has occurred, supportive measures must be provided until the effect of the block has dissipated. However, in the event of a life-threatening extension of a total spinal anesthesia, if attempted supportive measures are neither effective nor an option, cerebrospinal lavage may be considered as a last maneuver. A case report has suggested that 20–30 mL of CSF can be withdrawn and replaced with 30–40 mL of preservative-free normal saline, Ringer's lactate, or Plasmalyte via the epidural catheter.[43] This intervention may shorten recovery time, minimize the potential neurotoxic insult, and reduce the incidence of postdural puncture. However, in light of the limited experience and information on cerebrospinal lavage, the potential risks and benefits should be evaluated on a case-by-case basis before using this technique in children.

Clinical Pearls

- Epidural anesthesia and analgesia in otherwise healthy children rarely causes cardiovascular instability.
- The occurrence of hypotension should raise the suspicion of total spinal anesthesia and/or an intravascular injection leading to local anesthetic toxicity.
- After these complications are ruled out, other causes, such as hydration status, intravascular filling pressure, and inotropic state, and the depth of anesthesia should be assessed.

Local Anesthetic Systemic Toxicity

Local anesthetic systemic toxicity (LAST) often stems from accidental intravascular injection into epidural blood vessels. This complication can often be avoided by using careful aspiration and test dosing. Table 43–2 summarizes recommendations for test dosing in epidural blockade. For a single-injection caudal block, vascular puncture and local anesthetic absorption are more likely to occur when sharp-tipped needles are used. For continuous epidural infusion, neonates and very young infants are at greater risk for local anesthetic toxicity than older children. Seizures have been reported in children receiving continuous infusions of local anesthetics. This can be avoided by

TABLE 43–2. Test dosing for epidural blockade.

1. Use test dosing routinely, even though test dosing for all available agents is not 100% sensitive. In addition, because the true incidence of intravascular placement is relatively low, most positive tests (ie, heart rate increases) will be false-positives. When there is a borderline response, repeating the test dose increases the specificity and sensitivity of the test.
2. Continuously monitor the ECG, and cycle the blood pressure cuff repeatedly. With epinephrine-containing solutions, if the heart rate does not increase, an increase in blood pressure should raise suspicion of intravascular placement.
3. Avoid performing test dosing when the child is in a very light plane of anesthesia or when there is stimulation (eg, repositioning the patient on the operating table, instrumentation of the airway, incision). Performing the test dose under these conditions increases the likelihood of false-positive, stimulation-induced increases in heart rate or blood pressure.
4. After the test dose, the remainder of the full dose should be administered incrementally. Incremental dosing and continuous monitoring help increase the odds that an intravascular placement will be detected and that further injection will be halted before full cardiodepressant doses are administered.
5. Whenever possible, keep the patient under spontaneous ventilation throughout the placement and initial dosing of the epidural blockade. Any change in the patient's breathing pattern is an alert that an inadvertent intravascular or intrathecal injection may have taken place: tachypnea if pain on injection; respiratory depression if there has been systemic absorption of local anesthetic; or tachypnea followed by bradypnea caused by total spinal anesthesia if local anesthetic has been administerd intrathecally.

ECG, electrocardiogram.

using dilute solutions of local anesthetics (≤ 0.125% bupivacaine) and by following current dosing recommendations (see "Local Anesthetics for Epidural Anesthesia in Children," above).[44] More importantly, vigilant monitoring during the administration of epidural analgesia should be a priority. Guidelines for LAST treatment[45] should be readily accessible in all hospital areas where local anesthetics are used. All personnel of wards where patients undergoing epidural infusion are cared for should be trained in the recognition of symptoms and treatment of LAST. In addition, a complete record of the regional technique and infusion used in each case should be present alongside the patient's observations chart.

Other Adverse Effects

In a retrospective review based on prospective collected data from 286 pediatric patients, pruritus (26.1%), nausea and vomiting (16.9%), and urinary retention (20.8%) were the most common side effects encountered during epidural anesthesia using an infusion of bupivacaine and fentanyl.[46] Sedation and excessive block each occurred in less than 2% of patients. The incidence of respiratory depression was 4.2%, but the administration of naloxone for severe respiratory depression was never necessary. Perforation of the rectum may occur if the caudal needle is angled too steeply. Table 43–3 summarizes the recommended treatments for common adverse effects.

EPIDURAL BLOCKADE FOR PEDIATRIC SURGERY: TECHNIQUES

Epidural analgesia can be delivered via a single-injection or continuous-infusion technique. The needles and catheters can be inserted at the caudal, lumbar, or thoracic level. The main goal of the epidural technique is to accurately position the needle and/or catheter in the epidural space. Aspiration tests and test doses indicate possible inadvertent intravascular or intrathecal drug administration. Epidural stimulation, epidural electrocardiogram (ECG), and US techniques have been developed in addition to conventional X-ray imaging to assist with accurate epidural needle or catheter placement.

Confirmation of Proper Epidural Needle or Catheter Placement

Aspiration and Test Dose

An aspiration test performed before local anesthetic injection is used to avoid total spinal and intravascular injections. However, a negative aspiration of blood or CSF should not be considered an absolute indicator of proper needle and catheter placement. Veins are so small they may collapse easily on aspiration; therefore, it is recommended to use a 2-mL syringe, aspirate slowly, and consider opening to air to look for free flow.

TABLE 43–3. Summary of recommended treatments of effects in epidural blocks.

Itching
1. Exclude and/or correct other remediable causes.
2. Use low-dose naloxone infusions, partial agonist–antagonists (eg, nalbuphine), or antihistamines.
3. If itching persists, remove the opioid from the epidural infusion, and consider clonidine.

Nausea
1. Exclude and/or correct other remediable causes.
2. Use 5-HT antagonists (eg, ondansetron, dolasetron)
3. Use low-dose naloxone infusions or nalbuphine.
4. Avoid opioids in infusions, and consider clonidine.

Ileus and bowel dysfunction
1. Exclude and/or correct other remediable causes.
2. Give laxatives if not otherwise contraindicated.
3. Avoid opioids in infusions, and consider clonidine.
4. Use low-dose naloxone infusions or nalbuphine.
5. Use peripherally or enterally constrained opioid antagonists; for example, methylnaltrexone or alvimopan (currently investigational).

Sedation or hypoventilation
1. Exclude and/or correct other remediable causes.
2. Depending on severity, reduce or hold dosing of opioids or clonidine.
3. Awaken, stimulate, and encourage deep breathing.
4. If severe, consider naloxone or assisted ventilation as needed.

Urinary retention
1. Exclude and/or correct other remediable causes.
2. Avoid using anticholinergics or antihistaminics if alternatives are available.
3. Use low-dose naloxone infusions or nalbuphine.
4. Use bladder catheterization.

The patient's ECG should be continuously monitored while injecting local anesthetic into the caudal space. The ECG specificity changes (ie, > 25% increase in T wave) after the injection of an epinephrine test dose (0.5 mcg/kg) can help predict intravascular injection.[47]

If possible, the patient should be kept under spontaneous ventilation throughout the placement and initial dosing of the epidural blockade. Any change in the patient's breathing pattern is an alert that something might accidentally be happening: respiratory depression if there is systemic absorption of local anesthetic; tachypnea if there is pain on injection; or tachypnea followed by bradypnea if there has been an intratechal administration of local anesthetic (see Table 43–2). Table 43–4 summarizes various methods for confirming epidural catheter placement.

Radiographic Methods

X-ray imaging in conjunction with a contrasting agent precisely identifies the tip of the catheter at a specific spinal level.[47] A radiograph without contrast, however, cannot distinguish inadvertent intrathecal or subdural catheter placement from correct epidural placement. In addition, standard X-ray does not allow the anesthesiologist to adjust the position of the catheter during insertion unless fluoroscopy is used. Although fluoroscopy allows for real-time monitoring and adjustment of advancing catheters, it requires additional set-up, incurs increased expense, and increases the patient's exposure to ionizing radiation. As a result, fluoroscopy is not routinely recommended and is usually limited to difficult and/or special circumstances, such as long-term epidural catheter placement for cancer pain.

TABLE 43–4. Confirmation of epidural catheter position.

Intraoperatively (while the patient is under general anesthesia)

1. Ultrasonography is highly recommended to assess the spread of local anesthetic at the tip of catheter or within the epidural space.
2. Ensure negative aspiration; inject the local anesthetic slowly in small increments through the catheter; and evaluate response to surgery. If possible, maintain spontaneous ventilation.
3. Radiography with contrast.
4. Electrical stimulation and/or ECG technique.

Postoperatively (while the patient is awake, whether or not he or she can give verbal responses)

1. Ultrasonography is the currently recommended method. This is painless and can be done in the PACU without bothering the child too much.
2. If US is not available, the chloroprocaine test can be used. This involves incremental dosing of a chloroprocaine 3% solution to demonstrate analgesia (by self-report or behavioral measures as appropriate) *and* signs of segmental effect:
   a. Lumbar catheter tip:
      - At least partial sensory and motor blockade in both legs
      - Warming of the volar surface of the toes
   b. Lower thoracic catheter tip:
      - Reduced strength in hip flexion
      - Reduced abdominal skin reflexes
      - Some reduction in heart rate and blood pressure
   c. Upper thoracic catheter tip:
      - Some reduction in heart rate and blood pressure
      - Warming of the volar surface of the hands
      - Unilateral or bilateral Horner syndrome

ECG, electrocardiogram; PACU, post-anesthesia care unit.

Epidural Stimulation Test (Tsui Test) and Epidural ECG Technique

A low-current electrical stimulation test (the Tsui test; Figure 43–1) has been suggested to monitor and guide the position of the epidural catheter during insertion.[48,49] The setup requires the cathode lead (*b*lack for *b*lock) of the nerve stimulator to be connected to the epidural catheter via an electrode adapter while the anode lead is connected to an electrode on the patient's skin as the grounding site. To avoid misinterpretation of the stimulation response (eg, a local muscle contraction may be confused with epidural stimulation), the grounded electrode is placed on the lower extremity for thoracic epidurals and on the upper extremity for lumbar epidurals. Correct placement of the epidural catheter tip (1–2 cm from the nerve roots) is indicated by a motor response elicited with a current between 1 mA and 10 mA. A motor response observed with a significantly lower threshold current (< 1 mA) suggests that the catheter is in the subarachnoid or subdural space or is in close proximity to a nerve root.[50,51] Although chronic spinal cord stimulation is a safe and effective means of pain management, the safety of this epidural stimulation test is not completely known. However, it is anticipated that the risk of a brief intermittent electrical stimulation from this test is minimal. Table 43–5 summarizes the different catheter locations according to motor response and electrical current.

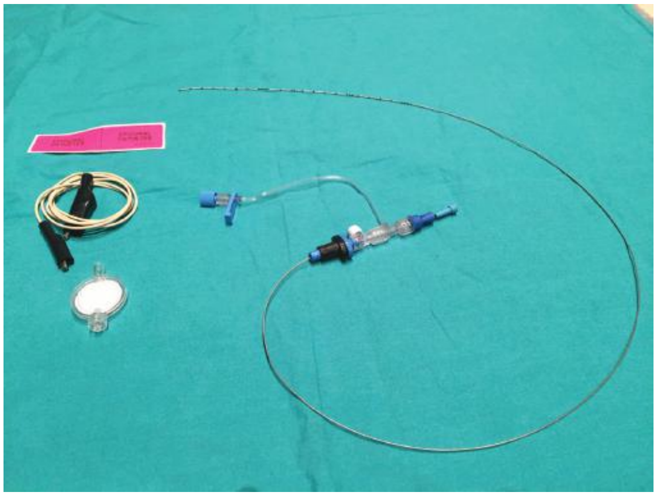

FIGURE 43–1. Tsui stimulating epidural catheter kit.

TABLE 43–5. Electrical stimulation test.

Catheter Location	Motor Response	Current
Subcutaneous	None	> 10 mA
Subdural	Bilateral (many segments)	< 1 mA
Subarachnoid	Unilateral or bilateral	< 1 mA
Epidural space		
Against nerve root	Unilateral	< 1 mA
Nonintravascular	Unilateral or bilateral	1–10 mA (threshold current increase after LA injection)
Intravascular	Unilateral or bilateral	1–10 mA (no change in threshold current after LA injection)

LA, local anesthetic.

One disadvantage of the epidural stimulation technique is that it cannot reliably be performed if any significant clinical neuromuscular blockade is present or if local anesthetics have been administered in the epidural space. To overcome this limitation, an alternative monitoring technique using ECG monitoring has been suggested.[52] A reference ECG is monitored at the required spinal level for surgery; this is then compared to the ECG formed from the epidural catheter tip as it is threaded cephalad. Unfortunately, this technique cannot easily differentiate subtle QRS complexes where the catheter is threaded a short distance; neither does it recognize intravascular or intrathecal catheter positioning.

Ultrasound-Guided Techniques

Since the main goal of an epidural block is to accurately place the needle and/or catheter in the epidural space, knowledge of the expected depth from the skin surface to the epidural space is extremely important. Table 43–1 summarizes some formulas to calculate this depth in children. Where available, US allows for the real-time identification of anatomical landmarks and a much more precise estimation of epidural space depth. It is highly recommended to scan the anatomy with ultrasonography in all children before performing the block and especially in difficult cases, such as patients with scoliosis or sacral dimples. US also allows for needle visualization[53] within the epidural space in neonates. In infants, US can detect epidural catheter advancement, either directly or indirectly by observing the injection of fluid.[54]

Epidural Approaches

The most common types of epidural analgesia are caudal analgesia (which constitutes the most commonly used regional technique in children), lumbar epidural analgesia, and thoracic epidural analgesia.

Caudal Epidural Analgesia: Single-Injection Technique

Single-injection caudal epidural blockade is widely used to provide perioperative analgesia in pediatric practice. As a single injection, it offers a reliable and effective block for patients undergoing urologic, general, and orthopedic surgery involving the lower abdomen and lower limbs. A single-injection caudal epidural may not be suitable for every case because it has a limited dermatomal distribution and a short duration of action. New local anesthetics and adjuvants, as well as continuous catheter approaches, may overcome these limitations.

Choice of Needle for Caudal Analgesia A variety of needles are available for single-injection caudal blockade. The size or type of needle does not appear to affect the rate of success or the incidence of complications of caudal blockade. Short-bevel Tuohy or Crawford needles (5 cm in length) with stylets offer a better tactile sensation when the sacrococcygeal ligament is punctured. For children aged 1 year or older, a 22-gauge needle is used; for children younger than 1 year of age, a 25-gauge needle may be used. The use of a styletted needle may reduce the risk of introducing a dermal plug into the caudal space,[55] although an epidermal cell graft tumor in the epidural space has yet to be reported. Some authors advocate the use of a 22-gauge angiocath, suggesting that it is easier to detect intravascular placement and intraosseous placement with this needle. The angiocath is used only for the single-injection caudal block and is withdrawn after the dose is administered (ie, it is not intended to be an epidural caudal catheter). To avoid tissue coring with the angiocath, the needle must be removed before any injection is made.

Technique for Performing a Single-Injection Caudal Epidural Block In all children, it is important to ensure adequate prevention of heat loss during the procedure. In infants, we recommend preventing heat loss with a sterile transparent drape as this will also allow visualization of patient's breathing (Figure 43–2). The patient is placed in a lateral decubitus position with the neck flexed and the knees drawn up to the chest. After proper positioning, the landmarks for caudal epidural block (Figure 43–3) are easily identified in children: Initially the coccyx is identified, and, continuing to palpate in the midline in a cephalad fashion, the sacral cornua can be felt on either side of the midline approximately 1 cm apart. The sacral hiatus is felt as a depression between two bony prominences of the sacral cornua. Under sterile conditions,

FIGURE 43–2. Transparent cover used in neonates and infants to allow for visualization of the patient and to prevent heat loss. The US machine is placed on the opposite side.

the needle is inserted and advanced into the sacral hiatus at approximately a 70-degree angle to the skin until a distinctive "pop" is felt as the sacrococcygeal ligament is punctured. After this puncture, the angle of the needle should be reduced to approximately 20–30 degrees while the needle is advanced 2–4 mm into the caudal canal. Any advancement past this point is not recommended because the risk of inadvertent dural puncture increases significantly. If an angiocath is used, the plastic catheter should be easily advanced over the needle into the caudal epidural space.

Clinical Pearl

- Care should be taken to ensure the prevention of heat loss during the procedure.

US[56–58] can be used to assess the caudal anatomy prior to the landmark-based technique or to guide needle placement. Preassessment is particularly useful in screening children with cutaneous stigmata of spinal dysraphism. The patient is placed in the lateral decubitus position with the knees flexed toward the chest. The US machine is placed opposite the operator so that he or she can look over his or her hands toward the screen. The patient is prepared, and the US probe is sterilely covered. A high-frequency probe is used: A linear hockey-stick probe is used in infants, whereas a probe with a large footprint is preferable in children weighing more than 10 kg, as it allows more intervertebral spaces to be imaged at a time in the sagittal plane.

FIGURE 43–3. Patient positioning and landmarks for a caudal block.

The probe is positioned first in a transverse plane at the sacrum level; this is called the short-axis view (SAX). The exact position of the cornua and the sacrococcygeal membrane (SCM) are defined (Figure 43–4). With the sacrococcygeal membrane in the middle of the image (Figure 43–5), the probe is then rotated 90 degrees into a midline sagittal position over the lower sacrum, which is called the long-axis view (LAX; Figure 43–6). The SCM and the ventral and dorsal layer of the os sacrum, with the caudal epidural space in between, are easily identified. In small children, the dural sac may be visible in this position, although in older children you need to scan more in a more cephalad direction (Figure 43–7). These movements can be performed in the opposite order, but a complete exploration of the space in both axes is recommended.

After this preprocedural US assessment of the caudal anatomy, the needle can be introduced into the sacral hiatus with the probe in either axis. If the probe is held in the SAX, the needle insertion will be automatically in the out-of-plane (OOP) approach (Figure 43–8). If the probe is held in the LAX, the needle insertion will then be in the in-plane (IP) approach (Figure 43–9).

The needle insertion angle is noted during the scan. The needle may be advanced 2–4 mm into the caudal space, and the stylet is removed. To ensure optimal caudal placement of the needle, a small bolus of saline or local anesthetic is

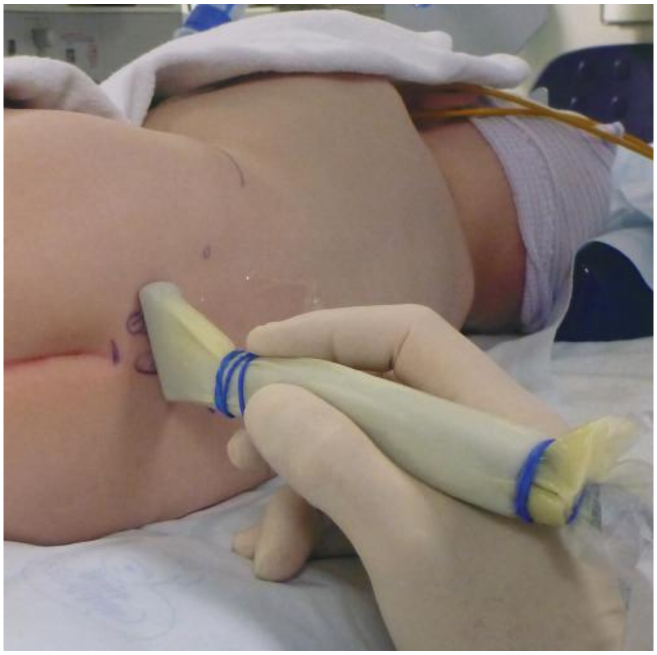

FIGURE 43–4. US probe in the short-axis view.

FIGURE 43–8. US probe in the short-axis view and out-of-plane needle insertion.

administered under US guidance with the probe in midline (LAX; Figure 43–10). The probe is positioned as cephalic as needed to visualize the dural sac in the US screen (Figure 43–11). When the injection starts, you will notice the dura being displaced ventrally, especially in younger children. The spread of local anesthetic can be monitored by moving the probe cephalic up the spine in the midline or in a paramedian sagittal axis (Figure 43–12). The same dura movement can be visualized with the probe in the SAX in the more cephalic positions (Figures 43–13 and 43–14).

Confirmation of Correct Local Anesthetic Distribution The classic "pop" felt as the SCM is pierced is usually sought to confirm proper caudal needle placement.

FIGURE 43–9. US probe in the long-axis view and in-plane needle insertion.

FIGURE 43–10. US-guided injection.

FIGURE 43–13. Dura visualized before injection in the short-axis view.

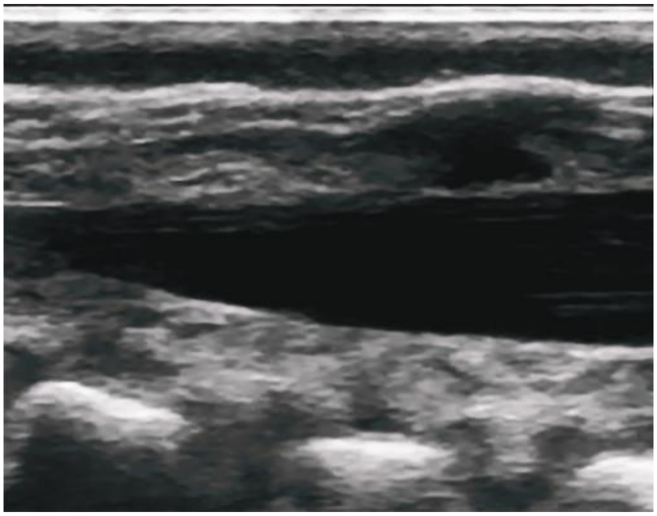

FIGURE 43–11. Dural sac visualized before injection in the long-axis view.

The absence of subcutaneous bulging and the lack of resistance upon injection are additional signs of correct needle placement and local anesthetic distribution. Aspiration of the needle should be clear of blood and CSF, and a negative response to a test dose of epinephrine should also be used to rule out intravascular placement. US has been used to provide real-time needle guidance into the caudal space and to assess the spread of local anesthetic.[59] Recent US studies have shown that the volume of local anesthetic does not correlate with its cranial spread during caudal blockade in infants and children.[60] Initially, US assessment of the spread of local anesthetic was thought to be a predictor of the dermatome reached, but this proved not to be the case as the majority of caudal blocks are successful despite an immediately monitored lack of spread cephalad. However, it has been found that there is a secondary spread of local anesthetic in the epidural space.[61,62] This occurs in two patterns: a horizontal intrasegmental redistribution from the dorsal to ventral epidural space and a delayed longitudinal cranial spread as the dura returns to its original position, thus pushing the epidural local anesthetic cephalad. The observed

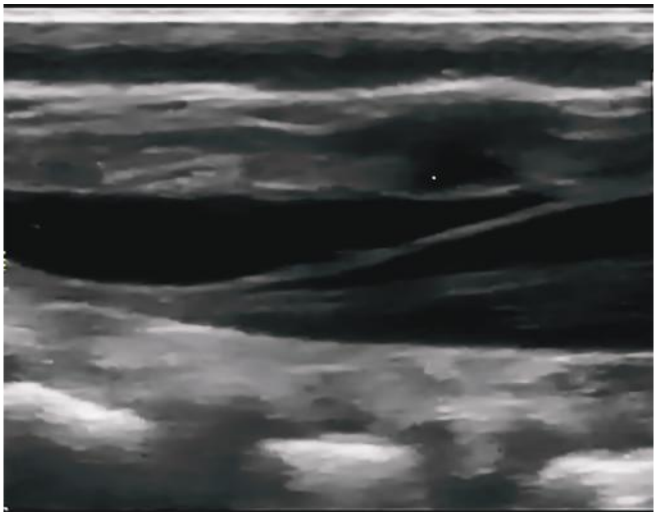

FIGURE 43–12. Dura movement following injection in the long-axis view.

FIGURE 43–14. Dura movement following injection in the short-axis view.

bidirectional movement of CSF (referred to as the "CSF rebound mechanism") also helps explain a component of the difference between the initial US-assessed spread and the final more cephalad effect determined by cutaneous testing. More studies with ultrasonography are needed to determine how best to predict in the spread of local anesthetic.

Caudal Epidural Analgesia: Continuous Technique

Continuous caudal epidural analgesia overcomes the limited duration and segmental effect of a single-injection technique. Caudal catheters can be advanced to the lumbar or thoracic level.[63] The technique for needle insertion for continuous caudal analgesia is very similar to the single-injection caudal approach. It can be done with an IV catheter (an 18-gauge angiocatheter for a 20-gauge epidural catheter or a 16-gauge angiocatheter for a 19-gauge epidural catheter) or with an 18-gauge Crawford or Tuohy needle inserted through the sacrococcygeal membrane, as described for the single-injection technique. The epidural catheter is then advanced carefully from the caudal space to the target level. Minor resistance to the passage of the catheter can usually be overcome by simple flexion or extension of the patient's vertebral column and/or by simultaneously injecting normal saline through the catheter. Some authors[64] use a specialized stimulation epidural catheter (the Epidural Positioning System using the Tsui test, Arrow International Inc., Reading, PA).

It is extremely important to know where the tip of the catheter is finally located: too low a catheter tip level will result in poor analgesia; too high may cause respiratory depression. However, because catheters don't travel linearly in the epidural space, measuring the length of the catheter against the patient's back does not accurately determine the targeted surgical level. Therefore, the location of the catheter tip should be verified using an objective test, as described as in the previous section (ie, radiography, nerve stimulation, electrocardiography, or, preferably, US).

These techniques may be considered cumbersome or redundant, and in children above 1 year of age, the development of a lumbar curve during infancy might prevent easy cephalad advancement of the catheter. Therefore, some have suggested that caudal catheter placement should be limited to patients younger than 1 year of age. It is the opinion of the authors that, at least in children older than 1 year of age, catheters should be placed as close to the surgical dermatome as possible. Appropriate pediatric and ultrasonographic training is therefore recommended in all cases and mandatory prior to performing lumbar or thoracic epidurals in young children.

Lumbar Epidural Anesthesia

Lumbar epidural analgesia is commonly used for continuous infusions and is rarely used as a single-injection technique. A direct lumbar approach is indicated primarily for pain control during and after lower extremity surgery. Lumbar epidural placement, particularly in young children, is performed after the induction of general anesthesia. However, this approach may also be performed awake in a select group of cooperative children and adolescents. Caution should be exercised whenever performing lumbar epidural analgesia above the level of spinal cord end to avoid direct needle trauma.

A midline approach to lumbar epidural needle placement is preferred. Identification of the epidural space is commonly achieved by loss of resistance (LOR) to saline. LOR to air should be avoided due to the risk of introducing a venous air embolism, particularly in neonates and infants. Children should be positioned in the lateral decubitus position for direct lumbar epidural placement. In children over 1 year of age, an 18-gauge, 5-cm Tuohy needle, marked every 0.5 cm, with a 20-gauge epidural catheter is often used. In children under 1 year of age, a 20-gauge, 5-cm Tuohy needle, marked every 0.5 cm, with a 22-gauge catheter should be considered. However, these narrower catheters get kinked, occlude, and leak more often. Although identification of the intervertebral space and ligamentum flavum in most pediatric patients is easy, the ligamentum flavum can be less tensile in children; hence a distinctive "pop" may not be easily felt when penetrating this layer. In addition, the distance from the skin to the epidural space can be very superficial. Formulas for estimating the distance from skin to epidural space have been proposed (see Table 43–1). However, formulas are only a guideline and change according to the angle of epidural needle placement. Today, the best available method to assess the epidural depth is US imaging. With the probe in a paramedian oblique sagittal plane, the distance from the skin to the ligamentum flavum is measured with the US machine's caliper. This measurement provides a good estimate of the depth at which the LOR is going to be felt. Therefore, a preprocedural US assessment of each individual patient is highly recommended.

For an exact description of the lumbar epidural technique, see "Thoracic Epidural Anesthesia," below (figures illustrate a thoracic epidural placement).

Lumbar-to-Thoracic Epidural Approach Catheters placed via the lumbar route may be advanced cephalad to thoracic vertebral levels. Similar to the problems encountered when advancing catheters in the caudal space in older children, significant resistance also prevents the easy advancement of lumbar epidural catheters to the thoracic levels. Despite favorable results using stimulation via a caudal approach, only one case report[65] has demonstrated the successful placement of a thoracic epidural catheter via the lumbar route with epidural stimulation guidance. Therefore, the authors recommend placing the catheter as close as possible to the surgical site.

Thoracic Epidural Analgesia

Controversy exists concerning the safety of placing thoracic epidurals under heavy sedation or general anesthesia, because unconscious patients are unable to report symptoms that may warn the anesthesiologist of potential neurologic complications.[66] Direct needle trauma to the spinal cord during epidural insertion is rare but can cause devastating complications. Reports have detailed cases of direct needle trauma to the spinal cord during epidural placement in both awake and anesthetized patients.[34,67,68] For thoracic surgery, the catheter should be introduced as close to the dermatomal level of incision as possible.

The advancement of catheters from the lumbar and caudal epidural spaces to the thoracic level is an alternative only in children upto 1 year of age. However, the advancement of catheters in the epidural space becomes increasingly difficult with advancing age because of the development of the lumbar curvature.

Direct placement of thoracic epidural catheters is more common at tertiary care centers, where well-trained pediatric anesthesiologists perform the blocks on children undergoing major surgery. Preprocedural ultrasonography imaging is strongly recommended.[69] Moreover, the authors believe that training in US-assisted thoracic epidurals should be provided for anesthesiologists willing to perform thoracic epidurals in children.

Clinical Pearls

- Children require a significantly higher volume (dose) of local anesthetic compared with adults to achieve the same dermatomal spread.
- Intended high thoracic catheter advancement from a lumbar insertion site is rarely successful.
- Thoracic epidural catheter insertion should be performed only by practitioners experienced in pediatric thoracic epidural technique.
- Epidural needle insertion in pediatric patients can be performed at any thoracic interspace using either a midline or paramedian approach; however, a midline approach is often preferred.

Thoracic Epidural Analgesia: Midline Approach

The use of the midline approach offers the advantage of being similar to the lumbar approach (with the needle angulated in only one plane). Using the midline approach, insertion of the needle is easier at the lower thoracic level (T10–T12) than at the midthoracic (T4–T7) level. The lower border of the shoulder blade, which is level with the seventh thoracic vertebra, is commonly used as an anatomical landmark. The patient is placed in the lateral decubitus position, and care is taken to prevent heat loss. An assessment of the patient's anatomy may be done in a nonsterile set-up before the block is performed; this is also helpful for teaching purposes. The spinous process of the targeted vertebral level should be identified by counting up from Tuffier's line and by counting down from the most prominent C7 cervical vertebra (Figure 43–15). Preprocedural US imaging is performed with the probe in three planes: transverse (SAX), median sagittal (median LAX), and paramedian oblique sagittal (paramedian oblique LAX). The distance from the patient's skin to the epidural space can thus be measured.

In the SAX (Figure 43–16), the window between two spinous processes must be found, and the anterior complex of the vertebral column (posterior longitudinal ligament, anterior dura, and vertebral body) in the depth of the image will be the first structures to be identified. The posterior complex (ligamentum flavum and posterior dura) may be more difficult to visualize but will be approximately at the level of the lamina (Figure 43–17).

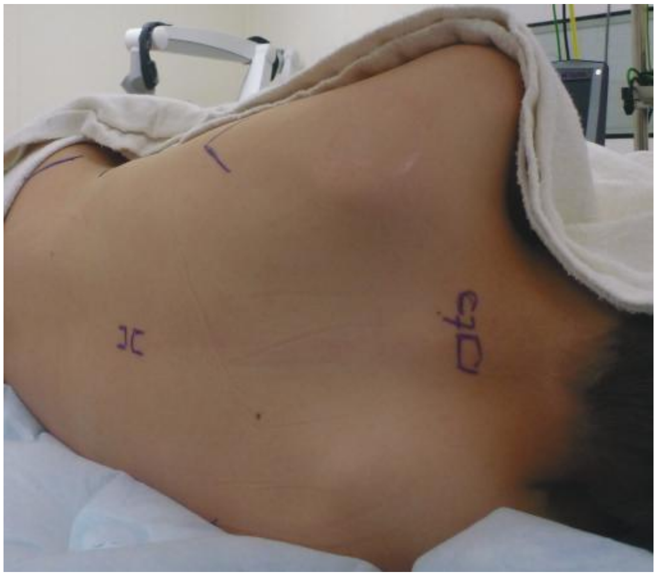

FIGURE 43–15. Thoracic epidural analgesia: patient positioning and landmarks for a midline approach.

FIGURE 43–16. Preprocedural scanning with nonsterile set-up for teaching purposes; the US probe is in the short-axis view.

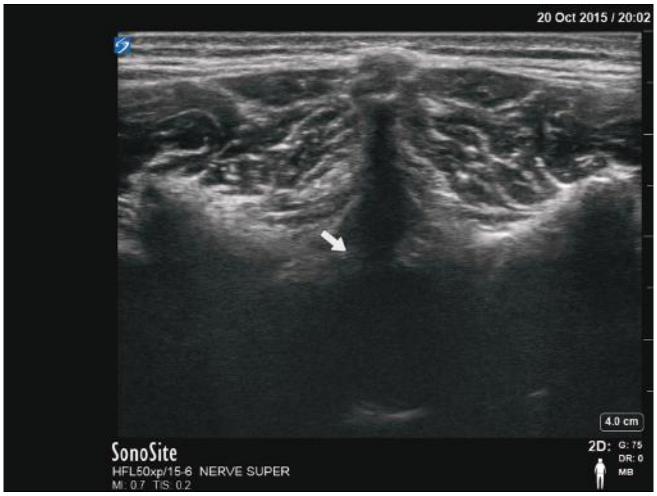

FIGURE 43–17. US image in the short-axis view, showing the posterior complex with the dura (white arrow).

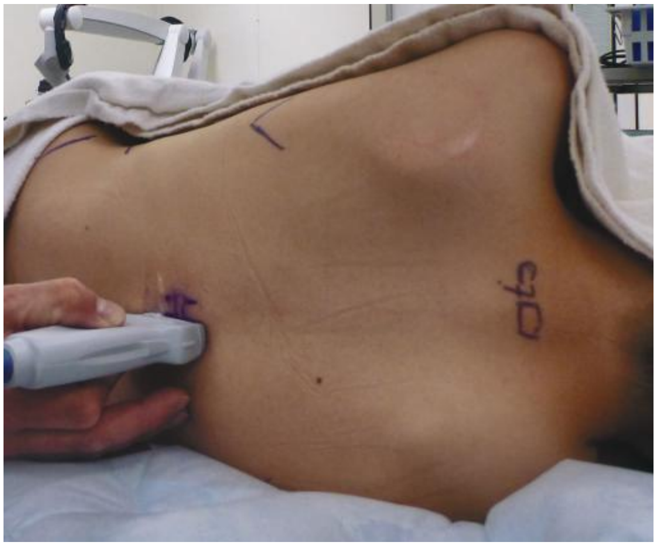

FIGURE 43–18. Preprocedural scanning with nonsterile set-up for teaching purposes; the US probe is in the median long-axis view. The probe must be exactly in the midline, but in this photo, it has been positioned in the paramedian long-axis view to see the direction.

FIGURE 43–20. Preprocedural scanning with nonsterile set-up for teaching purposes; the US probe is in the paramedian oblique long-axis view. The tilting of the probe can be compared to that shown in Figure 43–16.

If the patient is an infant, and the bony structures of the vertebral column are not yet fully ossified, a median LAX (Figure 43–18) provides clear, real-life imaging of the anatomy involved. With this probe position, the spinous process in the image will almost reach the skin (or the top of the US screen). In between the spinous process, the dura mater will be seen as a white double layer; it is found a little less deep than the level at which the posterior complex is found in the SAX (Figure 43–19).

In the paramedian oblique LAX (Figure 43–20), the transverse process and/or the lamina may be visualized, depending on how far lateral and oblique the probe is placed. The anterior complex is again easily visualized, and most of the time the pia mater can be seen in small children. The characteristic "horse heads" may be found in the image, and the dura mater will be seen in between, at a deeper level (Figure 43–21). The depth of the dura mater will be more or less equal, as in the SAX and median LAX positions.

After the preprocedural imaging to measure the depth at which the epidural space will be reached, the child's skin is prepared and draped (Figure 43–22). An 18-gauge Tuohy epidural needle, 5cm long, with markings every 0.5 cm, is then inserted at the interspace at a cephalad angle of approximately 70 degrees to the longitudinal axis of the spine. A useful maneuver is to insert the needle at a similar angle to that with which the US probe was held when the distance toward the epidural space was measured (Figure 43–23). Continuous resistance should be felt as the needle is inserted through the supraspinous and interspinous ligaments. When the interspinous ligament is reached, the stylet is removed and a saline-filled LOR syringe is connected to the needle. Continuous pressure is placed on the plunger as the needle is farther advanced

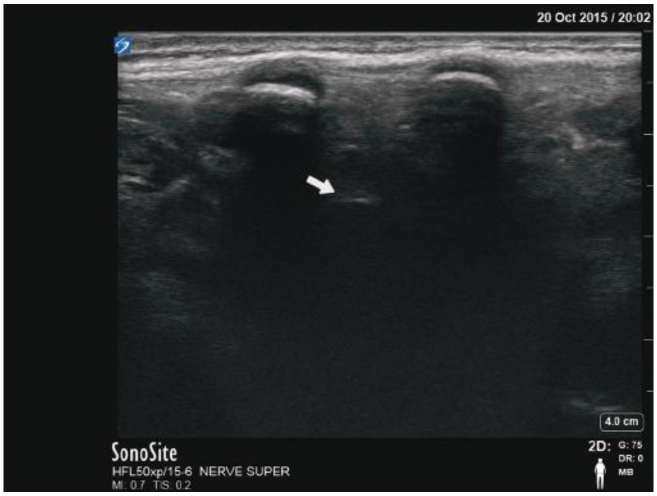

FIGURE 43–19. US image in the median long-axis view, showing the dura (white arrow).

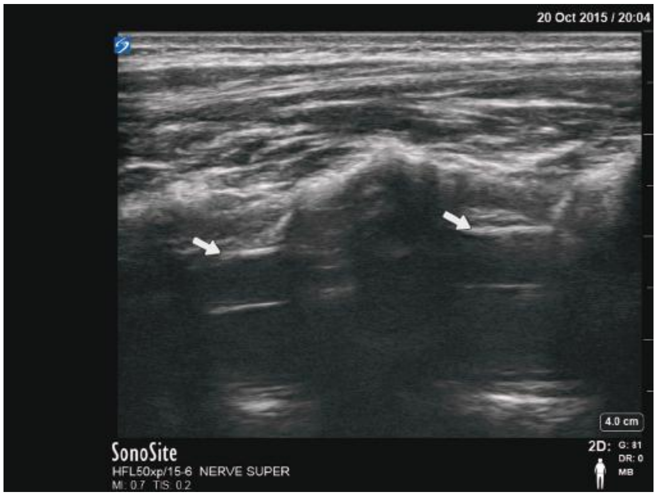

FIGURE 43–21. US image in the paramedian oblique long-axis view, showing the posterior complex with the dura (white arrows).

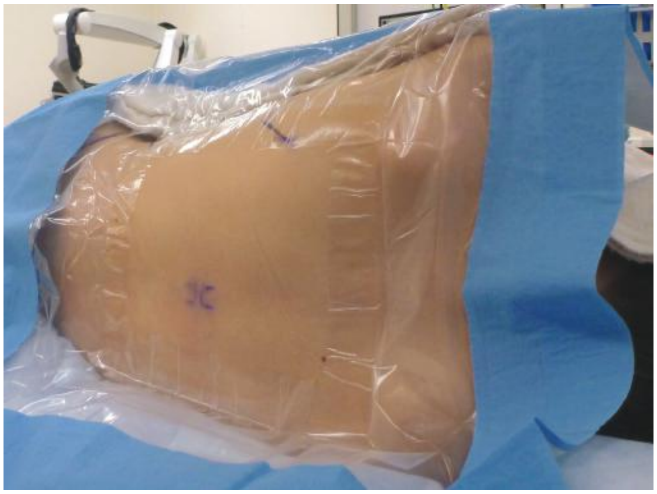

FIGURE 43–22. Sterile, transparent, plastic drape.

FIGURE 43–24. Needle advancement with continuous pressure placed on the plunger with the right hand as the left hand advances the needle.

(Figure 43–24). In older children, an increase in resistance is initially felt as the ligamentum flavum is entered, just before the LOR is felt. However, in younger children, the resistance met at the ligamentum flavum may not be noticeably different from that of the other ligaments.

The needle must not be inserted to a depth greater than the preprocedural US–estimated depth of the epidural space. The thoracic epidural space is identified with LOR to saline; air is not recommended in children. The syringe is then removed, and, after ruling out dural puncture, the catheter is inserted (Figure 43–25). The length of the catheter inserted should be only about 2 cm beyond the needle tip if the epidural puncture has been performed at the appropriate level. If the puncture has been performed one level beneath, the catheter can be inserted up to 3–4 cm, but it must be kept in mind that in small children, a few centimeters may represent several vertebral segments.

After withdrawing the needle and ensuring that an adequate length of catheter is kept in place, the connector is attached to the catheter. At this point, it is imperative to check for a falling meniscus and perform slow and careful aspiration through the catheter to check for blood or CSF (Figure 43–26). The filter is then connected, and incremental doses of local anesthetic can be administered with the spread assessed under US imaging.

We recommend tunneling the catheter or using a liquid bandage or the topical skin adhesive Histoacryl to close the entrance hole to prevent leakage. Preventing local anesthetic leakage in pediatric patients is important, as leaked anesthetic may consist of a significant percentage of the total drug delivered. Leaking underneath the fixation device or Tegaderm may present a problem for catheter fixation itself. A transparent epidural fixation device is recommended to allow for observation of any local anesthetic leakage or signs of infection (Figure 43–27).

FIGURE 43–23. Needle insertion. Note the direction compared to the probe in Figure 43–14.

FIGURE 43–25. Catheter insertion.

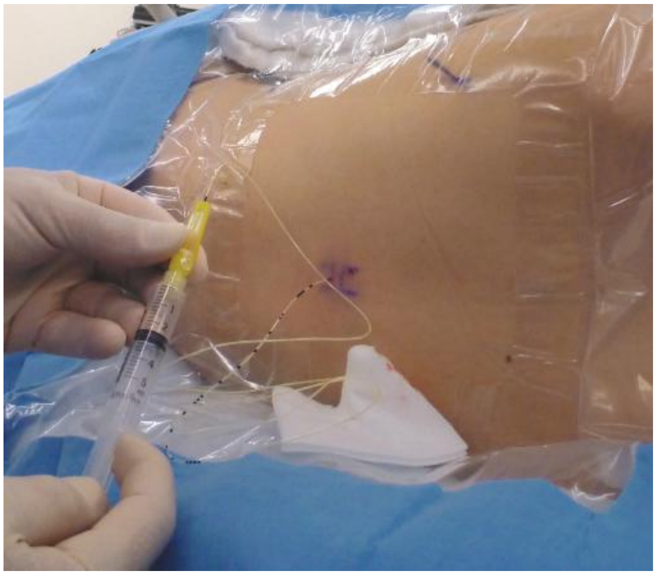

FIGURE 43–26. Aspiration test.

Clinical Pearls

- Various formulas exist for calculating the volume of local anesthetic required to block a given number of segments.
- A bolus of 1.0 mg/kg of 0.25% bupivacaine or 0.2% ropivacaine is administered to establish the block.
- In preschool-aged children and especially infants, irritability or agitation may occur despite an apparently well-functioning epidural analgesia. This is most likely the result of the IV line, nasogastric tube, urinary catheter, or the hospital environment.
- Satisfactory sedation can be achieved with either of the following:
  - IV boluses of morphine 25 mcg/kg as required, or
  - Adding clonidine 0.5 mcg/mL to the epidural mixture

FIGURE 43–27. Catheter securing and fixation.

POSTOPERATIVE EPIDURAL INFUSION MANAGEMENT

For effective and safe epidural analgesia, a systematic and protocol-based approach to patient care is advised. A dedicated pediatric acute pain team, consisting of anesthesiologists and nurses, is vital to ensure standardized assessments of pain, vigilant patient monitoring, and the proper treatment of adverse effects. Precise placement of epidural needles and catheters is the key to successful epidural analgesia. This requires the use of a reliable method to confirm the location of the catheter tip (ie, US, epidural stimulation). The average length of epidural infusion is about 72 hours, although it may be necessary to continue the infusion for longer periods, especially in children with complicated medical histories or a prolonged need for analgesia. In neonates, the length of epidural infusion should be limited to 48 hours due to the risk of systemic toxicity. A team of dedicated personnel with a focus on pain management should care for such patients. When plans to discontinue the epidural infusion are in place, an opioid should be considered to enable adequate analgesia. Finally, the success of the process is based on properly written orders—a crucial part of executing adequate analgesia.

Clinical Pearl

For postoperative analgesia, either bupivacaine 0.125% or ropivacaine 0.1–0.2%, with or without fentanyl 1–2 mcg/mL, is administered at the following rates:

- Age > 3 months: 0.20–0.35 mL/kg/h (< 0.4 mg/kg/h bupivacaine)
- Age < 3 months: 0.1–0.15 mL/kg/h (< 0.2 mg/kg/h bupivacaine)

SPINAL ANESTHESIA IN CHILDREN

INTRODUCTION

Spinal anesthesia is perhaps one of the oldest and most studied modalities for providing pain relief in patients undergoing surgery. J. Leonard Corning[70] is credited with administering the first spinal anesthetic in 1885, and his experience was subsequently published in a medical journal. Although the use of intrathecal anesthesia administration in children was described in the early twentieth century,[71,72] this technique was seldom used in the pediatric population until Melman[73] reported a series of high-risk infants who underwent successful surgery under spinal anesthesia. Reports of apnea following general anesthesia in preterm infants appeared in the literature in the early 1980s,[74–78] and a series from Abajian et al.[79] offered practitioners an impetus to offer an alternative technique with reportedly fewer complications than general anesthesia. A number of series have since been reported in all age groups for a variety of surgical procedures attesting to the safety and efficacy of spinal anesthesia.[80–82]

TABLE 43–6. Anatomic differences between adults and infants in the spinal canal.

Conus medullaris ends at L2–L3 in infants versus L1 in adults.

Infants have a small pelvis, and the sacrum begins more cephalad than in adults.

The dural sac ends more caudad in infants versus adults.

ANATOMY

Understanding the anatomical differences between adults and infants is crucial to safely administer spinal anesthesia in children in a technically proficient manner (Table 43–6).

The spinal cord terminates at a much more caudad level in neonates and infants than in adults. The conus medullaris ends at approximately L1 in adults and at the L2 or L3 level in neonates and infants. To avoid potential injury to the spinal cord, dural puncture should be performed below the level of the spinal cord; that is, below L2–L3 in neonates and infants. In adults, spinal anesthesia is often performed at the interspace nearest an imaginary line stretching across the top of the iliac crests, the intercristal or Tuffier's line, corresponding to the L3–L4 interspace. However, neonates and infants have a proportionally smaller pelvis than adults, and the sacrum is located more cephalad relative to the iliac crests. Therefore, Tuffier's line crosses the midline of the vertebral column at the L4–L5 or L5–S1 interspace, well below the termination of the spinal cord, making this landmark applicable in all pediatric patients.[83–85] The dural sac in neonates and infants also terminates in a more caudad location compared with that in adults, usually at about the level of S3 compared with the adult level of S1. The more caudad termination of the dural sac makes an inadvertent dural puncture more likely during the performance of a single-injection caudal block if the needle is advanced too far into the epidural space.[84]

CSF volume is higher on a milliliter-per-kilogram basis in infants and neonates (4 mL/kg) compared with adults (2 mL/kg). In addition, CSF in infants is distributed relatively more in the spinal canal than in the head, as opposed to the distribution in adults. This may, in part, account for the higher local anesthetic dose requirements and shorter duration of action of spinal anesthesia in infants. The high cardiac output characteristic of the pediatric population shortens the duration of spinal blocks in children still further.

LOCAL ANESTHETICS

A variety of local anesthetics and doses have been described in the literature, including bupivacaine[86] and ropivacaine.[87] Bupivacaine 0.5%, 0.5–1 mg/kg, is generally used for spinal anesthesia in children weighing less than 10 kg. A dose toward the higher end of the range is preferred for smaller children; the risk of total spinal anesthesia is low as long as the procedure is carried out diligently (Table 43–7). An "epinephrine wash" of the syringe, rather than a standard dose of epinephrine, is preferred. A hyperbaric bupivacaine solution with glucose 8% provides a block of similar quality and duration than isobaric bupivacaine with glucose 0.9%.[88]

TABLE 43–7. Spinal anesthesia dosage in children.

Local anesthetic solution: ropivacaine or bupivacaine 0.5% 0.5–1 mg/kg.

An easy way to calculate the dose for a single hernia repair in infants is as follows:

Age (mos)	Weight (kg)	Dose bupivacaine 0.5%
1	3	1 mg/kg
2	4	0.8 mg/kg
3	5	0.6 mg/kg
> 4	6	0.4 mg/kg

Possible additives:

- Epinephrine wash
- Clonidine 1 mcg/kg
- Morphine 10 mcg/kg only for cardiac surgery to facilitate earlier extubation)

Adjuvants to local anesthetics in spinal blocks have also been described. Clonidine in a dose of 1 mcg/kg added to bupivacaine (1 mg/kg) used in spinal anesthesia for newborn infants has been shown to prolong block duration to almost twice the duration of spinal anesthesia without clonidine.[89] However, the use of 2 mcg/kg of clonidine may cause a transient decrease in blood pressure and greater postoperative sedation. It may be advisable to use a dose of caffeine of 10 mg/kg intravenously to prevent potential postoperative apnea, especially if clonidine is used in the spinal anesthetic solution.[90]

In cases of bilateral hernia repair in former premature infants, the spinal block may be supplemented with a caudal block. The patient is turned on the side of the largest hernia while the block is performed; a spinal injection of 0.8 mg/kg bupivacaine is followed immediately by a caudal injection of 0.1% bupivacaine. This technique prolongs the duration of anesthesia and analgesia. Alternatively, a hypobaric solution of local anesthetic can be injected with the operative side up.

ADVERSE EFFECTS

Adverse effects from spinal anesthesia commonly seen in adults are less common in children. These include hypotension, bradycardia, PDPH, and transient radicular symptoms.

Hypotension and bradycardia are uncommon in children despite the high levels of blockade required. Fluid loading to increase preload is rarely needed in children but, if needed, can be done at a rate of 10 mL/kg.[91] Although some authors obtain venous access in the lower limbs of the patient after the spinal block has been performed (pain-free IV catheter placement), we recommend obtaining venous access before performing the spinal block. Puncuh et al.[86] reported their experience with

1132 consecutive spinal anesthetics in which hypotension was rarely reported: only a mild decrease in blood pressure was reported in 9 of 942 patients younger than 10 years old and in 8 of 190 patients older than 10 years old.

The incidence of PDPH is lower in children than in adults. However, an incidence of 8% has been reported in oncological patients after frequent lumbar punctures for spinal tap.[92] The use of different types of spinal needle was studied in this subgroup of patients, but no difference was found in the incidence of headache (15% Quincke; 9% pencil-point Whitacre; $p = 0.43$).[93] Moreover, the incidence of headache was not different by age group, with 8 of 11 PDPHs occurring in children under 10 years of age and the youngest reported in a 23-month-old. PDPHs have been treated with bed rest and caffeine in adults but are followed by blood patch if the headache doesn't resolve. In children, an optimal dose of caffeine is not known, and an epidural blood patch is performed with 0.3 mL/kg of blood when the headache persists.

Transient radicular symptoms have been reported in children but without long-term adverse effects.[94]

RELATIVE CONTRAINDICATIONS

The major contraindication for a spinal technique in a nonsedated child is a surgery duration of more than 60 minutes. Spinal anesthesia should be avoided in neonates and children who may have increased intracranial pressure. In children with neuromuscular diseases, ventricular shunts (atrial or peritoneal), and poorly controlled seizures, the use of spinal anesthesia is controversial. Other contraindications to spinal anesthesia are similar to those in the adult population and include severe anatomical deformities, systemic infection or at the site of puncture, underlying coagulopathy, and hemodynamic instability (Table 43–8).

When considering spinal anesthesia, special consideration should be given to children with a known difficult airway. Although spinal anesthesia may be a reasonable choice in these patients, the first consideration should be the ability of the practitioner to manage the airway. The need for IV sedation in preschool- and school-aged children poses its own set of risks in pediatric patients with a difficult airway. The surgical site, the anticipated length of the procedure, and the surgical position (ie, supine, lateral, or prone) are also important factors to be considered.

TABLE 43–8. Relative contraindications to spinal anesthesia in children.

Anatomical abnormalities of the spine
Degenerative neuromuscular disease
Patient and family dissent
Coagulopathy
Bacterial infection
Increased intracranial pressure
Ventriculoperitoneal shunts

Clinical Pearl

Special considerations for infants and children undergoing spinal anesthesia include the following:

- The expertise of the anesthesia provider
- The motivation of the surgeon
- The estimated length of surgery being less than 90 minutes

SPINAL ANESTHESIA FOR PEDIATRIC PATIENTS: TECHNIQUE

Preparation

Eutectic mixture of local anesthetic (EMLA) cream or LMX (4% lidocaine cream) may be applied to the site of insertion, although the risk of methemoglobinemia must be taken into account in very small premature infants. The operating room should be warmed before bringing the patient into to the room. Warm blankets and radiant heating lamps help to diminish heat loss in infants. With older children, the room should be quiet and, if possible, surgical instruments covered to minimize patient anxiety. Pediatric operating rooms may be equipped with stereo or video equipment, which may be used to distract older children if the block is performed without sedation. Standard monitoring devices (pulse oximeter, electrocardiogram, and blood pressure cuff) should be applied before performing the block.

A plan should be made regarding the concomitant use of IV sedation or inhalational general anesthesia. The approach should be dictated by the medical condition and age of the patient, the comfort level of the anesthesia provider, and the nature and anticipated length of the surgical procedure. General anesthesia may predispose very preterm infants to apnea and bradycardia.[95] Spinal anesthesia in infants lasts no more than 90 minutes due to their physiological characteristics. Therefore, in former preterm infants undergoing lower abdominal procedures of less than 90 minutes' duration, spinal anesthesia without adjuvant sedation may be performed. However, a short period of inhalational general anesthesia or supplemental IV sedation may sometimes be necessary while the block is being performed, especially if EMLA cream has not been used. Older children may require supplemental sedation or light general anesthesia prior to performing the block. In some cases, spinal anesthesia may be combined with caudal or epidural anesthesia to prolong analgesia.

Patient Position

Spinal anesthesia is customarily administered in the lateral or sitting position in children. If the lateral position is preferred, the patient is positioned at the very border of the surgical table and held firmly by an assistant. Otherwise, the patient can be placed in the middle of the surgical table but on top of several blankets; these will give the necessary height for the anesthesiologist's

FIGURE 43–28. Spinal anesthesia in the lateral position. The child is placed on top of several blankets to gain height for the anesthesiologist's hands while performing the block.

hands to be placed comfortably while performing the block (Figure 43–28). If the sitting position is preferred, special attention must be paid in infants to ensure that the neck is not flexed, as this could result in airway obstruction (Figure 43–29). It is essential to vigilantly monitor oxygen saturation in infants while performing the spinal to ensure adequacy and patency of the airway. Moreover, neck flexion is not necessary because it does not facilitate the performance of the block in small children.[96] In older children, an assistant should be present to maintain proper positioning and to reassure and distract the child while the block is being performed. The use of a pacifier while the block is being performed in a nonsedated infant is usually helpful.

Technique

In infants, the L4–L5 or L5–S1 interspace should be identified; the L3–L4 interspace may be used in older children. The area should be prepared and draped in a sterile fashion. If topical anesthetic cream was not applied preoperatively, local anesthesia should be administered before the block in awake or lightly sedated patients. The desired dose of spinal local anesthetic should be calculated and prepared in a syringe before dural puncture to ensure that the correct dose is administered. Because the volume of local anesthetic needed may be small in neonates, it is important to measure the volume corresponding to the hub of the needle and to count this volume, too, in the total dose of local anesthetic. An insulin syringe is helpful to measure the exact dose accurately. A short, 22- or 25-gauge spinal needle is often used (Figure 43–30). A midline approach

FIGURE 43–29. Spinal anesthesia in the sitting position. Head flexion must be avoided to prevent airway obstruction.

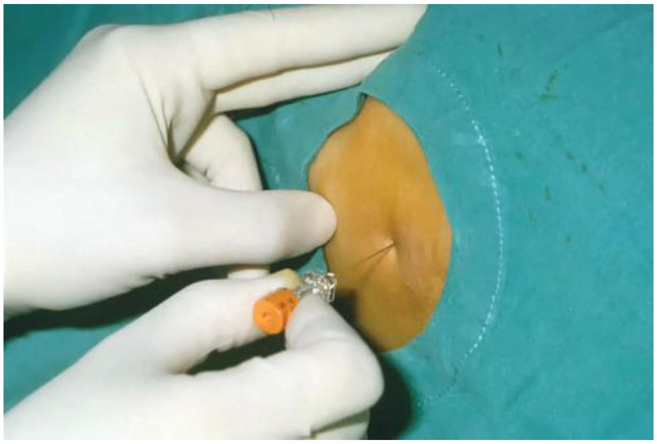

FIGURE 43–31. Spinal anesthesia needle insertion.

is usually recommended over a paramedian approach. The ligamentum flavum is very soft in children, and a distinctive "pop" may not be perceived when the dura is penetrated (Figure 43–31). Once clear CSF is exiting the needle, the drug(s) may be administered and, importantly, must be injected slowly (Figure 43–32).

The barbotage method is not recommended, as it may result in unacceptably high levels of motor blockade and has a potential for total spinal blockade. The patient's lower limbs should not be elevated for the placement of the electrocautery return electrode on the infant's back, as total spinal anesthesia can result from the spread of local anesthetic to a higher spinal level. To prolong the duration of surgical anesthesia in the case of bilateral hernia repair, spinal anesthesia can be supplemented with a caudal block.

Assessing the Block

Assessing the level of blockade may prove difficult in infants and young children, particularly in patients who have received sedation or in those in whom the block is being performed under general anesthesia. In infants, pin prick or response to cold stimuli (eg, an alcohol swab) may be used, as well as observation of ventilation rate and pattern. In children over 2 years of age, the Bromage scale is used. Following the block, care should be taken to avoid placing the patient in the Trendelenburg position or lifting the lower limbs; for example, to place an electrocautery pad on the infant's back. In the event of a rapidly rising level of blockade, the patient may be placed in the reverse Trendelenburg position.

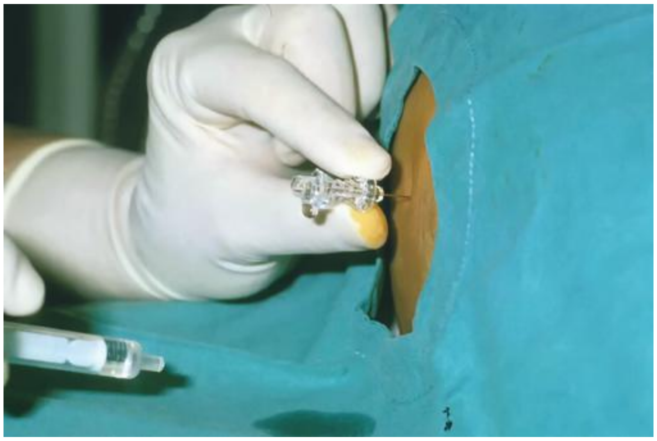

FIGURE 43–32. Spinal anesthesia: Cerebrospinal fluid exits the needle, and local anesthetic is injected.

Clinical Pearl

Evaluation of Spinal Anesthesia: The Bromage Scale

I. No block: Free movement of knees and feet is possible
II. Partial block: Able only to flex knees but free movement of feet still possible
III. Almost complete block: Unable to flex knees but flexion of feet still possible
IV. Complete: Unable to move legs or feet

CLINICAL USES

Apnea and Former Preterm Infants

The most common indication for spinal anesthesia in pediatric patients is in former preterm infants undergoing unilateral inguinal hernia repair (Table 43–9). Apnea can occur in former preterm patients following a general anesthetic.[77,79] Regional anesthesia may decrease, if not eliminate, the risk of postoperative apnea and certainly decreases the risk of desaturation and bradycardia.[97]

However, there is considerable disagreement regarding the incidence of apnea and the conceptual age at which a former preterm infant may safely undergo general anesthesia on an outpatient basis. Lack of uniformity in study design, small patient population sizes, and variations in methodology probably account for the differences noted. Cote at al.[77] performed a meta-analysis of eight studies, comprising 255 patients, investigating postoperative apnea in former preterm infants after general anesthesia. Overall, the risk was independently related to both gestational age and conceptual age. Additional risk factors for postoperative apnea were a hematocrit less than 30% and continued apneic episodes at home. The study stratified infants into two groups: a 5% risk group and a 1% risk group. For patients with a gestational age of 35 weeks, the risk of postoperative apnea did not fall below 5% (with a 95% statistical confidence interval) until patients reached a postconceptual age of 48 weeks and did not decrease below 1% until infants

TABLE 43–9. Indications for spinal anesthesia in children.

Inguinal hernia repair
Myelomeningocele repair
Lower limb and lower abdominal surgery
Early extubation desired after cardiac surgery

reached a postconceptual age of 54 weeks. In more preterm patients, such as those with a gestational age of 32 weeks, the risk of apnea did not fall below 1% (with a 95% statistical confidence interval) until infants reached a postconceptual age of 56 weeks.

The concomitant use of ketamine as a sedative in former preterm infants was also reported to increase the incidence of postoperative apnea above that reported in control patients.

However, these are all somewhat older studies. In the meantime, there have been substantial advances in the ventilatory management of premature neonates and infants, making the risk of apnea controversial at the present day. Moreover, improvements in anesthesia, such as the extended use of sevoflurane instead of halothane and laryngeal masks instead of tracheal intubation, have further decreased the incidence of the deleterious effects of general anesthesia in infants. Craven et al.[98] reviewed several randomized controlled studies and found only a borderline statistical advantage of spinal anesthetic over general anesthesia. In our opinion, administering sevoflurane while spontaneous ventilation for a short period of time may sometimes be useful to aid in performing the spinal block, especially if no EMLA cream is used.

Spinal anesthesia has also been used for a variety of other procedures, including myelomeningocele repair[99] and other abdominal, urological, and orthopedic procedures in children. The early report by Abajian et al.[79] included not only infants undergoing inguinal herniorrhaphy but also other noninfant patients whom the authors felt faced an increased risk for general anesthesia. This study included patients with a variety of medical conditions, including laryngomalacia, macroglossia, micrognathia, congenital heart disease, Down syndrome, adrenogenital syndrome, failure to thrive, and arthrogryposis. Blaise et al.[81] reported 30 patients aged 7 weeks to 13 years old who underwent spinal anesthesia for a variety of surgical procedures. Kokki et al.[88,100] reported satisfactory anesthesia in 92 of 93 children aged 1 to 17 years old undergoing spinal anesthesia with ropivacaine for lower abdominal or lower limb procedures.

Regional techniques have been used in cardiac surgery to facilitate early extubation.[101] This large series investigating spinal anesthesia for cardiac surgery comes from a prospective randomized analysis from Stanford University. The group who received spinal anesthesia for postoperative pain relief had less opioid requirement in the postoperative period after elective cardiac surgery with early extubation in the operating room.

In summary, spinal anesthesia in pediatrics is most commonly used in preterm infants undergoing anesthesia for inguinal hernia repair. Spinal anesthesia can also be used effectively in children for postoperative pain relief in cardiac surgery, especially if opioids are used.

CHAPTER 44

Peripheral Nerve Blocks for Children

Steve Roberts

INTRODUCTION

Peripheral nerve blocks have been gaining significant popularity in the daily practice among pediatric anesthesiologists. Nerve blocks in children have an excellent risk–benefit ratio and are readily acceptable by both parents and children. Although the performance of peripheral nerve blocks in anesthetized adults is often debated, such practice is well accepted in pediatric patients. Successive large prospective studies performed by the French-Language Society of Pediatric Anesthesiologists (ADARPEF) have demonstrated no increased incidence of complications when regional anesthesia techniques were performed under general anesthesia.[1,2] The overall incidence of regional anesthesia–related complications was less than 0.9 of 1000 anesthetic procedures performed. Interestingly, a six-fold increase in the complication rate for central versus peripheral techniques was demonstrated, which should further persuade pediatric anesthesiologists to modify their practice toward more peripherally based regional anesthetic strategies. The complication rate was four times higher in children under 6 months of age; as such, these patients should be managed only by suitably trained specialist pediatric anesthesiologists. Because of the concomitant use of general anesthesia in children, the intraoperative efficacy of nerve blocks is often assessed indirectly using hemodynamic parameters and required depth of anesthesia. Most regional techniques used in children are primarily used for the purpose of providing postoperative pain control rather than surgical anesthesia.

Although most peripheral nerve blocks in children are performed in an operating room environment, their application extends to the emergency department as well as the intensive care unit (ICU) setting.[3,4] Peripheral nerve blocks are also used in children with chronic pain conditions, such as chronic headache or chronic regional pain syndrome type 1 (CRPS-1). All adult regional anesthetic techniques are possible in children (Table 44–1); when these procedures are performed with skill and knowledge, their success rates and safety should not significantly differ from those in adults. This chapter will concentrate on the commonly performed pediatric blocks. For each technique, a short description of the relevant anatomy will be followed by descriptions of both landmark-based and ultrasound (US)-guided methods where appropriate. It is assumed for all blocks that appropriate monitoring, intravenous (IV) access, trained assistance, resuscitation equipment, and aseptic precautions are taken.

EQUIPMENT

Regional anesthesia in children must be performed only with the appropriate equipment. To this end, a selection of 18-gauge, short-beveled needles must be available; lengths of 40–50 mm and 90–100 mm will cover all patient ages. A short bevel is used as it improves the sensation of passing through tissues. The needle should be connected to a short extension tube to which a syringe can be attached; this prevents the needle being displaced as the injection is being made. Some anesthesiologists prefer to nick the skin with a sharp beveled needle to allow easy passage through the skin and ensure no superficial fascial clicks are missed.

A reliable nerve stimulator can be used to help locate mixed nerves for blockade. A nerve stimulator with adequate current output capable of eliciting percutaneous stimulation (eg, 5 mA/1 msec) for surface mapping is suggested. Once a needle is placed close to a nerve or plexus and proper stimulation is obtained, the current output is decreased to maintain the motor response at 0.4–0.2 mA to ensure intimate needle–nerve relationship. However, a number of recent human and animal studies have provided compelling evidence that peripheral nerve stimulation is not a specific determinate of the needle–nerve distance; indeed, it is possible for the needle to be placed intraneurally but have no motor response.[5,6]

TABLE 44–1. Pediatric regional anesthetic techniques: common indications and suggested volume of local anesthetic.

Block	Indication	Local Anesthetic Volume (mL/kg)[a]
Greater auricular	Otoplasty Mastoidectomy	1.0–3.0
Infraorbital	Cleft lip repair Endoscopic sinus surgery	Infants: 0.5–1.0 Children: 1.0–2.0
Supraorbital and supratrochlear	Frontal scalp incisions; eg, simple minor plastic surgery, frontal craniotomy	1.0–2.0
Superficial cervical plexus	Otoplasty Tympanomastoid surgery Cochlear implant	1.0–3.0
Greater occipital	Posterior fossa surgery Occipital neuralgia, migraine headaches	1.0–2.0
Nerve of Arnold	Myringotomy	0.5–1.0
Interscalene	Shoulder surgery	0.3–0.5
Supraclavicular	Upper arm surgery	0.3–0.5
Infraclavicular	Upper arm surgery	0.3–0.5
Axillary	Elbow and forearm surgery	0.3–0.5
Median, ulna, and radial	Syndactyly surgery	0.1–0.3
TAP, unilateral[b] TAP, bilateral[b]	Open appendectomy Inguinal herniorrhaphy Colostomy formation Subumbilical midline laparotomy	0.3–0.5 per side
Subcostal TAP	Cholecystectomy PEG	0.3–0.5 per side
Rectus sheath[c]	Umbilical herniotomy Pyloromyotomy[b]	0.2-0.3 per side
Ilioinguinal	Inguinal herniotomy	0.2–0.3
Penile	Circumcision Distal hypospadias	0.1 per side
Unilateral paravertebral Bilateral Paravertebral	Thoracotomy; eg, TOF Renal surgery Sternotomy Pectus surgery	0.3–0.5 per side
Intercostal	Chest drain insertion Thoroscopy	0.5
Lumbar plexus	Hip surgery	0.5
Femoral	Femoral fracture Slipped upper femoral epiphysis (combined with LFC)	0.2–0.4
Fascia iliaca	Femoral fracture Slipped upper femoral epiphysis	0.5
Lateral femoral cutaneous	Thigh muscle biopsy	0.1

TABLE 44–1. Pediatric regional anesthetic techniques: common indications and suggested volume of local anesthetic. (*Continued*)

Block	Indication	Local Anesthetic Volume (mL/kg)[a]
Proximal sciatic[d]	Cruciate ligament repair	0.3–0.5
Popliteal[d]	Tendon transfers/lengthening	0.3–0.5
Ankle	Syndactyly surgery	0.1–0.2
Digital nerve	Distal finger/toe surgery	0.05–0.1

[a]No volumes have been quoted for US-guided techniques, as the end point should be when the nerve is surrounded by local anesthetic solution. For US-guided fascial plane blocks, the volumes are the same as for the landmark-based techniques.
[b]Systemic analgesia for visceral pain is essential.
[c]Always bilateral.
[d]Depending on the operation, a femoral or saphenous nerve block may be required for complete analgesia.

LFC, lateral femoral cutaneous; PEG, percutaneous endoscopic gastrostomy; TAP, transverse abdominis plane; TOF, tracheoesophageal fistula.

As an adjunct to peripheral nerve stimulation, objective injection pressure monitoring during local anesthetic injection may decrease the risk of intraneural injection.[7]

The introduction of US to guide nerve blocks has significantly increased the efficacy of these techniques and may decrease the risk of neurologic and systemic complications (see Chapter 60). Due to the superficiality of the structures in children, a US machine with a high frequency probe (> 13 MHz) should be available. When scanning children with very superficial structures, a 5-mm sterile US gel pad may allow better focusing of the US beam. Linear probes with a small footprint approximately 25 mm in length are a necessity to allow blocks to be performed on infants and children weighing less than 15 kg, as larger footprints tend to be too cumbersome in such patients. Because of the wide range of ages cared for in pediatric anesthesiology, a curvilinear probe will still need to be purchased to facilitate deep blocks (eg, lumbar plexus blocks in adolescents).

LOCAL ANESTHETICS

This chapter describes the use of local anesthetic solutions in children. It is imperative, however, to remember that the dosage of local anesthetic solutions should be on a *milligram-per-kilogram basis* and *not* based on total volume used (see Chapter 42, Table 42–2), as is often the practice in regional anesthesia in adult population. Consideration should be given to using a more modern amino amide local anesthetic (eg, levobupivacaine or ropivacaine), particularly in neonates and infants and when infusions are planned. The dosage should be adjusted downward in infants and neonates owing to the decrease in protein binding and α_1-acid glycoprotein, allowing for a greater amount of the free fraction of the drug in the systemic circulation. The addition of epinephrine to the local anesthetic solution may offer additional advantages by revealing intravascular placement, particularly in children under general anesthesia, and by prolonging local anesthetic action when used for peripheral nerve blockade.[8]

Choosing the most appropriate concentration of local anesthetic for a given situation is imperative. In children, successful blocks can be provided using a medium concentration of amino amide (eg, 0.25% levobupivacaine). However, a weaker solution (eg, 0.125%) is more appropriate for neonates, when ambulation is important, and when there is a significant risk of compartment syndrome. In some circumstances, the administration of stronger concentrations of local anesthetic (eg, 0.5%) may be indicated; for example, when postoperative muscle spasms are a major issue.

NERVE LOCALIZATION METHODS

To assist standard landmark-based methods, a variety of techniques have been developed, including nerve stimulation, surface mapping, and ultrasonography. All techniques require a sound knowledge of anatomy.

Surface Mapping and Percutaneous Peripheral Nerve Stimulation

The most common method of nerve localization involves using a stimulating needle (sheathed needle). Mixed nerves can be identified percutaneously (surface mapping) and/or subcutaneously using a nerve stimulator. Surface mapping may decrease the number of needle insertions required.[9] To elicit stimulation percutaneously, the nerve stimulator must have an adequate current output (eg, 5 mA/1 msec). The negative electrode is attached to the needle (*b*lack to *b*lock), and the positive electrode is attached to the patient (*p*ositive to *p*atient). Prior to inserting the stimulating needle, it is possible to percutaneously stimulate and thus identify a superficial nerve's position using a higher current and/or duration. To provide effective contact, the skin should be covered with a lubricating jelly or wiped with an alcohol swab. Once the needle is inserted, the nerve is located by trying to position the needle such that a current of 0.5 mA produces an appropriate muscle group response. The disadvantages of nerve stimulation are that it is a "blind" technique, is insensitive to intraneural injection, cannot be used in conjunction with muscle relaxants, is unreliable in children with neuromuscular conditions, and is painful if an awake block is being performed in the trauma setting. For these reasons, neurostimulation is being superseded by ultrasonography.

Ultrasonography

US-guided regional anesthesia has been with us for more than a decade; interest in this technology to aid in nerve localization has significantly increased, coinciding with increasing worldwide experience and the advances made in portable US equipment.[10–12] US has been shown to reliably identify nerves and fascial planes in children, plan the safest needle trajectory, and visualize the dispersion of local anesthetic within the desired tissue planes.

This technology, however, requires significant training and skill for its successful implementation; the success of US techniques is highly operator dependent. The key to the successful use of US is a specific training module and mentorship from a skilled practitioner. Although children are generally easier subjects to scan due to the superficial nature of their nerves, there are challenging morbidities (eg, cerebral palsy; Figure 44–1). To succeed with these difficult patients, the operator must have an established routine for each block, such that similar scanning conditions are used each time so that the expected US pattern is easily recognized.

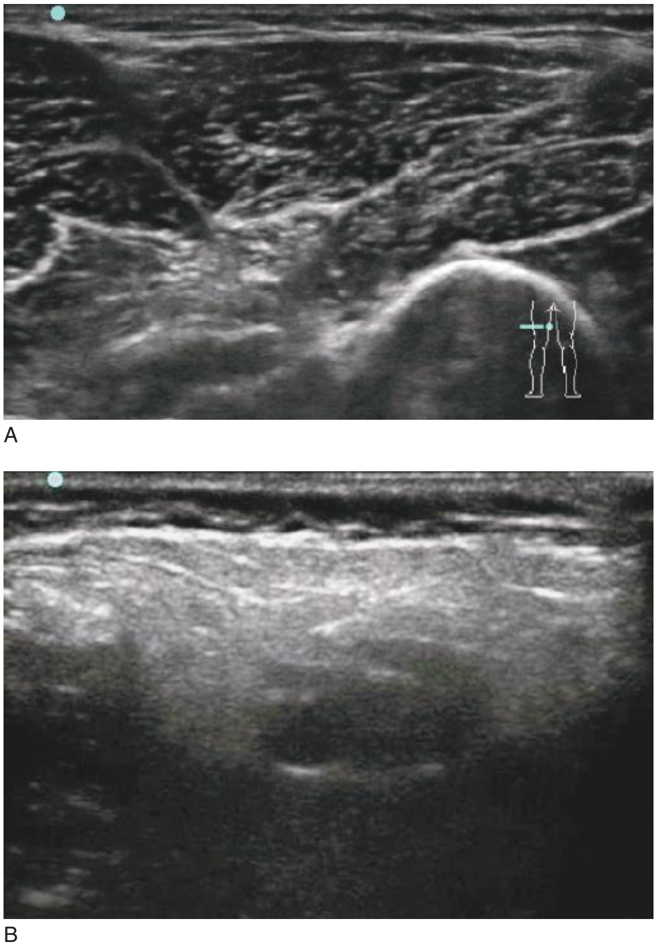

FIGURE 44–1. Comparison of US images of the popliteal fossae in (**A**) a healthy child and (**B**) a child with cerebral palsy.

TABLE 44–2. Specific advantages of pediatric ultrasound-guided regional anesthesia.

No ionizing radiation.
Because of the lower levels of ossification in pediatric patients, there are larger echo windows that can be used to visualize inside the spinal column.
Ultrasound allows for far lower doses of local anesthetic to be used, thereby reducing the risk of local anesthetic toxicity.
A lower volume of local anesthetic allows for multiple blocks to be performed within the maximum dose of local anesthetic.
In infants, the anatomy is compact and the risk of damage is greater; therefore, visualization of the nerve and adjacent structures makes for an inherently safer technique.

For very superficial nerves, it may be beneficial to use a 5-mm sterile US gel pad to allow the US beam to better focus on the target nerve. When learning, and particularly with small children, it is useful to initially use saline to identify correct needle placement; in this way, no local anesthetic is wasted. (See Chapter 30 for a detailed discussion of general US techniques.) Table 44–2 summarizes the advantages of US-guided regional anesthesia in children.

Peripheral Nerve Catheter Techniques

Peripheral catheters are becoming increasingly popular in pediatric anesthesia, providing prolonged analgesia for surgery associated with moderate to severe postoperative pain.[13] They are predominantly used for limb surgery, though they can be inserted for abdominal fascial plane blocks or indeed for simple wound irrigation. Other indications for the use of peripheral nerve catheters include the following:

- To facilitate intensive physiotherapy post–limb surgery
- To potentiate perfusion following reimplantation surgery
- To treat CRPS-1
- To manage nonsurgical pain (eg, epidermolysis bullosa)
- For palliative care (if the catheter is fixed correctly, it is the author's experience that patients can be managed at home for as many months as is required)

Infective complications are rare and also less common than in adults; nevertheless, a strict aseptic technique should be used when placing peripheral nerve catheters. It is debatable whether it is helpful to make a space around the nerve for the catheter to be inserted into. With US, an advantage of making a space with local anesthetic is that the anesthesiologist knows that he or she has at least provided a reliable single injection of local anesthetic. The position of the catheter is confirmed by using a neurostimulating catheter or US. However, neurostimulating catheters are expensive, and their advantages are insignificant. When using US, it is often helpful to identify the catheter tip by scanning in both the transverse and longitudinal planes; local anesthetic or saline can then be injected and the spread assessed. Generally, no more than 2–3 cm of the catheter is inserted beyond the needle tip.

To ensure catheter security, tunneling should be performed for the majority of techniques (Figure 44–2). In addition, tissue glue should be applied to the original and secondary puncture sites to stop local anesthetic solution from leaking during infusion. Leakage of infusion causes the dressing to become wet and lift off the skin, leading to catheter dislodgement. Indermil or Dermabond glue can be used; the advantage of the latter is that it can be easily removed with yellow paraffin. It is usually a good idea to flush the catheter once it is tunneled and secured to ensure no kink has formed under the skin. The local anesthetic pump should be run intraoperatively so that any occlusion is detected prior to the patient being recovered.

As confidence has grown with nerve catheter techniques, their use in older children at home is being increasingly described; this has been aided by the development of disposable elastomeric pumps. A typical infusion prescription of 0.125% levobupivacaine or ropivacaine runs at 0.1–0.3 mL/kg/h. For fascial plane blocks that require volume to work, a local anesthetic bolus regime may be preferable to running an infusion. The postoperative analgesia management should be clearly documented and verbally handed over to the ward staff and parents or caregivers. It should include rescue analgesia (eg, Oramorph or diazepam 0.1mg/kg to a maximum of 5 mg) for muscle spasms, an antiemetic, and a proposed time and date to stop the peripheral nerve catheter infusion. When the peripheral nerve catheter infusion is stopped, the patient should be loaded with simple analgesics. If the patient is managing their pain 4–6 hours later, the catheter can be removed.

Clinical Pearls

- Children under 6 months of age should undergo regional anesthetic techniques only by anesthesiologists with specific training in pediatric regional anesthesia.
- Always use the most peripheral technique possible.
- When learning catheter techniques, begin with easier sites for catheter insertion, such as the femoral nerve.
- When learning US-guided techniques, and particularly with small children, it is useful to initially use saline to identify correct needle placement; in this way, no local anesthetic is wasted and overdose is prevented.
- For the best US images of very superficial structures, a 5-mm jelly pad is useful.
- Local anesthetic absorption may be greater with US-guided fascial blocks.

ANATOMICAL DIVISIONS

Head & Neck Blocks

The use of nerve blocks for various head and neck procedures is gaining in popularity, particularly in the pediatric population. Most of these blocks are sensory nerve blocks, which are easy to administer (field blocks) and virtually devoid of complications. They can, however, provide quality analgesia in the postoperative period, facilitating immediate postoperative recovery and pain management. Most of the innervation for the face and scalp is derived from the trigeminal nerve (cranial nerve V) and the cervical plexus (C2–C4).

V1 Division of the Trigeminal Nerve

The supraorbital and supratrochlear nerves are branches of the first division of the trigeminal nerve that exit from the supraorbital foramen. The supraorbital nerve provides sensory innervation to the anterior portion of the scalp, except for the midportion of the forehead, which is innervated by the supratrochlear nerve. This block can be used for frontal craniotomies as well as for minor surgical procedures, including excision of scalp nevi.[14,15]

Technique The supraorbital nerve can be easily blocked as it exits the supraorbital foramen; the block location is easily correlated to the midpoint of the pupil. When the foramen is located, a subcutaneous injection of local anesthetic solution (1–2 mL 0.25% bupivacaine with 1:200,000 epinephrine) is performed. Once the local anesthetic solution is injected, gentle pressure is maintained to decrease the risk of hematoma formation. Complications with this block are rare.

V2 Branch of the Trigeminal Nerve

The second division of the trigeminal nerve is also referred to as the maxillary division of the trigeminal nerve. It exits from the maxillary foramen or the infraorbital foramen, which is located about 2 cm from the midline, and is usually aligned with the midpoint of the pupils. This nerve provides sensory supply to the upper lip, choana, maxillary sinus, part of the nasal septum, and tip of the nose. This block can be used to provide analgesia for cleft lip surgery, nasal septal repair, and endoscopic sinus surgery.[16–20]

Technique There are two approaches to the maxillary division of the trigeminal nerve:

1. ***Extraoral route:*** The needle is directed into the infraorbital foramen from an external location of the nerve. The foramen is located externally, and a 27-gauge needle is inserted into the foramen. After aspiration to rule out intravascular injection, 1–2 mL of local anesthetic solution is injected.
2. ***Intraoral route:*** The nerve is accessed through the subsulcal area in the buccal mucosa. This is our preferred modality for blocking the infraorbital nerve. The upper incisor or the second bicuspid on the side to be blocked is located; a needle is passed via a subsulcal route toward the location of the infraorbital foramen. After careful

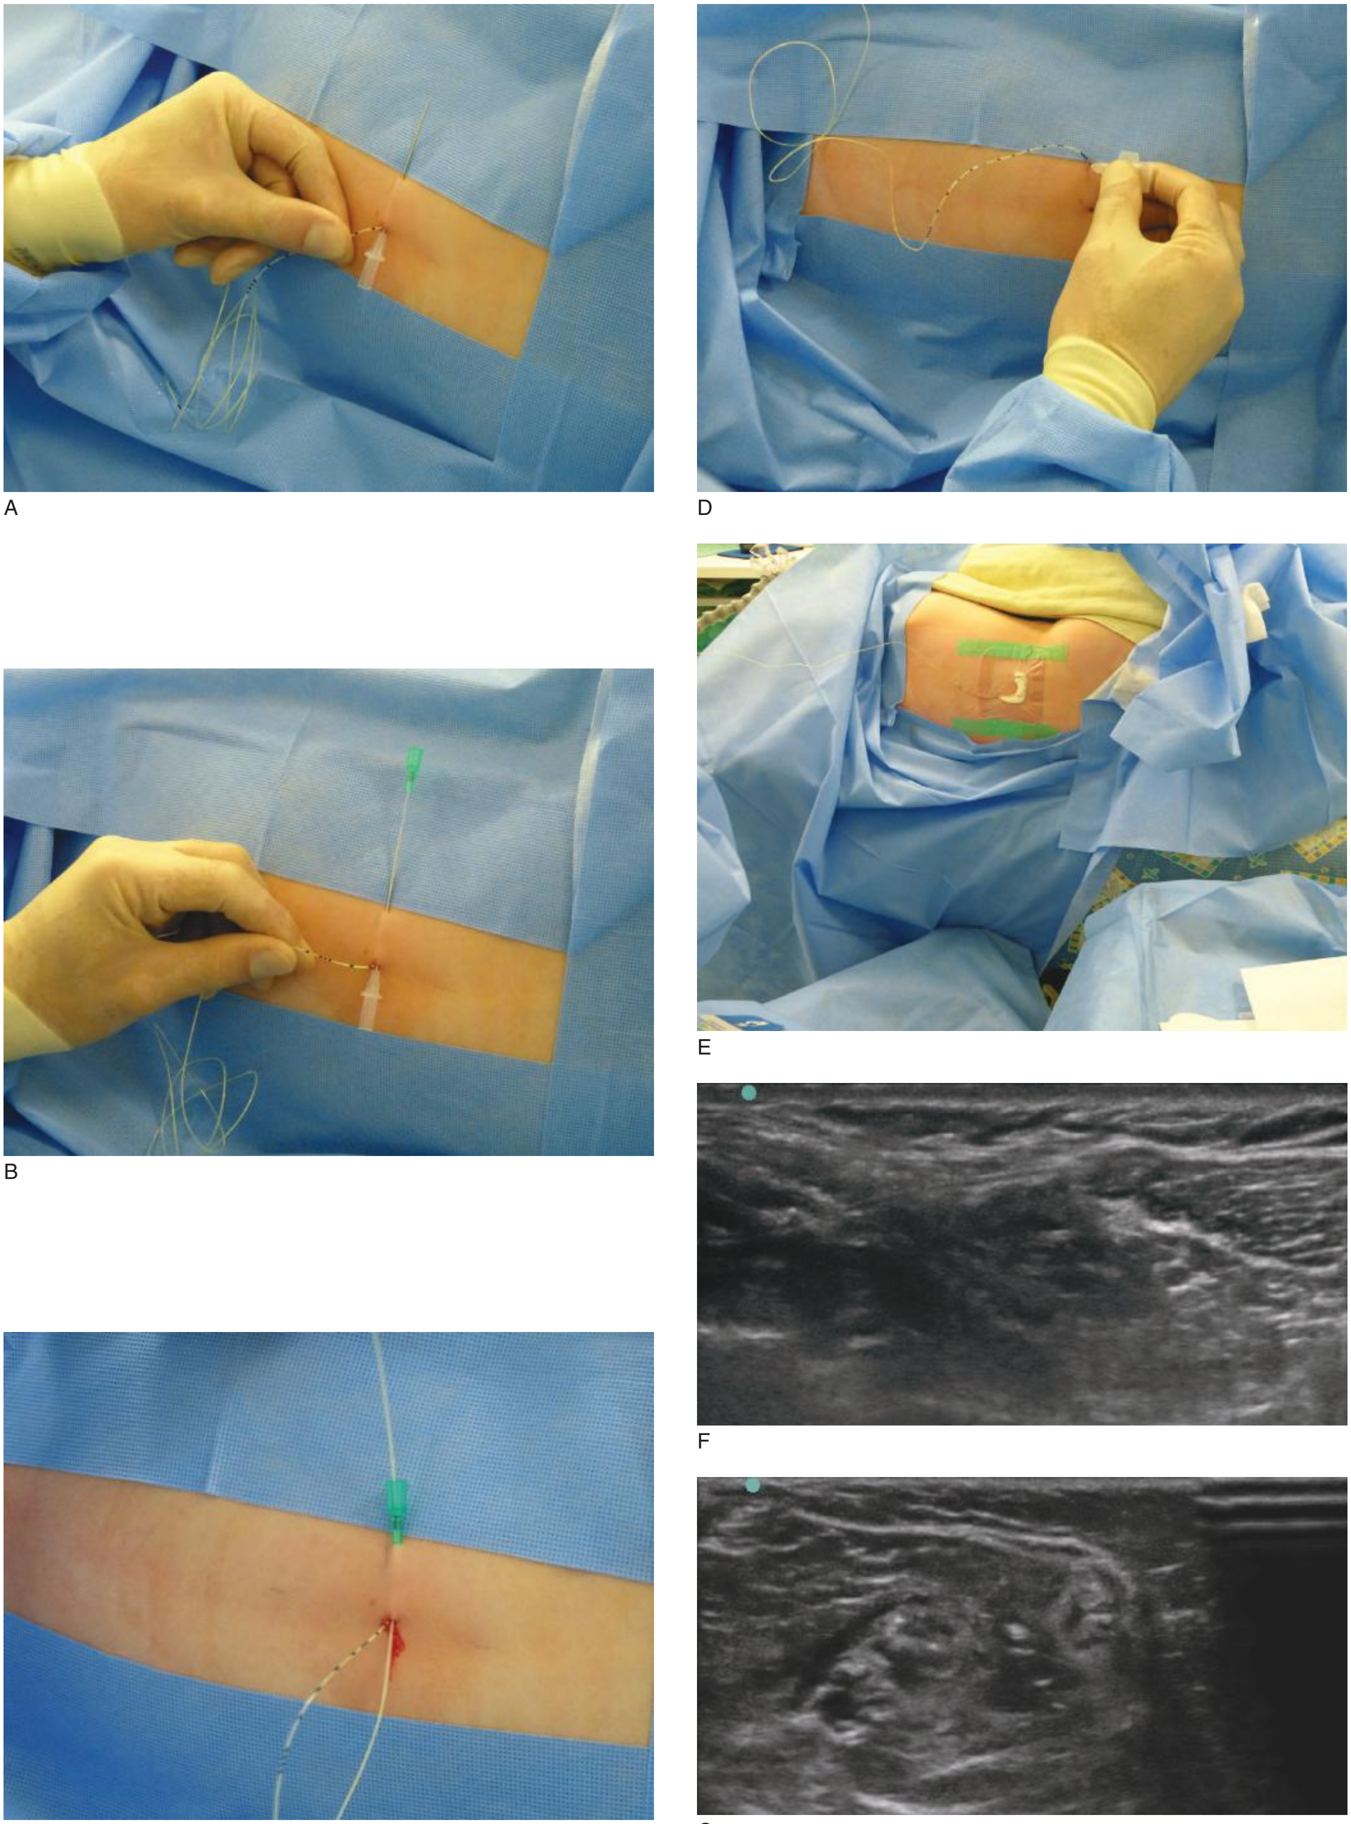

FIGURE 44–2. Tunneling of the popliteal catheter. The image in (**F**) illustrates an in-plane approach, whereas (**G**) illustrates an out-of-plane approach.

aspiration, local anesthetic solution is injected. For infants scheduled for cleft lip repairs, we use 0.5 mL of local anesthetic solution for each side; for older children and adolescents, we use 1.5–2 mL of local anesthetic solution. The upper lip is likely to remain numb for several hours after the block, which can be disconcerting to patients. Care should be provided to prevent biting of the upper lip during the period of emergence from anesthesia.

V3 Mandibular Division of the Trigeminal Nerve

The mandibular division of the trigeminal nerve provides analgesia for the lower jaw, lower lip, and portions of the temporoparietal portions of the scalp. The most common nerve targeted in children is the mental nerve, which exits from the mental foramen located at the level of the midline in line with the pupil and the supraorbital and infraorbital foramina.

Technique An intraoral route is again preferred for placement of the mental nerve block. The needle is directed at the level of the lower incisor toward the infraorbital foramen; 1.5 mL of local anesthetic solution is then injected after careful aspiration. Gentle massage of the area is carried out after the injection.

The auriculotemporal nerve supplies the lateral scalp and is blocked at the midpoint between the pinna and the angle of the eye. A block of this nerve involves a subcutaneous injection of 1–2 mL of local anesthetic solution.

Greater Occipital Nerve The greater occipital nerve is a branch of cervical root C2. The nerve pierces the aponeurosis and traverses medially to the occipital artery inferiorly and crosses over to the lateral aspect of the artery superiorly by the nuchal line as it innervates the posterior portions of the scalp. A greater occipital nerve block can be used for providing adequate block of the scalp for posterior fossa craniotomies as well as for patients with chronic occipital neuralgia.[14]

Technique The occipital protuberance is palpated. The midline is identified, and the occipital artery is palpated. A 27-gauge needle is inserted, and a subcutaneous injection of local anesthetic solution is performed (1.5–2 mL of 0.25% bupivacaine with 1:200,000 epinephrine). The area is massaged gently after the injection. Complications are rare with this technique.

Ultrasound-Guided Technique The US-guided technique is the same as that used for adults (see Chapter 31). A linear probe of 10 MHz or more is used to identify the obliquus capitis, and the nerve can be found superficial to the muscle.

Superficial Cervical Plexus

The superficial cervical plexus is a pure sensory nerve derived from the C2–C4 nerve roots. It wraps around the belly of the sternocleidomastoid at the level of the cricoid and divides into four branches: the lesser occipital supplying the posterior auricular area; the great auricular supplying the mastoid area and the pinna; the transverse cervical supplying the anterior portion of the neck; and the superficial cervical supplying the skin over the shoulder in a cape-like distribution over the shoulder joint. Blockade of the superficial cervical plexus can provide good postoperative analgesia for tympanomastoid surgery, otoplasty, thyroid surgery, and for procedures performed on the anterior portion of the neck.[21–24] The use of this nerve block decreases the use of opioids in the perioperative period, thereby decreasing the incidence of nausea and vomiting.[21]

Technique The technique is essentially identical to that used in the adult patient. The clavicular head of the sternocleidomastoid is identified, and a line drawn from the cricoid cartilage to intersect the posterior border of the sternocleidomastoid is identified. A subcutaneous injection of local anesthetic solution (1–3 mL of 0.25% bupivacaine with epinephrine 1:200,000) is performed. Caution must be exercised during injection because of the close proximity of the nerve to the external jugular vein. Deep injections should be avoided to prevent potential injection into the deep cervical plexus, which is associated with adverse effects including recurrent laryngeal nerve paralysis, paralysis of the hemidiaphragm, and Horner syndrome as a result of unilateral sympathetic ganglion blockade. Complications, though rare, are related to deep cervical plexus blockade and intravascular injection. (See Chapter 80A for a more detailed description of this technique.)

Ultrasound-Guided Technique The US-guided is the same as that used for adults (see Chapter 32A).

Nerve of Arnold

The nerve of Arnold is the auricular branch of the vagus nerve; it supplies sensory innervation to the auditory canal and the lower half of the tympanic membrane. A block of this nerve provides analgesia for myringotomy. Using a fine needle, 0.5–1 mL of local anesthetic is injected into the cartilage of the posterior tragus.

Upper Extremity Blocks

A complete review of the anatomy of the brachial plexus is provided in Chapters 3 and 32B–E. There are multiple approaches to the brachial plexus in children. Although the interscalene block is often used in adults for surgical procedures of the shoulder, this approach is used infrequently in children. This is due to the limited indications and increased incidence of complications associated with the use of the interscalene approach in children. The most common approaches to the brachial plexus in children include the supraclavicular, infraclavicular, and axillary approaches. The complications described include hematoma, intravascular injection, intraneural injection, and pneumothorax for the periclavicular blocks. Except for the axillary approach, all approaches should always be performed under US guidance. Often, these blocks are being performed on children with severe musculoskeletal complaints (eg, fixed contractures, muscles absent or fibrosed); in these patients, US is superior to neurostimulation in terms of its ability to define individual anatomy. For prolonged analgesia, peripheral catheters can be easily fixed in the supraclavicular or infraclavicular region.

Supraclavicular Approach

In the close anatomical relationships of children, only small probe movements are required to change from an interscalene view to a supraclavicular view. Prior to US, this block had been underused in children due to the close proximity of the cervical pleura. However, with appropriate training and mentorship, the sonoanatomy (Figure 44–3) becomes easy to understand, and the block generally becomes technically easy to perform. It is recommended that this block be performed only with the use of US.

Ultrasound-Guided Technique In the US-guided supraclavicular approach, the child is placed supine with a head ring and shoulder roll; this arrangement creates enough room for the anesthesiologist's needling hand to approach from the posterior aspect. In the younger child, the first rib may not be fully ossified. Always use Doppler to identify potentially dangerous vessels in the proposed needle trajectory. The probe is positioned parallel to and touching the clavicle and is angled caudad, aiming into the thorax. An in-plane needling technique from the posterolateral to anteromedial direction is employed (see Figure 44–3).[25]

Infraclavicular Approach

The US-guided infraclavicular approach is second choice to the supraclavicular approach as the brachial plexus is generally deeper at this point and an out-of-plane technique is employed.[10, 25] However, an infraclavicular approach is indicated if the supraclavicular fossa is inaccessible or there is local infection. US guidance is recommended for this approach (see Chapter 32D for more detail).

Axillary Approach

The axillary approach to the brachial plexus is the most commonly used landmark-based approach in children and adolescents and is used for procedures on the arm and hand. The primary advantage of the axillary approach is the relatively lower risk of complications. However, there is a 40–50% chance of missing the musculocutaneous nerve with this approach, owing to the proximal exit of this nerve from the axillary sheath. Hence, while performing a block using this approach, the musculocutaneous nerve should be blocked separately when analgesia of the biceps and anterior forearm is sought. Peripheral nerve catheters in the axilla are difficult to immobilize and protect from bacterial colonization. A US-guided technique has been described but differs little from the adult technique described in Chapter 32E.[26]

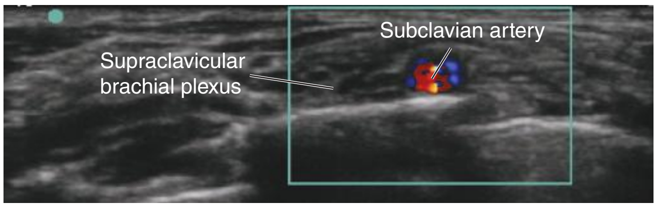

FIGURE 44–3. Supraclavicular block in a child: probe position and relevant sonoanatomy.

Technique There are several techniques for placing an axillary block. The commonly used approaches include the transarterial approach and the nerve stimulation approach. Although greater success with the transarterial approach has been reported in adults, this approach is not often used in children,[27] due to the higher incidence of vessel spasm and increased potential for ischemia in children versus adults. Although many methods have been reported in adults, the simple, common single-injection technique seems to be effective in children.[28]

For this technique, the patient is positioned with the arm abducted 90 degrees. The elbow is flexed, and the arm is placed above the head. A stimulating needle is inserted superior to the axillary artery at an angle of 30 degrees, with the tip pointed toward the midpoint of the clavicle. A "pop" may be felt as the needle enters the axillary sheath. After eliciting a response to nerve stimulation at 0.5 mA, local anesthetic solution is injected. A volume of 0.3–0.5 mL/kg is recommended, to a maximum of 20 mL. When anesthesia of the musculocutaneous nerve is required to augment this block, the needle is directed above the pulse of the axillary artery and toward the belly of the coracobrachialis muscle. Contraction of the biceps confirms placement of the needle close to the musculocutaneous nerve.

Nerve Block at the Wrist Blockade of the radial, ulnar, and median nerves can be accomplished at the level of the wrist. The advantage of these peripheral blocks is the absence of motor blockade. They are used primarily for surgery on the hand, such as syndactyly repair. These blocks are performed in conjunction with general anesthesia, since tourniquet pain cannot be eliminated with this block alone. (See Chapters 32G and 80F for more information on the US-guided and landmark-based techniques, respectively; these techniques are essentially identical to those used in adults.) With US, the nerves can be blocked at any point along their path. The following discussion outlines some specific issues that relate to the landmark application of wrist blocks in pediatric patients.

Radial Nerve The radial nerve is a superficial sensory nerve proximal to the radial head. The radial nerve divides into two branches: the thenar branch and the dorsal branch. This division takes place proximal to the distal end of the radius. This block is performed for children undergoing trigger thumb release or minor surgical procedures involving the thumb and index finger.

Technique The anatomical "snuff box" is identified, and local anesthetic is infiltrated subcutaneously approximately 2 cm proximal to the this location. A volume of 2 mL is adequate to provide good analgesia in the postoperative period.

Median Nerve The median nerve is located between the tendons of the palmaris longus and the flexor carpi radialis. The nerve can be blocked at the level of the flexor retinaculum or at midforearm level. One of the important anatomical advantages of blocking the median nerve at the wrist is the presence of a bursa at the level of the flexor retinaculum. This bursa encompasses the median nerve; hence, blockade of this nerve can be carried out without damage to the nerve.

Technique The tendons of the flexor carpi radialis and the palmaris longus are identified. Flexion of the wrist identifies the tendons. A 27-gauge needle is inserted at the medial border of the palmaris longus tendon. A "pop" is felt as the bursa is entered. An injection of 2 mL of local anesthetic solution is made. Smaller quantities are used in younger children and infants.

Ulnar Nerve The palmar cutaneous branch of the ulnar nerve accompanies the ulnar artery to the wrist. It perforates the flexor retinaculum and ends in the palm, communicating with the median nerve.

Technique The nerve is easily blocked at the wrist. The flexor carpi ulnaris tendon is identified. The nerve is blocked under the flexor carpi ulnaris tendon, just proximal to the pisiform bone. A 27-gauge needle is passed under the flexor carpi ulnaris, proximal to the pisiform bone, about 0.5 cm. After aspiration, 2 mL of local anesthetic solution is injected.

Lower Extremity Blocks

The lumbar plexus and sacral plexus supply the lower extremity. The lumbar plexus is contained in the psoas compartment and consists of a small portion of T12 and lumbar nerves L1–L4. The femoral, lateral femoral cutaneous, and obturator nerves are branches of the lumbar plexus and supply most of the thigh and upper leg. The lower leg is innervated by the sacral plexus, which is derived from the anterior rami of L4, L5, S1, S2, and S3. The sacral plexus gives rise to the sciatic nerve, which is the largest nerve in the body. The complications of lower extremity blocks described include hematoma, intravascular injection, and intraneural injection. The landmark/nerve stimulation method is made difficult in cerebral palsy patients in whom there are limb contractures and absent or hypoplastic or fibrosed muscles. The contractures are occasionally so severe that it is nearly impossible to gain access to perform the block.

Femoral Nerve

The femoral nerve block is the most commonly performed lower extremity peripheral nerve block in children. It is used to provide pain relief after femoral fractures, Ilizarov frame placement, patellar ligament realignment, and slipped upper femoral epiphysis fixation.[29–32] The femoral nerve is located at the level of the crease at the groin, lateral to the pulsation of the femoral artery.

Technique The technique for this block is similar to that used in adults (see Chapter 82C). The femoral artery pulse is located, and the needle is inserted immediately lateral to the pulse to elicit a quadriceps muscle contraction. The nerve stimulator is initially set at 1 mA and then reduced to 0.5 mA while observing the quadriceps contraction. The location of the needle is stabilized and aspiration performed repeatedly as 0.2–0.4 mL/kg of local anesthetic is injected.

Ultrasound-Guided Technique The patient is positioned supine, with the anesthesiologist on the side of the intended nerve block, facing the US machine opposite. The linear probe is placed just below and parallel to the inguinal ligament. Using minimal transducer pressure to avoid collapsing vessels, Doppler is used to identify the superficial circumflex iliac artery, as this artery frequently passes superficially to the femoral nerve (Figure 44–4). The needle is introduced in plane from a lateral to medial direction, aiming to just "pop" the fascia iliaca as it spreads over the femoral nerve. Note that more than two "pops" are often felt and that repeated test injections of 0.5 mL may be required to ensure that the correct plane has been located.[33] If required, the needle can then be rotated 180 degrees to block the lateral femoral cutaneous nerve.

Lateral Femoral Cutaneous Nerve The lateral femoral cutaneous nerve is derived from L3 and L4 segments of the lumbar plexus. It is a pure sensory nerve and passes superficially along the lateral border of the iliac crest. It appears from beneath the inguinal ligament medial to the anterior superior iliac spine, travelling between the fascia lata and the fascia iliaca. It supplies the skin of the lateral aspect of the buttock and the anterolateral aspect of the thigh below the greater trochanter. A lateral femoral cutaneous nerve is useful for providing analgesia for surgery on the lateral aspect of the thigh, including muscle biopsies and graft excisions.[34]

Note that the lateral femoral cutaneous nerve does not supply the skin of the thigh above the greater trochanter; this area is supplied by branches of the L1 and T12 nerve roots. If the incision is to extend this cephalad, a superficial infiltration around the upper lateral aspect of the thigh or a transverse abdominis plane (TAP) (T12–L1) block may be required. Where children have undergone previous hip surgery, scarring can make both the landmark- and US-based techniques difficult. The technique for this block is similar to that used in adults (see Chapter 33C).

Technique The anterior superior iliac spine is identified. A point 1–2 cm below and medial to the anterior superior iliac spine is identified. After careful aseptic preparation of the area, a blunt needle is introduced into the marked site. Once the

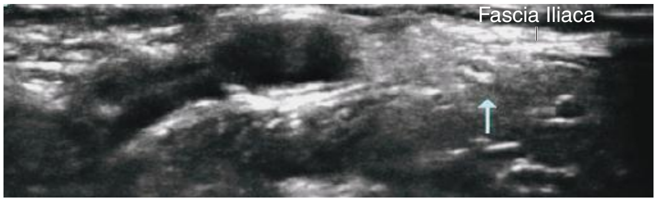

FIGURE 44–4. Femoral nerve block in a child: probe position and relevant sonoanatomy.

needle is through the skin, a "pop" is felt as the needle pierces the fascia lata. Once the needle is lodged within this space, loss of resistance may be felt as the local anesthetic solution is injected. A total volume of 0.1 mL/kg (to a maximum of 5 mL) of local anesthetic solution is injected.

Ultrasound-Guided Technique A reliable location to identify the nerve is 10–20 mm below the anterior superior iliac spine, in the groove between the sartorius muscle and the tensor fascia lata.[33] The lateral femoral cutaneous nerve is a small hyperechoic nerve (Figure 44–5). Note that the nerve may pass through the ligament or laterally to the anterior superior iliac spine.

Sciatic Nerve

The sacral plexus comprises the sciatic nerve and provides innervation to the posterior thigh, leg, and most of the foot, except the medial portion, which is innervated by the femoral nerve. A number of techniques are used in children for a sciatic nerve block. When choosing which level to block the nerve, it is essential that the most distal approach be chosen. Tourniquet pain is rarely a problem in children, as they are under general anesthesia. Further, distal nerve components are more likely to be missed if a proximal block is performed, thus creating a "patchy" block. We will address two techniques: the subgluteal and the popliteal fossa approaches. However, with US, the sciatic nerve can essentially be blocked at whichever level is appropriate to the surgery and where the nerve is easiest to visualize.

Subgluteal Approach This approach is indicated for hamstring releases and anterior cruciate ligament repairs. Catheter placement is straightforward; it is helpful to tunnel the catheter laterally subcutaneously 30–40 mm. Placing a tourniquet over the catheter is not problematic, though care should be taken on removal of the tourniquet to prevent catheter dislodgement by the surgeon.

Technique The subgluteal sciatic nerve block can be performed either in the lateral (operative side uppermost) or supine position with the limb elevated. The subgluteal line where the gluteal crease is present is marked. The biceps femoris tendon is identified, and a point inferior to the gluteal crease, just medial to the biceps femoris tendon, is delineated. A sheathed needle connected to a nerve stimulator is introduced in an anterior plane and cephalad at an angle of 60–70 degrees. Inversion of the foot indicates blockade of the tibial nerve.[35] The current is then reduced to 0.4 mA, and if inversion is still present, the local anesthetic solution is injected. If eversion is noted, the needle is withdrawn to the skin and inserted medially. If the biceps femoris tendon is contracting, the needle is drawn back to the skin and inserted medially, away from the muscle belly of the biceps femoris tendon. Plantar flexion is also an indicator of adequate block placement, although this yields a potential for failed blockade.[35] A volume of 0.3–0.5 mL/kg (to a maximum of 20 mL) is injected into the space. On initial injection of 1 mL of local anesthetic solution, the twitch disappears, confirming correct needle placement.

Ultrasound-Guided Technique A linear probe suffices in all but the largest adolescent. Applying probe pressure improves the US image, as this brings the sciatic nerve closer to the probe (Figure 44–6). Visualizing the nerve may be difficult in arthrogrypotic children, in whom it may be obscured by fibrosis. Where there is difficulty identifying the nerve, a longitudinal scan from medial to lateral and back may be attempted, looking for a band of hyperechogenicity (Figure 44–7). Once the sciatic nerve identified, rotate the probe back into the transverse plane. Alternatively, track down distally to the popliteal fossa, and identify the nerve before retracing your steps. With US, it is often possible to see the posterior cutaneous branch of the thigh, medial and superficial to the sciatic nerve, and it is important to ensure the local anesthetic covers it. An in-plane technique is advisable for single injections, whereas an out-of-plane technique is often better for catheter placement.[33] When placing catheters, first inject one-third of the available local anesthetic by the lateral aspect of the nerve; the remaining two-thirds is used medially to make space for the catheter. This technique ensures the nerve is surrounded.

Popliteal Fossa Block The indications for popliteal block include trauma surgery and correction of congenital abnormalities. In conjunction with a saphenous nerve block, the lower limb below the knee can be completely anesthetized.

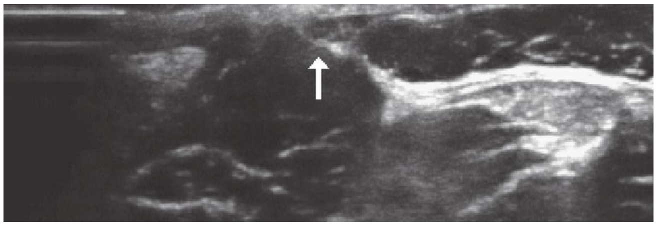

FIGURE 44–5. Lateral cutaneous nerve of the thigh in a 6-year-old: probe position and relevant sonoanatomy.

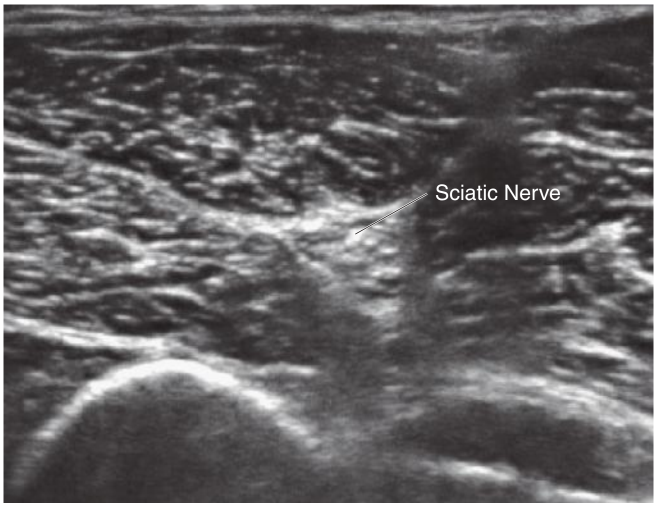

FIGURE 44–6. Probe position and sonoanatomy at the subgluteal level.

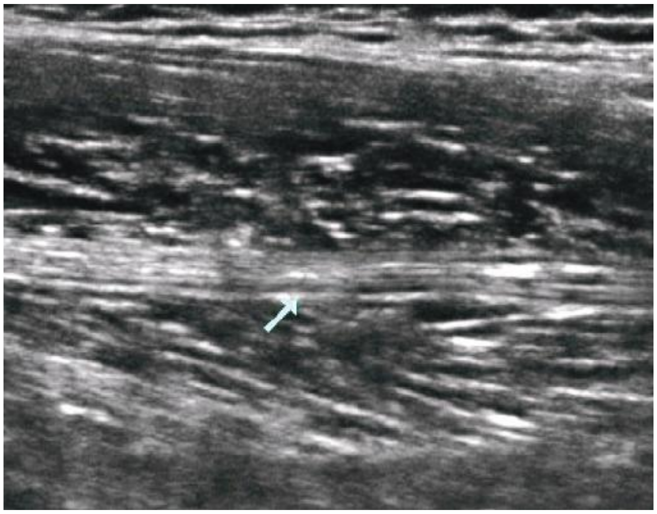

FIGURE 44–7. Longitudinal scan of the thigh highlighting the sciatic nerve in a 6-year-old.

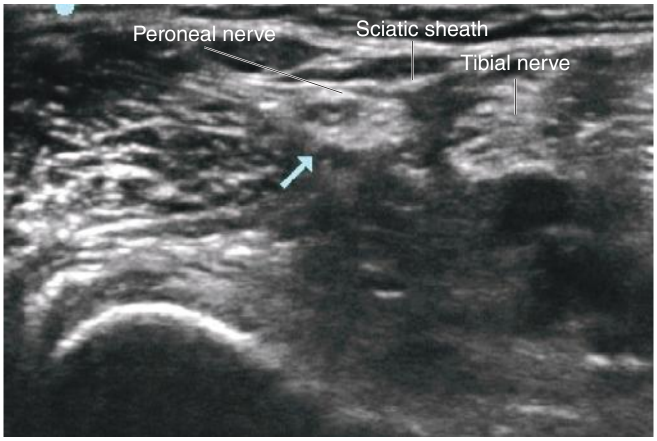

FIGURE 44–8. Popliteal block: probe position and sonoanatomy.

The popliteal fossa is a diamond-shaped area with the superior triangle formed by the tendons of the semitendinosus and semimembranosus medially and the biceps femoris tendon laterally.[36] The sciatic nerve divides into the common peroneal nerve and the tibial nerve. The common peroneal nerve exits the popliteal fossa laterally, and the tibial nerve exits medially. The branching of the sciatic nerve takes place at varying levels above the popliteal crease. A common epineural sheath is present that envelops both the tibial and common peroneal nerve; as a result, complete blockade of both branches may result.[37]

Technique The patient is positioned laterally (operative side uppermost to allow for better needle access), with the lower knee flexed or prone. The needle is inserted at the apex of the popliteal fossa, lateral to the artery. A response to nerve stimulation at 0.4 mA confirms the position of the needle and its proximity to the sciatic nerve. The tibial nerve is localized by the presence of inversion and plantar flexion (*i*nternal nerve = *i*nversion); the common peroneal nerve is localized by the presence of eversion and dorsiflexion (*e*xternal nerve = *e*version). After aspiration to rule out intravascular placement, local anesthetic solution is injected. A volume of 0.5 mL/kg is injected (to a maximum volume of 20 mL).

Ultrasound-Guided Technique The patient is positioned as described above, though, when supine, in many children with cerebral palsy, the leg will rotate externally sufficiently to allow the nerves to be approached medially. Children with flexed flexion deformities will not display the "see-saw" sign. For a single injection, an in-plane technique is recommended, from either the medial or lateral aspect of the leg.[33] With US, the exact level of sciatic nerve branching can be identified; at this point, the combined circumference of the two nerves will be greater than the circumference of the "sciatic" nerve; a block at this location provides greater local anesthetic–nerve contact (Figure 44–8).[38] For catheter insertion, an out-of-plane approach is preferred by the author; with a view to threading the catheter along the axis of the nerve, position can be checked in the longitudinal view. The catheter should be inserted at the level of sciatic nerve division.

Ankle

The ankle block is a very common and easy block to perform in children undergoing foot surgery. There are five main nerves to be blocked: the posterior tibial, deep peroneal, superficial peroneal, saphenous, and sural (Figure 44–9). All these nerves are distal branches of the sciatic nerve, except for the saphenous nerve, which is a branch of the femoral nerve. The nerves are superficial and therefore do not require much volume. Epinephrine should not be added to the local anesthetic solution because end arteries are present at the site of injection (see Chapter 82F for illustrations and a detailed description of the ankle block).

A US-guided approach is also possible (see Chapter 32H). Ideally, a probe with a small footprint and a frequency of 15 MHz or more should be readily available, but unfortunately, many of the highest-frequency probes have large footprints and do not readily sit on a small ankle. Once again, a sterile US gel pad may aid visualization.

Tibial Nerve The tibial nerve is the largest nerve supplying the plantar aspect of the foot and is an important nerve to be blocked for any foot surgery. We routinely use surface mapping with a current of 5 mA to locate the tibial nerve before injection. The nerve is located behind the posterior tibial pulsation, below the medial malleolus. A 27-gauge needle is advanced to the bone and slightly withdrawn to avoid injection into the periosteum; 2–5 mL of local anesthetic solution is then injected. Alternatively, a sheathed needle can be used, and plantar flexion or inversion can be elicited before injection.

Saphenous Nerve The saphenous nerve is the distal cutaneous branch of the femoral nerve. It is located superficially, anterior to the medial malleolus. A superficial ring is injected along the medial malleolus, and 2–5 mL of local anesthetic solution is injected. Caution must be exercised to

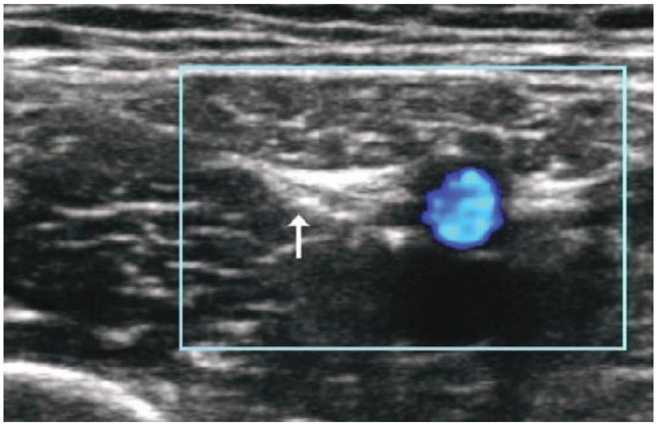

FIGURE 44–10. Subsartorial saphenous nerve block.

avoid intravascular injection, as the saphenous vein courses alongside the nerve. The saphenous nerve supplies the skin over the medial aspect of the leg below the knee and ankle. When performing a US-guided saphenous nerve block, it may be easier to find the nerve lateral to the artery, at the level of the adductor canal in the thigh, just before the vessels enter the posterior compartment (Figure 44–10). At this level, the nerve to the vastus medialis will also be blocked.

Deep Peroneal Nerve The peroneal nerve innervates the first web space of the foot. It can be blocked by depositing local anesthetic solution lateral to the extensor hallucis longus tendon. The needle is advanced until the periosteum of the tibia is encountered, then drawn back slightly. A volume of 2–3 mL of local anesthetic solution is then injected. When using US, the nerve is more easily found by identifying the dorsalis pedis artery and tracking the artery proximally until it lies on the distal tibia; at this point, the nerve can be seen travelling over the artery.

Superficial Peroneal Nerve The superficial peroneal nerve supplies sensory supply to the dorsum of the foot. It is superficial and can be easily blocked by injecting a superficial ring of local anesthesia between the lateral malleolus and the extensor hallucis longus tendon. This nerve is more easily visualized with US at the midcalf level, where it lies subcutaneously; it can be readily tracked back into the popliteal fossa, where it joins to form the common peroneal nerve.

Sural Nerve The sural nerve supplies sensory innervation to the lateral aspect of the foot. It can be easily blocked by injecting local anesthetic solution between the lateral malleolus and the calcaneus. This nerve is very difficult to visualize with US.

Digital Nerve Blocks

A digital nerve block is provided for analgesia of the fingers and toes. It is an ideal block for simple procedures such as trigger finger release and ingrown toenail excision and for foreign body removal and minor lacerations requiring suturing. We have used these blocks successfully for analgesia after laser therapy for warts in children. The digital nerve block technique is addressed in Chapter 80G.

Hand

Anatomy The common digital nerves of the hand are derived from the median and ulnar nerves and divide in the palm to supply the fingers. All digital nerves are accompanied by digital vessels. The median nerve provides three digital nerves. The first common palmar digital nerve divides into the three palmar digital nerves that supply the side of the thumb; the second common palmar digital nerve supplies the web space between the index and middle fingers, and the third common palmar digital nerve communicates with the ulnar nerve to supply the web space between the middle and ring fingers. These nerves then become the proper digital nerves that supply the skin of the distal phalanx. There are also smaller digital nerves derived from the radial and ulnar nerves that supply the dorsum of the fingers. The four dorsal digital nerves are located on the ulnar side of the thumb and the radial side of the index finger, adjacent to the index and middle fingers. All digital nerves terminate in two main branches: one supplying the skin under the fingertips, and the other supplying the pulp under the nail.

Technique The digital nerves are blocked using non–epinephrine-containing solution on each side of the finger at the bifurcation between the metacarpal heads. A dorsal or volar injection accomplishes similar results. A needle is inserted into the web space between the thumb and index finger to a distance of about 1 cm. A second needle is inserted into the thenar eminence on the radial aspect of the thumb. For the other fingers, the needle is inserted between the metacarpal heads. A needle is inserted proximal to the thenar web space at the distal palmar crease. After aspiration, 1 mL of local anesthetic solution (without epinephrine) is injected.

Complications A large volume of local anesthetic solution is contraindicated as it can cause vascular compromise.

Feet

Anatomy The digital nerves to the feet are derived from the plantar cutaneous branch of the tibial nerve. The proper digital nerve of the toe supplies the medial aspect of the great toe. The three common digital nerves split into two proper digital nerves each. The first supplies the adjacent areas of the great and second toes, the second supplies the adjacent sides of the second and third toes, and the third supplies the adjacent sides of the third and fourth toes. Each of these terminates at the tip of the toe. A branch from the superficial peroneal nerve supplies the dorsum of the foot. This is derived from two nerves: (1) the dorsal cutaneous nerve, which divides into two branches, a medial branch supplying the great toe and a lateral branch supplying the adjacent sides of the second and third toes; and (2) the intermediate dorsal cutaneous nerve, which passes along the lateral part of the foot, supplying the lateral aspect of the foot and communicating with the sural nerve. The two dorsal digital terminal branches supply the adjacent parts of the third and fourth toes and another branch supplying the adjacent sides of the fourth and fifth toes.

Technique It is easy to block the digital nerves by accessing the web space on the dorsolateral aspect of the foot. It is best to avoid these blocks in children who may have compromised blood flow to the toes. Vasoconstrictors are to be avoided for all these blocks.

Trunk Blocks

For most surgery involving truncal blocks, there will be an element of visceral pain that is not covered. Therefore, all children should receive some systemic analgesic adjuncts (eg, paracetamol and ibuprofen). Remember that with US-guided fascial blocks, local anesthetic absorption may be greater than with standard landmark-based techniques.

Ilioinguinal/Iliohypogastric Nerve

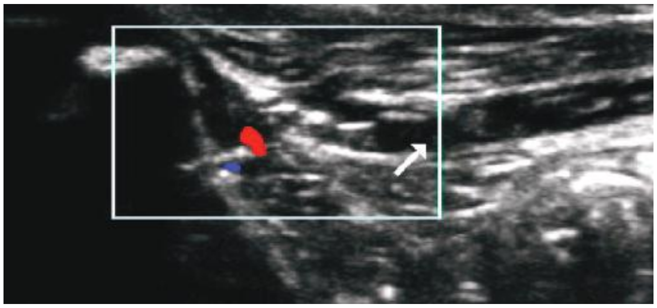
The ilioinguinal/iliohypogastric nerve block is indicated for inguinal hernia, orchidopexy, and varicocele surgery.

Anatomy The ilioinguinal and iliohypogastric nerves originate from the T12 (subcostal nerve) and L1 (ilioinguinal, iliohypogastric) nerve roots of the lumbar plexus. These nerves pierce the internal oblique aponeurosis 2–3 cm medial to the anterior superior iliac spine. The ilioinguinal nerve travels between the internal oblique and the external oblique aponeuroses. Here, it accompanies the spermatic cord and is part of the neurovascular bundle to the genital area.[39] US studies have shown that there is no relationship between a child's weight and the depth or position of the nerves.

Technique A line is drawn between the umbilicus and anterior superior iliac spine. A point is marked 2 mm medial from the anterior superior iliac spine. The needle is advanced toward the inguinal canal and passed in until a "pop" is felt. Local anesthetic solution is then injected into the area after aspiration. US studies have shown that blind administration usually does not inject the local anesthetic into the correct fascial plane between the internal oblique and transversus abdominis muscles; yet, clinically, the majority of blocks work, presumably due to the diffusion of the local anesthetic.[40] Alternatively, an ilioinguinal nerve block can be performed by the surgeon; the disadvantage of this is the need for a deeper plane of general anesthesia intraoperatively.

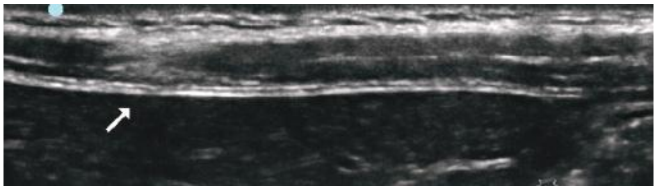
Ultrasound-Guided Technique The probe is placed on a line from the anterior superior iliac spine to the umbilicus, with the lateral end of the probe resting on the bone (Figures 44–11). With practice, the nerves can be tracked more proximally toward the midaxillary line, which prevents the local anesthetic spreading too far into the surgeon's field and disrupting their tissue planes.[41] Experts in this field have managed to

A



B

FIGURE 44–11. Ilioinguinal/iliohypogastric nerve block: (**A**) probe position; (**B**) US image.



A

B

FIGURE 44–12. Neonatal rectus sheath block: (**A**) sonoanatomy; (**B**) probe position.

successfully block these nerves with a volume of local anesthetic as little as 0.075 mL/kg.[42]

Complications An ilioinguinal/iliohypogastric nerve block is relatively safe. Perforation of the bowel wall can occur, however, and has been reported.[43] Femoral nerve blockade may occur in up to 11% of cases; therefore, all ambulant children should be tested for weight bearing prior to discharge.[44]

Rectus Sheath

A rectus sheath block (Figure 44–12) is useful in children for umbilical area surgery (eg, umbilical hernia, pyloromyotomy, duodenal atresia). It must be performed bilaterally, as the nerves cross over the midline from each side. The technique is essentially the same as that used in adults (see Chapter 81) but requires a greater degree of finesse when performed in neonates, in whom muscle thickness may be as little as 2 mm.

Anatomy The umbilical area is innervated by the tenth thoracoabdominal intercostal nerves from the right and left sides. Each nerve passes behind the costal cartilage and between the transverse abdominis and the internal oblique muscles. The nerve runs between the sheath and the posterior wall of the rectus abdominis muscle and ends at the anterior cutaneous branch, supplying the skin of the umbilical area. The rectus muscle is attached anteriorly to the sheath at three intertendinous intersections; however, posteriorly there are no attachments, and it is this which allows the spread of local anesthetic.

Technique The aim of this block is to deposit local anesthetic solution between the muscle and the posterior aspect of the sheath. The technique has been well described by Ferguson et al.[45] A 23-gauge needle is inserted above or below the umbilicus, 0.5 cm medial to the linea semilunaris in a perpendicular plane. The anterior rectus sheath is identified by moving the needle in a back-and-forth motion until a scratching sensation is felt and the rectus sheath is identified and entered. After the belly of the muscle is entered, the needle is farther advanced until the posterior aspect of the rectus sheath is appreciated with a scratching sensation as the needle is moved again in a back-and-forth motion. Once the sheath is felt, it is entered, and local anesthetic solution is deposited posterior to the sheath. The usual depth of needle entry is about 5–15 mm. After aspiration, 0.2–0.3 mL/kg of bupivacaine 0.25%–0.5% is injected on each side.

If resistance to injection is felt, the needle is advanced deeper, as resistance may indicate that the needle is within the body of the muscle. Caution should be taken, as US studies have shown that the depth from the skin to the posterior sheath is independent of age and weight. Indeed, the distance is rarely greater than 10 mm in children under 10 years of age.

Ultrasound-Guided Technique This block can be performed with a greater degree of precision with the assistance of US.[46] The anatomy is easy to understand, and the sonoanatomy is simple, with no anisotropy to contend with. As such, this block is an ideal one to teach a beginner, though initially older children should be practiced on. With practice, the anesthesiologist should be able to block both sides without having to swap his or her position or that of the US machine. An in-plane technique is ideally suited to this block, aiming from lateral to medial. Care should be taken when choosing the needle insertion point; it should be sufficiently lateral to allow a shallow needle trajectory. In this way, the needle tip can be slid into the potential space between muscle and sheath and avoid a trajectory down toward the abdominal cavity. Prior to needling, Doppler should be used to assess the position of the inferior epigastric artery; this is easily found lying deep to the muscle at the level of the arcuate line. It can then be tracked cephalad into the muscle belly. A volume of 0.1 mL/kg is sufficient to provide analgesia for an umbilical hernia; more extensive midline incisions will require greater volume. Holding the probe in a paramedian longitudinal plane, the local anesthetic spread can be readily assessed passing beneath the intertendinous intersections caudad and cephalad.

Transversus Abdominis Plane

The TAP block is a relative newcomer to regional anesthesia. It may be performed unilaterally (eg, for procedures such as stoma formation and open appendectomy) or bilaterally (eg, for vesicostomy).[47] Though single injections are generally employed, catheters may also be used. The block may be performed at a level midway between the iliac crest and costal margin for subumbilical surgery or higher as a subcostal approach (eg, for cholecystectomy).[48] Either way, the block must be performed using US guidance. This is an easy block to learn, as the sonoanatomy is simple and there is no anisotropy for the novice to contend with. As with all abdominal blocks, there is no visceral analgesia, and systemic analgesia must be given. The block is performed as in adults (see Chapter 34).

Anatomy The lateral abdominal wall consists of three muscles. From the peritoneum outward are the fascia transversalis and then the transversus abdominis, internal oblique, and external oblique muscles. The neurovascular plexus is fixed to the outer surface of transversus abdominis by a thick fascial sheet. It is unclear whether this must be breached for the block to be successful. Local anesthetic injected into the TAP will usually cover the T11–L1 segmental nerves and will also cover T10 50% of the time.[49]

Ultrasound-Guided Technique The patient is positioned supine, with the anesthesiologist standing on the side to be blocked and the US machine placed opposite. For bilateral blocks, it is unnecessary to change positions. The probe is placed over the midaxillary line, between the iliac crest and costal margin in a transverse plane. Count the muscle layers from inside out; if the layers are identified from out to in, it is easy to mistake a subcutaneous layer for a muscle layer, particularly in obese patients. An in-plane technique is used (Figure 44–13). If it is difficult to place the needle tip within the correct plane, insert the needle carefully into the transversus abdominis muscle; as you withdraw, have an assistant inject. As the needle tip enters the correct plane, loss of resistance will be felt.

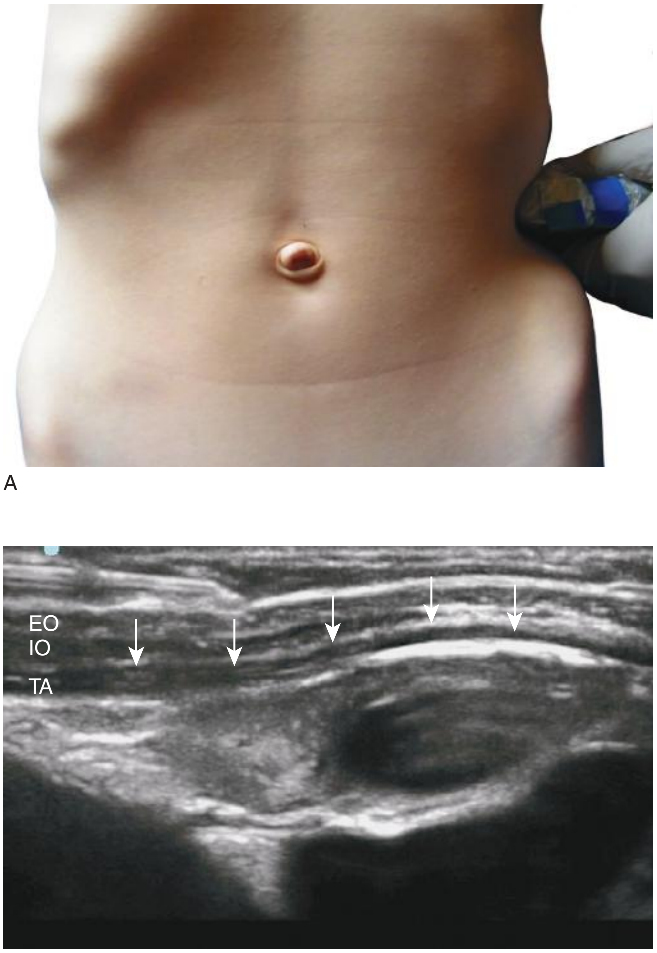


FIGURE 44–13. Transverse abdominis plane block: (**A**) probe position; (**B**) sonoanatomy. Arrows indicate TAP plane between transverse abdominis (TA); internal oblique muscles (IO); and external oblique (EO).

Penile Nerve

A penile nerve block is indicated for circumcision and distal hypospadias repair (where a caudal block is contraindicated). The sensory innervation of the penis is derived from the pudendal nerve. The pudendal nerve give rise to the dorsal nerves of the penis; these are accompanied by vessels medially as they enter the subpubic space at the level of the symphysis pubis before travelling distally to supply sensation to the shaft of the penis. The two nerves and their accompanying vessels are separated from one another by the suspensory ligament of the penis, hence the requirement for a bilateral approach. The subpubic space is roofed by Scarpa's fascia, a deep membranous continuation of the superficial abdominal fascia. A US-guided technique has been described but did not improve on the efficacy of the landmark-based technique. Epinephrine-containing solutions and ropivacaine, with its intrinsic vasoconstrictive properties, should not be used for penile nerve blocks.

Technique The subpubic approach requires the penis to be gently retracted downward to make the Scarpa's fascia taut. Just below the symphysis pubis, a needle is inserted 5–10 mm lateral to the midline and advanced slightly caudally until a "pop" is felt as the needle enters the fascial compartment bounded superficially by Scarpa's fascia. Depth varies from 5–30 mm and is independent of both the age and weight of the child. After careful aspiration, 0.1 mL/kg of plain local anesthetic is injected (to a maximum of 5 mL). The injection is then repeated on the other side of the midline. Some anesthesiologists recommend infiltrating the ventral aspect of the shaft of the penis for a more reliable block.

An alternative approach is to place a subcutaneous ring block around the base of the penile shaft. Although a simpler technique, it is associated with a higher incidence of inadequate postoperative pain relief.[50]

Complications The most feared complication associated with penile nerve block is hematoma formation.

Thoracic Paravertebral Space

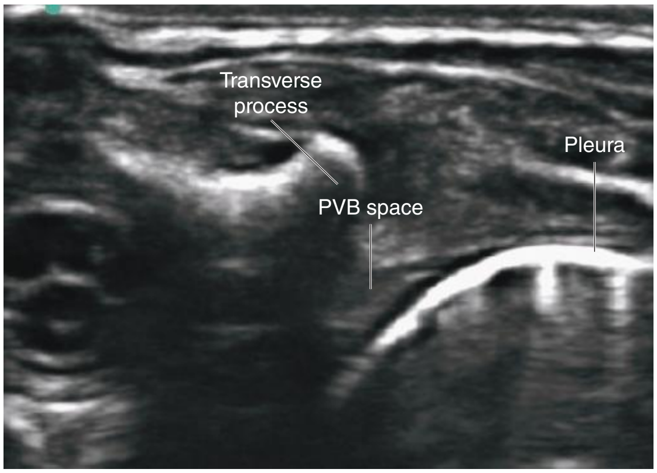
Thoracic paravertebral blocks should be performed only by specialist pediatric regional anesthesiologists. Both single-injection and catheter techniques have been described.[51] Indications for this block include postoperative thoracotomy pain, sternotomy, and unilateral abdominal surgery (eg, open splenectomy, nephrectomy).[52] Contraindications for this technique include severe coagulopathy, local infection, previous ipsilateral thoracic surgery (a relative contraindication), and previous total pleurectomy, as local anesthetic will not stay within the paravertebral space. Empyema or localized tumor near the injection site should be carefully considered to avoid seeding malignant cells or infection. An 18-gauge pediatric (50-mm length with 5-mm markings) epidural kit is suitable for all pediatric patients, except for infants and neonates, for whom a 19-gauge kit is preferred.

Anatomy The thoracic paravertebral space is wedge shaped. The base of the wedge is formed by the vertebral body and intervertebral discs. Posteriorly, it is bound by the costotransverse ligament; anterolaterally, it is bordered by parietal pleura. The costotransverse ligament is attached from the inferior edge of the transverse process to the superior edge of the rib tubercle. Laterally, it is continuous with the internal intercostal membrane (the aponeurosis of the internal intercostal muscle). The paravertebral space is filled with fatty tissue, through which the intercostal nerves and vessels, dorsal rami, rami communicantes, and sympathetic chain pass. The paravertebral space is connected laterally to the intercostal space and medially to the epidural space. The paravertebral space is limited inferiorly at T12 by the origin of the psoas major muscle.

Technique The patient is positioned in the lateral decubitus position in the neutral position, with the operative side uppermost; for bilateral blocks, the patient is positioned prone. Needle insertion should be at the level of T4 for sternotomy (a bilateral block is required), T6 for thoracotomy, T9 for renal surgery, and T12 and L1 for inguinal surgery. The needle point is typically positioned 1–2 cm lateral to the midline or equivalent to the interspinous process distance of the patient. The depth to the paravertebral space is estimated as 20 + (0.5 × weight in kg) mm. The needle is inserted through the skin, and the stylet is removed. A syringe of saline is attached for assessment of loss of resistance. The needle is advanced until the transverse process is contacted. At this point, the needle is advanced 1 cm past the transverse process. Alternatively, the syringe is advanced until the loss of resistance is appreciated. A bolus of 0.3–0.5 mL/kg of 0.25% bupivacaine is injected. The same technique can be used to insert a paravertebral catheter for continuous infusion.

Ultrasound-Guided Technique The patient is positioned as for the landmark-based technique. The probe is placed in a transverse plane over the spinous process at the desired level of needle insertion. The level is easily determined by counting down from C7 (the vertebra prominens). The probe is slid laterally to identify the transverse process and then moved caudad, between the transverse processes, to visualize the paravertebral space. The pleura is readily identifiable moving with respiration; superficial to this, forming the posterior border of the paravertebral space, is the internal intercostal membrane (Figure 44–14).

A



B

FIGURE 44–14. Thoracic paravertebral block: (**A**) probe position; (**B**) sonoanatomy.

An in-plane lateral-to-medial needling technique is employed, which requires excellent needle visualization skills, as the needle is being directed toward the spinal cord. A "pop" is seen and felt as the needle penetrates the membrane.[53,54] Local anesthetic spread caudad and cephalad can be assessed by scanning in a paramedian longitudinal plane. In neonates, it may be possible to see spread into the epidural space.

Complications The potential complications of this block are serious and include pneumothorax. As such, this block should be performed only by or under the supervision of a pediatric regional anesthesiologist. Other complications include hypotension (4.6% of cases), vascular puncture, and inadvertent epidural or intrathecal injection.

SUMMARY

Peripheral nerve blocks can be performed with ease in children and adolescents. Adequate knowledge of the anatomy of the area along with appropriate indications and knowledge of complications facilitate the use of peripheral nerve blocks in children. The fear of the use of peripheral nerve blocks in children under general anesthesia is not unfounded, but US guidance may make complications even less frequent than reported with current methods. With time, US-guided approaches will become the gold standard of regional anesthesia techniques.

CHAPTER 45

Acute and Chronic Pain Management in Children

Rishi M. Diwan

1. ACUTE PAIN MANAGEMENT

INTRODUCTION

The treatment and alleviation of pain constitute a basic human right that exists regardless of age.[1,2] Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage.[3] Previous experience and management of pain, even from very early stages in life, alter the responses and behavior toward further "painful" experiences and events. Hence, no two people experience pain the same way, which adds to the complexity of the management of pain.

Unfortunately, even when pain is obvious, children frequently receive no or inadequate treatment for pain and painful procedures. The newborn and critically ill child are especially vulnerable to receiving no treatment or undertreatment.[4,5] The conventional notion that children neither respond to nor remember painful experiences to the same degree that adults do is inaccurate. Many of the nerve pathways essential for the transmission and perception of pain are present and functioning by 24–29 weeks of gestation.[6,7] Research in newborn animals has revealed that failure to provide analgesia for pain results in "rewiring" of the nerve pathways responsible for pain transmission in the dorsal horn of the spinal cord, resulting in increased pain perception of *future* painful insults. This confirms human newborn research that found that the failure to provide anesthesia or analgesia for newborn circumcision resulted not only in short-term physiologic perturbations but also in longer-term behavioral changes.[8,9]

Nurses are traditionally taught or cautioned to be wary of physicians' orders and patients' requests for pain management, as well. The most common prescription order for potent analgesics, "to give as needed" (*pro re nata*, PRN), in reality means "to give as infrequently as possible." The PRN order also means that either the patient must know or remember to ask for pain medication or the nurse must be able to identify when a patient is in pain. Neither requirement may be met by children in pain. Children less than 3 years of age and critically ill children may be unable to adequately verbalize when they are in pain or where they hurt. Moreover, they may be afraid to report their pain. Several studies have documented the inability of nurses, physicians, and parents/guardians to correctly identify and treat pain, even in postoperative pediatric patients.

Societal fears of opioid addiction and lack of advocacy are also causal factors in the undertreatment of pediatric pain. Unlike adult patients, pain management in children is often dependent on the ability of parents/guardians to recognize and assess pain and on their decision whether to treat or not. Parental misconceptions concerning pain assessment and pain management may therefore also result in inadequate pain treatment. Even in hospitalized patients, most of the pain that children experience is managed by their parents/guardians. Parents/guardians may fail to report pain either because they are unable to assess it or are afraid of the consequences of pain therapy. In one study, false beliefs about addiction and the proper use of acetaminophen and other analgesics resulted in the failure to provide analgesia to children.[10] In another, the belief that pain was useful or that repeated doses of analgesics lead to medication underperformance resulted in the failure of the parents/guardians to provide or ask for prescribed analgesics to treat their children's pain.[11] Parental/guardian education is therefore essential if children are to be adequately treated for pain.

All of these factors make children an extremely vulnerable group. Fortunately, the past 25 years have seen substantial advances in research and interest in pediatric pain management and in the development of pediatric pain services, primarily under the direction of pediatric anesthesiologists. Pain service teams provide pain management for acute, postoperative, terminal, neuropathic, and chronic pain. Nevertheless, the assessment and treatment of pain in children are important aspects of pediatric care, regardless of who provides it. Failure to provide adequate control of pain amounts to substandard and unethical medical practice.

PAIN ASSESSMENT

The perception of pain is a subjective, conscious experience; operationally, it can be defined as "what the patient says hurts" and existing "when the patient says it does." Infants, preverbal children, and children between the ages of 2 and 7 years may be unable to describe their pain or their subjective experiences. This has led many to conclude incorrectly that children do not experience pain in the same way that adults do. Clearly, children do not have to know (or be able to express) the meaning of an experience to have an experience. Therefore, because pain is essentially a subjective experience, it is becoming increasingly clear that the child's perspective of pain is an indispensable facet of pediatric pain management and an essential element in the specialized study of childhood pain. Sometimes there is an overreliance on objective assessments of pain, whether from a healthcare professional or parental/guardian assessment. This objective assessment, though sometimes important, should remain only a minor partner in the assessment and management of pain, as objective assessments are also subject to bias and preconceived notions. Indeed, pain assessment and management are interdependent, and one is essentially useless without the other. The goal of pain assessment is to provide accurate data about the location and intensity of pain, as well as the effectiveness of measures used to alleviate or eradicate it.

Instruments currently exist to assess pain in children of all ages.[8,12–18] Indeed, the sensitivity and specificity of these instruments have been widely debated and have resulted in a plethora of studies to validate their reliability and validity. The most commonly used instruments measure the quality and intensity of pain and are "self-report measures" that make use of pictures or word descriptors to describe pain. Pain intensity or severity can be measured in children as young as 3 years of age by using either the Oucher scale (developed by Judith E. Beyer, RN, PhD; Antonia M. Villarreal, RN, PhD; and Mary J. Denyes, RN, PhD)—a two-part scale including both a numeric scale (from 0 to 100) and a photographic scale of six photographs of a young child's face expressing increasing degrees of discomfort—or a visual analog scale—a 10-cm line with a distraught, crying face at one end and a smiling face at the other. The visual analog scale has been validated by both sex and race. In our practice, we use the six-face Wong-Baker FACES Pain Rating Scale (developed by Dr. Donna Wong and Connie M. Baker), primarily because of its simplicity (Figure 45–1).[16] This scale is attached to the vital sign record, and nurses are instructed to use it or a more age-appropriate self-report measure whenever vital signs are taken.

Clinical Pearl

- Regular assessment using appropriate pain assessment tools, involving the patient and carers in decision making, and being as flexible as possible to the patient's needs all play a vital role in achieving a successful outcome.

Pain assessment in preverbal children poses challenges as they are unable to self-report. There are many pain assessment tools available in this age group, but none are ideal. The CRIES[19]

FIGURE 45–1. The six-face Wong-Baker FACES Pain Rating Scale. (Wong-Baker FACES Foundation (2015). Wong-Baker FACES® Pain Rating Scale. Retrieved January 28, 2017 with permission from http://www.WongBakerFACES.or.)

TABLE 45–1. CRIES pain scale for babies from 32 weeks' gestational age.

	0	1	2
Crying Characteristic cry of pain is high pitched	No cry or cry that is not high pitched	High-pitched cry but infant is consolable	High-pitched cry and infant is inconsolable
Requires O_2 to maintain SaO_2 > 95 Consider other changes in oxygenation	No	Requires O_2 < 30%	Requires O_2 > 30%
Increased vital signs Take BP last as this may cause difficulty with other assessments	HR and BP +/– 10% of baseline	10%–20% increase in BP or HR	> 20% increase in HR or BP
Expression Grimace characterized by brow bulge, eyes shut, open mouth, deepening nasolabial furrow	Neutral	Grimace	Grimace/grunt
Sleeplessness Based on state during the hour preceding the assessment	No	Wakes frequently	Constantly awake

Instructions: Each of the five categories is scored 0, 1, or 2, resulting in total score between 0 and 10.

pain score is frequently used to score pain in neonates (Table 45–1). Children with developmental delay, complex needs, and or in intensive care need special pain assessment tools to monitor pain. Most such tools incorporate physiological parameters for stress (cardiac, respiratory, and endocrine) with behavioral changes associated with pain (facial expressions, crying, body and limb movements).[20] A separate pain assessment scale called the Paediatric Pain Profile (PPP)[21] is available at our institution for use in children with complex needs. It is used primarily by parents/guardians to measure their child's pain and incorporates scoring of the aforementioned behavioral changes. Irrespective of the pain assessment tool used in these patient groups, it is important that healthcare professionals understand what causes pain, appreciate that pediatric patients perceive pain, and have a variety of assessment methods and treatments in their armamentarium to achieve effective pain control.

PAIN MANAGEMENT

Acute pediatric pain management is increasingly characterized by a multimodal or "balanced" approach in which smaller doses of opioid and nonopioid analgesics, such as nonsteroidal anti-inflammatory drugs (NSAIDs), local anesthetics, N-methyl-D-aspartate (NMDA) antagonists, and α_2-adrenergic agonists, are combined to maximize pain control and minimize drug-induced adverse side effects. Pain management also includes management of both patient and parental/guardian expectations and being knowledgeable, open, and frank about what to expect during the course of the postoperative and rehabilitation periods. It should be recognized that certain procedures "hurt" more than others and that, in spite of our best efforts, it is not always possible to achieve "no pain," although that should always be the aim. At the same time, preoperative discussion of the various analgesic strategies available and reassurance that the patient "will be looked after" go a long way to achieving a satisfactory outcome for all concerned. In addition, a multimodal approach utilizes nonpharmacological, complementary, and alternative medicine therapies, as well. These techniques include distraction, guided imagery, transcutaneous nerve stimulation, acupuncture, therapeutic massage, among others.[22]

Clinical Pearls

- The aim of acute pain management is providing a comfortable/pain-free perioperative period in order to facilitate early ambulation and rehabilitation.
- Preoperative discussions with the patient and his or her parents/guardians detailing the achievable outcome, expected course, and various available pain management modalities play an important role in achieving a satisfactory outcome for all concerned.
- A multimodal approach to pain management achieves the best results.
- If possible, regional anesthesia/analgesia should be part and parcel of any multimodal analgesia regime.

Clinical Pearl

Alternative medicine pain therapy:

- Distraction
- Guided imagery
- Transcutaneous nerve stimulation
- Acupuncture
- Therapeutic massage

Procedural pain is often a forgotten and ignored aspect of pain management in children admitted to hospital. Various interventions and procedures, some of which are done repeatedly, may inflict pain or are perceived as painful by an anxious child (eg, cannulation, phlebotomy, lumbar puncture, and wound dressing and cleaning). It is essential to practice how to explain procedures and how to prepare and reassure the child and parents/guardians. Simple techniques such as local anesthetic creams and play/distraction therapy can help in many situations. Some patients may also need formal psychological intervention and support or pharmacological aids such as sedation or nitrous oxide (N_2O), all of which require time and planning. Lastly, if conscious sedation or N_2O is required, adequate monitoring and emergency equipment, including oxygen, suction, and appropriate personnel, should be immediately available.

Pain management strategies for day case surgery should include local anesthetic infiltration, regional blocks, simple analgesics (eg, acetominophen/paracetamol, NSAIDS, and "milder" opioids such as codeine or tramadol, if necessary). "Strong" opioids should be avoided, although they are not contraindicated. Ultrasound-guided regional anesthesia is increasing in popularity, providing safer and more effective regional anesthesia.

Clinical Pearl

Pain management strategies for day case surgery:

- Local anesthetic infiltration
- Regional anesthesia
- Nonopioid analgesics (acetaminophen, NSAIDs)
- Mild opioids (codeine, tramadol) when necessary
- More potent opioids should be avoided when possible but are not contraindicated

Anesthesiologists must work closely with surgical colleagues to identify appropriate day case surgeries and develop patient care pathways with standard analgesia management plans for specific procedures.

For major surgery, in addition to all the above mentioned analgesics, opioid and/or local anesthetic infusions may be necessary. These can be complemented by other treatment modalities including ketamine, clonidine, or diazepam for muscle spasm after orthopedic surgeries; gabapentin for acute pain; intraoperative magnesium; and the addition of dexamethasone systemically or to a local anesthetic for nerve blocks.

Analgesics with Antipyretic Activity or Nonopioid ("Weaker") Analgesics

The "weaker" or milder analgesics with antipyretic activity, of which acetaminophen, ibuprofen, naproxen, and diclofenac are the classic examples, make up a heterogeneous group of NSAIDs that are nonopioid analgesics (Table 45–2).[23–25] They provide pain relief primarily by blocking peripheral and central prostaglandin production by inhibiting cyclooxygenase types I and II. These analgesic agents are primarily administered enterally via the oral or rectal route and are particularly useful for inflammatory, bone, and rheumatic pain. Parenterally administered acetaminophen and NSAIDs, such as ketorolac, are available for use in children in whom the oral or rectal routes of administration are not possible.[26] Unfortunately, regardless of dose, the nonopioid analgesics reach a "ceiling effect," above which pain cannot be relieved by these drugs alone. Because of this, these weaker analgesics are considered the basic building blocks in a multimodal therapeutic approach and are often administered in combination forms with opioids such as codeine, oxycodone, hydrocodone, or tramadol. Aspirin has been largely abandoned in pediatric practice because of its possible role in Reye syndrome, its effects on platelet function, and its gastric irritant properties.

Clinical Pearls

- The nonopioid analgesics have a "ceiling effect," above which pain cannot be relieved by these drugs alone, regardless of dose.
- Nonopioid analgesics are considered the basic building blocks in a multimodal therapeutic approach and are often administered in combination forms with opioids such as codeine, oxycodone, hydrocodone, or tramadol.

The most commonly used nonopioid analgesic in pediatric practice remains acetaminophen. Unlike NSAIDs, acetaminophen works primarily centrally and has minimal, if any, anti-inflammatory activity. When administered in normal doses (10–15 mg · kg^{-1}, PO), acetaminophen is extremely safe and has very few serious side effects. It is an antipyretic and, like all enterally administered NSAIDs, takes about 30 minutes to provide effective analgesia. Several investigators have reported that when administered rectally, acetaminophen should be given in significantly higher doses than previous recommendations had suggested.[27,28] However this author does not use acetaminophen loading doses when the drug is administered rectally. Regardless of route of delivery, to prevent hepatotoxicity, the daily maximum acetaminophen dose in the preterm neonate, term neonate, and older child is 30, 60, and 80 mg/kg, respectively (Table 45–3). The maximum adult dose is 4 g/day.

The discovery of at least two cyclooxygenase (COX) isoenzymes, referred to as COX-1 and COX-2, has increased our knowledge of NSAIDs.[29–32] These two COX isoenzymes share structural and enzymatic similarities but are uniquely regulated at the molecular level and may be distinguished by their functions. Protective prostaglandins, which preserve the integrity of the stomach lining and maintain normal renal function in a compromised kidney, are synthesized by COX-1.[29,30,33] COX-2 is an inducible isoform. The inducing stimuli include proinflammatory cytokines and growth factors, implying a role for COX-2 in both inflammation and control of cell growth. In

TABLE 45–2. Dosing guidelines for commonly used nonopioid analgesics *(Institutional or national guidelines may vary.)*

	Premature Neonates (32–36 weeks Postmenstrual Age[a])	Term Neonates (> 36–44 weeks Postmenstrual Age[a])	Infants and Children (> 44 weeks Postmenstrual Age[a] and up to 50 kg)	> 12 Years (and Weight > 50 kg[b])
Acetaminophen (Paracetamol)				
Acetaminophen (Paracetamol)	15 mg/kg PO/PR every 8 hours (max 60 mg/kg/day)	15 mg/kg PO/PR every 6 hours (max 60 mg/kg/day)	15–20 mg/kg PO/PR[bc] every 4–6 hours (max 90 mg/kg/day)	1g PO/PR every 4–6 hours (max 4 g/day)
IV acetaminophen	7.5 mg/kg IV every 8 hours (max 25 mg/kg/day)	7.5 mg/kg IV every 6 hours (max 30 mg/kg/day)	15 mg/kg IV[b] every 6 hours (max 60mg/kg/day)	15 mg/kg IV (maximum 1 g) every 6 hours
Nonsteroidal anti-inflammatory drugs (NSAIDs) Prescribe one drug only.				
Ibuprofen	Not recommended	Not recommended	Less than 3 months of age: 5 mg/kg PO every 8 hours From 3 months of age: 10 mg/kg PO (maximum 400 mg) every 8 hours (max 30 mg/kg/day)	400 mg PO every 8 hours
Diclofenac	Not recommended	Not recommended	From 6 months of age: 1 mg/kg PO/PR every 8 hours	50 mg PO/PR every 8 hours
Naproxen	Not recommended	Not recommended	5 mg/kg every 12 hours	5mg/kg every 12 hours (max 1g/day)

[a]Postmenstrual age in weeks is the gestational age plus the postnatal age (time elapsed after birth).

[b]Doses based on weight in obese patients or based on age in underweight patients may need to be reduced to avoid overdosage.

[c]A higher dose of acetaminophen 20 mg/kg PO/PR every 6 hours may be used when pain is not controlled with the standard dose (15 mg/kg) when no contraindications exist. This dose should be reviewed every 24 hours. Loading doses are not recommended in order to minimize the potential for error.

addition to the induction of COX-2 in inflammatory lesions, COX-2 is present constitutively in the brain and spinal cord, where it may be involved in nerve transmission, particularly for pain and fever. Prostaglandins made by COX-2 are also important in ovulation and in the birth process.[28,29,31] The discovery of COX-2 has made possible the design of drugs that reduce inflammation without removing the protective prostaglandins in the stomach and kidney made by COX-1. In fact, developing a more specific COX-2 inhibitor has been an important goal of much drug research because this class of drug has all of the anti-inflammatory and analgesic properties that one desires in a drug with none of the gastrointestinal and antiplatelet side effects. Unfortunately, the growing controversy regarding the potential adverse cardiovascular risks of the prolonged use of COX-2 inhibitors has dampened much of the enthusiasm for these drugs and has led to the removal of rofecoxib from the market by its manufacturer.[34,35] Other NSAIDs, especially diclofenac, are now facing similar scrutiny. Many orthopedic surgeons are also concerned about the negative effect of all NSAIDs on bone growth and healing.[36–38] While some pediatric orthopedic surgeons have recommended that these drugs not be used in their patients in the postoperative period, it is this

TABLE 45–3. Opioid analgesic initial dosage guidelines *(institutional or national guidelines may vary.)*

Drug	Equianalgesic Dose (mg) IV, IM, SC	Equianalgesic Dose (mg) Oral	Usual Starting IV Dose and Interval < 50 kg	Usual Starting IV Dose and Interval > 50 kg	IV/Oral Ratio	Usual Starting Oral Dose and Interval < 50 kg	Usual Starting Oral Dose and Interval > 50 kg
Codeine	120	200	NR	NR	1:2	0.5–1[a] mg/kg every 4-6 hours	0.5–1[a] mg/kg every 4–6 hours
Fentanyl	0.1	NA[b]	Bolus: 0.5–1 mcg/kg, 0.5–2 h (max 50 mcg) *NCA/PCA (drug concentration: 1 mcg/kg/mL, max 50 mcg/mL)* **NCA**: Bolus: 0.5–1 mcg/kg, 30 min–1 h; infusion: 0.5–1 mcg/kg/h **PCA**: Bolus: 0.5 mcg/kg, 10 min–1 h; infusion: 0.5–1 mcg/kg/h		NA	NA	NA
Hydrocodone	NA	10–20	NA	NA	NA	0.1 mg/kg every 3–4 hours	5–10 mg every 3–4 hours
Hydromorphone	1.5–2	3–5[c]	Bolus: 0.02 mg/kg, 0.5–2 h; infusion: 0.004 mg/kg/h	Bolus: 1 mg, 0.5–2 h; infusion: 0.3 mg/h	1:2	0.03–0.08 mg/kg every 4 hours	2–4 mg every 4 hours
Methadone	10	10–20	0.1 mg/kg every 4–8 hours	5–10 mg every 4–8 hours	1:2	0.2 mg/kg every 4–8 hours	10 mg every 4–8 hours
Morphine	10	30–50	Bolus: 0.03–0.1 mg/kg, 0.5–2 h (max 10 mg) *NCA/PCA(drug concentration 20mcg/kg/mL, max 1mg/mL)*[d] **NCA**: Bolus: 20 mcg/kg, 15 min–1 h; infusion: 20 mcg/kg/h **PCA**: Bolus: 20 mcg/kg (max 1 mg), 5min; infusion: 4 mcg/kg/h		1:2–3	0.2–0.3 mg/kg every 4–6 hours **Sustained release:** 0.4–0.5 mg/kg every 8–12 hours	15 mg/kg every 4–6 hours **Sustained release:** 30 mg every 8–12 hours
Oxycodone	NA	10–20	NA	NA	NA	0.1 mg/kg every 3–4 hours	5–10 mg every 3–4 hours[e]

[a]Due to the highlighted problem with "ultra-rapid metabolizers," it is best to start with a dose of 0.5 mg/kg.

[b]Oral transmucosal route available: dose 10–15 mcg/kg.

[c]The equianalgesic oral dose and parenteral/oral dose ratio are not well established.

[d]For neonates and infants younger than 13 weeks, the drug concentration is to be halved: bolus 5 mcg/kg,1 h; infusion 5–10 mcg/kg/h.

[e]A sustained-release preparation is available.

author's view that in spite of the controversies, NSAIDs remain effective and useful drugs in pediatric acute pain management when used wisely and for short duration.

Opioid Drug Selection

Many factors are considered when deciding which is the appropriate opioid analgesic to administer to a pediatric patient in pain. These include pain intensity, patient age, coexisting disease, potential drug interactions, treatment history, physician preference, patient preference, and route of administration. Some opioids are preferred over others, and some may be unavailable depending on institution, country, or continent, for reasons not entirely understood. The idea that some opioids are "weak" (eg, codeine) and others "strong" (eg, morphine) is outdated. All are capable of treating pain regardless of intensity if the dose is adjusted appropriately (Table 45–4). At equipotent doses, most opioids have similar effects and side effects. Meperidine (pethidine) at an equianalgesic dose has the same side effect profile as morphine;[39] however, it is no longer commonly prescribed.

Commonly Used Oral Opioids: Codeine, Oxycodone, Hydrocodone, Morphine, and Tramadol

Codeine, oxycodone, and hydrocodone are opioids that are frequently used to treat pain in children and adults, particularly less severe pain and when patients are being converted from parenteral to enteral opioids (see Table 45–3). Morphine is commonly used in regimens for chronic pain (eg, cancer). Codeine, oxycodone, and hydrocodone are most commonly administered in oral form, usually in combination with acetaminophen or aspirin.[40] Unfortunately, very few, if any, pharmacokinetic or dynamic studies have been performed in children, and most dosing guidelines are anecdotally based. In equipotent doses, codeine, oxycodone, hydrocodone, and morphine are equal both as analgesics and respiratory depressants (see Table 45–3). In addition, these drugs share common effects on the central nervous system with other opioids, including sedation, respiratory depression, and stimulation of the chemoreceptor trigger zone in the brain stem, the latter particularly the case for codeine. There are fewer nausea and vomiting side effects with oxycodone and hydrocodone. Codeine, hydrocodone, and oxycodone have a bioavailability of approximately 60% after oral ingestion. The analgesic effects occur as early as 20 minutes after ingestion and reach a maximum after 60–120 minutes. The plasma half-life of elimination is 2.5–4 hours. Codeine undergoes nearly complete metabolism in the liver before its final excretion in urine. Approximately 10% of codeine is metabolized into morphine (CYP2D6), and it is this 10% that is responsible for codeine's analgesic effect. Interestingly, approximately 10% of the population and most newborn infants cannot metabolize codeine into morphine, and in these patients, codeine produces little, if any, analgesia.

Codeine needs special mention, as its use has come under increased scrutiny at the time of writing this chapter. A few instances of fatalities and life-threatening episodes of respiratory depression have been reported in children who are cytochrome P450 CYP2D6 "ultra-rapid metabolizers" and were given codeine after tonsillectomy or adenoidectomy in the treatment of obstructive sleep apnea.[41,42] The CYP2D6 enzyme is subject to genetic polymorphism. Having multiple gene copies, some patients metabolize codeine more rapidly (and are thus termed "ultra-rapid metabolizers") and therefore have an increased risk of experiencing morphine toxicity, ie, respiratory depression. The prevalence of this varies with ethnicity, from as low as 0%–2% in Asians to as high as 10%–16% in Ethiopians and Saudi Arabians.[43]

The current position on codeine use is as follows. The U.S. Federal Drug Administration (FDA),[44] the Pharmacovigilance Risk Assessment Committee (PRAC) of the European Medicines Agency (EMA),[45] and the U.K. Medicines and Healthcare Products Regulatory Agency (MHRA) have recommended restrictions on the use of codeine in children. These include the following:

- Restrict the use of codeine to children over 12 years of age (EMA and MHRA).
- Avoid codeine use in patients under 18 years of age who are undergoing tonsillectomy or adenoidectomy, especially for obstructive sleep apnea (EMA and FDA).

TABLE 45–4. Maximum local anesthetic dosing guidelines.

Drug	Dose mg/kg Without Epinephrine	Dose mg/kg with Epinephrine	Duration in Hours	Contra-Indications	Comments
Bupivacaine[a]	2.5	3	3–6		Reduce dose by 50% in neonates
Chloroprocaine[b]	8	10	1	Plasma cholinesterase deficiency	Short-acting, rapid metabolism, useful in neonates and possibly patients with seizures or liver disease
Lidocaine	5	7	1		
Ropivacaine[c]	3	never mixed	3–6		Less cardiotoxicity than bupivacaine

[a]When given by epidural continuous infusion: 0.2–0.4 mg/kg/h.
[b]In neonatal epidural continuous infusion: 10–15 mg/kg/h.
[c]Infusion rates is 0.5 mg/kg for pediatric patients older than 4-6 months of age.

- In all other cases, use codeine only if required. It should be prescribed on an "as-needed basis" only, with the dose restricted to 0.5 mg/kg (maximum 30 mg) every 6 hours, and limited in treatment duration.
- Patient receiving codeine should be closely monitored for respiratory depression; nurses and parents/guardians should be advised to watch for signs of morphine overdose.

For many years codeine has been more or less universally used in pediatric practice for the relief of moderate pain, as a step-down medication, and as a take-home medication on discharge. Possible dilemmas include the following:

- Due to its widespread use, various "child-friendly" preparations and formulations exist to provide versatile delivery systems for all ages. However, recent developments may have led to discouraging the development of versatile formulations of other similar-"strength" opioids. Thus, many countries are left with limited or no suitable alternatives to codeine.
- Licensing and use of alternative drugs is lagging in certain countries. For instance, tramadol is not licensed in the U.K. for patients below 12 years of age.
- There are few data to determine if any the available alternatives are as effective as codeine.[46]
- Although morphine is the most logical alternative to codeine, issues of concern include controlled drug regulations in certain countries, institutional and local practices, and the reluctance of some healthcare professionals to prescribe oral morphine due to social concerns and the perceived potential for abuse.
- For institutions and countries where other safe, effective, and versatile formulations of codeine alternatives, such as tramadol, oxycodone, and buprenorphine, are available, local interim guidelines may need to be agreed upon (with or without the continued use of codeine) in order to continue to provide safe and effective analgesia to the pediatric population.
- These issues may encourage pharmaceutical companies to develop more "child-friendly" analgesic products and encourage similar research of other opioids to validate their efficacy in children.
- These concerns may also lead to the development of commercially viable patient genotyping.

Like codeine and oxycodone, morphine is very effective when given orally, but only about 40% of an oral dose of morphine reaches the systemic circulation. In the past, this led many to inappropriately conclude that morphine is ineffective when administered orally; instead, the lack of efficacy was simply the result of inadequate PO dosing. Therefore, when converting a patient's required intravenous morphine dose to an oral maintenance dose, one must multiply the intravenous dose by a factor of 2 to 3.

Clinical Pearl

- When converting a patient's required intravenous morphine dose to an oral maintenance dose, multiply the intravenous dose by a factor of 2 to 3.

Whereas oral morphine is prescribed alone, oral codeine, hydrocodone, oxycodone, and tramadol are usually prescribed in combination with either acetaminophen or aspirin. Acetaminophen potentiates the analgesia produced by codeine (and other opioids) and allows the use of a smaller dose of the opioid with satisfactory analgesia. In all "combination preparations," beware of inadvertently administering a hepatotoxic dose of acetaminophen when increasing opioid doses for uncontrolled pain.[47] Because of this concern, it is preferred to prescribe the opioid and acetaminophen (or ibuprofen) separately.

Although it is an effective analgesic when administered parenterally, intramuscular codeine has no advantage over morphine or any other opioid; hence, its use is discouraged. Similar to codeine, tramadol is used to treat moderate to severe pain. Although tramadol is often categorized as a μ-receptor agonist, it has multiple proposed mechanisms of action. It is also a serotonin releaser, a norepinephrine reuptake inhibitor, and an NMDA receptor antagonist. The licensing age of tramadol varies by country, but it has been studied in children as young as 1 year.[48] Tramadol is prescribed in a dose of 1–2 mg/kg every 6 hours to a maximum of 400 mg/day (in 4 divided doses for patients over 50 kg).

Hydrocodone is prescribed in a dose of 0.05–0.1 mg/kg. An elixir is available as 2.5 mg/5 mL combined with acetaminophen 167 mg/5 mL. As a tablet, it is available in hydrocodone doses between 2.5 mg and 10 mg, combined with 500–650 mg acetaminophen. Oxycodone is prescribed in a dose of 0.05–0.1 mg/kg. Unfortunately, an elixir is not available in most pharmacies. When it is, it is prepared as either 1 mg/mL *or* 20 mg/mL. This can obviously result in catastrophic dispensing errors. In tablet form, oxycodone is commonly available as a 5-mg tablet or as Tylox (500 mg acetaminophen and 5 mg oxycodone) or Percocet (325 mg acetaminophen and 5 mg oxycodone).

Oxycodone is also available without acetaminophen in a sustained-release tablet for use in chronic pain. Like many other timed-release tablets, it must *not* be crushed and therefore cannot be administered through a gastric tube. Breaking the tablet results in the immediate release of a huge amount of oxycodone. Like sustained-release morphine (see below), sustained-release oxycodone is only for use in opioid-tolerant patients with chronic pain, *not* for routine postoperative pain. Also, note that in patients with rapid gastrointestinal transit, sustained-release preparations may not be absorbed at all (liquid methadone may be an alternative).

Oral morphine is available as a liquid in various concentrations (as much as 20 mg/mL), a tablet (eg, MSIR [**m**orphine **s**ulfate **i**mmediate **r**elease], available in 15- and 30-mg tablets), and in a sustained-release preparation. Because it is so concentrated, the liquid is particularly easy to administer to children and severely debilitated patients. Indeed, in terminal patients who cannot swallow, liquid morphine provides analgesia when simply dropped into the patient's mouth.[40]

Patient- and Parent/Nurse-Controlled Analgesia

Among the many reasons for the undertreatment of pediatric pain is the lack of familiarity of physicians (and nurses) with appropriate drugs, drug dosing, and routes of administration. When drugs are given on demand (PRN), there is a lag between the time of the patient's request and the nurse's response and the preparation and administration of analgesia. In moderate to severe pain, around-the-clock administration interval administration (eg, q4h) is not always the answer either, however, because of the great individual variation in pain perception and opioid metabolism. Indeed, fixed doses and time intervals make little sense. Based on the pharmacokinetics of opioids, it should be clear that intravenous boluses of morphine may need to be given at intervals of 1–2 hours to avoid marked fluctuations in plasma drug levels.

Continuous intravenous infusions may provide steady analgesic levels, are preferable to intramuscular injections, and have been used with great safety and effectiveness in children. However, they are not a panacea because the perception and intensity of pain are not constant. For example, a postoperative patient may be very comfortable resting in bed and require little adjustment in pain management. But this same patient may experience excruciating pain when coughing, voiding, or getting out of bed. Thus, rational pain management requires some form of titration to effect whenever any opioid is administered. To give patients (in some cases nurses and, rarely, parents/guardians) some measure of control over pain therapy, demand analgesia, or patient-controlled analgesia (PCA), devices have been developed.[49,50] These devices are microprocessor-driven pumps with a button that the patient presses to self-administer a small dose of opioid.

PCA devices allow patients to administer small amounts of an analgesic whenever they feel a need for more pain relief. The opioid, usually morphine, hydromorphone, or fentanyl, is administered either intravenously or subcutaneously. The dosage of opioid (with or without background infusion), number of boluses per hour, and the time interval between boluses (the "lockout period") are programmed into the equipment by the pain service physician or nurse to allow maximum patient flexibility and a sense of control with minimal risk of overdosage. Generally, when older patients know that if they have severe pain, they can obtain relief immediately, many prefer dosing regimens that result in mild to moderate pain in exchange for fewer side effects such as nausea or pruritus. Typically, morphine is prescribed, 20 mcg/kg per bolus (or hydromorphone 3–4 mcg/kg/h or fentanyl 0.5 mcg/kg/h), with a 5- to 15-minute lockout interval between each bolus. Variations include larger or smaller boluses, shorter or longer time intervals, and varying background infusion; these tend to be based on institutional practice and preferences.

The PCA pump computer stores within its memory the number of boluses the patient has received as well as the number of attempts the patient has made to receive boluses. This allows the physician to evaluate how well the patient understands the use of the pump and provides information to program the pump more efficiently. Most PCA units allow low "background" continuous infusions (eg, morphine 2–30 mcg/kg/h, hydromorphone 3–4 mcg/kg/h, fentanyl 0.5-1 mcg/kg/h) in addition to self-administered boluses. A continuous background infusion is particularly useful at night and often provides more restful sleep by preventing the patient from awakening in pain. However, it also increases the potential for overdosage.[49–51] Although the adult literature on pain does not support the use of continuous background infusions, our experience has been that continuous infusions are essential for good pain management in the pediatric patient. Indeed, in our practice, we almost always use continuous background infusions when we prescribe PCAs or nurse-controlled analgesia (NCA).

PCA requires a patient with enough intelligence, manual dexterity, and strength to operate the pump. Thus, these devices were initially limited to adolescents, but the lower age limit in whom this treatment modality can be used continues to fall (currently around age 5–6 years). Contraindications to the use of PCA include inability to push the bolus button, inability to understand how to use the machine, and patient desire not to assume responsibility for his or her care.

In patients considered below "competent" age, neonates, toddlers, and patients with complex needs, the practice of allowing surrogates such as nurses to initiate a PCA bolus is called nurse-controlled analgesia (NCA). This is standard practice in our institution. It has been demonstrated that nurses and, in rare cases, parents can be empowered to initiate PCA boluses and to use this technology safely in children, even in those younger than 1 year of age, the incidence of common opioid-induced side effects being similar to that observed in older patients.[51] NCAs tend to have a slightly higher background infusion rate and longer lockout period than PCAs. For neonates and infants 1–3 months old, we use NCA morphine: a background infusion of 5 or 10 mcg/kg/h, respectively, with a bolus of 5 mcg/kg and a lockout of 60 minutes.

Interestingly, respiratory depression is very rare, but does occur, reinforcing the need for close monitoring and established nursing protocols. Difficulties with PCA include its increased cost, patient age limitations, and the bureaucratic obstacles (protocols, nurse education, storage arrangements) that must be overcome before its implementation.

Transmucosal, Intranasal, and Transdermal Fentanyl

Because fentanyl is extremely lipophilic, it can be readily absorbed across any biologic membrane, including the skin. Thus, it can be given painlessly by new, nonintravenous routes of drug administration, including the transmucosal (nose and mouth) and transdermal routes. The transmucosal route of fentanyl administration is extremely effective for acute pain relief. When given intranasally (2 mcg/kg), it produces rapid analgesia that is equivalent to intravenously administered fentanyl.[52]

Alternatively, fentanyl has been manufactured in a candy matrix (Actiq) attached to a plastic applicator (it looks like a lollipop) for transoral/transmucosal absorption. As the child sucks on the candy, fentanyl is absorbed across the buccal mucosa and is rapidly (over 10–20 minutes) absorbed into the systemic circulation.[53–58] If excessive sedation occurs, the fentanyl is removed from the child's mouth by the applicator. This method is more efficient than ordinary oral–gastric intestinal administration because transmucosal absorption bypasses the efficient first-pass hepatic metabolism of fentanyl that occurs after enteral absorption into the portal circulation. Actiq has been approved by the FDA for use in children for premedication before surgery and for procedure-related pain (eg, lumbar puncture, bone marrow aspiration).[59] It is also useful in the treatment of cancer pain and as a supplement to transdermal fentanyl.[60] When administered transmucosally, fentanyl is given in doses of 10–15 mcg/kg, is effective within 20 minutes, and lasts approximately 2 hours. Approximately 25%–33% of the given dose is absorbed. Thus, when administered in doses of 10–15 mcg/kg, blood levels equivalent to 3–5 mcg/kg IV fentanyl are achieved. The major side effect, nausea and vomiting, occurs in approximately 20%–33% of patients who receive it.[61]

The transdermal route is frequently used to administer chronically administered drugs, including scopolamine, clonidine, and nitroglycerin. Many factors, such as body site, skin temperature, skin damage, ethnic group, and age, affect the absorption of transdermally administered drugs. Placed in a selective semipermeable membrane patch, a reservoir of drug provides slow, steady-state absorption of drug across the skin. The patch is attached to the skin by a contact adhesive, which often causes skin irritation.

The use of transdermal fentanyl has revolutionized adult cancer pain management. As fentanyl is painlessly absorbed across the skin, a substantial amount is stored in the upper skin layers, which then acts as a secondary reservoir. The presence of a skin depot has several implications: it dampens the fluctuations of fentanyl effect, it needs to be reasonably filled before significant vascular absorption occurs, and it contributes to a prolonged residual fentanyl plasma concentration after patch removal. Indeed, the amount of fentanyl remaining within the system and skin depot after patch removal is substantial. At the end of a 24-hour period, approximately 30% of the total delivered dose from the patch remains in the skin depot. Thus, removing the patch does not stop the continued absorption of fentanyl into the body.[62]

Because of the long onset time, inability to rapidly adjust drug delivery, and long elimination half-life, the use of transdermal fentanyl for *acute* pain management is controversial. As stated above, the safety of this drug delivery system is compromised even further because fentanyl continues to be absorbed from the subcutaneous fat for almost 24 hours after the patch is removed. In fact, the use of this drug delivery system for acute pain has resulted in the death of an otherwise healthy patient. Transdermal fentanyl is generally reserved for patients with chronic pain (eg, cancer) and those who are opioid tolerant. Even when transdermal fentanyl is appropriate, the vehicle imposes its own constraints. The lowest-dose fentanyl "patch" delivers 25 mcg fentanyl per hour; the others deliver 50, 75, and 100 mcg of fentanyl per hour. Patches *cannot* be physically cut into smaller pieces to deliver less fentanyl. This often limits usefulness in patients with lower body weights, and, as with other opioids, this drug delivery system has neither been tested nor approved for use in children.

A new noninvasive method of transdermal PCA is on the horizon. Using iontophoresis (electrotransport), small doses of fentanyl (40 mcg) can be self-administered across the skin (E-Trans, Alza Corporation).[63] Transdermal PCA may offer logistic advantages for patients and nursing staff by eliminating the need for venous access, IV tubing, and specialized pumps.

Complications

Regardless of method of administration, all opioids produce common unwanted side effects, such as pruritus, nausea and vomiting, constipation, urinary retention, cognitive impairment, tolerance, and dependence.[64] Indeed, many patients suffer needlessly from agonizing pain because they would rather suffer pain than experience these opioid-induced side effects.[65] In addition, physicians are often reluctant to prescribe opioids because of these side effects and because of their fear of other less common, but more serious, side effects such as respiratory depression. Several clinical and laboratory studies have demonstrated that low-dose naloxone infusions (0.25–1 mcg/kg/h) can treat or prevent opioid-induced side effects without affecting the quality of analgesia or opioid requirements.[66,67]

Some opioids, when given concomitantly with selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors (MAOIs), or serotonin–norepinephrine reuptake inhibitors (SNRIs), have been associated with serotonin syndrome; these include fentanyl, oxycodone, hydrocodone, and tramadol.

Transition to Oral Medication

Successful transition from intravenous (or epidural) analgesics to oral medication depends on the clinician's ability to provide alternative therapy that is palatable, acceptable, and above all, equally effective in treating pain. There are many advantages in providing pain medication by the oral route. Enteral therapy consists of a less invasive route of drug administration and enables children to more rapidly return to their normal lives. Moreover, oral medications are easier and less expensive to deliver than IV and epidural drugs.

Certain criteria are essential for the successful transition to oral medication. Normal gastrointestinal function must be present before attempting enteral therapy. Thus, the child must be able to drink and/or eat (or have a functioning gastric tube). A child who is nauseated or vomits after eating will simply not tolerate oral analgesics. Second, severe pain is difficult, if not impossible, to control with oral analgesics alone. Therefore, oral analgesics should be reserved for the treatment of mild to moderate pain during the latter part of the recovery process. Assessment of the degree of pain and existing treatment modalities are steps that aid the transition process. Third, an oral formulation that is palatable and appropriate must be available. Finally, one must convert the current parenteral opioid dosing to a roughly equianalgesic oral dose.

This conversion is fairly straightforward even when patients are receiving multiple forms and doses of parenteral opioids. As a first step, convert the entire daily dose of administered opioids into IV morphine equivalents (Example 1). Then, convert that morphine dose to an equianalgesic dose of oral morphine (1:2) or other oral opioid, if desired. This formula actually underestimates the bioequivalence of the drugs but is used to minimize the risk of overdose during the transition.

Example 1

A 5-year-old, 20-kg boy was the victim of a motor vehicle accident and sustained a pelvic fracture. He has been on IV PCA morphine for 2 weeks and will be discharged home for further outpatient therapy and recovery. He receives morphine 2 mg/h and averages one bolus of 0.5 mg morphine every hour. He cannot swallow pills.

Step 1: 2 mg/h for 24 hours = 48 mg morphine/24 hours
Step 2: 0.5 mg/bolus for 24 boluses/day = 12 mg morphine
Step 3: Total 24-hour morphine = 48 mg + 12 mg = 60 mg
Step 4: 60 mg IV morphine = 120 mg PO morphine (actually, this represents a 25%–40% decrease in bioequivalence)
Step 5: Prescribe oral morphine 20 mg every 4 hours and an analgesic with antipyretic activity (eg, acetaminophen or ibuprofen).
Step 6: Stop the basal opioid infusion (PCA) immediately or concomitantly with oral dose; increase oral dose by 20%–25% if pain relief is deemed inadequate. If the opioid requirement is high, PCA can be used to provide "rescue" boluses only for the period of transition or to wean the background infusion/PCA doses to more manageable oral doses.

Local Anesthetics

Over the past 25 years, the use of local anesthetics and regional anesthetic techniques in pediatric practice has undergone a dramatic change. Unlike most drugs used in medical practice, local anesthetics must be physically deposited at their site of action by direct application. This requires patient cooperation and the use of specialized needles and equipment; because of this, children were long considered poor candidates for regional anesthetic techniques because of their overwhelming fear of needles. However, once it was recognized that regional anesthesia could be used as an adjunct, and not as a replacement for general anesthesia, its use has increased exponentially. Regional anesthesia offers the anesthesiologist and pain specialist many benefits. It modifies the neuroendocrine stress response, provides profound postoperative pain relief, ensures a more rapid recovery, and may shorten the hospital stay. Furthermore, because catheters placed in the epidural, upper or lower extremity, or lumbar plexi can be used for days or months, local anesthetics are increasingly being used not only for postoperative pain relief but also for medical (eg, sickle cell vaso-occlusive crisis), neuropathic, and terminal pain relief.[68–72] These techniques range from simple infiltration of local anesthetics to neuraxial blocks (eg, spinal and epidural analgesia). With the use of ultrasound guidance, regional anesthesia in the pediatric population has gained further popularity. Peripheral nerve blocks can also provide significant pain relief following many common pediatric procedures and have the potential to replace or provide an alternative to "gold standard" epidural treatment. This is particularly true in the neonatal population where paravertebral block for a thoracotomy or a transverse abdominis plane (TAP) block for a laparotomy can replace an epidural for effective pain relief and avoid the risks associated with neuroaxial blockade. To be used safely, a working knowledge of anatomy, limitations of technique, and differences in how local anesthetics are metabolized in infants and children is necessary. All aspects of local anesthetics are discussed in detail in previous chapters.

Other Adjutants in a Multimodal Analgesia Regime

Gabapentin

Gabapentin is well established in chronic pain management. A few studies have shown that perioperative gabapentin reduces acute postoperative opioid consumption[73] in patients undergoing a variety of surgeries, including coronary artery bypass[74] and knee arthroplasty.[75] In one study, gabapentin was shown to reduce perioperative opioid use but not opioid-related side effects in pediatric patients undergoing posterior spinal fusion.[76] Dosing varies from a single perioperative dose to treatment for 1–2 weeks. At our institution, we use gabapentin for spinal fusion surgeries and selected surgeries where postoperative pain relief is deemed challenging. We normally administer gabapentin at a dose of 5–10 mg/kg every 8 hours for 5 days. For patients with complex needs, doses may need to be revised down, as in some cases, gabapentin can produce noticeable sedation or drowsiness.

Ketamine

Ketamine is a well-known anesthetic that produces dissociative anesthesia but also provides a very good-quality analgesia at very low doses via its NMDA receptor antagonist activity. Healthcare professionals remain wary of ketamine, however, due to its unpleasant side effect of hallucinations and its recent implication in neuroapoptosis in the developing brain.[77,78] These concerns have now led to the avoidance of ketamine use in patients under 1 year of age and has also decreased the popularity of ketamine as an additive in caudal and epidural blocks.

However, in older children and adolescents, ketamine is still widely used with good effect. Ketamine can also be added to morphine PCA in a 1:1 ratio. At our institution, a single low dose of ketamine (0.1–0.25 mg/kg) forms part of a balanced intraoperative analgesic regime for adenotonsillectomy and major surgeries. Ketamine infusion is also used as a second-line IV analgesic for complex and painful conditions and in cases of acute or chronic pain where other treatments have failed to produce effective analgesia. The infusion dose of ketamine used is 0.05–0.2 mg/kg/h (using a drug concentration of 0.1 mg/kg/mL, up to a maximum of 250 mg in 50 mL).

Magnesium

Magnesium is used in variety of medical emergencies and treatments. The intravenous use of magnesium has been reported to improve postoperative analgesia. Though the mechanism of action is not yet fully understood, the analgesic properties of magnesium are believed be due to the regulation of calcium influx into the cell and NMDA receptor antagonist activity.[79,80] Evidence has been equivocal, however, and although relatively safe, magnesium is not without side effects. A recent meta-analysis concluded that perioperative intravenous magnesium reduces opioid consumption, and to a lesser extent pain scores, in the first 24 hours postoperatively without any reported serious adverse effects.[81] The use of magnesium, either as a bolus or infusion (at a dose of 30–50 mg/kg), for major surgeries, particularly spinal fusions, and for other major orthopedic and general surgeries, is standard practice at our institution.

2. CHRONIC PAIN MANAGEMENT

THE TRANSITION FROM ACUTE TO CHRONIC PAIN

Acute pain has evolved as a vital defense mechanism, alerting the animal to injury and physical harm in order to stop the exposure to injury, such as with the pain reflex or to signal the need for rest to allow healing to occur. Chronic pain, however, serves no protective function. Chronic pain is considered to be pain that extends beyond the expected period of healing.[82] There are increasing studies in the adult literature demonstrating the development of postoperative chronic pain, which is then associated with significant negative consequences for the individual, in terms of both physical and mental health, and for the wider society, in terms of both economic and healthcare resource burdens. The incidence of chronic postoperative pain varies depending on surgery type, with estimates between 5% and 50% in the most common surgical procedures,[83] including hernia repair, hip replacement, and cholecystectomy, versus up to 85% in amputations. Although the literature for the development of chronic pain postoperatively is sparse in pediatric age ranges, studies are beginning to indicate that it does occur, although its incidence may be lower than in the adult population.

Fortier[83] studied 113 children between the ages of 2 and 17 years who had undergone general urological or orthopedic surgery and found that 13.3% reported chronic pain resulting from surgery. The surgeries most related to the development of chronic pain were orthopedic. Over one-quarter reported interference in sleep patterns and extracurricular activities, and 1 in 6 reported interference in school activities. Chronic pain in adults after inguinal surgery has a reported incidence of 5%–35%; however, in children, studies suggest the incidence may be lower. One particular surgery in adolescents associated with a high incidence of persistent pain is scoliosis, where estimates of 50% are reported.[84] A study by Wong demonstrated a trend for those who experienced more severe postoperative pain to have a greater tendency toward developing persistent pain; only 39% of those with mild postoperative pain developed persistent pain compared with 74% of those with severe postoperative pain. Studies have indicated that persistent pain can be a complication for as long as 12 months after surgery; however, thoracotomy in childhood has been associated with pain persisting into adulthood up to 30 years later. This risk appears less when surgery takes place at a younger age and increases with the age at which surgery is performed. Although the mechanisms for the transition from acute to chronic pain are complex, some risk factors identified in the adult literature (in the absence of many studies in children) may also be relevant to the pediatric population. These include the presence of preoperative pain, the severity of acute postoperative pain, and open versus laparoscopic surgery. Good postoperative multimodal pain management therefore plays an important role in efforts to prevent the subsequent development of persistent pain in children.

Clinical Pearls

- Chronic pain can be a postoperative complication in the pediatric population.
- Chronic pain has a negative impact on sleep, activities, school attendance, and school achievement.
- Risks for the development of chronic pain include preoperative pain, the severity of acute postoperative pain, and open versus laparoscopic surgery.

THE MANAGEMENT OF ACUTE-ON-CHRONIC PAIN

The management of patients undergoing surgery with preoperative chronic pain can be problematic, and the presence of preoperative pain increases pain perception postoperatively. Good preoperative preparation and planning are important, incorporating education for both the child and parents/guardians and involving them in decision making. Psychological interventions, such as cognitive behavioral therapy and decatastrophization can be beneficial preparation. Patients experiencing preoperative pain may be taking adjuvant analgesia medications, some of which should not be stopped abruptly, such as anticonvulsants (eg, gabapentin). Other medications may have significant interactions with commonly used analgesic medications; for example, the combination of amitriptyline and tramadol has resulted in serotonin syndrome. There are a small number of pediatric patients who present for surgery on long-term opioids, and not all of these patients will be palliative. The prolonged administrations of opioids may occur in children in intensive care units, those requiring frequent and repeated surgery (eg, for burns), those with frequent disease exacerbations (eg, sickle cell), adolescents using opioids illicitly, and in a small number of children with medically unexplained pain. Recommendations for the management of such patients are primarily extrapolated from the adult literature due to a lack of evidence in children (Table 45–5).

SUMMARY

The past 25 years have seen an explosion in research and interest in pediatric pain management. In this brief review, we have tried to consolidate in a comprehensive manner some of the most commonly used agents and techniques in current practice.

PART 6

TABLE 45–5. Considerations for the perioperative management of children on long-term opioids.

Educate and involve the child and his or her parents/guardians in preoperative planning.
Continue maintenance opioids or consider conversion to parenteral opioids.
Supplementation with systemic opioid (oral or intravenous) may be necessary if a neuroaxial technique is used.
Titrate opioids postoperatively.
The dose may need to be 30%–100% higher than for opioid-naïve patients.
Use multimodal therapy, including adjuvant medications (eg, ketamine) and nonpharmacologic techniques.
Use regional anesthesia techniques where possible.
When transitioning from parenteral opioids to oral delivery calculate total dose requirement over 24 hours. Deliver 50% of the estimated oral dose as long-acting and the remainder as breakthrough.
Taper oral opioids to preoperative doses slowly, over a period of 2-4 weeks.
In the first 24 postoperative hours, reduce the dose by 20–40%.
Following the first 24 postoperative hours, reduce the dose by 5–20% (use a slower rate in the presence of withdrawal signs).
Ensure chronic pain service is involved in the transition to long-term pain management.

PART 7

ANESTHESIA IN PATIENTS WITH SPECIFIC CONSIDERATIONS

This page intentionally left blank

CHAPTER 46

Perioperative Regional Anesthesia in the Elderly

Jennifer E. Dominguez and Thomas M. Halaszynski

INTRODUCTION AND DEFINITION OF ELDERLY

Healthcare providers have become increasingly focused on providing effective management of acute perioperative pain in all patients, but especially older adults, as the size of this patient population has steadily increased in recent years.[1] Advances in anesthetic and surgical techniques, an improved understanding of the pathophysiology of pain, the development of new opioid and nonopioid analgesic drugs, the incorporation of regional techniques that reduce or eliminate reliance on traditional opioid analgesics, and novel methods of drug delivery have all led to greater numbers of older patients undergoing major surgery.[2,3] An increased prevalence of chronic medical conditions among older individuals may also lead to higher degrees of acute and chronic pain (including acute-on-chronic pain). For instance, acute exacerbations of arthritis, osteoporotic fractures of the spine, cancer pain, and pain from acute medical conditions (eg, ischemic heart disease, herpes zoster, peripheral vascular disease) must be properly addressed in order to maximize multimodal perioperative pain management.[4] In addition, older individuals are adopting more active lifestyles that can predispose them to trauma and orthopedic injuries that require surgery.

The term *elderly* encompasses both chronologic and physiologic factors. Chronologic age is the actual number of years an individual has lived, whereas physiologic age refers to functional capacity or reserve within organ systems defined in pathophysiologic parameters. The chronologic component can be divided into two separate groups: the "young old" (65 to 80 years of age) and the "older old" (greater than 80 years of age).[5] Physiologic reserve describes the functional capacity of organ systems to compensate for acute stress and traumatic derangements. When present, comorbid disease states such as diabetes mellitus, arthritis, renal insufficiency, ischemic heart disease, and chronic obstructive pulmonary disease (COPD) can all decrease a patient's physiologic reserve making it difficult for him or her to recover from traumatic or surgical injury.

There are a host of additional factors that may compromise the ability to provide optimal and effective acute pain management to older patients. A consequence of the comorbid diseases that afflict this patient population with increased frequency is the medications used in treatments for such diseased conditions, along with a subsequent increased risk of drug-to-drug and disease-to-drug interactions. An improved understanding of age-related changes in physiology, pharmacodynamics, and pharmacokinetics must be incorporated into any acute pain medicine care plan for older individuals. Altered responses to pain among the elderly population along with difficulties in pain assessment for certain individuals with cognitive dysfunction are potential problems that must also be considered.

Several theories have been advocated to describe the multidimensional aspects and consequences of aging that underscore the complexities and difficulties encountered in developing optimal regional anesthetic and analgesic choices for elderly patients. Therefore, the focus of this chapter is to outline the physiologic and pharmacologic implications of aging on surgical anesthesia and acute pain management, as well as the potential risks and benefits of neuraxial blockade along with peripheral nerve/nerve plexus blockade in geriatric patients.

PHYSIOLOGIC CHANGES ASSOCIATED WITH AGING AND CONSIDERATIONS FOR REGIONAL ANESTHESIA/ANALGESIA

Aging is characterized by progressive reductions in the homeostatic reserves of nearly every organ system.[6] Declining organ function, often referred to as *homeostenosis*, may be gradual or progressive and becomes evident by the third decade of life. The compromised function of each organ system generally occurs independent of changes to other organ systems and may be influenced by a host of factors, including diet, environment, habits, and genetic predisposition. Optimal anesthetic management using regional techniques in elderly patients depends upon a knowledge and understanding of normal age-related changes in anatomy, physiology, and response to pharmacologic agents. It is also important to distinguish normal physiologic alterations of the central nervous system (CNS), cardiovascular, pulmonary, and hepatorenal systems from disease-related pathophysiologic changes.

Clinical Pearls

- The pain thresholds to a variety of noxious stimuli are altered in older individuals.
- Older patients have a reduction in pain tolerance.
- Patient-controlled analgesia (PCA) and epidural analgesia are more effective in elderly patients than most other conventional (PO and IM) opioid analgesic regimens.
- Physiologic changes associated with aging vary markedly among individuals. The administration of pain medications warrants a decrease in dose (maintenance and/or bolus) of drug required for analgesia to avoid the risk of increased plasma drug accumulation and accumulation of active metabolites.

Nervous System Function

Aging results in anatomical and biochemical changes of the brain, spinal cord, and peripheral nervous system (PNS) that result in qualitative and quantitative alterations in function (Table 46–1). In addition, advanced age can be associated with decreased brain volume, a manifestation of the loss of neurons, as well as a reduction in cerebral white matter nerve fibers. Specifically, the number of cholinergic and dopaminergic neurons declines, and morphologic changes in neuronal fibers occur that result in fewer synaptic contacts and neuroreceptors. Levels of acetylcholine, dopamine, and other neurotransmitters also decline, and there may be an extraneuronal accumulation of amyloid, which underlies neurocognitive dysfunction. Alterations in brain phospholipid chemistry associated with changes in second messengers, such as diacylglycerol, are also evident in the elderly.[7] Overall, both cerebral electrical and metabolic activity are decreased in elderly compared to younger individuals and may be a result of the multitude of anatomic, structural, and biochemical changes that accompany aging. It is possible that degenerative changes in the myelin sheaths of nerve fibers in the CNS and PNS can also lead to changes in nerve conduction velocity and disrupt the normal timing of neuronal circuits. Additional anatomical changes occur that affect nervous system function, including decreased spinal cord volume and degeneration of the bony spinal canal.

Changes in the somatic nervous system of the PNS associated with aging include (1) peripheral nerve deterioration; (2) dysfunction of genes responsible for myelin sheath protein components; (3) decreased myelinated nerve fiber conduction velocity; (4) motor and sensory discriminatory changes in the feet; and (5) changes in sensation (eg, pain, touch).[8] The autonomic nervous system (ANS) of the PNS also experiences age-related changes that dictate most of the involuntary physiological functions of the body through the parasympathetic and sympathetic divisions. Aging of the ANS is characterized by (1) limited adaptability to stress; (2) decreased basal activity of the parasympathetic nervous system and overall net activation of the sympathetic nervous system; (3) decreased baroreflex sensitivity; and (4) slowing and weakening of homeostatic functions.[9] The increase in sympathetic tone in older patients should also be considered when choosing an anesthetic with sympathomimetic properties, as such anesthetics may be poorly tolerated by some individuals with cardiovascular disease.

Clinical Pearl

- Aging is associated with a shift in balance within the autonomic nervous system toward a predominance of sympathetic tone.

TABLE 46–1. Physiologic central nervous system changes associated with aging and effects on pharmacokinetic variables.

Physiologic Process	Magnitude of Change	Variable Kinetic/Dynamic Consequences	General Dosing Strategy
Cerebral blood flow, metabolism, and volume	↓ 20% ↓ 20%	↓ distribution to the CNS ↓ apparent volume in the CNS	Little net effect on drug dose
Active blood–brain barrier transport (efflux)	Drug-specific ↓	↑ apparent volume in the CNS	↓ bolus dose during drug titration ↓ maintenance dose
Pain threshold sensitivity	Little change	↑ apparent sensitivity of the CNS	Need for titration is unchanged
Concentration response (opioids)	↑ 50% for some opioids	↑ response to opioids	↓ bolus dose during titration ↓ maintenance dose

Aging affects peripheral nerves, resulting in deterioration and decreases in the number of myelinated nerve fibers. Large myelinated fibers are particularly affected by aging, resulting in atrophy along with degenerative changes to the myelin.[10] Levels of expression for key genes that encode major protein components of the myelin sheath, such as proteolipid protein and myelin basic protein, may influence this process.[11,12] Maintenance of myelin sheath integrity involves continued expression of genes specifically associated with myelin protein production. Restoration of myelin sheaths to demyelinated axons occurs spontaneously in the adult nervous system, but aging has a detrimental effect on this process. Spontaneous remyelination efforts and the rate of reappearance of proteolipids and myelin basic proteins are slowed. In the CNS, oligodendrocyte progenitor recruitment and differentiation are also impaired by age-related decline in remyelination.[11,12]

Changes in both the PNS and CNS may affect functional outcomes during the recovery phase following surgery and anesthesia and should be considered in the perioperative evaluation. The neurologic dysfunction of aging can produce altered pharmacodynamics, resulting in increased sensitivity to anesthetic medications with signs and symptoms of altered reflexes, deterioration of gait and mobility, altered sleep patterns, impairment of memory and intellect, and decrements of the senses. Perioperative delirium, a common form of acute cognitive impairment in elderly patients, can increase postoperative morbidity, present with difficult pain management scenarios, impair postoperative rehabilitation and prolong hospital stays.[13-17] Delirium can occur in up to 80% of elderly postoperative patients depending upon the type and extent of surgery, perioperative anesthesia and analgesic needs of the patient, and type of pain therapy administered. It is more common with emergency, trauma, and major surgery. Risk factors associated with the development of delirium are numerous and include increased age, level of patient education, preexisting pain, and use of preoperative medications such as opioids, ketamine, and benzodiazepines.[14-16,18-20] Subsequent to the negative effects of delirium, some patients may go on to experience postoperative cognitive dysfunction (POCD). A systematic review has confirmed that POCD is very common and that older patients are at a higher risk of POCD after major noncardiac surgery than are younger patients.[21]

Clinical Pearl

- Advancing age, level of patient education, and evidence of preexisting cerebral vascular disease are strong predictors of perioperative delirium.

Cardiovascular Function

There are a variety of morphological and functional changes in the cardiovascular system associated with aging, including a reduction in left ventricular compliance, generalized hypertrophy of the left ventricular wall, fibrotic changes of the heart, and decreased myocardial compliance. These changes can result in increased stroke volume and elevated diastolic and systolic blood pressure (Table 46–2).[22] Many elderly patients present with cardiac pathology, including moderate to severe coronary artery disease, valvular heart disease, and conduction defects that increase the risk of postsurgical morbidity and death. The effects of aging on cardiac output in the absence of coexisting disease may have minimal influence on the resting individual, but functional changes can become evident with stress and effort-dependent stress.[23] Anesthetics and anesthesia technique may also interact with the patient's preexisting cardiovascular disease in a manner that may be unfavorable. For example, patients with a fixed cardiac output (as in aortic stenosis) may not tolerate a decrease in systemic vascular resistance associated with neuraxial anesthesia well. Acute/extreme hemodynamic variability in the setting of regional anesthesia, however, can be overcome with careful titration of neuraxial anesthesia with an epidural or spinal catheter and skillful use of vasopressors.

Age-related influences on the cardiovascular system may have important clinical implications for the treatment of elderly surgical patients and for postoperative pain management, especially for those patients receiving regional anesthesia/analgesia. Several recent studies have demonstrated benefits of regional techniques on cardiac morbidity, intensive care unit (ICU) admissions and short-term survival.[24,25] Although there are sparse data to indicate evidence-based and statistically significant differences in the impact of anesthetic technique on mortality or major complications, regional analgesia can positively influence pain management and lead to better outcomes when the type of surgery being performed is considered. Regional anesthesia/analgesia may have positive implications for perioperative cardiac function. For example, ischemic heart disease and hypertension are more common among elderly than younger patients, and coronary blood flow in such patients could be compromised in response to the sympathetic stimulation of surgery, perioperative stress, pain, and anesthesia. In a study by Park et al, researchers investigated the use of epidural anesthesia/analgesia combined with general anesthesia for abdominal aortic aneurysm repair. They showed that the duration of postoperative tracheal intubation, mechanical ventilation, and total ICU stay were reduced. In addition, the quality of postoperative analgesia improved, whereas the incidence of major complications and death were reduced.[26] Research has also shown that placement of thoracic epidural analgesia can improve left ventricular function[27,28] and increase myocardial oxygen availability.[29] In addition, patients with ischemic heart disease treated with a high thoracic epidural injection of bupivacaine showed improved myocardial blood flow in response to sympathetic stimulation.[30] However, neuraxial anesthesia with an epidural in older patients undergoing coronary artery bypass grafting surgery has not been shown to improve perioperative outcomes.[31] Therefore, to permit physicians to development preliminary guidelines and anesthesia protocols that could positively affect the cardiovascular outcomes of elderly surgical patients, studies investigating regional techniques should be tailored to match the planned surgery and adjusted for comorbid diseases and perioperative patient management needs (ie, procedure- and patient-specific anesthesia/analgesia).

In addition to the mounting evidence of the regional anesthesia (with or without continuous local anesthetic infusion) on

TABLE 46–2. Physiologic cardiovascular changes associated with aging and effects on pharmacokinetic variables.

Physiologic Process	Magnitude	Variable Kinetic/Dynamic Consequences	General Dosing Strategy
Cardiac output	↓ 0–20%	↓ central compartment volume ↑ peak concentration of drug after bolus	Use smaller initial bolus dose Use slower injection rate **Potential for change in clearance and oral bioavailability* **Potential for change in cerebral effects*
Fat	↑ 10–50%, then ↓	Drug-specific changes are seen in distribution volume	Drug-specific (dose based on total body weight and/or lean body weight)
Muscle mass and blood flow	↓ 20%		
Plasma volume	Little change		
Total body water	↓ 10%	↓ distribution volume (water-soluble drugs)	
Plasma albumin	↓ 20%	↑ free fraction of drug	Potential for change in clearance and oral bioavailability Potential for change in cerebral effects
Alpha-1 glycoprotein	↑ 30–50%	Variable hepatic clearance of high-extraction drugs ↑ hepatic clearance of low-extraction drugs ↑ cerebral uptake of drugs	
Drug binding	Drug specific		

perioperative cardiac morbidity and mortality[32] effectively managed postoperative pain could mitigate myocardial dysfunction if catecholamine levels associated with stress and pain are reduced. Regional anesthesia can also may provide superior analgesia compared to systemic opioids. Peripheral nerve blocks and neuraxial anesthesia the elderly can provide preemptive analgesia, reduce the side-effects or eliminate the need for general anesthesia (or completely avoid it in certain surgical settings), reduce sympathetic stimulation and stress responses associated with surgery, and directly inhibit transduction, transmission, and conduction of nociception from the surgical trauma site(s). Regional techniques that complement multimodal analgesic therapies have been demonstrated to have beneficial effects on acute pain and may lead to a reduction in cardiac morbidity and mortality.[33] Another factor to consider is the duration of postoperative analgesic needs because pain from surgery, surgical stress, and effects on the cardiovascular system often do not subside until several days following surgery. Therefore, the use of an effective regional technique (eg, continuous catheter) may provide sustained benefits by reducing postsurgical pain and its associated sympathetic and neuroendocrine stress responses. However, patients with coexisting cardiovascular disease may be treated with anticoagulants or antiplatelet medications, or both, and careful attention should be paid to this issue prior to the administration of certain regional peripheral or neuraxial techniques.

Pulmonary Function

Respiratory compromise and complications among the elderly in the perioperative period can often be explained by functional and structural changes within the pulmonary system. Such alterations are commonly associated with aging as well as physiologic changes in response to hypoxemia and hypercarbia and increased sensitivity to the respiratory depressant effects of anesthetic agents and opioids. With aging, the elastic recoil of the lung parenchyma decreases in a fashion that functionally resembles emphysema, with less efficient alveolar gas exchange due to a loss of alveolar surface area and collapse of small airways. In addition, compliance of the chest wall decreases, which can lead to an increased work of breathing and increased risk for respiratory failure in the postoperative period for older patients.[34] In all patients, there are reductions in functional residual capacity (FRC) created by assuming the supine position, being under the influence of general anesthesia, and experiencing surgery. These negative effects on FRC may persist for 7 to 10 days following surgery.[35] FRC and closing volume gradually increase with age, and by age 45, closing volume exceeds FRC in the supine position.[33] Vital capacity can be reduced by 25% to 50% from inadequate postoperative pain management (ie, splinting), along with the administration of systemic opioid analgesics that also contribute to alterations in tidal volume and respiratory rate and that can impair clearing of secretions (via altered cough mechanics). Elderly also have decreased responsivity to hypoxia and hypercapnia, as well as a greater incidence of COPD and obstructive sleep apnea (OSA).[35] All of the above factors make opioid-sparing approaches to postoperative pain control desirable. However, while regional techniques may be beneficial in providing superior postoperative pain control with opioid-sparing effects, these modalities should be selected carefully given that patients with underlying pulmonary disease may poorly tolerate phrenic nerve dysfunction that can be associated with upper (interscalene and supraclavicular) brachial plexus blockade approaches.[36] Therefore, patients should be assessed frequently for evidence of any adverse side effects, respiratory dysfunction, and adequate pain control throughout the perioperative period regardless of chosen analgesic methods.

Airway manipulation can be avoided, and respiratory parameters of lung function, respiration rate, tidal volume, respiratory drive (effort), and end-tidal carbon dioxide concentration can be preserved if surgical anesthesia can be achieved with regional modalities. Careful attention to the type of sedation used as an adjunct during these regional block placement procedures should be considered given the potential for increased sensitivity to opioids and benzodiazepines in the elderly, as well as the decreased responses to hypoxemia and hypercapnia and the increased incidence of OSA in this population. Unchanged FRC from baseline has been observed during spinal and lumbar epidural anesthesia. However, intercostal blocks and cervical, thoracic paravertebral, and high thoracic epidural blockade can be associated with lung volume reductions secondary to intercostal muscle relaxation. Therefore, choice of anesthesia may affect the degree of pulmonary dysfunction. Studies comparing regional versus general anesthesia/analgesia in elderly patients undergoing lower extremity orthopedic and major abdominal surgical procedures have shown that (1) older patients experience fewer hypoxic events with epidural and regional anesthesia (using local alone) compared to systemic opioids; (2) general anesthesia in older patients results in lower PaO_2 levels (on postoperative day 1) compared to epidural and regional anesthesia; and (3) respiratory complications are less frequent when comparing general anesthesia with postoperative intravenous morphine analgesia versus general anesthesia with postoperative epidural analgesia.[37-39] However, the elderly have increased sensitivity to the respiratory depressant effects of neuraxial opiates, and therefore these should be used with caution.[40]

Pharmacokinetic and Pharmacodynamic Changes in the Elderly

Aging affects the pharmacokinetics and pharmacodynamics of medications (eg, sedative/hypnotics, opiates, nonopioid analgesics, local anesthetics), the physiologic functions of the body, and the composition/characteristics of organs and tissues within the body to variable degrees. The physiologic changes and effects on pharmacokinetics and pharmacodynamics in older patients, as well as some alterations that may be required for drug regimens in older patients, are listed in Tables 46–1, 46–2, and 46–3. Information in these tables addresses a number of issues related to local anesthetics and opioid analgesics in view of their widespread use and importance in perioperative pain management for older patients. The altered response to drugs associated with aging can be highly variable and somewhat unpredictable among individuals and are generally attributable to aging alone, but such responses may be compounded by a higher incidence of degenerative and other coexisting diseases in this patient population.[41]

Multimodal Drug Therapy and the Elderly

A perioperative plan of care that includes a regional technique in an elderly patient must consider the inherent risk of sedation/hypnosis, multimodal drug regimens, and local anesthetic medications. Safety principles of treatment with analgesic and sedative medications for pain management in older patients, specific to regional and regional peripheral nerve blockade, are discussed and listed in Tables 46–1, 46–2, and 46–3. Sedative drugs (eg, midazolam, propofol) used during block placement should be easy to administer, short-acting, have a high safety margin, and limited adverse effects. Epinephrine can prolong peripheral nerve blockade duration, but caution must be exercised as epinephrine may cause an ischemic neurotoxicity in peripheral nerves with preexisting neuropathy (eg, in patients with diabetes).[42,43]

There are several pharmacodynamic changes associated with aging.[44] Understanding of how medications may affect older patients can be complex and unpredictable. Studies that have examined opioid pain management have been somewhat arbitrary, and surrogate measurements of effect other than clinical pain relief have not been adequately studied. An animal study by Piva et al, identified fewer mu-opioid receptors in the hypothalami of older rats, and, in contrast, greater concentrations of kappa-opioid receptors in the thalamus and amygdala of these animals.[45] They also found that concentrations of delta-opioid receptors were not significantly different in young versus old rats. Scott et al. conducted a study of the pharmacokinetics and pharmacodynamics of fentanyl and alfentanil in older men by examining blood samples with a radioimmunoassay and found that the pharmacokinetics of these drugs were unaffected by age.[46] However, the sensitivity of the brain to these opioids as measured by electroencephalogram (EEG) proved to be increased by 50% in these older subjects. Whether this finding can be attributed to a change in the number or function of opioid receptors in the CNS that is associated with aging or due to an increased penetration of opioids in the CNS remains unclear.

There is no literature to support the need to alter ketamine doses in older patients. However, in aged animals, changes in composition of the N-methyl-D-aspartate (NMDA) receptor site and function have been reported.[44,47,48] If one can extrapolate from these earlier animal studies, older patients may be more sensitive to the effects of ketamine, and doses may need to be decreased in this patient population. Clearance of tricyclic antidepressant (TCA) drugs and their active metabolites by

TABLE 46–3. Physiologic hepatic and renal changes associated with aging and effects on pharmacokinetic variables.

Physiological Process	Magnitude	Variable Kinetic/Dynamic Consequences	General Dosing Strategy
Liver			
Liver size	↓ 25–40%	↓ hepatic clearance of high-extraction drugs Equivocal hepatic clearance of low-extraction drugs ↓ hepatic clearance of some low-extraction drugs	Minimal effect on drug IV bolus dose ↓ maintenance dose Potential for changes in oral bioavailability
Hepatic blood flow	↓ 25–40%		
Phase I (eg, oxidation)	↓ 25%		
Phase II	Little change		
Kidney			
Nephron mass	↓ 30%	↓ clearance of drugs Little effect on opioids (parent compound) ↓ clearance of some active metabolites (eg, M6G)	↓ maintenance dose (renally cleared drugs for renal clearance) Assume and monitor for accelerated accumulation of polar active (M6G) or toxic (M3G, norpethidine) metabolites
Renal blood flow	↓ 10% per 10 years		
Plasma flow at 80 years	↓ 50%		
Glomerular filtration rate	↓ 30–50%		
Creatinine clearance	↓ 50–70%		

The net effect of these changes in drug disposition may be minimal; M6G: morphine-6-glucuronide; M3G: morphine-3-glucuronide.

hepatic cytochrome P450 and the kidney, respectively, decreases with increasing patient age, and lower initial doses are recommended in older patients.[49,50] In addition, elderly patients may be particularly prone to the side effects of TCAs, including sedation, confusion, orthostatic hypotension, dry mouth, constipation, urinary retention, and gait disturbances (eg, increased risk of falls).[50] As with TCAs, initial doses of anticonvulsant agents used for pain management (pregabalin, gabapentin, and topiramate) should be lower than for younger patients, and increases in dose should be titrated carefully.[49] Adverse side effects such as somnolence and dizziness, especially with pregabalin, may be a problem in this group of patients.[51,52] As renal function declines with increasing age, elimination of gabapentin and pregabalin may be reduced, and lower doses may be required.[53]

Age-related changes in the body are responsible for alterations seen with systemic absorption, distribution, and clearance of local anesthetics that may result in an increased sensitivity, decreased dose requirement, and change in the onset and duration of action in elderly patients. For example, decreases in neural cell population, nerve conduction velocity, and inter-Schwann cell distance can produce an increased sensitivity to local anesthetics in the elderly. Advancing age also results in a decrease in the clearance of bupivacaine[54-56] and ropivacaine.[57] Older patients are more sensitive to the effects of local anesthetic agents secondary to a slowing of the conduction velocity (in the spinal cord and peripheral nerves) and a decrease in the number of neurons in the spinal cord.[58]

Clinical Pearls

- The administration of nonsteroidal anti-inflammatory drugs (NSAIDs) and cyclooxygenase-2 (COX-2) inhibitors in elderly patients requires caution; acetaminophen may be the preferred nonopioid analgesic.
- The age-related decrease in opioid requirements in the elderly patient is related to the changes in pharmacodynamics that accompany aging.

Physiology and the Perception of Pain in the Elderly and Clinical Implications

Several review articles have summarized the many age-related changes that occur in pain perception and the neurophysiology of nociception in elderly surgical patients.[59-61] There are extensive alterations in the structure, neurochemistry, and function of both the PNS and CNS of older patients. Included among these changes is the neurochemical deterioration of opioid and serotonergic systems. Therefore, there may be changes in nociceptive processing, including impairment of the pain inhibitory system, and pain intensity after surgery may be greater or less than otherwise expected from the severity of surgical trauma induced. In one study, older patients matched for surgical procedure reported less pain in the postoperative period, and pain intensity decreased by 10% to 20% for each decade after 60 years of age.[62]

The structural and neurochemical changes that have been described in the PNS and CNS of the elderly continue to compromise optimal pain medicine protocols for these patients. Studies of the elderly nervous systems show a decrease in the density of myelinated and, particularly, unmyelinated peripheral nerve fibers.[63] In addition, there is an increase in the number of nerve tissue fibers with evidence of degeneration and a slowing of nerve conduction velocity in older individuals.[64] Gagliese et al reviewed animal and human experimental evidence on the neurobiology of aging and reported the following findings: (1) reductions in level of the neuropeptide substance P; (2) lowered concentrations of calcitonin gene-related peptide (a vasodilator neuropeptide expressed in a subgroup of small neurons in the dorsal root); and (3) reduced somatostatin levels within the circulatory system.[65,66] Sensory neuron degenerative changes, loss of myelin in the dorsal horn of the spinal cord, and reductions in neurochemical mediators (substance P, somatostatin, and calcitonin gene-related peptide) have been noted.[67,68] Once again, the clinical implications of these degenerative changes in many older individuals translate into pain being expressed as less severe along with evidence of increased pain thresholds in older patients.[61,69]

A decrease in pain tolerance sometimes seen in elderly patients could also be secondary to decreases in noradrenergic and serotonergic neurons that contribute to the impairment of descending inhibitory mechanisms.[70,71] Age-related loss of neurons and dendritic connections, along with changes in neurotransmitter synthesis, axonal transport, and receptor binding seen in the human brain are particularly evident in the cerebral cortex, including areas of the brain involved in nociceptive processing.[11,72] The density of opioid receptors in the brain is decreased (although not evident in the spinal cord), and there may also be decreases in concentrations of circulating endogenous opioids.[11] Therefore, compared to younger patients having the same type of surgery performed, older patients may report less pain or atypical pain, complain of pain at a later time during recovery, or report no pain from a surgical insult that generally produces at least mild-to-moderate pain scores in younger patients.[73]

Clinical Pearl

- There is an age-related decrease in opioid requirements and significant interpatient variability in pain tolerance in elderly surgical patients.

Functional MRI (fMRI) studies performed on older individuals show more similarities than differences in the magnitude of activation in the brain response to acute noxious stimulation.[74] However, the functional consequences of age-related changes in the brain still remain a subject of debate. For example, studies investigating the effects of experimental pain stimuli (short periods of noxious stimuli not resulting in tissue injury) on pain thresholds are conflicting and appear to depend on the type of stimulus used.[75,76] In addition, elderly individuals tend to have higher pain thresholds for thermal stimuli, but results from mechanical stimulation appear equivocal, and there is evidence that no change is seen in response to electrical stimuli across all age groups.[61] However, in the clinical setting (where pain is often associated with tissue injury), these observations may explain the deficits seen in the early warning function of pain in older patients. For example, in elderly patients experiencing an acute myocardial infarction, a greater intensity of symptoms of chest discomfort and pain was inversely correlated with a lower pain threshold.[77] There also appears to be a gap between identification of pain stimulus and recognition of the stimulus as being capable of causing tissue injury.[69] Therefore, differences in the perception and reporting of pain by older surgical patients may result in pain therapy, medications, and regional analgesic interventions being delayed or deemed unnecessary.

A review of studies on age-related changes in pain tolerance (involving a variety of experimental pain stimuli) has shown a reduced ability of older individuals to endure or tolerate strong painful stimuli.[61] This may have deleterious effects in the more vulnerable elderly patient and could mean that severe pain may have a greater negative impact if not effectively treated. In addition, elderly individuals show smaller increases in pain thresholds following prolonged noxious stimulation and evidence of prolonged recovery from hyperalgesia.[69,78]

Clinical Pearl

- The assessment of pain and evaluation of pain management therapies in older patients present problems arising from differences in (1) reporting mechanisms; (2) cognitive dysfunction; (3) end-organ impairment/compromise (affecting medication metabolism and excretion); (4) variations in medication tolerance and abuse; and (5) inherent difficulties in the assessment of pain.

Assessment of Pain in Older Cognitively Impaired Patients

Inadequate treatment of acute pain is more likely to occur in older patients, especially those that are cognitively impaired.[79-82] Even though cognitively impaired patients are just as likely as others of the same age and younger to experience painful conditions, the number of pain complaints, along with reported pain intensity, has been shown to be inversely related to the degree of cognitive impairment (due to diminished memory, impairment of capacity to report, or because less pain is experienced).[83,84] However, studies in patients with dementia suggest that pain perception and processing are not diminished, and it would be false to assume that these patients experience less pain with surgery.[85-87] Therefore, careful consideration must be given to the ways in which pain is assessed in older cognitively impaired individuals. While cognitively intact elderly patients can use a range of unidimensional pain scales (visual analog scale [VAS], verbal rating scale [VRS], numeric rating scale [NRS], or facial pain scale [FPS]), in patients with mild to moderate or severe cognitive impairment, a VRS or behavioral scale (eg, Doloplus-2 or Algoplus) may prove to be better pain assessment tools.[88,89]

Clinical Pearls

- Elderly patients often describe pain as being less intense and often provide atypical descriptions of perioperative pain.
- The reported frequency and description of intensity of acute pain in clinical situations may often be reduced in older patients.
- Unidimensional measurements of pain can be used in older patients in the acute pain setting; in the clinical setting, VRS and NRS measurements provide the best validity in older adults.
- The undertreatment of acute pain is more likely to occur in cognitively impaired older patients than in those who are cognitively intact.
- Obtaining a history regarding past experiences with pain can be challenging in patients with cognitive impairment; the observations of caregivers may be helpful in these situations.

Considerations for the Use of Peripheral Regional and Neural Blockade in Elderly Patients

There are limited evidence-based guidelines regarding the use of specific regional analgesic modalities in older patients due to a host of secondary concerns, such as patient age, comorbidities, safety profile issues, and concurrent medications, which often exclude elderly individuals from clinical trials. However, many of these factors, along with several other concerns related to advanced age, need to be taken into consideration when choosing a procedure-specific analgesic regimen that may prove more advantageous than other more conventional pain management options, such as unimodal opioid analgesics. Decisions regarding regional options and peripheral nerve blockade choice should take into account the health status of the older patient, the operation being performed, and the expertise of the perioperative pain management healthcare providers. Therefore, to ensure safe use and conduct evidence-based research on regional and peripheral nerve blockade techniques in the elderly, needs should be assessed on a patient-to-type-of-surgery basis and geared toward regional pain medicine options that target the surgical site.

The number of elderly patients that present for anesthesia and surgery has increased exponentially in recent years, and neuraxial and peripheral nerve blockade techniques are frequently used in this patient population. Elderly patients can benefit from regional modalities of perioperative pain management. One important clinical observation that has emerged from the literature on regional anesthesia/analgesia is evidence that the use of regional techniques allows for the minimization or elimination of the negative side effect profiles of other systemic pain management options, such as bowel and bladder dysfunction, hemodynamic derangements, and cognitive effects often experienced with opiates and other analgesic adjuncts and sedative/hypnotics, to which older patients are often more sensitive.

A multitude of factors can influence surgical outcomes in older patients, such as the type, duration, and invasiveness of an operation, coexisting medical or mental status dysfunction, and the skill and expertise of both the anesthesiologist and surgeon.[41,90] These factors and others often make it difficult to decide if and when one regional analgesic technique is unequivocally better than another. Therefore, until evidence-based research can provide conclusive guidelines on regional anesthesia/analgesia in the elderly, it is important to focus on optimizing the overall perioperative pain management choices for elderly patients by implementing patient- and procedure-specific modes of regional anesthesia.

Anatomic changes associated with aging may make performing neuraxial and regional peripheral nerve anesthesia/analgesia more technically difficult in the geriatric population. Elderly individuals may have dorsal kyphosis, a tendency to flex their hips and knees because of osteoarthritic changes, decreased range of motion in the extremities, issues associated with advanced osteoporosis and rheumatoid arthritis, and calcification of cartilage. All of these issues may make positioning elderly patients for regional block placement more challenging. Neuraxial techniques may be complicated not only by difficultly with positioning patients, but also by degenerative disk and vertebral joint changes, along with the distortion and compression of intervertebral and epidural spaces associated with aging. The ligamentum flavum often becomes more calcified with age, such that attempts to accomplish an epidural block or dural puncture may be more challenging due to difficult needle placement and advancement through such dense, calcified ligaments. The presence of osteophytes may also decrease the size of the intervertebral space, which limits access to the subarachnoid space. A lateral (paramedian) needle approach to the epidural or subarachnoid space may avoid issues caused by vertebral midline ligament calcification and distortion of dorsal vertebrae. In addition, access to the epidural or subarachnoid space in patients with severe osteoarthritis and ossified ligaments may be more easily achieved by approaching the L5–S1 interspace, which is typically the largest intervertebral space.

Clinical Pearl

- A paramedian approach may facilitate needle placement to the epidural or subarachnoid space in patients with age-related changes to the vertebral anatomy.

Epidural Anesthesia and Analgesia

Epidural anesthesia/analgesia can provide an effective modality for pain management in a host of perioperative settings. The heterogeneity of studies regarding the use of epidural anesthesia/analgesia makes it difficult to draw conclusive evidence for optimal use in elderly patients. However, the consistent efficacy of epidural analgesia in the elderly has been well demonstrated, regardless of analgesic agent, location of catheter (if used), type of surgery, and type or time of pain assessment, and has been shown to provide superior pain relief compared to parenteral opioid administration.[37,91-94]

A host of additional outcome studies have noted reductions in morbidity with regional techniques provided to elderly patients undergoing certain surgical procedures. For example, following hip fracture surgery, a continuous epidural infusion (local anesthetic and opioid) provided better pain relief, both at rest and with movement, but did not lead to improved rehabilitation.[95] A meta-analysis reviewed studies that included a wide variety of epidural regimens and surgical procedures and examined the benefits of combining epidural analgesia with general anesthesia.[91] The author reported a reduction in a range of adverse outcomes with epidural analgesia, including a reduced incidence of arrhythmias, earlier extubation times, a reduced need for and time spent in the ICU, reduced stress hormone levels, lower cortisol and glucose concentrations, and a reduced incidence of renal failure, when local anesthetics were used in thoracic epidurals. Another meta-analysis compared systemic opioids delivered via PCA versus epidural analgesia (both patient-controlled epidural analgesia [PCEA] and continuous infusion) and concluded that epidural analgesia provided superior pain relief at rest and with movement and was superior in terms of overall pain management. Further, a lower incidence of nausea and vomiting and sedation following all types of surgery was found with epidural analgesia. However, this meta-analysis also revealed that epidural analgesia was associated with a higher incidence of pruritus and motor blockade.[96] Other studies have also supported the finding that older patients treated with neuraxial versus general anesthesia had lower pain scores at rest and with movement, higher satisfaction scores, improved mental status, more rapid recovery of bowel function, and a decreased risk of deep vein thrombosis and pulmonary embolism.[94,97,98]

Epidural opioid requirements can be decreased as patient age increases.[99-101] Some studies have revealed that older patients require a lower dose of opioid than younger patients to achieve the same degree of pain relief.[102-105] However, a large degree of interpatient variability remains, and doses should be titrated cautiously and to effect in all elderly patients. The decreased need for epidural opioids in elderly patients appears greater than would be predicted by age-related alterations in physiology alone and may also have pharmacodynamic components.[101] A comparison of fentanyl PCEA in patients over 65 years of age versus patients 20–64 years of age showed no difference in fentanyl PCEA requirements, pain scores at rest, or incidence of pruritus. However, dynamic pain (coughing) experienced from the abdominal surgery being performed was significantly better controlled in patients over age 65.[106]

Decreased glomerular filtration rate (GFR) in older patients can result in a more rapid accumulation of active opioid metabolites (eg, M6G, M3G, hydromorphone-3-glucuronide, nordextropropoxyphene, norpethidine, desmethyl-tramadol) following continuous epidural administration. In addition, concerns for respiratory depression in elderly patients, particularly those with obesity, OSA, or other respiratory disease, can sometimes lead to inadequate neuraxial opioid doses being administered. However, respiratory depression is rare if appropriate concentration guidelines are followed and appropriate monitoring is implemented. In addition, the incidence of nausea and vomiting and pruritus in the postoperative period seems to lessen with increasing age.[100,107] Some additional evidence shows that neuraxial fentanyl may cause less POCD than morphine,[94,108] along with less potential for confusion.[109] While the elderly may be more sensitive to the effects of opiates and require lower doses for analgesia, adequate postoperative pain control is also important to prevent delirium and maintain preoperative levels of cognitive function.[81,110,111]

Age is a factor when determining spread of injected local anesthetic into the neuraxial space and the subsequent sensory level and degree of motor blockade achieved.[57,112,113] Thus, the systemic absorption and disposition of long-acting local anesthetics dictate that smaller volumes are needed to cover the same number of dermatomes than in younger patients. The same bolus volume of epidural local anesthetic administered to all patients revealed that the concentration required to achieve an effective motor blockade decreased as patient age increased.[114] Therefore, older patients may be more susceptible to some of the adverse effects of epidural analgesia, including hypotension, if patient age and local anesthetic concentration/volume are not taken into consideration.[112,115,116] In addition, combinations of local anesthetic and opioid are commonly used for epidural analgesia and may provide an additive/synergistic effect, so it is reasonable to use lower infusion rates in older patients.[101]

Clinical Pearl

- The L5–S1 vertebral interspace is typically the largest intervertebral location to target for neuraxial techniques.

Intrathecal Opioid Analgesia

Subarachnoid administration of opioids (at varying doses) combined with local anesthetics during neuraxial techniques can provide effective anesthesia and perioperative analgesia, can create a synergistic effect with the local anesthetic, may prolong analgesic effects without associated motor blockade, and often provides for more effective targeted pain relief than with other routes (eg, intramuscular, PCA) of opioid administration. In addition, when used in combination with general anesthesia for major surgery, a spinal injection of opioid and local anesthetic can reduce the intraoperative requirement for inhalational anesthetic agents. However, caution must be exercised as the additional systemic administration (intravenous bolus or PCA) of opioid medications can create a risk of respiratory depression and pruritus.[40] Therefore, secondary to advanced patient age, the potential for respiratory depression effects can be considered a serious enough risk factor to warrant consideration of postoperative admission and recovery in a monitored environment or ICU setting for patients over the age of 70 years.[117] However, it has been reported that the subarachnoid administration of up to 200 mcg of intrathecal morphine with a local anesthetic for peripheral vascular surgery in older patients (average age 69 years) can be safely performed with minimal adverse respiratory sequelea.[118] In addition, it has also been shown that respiratory depression can be minimized through the implementation of respiratory safety protocols, education of nursing and other healthcare providers on general wards, and postoperative management by an acute pain medicine service following strict respiratory parameter guidelines.[118]

Intrathecal morphine provides excellent postoperative analgesia but may cause side effects such as postoperative nausea and vomiting, pruritus, and respiratory depression, particularly at larger doses; older patients may be at an increased risk of such side effects. The ideal or optimal dose of intrathecal opioid that should be mixed with local anesthetic during spinal anesthesia procedures for elderly patients is currently unknown. Despite a lack of evidence-based data, a subarachnoid morphine dose of 200 mcg has been suggested. Intrathecal morphine (200 mcg mixed with a local anesthetic) administration during spinal anesthesia in addition to general anesthesia in older patients (average age 70 years) undergoing abdominal aortic surgery resulted in improved postoperative analgesia along with a reduced need for postoperative analgesics when compared to elderly patients given general anesthesia alone.[119] In a dose-response study by Murphy et al, three different doses of intrathecal morphine for elective hip arthroplasty surgery in elderly patients (patients aged > 65 years) were studied. Patients received either 50, 100, or 200 mcg of subarachnoid morphine, along with 15 mg of bupivacaine hydrochloride. The investigators concluded that 100 mcg of morphine added to the spinal anesthetic during hip surgery provided the most optimal balance between analgesia, pain relief, and pruritus. In addition, they observed that there was no difference in the incidence of nausea and vomiting or respiratory depression among the three groups of patients.[120]

Evidence has shown that the strategic use of a low-dose opioid as an adjunct to local anesthetics during spinal anesthesia can reduce the concentration of inhalation agents required during general anesthesia. In addition, intrathecal morphine is a widely used method for postoperative pain relief after major abdominal and lower extremity orthopedic surgery. In many cases, it provides more effective perioperative analgesia with fewer side effects than intravenous opioid analgesics.[121-123] In a randomized study of patients over age 70 who underwent colorectal surgery, Beaussier et al. compared preoperative intrathecal morphine (300 mcg) in addition to postoperative PCA with morphine (study group) with PCA morphine alone (control group). The investigation concluded that intrathecal morphine plus intravenous PCA, as compared with intravenous PCA morphine alone, improves immediate postoperative pain intensity and significantly reduces daily parenteral morphine consumption following surgery.[124]

Clinical Pearl

- Intrathecal morphine at a dose below 200 mcg can be a useful adjunct for pain management following surgery with acceptable risk of respiratory depression.

Regional Anesthesia and Analgesia Using Peripheral Nerve and Nerve Plexus Blockade

One approach to perioperative pain management in geriatric patients is to consider the postoperative complications commonly associated with routine surgical procedures and then evaluate how one might mitigate these complications using peripheral nerve and nerve plexus blockade. Elderly patients are more likely to have underlying neurologic, pulmonary, and cardiovascular disease, all of which can lead to serious complications in any surgical setting. While there are established clinical practices and theoretical indications regarding the use of safe and effective regional techniques for elderly patients, a lack of consistency among studies has prevented the development of firm recommendations to guide which regional anesthetics and analgesia techniques offer the greatest advantages for elderly patients undergoing particular surgical procedures.

Peripheral nerve blockade can be a supplemental analgesic technique for medical interventions and satisfactory analgesia for a host of surgical procedures on the upper and lower extremities, abdomen, groin, and chest wall. Definitions and descriptions of regional peripheral nerve block techniques are variable, as are the definitions of the various techniques of analgesia and anesthesia (Table 46–4). Clinical investigations often use neuraxial anesthesia (with or without analgesia) in the definition of regional anesthesia. However, other studies include only peripheral nerve and nerve plexus blockade, local anesthetic infiltration, and local anesthetic injection in the definition of regional anesthesia. When strategically applied (ie, procedure- and patient-specific) and with effective results, regional peripheral nerve and nerve plexus block techniques may offer distinct advantages in the care of older surgical and medical patients. In particular, regional peripheral nerve and nerve plexus block techniques may allow for a reduction in the incidence of adverse side effects compared to other conventional pain management therapies (intramuscular, oral, and parenteral analgesics and central neuraxial blockade).[125]

Some clinicians feel that epidural analgesia remains the standard of care for pain relief for a host of surgical procedures in the elderly, but peripheral nerve and nerve plexus blockade have proven to be as effective and are gaining popularity since the incidence of potential side effects associated with neuraxial techniques may be less. Systematic reviews and meta-analyses of randomized trials comparing epidural analgesia with peripheral nerve blockade for major knee surgery have shown similar relative analgesic efficacy between both pain management strategies (neuraxial versus peripheral nerve block).[126,127] And, although pain profiles from peripheral nerve blockade techniques compared favorably with lumbar epidural analgesia for major knee surgery with no significant difference in pain scores at rest,

TABLE 46–4. Analgesia and anesthesia techniques.

Local Monitored Anesthesia Care (LMAC) (LMAC)	LMAC with or without Intravenous and Oral Sedatives, Hypnotics, Analgesics (Opioid and Nonopioid)
General Anesthesia and analgesia Anesthesia Analgesia	With or without perioperative medications Inhalation agents, intravenous agents, and/or total intravenous anesthesia (TIVA) Systemically administered analgesia with opioids, nonopioids, and other adjuncts • Intramuscular injections • Intravenous boluses • Patient-controlled analgesia (PCA) • Transdermal, mucous membrane, and oral routes
Regional Anesthesia and Analgesia Neuraxial Peripheral nerve/nerve plexus blockade Infiltration/field block	With or without other intravenous perioperative medications (analgesics, sedation) Spinal (subarachnoid) and/or epidural anesthesia and/or analgesia • Single injection, with or without catheters • Local anesthetic (type, concentration) with or without opioids and other adjuncts • Vertebral level of block placement/initiation • Level of blockade achieved • Length or duration of postoperative anesthesia and analgesia Peripheral nerve block • Local anesthetic with or without additives • Single injection or continuous catheter technique Brachial plexus blockade • Femoral block • Sciatic/popliteal blockade • Paravertebral block • Transverse abdominis plane block, etc. Local anesthetic infiltration/injection (diffusion blockade) • With or without indwelling catheters

complications such as hemodynamic variability, nausea and vomiting, urinary retention and bowel dysfunction, increased dynamic (ie, movement, rehabilitation) pain scores and an increased need for supplemental opioid analgesics for breakthrough pain occurred more frequently in the epidural group. Rehabilitation indices were similar between groups, but patient satisfaction was higher in the groups that received peripheral nerve blocks, and these modalities are not likely to cause neuraxial complications.

In an investigation by Zaric et al, epidural analgesia was compared to combined femoral and sciatic peripheral nerve blockade following total knee replacement surgery.[125] Primary outcome measures included the incidence of side effects, including urinary retention, moderate to severe degrees of dizziness, pruritus, sedation, and nausea and vomiting during the postoperative period. Intensity of motor blockade, pain at rest and on mobilization, and rehabilitation indices were also registered for three days after surgery. Side effects in the epidural group were present in 87% of patients (one or more side effects), whereas only 35% of patients in the femoral and sciatic block group were affected. In addition, motor blockade was more intense (operated and nonoperated limb) on the day of surgery and the first postoperative day in the epidural group. Pain on mobilization was well controlled in both groups, rehabilitation indices were similar, and there were no differences in the length of hospital stay between groups. The results demonstrate a reduced incidence of side effects in the femoral and sciatic nerve block group compared to the epidural group.

Similarly, epidural analgesia is considered to be a superior method of pain relief after major thoracic surgery. However, placement of a paravertebral blockade (PVB) using a PVB catheter can offer comparable analgesic effectiveness and a better side effect profile than neuraxial options with an epidural catheter.[128-130] In addition to there being no significant difference between each group in terms of pain relief, these systematic reviews and meta-analyses of relevant randomized trials comparing PVB with epidural analgesia for thoracic surgery revealed that hemodynamic variability, urinary retention, increased plasma cortisol concentrations (as a marker of postoperative stress), nausea, pruritus, respiratory depression (atelectasis, pneumonia), prolonged operative time, reports of incomplete (or failed) epidural, and paraplegia (in rare cases) were reported far more frequently in the epidural groups when compared to those in the paravertebral groups. The most common and often serious compromising side effect profiles of respiratory complications, nausea and vomiting, and hypotension were less common with PVBs, as were a lower rate of failed blocks and a reduced incidence of urinary retention.

Elderly patients may also benefit when they receive procedure-specific regional techniques for postoperative pain management as doses of intravenous opioid drugs may be reduced. In addition, optimal target-specific perioperative analgesic management and the potential to reduce negative cognitive effects[131] is possible by incorporating regional anesthesia procedure-specific pain therapy.[132] POCD can be a common complication after cardiac and major noncardiac surgery with general anesthesia in the elderly, and it has been hypothesized that POCD may occur less often with regional anesthesia.[133,134] The incidence of cognitive dysfunction after general or regional anesthesia in elderly patients raises the questions of whether a causative relationship exists between certain types of anesthesia and long-term POCD and whether regional anesthesia may decrease mortality and the incidence of POCD early after surgery.[135] In another study of older hip fracture patients, those who received a femoral nerve block for perioperative analgesia, in addition to regularly scheduled nonopioid analgesics, were less likely to develop postoperative delirium, were able to sit up at the bedside sooner, and required no supplemental opioid analgesics compared to patients administered only nonopioid analgesics (28% of whom required supplemental morphine analgesia).[136]

Proper patient selection and surgery-specific peripheral nerve and nerve plexus blockade when effectively administered (timed correctly and matched with appropriate type of surgical intervention) can provide excellent perioperative pain management in all patient populations.[137] However, there is some evidence to suggest that the effects of peripheral nerve blockade can be prolonged in some elderly patients, thereby reducing or eliminating the need for opioid medications for breakthrough pain following hospital discharge.[135] In addition, when considering prolonged duration of peripheral nerve blockade effects, elderly patients should be counseled appropriately regarding such effects prior to block placement, and care should be taken to ensure that older patients have appropriate assistance in their home if peripheral nerve blocks are to be placed for outpatient surgery.[138] With these safeguards in place, efficacious administration of regional analgesic modalities can result in a reduction or elimination of opioid analgesics for breakthrough pain in the postoperative period. For example, two studies showed a prolonged duration of effective analgesia in older patients following (1) a sciatic nerve block for lower extremity surgery;[139] and (2) brachial plexus blockade for upper extremity surgery.[140]

As mentioned previously, there are factors affecting the spread of both local anesthetics and adjuncts when placed into the epidural space. Therefore, could a paravertebral approach provide effective anesthesia or analgesia without unwanted spread of local anesthetics when placed in the neuraxial space of older patients? In a study by Akin et al, patients older than 65 years of age who underwent urological surgery following administration of a paravertebral lumbar plexus blockade (using ropivacaine or bupivacaine) showed improved pain scores, reduced incidence of cognitive dysfunction, and a stable heart rate and blood pressure.[141] Cheema et al. investigated patients undergoing paravertebral nerve block procedures for the treatment of chronic pain conditions. Findings from this study revealed that, unlike the variable spread of local anesthetics administered for epidural analgesia, the age of the patient did not influence the spread of bupivacaine when placed in the thoracic paravertebral space.[142]

An additional important factor to consider in all patients is the contraindication to regional anesthesia in anesthetized patients. Unlike neuraxial anesthesia, it may be safe to perform paravertebral blocks in heavily sedated or anesthetized patients without any apparent increased risk of neurological injury.[143] Therefore, in elderly patients who experience pain or discomfort during positioning for neuraxial or paravertebral blockade techniques, paravertebral blocks may be placed under heavy sedation or general anesthesia without concern for significant compromise of neurologic injury. Studies have also addressed whether a paravertebral block is as effective as epidural analgesia for pain management in elderly patients undergoing thoracic surgery. In a review of the literature (184 papers found with seven representing the best evidence), all studies agreed that a paravertebral block was at least as effective as epidural analgesia for post-thoracotomy pain control but with a more favorable side effect profile and lower complication rates.[125] Pain assessed via VAS at rest and with coughing was significantly lower in the paravertebral groups compared to the epidural groups ($P = 0.02$ and $P = 0.0001$, respectively). Pulmonary function assessed by peak expiratory flow rate (PEFR) was better preserved in the paravertebral groups; the lowest PEFR as a fraction of preoperative control was 0.73 in the paravertebral groups in contrast with 0.54 in the epidural groups ($P < 0.004$), and oxygen saturation was better in the paravertebral groups of patients compared to the epidural groups ($P = 0.0001$). Plasma concentrations of cortisol (marker of postoperative stress) increased markedly in both groups, but the increments were statistically different and more favorable in the paravertebral groups of patients ($P = 0.003$). Patients in the epidural block groups were associated with more frequent side effects such as (1) urinary retention (42%); (2) nausea (22%); (3) itching (22%); and (4) hypotension (3%). The epidural block groups experienced prolonged operative times and were associated with more technical failures and epidural displacement (8%) compared to the paravertebral groups. In addition, the epidural groups also experienced a higher complication of atelectasis and pneumonia compared to the paravertebral block groups, and the paravertebral block groups were found to experience a quicker return to normal pulmonary function.[130]

The incidence of cancer and cancer surgery is significantly greater in the elderly patient population.[144] Some evidence from animal and retrospective human studies has emerged indicating that regional analgesia may attenuate the immunosuppressive effects of surgery, anesthesia, and perioperative pain and may therefore improve patient outcomes.[145,146] Metastatic disease remains an important cause of cancer-related death, and the likelihood of tumor metastases depends on the balance between antimetastatic host defenses (eg, cell-mediated immunity, natural killer cell function) and the metastatic potential of any given tumor. Snyder et al suspected anesthetic technique along with other perioperative factors could have the potential to affect the long-term outcome after cancer surgery since surgery can inhibit important host defenses, thus increasing the likelihood of the development of metastases. The investigators questioned whether anesthetic technique and medication choices (eg, intravenous anesthetics, volatile agents) could interact with the cellular immune system and affect long-term outcome. The investigators had a particular interest in whether there was any beneficial effect from regional anesthesia and whether regional anesthesia may play a role in pain and stress reduction, along with other potentially important perioperative risk factors that might impact cancer recurrence.[146] In addition, opioid analgesia is suspected to induce some degree of suppression of cell-mediated immunity (notably natural killer cell activity). Therefore, using opioid-sparing anesthetic and analgesic techniques during the perioperative period could potentially have a positive effect on long-term survival and cancer disease recurrence.[147] Data regarding anesthetic technique and cancer survival or recurrence has been mixed, and further prospective studies are still needed to further elucidate these relationships.

SUMMARY

People over 65 years of age represent a fast-growing segment of society, and these older individuals have surgery more frequently than younger age-group populations. Effective postoperative analgesia remains essential in older patients because inadequate pain control after surgery is often associated with a host of well-documented adverse outcomes. Management of postoperative pain in older patients can be complicated by a number of variables, including a higher risk of age- and disease-related changes in physiology and anatomy, disease–drug and drug–drug interactions, altered cognitive baseline, potential negative effects from acute trauma (surgical or accidental), and lack of evidence-based, procedure-specific regional anesthesia and analgesia techniques for elderly individuals. Therefore, the concept of "diligence, start low, and go slow" should be adopted for any chosen analgesic strategy in the elderly surgical population.

With knowledge, skill, and comprehension of limitations, postoperative analgesic treatment using most medications (acetaminophen, NSAIDs, opioids, local anesthetics), analgesic techniques (intravenous or epidural PCA, intrathecal opioid, peripheral nerve and nerve plexus blockade), and pain management strategies (pre-emptive or multimodal analgesia) can be used effectively for acute perioperative pain management in older patients. The physiologic changes of aging need to be carefully considered because mammalian aging is often individualized and progressive. Proper assessment of pain management in the elderly must take into account chronological age, biological age, individual profiles of pathology, and prescribed medications, along with regard to organ system function and compromise. Methods of assessing pain in older individuals must also be carefully considered, particularly in those with cognitive impairment. Treatment options must be carefully adjusted and tailored to each patient in view of the pharmacokinetic and pharmacodynamic changes that occur in older individuals. In addition, since there is often a higher incidence of comorbidities and a greater use of concurrent medications in elderly versus younger populations, careful selection from among the multitude of analgesic options must be considered. Therefore, consistent and frequent evaluation of treatment efficacy of any selected regional technique along with monitoring and adjusting for incidence and severity of any adverse events should be thoughtfully and vigilantly controlled in the elderly.

CHAPTER 47

Regional Anesthesia & Cardiovascular Disease

Christiana C. Burt, Sanford M. Littwin, Jolaade Adebayo, Navin A. Mallavaram, and Daniel M. Thys

INTRODUCTION

The decision to utilize regional anesthesia is dependent on many factors. Patient characteristics, the type of surgery proposed, and the potential anesthetic risks will all have an impact on anesthetic choice and perioperative management. In patients with cardiovascular disease, regional anesthesia techniques (either alone or in conjunction with general anesthesia) can offer the potential perioperative benefits of stress response attenuation, cardiac sympathectomy, earlier extubation, shorter hospital stay, and intense postoperative analgesia. However, the decision to utilize regional anesthesia should be made with caution in some circumstances. The aim of this chapter is to provide an overview of the physiological effects of different regional anesthesia techniques on the cardiovascular system, to examine the role of regional anesthesia in cardiac surgery and noncardiac surgery and to provide an overview of the physiological requirements of patients with different types of cardiac and vascular disease.

THE CARDIOVASCULAR EFFECTS OF REGIONAL ANESTHESIA

Thoracic Epidural Anesthesia

High thoracic epidural anesthesia (TEA) from T1–T5 blocks the cardiac afferent and efferent sympathetic fibers with a loss of chronotropic and inotropic drive to the myocardium[1] and reduced perception of cardiac pain.

In healthy volunteers, there is some evidence that thoracic epidural blockade reduces left ventricular contractility as measured by transesophageal echocardiography[2] and that this effect is present in high thoracic epidural blockade but not in low thoracic epidural blockade,[3] which is consistent with a loss of inotropic drive to the myocardium with high epidural blockade. During exercise, it has been reported that TEA does not affect oxygen consumption (VO_2) but does reduce systemic arterial blood pressure compared to control subjects.[4] Another study compared the cardiovascular effects of 0.5% bupivacaine administered via the thoracic epidural route against the effects when administered via the intramuscular route and found no significant difference and postulated whether the effects of epidural anesthesia may in part be due to systemic effects. However, their conclusions are limited by the low number (9) of subjects enrolled.[5]

Several studies have documented the effects of TEA on cardiovascular function in patients with heart disease. In a small study of 10 patients scheduled for thoracotomy, a TEA with a mean analgesic level of C7 to T5 had only minor effects on the cardiovascular system.[6] In patients with severe coronary artery disease and unstable angina pectoris, Blomberg et al observed that TEA relieved chest pain.[7] It also significantly decreased heart rate and systolic arterial, pulmonary arterial, and pulmonary capillary wedge pressures without any significant changes in coronary perfusion pressure, cardiac output, stroke volume, or systemic or pulmonary vascular resistances. The investigators also found that TEA may increase the diameter of stenotic epicardial coronary arteries in patients with coronary artery disease without causing a dilation of coronary arterioles.[8]

Intraoperatively, during abdominal aortic aneurysm surgery, Reinhart et al observed a lower cardiac index and O_2 delivery (QO_2) in patients receiving TEA and general anesthesia (GA) than in those receiving GA alone; VO_2 was similar.[9] They also reported that the oxygen supply–demand ratio (QO_2/VO_2) was less in the TEA group throughout the perioperative period and about 30% below baseline values during early recovery. The authors attributed the reduced adaptation of cardiac output to tissue O_2 needs during TEA to negative inotropic and chronotropic effects of sympathetic blockade. In patients on chronic β-adrenergic blocking medication, TEA has been reported to induce a moderate decrease in mean arterial pressure and coronary perfusion pressure, but without producing clinically significant cardiovascular effects.[10]

Conversely, improvements in parameters of cardiac function have been reported, specifically in improved regional left ventricular function during coronary artery bypass surgery.[11] This was attributed to the cardiac sympathectomy effect of the thoracic epidural. A separate study evaluating left ventricular systolic and diastolic function in patients with coronary artery disease found that TEA induced a significant improvement in left ventricular diastolic function, whereas indices of systolic function did not change (Figure 47–1).[12]

Hemodynamic changes during laryngoscopy and intubation can increase the risk of ischemia in some patients with cardiac disease. Licker et al. reported that patients who received TEA in addition to GA had smaller increases in mean arterial pressure and heart rate during laryngoscopy and tracheal intubation than those who received GA only; this would suggest that TEA affords hemodynamic protection during these maneuvers.[13]

The effect of TEA on hemodynamic stability during open abdominal aortic surgery has been investigated, with findings of minimal effects on cardiac index (CI) and pulmonary capillary wedge pressure (PCWP) reported during aortic cross-clamping in a group who received GA with TEA as opposed to detrimental effects (decrease in CI and increase in PCWP) seen in the group who received GA only.[14] Whether this outcome results in a difference in morbidity or mortality is unclear, though, with some groups reporting no difference in outcome,[15,16] and one reporting detrimental effects in the epidural group with rebound myocardial ischemia seen on termination of the epidural.[17]

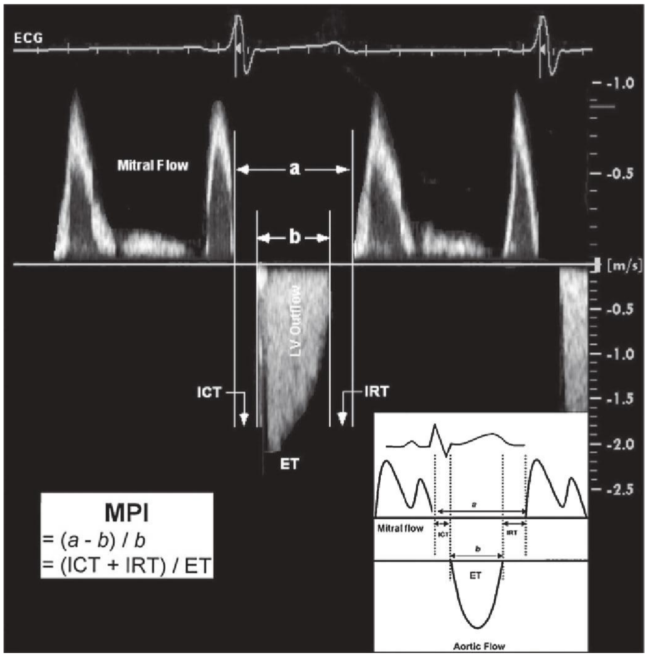

FIGURE 47–1. Estimation of the myocardial performance index (MPI; Tei index). MPI is calculated from two time intervals as a–b/b. Interval a: from cessation to next onset of mitral flow. Interval b: from onset to cessation of aortic flow. Time intervals a and b are indicated in milliseconds. A typical example of measuring the MPI using Doppler ECG registration of mitral and aortic flow velocity profiles is demonstrated. For illustrative purposes, the original Doppler tracings of mitral inflow and left ventricular (LV) outflow are plotted together. ET, ejection time of LV outflow; ICT, isovolumic contraction time; IRT, isovolumic relaxation time. (Reproduced with permission from Schmidt C, Hinder F, Van Aken H, et al: The effect of high thoracic epidural anesthesia on systolic and diastolic left ventricular function in patients with coronary artery disease. *Anesth Analg*. 2005 Jun;100(6):1561–1569.)

TEA has been reported to be beneficial in morbidly obese patients undergoing gastric bypass surgery with better postoperative pain relief but no firm conclusions regarding cardiovascular function other than a significant reduction in SVR and intrapulmonary shunt compared to GA.[18]

The clinical effect of cardiac sympathectomy and peripheral vasodilation caused by TEA appears to vary between populations of patients. The level of sympathetic blockade that follows a TEA depends in part on the degree of sympathetic tone before the block, which may explain some of the different effects on the cardiovascular system reported by different studies. In addition, the effect on cardiac function will depend on the exact nature of the patient's cardiovascular disease. This is explored in more detail later in this chapter.

Lumbar Epidural Anesthesia

Lumbar epidural anesthesia (LEA) predominantly results in a drop in systemic vascular resistance via peripheral vasodilation, without the effects of cardiac sympathectomy that occur with high TEA. The influence of LEA without cardiac sympathectomy on global and regional left ventricular function was investigated prior to surgery in healthy subjects and in patients suffering from stable mild, effort-related angina.[19] In both groups, epidural blockade was performed with 10 mL of 0.5% bupivacaine. Radionuclide angiography was used to determine cardiac output, left ventricular ejection fraction, and end-systolic and end-diastolic volumes and to analyze left ventricular wall motion. Throughout the procedure, patients with a history of angina exhibited neither chest pain nor electrocardiographic evidence of myocardial ischemia. At control, left ventricular ejection fraction (LVEF) and systolic pressure–volume ratio (SPVR) were lower in the patients with angina. These patients also had evidence of regional left ventricular dysfunction. Epidural blockade without volume loading resulted in slight improvements in LVEF and regional function. Such changes were not observed in normal patients. After volume loading, the improvements in ventricular function subsided. These observations led the authors to conclude that lumbar epidural anesthesia may improve global and regional ventricular function in patients with angina provided volume loading is limited.

In hypertensive patients, LEA has been shown to cause decreases in mean arterial pressure with associated decreases in systemic vascular resistance and cardiac output.[20]

The importance of good pain relief in reducing ischemic episodes has been studied in elderly patients undergoing surgery for hip fracture with a reduction in ischemic episodes shown in the groups that received continuous epidural analgesia preoperatively.[21,22] In addition, lumbar epidural anesthesia may reduce the risk of arterial thrombotic complications in patients undergoing lower extremity revascularization,[23,24] and this may be as a result of prevention of the postoperative inhibition of fibrinolysis.[25] However, other studies report no difference in major morbidity and mortality in patients with high cardiac risk undergoing peripheral vascular surgery with or without lumbar epidural anesthesia.[26,27]

The successful use of lumbar epidural anesthesia has been reported in obstetric patients with a variety of types of cardiac disease.[28]

Intrathecal Anesthesia

Intrathecal anesthesia using local anesthetic agents and/or opioids has been investigated in the context of cardiac and noncardiac surgery. Intrathecal anesthesia can be expected to produce profound vasodilation as well as motor and sensory blockade below the level of action.

The hemodynamic response to lumbar spinal anesthesia using single-shot hyperbaric bupivacaine or lidocaine with morphine has been evaluated in cardiac surgical patients.[29] It was observed that the induction of GA produced a decrease in mean arterial pressure and that the addition of spinal anesthesia produced a decrease in heart rate. Heart rate and mean arterial pressure did not change with sternotomy (suggesting good-quality analgesia).

In mixed populations (some with documented ischemic heart disease, some without), there has been no difference found in episodes of myocardial ischemia between patients receiving general anesthesia and patients receiving spinal anesthesia for transurethral surgery,[30,31] although there was a relatively high rate of silent ischemia in both groups in both studies. An interesting study looking at hemodynamics and markers of myocardial ischemia in patients with coronary artery disease undergoing elective hip surgery[32] found that while the number of patients who experienced episodes of ST segment depression did not differ between those who received incremental spinal anesthesia, single-shot spinal anesthesia, or general anesthesia, 56% of hypotensive patients developed ST-segment depression compared to only 10% of normotensive patients ($P < 0.003$). The incidence of hypotension and myocardial ischemia was lowest in the group receiving incremental spinal anesthesia.

Various investigators have reported on the effects of different doses of intrathecal local anesthetic as a single-shot spinal. A dose of 7.5 mg hyperbaric bupivacaine in combination with 5 mcg sufentanil has been reported to produce reliable anesthesia for repair of hip fractures in elderly patients with few episodes of hypotension and little need for vasopressor support of blood pressure.[33] Other investigators have reported 4 mg bupivacaine with 20 mcg fentanyl to be effective in the same population.[34]

Intrathecal anesthesia has not been reliably shown to have an effect on the stress response to surgery in terms of levels of serum catecholamines and serum cortisol. Some studies have reported a lower stress response during coronary artery bypass grafting (CABG) surgery in patients who received intrathecal bupivacaine in addition to general anesthesia compared to those who received general anesthesia and intravenous opioid (Figure 47–2),[35] whereas other authors have reported no attenuation of the stress response.[36,37]

Intrathecal opioid in addition to GA has been studied for elective abdominal aortic surgery.[38] The addition of intrathecal opioid provided more intense analgesia compared to PCA during the first 24 hours postoperatively, but there was no difference between the groups in the incidence of combined major cardiovascular, respiratory, and renal complications or mortality.

A group of patients judged to be at high risk for postoperative myocardial ischemia undergoing either elective hip arthroplasty or peripheral vascular surgery were randomized to receive either spinal anesthesia or general anesthesia.[39] There was no significant difference between the groups in the incidence of myocardial ischemia during or after surgery.

A number of case reports have reported on the usefulness of spinal anesthesia in obstetric patients with a variety of cardiac diseases. Velickovic et al. successfully used continuous spinal anesthesia for two patients with recurrent peripartum cardiomyopathy presenting in congestive heart failure for emergent cesarean section.[40] In one patient, a continuous spinal not only provided adequate anesthesia but also markedly reduced the patient's symptoms.[41] Others have reported similar success with spinal anesthesia in obstetric patients with hypertrophic obstructive cardiomyopathy,[42] severe pulmonary stenosis,[43] and coronary artery disease.[44]

Thoracic Blocks (Paravertebral and Intercostal)

The extent of a single percutaneous paravertebral injection was studied in 6 patients with chronic chest wall pain.[45] It was shown that a large unilateral somatic and sympathetic block was obtainable. No significant postural changes in blood pressure were seen, but there was a small but significant decrease in supine heart rate. While it has been shown that paravertebral blocks can spread to the epidural space,[46] a systematic review and meta-analysis concluded that paravertebral block causes less hypotension than epidural blockade after thoracotomy.[47]

There is anecdotal evidence that paravertebral blocks can be beneficial in patients with ischemic heart disease. Ho et al. reported on the intraoperative resolution of ST-segment depression after a right thoracic PVB,[48] although it is possible that this would have resolved spontaneously without PVB.

Intercostal nerve blocks have similarly been reported to be safe with no adverse hemodynamic consequences[49] with an ultrasound-assisted approach to blocking the intercostal nerves in the midaxillary line for nonreconstructive breast and axilla surgery.

Upper Extremity Regional Anesthesia and Cardiac Disease

Cervical Plexus Blockade

Several studies have investigated the difference in outcome after carotid endarterectomy (CEA) between general anesthesia (GA) and regional anesthesia (RA) in the form of deep and/or superficial cervical plexus blockade. As with other types of vascular surgery, CEA patients are more likely to be hypertensive, diabetic, and at increased risk for cardiac morbidity. In the context of this surgery, however, there are other causes of hemodynamic instability in addition to the effects of pain, specifically

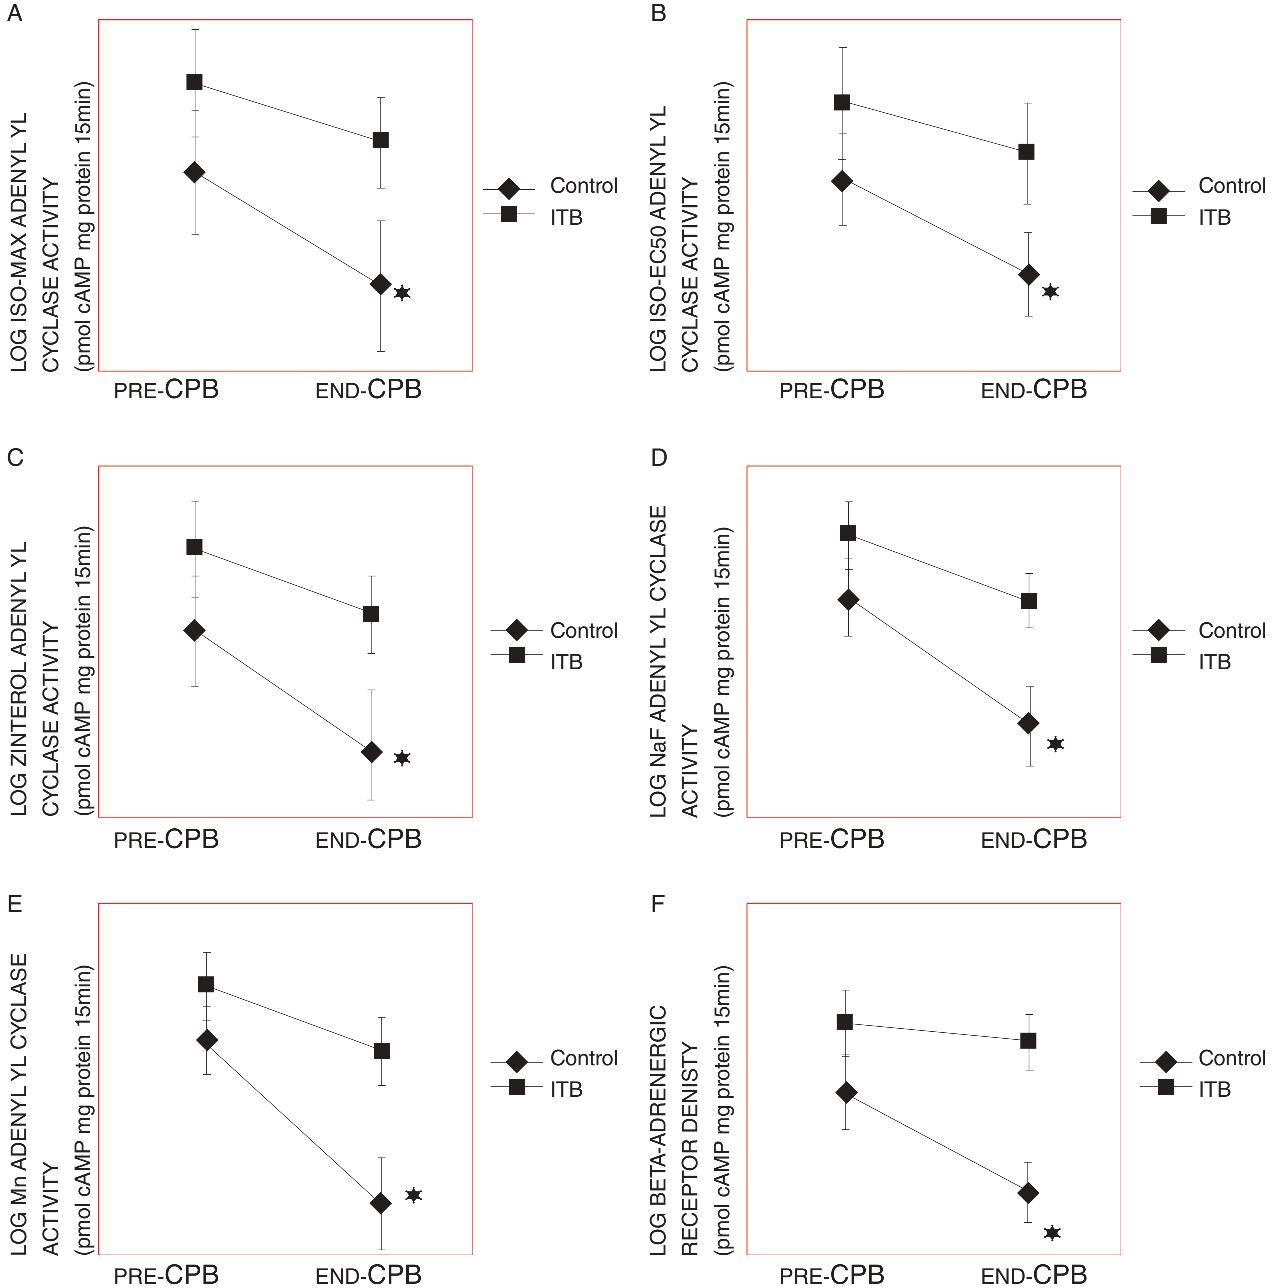

FIGURE 47–2. **A:** Maximal isproteronol (ISO MAX), **B:** 50% maximal isoproterenol (ISO EC_{50}), **C:** zinterol, **D:** sodium fluoride (NaF)-stimulated, and **E:** manganese (Mn)-stimulated -adrenergic receptor (AR) responsiveness, as measured by adenylyl cyclase activity in control and intrathecal bupivacaine (ITB) groups with cardiopulmonary bypass (CPB) times from 61–120 min. The control group shows a significant decline in adenylyl cyclase activity in each of these measures, whereas the ITB group does not. **F:** AR density in control and ITB groups with CPB times from 61–120 min. The control group shows a significant decline in AR density at *P* 0.02. Adenylyl cyclase activity and AR density (AR Bmax) are reported as picomoles of cyclic adenosine monophosphate per milligram of protein per 15 min and femtomoles per milligram of protein, respectively. The data were log-transformed. Results are expressed as mean SEM (**P* < 0.05, ‡*P* < 0.005).

baroreceptor stimulation and sensitivity and impaired arterial pressure regulation following cerebrovascular accident (CVA).

Although greater hemodynamic stability and reduced cardiovascular complications have been reported with the use of cervical plexus blockade compared to GA alone,[50] and a meta-analysis including prospective and retrospective studies[51] reported reduced incidences of stroke, myocardial infarction (MI), and death with the use of cervical plexus block without GA, these findings were potentially confounded by bias relating to the use of GA in higher-risk patients. A recent multicenter, randomized, prospective, controlled trial (General Anaesthetic versus Local Anaesthetic for Carotid Surgery [GALA]),[52] which included over 3500 patients randomly assigned to surgery under GA or RA, showed no difference in stroke, MI, or death in the first 30 days after surgery (among other outcomes). It is possible, though, that the highest-risk patients may not have been included in the study and that the study did not address whether there is any difference between GA or RA in higher-risk groups of patients.

Brachial Plexus Blockade

Most of the literature investigating the physiological consequences of interscalene brachial plexus blockade (BPB) has focused on its effect on the phrenic nerve and ventilatory function. A reasonable conclusion from the literature on hemodynamic effects would appear to be that significant hemodynamic effects occur as a result of intravascular absorption of local anesthetic rather than from the block itself. Continuous interscalene BPB performed with 1.25 mg/kg of 0.5% bupivacaine in 24 patients followed by an infusion of 0.25% bupivacaine at a dose of 0.25 mg/kg/h was reported to result in no hemodynamic problems after 30 minutes and in an undetectable concentration of free plasma bupivacaine after 24 hours of infusion.[53] Interscalene BPB alone for shoulder surgery was found to be more hemodynamically stable than interscalene BPB combined with GA, with a significant decrease in mean arterial pressure (MAP) when the patient was moved into the sitting position with block and GA; heart rate remained stable in both groups.[54] The addition of clonidine to interscalene BPB appears to have haemodynamic effects, with Culebras reporting that a dose of 150 mcg added to 40 mL of 0.5% bupivacaine resulted in a reduction in heart rate and blood pressure but did not prolong the duration of analgesia.[55] Hypotension and bradycardia were also reported to be more common with a dose of 2 mcg/kg clonidine compared to a dose of 1 mcg/kg clonidine added to 30 mL 0.5% bupivacaine.[56]

Lower Extremity Regional Anesthesia and Cardiac Disease

Lower extremity peripheral nerve blocks are associated with minimal hemodynamic disturbances. Fanelli et al. compared the hemodynamic changes induced by unilateral spinal anesthesia to the changes induced by combined sciatic–femoral nerve block in 20 ASA I–II patients undergoing elective orthopedic surgery with tourniquet.[57] Both groups had adequate anesthesia for the surgery. The combined sciatic–femoral nerve block group (obtained with 7 mg/kg of 2% mepivacaine) resulted in no significant hemodynamic changes, whereas the spinal anesthesia group (8 mg of hyperbaric 0.5% bupivacaine administered intrathecally) experienced small but significant differences in MAP, cardiac index, and stroke volume.

There are several case reports detailing the successful use of lower extremity peripheral nerve blocks in high-risk patients. Chia et al. presented the practical benefits of a combined sciatic–femoral nerve block on a 56-year-old man with severe sepsis and recent myocardial infarction requiring an urgent above-knee amputation.[58] Ho et al. have reported on the use of a combined paravertebral lumbar plexus and parasacral sciatic nerve block for the reduction of a hip fracture in an elderly patient with severe aortic stenosis.[59] Tanaka et al. have described the use of a psoas compartment block (PCB) in a 72-year-old female with severe heart failure due to rheumatoid myocarditis who required an open reduction of a left femoral neck (trochanteric) fracture.[60] With the patient in the lateral position with the fractured side up, the block was performed at L3/4' using a 22-gauge Tuohy needle to inject 10 mL of normal saline and 20 mL of 2% mepivacaine. No complications were reported. Rizzo et al. used regional anesthesia to anesthetize a 32-year-old male patient suffering from Eisenmenger's syndrome with left-type-only ventricle, who needed an extirpation of meniscus by arthroscopic surgery.[61] The investigators used sciatic, femoral, and lateral cutaneous thigh nerves blocks with ropivacaine without complications.

REGIONAL ANESTHESIA AND CARDIAC SURGERY

Several authors have examined the relationship between regional anesthesia and outcome in cardiac surgery. A selection of the literature looking at thoracic epidural anesthesia is summarized in Table 47–1, and a summary of the literature looking at intrathecal anesthesia is summarized in Table 47–2. One consistent conclusion from the literature is that the quality of pain relief overall appears to be better with regional anesthesia compared to intravenous morphine. Some studies also report a reduction in the incidence of atrial fibrillation and other supraventricular dysrhythmias with regional anesthesia versus intravenous morphine. Further conclusions regarding outcome in terms of patient morbidity and mortality with or without regional anesthesia are unclear, which is likely related to the nature of the surgery itself and the greater influence of this on parameters such as cardiac function and dysrhythmias.

Many studies examining the time to extubation after cardiac surgery did so in the days before fast-tracking protocols became widespread and as such are less applicable to the majority of practice today. Having said that, regional anesthesia undoubtedly had a role to play in the early days of cardiac fast-tracking and still does in many centers, with a seemingly low risk of complications. It is, however, the potential risk of neuraxial complications in the face of full systemic heparinization and the lack of conclusive data on hard patient outcome measures that has resulted in continued debate and differing practices across centers with regard to the use of neuraxial anesthesia in cardiac surgery. This is illustrated by a survey of 892 cardiac anesthesiologists, in which only 68 (7.6%) reported the use of spinal techniques.[62]

The timing of insertion and removal of the epidural catheter in cardiac surgery is still controversial. Some clinicians will insert the epidural 60–90 minutes before heparinization in off-pump coronary artery bypass (OPCAB) but will insert it a day before surgery in planned cardiopulmonary bypass cases.[63] This method presumably relies on a high success of OPCAB and a low conversion rate to cardiopulmonary bypass intraoperatively. However, it also raises a question regarding the efficient use of resources, as the insertion of an epidural the day before surgery will, in most cases, necessitate admission to hospital the day before surgery. Insertion in the operating room without reported epidural hematomas has also been described.[64] Removal of the epidural catheter after surgery requires normalization of coagulation for a period of time. In patients requiring

PART 7

TABLE 47–1. Studies investigating thoracic epidural anesthesia in cardiac surgery.

Author	Year	Population Studied	Type of Technique	Conclusion
Richter et al[75]	2002	37 patients with refractory angina	TEA	Decreased frequency of angina attacks and nitroglycerin intake. Increased self-rated quality of life.
Olausson et al[76]	1997	40 patients with severe refractory unstable angina	TEA vs standard anti-anginal therapy	Lower incidence of myocardial ischemia. Shorter duration of ischemic episodes in TEA group.
Salvi et al[77]	2004	106 patients undergoing OPCAB	TEA + GA	TEA with GA is a feasible technique for OPCAB with intense postoperative analgesia.
Kessler et al[78]	2005	90 patients undergoing OPCAB	TEA (30) vs TEA + GA (30) vs GA (30)	GA + TEA was the most comprehensive technique, providing good hemodynamic stability and reliable postoperative analgesia.
Stritesky et al[79]	2004	129 patients undergoing awake on-and-off pump cardiac surgery	TEA	10 conversions to GA intraoperatively. TEA provided rapid recovery from cardiac surgery.
Hansdottir et al[68]	2006	97 patients undergoing elective cardiac surgery	GA + TEA (48) vs GA + IV morphine (49)	Shorter time to extubation (2.3 h vs 7.3 h) in the TEA group. No differences in postoperative analgesia, lung volume, degree of ambulation, cardiac morbidity, neurologic outcome, length of ICU stay, or length of hospital stay (LOS).
Kessler et al[80]	2002	20 patients undergoing OPCAB	TEA	3 required conversion to GA. High degree of reported patient satisfaction.
Anderson et al[81]	2002	10 patients undergoing OPCAB via left anterior thoracotomy	TEA	1 required conversion to GA; 2 required brief periods of assisted ventilation. High degree of patient satisfaction.
Noiseaux et al[82]	2008	15 patients undergoing OPCAB	TEA + femoral NB	3 required conversion to GA; 5 experienced postoperative AF.
Barrington et al[83]	2005	120 patients undergoing CABG	GA vs GA + TEA	No difference in troponin T postoperatively. The TEA group had better analgesia and reduced time to extubation.
Kendall et al[84]	2004	30 patients undergoing OPCAB	Propofol vs isoflurane vs isoflurane + TEA	No difference in mean troponin T at 24 hours postoperatively.
Loick et al[85]	1999	70 patients undergoing CABG	GA + TEA vs GA + IV clonidine vs control group	TEA + GA had a beneficial effect on perioperative stress response and decreased postoperative myocardial ischemia as measured by troponin T.
Fillinger et al[86]	2002	60 patients undergoing cardiac surgery with bypass (prospective RCT)	GA + IV opioid vs GA + TEA	No differences in time to extubation, duration of ICU stay, length of hospital stay, pain control, urinary free cortisol, cardiopulmonary complication rate, or total hospital charges.

Author	Year	Population Studied	Type of Technique	Conclusion
Scott et al[87]	2001	420 patients undergoing CABG (prospective RCT)	GA vs GA + TEA	The TEA group experienced less supraventricular dysrhythmia, better maximal inspiratory lung volume, earlier extubation, less respiratory tract infection, less acute confusion, less acute renal failure, and no neurological complications associated with TEA.
Turfrey et al[88]	1997	218 patients undergoing CABG (retrospective)	GA vs GA + TEA	The TEA group experienced less dysrhythmia, a trend toward reduced respiratory complications, reduced time to extubation, and no serious neurological complications from the use of TEA.
Karagoz et al[89]	2003	137 patients undergoing CABG	TEA alone	5 converted to GA; no mortality; mean LOS in hospital 1 day.
Liu SS et al[90]	2004	Meta-analysis: TEA: 15 trials, 1178 patients undergoing CABG; IT: 17 trials, 668 patients undergoing CABG and CABG-valve.	TEA vs GA IT morphine vs GA	No difference in mortality or MI with central neuraxial analgesia vs GA, but faster tracheal extubation and decreased respiratory complications, cardiac dysrhythmias, and pain scores with neuraxial analgesia.
Hemmerling et al[91]	2004	30 patients undergoing AVR, AVR + CABG, ascending aorta repair, and PFO repair	TEA + GA	All patients extubated within 15 minutes of end of surgery; no complications related to TEA.
Klokocovnik et al[92]	2004	Case report: 1 patient undergoing awake minimally invasive AVR	TEA alone	Operation proceeded uneventfully; discharge on day 2; no complications within 30 days.
Slin'ko[93]	2000	55 children aged 1–14 years undergoing cardiac surgery using cardiopulmonary bypass	TEA using lidocaine and fentanyl + GA vs TEA using lidocaine and clonidine + GA	Endocrine stress response decreased in lidocaine–clonidine group compared to lidocaine–fentanyl group.
Peterson et al[94]	2000	220 children undergoing cardiac surgery (retrospective review)	GA + TEA vs GA + LEA vs GA + caudal vs GA + IT	Extubation in operating room achieved for 89% patients. Lower rate of adverse events following use of TEA compared to others.
Hammer et al[95]	2000	50 children undergoing open heart surgery (retrospective)	GA + TEA vs GA + IT	No significant differences in incidence of clinically significant changes in vital signs, O_2 desaturation, hypercarbia, or vomiting.
Royse et al[96]	2003	76 patients undergoing CABG with cardiopulmonary bypass (prospective)	GA + TEA (37) vs GA + IV morphine (39)	The TEA group experienced significantly less pain on days 1–2 postoperatively, earlier extubation, improved cooperation with physiotherapy, and a reduced risk of depression and posttraumatic stress.
Liem et al[97]	1992	54 patients undergoing uncomplicated CABG (retrospective)	GA + TEA (27) vs GA + IV opioid	The TEA group experienced better intraoperative and postoperative pain management and earlier waking and extubation.

Author	Year	Population Studied	Type of Technique	Conclusion
Hemmerling et al[98]	2004	100 patients undergoing OPCAB (prospective audit)	GA + TEA vs GA + IV opioid	Immediate extubation is possible using either TEA or IV opioid for pain relief. TEA results in lower pain scores compared to morphine PCA.
Bois et al[99]	1997	124 patients undergoing aortic surgery (prospective)	GA + TEA vs GA + IV opioid	The TEA group experienced better postoperative pain control. No difference in incidence of early myocardial ischemia.
Ho et al[100]	2002	244 patients undergoing CABG (retrospective survey on persistent pain)	GA + TEA vs GA + IV opioid	No difference in frequency or intensity of persistent pain postoperatively.
Jensen et al[101]	2004	49 patients undergoing cardiac valve surgery	GA + TEA (35) vs GA + IV opioid (14)	TEA provided excellent analgesia in the peri- and postoperative periods. No protective effect on chronic poststernotomy pain.
Pastor et al[64]	2003	714 patients undergoing CABG with cardiopulmonary bypass (prospective observational)	GA + TEA	TEA inserted in operating room just before surgery. Protocol for management followed. No epidural hematomas detected.
Sanchez et al[102]	1998	558 patients undergoing CABG	GA + TEA	TEA inserted the day before surgery and left in for 5 days. No documented neuraxial hematomas.

AF: atrial fibrillation; AVR: aortic valve replacement; CABG: coronary artery bypass grafting; GA: general anesthesia; ICU: intensive care unit; IT: intrathecal; IV: intravenous; LOS: length of stay; NB: nerve block; OPCAB: off-pump coronary artery bypass; PCA: patient-controlled analgesia; PFO: patent foramen ovale; RCT: randomized controlled trial; TEA: thoracic epidural anesthesia.

anticoagulation post–cardiac surgery, this practice increases the risk of thromboembolic consequences.

A systematic review and meta-analysis from 12 published cohorts, including over 14,000 patients, suggested the maximum risk for transient neurological injury following the use of thoracic epidural to be 1 in 1700 for cardiac and vascular surgery.[65] There were no reported cases of epidural hematoma or permanent neurological injury in this analysis, although there are case reports in the literature.[66,67]

As with all regional techniques, there is the possibility of failure. Hansdottir et al. reported a 5.2% (3 out of 52) failure rate of insertion and a 12.7% (7 out of 55) failure rate of placed catheters.[68]

The use of neuraxial anesthesia in the form of epidural and spinal anesthesia in cardiac surgery is controversial. An interesting analysis suggested that for each episode of neurologic complication, the use of neuraxial anesthesia would prevent 20 myocardial infarctions and 76 episodes of atrial fibrillation.[69] Whether this is an acceptable trade-off is the key question. Paravertebral and intercostal blockade, however, do not carry the same risks as neuraxial anesthesia and may be useful additions to postoperative analgesia (Table 47–3).

THE PATIENT WITH CARDIAC DISEASE PRESENTING FOR NONCARDIAC SURGERY

Cardiac disease is a blanket term that covers a wide range of pathology. In deciding whether to utilize regional anesthesia, a consideration of the type and severity of cardiac disease is essential in predicting the likely or possible response to a regional anesthetic. Table 47–4 lists the recommendations for active cardiac conditions for which it is recommended that the patient undergo evaluation and treatment before noncardiac surgery.

The Patient with Hypertension/Left Ventricular Hypertrophy

Severe long-standing hypertension is not only associated with a shift in the autoregulatory curve for many vascular beds but also commonly results in concentric left ventricular (LV)

TABLE 47–2. Studies investigating intrathecal anesthesia in cardiac surgery.

Author	Year	Population Studied	Type of Technique	Conclusion
Vanstrum et al[103]	1988	30 patients undergoing CABG (prospective, randomized)	GA + 0.5 mg IT morphine (16) vs GA + placebo (14)	The IT morphine group required less IV morphine and less sodium nitroprusside. No difference in pain scores.
Kowalewski et al[29]	1994	18 patients undergoing CABG (case series)	GA + IT bupivacaine and morphine	No change in heart rate or MAP with sternotomy. Postoperative analgesic requirements were minimal.
Bettex et al[104]	2002	24 patients undergoing elective cardiac surgery (prospective, randomized)	GA + IT sufentanil and morphine vs GA + IV sufentanil	The IT sufentanil and morphine group experienced earlier extubation, a reduced need for IV opioids postoperatively, and improved postoperative maximal inspiratory capacity.
Mehta et al[105]	2004	100 patients undergoing elective OPCAB (prospective, randomized)	GA + IT morphine 8 mcg/kg vs GA + placebo	The IT morphine group experienced better postoperative analgesia, better lung function as measured by spirometry, and earlier extubation.
Fitzpatrick et al[106]	1988	44 patients undergoing CABG	GA + IT morphine 1 mg (15), GA + IT morphine 2 mg (15) vs GA + IV morphine	The IT morphine groups reported lower pain scores, required less supplementary IV morphine, and had better PEFRs. Mean $PaCO_2$ was significantly higher in patients given 2 mg IT morphine.
Latham et al[107]	2000	40 patients undergoing elective CABG or valve surgery	GA + IV remifentanil + IT morphine vs GA + IV sufentanil	No difference between regimens in hemodynamic stability or recovery profile.
Alhashemi et al[108]	2000	50 patients undergoing elective CABG (prospective)	GA + 250 mcg IT morphine vs GA + 500 mcg IT morphine vs GA + placebo	The IT morphine group experienced decreased postoperative IV morphine requirements and no clinically relevant effect on extubation time. The study suggests 250 mcg IT morphine is the optimal dose to provide significant analgesia without delaying extubation.
Chaney et al[109]	1997	40 patients undergoing cardiac surgery (prospective, randomized)	GA + IT morphine 10 mcg/kg (19) vs GA + IT placebo (21)	No significant difference in postoperative IV morphine use. 3 IT morphine patients experienced prolonged ventilatory depression and delayed extubation.
Finkel et al[110]	2003	30 children aged 7 months to 13 years undergoing open heart surgery	GA + IT hyperbaric tetracaine with morphine	All age groups tolerated the technique well hemodynamically.
Pirat et al[111]	2002	30 children aged 6 months to 6 years undergoing cardiac surgery (prospective, randomized)	GA + IT fentanyl (10) vs GA + IV fentanyl (10) vs GA + combined IT and IV fentanyl	The combined group was the only group to experience nonsignificant rises in HR and MAP from presurgery to poststernotomy. A single IT injection of fentanyl 2 mcg/kg offered no benefit over IV fentanyl with regard to hemodynamic stability and reduced stress response.

TABLE 47–2. Studies investigating intrathecal anesthesia in cardiac surgery. (*Continued*)

Author	Year	Population Studied	Type of Technique	Conclusion
Williams et al[112]	1997	15 children undergoing PDA repair (series)	IT tetracaine	2 patients required supplemental isoflurane. Minimal changes in blood pressure noted.
Chaney et al[36]	1996	60 patients undergoing CABG (prospective, randomized)	GA + IT morphine vs GA + IT placebo	No significant differences in perioperative epinephrine and norepinephrine levels. The IT morphine group required significantly less postoperative IV morphine.
Hall et al[37]	2000	25 patients undergoing CABG (prospective)	GA + IT morphine vs GA + IV morphine	IT morphine partially attenuated the postsurgical stress response (measured via cortisol and plasma epinephrine levels).
Zarate et al[113]	2000	20 patients undergoing elective CABG or valve replacement	GA + IT morphine + remifentanil vs GA + sufentanil	Remifentanil combined with IT morphine provided superior pain control after cardiac surgery compared to a sufentanil-based technique.
Boulanger et al[114]	2002	62 patients undergoing elective cardiac surgery	GA + IT morphine + PCA vs GA + IT placebo + PCA vs GA + SC morphine	The IT group experienced a tendency toward longer extubation times. Comparable pain scores in all 3 groups.

CABG: coronary artery bypass grafting; GA: general anesthesia; HR: heart rate; IT: intrathecal; IV: intravenous; MAP: mean arterial pressure; OPCAB: off-pump coronary artery bypass; $PaCO_2$: partial pressure of carbon dioxide; PCA: patient-controlled analgesia; PDA: patent ductus arteriosus; PEFR: peak expiratory flow rate; SC: subcutaneous.

hypertrophy as a result of long-standing increased systemic vascular resistance (SVR) and pressure overload of the LV. Sudden drops in SVR must be avoided in these patients as such drops may not only compromise coronary perfusion and LV subendocardial perfusion but may also precipitate LV outflow tract obstruction as a result of systolic anterior motion (SAM) of the mitral valve or midcavity ventricular obstruction.

Diastole is the period of the cardiac cycle when the LV is perfused via the coronary arteries and when the LV chamber relaxes and fills. In general, tachycardia is poorly tolerated by hypertrophied hearts due to increased myocardial work, oxygen requirement, and a reduced diastolic time, which reduces both cardiac output via LV filling and coronary perfusion, further increasing the risk of myocardial ischemia. In addition, LV hypertrophy is usually associated with a degree of diastolic dysfunction, making the maintenance of sinus rhythm (if possible) and avoidance of tachycardia even more important.

A regional technique may be very helpful in the avoidance of tachycardia due to pain. A localized technique that minimizes vasodilation may be preferable to central neuraxial techniques, although careful titration of these can avoid hemodynamic instability.

The Patient with Ischemic Heart Disease

Ischemic heart disease is synonymous with coronary artery disease. The American College of Cardiology Foundation (ACCF) has published guidelines on the diagnosis and management of patients with known stable ischemic heart disease, including indications for investigation and revascularization.[70] There is also, however, a significant proportion of the population with undiagnosed, asymptomatic coronary artery disease. In 2010, the ACCF and the American Heart Association (AHA) published guidelines on how best to estimate cardiovascular risk in asymptomatic adults using a combination of history, examination, and investigation.[71] Guidance is also available on the perioperative management of patients with ischemic heart disease presenting for noncardiac surgery.[72,73]

Patients with ischemic heart disease may experience a range of complications, including myocardial infarction, dysrhythmias, heart failure, deteriorating ventricular function, and sudden death. Ischemic heart disease may also coexist with other cardiac pathologies, including valvular lesions and cardiomyopathies. The management of an individual patient will depend on the combination of these problems and the predominant lesion.

The relationship between hypotension and an increase in myocardial ischemia in patients with known coronary artery disease has been demonstrated in a population of elderly patients undergoing hip surgery.[32] In general terms, a patient with known coronary artery stenoses who has an otherwise normal, well-functioning heart will benefit from efforts to maintain preload (filling), prevent excessive vasodilation (causing a reduction in SVR), and prevent tachycardia, which would

TABLE 47–3. Studies investigating paravertebal and intercostal blockade in cardiac surgery.

Author	Year	Population Studied	Type of Technique	Conclusion
Canto et al[115]	2003	111 patients undergoing elective cardiac surgery using CP bypass (case series)	GA + 2 paravertebral catheters	Good hemodynamic stability, good postoperative analgesia, short times to tracheal extubation.
Exadaktylos et al[116]	2004	9 patients undergoing MIDCAB (case series)	GA + preoperative ipsilateral intercostal nerve blocks	All were extubated within 15 minutes and experienced good analgesia.
McDonald et al[117]	2005	17 patients undergoing cardiac surgery via midline sternotomy (prospective, randomized)	GA + parasternal block vs GA + placebo	The parasternal block with levobupicaine group used significantly less morphine in the first 4 hours postoperative; no patients needed rescue pain medication.
Behnke et al[118]	2002	43 patients undergoing MIDCAB (prospective, randomized)	GA + ICB vs GA + PCA	The ICB group experienced better pain relief.
Dowling et al[119]	2003	35 patients undergoing CABG (prospective, randomized)	GA + bilateral ICB with ropivacaine (16) vs GA + bilateral ICB with saline (19)	The ICB with ropivacaine group reported significantly lower pain scores and experienced a decrease in hospital LOS.
Dhole et al[120]	2001	41 patients undergoing MIDCAB (prospective, randomized)	GA + TEA vs GA + left-sided paravertebral catheter	No significant differences in pain scores or supplemental analgesia requirement. CI was higher in the TEA group. The PVB group had lower respiratory rates.

CABG: coronary artery bypass grafting; CI: cardiac index; CP: cardiopulmonary; GA: general anesthesia; ICB: intercostal blockade; LOS: length of stay; MIDCAB: minimally invasive direct coronary artery bypass; PCA: patient-controlled analgesia; PVB: paravertebral blockade; TEA: thoracic epidural anesthesia.

increase oxygen requirement by the myocardium while reducing the time available for coronary perfusion. A patient with coronary artery disease and poor LV systolic function (defined as an ejection fraction < 30%) can be challenging, as reducing systemic vascular resistance will reduce resistance to outflow and increase ejection fraction, but this must not done at the expense of coronary artery perfusion pressure. In this circumstance, careful titration of central neuraxial anesthesia and a reduced volume of total local anesthetic is advisable.

The Patient with Valvular Heart Disease

Regurgitant Valvular Disease

In general, regurgitant valvular disease is improved symptomatically by peripheral vasodilation and worsened by peripheral vasoconstriction. Central neuraxial block and peripheral neuraxial block therefore tend to be well tolerated cardiovascularly and are ideal for preventing a worsening in regurgitant fraction as a result of peripheral vasoconstriction caused by pain and anxiety. Care needs to be taken, however, in patients with concomitant coronary artery disease or stenotic valvular disease.

Stenotic Valvular Disease

Aortic and mitral valve stenoses are much more prevalent in the adult population than tricuspid or pulmonary valve stenosis. Although it is recommended that a patient with severe aortic stenosis or symptomatic mitral stenosis be referred for investigation and management before undergoing noncardiac surgery,[73] there may be emergency situations when this is not possible.

Aortic valve stenosis results in a fixed obstruction to LV systolic outflow and usually results in concentric LV hypertrophy. Sudden decreases in SVR need to be avoided as such decreases may compromise coronary perfusion. As with patients with LV hypertrophy from other causes, maintenance of filling status and avoidance of tachycardia and fast dysrhythmias is desirable.

Mitral stenosis results in a fixed obstruction to LV inflow. Particular care needs to be taken to maintain filling status and preload, but not excessively, as large boluses of fluid may result in pulmonary edema. Careful titration of regional anesthesia with a low threshold for invasive monitoring is desirable.

TABLE 47–4. Active cardiac conditions for which the patient should undergo evaluation and treatment before noncardiac surgery (class 1, level of evidence: B).

Condition	Examples
Unstable coronary syndromes	Unstable or severe angina (CCS class III or IV) Recent MI (7–30 days)
Decompensated heart failure	NYHA class IV Worsening or new-onset heart failure
Significant dysrhythmias	High-grade atrioventricular block Mobitz II atrioventricular block Third-degree atrioventricular block Symptomatic ventricular dysrhythmias Supraventricular dysrhythmias with uncontrolled ventricular rate (HR > 100 at rest) Symptomatic bradycardia Newly recognized ventricular tachycardia
Severe valvular disease	Severe aortic stenosis (mean pressure gradient > 40 mm Hg, aortic valve area < 1cm^2 or symptomatic) Symptomatic mitral stenosis (progressive dyspnea on exertion, exertional presyncope or heart failure)

CCS: Canadian Cardiovascular Society; HR: heart rate; MI: myocardial infarction; NYHA: New York Heart Association.

The Adult Patient with Congenital Heart Disease

The term *congenital heart disease* covers an extremely broad range of conditions, from relatively simple acyanotic lesions to complex cyanotic pathology requiring complex surgery. As pediatric congenital cardiac surgical techniques have advanced over the past few decades, more children with congenital heart disease are surviving into adulthood and presenting for noncardiac surgery where the use of regional anesthesia may be employed. Ideally, a patient with complex congenital heart disease should be managed in a specialist facility with support from clinicians and staff who are familiar with the patient, his or her condition, and his or her current medical status.

While it is not the aim of this chapter to provide a comprehensive review of every type of congenital heart disease, there are a number of general issues that should be taken into consideration when planning the use of regional anesthesia in these patients:

- Abnormal anatomy, including alterations as a result of previous surgery (Table 47–5)
- The presence of anticoagulation
- Cardiac function, including the presence of dysrhythmias
- Dependence of the pulmonary circulation on passive venous return without right ventricular assistance (Fontan or hemi-Fontan physiology)
- The likely effect on cardiovascular stability of a reduction in systemic vascular resistance
- The need for additional monitoring intraoperatively and postoperatively (the site of insertion of invasive monitoring will require knowledge of abnormal anatomy, including thrombosed veins and arterial shunts)

The most common causes of low cardiac output in a patient with Fontan physiology are inadequate preload, elevated pulmonary vascular resistance, ventricular dysfunction, and dysrhythmias.[74] The use of regional anesthesia may be very useful in these patients, as general anesthesia with positive pressure ventilation carries its own risks. Poorly controlled postoperative pain and poor respiratory effort may lead to life-threatening complications.

TABLE 47–5. Anesthetic relevance of previous surgical intervention in adult congenital heart disease.

Anatomic Lesion/Surgical Correction	Brief Description of Lesion	Anesthetic Relevance
Blalock–Taussig shunt	Subclavian artery to pulmonary artery	Avoid blood pressure measurement (invasive and noninvasive) in affected arm.
Bidirectional Glenn (hemi-Fontan)	Surgical connection of superior vena cava (SVC) to pulmonary artery	Blood flow through pulmonary circulation dependent on venous return and pulmonary vascular resistance.
Total cavopulmonary connection (Fontan type)	Surgical connection of SVC and inferior vena cava (IVC) to pulmonary artery	Blood flow through pulmonary circulation totally dependent on venous return and pulmonary vascular resistance.

Modifications to regional anesthetic technique in patients with complex congenital heart disease include the following:

- Consider a reduction in the total dose of local anesthetic administered, particularly in patients with poor cardiac function or a history of dysrhythmias.
- Use a slow titration of or avoid narcotic or anxiolytic sedation in patients with Fontan or hemi-Fontan physiology. Avoidance of hypoxia and hypercarbia is imperative due to the risk of precipitating an acute rise in pulmonary vascular resistance and the corresponding reduction in cardiac output.
- Avoid a sudden reduction in systemic vascular resistance in the patient with Fontan or hemi-Fontan physiology. Carefully titrate the central neuraxial block with appropriate fluid administration and close monitoring.

SUMMARY

Regional anesthesia, by virtue of its ability to provide intense analgesia and in some circumstances avoid general anesthesia, plays an essential role in the management of patients with cardiovascular disease undergoing surgery. The method proposed should take into account not only the type of surgery being undertaken but also the combination of issues present in the individual patient. In general terms, patients with a poor ejection fraction and regurgitant valvular lesions respond well to peripheral vasodilation, as long as adequate preload and coronary artery perfusion are maintained. Patients with stenotic valvular lesions, severe coronary artery stenosis not amenable (or practical in an emergency) to revascularization preoperatively, and/or left ventricular hypertrophy can still benefit greatly from regional anesthesia in terms of avoiding an increase in myocardial work and oxygen demand caused by pain and tachycardia. However, caution is required in these patients, as a sudden or excessive reduction in peripheral vascular resistance, particularly with central neuraxial blockade, may precipitate a drop in myocardial perfusion and/or a drop in preload and cardiac output with severe consequences. In these patients, the decision to utilize regional anesthesia should be made with caution and undertaken with appropriate monitoring. As in all other circumstances in which regional anesthesia is proposed, attention should be paid to anticoagulation, weighing the potential thromboembolic risks of stopping anticoagulation against the potential benefits. Skillfully performed major peripheral blocks for distal extremity (e.g. amputation, extremity debridement, etc), can be life-saving in patients with severe cardiovascular disease, such.

CHAPTER 48

Regional Anesthesia & Systemic Disease

Malikah Latmore, Matthew Levine, and Jeff Gadsden

INTRODUCTION

Patients with coexisting systemic disease may be at a higher risk for specific perioperative complications related to surgery and anesthesia. Regional anesthesia is often thought of as being particularly beneficial in patients. However, the physiologic changes that occur with some regional anesthesia techniques must be understood and viewed within the context of an individual patient's pathophysiology so that the technique used provides maximum patient benefit and reduces the risk of complications. This chapter focuses on the pathophysiology of systemic diseases frequently encountered by the regional anesthesiologist and discusses the interplay between common regional anesthesia techniques and patient disease.

PULMONARY DISEASE

Surgical patients with coexisting pulmonary impairment are at risk for intraoperative or postoperative pulmonary complications, regardless of anesthetic technique.[1] A growing body of evidence suggests that regional anesthesia may be associated with improved pulmonary outcomes compared with general anesthesia.[2–6] However, regional anesthetic blockade may carry risks in some patients. A thorough understanding of respiratory physiology and the implications of regional anesthetic techniques is crucial to the safe and effective use of regional anesthesia in these patients.

Epidural & Spinal Anesthesia

Most of the pulmonary effects of neuraxial anesthesia are due to motor block of the intercostal and abdominal musculature. If significant systemic uptake of local anesthetic occurs, some central and direct myoneural respiratory depression can also be seen, although this plays a minor role overall.[7] Since neuraxial anesthesia produces a "differential" blockade of motor, sensory, and autonomic fibers, the degree to which respiratory function is impaired depends on the relative extent of segmental motor blockade. Using dilute concentrations of epidural local anesthetic may provide adequate sensory block as high as the cervical levels, while sparing the motor function of the respiratory muscles in the lower somatic segments.[8] Diaphragmatic paralysis (phrenic nerve block, C3–C5) in the absence of total spinal anesthesia does not occur with neuraxial blockade, since even a sensory block as high as C3 will only produce a motor block at approximately T1 through T3.[7] Apnea following high neuraxial anesthesia is most likely precipitated by brainstem hypoperfusion as a result of hypotension and unlikely to be related to phrenic nerve blockade. Spontaneous respiration returns following adequate volume resuscitation and/or vasopressor therapy.

Clinical Pearls

- Apnea associated with a high spinal anesthetic is most often related to hypotension and hypoperfusion of the brainstem, rather than motor blockade of the nerve roots supplying the phrenic nerve (C3–5).
- Supporting ventilation while maintaining the blood pressure with fluids and vasopressor therapy is the key resuscitative strategy.

With a high level of epidural or spinal anesthesia, the chest wall musculature and intercostal muscles may become impaired. This may even result in altered chest wall motion during spontaneous respiration. During high neuraxial anesthesia, the more compliant chest wall is retracted during inspiration and may actually display paradoxical rib cage motion.[9,10] Some, however, have found that epidural blockade to sensory levels of T6 or even T1 may increase the contribution that chest wall expansion makes to tidal volume.[11,12] This may be explained by an incomplete motor block of high intercostal muscles or the compensatory role played by the "accessory" muscles of respiration, such as the anterior and middle scalene muscles.[13]

Lumbar epidural anesthesia does not affect resting minute ventilation, tidal volume, or respiratory rate.[14–16] Likewise, functional residual capacity (FRC) and closing capacity appear to be relatively unchanged during lumbar epidural anesthesia.[17–19] Effort-dependent tests of respiratory function, such as forced expiratory volume in one second (FEV_1), forced vital capacity, and peak expiratory flow, do exhibit modest decreases in the setting of lumbar epidural blockade, reflecting the reliance of these indices on intercostal and abdominal musculature.[20] This decrease in pulmonary function increases proportionally as the block progresses in a cephalad fashion from lower to upper lumbar regions.

Thoracic epidural anesthesia has no effect on minute ventilation, tidal volume, or respiratory rate but does result in a modest decrease in vital capacity (VC), FEV_1, total lung capacity, and maximal midexpiratory flow rate (Table 48–1).[17] Even low cervical/high thoracic epidural anesthesia (C4–T9) in patients with severe chronic obstructive pulmonary disease (COPD) undergoing breast surgery produces only a very mild decrease in FEV_1.[21] One volunteer study found that high thoracic epidural anesthesia (T1 sensory level) led to an increase in FRC of approximately 15% with no change in tidal volume or respiratory rate.[12] This somewhat surprising finding may be explained by two mechanisms offered by the investigators. First, most volunteers exhibited a decrease in intrathoracic blood volume, a physiologic phenomenon confirmed by Arndt and colleagues.[22] Second, the study also found that the end-expiratory position of the diaphragm was shifted caudally, which may be related to a relative increase in diaphragmatic tonic activity or a reduction in intra-abdominal pressure.

Cervical epidural anesthesia reduces the VC and FEV_1 to a degree similar to that of high thoracic epidurals that extend to lower cervical levels. Studies on healthy patients have demonstrated a 15–30% reduction in VC and FEV_1 with cervical epidurals (sensory block to C2) that varied by level and local anesthetic concentration.[8,23]

The ventilatory response to hypercarbia and hypoxia is preserved with neuraxial anesthesia.[11,16] Partial pressures of both oxygen (Po_2) and carbon dioxide (Pco_2) are essentially unchanged during epidural or spinal anesthesia.[11,12] In addition, bronchomotor tone is not altered to any significant degree, despite theoretical concerns of bronchoconstriction secondary to sympatholysis.[22] Indeed, epidural anesthesia has been used successfully in high-risk patients with COPD and asthma undergoing abdominal operations.[21,24]

Neuraxial anesthesia has been shown in a number of settings to lead to reduced postoperative pulmonary complications compared with general anesthesia. Perlas and colleagues reported an association between spinal anesthesia and lower 30-day mortality.[7] The reasons behind this are probably multifactorial, owing in part to superior analgesia, reduced diaphragmatic impairment, altered stress response, and a decreased incidence of postoperative hypoxemia.[25,26] Epidural anesthesia provides superior pain control over general anesthesia with postoperative opioids for abdominal and thoracic surgery, which leads to reduced splinting, a more effective cough mechanism, and preserved postoperative lung volumes, including FRC and VC.[27] One study directly comparing epidural and general anesthesia in high-risk patients concluded that overall outcomes, including the need for prolonged postoperative ventilation, were improved with the regional technique.[28] Another trial in patients undergoing lower limb vascular surgery reported a greater than 50% reduction in the incidence of respiratory failure in the group randomized to epidural anesthesia.[29]

Patients undergoing repair of hip fractures also benefits from regional anesthesia. Neuman et al. compared neuraxial versus general anesthesia for hip fracture repair in over 18,000 patients and found a 25% reduction in pulmonary complications in those who received neuraxial techniques.[6] A meta-analysis of 141 randomized trials (including over 9000 patients) comparing regional and general anesthesia for hip surgery showed a risk reduction for pulmonary embolism, pneumonia, and respiratory depression of 55%, 39%, and 59%, respectively, with the regional anesthesia.[26] Interestingly, these outcomes were unchanged regardless of whether neuraxial anesthesia was continued into the postoperative period, illustrating that the beneficial effect of epidural and spinal anesthesia on pulmonary physiology occurs, at least in part, at the time of surgical insult.

Brachial Plexus Block

In the absence of rare complications such as pneumothorax, any alterations in respiratory mechanics seen with brachial plexus block are due primarily to phrenic nerve blockade and hemidiaphragmatic paralysis (Figure 48–1). This has been shown to occur in 100% of patients receiving interscalene block when performed without ultrasound guidance and using between 34 and 52 mL of local anesthetic.[30] When diaphragmatic paresis occurs, there is an associated 27% reduction in

TABLE 48–1. The effect of epidural anesthesia on respirator volumes and mechanics.

	VC	TLC	FRC	VT	RR	MV	FEV_1	FVC	PEF
LEA	↔	↔	↔	↔	↔	↔	↓	↓	↓
TEA	↓	↓	↑	↔	↔	↔	↓	↓	↓

LEA: lumbar epidural anesthesia; TEA: thoracic epidural anesthesia; VC: vital capacity; TLC: total lung capacity; FRC: functional residual capacity; VT: tidal volume; RR: respiratory rate; MV: minute volume; FEV_1: forced expiratory volume in 1 second; FVC: forced vital capacity; PEF: peak expiratory flow. ↓ = decrease; ↑ = increase; ↔ = no change.

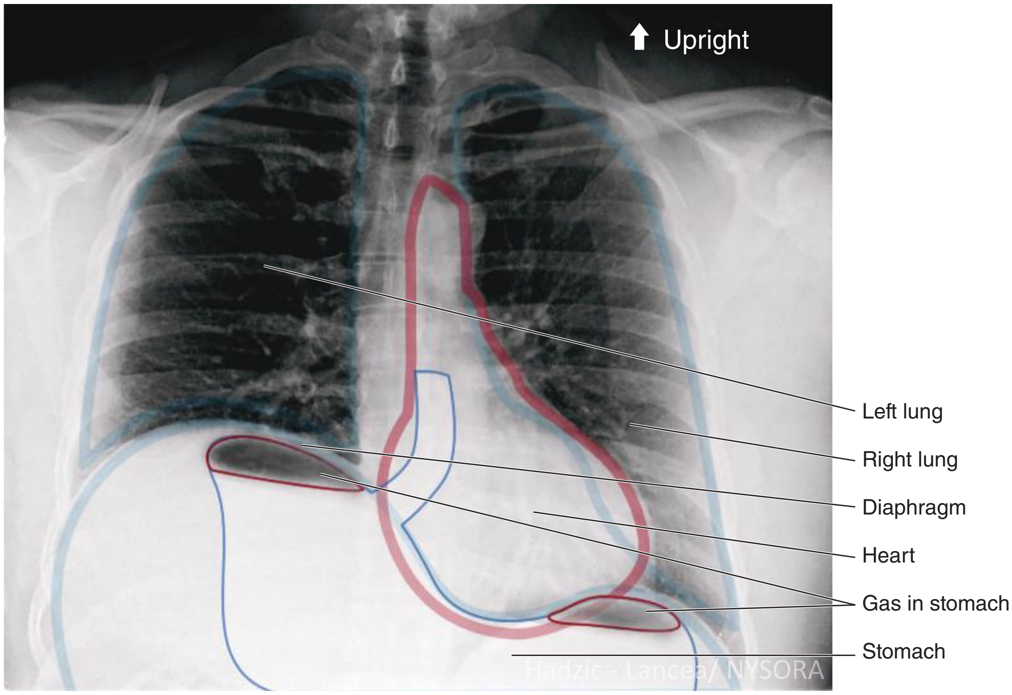

FIGURE 48–1. Upright chest radiograph of a patient who underwent a right interscalene brachial plexus block. Note the elevated right hemidiaphragm.

both FVC and FEV_1.[31] While the clinical significance of this reduction in healthy patients is not entirely clear, it may be useful to risk-stratify patients about to undergo interscalene blocks as one would a patient undergoing lung resection. In other words, ask the question, "Will this patient tolerate a perioperative FEV_1 reduction of 27%?"

Some investigators have attempted to reduce the incidence of phrenic nerve palsy by decreasing the volume of local anesthetic. However, Sinha et al. found no reduction in the incidence of hemidiaphragmatic paresis (as measured by ultrasound) when the volume of ropivacaine 0.5% was reduced from 20 mL to 10 mL.[32] Others have reported that reducing volume to 5 mL decreases the incidence by 45%–50% and results in a significantly reduced impairment of FEV_1 and peak expiratory flow (PEF).[33,34] Low volumes of local anesthetic are no guarantee of preservation of phrenic nerve function. Clinically significant respiratory compromise requiring tracheal intubation has been reported following an interscalene brachial plexus block using a volume of 3 mL of 2% mepivacaine.[35]

Clinical Pearls

- Interscalene block with low (≤ 5 mL) volumes of local anesthetic may reduce but not eliminate the risk of phrenic block and diaphragmatic paresis.
- Therefore, interscalene brachial plexus block should be avoided in patients who could not tolerated a 25% decrease in respiratory function.

The risk of phrenic nerve blockade decreases as one moves more distally along the plexus. The axillary approach to the brachial plexus has no effect on diaphragm function and presents a good choice for those patients with marginal pulmonary reserve (ie, cannot tolerate a 27% reduction in lung function). On the other hand, the supraclavicular block has been traditionally associated with a 50%–67% incidence of hemidiaphragmatic paralysis, although recent studies have shown that with ultrasound guidance the incidence can be as low as zero.[36–39] The infraclavicular approach is probably sufficiently distant from the course of the phrenic nerve so as to spare the diaphragm,[40,41] although there are case reports of phrenic nerve involvement.[42,43] These discrepancies probably relate to the different approaches to the infraclavicular block—for instance the "coracoid block" is performed with a relatively lateral or distal puncture site, whereas the vertical infraclavicular block begins at a more medial location. There may also be some anatomic variations in the course of the phrenic nerve, such as an accessory phrenic nerve, which would make it more susceptible to blockade at more distal levels of the brachial plexus.[44] Although the infraclavicular or axillary blocks may be desirable for their relative pulmonary-sparing profiles, they carry the disadvantage of providing incomplete anesthesia for the shoulder and require higher degree of expertise to perform. However, creative solutions have been employed to get around this issue. Martinez and colleagues combined an infraclavicular block with a suprascapular nerve block for emergent humeral head surgery in a patient with acute asthma and a baseline FEV_1 of 1.13 L (32% predicted). The combination of axillary and suprascapular blocks has also been suggested as an alternative to interscalene block.[45] Therefore, a carefully considered selection of peripheral nerve blocks can provide complete anesthesia of the upper limb while avoiding respiratory complications in patients with pulmonary disease.[46]

Continuous brachial plexus blocks with perineural catheters can extend the benefits of plexus blockade into the postoperative period and reduce postoperative pain, oral opioid requirements and their side effects, and sleep disturbances after shoulder surgery.[47,48] However, there have been reports of complications attributed to the prolonged phrenic nerve paresis that can occur with this technique. These have included chest pain, atelectasis, pleural effusion, and dyspnea.[49–51] This is of particular concern because many patients are being discharged home with catheters and may not have access to timely intervention should these complications arise. On the other hand, the degree of clinically significant respiratory impairment with continuous interscalene blockade varies among patients, and, in fact, interscalene blockade may be well tolerated, especially if using relatively dilute concentrations of local anesthetic that provide only a partial phrenic nerve block.[52,53] Maurer and associates reported a case of a patient with no preexisting pulmonary disease who underwent bilateral shoulder arthroplasty under combined bilateral continuous interscalene blockade and general anesthesia.[54] Postoperative analgesia was maintained in the hospital for 72 hours via the catheters using infusions of 7 mL/h of 0.2% ropivacaine for each side (total 14 mL/h). Despite a marked postoperative reduction in FVC (60%) from baseline as well as sonographic evidence of diaphragmatic impairment, the patient had an uneventful postoperative course (with excellent analgesia) and good recovery. This anecdotal example illustrates that the clinical significance of phrenic paresis in patients with good respiratory function is questionable. Regardless, the use of continuous brachial plexus techniques should be carefully considered in patients with preexisting pulmonary disease, especially if they are to be discharged home with the catheters in situ. Other complications that may have pulmonary implications include interpleural, epidural, or even intrathecal catheter migration and irritation of the phrenic nerve.[55–57]

Clinical Pearls

- The clinical consequences of phrenic in patients with normal respiratory function are typically asymptomatic or mild.
- The use of continuous brachial plexus techniques should be carefully considered in patients with preexisting significant pulmonary disease.
- When indicated, catheter can be bolus with a small amount of short-acting local anesthetic (eg, 2% chloroprocaine 5 ml) to evaluate the effect on the respiratory function before using long-acting local anesthetics.
- In symptomatic patients with indwelling catheter, an injection of 0.9% NaCl can shorten the duration of phrenic (and brachial plexus) block ("washout").

Paravertebral & Intercostal Nerve Blocks

Several studies have investigated the effects of paravertebral and intercostal blocks on pulmonary function in patients with rib fractures or those undergoing thoracotomy. Intercostal blockade has been shown to improve arterial oxygen saturation (Sao_2) and peak expiratory flow rate (PEFR) in patients with traumatic rib fractures associated with severe pain.[58] In addition to improved pulmonary function, some studies found significantly improved pain control and shortened hospital length of stay following intercostal catheter placement.[59] Likewise, Karmakar and co-investigators found that continuous paravertebral blockade over a period of four days in patients with multiple fractured ribs led to significant improvement in respiratory rate, FVC, PEFR, Sao_2, and the ratio of partial pressure of oxygen to fraction of inspired oxygen (Pao_2:Fio_2).[60] These findings are probably related to the favorable effect of analgesia on respiratory efforts by the patient and improved respiratory mechanics, facilitating weaning from ventilator support and return to activities of daily living in patients who were otherwise in distress from their injuries.[61,62]

Paravertebral blocks are effective for the management of pain following thoracotomy and can significantly improve postoperative spirometry. One review of 55 randomized, controlled trials of analgesic techniques following posterolateral thoracotomy revealed that paravertebral blockade was the method that best preserved pulmonary function compared with either intercostal or epidural analgesia.[63] The combined results showed an average preservation of approximately 75% of preoperative pulmonary function when paravertebral analgesia was used versus 55% for both intercostal and epidural analgesia. In addition, Davies et al showed that even when comparable analgesia was obtained with paravertebral block and thoracic epidural, the side effect profile with paravertebral blockade was significantly better, resulting in fewer pulmonary complications and less hypotension, nausea, and urinary retention.[64] It is unclear why paravertebral blockade might result in improved PEFR and SaO_2 compared with epidural analgesia in this and other studies, but it may be related to the increased utilization of opioids, a higher incidence of nausea and vomiting, and the presence of bilateral intercostal muscle blockade (and therefore diminished chest wall mobility) in the epidural cohorts.[65]

Clinical Pearls

- Paravertebral or intercostal blockade provides excellent analgesia following both rib fracture and thoracotomy.
- These blocks also result in improved spirometry and pulmonary outcomes.

Pulmonary Complications Not Related to Conduction Blockade

Pulmonary complications related to the use of regional anesthetic techniques fall into two categories. The first is those related directly or indirectly to the physiologic changes that occur with the blockade itself. Examples include atelectasis and pneumonia resulting from an inability to mobilize secretions. The second category comprises those that are independent of the effect of blockade, and although there are sporadic reports of rare complications such as pulmonary hemorrhage[66] and chylothorax,[67] the most common of these is pneumothorax. Not surprisingly, pneumothoraces occur most frequently when the puncture site overlies the pleura, and especially when performing supraclavicular and intercostal blocks. The overall reported incidence is low, but the actual numbers are likely to be underreported, since many pleural punctures will result in small pneumothoraces that resolve spontaneously.[68–72] Refinements of previously published infraclavicular techniques based on MRI studies and the widespread use of ultrasound guidance may confer additional safety to these procedures,[73–75] although is important to note that pneumothoraces have been reported with ultrasound-guided techniques, highlighting the fact that ultrasound guidance is an imperfect means of preventing adverse events.[76]

RENAL DISEASE

Renal dysfunction is commonly present in the surgical population. Perioperative acute kidney injury accounts for approximately 50% of all patients requiring acute hemodialysis in the United States. Patients with chronic renal insufficiency frequently present for procedures such as the creation of vascular shunts and revascularization of the lower limbs. Regional anesthetic techniques are frequently ideal options to provide anesthesia for these patients and procedures.

Effect of Regional Anesthesia on Renal Function

The treatment of patients at risk for perioperative renal dysfunction should focus on two principles: avoiding nephrotoxic agents and maintaining kidney perfusion. Local anesthetics do not possess any nephrotoxic properties per se, and in fact the coadministration of procaine has been shown to mitigate some of the nephrotoxic effects of cisplatin in rats.[77] Of greater relevance is the effect of anesthetic-induced hypotension on renal blood flow. The kidneys are capable of autoregulation over a wide variety of mean arterial pressures (approximately 80–180 mmHg) and maintain the glomerular filtration rate (GFR) by autonomous changes in renal vascular resistance.[78] Below the so-called lower limit of autoregulation, the kidney begins to shut down its energy-dependent physiologic processes, and the GFR and urinary output fall as a result. Ultimately, if left unchecked, renal ischemia develops, especially in the sensitive renal medulla. Although neuraxial anesthesia and the concurrent sympathectomy can reduce mean arterial pressure (MAP), renal blood flow is often preserved.[79] This is believed to reflect an increase in left ventricular stroke volume in response to the drop in systemic vascular resistance (SVR). Rooke and colleagues studied hemodynamic responses and abdominal organ perfusion (as measured by scintigraphy) in 15 patients undergoing lidocaine spinal anesthesia with a sensory block ranging from T1 to T10.[80] Whereas the MAP and SVR fell on average by 33% and 26%, respectively, blood volume in the kidneys increased by approximately 10%. There may be limits to the degree of compensation afforded by cardiac output, however. One study using a primate model showed that although renal blood flow was minimally affected by T10 spinal anesthesia, it was significantly reduced by a T1 sensory block.[81] This finding illustrates again that lumbar and low-thoracic levels of neuraxial anesthesia in patients with renal disease are well tolerated physiologically and that significant changes do not begin to manifest until higher levels are achieved.

The renin–angiotensin system, which is initiated in the kidney in response to a reduction in renal perfusion, plays an important role in blood pressure homeostasis. It serves as a complementary humoral mechanism to the sympathetic nervous systems. Hopf and colleagues conducted a study to determine if thoracic epidural anesthesia suppressed the renin response to induced hypotension.[82] Plasma renin and vasopressin concentrations were measured before, during, and after a hypotensive challenge with nitroprusside in patients with and without thoracic epidural anesthesia (sensory levels T1 through T11). With an intact sympathetic nervous system (ie, no epidural), plasma renin levels doubled in response to the hypotensive challenge lasting 15 minutes. In contrast, there was no change in the renin concentration when hypotension was induced to the same MAP in the epidural cohort. This suggests that sympathetic fibers play a key role in the renin–angiotensin system and that thoracic epidural anesthesia interferes with the functional integrity of that system.

Clinical Pearl

- Lumbar and low-thoracic levels of neuraxial anesthesia significantly renal hemodynamics.

For obvious reasons, postoperative renal function is of foremost concern when administering anesthesia for recipients of renal transplantation. Several studies have looked at the effect of general versus regional (or combined epidural/general) anesthesia on postoperative renal function in this setting. While regional anesthesia has been shown to reduce the stress response to renal transplant surgery and improve postoperative pain control, anesthetic technique was not shown to have an effect on graft outcome in either adult or pediatric populations.[83,84] Also, the choice of anesthetic technique for living donors was shown to be independent of recipient graft outcome.[85] Other nontransplant outcomes data, including those from the large meta-analysis by Rodgers et al., indicate that regional anesthesia is associated with a lower risk of postoperative renal failure than general anesthesia. However, the authors cautioned that the confidence intervals were wide and were compatible with both no effect and a two-thirds risk reduction.[26] Overall, it appears that a well-conducted regional anesthetic does not negatively affect perioperative kidney function or renal outcome compared with general anesthesia.

Considerations for Regional Anesthesia in Chronic Renal Failure

Patients with chronic renal failure often manifest a large number of pathophysiologic changes that may influence regional anesthetic care. These may include the presence of an anion-gap metabolic acidosis, electrolyte disturbances such as hyperkalemia, and coagulopathies due to uremia-induced platelet dysfunction. Plasma concentrations of local anesthetic following peripheral nerve blocks are often high enough to cause central nervous system (CNS) or cardiac toxicity in any patient, even when no obvious intravascular injection has occurred. This is probably dose-related when performing “high-volume blocks” such as plexus blocks. Some authors have recommended that dosages be adjusted in patients with chronic renal insufficiency based on observations of toxicity presumed to be related to concurrent acidosis or hyperkalemia.[86,87] Indeed, experimental evidence suggests that acidemia decreases the protein binding of bupivacaine, thereby increasing the free fraction and risk of toxicity.[88] In addition, it has been shown that hyperkalemia (5.4 vs 2.7 mEq/L) in dogs results in just half the dose of bupivacaine being required to induce cardiotoxicity.[89] Interestingly, the potassium level had no effect on in the same animals. This is an ominous finding, as it suggests that the so-called safety margin of plasma levels between CNS and cardiac toxicity, which is already relatively narrow with bupivacaine, is even less reliable in the presence of hyperkalemia.

Clinical Pearls

- Acidemia and hyperkalemia decrease the protein binding of bupivacaine, thereby increasing the free fraction and the risk of toxicity.
- Patients with uremia may have higher plasma levels of local anesthetic following peripheral nerve block.

Even in the absence of acid–base or electrolyte disturbances, plasma levels of local anesthetics following peripheral nerve block are often higher in patients with chronic renal failure.[90,91] The reason for this is not entirely clear but may relate to increased blood flow (and hence uptake at the injection site) due to the hyperdynamic circulation often seen in uremic patients.[92] On the other hand, a_1-acid glycoprotein (AAG) levels are increased in uremia and may lend a protective effect by binding more local anesthetic in the blood stream.[93,94] The increased levels of AAG also result in both a reduced free fraction available for hepatic metabolism and in a reduced volume of distribution. These two pharmacokinetic consequences appear to balance each other so that the serum half-life is not significantly changed.[90] Hemodialysis is ineffective in removing lidocaine from plasma and therefore cannot be relied on to treat toxicity.[95] However, lipid emulsion has been used successfully to treat both cardiovascular and neurologic systemic toxicity in patients with renal failure.[96,97]

No significant difference exists between patients with chronic renal failure and healthy patients with respect to peripheral nerve block latency, duration, or quality.[90,98,99] In one study of spinal anesthesia in patients with chronic renal failure versus healthy patients, Orko and associates found that block quality was similar but that both onset time and duration of the block were reduced in patients with uremia.[100] The authors postulated a volume-contracted intrathecal space in uremic patients as a mechanism for the quicker onset, but the actual cause remains unclear. The shorter duration of sensory block may again be related to enhanced uptake in the setting of a hyperdynamic circulation.

Uremic coagulopathy is characterized by a defect of platelet aggregation that is probably due to a toxic effect by uremic substances on the binding of fibrinogen to the platelet glycoprotein IIb/IIIa receptor.[101] This often manifests in clinically appreciable bleeding, and at least one case of subarachnoid hematoma leading to paraplegia after a spinal anesthetic in a chronic renal failure patient has been published.[102] Patients undergoing hemodialysis require intermittent anticoagulation and may present to the operating room with an unclear coagulation status. Care must be taken to delineate heparin or other anticoagulant regimens. Despite this platelet dysfunction, uremic patients are at higher risk for thrombotic events.[103] One case of hypoxia following a brachial plexus block in a uremic patient was later found to be secondary to pulmonary embolism.[104] The authors of the report suggested that a likely mechanism was the dislodgment of a preexisting thrombus from the proximal arm, facilitated by block-related manipulation and vasodilation of the upper extremity.

Several studies have compared anesthetic techniques for the creation of arteriovenous fistulae, a procedure that is common in patients with end-stage renal disease and is well suited to brachial plexus block.[105] Some investigators have concluded that little difference exists in outcome among general, local, and brachial plexus anesthesia for this operation.[106,107] Mouquet and colleagues specifically studied the effects of these three techniques on brachial artery blood flow and concluded that both general anesthesia and brachial plexus block improved blood flow through the fistula during surgery, whereas local infiltration did not.[108] Several subsequent studies have shown increased vein diameter, increased rates of native fistula formation, increased fistula blood flow, and shorter maturation time when regional anesthesia is used, compared to either general or local anesthesia.[109–111]

HEPATIC DISEASE

Liver injury or dysfunction can range from a mild, asymptomatic "transaminitis" to frank hepatic failure. There are many causes of liver disease, both acquired and congenital, but all manifest as either failure of parenchymal cell function (ie, acute and chronic hepatitis, cirrhosis) or cholestasis.[112] Considerations for regional anesthesia in patients with liver disease include the potential for altered disposition and metabolism of local anesthetics, the effect of regional anesthesia on hepatic perfusion, and possible coagulopathy related to liver dysfunction.

Pharmacokinetics of Local Anesthetics in Liver Disease

Amide local anesthetics are metabolized in liver microsomes by the cytochrome P450 system.[113] A decrease in microsomal function, as may be seen in acute or chronic liver disease, can lead to a reduction in biotransformation and clearance of these drugs, putting the patient at risk for local anesthetic toxicity. As with other drugs that are metabolized in the liver, the hepatic extraction ratio determines the relative importance of hepatic perfusion versus intrinsic enzyme activity in the overall clearance of the drug. For example, bupivacaine has a low extraction ratio (ie, its clearance is more sensitive to alterations in hepatic enzyme activity), whereas etidocaine exhibits a relatively high extraction ratio and depends on adequate liver perfusion for clearance.[114] Lidocaine has an intermediate hepatic extraction ratio and therefore relies on both perfusion and enzymatic activity. Severe hepatic disease such as cirrhosis can affect both liver perfusion and intrinsic enzyme function. In this scenario, the clearance of all amide local anesthetics, regardless of their extraction ratio, is likely to be reduced. Because the volume of distribution of local anesthetics (and many other drugs) is increased in hepatic disease, the actual plasma levels may not differ significantly from healthy patients with a single dose, despite the diminished clearance.[115–118] The altered distribution may be related to decreased levels of plasma AAG, which are reduced in proportion to the severity of liver disease.[119] Clinically, it appears that single-dose peripheral nerve blocks with amide local anesthetics probably do not require a dosage adjustment in this population, whereas continuous infusions or repeated boluses have the potential to accumulate to toxic levels.[118,120] This is supported by a study comparing plasma levels of levobupivacaine in patients undergoing hepatic resection or colorectal surgery who received epidural levobupivacaine by repeated bolus. Patients in the hepatic resection group were found to have significantly higher plasma levels, which correlated with indocyanine green clearance (a measure of hepatic function) and plasma bilirubin concentration.[121]

The cytochrome P450 enzyme system is subject to induction or inhibition by a variety of drugs and dietary nutrients. This may play a role in the subsequent metabolism of amide local anesthetics. For example, substances that inhibit microsomal enzymes, such as cimetidine or grapefruit juice, may lead to an accumulation of local anesthetic, augmenting the risk of toxicity, especially in the setting of preexisting hepatic dysfunction.[122]

Ester local anesthetics are cleared by plasma cholinesterases in the blood and liver. Severe hepatic disease may result in decreased levels of cholinesterase and result in prolonged plasma half-lives of esters such as procaine.[123] On the other hand, red cell esterases remain intact during liver disease and are able to provide some hydrolytic function.[124] Because plasma cholinesterase is extremely efficient, it is unlikely that an enzyme deficiency secondary to hepatic disease could impair the hydrolysis of ester-type local anesthetics to a degree sufficient to cause toxicity.[114]

Clinical Pearls

- The pharmacokinetics of local anesthetics in patients with liver disease can be complex due to the decrease in protein production and drug metabolism.
- Single injection-dose peripheral nerve blocks with amide local anesthetics probably do *not* require a dosage adjustment in patients with hepatic disease.

Effect of Regional Anesthesia on Hepatic Blood Flow

The hepatic blood supply is unique in that it relies on both portal venous return and hepatic artery blood flow, which make up approximately 75% and 25% of the total flow, respectively. The regulation of hepatic blood flow is complex. The portal system is passive and not subject to autoregulation, whereas the hepatic artery can increase or decrease its contribution to flow in response to alterations in portal venous flow.[125] The hepatic artery also autoregulates in response to MAP, in much the same way that cerebral or renal vessels do, but may rely on an intact sympathetic response.[126]

General anesthesia has been shown to cause a decrease in hepatic blood flow, which may lead to ischemia and postoperative liver dysfunction.[127] Less is known about the effects of regional anesthesia on hepatic perfusion. Grietz et al. performed a high epidural (block level T1 through T4) in 16 dogs and examined the effect on systemic and hepatic hemodynamics.[128] MAP and portal venous flow were both reduced compared with control values, by 52% and 26%, respectively. In contrast, hepatic artery flow was unchanged, probably relating to a reduction in hepatic artery resistance of 51%. In addition, hepatic oxygen uptake was preserved through an increased oxygen extraction. Another study by Vagts and colleagues found that thoracic epidural anesthesia in anesthetized pigs was associated with decreased mean arterial blood pressure and hepatic artery blood flow but no change in hepatic oxygen delivery or uptake or tissue oxygen partial pressure compared with pigs receiving general anesthesia alone.[129] Taken together, these findings should reassure the clinician that high neuraxial anesthesia may be well tolerated with respect to hepatic oxygenation, despite a modest reduction in MAP. Care should be taken to maintain cardiac output and perfusion pressure during anesthesia to ensure the adequate perfusion of all the vital organs.

Hepatic Coagulopathy

Severe hepatic disease is associated with abnormalities of the coagulation system. The cause is multifactorial and may include the decreased synthesis of procoagulant proteins, impaired clearance of activated coagulation factors, nutritional deficiency (eg, vitamin K, folate), the synthesis of functionally abnormal fibrinogen, splenomegaly secondary to portal hypertension (sequestrational thrombocytopenia), qualitative platelet defects, and bone marrow suppression of thrombopoiesis (eg, by alcohol, hepatitis virus infection).[130] Because of the potential complexity of the coagulopathy, it may be necessary to perform additional laboratory tests such as clotting factor and fibrinogen assays to completely delineate the nature of the problem. Clotting factor deficiencies can be treated with vitamin K supplementation fresh frozen plasma transfusion, or both. Platelet transfusion maybe necessary in the case of thrombocytopenia. Other therapies such as recombinant factor VIIa have also been used to correct bleeding associated with liver failure.[131]

Since the vitamin K–dependent clotting factors are more susceptible to hepatocellular disease, the prothrombin time (PT) and international normalized ratio (INR) are often used as markers of coagulation system integrity. However, the predictive value of PT/INR on hemorrhage during bedside procedures such as lumbar puncture or central line placement has been shown to be poor.[132] As such, it is important to carefully weigh the risks and benefits of a neuraxial anesthetic technique in a patient with suspected hepatic-induced coagulopathy.

Although an INR of less than 1.5 “should be associated with normal hemostasis” according to the American Society of Regional Anesthesia and Pain Medicine (ASRA) consensus guidelines on anticoagulation,[133] this statement applies primarily to warfarin-induced anticoagulation and may not be a reliable indicator of the likelihood of problematic bleeding in liver failure. Epidural analgesia is frequently used during and following major liver resection, although there are some safety concerns as postoperative derangement of coagulation parameters is common; however, there are no reports of epidural hematoma in this setting.[134] The risks associated with performing peripheral nerve blocks in patients with abnormal coagulation parameters are less clear. Obviously, the risk of bleeding is increased with techniques in which the needle is placed in the vicinity of a major blood vessel. Careful consideration of risks and benefits should be performed when considering lumbar plexus block in coagulopathic patients, as a retroperitoneal hemorrhage in this space may be extensive and not obvious until the patient is in shock. Likewise, care should be taken when performing blocks in the vicinity of noncompressible blood vessels (eg, the subclavian artery in the case of infraclavicular block) in patients who have a coagulation abnormality. The risks of regional anesthesia in the setting of a disorder are elaborated on in Chapter 53.

Clinical Pearls

- Deep blocks, such as anterior sciatic or lumbar plexus blocks, should be practiced with special care in patients with coagulopathy.
- Similarly, blocks in the vicinity of noncompressible blood vessels, such as the artery in the fossa, should be carefully considered.

DIABETES MELLITUS

Diabetes is a multisystem disease characterized by carbohydrate intolerance and insulin dysregulation that has many implications for the regional anesthesiologist.[135] Besides the usual anesthetic concerns, such as the presence of coronary artery, cerebrovascular, and renal disease, diabetics have a high incidence of preexisting peripheral neuropathy, which has implications for block performance and success and poses a risk for neurologic complications. Other considerations are the effect of regional anesthesia on glucose homeostasis and the increased risk of infection in diabetic patients.

Peripheral Neuropathy in Diabetics

Diabetic neuropathy is one of the most common neurologic diseases, affecting up to 100% of diabetic patients with long-standing disease.[136] Patients can be asymptomatic, but in affected patients, symptoms are typically described as paresthesias, sensory loss, or neuropathic pain. The mechanism of diabetic neuropathy is thought to be related to either a direct metabolic and osmotic effect of chronic hyperglycemia on neurons or a microvascular insult leading to nerve ischemia.[137]

Performing nerve blocks in patients with peripheral neuropathy is controversial. Kalichman and Calcutt studied sciatic nerve histology in rats following blockade with lidocaine and found significantly more nerve edema in the nerves of the rats with diabetes versus healthy controls.[138] The reason for the edema is probably multifactorial and may include the presence of an altered blood–nerve barrier or decreased uptake of local anesthetic, leading to a longer duration of nerve bathing. An increase in endoneural fluid pressure due to edema may constrict small transperineural vessels, precipitating ischemia in an already compromised nerve. This may translate to an increased incidence of postoperative paresthesias following nerve blocks, including neuraxial blocks, in diabetics. Al-Nasser reported a case of prolonged (> 8 weeks) bilateral lower limb paresthesias and pain following lumbar epidural analgesia with 0.2% ropivacaine in a diabetic patient undergoing radical prostatectomy.[139] Postoperative electromyographic studies showed widespread sensory neuropathy of both upper and lower limbs, indicating that the patient, although asymptomatic, had preexisting neuropathy that may have predisposed him to this rare complication. Studies have demonstrated a prolonged duration of sensory and motor blockade following sciatic nerve block in diabetics when compared to nondiabetics and that the duration of blockade increases as glycemic control worsens (as measured by glycosylated hemoglobin levels).[140,141] A study in diabetic rats showed a similar prolongation of local anesthetic effect which was reversed by 2 weeks of insulin treatment but unaffected by 6 hours of insulin, suggesting that the increased sensitivity to local anesthetics is mediated by chronic changes in the nervous system as opposed to the current blood glucose level.[142] It is unclear whether this increased sensitivity to local anesthetics represents an increased risk of neurological complications. The actual prevalence of neurologic complications in diabetics receiving nerve blocks is unknown but is probably quite low. Diabetes is a common disease, and reports of neurologic complications in the literature are sparse, suggesting that in the vast majority of cases, recovery from peripheral nerve blocks is uneventful.

Patients with diabetes should also be considered at increased risk for infectious complications of regional anesthesia due to the immune suppression that occurs as a result of the disease. Diabetes has been implicated as a risk factor for infection following both peripheral and neuraxial blockade.[143] Although it is unclear to what extent diabetes truly increases the risk of infection, it seems wise to be extra vigilant with infection control precautions in these patients.

The effect of diabetic neuropathy on electrolocation of nerves while using a nerve stimulator is another matter of controversy. Patients with long-standing diabetes may require somewhat higher current intensity in order to produce a motor response.[144,145] While nerve conduction studies in diabetics with neuropathy consistently show a reduction in conduction velocity and amplitude for both motor and sensory nerves, this does not tend to be the case in actual clinical practice, as most patients with diabetes have similar current intensity thresholds as non-diabetic patients without neuropathy.[146]

Clinical Pearls

- Patients with diabetes are prone to a metabolic neuropathy that impairs nerve conduction.
- A stimulating current of greater intensity is only occasionally needed to obtain visible muscle twitches when using a nerve stimulator to electrolocate nerves.

Effect of Regional Anesthesia on Glucose Homeostasis

It is well known that surgery performed in combination with general anesthesia provokes a counterregulatory response that significantly increases plasma levels of glucose, as well as levels of cortisol and catecholamines. This so-called stress response has long been considered a homeostatic defense mechanism that is important in an organism's adaptation to harmful stimuli, providing substrates for energy in times of need. However, prolonged periods of hyperglycemia may have deleterious effects on patients, with evidence supporting an increase in mortality rates, hospital length of stay, and incidence of nosocomial infection.[147,148] Hyperglycemia may be particularly hazardous in patients who have incurred trauma.[149]

Regional anesthesia has been shown to ameliorate the hyperglycemic response to surgery and therefore may play a role in this protective phenomenon. An intraoperative glucose tolerance test resulted in markedly elevated plasma glucose levels in patients receiving general versus epidural anesthesia for such procedures as inguinal herniorrhaphy and hysterectomy.[150,151] Likewise, abdominal hysterectomy performed under spinal anesthesia is associated with lower intra- and postoperative glucose levels compared with neuroleptanesthesia.[152] Retrobulbar block reduces the hyperglycemic stress response to both cataract[153] and scleral buckle[154] surgery.

Glucose homeostasis is complex, and several factors likely contribute to the salutary action of regional anesthesia on glycemic control. These may include the inhibition of hepatic gluconeogenesis as well as the inhibition of catecholamine and cortisol responses to surgery.[155] In addition, the "absence of general anesthesia" may be a causative factor in glycemic control, as volatile agents such as halothane and enflurane have been shown to impair glucose tolerance in dogs.[156] It seems clear from the available data that to improve outcomes from major surgery, anesthesiologists must prevent as much nociceptive input from reaching the central nervous and neuroendocrine systems as possible.[157] The use of regional anesthesia can easily facilitate this goal and may be especially pertinent for "brittle" diabetics in whom tight glycemic control is difficult at the best of times.

THYROID NEUROPATHY

Diabetes and uremia are the most common metabolic neuropathies; however, several other less common neuropathies also have implications for the regional anesthesiologist. These include those neuropathies that result from the use of certain medications or exposure to toxins and those related to connective tissue, autoimmune, and vascular diseases.[158] One of the most prevalent causes of metabolic neuropathy is that associated with overt hypothyroidism. Thyroid neuropathy is a largely sensory phenomenon that is poorly understood but present in approximately 40% of patients diagnosed with hypothyroidism.[159] It is most obvious in frank myxedema, but nerve conduction studies have shown evidence of velocity impairment in subclinical hypothyroidism.[160] Thyroid neuropathy is most likely to present as peripheral nerve entrapment, particularly of the median nerve, and these patients are frequently referred for carpal tunnel decompression.[161] Entrapment of the eighth cranial nerve leading to deafness is also common. Patients may complain of dysesthesias in a glove-and-stocking pattern, as well as lancinating pains suggestive of nerve root compression. "Hung" deep tendon reflexes (brisk reflex response with a delayed return to normal tone) are a hallmark of hypothyroidism and probably relate to both neuropathy and myopathy. Pathologically, affected nerves exhibit mucinous deposition and, in advanced cases, segmental demyelination with loss of large myelinated nerve fibers.[162]

Few data exist on the effect preexisting thyroid neuropathy may have on the management of regional anesthesia in this population. A potential consequence of performing regional anesthesia in patients with nerve entrapment is what has been termed the "double-crush syndrome."[163] This refers to the enhanced susceptibility of nerves to injury or impairment at one anatomic location when already compressed or otherwise injured at another, separate location. A classic example is the patient with symptoms of carpal tunnel syndrome after seemingly minor trauma or injury to the median nerve, who is later found to have compression of the C6 nerve root. Although originally described in terms of mechanical injury, it has been recognized that metabolic and pharmacologic factors can contribute to the double-crush syndrome,[164] including hypothyroidism. Thus, it may be that patients with thyroid neuropathy are at increased risk for neurologic injury when receiving regional anesthesia blocks, as minor needle trauma to a susceptible nerve may produce functional neurologic deficits. Although this remains speculative at present, this possibility reinforces the need for a detailed history and documentation of preexisting neurologic deficit in patients with hypothyroidism and the careful consideration of techniques in these patients. Finally, if suspected, thyroid neuropathy has been shown to be correctable in many cases by prompt treatment with thyroid replacement therapy, which may this complication.[165,166]

OBESITY

Obesity is an increasingly prevalent problem, with worldwide obesity rates having doubled since 1980.[167] Over the last 20 years, there has been a dramatic rise in obesity in the U.S., with 35% of adults and 17% of children and adolescents meeting the criteria for obesity in 2012.[168] In addition to the usual anesthetic considerations for morbidly obese patients, such as the presence of various cardiopulmonary, gastrointestinal, and endocrine comorbidities, the abundance of extra tissue can present a challenge to regional anesthesiologists. Obesity has been shown to impair the ability of anesthesiologists to correctly identify lumbar spinal interspaces.[169] Outcomes are similarly affected in overweight patients. In a study of over 9000 mixed blocks at a single institution, patients with a body mass index (BMI) greater than 30 kg/m^2 were 1.62 times more likely to experience a failed regional block than were those with a BMI less than 25 kg/m^2.[170] Not surprisingly, the investigators cited difficulty in landmark identification, patient positioning, and insufficient length of needle used as the main impediments to successful block placement. These findings are supported by a study of axillary blocks using nerve stimulator guidance, where obesity was associated with longer block performance time, decreased success rate, increased complication rate, and decreased patient satisfaction.[171] Despite these relative difficulties, block success rates in obese patients were high, and rates of serious complications were low. Regional anesthesia remains an attractive option for obese patients because it may reduce the incidence of cardiopulmonary and airway complications compared with those experienced during general anesthesia.

Clinical Pearls

- Obese patients are more likely to experience a failed regional block than patients with a BMI within the normal range.
- Reasons for this include difficult surface or sonographic landmarks, difficulty in patient positioning.

Obese patients seem to benefit from image-guided regional anesthetic blocks. Fluoroscopy has been used in the placement of axillary brachial plexus catheters,[172] in the performance of sciatic nerve blocks,[173] and as an aid in facilitating spinal anesthesia in morbidly obese patients.[174] However, its use is limited by the need to relate neural anatomy to structures that appear radiodense, such as bones, needles, or contrast-injected vessels.

Ultrasound may be especially useful in obese patients with obscured surface landmarks, although excess adipose tissue can make ultrasound examination itself more difficult due to attenuation of the ultrasound beam.[175,176] This difficulty can be partly overcome by decreasing the frequency of the transducer to increase penetration depth, although image resolution will be reduced (Figure 48–2). When median and sciatic nerves were scanned in normal-weight and obese volunteers, Marhofer et al. concluded that visualization of superficial peripheral nerves is independent of BMI, whereas deeper nerves are more difficult to visualize in obese subjects.[177] Studies conducted in obese parturients and in nonobstetric patients with difficult surface anatomic landmarks have verified the utility of ultrasound in identifying the epidural space and other spinal structures prior to the performance of a neuraxial block.[178–180] To date, few studies have compared ultrasound-guided peripheral nerve blocks with landmark or nerve stimulator–guided techniques in the obese population; however, ultrasound seems to be a useful modality for this potentially challenging group of patients.

Obesity may have an effect on the dosing of spinal medications, although the issue is somewhat controversial. A common notion is that increased abdominal mass leads to compression of intrathecal volume by engorgement of epidural plexuses, leading to an increased, and potentially dangerous, block height during spinal anesthesia. This is supported by data correlating block height with patient weight during standardized spinal anesthesia for cystoscopy.[181] Indeed, some authors have advocated the consideration of "low-dose" spinal anesthesia in the morbidly obese, due to wide variations in their dosing requirements. In one extremely overweight parturient (BMI = 66 kg/m^2), cesarean section was completed successfully with a 5-mg spinal dose of bupivacaine as the sole anesthetic agent.[182] However, patient weight does not necessarily correlate with the degree of

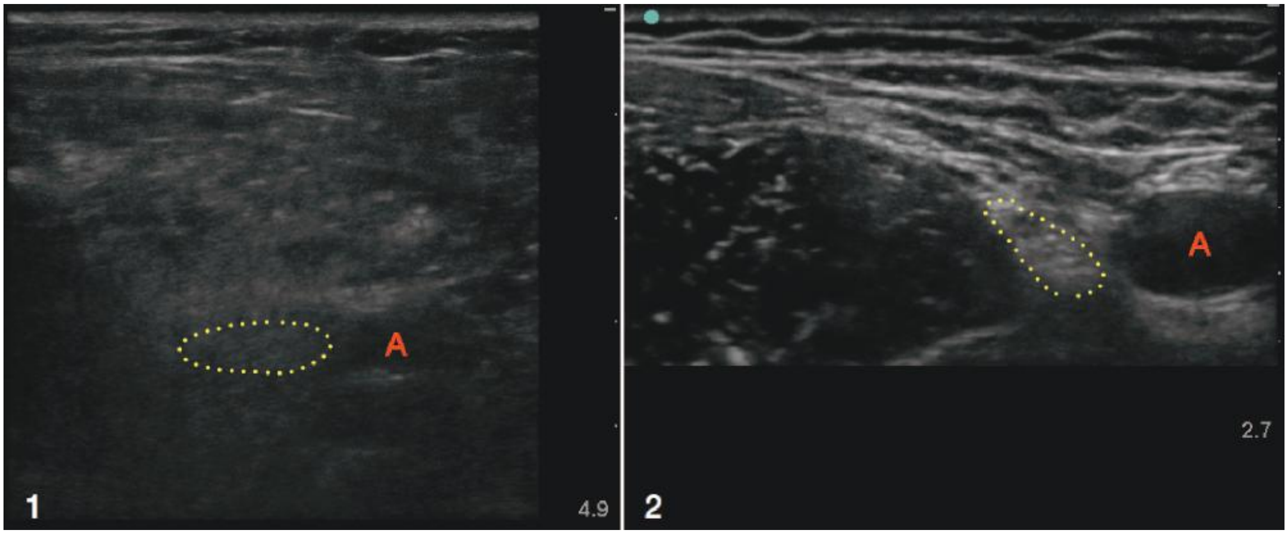

FIGURE 48–2. Ultrasound scans of the femoral regions in an obese (**1**) patient and a slim (**2**) patient. Note the increased depth required to image the artery (A) and nerve (dotted outline) in the obese example, as well as the overall poor resolution quality due to the excess adipose tissue. In contrast, the nerve, artery, muscles, and fascial planes in the slim patient are crisp and well defined.

compression of the thecal sac, and many investigators have argued that weight alone is not a reliable predictor of block height during spinal anesthesia.[183–185] A dose-finding study of hyperbaric bupivacaine in patients undergoing knee replacement found no difference in the dose required to achieve a block to T12 between obese and nonobese patients but did find a slightly longer duration of block and reduced incidence of tourniquet pain in the obese group.[186] However, no patients in the obese group had a BMI over 40, so these findings may not be reflective of the morbidly obese population. It is probably reasonable to approach the spinal dosing of morbidly obese patients with a degree of caution, and when practical, to incrementally adjust the anesthetic dose.

CHAPTER 49

Regional Anesthesia in the Patient with Preexisting Neurologic Disease

Adam K. Jacob, Sandra L. Kopp, and James R. Hebl

INTRODUCTION

Preexisting disorders of the peripheral nervous system, central nervous system, and spinal canal present a unique challenge to both patients and anesthesiologists who desire to use regional anesthetic techniques. Because each of these clinical conditions involves compromise to neural structures, the concern is that further insult from surgical (eg, intraoperative stretch or compression, tourniquet ischemia, hemorrhage) or anesthetic (eg, mechanical trauma, vasoconstrictor-induced ischemia, local anesthetic toxicity) causes may result in new or worsening postoperative neurologic deficits.

Regardless of the underlying etiology, the presence of chronic neural compromise secondary to mechanical (eg, spinal stenosis or compressive radiculopathy), ischemic (eg, peripheral vascular disease), toxic (eg, vincristine or cisplatin chemotherapy), metabolic (eg, diabetes mellitus), or autoimmune (eg, multiple sclerosis) derangements may place patients at increased risk of further neurologic injury.[1-3] Upton and McComas[1] were the first to describe the "double-crush phenomenon," which suggests that patients with preexisting neural compromise may be more susceptible to injury at another site when exposed to a secondary insult (Figure 49–1). Secondary insults may include a variety of acute surgical or anesthetic risk factors, including those of regional anesthetic techniques. Osterman[2] emphasized that not only are two low-grade insults along a peripheral nerve trunk worse than just one at a single site, but that the damage of the dual injury far exceeds the expected additive damage caused by each isolated insult. It may be further postulated that the second insult need not be along the peripheral nerve trunk itself, but rather at any point along the neural transmission pathway. Therefore, the performance of peripheral or neuraxial regional techniques in patients with preexisting neurologic disorders may place them at increased risk of the double-crush phenomenon.

Unfortunately, the data available regarding any association of pre-existing neurologic disease and post-regional anesthesia dysfunction often conflicting in terms of outcomes and conclusions. As a result, definitive recommendations can rarely be made from the existing scientific literature. However, the following discussion provides a comprehensive review of the available literature on the topic so that patients and clinicians can make an informed decision regarding the potential neurologic risk of performing regional anesthesia in the presence of preexisting neurologic disorders.

PERIPHERAL NERVOUS SYSTEM DISORDERS

The peripheral nervous system is composed of numerous cell types that serve diverse sensory, motor, and autonomic functions. Signs and symptoms of impaired function depend on the distribution and severity of the injury, in addition to the specific element of the nerve that is affected. More than 100 peripheral neuropathies have been identified, each with its own pathophysiology, symptoms, and prognosis.[4]

Hereditary Peripheral Neuropathy

Inherited neuropathies represent a heterogeneous group of diseases that often share the features of an insidious onset and indolent course over years to decades. A wide range of genotypes results in phenotypes ranging from mild symptoms and subclinical disease to severe, debilitating conditions. The most common inherited neuropathies are a group of disorders collectively referred to as Charcot–Marie–Tooth (CMT) disease. CMT affects approximately 1 in 2500 people, often beginning in childhood or adolescence.[5] CMT neuropathies are caused

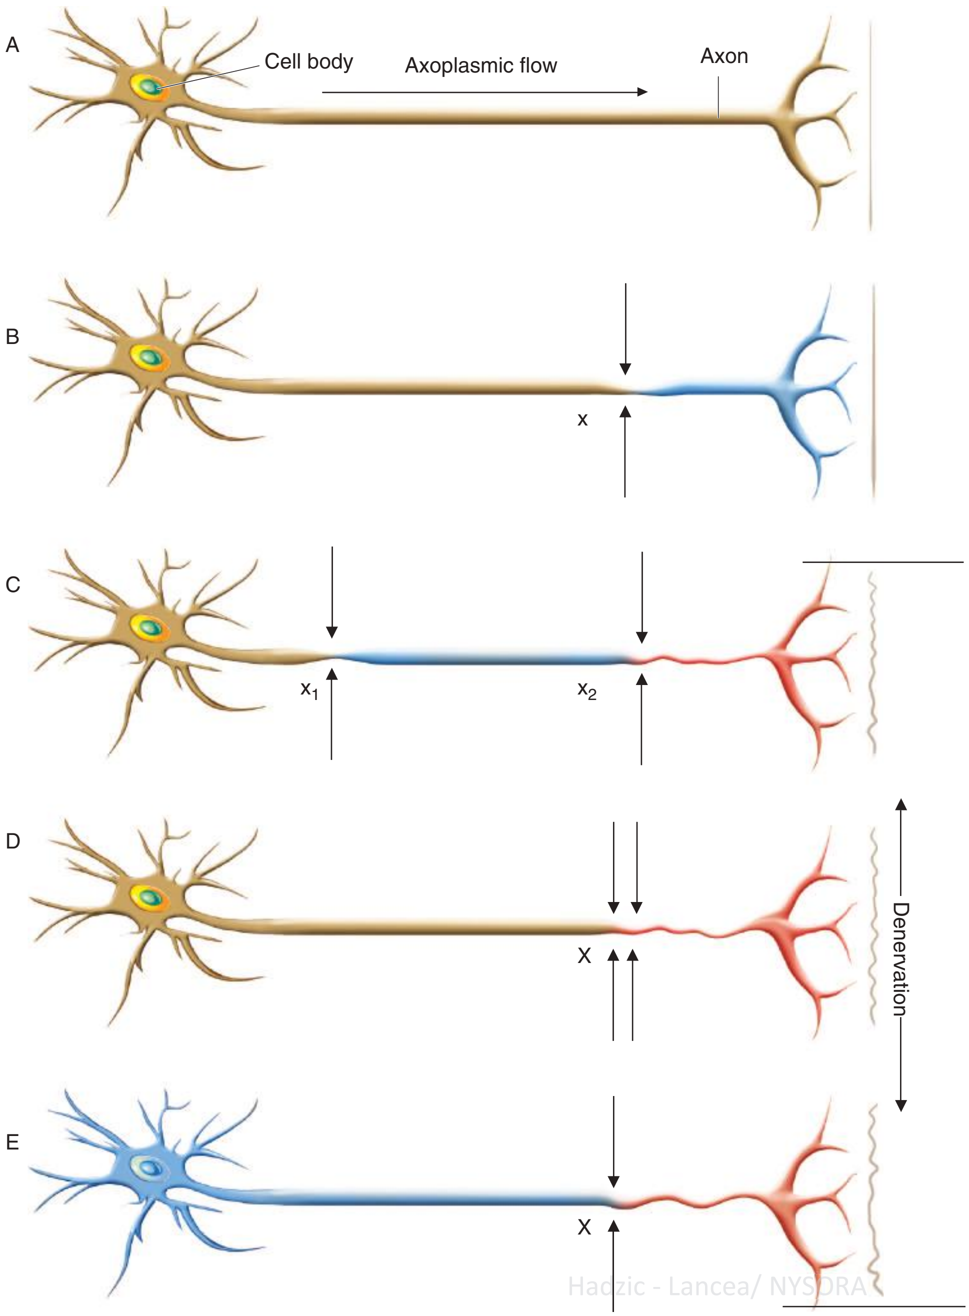

FIGURE 49–1. Neural lesions resulting in denervation. Axoplasmic flow is indicated by the degree of shading. Complete loss of axoplasmic flow results in denervation (C, D, E). **A:** Normal neuron. **B:** Mild neuronal injury at a single site (x) is insufficient to cause denervation distal to the insult. **C:** Mild neuronal injury at two separate sites (x_1 and x_2) may cause distal denervation (ie, "double crush"). **D:** Severe neuronal injury at a single site (X) may also cause distal denervation. **E:** Axon with a diffuse, preexisting underlying disease process (toxic, metabolic, ischemic) may have impaired axonal flow throughout the neuron, which may or may not be symptomatic but predisposes the axon to distal denervation following a single minor neural insult at x (ie, "double crush"). (Reproduced with permission from Mayo Foundation for Medical Education and Research.)

from mutations in more than 30 genes responsible for manufacturing neurons or the myelin sheath.[6] Typical signs and symptoms include extreme motor weakness and muscle wasting within the distal lower extremities and feet, gait abnormalities, loss of tendon reflexes, and numbness within the lower limbs.

The reported use of peripheral[7,8] or central[9–12] regional anesthetic techniques in patients with CMT has been limited to small case series and anecdotal case reports. All patients made uneventful recoveries without worsening of their neurologic conditions. Of note, two cases involving single-injection regional techniques (epidural anesthesia using 18 mL 0.75% ropivacaine[10] and supraclavicular analgesia using 30 mL 0.5% bupivacaine[7]) reported a prolonged effect (12 hours and 30 hours, respectively) of the regional technique compared to the anticipated duration. In both cases, the use of higher local anesthetic concentrations may have contributed to the delayed recovery.

Hereditary neuropathy with liability to pressure palsy (HNPP) is another rare inherited demyelinating peripheral neuropathy in which individuals suffer from repeated motor and sensory neuropathies following brief nerve compression or mild trauma (ie, pressure palsies). First described in the early 1990s, HNPP has been linked to a mutation on the PMP-22 gene resulting in reduced myelin production. Evidence of the use of a regional technique in the setting of HNPP has been limited to a single case report. Lepski and Alderson[13] reported the successful use of an epidural for labor analgesia in a 24-year-old parturient with HNPP. The patient made an uneventful recovery without a worsening of her neurologic condition.

Based upon the lack of clinical evidence, definitive recommendations cannot be made about the safety and use of regional anesthesia in patients with preexisting inherited peripheral neuropathies. However, isolated case reports suggest that peripheral and central regional techniques *may* be used without worsening a patient's stable neurologic condition. However, caution should be used to minimize other surgical (eg, tourniquet use) and anesthetic (eg, reduced concentration or dose of local anesthetic) risk factors for perioperative nerve injury when considering the use of regional anesthesia within this patient population.

Acquired Peripheral Neuropathy

Diabetic Polyneuropathy

The increasing prevalence of diabetes mellitus (DM) and its associated comorbidities will likely translate to a larger number of diabetic patients presenting for surgery. Despite the clinical benefits and widespread use of regional anesthesia (peripheral and neuraxial blockade), there remains concern regarding its use in patients with DM.[14–17] It has been suggested that patients with a history of chronic neural compromise secondary to metabolic conditions such as diabetes may be at an increased risk of worsening neurologic injury following neuraxial or peripheral nerve blockade.[16–18]

Diabetes mellitus is currently the most common cause of systemic polyneuropathy. There are several types of neuropathy associated with DM, but distal symmetric sensorimotor polyneuropathy is the most common form and is generally synonymous with the term *diabetic polyneuropathy* (DPN). The frequency of DPN ranges from 4%–8% at the time of diagnosis to more than 50% in patients with long-standing diabetes. Despite the fact that patients may be asymptomatic, nearly all will have evidence of abnormal nerve conduction.[19,20] Furthermore, it is relatively common for patients to present for surgery with either undiagnosed diabetes mellitus or known diabetes with uncontrolled hyperglycemia.[21]

The pathophysiology of DPN is poorly understood and likely multifactorial. Early symptoms, such as numbness, pain, and autonomic dysfunction, are caused by damage to small nerve fibers, which occurs before damage to large fibers becomes apparent.[22] There is pathophysiologic evidence of abnormalities in both large and small neural blood vessels, ultimately contributing to multifocal fiber loss. Axonal degeneration is the most prominent feature of DPN and occurs secondary to the reduced delivery of essential nutrients and other components (oxygen, blood, adenosine triphosphate, glucose) to the axon. Proposed mechanisms include (1) sorbitol deposition in the nerve due to glucose accumulation; (2) local tissue ischemia in sensory and autonomic fibers secondary to endoneurial hypoxia; (3) abnormal tissue repair mechanisms caused by excess glucose; and (4) mitochondrial dysfunction within the dorsal root ganglia.[23–26]

Currently, there is an abundance of animal data that suggests diabetic nerves may have an increased risk of neurologic injury following regional anesthesia compared to nondiabetic nerves.[27–29] Kalichman and Calcutt[18] were the first to hypothesize that diabetic nerve fibers may be more susceptible to local anesthetic neurotoxicity for two reasons: (1) the nerve is already stressed due to chronic ischemic hypoxia; and (2) the nerves are exposed to larger concentrations of local anesthetics due to decreased perineural blood flow. More recently, these findings have been supported with both animal and clinical data. Lirk and colleagues[30] used Zucker diabetic fatty rats exposed to hyperglycemia to demonstrate that although the overall neuronal survival difference was low, in vitro local anesthetic neurotoxicity was more pronounced in neurons from diabetic animals. The authors also reported that preexisting subclinical neuropathy led to substantial prolongation of the block duration in vivo. Kroin and colleagues[28] also reported that the duration of sciatic nerve block with lidocaine 1% or ropivacaine 0.5% was longer in streptozotocin-induced diabetic rats compared with nondiabetic rats and that block duration correlated with nerve fiber degeneration. In a subsequent study, the same authors also concluded that, with continuous glycemic control, diabetic rats had a block duration that was similar to nondiabetic rats and 40 minutes shorter than in diabetic rats without glycemic control.[27] Interestingly, acute glycemic control did not lessen the nerve block duration, suggesting that diabetic neuropathy is not rapidly reversed within this animal model. Currently, it is unclear whether the results from animal studies using experimentally induced hyperglycemia can be used to make recommendations for patients with long-standing diabetes mellitus.[31]

Although animal studies have consistently found that diabetic nerves are more sensitive to local anesthetics and potentially more susceptible to neural injury, it is unclear whether diabetic patients experience a higher incidence of neurologic injury after regional anesthesia.[18,27,28,32] There are limited clinical data suggesting that the success of peripheral nerve blockade (supraclavicular brachial plexus) may be higher in diabetic patients independent of other predictors of success (eg, body mass index) compared to nondiabetic patients.[32] Gebhard and colleagues[32] have proposed several theories for this finding, including (1) a higher sensitivity of diabetic nerve fibers to local anesthetics; (2) possible unknown intraneural penetration before injection; and (3) preexisting DPN with accompanying decreased sensation. Preexisting pathology has long been reported to play a role in the development of postoperative neurologic dysfunction.[33–35] A recent case report described a persistent postoperative femoral neuropathy after discontinuing a femoral nerve catheter in a patient with a preexisting subclinical diabetic neuropathy that had been undiagnosed preoperatively.[15]

In patients with diabetes mellitus, a decreased sensitivity to electrical stimulation combined with diminished sensory function and an increased sensitivity to local anesthetic toxicity may increase the risk of intraneural injection during peripheral nerve blockade using a peripheral nerve stimulator.[36–38] Currently, there is a lack of clinical evidence suggesting that the use of ultrasound guidance is safer than peripheral nerve stimulation within the general population.[39,40] However, this lack of established clinical benefit is less clear for diabetic patients. For example, there are a limited number of animal and clinical studies that suggest that ultrasound guidance may be a more desirable method of neural localization in diabetic patients. Animal studies have shown that low-threshold electrical stimulation may not offer protection from intraneural injection in the presence of hyperglycemia. Rigaud and colleagues[41] demonstrated that all needle insertions within a hyperglycemic dog model resulted in intraneural injection (6/6), whereas only one (1/18) intraneural injection occurred in control dogs. Sites and colleagues[38] also concluded that ultrasound guidance may be a preferred method of neural localization in diabetic patients after failing to elicit a motor response or paresthesia in two patients undergoing sciatic nerve blockade using peripheral nerve stimulation. The authors described a very weak motor response in both diabetic patients with a stimulating current of more than 2.4 mA despite perineural placement of the stimulating needle using ultrasound guidance. Another potential application of ultrasound technology is the ability to use the cross-sectional area of a peripheral nerve to identify a clinical or subclinical peripheral neuropathy: a diagnosis that historically would have required complex nerve conduction studies.[42,43]

Findings of spinal cord involvement in diabetic patients suggest that the same or similar mechanism of injury may affect not only peripheral nerves but neural elements within the central neuraxis as well.[44,45] Using magnetic resonance imaging, Selvarahah and colleagues[46] described early central nervous system involvement consisting of a significant reduction in the spinal cord cross-sectional area in patients with both subclinical and clinically detectable diabetic peripheral neuropathy. A case report of a diabetic patient experiencing a persistent lower extremity neuropathy after what appeared to be uneventful epidural analgesia reinforces concerns that diabetic patients may be at an increased risk of neurologic injury following neuraxial anesthesia.[14] A retrospective review also evaluated neurologic complications in patients with preexisting peripheral sensorimotor neuropathy or diabetic polyneuropathy who subsequently underwent neuraxial anesthesia or analgesia.[23] Of the 567 patients studied, two (0.4%; 95% CI 0.1%–1.3%) experienced new or progressive postoperative neurologic deficits when compared to preoperative findings. The authors concluded that although the risk of severe postoperative neurologic injury among diabetic patients is rare, it appears to be higher than that reported in the general population. Although the neuraxial technique could not be definitively implicated as the primary cause of the neurologic insult, it may have been a contributing factor among patients with preexisting neural compromise.

In summary, patients with DPN likely have neural elements that are more sensitive to the effects of local anesthetic. As a result, diabetic peripheral nerves may be more susceptible to subsequent injury from local anesthetic toxicity or ischemic insults. Ultimately, the decision to use regional anesthesia in diabetic patients should be made on an individual basis after a thorough discussion with the patient regarding the potential risks and benefits of the technique. Consideration should be given to decreasing the concentration or total dose of local anesthetic for both peripheral and neuraxial techniques[47]—particularly in profoundly symptomatic patients. Furthermore, the use of ultrasound guidance may facilitate perineural needle placement and the use of lower local anesthetic volumes in diabetic patients, although definitive data ensuring increased safety with ultrasound guidance are currently lacking.[48] Decreasing the concentration or dose of local anesthetic and eliminating epinephrine additives should also be considered given that diabetic nerves are already at risk of neural ischemia and infarction due to changes within the endoneural microvasculature.[26]

Chemotherapy-Induced Neuropathy

Chemotherapy-induced peripheral neuropathy (CIPN) is a frequent side effect of several commonly used chemotherapeutic agents. It is a dose-limiting side effect that occurs in approximately 30%–40% of patients.[49] The exact mechanism of injury is unclear, although damage to microtubules, interference with microtubule-based axonal transport, mitochondrial disruption, and cytotoxic effects on DNA are all possible mechanisms.[49,50] The degree of neurotoxicity depends on the agent used, the duration of administration, and the cumulative dose received. Cisplatin, oxaliplatin, and carboplatin characteristically induce a pure sensory, painful peripheral neuropathy, whereas vincristine, paclitaxel, and suramin tend to induce a mixed sensorimotor neuropathy with or without involvement of the autonomic nervous system.[51] Symptoms are often in the "glove-and-stocking" distribution and consist of pain or paresthesias. Patients at risk of developing CIPN include those with preexisting neural damage secondary to diabetes mellitus, excessive alcohol use, or inherited peripheral neuropathy. In general, a prolonged period of regeneration is required to restore neurologic function with incomplete recovery being the most common outcome.[50–52] However, patients who recover from CIPN have an increased risk of developing progressive neuropathic symptoms if exposed to additional neurotoxic agents.[53] Local anesthetics are potentially neurotoxic, and caution should be used when deciding whether to perform regional anesthesia in patients who have received chemotherapeutic agents known to cause CIPN. It is common for patients to have a subclinical neuropathy that presents only following a second neurologic insult, such as a peripheral or neuraxial block.[54]

Entrapment Neuropathy

Entrapment neuropathy, one of the most prevalent disorders of the peripheral nervous system, occurs when a single nerve is chronically compressed or mechanically injured at a specific location. Ulnar nerve entrapment at the elbow, referred to as "cubital entrapment syndrome," is the second most frequent upper extremity compression neuropathy.[55] The ulnar nerve is at increased risk because of its superficial location in the region of the medial elbow. Injury to the nerve may occur as a result of acute trauma, compression, repetitive traction, subluxation of the nerve, osteoarthritis, or gout or following an upper extremity surgical procedure. Initial symptoms include hyperesthesia in the ulnar nerve distribution, elbow pain, and paresthesias in the ring and small fingers. These symptoms are often intermittent and may progress over the course of months to years. In the later stages of the disease, weakness of the intrinsic muscles of the hand with or without visible atrophy may be observed. At present, the most common practice is to conservatively treat patients with mild symptoms without weakness or atrophy, whereas surgery is indicated for patients who do not improve after conservative management or present with severe neurological signs and symptoms (eg, persistent paraesthesia, objective weakness, muscular atrophy).[55]

General, regional, or local anesthesia can be used for surgical decompression of an entrapped ulnar nerve. The choice of anesthetic depends on the surgical procedure, whether nerve function will be tested intraoperatively, and the extent of damage accompanying the nerve injury. In a 2001 cohort study of 360 patients with preexisting ulnar neuropathy undergoing ulnar nerve transposition, Hebl and colleagues[56] found that anesthetic technique (general anesthesia versus regional anesthesia) did not affect the neurologic outcome immediately after surgery or two to six weeks postoperatively. A preoperative discussion with the surgeon to determine the intraoperative plan and address specific concerns related to the patient's disease process will assist the anesthesiologist in choosing the most appropriate anesthetic technique.

Inflammatory Neuropathy

Guillain–Barré Syndrome

Guillain–Barré syndrome (GBS) is an acute, inflammatory demyelinating polyneuropathy characterized by areflexia and diffuse ascending neuromuscular paralysis. The etiology of GBS is unclear, although infection, pregnancy, vaccinations, immunosuppression, systemic illnesses, and transfusion have all been proposed as potential triggers.[57] The degree and distribution of paralysis is variable and can include sensory nerve, cranial nerve, and autonomic nervous system involvement. Symptoms peak approximately two to four weeks after the initial onset with most patients experiencing a prolonged recovery. Unfortunately, many patients experience moderate to severe neurological impairment for years after the initial diagnosis.

There are several reports of GBS occurring in the postoperative period following a variety of surgical procedures using various types of anesthetic.[58–60] However, case reports of regional anesthesia use in patients with GBS are generally limited to the obstetric population.[61–64] Some patients with GBS may have autonomic instability and will subsequently experience an exaggerated response to neuraxial blockade,[63] whereas other GBS patients will exhibit a normal response to neuraxial anesthesia.[61,64] Although there have been reports of successful neuraxial anesthesia in parturients with GBS, the potential for local anesthetics to interact with peripheral myelin or cause direct nerve trauma cannot be ignored.[22] There is some evidence to suggest that epidural anesthesia may precipitate or reactivate GBS hours to weeks following surgery.[58,65,66] However, it is difficult to determine if this is due to the effects of the epidural, the natural progression of the disease, the surgical procedure, or the stress response related to surgery.

Although it has been suggested that acute neuronal inflammation may be a relative contraindication to regional anesthesia, existing data provide little information regarding the safety of neuraxial anesthesia or peripheral nerve blockade in patients with GBS.[22] Ultimately, the decision to perform regional anesthesia should be made on an individual basis after a thorough discussion with the patient regarding the potential risks and benefits.

Postsurgical Inflammatory Neuropathy

Postsurgical inflammatory neuropathy (PSIN) is a recently described autoimmune or inflammatory process that may be the cause of severe postoperative neurologic deficits. Staff and colleagues[67] recently described a series of 33 patients who developed PSIN within 30 days of surgery. The diagnosis was confirmed in most patients following a peripheral nerve biopsy. PSIN is believed to be an idiopathic, immune-mediated response to a physiologic stress such as an infectious process, a vaccination, or a surgical procedure.[67] The condition may present as focal, multifocal, or diffuse neurologic deficits in the setting of negative radiographic imaging. Complicating the diagnosis, the onset of neurologic deficits may not be apparent during the immediate postoperative period, and the deficits may be in an anatomic distribution remote from the surgical site or regional anesthetic technique. Risk factors or potential triggers for PSIN include malignancy, diabetes mellitus, tobacco use, systemic infection, volatile anesthetic use, and recent blood transfusion.[67] Suppression of the immune response with prolonged high-dose corticosteroids or intravenous immunoglobulin is the current treatment of choice. The goal of treatment is to sufficiently blunt the inflammatory response to allow for axonal regeneration. Fortunately, most patients improve with current treatment recommendations, with pain and sensory deficits improving before the resolution of motor deficits.[67]

The degree to which inflammatory mechanisms play a role in postoperative neurologic dysfunction is unknown and poorly characterized, particularly within the anesthesia literature.[68] As a result, anesthesia providers and surgeons rarely consider this potential etiology of nerve injury when evaluating patients with postoperative deficits. This is problematic, as the common approach of watchful waiting and conservative management will not be effective in patients with PSIN. Rather, PSIN is a clinical condition that must be suspected early in the disease process so that a definitive diagnosis can be obtained (via nerve biopsy) and aggressive immunotherapy initiated to attempt to improve neurologic outcome.[67]

CENTRAL NERVOUS SYSTEM DISORDERS

Historically, neuraxial anesthesia techniques have not been offered to patients with preexisting neurologic disorders of the central nervous system (eg, multiple sclerosis, postpolio syndrome, amyotrophic lateral sclerosis) for fear of worsening neurologic outcome.[69–72] In fact, many historians believe that the recommendation of Dripps and Vandam[70] in 1956 to avoid regional anesthesia in patients with preexisting neurologic disorders has impacted clinical management for nearly half a century. Several theoretical mechanisms have been proposed based upon the double-crush phenomenon, including neurologic injury from needle or catheter-induced trauma, local anesthetic neurotoxicity, and neural ischemia due to local anesthetic additives. However, the avoidance of regional anesthesia within this patient population may also be due to physician and patient biases or potential medicolegal concerns. There are several confounding factors (age, body habitus, surgical trauma, tourniquet times and pressures, positioning, anesthetic technique) that make it difficult to determine the etiology of worsening postoperative neurologic deficits.

A recent review evaluated 139 patients with a history of one or more central nervous system disorders who subsequently underwent a neuraxial anesthetic technique.[71] Preoperative neurologic disorders primarily included postpolio syndrome (PPS), multiple sclerosis (MS), amyotrophic lateral sclerosis (ALS), and chronic spinal cord injury (SCI). In contrast to the findings of Vandam and Dripps several decades ago, the authors identified no new or worsening postoperative neurologic deficits (0.0%; 95% CI, 0.0%–0.3%) within their patient cohort. This was despite the fact that 74% of the patients reported active neurologic symptoms (paresthesias, dysesthesias, hyperreflexia) or sensorimotor deficits during the immediate preoperative period and subsequently received standard doses of local anesthetics. Two smaller reviews in parturients receiving smaller doses of local anesthetic for labor analgesia have reported similar results.[73,74]

Clearly, further investigations with a larger number of patients are needed to make definitive recommendations. However, the current data suggest that the decision to perform neuraxial anesthesia in patients with preexisting central nervous system disorders be based on the risks and benefits for each individual patient. Some authors have postulated that the neurologic risk may be higher in patients who have progressive neurologic deficits compared to those with chronic, stable sensorimotor symptoms that have not changed over the course of several months or years.

Multiple Sclerosis

Multiple sclerosis is an inflammatory autoimmune disorder of the central nervous system with a lifetime risk of 1 in 400, making it the most common debilitating neurologic disease in young adults.[75] It is a chronic, degenerative disease characterized by focal demyelination within the spinal cord and brain. This demyelination results in a fluctuating conduction block that causes a classic "waxing and waning" of symptoms that is characteristic of the disease. Signs and symptoms include sensory or motor deficits, diplopia or vision loss, bowel or bladder dysfunction, and ataxia. The precise etiology is unclear; however, a combination of genetic risk factors and environmental factors likely play a role. Twenty-five percent of MS patients are essentially asymptomatic, and their activities of daily living are unaffected. However, up to 15% of patients may become severely disabled with significant sensorimotor deficits within a short period of time.[76]

Several factors common to surgery can negatively impact the disease process, including hyperpyrexia, emotional stress, and infection.[77] The mechanism of worsening neurologic function in patients with MS is unclear and may occur coincidentally within the postoperative period independent of anesthetic technique. Evidence regarding the risk of regional anesthesia in patients with MS is limited. Despite some evidence for demyelination of the peripheral nerves in MS, peripheral nerve blockade has traditionally been considered safe.[78] However, a recent report of severe brachial plexopathy following an ultrasound-guided interscalene block has raised the concern that a segment of MS patients may have subclinical peripheral neuropathy.[79] Several investigators have demonstrated evidence of axonal demyelinating peripheral lesions (sensory more than motor) in patients with MS.[80–82] Misawa and colleagues[81] demonstrated that peripheral demyelination may occur in 5% of MS patients, whereas Pogorzelski and colleagues[80] have reported peripheral demyelination may occur in up to 47% of patients. Similarly, Sarova-Pinhas and colleagues[82] have described nerve conduction abnormalities in up to 14.7% of peripheral nerves within MS patients compared to only 2.4% of nerves within the general population. Despite this evidence, the overall incidence and clinical relevance of this underlying peripheral neuropathy remains undefined in the setting of performing peripheral nerve blockade in patients with MS.

In contrast to peripheral nerve blockade, the potential risk of new or progressive neurologic deficits in MS patients after spinal anesthesia was first described in 1937. Critchley and colleagues[83] described three patients with [disseminated (multiple) sclerosis] who experienced a worsening of symptoms after spinal anesthesia. The authors concluded that [spinal anesthesia may be a precipitating agent in the evolution of disseminated (multiple) sclerosis.] Several subsequent studies demonstrated similar outcomes with the development of new or worsening neurologic deficits or a higher likelihood of symptom exacerbation after spinal anesthesia.[69,84–86] In contrast, a more recent study demonstrated no new or worsening neurologic symptoms after spinal anesthesia in 35 MS patients undergoing a variety of surgical procedures.[71]

The safety of epidural anesthesia and analgesia in MS patients has been focused almost exclusively within the obstetric population, which may not accurately represent the nonpregnant MS patient. Pregnancy is frequently associated with a decrease in disease relapse, whereas the postpartum period is often associated with an increased risk of relapse. The transition from cellular immunity to humoral immunity required for the mother's immune system to tolerate the fetus is thought to be protective during pregnancy.[73] However, as cell-mediated immunity rebounds during the postpartum period, patients will often experience a transient worsening of neurologic symptoms that could be falsely attributed to recent regional anesthetic techniques.

Confavreux and colleagues[73] have performed one of the few prospective studies evaluating risk factors associated with disease relapse during the postpartum period. They concluded that epidural analgesia during labor and delivery did not contribute to a higher risk of relapse compared to patients who did not receive neuraxial techniques. Similarly, Kuczkowski[87] found no association between any form of obstetric regional analgesia and the worsening of MS symptoms among obstetric patients. Epidural anesthesia and analgesia have traditionally been recommended over spinal anesthesia in MS patients because the concentration of local anesthetic in the white matter of the spinal cord is one-fourth the level after epidural injection compared to intrathecal injection.[88] It is believed that the lack of myelin may leave the spinal cord susceptible to the neurotoxic effects of local anesthetics.[88] Although definitive studies on the pharmacological effects of local anesthetic concentrations and doses are lacking, many recommend limiting neuraxial local anesthetic doses and concentrations to the lowest level possible. There is some evidence that lidocaine can reversibly worsen symptoms of MS by blocking sodium channels in demyelinated areas enough to cause symptoms compared to healthy myelinated areas that remain unaffected.[89] With regard to the obstetric patient, the risk of neuraxial anesthesia or analgesia needs to be weighed against the increased risk of general anesthesia. A recent survey from the United Kingdom demonstrated that 90% of obstetric anesthesiologists would perform spinal anesthesia for an emergency cesarean section in an MS patient after carefully weighing the potential risks and benefits.[90]

In summary, there remains little conclusive evidence to support or refute the use of regional anesthesia in patients with MS. Peripheral nerve blockade has not been definitively shown to be harmful in the setting of MS, and therefore MS should not be considered an absolute contraindication to this regional technique. In contrast, given that demyelinated fibers may be more prone to the toxic effects of local anesthetics, epidural anesthesia and analgesia may be considered safer than spinal techniques. However, reducing the local anesthetic concentration and total dose to the lowest effective levels may be prudent for both peripheral and neuraxial blockade. All decisions regarding the use of regional anesthesia and analgesia in patients with MS need to be made after careful consideration of the potential risks and benefits. Regardless of the anesthetic technique chosen, patients should be informed of the risk of new or worsening neurologic symptoms during the postoperative period because of exposure to multiple exacerbating factors.

Postpolio Syndrome

Postpolio syndrome refers to new-onset neurologic symptoms that develop several years after an acute poliomyelitis infection. The onset of new or progressive symptoms may occur up to 30 years after the initial episode of poliomyelitis. PPS affects anterior horn cells within the anterior portion of the spinal cord and is therefore considered a lower motor neuron disorder.[91] Initial symptoms include muscle weakness, fatigue, gait instability, joint pain, and muscle atrophy within muscle groups that were previously affected by the disease. Sensory deficits are generally not characteristic of the syndrome and are only observed if a secondary disorder is present (eg, compressive radiculopathy or disk herniation). The motor effects of PPS are thought to be related to an ongoing process of denervation and reinnervation that ultimately ends when denervation is no longer compensated for by reinnervation.[91]

Postpolio syndrome is the most prevalent motor neuron disease in North America. Furthermore, because acute poliomyelitis continues to occur in developing countries, PPS will likely remain an anesthetic concern for years to come.[22] It is not uncommon for patients with PPS to require orthopedic procedures; therefore, it is important to determine the safety of regional anesthetic techniques under these clinical circumstances. Although patients with PPS have fewer motor neurons than normal, it is difficult to know whether the remaining motor neurons are more susceptible to the toxic effects of local anesthetics. There have been no reports of worsening neurologic status following neuraxial anesthesia with normal doses of tetracaine and bupivacaine in patients with PPS.[92,93] However, this finding does not imply that regional anesthetic techniques are without risk.[94] As with all patients, the potential risk of regional anesthesia must be balanced against the disadvantages of general anesthesia, including a hypersensitivity to sedative or opioid medications, the risk of muscle relaxant use, and the risk of hypoventilation and aspiration. The largest series of patients with PPS (n = 79) undergoing neuraxial anesthesia or analgesia demonstrated no worsening of neurologic symptoms during the postoperative period.[71] However, the paucity of clinical data on this topic prevents clear recommendations from being made regarding the safety of neuraxial anesthesia or peripheral nerve blockade in patients with PPS. Ultimately, the decision to use regional anesthesia should be made on an individual basis after a thorough discussion of the potential risks and benefits with each patient. Given the increased sensitivity to opioid and sedative medications within this patient subgroup, these medications should always be used with caution.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis is a progressive degenerative disease of upper and lower motor neurons. The cause is unknown, but theories include glutamate excitotoxicity, oxidative stress, mitochondrial dysfunction, paraneoplastic tumors, autoimmune disease, and viral infection.[92] Initially, ALS presents as atrophy, weakness, and fasciculations in the intrinsic hand muscles. As it progresses, atrophy and weakness develop in all skeletal muscles including those of the tongue, pharynx, larynx, and respiratory muscles of the chest. Patients lose the ability to cough, increasing the risk of aspiration. Autonomic dysfunction may be evident and is manifested by orthostatic hypotension and an increased resting heart rate. Unfortunately, in the majority of patients, death from respiratory failure occurs within a few years of disease onset.[95]

The existing evidence, albeit limited, has not supported the fear that neuraxial or peripheral blockade will exacerbate preexisting symptoms in ALS patients.[65,96–100] However, given the potential for worsening respiratory failure following general anesthesia due to the use of muscle relaxants and opioid medications, the ability to avoid airway manipulation may be considered a benefit within this high-risk patient population. Regardless of anesthetic technique, the possibility of postoperative respiratory or neurologic deterioration is quite high in patients with

ALS. Ultimately, the decision to use regional anesthesia should be made on an individual basis after a thorough discussion of the potential risks and benefits with each patient.

Spinal Stenosis and Lumbar Disk Disease

Spinal canal pathology has been proposed as a potential risk factor for neurologic complications following neuraxial blockade. Several mechanisms of injury have been proposed, including an ischemic or compressive effect after the injection of large volumes of local anesthetic into a relatively confined space (ie, epidural anesthesia) and local anesthetic neurotoxicity (ie, spinal anesthesia). Although the precise mechanism(s) of injury remain unclear, there are several isolated case reports and large case series that are believed to support these hypotheses.

Spinal stenosis occurs as age-related changes within the intervertebral disks and facet joints resulting in a narrowing of the spinal canal or neural foramina. Changes include disk degeneration, facet joint hypertrophy, osteophyte formation, and an infolding of the ligamentum flavum. The precise mechanism by which spinal nerve root compression results in signs or symptoms of spinal stenosis is not completely understood.[101] Classic symptoms include back and leg radicular pain that significantly worsens with extension and is alleviated with flexion. Preexisting spinal stenosis or compressive lumbar disk disease has been proposed as a potential risk factor for neurologic complications following a neuraxial (spinal or epidural) technique. Proposed mechanisms of injury include mechanical trauma,[102,103] local anesthetic neurotoxicity,[104,105] ischemia,[106–108] or a multifactorial etiology.[109,110] Pathophysiologically, patients with spinal stenosis have a reduction in the diameter of the spinal canal resulting in less anatomic space for fluid collections such as blood or local anesthetic. As a result, small quantities of fluid may result in significant increases in pressure around the neuraxis that would have no clinical effect in a widely patent spinal canal.

Two relatively large case series and several case reports have been published that suggest undiagnosed spinal stenosis may be a risk factor for neurologic complications following neuraxial blockade.[102,104,106,109,111] The majority of cauda equina cases involved epidural analgesia, which may suggest an ischemic etiology (mechanical compression of the cord by the infusing local anesthetic) to the injury.[110] Hebl and colleagues[109] performed a retrospective review of 937 patients with preexisting spinal stenosis or lumbar disk disease with and without a history of prior spinal surgery and concluded that this cohort of patients were at an increased risk for the development or worsening of neurologic deficits when compared to the general population undergoing a neuraxial technique. In addition, patients with more than one neurologic diagnosis (eg, spinal stenosis, compressive radiculopathy, preexisting peripheral neuropathy) appeared to have an even higher risk of injury. Similarly, Moen and colleagues[104] performed a large epidemiologic survey in Sweden that revealed similar trends. During a 10-year study period, 1,260,000 spinal anesthetics and 450,000 epidural blocks were evaluated. Overall, the authors identified 127 serious complications, including 85 (67%) patients with permanent injuries. Although 14 patients had preexisting spinal stenosis, 13 (93%) of these were diagnosed in the postoperative period during the evaluation of the neurologic deficit. The authors concluded that the incidence of severe anesthesia-related complications may not be as low as previously reported and that preexisting spinal canal pathology may be a "neglected risk factor." Finally, although patients with prior spine surgery may have an increased risk of paraplegia following transforaminal epidural steroid injections,[112,113] no similar risk has been found in patients after neuraxial anesthesia or analgesia.

In summary, although it appears that patients with spinal stenosis or compressive lumbar disk disease may be at increased risk of neurologic complications following neuraxial blockade, the existing literature fails to provide a direct comparison of surgical patients with similar spinal pathology undergoing general anesthesia. Therefore, it is unclear whether the higher incidence of neurologic complications in this patient population is due to surgical factors, anesthetic technique, the natural progression of disease process, or a combination of these factors.

Spinal Cord Injury

Spinal cord injury affects over 10,000 Americans each year.[114] Of these, approximately 50% of injuries occur at the cervical level.[114] Most SCI cases are secondary to motor vehicle accidents, with a smaller percentage resulting from sports injuries, falls, or penetrating trauma. The ratio of complete to incomplete neurologic deficits in the United States appears to be decreasing over the past decade, reflecting a greater proportion of incomplete deficits.[114] A potentially dangerous condition that may develop in the month(s) after the resolution of acute spinal shock is autonomic dysreflexia (AD). AD is a life-threatening syndrome resulting from cutaneous or visceral stimulation below the level of the spinal cord injury, leading to extreme vascular instability. The lifetime prevalence of AD has been estimated to range from 17% to 70%, with most episodes occurring in SCI cases if the level of injury is at or above T6.[115]

General anesthesia with low-concentration volatile anesthetic does not offer protection against AD. Although higher concentrations of volatile anesthetic may be effective, anesthesia-related hemodynamic instability may not be well tolerated within this patient population. Therefore, neuraxial (spinal or epidural) regional anesthesia techniques can be valuable adjuncts in the management of patients with chronic SCI undergoing lower extremity, abdominal, obstetric, gynecologic, and urologic procedures. Numerous case reports and case series have demonstrated that neuraxial techniques are safe and effective in preventing episodes of AD in SCI patients, even those with high cord lesions.[87,116–118] At this point, there is no clear evidence to suggest that use of regional techniques may potentially worsen preexisting neurologic deficits in patients with SCI. However, difficulty in determining appropriate anesthetic level, the potential for hemodynamic instability and respiratory difficulty, and challenging block placement are important considerations when evaluating patients with SCI for a neuraxial technique.

SUMMARY

Patients with preexisting neurologic disease present a unique challenge to the anesthesiologist who is contemplating a regional anesthetic technique. A thorough preoperative assessment is vital in order to establish the patient's baseline neurologic status. Anesthesia providers should be aware of the risk factors for postoperative neurologic complications during their selection of suitable candidates for a central or peripheral block and adapt their technique to minimize these risks as much as possible. While most preexisting neurologic disorders are not absolute contraindications to regional anesthesia, the decision to proceed with a regional technique should be made on an individual, case-by-case basis as select patients may benefit from a regional anesthetic technique compared to other anesthetic or analgesic options.

CHAPTER 50

Acute Compartment Syndrome of the Limb: Implications for Regional Anesthesia

Xavier Sala-Blanch, Jose A de Andrés, and Steven Dewaele

INTRODUCTION

Compartment syndrome is an orthopedic emergency. It is an acute condition of the limbs in which the pressure of isolated or groups of poorly compliant muscle compartments increases dramatically and limits local soft tissue perfusion to the point of motor and sensory impairment and neuronal and tissue ischemic necrosis. Although regional anesthesia is often thought to delay diagnosis and treatment of acute compartment syndrome (ACS), there are only isolated case reports and a lack of evidence-based information to guide the clinical practice. Regardless, practitioners should be aware of the patient risk factors, clinical presentation, and management of this potentially limb-threatening condition. The musculoskeletal structures of the limbs are enclosed within compartments created by investing fascial layers with a limited ability to stretch. These compartments enclose skeletal muscles along with the neurovascular structures that pass through the compartments. If missed, compartment syndrome[1] can be a limb- and life-threatening condition.

Compartment syndrome is most common in the lower leg and forearm, although it can also occur in the hand, foot, thigh, and upper arm. In theory, the upper leg muscles are at a lower risk for injury than are the smaller muscles of the lower leg, because the muscles of the thigh can dissipate the large forces of direct trauma, causing less muscle injury and resultant edema.[2] Acute compartment syndrome occurs more commonly in one of the four smaller compartments of the lower leg.

The consequences of persistently elevated intracompartmental pressures were first described by Richard von Volkmann,[3] who documented nerve injury and late muscle contracture from compartment syndrome after supracondylar fracture of the distal humerus. Jepson[4] described ischemic contractures in dog hind legs, resulting from limb hypertension after experimentally induced venous obstruction. Only after about 40 years (since the 1970s) has the importance of measuring compartmental pressures become apparent.

Etiology

Any condition that can reduce the volume of the compartment or increase the size of the contents of the compartment can lead to an acute compartment syndrome. Examples of factors leading to these changes are presented in Table 50–1.

Pathophysiology

Compartment syndrome is essentially soft tissue ischemia, generally associated with trauma, fracture with subsequent casting, prolonged malpositioning during surgery, or reperfusion injury. However, the entire mechanism of compartment syndrome is unclear. Because various osseofascial compartments have a relatively fixed volume, introduction of excess fluid or external constriction increases pressure within the compartment and decreases tissue perfusion (Figure 50–1). As the compartmental pressure increases, the tissue hypoperfusion results in tissue hypoxia impeding cellular metabolism. If prolonged, permanent myoneural tissue damage occurs.[5–7] Under physiologic circumstances, the venous pressure exceeds that of the interstitial tissue pressure, sustaining venous outflow.[5] However, as tissue pressure increases, extrinsic venous luminal pressure is exceeded, resulting in vein collapse. The pressure at which this occurs is not known; however, it is generally agreed that compartmental pressures greater than 30 mm Hg require emergent intervention because ischemia is imminent.

Hypoxic injury causes cells to release free radicals, which increases endothelial permeability. This, in turn, leads to a vicious cycle of continued fluid loss, further increasing tissue pressure and injury. Diminished blood flow to local nerves first

PART 7

TABLE 50–1. Factors leading to compartment syndrome.

Conditions that Increase the Compartment Volume
• Direct soft tissue trauma with or without long bone fracture (10%–20% incidence after closed fracture)
• Closed tibial shaft fractures (40%) and closed forearm fractures (12%)
• Soft tissue crush injuries without fractures in 23% of cases of compartment syndrome[5,6]
• Open fractures, which should theoretically decompress the adjacent compartments, may lead to compartment syndrome[7]
• Hemorrhage: Vascular injury, coagulopathy
• Anticoagulation therapy[8]
• Revascularization of limb after ischemia
• High-energy trauma, as from high-speed motor vehicle accident or crush injury
• Increased capillary permeability after burns (especially circumferential)
• Infusions or high-pressure injections (eg, regional blocks, paint guns)
• Extravasations of arthroscopic fluid (eg, after routine knee arthroscopy[9])
• Reperfusion after prolonged periods of ischemia
• Anabolic steroid use, resulting in muscle hypertrophy[10]
• Decreased serum osmolarity (eg, nephritic syndrome[11])
• Strenuous exercise, especially in previously sedentary people
Conditions that Lead to a Reduction in Volume of Tissue Compartments
• Tight circumferential dressings (eg, can occur with cotton cast padding alone)
• Closure of fascial defects[12]
• Cast or splint, especially if placed before removal of surgical tourniquet
• Prolonged limb compression, as in Trendelenburg and lateral decubitus positions[6,13] or in patients obtunded from alcohol or drug abuse
• Excessive traction to fractured limbs[14]

manifests as sensory changes. Paresthesias develop within 30 minutes of onset of ischemia. Irreversible nerve damage begins after 12–24 hours of total ischemia.[5] Irreversible changes in the muscles begin after only 4–8 hours, leading to muscle fiber death and late myocontracture.[8]

DIAGNOSIS OF COMPARTMENT SYNDROME

Compartment syndrome is often a diagnosis based primarily on variation in the patient's clinical signs and symptoms in sequential examinations. Pain out of proportion to the injury, especially with passive stretch of the muscles in the suspicious compartment or limb, is one of the most significant indicators. A palpably tense extremity compared with the uninjured limb

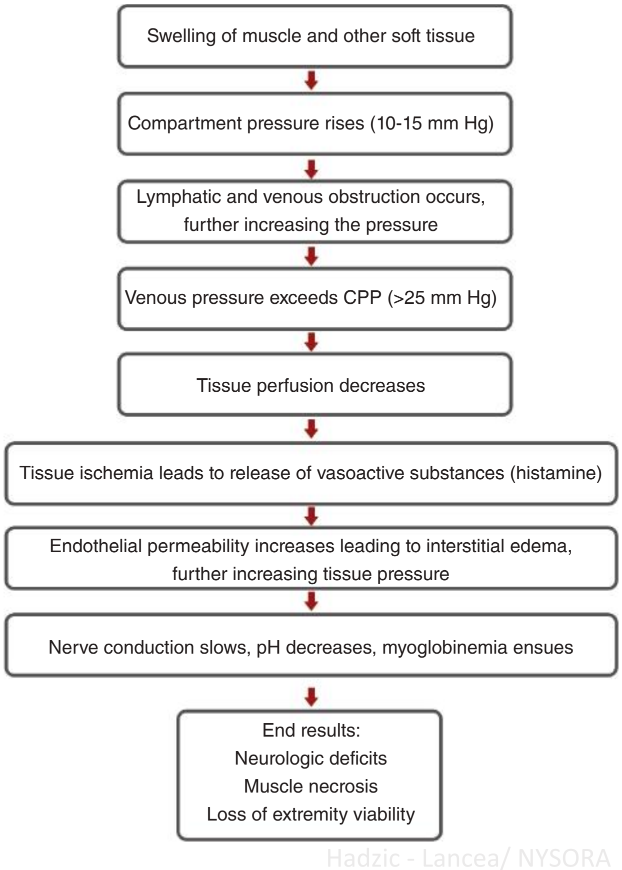

FIGURE 50–1. Pathophysiology of acute compartment syndrome. CPP, capillary perfusion pressure.

is also an important finding. However, none of these warning signs has proven to be reliable.[9] The other classic Ps of pallor, pulselessness, and paresis have very poor predictive value. In fact, pallor and pulselessness are rarely present in compartment syndrome, and by the time paresis manifests, the damage is largely irreversible. On the other hand, breakthrough pain in a patient with a previously well-functioning continuous block may be an early warning sign of ACS.

Clinical Pearl

- Pain out of proportion to the injury is an important symptom.

In general, establishment of the diagnosis based on clinical judgment alone can be difficult.[10–12] Instead, diagnosis should be supported by objective measurement of compartmental pressures with a needle and arterial line transducer or other pressure-measuring device(s). Assuming that the correct compartment is identified, measurement of interstitial tissue pressures remains the only objective reference method for the diagnosis of ACS and is particularly useful in the unresponsive, obtunded, or anesthetized patient (Figures 50–2 and 50–3). An absolute value above 30 mm Hg in the normotensive patient is consistent with compartment syndrome. This value is

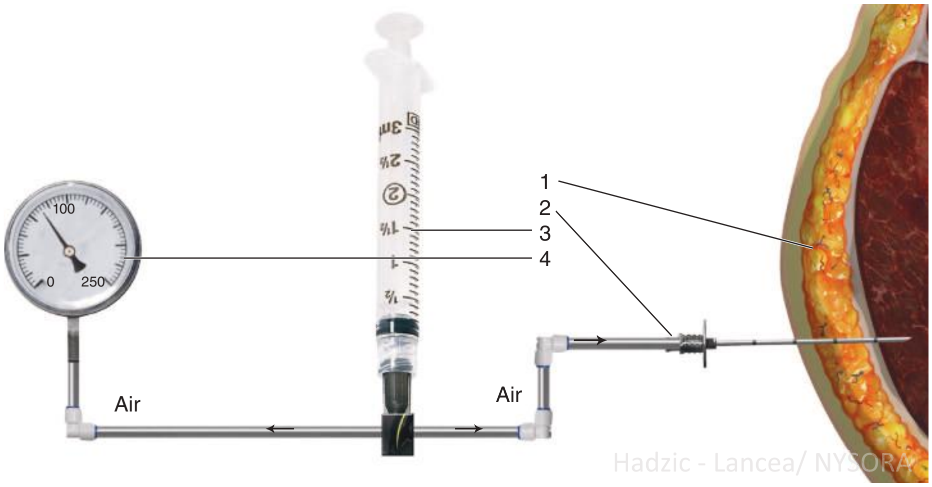

FIGURE 50–2. Intramuscular pressure measurement by the Whiteside technique. (1) Intramuscular needle, 18 gauge. (2) Perfusion line. (3) 20-mL syringe. (4) Mercury manometer.

diminished in the hypotensive patient as the lower arterial pressure renders the limbs even more susceptible to ischemic injury. Near-infrared spectroscopy is another noninvasive method suggested for monitoring the oxygen saturation of hemoglobin and myoglobulin in the tissue at risk (Figure 50–4).[13] More recently, intramuscular pH monitoring has been introduced as an additional diagnostic tool in order to accurately identify ACS.[14]

The Upper Limb

There are several compartments of the upper extremity that, when injured, may result in compartment syndrome requiring fasciotomy in the arm, forearm, or hand.

The arm has two compartments: anterior and posterior (Figure 50–5).

The forearm has three compartments: the volar and dorsal compartments and the compartment containing the muscles of the mobile wad. Mubarak et al.[15] have demonstrated that these compartments are interconnected, unlike the compartments of the leg (Figures 50–6 and 50–7). Consequently, decompression of the volar compartment alone may decrease the pressure in the other two compartments. Regardless, dorsal compartment fasciotomy should still be performed if the dorsal compartment remains tight after volar decompression.[16] The muscles of the volar compartment of the forearm include the digital and wrist flexors and the forearm pronators. These muscles are tested by passive extension of the digits and wrist and by supination of the forearm.

The dorsal forearm compartment contains the thumb and finger metacarpophalangeal joint extensors, the ulnar wrist extensors, and the forearm supinators and is tested by passive finger, thumb, and wrist flexion and by forearm pronation. The mobile wad includes the brachioradialis and the two radial wrist extensors and is tested by passive wrist flexion.

There are 10 compartments in the hand, the most prominent being the dorsal and palmar interosseous compartments, of which there are four and three, respectively (Figure 50–8). The other compartments are the hypothenar, thenar, and adductor. The compartment containing the adductor muscle of the thumb is often overlooked when doing fasciotomies. Studies using Renografin dye have shown no connection between the dorsal interossei and the other compartments, showing that each compartment must be decompressed separately.

The finger is enclosed in a tight investing fascia and is compartmentalized by the fascia and the volar skin at the flexor crease. Although no muscle bellies are distal from the metacarpophalangeal joints, ischemia and engorgement can lead to tissue loss (Figure 50–9).

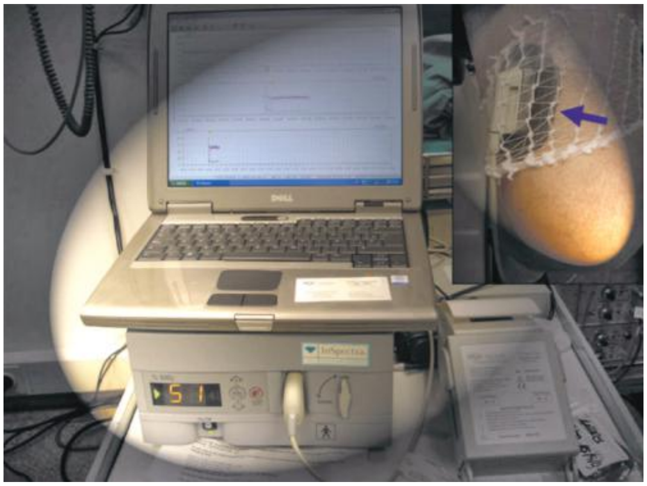

FIGURE 50–3. Near-infrared spectroscopy is a noninvasive method for monitoring the oxygen saturation of hemoglobin and myoglobulin.

The Lower Limb

Thigh

The thigh muscles are divided into three compartments invested by thick fascia: the anterior, medial, and posterior (Figures 50–10 and 50–11). Because thigh compartment syndrome is uncommon, it may go unrecognized. A history of anticoagulant use is common in patients with thigh

FIGURE 50–4. Intracompartmental pressure monitoring device with digital display.

compartment syndrome. Signs and symptoms include a history of thigh swelling and/or hematoma and pain after a minor injury in a patient who is anticoagulated.[17,18] Although rare, the thigh syndrome can also occur in patients after joint replacement surgery. The combination of minor trauma and anticoagulation produces bleeding into muscle and tissue spaces, leading to increased compartment pressure. Pain ranges from mild to severe and may be elicited only when the hip and knee are flexed and extended. Other findings of vascular occlusion—loss of pulse, pallor, paresthesias, and paralysis—are frequently absent.

Lower Leg

The lower leg contains four compartments, each invested by inelastic fascia (Figures 50–12 and 50–13). Each compartment contains a major nerve: the deep peroneal in the anterior compartment, the superficial peroneal in the lateral compartment, the saphenous in the superficial posterior compartment, and the tibial in the deep posterior compartment. Swelling in the lateral or anterior compartment can compress both the deep and superficial peroneal nerves against the neck of the fibula. The superficial peroneal nerve usually lies in the interval between the two peroneal muscles for a short distance and then emerges anterior to the peroneus brevis. It pierces the lateral compartment fascia at the junction of the middle and distal third of the leg. The anatomy of the superficial and deep posterior compartments is somewhat variable, but both compartments, and especially the deep compartment, are frequently involved in compartment syndrome.

Foot

The foot has numerous rigidly bound compartments, and even mild bleeding into these spaces can elevate the pressures dramatically (Figure 50–14). According to Manoli and Weber,[19] there are nine compartments in the foot. Three compartments run the entire length of the foot (medial, lateral, and superficial). Five compartments are contained within the forefoot (adductor and four interossei). The calcaneal compartment is confined to the hind foot but communicates with the posterior compartment of the leg. This compartment contains the quadratus muscle and the lateral plantar neurovascular bundle. The clinically most relevant compartments are the medial, central, lateral, and interossei.[20,21]

A wide spectrum of injuries can result in compartment syndrome of the foot, the most likely ones being crush injuries, especially those associated with multiple metatarsal fractures. Often, the only reliable method of diagnosis is by clinical suspicion and measurement of the intracompartmental pressures. Loss of posterior tibial or dorsalis pedis pulse is notoriously unreliable in the early diagnosis of compartment syndrome. The earliest clinical findings are muscle and nerve ischemia and pain. Although this pain might be confused with the pain of the injury itself, it may be exacerbated by gentle, passive dorsiflexion of the toes, which stretches the intrinsic muscles of the foot. Lack of sensation is generally accepted as an important

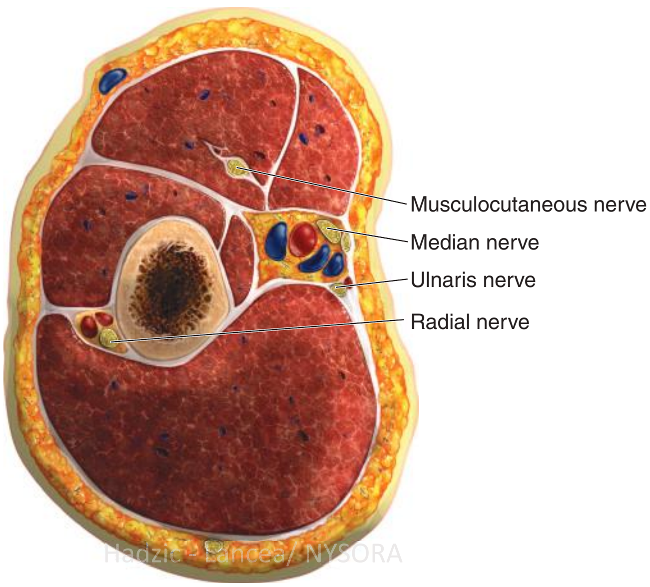

FIGURE 50–5. Tissue compartments of the arm.

sign of nerve ischemia, but it is not reliable when compared with a two-point discrimination and light touch over the plantar aspect of the foot and toes.

Clinical Pearl

- Compartment pressure measurement is the only objective and accurate test to diagnose and monitor compartment syndrome.

Compartment pressure measurement is the only objective and accurate test to diagnose and record compartment syndrome, particularly because changes in compartment pressures can precede the clinical signs of compartment syndrome.

The central compartment can be measured by passing a needle between the metatarsal and abductor hallucis muscle at the base of the first metatarsal. The interossei compartment is measured in two positions by introducing the needle through the intermetatarsal spaces, preferably between the second and forth web spaces to avoid punctures to the dorsalis pedis within the first intermetatarsal region.

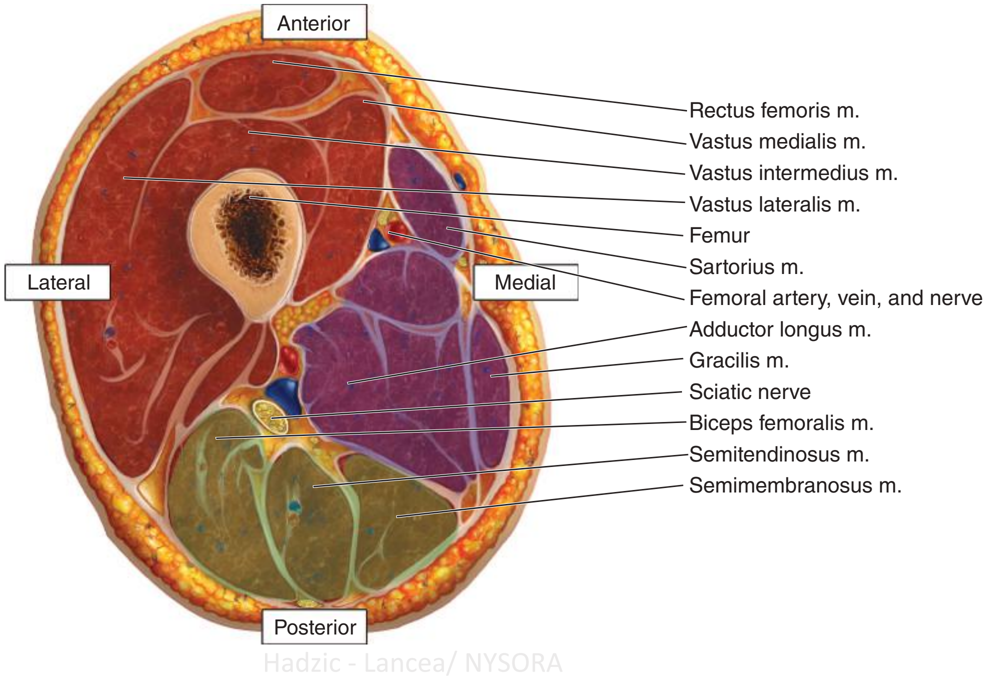

FIGURE 50–11. Compartments of the thigh.

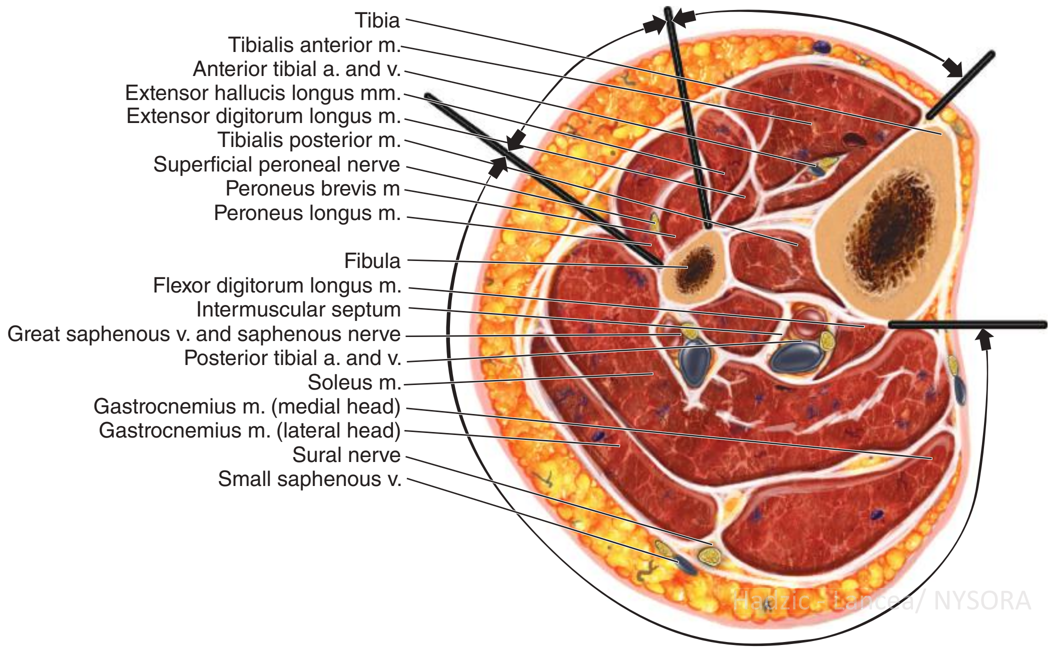

FIGURE 50–12. Contents of the four compartments of the lower leg.

The calcaneal or quadratus compartment is measured by inserting the needle 5 cm distal and 2 cm inferior to the medial malleolus and advancing through the abductor muscle.

Acute Compartment Syndrome and Regional Anesthesia

There is a significant medicolegal aspect of ACS and its outcome in clinical practice; in 50% of all cases and claims related to ACS, data show that decisions are ruled in favor of the plaintiff (the patient). Several case reports and case series suggest that regional anesthesia may have delayed diagnosis of ACS.[22–24] In contrast, there are also a number of cases and reviews suggesting that regional anesthesia may not mask timely diagnosis[25–30] and, in fact, may even facilitate detection of ACS.[31] Consequently, the use of a regional anesthesia technique in the face of risk factors for ACS remains controversial.

In recent literature, "best practice rules" have been suggested to reduce the risk of missing a compartment syndrome in children

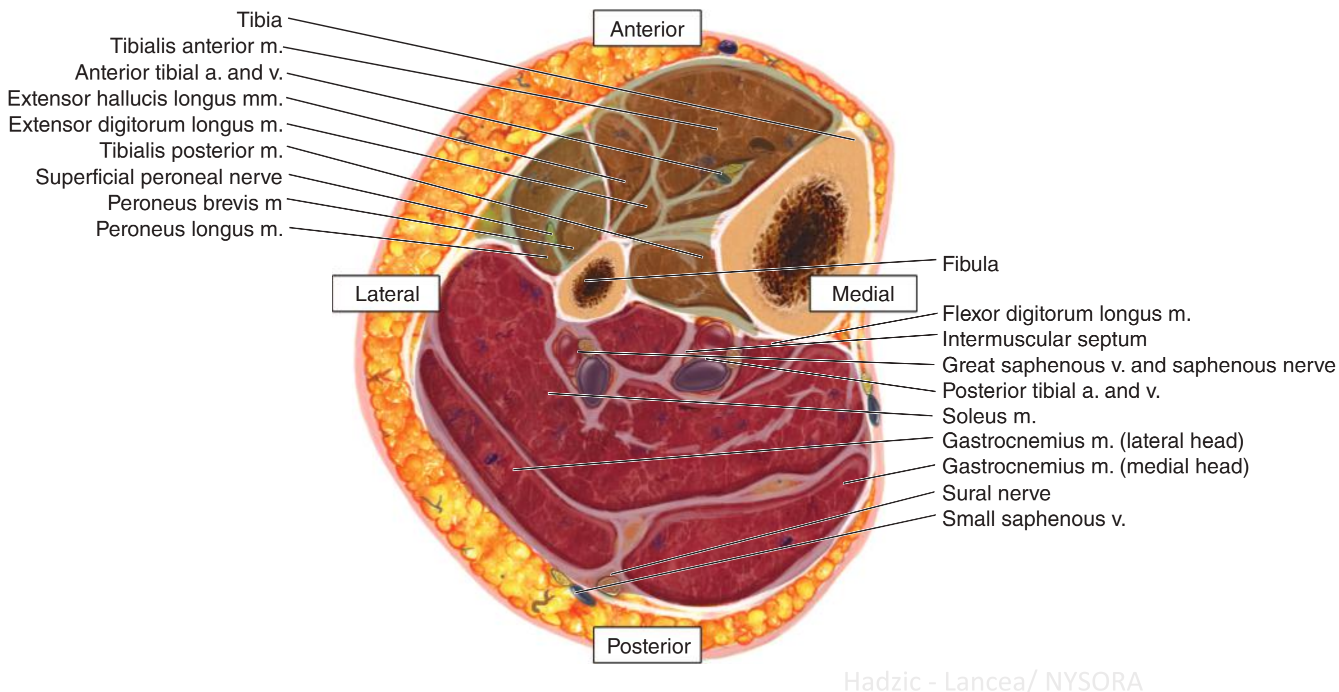

FIGURE 50–13. Lower leg compartments: Spatial distribution.

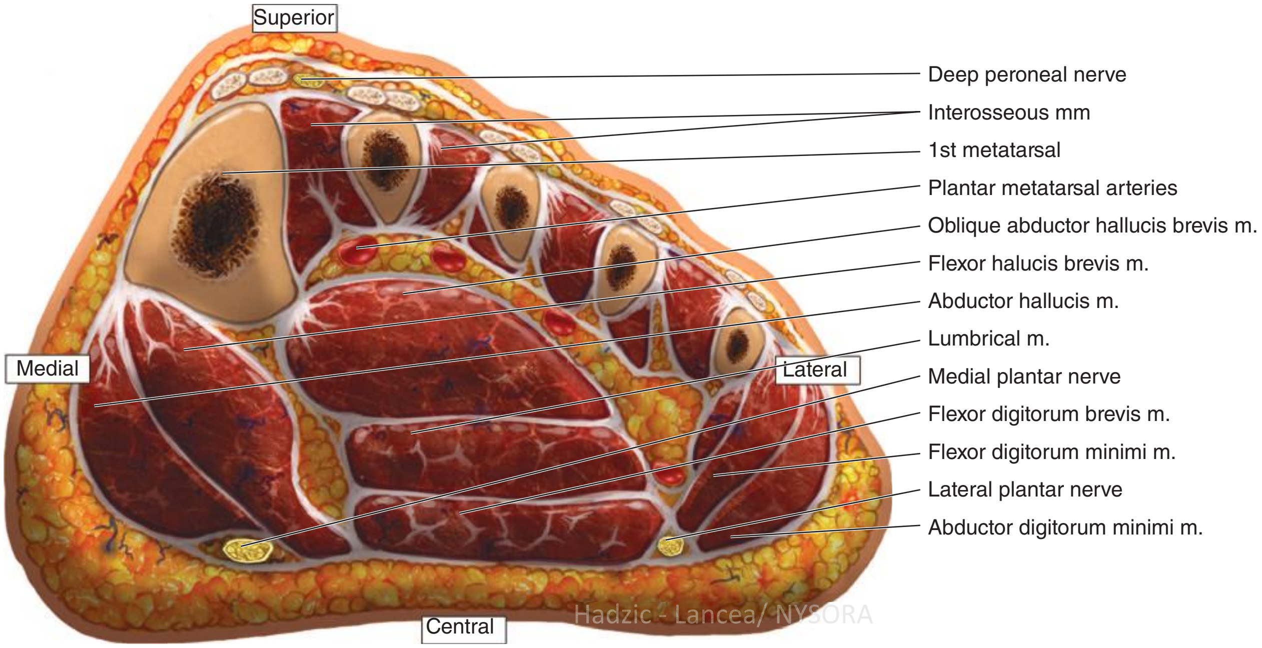

FIGURE 50–14. Coronal section of the foot through the base of the metatarsals depicting the medial, central, lateral, and interosseous compartments.

undergoing surgery with perioperative regional anesthesia; these rules may be also be applicable to adults.[32] It should be noted that although these recommendations appear succinct, they are largely theoretical considerations to help guide the clinical decision making; they have not been put to test in clinical practice.

Clinical Pearls

When regional analgesia is planned to treat intractable pain in patients with risk of compartment syndrome:

- Reduce the concentration of local anesthetics (0.1% to 0.25% bupivacaine, levobupivacaine, or ropivacaine) as lower concentrations are less likely to mask ischemic pain.
- For continuous infusions of bupivacaine, levobupivacaine, or ropivacaine, concentrations should be limited to 0.1%.
- In high-risk surgeries for compartment syndrome (eg, tibial compartment surgery), restricting both volume and concentration is advisable.
- Patients should have careful follow-up by acute pain services to allow for early detection of potential signs and symptoms (h).
- If ACS is clinically suspected, compartment pressure measurement without delay is mandatory.

TREATMENT OF COMPARTMENT SYNDROME

Emergency fasciotomy remains the definitive treatment for a diagnosis of compartment syndrome because of its well-documented, limb-saving results. It is universally accepted as being the best chance for complete recovery and for prevention of further tissue necrosis. Treatment is based primarily on the clinical picture together with corroborative compartmental pressure measurements (Figure 50–15). The surgeon should proceed emergently with a decompression fasciotomy when clinically indicated because the exact pressure at which fasciotomy should be performed remains controversial. Most studies have shown that fasciotomy is indicated when the compartment pressure reaches 30 mm Hg.[21,33–35] Fasciotomy is also recommended when the compartmental pressure is within 30 mm Hg of the patient's diastolic pressure.[34]

After a complete fasciotomy, there is rarely a need for additional releases. The fasciotomy incisions are always left open with wound closure delayed for a minimum of 5 days. The patient is followed up clinically unless anesthetized or obtunded, in which case regular compartment pressure measurements should be made.

Clinical Pearls

- Emergency fasciotomy remains the definitive treatment for compartment syndrome.
- Its limb-saving results make it universally accepted as the best chance for complete recovery and for prevention of further tissue necrosis.
- Fasciotomy is indicated when compartment pressure reaches 30 mm Hg.
- After a complete fasciotomy is performed, additional release is rarely needed.

SUMMARY

Prolonged surgery, especially in patients undergoing procedures in the Trendelenburg or lateral decubitus positions, poses a risk of compartment syndrome. The Trendelenburg position requires

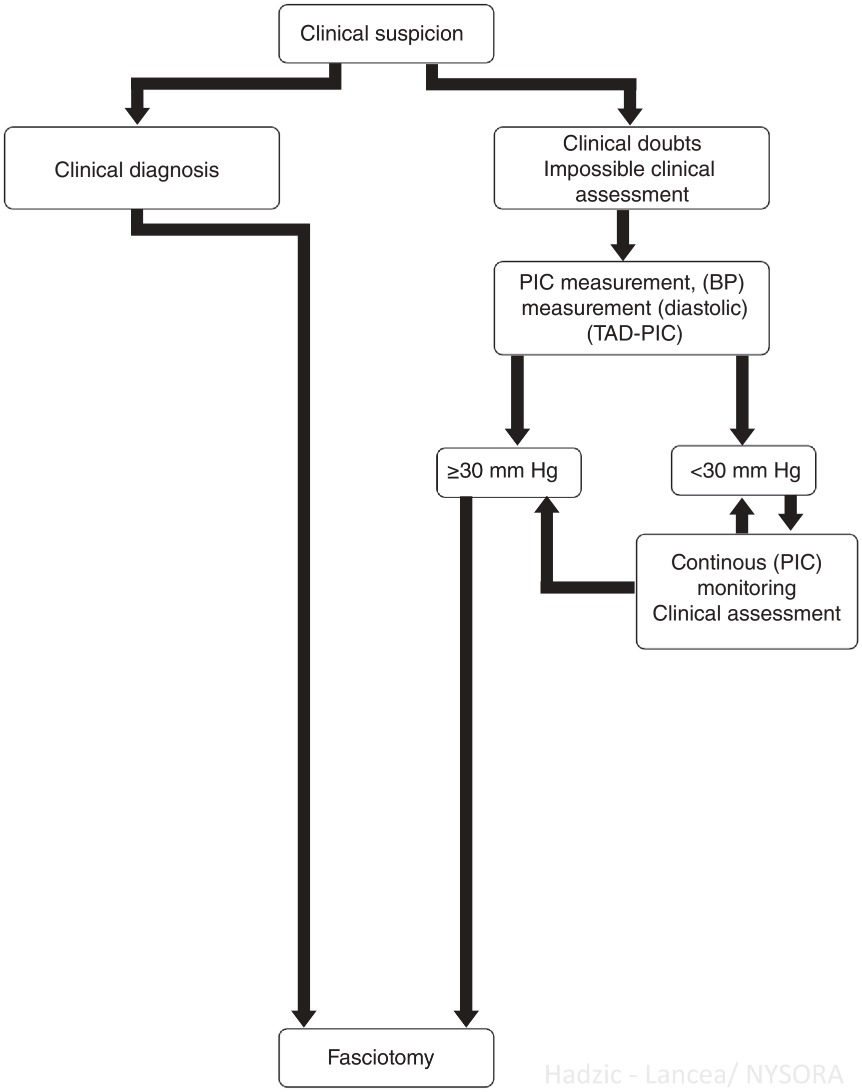

FIGURE 50–15. Diagnosis and management of compartment syndrome. BP, blood pressure; PIC, pressure within the compartment; TAD-PIC, diastolic blood pressure.

that the legs are strapped at a higher level than the heart. This can be avoided by repositioning and redraping the legs, or, if this is not possible, the head-down tilt position should be reversed every 2 hours so that reperfusion of the lower limbs can occur. In the lateral decubitus position, the down arm and the down leg must be well padded to avoid excessive compression.

On recent analysis of risk factors, age appeared to be a strong predictor of developing ACS ($P < 0.001$), with the highest prevalence between 12–19 years and 20–29 years. Occupation and implant type were the only other factors that remained significant after adjusting for age.[36]

Patients on anticoagulation medication tend to have a high risk of thigh compartment syndrome, even with relatively minor trauma or surgical interventions. This clinical scenario must be approached with a high index of suspicion.

In conclusion, the use of regional anesthesia in patients with risk of compartment syndrome is controversial. Therefore, regional blocks should be performed in consultation with the patient and with the surgical team. When deemed beneficial to patient care, regional anesthesia can be used when indicated to alleviate severe pain; however, astute management, compartment tissue monitoring, and perhaps lower concentrations and volumes of local anesthetics should be considered.

CHAPTER 51

Peripheral Nerve Blocks for Outpatient Surgery

Christina M. Spofford, Peter Foldes, and John Laur

INTRODUCTION

An increasing number of patients are undergoing surgical procedures in hospital outpatient departments (HOPDs) or ambulatory surgery centers (ASCs).[1] Outpatient surgical procedures have become more complex, and patients are presenting for surgery with a greater number of comorbid conditions than in the past.[2] Regional anesthesia (RA) and peripheral nerve blocks (PNBs) can help meet the goals of caring for these patients in the outpatient setting.

In 1976, there were 67 Medicare-certified ASCs in the United States, and in 2011, there were 5,344.[3] In 1982, 30 ambulatory surgical procedures were covered by Medicare; today there are hundreds.[4] In an analysis of National Survey of Ambulatory Surgery (NSAS) data, Tighe et al. found that 15% of an estimated 4 million orthopedic outpatient cases implemented a "regional block" as part of the anesthetic used.[6,7] Over 580,000 PNBs were performed in HOPDs or ASCs in 2006.[5]

From 2006 to 2010, outpatient services per Medicare enrollee increased by 5.7% annually. In 2011, the rate increased by 1.9%, accounting for $3.4 billion in charges, a 2.2% increase from 2010.[3,4] Currently, about 57 million outpatient procedures (surgical and nonsurgical) are performed in the United States at a cost of $3.2 billion.[4,8] In 2014, over 3 million of these cases are estimated to be orthopedic procedures.[5] At some institutions, including the authors', most PNBs are performed for orthopedic cases.[9] Based on NSAS data from 1996 through 2006, arthroscopic knee procedures in the U.S. increased by 49%.[10] As minimally invasive surgery becomes available for surgeries that require an inpatient stay due to the severity of postoperative pain, RA can allow for safe same-day discharge.[11] A study by Koenig and Gu indicated that the growth of ASCs may reduce Medicare spending due to lower reimbursements relative to number of hospitals.[12] There is preliminary evidence that outcomes at ASCs are better than those at in-hospital settings for similar otolaryngologic surgical cases.[13] Future research in this area needs to be completed for other services.

With the growth in both complex outpatient surgeries and ASCs, there is a need for more anesthesiologists with specific training in the use of acute pain medicine with integrated RA and PNB techniques. With the use of these techniques, the first priority should be on safety, the second on reducing patient pain and minimizing opioid and general anesthesia (GA) side effects, the third on economics, and the fourth on efficiency.[14,15]

Outpatient Surgery Stakeholders

Patients, providers, payers, and "internal customers," including anesthesiologists, nurses, and support staff,[16] may have differing views on the value on the various outpatient operational and clinical outcomes. In healthcare, value is defined as patient outcome per costs used to achieve those outcomes.[17,18] For payers, value consists of providing a service with good outcome at a lower cost than competitors.[4,5,16] Typically, a standalone outpatient surgery center can provide patient care with greater patient convenience and lower overhead costs than a hospital outpatient surgery department.[1] Busy surgeons focus on ASC efficiency[19] and understand the value of RA and PNBs, but they may object to additional procedures that could delay surgery.[20] The available data, however, point out that greater than half of surgery-start delays are caused by the surgeon rather than nerve block placement.[21] Factors that contribute to delays include the need for surgical consent, updating the patient's medical history and performing the physical examination, the patient's desire to speak with the surgeon prior to going to the operating room (OR), and the need for additional preoperative testing.[20]

Anesthesiologists work to provide safe high-quality care by applying methods that reduce or prevent adverse events and side-effects. Minimizing or eliminating nausea, vomiting, and pain are important for maintaining patient satisfaction. Secondary goals for anesthesiologists include accurate and fast RA placement and nerve block onset, sufficient duration of analgesia, avoidance of "rebound pain" when the nerve block resolves, post-anesthesia care unit (PACU) bypass, and rapid patient discharge from the facility.[15,18] Avoiding side effects, hence bypassing the PACU, can reduce hospital costs by an estimated 12% while still meeting the goals of the surgeons, anesthesiologists, payers, and patients.[18,20,22]

Patients fear nausea, vomiting, gagging on the endotracheal tube, surgical pain, recall, residual weakness, shivering, sore throat, and somnolence. They wish to experience restful sleep and then return to work and physical function with little pain or motor blockade.[23] Most of these patient-centric goals can be achieved by designing an appropriate anesthesia regimen tailored to the patient and surgical procedure(s). In many cases, the use of RA achieves these goals.

Clinical Pearls

- The anesthesiologist's priorities are (1) safety; (2) reducing patient pain and minimizing opioid and GA side effects; (3) economics; and (4) efficiency.
- Factors that contribute to surgery-start delays include the need for surgical consent, updating the patient's medical history and performing the physical examination, the patient's desire to speak with the surgeon prior to going to the OR, and the need for additional preoperative testing.
- Hospital costs can be reduced by bypassing the PACU while meeting the goals of the surgeon, anesthesiologist, payers, and patient through the avoidance of side effects.
- Most patient-centric goals can be achieved by designing an appropriate anesthesia regimen tailored to the patient and surgical procedure(s).

Defining Outpatient Regional Anesthesia Success

There are multiple, and possibly overlapping, metrics defining outpatient RA success.[18] A single set of outcomes may not please all stakeholders. In randomized, controlled trials (RCTs), success is determined by avoiding the following: conversion to GA, loss of sensation to pin-prick or cold, loss of motor function, and time to first pain medication request.[18] Many RCTs ask about patient satisfaction with RA, and it is important to understand what patients prefer with respect to outcomes after RA.[22] Recently, a validated, multidimensional, self-reported questionnaire was created to assess RA in the outpatient surgery setting.[24] Factors included avoiding RA-related delays and complications, providing anesthesia during the surgical procedure and continuing adequate postoperative analgesia, reducing the costs of drugs and equipment, reducing patient time spent in the healthcare facility, avoiding unplanned hospital admissions, ensuring patient satisfaction, maintaining postoperative function (particularly with a partially or wholly insensate body region), safety at home, and other clinical and economic outcomes.

Motor weakness can be desirable for surgery yet is often undesirable afterward when physical therapy is necessary or patients want to walk or hold an object.[25] While acknowledging that RA is superior to GA in terms of pain control and reduction of postoperative nausea and vomiting, orthopedic surgeons often report avoiding RA due to case-start delays and unpredictable RA success.[26]

Clinical Pearl

- Numerous factors must be taken into account in the outpatient surgery setting, including avoiding RA-related delays and complications, providing anesthesia during the surgical procedure and continuing adequate postoperative analgesia, reducing the costs of drugs and equipment, reducing patient time spent in the healthcare facility, avoiding unplanned hospital admissions, ensuring patient satisfaction, maintaining postoperative function (particularly with a partially or wholly insensate body region), safety at home, and other clinical and economic outcomes.

Peripheral Nerve Blocks and Multimodal Analgesia

Managing postoperative pain with minimal side effects is an important factor in determining if a surgical case can proceed in an outpatient setting. An anesthesiologist has an armamentarium of agents and methods to provide multimodal analgesic therapy. Boezaart and Tighe contend that PNBs are an inherent part of the rapidly developing field of acute pain medicine that they remark should focus on the patient and his or her pain control.[13] In an outpatient setting, RA with PNBs is a cornerstones of multimodal analgesia and opioid-sparing strategies. High-dose opioids can cause hyperalgesia by activating neurons and glial cells.[27] Furthermore, potent opioids, such as remifentanil and fentanyl, can cause hyperalgesia and rapid tolerance in humans.[28] Other undesirable side effects are nausea, somnolence, and respiratory depression, all which are highly undesirable in the outpatient setting.

Well-planned multimodal analgesia is important in the ambulatory surgery setting for several reasons. First, *patients* prefer to avoid side effects such as nausea, vomiting, and somnolence.[22,29] Second, uncontrolled side effects can result in unplanned hospital admission, which is costly and inconvenient for all parties. Third, the use of multimodal analgesia has the potential for real synergistic positive effects while also reducing the likelihood of serious side effects.[2] Lastly, multimodal analgesic regimens improve the likelihood of early recovery.[30] One example is the same-day discharge of patients undergoing unicompartment knee replacement surgery. By utilizing a continuous femoral nerve block and minimizing opioids as part of a multimodal analgesia regimen, these patients can safely undergo surgery in an ASC.[10]

Used in a multimodal analgesic regimen, gabapentinoids, nonsteroidal anti-inflammatory drugs (NSAIDs), acyclooxygenase-1 and -2 (COX-1 and COX-2) inhibitors, glucocorticoids, ketamine, clonidine, and lidocaine infusions can reduce postoperative opioid use by 20%–60%.[31–34] Intravenous lidocaine infusions have demonstrated a preventive analgesic effect lasting from 8.5 to 72 hours, which is greater than 5.5 lidocaine half-lives.[35] Local anesthetics may reduce pain scores and opioid consumption when administered via PNB *or* the intravenous route (using lidocaine), although the evidence for this is sometimes contradictory.[34,36]

Some facilities are performing "fast-track" total hip and knee replacement surgeries in an outpatient setting with 23-hour observation. The American Academy of Orthopaedic Surgeons guidelines on preventing venous thromboembolism recommend neuraxial anesthesia during hip and knee replacement procedures to reduce blood loss.[37] In fact, due to its superior analgesia in joint replacement surgery, RA is the centerpiece of a multimodal analgesia algorithm in such surgeries.[38]

Clinical Pearls

- PNBs have progressed to become a component of the larger field of acute pain medicine that focuses on the patients and their pain control.
- In the outpatient setting, RA with PNBs is the cornerstone of multimodal analgesia.

Nerve Blocks in Outpatients

A wide variety of PNBs can be used in the ambulatory setting, including upper and lower extremity blocks, truncal blocks, and head-and-neck PNBs (Table 51–1). Moreover, neuraxial RA techniques can achieve outpatient anesthesia goals.[39] In an ambulatory setting, surgeon-performed blocks can also be timely, cost effective, and remarkably safe. Done at the time of the procedure, they often include rapidly acting local anesthetics. Some of the most commonly used peripheral nerve blocks are listed in Table 51–2.[40–43]

TABLE 51–1. Peripheral nerve blocks.

Upper Extremity PNBs	Lower Extremity PNBs	Truncal Blocks
Cervical paravertebral	Subgluteal sciatic	Thoracic paravertebral
Interscalene	Femoral	Transverse abdominis plane
Interscalene	Popliteal	Ilioinguinal
Infraclavicular	Saphenous	
Axillary	Ankle	

TABLE 51–2. Commonly used regional anesthesia blocks.

Service	Type of Block
Ophthalmology	Retrobulbar, peribulbar
General surgery	Ilioinguinal
Urology	Penile
Orthopedics	Joint injections, local infiltration
Vascular surgery	Cervical plexus blocks
Gynecology	Paracervical block

Block Latency

One strategy to decrease onset time is to add mepivacaine to the longer-acting local anesthetics that are traditionally used (eg, ropivacaine, bupivacaine), albeit at the cost of shortening the duration of the blockade.[44,45] The best strategy is to have one provider perform the nerve block in the block room and have the other providers remain in the operating room. This procedure prevents delays in turnover, optimizes care by having a dedicated person providing specialized care, and creates a team atmosphere. This model can either be expensive or pay for itself, depending on the system and methods of reimbursement for care.[46] For example, it can be cost prohibitive in practices where there are too few blocks placed in a single day or too few personnel trained in peripheral nerve blockade.[20]

Peripheral Nerve Blocks and Adjuvants

Regional anesthesiologists combine local anesthetics with adjuvant drugs to achieve prolonged analgesia, reduce local anesthetic dose to avoid toxicity, and potentially reduce motor blockade.[34,47,48] Clinical doses of clonidine, buprenorphine, dexamethasone, and midazolam have no neurotoxicity in vitro.[46,49,50] These drugs are thought to act through an indirect mechanism without influencing the potency or duration of the local anesthetic, specifically ropivacaine or lidocaine.[49]

Providing surgical anesthesia and then maintaining the patient's motor strength while achieving postoperative analgesia may be difficult with single local injections. Adjuvants can prolong analgesia duration with single-injection PNBs.[34,51,52] This application reduces the mechanical, logistical, billing, and clinical management hurdles associated with outpatient indwelling PNB catheters and improves patient convenience.[53] While clonidine and dexmedetomidine may prolong analgesic duration in some blocks, these agents may not have the same benefit in other blocks (eg, sciatic) when combined with a long-acting local anesthetic.[54–56] The undesirable side effects of clonidine (and other alpha-2 blockers) include hypotension, bradycardia, orthostatic hypotension, and sedation.[53] Clonidine increases the duration of motor blockade, which may or may not be desirable depending on the type of surgery.[55]

Dexamethasone is an adjuvant that can enhance or prolong the duration of analgesia when injected perineurally *or intravenously*.[57–62] Recent work suggests that perineural adjuvants can control post-surgical pain while sparing motor strength.[15] However, safety data on perineural injections in animals are limited, and human safety data are also lacking.[46] Most PNB adjuvant drugs are used off label in the U.S.

Clinical Pearls

- Clinical doses of clonidine, buprenorphine, dexamethasone, and midazolam have been shown to have no neurotoxicity in vitro.
- Adjuvants may prolong analgesia duration with single-injection PNBs. Dexamethasone enhances and prolongs analgesia injected perineurally *or intravenously*.

Sedation for Ambulatory Peripheral Nerve Blocks

Patients having surgery on an outpatient basis are typically healthier than patients having surgery as inpatients and may have limited or no previous experience with surgery.[63] Many patients undergoing surgical procedures experience preoperative anxiety.[64–66] In an effort to improve the perioperative experience, short-acting anxiolytic agents and/or other medications (eg, midazolam, opioids, ketamine, gabapentinoids) are often given before a PNB is placed.[67,68] Historically, the placement of a PNB using anatomical landmarks has led to multiple attempts at nerve location (ie, seeking a specific motor response to electrical nerve stimulation). Adding nerve stimulation can help confirm proper needle location but may cause considerable discomfort to the patient.[69] Even with ultrasound guidance and the use of local anesthetics to anesthetize the needle pathway, many patients benefit from judicious premedication before undergoing PNB. Heavy premedication, however, may lead to loss of airway tone and subsequent hypoxia and hypercapnia.[70] Premedicating patients judiciously while maintaining a meaningful patient contact may improve the patient's experience and allow for beneficial patient feedback during the procedure. From a cost perspective, premedicated patients require bedside monitoring, and more personnel may be required depending on the physical layout, surgical case workload, and current staffing levels. Furthermore, heavily premedicated patients may take longer to recover and need to remain within the surgical center longer,[71] resulting in patient dissatisfaction. Lastly, from a patient satisfaction perspective, patients may appreciate ongoing dialogue and reassurance as the block is being placed and the opportunity of being an active participant in their care.

In an effort to reduce patient wait times, patients are instructed to arrive close to the time of surgical start based on mathematical principles.[72]

The Block Team and Block Nurse

In academic training centers, residents and fellows can be organized into block teams.[19,20,73] These teams can provide safe and efficient RA while allowing trainees to focus on a single aspect of their education. A multidisciplinary group at Duke University initiated a "block nurse" team in 2010. Block nurses completed a focused training program that emphasized patient flow, educating and preparing patients, assisting anesthesiologists, monitoring patients, and enhancing safety during the pre, intra- and post-procedure periods. Within a year, rapid OR turnover time increased by 26%, OR on-time starts increased by 7%, orthopedic cases receiving preoperative blocks increased by 19%, and patient safety (eg, no wrong-sided blocks) improved.[8] While resources are lean at free-standing ASCs, the block nurse concept could perhaps be incorporated into an existing nursing team, thus potentially improving a facility's processes by increasing the number of patients who can benefit from preoperative PNB, increasing PACU bypass rates, and improving patient satisfaction.

PACU Bypass Criteria

Fast-tracking patients is an important goal of ambulatory anesthesia strategy.[74] In a meta-analysis by Liu et al. of 15 trials including 1003 patients given central neuraxial block (CNB) and 7 trials of 359 patients given PNB, for RA versus GA, induction time was increased 9 minutes.[75] There was a greater PACU bypass with PNB versus CNB, perhaps due to lack of a formal PACU bypass criteria for CNB patients. The odds of bypassing PACU using PNB was 14 times greater compared to GA. Both PNB and CNB patients reported an increased satisfaction level compared to GA patients, though PNB patient satisfaction was much higher than those having CNB. Patients receiving regional anesthesia reported lower pain scores, had less need of analgesics, and experienced less nausea and vomiting.[76] Williams et al. and others who matched interventional technique to surgical pain[15,72] have remarked on the possibility of "rebound pain," that is, pain above baseline that patients experience after a nerve block resolves.[77,78]

Breast surgery on an outpatient basis using thoracic paravertebral blocks is another good example of the benefits of PNBs.[79] A review article by Thavaneswaran et al. has shown that length of stay was reduced for breast surgery when using paravertebral block versus GA alone. Length of hospital stay, postoperative nausea and vomiting, and patient satisfaction were improved over GA (relative risk 0.25; 95% CI 0.13–0.50).[80]

Clinical Pearl

- In the fast-paced outpatient setting, assistance in setting up equipment, preparing and positioning patients, monitoring patients after blockade, and educating patients regarding safety and protection of insensate body regions are important.

Outcomes

Through 2007, most literature reports on RA outcomes were based on neuraxial techniques.[81] Since 2007, more literature has been published focusing on PNBs in outpatient surgery settings.[82]

Improved outcomes from neuraxial use in the outpatient surgery setting include improved short-term and long-term pain control, reduced surgical stress, improved gastrointestinal function, lower rates of postoperative nausea and vomiting, and fewer unplanned admissions or readmissions.[73–75,78] More physiologically significant outcomes include reductions in perioperative myocardial infarction, pulmonary complications, and mortality.[83,84] However, a systematic study of these outcomes in ambulatory patients has not been published, and it is unclear whether outpatient surgical patients would achieve the same benefit.

In an effort to improve care after colorectal surgery, a working group analyzed outcomes from randomized controlled trials published through 2007 for colorectal surgeries and created recommendations for the use of thoracic epidural catheters, avoiding long-acting opioids, reducing the amount of time under GA, and preventing gut paralysis.[85,86] Epidurals provide efficient analgesia, reduce surgical stress responses, and minimize the side effects of systemic opioid administration (pulmonary, gastrointestinal, and cognitive dysfunction). Once RA methods are discontinued, the use of NSAIDs further reduces or avoids the need for opioid administration and their side effects. RA has been demonstrated to improve outcomes such as mortality, major morbidity, and rehabilitation.[87]

Since superior pain control has been shown with the use of RA, focus on functional outcome improvement has become paramount.[88] This requires the ability to measure outcomes accurately. For outpatient RA outcomes, some measures include electromechanical dynamometer, which measures motor contraction; the 36-item Short Form Health Survey (SF-36), which measures physical and mental status before and after surgery; and the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC), which assesses pain and stiffness in the hips and knees. The recently validated Patient Reported Outcome Measurement Information System (PROMIS) is a computerized, adaptive test that provides an excellent method for assessing outcomes in patients who have had foot or ankle surgery.[89]

In recent years, functional outcome studies comparing RA to GA have shown a tendency toward improved early outcomes with RA.[90,91] Patients undergoing stable fixation of distal radius fracture under brachial plexus block demonstrated improved pain scores and better wrist and finger motion at all time points during follow-up compared to GA. Disabilities of the Arm, Shoulder and Hand (DASH) scores also demonstrated higher function at both 3 and 6 months ($P = 0.04$ and $P = 0.02$, respectively).[88]

Spinal anesthesia is used for outpatient lower extremity surgery. Compared to GA, patients undergoing ankle fracture fixation under spinal anesthesia reported improved early pain scores and function as measured by the American Orthopaedic Foot and Ankle Society Clinical Rating Scale at 3 months (mean [SD] 81.7 [11.9] vs 78.1 [15.2], $P = 0.02$).[92] At 6 months, spinal patients had lower pain scores ($P = 0.04$). Functional outcomes for the spinal group were not statistically significant by 6 and 12 months.

Clinical Pearl

- RA has been demonstrated to improve outcomes such as mortality, major morbidity, and rehabilitation.

Complications in the Ambulatory Setting

Complications of regional anesthesia range from minor sensory deficits that resolve within weeks to devastating injuries that result in permanent nerve injury, strokes, and on occasion, death.[93–95] Cardiac dysrhythmias can occur as late as 30–75 minutes after the injection of local anesthetics and may be intractable despite adherence to advanced cardiac life support guidelines.[96] This delayed response highlights the need for continuous monitoring of patients in the block area as well as the operating room. Although uncommon, local anesthetic systemic toxicity (LAST) can be a life-threatening complication for patients. Guidelines on the care of patients with LAST include airway management, prevent hyperventilation (to avoid increase in seizure threshold), and treating a seizure if it occurs, intravenous lipid emulsion therapy, and transfer to a tertiary care setting with cardiopulmonary bypass capability.[97] Ambulatory facilities should consider creating LAST kits with checklists that are housed in the areas where blocks are performed.[95] Fortunately, ultrasound guidance coupled with decreasing doses and volumes of local anesthetics required for successful nerve blockade have resulted in a substantial decrease in the risk of LAST, a trend likely to continue as ultrasound-guided techniques become more refined.[98]

Other complications, such as wrong-sided blocks, can be greatly reduced by adherence to established time-out policies. Block site marking, as well as encouraging patients to engage in dialogue during block placement, can reinforce a culture of safety.[99] Permanent nerve injuries, with subsequent long-term morbidity and/or disability are uncommon.[100] The development of more objective methods of monitoring needle placement and administering local anesthetics, such as ultrasound guidance, low-current nerve stimulation, and opening injection pressure monitoring are likely to even further decrease the risk of intrafascicular injection and neurologic injury.[101–103] When present, however, intrafascicular injections and neurologic injuries require a thorough evaluation, and expert consultation by a neurologist should be considered.

When an RA complication occurs, prompt and well-planned disclosure is warranted. When possible, a quiet, private area is required for patient and family disclosure. Anesthesiologists should have another member of the healthcare team present during the disclosure. The provider should investigate how much is known about the adverse event and how much detail the patient and family require. With empathy, knowledge of the event needs to be conveyed in a manner that is clear and understandable. This often requires planned pauses, repetition of information, reassurance, and open body language. Saying "I'm sorry this event happened to you" does not imply fault; rather, it is a statement of empathy about the adverse event and the subsequent pain, suffering, or other inconvenience that may have been experienced. Lastly, all disclosure discussions need to be documented and patients and/or family need to have a mechanism for further follow-up.[104] Several studies suggest that thoughtful and prompt disclosure of adverse events or complications results in less legal action and possibly less emotional impact on the provider.[105,106]

PART 7

Clinical Pearls

- Guidelines on the care of patients who experience toxic reactions from local anesthetics include airway management, hyperventilation on prevention, seizure control, intravenous lipid emulsion therapy, and consideration of transfer to a tertiary care setting with cardiopulmonary bypass capability.
- Ambulatory facilities should develop LAST kits with checklists that are housed in the area where blocks are performed.
- Thoughtful and prompt disclosure of adverse events or complications may prevent or lessen the legal action and diminish the emotional impact on all parties.

Objective monitoring of the needle–nerve relationship and injection process during PNB, such as via ultrasound guidance, low-current intensity nerve stimulation, and avoidance of high opening injection pressures (> 15 psi), can further decrease the risk of already uncommon neurologic complications.

Peripheral Nerve Blocks and Outpatient Surgery Economics

Patient satisfaction, while perhaps intuitive in some ways, is not easily measured in a scientifically valid manner. In the United States, patient satisfaction and whether patients would recommend their family or friends to have surgery at a facility or institution are correlated with improved operating revenue margins.[14,107] A new patient-centered assessment by Szamburski et al. is the first psychometrically evaluated, internally and externally validated patient satisfaction instrument developed to date.[108] This new measure may prove useful in future work investigating linkages between RA and outcomes or economic indicators.

Physician-owned free-standing ASCs, through a profit motive, may be an incentive for physicians to divert cases from hospital operating rooms to their own centers.[1] ASCs have lower overhead than hospitals but are paid less by Medicare.[1] Physicians may also choose to steer their patients toward ASCs based on nonfinancial factors, such as convenience, enhanced patient experience, ease of scheduling, and the ability to complete more cases per day than in a hospital environment. An analysis of the 1996 and 2006 NSAS data found that a 10% increase in profit (facility fees, not professional fees) was associated with a 1.2%–1.4% increase in the probability that a surgery would be performed at an ASC.[1]

The presence and type of insurance also influence the choice to provide a PNB. When compared with self-pay patients or those receiving charity care, patients with government-paid care or private insurance were roughly 2.5 times more likely to receive a nerve block.[5] However, this association is not necessarily causal, and other confounding factors are likely to be involved. Hospital revenue streams may be reduced as patients are recruited to have surgery at nonhospital ASCs.[5] This may lower societal healthcare costs since ASCs are reimbursed at lower rates and have lower overhead costs than hospitals for a given procedure.[4,5,11]

By implementing RA techniques, facilities can potentially lower costs and enhance efficiency. One report demonstrated that when RA is used in a hospital at a rate higher than the median of its competing hospitals, that hospital can reduce patient length of stay and increase profit per diagnosis-related group (DRG) while also increasing patient satisfaction and reducing complications.[109]

Clinical Pearls

- By implementing RA techniques, facilities may be able to lower costs and enhance efficiency.
- Hospitals that use RA at a rate higher than the median of competing hospitals may reduce patient length of stay and increase profit per DRG while increasing patient satisfaction and reducing complications.

SUMMARY

Outpatient surgical cases are increasing, and regional anesthetic techniques, including PNB, are amenable to the types of cases performed in the outpatient setting. RA and PNBs can benefit patients by avoiding the side effects of GA and opioids. RA techniques and the use of local anesthetics are a major component of a multimodal analgesia and anesthesia plan. RA techniques offer improved patient outcomes, do not disproportionately delay case start time, can improve fast-tracking of patients, and may enhance economic outcomes for a facility. Complications may occur, however, and providers should be prepared to handle these situations appropriately, particularly in a standalone ASC with fewer resources than hospitals.

CHAPTER 52

Neuraxial Anesthesia & Peripheral Nerve Blocks in Patients on Anticoagulants

Honorio T. Benzon, Rasha S. Jabri, and Tom C. Van Zundert

INTRODUCTION

Intraspinal hematoma is a relatively rare condition resulting from a variety of causes. Traumatic causes include lumbar puncture and neuraxial anesthesia. It is more likely to occur in anticoagulated or thrombocytopenic patients, patients with neoplastic disease, or in those with liver disease or alcoholism. Approximately one-quarter to one-third of all cases are associated with anticoagulation therapy. The risk of intraspinal hematoma formation after administration of neuraxial anesthesia and analgesia is increased in patients who have received anticoagulant therapy or have a coagulation disorder.[1] For this reason, neuraxial anesthesia is often contraindicated in the presence of a coagulopathy. Other risk factors for the development of epidural or spinal hematoma include technical difficulty (multiple attempts) in the performance of the neuraxial procedures due to anatomic abnormalities of the spine and multiple or bloody punctures.

The incidence of spinal hematoma was originally reported to be one in 150,000 epidurals and one in 220,000 spinal anesthetics.[2] Recent epidemiologic studies have shown the incidence of spinal hematoma to be more frequent, ranging from one in 2700 to one in 19,505 epidurals.[3–6] The most recent study showed an overall risk of 1 in 21,643 epidural injections.[7] The elderly (one in 3800)[4] are at increased risk due to degenerative spine abnormalities, osteoporosis, and peripheral vascular disease.[8,9] Obstetric populations seems to have a lower incidence of spinal hematoma (one in 200,000),[4] probably secondary to the hypercoagulable state of pregnancy, the wider capacity of the epidural space in younger parturients, and higher intra-epidural pressure. Based on a recent large retrospective study, the incidence of epidural hematoma in patients with abnormal coagulation may be as low as one in 315 patients.[10]

The introduction of low-molecular-weight heparin (LMWH) was associated with a spike in the incidence of spinal hematoma, resulting in a warning by the Food and Drug Administration (FDA) and the introduction of the first consensus statement on regional anesthesia in patients on anticoagulants by the American Society of Regional Anesthesia and Pain Medicine (ASRA) in 1998.[11] The guidelines were based on an extensive review of the literature and of the pharmacology of the different anticoagulants. Recommendations were made on the timing of the neuraxial block, removal of the epidural catheter, and the subsequent administration of anticoagulants. In particular, the use of low concentrations of local anesthetics for epidural infusion (to preserve motor strength for easier monitoring) and subsequent neurologic monitoring were recommended by the ASRA. The consensus guidelines, published in 1998 and updated in 2003 and 2010,[12,13] have greatly assisted clinicians in decision making with regard to the use of neuraxial procedures in the setting of anticoagulation therapy. Two other sets of guidelines, published by the European Society of Anaesthesiology and the Scandinavian Society of Anaesthesiology and Intensive Care Medicine, are influential in Europe.[14,15]

In this chapter, we discuss the significance of common anticoagulants and hope to offer the reader a guide in decision making about the use of neuraxial anesthesia and peripheral nerve blocks (PNBs) in clinical practice. We will also discuss the new anticoagulants, drugs that were not adequately covered in the latest ASRA guidelines and only partly covered by the European and Scandinavian guidelines.

ANTIPLATELET THERAPY

Antiplatelet medications inhibit the platelet cyclooxygenase enzyme and prevent the synthesis of thromboxane A_2. Thromboxane A_2 is a potent vasoconstrictor that facilitates secondary platelet aggregation and release reactions. The role of platelets in coagulation and hemostasis is shown in Figures 52–1 and 52–2. Platelets from patients on these medications have normal platelet adherence to subendothelium and normal primary hemostatic plug formation. An adequate, although potentially fragile, clot may form. Although such plugs may be satisfactory hemostatic barriers for smaller vascular lesions, they may not ensure adequate perioperative hemostatic clot formation. Platelet function in patients receiving antiplatelet medications should be assumed to be decreased for 1 week with aspirin and 1–6 days with nonsteroidal anti-inflammatory drugs (NSAIDs).[16] This assumption does not take into consideration the continuous formation of new, functional platelets. The continuous production of fresh, normally functioning platelets, combined with the residual function of already circulating platelets, may explain the relative safety of performing neuraxial procedures in these patients.

The risk of epidural and spinal hematoma in patients on antiplatelet therapy has been raised by a case report of spontaneous epidural hematoma formation in the absence of spinal or epidural anesthesia in a patient with a history of aspirin ingestion.[17] Vandermeulen and colleagues implicated antiplatelet therapy in 3 of the 61 cases of spinal hematoma occurring after spinal or epidural anesthesia.[18] Other studies have shown a relatively low risk of spinal hematoma in patients on aspirin or NSAIDs undergoing a neuraxial procedure. The Collaborative Low-dose Aspirin Study in Pregnancy (CLASP) Group[19] included 1422 high-risk obstetric patients who were administered 60 mg of aspirin daily and underwent epidural anesthesia without any neurologic sequelae. In a retrospective study of 1013 spinal and epidural anesthetics in which antiplatelet drugs were taken by 39% of the patients, including 11% of patients who were on multiple antiplatelet medications, no patient developed signs of spinal hematoma.[20] The patients on antiplatelet medications, however, showed a higher incidence of blood aspiration through the spinal or epidural needle or the catheter. A subsequent prospective study in 1000 patients, 39% of whom reported preoperative antiplatelet therapy, noted the absence of hemorrhagic complications.[21] Therefore, preoperative antiplatelet therapy was not a risk factor for bloody needle or catheter placement. Female gender, increased age, history of excessive bruising or bleeding, continuous catheter technique, large needle gauge, multiple attempts, and difficult needle placement were noted to be significant risk factors. Clinical studies in pain clinic patients are similar to those undergoing surgery. Patients on aspirin[22] or NSAIDs[23] who underwent epidural steroid injections did not develop signs or symptoms of intraspinal hematoma.

The lack of correlation between antiplatelet medication and bloody needle or catheter placement provides some evidence that preoperative antiplatelet therapy does not represent a significant risk factor for the development of neurologic dysfunction from spinal hematoma in patients on antiplatelet therapy. It should be noted that there have been case reports of intraspinal hematoma in patients on aspirin or NSAIDs, although there were complicating factors in these case reports. These included concomitant heparin administration, coexisting epidural venous angioma, and technical difficulty in performing the procedure.[24] More recently, more case reports of spinal hematoma have been published in relation to pain interventional procedures, specifically spinal cord stimulation placements.[25]

Based on the available evidence, the ASRA has made several recommendations concerning antiplatelet medications.[12,13] Preoperative antiplatelet therapy does not represent a significant risk factor for the development of neurologic dysfunction from spinal hematoma in patients on antiplatelet therapy. The risk of bleeding complications, however, may be increased in patients on several antiplatelet medications and concurrent use of other medications affecting clotting mechanisms, such as oral anticoagulants, standard heparin, and LMWH.[24]

Clinical Pearls

- It is probably safe to do neuraxial and regional anesthesia procedures in patients on aspirin and NSAIDs.
- The risk factors for increased bleeding and spinal hematoma include the patient's intake of several antiplatelet drugs and making multiple attempts.

Aspirin and Interventional Pain Procedures

There have been several case reports of spinal hematoma after epidural steroid injection or placement or removal of a spinal cord stimulator in patients who were on aspirin alone, NSAIDs alone, or when the ASRA guidelines were followed.[26–30] These occurrences may be related to the frequent spine abnormalities found in these patients, the presence of fibrosis following spine surgery, larger needles used in spinal cord stimulator placement, or the frequent manipulations (advancements and retractions) of the electrodes. Medications used in pain managements also cause bleeding; these include oxcarbazepine and the selective serotonin reuptake inhibitors.[31,32] For these reasons, the ASRA liaised with the European Society of Regional Anaesthesia and Pain Therapy, the American Academy of Pain Medicine, the International Neuromodulation Society, the North American Neuromodulation Society, and the World Institute of Pain to formulate specific guidelines for interventional pain procedures.[33] In contrast to the ASRA regional anesthesia guidelines, the multisociety guidelines recommended that aspirin be stopped for 4–6 days before interventional pain procedures.

Clinical Pearl

- The guidelines on interventional pain procedures in patients on antiplatelet and anticoagulant medications are more restrictive than the ones on regional anesthesia.

COX-2 Inhibitors and P2Y12 Inhibitors

Cyclooxygenase-2 (COX-2) inhibitors gained popularity because of their analgesic properties and lack of platelet and gastrointestinal effects, and studies have shown their analgesic

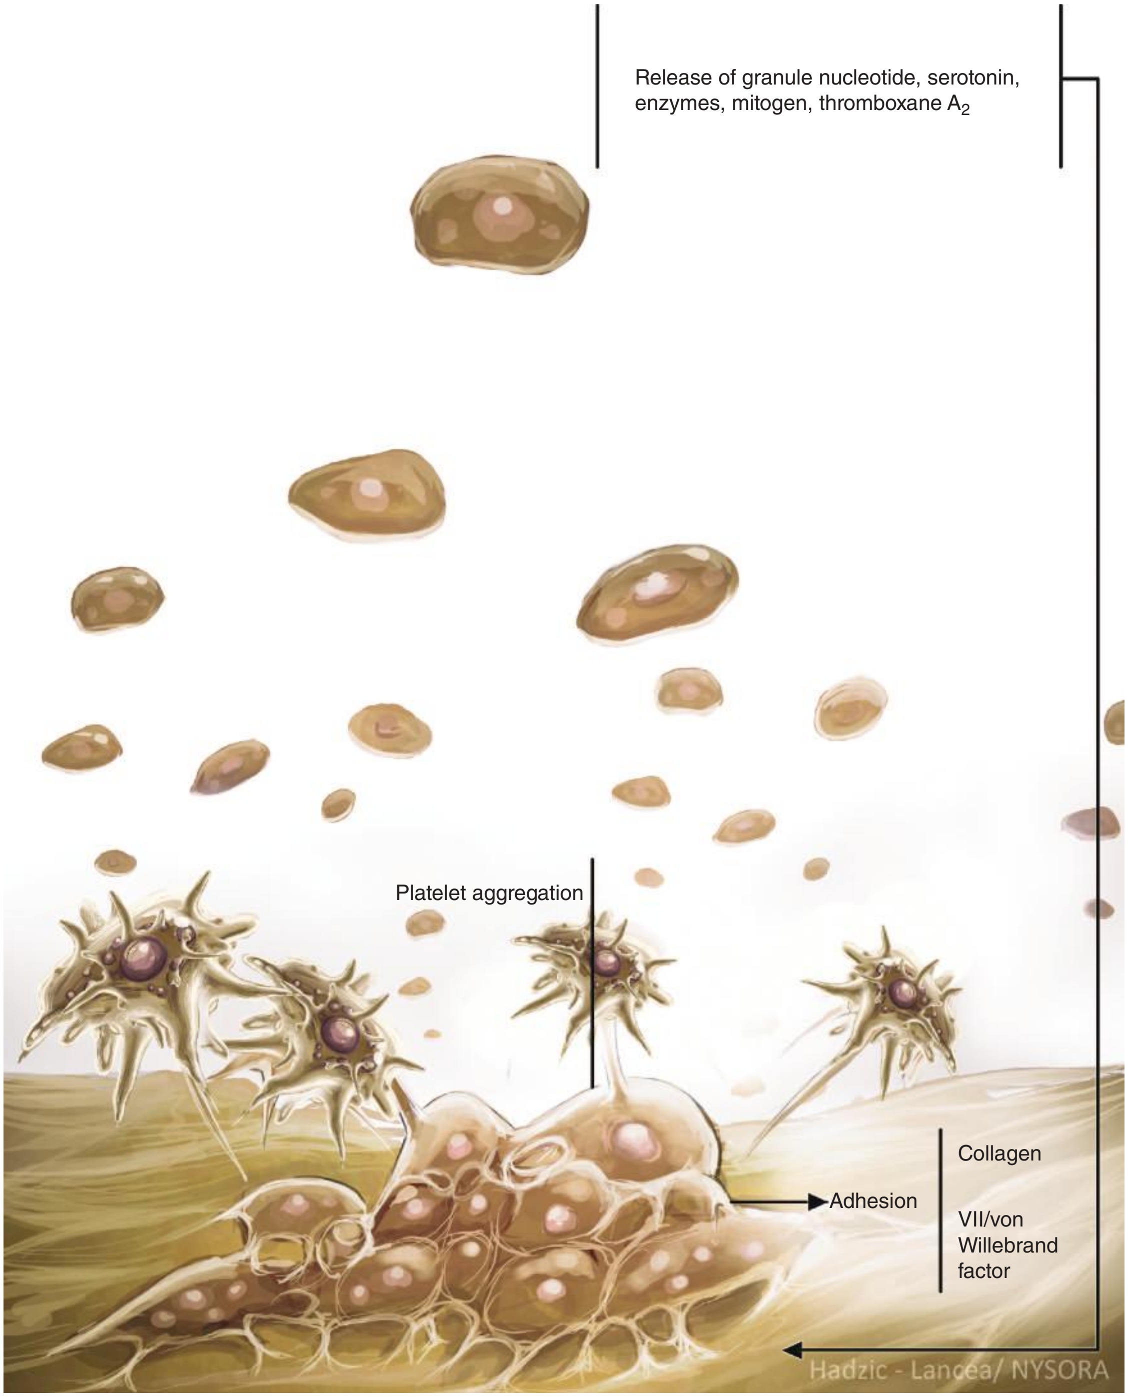

FIGURE 52–1. Role of platelets in coagulation. Platelets carry out their role in hemostasis through three basic reactions: adhesion, activation (and secretion), and aggregation. When vascular endothelium is damaged, platelets rapidly bind to the subendothelium by a process termed *adhesion*.

property in a variety of perioperative settings.[34–38] The drugs have minimal gastrointestinal (GI) toxicity and are ideal for patients who are at increased risk for serious upper GI adverse events. Compared with aspirin or NSAIDs, the effect of COX-2 inhibitors on platelet aggregation and bleeding times were not different from placebo.[39–41] Blood loss does not increase during spinal fusion surgery when COX-2 inhibitors are given preoperatively. The platelet properties of these drugs make them ideal for perioperative use when neuraxial anesthetic is planned. Unfortunately, rofecoxib and valdecoxib have been withdrawn from the market because of their cardiovascular side effects,[42] leaving only celecoxib available, but at dosages lower than previously recommendeded.

The thienopyridine drugs ticlopidine and clopidogrel have no direct effect on arachidonic acid metabolism. These drugs prevent platelet aggregation by inhibiting adenosine diphosphate (ADP) receptor–mediated platelet activation.[24,43] They also modulate vascular smooth muscle, reducing vascular contraction.[44] Ticlopidine is rarely used because it causes neutropenia, thrombocytopenic purpura, and hypercholesterolemia.

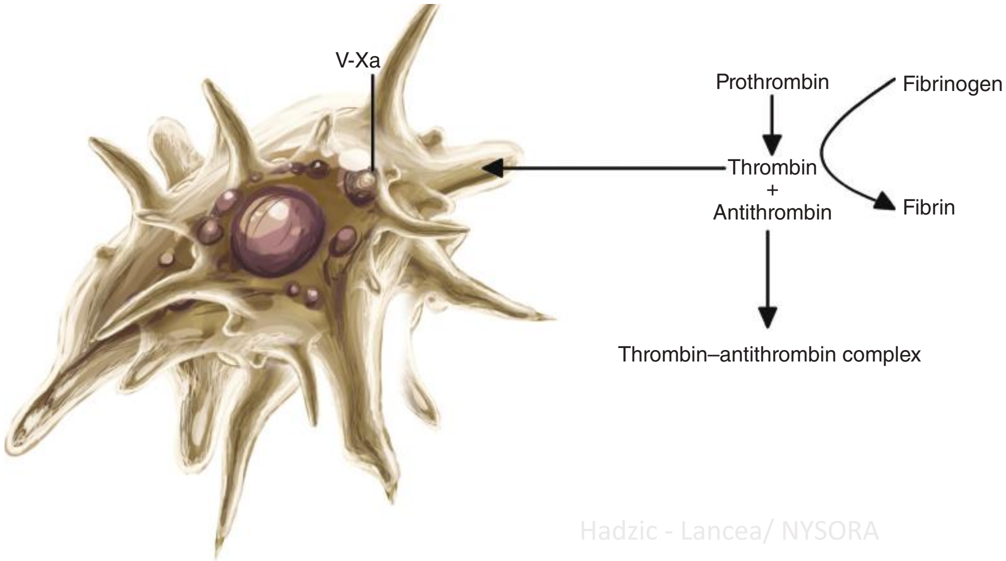

FIGURE 52–2. Role of platelets in coagulation: Platelets support plasma coagulation reactions. When activated, platelets bind several plasma protein complexes and secrete an activated form of factor V (factor Va), which binds to the platelet surface and binds factor Xa. Platelet-bound factor Xa then accelerates the conversion of prothrombin to thrombin.

Clopidogrel is preferred because of its improved safety profile and proven efficacy. It was noted to be better than aspirin in patients with peripheral vascular disease.[45] The maximal inhibition of ADP-induced platelet aggregation with clopidogrel occurs 3–5 days after initiation of a standard dose (75 mg) but within 4 to 6 hours after the administration of a large loading dose of 300–600 mg.[46] A large loading dose is usually given to patients before they undergo percutaneous coronary intervention (PCI). There has been a case report of spinal hematoma in a patient on ticlopidine.[47] Although there has been no case of intraspinal hematoma in a patient on clopidogrel alone, a case of quadriplegia in a patient on clopidogrel, diclofenac, and aspirin has been reported.[24]

For the thienopyridine drugs, it is recommended that ticlopidine be discontinued for 10–14 days and clopidogrel for 7 days before neuraxial injection. There have been case reports on the safety of spinal anesthesia 5 days after stoppage of clopidogrel. A study showed that most patients had minimal platelet inhibition 5 days after clopidogrel was stopped.[48] If a neuraxial procedure must be performed 5–6 days after discontinuation of clopidogrel, then a P2Y12 assay,[48] or another appropriate test, should be performed to ensure minimal or no inhibition of platelet activity.

Clinical Pearls

- The ASRA guidelines recommend a 7-day interval between discontinuation of clopidogrel and a neuraxial procedure.
- If a spinal or epidural must be performed is indicated, a test of platelet function is recommended to ensure that the residual platelet inhibition is gone or negligible.

For a spinal cord stimulation trial, a 5-day discontinuation may be observed since the patient will be off clopidogrel during the trial. A test of platelet function (eg, the VerifyNow P2Y12 assay or the platelet mapping portion of the Thrombelastograph [TEG]) must be performed to ensure adequate platelet activity.

Newer Antiplatelet Drugs

Clopidogrel is the commonly used antiplatelet drug in dual antiplatelet therapy, wherein aspirin is combined with a P2Y12 receptor inhibitor, in patients with acute coronary syndromes. Prasugrel is a pro-drug similar to clopidogrel but with salutary features over clopidogrel, and ticagrelor is a direct-acting P2Y12 receptor inhibitor.[49–51] The median time to peak effect is 1 hour with prasugrel and 4 hours with clopidogrel.[52] The mean time to peak plasma concentration with prasugrel is 30 minutes,[53] and its median half-life is 3.7 hours. These values do not reflect the duration of platelet inhibition because the inhibition of the P2Y12 receptor is irreversible. It takes 7 days for platelet activity to normalize after stopping prasugrel.[54]

Prasugrel and ticagrelor cause 90% inhibition of platelet function compared to 60%–70% for clopidogrel.[52] Patients with a low body mass index (BMI), those over 75 years of age, and those with a history of stroke are at risk for bleeding.[55,56] Unlike clopidogrel, prasugrel is reliably converted to its active metabolite and has no drug interactions. Also, it is not susceptible to genetic polymorphisms.[57,58]

Ticagrelor reversibly binds to the P2Y12 receptor, blocking ADP-mediated receptor activation. In contrast to the thienopyridines, the active metabolite and the parent drug exhibit antiplatelet activity with the parent drug responsible for the majority of the in vivo platelet inhibition.[59,60] The antiplatelet effect of ticagrelor is rapid; peak platelet inhibition occurs at 2 to 4 hours after intake compared to 24 hours with clopidogrel.[61] Mean platelet inhibition by ticagrelor is 93% compared to 58% for clopidogrel.[62] Platelet recovery is rapid with ticagrelor; platelet activity is normal at 5 days after the last dose.[62]

Time Between Discontinuation/Resumption of an Antiplatelet Drug and Neuraxial Injection

The interval between discontinuation of an antiplatelet drug and neuraxial injection is based on the percent platelet inhibition and percent platelet turnover. Prasugrel and ticagrelor cause 90% inhibition. Ten to 15 percent of the circulating platelet pool is formed every day,[63] resulting in new platelets comprising 50–75% of the circulating platelet pool 5–7 days after discontinuation of the drug.[48] An interval of 5–7 days has been recommended for ticagrelor and an interval of 7–10 days for prasugrel.[14,15] These recommendations are appropriate as platelet aggregation normalizes 7 days after stopping prasugrel[54] and 5 days after ticagrelor.[62,64]

The Scandinavian guidelines note that it is acceptable to restart antiplatelet drugs at the time of catheter removal,[15] whereas the European Society of Anaesthesiology guidelines recommended an interval of 6 hours between removal of epidural catheter and resumption of prasugrel or ticagrelor.[14] Other reviews have recommended caution in restarting prasugrel and ticagrelor because of their rapid effect and potent antiplatelet inhibition.[65] A 24-hour interval may be more appropriate for these agents.

Clinical Pearls

- Prasugrel and ticagrelor should be stopped 7 and 5 days, respectively, before a spinal or epidural.
- Antiplatelet drugs can be restarted 6–24 hours after a neuraxial procedure or catheter removal.

Monitoring Platelet Function

The Ivy bleeding time was considered to be a reliable predictor of abnormal bleeding in patients receiving antiplatelet drugs.[22] However, the post-aspirin bleeding time is not a reliable indicator of platelet function.[66] There is large intra- and interpatient variability in the results of the test, and there is no evidence to suggest that bleeding time can predict hemostatic function, as studies have failed to show a correlation between aspirin-induced prolongation of bleeding time and surgical blood loss.[67]

Special platelet function assays are now available to monitor platelet aggregation and degranulation. The platelet function analyzer (PFA) is a test of in vitro platelet function. It is a good screening test for von Willebrand disease and monitors the effect of desmopressin administration. The PFA is prolonged after antiplatelet therapy.[68] Unfortunately, the PFA-100 is not a sensitive test for monitoring the antiplatelet function of the P2Y12 inhibitors clopidogrel, prasugrel, and ticagrelor. However, the PFA-200, a recent update of the PFA-100,[69] appears to be sensitive to the effects of the P2Y12 inhibitors. However, point-of-care studies on this new PFA test are still lacking.

Newer tests that monitor P2Y12 receptor activity include the vasodilator-stimulated phosphoprotein (VASP) assay,[70,71] the VerifyNow assay,[72] the multiple-platelet aggregometry test (Multiplate),[73] and the platelet mapping component of the Thromboelastograph (TEG).[74] The VerifyNow assay can monitor the antiplatelet effects of aspirin and the P2Y12 inhibitors.[75] The platelet mapping component of the TEG is commonly used in surgery and anesthesiology, whereas VerifyNow is the predominant assay in clinical cardiology. A review on the monitoring of platelet function has been discussed by several reviews and is beyond the scope of this chapter.[48,76]

ORAL ANTICOAGULANTS

Warfarin exerts its anticoagulant effect by interfering with the synthesis of the vitamin K–dependent clotting factors (VII, IX, X, and thrombin)[77] (Figure 52–3). It also inhibits anticoagulant proteins C and S. Factor VII has a relatively short half-life (6–8 h), and the prothrombin time (PT) may be prolonged into the therapeutic range (1.5–2 times normal) within 24–36 hours. Anticoagulant protein C also has a short half-life (6–7 h). The initial prolongation of the international normalized ratio (INR) is the result of competing effects of reduced factor VII and protein C and the washout of existing clotting factors. Because of this, the INR is unpredictable during the initial stage of treatment with warfarin.[78,79] Factor VII participates only in the extrinsic pathway, and adequate anticoagulation is not achieved until the levels of biologically active factors II (half-life of 50 h) and X are sufficiently depressed. This requires 4–5 days. High loading doses of warfarin (15 mg) are occasionally employed for the first 2–3 days of therapy, and the desired anticoagulant effect is achieved within 48–72 hours.[80] The anticoagulant effect of warfarin persists for 4–6 days after termination of therapy while new biologically active vitamin K factors are synthesized. The drawbacks of warfarin therapy include the necessity of monitoring its effect with serial monitoring of INR, its interaction with other drugs, and the need for it to be discontinued a few days before surgery.[81] The effect of warfarin can be reversed by the transfusion of fresh frozen plasma and vitamin K injections. The 3-factor or 4-factor prothrombin complex concentrate (PCC) can be used to antagonize warfarin in emergency situations.

Few data exist regarding the risk of spinal hematoma in patients with indwelling spinal or epidural catheters who are subsequently anticoagulated with warfarin. Odoom and Sih[82] performed 1000 continuous lumbar epidural anesthetics in 950 patients who underwent vascular procedures and received preoperative oral anticoagulants. The thrombotest (a test of factor IX activity) was decreased and the activated partial thromboplastin time (aPTT) was prolonged in all the patients prior to epidural placement. Heparin was also administered intraoperatively. The epidural catheters remained in place for 48 hours postoperatively, and there were no neurologic complications. Unfortunately, the coagulation status of the patients at the time of catheter removal was not described. Although the results of this study are reassuring, the antiquated nature of the thrombotest as a measure of anticoagulation combined with the unknown coagulation status of the patients at the time of catheter removal limits the usefulness of the study.

The use of an indwelling epidural or intrathecal catheter and the timing of its removal in an anticoagulated patient are controversial. Although the trauma of needle placement occurs with both single-dose and continuous catheter techniques, the

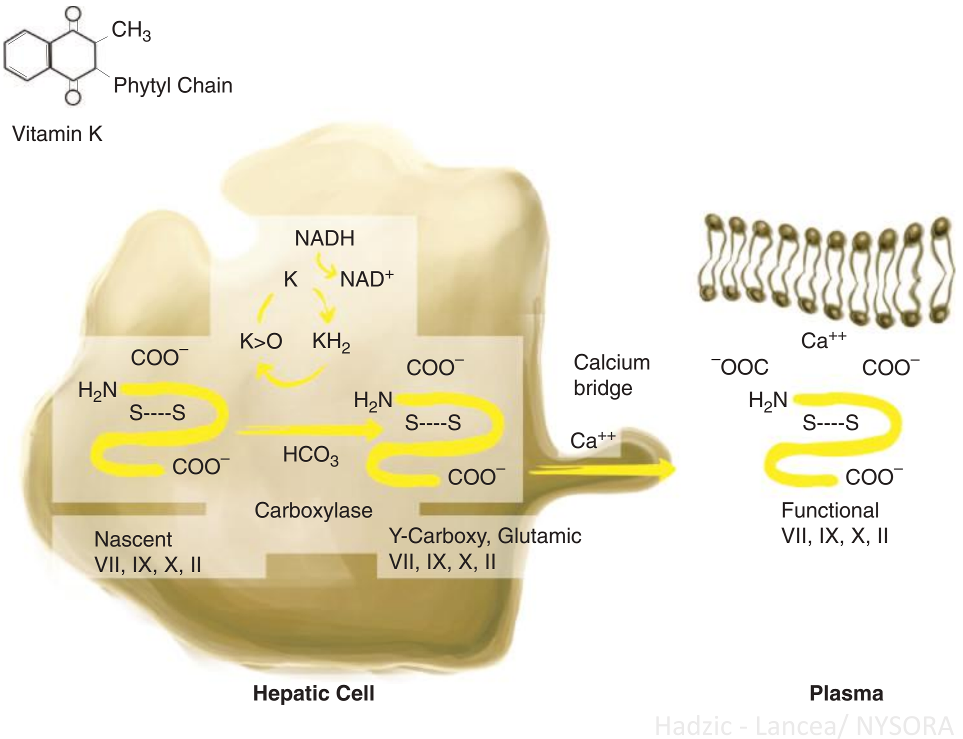

FIGURE 52–3. Vitamin K–dependent coagulation factor synthesis. Vitamin K is necessary for posttranslational modification of prothrombin; proteins C and S; and factors VII, IX, and X. Vitamin K is stored in hepatocytes.

presence of an indwelling catheter may result additional injury to tissues and vascular structures. Since intraspinal hematomas have occurred after catheter removal,[18] it is recommended that the same laboratory values apply to placement and removal of the epidural catheter.[83] No spinal hematomas were reported in 192 patients receiving postoperative epidural analgesia in conjunction with low-dose warfarin after total knee arthroplasty.[84] In this study, the patients received warfarin to prolong their PT to 15.0–17.3 seconds. The epidural catheters were left indwelling for 37 ± 15 hours (range 13–96 h). The mean PT at the time of epidural catheter removal was 13.4 ± 2 seconds (range 10.6–25.8 s). This and several subsequent studies have documented the relative safety of low-dose warfarin anticoagulation in patients with an indwelling epidural catheter.[85] Another study showed higher INR levels (up to 1.9) are acceptable for the removal of epidural catheters as long as it is done within 12–14 hours after warfarin intake.[79] A study showed the absence of spinal hematoma when the epidural catheters were removed 2–3 days after warfarin intake, even with markedly elevated INRs.[86] The practice of pulling the epidural catheter out 3 days after initiation of warfarin, when the levels of clotting factors VII, IX, and X are low (factor II levels may still be acceptable) needs to be studied. This is especially the case since patients vary greatly in their response to warfarin,[79] prompting some authors to recommend close monitoring of coagulation status to avoid excessive PT prolongation. Factors responsible for a prolonged PT and PTT are illustrated in Figures 52–4 and 52–5.

The ASRA recommended an INR value of 1.4 or less as acceptable for the performance of neuraxial blocks.[12,13,77] This value is based on studies that showed excellent perioperative hemostasis when the INR value was ≤1.5.[78] Studies on the levels of clotting factors at different INR values have shown that the decline of these factors may not be significant at an INR of 1.5. At INR values of 1.5–2.0, the concentrations of

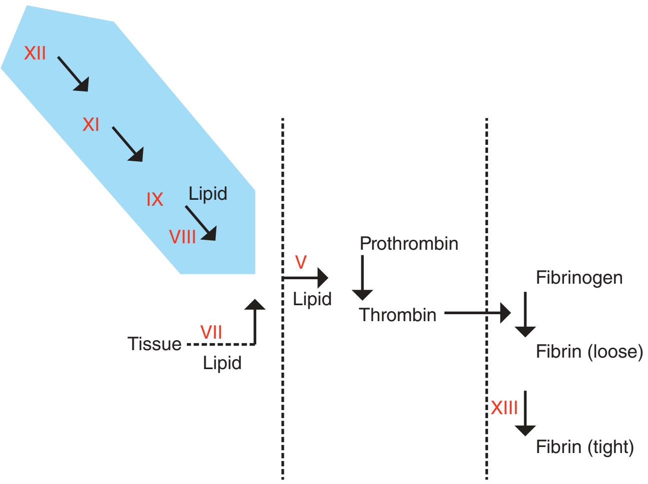

FIGURE 52–4. Coagulation reaction. Factors responsible for a prolonged PTT are in the shaded area. Patients who have an abnormal PTT but whose PT and other tests are normal can be divided into 2 groups: those who are prone to bleeding and those who are not. The patients who do not bleed may have an extremely prolonged PTT (90 seconds or more) but do not have a history of bleeding. They will have a deficiency in factor XII, prekalikrein, or high-molecular-weight kininogen. These patients should not be denied surgery or epidural anesthesia. The other group, patients who bleed, have both prolonged PTT and a history of bleeding. They will have a deficiency of factor VIII (hemophilia A), factor IX (hemophilia B or Christmas disease), or factor XI.

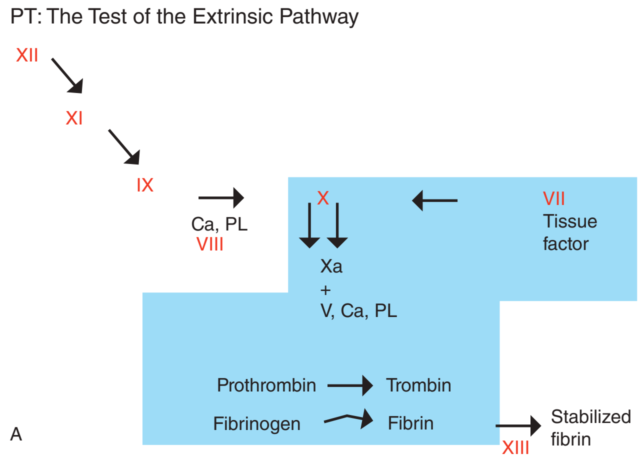

FIGURE 52–5A. Coagulation reaction. Factors involved in PT are in the shaded area. The PT is carried out by adding a source of tissue factor to the patient's plasma along with calcium or phospholipid. Tissue factor forms a complex with and activates factor VII. (Ca, calcium; PL, phospholipid.)

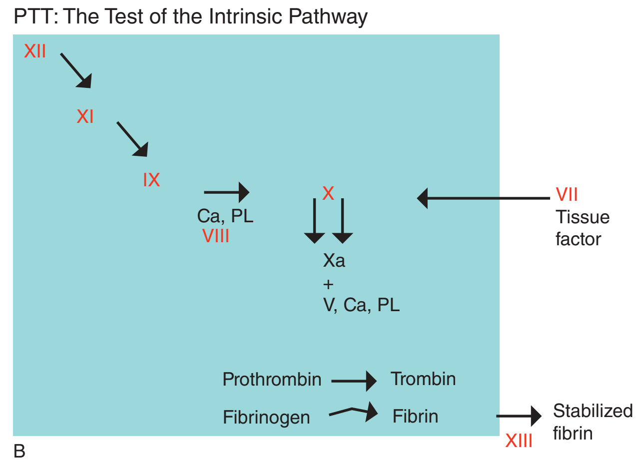

FIGURE 52–5B. Coagulation reaction. Factors involved in PTT are in the shaded area. In assessing PTT, coagulation is initiated by an agent that activates the Hageman factor–kininogen–prekalikrein complex. Most coagulation factors are screened by PTT, except factors VII and XIII, the protein that stabilizes fibrin clots by cross-linking them, and components of the fibrinolytic system. (Ca, calcium; PL, phospholipid.)

factor II were noted to be 74%–82% of baseline, whereas factor VII levels were 27%–54% of baseline values.[79] At INR values of 2.1 ± 1 during the initial phase of warfarin administration, factors II and VII were 65 ± 28% and 25 ± 20% of control values.[87] Activities of 40% are considered adequate for normal hemostasis at the time of major surgery. Another study[88] found that at INRs of 1.3–2, under stable anticoagulation with warfarin, the concentrations of clotting factors VII, IX, and X were within normal limits.

The clinician should be aware of the effect of warfarin on the coagulation cascade and the role of the INR in monitoring this effect. To minimize the risk of complications, the ASRA recommends several precautions.[12,13] Chronic oral warfarin therapy should be stopped and the INR measured before a neuraxial block is performed. The concurrent use of other medications, such as aspirin, NSAIDs, and heparins, which affect the clotting mechanism, increases the risk of bleeding complications without affecting the INR. If an initial dose of warfarin is given prior to surgery, the INR should be checked if the dose was given more than 24 hours earlier. If patients are on low-dose warfarin treatment (mean daily dose approximately 5 mg) during epidural analgesia, the INR should be checked daily and before catheter removal if the initial dose was given more than 36 hours previously. Higher daily doses may need more intensive monitoring. The warfarin dose should be held or reduced when the INR is >3 in patients with indwelling neuraxial catheters to prevent epidural hematoma and hemarthroma. While on warfarin therapy, the patient's neurologic status should be checked routinely during epidural analgesic infusion, as well as 24 hours after the catheter has been removed. Dilute concentrations of local anesthetic should be utilized to minimize the degree of sensory and motor blockade. Clinical judgment must be exercised in making decisions about removing or maintaining neuraxial catheters in patients with therapeutic levels of anticoagulation during neuraxial catheter infusion. The warfarin dose should be reduced for patients who are likely to have an enhanced response to the drug, especially the elderly. For patients on chronic oral anticoagulation, the warfarin must be stopped and the INR measured.

Clinical Pearls

- An INR of 1.4, in the absence of easy bruisability and normal liver function is acceptable before neuraxial injection in patients planned for neuraxial blocks.
- The INR should be checked if the patient took warfarin more than 24 hours earlier.
- The INR should be normal 5 days after warfarin is stopped before a neuraxial procedure.

HEPARIN

Intravenous Heparin

Heparin is a complex polysaccharide that exerts its anticoagulant effect by binding to antithrombin. The conformational change in antithrombin accelerates its ability to inactivate thrombin factors Xa and IXa.[89]

Unfractionated heparin releases tissue factor pathway inhibitor from endothelium, enhancing its activity against factor Xa.[89] The anticoagulant effect of subcutaneous heparin takes 1–2 hours, but the effect of intravenous heparin is immediate. In fact, the coagulation time is prolonged 2–4 times the baseline level 5 minutes after the intravenous injection of 10,000 units of heparin. Heparin has a half-life is 1.5–2 hours. The therapeutic dose of heparin ceases 4–6 hours after its administration. The aPTT is used to monitor the effect of heparin; therapeutic anticoagulation is achieved with a prolongation of the aPTT greater than 1.5 times the baseline value or a heparin level of 0.2–0.4 U/mL.[90] The aPTT is usually not prolonged by the subcutaneous administration of low doses of heparin and is not monitored. Protamine neutralizes the effect of intravenously administered heparin.

Heparin is not the ideal anticoagulant since it is a mixture of molecules, only a fraction of which have anticoagulant activity. It binds to platelet factor 4 and to the von Willebrand factor.[91] The heparin–antithrombin complex is also not very effective in neutralizing clot-bound thrombin. Finally, heparin is associated with immunologic thrombocytopenia and immune-mediated thrombosis.[91] For patients receiving standard heparin therapy, the risk of bleeding complications is increased in the presence of other medications that affect other clotting mechanisms, including aspirin, NSAIDs, LMWHs, and oral anticoagulants.

Several studies have demonstrated the safety of spinal or epidural anesthesia followed by systemic heparinization if certain precautions are observed. Rao and El-Etr[92] reported no spinal hematomas in over 4000 patients who underwent lower extremity vascular surgery under continuous spinal or epidural anesthesia. In their study, patients with preexisting coagulation disorders were excluded, heparinization occurred at least 60 minutes after catheter placement, the level of anticoagulation was carefully monitored, and the indwelling catheters were removed at a time when heparin activity was low. Surgery was canceled in patients when frank blood was noted in the needle and performed the following day under general anesthesia. The same findings were noted in a subsequent report in the neurologic literature. Ruff and Dougherty[93] noted spinal hematomas in 7 of 342 (2%) patients who underwent lumbar puncture and subsequent heparinization for evaluation of cerebral ischemia. The presence of blood during the procedure, concomitant aspirin therapy, and heparinization within 1 hour were identified as risk factors in the development of spinal hematoma.

The ASRA has made several recommendations for when a neuraxial technique is used in the presence of intraoperative anticoagulation.[12,13,94] The ASRA advises that technique should be avoided in patients with other coagulopathies. There should be at least a 1-hour delay between needle placement and heparin administration. The catheter should be removed 2–4 hours after the last heparin dose and 1 hour before subsequent heparin administration. The aPTT or activated clotting time (ACT) should be monitored to avoid excessive heparin effect. The patient should followed postoperatively for early detection of reoccurrence of motor blockade. Dilute concentrations of local anesthetics are recommended to minimize motor blockade. Although there may be an increased risk in the event of a traumatic (bloody) or difficult needle placement, there are no data to support mandatory cancellation of surgery. The decision to proceed should be based on appropriate clinical judgment and full discussion with the surgeon and patient.

Clinical Pearls

- There should be at least a 1-hour delay between a neuraxial procedure and heparin readministration.
- The catheter can be removed 2–4 hours after the last heparin dose.

Neuraxial procedures are occasionally performed in patients who undergo cardiopulmonary bypass. The following precautions have been recommended to prevent the development of intraspinal hematoma in these patients:[95]

1. Neuraxial procedures should be avoided in patients with known coagulopathy.
2. Surgery should be delayed 24 hours in patients with a traumatic tap.
3. The time from the neuraxial procedure to the systemic heparinization should exceed 1 hour.
4. Heparinization and reversal should be monitored and controlled tightly.
5. The epidural catheter should be removed when normal coagulation is restored, and the patient should be monitored closely for signs of spinal hematoma.

Subcutaneous Heparin

The therapeutic basis of low-dose twice-daily subcutaneous heparin (5000 units every 8–12 hours) is the heparin-mediated inhibition of activated factor X. Smaller doses of heparin are required when administered as prophylaxis rather than as treatment for thromboembolic disease. Following the intramuscular or subcutaneous injection of 5000 units of heparin, maximum anticoagulation effect is observed in 40–50 minutes and returns to baseline within 4 to 6 hours. The aPTT may remain in the normal range and often is not monitored. However, wide variations in individual patient responses to subcutaneous heparin have been reported. Neuraxial techniques are not contraindicated during subcutaneous (mini-dose) prophylaxis, but the risk of bleeding may be reduced by delaying heparin administration until after the block. Bleeding may be increased in debilitated patients or after prolonged therapy. The safety of major neuraxial anesthesia in the presence of anticoagulation with twice-daily subcutaneous doses of unfractionated heparin has been documented by several studies.[94] The twice-daily subcutaneous heparin regimen has been replaced by a thrice-daily regimen in most hospitals to decrease the incidence of postoperative venous thromboembolism.[96] However, this practice has been associated with spontaneous hematomas.[97] For this reason, the latest ASRA guidelines recommend against neuraxial procedures in patients on a thrice-daily regimen until more data become available.[13]

Clinical Pearls

- Neuraxial procedures can be performed in patients on twice-daily subcutaneous heparin.
- Because of the lack of adequate data, the ASRA recommends that neuraxial procedures not be performed in patients on thrice-daily subcutaneous heparin.

Low-Molecular-Weight Heparin

Unfractionated heparin is a heterogeneous mixture of polysaccharide chains that can be separated into fragments of various molecular weights.[98,99] The anticoagulant effect of LMWH is similar to that for unfractionated heparin; it activates antithrombin, accelerating antithrombin's interaction with thrombin and factor Xa. LMWH has a greater activity against factor Xa, whereas unfractionated heparin has equivalent activity against thrombin and factor Xa. The plasma half-life of the LMWHs ranges from 2–4 hours after an intravenous injection and 3–6 hours after a subcutaneous injection; the half-life of an LMWH is 2–4 times that of standard heparin. It has a low affinity for plasma protein, resulting in a greater bioavailability. The advantages of LMWH over unfractionated heparin include a higher and more predictable bioavailability after subcutaneous administration and a longer biological half-life. Also, laboratory monitoring of the anticoagulant response of LMWH is not required, and dose adjustment for weight is not necessary (although an overdose may occur in patients with a low BMI). LMWH exhibits a dose-dependent antithrombotic effect that is accurately assessed by measuring the anti-Xa activity level. The recovery of anti-factor Xa activity after a subcutaneous injection of LMWH approaches 100%,[100] making laboratory monitoring unnecessary except in patients with renal insufficiency or those with body weight less than 50 kg or more than 80 kg.[98] The reaction time from the thrombelastogram appears to correlate with the serum anti-Xa concentration.[101]

The three commercially available LMWHs in the United States are enoxaparin (Lovenox), dalteparin (Fragmin), and tinzaparin (Innohep), although the latter has been discontinued because of low usage. Enoxaparin is given either once daily or every 12 hours when used as prophylaxis, and dalteparin and tinzaparin are given once daily. The three drugs appear to have comparable efficacy in the treatment and prevention of venous thromboembolism.[102] Enoxaparin and dalteparin have comparable efficacy in the prevention of death or myocardial infarction among patients with unstable angina.[102]

The recommended thromboprophylactic dose in the United States is 30 mg enoxaparin twice daily, although some clinicians increase the dose in patients who are obese (1.5 mg/kg daily or 1 mg/kg every 12 hours). The European dosing schedule is enoxaparin 20–40 mg once daily, and patients receive their starting dose 12 hours before surgery, a practice not observed in the United States.

Numerous cases of neuraxial hematoma occurred in the United States, prompting the FDA to issue a health advisory in December 1997 and the convening of the first ASRA consensus conference on anticoagulation and neuraxial anesthesia.[103] The ASRA guidelines recommend the smallest effective dose of LMWH should be administered. The postoperative administration of LMWH therapy should be delayed as long as possible, for a minimum of 12 hours and ideally 24 hours postoperatively. A single-dose spinal anesthetic may be the safest neuraxial technique in patients receiving preoperative LMWH. Waiting for at least 12 hours after the prophylactic LMWH dose is recommended before performing a neuraxial technique. Patients who receive higher doses of LMWH (eg, enoxaparin 1 mg/kg twice daily) require longer delays (24 h). The catheter should be removed when anticoagulation activity is low, at least 12 hours after prophylactic LMWH administration and 4 hours before the next dose.[104] Extreme vigilance of the patient's neurologic status must be observed if LMWH thromboprophylaxis is implemented while an indwelling catheter is infusing. Dilute local anesthetic solution is recommended so that neurologic function can be better monitored. The use of other medications affecting hemostasis, such as antiplatelet drugs, standard heparin, dextran, or oral anticoagulants, in combination with LMWH creates an additional risk of bleeding complications.

Clinical Pearls

- In patients on a prophylactic dose of LMWH, a 12-hour interval is recommended before a neuraxial injection.
- For patients on a therapeutic dose of LMWH, a 24-hour interval is appropriate.
- A 4-hour delay following epidural catheter removal before LMWH is resumed has been recommended by the FDA.

THROMBOLYTIC THERAPY

Thrombolytic agents actively dissolve fibrin clots that have already formed. Exogenous plasminogen activators such as streptokinase and urokinase not only dissolve thrombus but also affect circulating plasminogen, leading to decreased levels of both plasminogen and fibrin. Recombinant tissue-type plasminogen activator (r-TPA), an endogenous agent, is more fibrin selective and has less effect on circulating plasminogen levels. Clot lysis leads to an elevation of fibrin degradation products, which have an anticoagulant effect by inhibiting platelet aggregation.

Although epidural or spinal needle and catheter placement with subsequent heparinization appears relatively safe, the risk of spinal hematoma in patients who receive thrombolytic therapy is not well defined. Cases of spinal hematoma in patients who had epidural or indwelling epidural catheters and who received thrombolytic agents have been reported in the literature.[105]

The ASRA guidelines make recommendations with respect to neuraxial procedures after thrombolytic or fibrinolytic therapy.[12,13,105] The concurrent use of heparin with fibrinolytic or thrombolytic drugs places patients at high risk of adverse neuraxial bleeding during spinal or epidural anesthesia. Except in highly unusual circumstances, patients receiving fibrinolytic or thrombolytic therapy should be cautioned against receiving spinal or epidural anesthesia. There are no available data to clearly determine the appropriate length of time after discontinuation of these drugs and the safe performance of a neuraxial technique. The European guidelines recommend leaving the epidural catheter in place when a patient is given a thrombolytic drug, removing it only once effect of the drug is gone.[14] The Scandinavian guidelines recommend a 24-hour interval between discontinuation of the drug and neuraxial procedure.[15] Frequent neurologic monitoring is recommended for an appropriate length of time in patients who have had neuraxial blocks after fibrinolytic or thrombolytic therapy. If a patient has a continuous epidural infusion and has received fibrinolytic or thrombolytic therapy, drugs that minimize sensory and motor blockade should be used. There has been no definitive recommendation on the timing of removal of neuraxial catheters in patients who unexpectedly receive fibrinolytic or thrombolytic therapy. Measurement of fibrinogen levels may be helpful in guiding a decision about catheter removal or maintenance.

Herbal Therapy

The most commonly used herbal medications are garlic, ginkgo, and ginseng. Garlic inhibits platelet aggregation, and its effect on hemostasis appears to last 7 days. Ginkgo inhibits platelet-activating factor, and its effect lasts 36 hours. Ginseng has a variety of effects: it inhibits platelet aggregation in vitro and prolongs both thrombin time (TT) and aPTT in laboratory animals; its effect lasts 24 hours.[12,13] In spite of their effect on platelet function, herbal drugs by themselves appear to present no added significant risk in the development of spinal hematoma in patients having epidural or spinal anesthesia. Mandatory discontinuation of these medications, or cancellation of surgery in patients in whom these medications have been continued, is not supported by available clinical data. However, the concurrent use of other medications that affect clotting mechanisms, such as oral anticoagulants or heparin, may increase the risk of bleeding complications in these patients. There is no accepted test to assess adequacy of hemostasis in the patient who has taken herbal medications. At this time, there appear to be no specific concerns as to the timing of neuraxial block in relationship to the dosing of herbal therapy, postoperative monitoring, or the timing of neuraxial catheter removal.[12,13]

Thrombin Inhibitors

Recombinant hirudin derivatives, including desirudin, and bivalirudin, inhibit both free and clot-bound thrombin.[12,13] Argatroban, an L-arginine derivative, has a similar mechanism of action. These drugs are primarily used in the treatment of heparin-induced thrombocytopenia. There is no pharmacologic reversal to the effect of these drugs. There have been no case reports of spinal hematoma related to neuraxial anesthesia in patients who have received a thrombin inhibitor. However, spontaneous intracranial bleeding has been reported.[12] According to the ASRA guidelines, no statement regarding risk assessment and patient management can be made.

Fondaparinux

Fondaparinux is a synthetic anticoagulant that produces its antithrombotic effect through selective inhibition of factor Xa.[106] The drug exhibits consistency in its anticoagulant effect since it is chemically synthesized. It is 100% bioavailable. Rapidly absorbed, it attains maximum concentration within 1.7 hours of administration. Its half-life is 17–21 hours.[106] Fondaparinux is recommended as an antithrombotic agent after major orthopedic surgery[107] and as initial treatment for pulmonary embolism.[108] The extended half-life (approximately 20 hours) allows once-daily dosing. The FDA has issued a black box warning for fondaparinux similar to that for the LMWHs and heparin.

The actual risk of spinal hematoma with fondaparinux is unknown. A study showed no complications in patients who received neuraxial injections.[109] In this study, the catheters were removed 36 hours after the last dose of fondaparinux, and dosing was delayed for 12 hours after catheter removal. Patients were excluded from the study if difficulties were encountered in performing the neuraxial procedure (more than 3 attempts required), the procedure was complicated by bleeding, they required antiplatelet drugs, or the plan was to withdraw the epidural catheter the day after surgery. Because of the unrealistic requirements in clinical practice, the ASRA[12,13] recommends against the use of fondaparinux in the presence of an indwelling epidural catheter. Their recommendations are based on the sustained and irreversible antithrombotic effect of fondaparinux, early postoperative dosing, and the spinal hematoma reported during the initial clinical trials of the drug. Close monitoring of the literature for risk factors associated with surgical bleeding may be helpful in risk assessment and patient treatment. Performance of neuraxial techniques should occur under conditions used in clinical trials (single needle pass, atraumatic needle placement, avoidance of indwelling neuraxial catheters).[12,13] If this is not feasible, an alternative method of prophylaxis should be considered.

Summary

The time interval between discontinuation of the anticoagulant and neuraxial procedure and between epidural catheter removal and resumption of the drug are summarized in Table 52–1.

NEW ANTICOAGULANTS

A discussion of the new anticoagulants dabigatran, rivaroxaban, and apixaban involves a review of certain background information.

The Interval Between Anticoagulant Discontinuation and Neuraxial Injection and Between Neuraxial Procedure or Epidural Catheter Removal and Resumption of Anticoagulant

It has been recommended that two half-lives is an adequate compromise between the risk of venous thromboembolism (VTE) and the prevention of spinal hematoma.[110] The European and Scandinavian guidelines recommended a 2-half-life interval between discontinuation of anticoagulant and neuraxial injection. This decision was like made because subclinical VTE occurs in a fair percentage of patients immediately after surgery and having residual anticoagulation might prevent this occurrence. The presence of residual anticoagulation facilitates the transition to full anticoagulation after a neuraxial procedure.

After 1, 2, 3, 4, 5, and 6 half-lives, the following percentages of drug remain in the circulation: 50%, 25%, 12.5%, 6.25%,

TABLE 52-1. Recommended time intervals before or after neuraxial procedure and epidural catheter removal.

Drug	Time Before Neuraxial Procedure or Catheter Removal	Time After Neuraxial Procedure or Catheter Removal	Comments
Aspirin	None	None	
NSAIDs	None	None	
Clopidogrel	7 days*	After catheter removal	Per European & & Scandinavian guidelines
Prasugrel	7-10 days	6h	Per European Guidelines
Ticagrelor	5 days	6h	(As above)
Warfarin	5 days (normal INR)	After catheter removal	
Heparin (IV)	4-6 h	1-2h	
Heparin			
(Sc, BID)	None	None	
(Sc, TID)	Not applicable		Neuraxial procedure
			Not recommended
LMWH			
Prophylactic	12 hours	4 hours	FDA recommendation
Therapeutic	24 hours	4 hours	
Fondaparinux	36-42 hours	6-12 hours	Per European guidelines. ASRA recommended against neuraxial procedures in patients on the drug.

*If neuraxial procedure has to be performed at 5 days, a test of platelet function is recommended (see text).

3.125%, and 1.5625%, respectively (Table 52–2).[111] However, these findings are based on studies in young healthy volunteers in single-dosing pharmacokinetic studies in the absence of other anticoagulants. By contrast, in clinical practice, patients are usually older and have concomitant comorbidities.

In patients who are at risk for VTE, such as those with a previous history of stroke,[112] a 2- or 3-half-life interval might be appropriate, recognizing that adequate hemostasis is not assured.

For patients without thrombotic risk factors, an interval of 4–6 half-lives between the last dose of anticoagulant and neuraxial injection ensures a more complete elimination of the drug and less risk of bleeding.[113,114] A compromise between the conservative recommendations of 4–6 half-lives and 2–3 half-lives[14,15] is an interval of 5 half-lives with LMWH bridge therapy.

Regarding the resumption of the anticoagulant after neuraxial injection or removal of epidural catheter, the Scandinavian

TABLE 52-2. Recommended time intervals before or after neuraxial procedure and epidural catheter for the new anticoagulants.

Drug	Half-life	European Guidelines	Scandinavian Guidelines	Five Half-lives
Dabigatran	12-17h 28 hours (renal disease)	(Contraindicated per manufacturer)	Data not available	85h (4d) 6d (renal patients)
Rivaroxaban	9-13h	22-26h	18h	65h (3d)
Apixaban	15.2 +/-8.5h	26-30h	Data not available	75h (3-4d)

At 5 half-lives, 96.8% of the drug is eliminated. The upper limit of the half-life was used to calculate the 5 half-lives of the drug.

The European and Scandinavian guidelines used a 2 half-life interval when data is available.

guidelines are based on the recommendation of Rosencher et al. of 8 hours minus the time it takes for the anticoagulant to reach peak effect.[110] Eight hours was presumed to be adequate for the clot to stabilize, a presumption supported by the efficacy of thrombolytic agents to lyze a clot if given within 6 hours of clot formation.[115] Tertri and colleagues also noted that giving enoxaparin within 24–48 hours after intracerebral hemorrhage did not enlarge the size of hematoma,[116] so a 24-hour interval is probably safer. Other authors recommend a more conservative approach because the reinstitution of antithrombotic therapy within 24 hours after a major procedure might increase the risk of periprocedural bleeding.[65] Liew and Douketis[117] recommend a minimum of 24 hours in patients with low bleeding risk and 48 hours in those with a high bleeding risk before resuming dabigatran, rivaroxaban, or apixaban. The options therefore are either 8 hours or 24 hours minus the peak effect of the drug. There is probably little difference between these two options since the risks of VTE, stroke, or acute coronary syndrome are probably the same. In addition, the onset and times to peak effect of the new anticoagulants are short.

Dabigatran

Dabigatran etexilate is a prodrug that is hydrolyzed by esterases in the stomach to the active drug. Dabigatran etexilate has a bioavailability of 7.2%.[118] Dabigatran is a direct thrombin inhibitor that blocks the interaction of thrombin with various substrates.[76,119,120] Peak plasma concentrations are attained 1.5–3 hours after intake of the prodrug.[121] It has a half-life of 14–17 hours.[121–123] Renal clearance accounts for 80% of the total clearance of dabigatran.[124] In cases of end-stage renal disease, the elimination half-life doubles from 14 hours to 28 hours.[124,125]

Dabigatran is effective in the treatment of acute VTE and in the prevention of recurrent VTE. In patients with atrial fibrillation, dabigatran reduces the rates of stroke and systemic embolism to a degree similar to that of warfarin. Dabigatran was not shown to be consistent in preventing VTE after total joint surgery. Studies have shown it to be either more effective,[126] noninferior,[127,128] or inferior to enoxaparin.[129] A meta-analysis of the trials noted no differences between dabigatran and enoxaparin in any of the endpoints analyzed.[130]

The manufacturer states that epidural catheters should not be placed in patients receiving dabigatran.[14] A 2-hour minimum interval between indwelling catheter removal and dabigatran administration has been recommended by Levy and collegues.[120] This interval appears to be shorter than 6 hours, that is, the difference between 8 hours minus the 2-hour time to reach peak effect of the drug. There have been reports of increased bleeding after taking dabigatran. The Haematology Society of Australia and New Zealand identified 78 bleeding episodes in approximately 7000 patients over a 2-month period.[131] An audit by the FDA, however, concluded that there was not an absolute increase of bleeding with dabigatran compared to warfarin.

The aPTT is prolonged after dabigatran, but the relationship is curvilinear.[113,132] The thrombin time (TT), also known as thrombin clotting time (TCT), is highly sensitive to the effects of dabigatran[113,133] and is more appropriately used for detecting the presence of the anticoagulant effect of dabigatran than quantifying the effect of the drug.[134] A dilute TT has linearity across pharmacologically relevant plasma dabigatran concentrations.[113,132] The ecarin clotting time (ECT), which directly measures thrombin generation, is dose-dependent prolonged by dabigatran.[134] It is the most sensitive assay for dabigatran, but few institutions have the test available. The prothrombin time (PT) is the least sensitive test. The dilute TT and the ECT are the tests of choice for dabigatran.[132]

To date, there is no antidote to reverse the effect of dabigatran or the other new oral anticoagulants.[135–137] Activated charcoal prevents absorption of the drug, but it needs to be given within 2 hours of dabigatran ingestion. Dialysis might speed drug elimination. Plasma complex concentrates (PCCs) that contain either 3 (factors II, IX, and X) or 4 (factors II, VII, IX, and X) clotting factors have been suggested,[133,134] but their efficacy has not been proven. Idarucizumab, a monoclonal antibody fragment that binds with free and thrombin-bound dabigatran, was recently approved by the FDA.

Clinical Pearls

- Dabigatran is primarily dependent on the kidneys for elimination, and its half-life is doubled in patients with kidney disease.
- A longer interval between stoppage of the drug and neuraxial procedure, probably 6 days, is recommended in these patients.

Rivaroxaban

Rivaroxaban is a direct factor Xa inhibitor. Peak plasma concentrations are observed within 2.5–4 hours,[138,139] and the maximum inhibition of factor Xa (up to 68%) occurs 3 hours after dosing and is maintained for at least 12 hours,[139] or 24–48 hours when higher doses are given in elderly patients.[140] Rivaroxaban has a terminal half-life of 5.7–9.2 hours,[138,139] but this can be as long as 11–13 hours in elderly patients due to age-related decline in renal function.[141,142] One-third of the drug is eliminated by the kidneys, one-third by the fecal/biliary route, and one-third is changed to inactive metabolites.[139,143] The maximum concentration is not affected by obesity (patients weighing ≥120 kg) but is increased by 24% in patients weighing ≤50 kg. The renal clearance of rivaroxaban decreases with increasing renal impairment.[144]

Rivaroxaban is effective in the treatment of symptomatic VTE[142] and noninferior to warfarin in the prevention of embolic stroke during atrial fibrillation.[145] The addition of rivaroxaban to standard antiplatelet therapy reduces the composite endpoint of death from cardiovascular causes, myocardial infarction, or stroke in patients with a recent acute coronary syndrome.[76]

Rivaroxaban was reported to be as effective or superior to enoxaparin in preventing VTE after total joint surgery[146–150] In the RECORD1, 2, 3, and 4 studies,[146–149] rivaroxaban was a more effective thromboprophylactic agent than enoxaparin, with a similar safety profile. Rosencher et al. stated that epidural catheters were not removed until at least 2 half-lives after the last dose of rivaroxaban, and the next rivaroxaban dose was given 4-6 hours after catheter removal.[151] None of the 1141 patients who were given rivaroxaban and had neuraxial anesthesia developed spinal hematoma. However, this small number of patients is not adequate to make a firm conclusion on the perioperative safety of this regimen.

The European and Scandinavian guidelines recommend a 2-half-life interval between rivaroxaban discontinuation and epidural catheter placement or removal (18 hours in the Scandinavian guidelines and 22–26 hours in the European guidelines).[14,15] These guidelines also recommend a 4–6-hour interval before resumption of the next dose, as rivaroxaban takes 2.5–4 hours to reach peak effect.

A linear correlation was observed between the effects of rivaroxaban and PT.[114,134] However, there is marked variability in the sensitivity of PT reagents to rivaroxaban, so it is recommended that each laboratory should calibrate their PT specifically for rivaroxaban. The aPTT lacks sufficient sensitivity to determine the effect of rivaroxaban.[114,134] The inhibition of factor Xa may also be a surrogate for the plasma concentrations of rivaroxaban.[152] The PT and anti-Xa are the recommended tests for monitoring the effects of rivaroxaban.[132]

The use of activated charcoal has been recommended to remove rivaroxaban, but it must be given within 8 hours of rivaroxaban intake. A 4-factor PCC has been shown to reverse the in vitro anticoagulant activity of rivaroxaban in healthy volunteers.[134] Because of their high protein binding, rivaroxaban and apixaban may not be dialyzable.

Apixaban

Apixaban is a highly specific factor Xa inhibitor. It is rapidly absorbed and attains peak concentrations in 1–2 hours. Studies have shown the terminal half-life of apixaban to be 13.5 +/− 9.9 hours, or 15.2 +/− 8.5 hours after a single 5 mg dose and 11.7 +/− 3.3 after multiple 5 mg doses.[153–155] Maximum plasma concentration is affected by body weight, with higher concentrations of apixaban in subjects with low body weight. Plasma anti–factor Xa activity has shown a direct linear relationship with apixaban plasma concentration.[155]

Apixaban has an oral bioavailability of more than 45%.[153] After oral administration, it is eliminated via multiple elimination pathways as well as direct renal and intestinal excretion.[156] Twenty-four to 29 percent of the dose is excreted via the kidneys, and 56% of the dose is recovered in the feces.[153] More than half of apixaban is excreted unchanged, lessening the risk of metabolic drug–drug interactions.

Apixaban is effective in reducing stroke or systemic embolism without increasing the risk of bleeding. Apixaban is superior to warfarin in preventing stroke or systemic embolism in patients with atrial fibrillation.[76] Apixaban provides effective thromboprophylaxis in total knee arthroplasty, comparable to enoxaparin or warfarin.[157] Apixaban is equally efficacious with enoxaparin in preventing VTE after total knee replacement (TKR) while having a lower[158] or similar[159] rate of major bleeding. Apixaban is more effective than enoxaparin in preventing VTE after total hip replacement (THR) without increased bleeding.[160] In this trial, "devices in connection with intrathecal or epidural anesthesia were removed at least 5 hours before the first dose" of apixaban. In all studies of apixaban, the drug was started 12–24 hours after surgery.

Compared to rivaroxaban, apixaban has little effect on PT when given in approved doses.[114] The dilute PT assay has improved sensitivity over conventional PT. There appears to be a linear correlation between anti-Xa activity and the plasma concentrations of apixaban. The anti-Xa assay was noted to be more sensitive than the PT and as sensitive as the dilute PT assay[161] and appears to be the best choice for clinical monitoring of the anticoagulant effect of apixaban.[132] Activated charcoal, given within 3 hours of ingestion, reduces the absorption of apixaban.

Andexanet is a recombinant modified human factor Xa decoy protein that binds and sequesters factor Xa inhibitors. Studies in volunteers and in patients showed andexanet to reveres the anticoagulant activity of rivaroxaban and apixaban.[162] As of 2016, andexanet is not yet clinically available in the United States.

Summary of Recommendations for the New Anticoagulants

While a 2–3-half-life interval may be acceptable in patients who are at high risk for VTE or stroke, an interval of 4–6 half-lives between stoppage of the drug and neuraxial injection is probably safer in most patients at low risk of thrombosis. A 5-half-life interval in conjunction with an LMWH bridge therapy is an alternative in most patients, as shown in Table 52–2. After a neuraxial procedure or removal of an epidural catheter, the anticoagulant can be resumed 6 hours (8 hours minus the onset/peak effect of the drug, which is usually 2 hours) later. Anticoagulants are typically resumed within 24–48 hours in most patients, but they can be resumed sooner in patients who are at higher risk for VTE or stroke; that is, 24 hours minus the time to peak effect of the drug. Others recommended a 24-houir interval (Table 52–3).

TABLE 52-3. Recommended time intervals for resumption of drug after neuraxial procedure or catheter removal.

Drug	European Guidelines	Scandinavian Guidelines	Liew & Douketis (102); Connolly and Spyropoulos (98)
Dabigatran	6h	6h	24h
Rivaroxaban	4-6h	6h	24h
Apixaban	4-6h	6h	24h

The interval from the European and Scandinavian guidelines was based on 8 hours (time for the clot to stabilize) minus the time to peak onset of the drug.

Laboratory monitoring of the anticoagulant effect is appropriate in some situations, and reversal agents are suggested when there is a need to rapidly restore hemostatic function.

Clinical Pearls

- For the new anticoagulants, a 5-half-life interval between discontinuation of the drug and neuraxial procedure is recommended until there is more experience with these agents.
- An interval of either 8 or 24 hours-time to peak effect of the drug is recommended before the drug is resumed after catheter removal; a 24-hour interval is probably the safest.

CLINICAL FEATURES, DIAGNOSIS & MANAGEMENT OF EPIDURAL HEMATOMA

Patients who develop spinal hematoma usually present with sudden, severe, constant back pain with or without a radicular component. Percussion over the spine aggravates the pain as do maneuvers that increase intraspinal pressure, including coughing, sneezing, or straining. In addition, the return of the motor weakness and/or sensory deficit after the apparent resolution of the epidural or spinal blockade is highly suggestive of epidural or spinal hematoma formation. Motor and sensory findings depend entirely on the level and size of the hematoma but may include weakness, paresis, loss of bowel or bladder function, and virtually any sensory deficit. Magnetic resonance imaging (MRI) is the diagnostic study of choice. The differential diagnosis includes spinal abscess, epidural neoplasm, acute disk herniation, and spinal subarachnoid hemorrhage. Recovery without surgery is rare, and neurosurgical consultation for consideration of emergent decompressive laminectomy should be obtained as soon as spinal hematoma is suspected. Functional recovery is related primarily to the length of time the symptoms are present before surgery. The clinical features, diagnosis, differential diagnosis, and treatment of a patient with a spinal hematoma are discussed in more detail in Chapter 65.

SUMMARY

Practitioners should periodically update their knowledge base on new anticoagulant medications, anticoagulation protocols, current guideline recommendations, and FDA alerts. Since spinal hematoma may occur even in the absence of identifiable risk factors, vigilance in monitoring is critical for early evaluation of neurologic dysfunction and prompt intervention. The decision to perform neuraxial blockade and the timing of catheter removal in a patient receiving anticoagulant therapy should be made on an individual basis, weighing the benefits of regional anesthesia against the small, though definite, risk of spinal hematoma.

Anticoagulation & Peripheral Nerve Blocks

If appropriate, peripheral nerve blocks can be performed in patients taking anticoagulants. In contrast to neuraxial procedures in the presence of anticoagulants, there have been no prospective studies on peripheral nerve blocks in the presence of anticoagulants. The ASRA recommends the same guidelines for peripheral nerve blocks as for neuraxial procedures. Cases of psoas and retroperitoneal hematomas have been reported after lumbar plexus blocks and psoas compartment blocks.[13] These patients were either on enoxaparin, ticlopidine, or clopidogrel. In some cases, the hematoma occurred in spite of adherence to the ASRA guidelines.

The symptoms of hematoma formation after peripheral nerve block may include pain (flank or paravertebral pain, or groin pain in psoas bleeding), tenderness in the area, a steady decline in hemoglobin/hematocrit, hypotension due to hypovolemia, and sensory–motor deficit. Definite diagnosis is made by computerized tomography (CT); ultrasound can also be used to detect the presence of renal subcapsular hematoma after psoas compartment block. Treatment may include surgical consultation, reversal of anticoagulation, blood transfusion as necessary, and watchful waiting versus surgical drainage.

It is probably too restrictive to adapt the ASRA guidelines on neuraxial blocks to patients undergoing peripheral nerve blocks. The European Society of Anaesthesiology has noted that the guidelines for neuraxial block do not routinely apply to peripheral nerve blocks. The Austrian Society for Anesthesiology, Resuscitation and Intensive Care, on the other hand, has suggested that superficial nerve blocks can be safely performed in the presence of anticoagulants.[161] Because of the possibility of retroperitoneal hematoma, lumbar plexus and paravertebral blocks merit the same recommendations as for neuraxial injections. The same guidelines should also apply to visceral sympathetic blocks. The ASRA guidelines may therefore be applicable to blocks in vascular and noncompressible areas, such as celiac plexus blocks, superior hypogastric plexus blocks, and lumbar plexus blocks. Clinicians should individualize their decision and discuss the risks and benefits of the block with the patient and the surgeon. Most importantly, the clinician should follow the patient closely after the block placement.

Clinical Pearls

- The guidelines on neuraxial injections should also apply to lumbar plexus blocks and visceral sympathetic blocks.
- For superficial nerve blocks, ultrasound-guided regional nerve blocks can probably be performed in the presence of residual anticoagulation.

CHAPTER 53

Regional Analgesia in the Critically Ill

Sebastian Schulz-Stübner

INTRODUCTION

Intensive care specialists play increasingly greater role in the prevention and treatment of physiologic and psychological stress in critically ill patients[1–3] in order to prevent detrimental consequences ranging from systemic inflammatory response syndrome,[4] to cardiac complications,[5,6] to posttraumatic stress disorder.[7–9] Studies have addressed the questions of an optimal sedation regimen, and several evidence-based guidelines and strategies have been published but are frequently not followed.[10–14] The analgesic component for sufficient stress relief, however, has not been addressed extensively, and few recommendations, primarily based on individual clinical practices, are currently available.[15–17]

In view of the side effects of opioids, especially respiratory depression, altered mental status, and reduced bowel function, regional analgesia utilizing neuraxial and peripheral nerve blocks offer significant advantages. The lack of a universally reliable pain assessment tool ("analgesiometer") in the critically ill contributes to the dilemma of adequate analgesia. Many patients in the critical care unit are not able to communicate or use a conventional visual or numeric analog scale to quantify pain. Alternative assessment tools derived from pediatric[18–20] or geriatric[21] practice that rely on grimacing and other physiologic responses to painful stimuli might be useful but have been inadequately studied in the intensive care unit (ICU). Changes in heart rate and blood pressure in response to nursing activities, dressing changes, or wound care can also serve as indirect measurements of pain,[22] and sedation measures like the Ramsay Sedation Scale or the Riker Sedation-Agitation Scale[23,24] scale might be helpful although not specifically designed for pain assessment.

The objective of this chapter is to describe the indications, limitations, and practical aspects of continuous regional analgesic techniques in the critically ill based on the available evidence, which at the moment is limited to case reports, cohort studies, expert opinion, and extrapolation from studies looking primarily at the intraoperative use of regional anesthesia extending into the postoperative ICU stay as summarized in a 2012 systematic review in *Regional Anesthesia Pain Medicine* by Stundner and Memtsoudis who conclude, "Regional anesthesia can be useful in the management of a large variety of conditions and procedures in critically ill patients. Although the attributes of regional anesthetic techniques could feasibly affect outcomes, no conclusive evidence supporting this assumption exists to date, and further research is needed to elucidate this entity."[25]

EPIDURAL ANALGESIA

Epidural analgesia is probably the most commonly used regional analgesic technique in the ICU setting.[26] Some indications in which epidural analgesia may not improve mortality rates but may facilitate management and improve patient comfort in the ICU include chest trauma,[27–30] thoracic[31,32] and abdominal surgery,[5,33,34] major vascular surgery,[35,36] major orthopedic surgery,[37] acute pancreatitis,[38] paralytic ileus,[39–42] cardiac surgery,[43,44] and intractable angina pain.[45,46] Although high-risk patients seem to profit most from epidural analgesia,[47,48] the current literature does not address the specific circumstances of the critically ill patient with multiple comorbidities and organ failure. For that reason, an individual approach is necessary when considering the application of epidural analgesia in this population.[49]

In a survey of 216 general ICUs in England, Low[50] found that 89% of the responding units used epidural analgesia, but only 32% had a written policy governing its use. Although 68% of the responding units would not place an epidural catheter in a patient with positive blood cultures, only 52% considered culture-negative sepsis or systemic inflammatory response syndrome (SIRS) to be a contraindication. The majority of respondents did not list lack of consent or the need for anticoagulation after catheter placement as contraindications to the insertion an epidural catheter. Although the issues of consent, possible coagulopathy, and infection can be addressed rather easily in elective procedures, they become major problems in newly admitted patients; for example, those with multiple trauma or painful intraabdominal processes, especially acute pancreatitis. There is also controversy regarding the safety of placing epidural catheters in sedated patients,[51,52] and confirmation of a good catheter position can be difficult in the critically ill patient if sensory level testing is not reliable.

Positioning the patient for the procedure may be difficult depending on the underlying injury, the number and position of drains and catheters, and the presence of external fixation devices. Table 53–1 summarizes the indications, contraindications, and practical problems involved with the placement of epidural catheters.

The help of trained nursing staff is essential for good positioning and safe handling of tubes and catheters during the procedure. Maximum barrier precautions, similar to those used in the placement of central lines, should also be considered when placing epidural catheters in the critically ill. Tunneling the catheter should be considered to prevent dislocation and reduce the risk of catheter site infection.[53] To confirm the correct position of the epidural catheter, electrical stimulation during placement or a postplacement radiograph with a small amount of nonneurotoxic contrast medium may be beneficial.[54,55]

Bolus injections of long-acting local anesthetics, such as bupivacaine, ropivacaine, or levobupivacaine, or the discontinuation of continuous infusion as needed will allow neurologic assessment when necessary. Monitoring of motor-evoked potentials (MEPs) to the lower extremities and somatosensory-evoked potentials (SSEPs) of the tibial nerve may serve as indicators when the neurologic examination is doubtful due to the patient's altered mental status. Although routinely used in the operating room for monitoring spinal cord integrity and for the diagnosis and prognosis of spinal cord injury, the use of this technology in the ICU in the context of epidural analgesia has not been adequately assessed.

The most common side effects of epidural blocks are bradycardia and hypotension related to sympathetic block. Hemodynamic changes can be more pronounced with intermittent

TABLE 53–1. Epidural analgesia in the critically Ill.

Indications	Contraindications	Practical Problems	Dose Suggestions
Thoracic epidurals:			
Chest trauma	Coagulopathy or current use of anticoagulants during catheter placement and removal[61,62]	Positioning of patient	*Bolus regimen:*
Thoracic surgery		Monitoring of neurologic function (consider MEP/SSEP)	5–10 mL 0.125–0.25% bupivacaine or 0.1–0.2% ropivacaine q 8–12 h
Abdominal surgery			
Paralytic ileus			Consider addition of 1–2 mcg clonidine in hemodynamically stable patients
Pancreatitis	Sepsis/bacteremia		
Intractable angina	Local infection at puncture site		
Lumbar epidurals:			
Orthopedic surgery or trauma of lower extremities	Severe hypovolemia		*Continuous infusion:*
	Acute hemodynamic instability		0.0625% bupivacaine or 0.1% ropivacaine at 5 mL/h
Peripheral vascular disease of lower extremities	Obstructive ileus		Consider addition of opioids (eg, hydromorphone, sufentanil) or clonidine if high systemic opioid demands persist

MEP, motor-evoked potentials; SSEP, somatosensory-evoked potentials.

bolus dosing, in patients with hypovolemia, and in those with reduced venous return secondary to high positive end-expiratory pressure (PEEP) ventilation. Based on data from lumbar punctures and meningitis from the beginning of the twentieth century,[56] current sepsis and bacteremia are considered contraindications for intrathecal opioid applications and, by analogy, for the placement of an epidural catheter. However, many ICU patients, especially after trauma or major surgery, present with a clinical picture of SIRS. Fever and increased white blood cell counts alone, that is, in the absence of positive blood cultures, do not provide a reliable diagnosis of bacteremia. The combination of the serum markers C-reactive protein (CRP), procalcitonin, and interleukin-6, on the other hand, have been shown to indicate bacterial sepsis with a high degree of sensitivity and specificity[57–60] and can guide the decision to place an epidural catheter. Regarding the patient's coagulation status, the current recommendations of the American Society of Regional Anesthesia and Pain Medicine (ASRA)[61] should be followed. Adequate safety intervals during the administration of anticoagulant drugs are equally important for the placement and removal of epidural catheters.[62,63] Although there is no compelling evidence of an increased risk of epidural bleeding with developing coagulopathy or therapeutic anticoagulation while an epidural catheter is in place, the benefits of epidural analgesia should be weighed against this potential, highly detrimental complication. This risk might lead to an increasing utilization of paravertebral blocks, as described in a U.K. survey of elective thoracic surgery.[64] However, Luvet and colleagues have described a high misplacement rate of paravertebral catheters using the landmark technique and a discrepancy between contrast medium spread and loss of sensation,[65] which makes an assessment of the effectiveness of this technique in the sedated critically ill patient very difficult.

In a small cohort study of 153 thoracic and 4 lumbar epidurals in critically ill patients, we could not identify an increased complication risk compared to the reference databank. However, the duration of catheter use was significantly longer (mean 5 days, range 1–21 days) in the critically ill group.[66]

Clinical Pearls

- The most common side effects of epidural blocks are bradycardia and hypotension related to sympathetic block.
- Hemodynamic changes can be more pronounced with intermittent bolus dosing, in patients with hypovolemia, or in patients with reduced venous return secondary to high positive end-expiratory pressure ventilation.
- Discontinuation of continuous infusion allows neurologic assessment when necessary.
- There is no hard evidence that there is increased risks of epidural bleeding with developing coagulopathy or therapeutic anticoagulation while an epidural catheter is in place. Nevertheless, the benefits of epidural analgesia should be weighed against the risk of this serious complication.

PERIPHERAL NERVE BLOCKS FOR THE UPPER EXTREMITIES

There are currently no randomized, controlled trials or large prospective trials evaluating the use of peripheral nerve blocks for the upper extremity in critically ill patients. Nevertheless, severe trauma to the shoulder or arm is often part of multiple injuries due to traffic or workplace accidents, often in combination with blunt chest trauma requiring mechanical ventilation. These injuries can contribute to severe pain, especially during positioning of the patient. If the orthopedic injury is part of complex trauma including brain injury in which the mental status of the patient is altered and opioid-based analgesic regimens might mask the neurologic situation, sufficient analgesia can be achieved for the shoulder or upper limb with either continuous interscalene,[65–69] continuous cervical paravertebral,[69–72] or infraclavicular[73] approaches to the brachial plexus.

Particular concerns arise concerning the placement of regional blocks in ICU patients with impaired mental status due to neurologic injury or therapeutic sedation. Benumof reported a small series of serious complications, including spinal cord injury related to the interscalene approach, which may have been associated with sedation or general anesthesia.[74] His case descriptions relate to spinal cord injury in heavily sedated or anesthetized patients and not to injury of the peripheral nerves. Despite this, the performance of blocks anatomically close to the centroneuraxis can indeed carry a higher risk of spinal cord needle or injection injury. In sedated critically ill patients, a combination of ultrasound and nerve stimulation for the placement of interscalene catheters and a technique with a less medial needle direction[75,76] should help to minimize the risk of complications. Perhaps most importantly, such blocks should be performed only by clinicians with adequate experience. The unavoidable blocking of the phrenic nerve and the loss of hemidiaphragmatic function[77] should be considered while planning the intervention. Although phrenic nerve blockade has negligible effects in mechanically ventilated patients, it may impair weaning from mechanical ventilation in high-risk patients. Furthermore, the proximity of the insertion site of the interscalene catheter to a tracheostomy tube might increase the risk of infection, and careful, standardized monitoring of the puncture site is therefore needed. Positioning problems might limit the use of the cervical paravertebral approach, which provides good analgesia for the shoulder, arm, and hand.

The continuous infraclavicular[69,73,78–80] and axillary[69,81–83] approaches provide good analgesia for most of the arm, elbow, and hand. A bolus injection of local anesthetic through the catheter should be considered especially in patients who need surgical anesthesia for procedures such as painful dressing changes or debridements for burns or large soft tissue wounds in the affected area. A lateral infraclavicular approach[84–86] avoids the pneumothorax and allows better securing of the catheter, compared to more proximal approaches to brachial plexus block where the catheter is placed more superficially and the soft tissue is more movable.

Clinical Pearls

- In patients with altered mental status in whom opioid-based analgesic regimens might make neurologic evaluation difficult, excellent analgesia can be achieved for the shoulder or upper limb with continuous interscalene, cervical paravertebral, or infraclavicular approaches to the brachial plexus.
- Performance of blocks anatomically close to the centroneuraxis can carry a higher risk of spinal cord needle or injection injury. In heavily sedated critically ill patients, such blocks should be performed only by clinicians with adequate experience.
- An interscalene brachial plexus block results in the loss of hemidiaphragmatic function. Although phrenic nerve blockade has negligible effects in mechanically ventilated patients, it may impair weaning from mechanical ventilation in high-risk patients.
- Real-time ultrasound guidance for peripheral catheter placement might be especially beneficial in the sedated critically ill patient.

PERIPHERAL NERVE BLOCKS FOR THE LOWER EXTREMITIES

Femoral nerve catheters are helpful in the management of acute pain from femoral neck fractures in the period between injury to shortly after surgical stabilization of the fracture.[87,88] Skilled use of ultrasound[89] might limit the unavoidable pain associated with nerve stimulation in this situation, which otherwise can be treated with small doses of intravenous remifentanil (0.3–0.5 mcg/kg) or ketamine (0.2–0.4 mg/kg). A fascia iliaca compartment block[90,91] might be a technical alternative.

A continuous femoral catheter in combination with a sciatic block provides excellent pain relief for the whole leg and even surgical anesthesia for procedures like external fixation.[92] Whether an anterior[93] or posterior approach (midgluteal[94] or subgluteal[95] classical Labat approach with one or two injections[96]) to the sciatic nerve is chosen depends largely on the skills of the operator and the ability to adequately position the patient for the procedure. If a combination of catheter techniques is used, as is often needed for the lower extremity, the total daily dose of local anesthetic should be adjusted based on catheter location, admixtures like epinephrine, drug interactions, and disease states as summarized in a recent review by Rosenberg and coworkers.[97]

A bolus injection of long-lasting local anesthetics in combination with clonidine[98] or buprenorphine[99] may help to reduce the overall amount of local anesthetic needed and minimize the effects of local anesthetic toxicity, although research results on these adjuvants are equivocal at present.[100,101]

OTHER REGIONAL ANALGESIC TECHNIQUES

Celiac plexus blocks may provide excellent analgesia for pancreatitis and cancer-related upper abdominal pain, but technical difficulties in the critically ill (computed tomography [CT] guidance, fluoroscopy, or transgastric ultrasound) and the need for repeated injections limit their value for acutely critically ill patients.

Intrapleural catheters for pain control after chest trauma are of limited value secondary to concurrent drainage from chest tubes. The risk of pneumothorax limits their benefits for the management of pain after conventional cholecystectomy compared with the epidural or paravertebral technique in ventilated patients. Thoracic paravertebral catheters can be a valuable alternative to epidural catheters for the management of unilateral pain restricted to a few dermatomes (eg, rib fractures[102] or zoster neuralgia). Table 53–2 provides a summary of the most utilized continuous peripheral catheters.

Single-injection nerve blocks (eg, intercostal blocks for the placement of chest tubes), scalp blocks[103] for the placement of halo fixation, and sufficient local infiltration anesthesia for typical ICU procedures (eg, placement of arterial and central venous catheters, lumbar punctures, and ventriculostomies) are often forgotten, although they are easy and safe to perform. If EMLA cream is used for topical anesthesia, it needs to be applied 30–45 minutes before the procedure to achieve optimal effect.

Intrathecal morphine[104–107] injections as a single shot or via spinal catheter (microcatheters are currently not approved in the United States but are available in Europe) can be an alternative to epidural catheters, especially if only short-term use after surgery is anticipated.

SYSTEMIC EFFECTS & COMPLICATIONS OF LOCAL ANESTHETICS IN THE CRITICALLY ILL PATIENT

Local anesthetics have been shown to have several positive systemic effects (including analgesic, bronchodilatory, neuroprotective, anti-inflammatory, antiarrhythmic, and antithrombotic properties)[108] when given or absorbed in adequate quantities (the exact dose–response relationships are widely unknown). They also have negative effects, such as neurotoxicity (dose dependent), myotoxicity,[109,110] inhibition of wound healing, cardiotoxicity (dose dependent), and central nervous excitation or depression (dose dependent).[111]

To prevent local anesthetic systemic toxicity from accidental intravascular injection, a test dose of local anesthetic or saline with 1:200,000 epinephrine can be used with catheter placement, but the sensitivity of heart rate, blood pressure increase, and T-wave changes[108] might be altered in ICU patients, especially those treated with beta-blockade and α_2-agonists or catecholamines. Careful aspiration to check for blood return should be performed before each bolus injection.

Most studies examining plasma levels of local anesthetics were not performed in critically ill patients. Scott and colleagues described the safe use of epidural ropivacaine 0.2% for 72 hours with plasma levels far below the toxic threshold,[112] and Gottschalk and associates observed safe plasma levels after 96 hours in patients treated with thoracic epidural ropivacaine 0.375%, indicating no significant accumulation over time.[113]

A lipid resuscitation protocol[114] should be in place and part of the regular resuscitation drills in the ICU, where

TABLE 53–2. Continuous peripheral nerve blocks in the critically Ill.

Block	Indications	Contraindications	Practical Problems	Dose Suggestions
Interscalene	Shoulder/arm pain	Untreated contralateral pneumothorax	Horner syndrome may obscure neurologic assessment	*Bolus regimen:*[a]
				10 mL 0.25% bupivacaine or 0.2% ropivacaine q 8–12 h and on demand
		Dependence on diaphragmatic breathing	Block of ipsilateral phrenic nerve	
		Contralateral vocal cord palsy	Close proximity to tracheostomy and jugular vein line sites	*Continuous infusion:*
				0.125% bupivacaine or 0.1–0.2% ropivacaine at 5 mL/h
		Local infection at puncture site		
Cervical paravertebral	Shoulder/elbow/wrist pain	Severe coagulopathy	Horner syndrome may obscure neurologic assessment	*Bolus regimen:*[a]
		Dependence on diaphragmatic breathing		10 mL 0.25% bupivacaine or 0.2% ropivacaine q 8–12 h and on demand
		Contralateral vocal cord palsy	Block of ipsilateral phrenic nerve	*Continuous infusion:*
		Local infection at puncture site	Patient positioning	0.125% bupivacaine or 0.1–0.2% ropivacaine at 5 mL/h
Infraclavicular	Arm/hand pain	Severe coagulopathy	Pneumothorax risk	*Bolus regimen:*[a]
		Untreated contralateral pneumothorax	Steep angle for catheter placement	10–20 mL 0.25% bupivacaine or 0.2% ropivacaine q 8–12 h and on demand
		Local infection at puncture site	Interference with subclavian lines	*Continuous infusion:*
				0.125% bupivacaine or 0.1–0.2% ropivacaine at 5–10 mL/h
Axillary	Arm/hand pain	Local infection at puncture site	Arm positioning	*Bolus regimen:*[a]
			Catheter maintenance	10–20 mL 0.25% bupivacaine or 0.2% ropivacaine q 8–12 h and on demand
				Continuous infusion:
				0.125% bupivacaine or 0.1–0.2% ropivacaine at 5–10 mL/h

(*continued*)

TABLE 53–2. Continuous peripheral nerve blocks in the critically Ill. (*Continued*)

Block	Indications	Contraindications	Practical Problems	Dose Suggestions
Paravertebral Thoracic Lumbar	Unilateral chest or abdominal pain restricted to few dermatomes	Severe coagulopathy	Patient positioning	*Bolus regimen:*[a]
		Untreated contralateral pneumothorax	Stimulation success sometimes hard to visualize	10–20 mL 0.25% bupivacaine or 0.2% ropivacaine q 8–12 h and on demand
		Local infection at puncture site		
				Continuous infusion:
				0.125% bupivacaine or 0.1–0.2% ropivacaine at 5–10 mL/h
Femoral or sciatic	Unilateral leg pain	Severe coagulopathy	Patient positioning	*Bolus regimen:*[a]
		Local infection at puncture site	Interference of femoral nerve catheters with femoral lines	10 mL 0.25% bupivacaine or 0.2% ropivacaine q 8–12 h and on demand
				Continuous infusion:
				0.125% bupivacaine or 0.1–0.2% ropivacaine at 5 mL/h

[a]Consider addition of 50–100 mcg clonidine in hemodynamically stable patient or 150–300 mcg buprenorphine[99,125] to each bolus dose q 12–24 h to prolong duration of action.

practitioners are often not as familiar with this topic as are operating room (OR) anesthesiologists but have easy access to the required quantities of lipid emulsion.

GENERAL MANAGEMENT ASPECTS OF CONTINUOUS REGIONAL ANALGESIA CATHETERS IN CRITICALLY ILL PATIENTS

In general, given the lack of cooperation and communication in many ICU patients, regional analgesia techniques using continuous catheters in the ICU require a higher level of vigilance than needed for regular ward patients. Close cooperation between the ICU team and the acute pain or anesthesia service of the hospital is required.

Critical care nursing personnel should be specifically trained in handling regional analgesia catheters and must be aware of the potential complications and their early warning signs. Because of the frequently large and confusing numbers of various infusion catheters in critically ill patients, the risk of drug errors and incorrect administration of drugs through continuous regional analgesia catheters may be higher in these patients. Well-trained and highly qualified personnel are the best safeguard against these complications aside from eye-catching labels, standardized care protocols, and perhaps specially designed connectors for those catheters.

Comprehensive diagnostic approaches, including magnetic resonance imaging (MRI) or CT, should be undertaken when there are clinical signs of possible bleeding complications (eg, suspected epidural or retroperitoneal hematoma). Structured observations of catheters for infectious complications and careful adherence to aseptic technique during catheter placement and tunneling, as well as the possible use of antibiotic-coated catheters in the future, may reduce possible infectious complications. Catheters should not be removed routinely after certain time intervals but only when clinical signs of infection appear.

A study by Langevin[115] suggests that if catheters become disconnected when the fluid in the catheter is static, the proximal 25 centimeters of the catheter may be immersed in a disinfectant, cut, and reconnected to a sterile connector. This technique is feasible only for catheters in which the fluid column can be observed. Stimulating catheters should never be cut because of the danger of unwinding the internal metal spiral wire, which conducts electrical current. No study has examined the risk of reconnecting these catheters after thorough disinfection of the outer surface, which is likely a common practice in many institutions. Cuvillon and colleagues[116] reported a high overall incidence of colonization (57%) of femoral catheters without septic complications. Therefore, the decision to reconnect or remove the catheter must be made on a case-by-case basis and based on the specific clinical circumstances. The overall risk of permanent neurologic damage (from direct trauma, bleeding, or serious infection) or death from regional anesthesia and analgesia seems to be low in the perioperative setting, as shown by large surveys by Auroy and coworkers[117,118] and Moen and associates.[119] Although both studies certainly include critically ill patients, there are no specific subgroup data available.

If the patient is cooperative enough, a patient-controlled regional anesthesia (PCRA) regimen is preferable,[120] and such systems can also be used in a nurse-controlled fashion for intermittent bolus application without the need for additional manipulation of the infusion system.

While the evidence for the overall improvement of patient safety using ultrasound-guided regional anesthesia (UGRA) placement techniques is limited[121] and a certain level of training necessary,[122] the use of ultrasound seems to be especially beneficial in the critically ill patient. In a semiquantitative review, Morin and coworkers demonstrated better analgesia with the use of stimulating catheters, which seem to be another instrument to improve the effectiveness of regional analgesia in the critically ill.[123]

The complexity of individual clinical situations can be demonstrated by the following case example:[124]

> A 55-year-old male patient with polycythemia vera, treated with periodic phlebotomy and a history of lower extremity DVTs [deep venous thromboses], was admitted to the hospital with acute ischemia of all 5 fingers of his right hand. His INR [international normalized ratio] on admission was 2.5. His fingers were cold and painful and showed bluish discoloration. The patient was evaluated by vascular surgeons and an angiogram showed arterial thrombosis of the right hand and rtPA [recombinant tissue plasminogen activator] thrombolysis was started by an indwelling catheter from the right femoral artery to the right subclavian artery. The patient was admitted to the Surgical Intensive Care Unit for monitoring during TPA [tissue plasminogen activator]-thrombolysis. Overnight, no significant improvement in limb perfusion could be seen and the patient underwent re-angiography on postoperative day 1. Given the amount of residual thrombosis, rtPA-treatment was continued. Overnight, on postoperative day 1, the patient became disoriented after receiving a single dose of meperidine in addition to his morphine PCA [patient-controlled analgesia] for worsening pain in his arm. A CT scan performed at that time to exclude an acute bleeding complication was read as normal and his neurologic status returned to baseline. rtPA treatment was discontinued after 48 hours on postoperative day 2, and the catheter was removed. A heparin infusion was titrated to a PTT [partial thromboplastin time] around 70 seconds. Around midnight the patient became agitated and disoriented. Another head CT was performed which showed left cerebellum hypodensity and the patient became more and more unresponsive. Brain MRI revealed multiple infarcts involving the left cerebellum, the right cerebellum, the bilateral thalami and the left medial temporal occipital region. MRA [magnetic resonance angiogram] showed left vertebral artery thrombosis. The patient was treated symptomatically with small doses of haloperidol and the heparin infusion was discontinued by the neurologist's recommendation to prevent hemorrhagic transformation of the cerebellar infarcts. In the morning, the patient was still somnolent but complained about severe pain in his right arm when aroused. Also, the discoloration of his fingers was slowly progressing proximally and the distal parts were cold and numb. The patient also described a burning sensation in addition to the sharp and shooting pain. Morphine PCA and systemic narcotics had been discontinued secondary to his worsened neurostatus. 18 hours after discontinuation of rtPA and 9 hours after discontinuation of the heparin infusion his fibrinogen levels were still markedly elevated but his INR and PTT had returned to high normal values. An axillary brachial plexus catheter was placed using the stimulating catheter (Stimucath®, Arrow International, Reading, USA) and a good motor response with hand extension and thumb adduction at 0.44 mA was elicited via the indwelling catheter after ultrasound guided advancement of the catheter. A bolus of 20 mL of mepivacaine 1.5 percent and 20 mL of ropivacaine 0.75 percent were injected through the catheter and resulted in pain relief after 10 minutes. The skin temperature in the affected hand rose from 34.5 degrees Celsius to 36 degrees Celsius 30 minutes after injection of the local anesthetic. Ultrasound guidance was used for the placement of the axillary catheter to avoid accidental puncture of the axillary artery or vein 4. The catheter was tunneled to prevent dislocation and there was mild oozing at the tunnel site but no hematoma formation. A cerebral angiogram was performed and showed left vertebral artery thrombosis and a patent right vertebral artery. Lower extremity duplex sonography showed extensive subacute deep venous thrombosis bilaterally and an inferior vena cava filter was placed. Transthoracic echo and transesophageal echo showed a small PFO [patent foramen ovale] with minimal right to left shunt with Valsalva maneuver. The axillary catheter was bolused with 10 mL of 0.5 percent ropivacaine every 8 hours. This regimen allowed consistent pain relief and sympathetic block. Finger cyanosis was improving rapidly. With improved neurostatus, the patient was also started on gabapentin 900 mg every 8 hours, 325 mg of aspirin and codeine tablets PRN. The hematologist recommended enoxaparin 100 mg sc q 12 hours for the treatment of his hypercoagulable state. The axillary catheter was removed after 5 days immediately before his evening dose of enoxaparin. No bleeding complications were observed. His neurological status as well as the finger ischemia continued to improve.

SUMMARY

Regional analgesia, whether utilizing single-injection regional blocks or continuous neuraxial or peripheral catheters, can play a valuable role in a multimodal approach to pain management in the critically ill patient to achieve optimum patient comfort and to reduce physiologic and psychological stress. By avoiding high systemic doses of opioids, several complications, such as withdrawal syndrome, delirium, mental status changes, and gastrointestinal dysfunction, can be reduced or minimized. Because of the limited patient cooperation that is common during the placement and monitoring of continuous regional analgesia in the critically ill, indications for its use must be carefully based on anatomy, clinical features of pain, coagulation status, and logistic circumstances. Highly trained nursing personnel and well-trained physicians are essential prerequisites for the safe use of these techniques in the critical care environment. These recommendations are based on small series, uncontrolled trials, and extrapolations from controlled trials in the perioperative setting; further research on the use of regional analgesia techniques in the critically ill is needed before definitive guidelines can be established.

CHAPTER 54

Acute Pain Management in the Opioid-Dependent Patient

Lisa Doan, Joseph Largi, Lynn Choi, and Christopher Gharibo

INTRODUCTION

Opioid use is increasing worldwide leading to an increasing amount of opioid-tolerant patients who may require acute pain management. Pain in this patient population is often poorly understood and therefore may be inadequately treated. The main goals in treating acute pain in opioid-tolerant patients are providing effective pain relief and minimizing withdrawal symptoms. Other challenges include assisting with social issues, poor coping, and psychiatric issues. This chapter discusses important factors to consider when treating acute pain in opioid-dependent patients.

DEFINITIONS

Tolerance

Tolerance is a physiologic adaptation in which increasing amount of a drug is required to achieve the same pharmacologic effects after prolonged use. Tolerance develops to most effects of opioids, including analgesia, euphoria, sedation, respiratory depression, and nausea; however, tolerance does not develop to miosis or constipation.[1]

Withdrawal

Withdrawal refers to physiologic symptoms resulting from the abrupt discontinuation of chronically administered opioids. Although withdrawal from opioids is rarely life threatening, it can be very uncomfortable. The symptoms of opioid withdrawal include abdominal cramps, anxiety, diarrhea, disturbed sleep, irritability, dysphoria, nausea and vomiting, rhinorrhea, urinary frequency, twitching, lacrimation, and increased muscle spasms.

Clinical Pearl

- The symptoms of opioid withdrawal include abdominal cramps, anxiety, diarrhea, disturbed sleep, irritability, dysphoria, nausea and vomiting, rhinorrhea, urinary frequency, twitching, lacrimation, and increased muscle spasms.

The onset and time course of opioid withdrawal are determined by the half-life of the drug (Figure 54–1). Withdrawal symptoms of short-acting opioids such as heroin and morphine typically begin more rapidly than long-acting agonist opioids such as methadone. Symptoms of withdrawal with short-acting opioids start 6–24 hours after the last dose, peak at 24–48 hours, and resolve within 5–10 days. Methadone is a long-acting opioid agonist; its withdrawal symptoms emerge 36–48 hours after the last dose. Some low-grade symptoms of withdrawal may linger for 3–6 weeks after last use due to its long half-life.[2]

Clinical Pearls

- Withdrawal symptoms may develop in opioid-tolerant patients if their usual dose of opioids is stopped, reduced too quickly, or the effect of the opioid is reversed by an antagonist such as naloxone.
- Withdrawal symptoms can occur even with small decreases (10%–15%) in opioid dosing and can manifest as myalgias and arthralgias in addition to return of the pain.

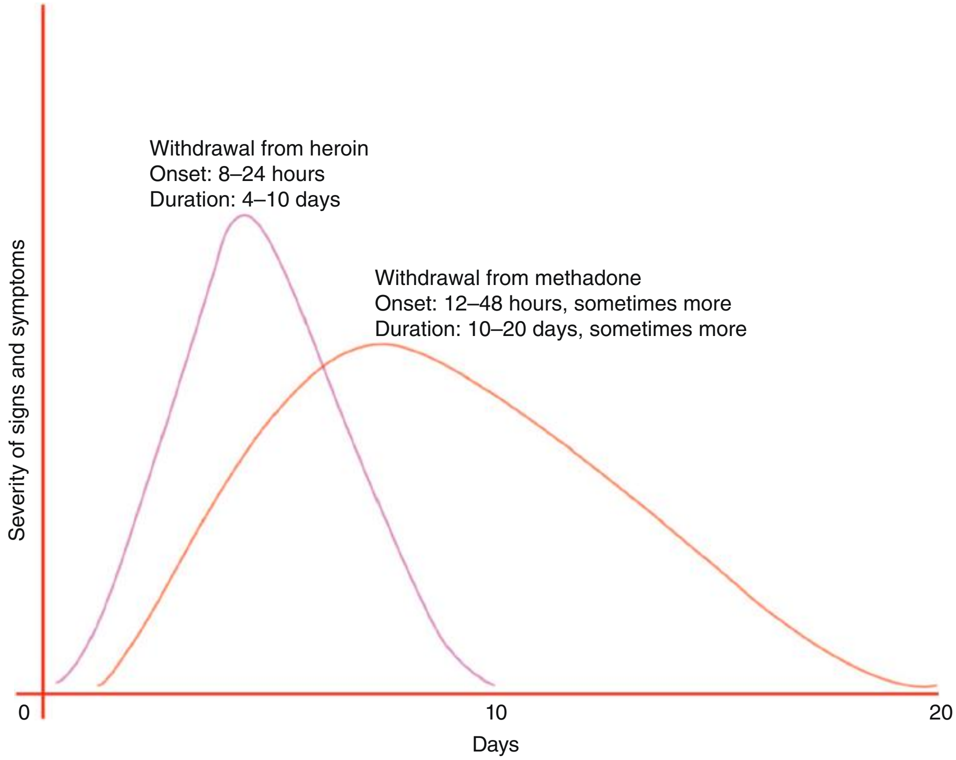

FIGURE 54–1. Symptoms and duration of heroin and methadone withdrawal.

Substance Abuse and Dependence

Before the release of the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders in 2013, substance abuse and dependence were considered two separate disorders. They are now considered to be a single disorder measured on a continuum from mild to severe. Substance abuse and dependence are now recognized as the recurrent maladaptive use of a substance that leads to clinically significant impairment or distress personally, professionally, or socially.[3] Physical dependence is recognized as a state of adaption manifested by withdrawal symptoms that can be elicited by abrupt discontinuation, rapid dose reduction, or the administration of an antagonist.[4]

Addiction

Addiction is defined as the continued use of a substance despite adverse consequences. It is a behavioral syndrome characterized by evidence of psychological dependence or craving, use despite harmful adverse effects, and other drug-related aberrant behavior (eg, altering prescriptions, drug hoarding or sales, unsanctioned dose escalation).

Maintenance

Maintenance therapy aims to prevent the craving and withdrawal symptoms of opioid-dependent individuals by substituting substances with long-acting and less euphoric opioids such as methadone and buprenorphine.[5] The goals of treatment are to achieve a stable maintenance dose of opioid agonist and mitigate withdrawal symptoms.

TYPES OF OPIOID-TOLERANT PATIENTS

Anesthesiologists and pain medicine specialists often encounter patients who are opioid dependent. The majority of this patient population have chronic pain conditions and have been using opioid analgesics for a prolonged period of time. The chronic pain can be a result of cancer or a nonmalignant process. The use of opioids in the management of cancer pain has been widely accepted.[6] The estimated cancer prevalence in the United States was over 12 million in 2009.[7] It is estimated that 20%–50% of cancer patients experience pain as a presenting symptom and that up to 90% experience pain in the advanced stages of disease.[8] The estimated prevalence of chronic noncancer pain is predicted to increase as the population ages. The use of opioids in chronic noncancer pain has become increasingly common, and guidelines have been set forth by the American Pain Society, the American Academy of Pain Medicine, and the American Society of Interventional Pain Physicians for this purpose.[9,10] However, evidence for the efficacy of long-term opioid use in noncancer pain has been inconclusive. With the increasing awareness of the potential adverse consequences of long-term opioid use, a "universal precautions" approach with appropriate risk assessment and management has been recommended. This approach includes proper diagnosis for the etiology of pain; informed consent; the use of treatment agreements; assessment of analgesia, activity, adverse effects, and aberrant behavior; and careful documentation.[11]

The smaller portion of the opioid-dependent population includes opioid abusers. Heroin is the most common illicit opioid that is abused, although its use has plateaued over the past 10 years. However, prescription opioids are increasingly being abused. Prescription opioid sales quadrupled between 1999 and 2010.[12] In 2010, the number of Americans reporting nonmedical use of prescription opioids reached 12 million.[13] Since 2003, more deaths due to opioid overdose have involved prescription opioid analgesics than heroin and cocaine combined.[14] Further complicating the picture is that opioid abuse and misuse may also be seen in patients prescribed opioids for chronic pain. In a review examining the prevalence of addiction in chronic pain patients, prevalence varied from 0%–31%.[15] Patients with a past history of opioid abuse in methadone or buprenorphine opioid treatment programs compose another subpopulation of opioid-dependent patients who may need acute pain management.

Pain is prevalent in patients with a history of opioid abuse. In studies of patients receiving methadone maintenance treatment, 61% report chronic pain, and 37% report severe chronic pain.[16,17] Increased reports of pain may occur as a result of opioid-induced hyperalgesia (OIH), which occurs when the long-term use of opioids causes a hypersensitivity to painful stimuli.[18]

TOLERANCE AND OPIOID-INDUCED HYPERALGESIA MECHANISMS

Tolerance can develop after the prolonged use of opioids. It is a phenomenon that is described as a decrease in the effect of a drug after repeated administration, which can be overcome by increasing the dose of the drug. OIH is a mechanism by which the analgesic properties of a drug are decreased secondary to increased pain sensitivity. As a result of OIH and tolerance, opioid-dependent patients may have a lower pain threshold and require higher doses of opioids to achieve adequate pain relief. It is important to recognize that while OIH and tolerance are distinctly different processes, they are related and have overlapping mechanisms. While tolerance causes a rightward shift in the dose-response curve, OIH leads to a downward shift in the dose-response curve (Figure 54–2).

Clinical Pearl

- The initial clinical strategy for the treatment of tolerance and OIH are similar: regional anesthesia techniques, optimize nonopioids, control withdrawal, and adjust opioid doses.

OIH should be suspected when the effect of opioids seems to decrease in the absence of disease progression, especially if found in the context of diffuse allodynia unrelated to the original pain or increased levels of pain with increasing opioid requirements.[19] The precise molecular mechanisms underlying tolerance and OIH are not fully understood and are still being

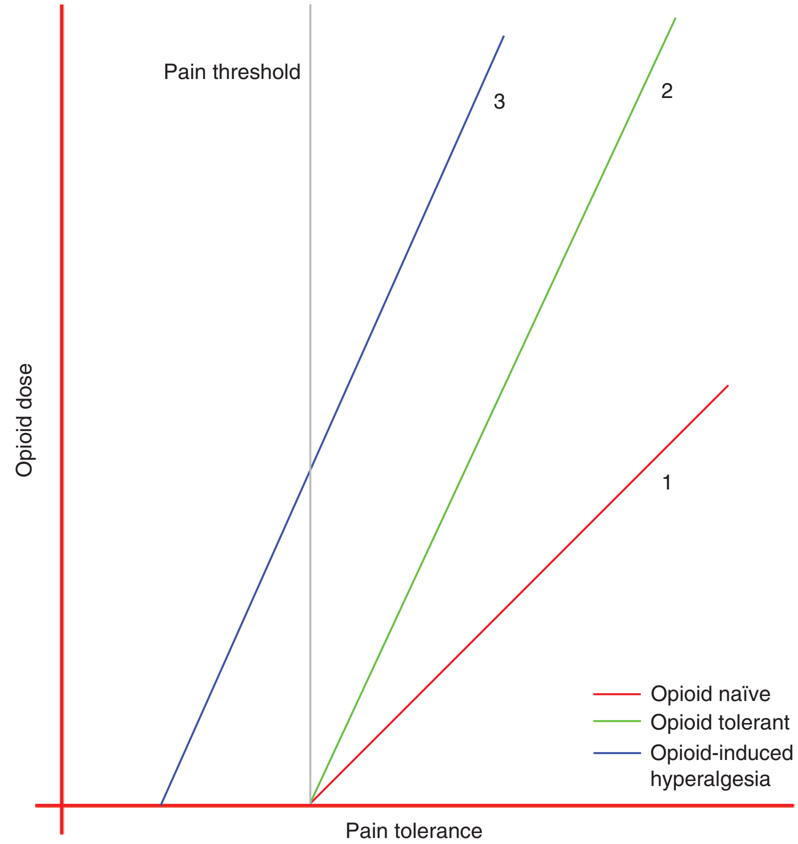

FIGURE 54–2. In opioid-naïve patients, increasing the opioid dose results in increased analgesia (1). In opioid-tolerant patients, the baseline threshold remains the same, but an increased dose of opioid is required to reach the same analgesic effect (2). Note that in opioid-induced hyperalgesia, maximal analgesic effect is not reached, baseline pain tolerance is reduced, and there is a downward shift from the opioid-tolerant patient (3).

investigated. Tolerance is classically thought to be due to the downregulation of opioid receptors. However, other mechanisms likely play a role, as well, such as adaptations downstream of receptor activation.[20] OIH has many proposed mechanisms, including those involving the central glutaminergic system, spinal dynorphins, descending facilitation, genetic mechanisms, and enhanced nociceptive responses.[21]

The Glutaminergic System

Current data suggest that the most likely molecular mechanism of OIH involves the central glutaminergic system. The main mechanisms by which opioids trigger the glutaminergic system involve the activation of N-methyl-D-aspartate (NMDA) receptors, which are glutamate receptors; the inhibition of glutamate reuptake; and the activation of protein kinase C.[22] Animal studies have shown that the coadministration of ketamine, an NMDA receptor antagonist, with morphine reduces analgesic tolerance as well as the development of OIH after the cessation of systemic or intrathecal morphine administration.[23] Similarly, human studies have found that the administration of ketamine attenuated remifentanil induced OIH as measured by intradermal electrical stimulation. Low-dose ketamine has been reported to prevent remifentanil-induced postoperative hyperalgesia in humans.[24]

Spinal Dynorphins

Spinal dynorphins are endogenous opioid peptides that are modulators of the pain response. It has been shown that levels of spinal dynorphin are increased with continuous infusions of opioids.[25] These increases are associated with hyperalgesia that can be reversed with dynorphin antiserum.

Descending Facilitation

Another proposed mechanism of the development of OIH is the facilitation of descending pathways from the rostral ventromedial medulla. The rostral ventromedial medulla has both descending inhibitory and excitatory projections to the spinal cord. The subset of excitatory neurons that facilitate nociceptive processing has been shown to be involved in OIH.[26]

Enhanced Nociceptive Responses

Another proposed mechanism of OIH is a decrease in the reuptake of neurotransmitters from the primary afferent fibers and enhanced responsiveness of spinal neurons to nociceptive neurotransmitters, such as substance P and glutamate. Morphine administration over several days has been shown to increase substance P and the expression of its receptor, the NK-1 receptor, in the spinal cord.[27]

Genetic Contributions

Many studies have supported the conclusion that genetic influences play a crucial role in pain sensitivity and analgesic response and therefore also in OIH.

ACUTE PAIN MANAGEMENT OF THE OPIOID-DEPENDENT PATIENT

Despite opioid tolerance and/or dependence, effective pain management during the perioperative period is an achievable goal by treating acute pain aggressively with nonopioid and opioid medications and by using nonpharmacological modalities and early mobilization.

Preoperative Assessment and Management

Clinical Pearls

- Opioid-tolerant patients can often be identified during preoperative assessment.
- In some patients, tolerance may not become evident until a diminished response to intraoperative opioids is noted or when postoperative pain control becomes challenging.
- Patients with chronic pain on opioids and other centrally acting analgesics should be advised to continue taking their medications as prescribed, including on the morning of surgery.

A crucial first step in the management of the perioperative pain in opioid-dependent patients is identifying the extent of opioid tolerance in a given patient. In some patients, the diagnosis can be made by the preoperative assessment, whereas in others, tolerance may not become evident until a diminished response to intraoperative opioids is noted or when postoperative pain control is found to be difficult. Some patients may be willing to divulge their opioid use or abuse history, whereas others may be reluctant due to a distrust of the medical community and concern of discrimination by being labeled a drug seeker by medical staff. Therefore, it is important that the provider begin to gain the patient's trust from the first meeting with the patient. A clue in the patient's history that may indicate possible opioid tolerance and dependence is the abuse of nonopioid substances. Patients who abuse other substances, such as alcohol, marijuana, or nicotine, are more likely to have opioid dependence than the general population.[28] When deception is suspected, the provider can administer a urine toxicology screen, which, in addition to screening for opioids, will also screen for other drugs of abuse, which can aid in the management of the patient.[29] The provider should provide reassurance that acute pain management is realistic and to make sure that both the patient and the medical team are working towards a common goal. The provider should also be careful to maintain privacy and confidentiality in an attempt to build trust. The plan for the patient should be discussed in a nonjudgmental manner. In addition to the usual preoperative assessment, certain additional information should be obtained from the opioid-dependent patient. This includes the documentation of all medications and their doses. This is especially important when trying to provide adequate postoperative analgesia and to prevent withdrawal from opioids or other medications. These medications and doses should be confirmed with the original provider of the prescriptions, the patient's pharmacy, and, when applicable, the patient's methadone clinic.

Clinical Pearls

- Provide reassurance that acute pain management is realistic.
- Maintain privacy and confidentiality, and build trust.
- Discuss the plan in a nonjudgmental manner.
- Document all medications the patient is taking, along with the medication doses
- Confirm medications and doses with the original provider.
- Keep in mind the psychosocial aspect of pain; pain is often compounded by anxiety and depression.
- Continue antidepressant and anti-anxiety medications perioperatively.
- Avoid naltrexone and naloxone in the perioperative period.
- Advise continuation of pain medications as prescribed, including the morning of surgery.

It is important to remember that patients who are being treated for chronic pain often exhibit poor coping and have a psychosocial aspect to their pain that is compounded by anxiety and depression. For this reason, antidepressants and anti-anxiety medications should be continued during the perioperative period. In patients with opioid abuse, it is also important to note that the perioperative period is not an optimal time to detoxify the patient. Opioid antagonists such as naltrexone and naloxone are not advised in the perioperative period for an opioid-dependent patient. The postoperative administration of these drugs can bring upon withdrawal symptoms in this patient population, which may place the patient at medical risk, especially in the presence of comorbidities. If the administration of an opioid antagonist is needed for respiratory depression, it should be administered carefully in titrated doses.

Patients with chronic pain on opioids should be advised to continue taking their medications as prescribed, including on the morning of surgery. Strong consideration can be given to preoperative dosing with nonsteroidal anti-inflammatory drugs (NSAIDs) such as celecoxib, intravenous acetaminophen, or anticonvulsants on the morning of surgery.

Patients with a history of opioid abuse may be in opioid treatment programs using methadone or buprenorphine. It is important for providers to understand that maintenance opioids typically have no analgesic effect at their prescribed dosages, likely because of tolerance or OIH; therefore, in most cases, the maintenance dose should be continued. Methadone and buprenorphine, in addition to being used for the treatment of opioid abuse, may also be used in the treatment of pain and are discussed below.

Clinical Pearls

- Patients on methadone maintenance should continue their verified methadone dose throughout hospitalization.
- The treatment of acute pain can be challenging in patients treated for opioid dependence with buprenorphine. Because of its long half-life and high affinity for the mu-opioid receptor, buprenorphine competes with other opioids attempting to bind to opioid receptors, thus preventing appropriate analgesia. Therefore, options include stopping buprenorphine or switching to another opioid before surgery.

Methadone

Methadone is a long-acting opioid agonist that also has activity as an NMDA antagonist. Methadone is the most commonly used medication to treat opioid addiction. The half-life of methadone is long and variable, ranging from 12–28 hours.[30] Methadone has a biphasic elimination curve with a rapid alpha-elimination phase followed by a much longer beta-elimination phase. Thus, for maintenance treatment of opioid addiction, the use of methadone once daily prevents withdrawal. However, the analgesic effects of methadone require more frequent dosing.[31] Due to methadone's properties as an NMDA antagonist, it may reduce opioid tolerance and OIH.

Methadone has certain pharmacological characteristics that require precautions with its use. Methadone is metabolized by the cytochrome P450 enzyme, primarily CYP3A4 and CYP2B6, in the liver. Because of its P450 metabolism, methadone has many drug interactions. For example, the use of P450 inducers (eg, phenytoin, rifampin), antiretrovirals (eg, efavirenz), and P450 inhibitors (eg, azole-based antifungals) will each result in a different methadone metabolism, thus affecting plasma levels and therapeutic effect. With inhibitors of methadone metabolism, side effects such as sedation and respiratory depression can also occur.[30]

Clinical Pearls

- Methadone is metabolized by the cytochrome P450 enzyme.
- Because of its P450 metabolism, methadone has many drug interactions.
- The use of P450-inducing medications such as phenytoin, rifampin, and antiretrovirals (eg, efavirenz or P450 inhibitors such as azole-based antifungals) affect the plasma level and therapeutic effect of methadone.

Methadone may prolong the QT interval, which can lead to fatal cardiac arrhythmias. Caution should be used when methadone is combined with other drugs that may also prolong the QT interval. Caution should be exercised when switching from one opioid to methadone, because the pharmacokinetics of methadone can vary greatly from person to person, potentially leading to overdose if the conversion results in greater than expected potency of methadone. Patients being switched from higher doses of opioids to methadone seem to be at greater risk for toxicity.[32] Due to the variable pharmacokinetics of methadone, consultation with a pain medicine specialist should be considered when the use of methadone is contemplated.

Patients on methadone maintenance with acute pain should continue their verified methadone dose and be prescribed multimodal analgesia, likely including short-acting opioids to treat the incident pain.

Buprenorphine

Buprenorphine is a partial mu-opioid agonist. For the treatment of opioid addiction, buprenorphine comes in tablets that are taken sublingually, formulated either with buprenorphine alone or combined with naloxone. Transdermal buprenorphine is indicated for the management of moderate to severe chronic pain. Buprenorphine has a long half-life of approximately 37 hours. Thus, for the treatment of addiction it can be used once daily. The transdermal formulation offered in the U.S. is meant to be changed every 7 days. Buprenorphine is also metabolized by the hepatic cytochrome P450 system, primarily CYP3A4 and CYP2B6. It may also be associated with a prolongation of the QT interval.[30] Buprenorphine has great affinity for the mu-opioid receptor, approximately 1000 times that of morphine.[33] For that reason, it may precipitate withdrawal in patients already on opioids because its high receptor affinity displaces other opioids. However, in a patient who has stopped using opioids and is in withdrawal, buprenorphine will ease symptoms of withdrawal through its partial agonist effect.[30] In the U.S., buprenorphine can be prescribed at a physician's office for opioid addiction treatment, which differs from methadone, which requires a specific methadone clinic to oversee prescription and distribution.

The treatment of acute pain can be challenging in a patient on buprenorphine with a history of opioid dependence. Because of its long half-life and high affinity for the mu-opioid receptor, buprenorphine competes with other opioids attempting to bind to opioid receptors, thus interfering with analgesia. For patients on buprenorphine maintenance, there are several treatment options to consider. One option is to continue buprenorphine and add additional short-acting opioids for the acute pain. It may take larger than normal doses of short-acting opioids to provide adequate analgesia. Another option is to divide the dose of buprenorphine and administer it every 6–8 hours in an attempt to utilize its analgesic properties; additional opioids may still be required to provide adequate analgesia. A further option is to discontinue the buprenorphine altogether several days before the surgery and then restart it when the patient no longer requires opioid management for acute pain. Alternatively, buprenorphine can be converted to methadone, and short-acting opioids can be titrated for the treatment of the acute pain.[34]

Clinical Pearl

Treatment options for patients on buprenorphine maintenance:

- Continue buprenorphine maintenance, and add a short-acting opioid for acute pain.
- Larger-than-normal doses of a short-acting opioid may be required for adequate analgesia.
- Consider dividing buprenorphine doses q6–8 h to optimize its analgesic properties and adding a short-acting opioid as needed.
- Consider discontinuing buprenorphine several days preoperatively and restarting postoperatively.
- Consider switching from buprenorphine to methadone perioperatively.

INTRAOPERATIVE MANAGEMENT

Clinical Pearls

- Respiratory rate can be used as a guide for titrating opioids intraoperatively.
- Opioid tolerant patients may be at an increased risk of awareness.

A multimodal approach for pain control including regional techniques and nonopioid analgesics should be considered for opioid-dependent patients. This plan ideally should be initiated preoperatively and followed throughout the perioperative period. Regional techniques and nonopioid analgesics are described in further detail in the section on postoperative care.

Patients who are opioid dependent should continue their baseline opioid dose during the perioperative period prior to the induction of anesthesia with additional analgesics provided as needed. Baseline opioids include sustained-release opioids, methadone maintenance, buprenorphine maintenance, transdermal fentanyl patches, and epidural or intrathecal opioid infusions. If a fentanyl patch is removed prior to surgery, a fentanyl infusion can be used during surgery as a substitute to provide maintenance opioid therapy. Patients who abuse illicit opioids such as heroin can be given either intravenous or oral doses of methadone and morphine as their baseline.[35] However, determination of a baseline dose can be difficult for illicit drugs, as their formulations are variable.

Opioid-dependent patients may require larger intraoperative opioid doses than opioid-naïve patients. Respiratory rate can be used as a method to appropriately dose opioids intraoperatively. If the patient is spontaneously breathing either throughout the case or at the end after reversal of muscle relaxant, the opioid dose may be titrated to a respiratory rate of 8–12 breaths per minute. Opioid effects can also occur in the opioid-tolerant patient, including nausea, vomiting, pruritus, and respiratory depression. Therefore, it is essential to monitor vital signs and sedation level in the perioperative period while opioids are being administered even in this group of patients. If remifentanil is being used for intraoperative analgesia, a long-acting opioid at the end of the surgery can be administered to ensure analgesia after the remifentanil infusion is discontinued.

Caution is warranted if a warming blanket is used with a patient who has been administered a transdermal fentanyl or buprenorphine patch, as the application of heat over the patch may lead to an increase in medication release.

Anesthesiologists should be aware that opioid-tolerant patients under anesthesia are at an increased risk of awareness intraoperatively.[36]

THE POSTOPERATIVE PERIOD

A multimodal analgesic plan should be continued into the postoperative period for opioid-dependent patients.

Opioids

Clinical Pearls

- PCA is an effective option for postoperative analgesia. Carefully consider the basal rate dosing to decrease the probability of opioid-related side effects and complications.
- Not all patients will need their preoperative opioid dose postoperatively. The pain generators may be different postoperatively, and the patient may require a decreased or increased dose of opioids.
- Opioid rotation may be useful in improving efficacy, decreasing daily opioid requirements, and reducing opioid-related side effects.

A patient's usual baseline dose of opioid is typically continued perioperatively. Intravenous patient-controlled analgesia (PCA) is an effective option for postsurgical analgesia especially in the opioid-dependent patient. PCA allows the patient to administer pain medication almost instantly on an as-needed basis, decreasing the risk of under-medication and breakthrough pain and increasing patient satisfaction. By allowing patients to administer their own pain medication, demands on nursing staff are also reduced. Though not recommended for opioid-naïve patients, a basal rate of opioid may be administered to opioid-dependent patients to supply baseline requirements in patients not able to take oral medications. The provider should be prepared to prescribe higher bolus doses in opioid-dependent patients compared to opioid-naïve patients and should shorten the lock-out interval for opioid-dependent patients using a PCA.

Once a patient can tolerate oral medications after surgery and the pain is well controlled with PCA, the patient may be switched to oral opioids. An equianalgesic table for conversion to oral opioids is featured in Table 54–1. Generally, the calculated equianalgesic amount of opioid medication is reduced by 50%–75% to account for incomplete cross-tolerance.

Opioid rotation or switching between different opioids is an option to improve analgesia while decreasing the overall daily opioid dose and opioid-related side effects for individual compound failures despite titration. Proposed mechanisms for the efficacy of opioid rotation include incomplete opioid cross-tolerance, active metabolites, and different opioid and nonopioid receptor affinity.[8] When rotating opioids, the equianalgesic dose should be reduced to account for incomplete cross-tolerance.

Clinical Pearl

- Regional anesthesia should be considered for opioid-dependent patients when appropriate.

Neuraxial Anesthesia

Neuraxial anesthesia with local anesthetics and opioids can provide effective pain control while minimizing the need to administer systemic analgesics. However, neuraxially administered opioids may not effectively prevent withdrawal if systemic opioids are not given as baseline. This is due to the fact that plasma concentrations and supraspinal binding of the opioid will decrease, resulting in withdrawal symptoms.[5]

Regional Anesthesia

Regional anesthesia should be considered for opioid-dependent patients where appropriate, especially for surgery on the extremities. Local anesthetic infiltration, specific nerve blocks, or plexus blocks all can provide complete or adjunct analgesia. The goal of regional anesthesia in the opioid-dependent patient is to provide adequate analgesia while also lowering or potentially eliminating the need to administer additional opioids.

Clinical Pearl

- Nonopioid adjuvants, including acetaminophen, NSAIDs, anticonvulsants, antidepressants, and ketamine, should be considered as part of a multimodal approach to pain control.

Ketamine

Ketamine, an NMDA receptor antagonist, can be used perioperatively as an infusion for adjunct analgesia. A ketamine infusion has been found to reduce pain intensity and opioid consumption at 48 hours postoperatively as well as at 6 months postoperatively following spinal surgery in opioid-dependent patients.[37] A low-dose ketamine infusion used intraoperatively and postoperatively may also enhance the effects of opioids, reduce opioid tolerance, and reduce opioid-induced hyperalgesia.[38,39]

Acetaminophen

A single dose of intravenous acetaminophen has been found to provide 4–6 hours of effective analgesia for patients in variety of postoperative pain models with a decrease in overall opioid consumption and an increase in patient satisfaction.[40] In a review of the use of intravenous acetaminophen perioperatively, the majority of studies examined showed improved analgesia and decreased opioid requirements.[41] Dosing is usually 1 g intravenously every 6–8 hours, not to exceed the daily maximum dose of 4 g in an average-size adult patient. An oral combination opioid containing acetaminophen can be given 4 hours after intravenous acetaminophen. Care should be taken when using opioid–acetaminophen combination products to not exceed the maximum recommended daily dose of 4 g due to the risk of hepatotoxicity.

NSAIDs and Cyclooxygenase-2 Inhibitors

NSAIDs should be considered for all patients with mild or moderate acute pain unless contraindicated.[42] Examples of NSAIDs include ketorolac, ibuprofen, naproxen, and the newer cyclooxygenase-2 inhibitors (COXIBs). NSAIDs provide analgesia by inhibiting prostaglandin synthesis, which results in an anti-inflammatory effect. The prostaglandin synthesis inhibition results in NSAID side effects, however, including gastritis and platelet and renal dysfunction. Because of these side effects, NSAIDs are contraindicated in patients with renal dysfunction, gastritis, and peptic ulcer disease. The COXIBs do not affect platelets and have fewer effects on the gastrointestinal system.

Ketorolac is an intravenous NSAID approved for use in the United States for the indication of acute pain. A dose of 30 mg of intravenous ketorolac is equipotent to approximately 6–10 mg of intravenous morphine. Ketorolac has been shown to have an opioid-sparing effect, and its use has resulted in reduced opioid-related side effects.[43] The maximum recommended duration of use of intravenous ketorolac is 5 days.

Tramadol

Tramadol is a synthetic analog of codeine that is a weak mu-opioid receptor agonist. In addition to its effect on opioid receptors, tramadol has an additional analgesic effect by inhibiting the reuptake of norepinephrine and serotonin. Though not particularly effective in the treatment of severe pain alone, it can be used to treat mild to moderate pain in the postoperative period and has a lower abuse potential than other opioids.

Gabapentinoids

The gabapentinoids gabapentin and pregabalin are another option for the multimodal treatment of acute pain when they are administered in the perioperative period. The gabapentinoids are anticonvulsants that bind to voltage-gated calcium channels, reducing the release of excitatory neurotransmitters and producing an analgesic effect. In a systematic review of the literature, a single preoperative dose of gabapentin 1200 mg improved postoperative analgesia and decreased postoperative opioid consumption. The efficacy of multiple doses of gabapentin perioperatively was less conclusive due to a limited number of trials.[44] Based on a meta-analysis, pregabalin for postoperative pain appears to decrease opioid consumption and lower the incidence of opioid-related adverse effects postoperatively; most studies used preoperative dosing.[45] Side effects of both gabapentin and pregabalin include dizziness, ataxia, and somnolence. Table 54–2 presents suggested dosing regimens for these agents.

A Multidisciplinary Approach

The multimodal analgesic plan should be communicated with the patient and other members of the care team. Patients with chronic pain may have anxiety or depression that may benefit from the input of psychology or psychiatry services. Consultation with addiction specialists should be considered in patients with substance abuse.

TABLE 54–2. Dosing of perioperative gabapentin and pregabalin.

Drug	Dosing Recommendations
Gabapentin	Single preoperative dose of 1200 mg by mouth.[44]
Pregabalin	300 mg or 600 mg by mouth 1 hour prior to or after surgery. Consider repeating dose 12 hours after first dose.[45]

DISCHARGE PLANNING
