Guidelines for the management of **HIV and hepatitis B** co-infection have been developed by various expert groups.[24-26] In patients not requiring HIV therapy interferon alfa for 4 to 6 months is considered suitable for non-cirrhotic HBeAg-positive patients, but limited evidence suggests that peginterferon alfa may be more effective.[24] Treatment of **HIV and hepatitis C** co-infected patients has been associated with a high rate of intolerance and a low rate of response. While combination therapy for hepatitis C is not as effective in co-infected patients as in those with hepatitis C alone, studies[27-29] have shown sustained virological responses with peginterferon alfa and ribavirin treatment in co-infected patients. Two studies[27,29] reported an SVR rate of 27% for patients given peginterferon alfa plus ribavirin as opposed to 12 to 20% in those treated with interferon alfa plus ribavirin. The APRICOT study group[28] reported an SVR rate of 40% for patients treated with peginterferon alfa plus ribavirin, compared with 20% for those given peginterferon alfa monotherapy and 12% for those given interferon alfa plus ribavirin. A much reduced rate of SVR to peginterferon alfa plus ribavirin therapy was found, however, in co-infected patients with hepatitis C virus genotype 1 (29%) compared with hepatitis C virus of genotypes 2 and 3 (62%) and further study is required to develop strategies for treating infection with genotype 1.[28,29] The British HIV Association guidelines[30] for the treatment and management of HIV and hepatitis C co-infection recommends combination therapy with peginterferon alfa and ribavirin for 48 weeks in patients with moderate liver disease and well controlled HIV disease. Similar recommendations have been made by the AASLD.[23] For further discussion on the management of chronic hepatitis B and C patients co-infected with HIV, see p.851.

Although antivirals are generally not required in **acute hepatitis**, treatment of acute hepatitis C with interferon alfa has been shown to produce more rapid resolution of viraemia[31] and may decrease the risk of chronic hepatitis developing.[32] Studies[33] with peginterferon alfa-2b, in a small number of patients with acute hepatitis C, have shown similar efficacy. The AASLD[23] recommends that either interferon or peginterferon alfa given for a period of at least 6 months should be considered for the treatment of acute hepatitis C if the infection persists 2 to 4 months after diagnosis. Similar views have been published by the Clinical Effectiveness Group of the British Association of Sexual Health and HIV[34] and by the Scottish Intercollegiate Guidelines Network.[35]

Herpes simplex infections. Herpes simplex infections are commonly treated with aciclovir (see p.854), but beneficial responses to topical interferon alfa have been reported in genital herpes, although results are mixed.[1] Interferon alfa has also been reported to have benefit in the treatment of herpes keratitis. A systematic review[2] of interventions for herpes simplex epithelial keratitis found that interferon monotherapy had a slightly beneficial effect on dendritic epithelial keratitis, but no more than that of other antivirals and concluded that the use of an antiviral nucleoside with interferon seemed to speed healing.

HIV infection and AIDS. Interferons have been tried with some success in the management of Kaposi's sarcoma and mycobacterial infections in patients with AIDS (see below and under Interferon Gamma, p.894, respectively).

Inflammatory bowel disease. Interferon alfa is one of many drugs that have been tried in inflammatory bowel disease (p.1697). A study[1] found that clinical remission was achieved in 26 of 28 patients with ulcerative colitis after 6 to 12 months of treatment with interferon alfa-2a. Partial remission was reported in 2 of 5 patients with Crohn's disease[2] given interferon alfa, but in another study in 12 patients[3] interferon alfa was of no benefit. Interferon beta has also been found to be of benefit for the treatment of ulcerative colitis unresponsive to corticosteroids.[4]

Kaposi's sarcoma. The various treatments used for Kaposi's sarcoma, including the role of HAART as first-line therapy in the AIDS-related form, are discussed on p.675. Interferon alfa has been used in AIDS-related Kaposi's sarcoma and in patients with the classical, nonepidemic form. In patients with AIDS-related Kaposi's sarcoma interferon alfa, either as monotherapy or with zidovudine, has shown benefit in HIV-positive patients provided they possess relatively elevated CD4+ T lymphocyte counts (greater than 150 cells/microlitre),[1] although other drugs have generally replaced interferon alfa as treatment for Kaposi's sarcoma.[2] Systemic and local therapy such as interferon alfa and chemotherapy may be combined with HAART.[3]

Malignant neoplasms. Many reports have been published on the effects of interferons on various neoplasms; most have involved interferon alfa.

Interferons have become established in the treatment of a few malignant disorders, notably hairy-cell leukaemia (but see p.654), Kaposi's sarcoma (see above), and chronic myeloid leukaemia (p.653). Alfa interferons may improve the duration of remission in multiple myeloma,[1-4] but not necessarily survival.[2,5] Combination therapy including interferons has also been used in indolent low-grade non-Hodgkin's lymphoma (p.656) and interferon alfa has been used alone to maintain remission. In renal cell carcinoma (p.667) response to interferon alfa used with interleukin-2 has been promising, but toxicity high; interferon alfa alone produces very modest benefit.[6] Beneficial responses have also been reported in a number of other neoplasms including melanoma (p.673); carcinoid tumours[7] (p.643); myelodysplasia; cutaneous T cell lymphomas including mycosis fungoides (p.657); and in meningioma.[8,9] Interferons have been given locally as an adjunct to surgery for superficial bladder tumours (p.659) and intralesionally or perilesionally in basal cell carcinoma[10-12] and also for keloid scars.[13,14] Use of interferon alfa with fluorouracil has been tried in inoperable colorectal cancer but does not appear to be more beneficial than fluorouracil alone.[15] Interferon alfa given with zidovudine has produced encouraging results in adult T-cell leukaemia-lymphoma.[16] Peginterferon alfa has also been shown to be effective in the management of chronic myeloid leukaemia and solid tumours, including metastatic melanoma and renal cell carcinoma.[17]

Mycobacterial infections. For the use of interferon alfa in mycobacterial infections, see Interferon Gamma, p.894.

Progressive multifocal leukoencephalopathy. Beneficial responses were reported in patients with HIV-associated progressive multifocal leukoencephalopathy (PML) after treatment with interferon alfa.[1] Daily intramuscular interferon alfa therapy for 2 weeks also resulted in some neurologic improvement in a patient identified as an asymptomatic human T-lymphotropic virus type I carrier, who developed PML and pneumocystis pneumonia.[2] However, in a retrospective analysis[3] of the relative value of HAART and interferon alfa in the treatment of PML associated with AIDS, prolonged survival associated with interferon alfa was found to be not independent of the effects of HAART and it was concluded that interferon alfa provided no additional benefit.

Skin disorders. For the use of interferon alfa in skin disorders associated with raised IgE concentrations, see Interferon Gamma, p.894.

Warts. Various interferons have been tried by various routes in the treatment of anogenital warts (condylomata acuminata) (p.1584).

Intralesional injection has been used to ensure relatively high concentrations of interferon in the wart but the occurrence of systemic adverse effects shows that there is absorption from this site. Complete responses were reported[1] in 36% of patients given intralesional interferon alfa-2b compared with 17% given placebo, and a corresponding overall reduction in the affected area of 62.4% compared with 1.2% respectively. However, follow-up was not sufficiently long to comment on relapse rates. Another study[2] found similar responses using interferons alfa-2b, alfa-n1, or beta in patients with refractory warts, with complete responses in 47% of patients given intralesional interferons compared with 22% of patients given placebo. A study[3] evaluating two different doses of intralesional interferon beta given three times weekly for 3 weeks reported complete responses in 63% of lesions injected with 1 million units compared with 38% of lesions injected with 33 000 units. Good responses have also been reported in patients with both refractory and recurrent warts given intralesional interferon alfa-n3.[4] Relapses were delayed and fewer warts recurred in patients who had received interferon rather than placebo. Intralesional interferon alfa-2b used with podophyllum was more effective that podophyllum alone,[5] although about 66% of patients in each group subsequently relapsed. A systematic review concluded that based on limited available evidence intralesional interferons may have a therapeutic effect, but have no significant advantage over simpler and safer treatments.[6]

Topical application of interferon alfa has also been reported to be more effective than podophyllotoxin.[7,8] Interferon beta has also been applied topically after surgical removal of warts.[9]

Theoretically, *systemic* use should have advantages in controlling subclinical infections and reducing relapses. However, responses to subcutaneous interferon alfa have generally been disappointing[10-12] although responses comparable with cauterisation and a reduction in relapse rates with either subcutaneous or intramuscular interferon alfa-2b have been obtained.[13] Information on the use of systemic interferons as an adjunct to conventional therapy is scarce but a study in 97 patients[14] with recurrent warts found no difference in either response or relapse rates in patients given cryotherapy with subcutaneous interferon alfa or cryotherapy alone. A study comparing subcutaneous interferon alfa, beta, and gamma used with cryotherapy found no significant difference in response rate, although patients given interferon beta or gamma developed new warts at a lower frequency.[15]

Intralesional plus subcutaneous interferon alfa has also been tried in treatment of oral warts; 4 HIV-positive patients with recurrent oral warts that had failed to respond to surgery and other treatments responded to interferon alfa treatment.[16]

Interferon Beta *(BAN, rINN)*

IFN-β; Interferón-β; Interferon-β; Interferón beta; Interféron bêta; Interferoni beta; Interferonum Beta; SH-Y-579A (interferon beta-1b).

Интерферон Бета

CAS — 74899-71-1 (interferon beta); 145258-61-3 (interferon beta-1a); 145155-23-3 (interferon beta-1b); 90598-63-3 (interferon beta-1b).

ATC — L03AB02 (natural); L03AB07 (1a); L03AB08 (1b).

ATC Vet — QL03AB02 (natural); QL03AB07 (1a); QL03AB08 (1b).

NOTE. Interferon beta was previously known as fibroblast interferon.

Interferon beta-1a and Interferon beta-1b are both *USAN*.

Nomenclature. Interferon beta may be derived from fibroblasts, or produced by recombinant DNA technology. Sub-species of the human beta gene produce interferon beta with protein variants designated by a number (as in interferon beta-1). Interferon beta-1 is further qualified by a letter to indicate the amino-acid sequences at positions 1 and 17, and to indicate whether or not glycosylation is present:

- interferon beta-1a has methionine at position 1 and cysteine at 17 and is glycosylated at position 80
- interferon beta-1b has serine at position 17 and is not glycosylated

The name may be further elaborated on the label by approved sets of initials in parentheses to indicate the method of production: (rch) indicates production from genetically engineered Chinese hamster ovary cells; (rbe) indicates production from bacteria (*Escherichia coli*) genetically modified by recombinant DNA technology.

Adverse Effects

As for interferons in general (see Interferon Alfa, p.885).

Severe local reactions at injection sites, including tissue necrosis, have been reported. Menstrual irregularities have been associated with interferon beta use. On injection, transient neurological symptoms that may mimic an exacerbation of multiple sclerosis have been reported. In addition transient episodes of hypertonia and/or severe muscular weakness may occur at any time during treatment.

◊ Reviews.

Auto-immune disorders. Reversible subacute cutaneous lupus erythematosus[1] and SLE[2] have been reported in patients given interferon beta. A case[3] of lupus erythematosus profundus has been reported in a patient after 4 years of treatment with interferon beta-1b for multiple sclerosis; the neurological symptoms and subcutaneous nodules resolved after stopping treatment. There have been case reports of patients developing myasthenia gravis while receiving interferon beta; the patients responded to treatment with pyridostigmine.[4]

3. Gono T, *et al.* Lupus erythematosus profundus (lupus panniculitis) induced by interferon-β in a multiple sclerosis patient. *J Clin Neurosci* 2007; **14:** 997–1000.
4. Dionisiotis J, *et al.* Development of myasthenia gravis in two patients with multiple sclerosis following interferon β treatment. *J Neurol Neurosurg Psychiatry* 2004; **75:** 1079.

Effects on the blood. Aplastic anaemia occurred[1] in a patient with multiple sclerosis after treatment with interferon beta-1a for about a year. The interferon was stopped and the patient had a good response to immunosuppressant treatment. The haematological effects of subcutaneous interferon beta-1a in multiple sclerosis patients have been reviewed.[2]

2. Rieckmann P, *et al.* Haematological effects of interferon-beta-1a (Rebif) therapy in multiple sclerosis. *Drug Safety* 2004; **27:** 745–56.

Effects on the cardiovascular system. Severe Raynaud's syndrome developed in a patient during treatment with interferon beta.[1] Symptoms subsided once interferon beta was stopped.

1. Linden D. Severe Raynaud's phenomenon associated with interferon-β treatment for multiple sclerosis. *Lancet* 1998; **352:** 878–9.

Effects on hearing. For a report of sensorineural hearing loss in patients receiving interferon beta, see Interferon Alfa, p.886.

Effects on the liver. Hepatotoxicity, sometimes severe and in rare cases fatal, has been reported with interferons and its association specifically with the use of interferon beta-1a in multiple sclerosis patients has been reviewed.[1]

1. Francis GS, *et al.* Hepatic reactions during treatment of multiple sclerosis with interferon-β-1a: incidence and clinical significance. *Drug Safety* 2003; **26:** 815–27.

Effects on the skin. Calcified subcutaneous nodules have been reported in a patient after 3 years of treatment with subcutaneous interferon beta-1a for the treatment of multiple sclerosis.[1] For a report of severe necrotising cutaneous lesions at injection sites in a patient receiving interferon beta, see Interferon Alfa, p.887. See also Auto-immune Disorders, above for a report of cutaneous lupus erythematosus associated with interferon beta.

Precautions

As for interferons in general (see Interferon Alfa, p.887).

Interferon beta in high doses is fetotoxic and abortifacient in *primates* and should be avoided during pregnancy.

Interactions

As for interferons in general (see Interferon Alfa, p.888).

Antiviral Action

As for interferons in general (see Interferon Alfa, p.888).

Pharmacokinetics

Interferons are not absorbed from the gastrointestinal tract. About 50% of a subcutaneous dose and 40% of an intramuscular dose of interferon beta is absorbed. For some formulations of interferon beta-1a, bioavailability and area under the plasma concentration-time curves are equivalent for subcutaneous and intramuscular dosage, but for others, intramuscular doses produce higher values than subcutaneous doses and subcutaneous doses therefore cannot be substituted for intramuscular doses. Peak serum concentrations of interferon beta-1a have been reported to occur 3 hours after subcutaneous injection and between 3 and 15 hours after intramuscular injection, and those for beta-1b have been reported to occur 1 to 8 hours after subcutaneous injection. The elimination half-life for intramuscular interferon beta-1a is about 10 hours. Interferon beta-1a is mainly metabolised and excreted by the liver and the kidneys.

Uses and Administration

Interferon beta is a cytokine with antiviral and immunomodulating activities. Two forms of interferon beta are available: interferon beta-1a and interferon beta-1b (see Nomenclature, above). Interferon beta is mainly used in the management of relapsing-remitting multiple sclerosis (below), although its mode of action is unclear. In the UK interferon beta-1b is also licensed for use in secondary progressive multiple sclerosis.

Interferon beta-1a is given in relapsing-remitting multiple sclerosis in a dose dependent upon the formulation used:

- *Avonex* (*Biogen*) is given in a dose of 6 million units (30 micrograms) once weekly by intramuscular injection.
- *Rebif* (*Serono*) is given in an escalating dose over 4 weeks, to 12 million units (44 micrograms) three times weekly by subcutaneous injection, or to 6 million units (22 micrograms) three times weekly by subcutaneous injection in patients unable to tolerate the higher dose.

Interferon beta-1b is given in both relapsing-remitting and in secondary progressive multiple sclerosis in an escalating dose over 3 to 6 weeks to a dose of 8 million units (250 micrograms) on alternate days by subcutaneous injection.

In the UK interferon beta-1a (*Avonex*) and interferon beta-1b are also indicated for the treatment of patients who have had a single demyelinating event with an active inflammatory process if it is sufficiently severe to warrant intravenous corticosteroids.

Guillain-Barré syndrome. Rapid improvement in motor function was reported during use of interferon beta-1a in a patient with Guillain-Barré syndrome associated with *Campylobacter jejuni* infection.[1] However, the relative contributions of interferon therapy and a course of plasma exchange that immediately preceded it could not be assessed.[2] Successful treatment of Guillain-Barré syndrome was reported in a patient after interferon beta-1a was added to treatment with intravenous immunoglobulin.[3] A small randomised, placebo-controlled pilot study[4] of subcutaneous interferon beta-1a or placebo, in addition to intravenous immunoglobulin, in patients with Guillain-Barré syndrome reported no significant difference in the rate of improvement.

Multiple sclerosis. Multiple sclerosis (MS)[1-3] is a chronic inflammatory and demyelinating disease affecting the CNS. It is the most common disabling neurological disease among young adults and is most often diagnosed in those between the ages of 20 and 40, with women being almost twice as likely to develop it as men. Although the etiology and pathogenesis of MS is poorly understood, it is thought that the disease has an immunological basis and occurs in genetically susceptible individuals. MS is characterised by multiple areas of inflammation and demyelination; activated T-cells enter the CNS and produce an immune cascade resulting in localised loss of myelin, oligodendrocytes, and axons. The resulting lesions (plaques) accumulate over time, with impairment or less electrical transmission along the nerve fibres (axons).

Patients with MS commonly present with an individual mix of symptoms, which tend to progress over years to decades. The type and number of symptoms may vary according to the areas affected but typically include bowel and bladder dysfunction, changes in cognitive function, dizziness, depression, fatigue, difficulties with walking and balance, paraesthesias, pain, sexual dysfunction, spasticity, problems with speech and swallowing, tremor, and visual impairment, notably from optic neuritis. Most patients improve to some degree after the initial attack but the course and severity of the disease are unpredictable.

People with MS generally follow one of four clinical courses of disease, which in turn may be mild, moderate, or severe. In about 85% of patients the disease follows a relapsing-remitting course (RR-MS) in which there are recurrent exacerbations (flare-ups) followed by clinical improvement and relatively long periods of remission. After about 10 to 15 years up to 50% of patients develop progressive neurological deterioration, categorised as secondary progressive disease (SP-MS). However, about 15% of people with RR-MS will have a mild course with little or no disability after 15 years (benign MS). About 10 to 15% of patients present without relapses but have slow continuous deterioration, classified as primary progressive disease (PP-MS). In about 5% of patients the disease is described as progressive relapsing; people with this type of MS have steadily worsening disease from the onset but also have acute exacerbations.

Choice of treatment.

A wide range of drugs with immunological actions (disease-modifying drugs) have been tried in the treatment of MS itself with the aim of improving recovery from acute attacks, preventing or reducing further attacks (relapses), and halting the progressive stage of the disease. Different therapies are used for patients having acute attacks, for patients who have RR-MS, for patients who have the progressive subtypes, and for symptomatic management.

Corticosteroids are used for their immunomodulatory and anti-inflammatory effects in acute attacks (relapses). Corticosteroid therapy reduces the duration of the episode and accelerates recovery, but it is not known whether it alters the course of the disease in the long term.[4] The drug of choice is methylprednisolone; usually given intravenously in high doses (typically 1 g daily) for 3 to 5 days and sometimes followed by a tapering dose of oral prednisolone. Doses of up to 2 g daily have been tried.[5] In patients with acute optic neuritis (frequently the first manifestation of multiple sclerosis), methylprednisolone delayed the onset of other symptoms of multiple sclerosis,[6] although the effect was not sustained beyond 2 years.[7] Beneficial responses have also been reported with oral methylprednisolone at doses including 500 mg once daily for 5 days followed by a tapering dose over 10 days[8] and 48 mg once daily for 7 days followed by a tapering dose over 14 days.[9] A small clinical study indicated that the bioavailability attained after large doses of oral prednisone may be similar to that of high dose intravenous methylprednisolone.[10] In patients with PP-MS, the benefits of short-course methylprednisolone lasted no longer than 3 months[11] although, in patients with SP-MS, a preliminary study has suggested that progression may be delayed by intermittent high-dose methylprednisolone therapy.[12]

Interferon beta has become established for treatment of RR-MS selected patients, and is also used in SP-MS. Studies[13-15] in patients with active RR-MS have shown the efficacy of interferon *beta-1b* given subcutaneously and at different doses. Similar results in RR-MS have been obtained with interferon *beta-1a* given by either subcutaneous or intramuscular routes;[16-18] although comparative studies[19,20] have suggested that subcutaneous interferon beta-1a (44 micrograms given three times a week) is more effective than intramuscular interferon beta-1a (30 micrograms weekly). A prospective, randomised, multicentre study[21] comparing the different frequencies of dosing with interferon beta-1a and beta-1b concluded that high-dose interferon beta-1b given on alternate days was more effective in RR-MS than once-weekly interferon beta-1a. Studies[22-24] in patients presenting with a first demyelinating event (clinically isolated syndrome), or other manifestation of early disease, have shown that treatment with interferon beta may reduce the rate of progression to clinical MS, a view confirmed by a recent systematic review.[25] A 3-year follow-up analysis[26] of one study[24] found that early treatment with interferon beta-1b prevented the development of confirmed disability.

Concern has been expressed over the detection of neutralising antibodies against interferon in up to 46% of patients;[27-29] development of neutralising antibodies correlates with reduced treatment efficacy and the possibility for renewed disease activity. The development of neutralising antibodies is greater in patients treated with higher doses of interferon and in those treated with interferon beta-1b.[30]

Encouraging results have also been obtained with interferon beta-1b in patients with SP-MS,[31] but no effect has been found on disability progression from use of interferon beta-1a in SP-MS.[32,33]

Results of studies[34,35] with *glatiramer* in patients with RR-MS have shown that it can reduce the number of relapses and may produce some improvements in neurological disability. Follow-up of these patients for approximately 3 years continued to show a beneficial effect on disease relapse rate. MRI data supported the beneficial clinical results.[36] These benefits are produced in a different way from those gained with interferon beta leading to expectations of possible treatment with both drugs.

Natalizumab is a humanised monoclonal antibody that has been found to decrease the frequency of exacerbations in RR-MS. A 2-year randomised, placebo-controlled study[37] to assess the safety and efficacy of intravenous natalizumab reported a 68% likelihood of remaining relapse-free and a 83% reduction in the number of new or enlarging brain lesions on MRI; the cumulative probability of sustained disability progression was 17% in the natalizumab patient group compared to 29% in the placebo group. Another 2-year study[38] reported that natalizumab plus intramuscular interferon beta-1a was more effective than interferon beta-1a monotherapy. Patients receiving combination therapy were 55% less likely to relapse and had a 83% reduction in the number of new or enlarging brain lesions on MRI compared with monotherapy. A 23% probability of progression of disability was reported for the combination treatment group compared with 29% for interferon alone. Natalizumab has, however, been associated with an increased risk of progressive multifocal leukoencephalopathy and its use is therefore limited to patients with highly active RR-MS who have had an inadequate response to, or are unable to tolerate, other therapies.

Although some studies have shown modest benefits with *immunosuppressants*, the general conclusions of large controlled studies have tended to be that any slight benefits of existing therapies with immunosuppressants such as azathioprine, ciclosporin, cyclophosphamide, and methotrexate are outweighed by the toxicity of the doses required to have an effect.[39-46] However, a systematic review[47] concluded that azathioprine reduced the number of patients who had relapses and the number who progressed during the first 2 to 3 years of treatment. It considered that azathioprine might be given as an alternative to interferon beta for maintenance treatment for patients who frequently relapse and require corticosteroids. Long-term toxicity (including the risk of malignancy) may be related to cumulative doses above 600 g and treatment for longer than 10 years. Mitoxantrone (given by intravenous infusion) has been studied in patients with RR-, PR-, and SP-MS and found to be moderately effective in reducing disease progression and the frequency of relapses.[48,49] Its use may, however, be limited by dose-related cardiotoxicity and it is suggested that mitoxantrone be used to treat patients with rapidly progressive disease or those not responding to high-dose interferon. A review[50] of cladribine indicated that it reduced the number of enhancing lesions but also had significantly more adverse effects (including myelosuppression) than placebo. The authors suggested that cladribine might have a role in the treatment of refractory patients with SP-MS.

Other immunological approaches evaluated have included the use of monoclonal antibodies such as alemtuzumab, daclizumab, and rituximab, and immunosuppressants such as mycophenolate mofetil. HMG-CoA reductase inhibitors (statins) have immunomodulatory effects and a small study[51] reported that simvastatin significantly decreases the number and volume of new MRI lesions in patients with RR-MS.

A systematic review[52] on the use of intermittent intravenous normal immunoglobulins in patients with RR-MS concluded that there was a reduction in relapse rate and an increased time to relapse, but no evidence that immunoglobulin treatment reduces the progression of MS or reverses existing damage. Intravenous normal immunoglobulins are not effective in SP-MS.[53] Autologous haematopoietic stem cell transplantation has shown benefit in some patients with progressive MS.[54,55]

Guidelines for the management of multiple sclerosis have been produced in the UK,[56,57] the USA,[58] and other countries.[59,60]

Symptomatic treatment.

MS can produce a wide range of symptoms, many of which are manageable; symptomatic treatment is aimed at the management of spasticity, ataxia, tremor, paroxysmal symptoms, pain, fatigue, and bladder dysfunction. Baclofen, dantrolene, diazepam, and tizanidine are the usual drugs given for spasticity (see p.1887). There is also some anecdotal evidence to suggest that cannabis and individual cannabinoids, including synthetic cannabinoids such as nabilone, may improve pain and spasticity;[61] a review[62] considered evidence of effectiveness to be lacking. Patients with MS can suffer from a number of different types of pain, including pain from spasticity, and therapy must be individualised for each specific pain syndrome (see Choice of Analgesic, p.2). Pain, spasms, and spasticity have responded to gabapentin in preliminary studies.[63-68] A review has noted, however, that the absolute and comparative efficacy and tolerability of anti-spasticity drugs is poorly documented.[69] Paraesthesia and dysaesthesia, which can be common, may respond to tricyclic antidepressants or antiepileptics. Amantadine, modafinil, pemoline, and fampridine have all been investigated for the management of fatigue associated with MS.[70] Treatment of bladder dysfunction may include an alpha blocker such as phenoxybenzamine and appropriate parasympathomimetic or antimuscarinic (such as oxybutynin) therapy to control bladder contractions (see Urinary Incontinence and Retention, p.2180). Fampridine and amifampridine have been reported to produce beneficial symptomatic responses such as improvement in walking, dexterity, and vision, possibly as a result of potassium-channel blocking activity but a systematic review[71] was unable to come to a conclusion about safety and efficacy, noting that publication bias posed a problem.

Conventional treatments are only partially effective and may produce adverse effects, and many patients with MS try alternative therapies. The most common *dietary interventions* are supplementation with polyunsaturated fatty acids (such as omega-3 and omega-6 fatty acids, often as fish, evening primrose, or sunflower oils), allergen-free diets, vitamins, and micronutrients and antioxidants (such as selenium, ginkgo biloba extracts, and coenzyme Q10). A review of the relationship between these dietary interventions and MS concluded that there was insufficient evidence to determine their benefits or risks.[72] Polyunsaturated fatty acids seem to have no major effect on disease progression and recurrence of exacerbations over 2 years. Research into the value of vitamin D is ongoing after findings that higher levels of serum vitamin D are associated with a lower risk of MS.[73]

The use of *hyperbaric oxygen* therapy in MS was a matter of debate for many years. Some workers reported benefit, especially in bladder and bowel function or in cerebellar function whereas others were unable to substantiate any long-term benefit and reviews have concluded that there is no convincing evidence that hyperbaric oxygen therapy is useful.[74,75]

Rheumatoid arthritis. Preliminary studies suggested that interferon beta might have a beneficial effect on rheumatoid arthritis,[1] the conventional management of which is described on p.11. However, a subsequent randomised, double-blind study[2] found that adding subcutaneous interferon beta to methotrexate treatment in patients with rheumatoid arthritis had no clinical or radiological benefit over adding placebo.

Interferon Gamma *(BAN, rINN)*

IFN-γ; Interferón-γ; Interferon-γ; Interféron gamma; Interferón gamma; Interferoni gamma; Interferonigamma; Interferonum Gamma.

Интерферон Гамма

CAS — 98059-18-8 (interferon gamma-1a); 98059-61-1 (interferon gamma-1b).
ATC — L03AB03.
ATC Vet — QL03AB03.

NOTE. Interferon gamma was previously known as immune interferon.
Interferon gamma-1b is *USAN* and was previously known as interferon gamma-2a.

Pharmacopoeias. *Eur.* (see p.vii) includes Interferon Gamma-1b Concentrated Solution.

Ph. Eur. 6.2 (Interferon Gamma-1b Concentrated Solution; Interferoni Gamma-1b Solutio Concentrata). It is a solution of the *N*-terminal methionyl form of interferon gamma. It is produced by a method based on recombinant DNA technology using bacteria as host cells. It is a clear, colourless or slightly yellowish liquid. The pH of the solution is 4.5 to 5.5. Store in airtight containers at a temperature of −70°. Protect from light.

Nomenclature. Interferon gamma may be derived from immunologically stimulated T-lymphocytes (hence its former name of immune interferon) or produced by recombinant DNA technology. Similarly to interferon alfa, protein variants of interferon gamma are designated by a number and further qualified by a letter to indicate the amino-acid sequences at terminal positions 1 and 139:

- interferon gamma-1a has at position 1 hydrogen, cysteine, tyrosine, and cysteine and at position 139 arginine, alanine, serine, glutamine, and a hydroxyl group
- interferon gamma-1b, formerly known as interferon gamma-2a, has at position 1 hydrogen and methionine and at position 139 a hydroxyl group

Interferon gamma derived through recombinant DNA technology is labelled (rbe).

Adverse Effects

As for interferons in general (see Interferon Alfa, p.885)

Precautions

As for interferons in general (see Interferon Alfa, p.887). Interferon gamma in high doses has been shown to increase the incidence of abortions in *primates* and should be avoided during pregnancy.

Interactions

As for interferons in general (see Interferon Alfa, p.888).

Antiviral Action

As for interferons in general (see Interferon Alfa, p.888).

Pharmacokinetics

Interferons are not absorbed from the gastrointestinal tract. Peak plasma concentrations of interferon gamma-1b occur about 4 hours after intramuscular injection and about 7 to 8 hours after subcutaneous injection. Half-lives of 38 minutes (intravenous dosage), 2.9 hours (intramuscular dosage), and 4.9 to 5.9 hours (subcutaneous dosage) have been reported.

Uses and Administration

Interferon gamma is a cytokine with antiviral and immunomodulating effects. Interferon gamma-1b is used for its action as a macrophage-stimulating factor as an adjunct to antimicrobial therapy in chronic granulomatous disease. It is also used to delay time to disease progression and reduce the frequency of serious infections in patients with severe malignant osteopetrosis.

Interferon gamma-1b is given in a dose of 50 micrograms/m^2 body-surface (1 million units/m^2) three times weekly by subcutaneous injection. Patients with a body-surface less than 0.5 m^2 should receive 1.5 micrograms/kg body-weight three times weekly.

Interferon gamma-1b is also under investigation for the treatment of cryptogenic fibrosing alveolitis (see below).

Interferon gamma-n1 has also been used for the treatment of cutaneous T-cell lymphomas.

◊ Reviews.

Bacterial infections. In addition to its use to control infections in chronic granulomatous disease, interferon gamma was used with some success as an adjunct to antibacterials in a patient with Whipple's disease[1] but was of no benefit in a study in burn-related infections.[2] For the conventional management of these infections, see Whipple's Disease, p.200 and Skin Infections, p.194.

MYCOBACTERIAL INFECTIONS. Experience with interferons for *nontuberculous mycobacterial infections* in patients with AIDS is limited. Interferon gamma given with antimycobacterials produced beneficial responses in 3 patients with *Mycobacterium avium* complex infections, but produced no response or only a transient response in 3 others given interferon gamma alone.[1,2]

Beneficial responses have also been reported after use of interferon alfa[3] or gamma[4] as an adjunct to antimycobacterial therapy in HIV-negative patients with mycobacterial infections unresponsive to conventional therapy. Interferon alfa has been tried as an adjunct to conventional therapy in *multibacillary leprosy*.[5]

Inhaled interferon alfa[6] or gamma[7] may be a useful adjunct to conventional antimycobacterial treatment for *pulmonary tuberculosis*.

For discussion of these infections and their standard treatment, see Leprosy, p.176, Nontuberculous Mycobacterial Infections, p.181, and Tuberculosis, p.196.

Cryptogenic fibrosing alveolitis. In a preliminary study[1] in patients with cryptogenic fibrosing alveolitis (CFA; idiopathic pulmonary fibrosis—see Diffuse Parenchymal Lung Disease, p.1502) who had not responded to treatment with corticosteroids or to other immunosuppressive therapy, lung capacity increased in 9 patients given interferon gamma-1b with prednisolone for 12 months, but deteriorated in 9 who were treated with prednisolone alone for the same period. The study was, however, criticised for its methodology and the statistical significance of its findings questioned.[2] A later study[3] involving 330 patients with CFA found that interferon gamma 1-b did not affect progression-free survival or pulmonary function; however, a trend toward lower mortality was seen in patients who received interferon gamma-1b compared with those given placebo. A subsequent study[4] to characterise the molecular effects of subcutaneous interferon gamma-1b versus placebo reported that interferon gamma-1b affected CFA through multiple pathways and could be of potential benefit. A randomised, prospective study[5] comparing interferon gamma-1b and colchicine (given for 24 months) in patients with mild-to-moderate CFA reported that 15.6% of patients treated with interferon gamma-1b and 38.8% of those given colchicine died. Patients treated with interferon gamma-1b also showed a higher forced vital capacity after 24 months of treatment. A review[6] of the use of interferon gamma-1b in the management of CFA found that efficacy of interferon gamma-1b was inconsistent with regard to changes in pulmonary function and mortality, although studies suggested that interferon gamma-1b may be of benefit in earlier-stage disease. A meta-analysis[7] of randomised controlled studies evaluating the use of interferon gamma-1b in the treatment of CFA concluded that interferon gamma-1b therapy was associated with reduced mortality.

Leishmaniasis. Interferon gamma has been tried both systemically and locally as an adjunct to standard treatment of leishmaniasis (p.824) with encouraging results. A review[1] of the use of interferon gamma in non-viral infections concluded that interferon gamma was effective when combined with antimony compounds for treatment failures in visceral leishmaniasis and could enhance the response to initial therapy in untreated patients. However, the response to adjunctive interferon gamma was limited in patients with a high degree of resistance to antimony compounds.[2] For cutaneous infections, intralesional interferon gamma has been shown to be effective[3] but less so than intralesional antimony compounds.[4] Subcutaneous interferon gamma (with antimony given intravenously) was no more effective than antimony alone when given as a short course over 10 days.[5] However, encouraging responses have been reported in patients who have failed to respond to antimony compounds alone.[6]

6. Falcoff E, *et al.* Clinical healing of antimony-resistant cutaneous or mucocutaneous leishmaniasis following the combined administration of interferon-γ and pentavalent antimonial compounds. *Trans R Soc Trop Med Hyg* 1994; **88:** 95–7.

Osteopetrosis. Interferon gamma has been tried in the treatment of malignant osteopetrosis (p.1509). A study[1] in 14 patients found that interferon gamma-1b increased bone resorption. In 11 who received this treatment for 18 months there was stabilisation or improvement in clinical condition and a reduction in the frequency of serious infection.

1. Key LL, *et al.* Long-term treatment of osteopetrosis with recombinant human interferon gamma. *N Engl J Med* 1995; **332:** 1594–9.

Skin disorders. Interferons have been tried in skin disorders in which IgE levels are raised. Subcutaneous interferon gamma improved *eczema* and reduced serum-IgE concentration in one patient, but the condition gradually returned within a week of stopping treatment.[1] In two studies[2,3] subcutaneous interferon gamma given to patients with severe atopic dermatitis and raised serum-IgE concentrations resulted in improvement of the skin condition; IgE concentrations were reduced in one study[2] but remained high in the other.[3] Subcutaneous interferon alfa, however, was unsuccessful in 2 patients with very severe atopic dermatitis; serum-IgE concentrations and severity of the skin condition remained unaffected.[4] Interferon alfa has been tried in subacute *cutaneous lupus erythematosus*[5,6] and *discoid lupus erythematosus*.[6] Although marked improvement generally occurred, the condition tended to recur within several weeks of stopping treatment. For discussion of the conventional treatment of eczema, see p.1579 and of lupus erythematosus, see Systemic Lupus Erythematosus, p.1513.

There have been reports[7,8] of the successful use of interferon alfa to control the symptoms of *urticaria* associated with mastocytosis (p.1138).

Interferons have also been proposed for antifibrotic therapy in the management of diffuse *scleroderma* (see p.1817). A multicentre study of interferon gamma in scleroderma[9] found that cutaneous symptoms might be improved but that treatment was associated with an unacceptable incidence of adverse effects. Interferon gamma has also been tried in *eosinophilic pustular folliculitis*.[10]

Interferons have also been used for the treatment of warts (see under Interferon Alfa, p.891).

Lamivudine *(BAN, USAN, rINN)*

3TC; (−)-2′-Deoxy-3′-thiacytidine; GR-109714X; Lamivudiini; Lamivudin; Lamivudina; Lamivudinum; Lamiwudyna; Lavmivudin. (−)-1-[(2R,5S)-2-(Hydroxymethyl)-1,3-oxathiolan-5-yl]cytosine.

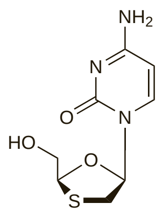
Ламивудин

$C_8H_{11}N_3O_3S$ = 229.3.

CAS — 131086-21-0; 134678-17-4.

ATC — J05AF05.

ATC Vet — QJ05AF05.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Lamivudine). A white or almost white powder. It exhibits polymorphism. Soluble in water, slightly soluble in alcohol; sparingly soluble in methyl alcohol. Protect from light.

USP 31 (Lamivudine). A white to off-white solid. Soluble in water. Protect from light.

Adverse Effects

Adverse effects commonly associated with lamivudine either as monotherapy or with other antiretrovirals for the treatment of HIV include abdominal pain, nausea, vomiting, diarrhoea, headache, fever, rash, alopecia, malaise, insomnia, cough, nasal symptoms, arthralgia, and musculoskeletal pain. There have also been reports of pancreatitis, anaemia, neutropenia, and thrombocytopenia. Increases in liver enzymes and serum amylase may occur. Lactic acidosis, usually associated with severe hepatomegaly and steatosis, has been reported during treatment with nucleoside reverse transcriptase inhibitors.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including lamivudine, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been seen in patients receiving antiretroviral therapy, including lamivudine. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported. NRTIs have also been associated with mitochondrial dysfunction manifesting as abnormal behaviour, anaemia, convulsions, hyperlipasaemia, hypertonia, and neutropenia. Elevated creatine phosphokinase, myalgia, myositis, and rarely rhabdomyolysis have been reported, particularly when nucleoside analogues have been given with HIV-protease inhibitors. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy. For further information on adverse effects associated with NRTIs see Zidovudine, p.914.

Patients taking a lower dose of lamivudine for the treatment of chronic hepatitis B often have abdominal discomfort and pain, diarrhoea, fatigue, headache, nausea, malaise, respiratory-tract infections, and vomiting. The most frequently reported laboratory abnormalities are elevated creatine phosphokinase, increases in serum lipase, and raised liver enzymes, in particular alanine aminotransferase. There have been rare reports of lactic acidosis, pancreatitis, and muscle disorders such as cramps, myalgia, and rhabdomyolysis.

Effects on the blood. Although anaemia associated with lamivudine usually occurs when it is used with zidovudine, there has been a report[1] of severe anaemia in a 62-year-old HIV-infected man given lamivudine alone.

1. Weitzel T, *et al.* Severe anaemia as a newly recognized side-effect caused by lamivudine. *AIDS* 1999; **13:** 2309–11.

Effects on the hair. Hair loss was associated with lamivudine treatment in 5 patients.[1]

1. Fong IW. Hair loss associated with lamivudine. *Lancet* 1994; **344:** 1702.

Effects on the nervous system. Exacerbation of peripheral neuropathy has been reported in a patient after substitution of lamivudine for zalcitabine.[1]

1. Cupler EJ, Dalakas MC. Exacerbation of peripheral neuropathy by lamivudine. *Lancet* 1995; **345:** 460–1.

Hypersensitivity. Angioedema, urticaria, and anaphylactoid reaction occurred in a patient 30 minutes after receiving the first dose of lamivudine.[1]

1. Kainer MA, Mijch A. Anaphylactoid reaction, angioedema, and urticaria associated with lamivudine. *Lancet* 1996; **348:** 1519.

Precautions

Lamivudine therapy should be stopped in patients who develop abdominal pain, nausea, or vomiting or with abnormal biochemical test results until pancreatitis has been excluded.

Treatment with lamivudine may be associated with lactic acidosis and should be stopped if there is a rapid increase in aminotransferase concentrations, progressive hepatomegaly, or metabolic or lactic acidosis of unknown aetiology. Lamivudine should be used with caution in patients with hepatomegaly or other risk factors for hepatic disease. Patients co-infected with HIV and chronic hepatitis B or C and treated with combination antiretroviral therapy are at increased risk for severe and potentially fatal hepatic adverse events. In patients with chronic hepatitis B, there is a risk of rebound hepatitis when lamivudine is stopped, and liver function should be monitored in such patients. The possibility of HIV infection should be excluded before beginning lamivudine therapy for hepatitis B, since the lower doses used to treat the latter may permit the development of lamivudine-resistant strains of HIV.

Dosage reduction may be necessary in patients with impaired renal function.

Interactions

The renal excretion of lamivudine may be inhibited by other drugs mainly eliminated by active renal secretion, for example trimethoprim. Usual prophylactic doses of trimethoprim are unlikely to necessitate reductions in lamivudine dosage unless the patient has renal impairment, but the co-administration of lamivudine with the high doses of trimethoprim (as co-trimoxazole) used in pneumocystis pneumonia and toxoplasmosis should be avoided. Although there is usually no clinically significant interaction with zidovudine, severe anaemia has occasionally been reported in patients given lamivudine with zidovudine (see Zidovudine, Interactions, p.915). Lamivudine may antagonise the antiviral action of zalcitabine and the two drugs should not be used together. Once daily triple nucleoside regimens of lamivudine and tenofovir with either abacavir or didanosine are associated with a high level of treatment failure and of emergence of resistance, and should be avoided.

Phenylpropanolamine. For a possible interaction between phenylpropanolamine and antiretrovirals, see Stavudine, p.907.

Antiviral Action

Lamivudine is converted intracellularly in stages to the triphosphate. This triphosphate halts the DNA synthesis of retroviruses, including HIV, through competitive inhibition of reverse transcriptase and incorporation into viral DNA. Lamivudine is also active against hepatitis B virus. Resistance to lamivudine has been reported in isolates of HIV and hepatitis B virus.

Pharmacokinetics

Lamivudine is rapidly absorbed after oral doses and peak plasma concentrations are achieved in about 1 hour. Absorption is delayed, but not reduced, by ingestion with food. Bioavailability is between 80 and 87%. Binding to plasma protein is reported to be up to 36%. Lamivudine crosses the blood-brain barrier with a ratio of CSF to serum concentrations of about 0.12. It crosses the placenta and is distributed into breast milk.

Lamivudine is metabolised intracellularly to the active antiviral triphosphate. Hepatic metabolism is low and it is cleared mainly unchanged by active renal excretion. An elimination half-life of 5 to 7 hours has been reported after a single dose.

Uses and Administration

Lamivudine is a nucleoside reverse transcriptase inhibitor structurally related to cytosine with antiviral activity against HIV-1 and hepatitis B virus. It is used in the treatment of HIV infection and AIDS, (p.856) and chronic hepatitis B infection (p.851). Viral resistance emerges rapidly when lamivudine is used alone in the treatment of HIV infection, and it is therefore used with other antiretrovirals.

For HIV infection, the dose of lamivudine for adults is 300 mg by mouth daily as a single dose or in two divided doses.

For chronic hepatitis B, the adult dose is 100 mg once daily by mouth. In patients with concomitant HIV and hepatitis B infection the dosage regimen appropriate for HIV should be used.

For details of doses in infants, children, and adolescents see below.

Reduction of dosage is recommended for patients with renal impairment (see below).

Fixed-dose combination products for the treatment of HIV infection and AIDS have been developed in order to improve patient adherence and avoid monotherapy, thereby decreasing the risk of acquired drug resistance. Products containing lamivudine in combination with zidovudine or abacavir and with abacavir plus zidovudine are available in some countries.

◊ Reviews.

1. Dando TM, Scott LJ. Abacavir plus lamivudine: a review of their combined use in the management of HIV infection. *Drugs* 2005; **65:** 285–302.

Administration in children. For the treatment of HIV infection in infants and children lamivudine is given orally either as tablets or a solution, together with other antiretroviral drugs. Doses are based on body-weight:

- in infants and children over 3 months of age and weighing less than 14 kg or in those unable to swallow tablets the oral solution may be given in a dose of 4 mg/kg twice daily to a maximum daily dose of 300 mg
- in children weighing 14 to 21 kg the tablet formulation may be given in a dose of 75 mg twice daily
- in children weighing 21 to 30 kg the tablet formulation may be given in a dose of 75 mg in the morning and 150 mg at night
- in children weighing over 30 kg the tablet formulation may be given in a dose of 150 mg twice daily

Dosage of lamivudine should be reduced in HIV-infected patients (at least 3 months of age and weighing less than 30 kg) with moderate to severe renal impairment (creatinine clearance (CC) below 50 mL/minute):

- CC 30 to 49 mL/minute: 4 mg/kg for the first dose then 4 mg/kg once daily
- CC 15 to 29 mL/minute: 4 mg/kg for the first dose then 2.6 mg/kg once daily

- CC 5 to 14 mL/minute: 4 mg/kg for the first dose then 1.3 mg/kg once daily
- CC less than 5 mL/minute: 1.3 mg/kg for the first dose then 0.7 mg/kg once daily

For the treatment of chronic hepatitis B infection in children and adolescents aged between 2 and 17 years, US licensed product information recommends an oral dose of lamivudine of 3 mg/kg once daily to a maximum daily dose of 100 mg. Dosage reduction would need to be considered in those with renal impairment. UK licensed product information does not recommend the use of lamivudine for the treatment of chronic hepatitis B in those under 17 years of age.

Administration in renal impairment. Dosage of lamivudine should be reduced in patients with moderate to severe renal impairment (creatinine clearance (CC) below 50 mL/minute).

adults: HIV infection:

- CC 30 to 49 mL/minute: 150 mg for the first dose then 150 mg once daily
- CC 15 to 29 mL/minute: 150 mg for the first dose then 100 mg once daily
- CC 5 to 14 mL/minute: 150 mg for the first dose then 50 mg once daily
- CC less than 5 mL/minute: 50 mg for the first dose then 25 mg once daily
- dialysis patients: no additional doses required after routine haemodialysis or peritoneal dialysis

adults: chronic hepatitis B infection:

- CC 30 to 49 mL/minute: 100 mg for the first dose then 50 mg once daily
- CC 15 to 29 mL/minute: 100 mg for the first dose then 25 mg once daily
- CC 5 to 14 mL/minute: 35 mg for the first dose then 15 mg once daily
- CC less than 5 mL/minute: 35 mg for the first dose then 10 mg once daily
- dialysis patients: no additional doses required after routine haemodialysis or peritoneal dialysis

children:

- see Administration in Children, above

Hepatitis. Lamivudine is one of the antivirals being used as an alternative to interferon alfa in the treatment of chronic hepatitis B (p.851).[1-3] In a preliminary study, lamivudine 100 or 300 mg daily reduced hepatitis B virus DNA to low or undetectable levels.[4] In a 1-year double-blind study involving about 350 patients with chronic hepatitis B, lamivudine 100 mg daily was associated with substantial histological improvement in many patients; a dose of 25 mg daily was less effective.[5] Relapses have been reported once treatment with lamivudine is stopped, and a case of reactivation of hepatitis B infection has been observed.[6] Lamivudine may also be effective in preventing re-infection with hepatitis B in patients during chemotherapy[7-9] and in those who have had liver transplants,[10,11] and beneficial responses have been seen in transplant patients with acute hepatitis B infection treated with lamivudine 100 mg daily for prolonged periods.[12]

HIV infection and AIDS. Lamivudine is a potent inhibitor of HIV-1 and HIV-2 *in vitro*, including variants resistant to zidovudine.[1] Resistance emerges rapidly when lamivudine is given alone to patients with HIV infections,[2] although sustained responses have been reported despite the emergence of resistance.[3] Combination therapy with lamivudine delays, and may even reverse, the emergence of zidovudine resistance and produces a sustained synergistic antiretroviral effect,[4] but HIV strains resistant to both lamivudine and zidovudine may arise.[5] As discussed on p.856, combination therapy, typically with two nucleoside reverse transcriptase inhibitors and either a non-nucleoside reverse transcriptase inhibitor or an HIV-protease inhibitor, is standard therapy for HIV infection. Treatment with lamivudine plus zidovudine has produced better responses than either drug alone in antiretroviral-naive patients,[6,7] and has produced additional responses in antiretroviral-experienced patients,[8,9] with little additional toxicity. The addition of lamivudine to existing antiretroviral therapy was reported to slow the progression of the disease and improve survival,[10] and treatment with lamivudine, indinavir, and nevirapine produced beneficial responses in patients who had previously failed on combined nucleoside analogue therapy.[11] Clinically useful CNS concentrations of lamivudine were achieved in patients with HIV infection given combination therapy with lamivudine and zidovudine or stavudine.[12]

Lamivudine is also used in prophylactic regimens after occupational exposure to HIV infection (see p.858) and has been tried for reducing vertical transmission from mother to neonate.[13,14]

Lopinavir *(BAN, USAN, rINN)*

A-157378.0; ABT-378; Lopinaviiri; Lopinavirum. (αS)-Tetrahydro-N-((αS)-α-{(2S,3S)-2-hydroxy-4-phenyl-3-[2-(2,6-xylyloxy)acetamido]butyl}phenethyl)-α-isopropyl-2-oxo-1(2H)-pyrimidineacetamide.

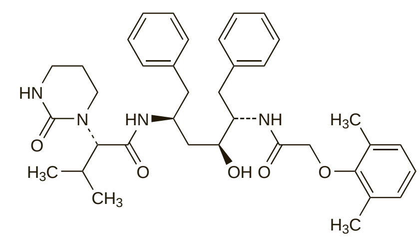
Лопинавир

$C_{37}H_{48}N_4O_5$ = 628.8.

CAS — 192725-17-0.

ATC — J05AE06.

ATC Vet — QJ05AE06.



Adverse Effects

The most common adverse effect associated with antiretroviral regimens containing lopinavir (formulated with ritonavir) is diarrhoea of mild to moderate severity. Pancreatitis has been seen in patients receiving lopinavir, including those who developed marked triglyceride elevations; in some cases fatalities have occurred. Other commonly reported adverse effects include asthenia, headache, insomnia, pain, paraesthesia, gastrointestinal disturbances, acne, and rash. Abnormal laboratory test results associated with lopinavir-containing regimens include increases in serum cholesterol and triglycerides and raised liver enzymes.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including lopinavir, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been seen in patients receiving antiretroviral therapy, including lopinavir. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported. Elevated creatine phosphokinase, myalgia, myositis, and rarely rhabdomyolysis have been reported with HIV-protease inhibitors, particularly when given with nucleoside analogues. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy.

For further information on adverse effects associated with HIV-protease inhibitors see under Indinavir Sulfate, p.882.

Precautions

Patients with advanced HIV disease may be at increased risk of elevated triglycerides and pancreatitis, and patients with a history of pancreatitis may be at increased risk for recurrence during treatment with ritonavir-boosted lopinavir. Such therapy should be stopped if symptoms of pancreatitis occur.

The oral solution (*Kaletra*, *Abbott*) has a high content of alcohol and propylene glycol, present as excipients, and appropriate precautions should be taken; it is contra-indicated in infants and young children, in pregnancy, and in hepatic or renal impairment. For further information on propylene glycol toxicity, see Adverse Effects and Precautions, p.2374.

Pregnancy. Licensed product information notes that in *rats* given toxic doses of ritonavir-boosted lopinavir, there was early resorption, decreased fetal viability and body weight, and an increased incidence of skeletal variation and delayed skeletal ossification in the offspring.

Interactions

Lopinavir is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4. It is formulated with low-dose ritonavir, which inhibits this enzyme and thus increases exposure. The combination is an inhibitor of CYP3A4 and increases plasma concentration of drugs mainly metabolised by this isoenzyme. It has also been shown *in vivo* to induce its own metabolism and to increase the biotransformation of some drugs metabolised by cytochrome P450 isoenzymes and by glucuronidation. Drugs that strongly induce CYP3A4 may result in decreased plasma concentrations of the combination.

Ritonavir-boosted lopinavir is contra-indicated with drugs that are highly dependent on CYP3A4 for clearance and for which elevated plasma concentrations are associated with serious or life-threatening events. These drugs include antihistamines (astemizole and terfenadine), ergot derivatives (dihydroergotamine, ergometrine, ergotamine, and methylergometrine), gastrointestinal prokinetics (cisapride), antipsychotics (pimozide), sedatives and hypnotics (midazolam and triazolam), and statins (simvastatin and lovastatin). Rifampicin and St John's wort decrease the concentration of lopinavir; use with the antiretroviral is not recommended due to the possible loss of its activity and development of resistance. UK licensed product information contra-indicates the use of vardenafil and amiodarone with ritonavir-boosted lopinavir.

For further information on drug interactions of HIV-protease inhibitors see under Indinavir Sulfate, p.883 and Table 1, p.917.

Antiviral Action

Lopinavir is a selective, competitive, reversible inhibitor of HIV-1 protease. It interferes with the formation of essential viral proteins making them incapable of infecting other cells. Viral resistance develops rapidly when HIV-protease inhibitors are given alone and therefore they are used with other antiretrovirals. Various degrees of cross-resistance between HIV-protease inhibitors may occur.

Pharmacokinetics

Lopinavir is rapidly absorbed from the gastrointestinal tract after oral doses, with peak plasma concentrations occurring after 4 hours. Bioavailability is enhanced when given with a high fat meal. Lopinavir is reported to be 98 to 99% bound to serum proteins. Lopinavir is extensively metabolised, mainly by oxidation by cytochrome P450 isoenzyme CYP3A4; 13 metabolites have been identified with some, such as 4-oxylopinavir and 4-hydroxylopinavir, having antiviral activity. Lopinavir is predominantly excreted in faeces and to a smaller extent in the urine; unchanged lopinavir accounts for about 2.2% of a dose excreted in the urine and 19.8% in the faeces. After multiple dosing, less than 3% of the absorbed lopinavir dose is excreted unchanged in the urine. The terminal elimination half-life of lopinavir is reported to be about 5 to 6 hours.

◊ References.

1. Jullien V, *et al.* Population analysis of weight-, age-, and sex-related differences in the pharmacokinetics of lopinavir in children from birth to 18 years. *Antimicrob Agents Chemother* 2006; **50:** 3548–55.

Uses and Administration

Lopinavir is an HIV-protease inhibitor with antiviral activity against HIV. It is formulated with low-dose ritonavir, which acts as a pharmacokinetic enhancer. The combination is used in the treatment of HIV infection and AIDS (p.856). Ritonavir-boosted lopinavir is also recommended for HIV postexposure prophylaxis (p.858). Viral resistance emerges rapidly when ritonavir-boosted lopinavir is used alone, and it is therefore used with other antiretrovirals.

The dose in treatment-naive and -experienced adults is lopinavir 400 mg (with ritonavir 100 mg) twice daily. Alternatively, treatment-naive patients may take a once-daily dose of lopinavir 800 mg (with ritonavir 200 mg).

US licensed product information recommends that if the tablets are given in a treatment regimen with either *amprenavir, fosamprenavir, nelfinavir, efavirenz*, or *nevirapine* in treatment-experienced patients consideration be given to increasing the dose of lopinavir to 600 mg (with ritonavir 150 mg) twice daily. For patients taking the oral solution in such regimens the dose should be increased to lopinavir 533 mg (with ritonavir 133 mg) twice daily.

Lopinavir film-coated tablets may be taken with or without food; the soft capsules and solution should be taken with food.

For details of doses in children, see below.

◊ Reviews.

1. Oldfield V, Plosker GL. Lopinavir/ritonavir: a review of its use in the management of HIV infection. *Drugs* 2006; **66:** 1275–99.

Administration in children. For the treatment of HIV infection in children, ritonavir-boosted lopinavir is given daily with other antiretroviral drugs. The US licensed product information permits use in infants as young as 14 days old, whereas in the UK the age is 2 years. The dose given should not exceed the maximum adult dose (see above).

In the UK the use of the oral solution is preferred to the soft capsules as a more accurate dose may be given. Doses are based on body-surface.

- In children 2 years of age or more the recommended dose of the *oral solution* is lopinavir 230 mg/m^2 (with ritonavir 57.5 mg/m^2) twice daily with food. The dose should be increased to 300 mg/m^2 (with ritonavir 75 mg/m^2) twice daily with food when given with *efavirenz* or *nevirapine*
- The recommended dose of the *oral soft capsules* in children is according to body-surface as follows:
  - 0.40 to 0.75 m^2: lopinavir 133.3 mg (with ritonavir 33.3 mg) twice daily
  - 0.80 to 1.3 m^2: lopinavir 266.6 mg (with ritonavir 66.6 mg) twice daily
  - 1.4 to 1.75 m^2: lopinavir 400 mg (with ritonavir 100 mg) twice daily

In the USA the dose is based on body-weight or body-surface as follows:

- given without interacting antiretrovirals
  - 14 days to 6 months of age: lopinavir 16 mg/kg (with ritonavir 4 mg/kg) twice daily or lopinavir 300 mg/m^2 (with ritonavir 75 mg/m^2) twice daily
  - 6 months or older and less than 15 kg: lopinavir 12 mg/kg (with ritonavir 3 mg/kg) twice daily or lopinavir 230 mg/m^2 (with ritonavir 57.5 mg/m^2) twice daily
  - 15 to 40 kg: lopinavir 10 mg/kg (with ritonavir 2.5 mg/kg) twice daily or lopinavir 230 mg/m^2 (with ritonavir 57.5 mg/m^2) twice daily
  - over 40 kg: normal adult dose
- given in a treatment regimen with either *amprenavir, fosamprenavir, efavirenz, nelfinavir,* or *nevirapine* (requiring the dose of lopinavir/ritonavir to be increased):
  - 6 months or older and less than 15 kg: lopinavir 13 mg/kg (with ritonavir 3.25 mg/kg) twice daily or lopinavir 300 mg/m^2 (with ritonavir 75 mg/m^2) twice daily
  - 15 to 45 kg: lopinavir 11 mg/kg (with ritonavir 2.75 mg/kg) twice daily or lopinavir 300 mg/m^2 (with ritonavir 75 mg/m^2) twice daily
  - over 45 kg: as for adults, above

SARS. In a preliminary open study[1] 41 patients with probable SARS were given ritonavir-boosted lopinavir as well as the local standard treatment of ribavirin and corticosteroids. At 21 days there was improved outcome with reductions in viral load, corticosteroid dose, and the incidence of nosocomial infections.

1. Chu CM, *et al.* Role of lopinavir/ritonavir in the treatment of SARS: initial virological and clinical findings. *Thorax* 2004; **59:** 252–6.

Maraviroc *(USAN, rINN)*

Maravirocum; UK-427857. 4,4-Difluoro-*N*-((1*S*)-3-{(1*R*,3*s*,5*S*)-3-[3-methyl-5-(propan-2-yl)-4*H*-1,2,4-triazol-4-yl]-8-azabicyclo[3.2.1]octan-8-yl}-1-phenylpropyl)cyclohexanecarboxamide.

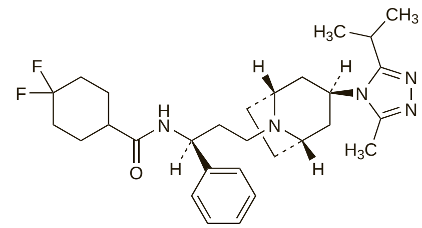
Маравирок

$C_{29}H_{41}F_2N_5O$ = 513.7.

CAS — 376348-65-1.

ATC — J05AX09.

ATC Vet — QJ05AX09.



Adverse Effects and Precautions

On the basis of limited data, maraviroc appears to be well tolerated; non-specific adverse effects associated with maraviroc-based regimens include asthenia, cough and upper respiratory-tract infections, dizziness, abdominal pain and distension, constipation, diarrhoea, dyspepsia, nausea, vomiting, fever, headache, insomnia, somnolence, muscle spasms and back pain, pruritus, and rash. Less frequently reported adverse effects include osteonecrosis and cardiovascular effects such as myocardial ischaemia and myocardial infarction; cardiac adverse effects were reported mainly for patients with pre-existing cardiac disease or risk factors.

Hepatotoxicity has occurred; raised liver enzyme values and bilirubin have also been reported and caution is advised in patients with pre-existing liver dysfunction or co-infection with hepatitis B or C. Although renal clearance normally accounts for only a small portion of the dose, maraviroc should be used with caution in patients with renal impairment (creatinine clearance less than 80 mL/minute) who are also taking potent inhibitors of the cytochrome P450 isoenzyme CYP3A4 as concentrations of maraviroc may be significantly increased.

Interactions

Maraviroc is a substrate for the cytochrome P450 isoenzyme CYP3A4 and for P-glycoprotein, and may therefore have a number of clinically significant interactions. Inhibitors of CYP3A4, such as HIV-protease inhibitors (other than tipranavir), increase the serum concentration of maraviroc. Inducers of CYP3A4 such as efavirenz may decrease serum maraviroc concentrations. No clinically significant interaction is expected between maraviroc and NRTIs, nevirapine, or boosted fosamprenavir or tipranavir.

Non-antiretroviral medications that significantly alter maraviroc metabolism include the CYP3A4 inhibitors ketoconazole, itraconazole, clarithromycin, and nefazodone and the CYP3A4 inducers rifampicin and St John's wort. Maraviroc does not appear to cause clinically significant changes in concentrations of other medications.

Antiviral Action

Maraviroc is an antagonist of the CCR5 chemokine receptor. During infection, HIV binds to the CD4 receptor on the surface of host cells, and then interacts with one of two co-receptors, CCR5 or CXCR4, to allow cell membrane fusion and entry to the cell. By binding to CCR5, maraviroc inhibits this process and prevents strains of HIV-1 that use CCR5 (CCR5-tropic viruses), which appear to be more common in early infection, from entering the cell. It is not active against CXCR4-tropic strains or those with dual or mixed tropism.

Pharmacokinetics
Maraviroc is absorbed after oral doses, and peak concentrations occur in 0.5 to 4 hours. There is considerable interindividual variation in the pharmacokinetics. It is 76% bound to plasma proteins. Maraviroc is metabolised by the cytochrome P450 system (specifically the isoenzyme CYP3A4) to inactive metabolites. It is excreted in both urine (20%) and faeces (76%) as unchanged drug and metabolites.

Uses and Administration
Maraviroc is an antagonist of the CCR5 chemokine receptor (see Antiviral Action, above). It is used, with other antiretrovirals, for the treatment of HIV infection and AIDS (p.856) in treatment-experienced adult patients with exclusively CCR5-tropic HIV-1 infection. Co-receptor tropism should be determined by specific testing before maraviroc is used.

Maraviroc is given orally in a dose of 300 mg twice daily, although dose adjustments may be needed depending on interactions with other medicines.

- For patients also taking CYP3A4 inhibitors such as HIV-protease inhibitors (other than fosamprenavir or tipranavir), delavirdine, ketoconazole, itraconazole, clarithromycin, nefazodone, and telithromycin, the recommended dose is 150 mg twice daily.
- In those whose therapy includes CYP3A4 inducers (without a CYP3A4 inhibitor) such as efavirenz, rifampicin, carbamazepine, phenobarbital, and phenytoin, the recommended dose is 600 mg twice daily.

Patients taking other antiretrovirals (including fosamprenavir or tipranavir), or other drugs, may be given the standard dose of 300 mg twice daily.

◊ References.

Administration in renal impairment. UK licensed product information recommends that the oral dose of maraviroc be adjusted in patients with renal impairment who are also taking potent inhibitors of cytochrome P450 isoenzyme CYP3A4. The dosing interval should be modified according to the creatinine clearance (CC) of the patient:

- For patients also taking CYP3A4 inhibitors such as ritonavir-boosted HIV-protease inhibitors (other than fosamprenavir, tipranavir, or saquinavir), ketoconazole, itraconazole, clarithromycin, and telithromycin and who have a CC less than 80 mL/minute: 150 mg every 24 hours
- For patients also taking ritonavir-boosted saquinavir:
  - CC 50 to 80 mL/minute: 150 mg every 24 hours
  - CC 30 to 49 mL/minute: 150 mg every 48 hours
  - CC 29 mL/minute or less: 150 mg every 72 hours

No adjustment is necessary when maraviroc is given without potent CYP3A4 inhibitors or with fosamprenavir or tipranavir

(nelfinavir)

NOTE. Nelfinavir should not be confused with nevirapine (below).

Pharmacopoeias. In *Int.*

Adverse Effects
The most common adverse effects associated with antiretroviral regimens containing nelfinavir are diarrhoea, flatulence, nausea, and rash. Raised liver enzymes and decreases in white blood cell counts have also been reported.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including nelfinavir, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been observed in patients receiving antiretroviral therapy, including nelfinavir. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported. Elevated creatine phosphokinase, myalgia, myositis, and rarely rhabdomyolysis have been reported with HIV-protease inhibitors, particularly when given with nucleoside analogues. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy. For further information on adverse effects associated with HIV-protease inhibitors see under Indinavir Sulfate, p.882.

Contamination. In June 2007, high levels of ethyl mesilate (ethyl methanesulfonate; EMS) were detected in European-made nelfinavir (*Viracept; Roche*). EMS may cause cancer in humans and has caused birth defects and cancer in *animals*. Nelfinavir was subsequently recalled from the European market in August 2007.[1] The manufacturer later identified and rectified the source of contamination and in September 2007 the EMEA recommended the lifting of the drug's suspension.[2] The US manufacturer (*Pfizer, USA*) notified doctors in September 2007 that EMS had been detected in nelfinavir manufactured in the USA but in much lower amounts than in European-made nelfinavir.[3] The FDA considered the risk of stopping nelfinavir therapy resulting from a drug recall to be greater than the risk of taking US-made nelfinavir but advised that children and pregnant women starting treatment with antiretrovirals for the first time not be given nelfinavir-containing regimens. Pregnant women taking nelfinavir as part of an HIV treatment regimen should be given alternative therapy. All other HIV-infected patients taking nelfinavir-containing regimens could continue to do so.

1. EMEA. European Medicines Agency agrees on action plan following the recall of Viracept and recommends suspension of the marketing authorisation (issued 21 June, 2007). Available at: http://www.emea.europa.eu/pdfs/general/direct/pr/27536707en.pdf (accessed 13/06/08).
2. EMEA. European medicines agency recommends lifing of suspension for Viracept (issued 20 September, 2007). Available at: http://www.emea.europa.eu/pdfs/general/direct/pr/41816807en.pdf (accessed 13/06/08).
3. Pfizer, USA. Viracept (nelfinavir mesylate) 250 mg, 625 mg tablets, and powder for oral suspension: important information for prescribers (issued 10 September 2007). Available at: http://www.fda.gov/medwatch/safety/2007/VIRACEPT_HCPLetter_9_10_07.pdf (accessed 13/06/08).

Precautions
Nelfinavir should be used with caution, and liver enzyme values monitored, in patients with moderate liver disease. Patients co-infected with chronic hepatitis B or C and treated with combination antiretroviral therapy are at increased risk for severe and potentially fatal hepatic adverse events. Caution is advised in treating patients with haemophilia A and B as reports of spontaneous bleeding have been associated with the use of HIV-protease inhibitors.

For cautions concerning use in children and in pregnancy see under Contamination, above

Interactions
Nelfinavir is reported to be metabolised in part by cytochrome P450 isoenzymes CYP3A4 and CYP2C19. Drugs that induce these isoenzymes may reduce the plasma concentration of nelfinavir. Conversely, when nelfinavir is given with drugs that inhibit CYP3A4 plasma concentrations, nelfinavir concentrations may be increased. It may also alter the pharmacokinetics of drugs metabolised by this isoenzyme system and possibly cause serious adverse effects.

Nelfinavir is contra-indicated with drugs that are highly dependent on CYP3A4 for clearance and for which elevated plasma concentrations are associated with serious or life-threatening events. These drugs include antiarrhythmics (amiodarone and quinidine), antihistamines (astemizole and terfenadine), ergot derivatives (dihydroergotamine, ergometrine, ergotamine, and methylergometrine), gastrointestinal motility agents (cisapride), antipsychotics (pimozide), sedatives and hypnotics (midazolam and triazolam), and statins (simvastatin and lovastatin). Omeprazole, rifampicin, and St John's wort decrease the concentration of nelfinavir; use with the antiretroviral is not recommended due to the possible loss of its activity and development of resistance.

For further information on drug interactions of HIV-protease inhibitors see under Indinavir Sulfate, p.883 and Table 1, p.917.

Antiviral Action
Nelfinavir is a selective, reversible inhibitor of HIV-1 protease. It interferes with the formation of essential viral proteins making them incapable of infecting other cells. Viral resistance develops rapidly when HIV-pro-

tease inhibitors are given alone and therefore they are used with other antiretrovirals. Mechanisms of resistance to nelfinavir may differ sufficiently from those to other HIV-protease inhibitors to reduce the occurrence of cross-resistance between nelfinavir and other HIV-protease inhibitors. Cross-resistance between nelfinavir and NNRTIs is unlikely because they target different enzymes.

Pharmacokinetics

Nelfinavir is absorbed from the gastrointestinal tract and peak plasma concentrations occur in 2 to 4 hours. Absorption is enhanced when given with food. Nelfinavir is extensively bound to plasma proteins (more than 98%). It is metabolised by oxidation by cytochrome P450 isoenzymes including CYP3A4 and CYP2C19. The major oxidative metabolite has *in-vitro* antiviral activity equal to that of nelfinavir. In patients 13 years of age and older the plasma terminal half-life is 3.5 to 5 hours; in children 2 to 13 years of age, clearance is two to three times greater than in adults. Nelfinavir is excreted mainly in the faeces both as unchanged drug (22%) and as metabolites (78%). Only about 1 to 2% is excreted in the urine, mainly as unchanged drug.

Uses and Administration

Nelfinavir is an HIV-protease inhibitor with antiviral activity against HIV-1. It is used in the treatment of HIV infection and AIDS (p.856). Viral resistance emerges rapidly when nelfinavir is used alone, and it is therefore used with other antiretrovirals.

Nelfinavir is given orally as the mesilate, but doses are expressed in terms of the base. Nelfinavir mesilate 292 mg is equivalent to about 250 mg of nelfinavir. Nelfinavir is available as tablets and oral powder. The oral powder should not be taken with acidic foods or drinks as this may result in a bitter taste. Nelfinavir is given in an adult dose of 1.25 g twice daily or 0.75 g three times daily with food.

For details of doses in children, see below.

◊ Reviews.

2. Perry CM, *et al.* Nelfinavir: a review of its use in the management of HIV infection. *Drugs* 2005; **65:** 2209–44.

Administration in children. For the treatment of HIV infection in children nelfinavir is given orally with other antiretroviral drugs. The US licensed product information permits the use of nelfinavir in children 2 years of age and older, whereas UK licensed product information permits use from 3 years of age.

In the UK, the recommended dose of nelfinavir is 50 to 55 mg/kg twice daily or 25 to 30 mg/kg three times daily with food. In the USA, the recommended dose is 45 to 55 mg/kg twice daily or 25 to 35 mg/kg three times daily with food.

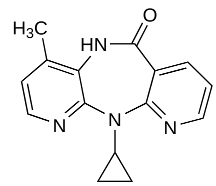
Невирапин

$C_{15}H_{14}N_4O$ = 266.3.

CAS — 129618-40-2.

ATC — J05AG01.

ATC Vet — QJ05AG01.



NOTE. Nevirapine should not be confused with nelfinavir (above).

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*
Int. permits anhydrous or the hemihydrate.

Ph. Eur. 6.2 (Nevirapine, Anhydrous). A white or almost white powder. Practically insoluble in water; sparingly soluble or slightly soluble in dichloromethane; slightly soluble in methyl alcohol.

USP 31 (Nevirapine). It is anhydrous or contains one-half molecule of water of hydration. A white to off-white, odourless to nearly odourless, crystalline powder. Practically insoluble in water; slightly soluble in alcohol and in methyl alcohol. The hydrous form is also slightly insoluble in propylene glycol. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°.

Adverse Effects

The most common adverse effect associated with antiretroviral regimens containing nevirapine is skin rash (usually mild to moderate, maculopapular, erythematous, and sometimes pruritic), generally occurring within 6 weeks of starting therapy. Severe and life-threatening skin reactions (with some fatalities) have occurred, including Stevens-Johnson syndrome and, more rarely, toxic epidermal necrolysis. Hypersensitivity reactions including angioedema, urticaria, and anaphylaxis have been reported. Rashes may occur alone or in the context of hypersensitivity reactions when they may be accompanied by other symptoms such as fever, arthralgia, myalgia, lymphadenopathy, eosinophilia, granulocytopenia, or renal dysfunction. Granulocytopenia occurs more commonly in children than in adults. Severe hepatotoxicity, including hepatitis and hepatic necrosis, occasionally fatal, has occurred and may be more prevalent in women and patients with high CD4+ cell counts at the start of treatment. Serious hepatotoxicity has also been reported in HIV-uninfected persons taking multiple doses of nevirapine for HIV postexposure-prophylaxis. Rhabdomyolysis has occurred in patients with skin and/or liver reactions. Other common adverse effects include nausea, vomiting, diarrhoea, abdominal pain, fatigue, drowsiness, fever, myalgia, and headache.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including nevirapine, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been seen in patients receiving antiretroviral therapy, including nevirapine. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy.

Precautions

Patients taking nevirapine should be closely monitored for adverse skin reactions and hepatotoxicity during the first 18 weeks of treatment; extra vigilance is advised during the first 6 weeks of treatment. Nevirapine should be used with extreme caution in patients with moderate hepatic impairment (Child-Pugh class B); it is contra-indicated in those with severe hepatic impairment (Child-Pugh class C). Patients with high CD4+ cell counts (greater than 250 cells/microlitre in women or 400 cells/microlitre in men), as well as patients co-infected with chronic hepatitis B or C are at increased risk of hepatotoxicity. The UK licensed product information suggests that liver function should be monitored every 2 weeks during the first 2 months of treatment, again at 3 months, and then regularly thereafter.

Treatment should be permanently stopped in patients who suffer a severe rash, rash accompanied by constitutional symptoms (such as fever, blistering, oral lesions, conjunctivitis, facial oedema, muscle or joint aches, or general malaise), hypersensitivity reactions, or clinical hepatitis. Transaminase levels should be checked for all patients who develop a rash in the first 18 weeks of treatment and nevirapine should be temporarily stopped if liver enzyme levels increase to greater than 5 times the upper limit of normal or the patient has symptoms suggestive of hepatitis. In some patients treatment may be restarted at the initial dose if liver function returns to baseline values and the patient has no clinical symptoms of hepatitis or signs of a rash (although permanent stoppage is necessary if abnormalities recur). In some cases hepatic injury progresses despite stopping the drug. Dose escalation should not be attempted in patients developing any rash during the first 14 days of treatment until the rash has resolved. Patients or their carers should be counselled on how to recognise hypersensitivity reactions and instructed to seek immediate medical attention if they occur. Doses may need to be modified in patients on renal dialysis.

Pregnancy. Nevirapine has not been associated with teratogenicity in *animals*. Licensed product information states that the Antiretroviral Pregnancy Registry has not found an increased risk of birth defects after first trimester exposures to nevirapine and the prevalence of birth defects after exposure in any trimester was comparable to the prevalence in the general population.

Interactions

Nevirapine is metabolised mainly by the cytochrome P450 isoenzymes CYP3A4 and CYP2B6. Consequently it may compete with other drugs metabolised by this system, possibly resulting in mutually increased plasma concentrations and toxicity. Alternatively, enzyme inducers may decrease plasma concentrations of nevirapine; nevirapine itself acts as a mild to moderate enzyme inducer and may thus reduce plasma concentrations of other drugs.

Rifampicin and St John's wort decrease the concentration of nevirapine; use with the antiretroviral is not recommended due to the possible loss of its activity and development of resistance. For further information on drug interactions of NNRTIs see Table 2, p.944.

Antivirals. For the effect of nevirapine on *HIV-protease inhibitors*, see p.883.

Methadone. Nevirapine may induce the metabolism of methadone (p.84) resulting in reduced plasma-methadone concentrations.

Antiviral Action

Nevirapine acts by non-competitive inhibition of HIV-1 reverse transcriptase; it binds to the enzyme, disrupting the conformation of its catalytic site and impairing its RNA- and DNA-dependent polymerase activity.

Resistance to nevirapine and emergence of cross-resistance to other non-nucleoside reverse transcriptase inhibitors has been seen.

Pharmacokinetics

Nevirapine is readily absorbed after oral doses and absorption is not affected by food or antacids. Bioavailability is greater than 90%. Nevirapine tablets and oral suspension are comparably bioavailable and interchangeable at doses up to 200 mg. Peak plasma concentrations occur 4 hours after a single dose. Nevirapine is about 60% bound to plasma proteins. Concentrations in the CSF are about 45% of those in plasma. Nevirapine crosses the placenta and is distributed into breast milk. It is extensively metabolised by hepatic microsomal enzymes, principally by the cytochrome P450 isoenzymes CYP3A4 and CYP2B6, to several hydroxylated metabolites. Autoinduction of these enzymes results in a 1.5- to 2-fold increase in apparent oral clearance after 2 to 4 weeks at usual dosage, and a decrease in terminal half-life from 45 hours to 25 to 30 hours over the same period. Nevirapine is mainly excreted in the urine as glucuronide conjugates of the hydroxylated metabolites.

In children, nevirapine elimination accelerates during the first years of life, reaching a maximum at around 2 years of age, followed by a gradual decline during the rest of childhood; values in children under 8 years are about twice those in adults.

Uses and Administration

Nevirapine is a non-nucleoside reverse transcriptase inhibitor with activity against HIV-1. It is used in the treatment of HIV infection and AIDS (p.856). Viral resistance emerges rapidly when nevirapine is used alone, and it is therefore used with other antiretrovirals.

Nevirapine is given orally in an adult dose of 200 mg once daily for the first 14 days, then increased to 200 mg twice daily provided that no rash is present (see Precautions, above).

If treatment is interrupted for more than 7 days, it should be reintroduced using the lower dose for the first 14 days as for new treatment.

For details of doses in infants, children, and adolescents, see below.

Nevirapine is often used in regimens for the prophylaxis of vertical transmission (mother-to-child) of HIV infection. In women in whom HAART is not indicated, or where it is not available, a single oral dose of nevirapine 200 mg may be given at the onset of labour, together with a course of zidovudine and lamivudine, for perinatal cover (see HIV Infection Prophylaxis, p.858).

Administration in children. For the treatment of HIV infection in infants, children, and adolescents nevirapine is given orally with other antiretroviral drugs. The following doses by body-weight have been suggested according to age:

- from 15 days to 8 years: 4 mg/kg once daily for 14 days and then, if no rash is present, 7 mg/kg twice daily
- 8 to 16 years: 4 mg/kg once daily for 14 days then 4 mg/kg twice daily thereafter

Alternatively, the dose may be calculated according to body-surface; an oral dose of 150 mg/m^2 once daily for two weeks is given followed by 150 mg/m^2 twice daily thereafter. A total dose of 400 mg daily should not be exceeded.

For information on the use of nevirapine in regimens for the prophylaxis of vertical transmission (mother-to-child) of HIV infection see HIV Infection Prophylaxis, p.858.

Administration in renal impairment. Dose adjustments are not required for patients with a creatinine clearance more than 20 mL/min. Patients on dialysis should receive an additional 200 mg of nevirapine after each dialysis session.

(oseltamivir)

Adverse Effects

The most commonly reported adverse effects associated with oseltamivir treatment or prophylaxis in adults are nausea and vomiting, abdominal pain, bronchitis, insomnia, and vertigo. Diarrhoea, dizziness, headache, cough, and fatigue may occur, but many adverse effects may be difficult to distinguish from the symptoms of influenza. Other adverse effects occurring less commonly have included unstable angina, anaemia, pseudomembranous colitis, pneumonia, pyrexia, and peritonsillar abscess. There have been occasional reports of anaphylaxis and skin rashes, including toxic epidermal necrolysis, Stevens-Johnson syndrome, and erythema multiforme. Elevated liver enzymes and hepatitis have been reported rarely. Prophylaxis in adults has also been associated with aches and pains, dyspepsia, rhinorrhoea, and upper respiratory-tract infections.

The most commonly reported adverse effects in children receiving treatment or prophylaxis with oseltamivir are vomiting and other gastrointestinal problems. Other commonly occurring adverse events include asthma, bronchitis, conjunctivitis, dermatitis, epistaxis, ear disorders and otitis media, lymphadenopathy, pneumonia, and sinusitis.

There have been postmarketing reports (mainly in Japanese children and adolescents) of neuropsychiatric adverse effects (see below).

Neuropsychiatric effects. A FDA review of the Adverse Event Reporting System (AERS) database from March 2004 to April 2005 reported 75 cases of serious adverse effects linked to the use of oseltamivir in children; 69 from Japan, 5 from USA, and 1 from Canada. Thirty-two cases of neuropsychiatric adverse effects including cases of delirium, abnormal behaviour, hallucinations, convulsions, and encephalitis, were reported, with 31 of these cases being reported from Japan. Twelve deaths were reported; 4 from sudden death, 4 due to cardiopulmonary arrest, and others due to disturbance of consciousness (without falling), pneumonia, asphyxiation, and acute pancreatitis with cardiopulmonary arrest. All deaths were reported from Japan.[1] The Japanese Ministry of Health Labour and Welfare reported that from 2001 to May 2007 they received 1377 adverse effects reports associated with the use of oseltamivir, including 567 reports of serious neuropsychiatric adverse effects and 211 cases of abnormal behaviour. Death was reported in 71 cases.[2] After the suicides of 2 adolescents, the Japanese authorities advised against the use of oseltamivir in adolescents aged 10 to 19 years.[3] However, given that influenza itself may have neuropsychiatric sequelae, any causal relationship with the drug remains unproven.[1,3]

3. Maxwell SRJ. Tamiflu and neuropsychiatric disturbance in adolescents. *BMJ* 2007; **334:** 1232–3.

Precautions

Oseltamivir is not recommended in patients with severe renal impairment and it should be given with caution and dosage should be reduced in patients with moderate renal impairment.

Patients should be monitored for abnormal behaviour throughout the treatment period.

Breast feeding. Oseltamivir and its active metabolite are distributed into breast milk in *rodents*. Licensed product information recommends that it should only be given to breast-feeding mothers if the potential benefit justifies the potential risk.

Pregnancy. Studies in *rodents* given high doses of oseltamivir have not found it to be fetotoxic or embryotoxic. There is little data available on the use of oseltamivir in pregnant women and licensed product information recommends that it should only be given to pregnant women if the potential benefit justifies the potential risk.

Interactions

Oseltamivir may potentially inhibit replication of the influenza virus in live influenza virus vaccines. Therefore, US licensed product information states that live influenza virus vaccines should not be given until 48 hours after stopping oseltamivir and that oseltamivir should not be given for 2 weeks after live influenza virus vaccines have been given. Inactivated (split virion or surface antigen) vaccines are not expected to be affected by oseltamivir.

Antiviral Action

Oseltamivir has antiviral activity similar to that of zanamivir (p.913). Its active metabolite, oseltamivir carboxylate, selectively blocks the viral surface enzyme neuraminidase, thereby preventing the release of virus particles from infected cells. Oseltamivir is active against influenza A and B viral neuraminidase.

Resistance. Oseltamivir-resistant type A virus, including H5N1 subtypes, have been reported in patients being treated for influenza.[1-3] A study[1] in Japan found that 9 of 50 (18%) children with influenza A (H3N2) virus infection who had been treated with oseltamivir had a virus with a drug-resistance mutation in the neuraminidase gene (predominantly R292K). Another study[4] in Japan reported resistant influenza A (H1N1) viruses with the H274Y mutation in 7 of 43 (16%) oseltamivir-treated children. In both these studies the children were given an oral dose of 2 mg/kg twice daily. However, a larger study[5] in the US reported no resistance in children who received age- and weight-tailored (and therefore sometimes substantially higher) doses than those used in the Japanese studies. No viruses resistant to zanamivir have been isolated from immunocompetent people,[6] although there is a case of resistance in an immunocompromised child.[7]

7. Gubareva LV, *et al.* Evidence for zanamivir resistance in an immunocompromised child infected with influenza B virus. *J Infect Dis* 1998; **178:** 1257–62.

Pharmacokinetics

Oseltamivir is readily absorbed from the gastrointestinal tract after oral doses and is extensively metabolised in the liver to the active entity, oseltamivir carboxylate. At least 75% of an oral dose reaches the systemic circulation as the carboxylate. Binding to plasma proteins is about 3% for the carboxylate and 42% for the parent drug. Oseltamivir has a plasma half-life of 1 to 3 hours and the carboxylate a plasma half-life of 6 to 10 hours. The carboxylate is not metabolised further and is eliminated in the urine.

◊ Reviews.

1. Abe M, *et al.* Pharmacokinetics of oseltamivir in young and very elderly subjects. *Ann Pharmacother* 2006; **40:** 1724–30.

Uses and Administration

Oseltamivir is a prodrug of oseltamivir carboxylate, an inhibitor of the enzyme neuraminidase (sialidase), which has a role in the infectivity and replication of influenza A and B viruses. It is used in adults and children over 1 year of age for the treatment and postexposure prophylaxis of influenza A and B (below).

Oseltamivir is given orally as the phosphate, but doses are expressed in terms of the base. Oseltamivir phosphate 98.5 mg is equivalent to about 75 mg of oseltamivir. For the *treatment* of adults a dose of 75 mg is given twice daily for 5 days, beginning as soon as possible (within 48 hours) after the onset of symptoms. For *postexposure prophylaxis* the usual dose is 75 mg given once daily for at least 10 days and for up to 6 weeks during an epidemic; therapy should begin within 48 hours of exposure.

For details of doses in children, see below.

Dosage should be reduced in patients with moderate renal impairment (see below).

Oseltamivir has been tried both for prophylaxis and treatment of H5N1 disease (avian influenza) and many countries are stockpiling the drug in order to contain any potential pandemic until an effective vaccine can be developed.

Administration in children. Oseltamivir is given orally in the treatment and prophylaxis of influenza A and B in children aged 1 year and over. Doses determined by body-weight may be given twice daily for treatment, or once daily for prophylaxis, of influenza A and B as follows:

- children over 40 kg: 75 mg
- more than 23 kg to 40 kg: 60 mg
- more than 15 kg to 23 kg: 45 mg
- 15 kg or less: 30 mg

Therapy should begin within 48 hours of exposure.

Administration in renal impairment. Dosage of oseltamivir should be reduced in patients with moderate renal impairment, according to creatinine clearance (CC):

- CC 10 to 30 mL/minute: *treatment of influenza*: 75 mg once daily or 30 mg twice daily; *prevention*: 75 mg on alternate days or 30 mg daily
- CC less than 10 mL/minute: not recommended
- dialysis patients: not recommended

Influenza. Reviews[1-8] of oseltamivir and other neuraminidase inhibitors in the treatment and prophylaxis of influenza (p.859). There is some evidence[9] that zanamivir is more effective than oseltamivir for influenza B.

Penciclovir *(BAN, USAN, rINN)*

BRL-39123; BRL-39123-D (penciclovir sodium); Penciclovirum; Penciklovir; Pensikloviiri; Pensiklovir. 9-[4-Hydroxy-3-(hydroxymethyl)butyl]guanine.

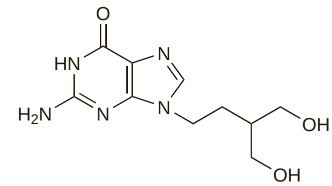
Пенцикловир

$C_{10}H_{15}N_5O_3 = 253.3.$

CAS — 39809-25-1 (penciclovir); 97845-62-0 (penciclovir sodium).

ATC — D06BB06; J05AB13.

ATC Vet — QD06BB06; QJ05AB13.



Adverse Effects and Precautions

Penciclovir applied topically may cause transient stinging, burning, and numbness.

For adverse effects of penciclovir after systemic use of famciclovir, see p.876.

Interactions

Plasma concentrations of penciclovir may be increased in patients receiving *probenecid* with the prodrug famciclovir.

Antiviral Action

Penciclovir has antiviral activity similar to that of aciclovir (p.863). It is active *in vitro* and *in vivo* against herpes simplex virus types 1 and 2 and against varicella-zoster virus. This activity is due to intracellular conversion by virus-induced thymidine kinase into penciclovir triphosphate, which inhibits replication of viral DNA and persists in infected cells for more than 12 hours. It also has activity against Epstein-Barr virus and hepatitis B virus.

◊ References.

1. Vere-Hodge RA. Famciclovir and penciclovir: the mode of action of famciclovir including its conversion to penciclovir. *Antiviral Chem Chemother* 1993; **4:** 67–84.
2. Boyd MR, *et al.* Penciclovir: a review of its spectrum of activity, selectivity, and cross-resistance pattern. *Antiviral Chem Chemother* 1993; **4** (suppl 1): 3–11.
3. Bacon TH, Boyd MR. Activity of penciclovir against Epstein-Barr virus. *Antimicrob Agents Chemother* 1995; **39:** 1599–1602.

Pharmacokinetics

Penciclovir is poorly absorbed from the gastrointestinal tract. For systemic use it is usually given orally as the prodrug famciclovir, which is rapidly converted to penciclovir. Peak plasma concentrations proportional to the dose (over the range 125 to 750 mg) are achieved after 45 minutes to 1 hour. The plasma elimination half-life is about 2 hours. The intracellular half-life of the active triphosphate metabolite is longer. Penciclovir is less than 20% bound to plasma proteins. Penciclovir is mainly excreted unchanged in the urine.

Uses and Administration

Penciclovir is a nucleoside analogue structurally related to guanine, which is active against herpesviruses. It is applied topically as a 1% cream every 2 hours during waking hours for 4 days in the treatment of herpes labialis (see Herpes Simplex Infections, p.854).

For systemic use, penciclovir is given orally as the prodrug famciclovir (see p.876). Intravenous dosage of penciclovir has been investigated.

Peptide T

D-Ala-peptide-T-amide; Péptido T.

Пептид Т

Profile

Peptide T is an octapeptide segment of the envelope glycoprotein of HIV. It has been investigated for the treatment of HIV infection and HIV-associated neurological disorders. Peptide T has also been tried in the treatment of psoriasis.

Pleconaril *(USAN, rINN)*

Pléconaril; Pleconarilo; Pleconarilum; VP-63843; Win-63843. 3-{4-[3-(3-Methyl-5-isoxazolyl)propoxy]-3,5-xylyl}-5-(trifluoromethyl)-1,2,4-oxadizole.

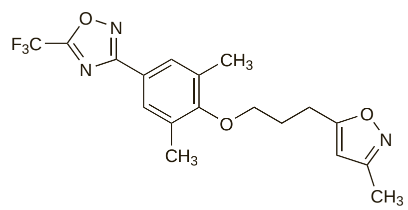
Плеконарил

$C_{18}H_{18}F_3N_3O_3$ = 381.3.

CAS — 153168-05-9.

ATC — J05AX06.

ATC Vet — QJ05AX06.



Profile

Pleconaril is an antiviral with activity against a range of picornaviruses. It has been investigated for the oral treatment of viral meningitis and encephalitis, upper respiratory-tract viral infections, and other enteroviral infections. However, there have been concerns over efficacy, viral resistance, and interactions with oral contraceptives. Development of an intranasal formulation for the common cold has also been investigated.

Poly I.poly C12U

Poli(I)²poli(C_{12}U); Poly(I):poly(C_{12},U).

Поли I.Поли C12U

Profile

Poly I.poly C12U is a synthetic mismatched polymer of double-stranded RNA with antiviral and immunomodulatory activity (see also Poly I. Poly C, p.2370). It is under investigation in the treatment of HIV infection, and also in renal cell carcinoma, chronic fatigue syndrome, invasive melanoma, and hepatitis B and C.

Preparations

Proprietary Preparations (details are given in Part 3)
USA: Ampligen.

Propagermanium *(rINN)*

Propagermanio. A polymer obtained from 3-(trihydroxygermyl)propionic acid.

Пропагерманий

$(C_3H_5GeO_{3.5})_n$.

CAS — 12758-40-6.

Profile

Propagermanium is an immunomodulator that has been used in chronic hepatitis B infections. Acute exacerbation of hepatitis, including some fatalities, has been reported in patients receiving propagermanium.

◊ References.

Raltegravir *(USAN, rINN)*

Raltégravir; Raltegravirum. *N*-{2-[4-(4-Fluorobenzylcarbamoyl)-5-hydroxy-1-methyl-6-oxo-1,6-dihydropyrimidin-2-yl]propan-2-yl}-5-methyl-1,3,4-oxadiazole-2-carboxamide.

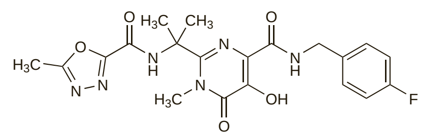
Ральтегравир

$C_{20}H_{21}FN_6O_5$ = 444.4.

CAS — 518048-05-0.

ATC — J05AX08.

ATC Vet — QJ05AX08.



Raltegravir Potassium *(USAN, rINNM)*

Kalii Raltegravirum; MK-0518; Raltegravir potásico; Raltégravir Potassique. Potassium 4-[(4-fluorobenzyl)carbamoyl]-1-methyl-2-(1-methyl-1-{[(5-methyl-1,3,4-oxadiazol-2-yl)carbonyl]amino}ethyl)-6-oxo-1,6-dihydropyrimidin-5-olate.

Калия Ральтегравир

$C_{20}H_{20}FKN_6O_5$ = 482.5.

CAS — 871038-72-1.

Adverse Effects and Precautions

On the basis of limited data, raltegravir appears to be well tolerated; non-specific adverse effects associated with raltegravir-based regimens include headache, abdominal pain, vomiting, asthenia, fatigue, and dizziness. Abnormal creatine phosphokinase values may occur and myopathy and rhabdomyolysis have been reported although a causal relationship has not been established; nonetheless, caution is advised in patients at increased risk of these conditions.

Interactions

Raltegravir is not a substrate for cytochrome P450 isoenzymes, and does not appear to interact with drugs metabolised by this mechanism. However, rifampicin induces the glucuronidase responsible for raltegravir metabolism (UGT1A1) and reduces plasma concentrations of raltegravir.

Antivirals. Plasma concentrations of raltegravir were modestly increased by *atazanavir* and ritonavir-boosted atazanavir in healthy subjects; this increase is not considered to be clinically significant.[1]

1. Iwamoto M, *et al.* Atazanavir modestly increases plasma levels of raltegravir in healthy subjects. *Clin Infect Dis* 2008; **47:** 137–40.

Pharmacokinetics

Raltegravir is absorbed on oral dosage, with peak concentrations achieved about 3 hours after a dose. There is considerable inter-individual variation in the pharmacokinetics. It is metabolised via glucuronidation, catalysed by the enzyme uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1), and excreted in both urine and faeces as unchanged drug and metabolites.

Uses and Administration

Raltegravir is an inhibitor of HIV integrase, an enzyme essential for insertion of viral DNA into the host genome, and thus for replication. It is added to treatment with other antiretrovirals for salvage therapy in patients with HIV infection and AIDS (p.856) who have evidence of viral replication and HIV-1 strains resistant to multiple antiretrovirals.

It is given orally as the potassium salt but doses are calculated in terms of the base; 434 mg of raltegravir potassium is equivalent to about 400 mg of raltegravir. The usual dose is the equivalent of 400 mg of raltegravir twice daily, with or without food.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Ribavirin). A white or almost white crystalline powder. It exhibits polymorphism. Freely soluble in water; slightly soluble in alcohol; slightly soluble or very slightly soluble in dichloromethane. A 2% solution in water has a pH of 4.0 to 6.5. Protect from light.

USP 31 (Ribavirin). A white crystalline powder. Freely soluble in water; slightly soluble in dehydrated alcohol. Store in airtight containers.

Adverse Effects

When given *by inhalation*, ribavirin has sometimes led to worsening of lung function, bacterial pneumonia, and pneumothorax, to cardiovascular effects (including a fall in blood pressure and cardiac arrest), and, rarely, to anaemia, haemolysis, and reticulocytosis. Conjunctivitis and skin rash have also occurred. Precipitation of inhaled ribavirin and consequent accumulation of fluid has occurred in the tubing of ventilating equipment.

The most common adverse effects reported by patients taking *oral* ribavirin, with either interferon alfa or peginterferon alfa, are psychiatric reactions (such as anxiety, depression, insomnia, and irritability) and flu-like symptoms. Life-threatening or fatal adverse effects include severe depression, suicidal ideation, relapse of drug abuse or overdose, and bacterial infection. Severe adverse effects include haemolytic anaemia, leucopenia, thrombocytopenia, aplastic anaemia, diabetes mellitus, auto-immune disorders, gastrointestinal symptoms, pancreatitis, pulmonary embolism, chest pain, liver dysfunction, and interstitial pneumonitis. Lupus erythematosus, rash (including very rarely Stevens-Johnson syndrome and toxic epidermal necrolysis), and photosensitivity have also been reported. Growth retardation (including decrease in height and weight) has been reported in children. A wide range of other adverse effects may occur as a result of the use of ribavirin with interferon alfa (see under Adverse Effects in Interferon Alfa, p.885).

Incidence of adverse effects. A review[1] of adverse effects reported in 110 patients with suspected or probable SARS who were treated with ribavirin found that 61% of the patients had evidence of haemolytic anaemia. In a smaller cohort of 76 patients hypocalcaemia and hypomagnesaemia were reported in 58% and 46% of patients, respectively, while 29% had evidence of both hypocalcaemia and hypomagnesaemia. A retrospective cohort study[2] found that the adverse effects strongly associated with the use of ribavirin (mostly high-dose) in 306 patients with confirmed or probable SARS, were progressive anaemia, hypomagnesaemia, and bradycardia.

1. Knowles SR, *et al.* Common adverse events associated with the use of ribavirin for severe acute respiratory syndrome in Canada. *Clin Infect Dis* 2003; **37:** 1139–42.
2. Muller MP, *et al.* Canadian SARS Research Network. Adverse events associated with high-dose ribavirin: evidence from the Toronto outbreak of severe acute respiratory syndrome. *Pharmacotherapy* 2007; **27:** 494–503.

Precautions

SPECIFIC CAUTIONS FOR INHALED TREATMENT. Standard supportive respiratory and fluid management should be maintained during aerosol treatment with ribavirin and electrolytes should be monitored closely. Equipment should be monitored for precipitation of ribavirin. Precautions should be taken to minimise atmospheric pollution with ribavirin during aerosol inhalation.

SPECIFIC CAUTIONS FOR ORAL TREATMENT. Ribavirin should not be given orally to patients with pre-existing medical conditions that could be exacerbated by ribavirin-induced haemolysis, including significant or unstable cardiac disease or haemoglobinopathies (thalassaemia or sickle-cell anaemia). Blood cell counts and chemistry should be measured at the start of treatment, after 2 and 4 weeks of treatment, and periodically thereafter. Patients with renal impairment and a creatinine clearance of less than 50 mL/minute should not receive oral ribavirin. It should be avoided in patients with severe hepatic impairment or decompensated cirrhosis of the liver (Child-Pugh 6 or more). The potential for development of gout should be considered in predisposed patients. Patients should be monitored for signs and symptoms of psychiatric disorders. Ribavirin therapy is contra-indicated in children and adolescents with a history of, or existing, psychiatric disorders. The growth of children should be monitored and thyroid function should be tested every 3 months. Patients infected with hepatitis C virus and HIV should be carefully monitored for signs of mitochondrial toxicity and lactic acidosis. Dental and periodontal disorders have been reported and regular dental examinations and good oral hygiene are advised.

Contact lenses. Report of damage to a nurse's soft contact lenses after intermittent occupational exposure to aerosolised ribavirin over a period of 1 month.[1]

1. Diamond SA, Dupuis LL. Contact lens damage due to ribavirin exposure. *DICP Ann Pharmacother* 1989; **23:** 428–9.

Pregnancy. Oral ribavirin has been reported to be teratogenic and embryocidal in *rodents* and is contra-indicated in pregnancy or in those who may become pregnant. Ribavirin was not found to be teratogenic in *baboons.* Although there are no case reports of teratogenicity after exposure to aerosolised ribavirin during pregnancy, licensed product information advises that pregnant women and those planning pregnancy should avoid exposure to the aerosol. Pregnancy should also be avoided in partners of male patients taking ribavirin orally. Effective contraception should be used during treatment and for 6 months after the end of treatment. Male patients whose partners are pregnant should use a condom to minimise vaginal exposure to ribavirin.

Interactions

Use of ribavirin with zidovudine is not recommended as patients are at increased risk of anaemia. Increased toxicity has also been seen with didanosine, and the combination should be avoided. Ribavirin inhibits the phosphorylation of NRTIs such as zidovudine, lamivudine, and stavudine, but although UK licensed product information suggests this may reduce their activity against HIV, US product information indicates that no such reduction has been seen in practice.

Anticoagulants. For reference to the effect of ribavirin on the activity of *warfarin*, see under Antivirals, p.1430.

Antiviral Action

Ribavirin inhibits many viruses *in vitro* and in *animal* models. However, this activity has not necessarily correlated with activity against human infections. Ribavirin is phosphorylated but its mode of action is still unclear; it may act at several sites, including cellular enzymes, to interfere with viral nucleic acid synthesis. The mono- and triphosphate derivatives are believed to be responsible for its antiviral activity. Susceptible DNA viruses include herpesviruses, adenoviruses, and poxviruses. Susceptible RNA viruses include Lassa virus, members of the bunyaviridae group, influenza, parainfluenza, measles, mumps, and RSV, and HIV.

Pharmacokinetics

Aerosolised ribavirin is absorbed systemically, but local concentrations in the respiratory tract secretions are much higher than plasma concentrations. Plasma half-life is about 9.5 hours. The bioavailability of aerosolised ribavirin is unknown and may depend on the mode of delivery.

Ribavirin is rapidly absorbed after oral doses and peak plasma concentrations have been reported within 1 to 2 hours. Absorption is extensive but oral bioavailability is about 45 to 65% as a result of first-pass metabolism. Steady state plasma concentrations are achieved after about 4 weeks with twice-daily oral doses resulting in peak plasma concentrations 6 times higher than that after single doses. On stopping dosing the plasma half-life is about 300 hours as a result of slow elimination from non-plasma compartments. Ribavirin does not bind to plasma proteins. Ribavirin is not metabolised by the cytochrome P450 system; it is metabolised by reversible phosphorylation and degradation involving deribosylation and amide hydrolysis to give a triazole carboxyacid metabolite. After a single oral dose the terminal half-life is about 120 to 170 hours. Ribavirin is mainly excreted in the urine as unchanged drug and metabolites. Insignificant amounts of the drug are removed by haemodialysis.

Uses and Administration

Ribavirin is a synthetic nucleoside analogue structurally related to guanine. It is given by aerosol in the treatment of RSV infections (p.860); this route appears to give better results than the oral route although its efficacy is questionable. It is used orally with an interferon alfa or peginterferon alfa in the treatment of chronic hepatitis C, including HIV co-infection (p.851). Ribavirin has been tried in haemorrhagic fevers (such as haemorrhagic fever with renal syndrome and Lassa fever) and in SARS.

For details of doses in children, see below.

Ribavirin is used, with an interferon alfa or peginterferon alfa, for the treatment of chronic **hepatitis C**. Doses of ribavirin depend upon the product used, but are given orally, usually twice daily, and are determined according to body-weight. Duration of treatment, and sometimes also dose, may be influenced by the genotype of the hepatitis C virus. In those with hepatitis C infection alone (*mono-infection*), patients with viral genotype 1, and probably genotype 4, should generally be treated for 48 weeks and those with genotype 2 or 3 for 24 weeks; data on genotypes 5 or 6 are insufficient to make recommendations. In *co-infection* with HIV, treatment should generally be given for 48 weeks regardless of genotype.

Rebetol (*Schering-Plough*) is used, with interferon alfa-2b or peginterferon alfa-2b for hepatitis C.

The following doses are recommended in the UK:
- adults up to 65 kg: 400 mg both in the morning and in the evening
- 65 to 85 kg: 400 mg in the morning and 600 mg in the evening
- from 85 to 105 kg: 600 mg both in the morning and in the evening
- over 105 kg: 600 mg in the morning and 800 mg in the evening

In the USA, the doses are:
- adults up to 75 kg: 400 mg in the morning and 600 mg in the evening
- over 75 kg: 600 mg both in the morning and in the evening

Copegus (*Roche*) is used in the UK with interferon alfa-2a or peginterferon alfa-2a and in the USA with peginterferon alfa-2a.

The following doses are used with peginterferon alfa-2a for mono-infection in genotype 1 or 4:
- adults up to 75 kg: 400 mg in the morning and 600 mg in the evening
- over 75 kg: 600 mg both in the morning and in the evening

For mono-infection in genotype 2 or 3 (with peginterferon alfa-2a):
- all adults: 400 mg both in the morning and in the evening

The following doses are used with interferon alfa-2a for mono-infection in genotype 1 to 4:
- adults up to 75 kg: 400 mg in the morning and 600 mg in the evening
- over 75 kg: 600 mg both in the morning and in the evening

For co-infection with HIV:
- all adults: 800 mg daily, irrespective of genotype

Dose reductions of ribavirin may be necessary in patients who develop low haemoglobin concentrations. Ribavirin is contra-indicated in patients with a creatinine clearance less than 50 mL/minute.

◊ Reviews.

4. Ventre K, Randolph AG. Ribavirin for respiratory syncytial virus infection of the lower respiratory tract in infants and young children. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2007 (accessed 13/06/08).
5. Keam SJ, Cvetković RS. Peginterferon-α-2a (40 kD) plus ribavirin: a review of its use in the management of chronic hepatitis C mono-infection. *Drugs* 2008; **68:** 1273–1317.

Administration in children. Preparations of ribavirin are available for aerosol administration to infants and children with severe **RSV** infection via a small particle aerosol generator. Solutions containing 20 mg/mL are used; 300 mL, representing 6 g of ribavirin, is delivered over a 12- to 18-hour period by aerosol at an average concentration of 190 micrograms/litre of air. Treatment is given for 3 to 7 days.

Ribavirin is used, with an interferon alfa, for the treatment of chronic **hepatitis C**. Doses of ribavirin depend upon the product used, but are given orally, usually twice daily, and are determined according to body-weight. Duration of treatment, and sometimes also dose, may be influenced by the genotype of the hepatitis C virus. In hepatitis C mono-infection, patients with viral genotype 1 should be treated for 48 weeks and those with genotype 2 or 3 for 24 weeks.

Rebetol (Schering-Plough) is used, with interferon alfa-2b or peginterferon alfa-2b, for hepatitis C.

The following doses are recommended in the UK:

- 47 to 49 kg: 200 mg in the morning and 400 mg in the evening
- 50 to 65 kg: 400 mg both in the morning and in the evening
- over 65 kg: the adult dose (above)

In the USA, the doses are:

- 25 to 36 kg: 200 mg both in the morning and in the evening
- 37 to 49 kg: 200 mg in the morning and 400 mg in the evening
- 50 to 61 kg: 400 mg both in the morning and in the evening
- over 61 kg: the adult dose

Copegus (Roche) is not licensed for use in those less than 18 years of age.

Encephalitis. A beneficial response to ribavirin was reported in a child with severe La Crosse encephalitis.[1] Ribavirin was given intravenously in a dose of 25 mg/kg over the first 24 hours and then reduced to 15 mg/kg daily for a further 9 days. A small open-label study[2] suggested that ribavirin might also be able to reduce mortality and neurological deficits in acute Nipah encephalitis.

Intraventricular ribavirin (plus intraventricular interferon and oral isoprinosine) was found to be effective in 4 of 5 patients with subacute sclerosing panencephalitis.[3] A concentration of ribavirin in the CSF of 50 to 200 micrograms/mL completely inhibited viral replication; doses of ribavirin given to achieve this concentration ranged from 1 to 9 mg/kg daily.

3. Hosoya M, *et al.* Pharmacokinetics and effects of ribavirin following intraventricular administration for treatment of subacute sclerosing panencephalitis. *Antimicrob Agents Chemother* 2004; **48:** 4631–5.

Haemorrhagic fevers. The treatment of haemorrhagic fevers (p.850) is primarily symptomatic. However, ribavirin has been reported to reduce mortality in patients with Lassa fever,[1] haemorrhagic fever with renal syndrome,[2] and possibly Crimean-Congo haemorrhagic fever[3,4] and Bolivian haemorrhagic fever.[5] Intravenous ribavirin has also been tried in the related hantavirus pulmonary syndrome,[6,7] but a small randomised, double-blind, placebo-controlled study[8] with intravenous ribavirin reported no significant difference in survival between the 2 groups.

For treatment of *Lassa fever*, ribavirin has been given intravenously in a dose of 2 g initially, then 1 g every 6 hours for 4 days, then 500 mg every 8 hours for 6 days.[1] Treatment is most effective if started within 6 days of the onset of fever. Experience has shown that rigors may occur if the drug is given as a bolus injection, but that this can be overcome by giving it as an infusion over 30 minutes.[9] For prophylaxis, an oral dose of ribavirin 600 mg 4 times daily for 10 days has been suggested for adults,[10] although this was considered to be excessive by other commentators[11] who suggested that oral doses of 1 g daily (after an intravenous loading dose for those in whom the start of prophylaxis is delayed) might be suitable.

(rimantadine)

Pharmacopoeias. In *US.*

USP 31 (Rimantadine Hydrochloride). Store at a temperature of 15° to 30°.

Adverse Effects and Precautions

The incidence and severity of adverse effects associated with rimantadine appear to be low. Those most commonly reported are gastrointestinal disturbances such as nausea, vomiting, abdominal pain, dry mouth, and anorexia, CNS effects such as headache, insomnia, nervousness, and dizziness, and asthenia. Other less frequently reported adverse effects include ataxia, agitation, concentration difficulties, diarrhoea, dyspepsia, depression, dyspnoea, skin rash, somnolence, and tinnitus.

There have been reports of convulsions, including grand mal convulsions, and rimantadine should be given with caution to patients with epilepsy. Doses are reduced in severe renal or hepatic impairment; reduced doses are also used in the elderly.

◊ A review[1] of clinical studies in adults concluded that rimantadine and amantadine were equally effective for prevention and treatment of influenza A, but rimantadine was significantly better tolerated than amantadine at usual doses. Another systematic review[2] evaluating the safety and efficacy of amantadine and rimantadine in children and the elderly with influenza A concluded that although rimantadine was safe in these groups, its efficacy was unproven and therefore its use could not be recommended.

In a study[3] to evaluate the safety of long-term rimantadine for elderly, chronically ill individuals during an influenza A epidemic, a significantly greater proportion of patients taking rimantadine developed anxiety and/or nausea compared with those taking placebo. There was also a significantly greater number of days in which anxiety, nausea, confusion, depression, or vomiting were reported. Most of these adverse effects lasted less than 9 days and were seldom severe except in 2 patients who withdrew from the study because of insomnia, anxiety, or both and a third who suffered a generalised convulsion. In a larger study[4] the incidence of these symptoms was similar in treatment and placebo groups.

Observations of seizures in 2 patients receiving influenza prophylaxis with rimantadine hydrochloride emphasised that chronically ill and elderly patients prone to seizures (especially those who may have had antiepileptic therapy withdrawn) may be at greater risk of developing seizures.[5] A precautionary measure of reducing the rimantadine hydrochloride dosage to 100 mg daily and temporary re-introduction of antiepileptics was suggested.

5. Bentley DW, *et al.* Rimantadine and seizures. *Ann Intern Med* 1989; **110:** 323–4.

Breast feeding. Rimantadine is distributed into breast milk in *animals* in concentrations about twice those measured in the serum. US licensed product information states that rimantadine should be avoided in breast-feeding mothers.

Pregnancy. Although there is no data available on the use of rimantadine in pregnant women, US licensed product information states that it should only be used if potential benefit justifies the risk to the fetus as embryotoxicity has been reported in *rats* given high doses of rimantadine.

Antiviral Action

Rimantadine is an M2 ion channel inhibitor that inhibits influenza A virus replication mainly by blocking the M2-protein ion channel, thereby preventing fusion of the virus and the host-cell membranes and the release of viral RNA into the cytoplasm of infected cells.

Resistance to rimantadine can occur rapidly and resistant virus may be transmitted to close contacts of patients treated with rimantadine and cause influenza. Rimantadine and amantadine show complete cross-resistance.

Resistance. Resistance of influenza A viruses to the adamantane M2 ion channel inhibitors amantadine and rimantadine can occur spontaneously or emerge rapidly during treatment. A single point mutation in the code sequence for the amino acids at positions 26, 27, 30, 31, or 34 of the M2 protein can confer cross-resistance to both amantadine and rimantadine. The resistant viruses can still replicate and be transmitted.[1-3] A report[4] describing the global prevalence of adamantane-resistant influenza A viruses over a 10 year period shows an increase in drug resistance from 0.4% during the 1994/5 influenza season to 12.3% during the 2003/4 season. During the 2005/6 influenza season, WHO and the National Respiratory and Enteric Virus Surveillance System (NREVSS) laboratories in the United States reported tests on 120 influenza viruses of which 109 (91%) were found to have substitutions in the M2 protein that would confer resistance to amantadine and rimantadine.[3] In the USA, the reported adamantane resistance rate for influenza A increased from 11% for the 2004/5 influenza season to 92% for the 2005/6 influenza season.[5] On the basis of this information, the CDC no longer recommends amantadine or rimantadine for the treatment or prophylaxis of influenza A infections.[3,6]

Pharmacokinetics

Rimantadine hydrochloride is well, but slowly, absorbed from the gastrointestinal tract and maximum plasma concentrations are reached after about 6 hours. It has a large volume of distribution and long elimination half-life; reported figures for half-life in healthy adults range from 13 to 65 hours (mean 25.4 hours) and from 20 to 65 hours (mean 32 hours) in those over 70 years of age. Protein binding of rimantadine is about 40%. It is extensively metabolised in the liver with less than 25% of a dose being excreted unchanged in the urine; about 75% is excreted as hydroxylated metabolites over 72 hours. In severe renal or hepatic impairment the elimination half-life is about double, necessitating a dosage reduction.

Uses and Administration

Rimantadine hydrochloride is used similarly to amantadine hydrochloride (p.792) in the prophylaxis and treatment of influenza A infections (p.859) in adults and for prophylaxis of influenza A infection in children. It is given orally in usual adult doses of

200 mg daily in divided doses. In elderly patients the usual daily dose is 100 mg. A dosage reduction is also necessary in patients with severe renal or severe hepatic impairment (see below).

For details of doses in children, see below.

◊ Reviews.

1. Jefferson T, *et al.* Amantadine and rimantadine for influenza A in adults. Available in The Cochrane Database of Systematic Reviews; Issue 2. Chichester: John Wiley; 2006 (accessed 13/06/08).

Administration in children. For the prophylaxis of influenza A in children from 1 year of age, an oral dose of 5 mg/kg daily, up to a maximum daily dose of 150 mg, may be given. Although not licensed for the treatment of influenza A some experts consider that it may be given to children from 1 year of age.

Administration in hepatic or renal impairment. The usual oral dose of rimantadine in patients with severe renal or severe hepatic impairment and in elderly nursing home patients is 100 mg daily.

USP 31 (Ritonavir). Practically insoluble in water; very soluble in acetonitrile; freely soluble in dichloromethane and in methyl alcohol. Store in airtight containers at a temperature between 5° and 30°. Protect from light.

Adverse Effects

The most common adverse effects associated with antiretroviral regimens containing ritonavir are asthenia, gastrointestinal effects (abdominal pain, anorexia, diarrhoea, nausea, and vomiting), headache, taste disorder, and numbness around the mouth. One of the more serious adverse effects of ritonavir is potentially fatal pancreatitis. Other commonly reported adverse effects include anxiety, dizziness, insomnia, fever, other gastrointestinal effects (dry mouth, dyspepsia, flatulence, local throat irritation), hyperaesthesia, mouth ulcer, malaise, pharyngitis, pruritus, rash, sweating, vasodilatation, and weight loss. Allergic reactions include urticaria, mild skin eruptions, bronchospasm, angioedema, and rarely anaphylaxis. A possible association with Stevens-Johnson syndrome has been reported with ritonavir. Reported abnormal laboratory results are decreased haemoglobin levels, increased eosinophil counts, raised liver enzymes and uric acid concentrations, and decreased free and total thyroxine concentrations; white blood cell and neutrophil counts may be reduced or increased.

Adverse effects associated with the use of ritonavir as a pharmacokinetic booster are dependent on the other HIV-protease inhibitor.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including ritonavir, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been seen in patients receiving antiretroviral therapy including ritonavir. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported. Elevated creatine phosphokinase, myalgia, myositis, and rarely rhabdomyolysis have been reported with HIV-protease inhibitors, particularly when given with nucleoside analogues. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy. For further information on adverse effects associated with HIV-protease inhibitors see under Indinavir Sulfate, p.882.

Precautions

Ritonavir (as an antiviral agent or as a pharmacokinetic enhancer) should not be used in patients with decompensated liver disease. Caution is advised in patients with severe hepatic impairment (Child-Pugh Grade C) without decompensation, when ritonavir is used as a pharmacokinetic booster with another HIV-protease inhibitor, although specific recommendations depend on the other drug. Patients with pre-existing liver disease or co-infected with chronic hepatitis B or C and treated with combination antiretroviral therapy are at increased risk for severe and potentially fatal hepatic adverse events. Caution is advised in treating patients with haemophilia A and B as reports of spontaneous bleeding have been associated with the use of HIV-protease inhibitors. Patients should be monitored for signs and symptoms of pancreatitis (abdominal pain, nausea, vomiting, and increased serum lipase or amylase levels) and ritonavir treatment should be stopped in patients developing pancreatitis.

Interactions

Ritonavir is reported to have a high affinity for several cytochrome P450 isoenzymes with the following ranked order:

CYP3A > CYP2D6 > CYP2C9

Consequently ritonavir may compete with other drugs metabolised by this system, potentially resulting in mutually increased plasma concentrations and toxicity. Ritonavir also has a high affinity for P-glycoprotein and may inhibit this transporter; it may also induce glucuronidation and oxidation by CYP1A2 and CYP2C19.

Oral liquid formulations of ritonavir currently contain alcohol and use with disulfiram or metronidazole should be avoided.

Ritonavir is contra-indicated with drugs that are highly dependent on CYP3A4 for clearance and for which elevated plasma concentrations are associated with serious or life-threatening events. These drugs include the alpha-adrenergic antagonist alfuzosin, antiarrhythmics (amiodarone, bepridil, encainide, flecainide, propafenone, and quinidine), antifungals (voriconazole), antihistamines (astemizole and terfenadine), ergot derivatives (dihydroergotamine, ergometrine, ergotamine, and methylergometrine), gastrointestinal prokinetics (cisapride), antipsychotics (clozapine and pimozide), sedatives and hypnotics (midazolam and triazolam), and statins (lovastatin and simvastatin). St John's wort decreases the concentration of ritonavir; use with the antiretroviral is not recommended due to the possible loss of its activity and development of resistance. UK licensed product information also contra-indicates the use of ritonavir with the analgesics pethidine, piroxicam, and dextropropoxyphene, bupropion, fusidic acid, rifabutin, and some other sedatives and hypnotics (clorazepate, diazepam, estazolam, and flurazepam).

For further information on drug interactions of HIV-protease inhibitors see under Indinavir Sulfate, p.883 and Table 1, p.917.

Antiviral Action

Ritonavir is a selective, competitive, reversible inhibitor of HIV protease. It is active against HIV-1 and, to a lesser extent, HIV-2. It interferes with the formation of essential viral proteins making them incapable of infecting other cells. Ritonavir is also a potent inhibitor of the cytochrome P450 subfamily CYP3A (chiefly the isoenzyme CYP3A4), and low-dose ritonavir is used with other HIV-protease inhibitors to decrease their metabolism and thus increase plasma concentrations of the other protease inhibitor; such use is referred to as ritonavir pharmacokinetic enhancement or ritonavir-boosted therapy. Viral resistance develops rapidly when HIV-protease inhibitors are given alone and therefore they are used with other antiretrovirals. Various degrees of cross-resistance between HIV-protease inhibitors may occur; in general the greater the number of mutations, the higher the level of resistance. Cross-resistance between HIV-protease inhibitors and NRTIs or NNRTIs is considered unlikely.

Pharmacokinetics

Ritonavir is absorbed after oral doses and peak plasma concentrations occur in about 2 to 4 hours. Absorption is enhanced when ritonavir is taken with food, and is dose-related. Protein binding is reported to be about 98% and penetration into the CNS is minimal. Ritonavir is extensively metabolised in the liver mainly by cytochrome P450 isoenzymes CYP3A4 and to a lesser extent by CYP2D6. Five metabolites have been identified and the major metabolite has antiviral activity, but concentrations in plasma are low. Studies in HIV-infected children 2 to 14 years of age indicate that ritonavir clearance is 1.5 to 1.7 times greater than in adults. About 86% of a dose is eliminated through the faeces (both as unchanged drug and as metabolites) and about 11% is excreted in the urine (3.5% as unchanged drug). The elimination half-life is 3 to 5 hours.

Uses and Administration

Ritonavir is an HIV-protease inhibitor with antiviral activity against HIV. It is used in the treatment of HIV infection and AIDS (p.856). Viral resistance emerges rapidly when ritonavir is used alone, and it is therefore given with other antiretrovirals.

Ritonavir is given orally in an adult dose of 600 mg twice daily with food. In order to minimise nausea, ritonavir may be started at a dose of 300 mg twice daily and gradually increased over a period of up to 14 days by 100 mg twice daily to a total of 600 mg twice daily.

For details of doses in children, see below.

When used as a pharmacokinetic enhancer ritonavir is given in doses of 100 to 200 mg once or twice daily with other HIV-protease inhibitors.

2. Cooper CL, *et al.* A review of low-dose ritonavir in protease inhibitor combination therapy. *Clin Infect Dis* 2003; **36:** 1585–92.

Administration. Adjusting the dosage of ritonavir from 600 mg twice daily to 300 mg every 6 hours improved tolerability in 2 patients who would otherwise have stopped the drug.[1]

1. Merry C, *et al.* Improved tolerability of ritonavir derived from pharmacokinetic principles. *Br J Clin Pharmacol* 1996; **42:** 787.

Administration in children. For the treatment of HIV infection in children, ritonavir is given daily with other antiretroviral drugs. US licensed product information permits the use of oral ritonavir in infants over 1 month of age, whereas in the UK it is recommended from 2 years of age. The dose given should not exceed the maximum adult dose of 600 mg twice daily.

The recommended dose regimen is an initial dose of 250 mg/m^2 twice daily increasing by 50 mg/m^2 twice daily at 2- or 3-day intervals up to 350 to 400 mg/m^2 twice daily.

Molluscum contagiosum. Intractable molluscum contagiosum, a viral skin infection, resolved when a patient was given ritonavir for treatment of HIV infection.[1]

Adverse Effects

The most common adverse effects associated with antiretroviral regimens containing saquinavir are gastrointestinal disorders (abdominal pain, diarrhoea, flatulence, nausea, vomiting) and fatigue. Other commonly reported adverse effects include alopecia, anaemia, anorexia, increased appetite, asthenia, constipation, dizziness, dry lips, mouth and skin, dyspepsia, dyspnoea, eczema, headache, hypersensitivity, decreased libido, malaise, muscle spasm, paraesthesia, peripheral neuropathy, pruritus, rash, sleep disturbances, and taste disorders. Commonly reported laboratory abnormalities include raised liver enzyme values, increased blood amylase, bilirubin, and creatinine, and lowered haemoglobin and platelet, lymphocyte, and white blood cell count. Rare but serious adverse effects that may be associated with saquinavir include acute myeloid leukaemia, haemolytic anaemia, allergic reactions, ascites, bullous skin eruptions, intestinal obstruction, jaundice, nephrolithiasis, pancreatitis, polyarthritis, portal hypertension, seizures, Stevens-Johnson syndrome, attempted suicide, and thrombocytopenia (occasionally fatal).

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including saquinavir, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been seen in patients receiving antiretroviral therapy, including saquinavir. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported. Elevated creatine phosphokinase, myalgia, myositis, and rarely rhabdomyolysis have been reported with HIV-protease inhibitors, particularly when given with nucleoside analogues. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy.

For further information on adverse effects associated with HIV-protease inhibitors see under Indinavir Sulfate, p.882.

Precautions

Ritonavir-boosted saquinavir should not be used in patients with decompensated liver disease and should be used with caution in patients with moderate hepatic or severe renal impairment. Patients with pre-existing liver disease or co-infected with chronic hepatitis B or C and treated with combination antiretroviral therapy are at increased risk for severe and potentially fatal hepatic adverse events. Caution is advised in treating patients with haemophilia A and B as reports of spontaneous bleeding have been associated with the use of HIV-protease inhibitors.

Interactions

Saquinavir is reported to be metabolised by the cytochrome P450 system, with the specific isoenzyme CYP3A4 responsible for more than 90% of the hepatic metabolism. Saquinavir is also a substrate and an inhibitor of P-glycoprotein. Drugs that affect this isoenzyme and/or P-glycoprotein may modify saquinavir plasma concentrations. Saquinavir may alter the pharmacokinetics of other drugs that are metabolised by this enzyme system or that are substrates for P-glycoprotein.

Saquinavir is contra-indicated with drugs that are highly dependent on CYP3A4 for clearance and for which elevated plasma concentrations are associated with serious or life-threatening events. These drugs include antiarrhythmics (amiodarone, bepridil, flecainide, propafenone, and quinidine), antihistamines (astemizole and terfenadine), antimycobacterial (rifampicin), ergot derivatives (dihydroergotamine, ergometrine, ergotamine, methylergometrine), gastrointestinal prokinetics (cisapride), antipsychotics (pimozide), sedatives and hypnotics (midazolam and triazolam), and statins (simvastatin and lovastatin). St John's wort decreases the concentration of saquinavir; use with the antiretroviral is not recommended due to the possible loss of its activity and development of resistance.

For further information on drug interactions of HIV-protease inhibitors see under Indinavir Sulfate, p.883 and Table 1, p.917.

Antiviral Action

Saquinavir is a selective, competitive, reversible inhibitor of HIV-1 and HIV-2 protease. It interferes with the formation of essential viral proteins making them incapable of infecting other cells. Viral resistance develops rapidly when HIV-protease inhibitors are given alone and therefore they are used with other antiretrovirals. HIV isolates resistant to saquinavir have been reported and variable cross-resistance with other HIV-protease inhibitors has been seen. Cross-resistance between saquinavir and NRTIs or NNRTIs is unlikely because these drugs have different target enzymes.

Pharmacokinetics

Saquinavir is absorbed to a limited extent (about 30%) after oral doses of the mesilate and undergoes extensive first-pass hepatic metabolism, resulting in a bioavailability of 4% when taken with food. Bioavailability was found to be greater from a soft gelatin capsule formulation of saquinavir base in a suitable vehicle (*Fortovase, Roche*) than from a hard capsule formulation (*Invirase, Roche*). Bioavailability is substantially less when saquinavir is taken in the fasting state. Plasma concentrations are reported to be higher in HIV-infected patients than in healthy subjects. Saquinavir is about 98% bound to plasma proteins and extensively distributed into the tissues, although CSF concentrations are reported to be negligible. It is rapidly metabolised by the cytochrome P450 system (specifically the isoenzyme CYP3A4) to a number of inactive monohydroxylated and dihydroxylated compounds. It is excreted mainly in the faeces with a reported terminal elimination half-life of 13.2 hours.

3. Acosta EP, *et al.* Pharmacokinetics of saquinavir plus low-dose ritonavir in human immunodeficiency virus-infected pregnant women. *Antimicrob Agents Chemother* 2004; **48:** 430–6.

Uses and Administration

Saquinavir is an HIV-protease inhibitor with antiviral activity against HIV. It is used in the treatment of HIV infection and AIDS (p.856). Viral resistance emerges rapidly when saquinavir is used alone, and it is therefore used with other antiretrovirals, including low-dose ritonavir which is given as a pharmacokinetic enhancer (ritonavir-boosted saquinavir).

Saquinavir is given orally as the mesilate but doses are expressed in terms of the base; 229 mg of saquinavir mesilate is equivalent to about 200 mg of saquinavir. The dose is 1 g twice daily given with ritonavir 100 mg twice daily with or after food.

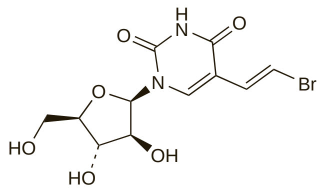
Sorivudine *(BAN, USAN, rINN)*

Bravavir; Bromovinylarauracil; Brovavir; BV-araU; BVAU; Sorivudina; Sorivudinum; SQ-32756; YN-72. (*E*)-1-β-D-Arabinofuranosyl-5-(2-bromovinyl)uracil.

Соривудин

$C_{11}H_{13}BrN_2O_6$ = 349.1.

CAS — 77181-69-2.



Profile

Sorivudine is a synthetic thymidine derivative with antiviral activity against varicella-zoster virus. It has been investigated for the treatment of herpes zoster but was withdrawn from the market in Japan after deaths in patients also given fluorouracil.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Stavudine). A white or almost white powder. It exhibits polymorphism. Soluble in water; sparingly soluble in alcohol; slightly soluble in dichloromethane. Protect from light and humidity.

USP 31 (Stavudine). A white to off-white, crystalline powder. Soluble in water, in dimethylacetamide, and in dimethyl sulfoxide; sparingly soluble in alcohol, in acetonitrile, and in methyl alcohol; slightly soluble in dichloromethane; insoluble in petroleum spirit. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects

The most common adverse effect reported with stavudine either as monotherapy or with other antiretrovirals is peripheral neuropathy; it occurs more frequently in patients taking stavudine with didanosine and hydroxycarbamide. Other common adverse effects include abdominal pain, nausea, diarrhoea, dyspepsia, fatigue, dizziness, depression, headache, insomnia, sleep disturbances, pruritus, and rash. Abnormal liver function tests may occur and hepatitis, hepatic failure, and pancreatitis have been reported rarely; fatalities have occurred and were reported most often in patients taking stavudine with didanosine and hydroxycarbamide. Lactic acidosis, usually associated with severe hepatomegaly and steatosis, has been associated with treatment with NRTIs. There have been reports of motor weakness associated with stavudine, occurring particularly in association with lactic acidosis.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including stavudine, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been seen in patients receiving antiretroviral therapy, including stavudine. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported. NRTIs have also been associated with mitochondrial dysfunction manifesting as abnormal behaviour, anaemia, convulsions, hyperlipasaemia, hypertonia, and neutropenia. Elevated creatine phosphokinase, myalgia, myositis, and rarely rhabdomyolysis have been reported, particularly when nucleoside analogues have been given with HIV-protease inhibitors. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy. For further information on adverse effects associated with NRTIs see Zidovudine, p.914.

Effects on the nervous system. Peripheral neuropathy is a well recognised adverse effect of stavudine and has been the subject of a review.[1]

1. Moyle GJ, Sadler M. Peripheral neuropathy with nucleoside antiretrovirals: risk factors, incidence and management. *Drug Safety* 1998; **19:** 481–94.

Gynaecomastia. Bilateral gynaecomastia was associated with stavudine use in a patient with HIV infection who was also receiving lamivudine and co-trimoxazole.[1] Symptoms resolved when stavudine was stopped. Four other cases of gynaecomastia were reported in HIV-infected patients given HAART regimens containing stavudine.[2]

1. Melbourne KM, *et al.* Gynecomastia with stavudine treatment in an HIV-positive patient. *Ann Pharmacother* 1998; **32:** 1108.
2. Manfredi R, *et al.* Gynecomastia associated with highly active antiretroviral therapy. *Ann Pharmacother* 2001; **35:** 438–9.

Precautions

Stavudine should be used with caution in patients with a history of peripheral neuropathy and treatment suspended if peripheral neuropathy develops; if symptoms resolve on withdrawal, stavudine may be resumed at half the previous dose. Treatment with stavudine may be associated with lactic acidosis and should be stopped if there is a rapid increase in aminotransferase concentrations, progressive hepatomegaly or steatosis, or metabolic or lactic acidosis of unknown aetiology. Stavudine should be given with caution to patients with hepatomegaly or other risk factors for liver disease. If liver enzymes increase to 5 times the upper limit of normal during treatment then stavudine should be stopped. Patients co-infected with chronic hepatitis B or C who are being treated with combination antiretroviral therapy are at an increased risk of severe and potentially fatal hepatic adverse events. Patients with a history of pancreatitis should also be observed carefully for signs of pancreatitis during stavudine treatment. Use with other drugs likely to cause peripheral neuropathy or pancreatitis should be avoided if possible. Stavudine should be used with caution and doses reduced in patients with renal impairment.

Interactions

The intracellular activation of stavudine and hence its antiviral effect may be inhibited by zidovudine, doxorubicin, and ribavirin.

Use of stavudine with other drugs known to cause pancreatitis or peripheral neuropathy should be avoided if possible. The combination of hydroxycarbamide and didanosine if given with stavudine, may carry a higher risk of adverse effects including hepatotoxicity, peripheral neuropathy, and pancreatitis (fatal and non-fatal).

Antidiabetics. Fatal lactic acidosis has been reported[1] in a patient given *metformin* with didanosine, stavudine, and tenofovir.

1. Worth L, *et al.* A cautionary tale: fatal lactic acidosis complicating nucleoside analogue and metformin therapy. *Clin Infect Dis* 2003; **37:** 315–16.

Antivirals. Reference to *in-vivo* antagonism of the antiretroviral effect of stavudine when used with *zidovudine*.[1]

1. Havlir DV, *et al.* In vivo antagonism with zidovudine plus stavudine combination therapy. *J Infect Dis* 2000; **182:** 321–5.

Phenylpropanolamine. Hypertensive crisis associated with use of phenylpropanolamine and clemastine occurred in a patient receiving HIV prophylaxis with indinavir, lamivudine, and stavudine.[1] The most likely cause was an interaction between phenylpropanolamine and stavudine, although interactions with the other antiretrovirals could not be ruled out.

1. Khurana V, *et al.* Hypertensive crisis secondary to phenylpropanolamine interacting with triple-drug therapy for HIV prophylaxis. *Am J Med* 1999; **106:** 118–19.

Antiviral Action

Stavudine is converted intracellularly in stages to the triphosphate. This triphosphate halts the DNA synthesis of retroviruses, including HIV, through competitive inhibition of reverse transcriptase and incorporation into viral DNA. Stavudine-resistant strains of HIV have been identified and cross-resistance to other nucleoside reverse transcriptase inhibitors may occur.

Pharmacokinetics

Stavudine is absorbed rapidly after oral doses producing peak plasma concentrations within 1 hour and with a reported bioavailability of about 86%. Giving it with food delays but does not reduce absorption. Stavudine crosses the blood-brain barrier producing a CSF to plasma ratio of about 0.4 after 4 hours. Binding to plasma proteins is negligible. Stavudine is metabolised intracellularly to the active antiviral triphosphate. The elimination half-life is reported to be about 1 to 1.5 hours after single or multiple doses. The intracellular half-life of stavudine triphosphate has been estimated to be 3.5 hours *in vitro*. About 40% of a dose is excreted in the urine by active tubular secretion and glomerular filtration. Stavudine is removed by haemodialysis.

3. Grasela DM, *et al.* Pharmacokinetics of single-dose oral stavudine in subjects with renal impairment and in subjects requiring hemodialysis. *Antimicrob Agents Chemother* 2000; **44:** 2149–53.

Uses and Administration

Stavudine is a nucleoside reverse transcriptase inhibitor related to thymidine with antiviral activity against HIV-1. It is used in the treatment of HIV infection and AIDS (p.856). Viral resistance emerges rapidly when stavudine is used alone, and it is therefore used with other antiretrovirals. Stavudine is given orally, usually as a capsule or solution. Usual adult doses of stavudine are 40 mg every 12 hours for patients weighing 60 kg or more or 30 mg every 12 hours for patients weighing less than 60 kg.

For details of doses in infants, children, and adolescents, see below.

For details of reduced doses of stavudine to be used in patients with renal impairment, see below.

◊ Reviews.

1. Hurst M, Noble S. Stavudine: an update of its use in the treatment of HIV infection. *Drugs* 1999; **58:** 919–49.
2. Cheer SM, Goa KL. Stavudine once daily. *Drugs* 2002; **62:** 2667–74.

Administration in children. For the treatment of HIV infection in infants, children, and adolescents stavudine is given orally with other antiretroviral drugs. Doses are based on body-weight:

- in neonates from birth to 13 days old a dose of 500 micrograms/kg every 12 hours may be given
- in infants at least 14 days old and those weighing less than 30 kg the dose is 1 mg/kg every 12 hours
- in children and adolescents weighing 30 kg or more, the adult dose is given (see above)

Administration in renal impairment. Dosage reduction according to creatinine clearance (CC) is recommended for patients receiving oral stavudine who have renal impairment:

- CC 26 to 50 mL/minute: 20 mg every 12 hours (those weighing 60 kg or more) or 15 mg every 12 hours (those weighing less than 60 kg)
- CC below 26 mL/minute: 20 mg every 24 hours (those weighing 60 kg or more) or 15 mg every 24 hours (those weighing less than 60 kg)

Telbivudine *(BAN, USAN, rINN)*

L-dT; Epavudine; LDT-600; NV-02B; Telbivudina; Telbivudinum. 2′-Deoxy-L-thymidine; 1-(2-Deoxy-β-L-*erythro*-pentofuranosyl)-5-methylpyrimidine-2,4(1*H*,3*H*)-dione.

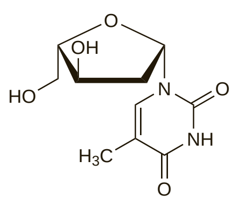
Тельбивудин

$C_{10}H_{14}N_2O_5$ = 242.2.

CAS — 3424-98-4.

ATC — J05AF11.

ATC Vet — QJ05AF11.



Adverse Effects

The most common adverse effects reported for telbivudine are cough, dizziness, fatigue, gastrointestinal effects including abdominal pain, diarrhoea, and nausea, and rash. There have also been reports of arthralgia, myalgia, myopathy, and malaise. Serum amylase, lipase and creatine phosphokinase levels may be increased. Raised serum alanine aminotransferase concentrations may occur and exacerbation of hepatitis has been reported after stopping treatment with telbivudine. There have been occasional reports of peripheral neuropathy, particularly when given with peginterferon alfa-2a.

Lactic acidosis, usually associated with severe hepatomegaly and steatosis, has been associated with treatment with nucleoside analogues (see Zidovudine, p.914).

Precautions

Telbivudine should be given with caution to patients with cirrhosis, hepatomegaly, or other risk factors for liver disease and should be withdrawn if there is a rapid increase in aminotransferase concentrations, progressive hepatomegaly or steatosis, or metabolic or lactic acidosis of unknown aetiology. Exacerbation of hepatitis B has been reported both during and after stopping treatment with telbivudine. Liver function should be monitored closely during treatment and for several months after treatment is stopped. Patients taking telbivudine should be monitored for peripheral neuropathy and treatment should be stopped if myopathy or peripheral neuropathy is diagnosed. Dosage reduction may be necessary in patients with renal impairment.

Interactions

Caution should be exercised when telbivudine is given with other drugs that alter renal function; serum concentrations of either drug may be affected. Telbivudine should be given with caution to patients taking other drugs associated with myopathy (such as azole antifungals, ciclosporin, corticosteroids, erythromycin, fibrates, HMG-CoA reductase inhibitors, penicillamine, and zidovudine).

Interferons. For mention of an increased risk of peripheral neuropathy in patients given both telbivudine and *peginterferon alfa-2a*, see Adverse Effects, above.

Antiviral Action

Telbivudine is phosphorylated intracellularly to the active triphosphate form, which competes with thymidine 5'-triphosphate, the natural substrate of hepatitis B virus reverse transcriptase, thereby causing DNA chain termination and inhibiting hepatitis B viral replication.

Telbivudine has no activity against HIV.

Pharmacokinetics

Telbivudine is absorbed from the gastrointestinal tract after oral doses. Peak plasma concentrations occur after about 3 hours. Absorption is not affected when given with food. Binding of telbivudine to plasma proteins is about 3.3% *in vitro*. Telbivudine is not metabolised by the cytochrome P450 system. It is mainly excreted renally by glomerular filtration as unchanged drug, with a terminal elimination half-life of 30 to 53.6 hours. Telbivudine is partially removed by haemodialysis.

Uses and Administration

Telbivudine is an orally bioavailable L-nucleoside analogue with specific activity against the hepatitis B virus. It is given orally for the treatment of chronic hepatitis B (p.851) in patients with compensated liver disease and evidence of active viral replication, persistently raised serum alanine aminotransferase concentrations, and histological evidence of active liver inflammation and fibrosis. The usual dose of telbivudine is 600 mg once daily. For details of dosage modification in patients with renal impairment, see below.

◊ References.

5. Keam SJ. Telbivudine. *Drugs* 2007; **67:** 1917–29.

Administration in renal impairment. The dosage of telbivudine should be reduced in patients with renal impairment by modifying the dosing interval according to the creatinine clearance (CC) of the patient:

- CC 50 mL or more per minute: 600 mg once daily
- CC 30 to 49 mL/minute: 600 mg every 48 hours
- CC less than 30 mL/minute (and not on dialysis): 600 mg every 72 hours
- end stage renal disease: 600 mg every 96 hours

Patients receiving haemodialysis should receive the appropriate dose after each dialysis session.

ATC — J05AF07.

ATC Vet — QJ05AF07.

Adverse Effects

Adverse effects commonly associated with tenofovir disoproxil fumarate either as monotherapy for the treatment of chronic hepatitis B or with other antiretrovirals for the treatment of HIV are mild to moderate gastrointestinal events such as anorexia, abdominal pain, diarrhoea, dyspepsia, flatulence, nausea, and vomiting. Other commonly reported adverse effects are dizziness, fatigue, and headache. Skin rashes may occur. Hypophosphataemia is also common. Serum-amylase concentrations may be raised and pancreatitis has been reported rarely. There have also been reports of raised liver enzymes, hepatitis, nephritis, nephrogenic diabetes insipidus, renal impairment, acute renal failure, and effects on the renal proximal tubules, including Fanconi syndrome.

Lactic acidosis, usually associated with severe hepatomegaly and steatosis, has been associated with treatment with nucleoside reverse transcriptase inhibitors.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including tenofovir disoproxil fumarate, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been seen in patients receiving antiretroviral therapy, including tenofovir disoproxil fumarate. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported. NRTIs have also been associated with mitochondrial dysfunction manifesting as abnormal behaviour, anaemia, convulsions, hyperlipasaemia, hypertonia, and neutropenia. Elevated creatine phosphokinase, myalgia, myositis, and rarely rhabdomyolysis have been reported, particularly when nucleoside analogues have been given with HIV-protease inhibitors. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy. For further information on adverse effects associated with NRTIs see Zidovudine, p.914.

Effects on the kidney. Use of tenofovir in patients with HIV infection has been associated with renal toxicity,[1] including Fanconi syndrome,[2] interstitial nephritis,[3] and acute renal failure.[4,5] The mechanism of acute renal failure appears to be tubular necrosis, which may not resolve on withdrawal of the drug.[6] Some studies have indicated that glomerular filtration rate or creatinine clearance was consistently decreased in patients given tenofovir-containing regimens;[7,8] it has been reported that this is greater if combined with HIV-protease inhibitors than NNRTIs.[8] Other studies have not found renal toxicity to be a significant problem.[9,10]

Precautions

Treatment with tenofovir disoproxil fumarate should be stopped if there is a rapid increase in aminotransferase concentrations, progressive hepatomegaly or steatosis, or metabolic or lactic acidosis of unknown aetiology. It should be given with caution to patients with hepatomegaly or other risk factors for liver disease. In particular, extreme caution should be exercised in patients with co-existing hepatitis C infection who are receiving interferon alfa and ribavirin. In patients co-infected with hepatitis B, there is a risk of severe acute exacerbation of hepatitis when tenofovir is stopped, and liver function should be monitored closely in such patients for at least several months.

Tenofovir should be used with caution, and doses modified, in patients with renal impairment. Renal function and serum phosphates should be monitored before treatment is started, every 4 weeks during the first year of therapy, and then every 3 months; in patients with a history of renal impairment or who are particularly at risk, more frequent monitoring may be needed. If serum-phosphate concentrations fall markedly or if creatinine clearance is below 50 mL/minute, renal function should be evaluated within a week, and the dose interval may need to be adjusted or treatment interrupted. Tenofovir disoproxil fumarate may be associated with reduction in bone density and patients should be observed for evidence of bone abnormalities; bone monitoring should be considered for patients with a history of bone fractures or those at risk of osteopenia.

Interactions

Use of tenofovir disoproxil fumarate with nephrotoxic drugs or with other drugs eliminated by active tubular secretion is not recommended; if such use is unavoidable, renal function should be monitored weekly. Tenofovir increases the plasma concentrations of didanosine (see p.871). Once daily triple nucleoside regimens of tenofovir and lamivudine with either abacavir or didanosine are associated with a high level of treatment failure and of emergence of resistance, and should be avoided. Decreased plasma concentrations of atazanavir and increased plasma concentrations of tenofovir occur when tenofovir is given with atazanavir; the effect is significantly reduced when ritonavir is added as a booster. Use of ritonavir-boosted lopinavir with tenofovir modestly increases the plasma concentrations of tenofovir.

Antidiabetics. Fatal lactic acidosis has been reported[1] in a patient given *metformin* with didanosine, stavudine, and tenofovir.

1. Worth L, *et al.* A cautionary tale: fatal lactic acidosis complicating nucleoside analogue and metformin therapy. *Clin Infect Dis* 2003; **37:** 315–16.

Antiviral Action

Tenofovir is converted intracellularly to the diphosphate. This diphosphate halts the DNA synthesis of HIV through competitive inhibition of reverse transcriptase and incorporation into viral DNA. Tenofovir-resistant strains of HIV have been identified and cross-resistance to other reverse transcriptase inhibitors may occur.

Pharmacokinetics

Tenofovir disoproxil fumarate is rapidly absorbed and converted to tenofovir after oral doses, with peak plasma concentrations occurring after 1 to 2 hours. Bioavailability in fasting patients is about 25%, but this is enhanced when tenofovir disoproxil fumarate is taken with a high fat meal. Tenofovir is widely distributed into body tissues, particularly the kidneys and liver. Binding to plasma proteins is less than 1% and that to serum proteins about 7%. The terminal elimination half-life of tenofovir is 12 to 18 hours. Tenofovir is excreted mainly in the urine by both active tubular secretion and glomerular filtration. It is removed by haemodialysis.

◊ Reviews.

1. Kearney BP, *et al.* Tenofovir disoproxil fumarate: clinical pharmacology and pharmacokinetics. *Clin Pharmacokinet* 2004; **43:** 595–612.
2. Kearney BP, *et al.* Pharmacokinetics and dosing recommendations of tenofovir disoproxil fumarate in hepatic or renal impairment. *Clin Pharmacokinet* 2006; **45:** 1115–24.

Uses and Administration

Tenofovir is a nucleotide reverse transcriptase inhibitor with antiviral activity against HIV-1 and hepatitis B. It is used in the treatment of HIV infection and AIDS (p.856) and chronic hepatitis B infection (p.851). Viral resistance emerges rapidly when tenofovir is used alone in the treatment of HIV infection, and it is therefore used with other antiretrovirals.

It is given orally as the disoproxil fumarate ester. Tenofovir disoproxil fumarate 300 mg is equivalent to about 245 mg of tenofovir disoproxil and to about 136 mg of tenofovir. For the treatment of either HIV or chronic hepatitis B infection the usual dose is 300 mg of the disoproxil fumarate ester once daily with food.

For details of doses of tenofovir disoproxil fumarate to be used in patients with renal impairment, see below.

Fixed-dose combination products for the treatment of HIV infection and AIDS have been developed in order to improve patient adherence and avoid monotherapy, thereby decreasing the risk of acquired drug resistance. Products containing tenofovir disoproxil fumarate in combination with emtricitabine, and with efavirenz plus emtricitabine are available in some countries.

A gel containing tenofovir is under investigation as a topical microbicide in the prevention of HIV infection.

◊ Reviews.

8. Pozniak A. Tenofovir: what have over 1 million years of patient experience taught us? *Int J Clin Pract* 2008; **62:** 1285–93.

Administration in renal impairment. Doses of tenofovir disoproxil fumarate should be modified by adjustment of the dosing interval in patients with renal impairment according to their creatinine clearance (CC):

- CC 50 mL or more per minute: usual once-daily dosage (above)
- CC 30 to 49 mL/minute: every 48 hours
- CC 10 to 29 mL/minute: every 72 to 96 hours
- haemodialysis patients: a dose every 7 days or after a cumulative total of 12 hours of dialysis

ATC Vet — QJ05AE09.

Adverse Effects

The most common adverse effects associated with antiretroviral regimens containing tipranavir are gastrointestinal disturbances (abdominal pain, diarrhoea, dyspepsia, flatulence, nausea, and vomiting), anorexia, fatigue, and headache. Serious adverse effects reported include increased risk of bleeding, lipid abnormalities (hyperlipidaemia and hypertriglyceridaemia), and severe hepatotoxicity (hepatitis and hepatic decompensation) and intracranial haemorrhage including some fatalities. Rashes, generally occurring after about 2 months of treatment and lasting about 3 weeks have been reported; rashes are sometimes accompanied by joint pain, stiffness, throat tightness, or generalised pruritus.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including tipranavir, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been seen in patients receiving antiretroviral therapy, including tipranavir. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported. Elevated creatine phosphokinase, myalgia, myositis, and rarely rhabdomyolysis have been reported with HIV-protease inhibitors, particularly when given with nucleoside analogues. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy.

For further information on adverse effects associated with HIV-protease inhibitors see under Indinavir Sulfate, p.882.

Precautions

Tipranavir should not be used in patients with moderate to severe hepatic impairment (Child-Pugh class B or C), and should be used with caution in those with mild impairment (Child-Pugh A). Treatment should not be started in patients with pre-treatment liver enzyme values more than 5 times the upper limit of normal. Patients should be closely monitored for clinical signs and symptoms of hepatitis; monitoring of liver enzymes is recommended before and during treatment with tipranavir. In patients with mild hepatic impairment, chronic hepatitis, or other underlying liver disease more frequent monitoring is recommended. Treatment should be interrupted or stopped if liver function deteriorates and should be permanently stopped in those patients with liver enzyme values more than 10 times the upper limit of normal or in those who develop signs or symptoms of clinical hepatitis. Patients with pre-existing liver disease or co-infected with chronic hepatitis B or C and treated with combination antiretroviral therapy are at increased risk for severe and potentially fatal hepatic adverse events.

Caution is advised in treating patients who are at increased risk of bleeding such as those with haemophilia A and B or who are taking antiplatelet drugs or anticoagulants as reports of spontaneous bleeding have been associated with the use of HIV-protease inhibitors. Tipranavir oral solution contains vitamin E and patients given the oral solution should not take high doses of supplemental vitamin E.

Tipranavir contains a sulfonamide moiety and should be used with caution in patients with a known sulfonamide allergy.

Interactions

Tipranavir is both an inducer and an inhibitor of the cytochrome P450 isoenzyme CYP3A4 although when given with low-dose ritonavir there is a net inhibition of CYP3A4; there is therefore the potential for complex interactions with other drugs metabolised by this enzyme. Ritonavir-boosted tipranavir is also a net inducer of P-glycoprotein.

Tipranavir is contra-indicated with drugs that are highly dependent on CYP3A4 for clearance and for which elevated plasma concentrations are associated with serious or life-threatening events. These drugs include antiarrhythmics (amiodarone, bepridil, flecainide, metoprolol, propafenone, and quinidine), antihistamines (astemizole and terfenadine), ergot derivatives (dihydroergotamine, ergometrine, ergotamine, and methylergometrine), gastrointestinal prokinetics (cisapride), antipsychotics (pimozide), sedatives and hypnotics (midazolam and triazolam), and statins (simvastatin and lovastatin). Rifampicin and St John's wort decrease the concentration of tipranavir; use with the antiretroviral is not recommended due to the possible loss of its activity and development of resistance.

For further information on drug interactions of HIV-protease inhibitors see under Indinavir Sulfate, p.883 and Table 1, p.917.

Antiviral Action

Tipranavir is a non-peptide HIV-protease inhibitor. It interferes with the formation of essential viral proteins making them incapable of infecting other cells. HIV isolates resistant to tipranavir have been reported and viral resistance develops rapidly when HIV-protease inhibitors are given alone and therefore they are used with other antiretrovirals. Various degrees of cross-resistance between HIV-protease inhibitors may occur.

Pharmacokinetics

Tipranavir is absorbed to a limited extent after oral doses. Food improves the tolerability and bioavailability is increased with a high fat meal. Peak plasma concentrations are reached within 1 to 5 hours and steady state is usually reached after 7 to 10 days of treatment. Tipranavir is about 99.9% bound to plasma proteins. It is metabolised by the cytochrome P450 system (predominantly the isoenzyme CYP3A4), although when given with ritonavir metabolism is minimal with the majority of tipranavir being excreted unchanged in the faeces. The mean elimination half-life of tipranavir is 4.8 to 6 hours.

Uses and Administration

Tipranavir is a non-peptide HIV-protease inhibitor with antiviral activity against HIV. It is used for the treatment of HIV infection and AIDS (p.856) in treatment-experienced patients or in those with multidrug-resistant HIV infection. Viral resistance emerges rapidly when tipranavir is used alone, and it is therefore used with other antiretrovirals.

It is given with low-dose ritonavir, which acts as a pharmacokinetic enhancer (ritonavir-boosted tipranavir). The dose is tipranavir 500 mg (with ritonavir 200 mg) twice daily with food.

For details of doses in children see below.

No dose adjustment is required for patients with renal impairment or mild liver disease. Tipranavir should not be given to patients with moderate to severe liver disease.

Administration in children. For the treatment of HIV infection in children, tipranavir is given orally with other antiretroviral drugs. It is given with low-dose ritonavir, which acts as a pharmacokinetic enhancer. US licensed product information permits the use of oral tipranavir in children from 2 years of age. Doses are based on body-weight or body-surface and should not exceed the maximum adult dose (see above).

- The usual recommended dose in children is: tipranavir 14 mg/kg (with ritonavir 6 mg/kg) twice daily *or* tipranavir 375 mg/m^2 (with ritonavir 150 mg/m^2) twice daily
- children who are intolerant or develop toxicities to the usual dose may take a reduced dose: tipranavir 12 mg/kg (with ritonavir 5 mg/kg) twice daily *or* tipranavir 290 mg/m^2 (with ritonavir 115 mg/m^2) twice daily

Trichosanthin

Compound Q; GLQ-223 (a purified form of trichosanthin); Tricosantina.

CAS — 60318-52-7 (trichosanthins); 116899-30-0 (Trichosanthes kirilowii); 160185-58-0 (Trichosanthes kirilowii root); 120947-28-6 (GLQ-223).

Profile

Trichosanthin is a polypeptide extracted from the tuber of the Chinese cucumber, *Trichosanthes kirilowii* (Cucurbitaceae). It has been investigated in the treatment of HIV infection and is used in China as an abortifacient.

HIV infection and AIDS. Trichosanthin has been given to patients with AIDS, AIDS-related complex, or HIV infection.[1,2] It has generally been given by intravenous injection, the use of the intramuscular route having been abandoned due to the occurrence of pain and necrosis at the injection site.[1] A common adverse effect with intravenous use was a flu-like syndrome with headache, myalgias, fever, and arthralgia and was generally mild to moderate,[3] although neurological effects progressing to coma with fatalities have been reported.[1,2] Improvements in surrogate markers for HIV infection have been reported including increases in CD4+ T lymphocyte counts in patients with moderate disease[3] and in patients failing to respond to reverse transcriptase inhibitors.[4]

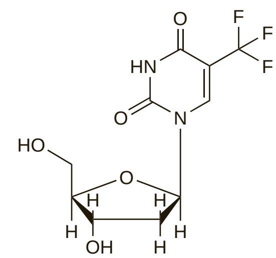
ATC Vet — QS01AD02.



Pharmacopoeias. In *US.*

USP 31 (Trifluridine). A white, odourless powder, appearing under the microscope as rod-like crystals. Store in airtight containers. Protect from light.

Adverse Effects

Adverse effects occurring after the use of trifluridine in the eyes are similar to those for idoxuridine (p.881) but have been reported to occur less frequently.

◊ References.

1. Udell IJ. Trifluridine-associated conjunctival cicatrization. *Am J Ophthalmol* 1985; **99:** 363–4.

Antiviral Action

Trifluridine acts similarly to idoxuridine to interfere with viral DNA synthesis after phosphorylation. It is reported to be active against herpes simplex viruses, some adenoviruses, vaccinia viruses, and CMV. Like idoxuridine it is incorporated into mammalian DNA.

Pharmacokinetics

Trifluridine is absorbed through the cornea after application to the eye and penetration may be increased in the presence of damage or inflammation. Systemic absorption does not appear to follow ocular administration.

Uses and Administration

Trifluridine is a pyrimidine nucleoside structurally related to thymidine. It is used in the treatment of primary keratoconjunctivitis and recurrent epithelial keratitis due to herpes simplex viruses (p.854). One drop of a 1% ophthalmic solution is instilled into the eye every 2 hours up to a maximum of 9 times daily until complete re-epithelialisation has occurred. Treatment is then reduced to one drop every 4 hours to a minimum of 5 drops daily for a further 7 days. Treatment should not be continued for more than a total of 21 days.

Trifluridine, alone or as a combined formulation with a thymidine phosphorylase inhibitor to reduce its metabolism (TAS-102), has been investigated in the treatment of malignant neoplasms.

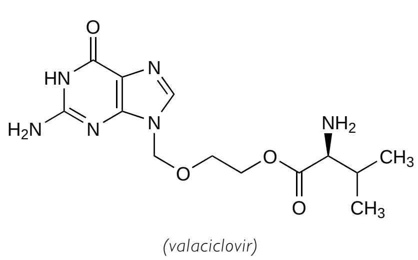
ATC — J05AB11.

ATC Vet — QJ05AB11.



(valaciclovir)

Pharmacopoeias. In *Chin.*

Adverse Effects and Precautions

As for Aciclovir, p.863.

Breast feeding. In a study in 5 women who took oral valaciclovir 500 mg twice daily for 7 days, concentrations of the active metabolite aciclovir in breast milk were 3.4 times those in maternal serum at 4 hours after the initial dose, although the ratio declined to 1.85 at steady-state concentrations. Nonetheless, it was calculated that the amount ingested by an infant would be negligible (about 2% of a standard neonatal dose of intravenous aciclovir, with exposure further reduced by the poor oral bioavailability of the drug), and valaciclovir was thus considered compatible with breast feeding.[1]

1. Sheffield JS, *et al.* Acyclovir concentrations in human breast milk after valaciclovir administration. *Am J Obstet Gynecol* 2002; **186:** 100–102.

Effects on the nervous system. Mononeuritis multiplex due to vasculitis has been reported[1] in a woman a week after a one-day course of valaciclovir for the treatment of herpes labialis. Symptoms improved within 10 days of treatment with oral prednisolone but reoccurred upon rechallenge with valaciclovir.

1. Pary LF, *et al.* Vasculitic mononeuritis multiplex induced by valacyclovir. *Neurology* 2004; **62:** 1906–7.

Interactions

As for Aciclovir, p.863.

Antiviral Action

As for Aciclovir, p.863.

Pharmacokinetics

As for Aciclovir, p.863.

Valaciclovir is readily absorbed from the gastrointestinal tract after oral doses, and is rapidly converted to aciclovir and valine by first-pass intestinal or hepatic metabolism. The bioavailability of aciclovir after dosage with valaciclovir is reported to be 54% and peak plasma concentrations of aciclovir are achieved after 1.5 hours. Valaciclovir is eliminated mainly as aciclovir and its metabolite 9-carboxymethoxymethylguanine; less than 1% of a dose of valaciclovir is excreted unchanged in the urine.

5. MacDougall C, Guglielmo BJ. Pharmacokinetics of valaciclovir. *J Antimicrob Chemother* 2004; **53:** 899–901.

Uses and Administration

Valaciclovir is a prodrug of the antiviral aciclovir (p.864). It is used in the treatment of herpes zoster (p.855) and herpes simplex infections (p.854) of the skin and mucous membranes, including genital herpes. Treatment should be started as soon as symptoms occur. Valaciclovir is used for the suppression of recurrent herpes simplex infections and can reduce the risk of transmission of genital herpes to susceptible partners when used as suppressive therapy and as part of safer sex practices. It is also used for the prophylaxis of CMV infection after renal transplantation. Valaciclovir is given orally as the hydrochloride; doses are expressed in terms of the base. Valaciclovir hydrochloride 1.11 g is equivalent to about 1 g of valaciclovir.

For **herpes zoster**, the dose is 1 g three times daily for 7 days. For treatment of **herpes simplex infections**, 500 mg is given twice daily for 5 days (3 days in the USA) for recurrent episodes or for up to 10 days for a first episode; in the USA, the recommended dose for a first episode of genital herpes is 1 g twice daily for 10 days. For the treatment of herpes labialis, a dose of 4 g in two divided doses 12 hours apart is recommended. For the *suppression* of herpes simplex infection in immunocompetent patients, a dose of 500 mg daily as a single dose or in two divided doses, is recommended; in the USA, a dose of 1 g daily as a single dose is recommended for suppression of recurrent genital herpes. A dose of 500 mg twice daily may be used in immunocompromised patients. To *reduce transmission* of genital herpes a dose of 500 mg daily is taken by the infected partner.

A dose of 2 g four times daily is recommended for prophylaxis of **CMV infection** in renal transplant recipients; prophylaxis should begin within 72 hours and is usually continued for 90 days.

Doses of valaciclovir may need to be reduced in patients with renal impairment (see below).

Administration in renal impairment. Oral doses of valaciclovir may need to be reduced in patients with renal impairment. The following dosage reductions are suggested by the UK licensed product information according to creatinine clearance (CC):

herpes zoster:
- CC 15 to 30 mL/minute: 1 g twice daily
- CC less than 15 mL/minute: 1 g daily
- patients on haemodialysis: 1 g daily after haemodialysis

herpes simplex infections:
- CC less than 15 mL/minute: 500 mg daily
- patients on haemodialysis: 500 mg daily after haemodialysis

suppression of herpes simplex:
- CC less than 15 mL/minute: *immunocompetent patients*: 250 mg once daily; *immunocompromised patients*: 500 mg once daily
- patients on haemodialysis: *immunocompetent patients*: 250 mg once daily after haemodialysis; *immunocompromised patients*: 500 mg once daily after haemodialysis

reduction of transmission of genital herpes:
- CC less than 15 mL/minute: 250 mg daily
- patients on haemodialysis: 250 mg daily after haemodialysis

prophylaxis of CMV:
- CC 50 to 74 mL/minute: 1.5 g four times daily
- CC 25 to 49 mL/minute: 1.5 g three times daily
- CC 10 to 24 mL/minute: 1.5 g twice daily
- CC less than 10 mL/minute: 1.5 g once daily
- patients on haemodialysis: 1.5 g once daily after haemodialysis

Adverse Effects, Treatment, and Precautions

As for Ganciclovir, p.879.

In the USA, valganciclovir is not indicated for use in liver transplant recipients, because of reports of a higher incidence of tissue-invasive CMV infection compared with patients treated with ganciclovir (although see Cytomegalovirus Infections, below). In the UK, valganciclovir is licensed for use in the prevention of CMV disease in all solid organ graft recipients.

Interactions

As for Ganciclovir, p.879.

Antiviral Action

As for Ganciclovir, p.880.

Pharmacokinetics

Valganciclovir is well absorbed from the gastrointestinal tract after oral doses and is rapidly converted to ganciclovir by first-pass intestinal or hepatic metabolism. The bioavailability of ganciclovir after an oral dose with food is reported to be about 60% and peak plasma concentrations of ganciclovir are achieved after 1 to 3 hours. Valganciclovir is eliminated in the urine as ganciclovir (see p.880).

Uses and Administration

Valganciclovir is a prodrug of the antiviral ganciclovir (p.880) that is used for the treatment of CMV retinitis in patients with AIDS, and for the prevention of CMV disease in transplant recipients who have received an organ from a CMV-positive donor (see below).

Valganciclovir is given orally with food as the hydrochloride; doses are expressed in terms of the base. Valganciclovir hydrochloride 1.1 g is equivalent to about 1 g of valganciclovir.

For *induction* in patients with active CMV retinitis, the dose is 900 mg twice daily for 21 days. For *maintenance* following induction, or in patients with inactive CMV retinitis, the dose is 900 mg daily. Patients whose retinitis deteriorates during maintenance may repeat induction but the possibility of viral resistance should be considered. For *prevention* of CMV disease in organ transplant recipients, the dose is 900 mg daily starting within 10 days and continuing until 100 days after transplantation.

Doses of valganciclovir should be reduced in renal impairment (see Administration in Renal Impairment, below).

◊ Reviews.

1. Freeman RB. Valganciclovir: oral prevention and treatment of cytomegalovirus in the immunocompromised host. *Expert Opin Pharmacother* 2004; **5:** 2007–16.
2. Cvetković RS, Wellington K. Valganciclovir: a review of its use in the management of CMV infection and disease in immunocompromised patients. *Drugs* 2005; **65:** 859–78.

Administration in renal impairment. Doses of oral valganciclovir should be reduced in renal impairment according to creatinine clearance (CC). Licensed product information recommends the following doses:

- CC 40 to 59 mL/minute: 450 mg twice daily for *induction* and 450 mg daily for *maintenance* or *prevention*
- CC 25 to 39 mL/minute: 450 mg daily for *induction* and 450 mg every two days for *maintenance* or *prevention*
- CC 10 to 24 mL/minute: 450 mg every two days for *induction* and 450 mg twice weekly for *maintenance* or *prevention*
- haemodialysis patients: not recommended

Cytomegalovirus infections. Valganciclovir produces high systemic concentrations of ganciclovir after oral doses; exposure may be higher than with intravenous ganciclovir regimens.[1] It is therefore active against CMV infections (p.853). It has been shown to be of benefit for both induction therapy and maintenance treatment of CMV retinitis in patients with AIDS,[2,3] and although this has become less widespread in the developed world with the advent of HAART, it continues to be a problem in resource-poor settings in particular; there have been calls for valganciclovir to be made more widely available for treatment in preference to less effective and convenient drugs.[3]

Valganciclovir is also used in the prophylaxis and preemptive treatment of CMV infections in transplant recipients,[4-8] and many centres consider it to be the standard of care for this indication (including in liver transplantation although it is contra-indicated for such use in the USA—see Adverse Effects, Treatment, and Precautions, above).[9]

CAS — 71002-10-3.

ATC — J05AB03; S01AD06.

ATC Vet — QJ05AB03; QS01AD06.

Adverse Effects

Adverse effects that may occur when vidarabine is applied to the eyes include irritation, pain, superficial punctate keratitis, photophobia, lachrymation, and occlusion of the lachrymal duct.

Pharmacokinetics

Systemic absorption does not occur after application of vidarabine to the eye; trace amounts of its principal metabolite hypoxanthine arabinoside (arabinosyl hypoxanthine), and vidarabine, if the cornea is damaged, may be found in the aqueous humour.

Uses and Administration

Vidarabine is a purine nucleoside obtained from *Streptomyces antibioticus*. It has been used in the treatment of herpes simplex and varicella-zoster infections (p.854 and p.855), although aciclovir and related drugs are generally preferred.

Vidarabine has been used topically in the treatment of herpes simplex keratitis and keratoconjunctivitis as a 3% ophthalmic ointment.

It has also been used as the sodium phosphate as a 10% gel for the treatment of genital herpes.

Vidarabine was formerly used intravenously in the treatment of severe and disseminated herpes simplex infections and herpes zoster but aciclovir is preferred.

Preparations

USP 31: Vidarabine Ophthalmic Ointment.

Zalcitabine *(BAN, USAN, rINN)*

ddC; ddCyd; Dideoxycytidine; NSC-606170; Ro-24-2027; Ro-24-2027/000; Tsalsitabiini; Zalcitabin; Zalcitabina; Zalcitabinum; Zalsitabin. 2′,3′-Dideoxycytidine.

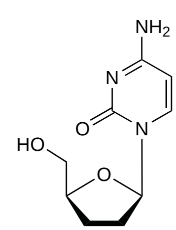
Зальцитабин

$C_9H_{13}N_3O_3$ = 211.2.

CAS — 7481-89-2.

ATC — J05AF03.

ATC Vet — QJ05AF03.



Pharmacopoeias. In *US.*

USP 31 (Zalcitabine). A white to off-white, crystalline powder. Soluble in water and in methyl alcohol; sparingly soluble in alcohol, in acetonitrile, in chloroform, and in dichloromethane; slightly soluble in cyclohexane. Store in airtight containers. Protect from light.

Adverse Effects

The most serious adverse effects of zalcitabine are peripheral neuropathy, which can affect up to one-third of patients, and pancreatitis which is rare, affecting up to about 1% of patients, but which can be fatal. Other severe adverse effects include oral and oesophageal ulceration, hypersensitivity reactions including anaphylaxis, cardiomyopathy and heart failure, lactic acidosis and severe hepatomegaly with steatosis (both potentially life-threatening), and hepatic failure.

Precautions

Zalcitabine should be interrupted or stopped if peripheral neuropathy develops. Neuropathy is usually slowly reversible if treatment is stopped promptly but may be irreversible if treatment is continued after symptoms develop. Zalcitabine should be avoided in patients who already have peripheral neuropathy and used with caution in patients at risk of developing it (especially those with a low CD4+ cell count) or taking other drugs that may cause it (see Interactions, below).

Treatment should be interrupted in patients who develop abdominal pain, nausea, or vomiting or with abnormal biochemical test results until pancreatitis has been excluded. Zalcitabine should be permanently withdrawn if pancreatitis develops. Patients with a history of pancreatitis or of raised serum amylase should be monitored closely. Zalcitabine should not be used with other drugs known to cause pancreatitis (see Interactions, below).

Zalcitabine should be used with caution in patients with hepatic impairment and treatment interrupted or stopped if hepatic function deteriorates or there are signs of hepatic damage or lactic acidosis. It should be used with caution in patients with renal impairment, and dosage reductions may be necessary. It should also be used with caution in patients with cardiomyopathy or heart failure.

Complete blood count and biochemical tests should be carried out before treatment starts and at regular intervals throughout therapy.

Handling. Exposure of the skin to zalcitabine and inhalation of zalcitabine powder should be avoided.

Interactions

Zalcitabine should not be used with other drugs known to cause pancreatitis (for example intravenous pentamidine). Caution is necessary when zalcitabine is given with other drugs that may cause peripheral neuropathy, such as other nucleoside reverse transcriptase inhibitors, chloramphenicol, dapsone, ethionamide, isoniazid (the clearance of which may also be affected—see p.290), metronidazole, nitrofurantoin, ribavirin, and vincristine. Use of zalcitabine with didanosine is not recommended.

The absorption of zalcitabine is reduced by about 25% when given with aluminium- or magnesium-containing antacids.

Cimetidine, probenecid, or trimethoprim can reduce the renal excretion of zalcitabine, resulting in elevated plasma concentrations. Renal excretion of zalcitabine may also be reduced by amphotericin B, aminoglycosides, or foscarnet, potentially increasing its toxicity.

The antiviral action of zalcitabine may be antagonised by lamivudine and the two drugs should not be used together.

Antiviral Action

Zalcitabine is converted intracellularly in stages to the triphosphate. This triphosphate halts the DNA synthesis of retroviruses, including HIV, through competitive inhibition of reverse transcriptase and incorporation into viral DNA.

The emergence of zalcitabine-resistant strains of HIV has been reported.

◊ References.

1. Jeffries DJ. The antiviral activity of dideoxycytidine. *J Antimicrob Chemother* 1989; **23** (suppl A): 29–34.

Pharmacokinetics

Zalcitabine is absorbed from the gastrointestinal tract with a bioavailability of greater than 80%. The rate of absorption is reduced if given with food. Peak plasma concentrations in the fasting state are achieved within about 1 hour. Zalcitabine crosses the blood-brain barrier producing CSF concentrations ranging from 9 to 37% of those in plasma. Binding to plasma proteins is negligible. The plasma elimination half-life is about 2 hours.

Zalcitabine is metabolised intracellularly to the active antiviral triphosphate. It does not appear to undergo any substantial hepatic metabolism and is excreted mainly in the urine, in part by active tubular secretion.

Uses and Administration

Zalcitabine is a nucleoside reverse transcriptase inhibitor derived from cytidine with antiviral activity against HIV. It is used in the treatment of HIV infection and AIDS (p.856). Viral resistance emerges rapidly when zalcitabine is used alone in the treatment of HIV infection, and it is therefore used with other antiretrovirals.

Zalcitabine is given orally in a dose of 750 micrograms every 8 hours. Doses should be reduced in patients with renal impairment (see below).

Administration in renal impairment. Doses of zalcitabine should be reduced for patients with renal impairment according to creatinine clearance (CC):

- CC 10 to 40 mL/minute: 750 micrograms every 12 hours
- CC less than 10 mL/minute: 750 micrograms every 24 hours

Preparations

USP 31: Zalcitabine Tablets.

Proprietary Preparations (details are given in Part 3)

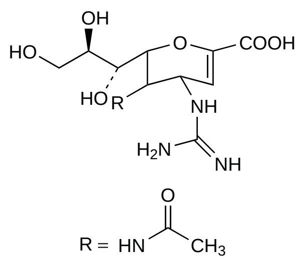
Zanamivir *(BAN, USAN, rINN)*

GG-167; GR-121167X; 4-Guanidino-2,4-dideoxy-2,3-dehydro-*N*-acetylneuraminic Acid; Tsanamiviiri; Zanamivirum. 5-Acetamido-2,6-anhydro-3,4,5-trideoxy-4-guanidino-D-*glycero*-D-*galacto*-non-2-enonic acid.

Занамивир

$C_{12}H_{20}N_4O_7$ = 332.3.
CAS — 139110-80-8.
ATC — J05AH01.
ATC Vet — QJ05AH01.



Adverse Effects

Inhaled zanamivir has generally been well tolerated. Acute bronchospasm or decline in respiratory function, with some fatalities, has been reported rarely in patients with a history of respiratory disease and very rarely in those with no such history. Other effects that have been noted include nasal symptoms, headache, gastrointestinal symptoms, cough, and bronchitis, but they may be difficult to distinguish from the symptoms of influenza. There have also been rare reports of hypersensitivity reactions, including oropharyngeal oedema and severe skin rashes.

There have been postmarketing reports (mostly from Japan) of neuropsychiatric adverse effects, such as delirium and abnormal behaviour, in patients taking neuraminidase inhibitors such as zanamivir.

◊ Reviews.

1. Freund B, *et al.* Zanamivir: a review of clinical safety. *Drug Safety* 1999; **21:** 267–81.
2. Gravenstein S, *et al.* Zanamivir: a review of clinical safety in individuals at high risk of developing influenza-related complications. *Drug Safety* 2001; **24:** 1113–25.

Precautions

Zanamivir should be used with caution in patients with chronic respiratory diseases as they may be at increased risk of bronchospasm; if zanamivir use is considered appropriate, patients with asthma or chronic obstructive pulmonary disease should have a fast-acting bronchodilator available during treatment. Patients on maintenance therapy with inhaled bronchodilators should inhale the bronchodilator before zanamivir. Patients experiencing bronchospasm should be advised to stop zanamivir and seek medical attention.

Patients should be monitored for abnormal behaviour throughout the treatment period.

Antiviral Action

Zanamivir inhibits the viral surface enzyme neuraminidase (sialidase) which is essential for the release of newly formed viral particles from infected cells, and may facilitate access of virus through mucus to the cell surface. Zanamivir is active against influenza A and B virus replication.

Resistance. For information on the development of resistance to zanamivir and other neuramidase inhibitors, see under Oseltamivir, p.901.

Pharmacokinetics

Zanamivir is poorly absorbed after oral doses with a bioavailability of about 2%. Inhaled doses produce high local concentrations in the respiratory tract. About 4 to 20% of the inhaled dose is absorbed producing peak serum concentrations at about 1 to 2 hours. Zanamivir is less than 10% bound to plasma protein. It is not metabolized and the absorbed portion is excreted unchanged in the urine with a serum half-life of 2.6 to 5 hours; unabsorbed drug is excreted in the faeces.

◊ References.

1. Aoki FY, Hayden FG (eds.). The pharmacokinetics of zanamivir: a new inhaled antiviral for influenza. *Clin Pharmacokinet* 1999; **36** (suppl 1): 1–58.

Uses and Administration

Zanamivir is a neuraminidase inhibitor used by inhalation for the treatment and prophylaxis (postexposure and seasonal) of influenza A and B (p.859). For *treatment*, it is given to adults in a dose of 10 mg twice daily for 5 days, starting as soon as possible (within 48 hours) after the onset of symptoms.

Zanamivir is given by inhalation for *postexposure prophylaxis* of influenza A and B in household or close contacts and should be started within 36 hours of exposure. The dose for adults is 10 mg once daily for 10 days. For *seasonal prophylaxis* in a community setting 10 mg once daily may be given to adults and adolescents for 28 days and treatment should start within 5 days of an outbreak.

For details of doses in children, see below.

Administration in children. Zanamivir is given by inhalation for the treatment and postexposure prophylaxis of influenza A and B. For *treatment*, children may be given the same dose as adults (10 mg twice daily for 5 days), starting within 36 to 48 hours after the onset of symptoms. In the USA it is approved for those from 7 years of age whereas UK licensed product information permits use from 5 years of age.

Postexposure prophylaxis after close contact with infected patients should be started within 36 hours of exposure. Children from 5 years of age may be given the same dose as adults (10 mg once daily for 10 days).

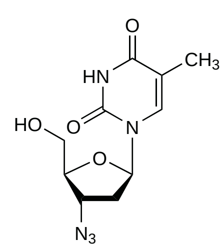
Zidovudine *(BAN, USAN, rINN)*

Azidodeoxythymidine; Azidothymidine; AZT; BW-A509U; BW-509U; Compound-S; Tsidovudiini; Zidovudin; Zidovudina; Zidovudinas; Zidovudinum; Zydowudyna. 3′-Azido-3′-deoxythymidine.

Зидовудин

$C_{10}H_{13}N_5O_4$ = 267.2.
CAS — 30516-87-1.
ATC — J05AF01.
ATC Vet — QJ05AF01.



NOTE. The abbreviation AZT has also been used for azathioprine.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Zidovudine). A white or brownish powder. It shows polymorphism. Sparingly soluble in water; soluble in dehydrated alcohol. Protect from light.

USP 31 (Zidovudine). A white to yellowish powder. Exhibits polymorphism. Sparingly soluble in water; soluble in alcohol.

Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects

The commonest serious adverse effects reported with zidovudine are haematological toxicities such as anaemia, leucopenia, and neutropenia. They occur most commonly when higher doses are used (1.2 to 1.5 g daily) and in patients with advanced HIV disease and a low CD4+ cell count (less than 100 cells/mm^3). These haematological toxicities are usually reversed by interrupting treatment or reducing dosage but the anaemia may be severe enough to require blood transfusion. Aplastic anaemia, pure red cell aplasia, pancytopenia, and thrombocytopenia have been rarely reported.

Other commonly reported adverse effects include dizziness, headache, malaise, myalgia, and gastrointestinal symptoms such as abdominal pain, diarrhoea, nausea, and vomiting. Long-term use of zidovudine has been associated with myopathy. Raised liver enzymes, hyperbilirubinaemia, lactic acidosis, and severe hepatomegaly with steatosis have been reported as rare, but potentially fatal, occurrences in patients taking zidovudine alone or with other antiretrovirals. Other rare but potentially serious adverse effects include cardiomyopathy, convulsions, and pancreatitis.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including zidovudine, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been seen in patients receiving antiretroviral therapy, including zidovudine. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported. NRTIs have also been associated with mitochondrial dysfunction manifesting as abnormal behaviour, anaemia, convulsions, hyperlipasaemia, hypertonia, and neutropenia. Elevated creatine phosphokinase, myalgia, myositis, and rarely rhabdomyolysis have been reported, particularly when nucleoside analogues have been given with HIV-protease inhibitors. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy.

Effects on the blood. Adverse haematological effects reported with zidovudine may be severe and include anaemia with erythroid aplasia or hypoplasia, and neutropenia.[1-5] Although these effects may be reversed by withdrawal,[5] they may persist for weeks afterwards[2,3] and blood transfusions may be required in some patients.[1-4] A study indicated that zidovudine-induced neutropenia only significantly increased the risk of bacterial infection in patients whose polymorphonuclear cell count fell below 500/microlitre.[6] The effects of zidovudine on the platelet count are considered to be complex, but patients with thrombocytopenia appeared not to be at risk during treatment.[7]

Recombinant erythropoietin has been used in an attempt to reduce blood-transfusion requirements in zidovudine-induced anaemia,[8,9] although the proportion of patients who derive benefit may be limited and some have reported it to have no effect.[10] Similarly granulocyte-macrophage colony-stimulating factor has been reported to improve the neutrophil count in some but not all patients.[11]

Effects on the CNS. Reports of adverse effects on the CNS associated with zidovudine include mania,[1,2] seizures[3,4] (following an overdose in one patient[5]), psychogenic panic,[6] and Wernicke's encephalopathy,[7] mostly involving one or two patients in each case. CNS toxicity, thought to be zidovudine-related, contributed to the death of an AIDS patient.[8]

For reports of neurological symptoms associated with mitochondrial dysfunction in infants whose mothers received perinatal zidovudine, see Effects on Mitochondria, below.

Effects on the heart. An observational study[1] evaluated whether NRTIs increase the risk of myocardial infarction in HIV-infected individuals. Of 33 347 patients enrolled in the D:A:D study, myocardial infarction was reported in 517. Recent use of abacavir or didanosine (but not cumulative use) was associated with an increased rate of myocardial infarction (relative risk 1.90 and 1.49 respectively) compared with those with no recent use of the drugs. The excess risk could not be explained by underlying established cardiovascular risk factors and was not present beyond 6 months after stopping the drug. No associations were found between the rate of myocardial infarction and use of zidovudine, stavudine, or lamivudine.

Effects on the liver. The development of acute cholestatic hepatitis necessitated stopping zidovudine in a patient who was later unable to tolerate its re-institution.[1] Zidovudine also had to be withdrawn in 3 patients after abnormal liver-function values occurred;[2] it was reinstated in 2 patients without further liver changes. Reversible increases in liver enzymes and rashes were also reported in 2 patients receiving prophylaxis with zidovudine and zalcitabine after exposure to HIV.[3] There has been a report of iron deposition in the liver of patients receiving blood transfusions for zidovudine-related anaemia.[4]

Fatal hepatic dysfunction associated with steatosis in the liver was reported in 6 patients with HIV infection, who were either receiving zidovudine or had previously done so.[5] Five of these patients also developed metabolic acidosis. Cases of fatal lactic acidosis and hepatic failure or steatosis have been reported in patients receiving zidovudine and other nucleoside analogues.[6,7]

Effects on the metabolism. Lactic acidosis, sometimes in association with myopathy or hepatotoxicity (see above) and in some instances fatal, has been reported after zidovudine treatment.[1-6] However, lactic acidosis with no apparent cause[7] has also been reported in 7 patients with HIV infection: 4 patients were receiving zidovudine, 1 ganciclovir, and 1 clofazimine. The disorder in these patients resembled Reye's syndrome and it was not clear whether the acidosis was induced by zidovudine or the HIV infection.

Lactic acidosis associated with nucleoside reverse transcriptase inhibitors responded to treatment with riboflavin in 4 patients.[8,9]

Effects on mitochondria. Concern has been expressed[1] over the effects of nucleoside reverse transcriptase inhibitors on mitochondria after reports in France[2] of mitochondrial dysfunction in 8 infants whose mothers had received zidovudine alone, or with lamivudine, to prevent vertical transmission of HIV infection during pregnancy. The effects manifested themselves as severe demyelinating neurological disorder in 2 of the 8, both of whom died after about one year of life. Three other infants experienced seizures, 1 with severe cardiomyopathy and 1 with spastic diplegia, while the remaining 3 were asymptomatic. None were infected with HIV. A study[3] involving echocardiograms performed from birth to 5 years of age in 382 infants without HIV infection (36 with zidovudine exposure) and 58 infants with HIV infection (12 with zidovudine exposure), all of whom were born to HIV-infected women, found, however, that there was no evidence of abnormality in left ventricular structure or function associated with perinatal zidovudine. While it was considered that further assessment of this toxicity was required, it was emphasised that current recommendations for zidovudine monotherapy during pregnancy should be maintained.[1,2]

Effects on the musculoskeletal system. Myalgia and other adverse effects on the muscle can occur in patients taking zidovudine, although it has sometimes been difficult to determine whether the effects were caused by the drug or by the underlying HIV infection.[1-4] Zidovudine-induced myopathy has been considered to be a distinct condition characterised by the presence of abnormal mitochondria in muscle-biopsy specimens;[2] this view is supported by the fact that the myopathy readily responds to the withdrawal of zidovudine or to treatment with corticosteroids or other anti-inflammatory drugs.[1-3] For further discussion of the effects of zidovudine on mitochondria, see above.

Arthralgia involving the knees, elbows, ankles, and wrists has been reported in a patient receiving zidovudine.[5]

Effects on the nails. Bluish or brownish discoloration of fingernails and/or toenails has been reported in a number of patients receiving zidovudine.[1-5] Dark-skinned patients appear to be most commonly affected.[2,4] Occasionally the abnormal pigmentation also involves the skin.[3,5] It has been pointed out that discoloration of nails has occurred in HIV-infected patients without exposure to zidovudine.[6] Painless periungual pyogenic granulomata has been reported in a patient 3 months after starting treatment with a combined antiretroviral regimen of zidovudine, lamivudine, plus efavirenz; one month after the zidovudine and the lamivudine was stopped the lesions had nearly resolved.[7] Paronychia was reported in 12 HIV-infected patients taking lamivudine.[8] In a further report, 6 patients developed paronychia while taking lamivudine with indinavir.[9]

Precautions

Zidovudine should be used with care in patients with anaemia or bone-marrow suppression. The incidence of neutropenia is greater in patients with low vitamin B_{12} concentrations. Dosage adjustments or treatment interruptions may be necessary and it has been recommended that zidovudine should not be used if the neutrophil count or haemoglobin value is abnormally low. In patients with advanced symptomatic HIV disease taking oral zidovudine, blood tests should be carried out at least every 2 weeks for the first 3 months of treatment and at least monthly thereafter; blood tests should be performed at least every week in those receiving intravenous zidovudine. In patients with early HIV infection blood tests may be performed less frequently (e.g. every 1 to 3 months).

Care is also required in the elderly and in patients with reduced renal or hepatic function who may require reductions in dose. Patients with risk factors for liver disease should be monitored during treatment. Zidovudine is not recommended in patients with moderate to severe liver disease (Child-Pugh scores 7 to 15). Patients co-infected with chronic hepatitis B or C and treated with combination antiretroviral therapy are at increased risk for severe and potentially fatal hepatic adverse events. Patients with hepatitis C receiving interferon alfa and ribavirin may be at special risk and particular care may be necessary in obese patients and in women. Treatment with zidovudine should be stopped if there is a rapid increase in aminotransferase concentrations, progressive hepatomegaly or steatosis, or metabolic or lactic acidosis of unknown aetiology.

Zidovudine should not be given to neonates with hyperbilirubinaemia severe enough to need treatment other than phototherapy or with markedly increased aminotransferase concentrations.

Interference with laboratory tests. Raised urinary thymine concentrations in neonates, due to maternal zidovudine treatment, could produce erroneous results in screening tests for inborn errors of metabolism.[1]

1. Sewell AC. Zidovudine and confusion in urinary metabolic screening. *Lancet* 1998; **352:** 1227.

Pregnancy. Giving zidovudine to pregnant women with HIV infection from 14 weeks of gestation until delivery, and subsequently to the neonate, has been shown to reduce vertical transmission of the infection (see Uses and Administration, below). However, studies have shown that zidovudine can be fetotoxic in *animals* when given early in pregnancy, and the long-term consequences for the infant are as yet unknown although no adverse effects were seen in a group of infants followed for up to 5.6 years.[1] Licensed product information therefore recommends that zidovudine should not generally be given before 14 weeks of gestation.

1. Culnane M, *et al.* Lack of long-term effects of in utero exposure to zidovudine among uninfected children born to HIV-infected women. *JAMA* 1999; **281:** 151–7.

Interactions

Care should be taken when using zidovudine with drugs that are myelosuppressive (such as amphotericin B, co-trimoxazole, dapsone, doxorubicin, flucytosine, ganciclovir, interferon, systemic pentamidine, pyrimethamine, and vinca alkaloids) or nephrotoxic. Drugs that undergo glucuronidation may delay the metabolism of zidovudine but few of these appear to produce clinically important increases in zidovudine plasma concentrations. Increased toxicity and decreased antiretroviral activity has been reported when zidovudine is given with some other antiviral drugs, and pharmacokinetic interactions have been reported with a number of anti-infective drugs used commonly in patients with HIV infection.

Analgesics. There may be an increased risk of haematotoxicity during use of zidovudine with *NSAIDs*.

Decreased zidovudine clearance[1] and increased area under the zidovudine plasma concentration-time curve[2] has been seen in patients receiving *methadone*.

Severe hepatotoxicity has occurred after use of *paracetamol* in a patient taking zidovudine and co-trimoxazole.[3] However, neither short-term[4] nor long-term[5] studies (the latter also in an individual patient) have shown any alteration of zidovudine elimination in patients taking zidovudine and paracetamol.

5. Burger DM, *et al.* Pharmacokinetics of zidovudine and acetaminophen in a patient on chronic acetaminophen therapy. *Ann Pharmacother* 1994; **28:** 327–30.

Antibacterials. Studies have indicated that the absorption of zidovudine could be reduced by *clarithromycin*.[1] Licensed product information recommends giving zidovudine and clarithromycin at least 2 hours apart since this has been shown to have no overall effect on the bioavailability of zidovudine.[2] Use of *rifampicin* by patients taking zidovudine has been reported to reduce exposure to zidovudine, probably by inducing glucuronidation and amination. Licensed product information for zidovudine has warned that this may result in a partial, or total, loss of efficacy of the drug.[3,4] *Rifabutin* has not been shown to have a marked effect on zidovudine clearance.[5] *Trimethoprim* has been reported[6,7] to decrease the renal clearance of zidovudine by up to 60% with a consequent increase in plasma concentrations, although it was only thought likely to be of clinical significance in patients with hepatic impairment.[7]

For a report of reduced *pyrazinamide* concentrations in patients receiving zidovudine, see p.321.

6. Chatton JY, *et al.* Trimethoprim, alone or in combination with sulphamethoxazole, decreases the renal excretion of zidovudine and its glucuronide. *Br J Clin Pharmacol* 1992; **34:** 551–4.
7. Lee BL, *et al.* Zidovudine, trimethoprim, and dapsone pharmacokinetic interactions in patients with human immunodeficiency virus infection. *Antimicrob Agents Chemother* 1996; **40:** 1231–6.

Antiepileptics. Giving *valproic acid* to 6 patients taking zidovudine produced increases in plasma-zidovudine concentrations and the area under the plasma concentration-time curve.[1] The evidence suggested that this was due to reduced glucuronidation of zidovudine. Zidovudine may possibly reduce or increase plasma concentrations of *phenytoin*.

1. Lertora JJL, *et al.* Pharmacokinetic interaction between zidovudine and valproic acid in patients infected with human immunodeficiency virus. *Clin Pharmacol Ther* 1994; **56:** 272–8.

Antifungals. Use of *fluconazole* with zidovudine produced higher serum-zidovudine concentrations, increased the area under the serum concentration-time curve, and prolonged terminal half-life compared with zidovudine alone in a study in 12 patients.[1] Studies *in vitro* suggested that fluconazole could inhibit the glucuronidation of zidovudine; inhibition was also seen with *amphotericin B*, *ketoconazole*, and *miconazole*, but not with *flucytosine* or *itraconazole*.[2]

1. Sahai J, *et al.* Effect of fluconazole on zidovudine pharmacokinetics in patients infected with human immunodeficiency virus. *J Infect Dis* 1994; **169:** 103–7.
2. Sampol E, *et al.* Comparative effects of antifungal agents on zidovudine glucuronidation by human liver microsomes. *Br J Clin Pharmacol* 1995; **40:** 83–6.

Antiprotozoals. Use of *atovaquone* with zidovudine produced moderate increases in the zidovudine plasma concentration and area under the plasma concentration-time curve, probably by inhibition of glucuronidation.[1]

1. Lee BL, *et al.* Atovaquone inhibits the glucuronidation and increases the plasma concentrations of zidovudine. *Clin Pharmacol Ther* 1996; **59:** 14–21.

Antivirals. Although there is some evidence from studies *in vitro* that *ribavirin* inhibits phosphorylation of zidovudine, and might therefore reduce its antiviral activity, it is unclear whether an interaction of clinical significance occurs; licensed product information for zidovudine does not recommend the combination, but product information for ribavirin varies, with the US product indicating that no clinical effect was seen. However, the combination may increase the risk of anaemia. Zidovudine product information also recommends that the use of zidovudine with *stavudine* be avoided since similar antagonism has been shown *in vitro*.[1] *Interferon alfa* and zidovudine had a synergistic cytotoxicity to bone-marrow progenitor cells.[2] Severe haematological toxicity occurred when zidovudine was added to *ganciclovir* therapy in AIDS patients with CMV retinitis, necessitating substantial dosage reductions or withdrawal of zidovudine in the majority of patients;[3,4] this additive toxicity with ganciclovir may be one reason why patients given zidovudine and ganciclovir do less well than those given zidovudine and foscarnet. Combined therapy with zidovudine and *aciclovir* is not generally associated with additional toxicity[5] but severe fatigue and lethargy were reported in a patient given aciclovir with zidovudine; this did not occur when either drug was given alone.[6] Evidence of a pharmacokinetic interaction between zidovudine and *didanosine* has been conflicting, with reports of no effect,[7] increased,[8] and decreased[9] plasma concentrations of zidovudine. Small reductions in didanosine plasma concentrations have been reported in patients also receiving zidovudine.[10] However, all changes have generally been small and are likely to be of limited clinical significance. Exposure to zidovudine (as measured by peak plasma concentrations and area under the concentration-time curve) was reduced in HIV patients also given *ritonavir*, whereas the pharmacokinetics of ritonavir were not affected by zidovudine;[11] the clinical relevance of this was not known. Modest increases in plasma-zidovudine concentrations occur on use with *lamivudine*. Although this interaction is usually clinically insignificant, profound anaemia has been reported rarely in patients given this combination.[12,13]

Probenecid. Use of probenecid with zidovudine results in increased plasma concentrations and area under the plasma concentration-time curve of zidovudine, probably due to inhibition of glucuronidation;[1] tubular secretion of the glucuronide metabolite is also reduced. A high incidence of adverse effects has been reported in some patients receiving this combination.[2]

Antiviral Action

Zidovudine is converted intracellularly in stages to the triphosphate via thymidine kinase and other kinases. This triphosphate halts the DNA synthesis of retroviruses, including HIV, through competitive inhibition of reverse transcriptase and incorporation into viral DNA. It has also been shown to possess activity against Epstein-Barr virus and Gram-negative bacteria *in vitro*.

Zidovudine-resistant strains of HIV emerge rapidly during zidovudine therapy and are responsible for the lack of benefit with long-term monotherapy. Cross-resistance to other nucleoside reverse transcriptase inhibitors has been recognised.

Resistance. The emergence of zidovudine-resistant HIV strains in patients receiving long-term therapy with zidovudine has been recognised since 1989.[1,2] The emergence of drug resistance is associated with the duration[3] of treatment with zidovudine, but not the dose,[4] and is attributed to a high frequency of mutations in the

HIV reverse transcriptase gene.[3,5] Development of high-level resistance to zidovudine in patients with advanced HIV infection has been associated with rapid disease progression and death.[6] Primary infection with zidovudine-resistant HIV strains has been recorded,[7] as has zidovudine resistance in patients receiving other nucleoside reverse transcriptase inhibitors,[8,9] although it is possible that these patients had unrecorded exposure to zidovudine.[8] Cross-resistance with other reverse transcriptase inhibitors has been recorded and, although the use of zidovudine with lamivudine has been reported to delay or reverse the emergence of some mutations conferring zidovudine resistance, dual resistance to zidovudine and lamivudine has occurred.[10] Analysis of the Delta trial[11] found no delay in the emergence of zidovudine resistance when used with didanosine or zalcitabine, although circulating concentrations of resistant virus were lower during combination therapy and antiviral activity was apparently not impaired. Nevertheless, it could be anticipated that the use of zidovudine with other antiretrovirals, and particularly the highly active regimens which suppress viral replication to a high degree, could delay the emergence of resistance. The clinical response of patients with previous exposure to a number of regimens could be compromised by the presence of multidrug resistance.[12,13]

Pharmacokinetics

Zidovudine is rapidly absorbed from the gastrointestinal tract and undergoes first-pass hepatic metabolism with a bioavailability of about 60 to 70%. Peak plasma concentrations occur after about 1 hour. Absorption is delayed when given with food, but bioavailability is probably unaffected. Zidovudine crosses the blood-brain barrier producing CSF to plasma ratios of about 0.5. It crosses the placenta and is distributed into breast milk. It has been detected in semen. Plasma protein binding is reported to be 34 to 38%. The plasma half-life is about 1 hour.

Zidovudine is metabolised intracellularly to the antiviral triphosphate. It is also metabolised in the liver, mainly to the inactive glucuronide, and is excreted in the urine as unchanged drug and metabolite.

Neonates. The pharmacokinetics of zidovudine in infants more than 14 days old are reported to be similar to those in adults. After maternal doses the half-life of zidovudine in 7 neonates has been reported to be extended to a mean of 13 hours.[1] In infants given zidovudine, those under 14 days of age had lower total clearance, longer terminal half-life (about 3 hours), and higher bioavailability than older infants.[2] Zidovudine clearance was low and the half-life prolonged to about 7 hours in premature infants.[3]

Pregnancy. In a study in 3 pregnant women with HIV infection,[1] the area under the concentration-time curve for zidovudine was reduced and the clearance of an oral dose increased during pregnancy when compared with up to 4 weeks postpartum. These results differed from those reported from another study which reported no differences during or after pregnancy.[2] This latter study, however, used values obtained no later than 48 hours postpartum for comparison, at which time it is unlikely that physiological functions would have returned to the nonpregnant state. Zidovudine and its glucuronide metabolite cross the placenta reaching concentrations in the fetal blood similar to those in maternal blood.[3,4] However, concentrations of zidovudine in the fetal CNS have been reported to be below those required to exert an anti-HIV effect.[5]

Uses and Administration

Zidovudine is a nucleoside reverse transcriptase inhibitor structurally related to thymidine with antiviral activity against HIV-1. It is used in the treatment of HIV infection and AIDS (p.856). Viral resistance emerges rapidly when zidovudine is used alone, and it is therefore usually used with other antiretrovirals. It may be used alone to prevent vertical transmission from mother to infant if combination antiretroviral therapy is not available.

Zidovudine is given orally in doses of 500 to 600 mg daily in 2 or 3 divided doses. Zidovudine may be given by intravenous infusion of a solution containing 2 to 4 mg/mL over 1 hour for short-term management of patients unable to take it orally. The dose is 1 to 2 mg/kg every 4 hours (equivalent to an oral dose of 1.5 to 3 mg/kg every 4 hours).

For the *prevention of maternal-fetal HIV transmission*, zidovudine may be given orally to **mothers** after the fourteenth week of pregnancy until the beginning of labour in a dose of 100 mg five times daily. During labour and delivery, zidovudine is given by intravenous infusion in a dose of 2 mg/kg over 1 hour, then 1 mg/kg per hour until the umbilical cord is clamped. When a caesarean section is planned the intravenous infusion is started 4 hours before the operation.

For details of doses in **infants and children**, including the prevention of maternal-fetal HIV transmission, see below.

Blood tests should be carried out regularly as described under Precautions, above. If the white cell count or haemoglobin level fall, the dose should be reduced or, alternatively, treatment interrupted briefly, until there is evidence of recovery. Treatment should be stopped if toxicity is severe and cautiously reintroduced once the bone marrow has recovered. Dosage adjustments may also be necessary in patients with renal (see below) or hepatic impairment.

Fixed-dose combination products have been developed in order to improve patient adherence and avoid monotherapy, thereby decreasing the risk of acquired drug resistance. Products containing zidovudine in combination with lamivudine or with abacavir plus lamivudine are available in some countries.

Administration in children. For the **treatment of HIV infection** in infants and children zidovudine is given orally or intravenously with other antiretroviral drugs. Doses are based on body-surface:

- *oral* zidovudine is given in a dose of 360 to 480 mg/m^2 daily in 3 or 4 divided doses; the maximum dose should not exceed 200 mg every 6 to 8 hours
- *intravenous* zidovudine is given in a dose of 80 to 160 mg/m^2 every 6 hours. An intravenous dose of 120 mg/m^2 every 6 hours is equivalent to an oral dose of about 180 mg/m^2 every 6 hours

There are slight discrepancies between countries in the age ranges for which the above doses are licensed. The UK licenses these oral and intravenous doses from 3 months of age; the USA permits oral use from 6 weeks of age, but does not include intravenous doses for treatment in children, although it does have intravenous doses for prevention of transmission (below).

For the **prevention of maternal-fetal HIV transmission** the newborn infant is given zidovudine 2 mg/kg orally every 6 hours starting within 12 hours after birth and continuing for 6 weeks. Neonates unable to receive oral doses are given 1.5 mg/kg by intravenous infusion over 30 minutes every 6 hours. (For doses to be given to the mother for the prevention of maternal-fetal transmission see above.)

Administration in renal impairment. Oral doses of zidovudine should be reduced in patients with severe renal impairment (creatinine clearance less than 10 to 15 mL/minute) and in those on haemodialysis or peritoneal dialysis. Licensed product information gives the following guidance:

- *oral* administration: 100 mg every 6 to 8 hours
- *intravenous* administration: 1 mg/kg every 6 to 8 hours

HIV infection and AIDS. As discussed on p.856, the use of antiretroviral drugs in HIV infection changed after studies indicated that combination therapy could improve response.

A combination of zidovudine and other antiretroviral drugs improves efficacy, minimises toxicity, and delays drug resistance. Results from the Delta study[1] and the US AIDS Clinical Trial Group 175 (ACTG 175) study[2] showed combination therapy to be more effective than monotherapy in antiretroviral-naive patients and have led to profound changes in clinical practice. Both studies showed substantial reductions in mortality at 30 months in antiretroviral-naive patients treated with zidovudine plus either didanosine or zalcitabine compared with those receiving zidovudine alone. Triple therapy, with zidovudine used with another nucleoside reverse transcriptase inhibitor and either an HIV-protease inhibitor or a non-nucleoside reverse transcriptase inhibitor (HAART regimens), has been found to reduce viral loads more effectively than monotherapy or two-drug combination therapy and such regimens are currently regarded as standard.

1. Delta Coordinating Committee. Delta: a randomised double-blind controlled trial comparing combinations of zidovudine plus didanosine or zalcitabine with zidovudine alone in HIV-infected individuals. *Lancet* 1996; **348:** 283–91.
2. Hammer SM, *et al.* A trial comparing nucleoside monotherapy with combination therapy in HIV-infected adults with CD4 cell counts from 200 to 500 per cubic millimeter. *N Engl J Med* 1996; **335:** 1081–90.

HIV infection prophylaxis. Antiretroviral drugs are used for chemoprophylaxis after *occupational and non-occupational exposure* to HIV infection. Zidovudine is commonly used with other antiretroviral drugs after exposure with a risk of infection (see p.858).

Zidovudine has been shown to be of value in *reducing vertical transmission*. For further information on the use of zidovudine in preventing HIV transmission from mother to child, see HIV Infection Prophylaxis, p.858.

Preparations

USP 31: Zidovudine Capsules; Zidovudine Injection; Zidovudine Oral Solution; Zidovudine Tablets.

	Amprenavir		**Atazanavir**		**Darunavir**	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Antivirals: Antiretrovirals						
Protease Inhibitors						
Amprenavir	N/A	N/A	Boosted atazanavir expected to increase concentration of amprenavir	Co-administration not recommended	Potential interaction	Dual therapy with protease inhibitors generally not recommended
Atazanavir	Boosted atazanavir expected to increase concentration of amprenavir	Co-administration not recommended	N/A	N/A	No clinically significant interaction	No dose adjustment required
Darunavir	Potential interaction	Dual therapy with protease inhibitors generally not recommended	No clinically significant interaction	No dose adjustment required	N/A	N/A
Indinavir	May increase concentration of amprenavir and decrease concentration of indinavir	Close monitoring – appropriate alteration of dose not established	Unspecified clinically significant interaction	Not recommended – both drugs have been associated with hyperbilirubinaemia	Increases concentration of both boosted darunavir and indinavir	Close monitoring; may need to decrease dose of indinavir
Lopinavir/Ritonavir	Increases concentrations of amprenavir and decreases concentration of lopinavir	Close monitoring; may need to alter the dose of ritonavir-boosted lopinavir but do not give as a single daily dose	Boosted atazanavir expected to increase concentration of lopinavir	Co-administration not recommended	Decreases concentration of boosted darunavir	Co-administration not recommended
Nelfinavir	No clinically significant interaction	Alteration of dose not usually needed	Boosted atazanavir expected to increase concentration of nelfinavir	Co-administration not recommended	Potential interaction	Dual therapy with protease inhibitors generally not recommended
Ritonavir	Increases concentration of amprenavir; (solution contains propylene glycol - potential of toxicity)	Dose of amprenavir should be reduced (co-administration of amprenavir and ritonavir solution - contraindicated)	Increases concentration of atazanavir	Co-administered as ritonavir-boosted atazanavir	Increases concentration of darunavir	Co-administered as ritonavir-boosted darunavir
Saquinavir	May decrease concentrations of amprenavir and saquinavir	Close monitoring - appropriate alteration of dose not established	Increases concentration of saquinavir	Close monitoring - appropriate alteration of dose not established	Decreases concentration of boosted darunavir	Dual therapy with protease inhibitors generally not recommended
Tipranavir	Boosted: decreases concentration of amprenavir	Close monitoring or alteration of dose; co-administration not recommended	Boosted: decreases concentration of atazanavir and increases concentration of tipranavir	Co-administration not recommended	Potential interaction	Dual therapy with protease inhibitors generally not recommended
NNRTIs						
Delavirdine	Decreases concentration of delavirdine and increases concentration of amprenavir	Appropriate doses not established; co-administration not recommended	Potential interaction	No established dose adjustment	Potential interaction	Close monitoring or alteration of dose
Efavirenz	May decrease concentration of amprenavir	Unboosted: no established dose adjustment; dose of amprenavir may need to be increased. Boosted: no dose adjustment needed	Decreases concentration of atazanavir	In treatment-naïve patients - give with atazanavir 300mg and ritonavir 100mg; treatment experienced patients - no established dose adjustments	Decreases concentration of boosted darunavir and increases concentration of efavirenz	Close monitoring - combination may be associated with CNS toxicity
Etravirine	Boosted and unboosted amprenavir increases concentration of amprenavir	Contraindicated	Unboosted atazanavir decreases concentration of atazanavir; boosted atazanavir decreases concentration of atazanavir and increases concentration of etravirine	Contraindicated	Boosted darunavir decreases concentration of etravirine	No dose adjustment required
Nevirapine	May decrease concentration of amprenavir	No established dose adjustment	Decreases concentration of atazanavir	No established dose adjustment; co-administration not recommended	Boosted darunavir increases concentration of nevirapine	Not a clinically significant interaction; co-administration without dose adjustments
NsRTIs/NtRTIs						
Abacavir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Didanosine	Decreases concentration of amprenavir (only with buffered didanosine formulation)	Doses of didanosine and amprenavir should be separated by at least 1 hour	Decreases concentration of atazanavir (only with buffered didanosine formulation)	Doses of didanosine and atazanavir should be separated by at least 2 hours	Potential interaction	Close monitoring; separate doses - give didanosine 1 hour before or 2 hours after boosted darunavir
Emtricitabine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Lamivudine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Stavudine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Tenofovir	Potential interaction	Close monitoring or alteration of dose	Unboosted - decreases concentration of atazanavir; boosted - increases concentration of tenofovir	Always use boosted atazanavir; close monitoring for tenofovir associated adverse effects	Boosted darunavir increases concentration of tenofovir	Close monitoring for tenofovir associated adverse effects; particularly in patients with renal patients
Zalcitabine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Zidovudine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required

Nelfinavir	Increases concentration of indinavir and nelfinavir	Close monitoring – appropriate alteration of dose not established	Increases concentration of nelfinavir and decreases concentration of lopinavir	Close monitoring; may need to alter the dose of ritonavir-boosted lopinavir	N/A	N/A
Ritonavir	Increases concentrations of both indinavir and ritonavir	Close monitoring - appropriate alteration of dose not established; combination associated with nephrolithiasis	Unboosted: increases concentration of lopinavir	Close monitoring – appropriate alteration of dose not established	Increases concentration of nelfinavir	Close monitoring – appropriate alteration of dose not established
Saquinavir	Unboosted: increases concentration of saquinavir Boosted: increases concentration of indinavir	Close monitoring – appropriate alteration of dose not established	Increases concentration of saquinavir	Close monitoring - dose of saquinavir is 1g twice daily when given with ritonavir-boosted lopinavir 400/100mg twice daily	Increases concentrations of saquinavir and nelfinavir	Close monitoring – appropriate alteration of dose not established
Tipranavir	Potential interaction	Close monitoring or alteration of dose; co-administration not recommended	Boosted: decreases concentration of lopinavir	Co-administration not recommended	Potential interaction	Close monitoring or alteration of dose; co-administration not recommended
NNRTIs						
Delavirdine	May increase concentration of indinavir	Close monitoring, may need to decrease dose of indinavir to 400 to 600mg every 8 hours	May increase concentrations of lopinavir	Close monitoring - appropriate alteration of dose not established	Increases concentration of nelfinavir and decreases concentration of delavirdine	Close monitoring – appropriate alteration of dose not established
Efavirenz	Decreases concentration of indinavir	Close monitoring, may need to increase dose of indinavir although appropriate alteration of dose not established	May decrease concentrations of lopinavir	Do not give as a once daily dose; in treatment-experienced patients increase dose of ritonavir-boosted lopinavir by about 33%	No clinically significant interaction	No dose adjustment required
Etravirine	Decreases concentration of indinavir	Contraindicated	Increases concentration of etravirine	Use with caution	Increases concentration of nelfinavir	Contraindicated
Nevirapine	Decreases concentration of indinavir	Close monitoring, may need to increase dose of indinavir to 1g every 8 hours	May decrease concentrations of lopinavir	Close monitoring - consider increasing dose of ritonavir-boosted lopinavir by about 33% (do not give as a once daily dose)	Decreases concentration of nelfinavir; not expected to be clinically significant	Close monitoring – alteration of dose not usually needed
NsRTIs/NtRTIs						
Abacavir	No clinically significant interaction	No dose adjustment required	May decrease concentrations of abacavir	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Didanosine	Potential interaction	Close monitoring; separate doses of didanosine and indinavir by 1 hour	Potential interaction	Close monitoring; separate doses – give didanosine 1 hour before or 2 hours after lopinavir/ ritonavir solution	Potential interaction due to formulation of didanosine	Close monitoring; separate doses – give nelfinavir 1 hour before or 2 hours after didanosine (or vice versa)
Emtricitabine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Lamivudine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Stavudine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Tenofovir	Increases concentration of indinavir	No dose adjustment required	Modest increase in concentration of tenofovir	Close monitoring for tenofovir associated adverse effects	Potential interaction	Close monitoring or alteration of dose
Zalcitabine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Zidovudine	No clinically significant interaction	No dose adjustment required	May decrease concentration of zidovudine	No dose adjustment required	No clinically significant interaction	No dose adjustment required

Table 1. Interactions: drugs used in the treatment of HIV. The HIV-Protease Inhibitors.

	Ritonavir		**Saquinavir**		**Tipranavir**	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Antivirals: Antiretrovirals						
Protease Inhibitors						
Amprenavir	Increases concentration of amprenavir; (solution contains propylene glycol – potential of toxicity)	Dose of amprenavir should be reduced (co-administration of amprenavir and ritonavir solution – contraindicated)	May decrease concentrations of amprenavir and saquinavir	Close monitoring – appropriate alteration of dose not established	Boosted: decreases concentration of amprenavir	Close monitoring or alteration of dose; co-administration not recommended
Atazanavir	Increases concentration of atazanavir	Co-administered as ritonavir-boosted atazanavir	Boosted: increases concentration of saquinavir and ritonavir	Close monitoring – appropriate alteration of dose not established	Boosted: decreases concentration of atazanavir and increases concentration of tipranavir	Close monitoring or alteration of dose; co-administration not recommended
Darunavir	Increases concentration of darunavir	Co-administered as ritonavir-boosted darunavir	Decreases concentration of ritonavir-boosted darunavir	Dual therapy with protease inhibitors generally not recommended	Potential interaction	Dual therapy with protease inhibitors generally not recommended
Indinavir	Increases concentrations of indinavir	Close monitoring – appropriate alteration of dose not established; combination associated with nephrolithiasis	Unboosted: increases concentration of saquinavir; Boosted: increases concentration of indinavir	Close monitoring - appropriate alteration of dose not established; Boosted regimens may cause nephrolithiasis	Potential interaction	Close monitoring or alteration of dose; co-administration not recommended
Lopinavir/Ritonavir	Unboosted: increases concentration of lopinavir	Close monitoring – appropriate alteration of dose not established	Unboosted: potential interaction	Close monitoring - dose of saquinavir is 1g twice daily when given with lopinavir/ritonavir 400/100mg twice daily	Boosted: decreases concentration of lopinavir	Close monitoring or alteration of dose; co-administration not recommended
Nelfinavir	Increases concentration of nelfinavir	Close monitoring – appropriate alteration of dose not established	Unboosted: increases concentration of nelfinavir and saquinavir; Boosted: not evaluated	No initial adjustment required; monitor	Potential interaction	Close monitoring or alteration of dose; co-administration not recommended
Ritonavir	N/A	N/A	Increases concentration of saquinavir	Close monitoring or alteration of dose (used clinically as a boosted combination)	Increases concentration of tipranavir	Co-administered as ritonavir-boosted tipranavir
Saquinavir	Increases concentration of saquinavir	Co-administered as ritonavir-boosted saquinavir	N/A	N/A	Boosted: decreases concentration of saquinavir	Close monitoring or alteration of dose; co-administration not recommended
Tipranavir	Increases concentration of tipranavir	Co-administered as ritonavir-boosted tipranavir	Boosted: decreases concentration of saquinavir	Not recommended	N/A	N/A
NNRTIs						
Delavirdine	Increases concentration of ritonavir; may increase concentration of delavirdine	Close monitoring; may need to decrease dose of ritonavir	Unboosted: increases concentration of saquinavir; Boosted: not evaluated	Close monitoring or alteration of dose may be required	Potential interaction	Close monitoring or alteration of dose
Efavirenz	Increases concentrations of efavirenz and ritonavir	Close monitoring or alteration of dose; high frequency of adverse effects reported	Unboosted: decreases concentration of saquinavir and efavirenz; Boosted: no relevant interaction	Close monitoring or alteration of dose may be required; boost with ritonavir	Boosted: limited data indicates no significant interactions	Use with caution until more data available
Etravirine	Decreases concentration of etravirine	Contraindicated	Boosted saquinavir decreases concentration of etravirine	No dose adjustment required	Boosted tipranavir decreases concentration of etravirine	Contraindicated
Nevirapine	No clinically significant interaction	No dose adjustment required	Unboosted: decreases concentration of saquinavir; Boosted: not evaluated	Monitor – although not considered clinically relevant	Boosted: limited data indicates no significant interactions	Use with caution until more data available
NsRTIs/NtRTIs						
Abacavir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	Boosted: decreases concentration of abacavir	No established dose adjustments; use an alternative NRTI
Didanosine	Potential interaction due to formulation of didanosine	Close monitoring; separate doses of didanosine and ritonavir by 2.5 hours	Boosted: potential interaction	Close monitoring or alteration of dose may be required	Boosted: decreases concentration of didanosine	Administration should be separated by at least 2 hours
Emtricitabine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Lamivudine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Stavudine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Tenofovir	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Zalcitabine	No clinically significant interaction	No dose adjustment required	Unboosted: no clinically significant interaction; Boosted: no studies	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Zidovudine	No clinically significant interaction	No dose adjustment required	Unboosted: no clinically significant interaction; Boosted: no studies	No dose adjustment required	Boosted: decreases concentration of zidovudine	No established dose adjustments; use an alternative NRTI

Other Antiretrovirals						
Enfuvirtide	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Maraviroc	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Raltegravir	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required
Antivirals						
Aciclovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Adefovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Cidofovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Famciclovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Foscarnet	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Ganciclovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Ribavirin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Valaciclovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Other Drugs						
Analgesics, Anti-inflammatory Drugs and Antipyretics						
Alfentanil	Potential Interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential Interaction	Close monitoring or alteration of dose
Aspirin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Buprenorphine	Potential Interaction	Close monitoring or alteration of dose	Increases concentration of buprenorphine	Close monitoring; may need to decrease dose of buprenorphine	Potential Interaction	Close monitoring or alteration of dose
Dextropropoxyphene	Potential Interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential Interaction	Close monitoring or alteration of dose
Diamorphine	Potential Interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential Interaction	Close monitoring or alteration of dose
Fentanyl	Potential Interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential Interaction	Close monitoring or alteration of dose
Ibuprofen	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Methadone	Decreases concentrations of methadone and amprenavir	May need to increase dose of methadone; monitor for symptoms of withdrawal; consider an alternative antiretroviral	Boosted atazanavir - no clinically significant interaction	No dose adjustment required	Decreases concentrations of methadone	May need to increase dose of methadone; monitor for symptoms of withdrawal
Morphine	Potential Interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential Interaction	Close monitoring or alteration of dose
Paracetamol	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Pethidine	Potential Interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential Interaction	Close monitoring or alteration of dose
Piroxicam	Potential Interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential Interaction	Close monitoring or alteration of dose
Tramadol	Potential Interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential Interaction	Close monitoring or alteration of dose

Other Antiretrovirals						
Enfuvirtide	No clinically significant interaction	No dose adjustment required	Boosted: no clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Maraviroc	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required
Raltegravir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Antivirals						
Aciclovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Adefovir	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required
Cidofovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Famciclovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Foscarnet	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Ganciclovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Ribavirin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Valaciclovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Other Drugs						
Analgesics, Anti-inflammatory Drugs and Antipyretics						
Alfentanil	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Aspirin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Buprenorphine	Increase in concentration of buprenorphine; not expected to be clinically significant	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Dextropropoxyphene	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Diamorphine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Fentanyl	May increase concentration of fentanyl	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Ibuprofen	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Methadone	Decreases concentration of methadone	May need to increase dose of methadone; monitor for symptoms of withdrawal	Boosted: decreases concentration of methadone	May need to increase dose of methadone; monitor for symptoms of withdrawal	Boosted: decreases concentration of methadone	May need to increase dose of methadone; monitor for symptoms of withdrawal
Morphine	May decrease concentration of morphine	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Paracetamol	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Pethidine	Decreases concentration of pethidine and increases concentration of its metabolite	Dose increases and long term use not recommended due to potential for serious CNS related reactions	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of pethidine and increases concentration of its metabolite	Long term use not recommended; close monitoring or alteration of dose
Piroxicam	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Tramadol	May increase concentration of tramadol	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose

Table 1. Interactions: drugs used in the treatment of HIV. The HIV-Protease Inhibitors.

	Amprenavir		Atazanavir		Darunavir

Antibacterials						
Antimycobacterials						
Ethambutol	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Isoniazid	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Pyrazinamide	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Rifabutin	Increases concentration of rifabutin and its metabolite	Decrease the dose of rifabutin	Increases concentration of rifabutin	Decrease the dose of rifabutin	Increases concentration of rifabutin; decreases concentration of darunavir	Decrease the dose of rifabutin
Rifampicin	Decreases concentration of amprenavir	Contraindicated - loss of antiretroviral activity	Decreases concentration of atazanavir	Contraindicated – loss of antiretroviral activity	Decreases concentration of darunavir	Contraindicated - loss of antiretroviral activity
Streptomycin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Macrolides						
Azithromycin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	Potential Interaction	Close monitoring or alteration of dose
Clarithromycin	Unboosted: no clinically significant interaction Boosted: may increase concentration of clarithromycin	Unboosted - no dose adjustment required; boosted decrease dose of clarithromycin in patients with renal impairment	Increases concentration of both atazanavir and clarithromycin and decreases concentration of clarithromycin metabolite	Decrease dose of clarithromycin by about 50% or consider alternatives except for *Mycobacterium avium* complex	Increases concentration of clarithromycin; concentration of clarithromycin metabolite not detectable	Normal renal function - caution and monitor; impaired renal function - decrease dose of clarithromycin
Erythromycin	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	Potential Interaction	Close monitoring or alteration of dose
Quinolones						
Ciprofloxacin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Ofloxacin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Others						
Clindamycin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Co-trimoxazole	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Dapsone	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Metronidazole	Potential risk of toxicity due to propylene glycol	Contraindicated - due to potential for serious or life-threatening reactions	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Quinupristin/Dalfopristin	—	—	—	—	—	—
Tetracyclines	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Antidepressants						
Tricyclics						
Amitriptyline	Increases concentrations of tricyclics	Close monitoring or alteration of dose	Increases concentrations of tricyclics	Caution – due to potential for serious or life-threatening reactions	Potential interaction	Close monitoring or alteration of dose
Desipramine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Doxepin	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Nortriptyline	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
SSRIs						
Citalopram	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Fluoxetine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Paroxetine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of paroxetine	Start with lowest dose of paroxetine and monitor
Sertraline	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of sertraline	Start with lowest dose of sertraline and monitor

Antibacterials						
Antimycobacterials						
Ethambutol	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Isoniazid	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Pyrazinamide	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Rifabutin	Increases concentration of rifabutin and its metabolite	Decrease the dose of rifabutin	Unboosted: increases concentration of rifabutin and decreases concentration of saquinavir; Boosted: not evaluated	Decrease the dose of rifabutin	Boosted: increases concentration of rifabutin and metabolites	Decrease dose of rifabutin
Rifampicin	Decreases concentration of ritonavir	Contraindicated – loss of antiretroviral activity	Unboosted: decreases concentration of saquinavir; Boosted: caused hepatocellular toxicity	Both boosted and unboosted saquinavir contraindicated with rifampicin	Boosted: decreases concentration of tipranavir	Contraindicated - loss of antiretroviral activity and possible resistance
Streptomycin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Macrolides						
Azithromycin	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Clarithromycin	Increases concentrations of clarithromycin	Normal renal function - no dose adjustments needed; impaired renal function - decrease dose of clarithromycin	Unboosted: increases concentration of clarithromycin and saquinavir; Boosted: not evaluated	Normal renal function - no dose adjustments needed; Impaired renal function - decrease dose of clarithromycin by 50 to 75%	Boosted: increases concentration of tipranavir and clarithromycin; decreases concentration of clarithromycin metabolite	Normal renal function – no dose adjustments needed; impaired renal function – decrease dose of clarithromycin
Erythromycin	May increase concentration of erythromycin	Close monitoring or alteration of dose	Unboosted: no clinically significant interaction; Boosted: not evaluated	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Quinolones						
Ciprofloxacin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Ofloxacin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Others						
Clindamycin	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Co-trimoxazole	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Dapsone	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Metronidazole	Ritonavir formulations contain alcohol	May cause disulfiram reaction	No clinically significant interaction	No dose adjustment required	Tipranavir capsules contain alcohol	May cause disulfiram reaction
Quinupristin/Dalfopristin	—	—	Unboosted: potential to increase concentration of saquinavir; Boosted: not evaluated	Close monitoring or alteration of dose	—	—
Tetracyclines	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Antidepressants						
Tricyclics						
Amitriptyline	May increase concentrations of tricyclics	Close monitoring or alteration of dose	Boosted: potential to decrease concentration of tricyclics	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Desipramine	Increases concentration of desipramine	Low starting dose of desipramine	Potential interaction	Close monitoring or alteration of dose	Boosted: may increase concentration of desipramine	May need to reduce dose of desipramine
Doxepin	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Nortriptyline	May increase concentrations of tricyclics	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
SSRIs						
Citalopram	May increase concentration of citalopram	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Fluoxetine	May increase concentration of fluoxetine	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	No studies but potential to increase concentration of fluoxetine	Close monitoring or alteration of dose
Paroxetine	May increase concentration of paroxetine	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	No studies but potential to increase concentration of paroxetine	Close monitoring or alteration of dose
Sertraline	May increase concentration of sertraline	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	No studies but potential to increase concentration of sertraline	Close monitoring or alteration of dose

Table 1. Interactions: drugs used in the treatment of HIV. The HIV-Protease Inhibitors.

	Amprenavir		Atazanavir		Darunavir	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Other Antidepressants						
Bupropion	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Mirtazapine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Nefazodone	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
St Johns Wort	Decreases concentration of amprenavir	Contraindicated - loss of antiretroviral activity and possible resistance to amprenavir	Decreases concentration of atazanavir	Contraindicated - loss of antiretroviral activity and possible resistance to atazanavir	Decreases concentration of darunavir	Contraindicated - loss of antiretroviral activity
Trazodone	Increases concentration of trazodone	Caution; may need to decrease dose of trazodone	Increases concentration of trazodone	Caution; may need to decrease dose of trazodone	Increases concentration of trazodone	Caution; may need to decrease dose of trazodone
Venlafaxine	—	—	—	—	—	—
Antidiabetics (Oral)						
Glimepiride	—	—	—	—	—	—
Glipizide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Glyburide	—	—	—	—	—	—
Metformin	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required
Pioglitazone	—	—	—	—	—	—
Rosiglitazone	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Repaglinide	—	—	—	—	—	—
Tolbutamide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Antiepileptics						
Carbamazepine	Decreases concentration of amprenavir	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of darunavir	Contraindicated - loss of antiretroviral activity
Clonazepam	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Ethosuximide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Gabapentin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Lamotrigine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Phenobarbital	Decreases concentration of amprenavir	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of darunavir	Contraindicated - loss of antiretroviral activity
Phenytoin	Decreases concentration of amprenavir	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of darunavir	Contraindicated - loss of antiretroviral activity
Valproate	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required
Vigabatrin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Antifungals						
Amphotericin B	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Caspofungin	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Fluconazole	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Flucytosine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Itraconazole	May increase concentration of itraconazole	Caution – dose adjustment may be needed for patients taking more than 400mg itraconazole daily	May increase concentration of itraconazole	Caution – dose adjustment may be needed for patients taking more than 200mg itraconazole daily	No studies - may increase concentration of itraconazole and darunavir	Caution - dose of itraconazole should not exceed 200mg daily
Ketoconazole	May increase concentration of ketoconazole	Caution – dose adjustment may be needed for patients taking more than 400mg ketoconazole daily	May increase concentration of ketoconazole	Caution – dose adjustment may be needed for patients taking more than 200mg ketoconazole daily	Increases concentration of ketoconazole and darunavir	Caution - dose of ketoconazole should not exceed 200mg daily
Miconazole	—	—	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Terbinafine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Voriconazole	Potential for bi-directional inhibition	Close monitoring or alteration of dose	Potential for bi-directional inhibition	Not recommended unless benefit outweighs risks	No studies - may decrease the concentration of voriconazole	Co-administration generally not recommended

Table 1. Interactions: drugs used in the treatment of HIV. The HIV-Protease Inhibitors.

	Indinavir		**Lopinavir (ritonavir-boosted)**		**Nelfinavir**	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Other Antidepressants						
Bupropion	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Mirtazapine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Nefazodone	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
St Johns Wort	Decreases concentration of indinavir	Contraindicated – loss of antiretroviral activity and possible resistance to indinavir	Decreases concentration of ritonavir-boosted lopinavir	Contraindicated – loss of antiretroviral activity and possible resistance to lopinavir	Decreases concentration of nelfinavir	Contraindicated – loss of antiretroviral activity and possible resistance to nelfinavir
Trazodone	Increases concentration of trazodone	Caution; may need to decrease dose of trazodone	Increases concentration of trazodone	Use with caution, consider a lower dose of trazodone	Increases concentration of trazodone	Use with caution, consider a lower dose of trazodone
Venlafaxine	Decreases concentration of indinavir	Unknown clinical significance	—	—	—	—
Antidiabetics (Oral)						
Glimepiride	—	—	—	—	—	—
Glipizide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Glyburide	—	—	—	—	—	—
Metformin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Pioglitazone	—	—	—	—	—	—
Rosiglitazone	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Repaglinide	—	—	—	—	—	—
Tolbutamide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Antiepileptics						
Carbamazepine	Decreases concentration of indinavir	Close monitoring or alteration of dose	Decreases concentration of lopinavir	Close monitoring or alteration of dose	May decrease concentration of nelfinavir	Close monitoring or alteration of dose
Clonazepam	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Ethosuximide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Gabapentin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Lamotrigine	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required
Phenobarbital	Decreases concentration of indinavir	Close monitoring or alteration of dose	May decrease concentration of lopinavir	Close monitoring or alteration of dose	May decrease concentration of nelfinavir	Close monitoring or alteration of dose
Phenytoin	Decreases concentration of indinavir	Close monitoring or alteration of dose	May decrease concentrations of lopinavir and phenytoin	Close monitoring or alteration of dose	Decreases concentration of phenytoin	Close monitoring or alteration of dose
Valproate	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Vigabatrin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Antifungals						
Amphotericin B	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Caspofungin	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required
Fluconazole	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	Modest increase in concentration of nelfinavir; not expected to be clinically significant	No dose adjustment required
Flucytosine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Itraconazole	Increases concentrations of indinavir	Caution – dose adjustment may be needed for patients taking more than 200mg itraconazole daily; consider reducing indinavir to 600mg every 8 hours	Increases concentration of itraconazole	Caution – dose adjustment may be needed for patients taking more than 200mg itraconazole daily	Potential for bi-directional inhibition; not expected to be clinically significant	No dose adjustment required; monitor for toxicities
Ketoconazole	May increase concentration of indinavir	Close monitoring – appropriate alteration of dose not established; consider reducing indinavir to 600mg every 8 hours	Increases concentration of ketoconazole	Close monitoring or alteration of dose; do not exceed 200mg ketoconazole daily	Increase in concentration of nelfinavir; not expected to be clinically significant	No dose adjustment required
Miconazole	No Data	No Data	Potential interaction	Close monitoring or alteration of dose	—	—
Terbinafine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Voriconazole	Unboosted - no clinically significant interaction; boosted - potential interaction	Boosted - close monitoring or alteration of dose	May decrease concentration of voriconazole	Contraindicated	Potential for bi-directional inhibition	Monitor for toxicities

Table 1. Interactions: drugs used in the treatment of HIV. The HIV-Protease Inhibitors.

	Ritonavir		Saquinavir		Tipranavir	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Other Antidepressants						
Bupropion	Increases concentration of bupropion	Caution – consider decreasing the dose of bupropion	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Mirtazapine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Nefazodone	May increase concentration of nefazodone	Close monitoring or alteration of dose	Unboosted: increases concentration of saquinavir; Boosted: not evaluated	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
St Johns Wort	Decreases concentration of ritonavir	Contraindicated – loss of antiretroviral activity and possible resistance to ritonavir	Unboosted: decreases concentration of saquinavir; Boosted: interaction not evaluated	Contraindicated – loss of antiretroviral activity and possible resistance to saquinavir	Decreases concentration of tipranavir	Contraindicated – loss of antiretroviral activity and possible resistance to tipranavir
Trazodone	Increases concentration of trazodone	Use with caution, consider a lower dose of trazodone	Boosted: increases concentration of trazodone	Use with caution, consider a lower dose of trazodone	Boosted: increases concentration of trazodone	Caution – consider a lower dose of trazodone
Venlafaxine	—	—	—	—	—	—
Antidiabetics (Oral)						
Glimepiride	—	—	—	—	No studies but potential for interactions	Caution and glucose monitoring
Glipizide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	No studies but potential for interactions	Caution and glucose monitoring
Glyburide	—	—	—	—	No studies but potential for interactions	Caution and glucose monitoring
Metformin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Pioglitazone	—	—	—	—	No studies but potential for interactions	Caution and glucose monitoring
Rosiglitazone	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Repaglinide	—	—	—	—	No studies but potential for interactions	Caution and glucose monitoring
Tolbutamide	May increase concentration of tolbutamide	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	No studies but potential for interactions	Caution and glucose monitoring
Antiepileptics						
Carbamazepine	May increase concentration of carbamazepine	Close monitoring or alteration of dose	Unboosted: potential to decrease concentration of saquinavir; Boosted: not evaluated	Close monitoring or alteration of dose	Boosted: decreases concentration of tipranavir	Monitoring of antiepileptic concentration advised
Clonazepam	May increase concentration of clonazepam	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Ethosuximide	May increase concentration of ethosuximide	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Gabapentin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Lamotrigine	May decrease concentration of lamotrigine	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Phenobarbital	Potential interaction	Close monitoring or alteration of dose	Unboosted: potential to decrease concentration of saquinavir; Boosted: not evaluated	Close monitoring or alteration of dose	Boosted: decreases concentration of tipranavir	Monitoring of antiepileptic concentration advised
Phenytoin	May decrease concentration of phenytoin	Close monitoring or alteration of dose	Unboosted: potential to decrease concentration of saquinavir; Boosted: not evaluated	Close monitoring or alteration of dose	Boosted: decreases concentration of tipranavir	Monitoring of antiepileptic concentration advised
Valproate	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	Decreases concentration of valproate	Monitoring of antiepileptic concentration advised
Vigabatrin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Antifungals						
Amphotericin B	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Caspofungin	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Fluconazole	No clinically significant interaction	No dose adjustment required	Modest increase in concentration of saquinavir	No dose adjustment required	Boosted: increases concentration of tipranavir	No dose adjustment needed for tipranavir; maximum dose for fluconazole is 200mg daily
Flucytosine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Itraconazole	Increases level of itraconazole	Close monitoring or alteration of dose; do not exceed 200mg itraconazole daily	Unboosted: potential for bi-directional inhibition; Boosted: not evaluated	Close monitoring or alteration of dose	Boosted: potential to increase concentration of itraconazole	Use with caution; do not exceed 200mg itraconazole daily
Ketoconazole	Increases concentration of ketoconazole	Close monitoring or alteration of dose; do not exceed 200mg ketoconazole daily	Unboosted: potential for bi-directional inhibition; Boosted: not evaluated	No dose adjustment required	Boosted: potential to increase concentration of ketoconazole	Use with caution; do not exceed 200mg ketoconazole daily
Miconazole	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Terbinafine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Voriconazole	High dose ritonavir decreases concentration of voriconazole; low dose ritonavir decreases concentration of voriconazole and ritonavir	High dose - contraindicated; low dose - avoid unless benefit outweighs risk	Potential for bi-directional inhibition	Monitor for toxicities	No studies but potential for interactions with boosted tipranavir	Not recommended unless benefit outweighs risk

Table 1. Interactions: drugs used in the treatment of HIV. The HIV-Protease Inhibitors.

	Amprenavir		Atazanavir		Darunavir	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Antihistamines						
Astemizole	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions
Cetirizine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Fexofenadine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Loratadine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Terfenadine	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions
Antimalarials/Antiprotozoals						
Artemisinins	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Atovaquone	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Chloroquine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Halofantrine	These drugs should not be co-administered	Contraindicated	These drugs should not be co-administered	Contraindicated	These drugs should not be co-administered	Contraindicated
Lumefantrine	These drugs should not be co-administered	Contraindicated	These drugs should not be co-administered	Contraindicated	These drugs should not be co-administered	Contraindicated
Mefloquine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Pentamidine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Proguanil	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Pyrimethamine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Pyrimethamine-Sulfadoxine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Quinine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Antimigraine Drugs						
Ergot derivatives	Increased risk of ergot toxicity	Contraindicated – due to potential for serious or life-threatening reactions	Increased risk of ergot toxicity	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated - due to potential for serious or life-threatening reactions
Sumatriptan	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Antineoplastics						
Cyclophosphamide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Doxorubicin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Irinotecan	—	—	Increased toxicity of irinotecan	Contraindicated	—	—
Paclitaxel	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Vinca alkaloids	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Anxiolytic Sedatives Hypnotics and Antipsychotics						
Antipsychotics						
Chlorpromazine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Clozapine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Haloperidol	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Olanzapine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Perphenazine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Pimozide	Increased risk of cardiac arrhythmias	Contraindicated – due to potential for serious or life-threatening reactions	Increased risk of cardiac arrhythmias	Contraindicated – due to potential for serious or life-threatening reactions	Increased risk of cardiac arrhythmias	Contraindicated - due to potential for serious or life-threatening reactions
Resperidone	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Thioridazine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose

Antihistamines						
Astemizole	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unboosted and boosted: thought to increase concentration of astemizole	Contraindicated – results in prolongation of QTc intervals	Unspecified clinically significant interaction with boosted tipranavir	Contraindicated – due to potential for serious or life-threatening reactions
Cetirizine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Fexofenadine	May increase concentration of fexofenadine	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Loratadine	May increase concentration of loratadine	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Terfenadine	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unboosted and boosted: increases concentration of terfenadine	Contraindicated – results in prolongation of QTc intervals	Unspecified clinically significant interaction with boosted tipranavir	Contraindicated – due to potential for serious or life-threatening reactions
Antimalarials/Antiprotozoals						
Artemisinins	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Atovaquone	May decrease concentration of atovaquone	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Chloroquine	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Halofantrine	These drugs should not be co-administered	Contraindicated	These drugs should not be co-administered	Contraindicated	Unspecified clinically significant interaction	Contraindicated
Lumefantrine	These drugs should not be co-administered	Contraindicated	These drugs should not be co-administered	Contraindicated	Unspecified clinically significant interaction	Contraindicated
Mefloquine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Pentamidine	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Proguanil	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Pyrimethamine	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Pyrimethamine-Sulfadoxine	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Quinine	May increase concentration of quinine	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Antimigraine Drugs						
Ergot derivatives	Increases concentration of ergot alkaloids	Contraindicated – due to potential for serious or life-threatening reactions	Boosted: increases concentration of ergot alkaloids	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction with boosted tipranavir	Contraindicated – due to potential for serious or life-threatening reactions
Sumatriptan	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Antineoplastics						
Cyclophosphamide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Doxorubicin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Irinotecan	—	—	—	—	—	—
Paclitaxel	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Vinca alkaloids	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Anxiolytic Sedatives Hypnotics and Antipsychotics						
Antipsychotics						
Chlorpromazine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Clozapine	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Haloperidol	May increase concentration of haloperidol	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Olanzapine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Perphenazine	May increase concentration of perphenazine	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Pimozide	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Boosted: increases concentration of pimozide	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction with boosted tipranavir	Contraindicated – due to potential for serious or life-threatening reactions
Resperidone	May increase concentration of resperidone	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Thioridazine	May increase concentration of thioridazine	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required

Table 1. Interactions: drugs used in the treatment of HIV. The HIV-Protease Inhibitors.

	Amprenavir		**Atazanavir**		**Darunavir**	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Anxiolytics						
Buspirone	—	—	—	—	—	—
Benzodiazepines						
Alprazolam	Increases concentration of alprazolam	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Clorazepate	Increases concentration of clorazepate	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Diazepam	Increases concentration of diazepam	Contraindicated – due to potential for serious or life-threatening reactions	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Flurazepam	Increases concentration of flurazepam	Contraindicated – due to potential for serious or life-threatening reactions	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Lorazepam	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Midazolam	Increases concentration of midazolam	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions
Triazolam	Increases concentration of triazolam	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions
Hypnotics						
Zolpidem	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Bronchodilators						
Theophylline	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Cardiovascular Drugs						
Digoxin	—	—	—	—	Increases concentration of digoxin	Start with the lowest possible dose of digoxin, then monitor
Anticoagulants						
Warfarin/Acenocoumarol	Potential to alter warfarin concentration	Monitor INR and alter dose if necessary	Potential to alter warfarin concentration	Monitor INR and alter dose if necessary	Potential to alter warfarin concentration	Monitor INR and alter dose if necessary
Antiarrhythmics						
Amiodarone	Increases concentration of amiodarone	Use with caution	May increase concentration of amiodarone	Caution – due to potential for serious or life-threatening reactions	Increases concentration of amiodarone	Contraindicated - due to potential for serious or life-threatening reactions
Disopyramide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Encainide	—	—	—	—	—	—
Flecainide	Unspecified clinically significant interaction	Contraindicated with ritonavir-boosted amprenavir	These drugs should not be co-administered	Contraindicated	These drugs should not be co-administered	Contraindicated
Lidocaine (systemic)	Increases concentration of lidocaine	Use with caution	May increase concentration of lidocaine	Caution – due to potential for serious or life-threatening reactions	Increases concentration of lidocaine	Contraindicated - due to potential for serious or life-threatening reactions
Mexiletine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Propafenone	Unspecified clinically significant interaction	Contraindicated with ritonavir-boosted amprenavir	These drugs should not be co-administered	Contraindicated	These drugs should not be co-administered	Contraindicated
Quinidine	Increases concentration of quinidine	Use with caution	May increase concentration of quinidine	Contraindicated – due to potential for serious or life-threatening reactions	Increases concentration of quinidine	Contraindicated – due to potential for serious or life-threatening reactions
Beta Blockers						
Atenolol	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Bisoprolol	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Carvedilol	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Metoprolol	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Propranolol	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Timolol	—	—	—	—	—	—

Table 1. Interactions: drugs used in the treatment of HIV. The HIV-Protease Inhibitors.

	Indinavir		**Lopinavir (ritonavir-boosted)**		**Nelfinavir**	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Anxiolytics						
Buspirone	—	—	—	—	—	—
Benzodiazepines						
Alprazolam	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Clorazepate	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Diazepam	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Flurazepam	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Lorazepam	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Midazolam	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions
Triazolam	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions
Hypnotics						
Zolpidem	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Bronchodilators						
Theophylline	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required
Cardiovascular Drugs						
Digoxin	—	—	May increase concentration of digoxin	Caution - close monitoring	—	—
Anticoagulants						
Warfarin/Acenocoumarol	Potential to alter warfarin concentration	Monitor INR and alter dose if necessary	Potential to alter warfarin concentration	Monitor INR and alter dose if necessary	Potential to alter acenocoumarol concentration	Monitor INR and alter dose if necessary
Antiarrhythmics						
Amiodarone	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	May increase concentration of amiodarone	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions
Disopyramide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Encainide	—	—	—	—	—	—
Flecainide	These drugs should not be co-administered	Contraindicated	These drugs should not be co-administered	Contraindicated	Potential interaction	Close monitoring or alteration of dose
Lidocaine (systemic)	May increase concentration of lidocaine	Close monitoring or alteration of dose	May increase concentration of lidocaine	Caution - close monitoring	Potential interaction	Close monitoring or alteration of dose
Mexiletine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Propafenone	Potential interaction	Close monitoring or alteration of dose	These drugs should not be co-administered	Contraindicated	Potential interaction	Close monitoring or alteration of dose
Quinidine	May increase concentration of quinidine	Close monitoring or alteration of dose	May increase concentration of quinidine	Caution - close monitoring	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions
Beta Blockers						
Atenolol	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required
Bisoprolol	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required
Carvedilol	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Metoprolol	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required
Propranolol	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required
Timolol	—	—	—	—	—	—

Table 1. Interactions: drugs used in the treatment of HIV. The HIV-Protease Inhibitors.

	Ritonavir		Saquinavir		Tipranavir	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Anxiolytics						
Buspirone	May increase concentration of buspirone	Close monitoring or alteration of dose	—	—	—	—
Benzodiazepines						
Alprazolam	May increase concentration of alprazolam	Close monitoring or alteration of dose	Boosted: increases concentration of alprazolam	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Clorazepate	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Boosted: increases concentration of clorazepate	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Diazepam	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Boosted: increases concentration of diazepam	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Flurazepam	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Boosted: increases concentration of flurazepam	Close monitoring or alteration of dose	—	—
Lorazepam	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No adjustment required	No clinically significant interaction	No dose adjustment required
Midazolam	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unboosted: increases concentration of midazolam; Boosted: not evaluated	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction with boosted tipranavir	Contraindicated – due to potential for serious or life-threatening reactions
Triazolam	Increases concentration of triazolam	Contraindicated – due to potential for serious or life-threatening reactions	Boosted: potential to increase concentration of triazolam	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction with boosted tipranavir	Contraindicated – due to potential for serious or life-threatening reactions
Hypnotics						
Zolpidem	Increases concentration of zolpidem	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Bronchodilators						
Theophylline	Decreases concentration of theophylline	Close monitoring; may need to increase dose of theophylline	No clinically significant interaction	No dose adjustment required	Potential to decrease concentration of theophylline with boosted tipranavir	Close monitoring; may need to increase dose of theophylline
Cardiovascular Drugs						
Digoxin	May increase concentration of digoxin	Close monitoring or alteration of dose	Boosted: increases concentration of digoxin	Close monitoring or alteration of dose	Boosted: may double exposure to digoxin after 1st dose but at steady state concentration of digoxin may be decreased	Close monitoring or alteration of dose until steady state is reached
Anticoagulants						
Warfarin/Acenocoumarol	Decreases concentration of warfarin	Monitor INR and alter dose if necessary	Potential to alter warfarin concentration	Monitor INR and alter dose if necessary	No studies but potential for interactions	Monitor INR and alter dose if necessary
Antiarrhythmics						
Amiodarone	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Boosted: increases concentration of amiodarone	Contraindicated – due to potential for serious or life-threatening cardiac arrhythmias	Unspecified clinically significant interaction with boosted tipranavir	Contraindicated – due to potential for serious or life-threatening reactions
Disopyramide	May increase concentration of disopyramide	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Encainide	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	—	—	—	—
Flecainide	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Boosted: increases concentration of flecainide	Contraindicated – due to potential for serious or life-threatening cardiac arrhythmias	Unspecified clinically significant interaction with boosted tipranavir	Contraindicated – due to potential for serious or life-threatening reactions
Lidocaine (systemic)	May increase concentration of lidocaine	Close monitoring or alteration of dose	Boosted: increases concentration of lidocaine	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Mexiletine	May increase concentration of mexiletine	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Propafenone	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Boosted: increases concentration of propafenone	Contraindicated - due to potential for serious or life-threatening cardiac arrhythmias	Unspecified clinically significant interaction with boosted tipranavir	Contraindicated – due to potential for serious or life-threatening reactions
Quinidine	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Boosted: increases concentration of quinidine	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction with boosted tipranavir	Contraindicated – due to potential for serious or life-threatening reactions
Beta Blockers						
Atenolol	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Bisoprolol	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Carvedilol	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Metoprolol	May increase concentration of metoprolol	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Propranolol	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Timolol	May increase concentration of timolol	Close monitoring or alteration of dose	—	—	—	—

	Amprenavir		Atazanavir		Darunavir	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Calcium Channel Blockers (CCB)						
Amlodipine	May increase concentration of CCB	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Bepridil	Increases concentration of CCB	Contraindicated – due to potential for serious or life-threatening reactions	May increase concentration of bepridil	Caution – due to potential for serious or life-threatening reactions	Increases concentration of CCB	Contraindicated - due to potential for serious or life-threatening reactions
Diltiazem	May increase concentration of CCB	Close monitoring or alteration of dose	Increases concentration of diltiazem	Caution - may need to reduce dose of diltiazem	Potential interaction	Close monitoring or alteration of dose
Felodipine	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of CCB	Close monitoring or alteration of dose
Isradipine	May increase concentration of CCB	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	—	—
Nicardipine	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of CCB	Close monitoring or alteration of dose
Nifedipine	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of CCB	Close monitoring or alteration of dose
Nimodipine	May increase concentration of CCB	Close monitoring or alteration of dose	—	—	—	—
Nisoldipine	May increase concentration of CCB	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Verapamil	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of CCB	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Lipid Regulating Drugs						
Atorvastatin	Increases concentration of atorvastatin	Use lowest possible dose of atorvastatin or change to pravastatin or fluvastatin	Increases concentration of atorvastatin	Caution – possible risk of myopathy; use lowest possible dose of atorvastatin	Increases concentration of atorvastatin	Start with lowest dose of atorvastatin and monitor
Cerivastatin	—	—	—	—	—	—
Clofibrate	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Fenofibrate	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Fluvastatin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Gemfibrozil	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Lovastatin	Potential for increased concentration of lovastatin	Not advised – increases risk of myopathy	Potential for increased concentration of lovastatin	Not advised – increases risk of myopathy	Potential for increased concentration of lovastatin	Contraindicated - increases risk of myopathy
Pravastatin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	May increase concentration of pravastatin in small numbers of patients	Start with lowest dose of pravastatin and monitor
Rosuvastatin	Potential interaction	Close monitoring or alteration of dose	Increases concentration of rosuvastatin	Caution - possible risk of myopathy; use lowest possible dose of rosuvastatin	Increases concentration of rosuvastatin	Start with lowest dose of rosuvastatin and monitor
Simvastatin	Potential for increased concentration of simvastatin	Not advised – increases risk of myopathy	Potential for increased concentration of simvastatin	Not advised – increases risk of myopathy	Potential for increased concentration of simvastatin	Contraindicated - increases risk of myopathy
Corticosteroids						
Budesonide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Dexamethasone	Decreases concentration of amprenavir	Caution - loss of antiretroviral activity	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of darunavir	Caution - loss of antiretroviral activity
Fluticasone	Increases concentration of fluticasone	Unboosted – consider an alternative for long term use; Boosted – contraindicated	Increases concentration of fluticasone	Unboosted – consider an alternative for long term use; Boosted – not recommended	Increases concentration of fluticasone	Consider an alternative for long term use
Prednisolone	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose

Table 1. Interactions: drugs used in the treatment of HIV. The HIV-Protease Inhibitors.

	Indinavir		Lopinavir (ritonavir-boosted)		Nelfinavir	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Calcium Channel Blockers (CCB)						
Amlodipine	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of CCB	Caution - close monitoring	May increase concentration of CCB	Close monitoring or alteration of dose
Bepridil	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of bepridil	Caution - close monitoring	May increase concentration of CCB	Close monitoring or alteration of dose
Diltiazem	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of CCB	Caution - close monitoring	May increase concentration of CCB	Close monitoring or alteration of dose
Felodipine	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of felodipine	Caution - close monitoring	May increase concentration of CCB	Close monitoring or alteration of dose
Isradipine	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of CCB	Caution - close monitoring	May increase concentration of CCB	Close monitoring or alteration of dose
Nicardipine	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of nicardipine	Caution - close monitoring	May increase concentration of CCB	Close monitoring or alteration of dose
Nifedipine	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of nifedipine	Caution - close monitoring	May increase concentration of CCB	Close monitoring or alteration of dose
Nimodipine	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of CCB	Caution - close monitoring	May increase concentration of CCB	Close monitoring or alteration of dose
Nisoldipine	Potential interaction	Close monitoring or alteration of dose	May increase concentration of CCB	Caution - close monitoring	May increase concentration of CCB	Close monitoring or alteration of dose
Verapamil	May increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of CCB	Caution - close monitoring	May increase concentration of CCB	Close monitoring or alteration of dose
Lipid Regulating Drugs						
Atorvastatin	Increases concentration of atorvastatin	Caution – possible risk of myopathy; use lowest possible dose of atorvastatin	Increases concentration of atorvastatin	Caution – possible risk of myopathy; use lowest possible dose of atorvastatin	Increases concentration of atorvastatin	Caution – possible risk of myopathy; use lowest possible dose of atorvastatin
Cerivastatin	—	—	—	—	—	—
Clofibrate	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Fenofibrate	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Fluvastatin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Gemfibrozil	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Lovastatin	Potential for increased concentration of lovastatin	Not advised – increases risk of myopathy	Potential for increased concentration of lovastatin	Not advised – increases risk of myopathy	Potential for increased concentration of lovastatin	Not advised – increases risk of myopathy
Pravastatin	No clinically significant interaction	No dose adjustment required	Increases concentration of pravastatin	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Rosuvastatin	Increases concentration of rosuvastatin	Caution - possible risk of myopathy; use lowest possible dose of rosuvastatin	Increases concentration of rosuvastatin	Caution - possible risk of myopathy; use lowest possible dose of rosuvastatin	Increases concentration of rosuvastatin	Caution - possible risk of myopathy; use lowest possible dose of rosuvastatin
Simvastatin	Potential for increased concentration of simvastatin	Not advised – increases risk of myopathy	Potential for increased concentration of simvastatin	Not advised – increases risk of myopathy	Increases concentration of simvastatin	Not advised – increases risk of myopathy
Corticosteroids						
Budesonide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Dexamethasone	Decreases concentration of indinavir	Close monitoring or alteration of dose	May decrease concentration of lopinavir	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Fluticasone	Increases concentration of fluticasone	Unboosted - consider an alternative for long term use; Boosted - not recommended	Ritonavir component increases concentration of fluticasone	Not recommended unless benefit outweighs risk of corticosteroid-related adverse effects	Increases concentration of fluticasone	Caution - consider an alternative for long term use
Prednisolone	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose

Table 1. Interactions: drugs used in the treatment of HIV. The HIV-Protease Inhibitors.

	Ritonavir		Saquinavir		Tipranavir	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Calcium Channel Blockers (CCB)						
Amlodipine	May increase concentration of amlodipine	Close monitoring or alteration of dose	Boosted: potential to increase concentration of CCB	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Bepridil	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Boosted: increases concentration of CCB	Contraindicated - due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction with boosted tipranavir	Contraindicated – due to potential for serious or life-threatening reactions
Diltiazem	May increase concentration of diltiazem	Close monitoring or alteration of dose	Boosted: potential to increase concentration of CCB	Close monitoring or alteration of dose	No studies but potential for interactions	Close monitoring or alteration of dose
Felodipine	—	—	Boosted: potential to increase concentration of CCB	Close monitoring or alteration of dose	May increase concentration of felodipine	Close monitoring or alteration of dose
Isradipine	May increase concentration of CCB	Close monitoring or alteration of dose	Boosted: potential to increase concentration of CCB	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Nicardipine	May increase concentration of CCB	Close monitoring or alteration of dose	Boosted: potential to increase concentration of CCB	Close monitoring or alteration of dose	No studies but potential for interactions	Close monitoring or alteration of dose
Nifedipine	May increase concentration of nifedipine	Close monitoring or alteration of dose	Boosted: potential to increase concentration of CCB	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Nimodipine	May increase concentration of CCB	Close monitoring or alteration of dose	Boosted: potential to increase concentration of CCB	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Nisoldipine	Potential interaction	Close monitoring or alteration of dose	Boosted: potential to increase concentration of CCB	Close monitoring or alteration of dose	No studies but potential for interactions	Close monitoring or alteration of dose
Verapamil	May increase concentration of verapamil	Close monitoring or alteration of dose	Boosted: potential to increase concentration of CCB	Close monitoring or alteration of dose	No studies but potential for interactions	Close monitoring or alteration of dose
Lipid Regulating Drugs						
Atorvastatin	Increases concentration of atorvastatin	Caution – possible risk of myopathy; use lowest possible dose of atorvastatin	Boosted: increased concentration of atorvastatin	Start with lowest dose of atorvastatin and monitor ***or*** consider alternative statin	Boosted: increases concentration of atorvastatin; decreases concentration of atorvastatin metabolite	Start with lowest dose of atorvastatin and monitor ***or*** consider alternative statin
Cerivastatin	—	—	—	—	—	—
Clofibrate	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Fenofibrate	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Fluvastatin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Gemfibrozil	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Lovastatin	Potential for increased concentration of lovastatin	Not advised – increases risk of myopathy	Boosted: increases concentration of lovastatin	Not advised – increases risk of myopathy	Boosted: increased concentration of lovastatin	Not advised – increases risk of myopathy
Pravastatin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Rosuvastatin	Increases concentration of rosuvastatin	Caution - possible risk of myopathy; use lowest possible dose of rosuvastatin	Boosted: increased concentration of rosuvastatin	Start with lowest dose of rosuvastatin and monitor *or* consider alternative statin	Boosted: increases concentration of rosuvastatin	Start with lowest dose of rosuvastatin and monitor *or* consider alternative statin
Simvastatin	Increases concentration of simvastatin	Not advised – increases risk of myopathy	Boosted: increases concentration of simvastatin	Not advised – increases risk of myopathy	Boosted: increased concentration of simvastatin	Not advised – increases risk of myopathy
Corticosteroids						
Budesonide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Dexamethasone	May increase concentration of dexamethasone	Close monitoring or alteration of dose	Unboosted: decreases concentration of saquinavir; Boosted: not evaluated	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Fluticasone	Increases concentration of fluticasone	Contraindicated unless benefit outweighs risk of corticosteroid-related adverse effects	Boosted: increases concentration of fluticasone	Contraindicated unless benefit outweighs risk of corticosteroid-related adverse effects	Boosted: increases concentration of fluticasone	Contraindicated unless benefit outweighs risk of corticosteroid-related adverse effects
Prednisolone	May increase concentration of prednisolone	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose

Table 1. Interactions: drugs used in the treatment of HIV. The HIV-Protease Inhibitors.

	Amprenavir		Atazanavir		Darunavir	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Gastro-intestinal Drugs						
Antacids	Decreases concentration of amprenavir	Doses of the antacid and amprenavir should be separated by at least 1 hour	Decreases concentration of atazanavir	Doses of the antacid and atazanavir should be separated by at least 1 to 2 hours	No clinically significant interaction	No dose adjustment required
GI Motility Agents						
Cisapride	Increased risk of cardiac arrhythmias	Contraindicated – due to potential for serious or life-threatening reactions	Increased risk of cardiac arrhythmias	Contraindicated – due to potential for serious or life-threatening reactions	Increased risk of cardiac arrhythmias	Contraindicated - due to potential for serious or life-threatening reactions
Domperidone	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Loperamide	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Metoclopramide	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
H_2 Antagonists						
Cimetidine	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of atazanavir – class effect	Administer 2 hours before or 10 hours after an H_2 antagonist	No clinically significant interaction	No dose adjustment required
Famotidine	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of atazanavir – class effect	Administer 2 hours before or 10 hours after an H_2 antagonist	No clinically significant interaction	No dose adjustment required
Nizatidine	—	—	Decreases concentration of atazanavir – class effect	Administer 2 hours before or 10 hours after an H_2 antagonist	No clinically significant interaction	No dose adjustment required
Ranitidine	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of atazanavir – class effect	Administer 2 hours before or 10 hours after an H_2 antagonist	No clinically significant interaction	No dose adjustment required
Proton Pump Inhibitors						
Lansoprazole	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of atazanavir – class effect	Contraindicated in treatment-experienced patients; in treatment-naïve patients give 12 hours before atazanavir	No clinically significant interaction	No dose adjustment required
Omeprazole	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of atazanavir – class effect	Contraindicated in treatment-experienced patients; in treatment-naïve patients give 12 hours before atazanavir	No clinically significant interaction	No dose adjustment required
General Anaesthetics						
Enflurane	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Halothane	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Ketamine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Immunosuppressants						
Ciclosporin	Increases concentration of ciclosporin	Close monitoring or alteration of dose	May increase concentration of ciclosporin	Close monitoring or alteration of dose	Increases concentration of ciclosporin	Close monitoring or alteration of dose
Sirolimus	Increases concentration of sirolimus	Close monitoring or alteration of dose	May increase concentration of sirolimus	Close monitoring or alteration of dose	Increases concentration of sirolimus	Close monitoring or alteration of dose
Tacrolimus	Increases concentration of tacrolimus	Close monitoring or alteration of dose	May increase concentration of tacrolimus	Close monitoring or alteration of dose	Increases concentration of tacrolimus	Close monitoring or alteration of dose
Oral Contraceptives						
Ethinylestradiol	Increases concentration of ethinylestradiol; decreases concentration of amprenavir	Unboosted and boosted: alternative or additional contraception is recommended	Increases concentration of ethinylestradiol	Alternative or additional contraception recommended	Decreases concentration of ethinylestradiol	Alternative or additional contraception is recommended; HRT - monitor for oestrogen deficiency
Norethindrone	Increases concentration of norethindrone; decreases concentration of amprenavir	Unboosted and boosted: alternative or additional contraception is recommended	Increases concentration of norethindrone	Alternative or additional contraception recommended	Decreases concentration of norethindrone	Alternative or additional contraception is recommended; HRT - monitor for oestrogen deficiency
Progestogens	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Sex Hormones						
Megestrol Acetate	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Nandrolone	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Stanozolol	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Testosterone	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose

Table 1. Interactions: drugs used in the treatment of HIV. The HIV-Protease Inhibitors.

	Indinavir		**Lopinavir (ritonavir-boosted)**		**Nelfinavir**	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Gastro-intestinal Drugs						
Antacids	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	—	—
GI Motility Agents						
Cisapride	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions
Domperidone	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Loperamide	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required
Metoclopramide	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
H_2 Antagonists						
Cimetidine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Famotidine	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Nizatidine	—	—	—	—	—	—
Ranitidine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Proton Pump Inhibitors						
Lansoprazole	Potential to decrease concentration of indinavir	Close monitoring or alteration of dose; use with boosted indinavir	No clinically significant interaction	No dose adjustment required	Potential to decrease concentration of nelfinavir (class effect)	Not recommended
Omeprazole	Decreases concentration of indinavir	Close monitoring or alteration of dose; use with boosted indinavir	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of nelfinavir	Contraindicated - loss of antiretroviral activity
General Anaesthetics						
Enflurane	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Halothane	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Ketamine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Immunosuppressants						
Ciclosporin	May increase concentration of ciclosporin	Close monitoring or alteration of dose	May increase concentration of ciclosporin	Close monitoring or alteration of dose	May increase concentration of ciclosporin	Close monitoring or alteration of dose
Sirolimus	May increase concentration of sirolimus	Close monitoring or alteration of dose	May increase concentration of sirolimus	Close monitoring or alteration of dose	May increase concentration of sirolimus	Close monitoring or alteration of dose
Tacrolimus	May increase concentration of tacrolimus	Close monitoring or alteration of dose	May increase concentration of tacrolimus	Close monitoring or alteration of dose	May increase concentration of tacrolimus	Close monitoring or alteration of dose
Oral Contraceptives						
Ethinylestradiol	Increases concentration of ethinylestradiol	Close monitoring or alteration of dose	Decreases concentration of ethinylestradiol	Alternative or additional contraception is recommended	Decreases concentration of ethinylestradiol	Alternative or additional contraception is recommended
Norethindrone	Increases concentration of norethindrone	Close monitoring or alteration of dose	—	—	Decreases concentration of norethindrone	Alternative or additional contraception is recommended
Progestogens	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Sex Hormones						
Megestrol Acetate	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Nandrolone	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Stanozolol	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Testosterone	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose

Table 1. Interactions: drugs used in the treatment of HIV. The HIV-Protease Inhibitors.

	Ritonavir		Saquinavir		Tipranavir	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Gastro-intestinal Drugs						
Antacids	—	—	No clinically significant interaction	No dose adjustment required	Boosted: decreases concentration of tipranavir	Doses of the antacid and tipranavir should be separated by at least 2 hours
GI Motility Agents						
Cisapride	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction with boosted tipranavir	Contraindicated – due to potential for serious or life-threatening reactions
Domperidone	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Loperamide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Boosted: decreases concentration of loperamide	Clinical relevance is not known
Metoclopramide	No clinically significant interaction	No dose adjustment required	—	—	No clinically significant interaction	No dose adjustment required
H_2 Antagonists						
Cimetidine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No data but potential for interaction due to increased gastric pH	Close monitoring or alteration of dose
Famotidine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No data but potential for interaction due to increased gastric pH	Close monitoring or alteration of dose
Nizatidine	—	—	—	—	No data but potential for interaction due to increased gastric pH	Close monitoring or alteration of dose
Ranitidine	No clinically significant interaction	No dose adjustment required	Unboosted: increases concentration of saquinavir; boosted: not evaluated	Close monitoring - appropriate alteration of dose not established	No data but potential for interaction due to increased gastric pH	Close monitoring or alteration of dose
Proton Pump Inhibitors						
Lansoprazole	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	No data but potential for interaction due to increased gastric pH	Close monitoring or alteration of dose
Omeprazole	No clinically significant interaction	No dose adjustment required	Boosted: increases concentration of saquinavir	Close monitoring or alteration of dose	No data but potential for interaction due to increased gastric pH; may decrease concentration of omeprazole	Close monitoring or alteration of dose
General Anaesthetics						
Enflurane	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Halothane	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Ketamine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Immunosuppressants						
Ciclosporin	May increase concentration of ciclosporin	Close monitoring or alteration of dose	Boosted: potential to increase concentration of ciclosporin	Close monitoring or alteration of dose	No studies but potential for interactions with boosted tipranavir	Frequent monitoring of immunosuppressant concentration
Sirolimus	May increase concentration of sirolimus	Close monitoring or alteration of dose	Boosted: potential to increase concentration of sirolimus	Close monitoring or alteration of dose	No studies but potential for interactions with boosted tipranavir	Frequent monitoring of immunosuppressant concentration
Tacrolimus	May increase concentration of tacrolimus	Close monitoring or alteration of dose	Boosted: potential to increase concentration of tacrolimus	Close monitoring or alteration of dose	No studies but potential for interactions with boosted tipranavir	Frequent monitoring of immunosuppressant concentration
Oral Contraceptives						
Ethinylestradiol	Decreases concentration of ethinylestradiol	Close monitoring; alternative or additional contraception recommended	Boosted: decreased concentration of ethinylestradiol	Close monitoring; alternative or additional contraception recommended	Boosted: decreases concentration of ethinylestradiol	Alternative or additional contraception is recommended; HRT – monitor for oestrogen deficiency
Norethindrone	—	—	—	—	No significant clinical effect	Alternative or additional contraception is recommended; HRT - monitor for oestrogen deficiency
Progestogens	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Sex Hormones						
Megestrol Acetate	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Nandrolone	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Stanozolol	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Testosterone	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose

Urological Drugs						
Alfusozin	—	—	—	—	—	—
Apomorphine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Sildenafil	Increases concentration of sildenafil	Caution – dose of sildenafil should not exceed 25mg every 48 hours	Increases concentration of sildenafil	Caution – dose of sildenafil should not exceed 25mg every 48 hours	Increases concentration of sildenafil	Caution – dose of sildenafil should not exceed 25mg every 48 hours
Tadalafil	Potential interaction	Caution – dose of tadalafil should not exceed 10mg every 72 hours	Increases concentration of tadalafil	Caution – dose of tadalafil should not exceed 10mg every 72 hours	Increases concentration of tadalafil	Caution – dose of tadalafil should not exceed 10mg every 72 hours
Vardenafil	Potential interaction	Caution – dose of vardenafil should not exceed 2.5mg every 72 hours	Increases concentration of vardenafil	Caution – dose of vardenafil should not exceed 2.5mg every 72 hours	Increases concentration of vardenafil	Caution – dose of vardenafil should not exceed 2.5mg every 72 hours
Miscellaneous						
Amphetamines	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Disulfiram	Potential risk of toxicity due to propylene glycol	Contraindicated – due to potential for serious or life-threatening reactions	Unspecified clinically significant interaction	Contraindicated – due to potential for serious or life-threatening reactions	—	—
Herbals etc.						
Echinacea	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Garlic (capsules)	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Grapefruit Juice	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Milk Thistle (Silymarin)	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Vitamin E	Unspecified clinically significant interaction	Supplementary vitamin E contraindicated	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required

Urological Drugs						
Alfuzosin	May increase concentration of alfuzosin	Contraindicated – due to potential for serious or life-threatening reactions	—	—	—	—
Apomorphine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Sildenafil	Increases concentration of sildenafil	Caution – dose of sildenafil should not exceed 25mg every 48 hours	Unboosted: increases concentration of sildenafil	Caution – dose of sildenafil should not exceed 25mg every 48 hours with boosted regimens	No studies but potential to increase concentration of sildenafil with boosted tipranavir	Caution – dose of sildenafil should not exceed 25mg every 48 hours
Tadalafil	Increases concentration of tadalafil	Caution – dose of tadalafil should not exceed 10mg every 72 hours	Boosted: increases concentration of tadalafil	Caution – dose of tadalafil should not exceed 10mg every 72 hours with boosted regimens	Potential to increase concentration of tadalafil with boosted tipranavir	Caution – dose of tadalafil should not exceed 10mg every 72 hours
Vardenafil	Increases concentration of vardenafil	Caution – dose of vardenafil should not exceed 2.5mg every 72 hours	Boosted: increases concentration of vardenafil	Caution – dose of vardenafil should not exceed 2.5mg every 72 hours with boosted regimens	No studies but potential to increase concentration of vardenafil with boosted tipranavir	Caution – dose of vardenafil should not exceed 2.5mg every 72 hours
Miscellaneous						
Amphetamines	May increase concentration of amphetamines	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Disulfiram	Ritonavir formulations contain alcohol	May cause disulfiram reaction	—	—	Tipranavir capsules contain alcohol	May cause disulfiram reaction
Herbals etc.						
Echinacea	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Garlic (capsules)	Potential interaction	Close monitoring or alteration of dose	Unboosted: decreased concentration of saquinavir; Boosted: interaction not evaluated	Contraindicated	Potential interaction	Close monitoring or alteration of dose
Grapefruit Juice	No clinically significant interaction	No dose adjustment required	Unboosted: no clinically significant interaction; Boosted: not evaluated	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Milk Thistle (Silymarin)	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Vitamin E	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose

Table 2. Interactions: drugs used in the treatment of HIV. NNRTIs.

	Delavirdine		Efavirenz		Etravirine		Nevirapine	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Antivirals: Antiretrovirals								
Protease Inhibitors								
Amprenavir	Decreases concentration of delavirdine and increases concentration of amprenavir	Appropriate doses not established; Co-administration not recommended	May decrease concentration of amprenavir	No established dose adjustment; no dose adjustment needed if used in boosted regimens	Boosted and unboosted amprenavir increases concentration of amprenavir	Contraindicated	May decrease concentration of amprenavir	No established dose adjustment; dose of amprenavir may need to be increased
Atazanavir	Potential interaction	No established dose adjustment	Decreases concentration of atazanavir	In treatment naïve patients - give with atazanavir 300mg and ritonavir 100mg; treatment experienced patients - no established dose adjustments	Unboosted atazanavir decreases concentration of atazanavir; boosted atazanavir decreases concentration of atazanavir and increases concentration of etravirine	Contraindicated	Decreases concentration of atazanavir	No established dose adjustment; co-administration not recommended
Darunavir	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of darunavir and increases concentration of efavirenz	Close monitoring - combination may be associated with CNS toxicity	Boosted darunavir decreases concentration of etravirine	No dose adjustment required	Boosted darunavir increases concentration of nevirapine	Not a clinically significant interaction; co-administration without dose adjustments
Indinavir	Increases concentration of indinavir	Dose reduction of indinavir to 400 to 600mg every 8 hours may be appropriate	Decreases concentration of indinavir	Close monitoring, may need to increase dose of indinavir although appropriate alteration of dose not established	Decreases concentration of indinavir	Contraindicated	Decreases concentration of indinavir	Increased dose of indinavir to 1g every 8 hours may be required
Indinavir/Ritonavir	—	—	No clinically significant interaction	No dose adjustment required	—	—	—	—
Lopinavir/Ritonavir	Increases concentration of both ritonavir & lopinavir	No established dose adjustment	Decreases concentration of lopinavir	Do not give as a once daily dose; in treatment experienced patients increase dose of ritonavir-boosted lopinavir by about 33%	Increases concentration of etravirine	Use with caution	Decreases concentration of lopinavir	Close monitoring - consider increasing dose of ritonavir-boosted lopinavir by about 33% (do not give as a once daily dose)
Nelfinavir	Decreases concentration of delavirdine and increases concentration of nelfinavir	No established dose adjustment	No clinically significant interaction	No dose adjustment required	Increases concentration of nelfinavir	Contraindicated	Decreases concentration of nelfinavir	No established dose adjustment
Ritonavir	Increases concentration of ritonavir	No established dose adjustment	Increases concentration of both ritonavir and efavirenz	Increased adverse effects; monitor liver enzymes	Decreases concentration of etravirine	Contraindicated	No clinically significant interaction	No dose adjustment required
Saquinavir	Unboosted: increases concentration of saquinavir; Boosted: not evaluated	May need to decrease dose of saquinavir	Decreases concentration of saquinavir	Should not be used as the sole protease inhibitor	Boosted saquinavir decreases concentration of etravirine	No dose adjustment required	Unboosted saquinavir decreases concentration of saquinavir; boosted - no clinically significant interaction	May need to increase dose of saquinavir (hard capsule formulation)
Tipranavir	Potential interaction	Close monitoring or alteration of dose	Boosted: limited data indicates no significant interactions	Use with caution until more data available	Boosted tipranavir decreases concentration of etravirine	Contraindicated	Boosted: limited data indicates no significant interactions	Use with caution until more data available
NNRTIs								
Delavirdine	N/A	N/A	Potential interaction	Close monitoring or alteration of dose	Increases concentration of etravirine	Contraindicated	Potential interaction	Close monitoring or alteration of dose
Efavirenz	Potential interaction	Close monitoring or alteration of dose	N/A	N/A	Decreases concentration of etravirine	Contraindicated	Decreases concentration of efavirenz	Contraindicated
Etravirine	Increases concentration of etravirine	Contraindicated	Decreases concentration of etravirine	Contraindicated	N/A	N/A	Decreases concentration of etravirine	Contraindicated
Nevirapine	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of efavirenz	Co-administration not recommended	Decreases concentration of etravirine	Contraindicated	N/A	N/A

	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
NsRTIs/NtRTIs								
Abacavir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Didanosine	For buffered tablets – concentration of delavirdine and didanosine decreased	Administration of the two tablets should be separated by at least 1 hour	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Emtricitabine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Lamivudine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Stavudine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Tenofovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Zalcitabine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	—	—	No clinically significant interaction	No dose adjustment required
Zidovudine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	Decreases concentration of zidovudine	No dose adjustment required
Other Antiretrovirals								
Enfuvirtide	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Maraviroc	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Raltegravir	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Antivirals								
Aciclovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Adefovir	Potential Interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Cidofovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Famciclovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Foscarnet	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Ganciclovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Ribavirin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Valaciclovir	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Other Drugs								
Analgesics, Anti-inflammatory Drugs and Antipyretics								
Buprenorphine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Fentanyl	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of fentanyl	Close monitoring or alteration of dose
Methadone	Increases concentrations of methadone	May need to decrease dose of methadone	Decreases concentration of methadone	May need to increase dose of methadone; monitor for symptoms of withdrawal	Potential interaction	May need to adjust dose of methadone; monitor for symptoms of withdrawal	Decreases concentration of methadone	May need to increase dose of methadone; monitor for symptoms of withdrawal
Antibacterials								
Antimycobacterials								
Ethambutol	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Isoniazid	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required

Table 2. Interactions: drugs used in the treatment of HIV. NNRTIs. *(Continued)*

	Delavirdine		Efavirenz		Etravirine		Nevirapine	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Pyrazinamide	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Rifabutin	Decreases concentration of delavirdine	Co-administration not recommended; possible loss of virologic response	Decreases concentration of rifabutin	Increase daily dose of rifabutin by 50%	Decreases concentration of etravirine and rifabutin	Contraindicated when given with boosted darunavir or saquinavir; if not given with a boosted protease inhibitor give usual daily dose of rifabutin	Increases concentration of rifabutin	Caution and close monitoring
Rifampicin	Decreases concentration of delavirdine	Co-administration not recommended; possible loss of virologic response	Decreases concentration of efavirenz	Increase dose of efavirenz to 800mg daily	Decreases concentration of etravirine	Contraindicated	Decreases concentration of nevirapine	Contraindicated - use rifabutin as an alternative
Rifapentine	Potential interaction	Co-administration not recommended; higher rate of tuberculosis relapse	Potential interaction	Co-administration not recommended; higher rate of tuberculosis relapse	Decreases concentration of etravirine	Contraindicated	Potential interaction	Co-administration not recommended; higher rate of tuberculosis relapse
Streptomycin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Macrolides								
Azithromycin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Clarithromycin	Increases concentration of clarithromycin	Reduce clarithromycin dose in patients with renal failure	Decreases concentration of clarithromycin	Alternatives to clarithromycin should be considered	Increases concentration of etravirine and decreases concentration of clarithromycin	Alternatives to clarithromycin should be considered	Significantly decreases concentration of clarithromycin	Alternatives should be considered
Erythromycin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Quinolones								
Ciprofloxacin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Ofloxacin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Others								
Clindamycin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Co-trimoxazole	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Dapsone	Potential interaction	May need to increase dose of dapsone	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Metronidazole	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Tetracyclines	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Antidepressants								
Tricyclics								
Doxepin	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
SSRIs								
Citalopram	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Fluoxetine	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Paroxetine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Sertraline	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of sertraline	Sertraline dose may need to be increased	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Other Antidepressants								
Bupropion	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Mirtazapine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Nefazodone	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose

Table 2. Interactions: drugs used in the treatment of HIV. NNRTIs. *(Continued)*

	Delavirdine		Efavirenz		Etravirine		Nevirapine	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Trazodone	Increases concentration of trazodone	Caution; may need to decrease dose of trazodone	—	—	—	—	—	—
St Johns Wort	Potential to decrease concentration of delavirdine	Co-administration not recommended; possible loss of virologic response	May decreases concentration of efavirenz	Contraindicated	Decreases concentration of etravirine	Contraindicated	May decrease concentration of nevirapine	Contraindicated
Antidiabetics (Oral)								
Glipizide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Metformin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Rosiglitazone	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Tolbutamide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Antiepileptics								
Carbamazepine	Decreases concentration of delavirdine	Co-administration not recommended; possible loss of virologic response	May decrease concentration of carbamazepine and/or efavirenz	Caution and monitor antiepileptic concentration	Decreases concentration of etravirine	Contraindicated	May decrease concentration of carbamazepine	Close monitoring or alteration of dose
Clonazepam	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of clonazepam	Close monitoring or alteration of dose
Ethosuximide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of ethosuximide	Close monitoring or alteration of dose
Gabapentin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Lamotrigine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Phenobarbital	Decreases concentration of delavirdine	Co-administration not recommended; possible loss of virologic response	Potential to decrease or increase concentrations of phenobarbital and/or efavirenz	Caution and monitor antiepileptic concentration	Decreases concentration of etravirine	Contraindicated	Potential interaction	Close monitoring or alteration of dose
Phenytoin	Decreases concentration of delavirdine	Co-administration not recommended; possible loss of virologic response	Potential to decrease or increase concentration of phenytoin and/or efavirenz	Caution and monitor antiepileptic concentration	Decreases concentration of etravirine	Contraindicated	Potential interaction	Close monitoring or alteration of dose
Valproate	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Vigabatrin	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Antifungals								
Amphotericin B	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Caspofungin	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Fluconazole	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	Increases concentration of etravirine	Close monitoring	Increases concentration of nevirapine	Caution and close monitoring – consider alternatives
Itraconazole	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of itraconazole	Clinical implication unknown; consider an alternative antifungal	Increases concentration of etravirine and decreases concentration of itraconazole	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Ketoconazole	Increases concentration of delavirdine	Close monitoring or alteration of dose	May decrease concentration of ketoconazole	Clinical implication unknown	Increases concentration of etravirine and decreases concentration of ketoconazole	Close monitoring or alteration of dose	Decreases concentration of ketoconazole and increases concentration of nevirapine	Contraindicated - consider alternatives
Posaconazole	—	—	Decreases concentration of posaconazole	Not recommended - consider an alternative antifungal	Increases concentration of etravirine	Close monitoring	—	—
Terbinafine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required

Table 2. Interactions: drugs used in the treatment of HIV. NNRTIs. *(Continued)*

	Delavirdine		Efavirenz		Etravirine		Nevirapine	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Voriconazole	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of voriconazole and increases concentration of efavirenz	Contraindicated	Increases concentration of etravirine and voriconazole	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Antihistamines								
Astemizole	Increased risk of cardiac arrhythmias	Contraindicated	Unspecified clinically significant interaction	Contraindicated	Unspecified clinical interaction	Contraindicated	Potential interaction	Close monitoring or alteration of dose
Cetirizine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Fexofenadine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Loratadine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required
Terfenadine	Increased risk of cardiac arrhythmias	Contraindicated	Unspecified clinically significant interaction	Contraindicated	Unspecified clinical interaction	Contraindicated	Potential interaction	Close monitoring or alteration of dose
Antimalarials/Antiprotozoals								
Amodiaquine	—	—	Unspecified clinically significant interaction	Contraindicated	—	—	—	—
Artemisinins	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Halofantrine	Contraindicated	Contraindicated	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Lumefantrine	Contraindicated	Contraindicated	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Quinine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Antimigraine Drugs								
Ergot derivatives	Increased risk of ergot toxicity	Contraindicated with ergot derivatives	Increased risk of ergot toxicity	Contraindicated with ergot derivatives	Unspecified clinical interaction	Contraindicated	May decrease concentration of ergotamine	Dose adjustments may be needed
Sumatriptan	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Antineoplastics								
Cyclophosphamide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of cyclophosphamide	Close monitoring or alteration of dose
Paclitaxel	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Vinca alkaloids	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Anxiolytic Sedatives Hypnotics and Antipsychotics								
Antipsychotics								
Chlorpromazine	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Clozapine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Haloperidol	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Olanzapine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Perphenazine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Pimozide	Increased risk of cardiac arrhythmias	Contraindicated	Unspecified clinically significant interaction	Contraindicated	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Resperidone	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Thioridazine	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Benzodiazepines								
Alprazolam	Unspecified clinically significant interaction	Contraindicated	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Diazepam	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Increases concentration of diazepam	May need to increase dose of diazepam	Potential interaction	Close monitoring or alteration of dose

Table 2. Interactions: drugs used in the treatment of HIV. NNRTIs. *(Continued)*

	Delavirdine		Efavirenz		Etravirine		Nevirapine	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Lorazepam	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Midazolam	Unspecified clinically significant interaction	Contraindicated	Unspecified clinically significant interaction	Contraindicated	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Oxazepam	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Temazepam	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Triazolam	Unspecified clinically significant interaction	Contraindicated	Unspecified clinically significant interaction	Contraindicated	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Hypnotics								
Zolpidem	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Cardiovascular Drugs								
Anticoagulants								
Warfarin	Potential to alter coagulation times; increases warfarin concentration	Monitor anticoagulation levels (INR)	Potential to alter coagulation times; can both increase or decrease warfarin concentration	Monitor anticoagulation levels (INR)	Potential to alter coagulation times; increases warfarin concentration	Monitor anticoagulation levels (INR)	Potential to alter coagulation times; can both increase or decrease warfarin concentration	Monitor anticoagulation levels (INR)
Antiarrhythmics								
Amiodarone	Increases concentration of amiodarone	Use with caution	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of amiodarone	Close monitoring or alteration of dose	May decrease concentration of amiodarone	Dose adjustments may be needed
Disopyramide	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of disopyramide	Close monitoring or alteration of dose	May decrease concentration of disopyramide	Dose adjustments may be needed
Flecainide	Potential interaction	Use with caution	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of flecainide	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Lidocaine (systemic)	Increases concentration of lidocaine	Use with caution	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of lidocaine	Close monitoring or alteration of dose	May increase concentration of lidocaine	Dose adjustments may be needed
Mexiletine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of mexiletine	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Propafenone	Potential interaction	Use with caution	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of propafenone	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Quinidine	Potential interaction	Use with caution	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of quinidine	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Beta Blockers								
Carvedilol	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Calcium Channel Blockers (CCB)								
Amlodipine	Increases concentration of dihydropyridine CCBs	Caution – for all dihydropyridine CCBs	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Bepridil	Increases concentration of CCBs	Use with caution	Unspecified clinically significant interaction	Contraindicated	May decrease concentration of bepridil	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Diltiazem	Increases concentration of dihydropyridine CCBs	Caution – for all dihydropyridine CCBs	Decreases concentration of diltiazem	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of diltiazem	Close monitoring or alteration of dose
Felodipine	Increases concentration of dihydropyridine CCBs	Caution – for all dihydropyridine CCBs	Potential to decrease concentration of felodipine	Close monitoring or alteration of dose	—	—	—	—
Isradipine	Increases concentration of dihydropyridine CCBs	Caution – for all dihydropyridine CCBs	—	—	—	—	—	—
Nicardipine	Increases concentration of dihydropyridine CCBs	Caution – for all dihydropyridine CCBs	Potential to decrease concentration of nicardipine	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Nifedipine	Increases concentration of dihydropyridine CCBs	Caution – for all dihydropyridine CCBs	Potential to decrease concentration of nifedipine	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of nifedipine	Close monitoring or alteration of dose

Table 2. Interactions: drugs used in the treatment of HIV. NNRTIs. *(Continued)*

	Delavirdine		Efavirenz		Etravirine		Nevirapine	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Nimodipine	Increases concentration of dihydropyridine CCBs	Caution – for all dihydropyridine CCBs	—	—	—	—	—	—
Nisoldipine	Increases concentration of dihydropyridine CCBs	Caution – for all dihydropyridine CCBs	—	—	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Verapamil	Increases concentration of dihydropyridine CCBs	Caution – for all dihydropyridine CCBs	Potential to decrease concentration of verapamil	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of verapamil	Close monitoring or alteration of dose
Lipid Regulating Drugs								
Atorvastatin	Increases concentration of atorvastatin	Use lowest possible dose of statin	Decreases concentration of atorvastatin	Adjust atorvastatin dose but do not exceed maximum	Decreases concentration of atorvastatin	Dose adjustment of atorvastatin may be needed	Potential interaction	Close monitoring or alteration of dose
Cerivastatin	Increases concentration of cerivastatin	Use lowest possible dose of statin	—	—	—	—	—	—
Fluvastatin	Increases concentration of fluvastatin	Use lowest possible dose of statin	Potential interaction	Close monitoring or alteration of dose	Increases concentration of fluvastatin	Dose adjustments may be needed	Potential interaction	Close monitoring or alteration of dose
Lovastatin	Unspecified clinically significant interaction	Not advised – increases risk of myopathy	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of lovastatin	Dose adjustments may be needed	Potential interaction	Close monitoring or alteration of dose
Pravastatin	No clinically significant interaction	No dose adjustment required	Decreases concentration of pravastatin	Close monitoring or alteration of pravastatin dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Simvastatin	Unspecified clinically significant interaction	Not advised – increases risk of myopathy	Decreases concentration of simvastatin	Adjust simvastatin dose but do not exceed maximum	Decreases concentration of simvastatin	Dose adjustments may be needed	Potential interaction	Close monitoring or alteration of dose
Corticosteroids								
Budesonide	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Dexamethasone	Decreases concentration of delavirdine	Use with caution	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of etravirine	For long term use consider alternatives	Potential interaction	Close monitoring or alteration of dose
Fluticasone	Increases concentration of fluticasone	Use with caution or consider an alternative	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Prednisolone	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Gastro-intestinal Drugs								
Antacids	Decreases concentration of delavirdine	Doses of the antacid and delavirdine should be separated by at least 1 hour	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
GI Motility Agents								
Cisapride	Increased risk of cardiac arrhythmias	Contraindicated	Unspecified clinically significant interaction	Contraindicated	Potential interaction	Close monitoring or alteration of dose	May decrease concentration of cisapride	Close monitoring or alteration of dose
Domperidone	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Loperamide	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Metoclopramide	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
H_2 Antagonists								
Cimetidine	Absorption of delavirdine may be reduced	Chronic use is not recommended	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required
Famotidine	Absorption of delavirdine may be reduced	Chronic use is not recommended	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Nizatidine	Absorption of delavirdine may be reduced	Chronic use is not recommended	—	—	—	—	—	—
Ranitidine	Absorption of delavirdine may be reduced	Chronic use is not recommended	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required

Table 2. Interactions: drugs used in the treatment of HIV. NNRTIs. *(Continued)*

	Delavirdine		Efavirenz		Etravirine		Nevirapine	
	Effect	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*	*Effect*	*Clinical Comment*
Proton Pump Inhibitors								
Lansoprazole	Absorption of delavirdine may be reduced	Chronic use is not recommended	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Omeprazole	Absorption of delavirdine may be reduced	Chronic use is not recommended	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
General Anaesthetics								
Enflurane	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Halothane	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Ketamine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Immunosuppressants								
Ciclosporin	Increases concentration of ciclosporin	Dose adjustments may be needed	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of ciclosporin	Close monitoring or alteration of dose	May decrease concentration of ciclosporin	Dose adjustments may be needed
Sirolimus	Increases concentration of sirolimus	Dose adjustments may be needed	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of sirolimus	Close monitoring or alteration of dose	May decrease concentration of sirolimus	Dose adjustments may be needed
Tacrolimus	Increases concentration of tacrolimus	Dose adjustments may be needed	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of tacrolimus	Close monitoring or alteration of dose	May decrease concentration of tacrolimus	Dose adjustments may be needed
Oral Contraceptives								
Ethinylestradiol	Increases concentration of ethinylestradiol	Clinical significance unknown; alternative or additional contraception is recommended	Increases concentration of ethinylestradiol	Alternative or additional contraception is recommended	No clinically significant interaction	No dose adjustment required	Decreases concentration of ethinylestradiol	Alternative or additional contraception recommended
Norethindrone	—	—	—	—	No clinically significant interaction	No dose adjustment required	Decreases concentration of norethindrone	Alternative or additional contraception recommended
Progestogens	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	No clinically significant interaction	No dose adjustment required	Potential interaction	Close monitoring or alteration of dose
Sex Hormones								
Megestrol Acetate	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Nandrolone	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Stanozolol	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Testosterone	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Urological Drugs								
Apomorphine	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Sildenafil	Increases concentration of sildenafil	Caution – increased risk of side effects. Do not exceed single dose sildenafil 25mg in 48 hours	Potential interaction	Close monitoring or alteration of dose	Decreases concentration of sildenafil	Close monitoring; may need to adjust dose of sildenafil	Potential interaction	Close monitoring or alteration of dose
Tadalafil	Potential interaction	Do not exceed 10mg every 72 hours	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Vardenafil	Potential interaction	Do not exceed 2.5mg ever 24 hours	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Miscellaneous								
Amphetamines	Increases concentration of amphetamine	Use with caution	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required	No clinically significant interaction	No dose adjustment required
Herbals etc.								
Echinacea	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Garlic	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose
Milk Thistle (Silymarin)	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose	Potential interaction	Close monitoring or alteration of dose

The drugs in this chapter include:

- anxiolytic sedatives, formerly called minor tranquillisers, which have been used in the management of anxiety disorders
- drugs used to produce sleep (hypnotics)
- drugs used in the treatment of psychoses (antipsychotics, formerly called major tranquillisers). The term neuroleptic is sometimes used to describe those antipsychotics that have effects on the extrapyramidal system

The difference in action between anxiolytics and hypnotics is mainly one of degree and the same drug or group of drugs can have both effects, larger doses being necessary to produce a state of sleep.

The benzodiazepines (typified by Diazepam, p.986) replaced the barbiturates (typified by Amobarbital, p.961) and related sedatives as the major group of drugs used as anxiolytics and hypnotics. Some benzodiazepines are also used for their muscle relaxant and anticonvulsant properties. Newer anxiolytics include buspirone (p.965), a drug that affects serotonin neurotransmission.

The classical antipsychotics (typified by Chlorpromazine, p.969) include the butyrophenones, the diphenylbutylpiperidines, the indole derivatives, the phenothiazines, and the thioxanthenes. Some newer antipsychotics such as clozapine (p.981), risperidone (p.1024), olanzapine (p.1012), quetiapine (p.1022), and amisulpride (p.961) are often referred to as atypical antipsychotics because of their reduced tendency to cause the extrapyramidal effects typical of classical antipsychotics.

Anxiety disorders

Anxiety is an emotional condition characterised by feelings such as apprehension and fear accompanied by physical symptoms such as tachycardia, increased respiration, sweating, and tremor. It can be a normal emotion but when it is severe and disabling it becomes pathological.

Anxiety disorders are difficult to define and various classifications exist:

- in **acute stress disorder** anxiety is associated with a recent extremely stressful event such as bereavement, and is likely to resolve within a few weeks
- in **generalised anxiety disorder** there is persistent pervasive anxiety and worry, usually lasting 6 months or more, resulting in distress or marked difficulty in performing daily tasks. Symptoms include fatigue and disturbed sleep, motor tension, autonomic hyperactivity, irritability, and loss of concentration

The first step in the **management** of anxiety that cannot be attributed to an underlying disease is the use of psychological treatments such as cognitive therapy. Such therapy can be effective in most types of anxiety. If unsuccessful, short-term treatment with a benzodiazepine may be considered.[1] Benzodiazepines exert an effect very rapidly, possibly even after the first dose, and this makes them suitable for treating an acute reaction.[2] However, their use in chronic conditions such as generalised anxiety disorder is limited by serious problems of dependence (see under Diazepam, p.987). Tolerance may develop to the anxiolytic effects of benzodiazepines although this appears to be less likely than tolerance to the psychomotor effects. No one benzodiazepine appears more effective than the others in the treatment of anxiety disorders.[3] However, adverse effects and pharmacokinetic parameters may influence choice.

Buspirone, an azaspirodecanedione, appears to have broadly similar efficacy to the benzodiazepines but a slower onset of action; it may cause less sedation and dependence. It is reported to lack euphoriant effect. Its efficacy is reduced in patients who have had previous extensive use of benzodiazepines.[4,5]

Increasingly, antidepressants are considered preferable to benzodiazepines for the treatment of generalised anxiety disorder;[1,2,4,6-10] they are particularly appropriate when medium or long-term therapy is necessary or when depression is also present. They may take several weeks to have an effect, so combined therapy with benzodiazepines may be required initially. Tricyclic antidepressants such as imipramine have a proven benefit in the treatment of generalised anxiety disorder.[2-4,6-8] More recently, SSRIs have been used as alternatives;[3,11,12] paroxetine has been the most extensively studied.[8] The noradrenaline and serotonin reuptake inhibitor venlafaxine may also be used.[1,8] These relatively newer drugs are safer in overdose and are associated with less severe adverse effects than the tricyclics and in the UK NICE[1] and others[9] consider SSRIs to be the antidepressants of choice in generalised anxiety disorder.

Beta blockers may be useful for the control of the physical symptoms of anxiety.[12] There is little evidence to support the efficacy of antihistamines such as hydroxyzine in anxious patients,[2] and the use of antihistamines solely for their sedative effect in anxiety is not considered appropriate. Antipsychotics have been used by some in severe anxiety for their sedative effects; long-term use should be avoided because of the risk of tardive dyskinesia. In a few studies, antiepileptics such as pregabalin and tiagabine have been found to be effective for the treatment of generalised anxiety disorder.[13]

Anxiety may be present with other disorders such as depression in **mixed anxiety and depressive disorders**, the management of which is discussed under Depression on p.373.

Obsessive-compulsive disorder. Obsessive-compulsive disorder is associated with intrusive, recurrent, obsessional thoughts and/or repetitive compulsive behaviour (e.g. hand washing) performed in a ritualistic manner. A combination of pharmacological, behavioural, and psychosocial methods appears to have the most successful long-term outcome in its treatment. **Drug therapy** is based on antidepressants that inhibit reuptake of serotonin.[1-9] These include clomipramine, the SSRIs, and the serotonin and noradrenaline reuptake inhibitor venlafaxine. There is some evidence that clomipramine is more effective than the SSRIs but its adverse effects are more problematic.[3,5,10] In the UK NICE considers SSRIs to be the antidepressants of choice in obsessive-compulsive disorder.[8] It may take 4 to 6 weeks before any response is obtained and up to about 12 weeks to achieve an optimal effect.[2,11] If one serotonin reuptake inhibitor fails then another can be tried;[2-5,8] for example, it has been suggested that patients who fail to respond to trials with two SSRIs might then try switching to a drug from a different class (e.g. clomipramine or venlafaxine).[6] Treatment should be continued for at least 12 months in those who respond.[8] However, about 40 to 60% of patients do not respond to these drugs and of those who do, many do not experience complete remission.[3] Also of those who do respond, many relapse when drug therapy is withdrawn and prolonged or even life-long therapy may be necessary;[7,11] however, long-term efficacy and tolerability of serotonin reuptake inhibitors in obsessive-compulsive disorder has yet to be established.[12] It has been suggested that patients may be maintained on reduced dosage[13] but the optimum dosage remains uncertain.[7] Gradual withdrawal over several months may be more successful if patients are also receiving behavioural therapy.[5]

Drugs such as buspirone, lithium, pindolol, and some antipsychotics including the atypicals have been tried as **adjuncts** when patients are refractory to serotonin reuptake inhibitors and behavioural therapy but results of such augmentation therapy have been variable.[2-7] NICE recommends adding an antipsychotic to an SSRI or clomipramine, or using clomipramine with citalopram in such patients.[8] Intravenous clomipramine has been tried in patients refractory to augmentation therapy.[6]

Panic disorder. Panic disorder is characterised by severe, sudden, unexpected, recurrent exacerbations of anxiety (panic attacks). During an attack there is a feeling of fear, terror, and impending doom or even death accompanied by autonomic symptoms. Attacks are followed by persistent worry (for at least 1 month) about further attacks and their consequences.

If behavioural or cognitive therapy fails in the management of panic disorder, drug therapy can then be tried but it may need to be prolonged as there is a high rate of relapse on withdrawal.[1] Antidepressants are the drugs of choice in the treatment of panic disorder. While some also consider the combination of psychotherapy with antidepressant therapy to be first-line treatment for panic disorder[2] others consider that a clear benefit of using cognitive behavioural therapy with drug treatment has not yet been shown.[3] Tricyclic antidepressants or SSRIs can reduce the frequency of panic attacks and can often prevent them completely.[4-7] Efficacy is broadly comparable, although SSRIs may be associated with a lower incidence of serious adverse effects;[7-12] in the UK NICE considers SSRIs to be the drugs of first choice in panic disorder.[13] MAOIs such as phenelzine are also effective but dietary restrictions and serious adverse effects limit their use to patients unresponsive to tricyclics and SSRIs.[6,8] Other antidepressants such as the serotonin and noradrenaline reuptake inhibitor venlafaxine are being evaluated in panic disorder.

It may take several weeks before the effects of antidepressants are seen and initially there may be an increase in anxiety and the frequency of panic attacks. Benzodiazepines are sometimes used as adjuncts until antidepressants exert their full effect.[6-10,12] Short courses of benzodiazepines may also be of use in patients who cannot tolerate, or who are refractory to, antidepressants.[4] However, any benefit may be outweighed by the risk of dependence[5] and NICE does not recommend their use in the treatment of panic disorder.[13] There is little evidence to support the use of beta blockers, but they may control physical symptoms. Other drugs that may produce beneficial effects in some patients include valproate[4,6,9,14] and possibly clonidine.[15]

Phobic disorders. Phobic disorders consist of an irrational or exaggerated fear of, and a wish to avoid, specific objects, activities, or situations. As there is a strong link between **agoraphobia** and panic disorder (see above) it is treated similarly. Simple or specific phobias are usually unresponsive to pharmacotherapy and respond better to behavioural therapy, although paroxetine or benzodiazepines may be considered for disabling phobias unresponsive to such measures.[1]

SSRIs, particularly paroxetine, are considered to be the drugs of choice for the treatment of **social anxiety disorder** (social phobia).[1-6] The serotonin and noradrenaline reuptake inhibitor venlafaxine is also used.[1] MAOIs such as phenelzine are effective in social anxiety disorder and can improve anticipatory anxiety and functional disability;[7,8] however, a systematic review found them to be less consistently effective than the SSRIs,[9] and their use is limited by dietary restrictions and serious adverse effects. Results with the reversible inhibitor of monoamine oxidase moclobemide have been variable.[2-5,9] The benzodiazepines bromazepam and clonazepam have been reported to be of some benefit,[1,2,4,5,7,10] although benzodiazepines should be used with caution because of the risk of dependence and abuse. Other drugs being investigated for the treatment of social anxiety disorder include gabapentin and pregabalin.[1,11]

Beta blockers may help to reduce the physical symptoms in **performance-related anxiety.**[4,7,10]

Post-traumatic stress disorder. In post-traumatic stress disorder (PSTD), anxiety is precipitated by persistent recall of a traumatic experience that was exceptionally threatening or catastrophic in nature. Patients may also suffer from negative symptoms such as avoidance, alienation, emotional numbness, and social withdrawal. The main treatment is psychotherapy.[1-5] Drug therapy is largely aimed at accompanying symptoms of anxiety or depression.[6] The combination of both methods of therapy is preferred for severe cases.[7] Negative symptoms are usually resistant to pharmacotherapy. Some 8 to 12 weeks of treatment is generally thought necessary to judge the efficacy of treatment.[2,3]

SSRIs are the drugs of choice for most of the symptoms of PTSD.[1-3,7-10] Tricyclic antidepressants or, in refractory patients, MAOIs, may be used as alternatives to SSRIs to help reduce traumatic recollections and nightmares, and to repress flashbacks.[1-3,8] The newer antidepressants nefazodone and venlafaxine have also been tried,[1-3,8] generally in patients refractory to SSRIs, and some consider these drugs to be more suitable alternatives than tricyclics or MAOIs, which may have serious adverse effects.[9] Atypical antipsychotics have been studied as monotherapy and as adjuncts when patients are refractory to SSRIs; they may also be considered where paranoia or flashbacks are prominent.[9]

In the UK NICE[5] recommends the use of paroxetine, mirtazapine, amitriptyline, or phenelzine in patients who refuse psychotherapy, where psychotherapy is inappropriate or ineffective, or as adjunctive therapy in those with significant comorbid depression or severe hyperarousal. In patients who do not respond, further drug therapy may be considered with a different class of antidepressant or adjunctive olanzapine. Drug therapy should be continued for at least 12 months in responders before gradual withdrawal.

It has been suggested that antiepileptics should be considered in those with comorbid bipolar disorder, and where impulsivity and anger predominate.[9] Carbamazepine and valproate appear to improve symptoms of hyper-reactivity, violent behaviour, and angry outbursts but only a small number of patients have been studied.[8,9,11] Lamotrigine may also relieve avoidance and intrusive symptoms although, again, patient numbers are small.[8,11]

Benzodiazepines may be helpful for short-term management of anxiety and sleep disturbances (although some studies have failed to show benefit[6]) but they must be used with caution because of the risk of dependence and abuse,[1,9,10] and the possibility of worsening PTSD;[10] some do not favour their use, even short-term.[3] In several small studies, prazosin has been found to be a promising and fairly well-tolerated drug in the management of sleep-related symptoms.[12]

Extrapyramidal disorders

Extrapyramidal disorders are movement disorders involving the brain's motor systems outside the pyramidal tract. They are usually characterised by akinesia (a loss of movement) or bradykinesia (abnormal slowness of movement) accompanied by an increase in muscle tone (typified by parkinsonism, p.791); or by dyskinesias (abnormal involuntary movements), often accompanied by a reduction in muscle tone (see below for some examples). Drug-induced extrapyramidal disorders are discussed under Chlorpromazine, p.971.

Ballism. Ballism, sometimes called hemiballism or hemiballismus because it is usually unilateral, consists of involuntary flinging movements of the extremities and most often results from acute vascular infarction or haemorrhage of the subthalamic nucleus. It often improves spontaneously but dopamine-blocking antipsychotics such as haloperidol or dopamine-depleting drugs such as tetrabenazine may be needed to control severe symptoms. Surgery may be necessary in severe cases.

Chorea. Chorea is characterised by brief involuntary muscle contractions and an inability to sustain voluntary contractions. It may be related to neurological abnormalities in the caudate nucleus and putamen of the striatum as well as other basal ganglia structures. Overactivity of dopaminergic nigrostriatal pathways and depletion of gamma-aminobutyric acid (GABA) and acetylcholine may also play a part. Chorea may be an adverse effect of some drugs, including antipsychotics, levodopa, and oral contraceptives; it may also be a symptom of an underlying disorder such as SLE.

Huntington's chorea (Huntington's disease, progressive hereditary chorea) is a hereditary autosomal dominant disease characterised by chorea, behavioural disturbances, and a progressive decline in cognitive function culminating in dementia and death. The identification of a gene marker for Huntington's chorea now makes it possible to identify carriers of the abnormal gene.[1-3] Symptoms usually appear in mid-life, with death following after about 15 years, although there are also juvenile-onset forms. Westphal variant, a form commonest in children, tends to be characterised more by rigidity than by chorea.[1]

Sydenham's chorea (St Vitus' dance; chorea minor) is an acute, usually self-limiting, disorder with an auto-immune basis, characterised by chorea and behavioural disturbances. It commonly occurs about 6 months after rheumatic fever but is now rare since the incidence of rheumatic fever has declined. It may also arise during pregnancy (chorea gravidarum).

Treatment of chorea is symptomatic only and does not alter the progressive decline of Huntington's chorea;[1-3] Sydenham's chorea resolves spontaneously within weeks or months but antibacterial prophylaxis to prevent recurrence of rheumatic fever (p.189) has been recommended. Other forms of chorea may resolve with treatment of the underlying disorder or withdrawal of any causative drug.

Tetrabenazine has been used effectively in chorea, although not all patients respond, and it may produce depression.[1-3] The mode of action is thought to involve depletion of striatal dopamine.[2] Reserpine, which has a similar action and effects, has also been used but is limited by its adverse effects.[2]

Phenothiazines such as fluphenazine[2] have dopamine-receptor blocking activity and have also been used to treat chorea. Other antipsychotics with a similar mode of action that have been used include haloperidol,[1,2] pimozide,[2] and sulpiride.[1,2] Some atypical antipsychotics[2] such as olanzapine, quetiapine, risperidone, and zotepine have also been tried. Adverse effects such as tardive dyskinesias may limit the use of antipsychotics,[1,2] and doses should be kept as low as possible;[2] attempts to control choreiform movements completely are not recommended. In addition to improving chorea, antipsychotics may also be of value in controlling the behavioural symptoms associated with Huntington's chorea; anxiolytics and antidepressants may also be of use.[1,2]

Carbamazepine[1] has been tried with some degree of success in a limited number of patients. The use of drugs to increase GABA activity has been of little value.[2] Other drugs being investigated include amantadine,[3] minocycline,[2,3] and ubidecarenone.[1-3] Implantation of human and porcine fetal neural cells is being studied,[1] as are various forms of gene therapy.

Tics. Tics may manifest as sudden, involuntary, brief, isolated, repetitive movements, both simple (e.g. eye blinking, nose twitching, or head jerking) and complex (e.g. touching, jumping, or kicking); they may also be sensory in nature or may present in a vocal or phonic way and can range from simple clearing of the throat to more complex symptoms such as echolalia (involuntary repetition of others speech) or coprolalia (involuntary and inappropriate swearing). Symptoms can usually be suppressed voluntarily and may increase with stress and decrease with distraction.[1-3] Some tics persist during sleep.[2,3] The most common cause is **Tourette's syndrome** (Gilles de la Tourette's syndrome), in which behavioural disturbances usually accompany the tics.[1-5] It is a genetic disorder with an onset during childhood and is characterised by recurrent multiple motor and vocal tics that are not due to the direct physiological effects of a substance or a medical condition, with a duration of at least 1 year.

Most patients' symptoms wax and wane and behavioural therapy and reassurance may be sufficient to resolve mild tics.[1,5] Drug treatment may be necessary if tics are severe enough to cause discomfort or embarrassment.[1,2,4,6] Clonidine[1,5-7] or guanfacine[1,5-7] are increasingly favoured for first-line treatment in patients with mild to moderate symptoms, because of a relative lack of serious adverse effects. For more severe cases the classical antipsychotics pimozide or haloperidol have been widely tried[3,8] to decrease the frequency and severity of tics, and may improve any accompanying behavioural disturbances. Superiority of either drug in terms of efficacy or adverse effects has not been clearly demonstrated,[8] and the risk of developing serious adverse effects such as tardive dyskinesia should be balanced against the perceived benefits of treatment.[8] Other antipsychotics such as fluphenazine, sulpiride, or tiapride have also been tried;[4,6,8] increasingly, atypical antipsychotics, notably risperidone but also including olanzapine, quetiapine, and ziprasidone, are preferred because their adverse effect profile is seen as more acceptable.[7] Doses should be as low as possible, bearing in mind that optimum treatment does not necessarily lead to the complete control of symptoms.[2,4]

Other drugs[1-4,6,8] that may be used in the management of tics and/or behavioural aspects of Tourette's syndrome include baclofen, botulinum toxin, clonazepam, levodopa, pergolide, and tetrabenazine. Nicotine has been reported to produce benefit when used alone or with haloperidol in patients whose symptoms were not satisfactorily controlled with haloperidol alone.[7,9]

For drugs used in the treatment of comorbid disorders commonly associated with Tourette's syndrome, such as obsessive-compulsive disorder and attention deficit hyperactivity disorder, see above and p.2148, respectively.

Hypochondriasis

Hypochondriasis (hypochondriacal neurosis) is a morbid preoccupation with one's health characterised by a fear or belief that normal bodily sensations are indicative of serious disease. It persists despite medical reassurance and management is difficult. If hypochondriasis is secondary to a psychiatric disorder, particularly depression and some anxiety disorders, treatment aimed at the primary condition may also lead to resolution of the hypochondriacal symptoms.[1-3]

Cognitive and behavioural therapies may be useful in the treatment of hypochondriasis; drug treatment of primary hypochondriasis has been less well studied although antidepressants such as the SSRIs may be effective.[1-4] Pimozide is used in the management of hypochondriacal psychoses such as delusions of parasitic infestation.[5] Atypical antipsychotics such as quetiapine and risperidone have been used as alternatives to pimozide in the treatment of delusional parasitosis.[6]

Psychoses

Psychoses and psychotic disorders are terms that have been used to describe a collection of severe psychiatric disorders in which the patient has disordered thinking and loses contact with reality due to delusions and/or hallucinations. There may be accompanying mood or behavioural disturbances. *Organic psychoses* arise from organic brain disease produced by toxic insults, metabolic disturbances, infections, or structural abnormalities and may be acute (delirium) or chronic (dementia) in nature.

Disturbed behaviour. Drug therapy is sometimes indicated for the immediate control of severely disturbed, agitated, or violent behaviour associated with a variety of conditions such as toxic delirium, brain damage, mania (see Bipolar Disorder, p.372), or other psychotic disorders. In the UK NICE has issued guidelines on the short-term management of disturbed or violent behaviour in adults.[1] Antipsychotics and benzodiazepines, either alone or in combination, are commonly used for disturbed behaviour. There is little agreement on the best antipsychotic for these indications, selection depending mainly on the condition of the patient and the adverse effect profile of the drug.[2-6] Oral therapy should be tried first and parenteral therapy only given if this is ineffective or refused. The high-potency butyrophenone haloperidol is commonly used for **acutely disturbed behaviour** although it lacks any sedative effects and may be associated with severe extrapyramidal adverse effects. The atypical antipsychotics such as olanzapine and risperidone are increasingly used in acute situations. A systematic review,[7] albeit of 3 small studies, concluded tentatively that there was no difference in efficacy and incidence of adverse effects between low-dose haloperidol and olanzapine or risperidone in the management of delirium; high-dose haloperidol was associated with a greater incidence of extrapyramidal effects. Benzodiazepines such as diazepam and lorazepam are valuable sedatives for the disturbed or delirious patient. A combination of an antipsychotic and a benzodiazepine allows the use of lower doses of each drug. However, a systematic review[8] considered that there were insufficient data to support or refute the use of benzodiazepines, either alone or with an antipsychotic, in the treatment of acute psychosis. Another systematic review[9] found the combination of haloperidol and the antihistamine promethazine, both given intramuscularly, to be effective.

Other drugs that have had some success in the control of symptoms such as agitation, aggression, rage, or violent behaviour include beta blockers, lithium, carbamazepine, and valproate. Buspirone and antidepressants such as the SSRIs and trazodone may also be useful.

Antipsychotics appear to be modestly effective for the control of disturbed behaviour associated with the **dementia** of chronic conditions such as Alzheimer's disease (p.362).[10-15] However, antipsychotics can themselves precipitate confusion or exacerbate dementia and may hasten cognitive decline, increase the risk of falls, incontinence, and drowsiness, and interfere with the performance of motor skills.[16] Elderly patients with dementia, especially Lewy-body dementia, are reported to be highly susceptible to the extrapyramidal adverse effects of antipsychotics and the reaction can be life-threatening. Antipsychotics are used only after careful consideration of the causes of disturbed behaviour and the benefits and risks of antipsychotic treatment. Very low doses are given at first and increased gradually according to clinical response and development of adverse effects; the necessity for continued use is reviewed periodically. Again, there is no agreement over the choice of antipsychotic. A systematic review noted that while there was limited evidence to support the routine use of haloperidol for agitation in dementia, it appeared to reduce aggression.[17] Atypical antipsychotics such as olanzapine, quetiapine, and risperidone have been used and although they may be less likely to produce extrapyramidal effects, cerebrovascular adverse effects are a problem. The UK CSM recommended[18] in 2004 that risperidone and olanzapine should not be used to treat behavioural problems in elderly patients with dementia after analysis of placebo-controlled clinical studies revealed an increased risk of stroke with these 2 atypical antipsychotics. Guidelines for the management of behavioural and psychiatric symptoms in patients with dementia and a history of stroke or transient ischaemic attacks issued in the UK[19] state that consideration should be given to the withdrawal of existing olanzapine and risperidone therapy, and starting treatment with a classical antipsychotic or an atypical that has not been associated with an increased risk of cerebrovascular adverse effects. Further placebo-controlled studies have shown an increased risk of mortality with the use of the atypical antipsychotics aripiprazole, olanzapine, quetiapine, and risperidone in these patients; most of the deaths appeared due to cardiovascular events or infection. Consequently, in 2005 the FDA issued advice against the use of all atypicals, including clozapine and ziprasidone in patients with dementia-related psychosis[20] (for further details, see Dementia, under Risperidone, p.1024). Furthermore, a large multicentre study[21] concluded that adverse effects of atypical antipsychotics (olanzapine, quetiapine, and risperidone) outweigh their benefits in treating behavioural disturbances in patients with Alzheimer's disease. A long-term placebo-controlled study[22] in patients with Alzheimer's disease given antipsychotics (chlorpromazine, haloperidol, risperidone, thioridazine, or trifluoperazine) also concluded that, for most patients, stopping antipsychotic therapy had no overall detrimental effect on functional and cognitive status. The authors suggested that although antipsychotics may have some value in the maintenance treatment of more severe behavioural disturbances, any potential benefits must be weighed against the risk of serious adverse effects. In addition, in 2008, the FDA extended its advice against the use of antipsychotics in elderly patients with dementia-related psychosis to include classical antipsychotics;[23] the FDA were aware of 2 observational studies showing that the risk of death in such patients taking classical antipsychotics was similar to that seen in those taking atypical antipsychotics. Methodological limitations precluded any conclusion that classical antipsychotics have a greater mortality risk than atypical antipsychotics.

The sedative drug, clomethiazole, may be a useful alternative to antipsychotics for the control of agitated behaviour in elderly patients, generally causing fewer adverse effects; respiratory depression, excessive sedation, and dependence may, however, be a problem. Benzodiazepines are not generally indicated for the management of elderly demented patients because of the risks of dependence with continued use, disinhibiting effects, and the particular problems of these drugs in old people (see the Elderly, under Diazepam, p.989). They are not as effective as antipsychotics in reducing behavioural problems, but may be useful in short courses for the management of severe anxiety disorders, or given as required for patients who only have rare episodes of agitation.

The use of antipsychotics in the control of **disturbed behaviour in children** is controversial and can probably be justified only in severe cases resistant to non-pharmacological therapy.[24-26] Aggression in children (with autism, conduct disorder, and mental retardation) has been treated with antipsychotics on a short-term basis. High-potency classical antipsychotics such as haloperidol may be less likely to cause sedation or impair arousal, cognitive function, and learning. Atypical antipsychotics such as olanzapine and risperidone have been used for the control of aggression in children with autism and conduct disorder but are associated with weight gain.[25,26] Nonetheless, in some countries, including the USA, risperidone is licensed for the treatment of irritability associated with autistic disorder in children and adolescents. Aripiprazole, quetiapine, and ziprasidone have also been tried in the treatment of behavioural disturbances associated with autistic disorder.[27] The tendency of antipsychotics to lower the seizure threshold is an important consideration in autistic children who are at an increased risk of seizure disorders. Other drugs that have been tried include clonidine, lithium, and the SSRIs.[25,26] Guidance on the management of autism spectrum disorders has been issued by the American Academy of Pediatrics.[28]

Antipsychotics have been used to control the symptoms of **drug-induced psychosis** in patients with Parkinson's disease.[29-31] Initially, other possible causes such as infections or metabolic and endocrine changes should be eliminated.[30] If psychotic symptoms persist, antiparkinsonian drugs should be gradually stopped or used at the lowest effective dose. Treatment of sleep disturbances in these patients may reduce psychosis; low doses of sedating antidepressants, such as mirtazapine, nortriptyline, or trazodone, are preferable to benzodiazepines or antihistamines which may contribute to confusion and psychosis.[31] Psychosis may be particularly difficult to treat, since the extrapyramidal effects of classical antipsychotics can exacerbate the movement disorder. Benefit has been reported with the atypical antipsychotic clozapine (which must be used with caution because of the risk of agranulocytosis) but results with other atypical antipsychotics such as risperidone and olanzapine have been mixed; quetiapine appears to be reasonably well tolerated. Other drugs that have been tried include anticholinesterases such as donepezil and rivastigmine; ECT may be considered in patients refractory to drug treatment.[30,31]

Antipsychotics have been used for palliative treatment of agitation and restlessness in patients with **terminal restlessness**.[32,33] Although antipsychotics may exacerbate the existing tendency to myoclonus and convulsions in these patients and may not produce adequate sedation in the terminal phase, haloperidol can be used where sedation is not required. Some[32,33] even consider haloperidol to be the drug of choice; chlorpromazine[32,33] and olanzapine have been used as alternatives. Benzodiazepines (such as lorazepam or midazolam), levomepromazine, and propofol have also been used.[32]

Paraphilias and other **deviant sexual behaviour** are rare in women so treatment is focused largely towards men; it consists mainly of psychotherapy and the use of libido-suppressing drugs such as the anti-androgens.[34-36] The use of such pharmacotherapy is controversial and involves not only medical but legal issues. Drugs used for their anti-androgenic action include cyproterone and medroxyprogesterone. Gonadorelin analogues have also been tried for suppression of libido.[35] Medroxyprogesterone has also been used for the control of intrusive disinhibited sexual behaviour in elderly men with dementia. SSRIs may be used in less severe cases, especially in the control of fantasies associated with various paraphilias; they may also be used together with an antihormonal drug if the latter provides inadequate improvement alone.[36] The antipsychotic benperidol is used in some countries for the management of sexual deviations but its value is not established. In general, few well-controlled blinded studies have been conducted into the pharmacological treatment of sexual offenders and there is no evidence that drug treatment reduces the rate of re-offending.

Mania. Mania usually occurs as part of bipolar disorder. The treatment of acute attacks of mania including mention of the role of antipsychotics is described under Bipolar Disorder, p.372.

Schizophrenia. Schizophrenia is a complex disorder associated with a high morbidity; it may be a group of related syndromes rather than a single disorder. Schizophrenia begins most commonly in late adolescence to the early twenties and many patients develop a chronic illness with repeated relapses. The estimated prevalence is between 0.2 to 1% in the general population. The main clinical features of acute schizophrenia syndrome can be divided into psychotic features such as delusions and hallucinations, and disorganised features involving speech, thought, and behaviour (together often known as 'positive' symptoms). The main features of the chronic syndrome are apathy, lack of drive, and social withdrawal (so-called 'negative' symptoms). Positive symptoms tend to respond better to drug therapy than negative symptoms. The pathophysiological mechanism of schizophrenia is unclear. Since classical antipsychotics used in the treatment of schizophrenia block dopamine D_2 receptors in the midbrain it has been suggested that dopaminergic system overactivity may be involved. However, the efficacy of atypical antipsychotics such as clozapine (see below), which is a relatively weak dopamine D_2 inhibitor, has raised the possibility that an imbalance of other neurotransmitters such as serotonin and adenosine may also be involved (see also Action, under Chlorpromazine, p.975).

The **treatment** of schizophrenia consists mainly of a combination of social therapy and antipsychotics.[1-17] Drug treatment must be started as soon as possible for best outcome. There is little difference in the efficacy of classical antipsychotics such as chlorpromazine and haloperidol. The atypical antipsychotic clozapine appears to be more effective than classical antipsychotics in the management of both positive and negative symptoms, but its use is restricted because it can cause potentially fatal agranulocytosis. Comparative studies have shown that other atypical antipsychotics are at least as effective on positive symptoms as the classical antipsychotics, although claims of greater effects on negative symptoms remain to be proven.

Choice of therapy depends on the risk of adverse effects (which vary between the different groups of antipsychotics), any past treatment, and, unfortunately, cost. UK guidelines issued by NICE[18] recommend that the oral atypical antipsychotics amisulpride, olanzapine, quetiapine, risperidone, and zotepine are considered as first-line treatments for patients with newly-diagnosed schizophrenia. These atypical antipsychotics should also be considered in patients responding to classical antipsychotics but experiencing unacceptable extrapyramidal or other adverse effects and in those who have relapsed and who experienced poorly-controlled symptoms or unacceptable adverse effects with their previous therapy. However, classical antipsychotics are still widely used, since the diversity of their preparations (tablets, oral liquids, injections, and depot injections) and lower cost offer advantages over the atypical antipsychotics. NICE therefore does not recommend changing to an atypical in patients who are already adequately controlled by classical antipsychotic treatment without unacceptable adverse effects. Because risperidone and olanzapine have been associated with an increased risk of stroke when used in elderly patients with dementia (see p.1024), UK guidelines[19] have recommended that other antipsychotics should be considered for patients with a history of stroke, transient ischaemic attacks, or other cere-brovascular disease even in the absence of dementia. However, there is little evidence to guide prescribing in older patients.[20]

There is great interindividual variation in response to antipsychotics, and choosing the most appropriate one may require a trial of antipsychotics from different chemical groups and careful adjustment of dosage. The Royal College of Psychiatrists in the UK has issued advice for those considering the use of higher than normally recommended doses of antipsychotics (see under Administration in the Uses and Administration of Chlorpromazine, p.976). However, in recent years there has been a trend in favour of lower doses of antipsychotics, often with adjunctive benzodiazepines (see below). The use of more than one antipsychotic at the same time is not usually recommended.

About 30% of patients may have little or no response to classical antipsychotics while many others have only a partial response. Such **resistant schizophrenia** may be due to poor patient compliance, which is a major problem in schizophrenic patients; lack of compliance may be a result of adverse effects (see below for possible treatments) or because the patient experiences a relapse while on medication and is unable to maintain treatment.[21] A patient should not be considered resistant to therapy until at least 2 different antipsychotics (NICE also recommends that at least one of these should have been an atypical[11]) have each been given for an adequate trial period (at least 6 to 8 weeks). If other drugs are still ineffective, clozapine may be tried; it should be given for at least 3 months before resorting to measures such as ECT or the use of adjunctive drugs (see below).

After the initial control of schizophrenia with antipsychotics, relapse rates are high in those who stop treatment, therefore **maintenance** therapy is probably warranted. Some recommend the use of lower doses of antipsychotics during maintenance to reduce adverse effects, although this may increase the risk of relapse. The decision to withdraw an antipsychotic completely in a stabilised patient is complex and depends on the number of previous psychotic episodes. In some cases maintenance therapy may need to be indefinite. Regular injections of long-acting depot antipsychotics are sometimes used for maintenance therapy especially if compliance is a problem.[22] They are particularly useful for patients living in the community, and may also be advantageous for those who respond poorly to therapy because of increased first-pass metabolism or intestinal malabsorption. Concern over the possibility of increased extrapyramidal effects and other adverse effects with depot antipsychotics has not been substantiated.

Adjunctive drugs have been used in schizophrenia either to augment antipsychotics or reduce their adverse effects.[23] The short-term addition of a *benzodiazepine* to the initial treatment of acute episodes of schizophrenia can provide a useful extra sedative and anxiolytic effect. It may also allow a smaller dose of antipsychotic to be used and thereby reduce the likelihood of extrapyramidal effects. However, a systematic review[24] concluded that the available evidence for such use is poor and inconclusive.

The use of *antimuscarinic antiparkinsonian drugs* for the treatment or prophylaxis of antipsychotic-induced extrapyramidal adverse effects is controversial (see Extrapyramidal Disorders on p.971, *et seq.*). They are particularly effective in the management of acute dystonic reactions but efficacy in drug-induced parkinsonism itself may be minimal and little benefit has been found in akathisia. Fears that the long-term use of antimuscarinics increases the risk of tardive dyskinesia appear to be unfounded, although they may worsen the condition and should be stopped if it develops. However, the adverse effects of antimuscarinics can be troublesome and may compound the antimuscarinic actions of the antipsychotic. Antimuscarinics also have euphoric effects. Routine use of prophylactic antimuscarinics is therefore not indicated with the possible exception of short-term use in patients at high risk of developing dystonias, or in patients with a previous history of drug-induced dystonias. Antimuscarinics may be given on a short-term basis to treat dystonias.

Addition of *lithium* to antipsychotic treatment may be worthwhile in some patients who fail to respond to an antipsychotic alone, although there is the danger of an interaction (see p.405).

The value of treatment of depressive symptoms of schizophrenia with *antidepressants* is not established but the addition of antidepressants such as the tricyclics is considered worth a trial for depression occurring during the recovery phase after an acute episode of psychosis.

Carbamazepine has produced modest benefit in some patients with refractory schizophrenia, the main effect being a reduction in accompanying symptoms such as excitement, impulsivity, and aggression, but use of carbamazepine with haloperidol has also resulted in reduced haloperidol concentrations and clinical deterioration in a few patients. A systematic review[25] found no significant benefit of adjunctive carbamazepine therapy. *Valproate* has also been tried.

Propranolol in high doses has been reported to be beneficial in refractory schizophrenia but several controlled studies of adjunctive use have found slight or no benefit. However, it may be of use as an adjunct in patients who develop akathisia unresponsive to antimuscarinics.

Sedation

Since sedatives reduce excitement and anxiety, they may be used before or during various medical procedures to alleviate fear and produce a state of calmness in the patient. A practical aim for situations requiring **conscious sedation**, for example in *dentistry* or during investigative procedures such as *endoscopy*, may be the reduction or abolition of physiological and psychological responses to the stress without loss of consciousness, cooperation, or protective reflexes. A greater degree of sedation may be required for patients in *intensive care* and some consider that patients should be maintained asleep but easily rousable. The difference between sedatives and hypnotics is mainly dose related. The same drug or group of drugs can have both effects, larger doses being necessary for a hypnotic effect, that is to produce a state of sleep.

Some specific situations where sedation may be required are discussed below. The use of sedatives in premedication for anaesthesia is discussed on p.1780.

Dental sedation. Intravenous midazolam has largely superseded diazepam for sedation in dental procedures. However, midazolam needs to be given slowly in small increments as its sedative end-point is reached much more abruptly than with diazepam. Midazolam has a more rapid onset of action and recovery, and produces a greater degree of amnesia than diazepam, but it can cause hallucinations in children.[1] There is insufficient evidence to support the routine use of intravenous sedation for dental procedures in children under the age of 16 years and it is recommended that such use, along with the use of general anaesthetics, combination regimens, and non-standard routes, should be restricted to specialist centres or hospital settings.[2]

Inhaled nitrous oxide (usually 20 to 40% with oxygen[3]) is a widely used analgesic and sedative for conscious sedation of patients with mild to moderate anxiety about dental procedures.[3,4] It is relatively safe and simple to use although there is some concern over its long-term effect on dental staff.[3,4] Nitrous oxide inhalation is well tolerated by children and remains the preferred technique in the management of anxiety in such patients although a certain amount of patient cooperation is required[1,2,5] and supplementary local analgesia is recommended in potentially painful procedures.[2]

Oral sedatives may also be used to provide conscious sedation[4] and are particularly useful to ensure that the patient has a restful night before the procedure; hypnotics may be used for 1 to 3 nights before. Those drugs used include the benzodiazepines diazepam, nitrazepam, and temazepam; temazepam is preferred when it is important to minimise any residual effects. The antihistamines hydroxyzine and promethazine have been used in children.[1,4,5] Oral sedatives have no analgesic effects and appropriate analgesia should be given.[5] It has been suggested that the efficacy of the oral sedative in adult patients can be enhanced by the careful addition of inhaled nitrous oxide; the depth of sedation can be changed as necessary by varying the titration of the latter.[4]

Endoscopy. The practice of giving sedation routinely before endoscopy varies widely between and within countries.[1-3] It is unclear whether sedation improves patient comfort and the ease of performing the procedure;[1] there may be a failure to distinguish between the need for sedation and the need for analgesia in such procedures. Ultimately the acceptability of unsedated endoscopy differs from patient to patient and procedure to procedure,[2] and it may be appropriate to offer patients the choice.[4]

Intravenous benzodiazepines are commonly used for sedation during endoscopy.[1,2,5,6] Midazolam is generally preferred to diazepam because of its shorter duration of action and greater amnestic effects.[5] Since hypoventilation and oxygen desaturation may occur with benzodiazepines and the procedure itself can lower oxygen saturation, some recommend the use of prophylactic nasal oxygen with oxygen saturation monitoring.[2,3,5,6]

Intravenous opioid analgesics such as morphine and pethidine have also been given but they have largely been replaced by the newer shorter-acting opioids, for example fentanyl, which have faster recovery times.[3,5] Benzodiazepines have often been given with opioids, including pethidine, since such combinations may reduce gagging and increase patient tolerance.[2] They can be used together to achieve deep sedation at higher doses than those used for conscious sedation.[7] However, there is an increased risk of cardiorespiratory effects and, possibly, fatalities with such combinations.[2,5,6] Therefore, the use of the lowest effective doses has been recommended[3,6] and opioids should be given before benzodiazepines, where possible, and their effects monitored before proceeding.[6]

Low-dose intravenous propofol has also been used for conscious sedation as an alternative to, or with, midazolam and opioids.[4] It potentiates the effects of benzodiazepines and opioids, thus reducing the doses required for sedation and analgesia.[7] Propofol has been used alone for deep sedation especially in prolonged or complex procedures; benefit has not been shown conclusively for shorter procedures.[7] The risk of adverse effects may limit its use and the presence of an anaesthetist is usually required.[6,7]

Continuous monitoring of the sedated patient's haemodynamic and ventilatory status, and level of consciousness is recommended.[2-10]

The use of topical anaesthetics such as lidocaine should probably be reserved for those who prefer to undergo endoscopy without sedation as topical anaesthesia appears to serve little useful function in patients premedicated with benzodiazepines or opioids.[4,5,11] There appears to be no practical difference between individual topical anaesthetics. Sprays are safer and may be more effective than lozenges, but even when using a spray it is difficult to anaesthetise the oropharyngeal region effectively.

There is great variation in the methods of sedation and analgesia used for **children** undergoing endoscopy.[8-10] The choice between general anaesthesia and sedation in these patients is subject to debate.[8] Many of the regimens used appear to be similar to those used in adults; drugs commonly used include midazolam, opioids such as fentanyl or pethidine, and propofol.[8] However, the use of propofol is generally not recommended in children (see Incidence of Adverse Effects, under Propofol, p.1791). In the UK, general anaesthesia is the favoured method for younger children; premedication with oral midazolam has also been used.[9]

Intensive care. Not all patients in intensive care units require sedatives if sufficient analgesia is achieved, particularly after the first 24 to 48 hours, but most will require a balanced combination of analgesics and sedatives to relieve pain and anxiety.[1-9] It is inappropriate to use high doses of analgesics to achieve deep sedation and it is also inappropriate to use sedatives alone for patients who are in pain. Adequate analgesia is recommended before giving sedatives in order to avoid over-sedation.[6,7] The required level of sedation may vary but, in general, many consider patients should be maintained asleep but easily rousable.

Most sedatives and analgesics are given parenterally. Continuous intravenous infusion avoids the peaks and troughs of analgesia and sedation associated with intermittent intramuscular or intravenous dosage, but to what extent it improves patient outcomes is unclear: sedation produced in this way may prolong the need for mechanical ventilation and increase pulmonary complications.

Opioid analgesics have both sedative and analgesic properties and are appropriate for sedation when pain is anticipated, although special care is required in those not artificially ventilated. The antitussive action of the opioids may also help ventilated patients to tolerate a tracheal tube. The choice of opioid may vary between centres, as well as with patient characteristics. Morphine is a suitable opioid in many situations in intensive care[6] but has a slow onset of action. If prolonged sedation is required, analgesia can be obtained by a loading dose followed by a continuous infusion. Many centres now favour the use of one of the phenylpiperidine derivatives, fentanyl, alfentanil, sufentanil, or remifentanil.[5-9]

Propofol is widely used for short-term sedation (up to 72 hours) in intensive care units,[4-9] although concerns have been raised about its safety, particularly in children (in whom use is generally not recommended), or with prolonged use or higher rates of infusion (see also Incidence of Adverse Effects, under Propofol, p.1791). It may be particularly useful in neurosurgical patients to reduce raised intracranial pressure,[6,8] or when rapid awakening is important.[6]

Benzodiazepines induce sleep and reduce anxiety and muscle tone as well as providing profound amnesia; however, they do not provide analgesia. Midazolam has a rapid onset and short duration of action following single doses, and has largely replaced diazepam as the benzodiazepine of choice for sedation. It is particularly favoured for longer-term sedation (more than 72 hours).[5,9] The half-life of midazolam can be substantially increased when given as a continuous intravenous infusion for long-term sedation in patients in intensive care. Lorazepam has also been used[1,6] particularly in the USA,[6] and may be associated with less variability in awakening times, although onset of action may be slower than midazolam. All benzodiazepines tend to produce cardiovascular and respiratory depression and care is required if they are used with opioids as is usually the case in this setting.

Flumazenil is a specific benzodiazepine antagonist and some suggest that it may be of use to assist the return of spontaneous respiration and consciousness in patients receiving benzodiazepines. Multiple doses may be required as it has a short duration of action.[1] However, its routine use after prolonged benzodiazepine treatment is not usually recommended because of the risk of inducing withdrawal symptoms.[6]

Dexmedetomidine is also approved for use in intensive care as a sedative; it is stated to have analgesic-sparing properties.[6]

Ketamine has been investigated for sedation in the intensive care setting[4] and appears to be effective; it may be used as an adjuvant.[8,9] Clonidine is also used as an adjuvant to other drugs.[3,6,8,9] In agitated or delirious patients haloperidol may be used.[4,6]

Stopping treatment with sedatives such as benzodiazepines, opioids, and propofol too rapidly may lead to withdrawal symptoms,[6,7] especially after high doses or prolonged sedation (more than 1 week). Doses should be tapered to prevent such symptoms. Tolerance to benzodiazepines can develop and may be related to long-term sedation (2 days or more); tolerance to opioids has also been reported.[7]

Methods of sedation and analgesia for **children** in intensive care are subject to debate. Many of the regimens used appear to be similar to those used in adults or modifications of existing regimens for paediatric sedation. Drugs commonly used include midazolam and opioids such as fentanyl or, in particular, morphine.[3] However, there has been some concern over a report of encephalopathy associated with the prolonged use of midazolam with fentanyl for sedation in infants under intensive care (see Encephalopathy, under Effects on the Nervous System, p.988). As mentioned above, propofol is not recommended for children in intensive care.

Sleep disorders

The exact function of sleep is uncertain but it is believed to be involved in energy conservation, total body restoration and recuperation, and development and growth. There are two states of sleep: non-rapid-eye-movement (non-REM) sleep, which is subdivided into 4 stages, and rapid-eye-movement (REM) sleep, sometimes called stage 5. Initially there is a period of light sleep (stages 1 and 2) followed by deep sleep (stages 3 and 4); this latter period is also known as slow-wave sleep. After stage 4, which occurs about 90 minutes after first falling asleep, there is a period of REM sleep (stage 5) during which most dreams occur and EEG traces show high-frequency waves. During a period of sleep there are several cycles of stages 1 to 4 followed by REM sleep, with periods of non-REM sleep becoming shorter and periods of REM sleep longer. It is the slow-wave sleep that is considered to be the more restorative. Most healthy adults sleep for single periods of between 7 to 8 hours a day, although there is a wide range of normal sleeping time (from 4 to 11 hours). In old age there is less slow-wave sleep and sleep becomes more fragmented.

Sleep disorders include insomnia (see below), hypersomnia such as narcolepsy, p.2148, in which the timing, length, and quality of sleep is altered, and the parasomnias (see Sleep-associated Movement Disorders, below) in which abnormal events occur during sleep.

Insomnia. Insomnia is the inability to achieve or maintain sleep and is the most common of the sleep disorders.[1-14] It often leaves sufferers feeling unrefreshed by sleep and may lead to impaired daytime performance.

- Transient insomnia may occur in those who normally sleep well and may be due to an alteration in the conditions that surround sleep, for example noise, or to an unusual pattern of rest as in shift work or travelling between time zones (jet lag). It may also be associated with acute disorders.
- Short-term insomnia is often related to an emotional problem or more serious medical illness such as acute pain. It may last for a few weeks and may recur.
- Chronic insomnia may be attributed to an underlying psychiatric disorder, especially depression or anxiety, to alcohol or drug abuse, to certain drug treatments, to excessive caffeine intake, to daytime napping, or to physical causes such as pain, pruritus, or dyspnoea.

Management of insomnia requires resolution of any stressful precipitant or identification and treatment of any underlying causes, with an emphasis on non-pharmacological measures such as counselling, behavioural therapy, development of relaxation techniques, and avoidance of stimulant substances. Hypnotic drugs should ideally be reserved for short courses in the acutely distressed patient; they should be avoided in the elderly, and their use is rarely justified in children. Generally, hypnotics should be given at the lowest effective dose for as short a period as possible. In transient insomnia one or two doses of a short-acting hypnotic may be indicated, whereas in short-term insomnia intermittent doses of a short-acting hypnotic given for no more than 3 weeks (preferably only 1 week) may be appropriate. Chronic insomnia rarely benefits from hypnotics and routine use of hypnotics is undesirable. Tolerance can develop rapidly (in 3 to 14 days with continuous use) and withdrawal after long-term use can lead to rebound insomnia and a withdrawal syndrome.

Benzodiazepines are generally regarded as the hypnotics of choice. They hasten sleep onset, decrease nocturnal awakenings, increase total sleeping time, and often impart a sense of deep and refreshing sleep. Slow-wave sleep and REM sleep are, however, reduced and the extra sleeping time is largely made up of relatively light sleep. A short-acting benzodiazepine such as temazepam is generally used when residual sedation is undesirable, if falling asleep is a problem, or, when necessary, in elderly patients. However, a withdrawal syndrome is more common with the short-acting benzodiazepines. Longer-acting benzodiazepines such as nitrazepam are indicated when early waking is a problem and possibly when an anxiolytic effect is needed during the day or when some impairment of psychomotor function is acceptable.

Because of the hazard of dependence with benzodiazepines (see p.987), the UK CSM[15] has issued certain recommendations:

- they should be used to treat insomnia only when it is severe, disabling, or subjecting the individual to extreme distress
- they should be given in the lowest dose which controls symptoms (if possible, intermittently)
- they should not be continued beyond 4 weeks
- they should be withdrawn by gradual tapering of the dose to zero

Subsequently, the EU Committee on Proprietary Medicinal Products (CPMP) has recommended that the treatment period should be limited to 2 weeks when brotizolam, midazolam, or triazolam are used.[16]

Tolerance to the hypnotic effects of benzodiazepines develops rapidly, with sleep latency and pattern returning to pretreatment levels within a few weeks of starting treatment.

A number of other drugs have been used as alternatives to the benzodiazepines. Zaleplon, zopiclone, and zolpidem act on the same receptors or receptor subtypes as the benzodiazepines although structurally they are unrelated. Their short duration of action makes them more suitable for patients who have trouble falling asleep. The CPMP has recommended that treatment with zolpidem should be limited to a maximum of 4 weeks.[16] It remains to be proven whether these drugs offer any advantages over the benzodiazepines. Indeed, the CSM considers that zopiclone has the same potential for adverse psychiatric reactions, including dependence, as benzodiazepines.[17] NICE[18] in the UK found no compelling evidence of any clinically useful differences between these drugs and the shorter-acting benzodiazepines in terms of effectiveness, adverse effects, or potential for dependence or abuse, and recommends that patients who do not respond to zaleplon, zopiclone, zolpidem, or benzodiazepines should not be switched between these hypnotics; patients may be switched if adverse effects directly related to a specific drug occur.

The use of cloral hydrate and its derivatives as hypnotics is now very limited. They have been used as alternatives to benzodiazepines in the elderly, although there is no convincing evidence of any special value in these patients. They used to be considered useful hypnotics for children but such use is rarely justified.

Clomethiazole has also been used as an alternative to benzodiazepines in the elderly. Nasal and conjunctival irritation may be troublesome, and the danger of overdosage and risk of dependence should be considered.

Some antihistamines have hypnotic properties and a number, including alimemazine, diphenhydramine, doxylamine, and promethazine, are marketed for insomnia. They may cause troublesome antimuscarinic effects and those with longer half-lives may cause hangover effects. Promethazine is also popular for use in children, but such use is not usually justified (see Sudden Infant Death Syndrome under Adverse Effects of Promethazine, p.588, for further details).

Barbiturates are no longer recommended as hypnotics because of their adverse effects. The CSM[19] has advised that barbiturates should only be used for insomnia that is severe and intractable when there are compelling reasons to, and then only in patients already taking barbiturates. It was also advised that attempts should be made to wean patients off barbiturate hypnotics. Similarly, compounds such as ethchlorvynol, glutethimide, and methaqualone are not recommended.

Alcohol is not recommended because it has a short weak hypnotic action, and rebound excitation can result in early morning insomnia. Its diuretic effects can interrupt sleep and chronic use can lead to rapid development of tolerance and addiction.

Tryptophan, sometimes in the form of dietary supplements, has enjoyed some popularity in the treatment of insomnia. Its efficacy is difficult to substantiate and, since the publication of reports linking tryptophan with the eosinophilic-myalgia syndrome, preparations indicated for insomnia have been withdrawn from the market in many countries.

Melatonin, a hormone believed to be involved in the maintenance of circadian rhythms, may be useful in the treatment of insomnias such as those due to **jet lag**[20] or other disorders (where it might act by resetting the body clock), and in the elderly. However, its benefits have been questioned,[21] and certainly evidence for a direct hypnotic effect is less conclusive; its sleep-inducing properties are usually only seen after very high, supraphysiological concentrations have been attained.[5,6] Ramelteon, a melatonin receptor agonist, is used as a hypnotic in some countries.

Sleep-associated movement disorders. Parasomnias are motor disorders, with or without autonomic features, that occur during sleep or are exaggerated by sleep. Some of the main parasomnias include nightmares, night terrors, sleepwalking (somnambulism), nocturnal enuresis (p.2180), bruxism (teeth grinding), head banging, and aggression during sleep. Other common movement disorders associated with sleep are restless legs syndrome and periodic limb movements in sleep. Parasomnias are common but rarely require treatment with drugs other than the symptomatic treatment of sleep-related medical problems. The management of some of these conditions is discussed briefly below.

The **restless legs syndrome** is characterised by an unpleasant creeping sensation deep in the legs with an irresistible urge to move them. Symptoms begin during relaxation in the evenings and in bed, and interfere with the ability to fall asleep. The aetiology of this condition is obscure and treatment has been largely empirical.[1-11] Drug treatment may not always be necessary and non-pharmacological methods such as good sleep hygiene should be tried initially.[1,3,7,8,12] There have been reports of efficacy with a wide range of treatments, although few have been well studied. Dopaminergic therapy has emerged as a common first-line treatment, a long-acting agonist, such as cabergoline, pergolide, pramipexole, or ropinirole, being preferred in order to avoid the complications associated with levodopa.[5,6,8-12] Anticonvulsants, such as carbamazepine, clonazepam, and gabapentin may be of use in those intolerant of dopamine agonists or in those who require additional medication.[5,8-11] Other drugs that have been reported to be of benefit include some opioids, clonidine, and the benzodiazepines.[5,7-12] Iron supplementation may be effective if the syndrome is associated with iron deficiency.[2-4,7-12] Many patients with restless legs syndrome exhibit **periodic limb movements in sleep**,[2,3] characterised by repetitive periodic leg and foot jerking during sleep. Treatments tried are similar to those for the restless legs syndrome; clonazepam and levodopa are amongst the drugs shown to be of benefit.

Some **parasomnias** have responded to treatment with benzodiazepines.[13,14] These include bruxism, head banging, aggression during sleep, night terrors, and sleepwalking.

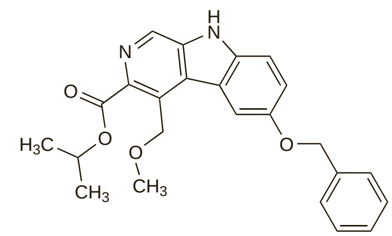
Abecarnil *(rINN)*

Abécarnil; Abecarnilo; Abecarnilum; ZK-112119. Isopropyl 6-(benzyloxy)-4-(methoxymethyl)-9*H*-pyrido(3,4-*b*)indole-3-carboxylate.

Абекарнил

$C_{24}H_{24}N_2O_4$ = 404.5.

CAS — 111841-85-1.



Profile

Abecarnil is a beta-carboline compound reported to be a partial agonist at benzodiazepine receptors. It has been studied for its anxiolytic and anticonvulsant actions in anxiety disorders and alcohol withdrawal syndrome.

Acamprosate Calcium *(BANM, USAN, rINNM)*

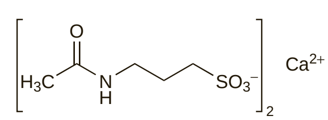
Acamprosate calcique; Acamprosate de Calcium; Acamprosato de calcio; Acamprosatum calcicum; Akamprosaattikalsium; Akamprosát vápenatá sůl; Akamprosatkalcium; Akamprosato kalcio druska; Akamprozát-kalcium; Calcii Acamprosatum; Calcium Acetylhomotaurinate. Calcium 3-acetamido-1-propanesulphate.

Кальций Акампрозат

$C_{10}H_{20}CaN_2O_8S_2$ = 400.5.

CAS — 77337-76-9 (acamprosate); 77337-73-6 (acamprosate calcium).

ATC — N07BB03.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Acamprosate Calcium). A white or almost white powder. Freely soluble in water; practically insoluble in alcohol and in dichloromethane. A 5% solution in water has a pH of 5.5 to 7.0.

Adverse Effects

The main adverse effect of acamprosate is dosage-related diarrhoea; nausea, vomiting, and abdominal pain occur less frequently. Other adverse effects have included pruritus, and occasionally a maculopapular rash; bullous skin reactions have occurred rarely. Depression and fluctuations in libido have also been reported. Hypersensitivity reactions including urticaria, angioedema, and anaphylaxis have been reported very rarely.

Effects on the skin. A case of erythema multiforme in a woman with cirrhosis of the liver has been attributed to use of acamprosate[1] although both the diagnosis and any association with acamprosate have been seriously challenged.[2]

1. Fortier-Beaulieu M, *et al*. Possible association of erythema multiforme with acamprosate. *Lancet* 1992; **339:** 991.
2. Potgieter AS, Opsomer L. Acamprosate as cause of erythema multiforme contested. *Lancet* 1992; **340:** 856–7.

Precautions

In the UK, acamprosate is contra-indicated in patients with severe hepatic impairment (Child-Pugh Class C). US licensed product information states that acamprosate is not metabolised via the liver and its pharmacokinetics are not altered in those with mild to moderate hepatic impairment (Child-Pugh Classes A and B); no change in dose is required in such patients. (No advice is given regarding use in those with more severe impairment.) For precautions regarding the use of acamprosate in patients with renal impairment, see under Uses and Administration, below.

Pharmacokinetics

Absorption of acamprosate from the gastrointestinal tract is slow but sustained and is subject to considerable interindividual variation. Steady-state concentrations are achieved after dosage for 7 days. Bioavailability is reduced if given with food. Acamprosate is not protein bound and although it is hydrophilic it is reported to cross the blood-brain barrier. Acamprosate does not appear to be metabolised and is excreted unchanged in the urine. The elimination half-life after oral doses has been reported to be about 33 hours.

◊ References.

1. Saivin S, *et al*. Clinical pharmacokinetics of acamprosate. *Clin Pharmacokinet* 1998; **35:** 331–45.

Uses and Administration

Acamprosate has a chemical structure similar to that of the endogenous amino acid, homotaurine, which is a structural analogue of gamma-aminobutyric acid (GABA—p.2308) and taurine (p.2395). It is given as the calcium salt to prevent relapse in alcoholics who have been weaned off alcohol. The usual oral dose is 666 mg of acamprosate calcium given three times daily. UK licensed product information also recommends that patients weighing less than 60 kg should be given a dose of 666 mg at breakfast followed by 333 mg at midday and 333 mg at night. For doses in patients with renal impairment, see below. Treatment should be started as soon as possible after alcohol withdrawal and maintained, even if the patient relapses, for the recommended period of 1 year.

Administration in renal impairment. It is considered[1] likely that accumulation of acamprosate would occur with prolonged use of therapeutic doses in patients with renal impairment. It has been reported that the mean maximum concentration of acamprosate after a single 666-mg dose was 813 nanograms/mL in 12 patients with moderate or severe renal impairment compared with 198 nanograms/mL in 6 healthy subjects; values for the plasma elimination half-life were 47 and 18 hours, respectively.

Licensed product information in the UK does not recommend the use of acamprosate in patients with renal impairment (serum creatinine greater than 120 micromoles/litre).

In the USA the use of acamprosate is contra-indicated in those with severe renal impairment (creatinine clearance (CC) less than 30 mL/minute). However, in those with moderate impairment (CC 30 to 50 mL/minute), a starting dose of 333 mg three times daily may be given.

1. Wilde MI, Wagstaff AJ. Acamprosate: a review of its pharmacology and clinical potential in the management of alcohol dependence after detoxification. *Drugs* 1997; **53:** 1038–53.

Alcohol dependence. Acamprosate is considered to be of use as an adjunct to psychotherapy in maintaining abstinence after alcohol withdrawal in patients with alcohol dependence (p.1626). Reviews[1-4] of placebo-controlled studies conclude that acamprosate helps to prevent relapse and increase the number of drink-free days during a 1-year course of treatment and possibly for up to one year thereafter. Efficacy appears to be dose related but its effects in promoting abstinence may wane during treatment. Use with disulfiram or naltrexone may improve results but a large multicentre study in the USA found that adding acamprosate to naltrexone or behavioural therapy did not produce any additional benefit, and that the drug was ineffective when used alone.[5] Several mechanisms have been proposed to account for acamprosate's action including inhibition of neuronal hyperexcitability by antagonising excitatory amino acids such as glutamate.

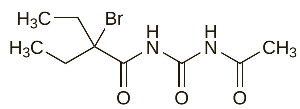
Acecarbromal *(rINN)*

Acécarbromal; Acecarbromalum; Acetcarbromal; Acetylcarbromal. *N*-Acetyl-*N*′-(2-bromo-2-ethylbutyryl)urea.

Ацекарбромал

$C_9H_{15}BrN_2O_3$ = 279.1.
CAS — 77-66-7.



Profile

Acecarbromal is a bromureide with similar actions to those of carbromal (p.967). It has been used for its sedative properties but the use of bromides is generally deprecated.

Preparations

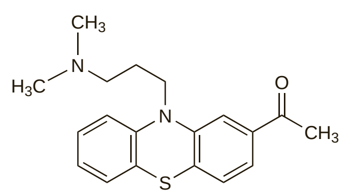
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Cz.:*** Afrodor; ***Ger.:*** Afrodor; ***Hung.:*** Afrodor†; ***Rus.:*** Afrodor (Афродор).

Acepromazine *(BAN, rINN)*

Acepromazin; Acepromazina; Acépromazine; Acepromazinum; Asepromatsiini. 10-(3-Dimethylaminopropyl)phenothiazin-2-yl methyl ketone.

Ацепромазин

$C_{19}H_{22}N_2OS$ = 326.5.
CAS — 61-00-7.
ATC — N05AA04.
ATC Vet — QN05AA04.



Acepromazine Maleate *(BANM, USAN, rINNM)*

Acépromazine, Maléate d'; Acepromazini Maleas; Acetylpromazine Maleate; Asepromazin Maleat; Maleato de acepromazina. 10-(3-Dimethylaminopropyl)phenothiazin-2-yl methyl ketone hydrogen maleate.

Ацепромазина Малеат

$C_{19}H_{22}N_2OS,C_4H_4O_4$ = 442.5.
CAS — 3598-37-6.
ATC — N05AA04.
ATC Vet — QN05AA04.

Pharmacopoeias. In *US* for veterinary use only. Also in *BP(Vet)*.

BP(Vet) 2008 (Acepromazine Maleate). A yellow crystalline powder. Soluble in water and in alcohol; freely soluble in chloroform; slightly soluble in ether. A 1% solution in water has a pH of 4.0 to 4.5.

USP 31 (Acepromazine Maleate). pH of a 1% solution is between 4.0 and 5.5. Protect from light.

Profile

Acepromazine is a phenothiazine with general properties similar to those of chlorpromazine (p.969). It has been given orally as the maleate in the treatment of anxiety disorders, hiccups, and nausea and vomiting. Acepromazine, as the base, has also been given in preparations for the management of insomnia.

Preparations

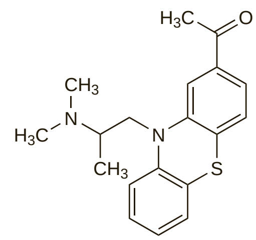
Proprietary Preparations (details are given in Part 3)
Denm.: Plegicil; ***Turk.:*** Plegicil.
Multi-ingredient: ***Fr.:*** Noctran.

Aceprometazine *(rINN)*

16-64 CB; Aceprometazina; Acéprométazine; Aceprometazinum. 10-(2-Dimethylaminopropyl)phenothiazin-2-yl methyl ketone.

Ацепрометазин

$C_{19}H_{22}N_2OS$ = 326.5.
CAS — 13461-01-3.



Profile

Aceprometazine is a phenothiazine with general properties similar to those of chlorpromazine (p.969). It is available usually as the maleate in preparations for the management of insomnia.

Preparations

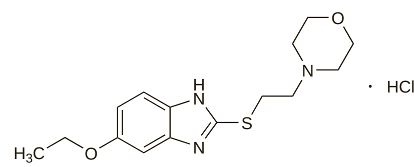
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Fr.:*** Mepronizine; Noctran.

Afobazol

Afobazole; Aphobazole; CM-346; SM-346. 5-Ethoxy-2-{[2-(4-morpholinyl)ethyl]thio}-1*H*-benzimidazole Monohydrochloride.

Афобазол

$C_{15}H_{21}N_3O_2S.HCl$ = 343.9.
CAS — 173352-39-1.



NOTE. Afobazol has also been described as the dihydrochloride.

Profile

Afobazol is a non-benzodiazepine anxiolytic used in the treatment of anxiety disorders. It has been given orally in a usual dose of 10 mg three times daily. A maximum of 60 mg may be given daily.

◊ References.

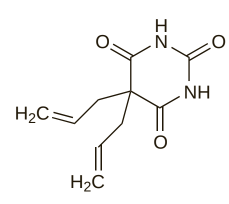
1. Neznamov GG, *et al.* Aphobazol—new selective anxyolytic drug. *Zh Nevrol Psikhiatr Im S S Korsakova* 2005; **105:** 35–40.

Allobarbital *(USAN, rINN)*

Allobarbitaali; Allobarbitalum; Allobarbitone; Alobarbital; Diallylbarbitone; Diallylbarbituric Acid; Diallylmalonylurea; Diallymalum; NSC-9324. 5,5-Diallylbarbituric acid.

Аллобарбитал

$C_{10}H_{12}N_2O_3$ = 208.2.
CAS — 52-43-7.
ATC — N05CA21.
ATC Vet — QN05CA21.



Profile

Allobarbital is a barbiturate with general properties similar to those of amobarbital (p.961). It has been used in combination preparations for the treatment of sleep disorders and pain but barbiturates are no longer considered appropriate for such purposes.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Cz.:*** Dinyl†; Eunalgit†; ***Hung.:*** Demalgonil; ***Pol.:*** Krople Zoladkowe; Pabialgin P; ***Turk.:*** Spasmo-Panalgine.

Alprazolam *(BAN, USAN, rINN)*

Alpratsolaami; Alprazolám; Alprazolamas; Alprazolamum; U-31889. 8-Chloro-1-methyl-6-phenyl-4*H*-1,2,4-triazolo[4,3-*a*]-[1,4]benzodiazepine.

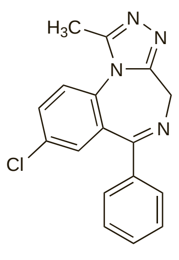
Алпразолам

$C_{17}H_{13}ClN_4$ = 308.8.

CAS — 28981-97-7 (alprazolam).

ATC — N05BA12.

ATC Vet — QN05BA12.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of alprazolam:

Benzo; Coffins; Dogbones; Fo' Bars; Fo's; Footballs; Forgetful Pills; Four Bars; French Fries; Gold Bars; Green Bars; Quad bar; School Buses; Sticks; Totem Poles; White Bars; X-Boxes; Xan-Bars; Xannies; Xanny; Zanny; Z-Bars; Zan-Bars; Zannies; Zanny-Bars.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Alprazolam). A white or almost white, crystalline powder. It exhibits polymorphism. Practically insoluble in water; sparingly soluble in alcohol and in acetone; freely soluble in dichloromethane. Protect from light.

USP 31 (Alprazolam). A white to off-white crystalline powder. Insoluble in water; soluble in alcohol; sparingly soluble in acetone; freely soluble in chloroform; slightly soluble in ethyl acetate.

Dependence and Withdrawal

As for Diazepam, p.987. Dependence may be a particular problem at the high doses used in the treatment of panic attacks.

Adverse Effects and Treatment

As for Diazepam, p.987.

Effects on the liver. A patient receiving phenelzine for depression developed abnormal liver enzyme values on 2 occasions when alprazolam was added to the treatment.[1] It was not possible to say if this was due to alprazolam alone or a synergistic effect with phenelzine.

1. Roy-Byrne P, *et al.* Alprazolam-related hepatotoxicity. *Lancet* 1983; **ii:** 786–7.

Effects on the skin. There have been some reports of alprazolam-induced photosensitivity.[1,2]

1. Kanwar AJ, *et al.* Photosensitivity due to alprazolam. *Dermatologica* 1990; **181:** 75.
2. Watanabe Y, *et al.* Photosensitivity due to alprazolam with positive oral photochallenge test after 17 days administration. *J Am Acad Dermatol* 1999; **40:** 832–3.

Overdosage. A retrospective analysis[1] of 2063 hospital admissions for benzodiazepine overdosage in one region of Australia between January 1987 and October 2002 found that patients who took an overdose of alprazolam were about twice as likely to require admission to intensive care. Flumazenil was required in 14% of the 131 alprazolam overdoses, and ventilation in 16%, which was significantly more than for other benzodiazepines. Given the apparently greater toxicity of alprazolam in overdosage, its increasing prescription to groups at risk of self-poisoning was of concern.

1. Isbister GK, *et al.* Alprazolam is relatively more toxic than other benzodiazepines in overdose. *Br J Clin Pharmacol* 2004; **58:** 88–95.

Precautions

As for Diazepam, p.988.

Abuse. High doses of alprazolam taken after maintenance doses of methadone produced a 'high' without pronounced sedation; the drug was also misused by nonopioid-drug abusers.[1] The usual urine toxicology screens for benzodiazepines often give false-negative results for alprazolam because of the extremely low concentrations of metabolites excreted, making abuse difficult to detect. A subsequent review[2] considered that the literature did not support the widely held belief that alprazolam had a greater liability for abuse than other benzodiazepines, but the possibility could not be discounted.

1. Weddington WW, Carney AC. Alprazolam abuse during methadone maintenance therapy. *JAMA* 1987; **257:** 3363.
2. Rush CR, *et al.* Abuse liability of alprazolam relative to other commonly used benzodiazepines: a review. *Neurosci Biobehav Rev* 1993; **17:** 277–85.

Breast feeding. The American Academy of Pediatrics[1] considers that, although the effect of alprazolam on breast-fed infants is unknown, its use by mothers during breast feeding may be of concern since anxiolytic drugs do appear in breast milk and thus could conceivably alter CNS function in the infant both in the short and long term.

From a study[2] of the distribution of alprazolam into breast milk in 8 lactating women it was estimated that the average daily dose of alprazolam ingested by a breast-fed infant would range from 0.3 to 5 micrograms/kg or about 3% of a maternal dose.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/04/04)
2. Oo CY, *et al.* Pharmacokinetics in lactating women: prediction of alprazolam transfer into milk. *Br J Clin Pharmacol* 1995; **40:** 231–6.

Handling. Care should be taken to prevent inhaling particles of alprazolam and exposing the skin to it.

Hepatic impairment. Alprazolam 1 mg by mouth was absorbed more slowly in 17 patients with alcoholic cirrhosis with no ascites than in 17 healthy subjects.[1] Mean peak alprazolam concentrations were achieved after 3.34 hours in the cirrhosis patients and 1.47 hours in the healthy subjects. Mean elimination half-life for cirrhosis patients was 19.7 hours compared with 11.4 hours for subjects from the healthy group. However, there were no significant differences in the maximum plasma concentrations achieved. The results indicate that alprazolam, in common with other benzodiazepines that undergo oxidative metabolism, would accumulate to a greater extent in patients with alcoholic liver disease than in healthy subjects; the daily dose of alprazolam may need to be reduced by half in this population. See also Administration in Hepatic or Renal Impairment, below.

1. Juhl RP, *et al.* Alprazolam pharmacokinetics in alcoholic liver disease. *J Clin Pharmacol* 1984; **24:** 113–19.

Porphyria. Alprazolam is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Interactions

As for Diazepam, p.989.

Pharmacokinetics

Alprazolam is well absorbed from the gastrointestinal tract after oral doses, peak plasma concentrations being achieved within 1 to 2 hours of a dose. The mean plasma half-life is 11 to 15 hours. Alprazolam is 70 to 80% bound to plasma proteins, mainly albumin. It is metabolised in the liver, primarily by the cytochrome P450 isoenzyme CYP3A4. Metabolites include α-hydroxyalprazolam, which is reported to be about half as active as the parent compound, 4-hydroxyalprazolam, and an inactive benzophenone. Plasma concentrations of metabolites are very low. Alprazolam is excreted in urine as unchanged drug and metabolites.

Uses and Administration

Alprazolam is a short-acting benzodiazepine with general properties similar to those of diazepam (p.992). It is used in the short-term treatment of anxiety disorders in oral doses of 250 to 500 micrograms three times daily, increased where necessary to a total daily dose of 3 or 4 mg. In elderly or debilitated patients, an initial dose of 250 micrograms two or three times daily has been suggested. For doses in patients with hepatic or renal impairment, see below.

Doses of up to 10 mg of alprazolam daily have been used in the treatment of panic attacks. A modified-release preparation of alprazolam is also available for once-daily dosing.

Administration in hepatic or renal impairment. UK licensed product information advises caution when using alprazolam in patients with hepatic or renal impairment; it is contraindicated in those with severe hepatic impairment. In the USA, licensed product information states that patients with advanced liver disease may be given an initial dose of 250 micrograms two or three times daily.

Anxiety disorders. The management of anxiety disorders, including the use of benzodiazepines, is discussed on p.952.

Depression. Although they may be useful for associated anxiety, benzodiazepines are not usually considered appropriate for treatment of depression (p.373); however, some drugs such as alprazolam have been tried for this indication.[1]

1. Kravitz HM, *et al.* Alprazolam and depression: a review of risks and benefits. *J Clin Psychiatry* 1993; **54:** (suppl.): 78–84.

Premenstrual syndrome. Alprazolam has been reported[1-3] to have produced a marginal to good response in the premenstrual syndrome (p.2099) but others have not found it to be of benefit,[4] and the role of benzodiazepines is limited by their adverse effects. If benzodiazepines are selected it is recommended that in order to reduce the risk of dependence and withdrawal symptoms they should be carefully restricted to the luteal phase in selected patients.[5] Withdrawal symptoms may be more severe after short-acting drugs such as alprazolam. Antidepressant drugs such as SSRIs may be preferred.

Amisülprid; Amisulprid; Amisulprida; Amisulpridas; Amisulpridi; Amisulpridum; Amiszulprid; DAN-216. 4-Amino-*N*-[(1-ethyl-2-pyrrolidinyl)methyl]-5-(ethylsulphonyl)-2-methoxybenzamide; (*RS*)-4-Amino-*N*-[(1-ethylpyrrolidin-2-yl)methyl]-5-(ethylsulfonyl)-*o*-anisamide.

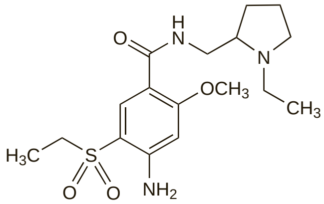
Амисульприд

$C_{17}H_{27}N_3O_4S$ = 369.5.

CAS — 71675-85-9.

ATC — N05AL05.

ATC Vet — QN05AL05.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Amisulpride). A white or almost white crystalline powder. Practically insoluble in water; sparingly soluble in dehydrated alcohol; freely soluble in dichloromethane.

Adverse Effects, Treatment, and Precautions

Although amisulpride may share some of the adverse effects seen with the classical antipsychotics (see Chlorpromazine, p.969), the incidence and severity of such effects may vary. Insomnia, anxiety, and agitation are common adverse effects with amisulpride. Other less common effects include drowsiness and gastrointestinal disorders such as constipation, nausea, vomiting, and dry mouth. Allergic reactions, abnormal liver function tests, and seizures have been reported rarely.

Hyperprolactinaemia, which may result in galactorrhoea, amenorrhoea, impaired fertility, gynaecomastia, breast pain, and sexual dysfunction, has occurred with amisulpride use. Weight gain has also been noted. Dose-related extrapyramidal dysfunction may occur, but symptoms such as acute dystonia, parkinsonism, and akathisia are generally mild at licensed doses. Tardive dyskinesia has been reported after long-term use and there have been rare cases of neuroleptic malignant syndrome. Hypotension and bradycardia have been reported occasionally; QT prolongation, in rare cases leading to torsade de pointes, has also been noted. The risk of QT prolongation is increased by pre-existing conditions such as bradycardia, hypokalaemia, and congenital or acquired QT prolongation; patients should be reviewed for these conditions before starting amisulpride treatment. Certain medications may also increase the risk (see Interactions, below).

Amisulpride should not be given to patients with phaeochromocytoma or prolactin-dependent tumours. It should be used with caution in patients with severe renal impairment, or a history of epilepsy or Parkinson's disease. The risk of hypotension and sedation is increased in elderly patients.

Amisulpride may affect the performance of skilled tasks including driving.

Withdrawal symptoms have occurred rarely when amisulpride has been stopped abruptly; a gradual dose reduction may be appropriate when stopping amisulpride.

Dementia. The FDA has issued advice against the use of atypical antipsychotics in the treatment of behavioural problems in elderly patients with dementia after analysis of placebo-controlled studies showed an increased risk of mortality with certain drugs of this class. See under Risperidone, p.1024.

Effects on body-weight. A review[1] has suggested that the risk of weight gain with amisulpride treatment is less than with olanzapine or risperidone, although cases have been reported.[2] The increased risk of weight gain with some atypical antipsychotics is also discussed under Adverse Effects of Clozapine, p.981.

2. Papadimitriou GN, *et al.* Acute weight gain induced by amisulpride monotherapy in a first-episode schizophrenic patient. *Int Clin Psychopharmacol* 2006; **21:** 181–4.

Effects on carbohydrate metabolism. The increased risk of glucose intolerance and diabetes mellitus with some atypical antipsychotics, and recommendations on monitoring, are discussed under Adverse Effects of Clozapine, p.981.

Effects on lipid metabolism. The increased risk of hyperlipidaemia with some atypical antipsychotics is discussed under Adverse Effects of Chlorpromazine, p.970. See also Effects on Carbohydrate Metabolism under Adverse Effects of Clozapine, p.981.

Overdosage. The effects of overdosage of amisulpride in 2 patients have been reported.[1] The first patient had taken about 3 g of amisulpride and an unknown amount of dosulepin and was found to have had a blood-amisulpride concentration of 9.63 micrograms/mL. Generalised convulsions, which resolved spontaneously, were followed by coma, motor restlessness, tachycardia, and slight prolongation of the QT interval. The patient was treated with gastric lavage and had recovered within 48 hours. The second patient, who had been found dead, had a blood-amisulpride concentration of 41.7 micrograms/mL. Severe cardiotoxicity occurred in 4 further cases of amisulpride overdoses of between about 4 and 32 g reported to Australian poisons information centres;[2] all 4 had marked QT prolongation, with bundle branch block or torsade de pointes, and one, who was thought to have ingested between 16 and 24 g, died after cardiac arrest.

2. Isbister GK, *et al.* Amisulpride deliberate self-poisoning causing severe cardiac toxicity including QT prolongation and torsades de pointes. *Med J Aust* 2006; **184:** 354–6.

Pregnancy. For comments on the use of some atypical antipsychotics during pregnancy, see under Precautions of Clozapine, p.983.

Interactions

Amisulpride should not be given with drugs that may induce arrhythmias (including torsade de pointes); such drugs include some antiarrhythmics, cisapride, thioridazine, erythromycin, and halofantrine. The risk of arrhythmias is also increased with drugs that prolong the QT interval, such as pimozide, haloperidol, and tricyclic antidepressants, and with drugs that produce bradycardia or hypokalaemia, including beta blockers, some calcium-channel blockers, clonidine, digoxin, guanfacine, potassium-depleting diuretics, and lithium; use of these drugs with amisulpride requires caution.

The central effects of other CNS depressants including alcohol may be enhanced by amisulpride. Amisulpride may also enhance the effects of antihypertensive drugs. The dopamine-blocking activity of amisulpride may antagonise the actions of dopaminergics such as levodopa and they should not be given together.

◊ In 7 patients receiving amisulpride, introduction of *lithium* resulted in an average increase of 32% of the dose-corrected plasma concentration of amisulpride.[1] An earlier study had noted that plasma concentrations of amisulpride were raised in patients also taking *clozapine*.[2]

1. Bergemann N, *et al.* Increase in plasma concentrations of amisulpride after receiving co-medication with lithium. *Pharmacopsychiatry* 2005; **38:** 44.
2. Bergemann N, *et al.* Plasma amisulpride levels in schizophrenia or schizoaffective disorder. *Eur Neuropsychopharmacol* 2004; **14:** 245–50.

Pharmacokinetics

Amisulpride is absorbed from the gastrointestinal tract but bioavailability is reported to be only about 48%. An initial peak in plasma concentration has been reported to occur 1 hour after oral doses and a second higher peak after 3 to 4 hours. Plasma protein binding is reported to be only about 16%. Metabolism is limited, with most of a dose appearing in the urine as unchanged drug. The terminal elimination half-life is about 12 hours.

◊ References.

1. Rosenzweig P, *et al.* A review of the pharmacokinetics, tolerability and pharmacodynamics of amisulpride in healthy volunteers. *Hum Psychopharmacol* 2002; **17:** 1–13.

Uses and Administration

Amisulpride is a substituted benzamide atypical antipsychotic. It is reported to have a high affinity for dopamine D_2 and D_3 receptors. Amisulpride is used mainly in the management of psychoses such as schizophrenia but in some countries it has also been tried in depression (p.373).

For acute psychotic episodes in adults and adolescents aged 15 years and over a daily dosage of between 400 and 800 mg may be given orally in 2 divided doses, increased if necessary to 1200 mg daily. For patients with mainly negative symptoms, daily doses between 50 and 300 mg are recommended. Daily doses of up to 300 mg may be given as a single dose. Amisulpride has also been given by intramuscular injection in doses of 400 mg daily.

Administration in renal impairment. For patients with renal impairment, the oral dose of amisulpride should be reduced according to creatinine clearance (CC):

- CC between 30 and 60 mL/minute, half the usual dose
- CC between 10 and 30 mL/minute, one-third the usual dose

Similar reductions are also recommended when amisulpride is given intramuscularly.

Schizophrenia. Reviews[1,2] of amisulpride indicate that it may be more effective than classical antipsychotics against general and negative symptoms of schizophrenia (p.955), and has fewer extrapyramidal adverse effects.

Amobarbital *(BAN, rINN)*

Amobarbitaali; Amobarbitál; Amobarbitalis; Amobarbitalum; Amylobarbitone; Pentymalum. 5-Ethyl-5-isopentylbarbituric acid.

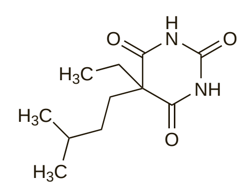
Амобарбитал

$C_{11}H_{18}N_2O_3$ = 226.3.

CAS — 57-43-2.

ATC — N05CA02.

ATC Vet — QN05CA02.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of amobarbital:

Amys; Birds; Blue; Blue angels; Blue birds; Blue bullets; Blue clouds; Blue devils; Blue dolls; Blue heaven; Blue heavens; Blues.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *Jpn.*

Ph. Eur. 6.2 (Amobarbital). A white or almost white, crystalline powder. Very slightly soluble in water; freely soluble in alcohol; soluble in dichloromethane. Forms water-soluble compounds with alkali hydroxides and carbonates and with ammonia.

Amobarbital Sodium *(BANM, rINNM)*

Amobarbitaalinatrium; Amobarbital sódico; Amobarbital sodique; Amobarbital sodná sůl; Amobarbitalio natrio druska; Amobarbitalnatrium; Amobarbitál-nátrium; Amobarbitalum natricum; Amylobarbitone Sodium; Barbamylum; Natrii Amobarbitalum; Pentymalnatrium; Sodium Amobarbital; Soluble Amylobarbitone. Sodium 5-ethyl-5-isopentylbarbiturate.

Натрий Амобарбитал

$C_{11}H_{17}N_2NaO_3$ = 248.3.

CAS — 64-43-7.

ATC — N05CA02.

ATC Vet — QN05CA02.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US*.
Jpn includes Amobarbital Sodium for Injection.
Ph. Eur. 6.2 (Amobarbital Sodium). A white or almost white, hygroscopic, granular powder. Very soluble in carbon dioxide-free water (a small fraction may be insoluble); freely soluble in alcohol. A 10% solution in water has a pH of not more than 11.0. Store in airtight containers.
USP 31 (Amobarbital Sodium). A white, odourless, hygroscopic, friable, granular powder. Very soluble in water; soluble in alcohol; practically insoluble in chloroform and in ether. Solutions decompose on standing; decomposition is accelerated by heat. pH of a 10% solution in water is not more than 11.0. Store in airtight containers.

Incompatibility. Amobarbital may be precipitated from preparations containing amobarbital sodium, depending on the concentration and pH. Amobarbital sodium has, therefore, been reported to be incompatible with many other drugs, particularly acids and acidic salts.

Dependence and Withdrawal of Barbiturates

The development of dependence is a high risk with amobarbital and other barbiturates and may occur after regular use even in therapeutic doses for short periods. Barbiturates should not therefore be stopped abruptly, but should be withdrawn by gradual reduction of the dose over a period of days or weeks. A long-acting barbiturate such as phenobarbital may be substituted for a short- or intermediate-acting one, followed by gradual reduction of the phenobarbital dose.

Withdrawal symptoms are similar to those of alcohol withdrawal and are characterised after several hours by apprehension and weakness, followed by anxiety, headache, dizziness, irritability, tremors, nausea and vomiting, abdominal cramps, insomnia, distortion in visual perception, muscle twitching, and tachycardia. Orthostatic hypotension and convulsions may develop after a day or two, sometimes leading to status epilepticus. Hallucinations and delirium tremens may develop after several days followed by coma before the symptoms disappear or death occurs.

Adverse Effects

Drowsiness, sedation, and ataxia are the most frequent adverse effects of amobarbital and other barbiturates and are a consequence of dose-related CNS depression. Other adverse effects include respiratory depression, headache, gastrointestinal disturbances, skin reactions, confusion, and memory defects. Paradoxical excitement and irritability may occur, particularly in children, the elderly, and patients in acute pain. Hypersensitivity reactions occur rarely and include skin rashes (erythema multiforme and exfoliative dermatitis, sometimes fatal, have been reported), hepatitis and cholestasis, and photosensitivity. Blood disorders, including megaloblastic anaemia after chronic use of barbiturates, have also occurred occasionally.

Neonatal intoxication, drug dependence, and symptoms resembling vitamin-K deficiency have been reported in infants born to mothers who received barbiturates during pregnancy. Congenital malformations have been reported in children of women who took barbiturates during pregnancy, but the causal role is a matter of some debate.

Nystagmus, miosis, slurred speech, and ataxia may occur with excessive doses of barbiturates. The toxic effects of overdosage result from profound central depression and include coma, respiratory and cardiovascular depression, with hypotension and shock leading to renal failure and death. Hypothermia may occur with subsequent pyrexia on recovery. Erythematous or haemorrhagic blisters reportedly occur in about 6% of patients, but are not characteristic solely of barbiturate poisoning.

Solutions of the sodium salts of barbiturates are extremely alkaline, and necrosis has followed subcutaneous injection. Intravenous injection may be hazardous; hypotension, shock, laryngospasm, and apnoea have occurred particularly after rapid injection. Gangrene has resulted from intra-arterial injection into an extremity.

Overdosage. A detailed review of drug-induced stupor and coma, including that caused by barbiturates.[1]

1. Ashton CH, *et al*. Drug-induced stupor and coma: some physical signs and their pharmacological basis. *Adverse Drug React Acute Poisoning Rev* 1989; **8:** 1–59.

Treatment of Adverse Effects

After an overdose of a barbiturate, endotracheal intubation may be necessary if the patient is unconscious. Giving activated charcoal by mouth or nasogastric tube is recommended in patients who have ingested more than 10 mg/kg and present within 1 hour of ingestion; repeat doses may be necessary. Patients should be managed with intensive supportive therapy, with particular attention being paid to the maintenance of cardiovascular, respiratory, and renal functions, and to the maintenance of the electrolyte balance. Charcoal haemoperfusion can be life-saving in the most severe cases and should be considered if there is no improvement after 24 hours of supportive care. The value of other measures aimed at the active removal of barbiturates is questionable.

Precautions

Amobarbital and other barbiturates are best avoided in elderly and debilitated patients, in young adults, in children, and in those with depression.

Amobarbital is contra-indicated in patients with pulmonary insufficiency, sleep apnoea, pre-existing CNS depression or coma, and severe hepatic impairment, and should be given with caution to those with renal impairment. Barbiturates given to patients in pain may provoke a paradoxical excitatory reaction, unless an analgesic is also given. With continued use, tolerance develops to the sedative or hypnotic effects of the barbiturates to a greater extent than to their lethal effects. Barbiturates may cause drowsiness which may persist the next day; affected patients should not drive or operate machinery.

See Adverse Effects, above, for the hazards of giving barbiturates during pregnancy and Breast Feeding, below, for cautions on their use in nursing mothers.

Dependence readily develops after use of barbiturates with a **withdrawal syndrome** if stopped abruptly (see Dependence and Withdrawal, above).

Barbiturates are abused for their euphoriant effects.

Breast feeding. Small amounts of barbiturates are distributed into breast milk, and most authorities, such as the *BNF*, consider that they should not be taken while breast feeding. The American Academy of Pediatrics notes[1] that the long-acting antiepileptic barbiturate, phenobarbital, has been associated with significant effects on some nursing infants, although it suggests that some other barbiturates may be compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/04/04)

Porphyria. Barbiturates including amobarbital have been associated with acute attacks of porphyria and are considered unsafe in porphyric patients.

Interactions

Sedation or respiratory depression may be enhanced by drugs with CNS-depressant properties; in particular alcohol should be avoided. Barbiturates generally induce liver enzymes, and thus increase the rate of metabolism (and decrease the activity) of many other drugs as well as endogenous substances. Continued use may result in induction of their own metabolism. MAOIs may prolong the CNS depressant effects of some barbiturates, probably by inhibition of their metabolism. However, MAOIs, like other antidepressants, also reduce the convulsive threshold and thereby antagonise the anticonvulsant action of barbiturates.

For some further interactions involving barbiturates, see under Phenobarbital, p.493.

Pharmacokinetics

Amobarbital is readily absorbed from the gastrointestinal tract. It is about 60% bound to plasma proteins. It has a half-life of about 20 to 25 hours which is considerably extended in neonates. It crosses the placenta and small amounts are distributed into breast milk. Amobarbital is metabolised in the liver; up to about 50% is excreted in the urine as 3′-hydroxyamylobarbital and up to about 30% as *N*-hydroxyamylobarbital, less than 1% appearing unchanged; up to about 5% is excreted in the faeces.

Uses and Administration

Amobarbital is a barbiturate that has been used as a hypnotic and sedative. Its use can no longer be recommended because of its adverse effects and risk of dependence, although continued use may occasionally be considered necessary for severe intractable insomnia (p.957) in patients already taking it. The usual oral dose was 100 to 200 mg of the base or 60 to 200 mg of the sodium salt, taken at bedtime. A more rapid onset of effect was obtained with the sodium salt.

Barbiturates with a longer action such as phenobarbital (p.492) are still used in epilepsy and those with a shorter action such as methohexital (p.1788) or thiopental (p.1795) for anaesthesia.

Cerebrovascular disorders. For reference to the use of barbiturate-induced coma in the management of patients with cerebral ischaemia, see p.1796.

Epilepsy. Amobarbital is used for specialised procedures in expert epilepsy centres only. It is given by deep intramuscular or slow intravenous injection as the sodium salt.

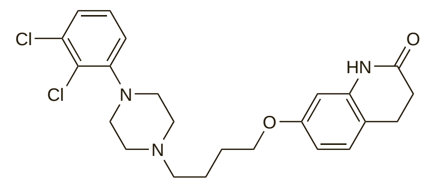
Profile

Amperozide is an antipsychotic that has been used in veterinary medicine.

Aripiprazole *(BAN, USAN, rINN)*

Aripiprazol; Aripiprazolum; OPC-31; OPC-14597. 7-{4-[4-(2,3-Dichlorophenyl)-piperazin-1-yl]butoxy}-3,4-dihydroquinolin-2(1*H*)-one.
Арипипразол
$C_{23}H_{27}Cl_2N_3O_2 = 448.4.$
CAS — 129722-12-9.
ATC — N05AX12.
ATC Vet — QN05AX12.



Adverse Effects, Treatment, and Precautions

Although aripiprazole may share some of the adverse effects seen with the classical antipsychotics (see Chlorpromazine, p.969), the incidence and severity of such effects may vary. Common adverse effects with aripiprazole include gastrointestinal disorders such as constipation, dyspepsia, nausea, and vomiting, headache, anxiety, insomnia, lightheadedness, and drowsiness. Weight gain has been reported; however, this appears to be slight. The incidence of extrapyramidal effects with aripiprazole is low with akathisia being most commonly reported. Tardive dyskinesia has been reported infrequently and there have been a few cases of neuroleptic malignant syndrome.

Tachycardia and orthostatic hypotension are uncommon with aripiprazole treatment; bradycardia, ventricular arrhythmias, cardiac arrest, and sudden unexplained death have been reported very rarely as have QT prolongation and torsade de pointes. Nonetheless aripiprazole should be used with caution in patients with cardiovascular or cerebrovascular disease, or in those with conditions that would predispose to hypotension.

Seizures are rare with aripiprazole but it should be used with care in those with a history of seizures or with conditions that lower the seizure threshold.

When aripiprazole is used as an adjunct in depression, patients should be closely monitored during early therapy until significant improvement in depression is observed because suicide is an inherent risk in depressed patients. For further details, see under Depression, p.373.

Aripiprazole may affect the performance of skilled tasks including driving.

Dementia. The FDA[1] has issued advice against the use of atypical antipsychotics in the treatment of behavioural problems in elderly patients with dementia after analysis of placebo-controlled studies showed an increased risk of mortality with certain drugs of this class, including aripiprazole; most of the deaths appeared due to cardiovascular events or infection. See also under Risperidone, p.1024.

The manufacturer subsequently also included a warning in the licensed product information for aripiprazole about evidence of a dose-response relationship between cerebrovascular adverse events and the use of aripiprazole in elderly patients with psychosis associated with Alzheimer's disease.

1. FDA. FDA issues public health advisory for antipsychotic drugs used for treatment of behavioral disorders in elderly patients (issued 11th April, 2005). Available at: http://www.fda.gov/bbs/topics/ANSWERS/2005/ANS01350.html (accessed 24/05/05)

Effects on body-weight. The increased risk of weight gain with some atypical antipsychotics is discussed under Adverse Effects of Clozapine, p.981.

Further references.

Effects on carbohydrate metabolism. The increased risk of glucose intolerance and diabetes mellitus with some atypical antipsychotics, and recommendations on monitoring, are discussed under Adverse Effects of Clozapine, p.981.

Effects on lipid metabolism. The increased risk of hyperlipidaemia with some atypical antipsychotics is discussed under Adverse Effects of Chlorpromazine, p.970. See also Effects on Carbohydrate Metabolism under Adverse Effects of Clozapine, p.981.

Overdosage. The manufacturer has reported that patients have taken estimated overdoses of up to 1080 mg of aripiprazole with no fatalities. Signs and symptoms have included nausea, vomiting, asthenia, diarrhoea, and somnolence. In one report a 27-year-old woman who ingested 330 mg of aripiprazole with cyclobenzaprine 10 mg and quetiapine 25 mg was found to be drowsy but easily rousable 50 minutes later.[1] Initial treatment consisted of oral activated charcoal; recovery was subsequently uneventful. Serum concentrations of aripiprazole and its main metabolite dehydro-aripiprazole, measured 195 minutes after ingestion, were 596 nanograms/mL and 120 nanograms/mL respectively. In another report[2] a 2⁄-year-old child vomited and became lethargic within 1 hour of taking 195 mg of aripiprazole (17.1 mg/kg). Activated charcoal was given 3 hours after ingestion but she subsequently became unconscious. However, respiratory support was not required and the child gradually regained consciousness over the next 24 hours. Symptoms of somnolence, ataxia and tremulousness resolved over 7 days. The serum concentration of aripiprazole plus dehydro-aripiprazole was found to be 1873 nanograms/mL 10 hours after ingestion.

2. Seifert SA. Aripiprazole (Abilify) overdose in a 2.5 year-old. *J Toxicol Clin Toxicol* 2003; **41:** 647–8.

Pregnancy. For comments on the use of some atypical antipsychotics, including aripiprazole, during pregnancy, see under Precautions of Clozapine, p.983.

Licensed product information states that aripiprazole showed possible teratogenic effects in some *animals*; it was noted that there are no adequate and well-controlled studies in human pregnancy. Aripiprazole should only be used if the benefits to the mother outweigh the risks to the fetus.

Interactions

The central effects of other CNS depressants including alcohol may be enhanced by aripiprazole. Aripiprazole may also enhance the effects of antihypertensive drugs. It should be used with caution in patients also receiving drugs that prolong the QT interval or cause electrolyte imbalance.

Aripiprazole is metabolised by the cytochrome P450 isoenzymes CYP3A4 and CYP2D6. Ketoconazole, a potent CYP3A4 inhibitor, can increase aripiprazole plasma concentrations by about 60%; licensed product information states that the dose of aripiprazole should be reduced by half when given with ketoconazole. Similarly, the dose of aripiprazole should be halved when given with quinidine, a potent inhibitor of CYP2D6. Conversely, plasma concentrations of aripiprazole may decrease by about 70% when given with carbamazepine, a potent CYP3A4 inducer; the dose of aripiprazole should be doubled if carbamazepine is added to aripiprazole treatment. Similar effects may occur with other potent inhibitors or inducers of these isoenzymes and a reduced or increased dose of aripiprazole, respectively, in such combinations is recommended.

Antiepileptics. For a report of Stevens-Johnson syndrome occurring on use of aripiprazole with *lamotrigine*, see p.486.

Pharmacokinetics

Aripiprazole is well absorbed from the gastrointestinal tract after oral doses with peak plasma concentrations reached in about 3 to 5 hours. Following intramuscular injection, peak plasma concentrations are reached between 1 to 3 hours. The absolute bioavailability is reported to be 87% with tablet formulations and 100% with the intramuscular injection; it is widely distributed. Aripiprazole is metabolised mainly in the liver and pathways involved include dehydrogenation and hydroxylation, via the cytochrome P450 isoenzymes CYP3A4 and CYP2D6, and *N*-dealkylation, via CYP3A4. The major metabolite, dehydro-aripiprazole, is also active and represents about 40% of the plasma levels of aripiprazole. The mean elimination half-lives of aripiprazole and dehydro-aripiprazole are about 75 and 95 hours, respectively; in a minority of poor metabolisers the half-life of aripiprazole may be extended to about 146 hours. Protein binding of aripiprazole and its major metabolite is about 99%, mainly to albumin. Elimination is mostly in the faeces (about 55%), with about 25% of a dose appearing in the urine, mainly in the form of metabolites. On the basis of studies in *rats*, it is thought to be distributed into breast milk.

Uses and Administration

Aripiprazole is an atypical antipsychotic that has serotonin 5-HT_{1A}-receptor partial agonist and 5-HT_{2A}-receptor antagonist properties as well as being a partial agonist at dopamine D_2 receptors. It is used in the management of schizophrenia and in acute manic or mixed episodes associated with bipolar disorder. Aripiprazole is also used as an adjunct in the treatment of depression.

For the treatment of **schizophrenia**, aripiprazole is given in an initial oral dose of 10 or 15 mg once daily. The usual maintenance dose is 15 mg once daily although the dose may be adjusted at intervals of not less than 2 weeks up to a maximum of 30 mg daily.

Aripiprazole is also used for the treatment of **mania** associated with bipolar disorder. In the USA, it is given in an initial oral dose of 30 mg once daily, this may subsequently be decreased to 15 mg once daily according to tolerance. Similar doses are licensed in the UK although licensed product information recommends an initial dose of 15 mg once daily.

Aripiprazole may be given by deep intramuscular injection for acute agitation in patients with schizophrenia or bipolar mania. The recommended initial dose is 9.75 mg although some patients may only need 5.25 mg and others up to 15 mg. If necessary, further doses may be given after at least 2 hours, up to a maximum total daily dose of 30 mg. Patients should be switched to oral therapy as soon as possible if ongoing treatment is required.

Aripiprazole is used as adjunctive therapy in **depression**. US licensed product information recommends an initial oral dose of 2 to 5 mg once daily, which may be adjusted in increments of up to 5 mg at intervals of not less than 1 week to a maximum of 15 mg daily. The usual recommended dose is 5 to 10 mg once daily.

Dose adjustments of aripiprazole may be necessary in patients also taking potent inhibitors or inducers of cytochrome P450 isoenzymes. See Interactions, above for further details.

For details of uses and associated doses in children, see below.

Administration in children. In the USA, aripiprazole may be used for the treatment of schizophrenia in adolescents aged 13 to 17 years and for the treatment of acute manic or mixed episodes associated with bipolar disorder in those aged 10 to 17 years. For both indications, the recommended initial oral dose is 2 mg daily increased to 5 mg daily after 2 days and then to the target dose of 10 mg daily after another 2 days; subsequent dose increases should be made in 5-mg increments up to a total maximum dose of 30 mg daily.

Dose adjustments of aripiprazole may be necessary in patients also taking potent inhibitors or inducers of cytochrome P450 isoenzymes. See Interactions, above for further details.

Psychiatric disorders. Aripiprazole is used in the management of *schizophrenia* (p.955) and *bipolar disorder* (p.372).[1-9] Although data are scanty, systematic reviews[8,9] have concluded that aripiprazole does not have significant advantages over other atypical and classical antipsychotics in the treatment of schizophrenia. However, it was found to have a lower risk for hyperprolactinaemia and QT interval prolongation compared with other atypical antipsychotics, and a higher risk for insomnia compared with classical antipsychotics. Aripiprazole is also used as an adjunct in the treatment of *depression*.[10,11]

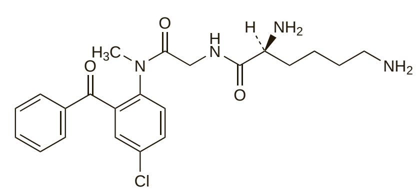
Avizafone *(BAN, rINN)*

Avizafona; Avizafonum; Prodiazepam; Ro-03-7355; Ro-03-7355/000; Ro-03-7355/002 (avizafone hydrochloride). L-Lysyl-(2′-benzoyl-4′-chloro-*N*′-methyl)glycinanilide.

Авизафон

$C_{22}H_{27}ClN_4O_3$ = 430.9.

CAS — 65617-86-9 (avizafone); 60067-16-5 (avizafone hydrochloride).



Profile

Avizafone is rapidly metabolised in the body to diazepam (p.986) and is included as the anticonvulsant component of an intramuscular injection used by military personnel as an antidote to nerve agents. The usual dose of avizafone given in this preparation is 10 mg, repeated every 15 minutes if necessary up to a total dose of 30 mg.

Preparations

Proprietary Preparations (details are given in Part 3)

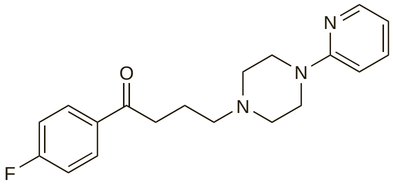
Multi-ingredient: ***UK:*** Nerve Agent Antidote L4A1.

Azaperone *(BAN, USAN, rINN)*

Atsaperoni; Azaperon; Azaperona; Azapérone; Azaperonum; R-1929. 4′-Fluoro-4-[4-(2-pyridyl)piperazin-1-yl]butyrophenone.

Азаперон

$C_{19}H_{22}FN_3O$ = 327.4.
CAS — 1649-18-9.
ATC Vet — QN01AX91; QN05AD90.



Pharmacopoeias. In *Eur.* (see p.vii) and *US* for veterinary use only.
Ph. Eur. 6.2 (Azaperone for Veterinary Use; Azaperone BP(Vet) 2008). A white or almost white powder. It exhibits polymorphism. Practically insoluble in water; soluble in alcohol; freely soluble in acetone and in dichloromethane. Protect from light.
USP 31 (Azaperone). M.p. 92° to 95°. Protect from light.

Profile

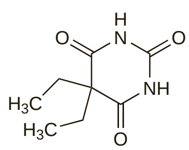
Azaperone is a butyrophenone antipsychotic used as a tranquilliser in veterinary medicine.

Barbital *(BAN, rINN)*

Barbitaali; Barbitál; Barbitalis; Barbitalum; Barbitone; Diemalum; Diethylmalonylurea. 5,5-Diethylbarbituric acid.

Барбитал

$C_8H_{12}N_2O_3$ = 184.2.
CAS — 57-44-3.
ATC — N05CA04.
ATC Vet — QN05CA04.



Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*
Ph. Eur. 6.2 (Barbital). A white or almost white, crystalline powder or colourless crystals. Slightly soluble in water; soluble in boiling water and in alcohol. It forms water-soluble compounds with alkali hydroxides and carbonates and with ammonia.

Barbital Sodium *(BANM, rINN)*

Barbital de sodio; Barbital sódico; Barbital sodique; Barbital sodowy; Barbitalum Natricum; Barbitone Sodium; Diemalnatrium; Soluble Barbitone. Sodium 5,5-diethylbarbiturate.

Барбитал Натрий

$C_8H_{11}N_2NaO_3$ = 206.2.
CAS — 144-02-5.
ATC — N05CA04.
ATC Vet — QN05CA04.

Profile

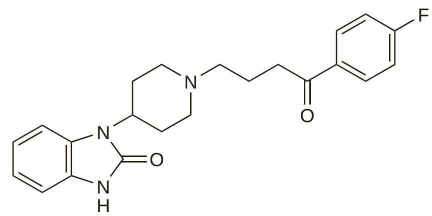
Barbital is a barbiturate with general properties similar to those of amobarbital (p.961). It was formerly used for its hypnotic and sedative properties but barbiturates are no longer considered appropriate for such purposes.

Benperidol *(BAN, USAN, rINN)*

Benpéridol; Benperidoli; Benperidolis; Benperidolum; Benzperidol; CB-8089; McN-JR-4584; R-4584. 1-{1-[3-(4-Fluorobenzoyl)propyl]-4-piperidyl}benzimidazolin-2-one.

Бенперидол

$C_{22}H_{24}FN_3O_2$ = 381.4.
CAS — 2062-84-2.
ATC — N05AD07.
ATC Vet — QN05AD07.



Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Benperidol). A white or almost white powder. It exhibits polymorphism. Practically insoluble in water; slightly soluble in alcohol; soluble in dichloromethane; freely soluble in dimethylformamide. Protect from light.

Profile

Benperidol is a butyrophenone with general properties similar to those of haloperidol (p.1000). Doses of 0.25 to 1.5 mg daily in divided doses are given orally in the management of deviant sexual behaviour. Elderly or debilitated patients may require reduced doses and half the usual dose may be sufficient.

In some countries benperidol is given by mouth or parenterally for the treatment of psychotic conditions (p.954).

Deviant sexual behaviour. Results of a double-blind placebo-controlled crossover study found no difference between the effect of benperidol 1.25 mg daily, chlorpromazine 125 mg daily, or placebo on sexual drive and arousal in 12 paedophilic sexual offenders, except for a lower frequency of sexual thoughts with benperidol.[1] The effects of benperidol are unlikely to be sufficient to control severe forms of antisocial sexually deviant behaviour. The management of deviant sexual behaviour is discussed under Disturbed Behaviour on p.954.

1. Tennent G, *et al*. The control of deviant sexual behaviour by drugs: a double-blind controlled study of benperidol, chlorpromazine, and placebo. *Arch Sex Behav* 1974; **3:** 261–71.

Preparations

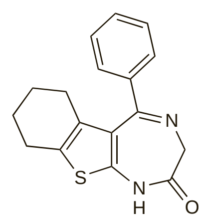
Proprietary Preparations (details are given in Part 3)
Belg.: Frenactil; ***Ger.:*** Glianimon; ***Gr.:*** Glianimon; ***Irl.:*** Anquil†; ***Neth.:*** Frenactil; ***UK:*** Anquil; Benquil†.

Bentazepam *(USAN, rINN)*

Bentazépam; Bentazepamum; CI-718; QM-6008. 1,3,6,7,8,9-Hexahydro-5-phenyl-2*H*-[1]benzothieno[2,3-e]-1,4-diazepin-2-one.

Бентазепам

$C_{17}H_{16}N_2OS$ = 296.4.
CAS — 29462-18-8.



Profile

Bentazepam is a benzodiazepine with general properties similar to those of diazepam (p.986). It has been given, in usual oral doses of 25 mg every 8 hours, in the short-term treatment of anxiety disorders; it has also been used in insomnia.

Effects on the liver. Severe chronic active hepatitis has been reported in a 65-year-old man who had received long-term treatment with bentazepam.[1]

1. Andrade RJ, *et al*. Bentazepam-associated chronic liver disease. *Lancet* 1994; **343:** 860.

Preparations

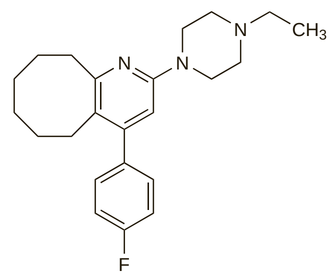
Proprietary Preparations (details are given in Part 3)
Spain: Tiadipona.

Blonanserin *(rINN)*

AD-5423; Blonanserina; Blonansérine; Blonanserinum. 2-(4-Ethyl-1-piperazinyl)-4-(*p*-fluorophenyl)-5,6,7,8,9,10-hexahydrocyclo-octa[*b*]pyridine.

Блонансерин

$C_{23}H_{30}FN_3$ = 367.5.
CAS — 132810-10-7.



Profile

Blonanserin is an antipsychotic reported to be an antagonist at dopamine D_2 and serotonin ($5\text{-}HT_2$) receptors. It is given orally for the treatment of schizophrenia in an initial dose of 4 mg twice daily, increased gradually according to response thereafter. The usual maintenance dose is 8 to 16 mg daily; the maximum daily dose is 24 mg.

Preparations

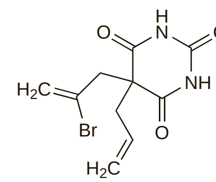
Proprietary Preparations (details are given in Part 3)
Jpn: Lonasen.

Brallobarbital *(rINN)*

Brallobarbitaali; Brallobarbitalum; Bralobarbital; UCB-5033. 5-Allyl-5-(2-bromoallyl)barbituric acid.

Браллобарбитал

$C_{10}H_{11}BrN_2O_3$ = 287.1.
CAS — 561-86-4.



Profile

Brallobarbital is a barbiturate with general properties similar to those of amobarbital (p.961). It has been used in preparations for the management of insomnia but barbiturates are no longer considered appropriate for such purposes. Brallobarbital calcium has been used similarly.

Preparations

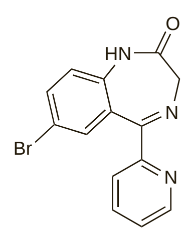
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Port.:*** Vesparax†.

Bromazepam *(BAN, USAN, rINN)*

Bromatsepaami; Brómazepám; Bromazépam; Bromazepamas; Bromazepamum; Ro-5-3350. 7-Bromo-1,3-dihydro-5-(2-pyridyl)-1,4-benzodiazepin-2-one.

Бромазепам

$C_{14}H_{10}BrN_3O$ = 316.2.
CAS — 1812-30-2.
ATC — N05BA08.
ATC Vet — QN05BA08.



Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*
Ph. Eur. 6.2 (Bromazepam). A white or yellowish crystalline powder. Practically insoluble in water; slightly soluble or sparingly soluble in alcohol and in dichloromethane. Protect from light.

Profile

Bromazepam is a benzodiazepine with general properties similar to those of diazepam (p.992). It has been used in the short-term treatment of anxiety disorders (p.952) occurring alone or associated with insomnia. A usual initial oral dose for anxiety is 6 to 18 mg daily in divided doses. Higher doses up to 60 mg daily have occasionally been given. Initial doses for elderly and debilitated patients should not exceed 3 mg daily in divided doses.

Brompéridol, décanoate de; Bromperidoldekanoat; Brómperidol-dekanoát; Bromperidol-dekanoát; Bromperidoli decanoas; Bromperidolidekanoaatti; Bromperidolio dekanoatas; Decanoato de bromperidol; R-46541.

Бромперидола Деканоат

$C_{31}H_{41}BrFNO_3$ = 574.6.

CAS — 75067-66-2.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Bromperidol Decanoate). A white or almost white powder. Practically insoluble in water; soluble in alcohol; very soluble in dichloromethane. It melts at about 60°. Store at a temperature below 25°. Protect from light.

Profile

Bromperidol is a butyrophenone with general properties similar to those of haloperidol (p.1000). It is given in the treatment of schizophrenia (p.955) and other psychoses. Some bromperidol preparations are prepared with the aid of lactic acid and may be stated to contain bromperidol lactate. However, doses are expressed in terms of the equivalent amount of bromperidol. A usual oral dose is 1 to 15 mg daily, although up to 50 mg daily has been given. Elderly patients may require reduced doses of bromperidol. Bromperidol has also been given by intramuscular or intravenous injection.

The long-acting decanoate ester may be used for patients requiring long-term therapy with bromperidol. Doses are expressed in terms of the base; bromperidol decanoate 68.4 mg is equivalent to about 50 mg of bromperidol. Doses equivalent to up to 300 mg of bromperidol every 4 weeks have been given by deep intramuscular injection.

Brotizolam *(BAN, USAN, rINN)*

Brotitsolaami; Brotizolamum; Brotyzolam; We-941; We-941-BS. 2-Bromo-4-(2-chlorophenyl)-9-methyl-6*H*-thieno[3,2-*f*][1,2,4]triazolo[4,3-*a*][1,4]diazepine.

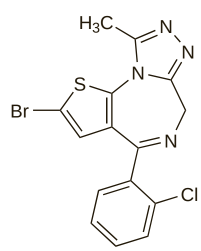
Бротизолам

$C_{15}H_{10}BrClN_4S$ = 393.7.

CAS — 57801-81-7.

ATC — N05CD09.

ATC Vet — QN05CD09.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Brotizolam). A white or yellowish powder. Practically insoluble in water; slightly soluble in alcohol; sparingly soluble or slightly soluble in methyl alcohol.

Profile

Brotizolam is a short-acting benzodiazepine with general properties similar to those of diazepam (p.986). It is given for the short-term (up to 2 weeks) management of insomnia (p.957) in usual oral doses of 250 micrograms at night. The suggested dose for elderly and debilitated patients is 125 micrograms.

Abuse. Reference to abuse of brotizolam in Germany and Hong Kong.[1]

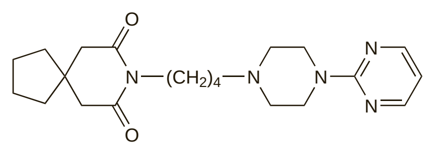
Буспирона Гидрохлорид

$C_{21}H_{31}N_5O_2$,HCl = 422.0.

CAS — 36505-84-7 (buspirone); 33386-08-2 (buspirone hydrochloride).

ATC — N05BE01.

ATC Vet — QN05BE01.



(buspirone)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Buspirone Hydrochloride). A white or almost white, crystalline powder. It exhibits polymorphism. Freely soluble in water and in methyl alcohol; practically insoluble in acetone. Protect from light.

USP 31 (Buspirone Hydrochloride). A white crystalline powder. Very soluble in water; sparingly soluble in alcohol and in acetonitrile; freely soluble in dichloromethane and in methyl alcohol; very slightly soluble in ethyl acetate; practically insoluble in hexanes. Store in airtight containers at a temperature between 15° and 30°. Protect from light.

Dependence and Adverse Effects

Dizziness, nausea, headache, nervousness, light-headedness, excitement, paraesthesias, sleep disturbances, chest pain, tinnitus, sore throat, and nasal congestion are amongst the most frequent adverse effects reported after the use of buspirone hydrochloride. Other adverse effects have included tachycardia, palpitations, drowsiness, confusion, seizures, dry mouth, fatigue, and sweating. A syndrome of restlessness appearing shortly after the start of treatment has been reported in a small number of patients given buspirone. Buspirone is reported to produce less sedation, and to have a lower potential for dependence, than the benzodiazepines.

Effects on the nervous system. Mild acute hypertension and panic were reported on two occasions after the addition of single 10-mg doses of buspirone to therapy with tricyclic antidepressants in a 40-year-old man with panic disorder. Adrenergic or serotonin dysfunction were postulated as possible mechanisms for the reaction.[1,2] Psychotic reactions associated with buspirone treatment have also been reported in a few patients.[3] There have also been isolated reports of mania,[4] and seizures have been reported, primarily in overdosage.[5]

5. Catalano G, *et al.* Seizures associated with buspirone overdose: case report and literature review. *Clin Neuropharmacol* 1998; **21:** 347–50.

EXTRAPYRAMIDAL DISORDERS. There have been isolated reports of exacerbation or precipitation of movement disorders[1-4] associated with the use of buspirone. However, buspirone has also been reported to have been of benefit in some patients with tardive dyskinesia (see Extrapyramidal Disorders under Uses and Administration, below).

1. Hammerstad JP, *et al.* Buspirone in Parkinson's disease. *Clin Neuropharmacol* 1986; **9:** 556–60.

2. Ritchie EC, *et al.* Acute generalized myoclonus following buspirone administration. *J Clin Psychiatry* 1988; **49:** 242–3.
3. Strauss A. Oral dyskinesia associated with buspirone use in an elderly woman. *J Clin Psychiatry* 1988; **49:** 322–3.
4. LeWitt PA, *et al.* Persistent movement disorders induced by buspirone. *Mov Disord* 1993; **8:** 331–4.

Precautions

Buspirone hydrochloride should be used with caution in patients with renal or hepatic impairment and is contra-indicated if the impairment is severe. It should not be used in patients with epilepsy or a history of such disorders. It does not exhibit cross-tolerance with benzodiazepines or other common sedatives or hypnotics and will not block symptoms of their withdrawal; they should, therefore, be gradually withdrawn before starting treatment with buspirone. Buspirone may impair the patient's ability to drive or operate machinery.

Diagnosis and testing. Buspirone may interfere with diagnostic assays of urinary catecholamines.[1]

1. Cook FJ, *et al.* Effect of buspirone on urinary catecholamine assays. *N Engl J Med* 1995; **332:** 401.

Hepatic impairment. Caution has been advised when using buspirone in patients with liver disease. The mean peak plasma-buspirone concentration after an oral dose was about 16 times higher in cirrhotic patients than in controls[1] and the elimination half-life was prolonged about twofold. A secondary peak concentration was seen in some subjects, occurring between 4 and 24 hours after a dose in the cirrhotics and after between 2 and 8 hours in controls. Data from a multiple-dose study[2] suggested that there was accumulation of buspirone and its metabolite 1-(2-pyrimidinyl)-piperazine in hepatic impairment, but that plasma concentrations appeared to reach steady state after 3 days regardless of the state of liver function. The area under the curve and mean peak concentration for buspirone were both higher in patients with hepatic impairment than in healthy subjects, but there were no significant differences for its metabolites. Specific dosing recommendations could not be made for patients with hepatic impairment because of the high intra- and inter-subject variations in plasma-buspirone concentrations.

1. Dalhoff K, *et al.* Buspirone pharmacokinetics in patients with cirrhosis. *Br J Clin Pharmacol* 1987; **24:** 547–50.
2. Barbhaiya RH, *et al.* Disposition kinetics of buspirone in patients with renal or hepatic impairment after administration of single and multiple doses. *Eur J Clin Pharmacol* 1994; **46:** 41–7.

Pregnancy and breast feeding. In some *animal* studies, large doses of buspirone during pregnancy had adverse effects on survival and on birth and weanling weight. Recommendations in licensed product information for use during pregnancy or breast feeding vary from avoid, if possible, to contra-indicated.

Renal impairment. Caution has been advised when giving buspirone to patients with renal impairment.[1,2] There is evidence of accumulation of buspirone and its metabolite after repeated doses but plasma concentrations appeared to reach steady state after 3 days regardless of the degree of renal function. At steady state both the area under the curve and maximum concentrations for buspirone and its metabolite were greater in patients with renal failure than in healthy subjects. The metabolite, but not the parent drug, was removed by haemodialysis. Specific dosing recommendations could not be made for patients with renal impairment because of the high intra- and inter-subject variations in buspirone plasma concentrations on repeated dosage.

1. Caccia S, *et al.* Clinical pharmacokinetics of oral buspirone in patients with impaired renal function. *Clin Pharmacokinet* 1988; **14:** 171–7.
2. Barbhaiya RH, *et al.* Disposition kinetics of buspirone in patients with renal or hepatic impairment after administration of single and multiple doses. *Eur J Clin Pharmacol* 1994; **46:** 41–7.

Interactions

The sedative effects of buspirone may be enhanced if taken with alcohol or other CNS depressants. Because of reports of increased blood pressure in patients receiving buspirone hydrochloride with an MAOI, licensed product information for buspirone recommends that it should not be given with an MAOI.

The metabolism of buspirone is mediated by the cytochrome P450 isoenzyme CYP3A4 and therefore there is the potential for interactions between buspirone and other drugs that inhibit or act as a substrate for this isoenzyme. The dose of buspirone may need to be reduced if given at the same time as potent inhibitors of CYP3A4. Plasma concentrations of buspirone may be reduced by enzyme-inducing drugs such as rifampicin.

Antibacterials. Pretreatment with *erythromycin* in healthy subjects given buspirone resulted in mild to moderate adverse effects associated with increased plasma concentrations of buspirone.[1]

Pretreatment with *rifampicin* greatly reduced plasma concentrations of buspirone in healthy subjects.[2] A reduced anxiolytic effect could be expected if buspirone is used with rifampicin or other potent inducers of the cytochrome P450 isoenzyme CYP3A4.

1. Kivistö KT, *et al.* Plasma buspirone concentrations are greatly increased by erythromycin and itraconazole. *Clin Pharmacol Ther* 1997; **62:** 348–54.
2. Lamberg TS, *et al.* Concentrations and effects of buspirone are considerably reduced by rifampicin. *Br J Clin Pharmacol* 1998; **45:** 381–5.

Antidepressants. Use of buspirone with *nefazodone* can raise plasma concentrations of buspirone. US licensed product information for nefazodone recommends that the initial dose of buspirone be lowered (e.g. 2.5 mg daily) and subsequent dose adjustments of either drug should be based on clinical assessment. A possible serotonin syndrome (p.416) has been reported[1] in a patient using buspirone with *fluoxetine*.

1. Manos GH. Possible serotonin syndrome associated with buspirone added to fluoxetine. *Ann Pharmacother* 2000; **34:** 871–4.

Antifungals. Pretreatment with *itraconazole* in healthy subjects given buspirone resulted in mild to moderate adverse effects associated with increased plasma concentrations of buspirone.[1]

1. Kivistö KT, *et al.* Plasma buspirone concentrations are greatly increased by erythromycin and itraconazole. *Clin Pharmacol Ther* 1997; **62:** 348–54.

Antipsychotics. For the effect of buspirone on serum concentrations of *haloperidol*, see under Chlorpromazine, p.974. For a report of potentially fatal gastrointestinal bleeding and marked hyperglycaemia after use of buspirone with *clozapine*, see under Clozapine, p.984.

Antivirals. Parkinson-like symptoms developed in a 54-year-old man taking a drug regimen that included buspirone, *indinavir*, and *ritonavir*.[1] It was suspected that ritonavir inhibited the metabolism of buspirone, which is mediated by the cytochrome P450 isoenzyme CYP3A4, leading to increased plasma concentrations of the latter. The inhibitory effect of indinavir on CYP3A4 was considered to be less than that of ritonavir. Symptoms resolved after a change in antiviral regimen and reduction in the dose of buspirone.

1. Clay PG, Adams MM. Pseudo-Parkinson disease secondary to ritonavir-buspirone interaction. *Ann Pharmacother* 2003; **37:** 202–5.

Calcium-channel blockers. Increases in buspirone plasma concentrations have been seen in healthy subjects pretreated with *diltiazem* or *verapamil*.[1]

1. Lamberg TS, *et al.* Effects of verapamil and diltiazem on the pharmacokinetics and pharmacodynamics of buspirone. *Clin Pharmacol Ther* 1998; **63:** 640–5.

Grapefruit juice. Grapefruit juice increased the plasma concentrations of buspirone in healthy subjects.[1]

1. Lilja JJ, *et al.* Grapefruit juice substantially increases plasma concentrations of buspirone. *Clin Pharmacol Ther* 1998; **64:** 655–60.

Pharmacokinetics

Buspirone hydrochloride is rapidly absorbed from the gastrointestinal tract reaching peak plasma concentrations within 40 to 90 minutes after an oral dose. Systemic bioavailability is low because of extensive first-pass metabolism, but may be increased if given with food as this delays absorption from the gastrointestinal tract and thereby reduces presystemic clearance. Buspirone is about 95% bound to plasma proteins. Metabolism in the liver is extensive via the cytochrome P450 isoenzyme CYP3A4; hydroxylation yields several inactive metabolites and oxidative dealkylation produces 1-(2-pyrimidinyl)-piperazine, which is reported to be about 25% as potent as the parent drug in one model of anxiolytic activity. The elimination half-life of buspirone is usually about 2 to 4 hours but half-lives of up to 11 hours have been reported. Buspirone is excreted mainly as metabolites in the urine, and also in the faeces.

Uses and Administration

Buspirone hydrochloride is an azaspirodecanedione (azapirone) anxiolytic. It is reported to be largely lacking in sedative, anticonvulsant, and muscle relaxant actions.

Buspirone hydrochloride is given, in initial oral doses of 5 mg two or three times daily, in the short-term management of anxiety disorders. The dose may be increased in increments of 5 mg at 2- to 3-day intervals if required. The recommended maximum daily dose, to be given in divided doses, is 45 mg in the UK and 60 mg in the USA.

Action. Buspirone has dopaminergic, noradrenergic, and serotonin-modulating properties[1] and its anxiolytic effects appear to be related to its action on serotonin (5-hydroxytryptamine, 5-HT) neurotransmission. Buspirone, and the related drugs gepirone (p.999) and ipsapirone (p.1002), are partial agonists at 5-HT_{1A} receptors.[1,2] While such drugs may inhibit serotonin neurotransmission (most likely via 5-HT_{1A} autoreceptor stimulation), they may also have postsynaptic 5-HT_{1A} agonist activity and thus facilitate serotonin neurotransmission.[1] To complicate matters further, 5-HT_{1A} partial agonists have shown both anxiolytic and anxiogenic properties in *animal* models of anxiety. Clinical studies have, however, shown that buspirone is effective in the treatment of generalised anxiety.[1,2]

Clinical studies with buspirone and gepirone suggest that 5-HT_{1A} partial agonists may be useful in the treatment of depression, possibly by downregulation of either 5-HT_{1A} or 5-HT_2 receptors or both.[1] There is some suggestion that buspirone has an anti-aggressive action in humans; it is unclear whether this is mediated via dopaminergic or serotonergic mechanisms.

Buspirone also has characteristics of both a dopamine agonist and antagonist; this may result in stimulation of both growth hormone and prolactin secretion.[3]

Administration in hepatic or renal impairment. For cautions on the use of buspirone in patients with impaired liver or kidney function see under Precautions, above.

Anxiety disorders. Buspirone has been shown to be as effective as the benzodiazepines in the short-term treatment of generalised anxiety disorder (p.952) and to be less likely to cause sedation or psychomotor and cognitive impairment. It also appears to have a lower propensity for interaction with alcohol and a lower risk of abuse and dependence. However, its usefulness may be limited by a relatively slow response to treatment, which may take up to 2 to 4 weeks to appear. Its efficacy may be reduced in patients who have recently taken benzodiazepines. It appears to be ineffective in panic disorder and convincing evidence of efficacy in other anxiety disorders is lacking.

2. Bostwick JM, Jaffee MS. Buspirone as an antidote to SSRI-induced bruxism in 4 cases. *J Clin Psychiatry* 1999; **60:** 857–60.

Cerebellar ataxias. In general the management of cerebellar ataxias is mainly supportive; buspirone improved some symptoms of ataxia in a small study of patients with cerebellar cortical activity.[1]

1. Trouillas P, *et al.* Buspirone, a 5-hydroxytryptamine agonist, is active in cerebellar ataxia: results of a double-blind drug placebo study in patients with cerebellar cortical atrophy. *Arch Neurol* 1997; **54:** 749–52.

Depression. Buspirone has been investigated for augmentation of therapy with antidepressants with serotonin reuptake inhibiting activity in patients with refractory depression (p.373), but results have been variable.

References.

5. Önder E, Tural Ü. Faster response in depressive patients treated with fluoxetine alone than in combination with buspirone. *J Affect Disord* 2003; **76:** 223–7.

Disturbed behaviour. Buspirone has been tried in various disorders for the control of symptoms such as agitation, aggression, and disruptive behaviour (see Disturbed Behaviour, p.954) but evidence of efficacy is limited. Nonetheless, in the management of dementia, some[1] consider that it might be worth trying in nonpsychotic patients with disturbed behaviour, especially those with mild symptoms or those intolerant or unresponsive to antipsychotics.

1. Rabins PV, *et al.* APA Work Group on Alzheimer's Disease and other Dementias. Steering Committee on Practice Guidelines. American Psychiatric Association practice guideline for the treatment of patients with Alzheimer's disease and other dementias. Second edition. *Am J Psychiatry* 2007; **164** (12 suppl): 5–56. Also available at: http://www.psychiatryonline.com/pracGuide/loadGuidelinePdf.aspx?file=AlzPG101007 (accessed 23/07/08)

Extrapyramidal disorders. Although there have been reports[1,2] that buspirone may improve symptoms of drug-induced dyskinesia (p.971), drugs with dopaminergic actions have mostly exacerbated symptoms and there are a few reports of extrapyramidal disorders with buspirone (see under Adverse Effects, above).

1. Moss LE, *et al.* Buspirone in the treatment of tardive dyskinesia. *J Clin Psychopharmacol* 1993; **13:** 204–9.
2. Bonifati V, *et al.* Buspirone in levodopa-induced dyskinesias. *Clin Neuropharmacol* 1994; **17:** 73–82.

Substance dependence. ***ALCOHOL.*** Despite an early study[1] suggesting that buspirone could reduce alcohol craving in alcohol dependent patients, later studies[2-4] have overall failed to confirm that buspirone improves abstinence or reduces alcohol consumption. Although some studies[4,5] have found that buspirone may improve certain psychopathological symptoms in these patients, others[2] have found no such benefit; a meta-analysis[6] of 5 studies favoured the former interpretation.

The management of alcohol withdrawal and abstinence is discussed on p.1626.

6. Malec TS, *et al.* Efficacy of buspirone in alcohol dependence: a review. *Alcohol Clin Exp Res* 1996; **20:** 853–8.

NICOTINE. Buspirone has produced conflicting results[1-5] in the management of smoking cessation (p.2354). Although some studies suggest that in the short-term buspirone can increase the numbers of patients who are able to cease smoking, it does not necessarily decrease withdrawal symptoms.

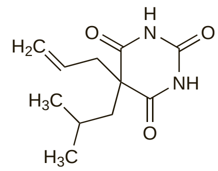
Butalbital *(USAN, rINN)*

Alisobumalum; Allylbarbital; Allylbarbituric Acid; Butalbitaali; Butalbitalum; Itobarbital; Tetrallobarbital. 5-Allyl-5-isobutylbarbituric acid.

Буталбитал

$C_{11}H_{16}N_2O_3$ = 224.3.

CAS — 77-26-9.



NOTE. The name Butalbital has also been applied to talbutal, the *S*-butyl analogue, which was formerly used as a hypnotic and sedative.

Compounded preparations of butalbital may be represented by the following names:

- Co-bucafAPAP (*PEN*)—butalbital, paracetamol, and caffeine

Pharmacopoeias. In *US.*

USP 31 (Butalbital). A white odourless crystalline powder. Slightly soluble in cold water; soluble in boiling water; freely soluble in alcohol, in chloroform, and in ether; soluble in solutions of fixed alkalis and alkali carbonates. A saturated solution is acid to litmus.

Profile

Butalbital is a barbiturate with general properties similar to those of amobarbital (p.961). It has been used mainly in combination preparations with analgesics in the treatment of occasional tension-type headaches, but other treatments are generally preferred.

Preparations

USP 31: Butalbital and Aspirin Tablets; Butalbital, Acetaminophen, and Caffeine Capsules; Butalbital, Acetaminophen, and Caffeine Tablets; Butalbital, Aspirin, and Caffeine Capsules; Butalbital, Aspirin, and Caffeine Tablets; Butalbital, Aspirin, Caffeine, and Codeine Phosphate Capsules.

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Canad.:*** Fiorinal; Fiorinal C; ratio-Tecnal; ratio-Tecnal C; Trianal; Trianal C; ***Chile:*** Cafergot-PB†; ***Denm.:*** Gynergen Comp; ***Ital.:*** Optalidon; ***S.Afr.:*** Cafergot-PB†; ***Spain:*** Cafergot-PB†; ***Switz.:*** Cafergot-PB; ***USA:*** Amaphen with Codeine; Americet; Anolor; Ascomp with Codeine; Bupap; Butex; Dolgic; Dolgic LQ; Dolgic Plus; Endolor; Esgic; Esgic-Plus; Fioricet; Fioricet with Codeine; Fiorinal; Fiorinal with Codeine; Margesic; Marten-Tab; Medigesic; Pacaps; Phrenilin; Phrenilin w Caffeine and Codeine; Promacet; Prominol; Pyridium Plus; Repan; Repan CF†; Sedapap; Tencet; Tencon; Trellium Plus; Triad.

Butobarbital *(BAN)*

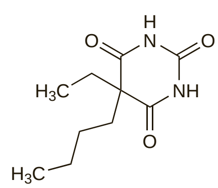
Butethal; Butobarbitaali; Butobarbitalum; Butobarbitone. 5-Butyl-5-ethylbarbituric acid.

$C_{10}H_{16}N_2O_3$ = 212.2.

CAS — 77-28-1.

ATC — N05CA03.

ATC Vet — QN05CA03.



NOTE. Butobarbital should be distinguished from Butabarbital, which is Secbutabarbital (p.1027).

Dependence and Withdrawal

As for Amobarbital, p.962.

Adverse Effects, Treatment, and Precautions

As for Amobarbital, p.962.

Interactions

As for Amobarbital, p.962.

Antibacterials. The metabolism of butobarbital may be altered by *metronidazole.*[1]

1. Al Sharifi MA, *et al.* The effect of anti-amoebic drug therapy on the metabolism of butobarbitone. *J Pharm Pharmacol* 1982; **34:** 126–7.

Pharmacokinetics

Butobarbital is metabolised in the liver mainly by hydroxylation; small amounts are excreted in the urine as unchanged drug. It has been reported to have a half-life of about 40 to 55 hours and to be about 26% bound to plasma proteins.

Uses and Administration

Butobarbital is a barbiturate with general properties similar to those of amobarbital (p.962). Its use can no longer be recommended because of the risk of its adverse effects and of dependence, although continued use may occasionally be considered necessary for severe intractable insomnia (p.957) in patients already taking it. It is given in usual oral doses of 100 to 200 mg at night.

Preparations

Proprietary Preparations (details are given in Part 3)

UK: Soneryl.

Multi-ingredient: ***Cz.:*** Dinyl†; ***Fr.:*** Hypnasmine†.

Calcium Bromolactobionate

Bromolactobionato de calcio; Calcium Galactogluconate Bromide. Calcium bromide lactobionate hexahydrate.

$Ca(C_{12}H_{21}O_{12})_2,CaBr_2,6H_2O$ = 1062.6.

CAS — 33659-28-8 (anhydrous calcium bromolactobionate).

Profile

Calcium bromolactobionate has sedative properties and has been given orally in the treatment of insomnia and anxiety disorders. The use of bromides is generally deprecated.

Overdosage. Bromide intoxication has been reported[1] in a patient after overdosage with calcium bromolactobionate tablets.

1. Danel VC, *et al.* Bromide intoxication and pseudohyperchloremia. *Ann Pharmacother* 2001; **35:** 386–7.

Preparations

Proprietary Preparations (details are given in Part 3)

Chile: Bromocalcio; Nervolta; Sedofantil; ***Cz.:*** Calabron†; ***Ital.:*** Calcibronat; ***Mex.:*** Calcibronat†; ***Mon.:*** Calcibronat; ***Venez.:*** Sedabron†.

Captodiame Hydrochloride *(BANM, pINNM)*

Captodiame, Chlorhydrate de; Captodiami Hydrochloridum; Captodiamine Hydrochloride; Hidrocloruro de captodiamo. 2-(4-Butylthiobenzhydrylthio)ethyldimethylamine hydrochloride.

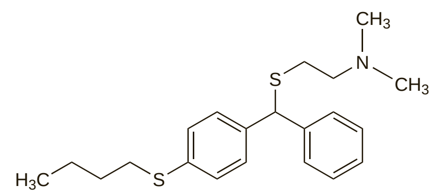
Каптодиама Гидрохлорид

$C_{21}H_{29}NS_2,HCl$ = 396.1.

CAS — 486-17-9 (captodiame); 904-04-1 (captodiame hydrochloride).

ATC — N05BB02.

ATC Vet — QN05BB02.



(captodiame)

Profile

Captodiame hydrochloride has been given in oral doses of 50 mg three times daily for the treatment of anxiety disorders (p.952).

Preparations

Proprietary Preparations (details are given in Part 3)

Fr.: Covatine.

Carbromal *(BAN, rINN)*

Bromodiethylacetylurea; Carbromalum; Karbromaali; Karbromal. *N*-(2-Bromo-2-ethylbutyryl)urea.

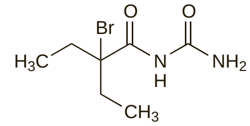
Карбромал

$C_7H_{13}BrN_2O_2$ = 237.1.

CAS — 77-65-6.

ATC — N05CM04.

ATC Vet — QN05CM04.



Profile

Carbromal is a bromureide with general properties similar to those of the barbiturates (see Amobarbital, p.961). It was formerly used for its hypnotic and sedative properties. Chronic use of carbromal could result in bromide accumulation and symptoms resembling bromism (see Bromides, p.2269). The use of bromides is generally deprecated.

Porphyria. Carbromal has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Preparations

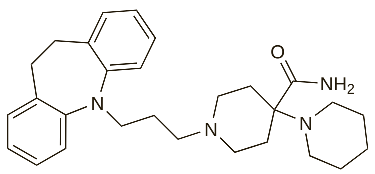
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Hung.:*** Demalgon.

Carpipramine Hydrochloride *(rINNM)*

Carpipramine, Chlorhydrate de; Carpipramini Hydrochloridum; Hidrocloruro de carpipramina; PZ-1511. 1-[3-(10,11-Dihydro-5*H*-dibenz[*b,f*]azepin-5-yl)propyl]-4-piperidinopiperidine-4-carboxamide dihydrochloride monohydrate.

Карпипрамина Гидрохлорид

$C_{28}H_{38}N_4O,2HCl,H_2O$ = 537.6.
CAS — 5942-95-0 (carpipramine); 7075-03-8 (anhydrous carpipramine hydrochloride).



(carpipramine)

Profile

Carpipramine is structurally related both to imipramine (p.400) and to butyrophenones such as haloperidol (p.1000). It has been used in the management of anxiety disorders (p.952) and psychoses such as schizophrenia (p.955). Carpipramine is given as the hydrochloride although doses are expressed in terms of the base; carpipramine hydrochloride 60.2 mg is equivalent to about 50 mg of carpipramine. A usual oral dose is equivalent to 150 mg of the base daily in 2 or 3 divided doses, with a range of 50 to 400 mg daily.

Porphyria. Carpipramine is considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity.

Preparations

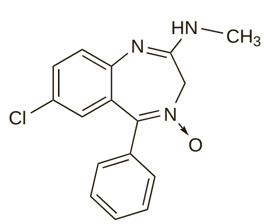
Proprietary Preparations (details are given in Part 3)
Fr.: Prazinil.

Chlordiazepoxide *(BAN, rINN)*

Chlordiazepoksidas; Chlordiazepoxid; Chlordiazépoxide; Chlordiazepoxidum; Chlorodiazepoksyd; Clordiazepóxido; Klooridiatsepoksidi; Klordiazepoksit; Klórdiazepoxid; Klordiazepoxid; Methaminodiazepoxide. 7-Chloro-2-methylamino-5-phenyl-3*H*-1,4-benzodiazepine 4-oxide.

Хлордиазепоксид

$C_{16}H_{14}ClN_3O$ = 299.8.
CAS — 58-25-3.
ATC — N05BA02.
ATC Vet — QN05BA02.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of chlordiazepoxide: Lib.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*
Ph. Eur. 6.2 (Chlordiazepoxide). An almost white or light yellow, crystalline powder. It exhibits polymorphism. Practically insoluble in water; sparingly soluble in alcohol. Protect from light.
USP 31 (Chlordiazepoxide). A yellow, practically odourless, crystalline powder. Insoluble in water; soluble 1 in 50 of alcohol, 1 in 6250 of chloroform, and 1 in 130 of ether. Store in airtight containers. Protect from light.

Chlordiazepoxide Hydrochloride *(BANM, USAN, rINNM)*

Chlordiazepoksido hidrochloridas; Chlordiazepoksydu chlorowodorek; Chlordiazépoxide, chlorhydrate de; Chlordiazepoxid-hydrochlorid; Chlordiazepoxidi hydrochloridum; Hidrocloruro de clordiazepóxido; Klooridiatsepoksidihydrokloridi; Klordiazepoksit Hidroklorür; Klórdiazepoxid-hidroklorid; Klordiazepoxidhydroklorid; Methaminodiazepoxide Hydrochloride; NSC-115748; Ro-5-0690.

Хлордиазепоксида Гидрохлорид

$C_{16}H_{14}ClN_3O,HCl$ = 336.2.
CAS — 438-41-5.
ATC — N05BA02.
ATC Vet — QN05BA02.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*
Ph. Eur. 6.2 (Chlordiazepoxide Hydrochloride). A white or slightly yellow, crystalline powder. It exhibits polymorphism. Soluble in water; sparingly soluble in alcohol. Protect from light.
USP 31 (Chlordiazepoxide Hydrochloride). A white or practically white, odourless, crystalline powder. Soluble in water; sparingly soluble in alcohol; insoluble in petroleum spirit. Store in airtight containers. Protect from light.

Dependence and Withdrawal

As for Diazepam, p.987.

◊ For the purpose of withdrawal regimens, 15 mg of chlordiazepoxide is considered equivalent to about 5 mg of diazepam.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987.

Hepatic impairment. Progressive drowsiness began after 20 days of treatment with chlordiazepoxide in a woman with cirrhosis and hepatitis.[1] One week after stopping the drug the patient could not be roused, and full consciousness was not regained for another week. Accumulation of active metabolites of chlordiazepoxide may have been responsible for the prolonged stupor.

1. Barton K, *et al.* Chlordiazepoxide metabolite accumulation in liver disease. *Med Toxicol* 1989; **4:** 73–6.

Porphyria. Chlordiazepoxide has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for Diazepam, p.989.

Pharmacokinetics

Absorption of chlordiazepoxide is almost complete after oral doses; peak plasma concentrations are achieved after 1 to 2 hours. Absorption after intramuscular injection may be slow and erratic depending on the site of injection. Chlordiazepoxide is about 96% bound to plasma proteins. Reported values for the elimination half-life of chlordiazepoxide have ranged from about 5 to 30 hours, but its main active metabolite desmethyldiazepam (nordazepam, p.1012) has a half-life of several days. Other pharmacologically active metabolites of chlordiazepoxide include desmethylchlordiazepoxide, demoxepam, and oxazepam (p.1014). Chlordiazepoxide passes into the CSF and breast milk, and crosses the placenta. Unchanged drug and metabolites are excreted in the urine, mainly as conjugated metabolites.

◊ References.

1. Greenblatt DJ, *et al*. Clinical pharmacokinetics of chlordiazepoxide. *Clin Pharmacokinet* 1978; **3:** 381–94.

Uses and Administration

Chlordiazepoxide is a benzodiazepine with general properties similar to those of diazepam (p.992). It is used in the short-term treatment of anxiety disorders (p.952) and insomnia (p.957). Chlordiazepoxide is also used in muscle spasm (p.1887), in alcohol withdrawal syndrome (p.1626), and for premedication (p.1780).

Chlordiazepoxide is given orally as the hydrochloride or the base; the doses given refer equally to both. It may also be given by deep intramuscular or slow intravenous injection as the hydrochloride. Preparations formulated for intramuscular use are considered unsuitable for intravenous injection due to the formation of air bubbles in the solvent.

Elderly and debilitated patients should be given one-half or less of the usual adult dose.

The usual oral dose for the treatment of **anxiety** is up to 30 mg daily in divided doses; in severe conditions up to 100 mg daily has been given. For acute or severe anxiety an initial dose of 50 to 100 mg of the hydrochloride has been given by injection, followed if necessary by 25 to 50 mg three or four times daily.

For relief of **muscle spasm** a dose of 10 to 30 mg daily orally in divided doses is recommended, and 10 to 30 mg orally may be given before bedtime for insomnia associated with anxiety.

For the control of the acute symptoms of **alcohol withdrawal** chlordiazepoxide or chlordiazepoxide hydrochloride may be given in an oral dose of 25 to 100 mg repeated as needed up to a maximum of 300 mg daily. For severe symptoms treatment may be begun by injection of 50 to 100 mg, repeated if necessary after 2 to 4 hours.

Chlordiazepoxide hydrochloride has also been given for anaesthetic **premedication** in a dose of 50 to 100 mg intramuscularly one hour before surgery.

Preparations

BP 2008: Chlordiazepoxide Capsules; Chlordiazepoxide Hydrochloride Tablets;
USP 31: Chlordiazepoxide and Amitriptyline Hydrochloride Tablets; Chlordiazepoxide Hydrochloride and Clidinium Bromide Capsules; Chlordiazepoxide Hydrochloride Capsules; Chlordiazepoxide Hydrochloride for Injection; Chlordiazepoxide Tablets.

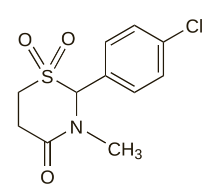
Chlormezanone *(BAN, rINN)*

Chlormethazanone; Chlormézanone; Chlormezanonum; Clormezanona; Kloormetsanoni; Klormezanon. 2-(4-Chlorophenyl)-3-methylperhydro-1,3-thiazin-4-one 1,1-dioxide.

Хлормезанон

$C_{11}H_{12}ClNO_3S$ = 273.7.
CAS — 80-77-3.
ATC — M03BB02.
ATC Vet — QM03BB02.



Profile

Chlormezanone has been used in the treatment of anxiety disorders and insomnia. It was also used in conditions associated with painful muscle spasm, often in compound preparations with analgesics; its mechanism of action is not clear but is probably related to its sedative effect. Chlormezanone was withdrawn from use in many countries after reports of serious skin reactions (see below).

Effects on the skin. Chlormezanone was responsible for 5 of 86 cases of fixed drug eruption detected in a Finnish hospital from 1971 to 1980.[1] In the period from 1981 to 1985 chlormezanone was responsible for 1 out of 77 such eruptions.[2] In a case control study[3] comparing drug use in 245 patients hospitalised because of toxic epidermal necrolysis or Stevens-Johnson syndrome and 1147 controls, 13 patients and one control were found to have taken chlormezanone. From these figures a high crude relative risk of 62 was calculated; the excess risk was estimated to be 1.7 cases per million users per week.

Chlorproethazine Hydrochloride *(rINNM)*

Chlorproéthazine, Chlorhydrate de; Chlorproethazini Hydrochloridum; Hidrocloruro de clorproetazina; RP-4909 (chlorproethazine). 3-(2-Chlorophenothiazin-10-yl)-*NN*-diethylpropylamine hydrochloride.

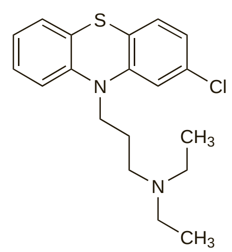
Хлорпроэтазина Гидрохлорид

$C_{19}H_{23}ClN_2S,HCl = 383.4.$

CAS — 84-01-5 (chlorproethazine); 4611-02-3 (chlorproethazine hydrochloride).

ATC — N05AA07.

ATC Vet — QN05AA07.



(chlorproethazine)

Profile

Chlorproethazine is a phenothiazine derivative differing chemically from chlorpromazine by the substitution of a diethyl for a dimethyl group. It has general properties similar to those of chlorpromazine (below) but has been used mainly as a muscle relaxant in the management of muscle spasm (p.1887). Although exposure of the skin to phenothiazines has been associated with sensitivity reactions, chlorproethazine hydrochloride has been applied topically with the warning to avoid direct exposure to sunlight. It has also been given orally or by intramuscular or slow intravenous injection.

Preparations

Proprietary Preparations (details are given in Part 3)
Fr.: Neuriplege†.

Chlorpromazine *(BAN, rINN)*

Chlorpromazinum; Clorpromazina; Klooripromatsiini; Klorpromazin. 3-(2-Chlorophenothiazin-10-yl)propyldimethylamine.

Aminazine; Chloropromazyny chlorowodorek; Chlorpromazin hydrochlorid; Chlorpromazine, chlorhydrate de; Chlorpromazini hydrochloridum; Chlorpromazino hidrochloridas; Hidrocloruro de clorpromazina; Klooripromatsiinihydrokloridi; Klorpromazin Hidroklorür; Klórpromazin-hidroklorid; Klorpromazinhydroklorid.

Хлорпромазина Гидрохлорид

$C_{17}H_{19}ClN_2S,HCl = 355.3.$

CAS — 69-09-0.

ATC — N05AA01.

ATC Vet — QN05AA01.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Chlorpromazine Hydrochloride). A white or almost white crystalline powder. It decomposes on exposure to air and light. Very soluble in water; freely soluble in alcohol. A freshly prepared 10% solution in water has a pH of 3.5 to 4.5. Store in airtight containers. Protect from light.

USP 31 (Chlorpromazine Hydrochloride). A white or slightly creamy-white odourless crystalline powder. It darkens on prolonged exposure to light. Soluble 1 in 1 of water, 1 in 1.5 of alcohol, and 1 in 1.5 of chloroform; insoluble in ether and in benzene. Store in airtight containers. Protect from light.

Dilution. Solutions containing 2.5% of chlorpromazine hydrochloride may be diluted to 100 mL with 0.9% sodium chloride solution provided the pH of the saline solution is such that the pH of the dilution does not exceed the critical range of pH 6.7 to 6.8.[1] With saline of pH 7.0 or 7.2, the final solution had a pH of 6.4.

1. D'Arcy PF, Thompson KM. Stability of chlorpromazine hydrochloride added to intravenous infusion fluids. *Pharm J* 1973; **210:** 28.

Incompatibility. Incompatibility has been reported between chlorpromazine hydrochloride injection and several other compounds; precipitation of chlorpromazine base from solution is particularly likely if the final pH is increased. Compounds reported to be incompatible with chlorpromazine hydrochloride include aminophylline, amphotericin B, aztreonam, some barbiturates, chloramphenicol sodium succinate, chlorothiazide sodium, dimenhydrinate, heparin sodium, morphine sulfate (when preserved with chlorocresol), some penicillins, and remifentanil.

For a warning about incompatibility between chlorpromazine solution (*Thorazine*; *GSK, USA*) and carbamazepine suspension (*Tegretol*; *Novartis, USA*), see p.471.

Sorption. There was a 41% loss of chlorpromazine hydrochloride from solution when infused for 7 hours via a plastic infusion set (cellulose propionate burette with PVC tubing), and a 79% loss after infusion for 1 hour from a glass syringe through silastic tubing.[1] Loss was negligible after infusion for 1 hour from a system comprising a glass syringe with polyethylene tubing.

1. Kowaluk EA, *et al.* Interactions between drugs and intravenous delivery systems. *Am J Hosp Pharm* 1982; **39:** 460–7.

Adverse Effects

Chlorpromazine generally produces less central depression than the barbiturates or benzodiazepines, and tolerance to its initial sedative effects develops fairly quickly in most patients. It has antimuscarinic properties and may cause adverse effects such as dry mouth, constipation, difficulty with micturition, blurred vision, and mydriasis. Tachycardia, ECG changes (particularly Q- and T-wave abnormalities), and, rarely, cardiac arrhythmias may occur; hypotension (usually orthostatic) is common. Other adverse effects include delirium, agitation and, rarely, catatonic-like states, insomnia or drowsiness, nightmares, depression, miosis, EEG changes and convulsions, nasal congestion, minor abnormalities in liver function tests, inhibition of ejaculation, impotence, and priapism.

Hypersensitivity reactions include urticaria, exfoliative dermatitis, erythema multiforme, and contact sensitivity. A syndrome resembling SLE has been reported. Jaundice has occurred, and probably has an immunological origin. Prolonged therapy may lead to deposition of pigment in the skin, or more frequently the eyes; corneal and lens opacities have occurred. Pigmentary retinopathy has occurred only rarely with chlorpromazine. Photosensitivity reactions are more common with chlorpromazine than with other antipsychotics.

Haematological disorders, including haemolytic anaemia, aplastic anaemia, thrombocytopenic purpura, eosinophilia, and a potentially fatal agranulocytosis have occasionally been reported; they may be manifestations of a hypersensitivity reaction. Most cases of agranulocytosis have occurred within 4 to 10 weeks of starting treatment, and symptoms such as sore throat or fever should be watched for and white cell counts instituted should they appear. Mild leucopenia has been stated to occur in up to 30% of patients on prolonged high dosage.

Extrapyramidal dysfunction and resultant disorders include acute dystonia, a parkinsonism-like syndrome, and akathisia; late effects include tardive dyskinesia and perioral tremor. The neuroleptic malignant syndrome may also occur.

Chlorpromazine alters endocrine and metabolic functions. Patients have experienced amenorrhoea, galactorrhoea, and gynaecomastia due to hyperprolactinaemia, weight gain, and hyperglycaemia and altered glucose tolerance. Body temperature regulation is impaired and may result in hypo- or hyperthermia depending on environment. There have also been reports of hypercholesterolaemia.

There have been isolated reports of sudden death with chlorpromazine; possible causes include cardiac arrhythmias or aspiration and asphyxia due to suppression of the cough and gag reflexes.

Pain and irritation at the injection site may occur on injection. Nodule formation may occur after intramuscular injection.

Phenothiazines do not cause dependence of the type encountered with barbiturates or benzodiazepines. However, withdrawal symptoms have been seen on abrupt withdrawal in patients receiving prolonged and/or high-dose maintenance therapy.

Although the adverse effects of **other phenothiazines** are broadly similar in nature to those of chlorpromazine, their frequency and pattern tend to fall into 3 groups:

- group 1 (e.g. chlorpromazine, levomepromazine, and promazine) are generally characterised by pronounced sedative effects and moderate antimuscarinic and extrapyramidal effects
- group 2 (e.g. pericyazine, pipotiazine, and thioridazine) are generally characterised by moderate sedative effects, marked antimuscarinic effects, and fewer extrapyramidal effects than groups 1 or 3
- group 3 (e.g. fluphenazine, perphenazine, prochlorperazine, and trifluoperazine) are generally characterised by fewer sedative and antimuscarinic effects but more pronounced extrapyramidal effects than groups 1 or 2

Classical antipsychotics of **other chemical groups** tend to resemble the phenothiazines of group 3. They include the butyrophenones (e.g. benperidol and haloperidol); diphenylbutylpiperidines (e.g. pimozide); thioxanthenes (flupentixol and zuclopenthixol); substituted benzamides (e.g. sulpiride); oxypertine; and loxapine.

Carcinogenicity. See Effects on Endocrine Function, below.

Convulsions. Treatment with antipsychotics can result in EEG abnormalities and lowered seizure threshold.[1] Seizures can be induced particularly in patients with a history of epilepsy or drug-induced seizures, abnormal EEG, previous electroconvulsive therapy, or pre-existing CNS abnormalities. The risk appears to be greatest at the start of antipsychotic therapy, or with high doses, or abrupt increases of dose, or with the use of more than one antipsychotic. The incidence of antipsychotic-induced convulsions is, however, probably less than 1%.

In general, the epileptic potential has been correlated with the propensity of the antipsychotic to cause sedation. Phenothiazines with marked sedative effects [group 1] such as chlorpromazine appear to present a higher risk than those with strong extrapyramidal effects [group 3]. Haloperidol appears to carry a relatively low risk of seizures. The following drugs have been suggested when classical antipsychotic therapy is considered necessary in patients at risk of seizures or being treated for epilepsy: fluphenazine, haloperidol, pimozide, or trifluoperazine. Antipsychotic dosage should be increased slowly and the possibility of interactions with antiepileptic therapy considered (see under Interactions, below).

The atypical antipsychotic clozapine appears to be associated with a particularly high risk of seizures (see Effects on the Nervous System, under Clozapine, p.982). Risperidone may be preferred if an atypical antipsychotic is to be used in patients at risk of seizures.

Effects on the blood. The UK CSM provided data on the reports it had received between July 1963 and January 1993 on agranulocytosis and neutropenia.[1] Several groups of drugs were commonly implicated, among them phenothiazines for which there were 87 reports of agranulocytosis (42 fatal) and 33 of neutropenia (22 fatal). The most frequently implicated phenothiazines were chlorpromazine with 51 reports of agranulocytosis (26 fatal) and 12 of neutropenia (2 fatal) and thioridazine with 20 reports of agranulocytosis (9 fatal) and 10 of neutropenia (none fatal).

1. CSM/MCA. Drug-induced neutropenia and agranulocytosis. *Current Problems* 1993; **19:** 10–11. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2024456&RevisionSelectionMethod=LatestReleased (accessed 18/07/08)

Effects on body-weight. Most antipsychotic drugs are associated with weight gain. A meta-analysis[1] found evidence of weight gain in patients receiving both classical (chlorpromazine, fluphenazine, haloperidol, loxapine, perphenazine, thioridazine, tiotixene, or trifluoperazine) and atypical (clozapine, olanzapine, quetiapine, risperidone, sertindole, and ziprasidone) antipsychotics. Two drugs, molindone and pimozide, appeared in contrast to be associated with weight loss, although in the case of pimozide this could not be confirmed statistically. Placebo treatment was also associated with weight loss. For further details, see Effects on Body-weight, in Clozapine, p.981.

1. Allison DB, *et al.* Antipsychotic-induced weight gain: a comprehensive research synthesis. *Am J Psychiatry* 1999; **156:** 1686–96.

Effects on the cardiovascular system. Orthostatic hypotension is a common problem in patients taking psychotropic drugs and is particularly pronounced with low-potency antipsychotics.[1]

Various **EEG changes** or frank **arrhythmias** have occurred in patients receiving antipsychotics. T-wave changes have been reported with low-potency antipsychotics; they are usually benign and reversible, and subject to diurnal fluctuations. Low-potency antipsychotics, particularly *thioridazine* and *mesoridazine*, and the high-potency drug *pimozide*, prolong the QT interval in a similar manner to class I antiarrhythmics such as quinidine or procainamide; their use is therefore contra-indicated in patients taking such antiarrhythmics. *Droperidol*, another high-potency drug, has also been reported to prolong the QT interval.[2] Thioridazine is most frequently discussed in case reports of psychotropic drug-induced torsade de pointes,[2] which has led to restrictions on its use (see Precautions, and Uses and Administration of Thioridazine, p.1031); *chlorpromazine* and *pimozide* have also been implicated. Torsade de pointes has also been reported after overdosage[3-5] with, or high intravenous[6] doses of, the high-potency antipsychotic *haloperidol*. There are also isolated reports of cardiac arrhythmias after attempts at rapid control with high doses of haloperidol.[7,8] *Melperone*, a butyrophenone antipsychotic related to haloperidol, has been reported to have class III electrophysiologic and antiarrhythmic activity.[9,10]

In the UK, the risk of arrhythmias with antipsychotic treatment has been considered by an expert working group of the CSM;[11] the following recommendations were made regarding ECG monitoring:

- the need for an ECG should be based on a patient's relevant medical history, family history, and clinical examination; the elderly and those with a personal or family history of heart disease or any cardiac abnormalities would benefit the most from a baseline ECG
- during treatment an ECG should be performed in patients who experience palpitations or other symptoms suggestive of cardiac disease; if the QT interval is prolonged then a reduction in dose may be required, if it exceeds 500 milliseconds treatment may need to be stopped
- an ECG should be considered during dose increases
- potassium levels should be monitored before and during treatment and in particular during periods of acute illnesses

Sudden unexpected deaths have long been reported in patients receiving antipsychotics.[12] Whether this is due to the disease being treated or to the treatment is still unclear. However, in a retrospective cohort study[13] involving about 482 000 patients, analysis of 1487 sudden cardiac deaths indicated that patients receiving antipsychotics in doses of more than 100 mg of thioridazine or its equivalent had a 2.4-fold increase in the rate of sudden cardiac death, rising to a 3.53-fold increase in those patients with pre-existing severe cardiovascular disease. A later case-control study[14] in 5 UK psychiatric hospitals found that sudden unexplained death in psychiatric patients was associated with hypertension, ischaemic heart disease, and current treatment with thioridazine. Although several mechanisms have been suggested for the effect, prolongation of the QT interval has been implicated in a proportion of the cases.[12]

Results from a case-control study[15] have suggested that use of classical antipsychotics may be associated with an increased risk of idiopathic **venous thromboembolism.** The risk was most pronounced during the first 3 months of treatment, and was higher for low potency than high potency antipsychotics. This study did not examine the risk of venous thromboembolism with atypical antipsychotics, but see under Clozapine, p.982.

Effects on endocrine function. Antipsychotics can alter the secretion of prolactin, growth hormone, and thyrotrophin from the anterior pituitary via their ability to block central dopamine-D_2 receptors. Therapeutic doses of classical antipsychotics (and some atypical antipsychotics such as amisulpride and risperidone) increase serum-prolactin concentrations; this effect occurs at lower doses and after shorter latent periods than the antipsychotic effects. However, partial tolerance to the hyperprolactinaemic effect may develop on long-term use.[1] Serum prolactin declines to normal values within 3 weeks of stopping oral antipsychotic therapy but may remain raised for 6 months after an intramuscular depot injection.[1]

The long-term consequences of gonadal hormone deficiency, secondary to raised prolactin concentrations, have caused concern. There is evidence[2] that patients taking long-term prolactin-raising antipsychotics are at high risk of osteoporosis associated with hypogonadism. Long-term antipsychotic treatment has also been shown to increase the incidence of mammary tumours in the *rat*. Although early studies[3,4] found little or no evidence that chronic use in humans alters the risk of breast cancer among women with schizophrenia, a later retrospective cohort study[5] found a modest dose-related increase in the risk of breast cancer in women using antipsychotic dopamine antagonists. A similar increase was seen in women receiving antiemetic dopamine antagonists. Fears that pituitary abnormalities, including pituitary tumours,[6] might develop in patients on long-term phenothiazine therapy have not been confirmed.[7,8]

Antipsychotics can in some circumstances reduce both basal and stimulated growth-hormone secretion but attempts to use them to treat dysfunctions in growth-hormone regulation have not been successful.[9] Although a number of clinical studies show that acute dosage of antipsychotics increased both basal and stimulated thyrotrophin secretion, the majority of studies find either no change or only a small increase in thyrotrophin secretion following long-term use.

A small study[10] has suggested that thioridazine may be more likely than other antipsychotics to decrease serum concentrations of testosterone or luteinising hormone in men. However, concentrations were within the normal range in most patients taking antipsychotics.

Effects on the eyes. Phenothiazines may induce a pigmentary retinopathy which is dependent on both the dose and the duration of treatment.[1] Those phenothiazine derivatives with piperidine side-chains such as thioridazine have a higher risk of inducing retinal toxicity than other phenothiazine derivatives, with relatively few cases reported for those with aliphatic side-chains such as chlorpromazine; the piperazine group does not appear to exert direct ocular toxicity.[2] The retinopathy may present either acutely, (sudden loss of vision associated with retinal oedema and hyperaemia of the optic disc), or chronically, (a fine pigment scatter appearing in the central area of the fundus, extending peripherally but sparing the macula). Chronic paracentral and pericentral scotomas may be found. Although pigmentary disturbances may progress after withdrawal of thioridazine, they are not always paralleled by deterioration in visual function; nonetheless, some cases have led to progressive chorioretinopathy.[3] The critical ocular toxic dose of thioridazine is reported to be 800 mg daily[1] and UK licensed product information has recommended that a daily dose of 600 mg should not usually be exceeded. However, there is a report[4] of pigmentary retinopathy in a patient who received long-term thioridazine in daily doses not exceeding 400 mg; the total dose was 752 g.

Pigmentation may also occur in the cornea, lens, and conjunctiva following use of phenothiazines. It may occur in association with pigmentary changes in the skin and is dose-related. In a study of 100 Malaysian patients, ocular pigmentation was observed in slightly more than half of those who had received a total dose of chlorpromazine of 100 to 299 g and in 13 of 15 who had received 300 to 599 g.[5] All those who had received more than 600 g of chlorpromazine or thioridazine had ocular pigmentation. Cataract formation, mainly of an anterior polar variety, has been observed rarely, mainly in patients on chlorpromazine. It does not appear to be dose-related.[2]

A patient who had received fortnightly injections of fluphenazine 12.5 mg for 10 years (total dose 3.25 g) developed bilateral maculopathy following unprotected exposure of less than 2-minute's duration to a welding arc.[6] It was postulated that accumulation of phenothiazine in the retinal epithelium sensitised the patient to photic damage. However, another patient who had received fortnightly injections of fluphenazine 25 mg for 25 years (total dose 16.25 g) developed bilateral maculopathy without exposure to any extreme photochemical sources.[7] The authors concluded that this was due to a direct effect of fluphenazine secondary to its accumulation in the retinal epithelium.

Effects on fluid and electrolyte homoeostasis. There have been occasional reports of water intoxication in patients taking antipsychotics. A review[1] of hyponatraemia and the syndrome of inappropriate antidiuretic hormone secretion associated with psychotropics summarised 20 such reports for antipsychotics in the literature. The drugs implicated were thioridazine (8 reports), haloperidol (3 reports), chlorpromazine, trifluoperazine, and fluphenazine (2 reports each), and flupentixol, tiotixene, and clozapine (1 report each). The majority of reports did not permit clear conclusions and, particularly in the cases of prolonged treatment, the role of the medication was unclear. However, at least 3 of the cases were well documented and supported the view that antipsychotics could cause hyponatraemia.

A report not considered by the above review described water retention and peripheral oedema associated with chlorpromazine.[2] A small controlled study[3] found that 5 of 10 evaluated patients receiving haloperidol decanoate had impaired fluid homoeostasis.

Effects on lipid metabolism. Most antipsychotics are associated with hyperlipidaemia. A review[1] found evidence of a higher risk of hyperlipidaemia in patients receiving low-potency classical antipsychotics, such as chlorpromazine and thioridazine, or the atypical antipsychotics, clozapine, olanzapine, and quetiapine. High-potency classical antipsychotics, such as haloperidol, and the atypical antipsychotics aripiprazole, risperidone, and ziprasidone, appeared to be associated with a lower risk of hyperlipidaemia. Possible mechanisms for dyslipidaemia associated with antipsychotic therapy include the development of glucose intolerance, weight gain, and dietary changes. For further details, see Effects on Body-weight under Adverse Effects of Clozapine, p.981 and Effects on Body-weight, above.

Effects on the liver. Chlorpromazine and other phenothiazines may cause hepatocanalicular cholestasis often with hepatocyte damage suggestive of immunological liver injury.[1] Only a small number of patients taking the drug are affected and the onset is usually in the first 4 weeks of therapy. The drug or one of its metabolites may induce alteration in the liver-cell membrane so that it becomes antigenic; there is also good evidence for direct hepatotoxicity related to the production of free drug radical. There may be an individual idiosyncrasy in the metabolism of chlorpromazine and in the production of these radicals. A study has suggested that patients who have poor sulfoxidation status combined with unimpaired hydroxylation capacity may be most likely to develop jaundice with chlorpromazine.[2]

A preliminary study[3] showing a high incidence of gallstones in psychiatric inpatients in Japan found a correlation between the presence of gallstones and the duration of illness and use of antipsychotics. It was speculated that gallstones could be a consequence of phenothiazine-induced cholestasis.

Effects on sexual function. The phenothiazines can cause both impotence and ejaculatory dysfunction.[1] Thioridazine has been frequently implicated, and in an early report 60% of 57 male patients taking the drug reported sexual dysfunction compared with 25% of 64 men taking other antipsychotics.[2] There are also several reports of priapism with phenothiazines;[1,3-5] alpha-adrenoceptor blocking properties of these compounds may be partly responsible. Male sexual dysfunction, including priapism, has been reported only rarely with other classical antipsychotics such as the butyrophenones, diphenylbutylpiperidines, and thioxanthenes.[6] Priapism has also been reported with clozapine[7] and other atypical antipsychotics. The effects of antipsychotics on female sexual function are less well studied. Orgasmic dysfunction has been reported with thioridazine, trifluoperazine, and fluphenazine.[8]

The effects of hyperprolactinaemia (see Effects on Endocrine Function, above) on sexual function are described on p.2079.

Effects on the skin. *DEPOT INJECTION.* Of 217 patients who received a combined total of 2354 depot antipsychotic injections 42 (19.4%) had local problems at the site of injection; 18 (8.3%) experienced chronic complications and 30 (13.8%) acute reactions.[1] Acute problems reported included 31 episodes of unusual pain, 21 of bleeding or haematoma, 19 of clinically important leakage of drug from injection site, 11 of acute inflammatory indurations, and 2 of transient nodules. Complications were more common in patients receiving concentrated preparations, higher doses, weekly injections, haloperidol decanoate or zuclopenthixol decanoate, and injection volumes greater than 1 mL and in those treated for more than 5 years. Chronic reactions were more common in patients aged over 50 years.

1. Hay J. Complications at site of injection of depot neuroleptics. *BMJ* 1995; **311:** 421.

PHOTOSENSITIVITY. Testing in 7 subjects taking chlorpromazine revealed that photosensitivity reactions manifested primarily as immediate erythema and that sensitivity was primarily to light in the long ultraviolet (UVA) and visible wavebands. Sensitivity to UVB was normal.[1] The incidence of photosensitivity reactions to chlorpromazine has been given as 3%. However, a higher incidence of 16-25% has also been reported.[2]

PIGMENTATION. The pigment found in the skin of patients treated with chlorpromazine was considered[1] to be a chlorpromazine-melanin polymer formed in a light-catalysed anaerobic reaction. Hydrogen chloride liberated during the reaction could account for the skin irritation. Intracutaneous injection of a preparation of the polymer into 2 volunteers produced a bluish-purple discoloration which faded in 3 days.

Extrapyramidal disorders. Antipsychotics and a number of other drugs, including antiemetics such as metoclopramide and some antidepressants, can produce a range of dyskinesias or involuntary movement disorders involving the extrapyramidal motor system, including parkinsonism, akathisia, acute dystonia, and chronic tardive dyskinesia.[1-4] Such reactions are a major problem in the clinical management of patients receiving antipsychotics. Reactions of this type can occur with any antipsychotic, but (excluding tardive dyskinesia) are particularly prominent during treatment with high-potency drugs such as the tricyclic piperazines and butyrophenones. Antipsychotics such as clozapine carry a low risk of extrapyramidal effects and are therefore described as atypical antipsychotics. The incidence of tardive dyskinesia does appear to be minimal with clozapine, although there is less evidence for other atypical antipsychotics (p.982; but see also below).

Of 2811 patients studied[5] in the first few months of therapy with prochlorperazine (a drug with a high propensity to cause extrapyramidal reactions), 57 reported adverse effects, 16 of which involved the extrapyramidal system. There were 4 dystonic-dyskinesic reactions (an incidence of 1 in 464 and 1 in 707 for patients aged under and over 30 years respectively), 9 reports of parkinsonism (under 60 years, 1 in 1555; over 60 years, 1 in 159), and 3 reports of akathisia (1 in 562).

One explanation of extrapyramidal disorders is an imbalance between dopaminergic and cholinergic systems in the brain. However, this simple model fails to explain the co-existence of a variety of extrapyramidal effects, and several alternative mechanisms have been proposed.[2,6] Hypotheses based on interactions between different dopamine receptor types may help to explain the decreased tendency of some antipsychotic drugs to induce these reactions (see Action under Uses and Administration, below).

AKATHISIA. Akathisia is a condition of mental and motor restlessness in which there is an urge to move about constantly and an inability to sit or stand still. It is the most common motor adverse effect of treatment with antipsychotics.[1] Acute akathisia is dose-dependent, usually develops within a few days of beginning treatment or after a rapid increase in dose, and usually improves if the drug is stopped or the dose reduced. *Antimuscarinic antiparkinsonian drugs* appear to provide only limited benefit, although success may be more likely in patients with concomitant parkinsonism. A low dose of a *beta blocker* such as *propranolol* (although good evidence is lacking[2]) or a *benzodiazepine*[3] may be helpful. Improvement has also been reported with *clonidine* and *amantadine* but the usefulness of these drugs may be limited by adverse effects or development of tolerance, respectively. The tardive form, like tardive dyskinesia (see below), which appears after several months of treatment, does not respond to antimuscarinics and is difficult to treat.

DYSTONIA. Acute dystonic reactions, which mainly affect the muscles of the face, neck, and trunk and include jaw clenching (trismus), torticollis, and oculogyric crisis are reported to occur in up to 10% of patients taking antipsychotics. Laryngeal dystonia is rare, but potentially fatal.[1] Dystonias usually occur within the first few days of treatment or after a dosage increase but may also develop on withdrawal. They are transitory, and are most common in children and young adults. Dystonic reactions may be controlled by *antimuscarinics* such as *biperiden* or *procyclidine*, or *antihistamines* such as *diphenhydramine* or *promethazine*.[2] *Benzodiazepines* such as *diazepam* can also be used. Prophylactic antimuscarinics can prevent the development of dystonias, but routine use is not recommended as not all patients require them and tardive dyskinesia may be unmasked or worsened (see below); such a strategy should probably be reserved for short-term use in those at high risk of developing dystonic reactions, such as young adults starting treatment with high-potency antipsychotics or in patients with a history of drug-induced dystonias.[3,4] Some patients may develop tardive dystonia. A range of drugs has been tried in this condition but without consistent benefit.[5]

PARKINSONISM. Parkinsonism, often indistinguishable from idiopathic Parkinson's disease (p.791), may develop during therapy with antipsychotics, usually after the first few weeks or months of treatment. It is generally stated to be more common in adults and the elderly, although a retrospective study with haloperidol found an inverse relationship between drug-induced parkinsonism and age.[1] This parkinsonism is generally reversible on drug withdrawal or dose reduction, and may sometimes disappear gradually despite continued drug therapy. *Antimuscarinic antiparkinsonian* drugs are used to suppress the symptoms of parkinsonism.[2] However, they are often minimally effective and commonly cause adverse effects. Routine use for prophylaxis is not recommended because of the risk of unmasking or exacerbating tardive dyskinesia (see below). *Amantadine* is an alternative to the antimuscarinics.[2]

2. Mamo DC, *et al.* Managing antipsychotic-induced parkinsonism. *Drug Safety* 1999; **20:** 269–75.

TARDIVE DYSKINESIA. The central feature of tardive dyskinesia is orofacial dyskinesia characterised by protrusion of the tongue ('fly catching'), lipsmacking, sucking, lateral chewing, and pouting of the lips and cheeks. The trunk and limbs also become involved with choreiform movements such as repetitive 'piano-playing' hand movements, shoulder shrugging, foot tapping, or rocking movements. The prevalence of tardive dyskinesia among those receiving antipsychotics varies widely but up to 60% of patients may develop symptoms. In most cases the condition is mild and not progressive and tends to wax and wane. Although tardive dyskinesia usually develops after many years of antipsychotic therapy no clear correlation has been shown between development of the condition and the length of drug treatment or the type and class of drug. However, *clozapine* does not appear to be associated with the condition and in some cases use has resulted in improvement of established tardive dyskinesia (see Schizophrenia under Clozapine, p.985). Whether other atypical antipsychotics also have a lower incidence of tardive dyskinesia remains to be established, although there are some data to suggest that this may be the case.[1-3] Symptoms of tardive dyskinesia often develop after stopping the antipsychotic or after dose reduction. Risk factors include old age, female sex, affective disorder, schizophrenia characterised by negative symptoms, and organic brain damage.

Suggested causes of tardive dyskinesia include dopaminergic overactivity, imbalance between dopaminergic and cholinergic activity, supersensitivity of postsynaptic dopamine receptors, presynaptic catecholaminergic hyperfunction, and alterations of the gamma-aminobutyric acid (GABA) system.

Options in the management of tardive dyskinesia include attempts at treatment while maintaining antipsychotic therapy, or withdrawal of antimuscarinic therapy, and either withdrawal of the antipsychotic or reduction of the dosage to the minimum required or transfer to an atypical antipsychotic.

Although many drugs have been tried in the **treatment** of tardive dyskinesia there have been relatively few double-blind studies. Reviews of tardive dyskinesia[1,4-6] have concluded that there appeared to be no reliable or safe treatment. Overall, classical antipsychotics appeared to be the most effective in masking symptoms of tardive dyskinesia but tolerance may develop and a worsening of the underlying pathophysiology by antipsychotics had to be assumed on theoretical grounds. Other drugs with antidopaminergic actions which were probably of comparable efficacy included *reserpine*, *oxypertine*, *tetrabenazine*, and *metirosine*. The next most effective drugs were considered to be noradrenergic antagonists such as *clonidine*. Some encouraging results had also been obtained with GABAergic drugs such as the *benzodiazepines*, *baclofen*, *progabide*, *valproate*, and *vigabatrin*, although systematic reviews of studies of some GABAergic drugs[7] including benzodiazepines[8] found the evidence inconclusive and/or unconvincing. The efficacy of cholinergics could not be confirmed.[9,10] Dopaminergics and antimuscarinics mostly exacerbated symptoms but others[11] had commented that there was no convincing evidence that long-term use of antimuscarinics increased the risk of developing the condition. Other drugs whose value is unclear include *vitamin E*[12] and some calcium-channel blockers.[13]

Withdrawal of the causative drug usually worsens the condition although symptoms often diminish or disappear over a period of weeks or sometimes a year or so. Success is most likely in younger patients. During withdrawal, drugs such as *diazepam* or *clonazepam* may be given to alleviate symptoms. Although classical antipsychotics are effective, their routine use to suppress symptoms is not recommended but they may be required for acute distressing or life-threatening reactions or in chronic tardive dyskinesia unresponsive to other treatment. In extremely severe resistant cases some have used an antipsychotic with *valproate* or *carbamazepine* or *reserpine* with *metirosine*.

In view of the unsatisfactory management of tardive dyskinesia, emphasis is placed on its **prevention**. Antipsychotics should be prescribed only when clearly indicated, should be given in the minimum dose, and continued only when there is evidence of benefit. Although drug holidays have been suggested for reducing the risk of tardive dyskinesia, the limited evidence indicates that interruptions in drug treatment may increase the risk of both persistent dyskinesia and psychotic relapse.[14] Increasing the dose of antipsychotic generally improves the condition, but only temporarily.

Neuroleptic malignant syndrome. The neuroleptic malignant syndrome (NMS) is a potentially fatal reaction to a number of drugs including antipsychotics and other dopamine antagonists such as metoclopramide. The clinical **features** of the classic syndrome are usually considered to include hyperthermia, severe extrapyramidal symptoms including muscular rigidity, autonomic dysfunction, and altered levels of consciousness. Skeletal muscle damage may occur and the resulting myoglobinuria may lead to renal failure. However, there appear to be no universal criteria for diagnosis. Some believe the classic syndrome to be the extreme of a range of effects associated with antipsychotics and have introduced the concept of milder variants or incomplete forms. Others consider it to be a rare idiosyncratic reaction and suggest that the term neuroleptic malignant syndrome should be reserved for the full-blown reaction. Consequently, estimates of the **incidence** vary greatly and recent estimates have ranged from 0.02 to 2.5%. The mortality rate has been substantial; although it has decreased over the years with improved diagnosis and management, this may also be due to the detection and inclusion of the milder or incomplete variants. Possible risk factors include dehydration, pre-existing organic brain disease, and a history of a previous episode; young males have also been reported to be particularly susceptible.

The **pathogenesis** of NMS is still unclear. Blockade of dopaminergic receptors in the corpus striatum is thought to cause muscular contraction and rigidity generating heat while blockade of dopaminergic receptors in the hypothalamus leads to impaired heat dissipation. Peripheral mechanisms such as vasomotor paralysis may also play a role. Also a syndrome resembling NMS has been seen after withdrawal of treatment with dopamine agonists such as levodopa (see p.806). Symptoms develop rapidly over 24 to 72 hours and may occur days to months after starting antipsychotic medication or increase in dosage, but no consistent correlation with dosage or length of therapy has been found. Symptoms may last for up to 14 days after stopping oral antipsychotics, or for up to 4 weeks after stopping depot preparations. All antipsychotics are capable of inducing NMS; depot preparations may, however, be associated with prolonged recovery once it develops, and hence a higher mortality rate. Use with lithium carbonate or antimuscarinics may increase the likelihood of developing the syndrome.

Antipsychotic medication should be withdrawn immediately once the diagnosis of the classic syndrome is made; this should be followed by symptomatic and supportive **therapy** including cooling measures, correction of dehydration, and treatment of cardiovascular, respiratory, and renal complications. Whether antipsychotics should be withdrawn from patients with mild attacks and how they should be managed is a matter of debate.

The efficacy of specific drug therapy remains to be proven, and justification for use is based mainly on case reports.

- *Dantrolene* was first used because of its effectiveness in malignant hyperthermia. It has a direct action on skeletal muscle and may be particularly effective for the reversal of hyperthermia of muscle origin.
- In contrast, dopaminergic agonists may resolve hyperthermia of central origin, restoring dopaminergic transmission and hence alleviating extrapyramidal symptoms. There have been isolated reports of success with *amantadine* and *levodopa* but *bromocriptine* is generally preferred. Any underlying psychosis may, however, be aggravated by dopaminergic drugs.
- Since dantrolene and dopaminergics act in different ways a combination of the two might be useful, but any advantage remains to be demonstrated.
- *Antimuscarinics* are generally considered to be of little use and may aggravate the associated hyperthermia.
- *Benzodiazepines* may be used for sedation in agitated patients and may be of use against concomitant catatonia. ECT may be an alternative in refractory cases of NMS or when catatonic symptoms are present.

Re-introduction of antipsychotic therapy may be possible but is not always successful and extreme caution is advised. It has been recommended that a gap of at least 5 to 14 days should be left after resolution of the symptoms before attempting re-introduction.

Withdrawal. Stopping treatment with an antipsychotic abruptly may produce withdrawal symptoms, the most common of which are nausea, vomiting, anorexia, diarrhoea, rhinorrhoea, sweating, myalgias, paraesthesias, insomnia, restlessness, anxiety, and agitation.[1] Patients may also experience vertigo, alternate feelings of warmth and coldness, and tremor. Symptoms generally begin within 1 to 4 days of withdrawal and abate within 7 to 14 days. They are more severe and frequent when antimuscarinics are stopped simultaneously.

Treatment of Adverse Effects

After an overdose of chlorpromazine, patients should be managed with intensive symptomatic and supportive therapy. Activated charcoal should be given by mouth if a substantial amount of the phenothiazine has been taken within 1 hour of presentation, provided that the airway can be protected; emptying the stomach by gastric lavage has sometimes been recommended. Dialysis is of little or no value in poisoning by phenothiazines.

Hypotension should be corrected by raising the patient's legs, or in severe cases by intravascular volume expansion. An inotrope such as dopamine may be considered in refractory cases. If a vasoconstrictor is considered necessary in the management of phenothiazine-induced hypotension the use of adrenaline or other sympathomimetics with high beta-adrenergic agonist properties should be avoided since the alpha-blocking effects of phenothiazines may impair the usual alpha-mediated vasoconstriction of these drugs, resulting in unopposed beta-adrenergic stimulation and increased hypotension.

The treatment of neuroleptic malignant syndrome and the difficulties of treating extrapyramidal adverse effects, especially tardive dyskinesia, are discussed above.

Precautions

Chlorpromazine and other phenothiazines are contra-indicated in patients with pre-existing CNS depression or coma, bone-marrow suppression, phaeochromocytoma, or prolactin-dependent tumours. They should be used with caution or not at all in patients with impaired liver, kidney, cardiovascular, cerebrovascular, and respiratory function and in those with angle-closure glaucoma, a history of jaundice, parkinsonism, diabetes mellitus, hypothyroidism, myasthenia gravis, paralytic ileus, prostatic hyperplasia, or urinary retention. Care is required in patients with epilepsy or a history of seizures as phenothiazines may lower the seizure threshold. Debilitated patients may be more prone to the adverse effects of phenothiazines as may the elderly, especially those with dementia. For precautions of phenothiazines in pregnancy, see below.

The sedative effects of phenothiazines are most marked in the first few days of treatment; affected patients should not drive or operate machinery.

The effects of phenothiazines on the vomiting centre may mask the symptoms of overdosage of other drugs, or of disorders such as gastrointestinal obstruction. Use at extremes of temperature may be hazardous since body temperature regulation is impaired by phenothiazines.

Regular eye examinations are advisable for patients receiving long-term phenothiazine therapy and avoidance of undue exposure to direct sunlight is recommended. Phenothiazines should be used with caution in the presence of acute infection or leucopenia. Blood counts are advised if the patient develops an unexplained infection or fever.

Patients should remain supine for at least 30 minutes after parenteral doses of chlorpromazine; blood pressure should be monitored.

Abrupt withdrawal of phenothiazine therapy is best avoided.

AIDS. Isolated reports[1,2] have suggested that patients with AIDS may be particularly susceptible to antipsychotic-induced extrapyramidal effects.

2. Edelstein H, Knight RT. Severe parkinsonism in two AIDS patients taking prochlorperazine. *Lancet* 1987; **ii:** 341–2.

Asthma. Findings of a retrospective case-control study[1] appeared to indicate that asthmatic patients given antipsychotics were at an increased risk of death or near death from asthma.

1. Joseph KS, *et al.* Increased morbidity and mortality related to asthma among asthmatic patients who use major tranquillisers. *BMJ* 1996; **312:** 79–82.

Breast feeding. The American Academy of Pediatrics[1] considers that the use of chlorpromazine by mothers during breast feeding may be of concern, since there have been reports of galactorrhoea in the mother and of drowsiness, lethargy, and declines in developmental scores in the infant. The *BNF* considers that the use of antipsychotics such as chlorpromazine should be avoided by breast-feeding mothers unless absolutely necessary.

Chlorpromazine was detected[2] in all milk samples from 4 women at concentrations ranging from 7 to 98 nanograms/mL. Two of the women breast-fed their infants, but one infant showed no effects while the other was noted to be drowsy and lethargic;

milk-chlorpromazine concentrations were 7 and 92 nanograms/mL, respectively.

Children. Few phenothiazines are recommended for use in children; in particular there have been concerns about the use of phenothiazine derivatives in infants (see Sudden Infant Death Syndrome, p.588). For reference to the use of chlorpromazine in infants suffering neonatal abstinence syndrome see Substance Dependence, Opioids, under Uses and Administration, below.

Contact sensitisation. The *BNF* warns that because of the risk of contact sensitisation, health workers should avoid direct contact with chlorpromazine; tablets should not be crushed and solutions should be handled with care.

The elderly. The risk of *hip fracture* has been reported to be increased in elderly patients given antipsychotics. A large case-control study in patients over 65 found that current users of antipsychotics had a twofold increase in the risk of hip fractures.[1] The effect was dose-related and the increased risk was similar for chlorpromazine, haloperidol, and thioridazine. It was suggested that antipsychotic-induced sedation or orthostatic hypotension could increase the risk of falls in elderly persons. A study in 12 schizophrenic patients receiving antipsychotics plus other drugs such as antimuscarinics or benzodiazepines has suggested that long-term treatment with antipsychotics may decrease bone mineralisation.[2] A later study suggested that any increased risk of falls might be due to an effect of antipsychotics on balance as thioridazine was found to increase sway in elderly but not young subjects.[3] A meta-analysis of 40 studies[4] concluded that there was a small, but consistent, association between the use of most classes of psychotropic drugs, including antipsychotics, and falls. However, the evidence from these studies was based solely on observational data, with minimal adjustment for confounders, dosage, or duration of therapy.

There is some evidence[5,6] to suggest that the use of antipsychotics to manage behavioural complications of *dementia* may increase the rate of cognitive decline. Elderly patients with dementia, especially Lewy-body dementia, are reported to be highly susceptible to the extrapyramidal adverse effects of antipsychotic drugs,[7,8] and the reaction can be extremely serious, even fatal. If these drugs are to be used in elderly patients with dementia, then very low doses should be used, and special care should be taken if the dementia is suspected to be of the Lewy-body type since sudden life-threatening deterioration may occur.[9] Depot preparations should not be used and, since dopamine D_2 receptors may be involved, it has been suggested that consideration could be given to using an antipsychotic such as clozapine that does not principally antagonise those receptors;[8] however, the FDA now recommends that atypical antipsychotics should not be used in such patients because of evidence of an increased death rate (see Dementia, p.1024).

An *increased risk of death* has also been noted in elderly patients given classical antipsychotics. A retrospective cohort study,[10] involving nearly 23 000 patients given atypical or classical antipsychotics, found that classical antipsychotics were at least as likely as the atypicals to increase the risk of death in the elderly. The authors also suggested that the greatest increase in risk occurred soon after starting therapy and with higher doses of classical antipsychotics. A similar increase in risk with use of classical antipsychotics was also seen in a large retrospective population-based study[11] in elderly patients with dementia when compared with that seen with use of atypicals in this patient group.

For further discussion of the problems associated with the use of antipsychotics in disturbed behaviour in the elderly, see p.954.

Epilepsy. See Convulsions under Adverse Effects, above.

Folic acid deficiency. Concentrations of folate in serum and erythrocytes were reduced in 15 patients receiving long-term treatment with chlorpromazine or thioridazine.[1] All the patients had significant induction of hepatic microsomal enzymes. It was suggested that folate deficiency due to the induction of microsomal enzymes might subsequently limit enzyme induction and hence reduce drug metabolism, which could lead to symptoms of toxicity in patients apparently stabilised for a number of years. The dietary intake of patients on long-term treatment with enzyme-inducing drugs might be inadequate.

1. Labadarios D, *et al*. The effects of chronic drug administration on hepatic enzyme induction and folate metabolism. *Br J Clin Pharmacol* 1978; **5:** 167–73.

Hypoparathyroidism. There have been rare reports[1,2] of acute dystonic reactions associated with the use of phenothiazines in patients with untreated hypoparathyroidism. Caution was recommended in giving phenothiazine derivatives to patients with hypoparathyroidism and it was suggested that any acute reaction to such a drug should prompt investigation for some form of latent tetany.

2. Gur H, *et al.* Acute dystonic reaction to methotrimeprazine in hypoparathyroidism. *Ann Pharmacother* 1996; **30:** 957–9.

Pregnancy. Licensed product information generally does not recommend the use of phenothiazines in late pregnancy; such use may be associated with intoxication of the neonate. Chlorpromazine may prolong labour and should be withheld until the cervix is dilated 3 to 4 cm. Overall, however, it has been suggested[1] that the criteria for the selection of an antipsychotic for use in pregnant women do not differ from those used in non-pregnant women. It was also concluded that the benefits of continuing antipsychotic treatment at the minimum effective dose would usually outweigh any risks to the fetus.

A review[2] of the use of phenothiazines in pregnancy concluded that there was no clear evidence that these drugs caused a significant increase in fetal malformations. Nevertheless it was considered advisable that if pregnant patients required such treatment, then a single phenothiazine should be used and that it should be one of the established drugs.

A subsequent review[3] of the literature reported that women with schizophrenia are generally at increased risk for poor obstetric outcomes including preterm delivery, low birth-weight, and neonates who are small for their gestational age. It was also considered that there was an increased risk of congenital malformation when the fetus was exposed to phenothiazines during weeks 4 to 10 of gestation but this conclusion and the methods used to select the data to review have been criticised.[4]

See also p.563 for the use of phenothiazines as antiemetics during pregnancy.

Renal impairment. Although there do not seem to be specific indications for dosage adjustment of phenothiazines in renal impairment, the *BNF* considers that cerebral sensitivity to antipsychotics may be increased in severe renal impairment. Phenothiazine-induced toxic psychosis occurred in 4 patients with chronic renal failure who had been given chlorpromazine.[1]

1. McAllister CJ, *et al.* Toxic psychosis induced by phenothiazine administration in patients with chronic renal failure. *Clin Nephrol* 1978; **10:** 191–5.

Interactions

The most common interactions encountered with phenothiazines such as chlorpromazine result from use with drugs that have similar pharmacological actions. Symptoms of CNS depression may be enhanced by other drugs with CNS-depressant properties including alcohol, general anaesthetics, hypnotics, anxiolytics, and opioids. When given with other drugs that produce orthostatic hypotension, dosage adjustments may be necessary. However, it should be noted that phenothiazines have been reported to reduce the antihypertensive action of guanethidine and other adrenergic neurone blockers. As many phenothiazines possess antimuscarinic actions they can potentiate the adverse effects of other drugs with antimuscarinic actions, including tricyclic antidepressants and the antimuscarinic antiparkinsonian drugs that may be given to treat phenothiazine-induced extrapyramidal effects. In theory, antipsychotics with dopamine-blocking activity and dopaminergic drugs such as those used to treat parkinsonism may be mutually antagonistic. Use with metoclopramide may increase the risk of antipsychotic-induced extrapyramidal effects.

There is an increased risk of arrhythmias when antipsychotics are used with drugs that prolong the QT interval, including certain antiarrhythmics, other antipsychotics, some non-sedating antihistamines, antimalarials, and cisapride; use with diuretics that cause electrolyte imbalance (particularly hypokalaemia) may also have the same effect. There is also an increased risk of arrhythmias when tricyclic antidepressants are used with antipsychotics that prolong the QT interval.

Because of an increased risk of seizures US licensed product information for chlorpromazine recommends withdrawal before the use of metrizamide for radiographic procedures.

◊ Most interactions with antipsychotics are as a result of additive pharmacological effects.[1] Since tolerance develops to many of these adverse effects, interactions are likely to be most important in the early stages of combination therapy.

1. Livingston MG. Interactions that matter: 11 antipsychotic drugs. *Prescribers' J* 1987; **27** (Dec): 26–9.

Alcohol. Phenothiazines may increase the CNS depressant effects of alcohol. There has been a report of akathisia and dystonia after consumption of alcohol by patients taking antipsychotics;[1] alcohol might lower the threshold of resistance to neurotoxic adverse effects.

1. Lutz EG. Neuroleptic-induced akathisia and dystonia triggered by alcohol. *JAMA* 1976; **236:** 2422–3.

Antacids. Studies in 6 patients showed that chlorpromazine plasma concentrations were significantly lower after giving chlorpromazine with an *aluminium hydroxide* and *magnesium trisilicate* antacid gel (*Gelusil*) than after chlorpromazine alone.[1] *In-vitro* studies indicated that chlorpromazine was highly bound to the gel.

1. Fann WE, *et al*. Chlorpromazine: effects of antacids on its gastrointestinal absorption. *J Clin Pharmacol* 1973; **13:** 388–90.

Antiarrhythmics. There is an increased risk of arrhythmias when antipsychotics are given with other drugs that prolong the QT interval. It has been recommended that the use of pimozide or thioridazine with antiarrhythmics (especially *amiodarone*, *disopyramide*, *procainamide*, and *quinidine*) should be avoided. Use of haloperidol with amiodarone is also not recommended. A study[1] in healthy subjects has suggested that quinidine might increase plasma concentrations of haloperidol.

1. Young D, *et al.* Effect of quinidine on the interconversion kinetics between haloperidol and reduced haloperidol in humans: implications for the involvement of cytochrome P450IID6. *Eur J Clin Pharmacol* 1993; **44:** 433–8.

Antibacterials. Seven schizophrenic patients whose antitubercular therapy included *rifampicin* (in addition to isoniazid, and in some cases also ethambutol) had lower serum concentrations of haloperidol compared with tuberculotic schizophrenic patients receiving no antimycobacterials and with non-tuberculotic schizophrenics.[1] Pharmacokinetic studies involving some of these patients indicated accelerated haloperidol clearance in the presence of rifampicin. Abnormally high serum-haloperidol concentrations were observed in 3 of 18 patients treated with *isoniazid* alone.

Black galactorrhoea occurred in a patient receiving *minocycline*, perphenazine, amitriptyline hydrochloride, and diphenhydramine hydrochloride.[2] Simultaneous occurrence of phenothiazine-induced galactorrhoea and tetracycline-induced pigmentation was considered responsible.

Sudden cardiac deaths have been reported[3] in patients given *clarithromycin* and pimozide. Elevated pimozide plasma concentrations were recorded after pretreatment with clarithromycin.[4] The manufacturer of pimozide has recommended that pimozide should not be used with macrolide antibacterials.

4. Desta Z, *et al.* Effect of clarithromycin on the pharmacokinetics and pharmacodynamics of pimozide in healthy poor and extensive metabolisers of cytochrome P450 2D6 (CYP2D6). *Clin Pharmacol Ther* 1999; **65:** 10–20.

Anticoagulants. For reference to the effects of some antipsychotics on the activity of anticoagulants, see under Warfarin, p.1430.

Antidepressants. Interactions between antipsychotics and *tricyclic antidepressants* are generally of two forms: additive pharmacological effects such as antimuscarinic effects or hypotension; or pharmacokinetic interactions. Although not commonly reported in the literature, additive antimuscarinic activity may be a significant risk especially in the elderly. Careful drug selection might help to prevent the development of serious adverse effects. Mutual inhibition of liver enzymes involved in the metabolism of both the antipsychotic and the tricyclic antidepressant might result in increased plasma concentrations of either drug. In one study,[1] addition of *nortriptyline* to chlorpromazine therapy produced an increase in plasma concentrations of chlorpromazine but this resulted in a paradoxical increase in agitation and tension.

There is an increased risk of arrhythmias when tricyclic antidepressants are given with other drugs that prolong the QT interval. It has been recommended that the use of pimozide or thioridazine with tricyclic antidepressants should be avoided.

Increased serum concentrations of haloperidol have occurred when patients were also given *fluoxetine*,[2] *fluvoxamine*,[3] or *nefazodone*. Isolated reports[4-9] of extrapyramidal symptoms, psychoneuromotor syndrome, stupor, bradycardia, and urinary retention associated with use of fluoxetine with antipsychotics suggest that fluoxetine might exacerbate the adverse effects of antipsychotics or produce additive toxicity. Similar CNS effects have been noted in subjects given perphenazine and *paroxetine*.[10] There has also been an isolated report of a patient who complained of amenorrhoea and galactorrhoea after fluvoxamine was added to loxapine therapy.[11] Significant increases in the plasma concentrations of thioridazine have occurred after use with fluvoxamine.[12] Paroxetine may also inhibit the metabolism of thioridazine, resulting in increased thioridazine plasma concentrations; UK licensed product information for paroxetine contra-indicates their concomitant use. The US licensed product information for paroxetine states that giving paroxetine with pimozide was associated with a mean increase of 151% in the area under the concentration-time curve of pimozide and 62% in its mean maximum plasma concentration. Due to the narrow therapeutic index of pimozide concomitant use of these 2 drugs is contra-indicated.

Combinations of antipsychotics and *lithium* should be used with care. Lithium can reduce plasma-chlorpromazine concentrations and there is a report of ventricular fibrillation on withdrawal of lithium from a patient also taking chlorpromazine. Chlorpromazine has also been reported to enhance the excretion of lithium. Neurotoxic or extrapyramidal symptoms have been reported rarely in patients taking antipsychotics and lithium; these may be atypical cases of lithium toxicity or neuroleptic malignant syndrome. The above issues are discussed in detail, and references given, on p.405.

A patient on long-term trifluoperazine treatment developed neuroleptic malignant syndrome after a single dose of *venlafaxine*.[13] The authors noted that the manufacturers of venlafaxine have received a small number of similar reports after introduction of venlafaxine in patients receiving antipsychotics including molindone.

There have been occasional reports of sexual disinhibition in patients taking *tryptophan* with phenothiazines.

Antidiabetic drugs. Since chlorpromazine may cause hyperglycaemia or impair glucose tolerance the dose of *oral hypoglycaemics* or of *insulin* may need to be increased in diabetics.

Antiepileptics. *Carbamazepine*, *phenobarbital*, and *phenytoin* are potent enzyme inducers and use may decrease plasma concentrations of antipsychotics or their active metabolites.[1-5] The clinical effect of any interaction has not been consistent; worsening, improvement, or no change in psychotic symptoms have all been noted. Delirium has been reported in a patient given haloperidol and carbamazepine.[6] Phenytoin might also exacerbate antipsychotic-induced dyskinesia.[7] Care should be taken when withdrawing enzyme-inducing antiepileptics as this may result in a rise in antipsychotic serum concentrations.[8]

The effect of antipsychotics on antiepileptic concentrations is discussed on p.475 (carbamazepine) and p.499 (phenytoin). It should also be remembered that antipsychotics may lower the seizure threshold.

Antihistamines. For the effect of a preparation containing *chlorphenamine maleate* and phenylpropanolamine hydrochloride on thioridazine, see Sympathomimetics (below). There is an increased risk of arrhythmias when antipsychotics are given with other drugs that prolong the QT interval. It has been recommended that the use of pimozide or thioridazine with antihistamines such as *astemizole* or *terfenadine* should be avoided.

Antihypertensives. For discussion of the interaction between phenothiazines and drugs with hypotensive properties, see Interactions, above. For a report of chlorpromazine enhancing the hyperglycaemic effect of *diazoxide*, see p.1258. For reports of hypertension or dementia in patients given *methyldopa* and antipsychotics, see p.1335.

Antimalarials. Pretreatment with single doses of *chloroquine sulfate*, *amodiaquine hydrochloride*, or *sulfadoxine with pyrimethamine* increased the plasma concentrations of chlorpromazine and 7-hydroxychlorpromazine, but not of chlorpromazine sulfoxide, in schizophrenic patients maintained on chlorpromazine.[1] The raised plasma concentrations appeared to be associated with a greater level of sedation.

There is an increased risk of arrhythmias when antipsychotics are given with other drugs that prolong the QT interval. It has been recommended that the use of antipsychotics, and pimozide in particular, with antimalarials such as *halofantrine*, *mefloquine*, or *quinine* should be avoided. For the possible effects of the use of *quinidine* with antipsychotics see Antiarrhythmics, above.

1. Makanjuola ROA, *et al.* Effects of antimalarial agents on plasma levels of chlorpromazine and its metabolites in schizophrenic patients. *Trop Geogr Med* 1988; **40:** 31–3.

Antimigraine drugs. A report[1] of a patient receiving loxapine who had a dystonic reaction within 15 minutes of subcutaneous *sumatriptan* suggests that these two drugs might interact or potentiate each other's adverse effects. However, the patient had a previous history of dystonic reactions associated with haloperidol and was receiving benzatropine prophylactically. Furthermore, the dose of loxapine had been increased 2 days before the event and this may have predisposed the patient to dystonia.

1. Garcia G, *et al.* Dystonic reaction associated with sumatriptan. *Ann Pharmacother* 1994; **28:** 1199.

Antiparkinsonian drugs. Antiparkinsonian drugs are sometimes given with antipsychotics for the management of antipsychotic-induced adverse effects including extrapyramidal disorders (see under Adverse Effects, above). Theoretically, dopaminergics such as *levodopa* and *bromocriptine* might induce or exacerbate psychotic symptoms. A study in 18 subjects and review of the literature suggested that bromocriptine can be used safely in patients at risk of psychotic illness provided they are clinically stable and maintained on antipsychotics.[1] Conversely, antipsychotics might antagonise the effects of dopaminergics; diminished therapeutic effects of levodopa have been noted with several antipsychotics (see p.808) and thioridazine has been reported to oppose the prolactin-lowering action of bromocriptine (see p.800).

Additive antimuscarinic adverse effects are obviously a risk when antimuscarinic antiparkinsonian drugs are given with antipsychotics. Although these are generally mild, serious reactions have occurred. *Trihexyphenidyl*[2] and *orphenadrine*[3] have both been reported to decrease plasma concentrations of chlorpromazine, possibly by interfering with absorption from the gastrointestinal tract. Reports suggesting that antimuscarinics may antagonise the antipsychotic effects of antipsychotics at the neurotransmitter level require substantiating.

1. Perovich RM, *et al.* The behavioral toxicity of bromocriptine in patients with psychiatric illness. *J Clin Psychopharmacol* 1989; **9:** 417–22.
2. Rivera-Calimlim L, *et al.* Effects of mode of management on plasma chlorpromazine in psychiatric patients. *Clin Pharmacol Ther* 1973; **14:** 978–86.
3. Loga S, *et al.* Interactions of orphenadrine and phenobarbitone with chlorpromazine: plasma concentrations and effects in man. *Br J Clin Pharmacol* 1975; **2:** 197–208.

Antipsychotics. Elevated plasma levels of haloperidol were reported[1] in a patient being treated for schizophrenia when *chlorpromazine* or *clozapine* were also given.

1. Allen SA. Effect of chlorpromazine and clozapine on plasma concentrations of haloperidol in a patient with schizophrenia. *J Clin Pharmacol* 2000; **40:** 1296–7.

Antivirals. *Ritonavir* may increase the plasma concentration of some antipsychotics. The increases expected for pimozide were considered in licensed product information for ritonavir to be large enough to recommend that these drugs should not be used together. Other classical antipsychotics predicted to have increases include haloperidol, perphenazine, and thioridazine; it was recommended that monitoring of drug concentrations and/or adverse effects were required when used with ritonavir.

Beta blockers. Chlorpromazine and *propranolol* may mutually inhibit each other's hepatic metabolism. Propranolol has been reported to increase plasma concentrations of chlorpromazine[1] and thioridazine,[2,3] and *pindolol* to increase plasma-thioridazine concentrations.[4] Neither beta blocker tested had a significant effect on haloperidol concentrations,[3,4] although there is a report of severe hypotension or cardiopulmonary arrest occurring on 3 occasions in a schizophrenic patient given haloperidol with propranolol.[5] The clinical significance of antipsychotic-beta blocker interactions is unclear.

For the effect of chlorpromazine on propranolol, see Anxiolytics and Antipsychotics, under Interactions of Beta Blockers, p.1228.

There is an increased risk of arrhythmias when antipsychotics are given with other drugs that prolong the QT interval. The use of antipsychotics, and pimozide in particular, with *sotalol* should be avoided.

5. Alexander HE, *et al.* Hypotension and cardiopulmonary arrest associated with concurrent haloperidol and propranolol therapy. *JAMA* 1984; **252:** 87–8.

Buspirone. The use of haloperidol with buspirone has resulted in increased serum haloperidol concentrations. However, while some[1] found the mean rise in serum-haloperidol concentrations to be 26%, that observed by others[2] was not statistically significant.

1. Goff DC, *et al.* An open trial of buspirone added to neuroleptics in schizophrenic patients. *J Clin Psychopharmacol* 1991; **11:** 193–7.
2. Huang HF, *et al.* Lack of pharmacokinetic interaction between buspirone and haloperidol in patients with schizophrenia. *J Clin Pharmacol* 1996; **36:** 963–9.

Cimetidine. Despite expectations that cimetidine might reduce the metabolism of chlorpromazine, mean steady-state plasma concentrations of chlorpromazine fell rather than rose in 8 patients given cimetidine for 7 days in addition to regular chlorpromazine therapy.[1] The explanation was probably that cimetidine interfered with chlorpromazine absorption. Excessive sedation, necessitating a reduction in chlorpromazine dosage, has been reported[2] after addition of cimetidine to the drug therapy of 2 chronic schizophrenics.

1. Howes CA, *et al.* Reduced steady-state plasma concentrations of chlorpromazine and indomethacin in patients receiving cimetidine. *Eur J Clin Pharmacol* 1983; **24:** 99–102.
2. Byrne A, O'Shea B. Adverse interaction between cimetidine and chlorpromazine in two cases of chronic schizophrenia. *Br J Psychiatry* 1989; **155:** 413–15.

Cocaine. The risk of antipsychotic-induced dystonic reactions may be increased in cocaine abusers. Dystonia occurred in 6 of 7 cocaine abusers treated with haloperidol.[1]

1. Kumor K, *et al.* Haloperidol-induced dystonia in cocaine addicts. *Lancet* 1986; **ii:** 1341–2.

Desferrioxamine. Loss of consciousness lasting 48 to 72 hours occurred in 2 patients given prochlorperazine during desferrioxamine therapy.[1] Prochlorperazine may enhance the removal of transition metals from brain cells by desferrioxamine.

1. Blake DR, *et al.* Cerebral and ocular toxicity induced by desferrioxamine. *Q J Med* 1985; **56:** 345–55.

Disulfiram. A psychotic patient, previously maintained with plasma-perphenazine concentrations of 2 to 3 nanomol/mL on a dose of 8 mg twice daily by mouth, was readmitted with subtherapeutic plasma-perphenazine concentrations of less than 1 nanomol/mL, despite unchanged dosage, after disulfiram therapy.[1] The concentration of the sulfoxide metabolite of perphenazine was much increased. After a change from oral to intramuscular perphenazine therapy there was a substantial clinical improvement associated with a return to therapeutic plasma concentrations of perphenazine and a fall in concentration of the metabolite. Disulfiram appears to greatly enhance biotransformation of oral perphenazine to inactive metabolites, but parenteral administration avoids the 'first-pass' effect in the liver.

1. Hansen LB, Larsen N-E. Metabolic interaction between perphenazine and disulfiram. *Lancet* 1982; **ii:** 1472.

General anaesthetics. A schizophrenic patient without a history of epilepsy who was receiving oral chlorpromazine and flupentixol depot injection had a convulsive seizure when given *enflurane* anaesthesia.[1]

1. Vohra SB. Convulsions after enflurane in a schizophrenic patient receiving neuroleptics. *Can J Anaesth* 1994; **41:** 420–2.

Naltrexone. Two patients maintained on thioridazine experienced intense sleepiness and lethargy after receiving 2 doses of naltrexone.[1]

1. Maany I, *et al.* Interaction between thioridazine and naltrexone. *Am J Psychiatry* 1987; **144:** 966.

NSAIDs. A report of severe drowsiness and confusion in patients given haloperidol with *indometacin*.[1]

1. Bird HA, *et al.* Drowsiness due to haloperidol/indomethacin in combination. *Lancet* 1983; **i:** 830–1.

Opioid analgesics. For reference to the effects of phenothiazines on *pethidine*, see p.114.

Piperazine. There has been an isolated report[1] of convulsions associated with the use of chlorpromazine in a child who had received piperazine several days earlier. Subsequent *animal*[1-3] studies produced conflicting evidence for an interaction and it was suggested[3] that an interaction would only be clinically significant when high concentrations of piperazine were reached in the body.

1. Boulos BM, Davis LE. Hazard of simultaneous administration of phenothiazine and piperazine. *N Engl J Med* 1969; **280:** 1245–6.
2. Armbrecht BH. Reaction between piperazine and chlorpromazine. *N Engl J Med* 1970; **282:** 1490–1.
3. Sturman G. Interaction between piperazine and chlorpromazine. *Br J Pharmacol* 1974; **50:** 153–5.

Sympathomimetics. For reference to the possible interaction between phenothiazines and *adrenaline*, see Treatment of Adverse Effects, above.

A 27-year-old woman with schizophrenia and T-wave abnormality of the heart,[1] receiving thioridazine 100 mg daily with procyclidine 2.5 mg twice daily, died from ventricular fibrillation within 2 hours of also taking a single dose of a preparation reported to contain chlorphenamine maleate 4 mg with *phenylpropanolamine hydrochloride* 50 mg (*Contac C*).

1. Chouinard G, *et al.* Death attributed to ventricular arrhythmia induced by thioridazine in combination with a single Contac C capsule. *Can Med Assoc J* 1978; **119:** 729–31.

Tobacco smoking. Smoking has been shown to decrease the incidence of chlorpromazine-induced sedation[1,2] and orthostatic hypotension.[2] Studies indicate that the clearance of chlorpromazine,[3] fluphenazine,[4] tiotixene,[5] haloperidol,[6] and thioridazine[7] may be increased in patients who smoke. It has been suggested that some of the components of smoke may act as liver-enzyme inducers. The clinical significance of this effect is unclear but the possible need to use increased doses in smokers should be borne in mind.

1. Swett C. Drowsiness due to chlorpromazine in relation to cigarette smoking: a report from the Boston Collaborative Drug Surveillance Program. *Arch Gen Psychiatry* 1974; **31:** 211–13.
2. Pantuck EJ, *et al.* Cigarette smoking and chlorpromazine disposition and actions. *Clin Pharmacol Ther* 1982; **31:** 533–8.

Vitamins. Giving *ascorbic acid*, for vitamin C deficiency, to a patient receiving fluphenazine for bipolar disorder was associated with a fall in serum concentrations of fluphenazine and a deterioration of behaviour.[1]

1. Dysken MW, *et al.* Drug interaction between ascorbic acid and fluphenazine. *JAMA* 1979; **241:** 2008.

Xanthine-containing beverages. Studies *in vitro* have shown precipitation of some antipsychotics from solution by addition of coffee and tea.[1,2] However, in a study of 16 patients taking antipsychotics no correlation could be found between plasma-antipsychotic concentrations or behaviour and tea or coffee consumption.[3]

Pharmacokinetics

Chlorpromazine is readily, although sometimes erratically, absorbed from the gastrointestinal tract; peak plasma concentrations are attained 2 to 4 hours after ingestion. It is subject to considerable first-pass metabolism in the gut wall and is also extensively metabolised in the liver and is excreted in the urine and bile in the form of numerous active and inactive metabolites; there is some evidence of enterohepatic recycling. Owing to the first-pass effect, plasma concentrations after oral doses are much lower than those after intramuscular doses. Moreover, there is very wide intersubject variation in plasma concentrations of chlorpromazine; no simple correlation has been found between plasma concentrations of chlorpromazine and its metabolites, and their therapeutic effect (see Administration under Uses and Administration, below). Paths of metabolism of chlorpromazine include hydroxylation and conjugation with glucuronic acid, *N*-oxidation, oxidation of a sulfur atom, and dealkylation. Although the plasma half-life of chlorpromazine itself has been reported to be about 30 hours, elimination of the metabolites may be very prolonged. There is limited evidence that chlorpromazine induces its own metabolism.

Chlorpromazine is about 95 to 98% bound to plasma proteins. It is widely distributed in the body and crosses the blood-brain barrier to achieve higher concentrations in the brain than in the plasma. Chlorpromazine and its metabolites also cross the placenta and are distributed into breast milk.

Uses and Administration

Chlorpromazine is a phenothiazine antipsychotic. It has a wide range of activity arising from its depressant actions on the CNS and its alpha-adrenergic blocking and antimuscarinic activities. Chlorpromazine is a dopamine inhibitor; the turnover of dopamine in the brain is also increased. There is some evidence that the antagonism of central dopaminergic function, especially at the D_2-dopaminergic receptor, is related to therapeutic effect in psychotic conditions. Chlorpromazine possesses sedative properties but patients usually develop tolerance rapidly to the sedation. It has antiemetic, serotonin-blocking, and weak antihistaminic properties and slight ganglion-blocking activity. It inhibits the heat-regulating centre so that the patient tends to acquire the temperature of the surroundings (poikilothermy). Chlorpromazine can relax skeletal muscle.

Chlorpromazine is widely used in the management of psychotic conditions as well as in some non-psychotic disorders, such as:

- acute and chronic schizophrenia (p.955) in adults and children
- to reduce acute mania, as in bipolar disorder (p.372)
- control of severely disturbed, agitated, or violent behaviour in adults and children (p.954) and sometimes other psychiatric conditions
- in autistic children
- as an adjunct for the short-term treatment of severe anxiety (but see also p.952), and to reduce pre-operative anxiety in adults and children
- as an antiemetic in some forms of nausea and vomiting (p.1700) in adults and children; it is ineffective in motion sickness
- in the alleviation of intractable hiccup (below)
- as an adjunct in the treatment of tetanus in adults and children (p.196 and p.1901) and to control symptoms in acute intermittent porphyria (p.1448)
- for induction of hypothermia

Chlorpromazine is given orally as the hydrochloride and the embonate. For both salts, the doses are expressed as the hydrochloride; chlorpromazine embonate 144 mg is equivalent to about 100 mg of chlorpromazine hydrochloride. Chlorpromazine is also given by injection as the hydrochloride and doses are expressed in terms of this salt. The base is given rectally as suppositories; doses are in terms of the base.

Dosage varies both with the individual and with the purpose for which the drug is being used. In most patients with **psychiatric conditions** *oral treatment* may be used from the start, typically commencing with a dosage of 25 mg of the hydrochloride, or its equivalent as the embonate, three times daily and increasing as necessary; daily doses of 75 mg may be given as a single dose at night. In some patients doses of 10 mg three times daily may be adequate. Maintenance doses, when required, usually range from 25 to 100 mg three times daily, although psychotic patients may require daily doses of up to 1 g or more.

For *parenteral use*, deep intramuscular injection is preferable, but diluted solutions have sometimes been given by slow intravenous infusion for indications such as tetanus, severe intractable hiccup, or nausea and vomiting associated with surgery. Subcutaneous injection is contra-indicated. After injection of chlorpromazine, patients should remain in the supine position for at least 30 minutes; blood pressure should be monitored. The usual dose by intramuscular injection is 25 to 50 mg repeated every 6 to 8 hours if required, although oral therapy should be substituted as soon as possible.

If the oral and parenteral routes are not suitable chlorpromazine may be given *rectally* as suppositories containing 100 mg of chlorpromazine base; this is stated to have an effect comparable with 40 to 50 mg of the hydrochloride orally or 20 to 25 mg intramuscularly. The usual rectal dose is 100 mg every 6 to 8 hours.

Initial oral doses of chlorpromazine of one-third to one-half the usual adult dose have been recommended for *elderly* or *debilitated patients*; doses should be increased more gradually. Intramuscular doses in the elderly may need to be reduced to up to one-quarter of the usual dose.

Chlorpromazine hydrochloride may be given to *children* aged 1 to 12 years in a dose of 500 micrograms/kg every 4 to 6 hours orally or every 6 to 8 hours by intramuscular injection. However, for psychiatric indications the oral dose for children aged over 5 years is usually one-third to one-half the adult dose; alternatively, the *BNFC* suggests a dose of 10 mg 3 times daily. Daily doses should not normally exceed 40 mg of chlorpromazine hydrochloride for children aged 1 to 5 years or 75 mg for children over 5 years of age. Chlorpromazine may be given to infants under 1 year of age if considered to be life-saving. Suppositories containing 25 mg of chlorpromazine base are available in some countries for use in children.

Doses of 10 to 25 mg every 4 to 6 hours orally are recommended for control of **nausea and vomiting**. If necessary, an initial dose of 25 mg may be given by intramuscular injection, followed by 25 to 50 mg every 3 to 4 hours until vomiting stops.

If **intractable hiccup** does not respond to an oral dose of 25 to 50 mg three or four times daily for 2 to 3 days then 25 to 50 mg may be given intramuscularly; if this fails 25 to 50 mg in 500 to 1000 mL of 0.9% sodium chloride should be given by slow intravenous infusion, with the patient supine, and careful monitoring of the blood pressure.

Action. The therapeutic effects of antipsychotics appear to be mediated, at least in part, by interference with dopamine transmission in the brain. Chlorpromazine, thioridazine, and thioxanthene derivatives have relatively equal affinity for D_1 or D_2 receptors, although their metabolites tend to be more potent as D_2 blockers.[1] Butyrophenones (such as haloperidol) and diphenylbutylpiperidines (such as pimozide) are relatively selective for D_2 receptors, and the substituted benzamides (such as sulpiride) are highly D_2-specific. Clozapine has complex actions: it is a relatively weak inhibitor of D_2 receptors but has a high affinity for a number of other receptors including D_1, D_4, and serotonin$_2$ (5-HT_2) receptors.[2] Other atypicals mostly share this profile of greater 5-HT_2 than D_2 antagonism.[2]

The traditional hypothesis of the action of antipsychotics has been that blockade of D_2 receptors in the limbic and cortical regions is responsible for the antipsychotic effects, and that adverse extrapyramidal motor effects result from blockade of D_2 receptors in the striatum (a typical motor region of the basal ganglia).[3] Modification of prolactin secretion results from blockade of D_2

receptors in the anterior pituitary. However, this hypothesis cannot satisfactorily account for the pharmacological profiles of atypical antipsychotics and the debate concerning their mechanism of action continues. It has been suggested that the balance between 5-HT_2 and D_2 antagonism is important in determining 'atypicality' (but the atypical antipsychotic amisulpride lacks marked 5-HT_2 antagonism), or that rapid dissociation from the D_2 receptor may be the determining factor (but it is not clear that some atypicals such as risperidone meet this criterion).[2] Other systems, such as glutamate, may play a role in modulating effectiveness against negative versus positive symptoms;[2] it has been suggested that the calcium antagonist actions of the diphenylbutylpiperidines may also be important in this respect.[4]

Division of antipsychotics into low- and high-potency drugs is discussed in Administration, below. For reference to the actions of antipsychotics on neuroendocrine function, see Effects on Endocrine Function under Adverse Effects, above.

2. Remington G. Understanding antipsychotic 'atypicality': a clinical and pharmacological moving target. *J Psychiatry Neurosci* 2003; **28:** 275–84.
3. Anonymous. Now we understand antipsychotics? *Lancet* 1990; **336:** 1222–3.
4. Snyder SH. Drug and neurotransmitter receptors: new perspectives with clinical relevance. *JAMA* 1989; **261:** 3126–9.

Administration. The classical antipsychotics are often divided into:

- **low-potency** drugs (phenothiazines with an aliphatic or piperidine side-chain or thioxanthenes with an aliphatic side-chain)
- **high-potency** drugs (butyrophenones, diphenylbutylpiperidines, and phenothiazines or thioxanthenes with a piperazine side-chain)

At doses with equipotent antipsychotic activity, the low-potency drugs are more prone to cause sedation and antimuscarinic or α-adrenergic-blocking effects than the high-potency drugs. However, they are associated with a lower incidence of extrapyramidal effects, with the exception of tardive dyskinesia which is likely to occur to the same extent with all classical antipsychotics.

Equivalent doses of antipsychotics quoted in the literature have varied considerably. In the UK the following daily doses of oral antipsychotics have been suggested to have approximately equipotent antipsychotic activity for doses up to the maximum licensed doses:

- chlorpromazine hydrochloride 100 mg
- clozapine 50 mg
- haloperidol 2 to 3 mg
- pimozide 2 mg
- risperidone 0.5 to 1 mg
- sulpiride 200 mg
- thioridazine 100 mg
- trifluoperazine 5 mg

It should be noted that all patients receiving pimozide require an annual ECG and all those receiving more than 16 mg of pimozide daily require periodic ECGs (see p.1018). Thioridazine also requires specialist supervision (p.1032).

Suggested equipotent doses of intramuscular depot antipsychotics are:

- flupentixol decanoate 40 mg every 2 weeks
- fluphenazine decanoate 25 mg every 2 weeks
- haloperidol (as the decanoate) 100 mg every 4 weeks
- pipotiazine palmitate 50 mg every 4 weeks
- zuclopenthixol decanoate 200 mg every 2 weeks

It has been noted[1] that *high doses* of antipsychotics (greater than the equivalent of 600 mg of chlorpromazine daily) are generally not necessary for the treatment (both initial and maintenance) of psychotic disorders, and may be associated with an increased risk of adverse effects as well as with a diminished clinical response. However, if high doses of antipsychotics have to be used, then doses should be increased gradually with caution and under the supervision of a specialist with facilities for emergency resuscitation available. The Royal College of Psychiatrists in the UK (which defines high-dose therapy as that involving a total daily dose greater than the upper limit recommended in the *BNF*) has issued recommendations concerning the use of high-dose antipsychotic medication.[2] It considers:

- current evidence does not justify the routine use of high-dose therapy with antipsychotics
- if high-dose therapy is used, this should only be after evidence-based strategies have failed, and as a carefully-monitored therapeutic trial
- the decision to use high-dose therapy, and the expected outcome, should be fully documented, after expert assessment of the patient
- the possible contra-indications to therapy, and the risk of drug interactions, should be assessed beforehand
- an ECG should be carried out before starting high-dose therapy and should be repeated after a few days, and then every 1 to 3 months in the early stages of treatment, or as clinically indicated
- doses should be increased in relatively small increments, with time to assess response before a further increase
- the use of 'as-required' antipsychotic medication, and of drug combinations, should be carefully monitored to avoid the inadvertent increase of total doses above high-dose thresholds

The existence of a *therapeutic range* (or therapeutic window) has not been demonstrated for most antipsychotics (with the possible exception of haloperidol[3]), and plasma concentrations of these drugs must be interpreted with caution.[1,3] Many factors make it difficult to establish a meaningful correlation between dose, plasma concentrations, and clinical improvement. These include incomplete absorption, first-pass effect, enzyme induction, the presence of active and inactive metabolites, ethnicity, smoking, and factors occurring at the receptor level.[3]

Administration in children. For reference to the use of lytic cocktails containing chlorpromazine, promethazine, and pethidine, and the view that alternatives should be considered in children, see Lytic Cocktails, under Sedation, p.115.

Bipolar disorder. Patients with bipolar disorder (p.372) suffering from acute mania with coexisting psychotic features, agitation, or disruptive behaviour are usually treated with antipsychotics as they produce rapid control of symptoms. Classical antipsychotics such as chlorpromazine or haloperidol have been widely used, although use of atypical antipsychotics, such as clozapine or olanzapine, is growing.

Chorea. For a discussion of the management of various choreas, including mention of the use of phenothiazines such as chlorpromazine, see p.953.

Dyspnoea. It has been shown that in healthy subjects an oral dose of 25 mg of chlorpromazine hydrochloride can reduce exercise-induced breathlessness without affecting ventilation or causing sedation.[1] Although other drugs may be preferred in patients with advanced cancer and dyspnoea (p.104), chlorpromazine may relieve air hunger unresponsive to usual measures,[2] and, if required, can be used to sedate dying patients who have unrelieved distress. It is recommended that initial doses should be small: 12.5 mg by slow intravenous injection or 25 mg by suppository may be given.

2. Walsh D. Dyspnoea in advanced cancer. *Lancet* 1993; **342:** 450–1.

Dystonia. Antipsychotics such as phenothiazines, haloperidol, or pimozide are sometimes useful in the treatment of idiopathic dystonia (p.809) in patients who have failed to respond to other drugs.[1] However, they often act non-specifically, damping down excessive movements by causing a degree of drug-induced parkinsonism and there is the risk of adding drug-induced extrapyramidal disorders to the dystonia being treated (see Extrapyramidal Disorders under Adverse Effects, above).

1. Marsden CD, Quinn NP. The dystonias. *BMJ* 1990; **300:** 139–44.

Eclampsia and pre-eclampsia. Drug combinations known as lytic cocktails have been used in many countries for the management of pre-eclampsia and imminent eclampsia. The cocktail has usually consisted of a combination of chlorpromazine, pethidine, and/or promethazine. In general, however, phenothiazines are not recommended in late pregnancy, and other treatments are preferred for hypertension (see Hypertension in Pregnancy, under Hypertension, p.1171); the management of eclampsia, which is the convulsive phase, is discussed on p.470.

Headache. Some phenothiazines such as chlorpromazine, levomepromazine, and prochlorperazine have been used in migraine to control severe nausea and vomiting unresponsive to antiemetics such as metoclopramide and domperidone (see p.616), and to relieve the pain of severe migraine attacks unresponsive to parenteral dihydroergotamine or sumatriptan.

Hiccup. A hiccup is an involuntary spasmodic contraction of the diaphragm that causes a sudden inspiration of air which is then checked abruptly by closure of the glottis. Hiccups often have a simple cause such as gastric distension and usually resolve spontaneously or respond to simple measures. Intractable hiccups may stem from a serious underlying cause such as brain disorders, metabolic or endocrine disturbances, CNS infections, and oesophageal or other gastrointestinal disorders. Other precipitants include anaesthesia or drug therapy.

Treatment of intractable hiccups should initially be aimed at controlling or removing the underlying cause including the relief of gastric distension or oesophageal obstruction.[1-5] Measures that raise carbon dioxide pressure such as breath holding, rebreathing, or alteration of normal respiratory rhythm can be effective. Stimulation of the pharynx can also interrupt hiccups and may explain the action of a host of remedies such as sipping iced water, gargling, and swallowing granulated sugar. Many drugs have been tried in the treatment of hiccups but evidence of efficacy is largely from anecdotal reports or uncontrolled studies. An early treatment protocol[6] for intractable hiccups (based on a review of the literature and the authors' experience) suggested stepwise management until an effective measure was found, as follows:

- correction of any metabolic abnormality
- swallowing dry granulated sugar
- decompressing the stomach via nasogastric tube, then irritation of the pharynx
- intravenous chlorpromazine 25 to 50 mg, repeated up to 3 times if necessary; if parenteral therapy is effective maintain on chlorpromazine by mouth for 10 days (licensed information recommends the use of oral therapy first —see Uses and Administration, above)
- metoclopramide 10 mg intravenously; if successful maintain on metoclopramide by mouth for 10 days
- quinidine 200 mg by mouth 4 times daily
- if this fails, consider left phrenic nerve block and crush

In later discussions,[1,3] chlorpromazine still emerged as the most consistently effective drug treatment; metoclopramide appeared to be an acceptable second choice and nifedipine an appropriate third choice,[3] although haloperidol was also considered to be of value.[1,4] Other phenothiazines that have been used for intractable hiccup include perphenazine and promazine. It was also considered that clonazepam, carbamazepine, phenytoin, and valproic acid might be of value, especially in neuropathic hiccups.[1] Some beneficial results have been reported with amitriptyline and amantadine; other drugs being tried in the treatment of hiccups include baclofen and gabapentin. The *BNF* recommends that in palliative care patients, a preparation combining an antacid with an antiflatulent be given for hiccups due to gastric distension. If this fails, metoclopramide (orally or by subcutaneous or intramuscular injection) should be added; baclofen, nifedipine, or chlorpromazine should be reserved for those patients in whom metoclopramide is also ineffective.

Lesch-Nyhan syndrome. The Lesch-Nyhan syndrome is an inherited disorder caused by a complete deficiency of hypoxanthine-guanine phosphoribosyl transferase, an enzyme involved in purine metabolism. It is characterised by hyperuricaemia, spasticity, choreoathetosis, self-mutilation, and mental retardation. The hyperuricaemia (see p.552) can be controlled by drugs such as allopurinol but there appears to be no effective treatment for the neurological deficits. It has been suggested that the behavioural problems might be associated with alterations in the brain's dopamine system. There have been rare reports of improvement in self-mutilation in patients given antipsychotics or antiepileptics such as carbamazepine and gabapentin.

Migraine. See under Headache, above.

Nausea and vomiting. Many antipsychotics, with the notable exception of thioridazine, have antiemetic properties and have been used in the prevention and treatment of nausea and vomiting (p.1700) arising from a variety of causes such as radiation sickness, malignancy, and emesis caused by drugs, including antineoplastics and opioid analgesics. Reference to the risk to the fetus of therapy with phenothiazines during pregnancy can be found under Precautions, above and on p.563.

Schizophrenia. Classical antipsychotics such as chlorpromazine, haloperidol, and thioridazine have been the traditional drug treatment of choice for patients with schizophrenia (p.955); however, atypical antipsychotics may now be preferred as first-line therapy. There is little difference in efficacy between the classical antipsychotics, but the use of thioridazine is now restricted in the treatment of schizophrenia because of the risk of cardiotoxicity.

Substance dependence. ***ALCOHOL.*** For advice against the use of antipsychotics for alcohol withdrawal, see p.1626.

OPIOIDS. In a discussion of neonatal abstinence syndrome (p.102), it was observed in 1986 that, although opioids, diazepam, and phenobarbital were widely used in the USA for the management of this condition, chlorpromazine had tended to be the preferred treatment in the UK.[1] This was still true as late as the mid-1990s, although practice varied widely.[2] However, a systematic review[3] found insufficient evidence to support the use of chlorpromazine in the management of neonatal abstinence syndrome. The following dosage schedule has been suggested:[1] chlorpromazine is begun with a loading dose of 3 mg/kg, followed by a total oral maintenance dose of 3 mg/kg daily, divided into 4 or 6 doses. The authors suggested that this dose might be increased by 3 mg/kg daily if withdrawal symptoms were particularly severe. Once stabilised a reduction in the dose of chlorpromazine by 2 mg/kg every third day is attempted.[1] Complications of phenothiazine usage have been notably absent, although rarely seizures may occur.

Taste disorders. Disturbances of the sense of taste may be broadly divided into either loss or distortion of taste. Loss of taste may be either complete (ageusia) or partial (hypogeusia). Distortion of taste (dysgeusia) may occur as aliageusia in which stimuli such as food or drink produce an inappropriate taste or as phantogeusia in which an unpleasant taste is not associated with an external stimuli and is sometimes referred to as a gustatory hallucination. Taste disturbances have many causes including infections, metabolic or nutritional disturbances, radiation, CNS disorders, neoplasms, drug therapy, or may occur as a consequence of normal ageing.[1] Management primarily consists of treatment of any underlying disorder. Withdrawal of offending drug therapy is commonly associated with resolution but occasionally effects persist and may require treatment.[2] Zinc or vitamin therapy has been used but there is insufficient evidence to indicate efficacy[1,3] for taste disturbances secondary to drug therapy or medical conditions that do not involve low zinc or vitamin concentrations. Phantogeusia might be linked to excessive activity of dopaminergic receptors as it has been reported[4] to respond to short-term treatment with small doses of antipsychotic drugs such as haloperidol or pimozide.

Profile

Chlorprothixene is a thioxanthene antipsychotic with general properties similar to those of the phenothiazine, chlorpromazine (p.969). It is used mainly in the treatment of psychoses (p.954). Chlorprothixene is given as the acetate and the hydrochloride. Preparations of chlorprothixene prepared with the aid of lactic acid have been stated to contain chlorprothixene lactate. The citrate and the mesilate have also been used.

Chlorprothixene is usually given orally as the hydrochloride and doses are expressed in terms of this salt. The acetate is given by injection with doses expressed in terms of the base. A usual oral initial dose for the treatment of psychoses is 15 to 50 mg three or four times daily, increased according to response; doses of up to 600 mg or more daily have been given in severe or resistant cases. It may also be given intramuscularly or intravenously in single doses of up to 100 mg. Chlorprothixene should be used in reduced dosage for elderly or debilitated patients.

Adverse effects. A 59-year-old man receiving chlorprothixene (for the second time) for acute mania developed severe obstructive jaundice within a few days; he was also taking chlorpropamide, digoxin, and diuretics.[1] Chlorprothixene was considered the most likely cause of the jaundice, though chlorpropamide could not be excluded.

1. Ruddock DGS, Hoenig J. Chlorprothixene and obstructive jaundice. *BMJ* 1973; **1:** 231.

Breast feeding. The American Academy of Pediatrics[1] considers that, although the effect of chlorprothixene on breast-fed infants is unknown, its use by mothers during breast feeding may be of concern since antipsychotics do appear in breast milk and thus could conceivably alter CNS function in the infant both in the short and long term.

Chlorprothixene and its sulfoxide metabolite were concentrated in the breast milk of 2 mothers given chlorprothixene 200 mg daily but it was calculated that the amount ingested by the nursing infant was only 0.1% of the maternal dose per kg bodyweight.[2]

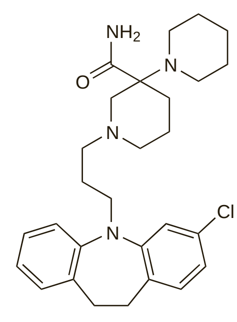
Clocapramine Hydrochloride *(rINNM)*

Chlorcarpipramine Hydrochloride; Clocapramine, Chlorhydrate de; Clocapramini Hydrochloridum; Hidrocloruro de clocapramina; Y-4153. 1′-[3-(3-Chloro-10,11-dihydro-5*H*-dibenz[*b,f*]azepin-5-yl)propyl][1,4′-bipiperidine]-4′-carboxamide dihydrochloride monohydrate.

Клокапрамина Гидрохлорид

$C_{28}H_{37}ClN_4O,2HCl,H_2O$ = 572.0.
CAS — 47739-98-0 (clocapramine); 28058-62-0 (clocapramine hydrochloride).



(clocapramine)

Pharmacopoeias. In *Jpn.*

Profile

Clocapramine is a chlorinated derivative of carpipramine (p.968). The hydrochloride has been given orally in the treatment of schizophrenia.

Clomethiazole *(BAN, rINN)*

Chlormethiazole; Clométhiazole; Clomethiazolum; Clometiazol; Klometiatsoli; Klometiazol. 5-(2-Chloroethyl)-4-methyl-1,3-thiazole.

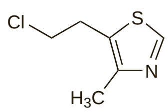
Клометиазол

C_6H_8ClNS = 161.7.

CAS — 533-45-9.

ATC — N05CM02.

ATC Vet — QN05CM02.



Pharmacopoeias. In *Br.*

BP 2008 (Clomethiazole). A colourless to slightly yellowish-brown liquid with a characteristic odour. Slightly soluble in water; miscible with alcohol, with chloroform, and with ether. A 0.5% solution in water has a pH of 5.5 to 7.0. Store at a temperature of 2° to 8°.

Clomethiazole Edisilate *(BANM, rINNM)*

Chlormethiazole Edisylate; Chlormethiazole Ethanedisulphonate; Clométhiazole, Edisilate de; Clomethiazole Edisylate *(USAN)*; Clomethiazoli Edisilas; Edisilato de clometiazol; Klometiazolu edysylan; NEX-002. 5-(2-Chloroethyl)-4-methylthiazole ethane-1,2-disulphonate.

Клометиазола Эдизилат

$(C_6H_8ClNS)_2,C_2H_6O_6S_2$ = 513.5.

CAS — 1867-58-9.

ATC — N05CM02.

ATC Vet — QN05CM02.

Pharmacopoeias. In *Br.* and *Pol.*

BP 2008 (Clomethiazole Edisilate). A white crystalline powder with a characteristic odour. Freely soluble in water; soluble in alcohol; practically insoluble in ether.

Incompatibility. Several studies have shown that clomethiazole edisilate may permeate through or be sorbed onto plastics used in intravenous infusion bags or giving sets.[1-4] The drug may also react with and soften the plastic.[1] The manufacturers of clomethiazole edisilate have suggested that thrombophlebitis, fever, and headache reported in young children during prolonged infusions may have been due to reaction with plastic giving sets and silastic cannulae. Recommendations for intravenous use have therefore included the use of a motor-driven glass syringe in preference to a plastic drip set in small children, changing plastic drip sets at least every 24 hours when used in older patients, and use of teflon intravenous cannulas.

4. Lee MG. Sorption of four drugs to polyvinyl chloride and polybutadiene intravenous administration sets. *Am J Hosp Pharm* 1986; **43:** 1945–50.

Dependence and Withdrawal

Dependence may develop, particularly with prolonged use of higher than recommended doses of clomethiazole. Features of dependence and withdrawal are similar to those of barbiturates (see Amobarbital, p.962).

Adverse Effects, Treatment, and Precautions

Clomethiazole may produce nasal congestion and irritation, sneezing, and conjunctival irritation sometimes associated with a headache. Nasopharyngeal or bronchial secretions may be increased. Skin rashes and urticaria have also occurred and in rare cases bullous eruptions have been reported. Gastrointestinal disturbances including nausea and vomiting, have been reported after oral doses. Reversible increases in liver enzyme values and blood-bilirubin concentrations have also been noted. Clomethiazole can cause excessive drowsiness, particularly in high doses; drowsiness may persist the next day, and patients affected should not drive or operate machinery. Paradoxical excitation or confusion may occur rarely. Anaphylaxis has also been reported rarely.

Excessive doses may produce coma, respiratory depression, hypotension, and hypothermia; pneumonia may follow increased respiratory secretion. Treatment is as for barbiturate overdose (see Amobarbital, p.962).

Clomethiazole is contra-indicated in patients with acute pulmonary insufficiency, and should be given with care to patients with sleep apnoea syndrome, chronic pulmonary insufficiency, or renal, liver, cerebral, or cardiac disease. Clomethiazole should be given with caution to elderly patients as there may be increased bioavailability and delayed elimination. Paradoxical worsening of epilepsy may occur in the Lennox Gastaut syndrome.

Administration by intravenous infusion. Severe adverse effects have followed the intravenous use of clomethiazole, and intravenous preparations are no longer generally available. Facilities for intubation and resuscitation were required when clomethiazole was given intravenously, with care taken to ensure that the patient's airway was maintained since there is a risk of mechanical obstruction during deep sedation. At too high a rate of infusion, sleep induced with clomethiazole could lapse into deep unconsciousness and patients required close and constant observation. Rapid infusion has also caused transient apnoea and hypotension, and special care was needed in patients susceptible to cerebral or cardiac complications, including the elderly. With prolonged infusion there was also a risk of electrolyte imbalance due to the water load involved with the glucose vehicle. Recovery has been considerably delayed after prolonged infusion.

Effects on the heart. Cardiac arrest in 2 chronic alcoholics might have been associated with clomethiazole infusion.[1]

1. McInnes GT, *et al.* Cardiac arrest following chlormethiazole infusion in chronic alcoholics. *Postgrad Med J* 1980; **56:** 742–3.

Overdosage. A report of clomethiazole poisoning on 16 occasions in 13 patients, some of whom had also taken other drugs and alcohol.[1] There was increased salivation on 7 occasions; otherwise the clinical features were those of barbiturate poisoning (see Adverse Effects of Amobarbital, p.962). The highest plasma-clomethiazole concentration was 36 micrograms/mL, with the highest value in a conscious patient 11.5 micrograms/mL. All the patients survived following intensive supportive treatment as for barbiturate poisoning.

1. Illingworth RN, *et al.* Severe poisoning with chlormethiazole. *BMJ* 1979; **2:** 902–3.

Parotitis. Acute bilateral parotitis has been reported in a patient given clomethiazole.[1] The swelling disappeared after withdrawal of clomethiazole and recurred on rechallenge.

1. Bosch X, *et al.* Parotitis induced by chlormethiazole. *BMJ* 1994; **309:** 1620.

Pregnancy. There have been reports of neonates being adversely affected by clomethiazole given to their mothers for toxaemia of pregnancy.[1,2] Effects included sedation, hypotonia, and apnoea. In a report[1] it was suggested that the effects might have been due to a synergistic interaction between clomethiazole and diazoxide as these drugs were given to most of the mothers with affected infants.

1. Johnson RA. Adverse neonatal reaction to maternal administration of intravenous chlormethiazole and diazoxide. *BMJ* 1976; **1:** 943.
2. Wood C, Renou P. Sleepy and hypotonic neonates. *Med J Aust* 1978; **2:** 73.

Interactions

The sedative effects of clomethiazole are enhanced by CNS depressants such as alcohol, barbiturates, other hypnotics and sedatives, and antipsychotics.

Alcohol. Although clomethiazole has been a popular choice for the treatment of alcohol withdrawal symptoms (p.1626), if it is given long-term, patients readily transfer dependency to it; if they also continue to abuse alcohol this may lead to severe self-poisoning with deep coma and potentially fatal respiratory depression.[1]

1. McInnes GT. Chlormethiazole and alcohol: a lethal cocktail. *BMJ* 1987; **294:** 592.

Beta blockers. Sinus bradycardia developed in an 84-year-old woman taking *propranolol* for hypertension 3 hours after she took a second dose of clomethiazole 192 mg.[1] Her pulse rate increased on stopping propranolol and clomethiazole and later stabilised when she took propranolol with haloperidol.

1. Adverse Drug Reactions Advisory Committee (Australia). *Med J Aust* 1979; **2:** 553.

Diazoxide. For a report of adverse reactions in neonates born to mothers given clomethiazole and diazoxide, see Pregnancy under Adverse Effects, Treatment, and Precautions, above.

Histamine H_2-antagonists. A study of the pharmacokinetics of clomethiazole edisilate 1 g orally in 8 healthy subjects, before and after doses of *cimetidine* 1 g daily for 1 week, showed that mean clearance of clomethiazole was reduced by 31% by cimetidine.[1] This was associated with an increase in the mean peak plasma concentration of the hypnotic from 2.664 to 4.507 micrograms/mL and an increase in the mean elimination half-life from 2.33 to 3.63 hours. After the original dose of clomethiazole subjects slept for 30 to 60 minutes, whereas after cimetidine, most slept for at least 2 hours.

Ranitidine did not significantly affect the pharmacokinetics of clomethiazole in a study in 7 healthy subjects.[2]

1. Shaw G, *et al.* Cimetidine impairs the elimination of chlormethiazole. *Eur J Clin Pharmacol* 1981; **21:** 83–5.
2. Mashford ML, *et al.* Ranitidine does not affect chlormethiazole or indocyanine green disposition. *Clin Pharmacol Ther* 1983; **34:** 231–3.

Pharmacokinetics

Clomethiazole is rapidly absorbed from the gastrointestinal tract, peak plasma concentrations occurring about 15 to 90 minutes after oral doses depending on the formulation used. It is widely distributed in the body and is reported to be 65% bound to plasma proteins. Clomethiazole is extensively metabolised, probably by first-pass metabolism in the liver with only small amounts appearing unchanged in the urine. The elimination half-life has been reported to be about 4 hours but this may be increased to 8 hours or longer in the elderly or in patients with hepatic impairment. Clomethiazole crosses the placenta and is distributed into breast milk.

Hepatic impairment. Studies in 8 patients with advanced cirrhosis of the liver and in 6 healthy men showed that the amount of unmetabolised clomethiazole reaching the circulation after an oral dose was about 10 times higher in the patients than in the controls.[1] Low concentrations in the controls were related to extensive first-pass metabolism in the liver.

1. Pentikäinen PJ, *et al.* Pharmacokinetics of chlormethiazole in healthy volunteers and patients with cirrhosis of the liver. *Eur J Clin Pharmacol* 1980; **17:** 275–84.

Uses and Administration

Clomethiazole is a hypnotic and sedative with anticonvulsant effects. It is used orally in the treatment of agitation and restlessness (see Disturbed Behaviour, p.954) in elderly patients, in the short-term management of severe insomnia (p.957) in the elderly, and in the treatment of acute alcohol withdrawal symptoms (p.1626). It was also given as an intravenous infusion in the management of status epilepticus (p.469) and impending or actual eclampsia (p.470); however, a parenteral formulation of clomethiazole no longer appears to be available.

In the UK, clomethiazole (as *Heminevrin*; *AstraZeneca*) is available as capsules containing 192 mg of clomethiazole base and as syrup containing 250 mg of the edisilate in 5 mL. As a result of differences in the bioavailability of these preparations, 192 mg of the base in the capsules is considered therapeutically equivalent to 250 mg (5 mL) of the edisilate in the syrup, i.e. one capsule or 5 mL of syrup are equivalent in their effects.

The usual hypnotic dose of clomethiazole for **insomnia** is 1 or 2 capsules (192 or 384 mg of the base) or the equivalent. For **restlessness and agitation** in the elderly 1 capsule (192 mg of the base), or the equivalent dose as one of the other dosage forms, may be given 3 times daily.

Various clomethiazole regimens have been suggested for the treatment of **alcohol withdrawal**, usually starting with 9 to 12 capsules, or the equivalent, divided into 3 or 4 doses, on the first day, and gradually reducing the dosage over the next 5 days. Treatment should be carried out in hospital or in specialist centres, and use for longer than 9 days is not recommended because of the risk of dependence (see above).

Porphyria. Clomethiazole is one of the drugs that has been used for seizure prophylaxis in patients with porphyria (p.471) who continue to experience convulsions while in remission.

Stroke. Clomethiazole has been studied[1,2] as a neuroprotective drug in the acute management of patients with stroke, but no beneficial effect on long-term outcome was found.

1. Wahlgren NG, *et al.* CLASS Study Group. Clomethiazole Acute Stroke Study (CLASS): results of a randomized, controlled trial of clomethiazole versus placebo in 1360 acute stroke patients. *Stroke* 1999; **30:** 21–8.
2. Lyden P, *et al.* Clomethiazole Acute Stroke Study in ischemic stroke (CLASS-I): final results. *Stroke* 2002; **33:** 122–8.

Substance dependence. For a discussion of the management of *opioid* withdrawal symptoms, including mention of the use of clomethiazole, see p.101.

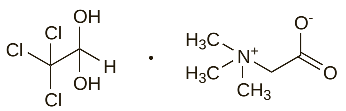
Cloral Betaine *(BAN, rINN)*

Chloral Betaine *(USAN)*; Cloral betaína; Cloral Bétaïne; Cloralum Betainum; Compound 5107. An adduct of cloral hydrate and betaine.

Хлораль Бетаин

$C_7H_{12}Cl_3NO_3,H_2O$ = 282.5.
CAS — 2218-68-0.



Profile

Cloral betaine rapidly dissociates in the stomach to release cloral hydrate and has actions and uses similar to those of cloral hydrate (below). It is given orally in the short-term management of insomnia (p.957), as tablets containing 707 mg (equivalent to about 414 mg of cloral hydrate). The usual hypnotic dose is one or two tablets taken at night with water or milk. The maximum daily dose is five tablets (equivalent to about 2 g of cloral hydrate). A reduction in dosage may be appropriate in frail elderly patients or in those with hepatic impairment.

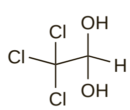
Preparations

Proprietary Preparations (details are given in Part 3)
UK: Somnwell; Welldorm.

Cloral Hydrate

Chloral Hydrate *(BAN)*; Chloral, hydrate de; Chloralhydrát; Chlorali hydras; Chloralio hidratas; Chloralu wodzian; Cloral, hidrato de; Kloraalihydraatti; Kloral Hidrat; Klorál-hidrát; Kloralhydrat.
2,2,2-Trichloroethane-1,1-diol.

$C_2H_3Cl_3O_2$ = 165.4.
CAS — 302-17-0.
ATC — N05CC01.
ATC Vet — QN05CC01.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of cloral hydrate:
Jellies; Jelly beans; Joy Juice; Knockout Drops; Knock out drops; Mickey; Mickeys; Mickey Finn; Mickey Finns; Peter; Torpedo.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Chloral Hydrate). Colourless, transparent crystals. Very soluble in water; freely soluble in alcohol. A 10% solution in water has a pH of 3.5 to 5.5. Store in airtight containers.

USP 31 (Chloral Hydrate). Colourless, transparent, or white crystals having an aromatic, penetrating, and slightly acrid odour. It volatilises slowly on exposure to air and melts at about 55°. Soluble 1 in 0.25 of water, 1 in 1.3 of alcohol, 1 in 2 of chloroform, and 1 in 1.5 of ether; very soluble in olive oil. Store in airtight containers.

Incompatibility. Cloral hydrate is reported to be incompatible with alkalis, alkaline earths, alkali carbonates, soluble barbiturates, borax, tannin, iodides, oxidising agents, permanganates, and alcohol (cloral alcoholate may crystallise out). It forms a liquid mixture when triturated with many organic compounds, such as camphor, menthol, phenazone, phenol, thymol, and quinine salts.

Dependence and Withdrawal, Adverse Effects, and Treatment

Cloral hydrate has an unpleasant taste and is corrosive to skin and mucous membranes unless well diluted. The most frequent adverse effect is gastric irritation; abdominal distension and flatulence may also occur. CNS effects such as drowsiness, lightheadedness, ataxia, headache, and paradoxical excitement, hallucinations, nightmares, delirium, and confusion (sometimes with paranoia) occur occasionally. Hypersensitivity reactions include skin rashes (erythema multiforme and Stevens-Johnson syndrome have been reported with the related compound triclofos). Ketonuria may occur.

The effects of acute overdosage resemble acute barbiturate intoxication (see Amobarbital, p.962 and below), and are managed similarly. In addition the irritant effect may cause initial vomiting, and gastric necrosis leading to strictures. Cardiac arrhythmias have been reported. Jaundice may follow liver damage, and albuminuria may follow kidney damage.

Tolerance may develop and dependence may occur. Features of dependence and withdrawal are similar to those of barbiturates (see Amobarbital, p.962).

Incidence of adverse effects. In a drug surveillance programme,[1] adverse effects of cloral hydrate, which were reversible, occurred in 2.3% of 1130 patients evaluated and included gastrointestinal symptoms (10 patients), CNS depression (20), and skin rash (5). In 1 patient the prothrombin time was increased; in 1 patient hepatic encephalopathy seemed to worsen; and bradycardia developed in 1 patient. In another such programme, adverse effects occurred in about 2% of 5435 patients given cloral hydrate.[2] Three reactions were described as life-threatening.

1. Shapiro S, *et al*. Clinical effects of hypnotics II: an epidemiologic study. *JAMA* 1969; **209:** 2016–20.
2. Miller RR, Greenblatt DJ. Clinical effects of chloral hydrate in hospitalized medical patients. *J Clin Pharmacol* 1979; **19:** 669–74.

Carcinogenicity. Cloral hydrate has been widely used as a sedative, especially in children. Concern over warnings that cloral hydrate was carcinogenic in *rodents*[1] has prompted some experts, including the American Academy of Pediatrics, to review the relative risks of the medical use of this drug.[2,3] The original warnings appear to have been based, in part, on the assumption that cloral hydrate was a reactive metabolite of trichloroethylene and was responsible for its carcinogenicity, but there is evidence to suggest that the carcinogenicity of trichloroethylene is due to a reactive intermediate epoxide metabolite. Studies *in vitro* indicate that cloral hydrate can damage chromosomes in some mammalian test systems but there have been no studies of the carcinogenicity of cloral hydrate in humans. Some long-term studies in *mice* have linked cloral hydrate with the development of hepatic adenomas or carcinomas. However, it was noted that cloral hydrate was not the only sedative that had been shown to be a carcinogen in experimental *animals*. The American Academy of Pediatrics considered cloral hydrate to be an effective sedative with a low incidence of acute toxicity when given short-term as recommended and, although the information on carcinogenicity was of concern, it was not sufficient to justify the risk associated with the use of less familiar sedatives. There was no evidence in infants or children showing that any of the available alternatives were safer or more effective. However, the use of repetitive dosing with cloral hydrate to maintain prolonged sedation in neonates and other children was of concern because of the potential for accumulation of drug metabolites and resultant toxicity. A recent cohort study[4] found no persuasive evidence to support a relationship between the use of cloral hydrate and the development of cancer. However, the statistical power was low for weak associations, particularly for some individual cancer sites.

1. Smith MT. Chloral hydrate warning. *Science* 1990; **250:** 359.
2. Steinberg AD. Should chloral hydrate be banned? *Pediatrics* 1993; **92:** 442–6.
3. American Academy of Pediatrics Committee on Drugs and Committee on Environmental Health. Use of chloral hydrate for sedation in children. *Pediatrics* 1993; **92:** 471–3.
4. Haselkorn T, *et al*. Short-term chloral hydrate administration and cancer in humans. *Drug Safety* 2006; **29:** 67–77.

Effects on the CNS. A 2-year-old child[1] had the first of 2 seizures 60 minutes after receiving cloral hydrate 70 mg/kg for sedation.

1. Muñoz M, *et al*. Seizures caused by chloral hydrate sedative doses. *J Pediatr* 1997; **131:** 787–8.

Hyperbilirubinaemia. Small retrospective studies[1] have suggested that prolonged use of cloral hydrate in neonates may be associated with the development of hyperbilirubinaemia. This may possibly be related to the prolonged half-life of the metabolite trichloroethanol in neonates.

1. Lambert GH, *et al*. Direct hyperbilirubinemia associated with chloral hydrate administration in the newborn. *Pediatrics* 1990; **86:** 277–81.

Overdosage. The general management of poisoning with cloral hydrate resembles that for barbiturates (see Treatment of Adverse Effects, under Amobarbital, p.962). Activated charcoal may be given orally to adults and children within 1 hour of ingestion of more than 30 mg/kg, provided that the airway can be protected; the value of gastric decontamination for overdose is uncertain. Of 76 cases of cloral hydrate poisoning reported to the UK National Poisons Information Service (NPIS), 47 were severe.[1] Of 39 adults, 12 had cardiac arrhythmias including 5 with cardiac arrest. Antiarrhythmic drugs were recommended unless obviously contra-indicated. Haemoperfusion through charcoal or haemodialysis was recommended for patients in prolonged coma. Cardiac arrhythmias and CNS depression were also major features of 12 cases of cloral hydrate overdosage reported from Australia.[2] Lidocaine was not always successful in controlling arrhythmias, but propranolol was successful in all 7 patients in whom it was used. It was noted that resistant arrhythmias, particularly ventricular fibrillation, ventricular tachycardia, and supraventricular tachycardia, were the usual cause of death in patients who had taken an overdosage of cloral hydrate. Although there had been no controlled studies of antiarrhythmic therapy in overdosage with cloral hydrate, the successful use of beta blockers appeared to be a recurring feature in reports in the literature. Indeed, the UK NPIS notes that tachyarrhythmias usually respond readily to an intravenous beta blocker such as esmolol or propranolol.

Giving flumazenil produced an increased level of consciousness, pupillary dilatation, and return of respiratory rate and blood pressure towards normal in a patient who had taken an overdosage of cloral hydrate.[3]

1. Wiseman HM, Hampel G. Cardiac arrhythmias due to chloral hydrate poisoning. *BMJ* 1978; **2:** 960.
2. Graham SR, *et al*. Overdose with chloral hydrate: a pharmacological and therapeutic review. *Med J Aust* 1988; **149:** 686–8.
3. Donovan KL, Fisher DJ. Reversal of chloral hydrate overdose with flumazenil. *BMJ* 1989; **298:** 1253.

Precautions

Cloral hydrate should not be used in patients with marked hepatic or renal impairment or severe cardiac disease, and oral dosage is best avoided in the presence of gastritis. As with all sedatives, it should be used with caution in those with respiratory insufficiency.

Cloral hydrate can cause drowsiness that may persist the next day; affected patients should not drive or operate machinery. Prolonged use and abrupt withdrawal of cloral hydrate should be avoided to prevent precipitation of withdrawal symptoms. Repeated doses in infants and children may lead to accumulation of metabolites and thereby increase the risk of adverse effects. Use is best avoided during pregnancy.

Cloral hydrate may interfere with some tests for urinary glucose or 17-hydroxycorticosteroids.

Breast feeding. The American Academy of Pediatrics[1] states that, although usually compatible with breast feeding, use of cloral hydrate by breast-feeding mothers has been reported to cause sleepiness in the infant.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/04/04)

Neonates. The half-life of trichloroethanol, an active metabolite of cloral hydrate, is prolonged in neonates;[1] values of up to 66 hours have been reported in some studies. Short-term sedation in the neonate with single oral doses of 25 to 50 mg/kg of cloral hydrate is considered[1] to be probably relatively safe, but repeated dosage carries the risk of accumulation of metabolites which may result in serious toxicity. Toxic reactions may occur even after the drug has been stopped since the metabolites may accumulate for several days.

1. Jacqz-Aigrain E, Burtin P. Clinical pharmacokinetics of sedatives in neonates. *Clin Pharmacokinet* 1996; **31:** 423–43.

Obstructive sleep apnoea. Children with obstructive sleep apnoea could be at risk from life-threatening respiratory obstruction if cloral hydrate is used for sedation. Details of 2 such children who suffered respiratory failure after sedation with cloral hydrate for lung function studies have been reported.[1]

1. Biban P, *et al*. Adverse effect of chloral hydrate in two young children with obstructive sleep apnea. *Pediatrics* 1993; **92:** 461–3.

Porphyria. UK licensed product information recommends that cloral hydrate should not be used in patients with porphyria, although some[1] consider it safe; caution would seem appropriate.

1. Welsh Medicines Information Centre. Drugs that are considered to be safe for use in acute porphyrias. Available at: http://www.wmic.wales.nhs.uk/pdfs/porphyria/PorphyriaSafeList.pdf (accessed 24/06/08)

Interactions

The sedative effects of cloral hydrate are enhanced by other CNS depressants such as alcohol (the 'Mickey Finn' of detective fiction), barbiturates, and other sedatives.

Cloral hydrate may alter the effects of coumarin anticoagulants (see Warfarin, p.1430). A hypermetabolic state, apparently due to displacement of thyroid hormones from their binding proteins, has been reported in patients given an intravenous dose of furosemide subsequent to cloral hydrate.

Pharmacokinetics

Cloral hydrate is rapidly absorbed from the gastrointestinal tract and starts to act within 30 minutes of oral doses. It is widely distributed throughout the body. It is rapidly metabolised to trichloroethanol and trichloroacetic acid (p.1620) in the erythrocytes, liver, and other tissues. It is excreted partly in the urine as trichloroethanol and its glucuronide (urochloralic acid) and as trichloroacetic acid. Some is also excreted in the bile.

Trichloroethanol is the active metabolite, and passes into the CSF, into breast milk, and across the placenta. The half-life of trichloroethanol in plasma is reported to range from about 7 to 11 hours but is considerably prolonged in the neonate. Trichloroacetic acid has a plasma half-life of several days.

Uses and Administration

Cloral hydrate is a hypnotic and sedative with properties similar to those of the barbiturates. It is used in the short-term management of insomnia (p.957) and has been used for sedation and as a sedative for premedication (p.1780); its use as a hypnotic, particularly in children, is now limited. It has been widely used for sedation of children before diagnostic, dental, or medical procedures (but see under Carcinogenicity above).

Externally, cloral hydrate has a rubefacient action and has been used as a counter-irritant.

Cloral hydrate is given by mouth as an oral liquid or as gelatin capsules with cloral hydrate dissolved in a suitable vehicle. It has also been dissolved in a bland fixed oil and given by enema or as suppositories.

It should not be given as tablets because of the risk of damage to the mucous membrane of the alimentary tract.

The usual oral hypnotic dose in adults is 0.5 to 2 g given as a single dose at night; as a sedative 250 mg can be given three times daily to a maximum daily dose of 2 g. Oral dosage forms should be taken well diluted or with plenty of water or milk. The *BNFC* suggests that children aged 1 month to 12 years be given 30 to 50 mg/kg to a maximum single dose of 1 g by mouth as a hypnotic (but see above); those aged 12 to 18 years may be given 0.5 to 1 g. Although not licensed in the UK for sedation of children before a painless procedure, the *BNFC* suggests the following oral doses, given 45 to 60 minutes beforehand: 1 month to 12 years, 30 to 50 mg/kg (maximum of 1 g), although up to 100 mg/kg (maximum of 2 g) may be used with respiratory monitoring; 12 to 18 years, 1 to 2 g. The *BNFC* states that the doses above may be given rectally if the oral route is unavailable. In the USA, a suggested oral or rectal sedative dose for children is 8.3 mg/kg three times daily to a maximum daily dose of 1.5 g; a dose of 20 to 25 mg/kg has been given as a premedicant prior to EEG evaluation.

A reduction in dosage may be appropriate in frail elderly patients or in those with hepatic impairment.

Derivatives of cloral hydrate, such as cloral betaine (above), chloralose (p.2037), and dichloralphenazone (p.994), which break down in the body to yield cloral hydrate, have been used similarly.

Preparations

USP 31: Chloral Hydrate Capsules; Chloral Hydrate Syrup.

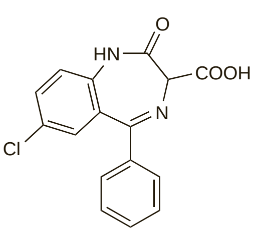
Proprietary Preparations (details are given in Part 3)
Ger.: Chloraldurat; ***Switz.:*** Chloraldurat; Medianox; Nervifene; ***UK:*** Welldorm; ***USA:*** Aquachloral; Somnote.

Multi-ingredient: ***Belg.:*** Dentophar; Sedemol; Sulfa-Sedemol; Synthol; ***Fr.:*** Bain de Bouche Lipha; ***Rus.:*** Efcamon (Эфкамон); ***Spain:*** Dentol Topico; ***Turk.:*** Dilan.

Clorazepic Acid *(BAN)*

Clorazépico, ácido. 7-Chloro-2,3-dihydro-2,2-dihydroxy-5-phenyl-1*H*-1,4-benzodiazepine-3-carboxylic acid.

$C_{16}H_{11}ClN_2O_3$ = 314.7.
CAS — 23887-31-2; 20432-69-3.



Clorazepate Monopotassium *(USAN)*

Abbott-39083; 4311-CB; Clorazepato monopotásico. Potassium 7-chloro-2,3-dihydro-2-oxo-5-phenyl-1*H*-1,4-benzodiazepine-3-carboxylate.

$C_{16}H_{10}ClKN_2O_3$ = 352.8.
CAS — 5991-71-9.

Dipotassium Clorazepate *(BANM, rINN)*

Abbott-35616; AH-3232; 4306-CB; Clorazépate dipotassique; Clorazepate Dipotassium *(USAN)*; Clorazepato de dipotasio; Dikalii clorazepas; Dikalio klorazepatas; Dikaliumkloratsepaatti; Dikaliumklorazepat; Dikálium-klórazepát; Kalii Clorazepas; Kaliumkloratsepaatti; Klaiumklorazepat; Klorazepát didraselná sůl; Klorazepat Dipotasyum; Potassium Clorazepate. Compound of Potassium 7-chloro-2,3-dihydro-2-oxo-5-phenyl-1*H*-1,4-benzodiazepine-3-carboxylate with potassium hydroxide.

Дикалия Клоразепат

$C_{16}H_{11}ClK_2N_2O_4$ = 408.9.
CAS — 57109-90-7.
ATC — N05BA05.
ATC Vet — QN05BA05.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Dipotassium Clorazepate). A white or light yellow, crystalline powder. Solutions in water and in alcohol are unstable and should be used immediately. Freely soluble or very soluble in water; very slightly soluble in alcohol; practically insoluble in dichloromethane. Store in airtight containers. Protect from light.

USP 31 (Clorazepate Dipotassium). A light yellow, crystalline powder which darkens on exposure to light. Soluble in water but, upon standing, may precipitate from the solution; slightly soluble in alcohol and in isopropyl alcohol; practically insoluble in acetone, in chloroform, in dichloromethane, in ether, and in benzene. Store under nitrogen in airtight containers. Protect from light.

Dependence and Withdrawal

As for Diazepam, p.987.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987.

Effects on the liver. Jaundice and hepatic necrosis has been associated with clorazepate.[1]

1. Parker JLW. Potassium clorazepate (Tranxene)-induced jaundice. *Postgrad Med J* 1979; **55:** 908–910.

Effects on the nervous system. For reference to extrapyramidal disorders associated with the use of benzodiazepines, including clorazepate, see Diazepam, p.988.

Porphyria. Clorazepate has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for Diazepam, p.989.

Pharmacokinetics

Clorazepate is decarboxylated rapidly at the low pH in the stomach to form desmethyldiazepam (nordazepam, see p.1012), which is quickly absorbed.

◊ References.

1. Ochs HR, *et al.* Comparative single-dose kinetics of oxazolam, prazepam, and clorazepate: three precursors of desmethyldiazepam. *J Clin Pharmacol* 1984; **24:** 446–51.

Uses and Administration

Clorazepate is a long-acting benzodiazepine with general properties similar to those of diazepam (p.992). It is mainly used in the short-term treatment of anxiety disorders (p.952), as an adjunct in the management of epilepsy, and in the alcohol withdrawal syndrome (p.1626).

Dipotassium clorazepate is usually given orally but preparations for intravenous or intramuscular use are also available in some countries. Modified-release preparations given once daily are available in some countries for maintenance therapy.

In the UK, an oral dose of 7.5 mg of dipotassium clorazepate was given up to three times daily for the treatment of anxiety. In the USA rather higher doses have been recommended; 15 to 60 mg of dipotassium clorazepate may be given daily, in divided doses or as a single dose at night.

Up to 90 mg has been given daily in divided doses in the management of **epilepsy** or the **alcohol withdrawal syndrome**. Children aged between 9 and 12 years may be given a maximum of 60 mg daily in the management of epilepsy.

Reduced doses should be given to elderly or debilitated patients.

Preparations

USP 31: Clorazepate Dipotassium Tablets.

Proprietary Preparations (details are given in Part 3)

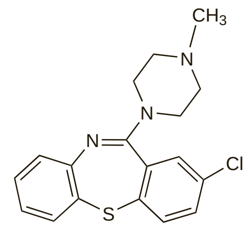
Clotiapine *(BAN, rINN)*

Clothiapine *(USAN)*; Clotiapina; Clotiapinum; HF-2159. 2-Chloro-11-(4-methylpiperazin-1-yl)dibenzo[*b,f*][1,4]thiazepine.

Клотиапин

$C_{18}H_{18}ClN_3S$ = 343.9.
CAS — 2058-52-8.
ATC — N05AX09.
ATC Vet — QN05AX09.



Profile

Clotiapine is a dibenzothiazepine antipsychotic with general properties similar to those of the phenothiazines (see Chlorpromazine, p.969). It is used in a variety of psychiatric disorders including schizophrenia (p.955), mania (see Bipolar Disorder, p.372), and anxiety (p.952). It is given orally in doses ranging from 10 to 200 mg daily in divided doses; up to 360 mg daily has been given in severe or resistant psychoses. It may also be given by slow intravenous or deep intramuscular injection.

Psychoses. A systematic review[1] found that good evidence to support the use of clotiapine over other treatments in acute psychotic illness was lacking.

1. Berk M, *et al.* Clotiapine for acute psychotic illnesses. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2004 (accessed 21/08/08).

Preparations

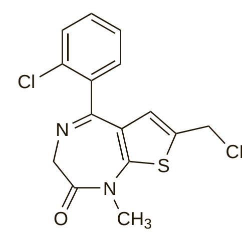
Proprietary Preparations (details are given in Part 3)
Arg.: Etumina; ***Belg.:*** Etumine; ***Israel:*** Entumin; ***Ital.:*** Entumin; ***S.Afr.:*** Etomine; ***Spain:*** Etumina; ***Switz.:*** Entumine.

Clotiazepam *(rINN)*

Clotiazépam; Clotiazepamum; Y-6047. 5-(2-Chlorophenyl)-7-ethyl-1,3-dihydro-1-methyl-2*H*-thieno[2,3-e]-1,4-diazepin-2-one.

Клотиазепам

$C_{16}H_{15}ClN_2OS$ = 318.8.
CAS — 33671-46-4.
ATC — N05BA21.
ATC Vet — QN05BA21.



Pharmacopoeias. In *Jpn.*

Profile

Clotiazepam is a short-acting thienodiazepine with general properties similar to those of diazepam (p.986). A usual oral daily dose for the short-term management of anxiety disorders (p.952) is 5 to 15 mg given in divided doses but up to 60 mg daily has been used. For sleep disorders (p.957) 10 mg has been given as a single dose at night. An oral dose of 10 to 15 mg has been given for premedication (see Anaesthesia, p.1780). Reduced doses may be required in elderly or debilitated patients.

◊ References.

1. Jibiki I, *et al.* Beneficial effect of high-dose clotiazepam on intractable auditory hallucinations in chronic schizophrenic patients. *Eur J Clin Pharmacol* 1994; **46:** 367–9.

Effects on the liver. Development of hepatitis in a 65-year-old woman was attributed to clotiazepam begun 7 months earlier.[1] The patient took triazolam and lorazepam without any apparent effect on the liver, and it was speculated that the hepatotoxic effect of clotiazepam was related to the thiophene ring present in the chemical structure.

Adverse Effects and Treatment

Although clozapine may share some of the adverse effects seen with the classical antipsychotics (see Chlorpromazine, p.969), the incidence and severity of such effects may vary; antimuscarinic effects with clozapine may be more pronounced. Sedation and weight gain may also be more prominent. Clozapine can cause reversible neutropenia which may progress to a potentially fatal agranulocytosis; strict monitoring of white blood cell counts is essential (see Precautions, below). Eosinophilia may also occur. Anaemia, thrombocytopenia, and thrombocythaemia have been reported rarely.

Extrapyramidal disorders, including tardive dyskinesia, appear to be rare with clozapine. Clozapine has little effect on prolactin secretion. Clozapine appears to have a greater epileptic potential than chlorpromazine but a comparable risk of cardiovascular effects such as tachycardia and orthostatic hypotension. In rare cases, circulatory collapse with cardiac and respiratory arrest has occurred, and hypertension has also been reported. Clozapine is also associated with an increased risk of developing myocarditis that may, in rare cases, be fatal; cardiomyopathy and pericarditis have also been reported.

Additional adverse effects of clozapine include dizziness, hypersalivation (particularly at night), headache, nausea, vomiting, constipation (which, in a few cases, has led to gastrointestinal obstruction, faecal impaction, and paralytic ileus), urinary incontinence and retention, fatigue, and transient fever which must be distinguished from the signs of impending agranulocytosis. There have also been rare reports of dysphagia, parotid gland enlargement, confusion, delirium, thromboembolism, acute pancreatitis, hepatitis and cholestatic jaundice, and very rarely fulminant hepatic necrosis. Isolated cases of acute interstitial nephritis have been reported. Abnormalities of glucose homoeostasis and the onset of diabetes mellitus occur uncommonly; severe hyperglycaemia, sometimes leading to ketoacidosis or hyperosmolar coma, has been reported very rarely. There have also been rare reports of hypercholesterolaemia and hypertriglyceridaemia. Many of the adverse effects of clozapine are most common at the start of therapy and may be minimised by gradual increase in dosage.

Effects on the blood. Clozapine can cause reversible neutropenia which, if the drug is not withdrawn immediately, may progress to a potentially fatal **agranulocytosis**. Particular concern over this adverse effect dates from 1975 when 17 cases of neutropenia or agranulocytosis, 8 of them fatal, were reported in Finland;[1] the calculated incidence[2] of agranulocytosis or severe granulocytopenia during this Finnish epidemic was 7.1 per 1000. These reports led to the withdrawal of clozapine in some countries or to restrictions in its use and intense haematological monitoring in others. After studies showing the efficacy of clozapine in severely ill schizophrenic patients unresponsive to adequate therapy with classical antipsychotics, the drug became available in the UK and USA in 1990 with strict procedures for monitoring of white blood cell counts. The UK CSM provided data on the reports it had received between July 1963 and January 1993 on agranulocytosis and neutropenia.[3] Clozapine was one of the individual drugs most frequently implicated, with 14 reports of agranulocytosis (1 fatal) and 119 of neutropenia (none fatal). Various estimates of the **incidence** of clozapine-associated agranulocytosis have been made; analysis of data from 11 555 patients given clozapine in the USA[4] showed a cumulative incidence of agranulocytosis of 8.0 per 1000 at 1 year and 9.1 per 1000 at 1 ⁄ years with the risk being increased in elderly patients. The majority of cases of agranulocytosis occurred within 3 months of the start of treatment with the risk peaking in the third month. The manufacturers report a lower incidence of agranulocytosis of 4.8 per 1000 patients for the first 6 months[5] and an annual rate of 0.8 per 1000 patients during the next 2 ⁄ years. These figures were based on data on 56 000 patients in the USA given clozapine up to the end of March 1993. Analysis of data[6] on 6316 patients registered in the UK and Ireland between January 1990 and July 1994 to receive (although not necessarily given) clozapine produced a cumulative incidence of agranulocytosis of 0.7% during the first year and 0.8% over the whole study period. Most cases of agranulocytosis and neutropenia occurred during the first 6 to 18 weeks of treatment. The incidence of agranulocytosis (0.07%) and neutropenia (0.7%) seen during the second year of therapy was of the same order of magnitude noted for some phenothiazine antipsychotics.

These data[6] and comparable data from the USA[7] were considered to indicate that mandatory haematological monitoring (see Precautions, below) helped to reduce the risks of clozapine-induced neutropenia and agranulocytosis and associated deaths.

The mechanism for clozapine-induced agranulocytosis is unclear and may be the result of direct toxicity or an immune response.[8,9] **Predisposing factors** for development of agranulocytosis have not been identified, apart from a possible excess of cases in female patients and an increased risk with increasing age. Furthermore, both agranulocytosis and neutropenia do not appear to be dose-related effects with clozapine. A postulated higher incidence of agranulocytosis in patients of Jewish background may be related to genetic factors.[10] Africans and Afro-Caribbeans appear to be at increased risk of developing neutropenia[6] and it has been noted[11] that many patients from these ethnic groups are currently already excluded from treatment with clozapine because their normal white blood cell and neutrophil counts are below the recommended range for treatment (see Precautions, below). However, UK licensed product information recommends that patients who have low white blood cell counts due to benign ethnic neutropenia may begin clozapine treatment with the agreement of a haematologist.

Evidence would suggest that development of clozapine-induced leucopenia or granulocytopenia precludes **retreatment** with clozapine at any future date; in a series of 9 re-treated patients, all developed leucopenia or agranulocytosis again.[12] In the USA, patients who have had clozapine withdrawn because of moderate leucopenia (judged to be when counts fall to 2000 to 3000 cells/mm^3) are considered eligible for a return to clozapine treatment when this count returns to normal; such patients are considered to have a five- or sixfold greater risk of agranulocytosis.[5]

Effects on body-weight. Most antipsychotic drugs are associated with weight gain. A meta-analysis[1] found evidence of weight gain in patients receiving both classical (chlorpromazine, fluphenazine, haloperidol, loxapine, perphenazine, thioridazine, tiotixene, or trifluoperazine) and atypical (clozapine, olanzapine, quetiapine, risperidone, sertindole, and ziprasidone) antipsychotics. Two drugs, molindone and pimozide, appeared in contrast to be associated with weight loss, although in the case of pimozide this could not be confirmed statistically. Placebo treatment was also associated with weight loss. However, a later review considered that there was overwhelming evidence that atypical antipsychotics induced more weight gain than classical antipsychotics.[2]

A separate review[3] calculated the average monthly weight gain associated with atypical antipsychotics to be:

- olanzapine (2.28 kg)
- zotepine (2.28 kg)
- quetiapine (1.76 kg)
- clozapine (1.72 kg)
- risperidone (0.96 kg)
- ziprasidone (0.80 kg)

Weight gain occurred most frequently during the first 6 to 12 months of treatment. It was recommended that if weight gain was more than 2 kg during the first 2 weeks, a strict dietary regimen should be started immediately. However, more recent opinion is that a change of antipsychotic may be necessary. Anti-obesity drugs have been tried although their routine use is not generally recommended.[2,4]

Effects on carbohydrate metabolism. Treatment with clozapine may be associated with an increased risk of glucose intolerance and diabetes mellitus; a similar association has also been noted for some other atypical antipsychotics.[1]

Data received by WHO indicated that up to December 2000, there had been 480 reports of glucose intolerance with clozapine, 253 with olanzapine, and 138 with risperidone.[2] In some cases weight gain was also reported, which may predispose to development of glucose intolerance. Other risk factors identified included an underlying diabetic condition, male gender, and use with some other medications including valproate, SSRIs, and buspirone. Regular monitoring of weight, blood glucose, and blood lipids was recommended in patients receiving clozapine, olanzapine, and risperidone.

Glucose intolerance has also been reported for the atypical antipsychotic quetiapine.[3,4]

Other reviewers have also found similar evidence of an increased risk of diabetes with atypical antipsychotics.[5] In September 2003 the FDA therefore requested labelling changes for all atypical antipsychotics to include the following recommendations and warnings:

- patients with diabetes mellitus receiving atypical antipsychotics should be monitored regularly for worsening glucose control
- patients with risk factors for diabetes mellitus should undergo fasting blood glucose testing at the start of, and during, treatment with atypical antipsychotics
- all patients given atypical antipsychotics should be monitored during treatment and those who develop hyperglycaemia should undergo fasting blood glucose testing
- in some cases hyperglycaemia resolved on withdrawal but some patients needed to continue antidiabetic therapy despite withdrawal

However, the American Diabetes Association and several other American medical associations[6] consider that the risks vary between atypical antipsychotics and have recommended that this should be taken into account when prescribing. The risk of weight gain, diabetes, and dyslipidaemia was considered to be greatest for clozapine and olanzapine, with risperidone and quetiapine having intermediate effects, and aripiprazole and ziprasidone having little effect (see also Effects on Body-Weight, above). They recommended that *baseline monitoring* should include:

- personal and family history of obesity, diabetes, dyslipidaemia, hypertension, or cardiovascular disease
- weight, height, and waist circumference
- blood pressure
- fasting blood glucose
- fasting lipid profile

Patients at risk for diabetes should receive an atypical drug with a lower propensity for weight gain and glucose intolerance. *Follow-up monitoring* should consist of reassessment of weight at 4, 8, and 12 weeks, and it was recommended that a change of antipsychotic should be considered for any patient who gained more than 5% of their original weight during treatment. Fasting plasma glucose and blood pressure should be assessed at 3 months and annually or more frequently thereafter according to risk. Lipid levels should also be assessed after 3 months and, if normal, at 5-year intervals thereafter. Any patient with worsening glycaemia or dyslipidaemia should be changed to an antipsychotic that has not been associated with significant weight gain or diabetes.

Effects on the cardiovascular system. The UK CSM[1] issued a warning in November 1993 of the risk of **myocarditis** with clozapine. Three patients who died while taking clozapine had evidence of myocarditis. The CSM had also received one other report of myocarditis and one of cardiomyopathy associated with clozapine. The Australian Adverse Drug Reactions Advisory Committee (ADRAC) subsequently reported[2] another 5 cases of clozapine-associated myocarditis in November 1994. A later report[3] from Australia identified 15 cases of myocarditis, including 5 fatalities, between January 1993 and March 1999 (these figures were established using both data from ADRAC and the Australian manufacturers). Between September 1989 and December 1999 the FDA had received reports of 28 cases of myocarditis (18 fatal) and 41 of cardiomyopathy (10 fatal) temporally associated with clozapine use.[4] A review[5] by the pharmacovigilance authorities in New Zealand stated that by November 1999 the manufacturers (*Novartis*) had analysed 125 reports of myocarditis received worldwide including 35 fatalities; 53% had occurred during the first month of treatment but about 5% occurred more than 2 years after starting treatment. A more recent review[6] of reports submitted to ADRAC between 1993 and 2003 identified 116 cases of myocarditis; of these, 60 patients were known to have recovered and 12 died. Myocarditis developed within a median of 17 days of starting clozapine therapy. In a reminder article,[7] the CSM has also commented that myocarditis occurs most commonly in the first 2 months whereas cardiomyopathy generally develops later in therapy. Pericarditis and pericardial effusions have also been reported. As myocarditis can be difficult to diagnose and confirmation is not always possible, the CSM recommended that if there was a high clinical suspicion of myocarditis, antipsychotic medication should be stopped. Presenting features might include persistent tachycardia at rest, heart failure, arrhythmia, or symptoms mimicking myocardial infarction or pericarditis. Patients who have developed clozapine-induced myocarditis or cardiomyopathy should not be re-exposed to clozapine.

There is also evidence that clozapine may be associated with fatal **thromboembolism**. Between February 1990 and December 1999, the FDA[8] had received 99 reports of venous thromboembolism associated with clozapine treatment. Of these reports, 83 mentioned pulmonary embolism with or without deep-vein thrombosis and 16 mentioned deep-vein thrombosis alone; 63 deaths were due to pulmonary embolism. The Swedish Adverse Reactions Advisory Committee had received reports[9] on 6 cases (5 fatal) of pulmonary embolism and 6 of venous thrombosis associated with clozapine treatment as of March 2000. The effect seemed to occur mainly in the first 3 months of treatment, and the majority of the cases involved men. However, analysis of data[10] from Germany and Switzerland suggests that the incidence of clozapine-associated thromboembolism is no different from that in psychiatric patients treated with classical antipsychotics or no antipsychotics at all.

There have been isolated reports[11,12] of **paradoxical hypertension** in patients receiving clozapine. Use with atenolol has controlled the hypertension and allowed clozapine therapy to be continued.

Some studies[13] have suggested that serious cardiovascular effects might occur more frequently and might be more severe in healthy subjects given clozapine than in patients with schizophrenia. The manufacturers had therefore requested that pharmacokinetic studies of clozapine should be performed in patients with treatment-resistant schizophrenia rather than in healthy subjects.

For further details of effects of clozapine on the cardiovascular system, see Benzodiazepines under Interactions, below.

Effects on fluid and electrolyte homoeostasis. Hyponatraemia has been reported to be associated with clozapine,[1] as with other antipsychotics (p.970). It was emphasised that hyponatraemia should be excluded as a possible trigger when considering the epileptogenic potential of clozapine.

1. Ogilvie AD, Croy MF. Clozapine and hyponatraemia. *Lancet* 1992; **340:** 672.

Effects on the gastrointestinal tract. The UK CSM had received 20 reports of serious gastrointestinal reactions resembling obstruction associated with clozapine treatment as of March 1999, of which 3 were fatal.[1] These reactions were thought to be due to the antimuscarinic actions of clozapine and, therefore, more likely to occur when clozapine was taken with other drugs with antimuscarinic actions such as tricyclic antidepressants, some antiparkinsonian drugs, and other antipsychotics; care was also warranted in those patients with a history of colonic disease or previous bowel surgery. It was also important to recognise and treat constipation in patients receiving clozapine to prevent the development of more serious complications such as obstruction and paralytic ileus.

1. CSM/MCA. Clozapine (Clozaril) and gastrointestinal obstruction. *Current Problems* 1999; **25:** 5. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2023235&RevisionSelectionMethod=LatestReleased (accessed 15/05/06)

Effects on the kidneys. There have been reports[1-3] of acute interstitial nephritis associated with clozapine treatment. All 3 patients had acute renal failure which resolved when the drug was stopped. The authors of 1 report noted that the UK CSM had received 7 reports of acute renal failure associated with clozapine treatment, including 1 death, between December 1989 and February 1999.[2]

Effects on lipid metabolism. The increased risk of hyperlipidaemia with some atypical antipsychotics is discussed under Adverse Effects of Chlorpromazine, p.970. See also Effects on Carbohydrate Metabolism, above.

Effects on the nervous system. As with other antipsychotics (see Convulsions, p.969), clozapine can lower the seizure threshold and cause EEG abnormalities, although treatment with clozapine appears to be associated with a higher frequency of seizures. A review[1] of 1418 patients treated with clozapine in the USA between 1972 and 1988 found that 41 had experienced generalised tonic-clonic seizures. It was considered that the risk of clozapine-induced seizures was dose-related. The seizure frequency was calculated to be:

- 1% at a dosage less than 300 mg daily
- 2.7% at 300 to 599 mg daily
- 4.4% with a dosage of 600 mg or more daily

Six of the patients had been taking other drugs reported to lower the seizure threshold. Therapy with clozapine was continued in 31 of the 41 patients by reducing the total daily dose of clozapine; antiepileptic drug therapy was begun in about half of the patients.

The UK CSM[2] considered that, although the epileptogenic effect of clozapine was claimed to be dose-related, the metabolism and plasma concentrations of clozapine were highly variable, and data from 8 cases reported to the CSM suggested that convulsions might possibly be related to high plasma concentrations in susceptible individuals. A low initial dosage followed by careful increases according to response and downward titration thereafter to a maintenance dose was recommended to avoid convulsions in susceptible individuals.

Effects on the pancreas. There have been isolated reports of pancreatitis associated with clozapine therapy[1-3] and overdosage.[4] A systematic review[5] of the FDA's surveillance database and published case reports up to February 2002 found 192 patients who had pancreatitis (22 fatalities) after treatment with one or more antipsychotics. This included monotherapy with clozapine (72 patients), olanzapine (62), risperidone (31), and haloperidol (12). Most cases occurred within 6 months of starting therapy.

Extrapyramidal disorders. Clozapine retains a place in therapy, despite its propensity to cause agranulocytosis, because, in part, of its reduced rate of extrapyramidal effects (see also p.971). Other drugs in the class have since been developed. However, although atypical antipsychotics carry a lower risk of causing extrapyramidal disorders, the risk is not zero; acute effects and tardive syndromes have been reported with these drugs, and the developing tendency to use them for high-dose therapy may perhaps narrow the margin of advantage.[1]

1. Pierre JM. Extrapyramidal symptoms with atypical antipsychotics: incidence, prevention and management. *Drug Safety* 2005; **28:** 191–208.

Hypersalivation. Hypersalivation has been reported[1] to occur in up to 54% of patients receiving clozapine. The pathophysiology for this effect is unclear, but proposed mechanisms include action at muscarinic (M_3 and M_4) receptors, blockade of

α_2-adrenoceptors, or distortion of the swallowing reflex. Management strategies have included chewing gum to increase frequency of swallowing or reduction of clozapine dosage in stabilised patients; antimuscarinics or α_2-agonists have been tried when other methods have failed. However, antimuscarinics could potentially exacerbate the antimuscarinic adverse effects of clozapine, and intranasal ipratropium bromide has been tried as an alternative with beneficial results in one small uncontrolled study.[2]

Neuroleptic malignant syndrome. A review of the literature[1] suggested that clozapine may produce fewer extrapyramidal effects and a lower rise in creatine kinase concentrations than classical antipsychotics. The incidence of neuroleptic malignant syndrome (NMS— p.972) with clozapine appeared to be similar to that with classical antipsychotics;[1] however, its presentation may differ, with fever and rigidity less frequent, and possibly less severe, but diaphoresis more common.[2] Nevertheless, a later review[3] concluded that manifestations of NMS associated with the atypical antipsychotics clozapine, olanzapine, quetiapine, and risperidone were of similar nature and severity to those associated with classical antipsychotics. NMS has also been reported[4] with the use of amisulpride and aripiprazole.

Withdrawal. Abrupt withdrawal of clozapine may be associated with symptoms that have been described as 'cholinergic rebound' although the manifestations, which may include headache, profuse sweating, hypersalivation, bronchoconstriction, agitation, enuresis, and diarrhoea also have some common features with the serotonin syndrome (p.416); motor disorders and exacerbation of extrapyramidal disorders have also occurred. In addition, as with other antipsychotics, abrupt withdrawal of clozapine may be associated with rapid relapse of the original psychosis. In a retrospective case-note study of 29 schizophrenic patients whose clozapine treatment was withdrawn, abrupt withdrawal in 20 resulted in a marked, immediate deterioration in their mental state.[1] Of 3 further patients who experienced delirium with psychotic symptoms shortly after stopping clozapine, symptoms developed in 1 within 24 hours despite gradual withdrawal of clozapine over a 2-week period.[2] All the patients responded rapidly to resumption of low doses of clozapine.

2. Stanilla JK, *et al.* Clozapine withdrawal resulting in delirium with psychosis: a report of three cases. *J Clin Psychiatry* 1997; **58:** 252–5.

Precautions

Clozapine should not be given to patients with uncontrolled epilepsy, alcoholic or toxic psychoses, drug intoxication, or a history of circulatory collapse. It should be used with caution in patients with a history of seizures or with conditions that lower the seizure threshold. It is contra-indicated in patients with bone-marrow suppression, myeloproliferative disorders, or any abnormalities of white blood cell count or differential blood count. It is also contra-indicated in patients with a history of drug-induced neutropenia or agranulocytosis with the exception of that due to chemotherapy. It should not be used with drugs that carry a high risk of bone-marrow suppression (see Interactions, below).

Clozapine is contra-indicated in patients with severe renal impairment; caution is required in mild to moderate renal impairment. It should be used with caution in hepatic impairment and avoided in symptomatic or progressive liver disease or hepatic failure. Patients with a history of cardiac impairment or abnormal cardiac findings on examination should be referred to a specialist for further evaluation, which may include an ECG; treatment with clozapine should only then be started if the potential benefits clearly outweigh any risk. Clozapine should not be used in severe heart failure.

Clozapine possesses antimuscarinic properties and consequently it is contra-indicated in patients with paralytic ileus; it should also be used with caution in benign prostatic hyperplasia and angle-closure glaucoma.

Clinical monitoring for hyperglycaemia has been recommended, especially in patients with or at risk of developing diabetes (see Effects on Carbohydrate Metabolism, above).

Monitoring the white blood cell and absolute neutrophil counts is mandatory during clozapine treatment and should be carried out in accordance with official recommendations; these may vary between countries (see Monitoring, below for further details). Patients or their carers should report the development of any infection or signs such as fever, sore throat, or flu-like symptoms which suggest infection.

Patients who develop tachycardia at rest, dyspnoea, arrhythmias, chest pain, or other signs and symptoms of heart failure should be investigated immediately and clozapine treatment stopped if a diagnosis of myocarditis or cardiomyopathy is suspected.

Because of an increased risk of collapse due to orthostatic hypotension associated with rapid dose escalation during initial titration of clozapine dosage, it is recommended that treatment should be begun under close medical supervision. In addition, patients with Parkinson's disease should have their blood pressure monitored for the first weeks of treatment.

On planned withdrawal, the dose of clozapine should be reduced gradually over at least a 1- to 2-week period in order to avoid the risk of rebound psychosis and other withdrawal symptoms (see above). If abrupt withdrawal is necessary then patients should be observed carefully.

Clozapine may affect the performance of skilled tasks such as driving.

Breast feeding. The American Academy of Pediatrics[1] considers that, although the effect of clozapine on breast-fed infants is unknown, its use by mothers during breast feeding may be of concern since antipsychotic drugs do appear in breast milk and thus could conceivably alter CNS function in the infant both in the short and long term.

Clozapine appears to be distributed into breast milk in relatively high concentrations.[2] Concentrations in a patient given 50 mg daily were 63.5 nanograms/mL in breast milk and 14.7 nanograms/mL in plasma; at 100 mg daily they were 115.6 nanograms/mL and 41.4 nanograms/mL, respectively.

The manufacturers have also stated that studies in *animals* suggest that clozapine is excreted into breast milk and has an effect on nursing infants; they recommend that mothers receiving clozapine should not breast feed.

2. Barnas C, *et al.* Clozapine concentrations in maternal and fetal plasma, amniotic fluid, and breast milk. *Am J Psychiatry* 1994; **151:** 945.

Dementia. The FDA[1] has issued advice against the use of atypical antipsychotics, including clozapine, in the treatment of behavioural problems in elderly patients with dementia after analysis of placebo-controlled studies showed an increased risk of mortality with certain drugs in this class. See under Risperidone, p.1024.

1. FDA. FDA issues public health advisory for antipsychotic drugs used for treatment of behavioral disorders in elderly patients (issued 11th April, 2005). Available at: http://www.fda.gov/bbs/topics/ANSWERS/2005/ANS01350.html (accessed 24/05/05)

Monitoring. *WHITE CELL COUNTS.* A white blood cell count and a differential blood count must be performed before starting clozapine therapy and regularly throughout treatment. Treatment should not be started if the white blood cell count is less than 3500 cells/mm^3 and the absolute neutrophil count (ANC) is less than 2000 cells/mm^3, or if there is an abnormal differential count. Monitoring should continue throughout therapy and for 4 weeks after withdrawal.

In the EU, including the UK, monitoring is performed at weekly intervals for the first 18 weeks and then at least every 2 weeks between weeks 18 and 52; after 1 year of treatment with stable neutrophil counts, patients may be monitored at least every 4 weeks.

- If during therapy the white blood cell count falls to between 3000 and 3500 cells/mm^3 or the ANC falls to between 1500 and 2000 cells/mm^3 then monitoring should be performed **twice weekly** until values stabilise or increase.
- Clozapine should be **withdrawn** immediately if the white blood cell count falls below 3000 cells/mm^3 or the ANC drops below 1500 cells/mm^3; counts should be monitored daily until they return to normal. Clozapine should not be restarted in these patients.

In the USA, white blood cell and ANC are monitored weekly for the first 6 months and then every 2 weeks thereafter; after 1 year of therapy, patients may be monitored every 4 weeks.

- If during therapy the white blood cell count falls to between 3000 and 3500 cells/mm^3 and the ANC is above 1500 cells/mm^3 then monitoring should be performed **twice weekly**.
- If the white blood cell count falls below 3000 cells/mm^3 or the ANC is below 1500 cells/mm^3 then clozapine treatment should be **interrupted** and counts performed daily. Clozapine may be restarted if the white blood cell count recovers to above 3500 cells/mm^3 and the ANC to above 2000 cells/mm^3. After recovery, weekly monitoring is recommended for the next 12 months before reducing to every 2 weeks for 6 months, and then every 4 weeks thereafter.
- Clozapine should be **withdrawn** if the white blood cell count falls below 2000 cells/mm^3 or the ANC drops below 1000 cells/mm^3; counts should be monitored daily until they return to normal. Clozapine should not be restarted in these patients.

In patients with decreased white blood cell or ANC it is especially important that they or their carers report the development of any infection or signs such as fever, sore throat, or flu-like symptoms which suggest infection.

EOSINOPHIL COUNT. In the EU, clozapine should be withdrawn if the eosinophil count is greater than 3000 cells/mm^3; it should only be restarted once the count has fallen to below 1000 cells/mm^3.

Similar advice is given in the USA although the values differ: clozapine should be withdrawn if the eosinophil count is above 4000 cells/mm^3 and restarted once the count has fallen to below 3000 cells/mm^3.

PLATELET COUNT. European licensing information states that clozapine should be stopped if the platelet count falls below 50 000 cells/mm^3.

TREATMENT BREAK. If treatment with clozapine is interrupted for reasons other than abnormal haematological values then more frequent monitoring may be required following resumption of therapy.

In the EU, patients who have taken clozapine for at least 18 weeks and stopped therapy for more than 3 days but less than 4 weeks should resume weekly monitoring for the next 6 weeks before reducing to at least every 4 weeks if the counts are stable; a break of 4 weeks or more would require weekly monitoring for the next 18 weeks.

US licensed product information recommends resuming weekly monitoring for 6 months in patients whose therapy has been interrupted for more than 1 month; frequency of monitoring is then reduced as described in White Cell Counts, see above. Those who have taken clozapine for at least 6 months and stopped therapy for more than 3 days but less than 4 weeks should resume weekly monitoring for the next 6 weeks before reducing to at least every 2 weeks for 6 months if the counts are stable; those on clozapine for over 1 year may be monitored every 4 weeks after initial weekly monitoring for 6 weeks.

Pregnancy. A review of the literature[1] between 1993 and April 2004 suggested that clozapine and olanzapine do not appear to increase the risk of fetal teratogenicity; literature regarding aripiprazole, quetiapine, risperidone, and ziprasidone was incomplete or not available. The rate of spontaneous abortions in pregnant women exposed to clozapine or olanzapine was not found to be higher than that of the general population; however, these 2 drugs increased the risk of hyperglycaemia in pregnant women. A prospective comparative study[2] of pregnancy outcomes in women taking clozapine, olanzapine, quetiapine, and risperidone also concluded that atypicals do not appear to be associated with an increased risk for major malformations when compared to the baseline risk in the general population. The authors recommended that benefits and risks be weighed carefully in each case and optimal control of the psychiatric disorder be maintained throughout pregnancy and postpartum together with careful monitoring.

Interactions

Clozapine may enhance the central effects of MAOIs and CNS depressants including alcohol, antihistamines, benzodiazepines, and opioid analgesics.

Clozapine should not be used with drugs that carry a high risk of bone-marrow suppression including carbamazepine, co-trimoxazole, chloramphenicol, penicillamine, sulfonamides, antineoplastics, or pyrazolone analgesics such as azapropazone. Long-acting depot antipsychotics have myelosuppressive potential and should not be used with clozapine as they cannot be withdrawn rapidly should neutropenia occur. Additive effects may occur when clozapine is given with drugs that possess antimuscarinic, hypotensive, or respiratory depressant effects. Clozapine may reduce the effects of alpha-adrenoceptor agonists such as noradrenaline.

The metabolism of clozapine is mediated mainly by the cytochrome P450 isoenzyme CYP1A2. Use with drugs that inhibit or act as a substrate to this isoenzyme may affect plasma concentrations of clozapine and the dose of clozapine may need to be altered. Increased plasma-clozapine concentrations, with an increased risk of adverse effects, may be seen in patients who suddenly stop smoking. Use with phenytoin or other enzyme-inducing drugs may accelerate the metabolism of clozapine and reduce its plasma concentrations.

Antibacterials. A patient with schizophrenia controlled with clozapine therapy had a tonic-clonic seizure 7 days after starting treatment with *erythromycin*.[1] It appeared that erythromycin had inhibited the metabolism of clozapine and raised its serum concentrations. Increased drowsiness and hypersalivation have been seen in a patient receiving clozapine and *ampicillin*; he recovered when ampicillin was replaced with doxycycline.[2]

Giving clozapine with *rifampicin* has resulted in decreased clozapine concentrations with consequent return of paranoid thoughts in a patient with a complicated history of schizophrenia.[3] An improvement was seen after rifampicin was replaced with ciprofloxacin. The interaction was thought to be due to the induction of cytochrome P450 isoenzymes, particularly CYP1A2, by rifampicin, resulting in the accelerated metabolism of clozapine.

3. Joos AAB, *et al.* Pharmacokinetic interaction of clozapine and rifampicin in a forensic patient with atypical mycobacterial infection. *J Clin Psychopharmacol* 1998; **18:** 83–5.

Antidepressants. Rises in serum concentrations of clozapine have been found in patients receiving clozapine after addition of *fluoxetine*[1] or *fluvoxamine*[2] to therapy. Increased serum concentrations of clozapine have also been reported when *paroxetine* or *sertraline* was added to therapy.[3] A possible serotonin syndrome (p.416) has been reported[4] in a patient receiving *clomipramine* after clozapine was gradually withdrawn from the treatment regimen, although the symptoms were also similar to those of clozapine withdrawal (see above). There has been an isolated report[5] of a patient who developed myoclonic jerks 79 days after fluoxetine was added to treatment with clozapine and lorazepam, although some[6] doubt whether the effects were entirely due to an interaction. Giving clozapine with *lithium* may increase the risk of neuroleptic malignant syndrome. For reference to neurological reactions in patients receiving lithium with clozapine, see p.405.

Antiepileptics. Use of *phenytoin* or other *enzyme-inducing antiepileptics* may accelerate the metabolism of clozapine and reduce its plasma concentrations. Studies have found that addition of *sodium valproate* to clozapine therapy may increase[1] or decrease[2] plasma concentrations of clozapine. Although no increase in clozapine-related adverse effects or loss of control of psychotic symptoms were reported in these studies, there has been a report[3] of a patient who experienced sedation, confusion, slurring of speech and other functional impairment after valproate was given with clozapine.

Antipsychotics. Giving *risperidone* to a patient with schizoaffective disorder partially controlled by clozapine produced clinical improvement but was associated with a 74% rise in serum-clozapine concentrations over a 2-week period.[1] Although no adverse effects occurred in this patient, the potential for serious adverse effects requires caution if these drugs are used together. Neuroleptic malignant syndrome associated with use of clozapine with *haloperidol* has been reported.[2]

Antivirals. Although the UK manufacturers of *ritonavir* have stated that it may increase plasma concentrations of clozapine with a resultant increase in the risk of toxicity, there is evidence to suggest that, in fact, ritonavir may decrease the plasma concentrations of clozapine.[1] Ritonavir has been noted to induce the cytochrome P450 isoenzyme CYP1A2 and hence, as clozapine is primarily metabolised via this isoenzyme, an acceleration of the metabolism of clozapine would be expected. US prescribing information has been amended accordingly.

1. Penzak SR, *et al.* Comment: significant interactions with new antiretrovirals and psychotropic drugs. *Ann Pharmacother* 1999; **33:** 1372–3.

Benzodiazepines. Concern has been expressed over reports of cardiorespiratory collapse in patients taking both clozapine and benzodiazepines.[1,2] In response, the manufacturers of clozapine outlined[3] similar cases reported to them in the USA. Of 7 cases of respiratory arrest or depression only 2 involved recent use of a benzodiazepine; among 26 cases of orthostatic hypotension with syncope reported during the first year the drug was marketed, only 8 included recent benzodiazepine use. The manufacturers concluded that an increased risk of such reactions in patients taking both drugs simultaneously was possible but not established, and advised caution when starting clozapine therapy in patients taking benzodiazepines.

Hypersalivation associated with clozapine and benzodiazepines may be exacerbated when these drugs are used together. A patient[4] experienced increased hypersalivation, salivary thickening, and distension of the parotid glands when *clonazepam* was added to treatment with clozapine. Adverse effects reported in 5 other patients given clozapine and benzodiazepines together included hypersalivation, sedation, ataxia, and symptoms of delirium.[5,6]

6. Jackson CW, *et al.* Delirium associated with clozapine and benzodiazepine combinations. *Ann Clin Psychiatry* 1995; **7:** 139–41.

Buspirone. Potentially fatal gastrointestinal bleeding, accompanied by severe acidosis and hyperglycaemia, developed in a patient given buspirone with clozapine.[1] The patient had previously been taking clozapine for over a year without adverse effect, and was subsequently maintained on clozapine alone without a recurrence of symptoms.

1. Good MI. Lethal interaction of clozapine and buspirone? *Am J Psychiatry* 1997; **154:** 1472–3.

Gastrointestinal drugs. A patient stabilised on clozapine developed increased serum clozapine concentrations and signs of clozapine toxicity after starting treatment with *cimetidine*.[1] Cimetidine was withdrawn and ranitidine substituted without recurrence of toxicity.

A marked reduction in plasma-clozapine concentrations was seen in 2 smokers stabilised on the antipsychotic who began treatment with *omeprazole*,[2] which is a known inducer of the cytochrome P450 isoenzyme CYP1A2. However, a small retrospective analysis of the effect of stopping omeprazole in 13 patients taking both drugs suggested that the effect of omeprazole was only significant in non-smokers, and the clozapine dose did not need to be adjusted in any of these patients.[3]

Pharmacokinetics

Although clozapine is well absorbed from the gastrointestinal tract, its bioavailability is limited to about 50% by first-pass metabolism. Peak plasma concentrations are achieved, on average, about 2.5 hours after oral doses. Clozapine is about 95% bound to plasma proteins and has a mean terminal elimination half-life of about 12 hours at steady state. It is almost completely metabolised and routes of metabolism include *N*-demethylation, hydroxylation, and *N*-oxidation; the desmethyl metabolite (norclozapine) has limited activity. The metabolism of clozapine is mediated mainly by the cytochrome P450 isoenzyme CYP1A2. Metabolites and trace amounts of unchanged drug are excreted mainly in the urine and also in the faeces. There is wide interindividual variation in plasma concentrations of clozapine and no simple correlation has been found between plasma concentrations and therapeutic effect. It is distributed into breast milk.

Uses and Administration

Clozapine is a dibenzodiazepine derivative and the prototype of the atypical antipsychotics. It has relatively weak dopamine receptor-blocking activity at D_1, D_2, D_3, and D_5 receptors but has a high affinity for the D_4 receptor. Clozapine possesses alpha-adrenergic blocking, antimuscarinic, antihistaminic, antiserotonergic, and sedative properties.

Clozapine is used for the management of schizophrenia; however, because of the risk of agranulocytosis, it is reserved for patients who fail to respond to other antipsychotics, including other atypicals, or who experience severe neurological effects with such drugs. In the USA, it may also be used for reducing the risk of recurrent suicidal behaviour in those with schizophrenia or schizoaffective disorder who are at chronic risk for suicidal behaviour. In the UK, it is also used in the management of treatment-resistant psychoses associated with Parkinson's disease.

Clozapine use must be accompanied by strict procedures for the monitoring of white blood cell counts (see Precautions, above). To minimise the incidence of adverse effects, clozapine therapy should be introduced gradually, beginning with low doses and increasing according to response.

In the treatment of **schizophrenia**, including reducing the risk of suicidal behaviour, the usual oral dose is 12.5 mg once or twice on the first day followed by 25 mg once or twice on the second day. Thereafter the daily dosage may be increased gradually in steps of 25 to 50 mg to achieve a daily dose of up to 300 mg within 14 to 21 days (in the USA, up to 450 mg daily is permitted by the end of 2 weeks). Subsequent increases in steps of 50 to 100 mg may be made once or twice weekly; a daily dosage of 900 mg should not be exceeded. Once a therapeutic response has been obtained, a gradual reduction of dosage to a suitable maintenance dose is recommended; most patients respond to 200 to 450 mg daily. The total daily dose is given in divided doses; a larger portion may be given at night. Daily maintenance doses of 200 mg or less may be given as a single dose in the evening. If clozapine is to be withdrawn, this should be done gradually over a 1- to 2-week period. However, immediate withdrawal with careful observation is essential if neutropenia develops or if myocarditis or cardiomyopathy is suspected (see Precautions, above).

Elderly patients may require lower doses of clozapine and it is recommended that treatment should start with a dose of 12.5 mg on the first day and that subsequent dose increments should be restricted to 25 mg.

For patients who are restarting treatment after an interval of more than 2 days, 12.5 mg may be given once or twice on the first day. If this dose is well tolerated it may be possible to increase the dosage more quickly than when first starting. However, patients who have had respiratory or cardiac arrest with initial dosing, but were then successfully titrated to a therapeutic dose, should be re-titrated with extreme caution after a break of even 24 hours. Additional monitoring of blood cell counts may also be required if treatment is interrupted, see Treatment Break, under Monitoring, above.

It is recommended that oral therapy with other antipsychotics should be withdrawn gradually before treatment with clozapine is started.

Clozapine has also been given by intramuscular injection.

In the management of treatment-resistant **psychoses in Parkinson's disease**, the initial oral dose of clozapine is no more than 12.5 mg once daily in the evening. Thereafter, the daily dosage may be increased in increments of 12.5 mg up to twice a week; a dose of 50 mg daily should not be reached before the end of the second week. The usual dose ranges from 25 to 37.5 mg daily. Increases in the daily dose above 50 mg should only be made in exceptional cases in increments of 12.5 mg at weekly intervals up to a maximum of 100 mg daily. The total daily dose should preferably be given as a single dose in the evening. Dosage of antiparkinsonian drugs may be increased when there has been complete remission of psychotic symptoms after at least 2 weeks of clozapine therapy. If psychotic symptoms recur after increases in antiparkinsonian therapy, the dose of clozapine may need to be increased in line with the above guidance. As in patients with schizophrenia, planned withdrawal of clozapine in patients with Parkinson's disease should also be gradual in decrements of 12.5 mg over 1 to 2 weeks.

Action. Antipsychotics are thought to work through inhibition of dopamine D_2-receptors (see p.975), but this hypothesis fails to explain the activity of the atypical antipsychotics such as clozapine. How clozapine produces its antipsychotic activity is not clear; it has a high affinity for a number of different receptors.[1]

1. Kerwin RW. The new atypical antipsychotics: a lack of extrapyramidal side-effects and new routes in schizophrenia research. *Br J Psychiatry* 1994; **164:** 141–8.

Administration. There has been controversy over the bioequivalence or otherwise of different brands of clozapine. Although some reports indicate that it is perfectly possible to switch from branded to generic clozapine,[1-4] the need for monitoring and concerns about any requirement for retitration of doses (because of potential lack of bioequivalence[5]) have to be taken into account. There have been a few reports of exacerbation of psychotic symptoms in patients who were switched to a generic formulation.[6,7]

7. Mofsen R, Balter J. Case reports of the reemergence of psychotic symptoms after conversion from brand-name clozapine to a generic formulation. *Clin Ther* 2001; **23:** 1720–31.

Bipolar disorder. Clozapine is of benefit for the treatment of mania in patients with bipolar disorder (p.372), and the use of atypical antipsychotics in the management of such patients is increasing. However, the adverse effects of clozapine may restrict its use.

Dementia. Although atypical antipsychotics such as clozapine have been tried in elderly patients with dementia, the licensing authorities in the USA now recommend against such use, see under Precautions, above. For further discussion of the management of disturbed behaviour, see p.954.

Parkinsonism. Clozapine is used as an alternative to classical antipsychotics in the management of **treatment-resistant psychoses** in patients with Parkinson's disease (p.791). Some neurologists even consider clozapine to be the antipsychotic of choice in these patients,[1] although this remains to be determined. A review[2] in 1994 considered that there was little evidence to support clozapine as first choice given the quality of the available studies and the need for extensive monitoring. However a subsequent double-blind, placebo-controlled study[3] showed that low-dose clozapine treatment (up to 50 mg daily) significantly improved drug-induced psychosis without worsening parkinsonism. Adverse effects noted in this study were generally mild, although in the clozapine group of 30 patients, there was 1 report of leucopenia. A similar study also reported benefit,[4] although 7 of 32 patients noted some aggravation of parkinsonism, usually mild and transient, while receiving clozapine. Adverse effects reported from other individuals have also included a patient with parkinsonism who had worsening of psychotic symptoms when her dose of clozapine was increased,[5] and the sudden return of psychosis in another patient with parkinsonism whose psychosis was successfully treated with clozapine for 5 years.[6]

Low-dose clozapine (about 40 mg daily) also appears to be of benefit in the management of **levodopa-induced dyskinesias** in patients with severe Parkinson's disease.[7]

Schizophrenia. Clozapine is an effective antipsychotic for the management of schizophrenia (p.955) but its use is limited by its blood toxicity. Its effectiveness and superiority over classical antipsychotics was shown in a multicentre study.[1] Patients refractory to at least 3 different antipsychotics and who failed to improve after a single-blind trial of haloperidol, were randomised, double-blind, to treatment for 6 weeks with either clozapine up to 900 mg daily, or chlorpromazine hydrochloride up to 1800 mg daily with benzatropine mesilate up to 6 mg daily. Of the 267 patients included in the evaluation, 5 of 141 (4%) improved with chlorpromazine and benzatropine, and 38 of 126 (30%) improved with clozapine. Clozapine was superior to chlorpromazine in the treatment of negative as well as positive symptoms. Reviews[2,3] of clozapine indicate that these findings have been well replicated both in subsequent studies and in clinical practice. It is, however, unclear for how long clozapine should be tried: although 1 study[4] identified new responses up to 12 months after starting therapy, others have indicated that if improvement was not seen within the first 6 to 24 weeks, it was unlikely to occur.[2,5]

Clozapine is also used to reduce suicide risk in patients with refractory chronic schizophrenia.[6] The reported suicide rate of 0.05% per year in 6300 patients in the UK given clozapine since 1990 was considered to be tenfold less than expected.[7] A subsequent study[8] found it to be more effective than olanzapine in preventing suicide attempts in patients with schizophrenia or schizoaffective disorder at high risk.

Clozapine has shown consistent clinical benefit in schizophrenic patients with persistent aggressive or violent behaviour.[2,9] Whether this is due to a sedative effect, a specific antiaggressive action, or just reflects an overall improvement in psychosis is unknown.

Clozapine has been advocated for use in schizophrenic patients with moderate to severe tardive dyskinesia. It is still unclear whether clozapine can itself cause tardive dyskinesia but some patients with established tardive dyskinesia have experienced improvement in their symptoms when using clozapine.[10,11]

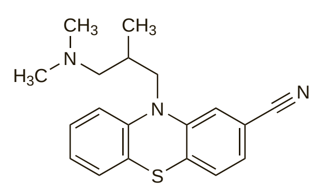
Cyamemazine *(rINN)*

Ciamemazina; Cyamémazine; Cyamemazinum; Cyamepromazine; RP-7204. 10-(3-Dimethylamino-2-methylpropyl)phenothiazine-2-carbonitrile.

Циамемазин

$C_{19}H_{21}N_3S$ = 323.5.
CAS — 3546-03-0 (cyamemazine); 93841-82-8 (cyamemazine tartrate).
ATC — N05AA06.
ATC Vet — QN05AA06.



Profile

Cyamemazine is a phenothiazine with general properties similar to those of chlorpromazine (p.969). It is used in the management of a variety of psychiatric disorders including anxiety disorders (p.952) and aggressive behaviour (p.954).

Cyamemazine has been given orally as the base or the tartrate and by injection as the base. Doses are expressed in terms of the base; cyamemazine tartrate 36.6 mg is equivalent to about 25 mg of cyamemazine. Oral doses have ranged from 25 to 600 mg daily, depending on the individual and the condition being treated; the daily dosage is given in 2 or 3 divided doses. Doses given by intramuscular injection have ranged from 25 to 200 mg daily.

Cyamemazine should be given in reduced dosage to elderly patients; the parenteral route is not recommended for the elderly.

Preparations

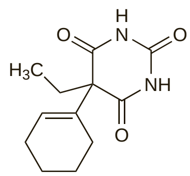
Proprietary Preparations (details are given in Part 3)
Fr.: Tercian; ***Port.:*** Tercian.

Cyclobarbital *(BAN, rINN)*

Ciclobarbital; Cyclobarbitalum; Cyclobarbitone; Cyklobarbital; Ethylhexabital; Hexemalum; Syklobarbitaali. 5-(Cyclohex-1-enyl)-5-ethylbarbituric acid.

Циклобарбитал

$C_{12}H_{16}N_2O_3$ = 236.3.
CAS — 52-31-3.
ATC — N05CA10.
ATC Vet — QN05CA10.



NOTE. The name ciclobarbital has sometimes been applied to hexobarbital.

Cyclobarbital Calcium *(BANM, rINNM)*

Calcii Cyclobarbitalum; Ciclobarbital cálcico; Ciclobarbital Calcium; Cyclobarbital Calcique; Cyclobarbitalum Calcicum; Cyclobarbitone Calcium; Cyklobarbital wapniowy; Hexemalcalcium. Calcium 5-(cyclohex-1-enyl)-5-ethylbarbiturate.

Кальций Циклобарбитал

$(C_{12}H_{15}N_2O_3)_2Ca$ = 510.6.
CAS — 5897-20-1.
ATC — N05CA10.
ATC Vet — QN05CA10.

Pharmacopoeias. In *Pol.*

Profile

Cyclobarbital is a barbiturate with general properties similar to those of amobarbital (p.961). The calcium salt has been used as a hypnotic but barbiturates are no longer considered appropriate for such purposes.

Preparations

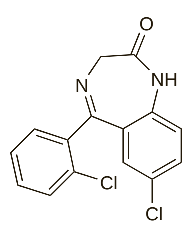
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Rus.:*** Reladorm (Реладорм).

Delorazepam *(pINN)*

Chlordesmethyldiazepam; Clordesmethyldiazepam; Délorazépam; Delorazepamum. 7-Chloro-5-(2-chlorophenyl)-1,3-dihydro-2*H*-1,4-benzodiazepin-2-one.

Делоразепам

$C_{15}H_{10}Cl_2N_2O$ = 305.2.
CAS — 2894-67-9.



Profile

Delorazepam is a long-acting benzodiazepine with general properties similar to those of diazepam (p.986). It has been used in the short-term treatment of anxiety disorders, insomnia, and epilepsy, and for premedication.

Administration in hepatic or renal impairment. The pharmacokinetics of total delorazepam were unchanged in patients with renal failure undergoing haemodialysis compared with controls.[1] However, the apparent volume of distribution of unbound drug was smaller and the clearance slower. The volume of distribution and clearance of unchanged drug was also reduced in patients with liver disease.[2]

2. Bareggi SR, *et al.* Effects of liver disease on the pharmacokinetics of intravenous and oral chlordesmethyldiazepam. *Eur J Clin Pharmacol* 1995; **48:** 265–8.

Preparations

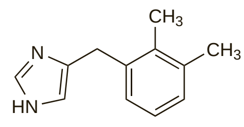
Proprietary Preparations (details are given in Part 3)
Ital.: Dadumir; En.

Detomidine Hydrochloride *(BANM, USAN, rINNM)*

Demotidini Hydrochloridum; Detomidiinihydrokloridi; Detomidin hydrochlorid; Détomidine, chlorhydrate de; Detomidin-hidroklorid; Detomidinhydroklorid; Detomidini hydrochloridum; Hidrocloruro de detomidina; MPV-253-AII. 4-(2,3-Dimethylbenzyl)imidazole hydrochloride.

Детомидина Гидрохлорид

$C_{12}H_{14}N_2$,HCl = 222.7.
CAS — 76631-46-4 (detomidine); 90038-01-0 (detomidine hydrochloride).



(detomidine)

Pharmacopoeias. In *Eur.* (see p.vii) for veterinary use only.
Ph. Eur. 6.2 (Detomidine Hydrochloride for Veterinary Use; Detomide Hydrochloride BP(Vet) 2008). A white or almost white, hygroscopic, crystalline powder. Soluble in water; freely soluble in alcohol; practically insoluble in acetone; very slightly soluble in dichloromethane. Protect from moisture.

Profile

Detomidine is an α_2-adrenoceptor agonist with sedative, muscle relaxant, and analgesic properties. It is used as the hydrochloride in veterinary medicine.

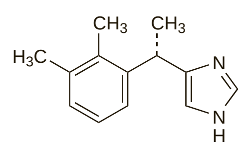
Dexmedetomidine Hydrochloride

(BANM, USAN, rINNM)

Deksmedetomidin Hidroklorür; Dexmédétomidine, Chlorhydrate de; Dexmedetomidini Hydrochloridum; Hidrocloruro de dexmedetomidina; MPV-1440 (dexmedetomidine). (*S*)-4-[1-(2,3-Xylyl)ethyl]imidazole hydrochloride.

Дексмедетомидина Гидрохлорид

$C_{13}H_{16}N_2$,HCl = 236.7.
CAS — 113775-47-6 (dexmedetomidine); 145108-58-3 (dexmedetomidine hydrochloride).
ATC — N05CM18.
ATC Vet — QN05CM18.



(dexmedetomidine)

Adverse Effects and Precautions

The most frequently observed adverse effect with dexmedetomidine is hypotension. Other common adverse effects include hypertension, nausea and vomiting, bradycardia, tachycardia, fever, hypoxia, and anaemia. Patients should be continuously monitored during use. Dexmedetomidine should be used with caution in patients with advanced heart block, or hepatic or renal impairment, or in the elderly.

Interactions

The effects of other CNS depressants may be enhanced by dexmedetomidine. Dexmedetomidine may also increase the effects of other vasodilators or drugs such as cardiac glycosides, that have negative chronotropic effects.

Pharmacokinetics

Dexmedetomidine is about 94% protein bound, but this has been reported to be significantly decreased in patients with hepatic impairment. Dexmedetomidine is almost completely metabolised by direct glucuronidation or by cytochrome P450 isoenzymes. It is excreted mainly as metabolites in the urine and faeces. The terminal elimination half-life is about 2 hours.

Uses and Administration

Dexmedetomidine is a selective alpha$_2$-adrenergic receptor agonist with anxiolytic, analgesic, and sedative properties. It is used for the sedation of mechanically ventilated patients in intensive care. Dexmedetomidine is given as the hydrochloride, but doses are expressed in terms of the base. Dexmedetomidine hydrochloride 118 micrograms is equivalent to about 100 micrograms of dexmedetomidine.

It is given in sodium chloride 0.9% by intravenous infusion in a loading dose equivalent to 1 microgram/kg of dexmedetomidine over 10 minutes, followed by a maintenance infusion of 0.2 to 0.7 micrograms/kg per hour for up to 24 hours. Reduced doses may be necessary in patients with hepatic or renal impairment, or in the elderly.

The racemate, medetomidine (p.1006), is used as the hydrochloride in veterinary medicine.

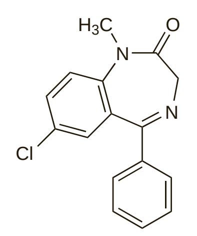
Diazepam *(BAN, USAN, rINN)*

Diatsepaami; Diazépam; Diazepám; Diazepamas; Diazepamum; LA-III; NSC-77518; Ro-5-2807; Wy-3467. 7-Chloro-1,3-dihydro-1-methyl-5-phenyl-2*H*-1,4-benzodiazepin-2-one.

Диазепам

$C_{16}H_{13}ClN_2O$ = 284.7.
CAS — 439-14-5.
ATC — N05BA01.
ATC Vet — QN05BA01.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of diazepam:
Benzo; Blue; Blues; Drunk pills; La Roche; Ludes; Mother's little helper; Mother's little helpers; Pami; Roaches; Roachies; Roche; V; V's blues; Vallies; Vals.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*
Ph. Eur. 6.2 (Diazepam). A white or almost white, crystalline powder. Very slightly soluble in water; soluble in alcohol. Protect from light.
USP 31 (Diazepam). An off-white to yellow, practically odourless, crystalline powder. Soluble 1 in 333 of water, 1 in 16 of alcohol, 1 in 2 of chloroform, and 1 in 39 of ether. Store in airtight containers. Protect from light.

Incompatibility. Incompatibility has been reported between diazepam and several other drugs. Manufacturers of diazepam injection (*Roche* and others) have advised against its admixture with other drugs.

Sorption. Substantial adsorption of diazepam onto some plastics may cause problems when giving the drug by continuous intravenous infusion. More than 50% of diazepam in solution may be adsorbed onto the walls of PVC infusion bags and their use should, therefore, be avoided. Giving sets should contain the minimum amount of PVC tubing and should not contain a cellulose propionate volume-control chamber. Suitable materials for infusion containers, syringes, and giving sets for diazepam include glass, polyolefin, polypropylene, and polyethylene.

Stability. Care should be observed when diluting diazepam injections for infusion because of problems of precipitation. The manufacturer's directions should be followed regarding diluent and concentration of diazepam and all solutions should be freshly prepared.

Dependence and Withdrawal

The development of dependence is common after regular use of benzodiazepines, even in therapeutic doses for short periods. Dependence is particularly likely in patients with a history of alcohol or drug abuse and in those with marked personality disorders. Benzodiazepines should therefore be withdrawn by gradual reduction of the dose after regular use for even a few weeks; the time needed for withdrawal can vary from about 4 weeks to a year or more. The extent to which tolerance occurs has been debated but appears to involve psychomotor performance more often than anxiolytic effects. Drug-seeking behaviour is uncommon with therapeutic doses of benzodiazepines. High doses of diazepam and other benzodiazepines, injected intravenously, have been abused for their euphoriant effects.

Benzodiazepine withdrawal syndrome. Development of dependence to benzodiazepines cannot be predicted but risk factors include high dosage, regular continuous use, the use of benzodiazepines with a short half-life, use in patients with dependent personality characteristics or a history of drug or alcohol dependence, and the development of tolerance. The mechanism of dependence is unclear but may involve reduced gamma-aminobutyric acid (GABA) activity resulting from down-regulation of GABA receptors.

Symptoms of benzodiazepine withdrawal include anxiety, depression, impaired concentration, insomnia, headache, dizziness, tinnitus, loss of appetite, tremor, perspiration, irritability, perceptual disturbances such as hypersensitivity to physical, visual, and auditory stimuli and abnormal taste, nausea, vomiting, abdominal cramps, palpitations, mild systolic hypertension, tachycardia, and orthostatic hypotension. Rare and more serious symptoms include muscle twitching, confusional or paranoid psychosis, convulsions, hallucinations, and a state resembling delirium tremens. Broken sleep with vivid dreams and increased REM sleep may persist for some weeks after withdrawal of benzodiazepines.

Symptoms typical of withdrawal have occurred despite continued use of benzodiazepines and have been attributed either to the development of tolerance or, as in the case of very short-acting drugs such as triazolam, to rapid benzodiazepine elimination. Pseudowithdrawal has been reported in patients who believed incorrectly that their dose of benzodiazepine was being reduced. Benzodiazepine withdrawal syndrome can theoretically be distinguished from these reactions and from rebound phenomena (return of original symptoms at greater than pretreatment severity) by the differing **time course**. A withdrawal syndrome is characterised by its onset, by the development of new symptoms, and by a peak in intensity followed by resolution. Onset of withdrawal symptoms depends on the half-life of the drug and its active metabolites. Symptoms can begin within a few hours after withdrawal of a short-acting benzodiazepine, but may not develop for up to 3 weeks after stopping a longer-acting benzodiazepine. Resolution of symptoms may take several days or months. The dependence induced by short- and long-acting benzodiazepines appears to be qualitatively similar although withdrawal symptoms may be more severe with short-acting benzodiazepines. Rebound effects are also more likely with short-acting benzodiazepines. Rebound and withdrawal symptoms develop particularly rapidly with the very short-acting drug triazolam.

With increased awareness of the problems of benzodiazepine dependence, emphasis has been placed on **prevention** by proper use and careful patient selection. For example, the UK CSM has recommended that benzodiazepines should be reserved for the short-term relief (2 to 4 weeks only) of anxiety that is severe, disabling, or subjecting the individual to unacceptable distress and is occurring alone or in association with insomnia or short-term psychosomatic, organic, or psychotic illness. These recommendations are similar to those of the UK Royal College of Psychiatrists.

Withdrawal from long-term benzodiazepine use should generally be encouraged. Established dependence can be difficult to treat; the patient should have professional and family support and behavioural therapy may be helpful. Withdrawal in a specialist centre may be required for some patients. Since abrupt withdrawal of benzodiazepines may result in severe withdrawal symptoms dosage should be tapered. The *BNF* considers that benzodiazepines can be withdrawn in steps of about one-eighth of the daily dose every fortnight (range one-tenth to one-quarter). There are no comparative studies of the efficacy of various withdrawal schedules and in practice the protocol should be titrated against the response of the patient. Clinicians often favour transferring the patient to an equivalent dose of diazepam given at night and the following rough dosage equivalents to *diazepam 5 mg* have been recommended in the UK:

- chlordiazepoxide 15 mg
- loprazolam 0.5 to 1 mg
- lorazepam 500 micrograms
- lormetazepam 0.5 to 1 mg
- nitrazepam 5 mg
- oxazepam 15 mg
- temazepam 10 mg

The daily dosage of diazepam can then be reduced in steps of 0.5 to 2.5 mg at fortnightly intervals. If troublesome abstinence effects occur the dose should be held level for a longer period before further reduction; increased dosage should be avoided if possible. It is better to reduce too slowly than too quickly. Time required for withdrawal can vary from about 4 weeks to a year or longer. In many cases the rate of withdrawal is best decided by the patient.

Adjuvant therapy should generally be avoided. Although a beta blocker may be given for prominent sympathetic overactivity the *BNF* recommends that this be tried only if other measures fail; antidepressants should be used only for clinical depression or panic attacks. Antipsychotic drugs should be avoided as they may aggravate symptoms.

Symptoms gradually improve after withdrawal but postwithdrawal syndromes lasting for several weeks or months have been described. Continued support may be required for the first year after withdrawal to prevent relapse.

Adverse Effects

Drowsiness, sedation, muscle weakness, and ataxia are the most frequent adverse effects of diazepam use. They generally decrease on continued dosage and are a consequence of CNS depression. Less frequent effects include vertigo, headache, confusion, depression (but see Effects on Mental Function, below), slurred speech or dysarthria, changes in libido, tremor, visual disturbances, urinary retention or incontinence, gastrointestinal disturbances, changes in salivation, and amnesia. Some patients may experience a paradoxical excitation which may lead to hostility, aggression, and disinhibition. Jaundice, blood disorders, and hypersensitivity reactions have been reported rarely. Respiratory depression and hypotension occasionally occur with high dosage and parenteral use.

Pain and thrombophlebitis may occur with some intravenous formulations of diazepam; raised liver enzyme values have occurred.

Overdosage can produce CNS depression and coma or paradoxical excitation. However, fatalities are rare when taken alone.

Use of diazepam in the first trimester of pregnancy has occasionally been associated with congenital malformations in the infant but no clear relationship has been established. This topic is reviewed under Pregnancy below. Use of diazepam in late pregnancy has been associated with intoxication of the neonate.

Carcinogenicity. The International Agency for Research on Cancer concluded[1] that there was sufficient evidence from human studies that diazepam did not produce breast cancer, and that there was inadequate data to support its potential carcinogenicity at other sites. For most other benzodiazepines the lack of human studies meant that the carcinogenic risk to humans was not classifiable. However, there appeared to be sufficient evidence of carcinogenicity in *animal* studies for oxazepam to be classified as possibly carcinogenic in humans.

Effects on body temperature. Studies in healthy subjects[1,2] indicate that benzodiazepines can reduce body temperature. After a single dose of diazepam 10 mg by mouth in 11 subjects, body temperature on exposure to cold fell to a mean of 36.93° compared with 37.08° on exposure without the drug.[1] An 86-year-old woman developed hypothermia[3] after being given nitrazepam 5 mg. After recovery she was mistakenly given another 5-mg dose of nitrazepam and again developed hypothermia. Midazolam (given as anaesthetic premedication) also produces modest decreases in core body temperature, which can be abolished by atropine,[4] but its effects are negligible compared with other elements of the anaesthetic regimen.[5]

Hypothermia has been reported in the neonates of mothers given benzodiazepines during the late stages of pregnancy.

Effects on endocrine function. Galactorrhoea with normal serum-prolactin concentrations has been noted in 4 women taking benzodiazepines.[1] Gynaecomastia has been reported in a man taking up to 140 mg diazepam daily[2] and in 5 men taking diazepam in doses of up to 30 mg daily.[3] Serum-oestradiol concentrations were raised in the latter group. However, raised plasma-testosterone concentrations have also been observed in men taking diazepam 10 to 20 mg daily for 2 weeks.[4]

4. Argüelles AE, Rosner J. Diazepam and plasma-testosterone levels. *Lancet* 1975; **ii:** 607.

Effects on the eyes. Brown opacification of the lens occurred in 2 patients who took diazepam 5 mg or more daily by mouth over several years.[1] Severe visual field loss associated with very high doses (100 mg) of diazepam has also been described.[2]

1. Pau H. Braune scheibenförmige Einlagerungen in die Linse nach Langzeitgabe von Diazepam (Valium). *Klin Monatsbl Augenheilkd* 1985; **187:** 219–20.

2. Tedesco FJ, Mills LR. Diazepam (Valium) hepatitis. *Dig Dis Sci* 1982; **27:** 470–2.

Effects on mental function. The effects of benzodiazepines on psychomotor performance in laboratory tests[1] are not easily extrapolated to the clinical situation. For example postoperative cognitive dysfunction in the elderly does not seem to be related to benzodiazepine concentration in the blood.[2]

Concern has been expressed over the possible effects of long-term benzodiazepine use on the brain. A detailed study[3] found that performance of tasks involving visual-spatial ability and sustained attention was poor in patients taking high doses of benzodiazepines for long periods of time. There was no evidence of impairment in global measures of intellectual functioning such as memory, flexibility, and simple reaction time. The authors could draw no conclusions about the effect of benzodiazepine withdrawal on these changes. A study of 17 long-term users of benzodiazepines has indicated a dose-dependent increase in cerebral ventricle size.[4]

Sexual fantasies have been reported in women sedated with intravenous diazepam or midazolam.[5] These appear to be dose-related.[6]

The view that benzodiazepines can cause depression, albeit infrequently, has been queried.[7]

Adverse effects of alprazolam on behaviour have also been reviewed.[8]

8. Cole JO, Kando JC. Adverse behavioral events reported in patients taking alprazolam and other benzodiazepines. *J Clin Psychiatry* 1993; **54** (suppl): 49–61.

Effects on the nervous system. There are a few isolated reports of extrapyramidal symptoms in patients taking benzodiazepines.[1-4] Benzodiazepines have been used to treat such symptoms induced by antipsychotics (see Extrapyramidal Disorders under Chlorpromazine, p.971).

Encephalopathy. Prolonged use of midazolam with fentanyl has been associated with encephalopathy in infants sedated under intensive care.[1]

1. Bergman I, *et al.* Reversible neurologic abnormalities associated with prolonged intravenous midazolam and fentanyl administration. *J Pediatr* 1991; **119:** 644–9.

Effects on sexual function. The sedative effects of benzodiazepines may reduce sexual arousal and lead to impotence in some patients. Conversely sexual performance may be improved by therapy if it was previously impaired by anxiety.

Increased libido and orgasmic function has been reported in 2 women after withdrawal of long-term benzodiazepine use.[1]

1. Nutt D, *et al.* Increased sexual function in benzodiazepine withdrawal. *Lancet* 1986; **ii:** 1101–2.

Effects on skeletal muscle. In a report[1] of 2 patients who developed rhabdomyolysis secondary to hyponatraemia it was suggested that the use of benzodiazepines might have contributed to the rhabdomyolysis. Of 8 reported cases of rhabdomyolysis associated with hyponatraemia, 5 had received benzodiazepines. Rhabdomyolysis associated with intravenous drug abuse of oral temazepam formulations has also been reported.[2]

1. Fernández-Real JM, *et al.* Hyponatremia and benzodiazepines result in rhabdomyolysis. *Ann Pharmacother* 1994; **28:** 1200–1.
2. Deighan CJ, *et al.* Rhabdomyolysis and acute renal failure resulting from alcohol and drug abuse. *Q J Med* 2000; **93:** 29–33.

Effects on the skin. There have been rare reports of cutaneous reactions to benzodiazepines, including contact dermatitis, fixed drug eruptions, toxic epidermal necrolysis, and Stevens-Johnson syndrome. Analysis by the Boston Collaborative Drug Surveillance Program of data on 15 438 patients hospitalised between 1975 and 1982 detected 2 allergic skin reactions attributed to diazepam among 4707 recipients of the drug.[1] A reaction rate of 0.4 per 1000 recipients was calculated from these figures.

1. Bigby M, *et al.* Drug-induced cutaneous reactions. *JAMA* 1986; **256:** 3358–63.

Hypersensitivity. Hypersensitivity reactions including anaphylaxis are very rare after use of diazepam. Reactions have been attributed to the polyoxyl castor oil (p.1918) vehicle used for some parenteral formulations.[1] There is also a report of a type I hypersensitivity reaction to a lipid emulsion formulation of diazepam.[2]

See also under Effects on the Skin, above.

2. Deardon DJ, Bird GLA. Acute (type 1) hypersensitivity to iv Diazemuls. *Br J Anaesth* 1987; **59:** 391.

Local reactions. Ischaemia and gangrene have been reported after accidental intra-arterial injection of diazepam.[1,2] Clinical signs may not occur until several days after the event. Pain and thrombophlebitis after intravenous use may be similarly delayed. Local reactions after intravenous injection have been attributed to the vehicle, and have been observed more often when diazepam is given as a solution in propylene glycol than in polyethoxylated castor oil.[3] An emulsion of diazepam in soya oil and water has been associated with a lower incidence of local reactions.[3] Pain and phlebitis may also be caused by precipitation of diazepam at the site of infusion.[4] Arterial spasm experienced by a patient given diazepam intravenously was probably due to pressure from a cuff on the arm being inflated causing extravasation of diazepam out of the vein and into the radial artery.[5]

Local irritation has also occurred after rectal use of diazepam.[6]

For a report of the exacerbation of diazepam-induced thrombophlebitis by penicillamine, see p.991.

Overdosage. Impairment of consciousness is fairly rapid in poisoning by benzodiazepines.[1] Deep coma or other manifestations of severe depression of brainstem vital functions are rare; more common is a sleep-like state from which the patient can be temporarily roused by appropriate stimuli. There is usually little or no respiratory depression, and cardiac rate and rhythm remain normal in the absence of anoxia or severe hypotension. Since tolerance to benzodiazepines develops rapidly, consciousness is often regained while concentrations of drug in the blood are higher than those which induced coma. Anxiety and insomnia can occur during recovery from acute overdosage, while a full-blown withdrawal syndrome, possibly with major convulsions, can occur in patients who have previously been chronic users.

During the years 1980 to 1989, 1576 fatal poisonings in Britain were attributed to benzodiazepines.[2] Of these, 891 were linked to overdosage with benzodiazepines alone and another 591 to overdosage combined with alcohol. A comparison of these mortality statistics with prescribing data for the same period, to calculate a toxicity index of deaths per million prescriptions, suggested that there were differences between the relative toxicities of individual benzodiazepines in overdosage. A later study of another 303 cases of benzodiazepine poisoning[3] supported these findings of differences in toxicity as well as pointing to the relative safety of the benzodiazepines in overdosage.

2. Serfaty M, Masterton G. Fatal poisonings attributed to benzodiazepines in Britain during the 1980s. *Br J Psychiatry* 1993; **163:** 386–93.
3. Buckley NA, *et al.* Relative toxicity of benzodiazepines in overdose. *BMJ* 1995; **310:** 219–21.

Treatment of Adverse Effects

The treatment of benzodiazepine overdosage is generally symptomatic and supportive. Activated charcoal may be given orally within one hour of ingestion of more than 100 mg of diazepam (or its equivalent) by adults, or 1 mg/kg by children, provided they are not too drowsy. Gastric lavage is generally not advocated in overdoses of benzodiazepines alone. The specific benzodiazepine antagonist, flumazenil, is rarely required and can be hazardous, particularly in mixed overdoses involving tricyclic antidepressants or in benzodiazepine-dependent patients (see p.1446); the UK Poisons Information Service, contra-indicates its use in mixed overdoses. The *BNF* recommends that flumazenil should be used on expert advice only.

Precautions

Diazepam should be avoided in patients with pre-existing CNS depression or coma, respiratory depression, acute pulmonary insufficiency, myasthenia gravis, or sleep apnoea, and used with care in those with chronic pulmonary insufficiency. Diazepam should be given with care to elderly or debilitated patients who may be more prone to adverse effects. Caution is required in patients with muscle weakness, or those with hepatic or renal impairment, who may require reduced doses; its use should be avoided in severe hepatic impairment. The sedative effects of diazepam are most marked during the first few days of use; affected patients should not drive or operate machinery (see also Driving, below). Monitoring of cardiorespiratory function is generally recommended when benzodiazepines are used for deep sedation.

Diazepam is not appropriate for the treatment of chronic psychosis or for phobic or obsessional states. Diazepam-induced disinhibition may precipitate suicide or aggressive behaviour and it should not, therefore, be used alone to treat depression or anxiety associated with depression; it should also be used with care in patients with personality disorders. Caution is required in patients with organic brain changes particularly arteriosclerosis. In cases of bereavement, psychological adjustment may be inhibited by diazepam.

Many manufacturers of diazepam and other benzodiazepines advise against their use in patients with glaucoma, but the rationale for this contra-indication is unclear.

For warnings on benzodiazepines during pregnancy and breast feeding, see below.

Dependence characterised by a withdrawal syndrome may develop after regular use of diazepam, even in therapeutic doses for short periods (see above); because of the risk of dependence, diazepam should be used with caution in patients with a history of alcohol or drug addiction.

Since hypotension and apnoea may occur when benzodiazepines are given intravenously it has been recommended that this route should only be used when facilities for reversing respiratory depression with mechanical ventilation are available. Patients should remain supine and under medical supervision for at least one hour after intravenous injection. Intravenous infusion is best undertaken in specialist centres with intensive care facilities where close and constant supervision can be undertaken.

Administration. ***Intravenous.*** Prolonged use of high-dose intravenous infusions of diazepam preparations containing benzyl alcohol can result in benzyl alcohol poisoning.[1] (Such preparations should never be used in neonates—see p.1632.)

1. López-Herce J, *et al.* Benzyl alcohol poisoning following diazepam intravenous infusion. *Ann Pharmacother* 1995; **29:** 632.

Breast feeding. The American Academy of Pediatrics considers that benzodiazepine use by nursing mothers for long periods was a cause for concern; anxiolytic drugs appear in breast milk and could conceivably alter CNS function in the infant both in the short and long term.[1] Similarly, in the UK the CSM has recommended[2] that benzodiazepines should not be given to breast-feeding mothers. In one reviewer's opinion[3] the limited distribution into breast milk did not constitute a hazard to the breast-fed infant but the infant should be monitored for sedation and the inability to suckle. Another group has also reported a low incidence of toxicity and adverse effects in the breast-fed infants of mothers taking psychotropic drugs including benzodiazepines.[4] It has been suggested[5] that if a benzodiazepine must be used during breast feeding it would be preferable to use a short-acting drug with minimal distribution into breast milk and inactive metabolites; oxazepam, lorazepam, alprazolam, or midazolam might be suitable.

Cardiovascular disorders. See under Respiratory System Disorders, below.

Driving. Most benzodiazepines can adversely affect parameters of driving performance in healthy subjects.[1] It is not entirely clear to what extent benzodiazepines contribute to the risk of driving accidents. A large case-control cohort study[2] in elderly drivers suggested that the risk of accidents was increased in those who took longer-acting benzodiazepines. However, younger drivers are more susceptible to the effects of benzodiazepines or zopiclone as a group;[3,4] the risk is increased by alcohol consumption.[3] Patients affected by drowsiness while taking benzodiazepines should not drive or operate machinery. In the UK, it is an offence to drive while unfit due to the influence of any drug, and benzodiazepines are considered to be the most likely psychotropic medication to impair driving performance, particularly the long-acting compounds.[5] However, it is also noted that drivers with psychiatric illnesses may be safer when well controlled with regular medication than when ill. Drowsiness often becomes less troublesome with continued use of these drugs.

The elderly. Old age may alter the distribution, elimination, and clearance of benzodiazepines.[1,2] Metabolic clearance of benzodiazepines metabolised principally by oxidation appears to be reduced but not clearance of those biotransformed by glucuronide conjugation or nitroreduction. Prolonged half-life in the elderly may be a result of such a decrease in clearance or of an increase in the volume of distribution. The clinical consequence of these changes depends on factors such as dosage schedule and extent of first-pass extraction by the liver.

Irrespective of pharmacokinetic changes, the elderly may exhibit increased sensitivity to acute doses of benzodiazepines.[1-3] Impairment of memory, cognitive function, and psychomotor performance and behaviour disinhibition may be more common than with younger patients.[4] Long-term use commonly exacerbates underlying dementia in elderly patients.[4]

The upshot of the pharmacokinetic and pharmacodynamic changes of benzodiazepines in the elderly is that adverse effects may be more frequent in these patients and lower doses are commonly required. An epidemiological study of persons 65 years and older found an increased rate of hip fracture among current users of long-acting benzodiazepines (*chlordiazepoxide*, *clorazepate*, *diazepam*, and *flurazepam*), but not among users of short-acting drugs (*alprazolam*, *bromazepam*, *lorazepam*, *oxazepam*, and *triazolam*).[5] A case-control study[6] of patients with falls leading to femur fractures suggested that the most important factor in increasing risk was the dose of benzodiazepine. However, another case-control study[7] found no correlation between hip fracture and benzodiazepines either as a group or according to half-life or to characterisation as an anxiolytic or a hypnotic; there might, though, be an increase in risk with lorazepam. There was also an increased risk associated with use of two or more benzodiazepines. Nonetheless, if use of a benzodiazepine is considered necessary in elderly patients, a short-acting drug is to be preferred. It should also be remembered that the elderly are at increased risk of sleep-related breathing disorders, such as sleep apnoea and the use of hypnotics such as benzodiazepines should be avoided in these patients (see Respiratory System Disorders, below).

Hangover effects. Long-acting benzodiazepines accumulate in the body to a greater extent than ones with a shorter half-life. Although this might be expected to increase the frequency of daytime sedation and impairment of performance (so-called hangover effects) after a hypnotic dose, such a straightforward relationship has not always been observed in practice.[1]

Anterograde amnesia is more common with short-acting drugs such as triazolam; 'traveller's amnesia' has been used to describe amnesia in persons taking benzodiazepines for sleep disturbances resulting from jet lag.[2]

High-altitude disorders. Sleep may be impaired at high altitude due to frequent arousals associated with pronounced oxygen desaturation and periodic breathing. Traditional advice has been that sedatives should not be given at high altitude.[1] Caution may also be warranted at moderate altitudes especially in nonacclimatised climbers.[2] It has been argued that since diazepam, and possibly other sedatives, blunt the hypoxic ventilatory response, sleep hypoxaemia might be exacerbated. A small study[3] has suggested that small doses of a short-acting benzodiazepine, such as temazepam, might actually improve the subjective quality of sleep and reduce episodes of arterial desaturation without changing mean oxygen saturation. However the possibility of an interaction between acetazolamide taken for prophylaxis or treatment of acute mountain sickness and the benzodiazepine should be borne in mind; ventilatory depression in a mountain climber with acute mountain sickness was considered to be due to the potentiation of triazolam by acetazolamide.[4]

Neonates. A retrospective review of records from 63 infants given lorazepam or midazolam in a neonatal intensive-care unit indicated that there were 14 cases of adverse effects associated with benzodiazepine use (seizures in 6 cases, hypotension in 5, and respiratory depression in 3).[1] Seven of these were associated with intravenous bolus doses of lorazepam and the remainder with continuous midazolam infusions. Despite the limitations of the study, the incidence of adverse effects in this group seemed high, and the authors recommended that benzodiazepine use in neonates be accompanied by close monitoring.

Nervous system disorders. Benzodiazepines can reduce cerebral perfusion pressure and blood oxygenation to an extent that results in irreversible neurological damage in patients with head injuries. Consequently, they should be given with great care to such patients.[1,2] Their use should be avoided for the control of seizures in patients with head injuries or other acute neurological lesions as these patients can be managed effectively with phenytoin.

EPILEPSY. As with other antiepileptic drugs,[1] there have been rare reports of benzodiazepines producing paradoxical exacerbation of seizures in patients with epilepsy.[2-5]

Porphyria. Diazepam has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Intravenous diazepam has been used successfully, however, to control status epilepticus occurring after the acute porphyric attack. For a discussion of the management of seizures associated with acute porphyric attacks, see p.471.

Pregnancy. Benzodiazepines have been widely used in pregnant patients.[1] Use of benzodiazepines in the *third trimester* and during *labour* seems to be associated in some infants with neonatal withdrawal symptoms or the floppy infant syndrome. Also a small number exposed *in utero* to benzodiazepines have shown slow development in the early years but by 4 years of age most had developed normally, and for those that had not it was not possible to prove a cause-effect relationship with benzodiazepine exposure. In a meta-analysis[2] of live births after benzodiazepine use during the *first trimester* of pregnancy, pooled data from cohort studies showed no apparent association between benzodiazepine use and the risk of major malformations or oral cleft alone. There was, however, a small but significantly increased risk of oral cleft according to data from case-control studies. Although benzodiazepines did not appear to be a major human teratogen, use of ultrasonography was advised to rule out visible forms of cleft lip. The UK CSM has recommended[3] that women of child-bearing potential prescribed benzodiazepines should be advised to contact the physician about stopping the drug if they intend to become, or suspect that they are, pregnant.

Respiratory system disorders. Benzodiazepines may affect the control of ventilation during sleep and may worsen sleep apnoea or other sleep-related breathing disorders especially in patients with chronic obstructive pulmonary disease or cardiac failure.[1] Risk factors for sleep apnoea, which often goes undiagnosed, include old age, obesity, male sex, postmenopausal status in women, and a history of heavy snoring. Although benzodiazepines may reduce sleep fragmentation, their long-term use may result in conversion from partial to complete obstructive sleep apnoea in heavy snorers or in short repetitive central sleep apnoea in patients with recent myocardial infarction.

Interactions

Enhanced sedation or respiratory and cardiovascular depression may occur if diazepam or other benzodiazepines are given with other drugs that have CNS-depressant properties; these include alcohol, antidepressants, sedative antihistamines, antipsychotics, general anaesthetics, other hypnotics or sedatives, and opioid analgesics. The sedative effect of benzodiazepines may also be enhanced by cisapride. Adverse effects may also be produced by use with drugs that interfere with the metabolism of benzodiazepines. Drugs that have been reported to alter the pharmacokinetics of benzodiazepines are discussed in detail below but few of these interactions are likely to be of clinical significance. Benzodiazepines such as diazepam that are metabolised primarily by hepatic microsomal oxidation may be more susceptible to pharmacokinetic changes than those eliminated primarily by glucuronide conjugation.

Analgesics. The peak plasma concentration of oxazepam was significantly decreased when *diflunisal* was given to 6 healthy subjects, while the renal clearance of the glucuronide metabolite was reduced and its mean elimination half-life increased from 10 to 13 hours.[1] Diflunisal also displaced oxazepam from plasma protein binding sites *in vitro*. *Aspirin* shortened the time to induce anaesthesia with midazolam in 78 patients also possibly due to competition for plasma protein binding sites.[2] *Paracetamol* produced no significant change in plasma concentrations of diazepam or its major metabolite and only marginal changes in urine concentrations in 4 healthy subjects.[3]

Benzodiazepines such as diazepam, lorazepam, and midazolam may be used with opioid analgesics in anaesthetic or analgesic regimens. An additive sedative effect is to be expected[4] but there are also reports of severe respiratory depression with midazolam and *fentanyl*[5] or sudden hypotension with midazolam and fentanyl[6] or *sufentanil*.[7] The clearance of midazolam appears to be reduced by fentanyl,[8] possibly as a result of competitive inhibition of metabolism by the cytochrome P450 isoenzyme CYP3A. Careful monitoring is therefore required during use of midazolam with these opioids and the dose of both drugs may need to be reduced. Synergistic potentiation of the induction of anaesthesia has been reported between midazolam and fentanyl,[9] but one study has suggested that midazolam can reduce the analgesic effects of sufentanil.[10] Pretreatment with *morphine* or *pethidine* has decreased the rate of oral absorption of diazepam. This has been attributed to the effect of opioid analgesics on gastrointestinal motility.[11]

Dextropropoxyphene prolonged the half-life and reduced the clearance of alprazolam but not diazepam or lorazepam in healthy subjects.[12]

Antiarrhythmics. An interaction between clonazepam and existing therapy with *amiodarone* was suspected in a 78-year-old man who experienced symptoms of benzodiazepine toxicity 2 months after starting with clonazepam 500 micrograms given at bedtime for restless leg syndrome;[1] symptoms resolved on withdrawal of clonazepam.

1. Witt DM, *et al.* Amiodarone-clonazepam interaction. *Ann Pharmacother* 1993; **27:** 1463–4.

Antibacterials. Both *erythromycin*[1] and *troleandomycin*[2] have been reported to inhibit the hepatic metabolism of triazolam in healthy subjects. Peak plasma-triazolam concentrations were increased, half-life prolonged, and clearance reduced. Troleandomycin prolonged the psychomotor impairment and amnesia produced by triazolam.[2] Loss of consciousness after erythromycin infusion in a child premedicated with midazolam was attributed to a similar interaction,[3] and increases in peak plasma concentrations of midazolam with profound and prolonged sedation have been reported after use of erythromycin.[4] Use of midazolam with erythromycin should be avoided or the dose of midazolam reduced by 50 to 75%. The clearance of midazolam is also reduced by *clarithromycin*, with an approximate doubling of the benzodiazepine's oral bioavailability.[5] The manufacturers of *quinupristin/dalfopristin* state that it too may increase plasma concentrations of midazolam. *Roxithromycin* has been reported[6] to have some effects on the pharmacokinetics and pharmacodynamics of midazolam but these changes were not thought clinically relevant. However, it was recommended that as a precaution the lowest possible effective dose of midazolam should be used when given with roxithromycin. In another study[7] *azithromycin* did not appear to have any effect on the metabolism or psychomotor effects of midazolam.

There is an isolated report of significant rises in steady-state blood-midazolam concentration coinciding with dosage of *ciprofloxacin*.[8] Also ciprofloxacin has been reported to reduce diazepam clearance and prolong its terminal half-life,[9] although psychometric tests did not show any changes in diazepam's pharmacodynamics. However, ciprofloxacin appears to have no effect on the pharmacokinetics or pharmacodynamics of temazepam.[10]

Isoniazid has been reported to increase the half-life of a single dose of diazepam[11] and triazolam[12] but not of oxazepam[12] in healthy subjects. In contrast, *rifampicin* has decreased the half-life of alprazolam,[13] diazepam,[14] midazolam,[15] and nitrazepam[16] and more or less abolishes the effects of triazolam,[17] while *ethambutol* has no effect on diazepam pharmacokinetics.[11] In patients receiving therapy for tuberculosis with isoniazid, rifampicin, and ethambutol the half-life of a single diazepam dose was shortened and its clearance increased.[11] Thus the enzyme-inducing effect of rifampicin appears to predominate over the enzyme-inhibiting effect of isoniazid.

Anticoagulants. Plasma binding of diazepam and desmethyldiazepam was reduced, and free concentrations increased, immediately following *heparin* intravenously.[1]

Benzodiazepines do not usually interact with oral anticoagulants although there have been rare reports of altered anticoagulant activity.

1. Routledge PA, *et al.* Diazepam and N-desmethyldiazepam redistribution after heparin. *Clin Pharmacol Ther* 1980; **27:** 528–32.

Antidepressants. It has been recommended that the dosage of alprazolam should be reduced when given with *fluvoxamine*, as concomitant use has resulted in doubling of plasma-alprazolam concentrations.[1] Since plasma concentrations of bromazepam[2] and of diazepam[3] also appear to be affected by fluvoxamine, it has been suggested that patients taking fluvoxamine who require a benzodiazepine should preferentially receive one such as lorazepam, which has a different metabolic pathway.[3] Small studies suggest that *fluoxetine* can also increase plasma concentrations of alprazolam.[4,5] Fluoxetine appears to have a similar effect on diazepam but plasma concentrations of diazepam's active metabolite desmethyldiazepam are reduced and it is considered that the overall effect is likely to be minor.[6] The potential for a clinically significant interaction with *sertraline*, *paroxetine*, or *citalopram* is considered to be less.[7]

The US manufacturers have reported that alprazolam may increase the steady-state plasma concentrations of *imipramine* and *desipramine*, although the clinical significance of such changes is unknown. For a suggestion that benzodiazepines may increase the oxidation of *amineptine* to a toxic metabolite, see Effects on the Liver under Adverse Effects of Amitriptyline, p.377.

Nefazodone has been reported to raise concentrations of alprazolam and triazolam, resulting in increased sedation, and impairment of psychomotor performance.[8,9] Nefazodone may inhibit the oxidative metabolism of alprazolam and triazolam. Raised concentrations of midazolam have similarly been seen when given by mouth with nefazodone.[10] No interaction was reported with lorazepam, which is primarily eliminated by conjugation.

For reference to an isolated report of hypothermia after administration of diazepam and *lithium*, see p.405.

There have been occasional reports of sexual disinhibition in patients taking *tryptophan* with benzodiazepines.

Antiepileptics. *Carbamazepine*, *phenobarbital*, and *phenytoin* are all inducers of hepatic drug-metabolising enzymes. Therefore, in patients receiving long-term therapy with these drugs the metabolism of benzodiazepines may be enhanced. For oral midazolam the effects of carbamazepine or phenytoin may be sufficient to virtually abolish the effects of a standard dose, with a more than 90% reduction in peak serum concentrations of the benzodiazepine.[1] Interactions between benzodiazepines and these antiepileptics are further discussed on p.475 (carbamazepine) and p.499 (phenytoin).

Results from a study[2] involving 66 children and adults receiving clobazam as adjunctive therapy for epilepsy showed a significant increase in clobazam clearance, leading to accumulation of its principal active metabolite *N*-desmethylclobazam, in the 16 patients also taking *felbamate*. The metabolism of clobazam and *N*-desmethylclobazam was reduced by *stiripentol*, a potent hepatic enzyme inhibitor, resulting in a threefold increase in the plasma concentrations of this metabolite.[3]

Serum-clonazepam concentrations fell markedly in 4 of 8 children who had *lamotrigine* added to their therapy.[4]

Sodium valproate has been reported to displace diazepam from plasma-protein binding sites.[5] Sporadic reports exist of adverse effects when valproate is given with clonazepam[6,7] with the development of drowsiness and, more seriously, absence status epilepticus, but the existence of an interaction is considered to be unproven.[8] Drowsiness has also been reported when valproate was given with nitrazepam.[9] Use of valproate semisodium with lorazepam has resulted in raised concentrations of lorazepam due to inhibition of glucuronidation of lorazepam.[10]

Antifungals. Both a single dose and multiple doses of *ketoconazole* decreased the clearance of a single intravenous injection of chlordiazepoxide.[1] Studies[2-4] have shown that ketoconazole and *itraconazole* can produce marked pharmacokinetic interactions with midazolam or triazolam and greatly increase the intensity and duration of action of these benzodiazepines. The area under the plasma concentration-time curve for midazolam was increased by 15 times by ketoconazole and by 10 times by itraconazole while peak plasma concentrations of midazolam were increased fourfold and threefold, respectively.[2] The area under the curve for triazolam was increased by 22 times by ketoconazole and by 27 times by itraconazole;[3] peak plasma concentrations of triazolam were increased about threefold by both antifungals. Ketoconazole has also been reported to have a similar effect on alprazolam.[5] One study[6] indicated that the risk of interaction persists for several days after cessation of itraconazole therapy. It is recommended that the use of these antifungals with benzodiazepines should be avoided or that the dose of the benzodiazepine should be greatly reduced. A similar but less pronounced interaction occurs between *fluconazole* and midazolam[7] or triazolam;[8] nonetheless the dosage of the benzodiazepine should be reduced during use together.

Antihistamines. A suggestion[1] that a reduction in temazepam metabolism caused by *diphenhydramine* may have contributed to perinatal death after ingestion of these drugs by the mother.

1. Kargas GA, *et al.* Perinatal mortality due to interaction of diphenhydramine and temazepam. *N Engl J Med* 1985; **313:** 1417–18.

Antivirals. The NNRTIs *delavirdine* and *efavirenz*,[1] and HIV-protease inhibitors such as *indinavir*, *nelfinavir*, *ritonavir*,[1-3] and *saquinavir*[1,4] may inhibit the hepatic microsomal systems involved in the metabolism of some benzodiazepines. Prolonged use of protease inhibitors may also *induce* these metabolic systems; interactions may therefore be complex and difficult to predict. Monitoring and dosage adjustments for the benzodiazepine may be needed, or the combination should be avoided. Benzodiazepines which should **not** be used with HIV-protease inhibitors include alprazolam, clorazepate, diazepam, estazolam, flurazepam, midazolam, and triazolam.

4. Palkama VJ, *et al.* Effect of saquinavir on the pharmacokinetics and pharmacodynamics of oral and intravenous midazolam. *Clin Pharmacol Ther* 1999; **66:** 33–9.

Beta blockers. A clear pattern of interactions between benzodiazepines and beta blockers has not emerged. *Propranolol* may inhibit the metabolism of diazepam[1,2] and bromazepam,[3] and *metoprolol* may inhibit the metabolism of diazepam[1,4] or bromazepam[5] to some extent, although in many cases the effect on pharmacokinetics and pharmacodynamics is unlikely to be of clinical significance. No significant pharmacokinetic interaction has been seen between propranolol and alprazolam,[2] lorazepam,[2] or oxazepam,[6] although the rate of alprazolam absorption may be decreased.[2] Similarly no pharmacokinetic interaction has been seen between *atenolol* and diazepam,[1] *labetalol* and oxazepam,[6] or metoprolol and lorazepam.[5]

Calcium-channel blockers. Peak plasma concentrations of midazolam were doubled and the elimination half-life of midazolam prolonged when given to healthy subjects receiving *diltiazem* or *verapamil*.[1] A similar interaction has been found between diltiazem and triazolam.[2,3] Concomitant use should be avoided or the dose of these benzodiazepines reduced in such use.

1. Backman JT, *et al.* Dose of midazolam should be reduced during diltiazem and verapamil treatments. *Br J Clin Pharmacol* 1994; **37:** 221–5.

3. Kosuge K, *et al.* Enhanced effect of triazolam with diltiazem. *Br J Clin Pharmacol* 1997; **43:** 367–72.

Ciclosporin. *In-vitro* studies suggested that ciclosporin could inhibit the metabolism of midazolam.[1] However, blood-ciclosporin concentrations in patients given ciclosporin to prevent graft rejection were considered too low to result in such an interaction.

1. Li G, *et al.* Is cyclosporin A an inhibitor of drug metabolism? *Br J Clin Pharmacol* 1990; **30:** 71–7.

Clonidine. Anxiety was reduced and sedation was enhanced when clonidine was given with flunitrazepam for premedication.[1]

1. Kulka PJ, *et al.* Sedative and anxiolytic interactions of clonidine and benzodiazepines. *Br J Anaesth* 1994; **72** (suppl 1): 81.

Clozapine. For reports of cardiorespiratory collapse and other adverse effects in patients taking benzodiazepines and clozapine, see p.984.

Corticosteroids. The metabolism of midazolam was increased in chronic users of *glucocorticoids*,[1] perhaps due to the induction of cytochrome P450 isoenzyme CYP3A4, or of enzymes responsible for glucuronidation. The changes were not considered clinically relevant if midazolam was given intravenously, but might be so if it was given orally.

Digoxin. For the effects of alprazolam and diazepam on digoxin pharmacokinetics, see p.1262.

Disulfiram. Evidence from healthy and alcoholic subjects suggests that chronic use of disulfiram can inhibit the metabolism of chlordiazepoxide and diazepam leading to a prolonged half-life and reduced clearance; there was little effect on the disposition of oxazepam.[1] No significant pharmacokinetic interaction was observed between disulfiram and alprazolam in alcoholic patients.[2] Temazepam toxicity, attributed to use of disulfiram with temazepam, has been reported.[3]

Gastrointestinal drugs. *Antacids* have variable effects on the absorption of benzodiazepines[1-6] but any resulting interaction is unlikely to be of major clinical significance.

Several studies, usually involving single doses of diazepam given to healthy subjects, have shown that *cimetidine* can inhibit the hepatic metabolism of diazepam.[7-10] The clearance of diazepam has generally been decreased and the half-life prolonged. Some studies have also shown impaired metabolic clearance of the major metabolite, desmethyldiazepam (nordazepam). Cimetidine has also been reported to inhibit the metabolism of other benzodiazepines (generally those metabolised by oxidation) including alprazolam,[11,12] bromazepam,[13] chlordiazepoxide,[14] clobazam,[15,16] flurazepam,[17] midazolam,[18] nitrazepam,[19] and triazolam.[11,12] Cimetidine does not appear to inhibit the hepatic metabolism of lorazepam,[17] oxazepam,[17] or temazepam.[20] The clinical significance of these interactions between cimetidine and benzodiazepines remains dubious, and little effect on cognitive function or degree of sedation has been shown.

Most studies have failed to find an effect of *ranitidine* on the hepatic metabolism of diazepam,[21-24] although one study[25] reported an increase in the bioavailability of a single oral dose of midazolam, and considered that an effect on hepatic clearance was more likely than an effect on absorption. These results were consistent with those of another study which showed an enhanced sedative effect of midazolam in patients pretreated with ranitidine.[26] Ranitidine has been reported to have no effect on the pharmacokinetics of lorazepam[22] or on the sedative effect of temazepam[26] but has increased the bioavailability of triazolam.[27] *Famotidine*[10] or *nizatidine*[24] do not appear to inhibit the hepatic metabolism of diazepam.

Oral diazepam was absorbed more rapidly after intravenous *metoclopramide*.[28] Enhanced motility of the gastrointestinal tract was implicated. *Cisapride* may also accelerate the absorption of diazepam.[29]

Studies of continuous *omeprazole* dosage on the pharmacokinetics of a single intravenous dose of diazepam in healthy subjects indicate inhibition of diazepam metabolism in a similar manner to cimetidine.[30,31] Omeprazole decreases the clearance and prolongs the elimination half-life of diazepam; in addition both the formation and elimination of desmethyldiazepam appear to be decreased. The effects may be greater in rapid than in slow metabolisers of omeprazole[32] and vary between ethnic groups.[33] The clinical significance of the interaction remains to be established. *Lansoprazole*[34] and *pantoprazole*[35] have been reported not to affect the pharmacokinetics of diazepam.

General anaesthetics. A synergistic interaction has been found for the hypnotic effects of midazolam and *thiopental*.[1] Although midazolam failed to produce anaesthesia at the doses used, the drug caused a twofold increase in the anaesthetic potency of thiopental. Similar synergistic interactions have been seen between midazolam and both *methohexital*[2] and *propofol*.[3,4] The interaction between midazolam and propofol could not be explained solely by alteration in free-plasma concentration of either drug,[5] although a later study[6] does suggest that propofol reduces the clearance of midazolam via its inhibitory effects on the metabolism of midazolam by the cytochrome P450 isoenzyme CYP3A4. It has been reported that midazolam can produce a marked reduction in the concentration of *halothane* required for anaesthesia.[7]

Grapefruit juice. Grapefruit juice has been reported to be able to increase the bioavailability of oral midazolam[1] or triazolam[2] and to raise peak plasma concentrations. However, these results have been contradicted by another study,[3] which found no evidence for an interaction.

1. Kupferschmidt HHT, *et al.* Interaction between grapefruit juice and midazolam in humans. *Clin Pharmacol Ther* 1995; **58:** 20–8.

Levodopa. For reference to the effects of benzodiazepines on levodopa, see Anxiolytics, p.808.

Neuromuscular blockers. For reference to the effect of diazepam on neuromuscular blockade, see p.1904.

Oral contraceptives. Some studies with alprazolam,[1] chlordiazepoxide,[2] and diazepam[3] have supported suggestions that oral contraceptives may inhibit the biotransformation of benzodiazepines metabolised by oxidation, although no significant pharmacokinetic alterations have been observed with clotiazepam,[4] or triazolam.[1] The biotransformation of benzodiazepines metabolised by conjugation, such as lorazepam, oxazepam, or temazepam, may be enhanced[1,2] or unchanged.[5] No consistent correlation has been observed between the above pharmacokinetic changes and clinical effects. It has been observed[6] that psychomotor impairment due to oral diazepam was greater during the menstrual pause than during the 21-daily oral contraceptive cycle. This may have been due to an effect of oral contraceptives on diazepam absorption. Another study[7] noted that women taking oral contraceptives appeared to be more sensitive to psychomotor impairment after single oral doses of alprazolam, lorazepam, or triazolam, than controls. The effects of temazepam were minimal in both groups. Alterations in sedative or amnesic effect could not be established with any certainty.

Penicillamine. Phlebitis associated with intravenous diazepam resolved with local heat but recurred on two separate occasions after oral penicillamine.[1]

1. Brandstetter RD, *et al.* Exacerbation of intravenous diazepam-induced phlebitis by oral penicillamine. *BMJ* 1981; **283:** 525.

Probenecid. Probenecid increased the half-life of intravenous lorazepam in 9 healthy subjects.[1] Probenecid was considered to impair glucuronide formation selectively and thus the clearance of drugs like lorazepam. Probenecid has also shortened the time to induce anaesthesia with midazolam in 46 patients.[2] The effect was considered to be due to competition for plasma protein binding sites. Probenecid has also been reported[3] to reduce the clearance of nitrazepam but not of temazepam.

3. Brockmeyer NH, *et al.* Comparative effects of rifampin and/or probenecid on the pharmacokinetics of temazepam and nitrazepam. *Int J Clin Pharmacol Ther Toxicol* 1990; **28:** 387–93.

Smooth muscle relaxants. Intracavernosal *papaverine* produced prolonged erection in 2 patients who had been given intravenous diazepam as an anxiolytic before the papaverine.[1]

1. Vale JA, *et al.* Papaverine, benzodiazepines, and prolonged erections. *Lancet* 1991; **337:** 1552.

Tobacco smoking. The Boston Collaborative Drug Surveillance Program reported drowsiness as an adverse effect of diazepam or chlordiazepoxide less frequently in smokers than non smokers.[1] Pharmacokinetic studies have, however, been divided between those indicating that smoking induces the hepatic metabolism of benzodiazepines and those showing no effect on benzodiazepine pharmacokinetics.[2] Hence, diminished end-organ responsiveness may in part account for the observed clinical effects. Taking large amounts of xanthine-containing beverages as well may decrease any enzyme-inducing effects of smoking.[3]

1. Boston Collaborative Drug Surveillance Program, Boston University Medical Center. Clinical depression of the central nervous system due to diazepam and chlordiazepoxide in relation to cigarette smoking and age. *N Engl J Med* 1973; **288:** 277–80.

3. Downing RW, Rickels K. Coffee consumption, cigarette smoking and reporting of drowsiness in anxious patients treated with benzodiazepines or placebo. *Acta Psychiatr Scand* 1981; **64:** 398–408.

Xanthines. There are reports of *aminophylline* given intravenously reversing the sedation from intravenous diazepam,[1-3] although not always completely[2] nor as effectively as flumazenil.[4] Blockade of adenosine receptors by aminophylline has been postulated as the mechanism of this interaction.[3,5]

Xanthine-containing beverages may be expected to decrease the incidence of benzodiazepine-induced drowsiness because of their CNS-stimulating effects and their ability to induce hepatic drug-metabolising enzymes. However, decreased drowsiness has only sometimes been seen and the actions of xanthines may themselves be decreased by heavy tobacco smoking.[6,7]

Pharmacokinetics

Diazepam is readily and completely absorbed from the gastrointestinal tract, peak plasma concentrations occurring within about 30 to 90 minutes of oral doses. Diazepam is rapidly absorbed when given as a rectal solution; peak plasma concentrations are achieved after about 10 to 30 minutes. Absorption may be erratic after intramuscular injection and lower peak plasma concentrations may be obtained compared with those after oral doses. Diazepam is highly lipid soluble and crosses the blood-brain barrier; it acts promptly on the brain, and its initial effects decrease rapidly as it is redistributed into fat depots and tissues.

Diazepam has a biphasic half-life with an initial rapid distribution phase and a prolonged terminal elimination phase of 1 or 2 days; its action is further prolonged by the even longer half-life of 2 to 5 days of its principal active metabolite, desmethyldiazepam (nordazepam). Diazepam and desmethyldiazepam accumulate on repeated dosage and the relative proportion of desmethyldiazepam in the body increases with long-term use. No simple correlation has been found between plasma concentrations of diazepam or its metabolites and their therapeutic effect.

Diazepam is extensively metabolised in the liver, notably via the cytochrome P450 isoenzyme CYP2C19; in addition to desmethyldiazepam, its active metabolites include oxazepam, and temazepam. It is excreted in the urine, mainly in the form of free or conjugated metabolites. Diazepam is 98 to 99% bound to plasma proteins.

The plasma elimination half-life of diazepam and/or its metabolites is prolonged in neonates, in the elderly, and in patients with liver disease. In addition to crossing the blood-brain barrier, diazepam and its metabolites also cross the placental barrier and are distributed into breast milk.

Absorption and plasma concentrations. *CHRONIC ORAL ADMINISTRATION.* In 36 patients who had received diazepam 2 to 30 mg daily for periods from one month to 10 years, plasma-diazepam concentrations were directly related to dose and inversely related to age.[1] There was a close association between the plasma concentrations of diazepam and its metabolite desmethyldiazepam and both concentrations were independent of the duration of therapy. Plasma-diazepam concentration ranges were 0.02 to 1.01 micrograms/mL, and plasma-desmethyldiazepam concentration ranges were 0.055 to 1.765 micrograms/mL. A similar study[2] reached the same general conclusions.

RECTAL. In 6 *adults* given diazepam 10 mg by mouth or as a solution (*Valium injection*) by rectum, mean bioavailability was 76 and 81%, respectively compared with the same dose by intravenous injection.[1] Bioavailability was lower with suppositories than with the solution given rectally. Studies support the use of rectal solution rather than suppositories in children.[2,3]

The elderly. For mention of pharmacokinetics in the elderly, see under Precautions, above.

Hepatic impairment. For reference to the altered pharmacokinetics of diazepam in patients with hepatic impairment see Administration in Hepatic Impairment, below.

Metabolism. Most benzodiazepines are highly lipophilic compounds requiring biotransformation before excretion from the body, and many form active metabolites that affect the duration of action. The benzodiazepines may be classified as long-, intermediate-, or short-acting compounds.[1]

- **Long-acting** benzodiazepines are either N_1-desalkyl derivatives (*delorazepam* and *nordazepam*) or are oxidised in the liver to N_1-desalkyl derivatives (benzodiazepines so oxidised include *chlordiazepoxide*, *clobazam*, *clorazepate*, *cloxazolam*, *diazepam*, *flurazepam*, *halazepam*, *ketazolam*, *medazepam*, *oxazolam*, *pinazepam*, *prazepam*, and *quazepam*). Clorazepate and prazepam may be considered as prodrugs since the metabolite is the expected active principle. Both parent drug and metabolites contribute to the activity of the other long-acting drugs. Further biotransformation of N_1-desalkylated metabolites proceeds much more slowly than for the parent drug, and they therefore accumulate in the body after a few days of treatment. The rate-limiting step of their metabolism (with the exception of the 1,5-derivatives) is C3-hydroxylation to the pharmacologically active oxazepam or its 2′-halogenated analogues.
- **Intermediate-acting** benzodiazepines are 7-nitrobenzodiazepines such as *clonazepam*, *flunitrazepam*, and *nitrazepam* which are metabolised by nitroreduction with no important known active metabolites. The metabolites of long- and intermediate-acting benzodiazepines require conjugation before excretion in the urine.
- **Short-acting** benzodiazepines include the C3-hydroxylated benzodiazepines such as *lorazepam*, *lormetazepam*, *oxazepam*, and *temazepam* which undergo rapid conjugation with glucuronic acid to water-soluble inactive metabolites that are excreted in the urine, and drugs such as *alprazolam*, *brotizolam*, *estazolam*, *etizolam*, *midazolam*, *tofisopam*, and *triazolam* which require oxidation involving aliphatic hydroxylation before subsequent conjugation. Although these hydroxylated metabolites may retain pharmacological activity, they are unlikely to contribute significantly to clinical activity because of their negligible plasma concentrations and rapid inactivation by glucuronidation.

Drug-metabolising capacity is influenced by many factors including genetics, age, sex, endocrine and nutritional status, smoking, disease, and concurrent drug therapy. This results in wide interindividual variation in both parent drug concentrations and metabolite-to-parent drug ratios.

Pregnancy. The passage of diazepam across the placenta depends in part on the relative degrees of protein binding in mother and fetus. This in turn is influenced by factors such as stage of pregnancy and plasma concentrations of free fatty acids in mother and fetus.[1-6] Adverse effects may persist in the neonate for several days after birth because of immature drug-metabolising enzymes. Competition between diazepam and bilirubin for protein binding sites could result in hyperbilirubinaemia in the neonate.[7]

For further adverse effects associated with the use of benzodiazepines during pregnancy, see under Precautions, above.

Uses and Administration

Diazepam is a long-acting benzodiazepine with anticonvulsant, anxiolytic, sedative, muscle relaxant, and amnestic properties. Its actions are mediated by enhancement of the activity of gamma-aminobutyric acid (GABA), a major inhibitory neurotransmitter in the brain. Diazepam is used in the short-term treatment of severe anxiety disorders (p.952), as a hypnotic in the short-term management of insomnia (p.957), as a sedative (p.956) and premedicant (p.1780), as an anticonvulsant (particularly in the management of status epilepticus and febrile convulsions), in the control of muscle spasm, and in the management of withdrawal symptoms (see also the references below).

Diazepam is **administered** orally, rectally, and parenterally with the risk of dependence very much influencing the dose and duration of treatment. Doses should be the lowest that can control symptoms and courses of treatment should be short, not normally exceeding 4 weeks, with diazepam being withdrawn gradually (see above). Elderly and debilitated patients should be given not more than one-half the usual adult dose. Dosage reduction may also be required in patients with hepatic or renal impairment.

Oral use is appropriate for many indications and modified-release formulations are available in some countries. *Rectal* use may be by suppository or rectal solution or gel. Diazepam is also given by deep intramuscular or slow intravenous injection, although absorption after *intramuscular injection* may be erratic and provides lower blood concentrations than those after oral doses. *Intravenous injection* should be carried out slowly into a large vein of the antecubital fossa at a recommended rate of no more than 1 mL of a 0.5% solution (5 mg) per minute. It is advisable to keep the patient in the supine position and under medical supervision for at least an hour after the dose. Diazepam may be given by continuous *intravenous infusion*; because of the risk of precipitation of diazepam, solutions should be freshly prepared following the manufacturer's directions regarding diluent and concentration of diazepam. Diazepam is substantially adsorbed onto some plastics (see Sorption, above). Facilities for resuscitation should always be available when diazepam is given intravenously.

Diazepam may be given for **severe anxiety** in *oral* doses of 2 mg three times daily to a maximum of 30 mg daily. A wider dose range of 4 to 40 mg daily in divided doses is used in the USA with children over 6 months of age receiving up to 10 mg daily. Diazepam may be given as a *rectal solution* in a dose of 500 micrograms/kg repeated after 12 hours if necessary or as *suppositories* in a dose of 10 to 30 mg. Diazepam may sometimes have to be given by intramuscular or intravenous *injection* when a dose of up to 10 mg may be used, repeated if necessary after 4 hours.

The benzodiazepines have a limited role in **insomnia** and diazepam is used for the short-term management of insomnia associated with anxiety. The *BNF* recommends an *oral* dose of 5 to 15 mg at bedtime, although doses up to 30 mg are licensed. Doses of 1 to 5 mg at bedtime have been used in children and adolescents aged from 12 to 18 years to control **night terrors** and **sleepwalking**.

Diazepam may be given for **premedication** before general anaesthesia or to provide sedative cover for minor surgical or investigative procedures. In adults, *oral* doses are in the range of 5 to 20 mg and when given by intravenous *injection* the dose is usually 100 to 200 micrograms/kg. Diazepam may also be given for **sedation** during minor surgical and medical procedures; in adults doses of 10 to 20 mg, given by intravenous injection over 2 to 4 minutes, are recommended. Diazepam 500 micrograms/kg may also be given as a rectal solution. For premedication and sedation in children and adolescents aged from 1 month to 18 years, the *BNFC* suggests that an oral dose of 200 to 300 micrograms/kg may be given 45 to 60 minutes beforehand; the maximum dose is 10 mg for those aged up to 12 years and 20 mg for adolescents aged up to 18 years. Diazepam 100 to 200 micrograms/kg may be given by intravenous injection over 2 to 4 minutes, immediately before the procedure, to those aged 1 month and older; the maximum dose is 5 mg for children aged up to 12 years and 20 mg for adolescents aged up to 18 years. When given as a rectal solution, the *BNFC* suggests the following doses based on age: 1 to 3 years, 5 mg; 3 to 12 years, 5 to 10 mg; 12 to 18 years, 10 mg. Some regard the perioperative use of diazepam in children undesirable since its effect and onset of action are unreliable and paradoxical effects may occur.

Diazepam is used in a variety of **seizures**. It is given *orally* as an adjunct in some types of epilepsy; for this purpose, 2 to 60 mg may be given daily in divided doses. A *rectal gel* formulation is also available for adjunctive use in the management of episodes of increased seizure activity in adults and children aged 2 years and over with refractory epilepsy; doses range from 200 to 500 micrograms/kg, depending on age, repeated after 4 to 12 hours if necessary. For febrile convulsions, status epilepticus, and convulsions due to poisoning, giving a *rectal solution* may be appropriate; suppositories are not suitable because absorption is too slow. Recommended doses for the rectal solution differ but a typical dose is 500 micrograms/kg for adults and children over 10 kg, repeated every 12 hours if necessary; if convulsions are not controlled by the first dose the use of other anticonvulsive measures is recommended. Rectal solutions are not licensed for such use in children under 1 year of age in the UK, but the *BNFC* suggests giving the following doses, repeated after 10 minutes if necessary, based on age: neonates, 1.25 to 2.5 mg; 1 month to 2 years, 5 mg. For older children it recommends: 2 to 12 years, 5 to 10 mg; 12 to 18 years, 10 mg. Alternatively, diazepam may be given *intravenously* to adults in a dose of 10 to 20 mg given at a rate of 5 mg/minute and repeated if necessary after 30 to 60 minutes. Other schedules involve giving smaller amounts more frequently or giving diazepam *intramuscularly*, though again absorption may be too slow. Once the seizures have been controlled, a slow intravenous infusion providing up to 3 mg/kg over 24 hours has been used to protect against recurrence. Doses by intravenous injection in children are within the range of 200 to 300 micrograms/kg; alternatively 1 mg may be given for each year of age. The *BNFC* has suggested that neonates and children aged from 1 month to 12 years may be given doses of 300 to 400 micrograms/kg by intravenous injection over 3 to 5 minutes, repeated after 10 minutes if necessary.

Diazepam may be given *orally* in daily divided doses of 2 to 15 mg to alleviate **muscle spasm**. The dose may be increased in severe spastic disorders, such as cerebral palsy, to up to 60 mg daily in adults. The *BNFC* suggests initial oral doses in children and adolescents, based on age and given twice daily, as follows: 1 to 12 months, 250 micrograms/kg; 1 to 5 years, 2.5 mg; 5 to 12 years, 5 mg; 12 to 18 years, 10 mg (maximum of 40 mg daily). If given by intramuscular or slow intravenous *injection* the dose is 10 mg repeated if necessary after 4 hours. Larger doses are used in tetanus in adults and children aged 1 month and over with 100 to 300 micrograms/kg being given every 1 to 4 hours by intravenous injection. Alternatively 3 to 10 mg/kg may be given over 24 hours by continuous intravenous infusion or by nasoduodenal tube using a suitable liquid oral dose form. Diazepam may also be given by the rectal route as a *rectal solution* in a dose of 500 micrograms/kg for adults and children over 10 kg in weight, repeated every 12 hours if necessary.

Symptoms of the **alcohol withdrawal syndrome** may be controlled by diazepam given *orally* in a dose of 5 to 20 mg, repeated if required after 2 to 4 hours; another approach is to give 10 mg three or four times on the first day reducing to 5 mg three or four times daily as required. Diazepam may need to be given by *injection* if the symptoms are severe and if delirium tremens has developed; 10 to 20 mg by intramuscular or intravenous injection may be adequate, although some patients may require higher doses.

◊ Reviews.

1. Ashton H. Guidelines for the rational use of benzodiazepines: when and what to use. *Drugs* 1994; **48:** 25–40.

Administration in hepatic impairment. Oxidative metabolism of diazepam is apparently reduced in patients with hepatic impairment, resulting in a prolonged half-life and reduced clearance.[1-3] A reduction in dosage was generally required in these studies, but no specific advice is given in licensed information for the UK or USA.

1. Branch RA, *et al.* Intravenous administration of diazepam in patients with chronic liver disease. *Gut* 1976; **17:** 975–83.
2. Klotz U, *et al.* Disposition of diazepam and its major metabolite desmethyldiazepam in patients with liver disease. *Clin Pharmacol Ther* 1977; **21:** 430–6.
3. Ochs HR, *et al.* Repeated diazepam dosing in cirrhotic patients: cumulation and sedation. *Clin Pharmacol Ther* 1983; **33:** 471–6.

Administration in renal impairment. Diazepam and its metabolites are excreted in urine, and licensed drug information suggests that dosage reduction may be required in patients with renal impairment, but gives no specific advice on how to do this.

Cardiac arrhythmias. Although not considered to be an antiarrhythmic, diazepam has been tried with good effect in treating the cardiotoxicity of chloroquine poisoning (see p.601). However, diazepam has been reported to possess both antiarrhythmic and pro-arrhythmic properties, possibly depending on the dose.[1]

1. Kumagai K, *et al.* Antiarrhythmic and proarrhythmic properties of diazepam demonstrated by electrophysiological study in humans. *Clin Cardiol* 1991; **14:** 397–401.

Chloroquine poisoning. For reference to the possible use of diazepam to decrease the cardiotoxic effects of chloroquine, see p.601.

Conversion and dissociative disorders. Conversion and dissociative disorders (formerly known as hysteria) are characterised by physical symptoms that occur in the absence of organic disease. Medication has no part to play in the treatment of these disorders unless they are secondary to conditions such as depression or anxiety disorders requiring treatment in their own right.

There have been suggestions that sedatives such as diazepam or midazolam may be used to confirm the diagnosis of hysterical paralysis.[1,2] The test tends to exacerbate organic disease while psychiatric dysfunction may improve.

1. Ellis SJ. Diazepam as a truth drug. *Lancet* 1990; **336:** 752–3.
2. Keating JJ, *et al.* Hysterical paralysis. *Lancet* 1990; **336:** 1506–7.

Disturbed behaviour. For a discussion of the management of behaviour disturbances associated with various psychotic disorders, and the value of benzodiazepines, see p.954. Benzodiazepines may sometimes be useful in palliative care for the relief of terminal restlessness. Midazolam is often used although other benzodiazepines such as diazepam have also been tried.[1] A suggested dose for diazepam is 5 to 10 mg given slowly as a rectal solution and repeated every 8 to 12 hours. In practice, however, haloperidol may be preferred; a review suggested that benzodiazepines used alone might exacerbate the problem. If agitation was severe haloperidol or risperidone could be combined with lorazepam, reserving subcutaneous midazolam for refractory cases.[2]

2. Jakobsson M, Strang P. Midazolam (Dormicum) vid terminal oro och agitation: sistahandsalternativ i palliativ vård. *Lakartidningen* 1999; **96:** 2079–81.

Dyspnoea. Despite the hazards of use in patients with any form of respiratory depression or pulmonary insufficiency (see Respiratory System Disorders under Precautions, above) benzodiazepines such as diazepam have been tried in the treatment of dyspnoea (p.104), in the belief that reduction of an elevated respiratory drive may alleviate respiratory distress. However, benefits have not been confirmed. Benzodiazepines may be of use in patients with advanced cancer who have rapid shallow respiration. A daily dose of 5 to 10 mg has been suggested for diazepam.

Eclampsia and pre-eclampsia. Diazepam has been used for the initial control of impending or actual eclampsia (p.470), but magnesium sulfate is now generally the preferred treatment.

Epilepsy and other convulsive disorders. Some benzodiazepines such as diazepam are used for the control of status epilepticus (p.469), including status epilepticus in patients with porphyria (p.471—but see also Porphyria under Precautions, above), and for febrile convulsions (p.470); diazepam has also been used in eclampsia (see above) and for neonatal seizures (p.471). Benzodiazepines such as clobazam and clonazepam may be used in the management of epilepsy (p.465), but their long-term use is limited by problems of sedation, dependence, and tolerance to the antiepileptic effects. Diazepam has been used as an adjunct in the management of some types of epilepsy including myoclonus.

Extrapyramidal disorders. For reference to the use of benzodiazepines in the treatment of antipsychotic-induced extrapyramidal disorders, see Chlorpromazine, p.971.

Irritable bowel syndrome. Although some benzodiazepines have been used in the management of irritable bowel syndrome (p.1699) there is no evidence to support their use in this condition. The related compound dextofisopam is under investigation.

Mania. Benzodiazepines have been used as short-term adjuncts in the initial control of manic episodes in patients with bipolar disorder (p.372) until lithium has achieved its full effect.

Muscle spasm. Diazepam and other benzodiazepines may be used for the relief of muscle spasm (p.1887) of various aetiologies including that secondary to muscle or joint inflammation or trauma, such as in acute **low back pain** (p.7), or resulting from **spasticity** (p.1887), **dystonias** (p.809), **stiff-man syndrome** (see below), **cerebral palsy**, **poisoning**, or **tetanus** (p.1901). High doses are often required and treatment may be limited by adverse effects or by risk of dependence.

STIFF-MAN SYNDROME. Stiff-man syndrome is a rare condition characterised by painful intermittent spasms and rigidity of the axial and limb muscles. Its exact cause is unknown but there is some evidence to implicate autoantibodies against one of the enzymes involved in the synthesis of the neurotransmitter gamma-aminobutyric acid. It is frequently associated with auto-immune diseases and type 1 diabetes mellitus. Patients typically respond to benzodiazepines and this may be of use in the differential diagnosis of the syndrome. Diazepam has been the mainstay of treatment but clonazepam may also be of use, especially in familial startle disease, a rare congenital form of stiff-man syndrome. Although rigidity and spasms in stiff-man syndrome are not completely resolved by diazepam the degree of improvement can be sufficient to restore the functional level to near normal. However, large doses are often required and sedation might be a limiting factor in some patients. Other drugs that have been used when diazepam is ineffective or poorly tolerated include baclofen or sodium valproate but benefit may be less evident. There have been isolated anecdotal reports of improvement with vigabatrin, tiagabine, and gabapentin. Antiepileptics or baclofen may sometimes be combined with benzodiazepines. Cortico-steroids may be of benefit, although any response may take several weeks, and the chronic nature of the disorder and the high incidence of type 1 diabetes mellitus may make their use problematic. Other attempts at immunomodulation such as plasmapheresis have yielded variable results; there is some evidence of the efficacy of immunoglobulins.

Nausea and vomiting. Benzodiazepines, particularly lorazepam, are used as adjuncts in the management of nausea and vomiting induced by cancer chemotherapy (p.1700), particularly anticipatory emesis.

Premenstrual syndrome. For mention of the limited role of benzodiazepines in the management of premenstrual syndrome, see p.2099.

Schizophrenia. Benzodiazepines may be useful adjuncts to antipsychotics in the initial management of schizophrenia (p.955).

Sleep-associated movement disorders. Sleep-associated movement disorders (p.958) rarely require treatment other than the symptomatic treatment of sleep-related medical problems. A number of such conditions, including restless legs syndrome, sleepwalking, and night terrors, have been reported to respond to benzodiazepines. Although the muscle relaxant and anxiolytic action of a benzodiazepine can be helpful in bruxism (teeth grinding) it has been recommended that they should only be prescribed on a short-term basis during the acute phase.

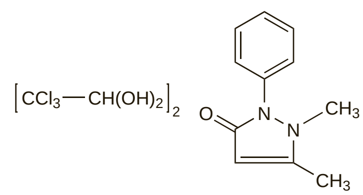
Dichloralphenazone *(BAN)*

Dicloralfenazona; Dikloraalifenatsoni; Dikloralfenazon.

$C_{15}H_{18}Cl_6N_2O_5$ = 519.0.
CAS — 480-30-8.
ATC — N05CC04.
ATC Vet — QN05CC04.



Pharmacopoeias. In *US.*

USP 31 (Dichloralphenazone). A white microcrystalline powder with a slight odour characteristic of cloral hydrate. Freely soluble in water, in alcohol, and in chloroform; soluble in dilute acids. It is decomposed by dilute alkalis liberating chloroform.

Profile

Dichloralphenazone dissociates when given, to form cloral hydrate and phenazone. It has the general properties of cloral hydrate (p.979), although it is less likely to cause gastric irritation after oral doses. Phenazone-induced skin eruptions may, however, occur (see p.116). Dichloralphenazone is used in some countries in combination preparations mainly for the treatment of tension and vascular headaches.

Porphyria. Dichloralphenazone has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Preparations

USP 31: Isometheptene Mucate, Dichloralphenazone, and Acetaminophen Capsules.

Proprietary Preparations (details are given in Part 3)

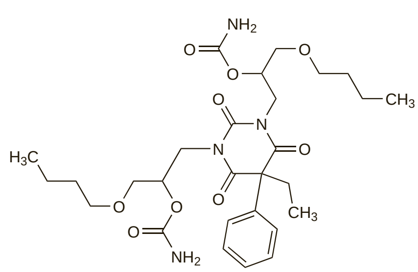
Multi-ingredient: ***USA:*** Duradrin†; Midrin; Migratine†.

Difebarbamate *(rINN)*

Difébarbamate; Difebarbamato; Difebarbamatum. 1,3-Bis(3-butoxy-2-hydroxypropyl)-5-ethyl-5-phenylbarbituric acid dicarbamate ester.

Дифебарбамат

$C_{28}H_{42}N_4O_9$ = 578.7.
CAS — 15687-09-9.



Profile

Difebarbamate is a barbiturate with general properties similar to those of amobarbital (p.961). Tetrabamate, a complex of difebarbamate, febarbamate, and phenobarbital, has been used in the management of anxiety disorders and alcohol withdrawal syndrome but was also associated with the development of hepatitis. Furthermore barbiturates are not considered appropriate in the management of these conditions.

Preparations

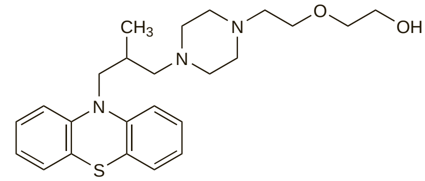
Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Hung.:*** Atrium†.

Dixyrazine

Diksyratsiini; Dixirazina; Dixyrazin; Dixyrazinum; UCB-3412. 2-(2-{4-[2-Methyl-3-(phenothiazin-10-yl)propyl]piperazin-1-yl}ethoxy)ethanol.

$C_{24}H_{33}N_3O_2S$ = 427.6.
CAS — 2470-73-7.
ATC — N05AB01.
ATC Vet — QN05AB01.



Profile

Dixyrazine is a phenothiazine with general properties similar to those of chlorpromazine (p.969). It has a piperazine side-chain. It is given for its antipsychotic, antiemetic, and sedative properties in oral doses ranging from 20 to 75 mg daily. Dixyrazine has also been given by injection.

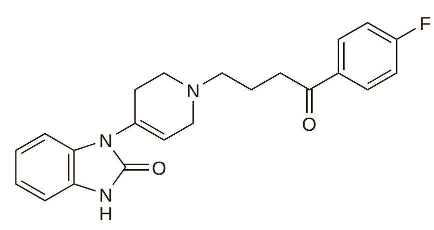
Droperidol *(BAN, USAN, rINN)*

Dropéridol; Droperidoli; Droperidolis; Droperidolum; McN-JR-4749; R-4749. 1-{1-[3-(4-Fluorobenzoyl)propyl]-1,2,3,6-tetrahydro-4-pyridyl}-benzimidazolin-2-one.

Дроперидол

$C_{22}H_{22}FN_3O_2$ = 379.4.
CAS — 548-73-2.
ATC — N01AX01; N05AD08.
ATC Vet — QN01AX01; QN05AD08.



Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Droperidol). A white or almost white powder. It exhibits polymorphism. Practically insoluble in water; sparingly soluble in alcohol; freely soluble in dichloromethane and in dimethylformamide. Protect from light.

USP 31 (Droperidol). A white to light tan amorphous or microcrystalline powder. Practically insoluble in water; soluble 1 in 140 of alcohol, 1 in 4 of chloroform, and 1 in 500 of ether. Store under nitrogen in airtight containers at a temperature of 8° to 15°. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969. There is an increased risk of cardiotoxicity and prolongation of the QT interval (see p.970) with droperidol. Droperidol should not be used in patients with known or suspected QT prolongation; it should also be used with extreme caution in patients at risk of arrhythmias, including those with impairment of cardiac function, hypokalaemia, or other electrolyte imbalance. It is recommended that a baseline ECG is performed in all patients before use of droperidol.

Uses and Administration

Droperidol is a butyrophenone with general properties similar to those of haloperidol (p.1001). The duration of action of droperidol has been reported to last about 2 to 4 hours although alteration of alertness may last for up to 12 hours.

One manufacturer of droperidol (*Janssen-Cilag*) voluntarily withdrew it from the market worldwide in March 2001 after reports of QT prolongation, serious ventricular arrhythmias, or sudden death in association with its use. However, in the USA, droperidol remained available from other manufacturers although its use was restricted to the management of nausea and vomiting after surgical or diagnostic procedures in patients who fail to show an adequate response to other treatments. It is also still available, in some other countries, for use as a premedicant, as an adjunct in anaesthesia, and for the control of agitated patients in acute psychoses and in mania. Droperidol has been used in the management of chemotherapy-induced nausea and vomiting. It has also been used with an opioid analgesic such as fentanyl citrate to maintain patients in a state of neuroleptanalgesia in which they are calm and indifferent to the surroundings and able to cooperate with the surgeon. The longer duration of action of droperidol must be kept in mind when using it with such opioid analgesics.

For the prevention of postoperative **nausea and vomiting** a maximum initial dose of 2.5 mg intramuscularly or intravenously has been given; additional doses of 1.25 mg may be given if necessary. Children aged 2 years and over have been given a maximum initial dose of 100 micrograms/kg intramuscularly or intravenously.

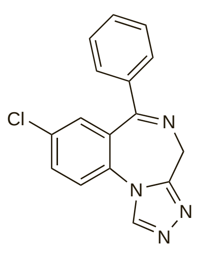
Estazolam *(USAN, rINN)*

Abbott-47631; D-40TA; Estatsolaami; Estazolamum. 8-Chloro-6-phenyl-4*H*-1,2,4-triazolo[4,3-*a*]-1,4-benzodiazepine.

Эстазолам

$C_{16}H_{11}ClN_4$ = 294.7.
CAS — 29975-16-4.
ATC — N05CD04.
ATC Vet — QN05CD04.



Pharmacopoeias. In *Chin.* and *Jpn.*

Dependence and Withdrawal

As for Diazepam, p.987.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987.

Interactions

As for Diazepam, p.989.

Pharmacokinetics

Peak plasma concentrations of estazolam are reached on average within 2 hours of oral doses. Estazolam is about 93% protein bound. Reported mean elimination half-lives have generally been in the range of 10 to 24 hours. Estazolam is extensively metabolised, mainly to 4-hydroxyestazolam and 1-oxoestazolam, which are considered inactive. These metabolites are excreted, either free or conjugated, in the urine with small amounts detected in the faeces. Only a small proportion of a dose is excreted as unchanged drug.

Uses and Administration

Estazolam is a short-acting benzodiazepine with general properties similar to those of diazepam (p.992). It is given as a hypnotic in the short-term management of insomnia (p.957) in usual oral doses of 1 to 2 mg at night. Small or debilitated elderly patients may be given an initial dose of 0.5 mg.

Preparations

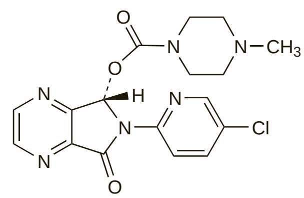
Proprietary Preparations (details are given in Part 3)
Arg.: Somnatrol†; ***Braz.:*** Noctal; ***Denm.:*** Domnamid†; ***Fr.:*** Nuctalon; ***Indon.:*** Esilgan; ***Ital.:*** Esilgan; ***Jpn:*** Eurodin; ***Mex.:*** Tasedan; ***Philipp.:*** Esilgan; ***Port.:*** Kainever; ***USA:*** Prosom†.

Eszopiclone *(USAN, rINN)*

Eszopiclona; Eszopiclonum; (*S*)-Zopiclone; (+)-Zopiclone. (+)-(5*S*)-6-(5-Chloropyridin-2-yl)-7-oxo-6,7-dihydro-5*H*-pyrrolo[3,4-*b*]pyrazin-5-yl 4-methylpiperazine-1-carboxylate.

Эсзопиклон

$C_{17}H_{17}ClN_6O_3$ = 388.8.
CAS — 138729-47-2.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of eszopiclone:
Sleepeasy.

Profile

Eszopiclone is the (+)-isomer of zopiclone (p.1039) and is used similarly as a hypnotic in the short-term management of insomnia.

The usual oral dose is 2 mg immediately before bedtime; if appropriate, the dose may be started at or increased to 3 mg. In elderly patients who have difficulty falling asleep, the initial dose is 1 mg; this may be increased to 2 mg. For elderly patients who have difficulty staying asleep, the starting dose is 2 mg.

The starting dose should be reduced in patients taking potent inhibitors of the cytochrome P450 isoenzyme CYP3A4; a dose not exceeding 1 mg is recommended which may then be increased to 2 mg. For doses in patients with hepatic impairment, see below.

◊ Reviews.

1. Melton ST, *et al.* Eszopiclone for insomnia. *Ann Pharmacother* 2005; **39:** 1659–66.
2. Halas CJ. Eszopiclone. *Am J Health-Syst Pharm* 2006; **63:** 41–8.

Administration in hepatic impairment. The starting oral dose of eszopiclone should be reduced to 1 mg at bedtime in patients with severe hepatic impairment. No dose adjustment is necessary in patients with mild to moderate impairment.

Preparations

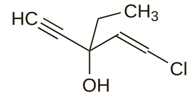
Proprietary Preparations (details are given in Part 3)
Arg.: Inductal; ***USA:*** Lunesta.

Ethchlorvynol *(BAN, rINN)*

β-Chlorovinyl Ethyl Ethynyl Carbinol; Etclorvinol; Éthchlorvynol; *E*-Ethchlorvynol; Ethchlorvynolum; Etkloorivinoli; Etklorvinol. 1-Chloro-3-ethylpent-1-en-4-yn-3-ol.

Этхлорвинол

C_7H_9ClO = 144.6.
CAS — 113-18-8.
ATC — N05CM08.
ATC Vet — QN05CM08.



Pharmacopoeias. In *US.*

USP 31 (Ethchlorvynol). A colourless to yellow, slightly viscous liquid having a characteristic pungent odour. It darkens on exposure to air and light. Immiscible with water; miscible with most organic solvents. Store in airtight containers of glass or polyethylene, using polyethylene-lined closures. Protect from light.

Dependence and Withdrawal

Prolonged use of ethchlorvynol may lead to dependence similar to that with barbiturates (see Amobarbital, p.962).

Adverse Effects

Adverse effects of ethchlorvynol include gastrointestinal disturbances, dizziness, headache, unwanted sedation and other symptoms of CNS depression such as ataxia, facial numbness, blurred vision, and hypotension. Hypersensitivity reactions include skin rashes, urticaria, and occasionally, thrombocytopenia and cholestatic jaundice. Idiosyncratic reactions include excitement, severe muscular weakness, and syncope without marked hypotension.

Acute overdosage is characterised by prolonged deep coma, respiratory depression, hypothermia, hypotension, and relative bradycardia. Pancytopenia and nystagmus have occurred.

Pulmonary oedema has followed abuse by intravenous injection.

Treatment of Adverse Effects

Treatment is as for barbiturate overdose (see Amobarbital, p.962). Haemoperfusion may be of value in the treatment of severe poisoning with ethchlorvynol.

Precautions

Ethchlorvynol should be used with caution in patients with hepatic or renal impairment or with depression, in patients with severe uncontrolled pain, and, as with all sedatives, in those with impaired respiratory function. It may cause drowsiness; affected patients should not drive or operate machinery.

Excessively rapid absorption of ethchlorvynol in some patients has been reported to produce giddiness and ataxia; this may be reduced by giving it with food.

Porphyria. Ethchlorvynol has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

The effect of ethchlorvynol may be enhanced by alcohol, barbiturates, and other CNS depressants. Ethchlorvynol has been reported to decrease the effects of coumarin anticoagulants.

Tricyclic antidepressants. Transient delirium has been reported from the use of ethchlorvynol with *amitriptyline* but details of such an interaction do not appear to have been published in the literature.

Pharmacokinetics

Ethchlorvynol is readily absorbed from the gastrointestinal tract, peak plasma concentrations usually occurring within 2 hours of ingestion. It is widely distributed in body tissues and is extensively metabolised in the liver, and possibly to some extent in the kidneys. It has a biphasic plasma half-life with a rapid initial phase and a terminal phase reported to last from 10 to 20 hours. Ethchlorvynol is excreted mainly in the urine as metabolites and their conjugates. Ethchlorvynol crosses the placenta.

Uses and Administration

Ethchlorvynol is a hypnotic and sedative with some anticonvulsant and muscle relaxant properties. It is given for the short-term management of insomnia (p.957) but has been largely superseded by other drugs. Use for periods greater than one week is not recommended. The usual oral hypnotic dose is 500 mg at night but doses ranging from 200 mg to 1 g have been given. Taking doses with food has been recommended—see Precautions, above.

Preparations

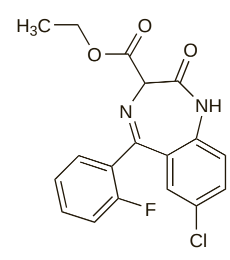
USP 31: Ethchlorvynol Capsules.

Ethyl Loflazepate *(rINN)*

CM-6912; Éthyle, Loflazépate d'; Ethylis Loflazepas; Loflazepato de etilo. Ethyl 7-chloro-5-(2-fluorophenyl)-2,3-dihydro-2-oxo-1*H*-1,4-benzodiazepine-3-carboxylate.

Этил Лофлазепат

$C_{18}H_{14}ClFN_2O_3$ = 360.8.
CAS — 29177-84-2.
ATC — N05BA18.
ATC Vet — QN05BA18.



Profile

Ethyl loflazepate is a long-acting benzodiazepine derivative with general properties similar to those of diazepam (p.986). It is used in the short-term treatment of anxiety disorders (p.952) in usual oral doses of 1 to 3 mg daily in a single dose or in divided doses.

Preparations

Proprietary Preparations (details are given in Part 3)
Arg.: Victan†; ***Belg.:*** Victan; ***Fr.:*** Victan; ***Jpn:*** Meilax; ***Mex.:*** Victan; ***Port.:*** Victan; ***Thai.:*** Victan.

Profile

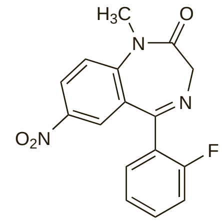
Fludiazepam is a short-acting benzodiazepine with general properties similar to those of diazepam (p.986). It has been used in the short-term treatment of anxiety disorders.

Flunitrazepam *(BAN, USAN, rINN)*

Flunitratsepaami; Flunitrazépam; Flunitrazepám; Flunitrazepamas; Flunitrazepamum; Ro-5-4200. 5-(2-Fluorophenyl)-1,3-dihydro-1-methyl-7-nitro-1,4-benzodiazepin-2-one.

Флунитразепам

$C_{16}H_{12}FN_3O_3$ = 313.3.
CAS — 1622-62-4.
ATC — N05CD03.
ATC Vet — QN05CD03.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of flunitrazepam:

Benzo; Circles; Date rape drug; Forget me drug; Forget pill; Forget-me pill; Forget-Me-Pill; Getting roached; La Rocha; La Roche; Lunch money drug; Mexican valium; Pingus; R2; R-2; Reynolds; Rib; Rick James Biatch; Roach 2; Roach-2; Roaches; Roachies; Roapies; Robutal; Rochas dos; Roche; Roches; Rolpes; Roofie; Roofies; Roopies; Rope; Rophies; Rophy; Ropies; Roples; Ropples; Row-shay; Ruffies; Ruffles; Sedexes; Wolfies.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*

Ph. Eur. 6.2 (Flunitrazepam). A white or yellowish crystalline powder. Practically insoluble in water; slightly soluble in alcohol; soluble in acetone. Protect from light.

Dependence and Withdrawal

As for Diazepam, p.987.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987.

Abuse. A WHO review[1] concluded that flunitrazepam had a moderate abuse potential that might be higher than that of other benzodiazepines. It was reported that there was current evidence of widespread abuse of flunitrazepam among drug abusers, particularly among those who used opioids or cocaine.

Flunitrazepam is tasteless and odourless and has been misused to incapacitate the victim and produce amnesia in sexual assaults[2] and drug-facilitated rape ('date rape').[3] A 1-mg dose may produce impairment for 8 to 12 hours.[4] Some manufacturers have incorporated a blue dye into flunitrazepam tablets to increase visibility when placed into drinks but caution is still necessary as it has been reported that blue tropical drinks and punches are being used to overcome this.[3]

3. National Institute on Drug Abuse. Rohypnol and GHB (issued May 2006). Available at: http://www.nida.nih.gov/PDF/Infofacts/Rohypnol06.pdf (accessed 21/08/08)
4. Smith KM, *et al.* Club drugs: methylenedioxymethamphetamine, flunitrazepam, ketamine hydrochloride, and γ-hydroxybutyrate. *Am J Health-Syst Pharm* 2002; **59:** 1067–76.

Breast feeding. Concentrations in breast milk the morning after a single evening 2-mg dose of flunitrazepam were considered to be too low to produce clinical effects in breast-fed infants, although accumulation in the milk might occur after repeated use.[1]

1. Kanto J, *et al*. Placental transfer and breast milk levels of flunitrazepam. *Curr Ther Res* 1979; **26:** 539–46.

Local reactions. Of 43 patients given a single intravenous dose of flunitrazepam 1 to 2 mg, two had local thrombosis 7 to 10 days later.[1] The incidence was lower than in those given diazepam [in solution]. However, there was little difference in the incidence of local reactions after intravenous use of flunitrazepam and diazepam in another study.[2]

1. Hegarty JE, Dundee JW. Sequelae after the intravenous injection of three benzodiazepines—diazepam, lorazepam, and flunitrazepam. *BMJ* 1977; **2:** 1384–5.
2. Mikkelsen H, *et al.* Local reactions after iv injections of diazepam, flunitrazepam and isotonic saline. *Br J Anaesth* 1980; **52:** 817–19.

Porphyria. Flunitrazepam has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for Diazepam, p.989.

Pharmacokinetics

Flunitrazepam is readily absorbed from the gastrointestinal tract. About 77 to 80% is bound to plasma proteins. It is extensively metabolised in the liver and excreted mainly in the urine as metabolites (free or conjugated). Its principal metabolites are 7-aminoflunitrazepam and *N*-desmethylflunitrazepam; *N*-desmethylflunitrazepam is reported to be pharmacologically active. The elimination half-life of flunitrazepam is reported to be between 16 and 35 hours. Flunitrazepam crosses the placental barrier and is distributed into breast milk.

2. Pariente-Khayat A, *et al.* Pharmacokinetics and tolerance of flunitrazepam in neonates and in infants. *Clin Pharmacol Ther* 1999; **66:** 136–9.

Pregnancy. Concentrations of flunitrazepam in umbilical-vein and umbilical-artery plasma were lower than those in maternal venous plasma about 11 to 15 hours after a dose of flunitrazepam 1 mg in 14 pregnant women; concentrations in amniotic fluid were lower still.[1]

1. Kanto J, *et al.* Placental transfer and breast milk levels of flunitrazepam. *Curr Ther Res* 1979; **26:** 539–46.

Uses and Administration

Flunitrazepam is a short-acting benzodiazepine with general properties similar to those of diazepam (p.992). It is used in the short-term management of insomnia (p.957), as a premedicant in surgical procedures, and for induction of anaesthesia (p.1780).

A usual oral dose for **insomnia** is 0.5 to 1 mg at night; up to 2 mg may be given if necessary. In elderly or debilitated patients the initial dose should not exceed 0.5 mg at night; up to 1 mg may be given if necessary.

A dose of 1 to 2 mg (15 to 30 micrograms/kg) has been given intramuscularly or orally for **premedication** or by slow intravenous injection for **induction** of general anaesthesia.

Adverse Effects and Treatment

As for Chlorpromazine, p.969. Flupentixol is less likely to cause sedation, but extrapyramidal effects are more frequent.

Sudden death. There has been a report of sudden death in 3 patients given depot injections of flupentixol decanoate.[1]

1. Turbott J, Smeeton WMI. Sudden death and flupenthixol decanoate. *Aust N Z J Psychiatry* 1984; **18:** 91–4.

Precautions

As for Chlorpromazine, p.972. Flupentixol is not recommended in states of excitement or overactivity, including mania.

Porphyria. Flupentixol is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Interactions

As for Chlorpromazine, p.973.

Pharmacokinetics

Flupentixol is readily absorbed from the gastrointestinal tract and is probably subject to first-pass metabolism in the gut wall. It is also extensively metabolised in the liver and is excreted in the urine and faeces in the form of numerous metabolites; there is evidence of enterohepatic recycling. Owing to the first-pass effect, plasma concentrations after oral doses are much lower than those after estimated equivalent doses of the intramuscular depot preparation. Moreover, there is very wide intersubject variation in plasma concentrations of flupentixol, but, in practice, no simple correlation has been found between the therapeutic effect and plasma concentrations of flupentixol and its metabolites. After oral doses, peak plasma concentrations occur in about 4 hours and the biological half-life is about 35 hours. Paths of metabolism of flupentixol include sulfoxidation, side-chain *N*-dealkylation, and glucuronic acid conjugation. Flupentixol is more than 95% bound to plasma proteins. It is widely distributed in the body and crosses the blood-brain barrier. Flupentixol crosses the placental barrier and small amounts have been detected in breast milk.

The decanoate ester of flupentixol is very slowly absorbed from the site of intramuscular injection and is therefore suitable for depot injection. It is gradually released into the bloodstream where it is rapidly hydrolysed to flupentixol.

Uses and Administration

Flupentixol is a thioxanthene antipsychotic with general properties similar to those of the phenothiazine, chlorpromazine (p.975). It has a piperazine side-chain. Flupentixol is used mainly in the treatment of schizophrenia (p.955) and other psychoses. Unlike chlorpromazine, an activating effect has been ascribed to flupentixol, and it is not indicated in overactive or manic patients. Flupentixol has also been used for its antidepressant properties.

Flupentixol is given orally as the hydrochloride although doses are expressed in terms of the base; flupentixol hydrochloride 3.5 mg is equivalent to about 3 mg of flupentixol. Flupentixol is also given as the longer-acting decanoate ester by deep intramuscular injection. The long-acting preparation available in the UK contains flupentixol decanoate as the *cis(Z)*-isomer (see Action, below) and doses are expressed in terms of the amount of *cis(Z)*-flupentixol decanoate.

The usual initial *oral* dose for the treatment of **psychoses** is the equivalent of 3 to 9 mg of flupentixol twice daily adjusted according to response; the maximum recommended daily dose is 18 mg. The initial dose in elderly and debilitated patients may need to be reduced to a quarter or a half of the usual starting dose. If given by *deep intramuscular* injection, an initial test dose of 20 mg of the decanoate, as 1 mL of a 2% oily solution, is used. Then after at least 7 days and according to response, this may be followed by doses of 20 to 40 mg every 2 to 4 weeks. Shorter dosage intervals or greater amounts may be required according to the patient's response. The initial dose in elderly and debilitated patients may need to be reduced to a quarter or a half of the usual starting dose. If doses greater than 40 mg (2 mL) are considered necessary they should be divided between 2 separate injection sites. Another means of reducing the volume of fluid to be injected in patients requiring high-dose therapy with flupentixol decanoate is to give an injection containing 100 or 200 mg/mL of the decanoate (10 or 20%). The usual maintenance dose is between 50 mg every 4 weeks and 300 mg every 2 weeks but doses of up to 400 mg weekly have been given in severe or resistant cases.

Flupentixol has also been given as the hydrochloride for the treatment of mild to moderate **depression**, with or without anxiety (p.373). The usual initial *oral* dose, expressed in terms of the equivalent amount of flupentixol, is 1 mg (0.5 mg in the elderly) daily, increased after 1 week to 2 mg (1 mg in the elderly) and then to a maximum of 3 mg (2 mg in the elderly) daily. Doses above 2 mg (1 mg in the elderly) should be given in 2 divided doses. The last dose of the day should be given no later than 4 p.m. and if no effect has been noted within 1 week of reaching the maximum dose, treatment should be withdrawn.

Action. Patients with acute schizophrenic illnesses taking α-flupentixol [(*Z*)-flupentixol or *cis*-flupentixol] improved more after 3 weeks than patients who were taking equal doses of β-flupentixol [(*E*)-flupentixol or *trans*-flupentixol] or a placebo.[1] The α-isomer had more effect on the positive symptoms of the disease; this difference was less apparent for the negative symptoms. The difference in activity between the isomers was attributed to the greater dopamine-receptor blocking activity of the α-isomer rather than to differences in distribution.[2]

Pharmacopoeias. In *Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Fluphenazine Enantate). A pale yellow viscous liquid or a yellow solid. Practically insoluble in water; very soluble in dehydrated alcohol and in dichloromethane; freely soluble in methyl alcohol. Protect from light.

USP 31 (Fluphenazine Enanthate). A pale yellow to yellow-orange, clear to slightly turbid, viscous liquid having a characteristic odour. Insoluble in water; soluble 1 in less than 1 of alcohol and of chloroform and 1 in 2 of ether. Stable in air at room temperature but unstable in strong light. Store in airtight containers. Protect from light.

Fluphenazine Hydrochloride *(BANM, rINNM)*

Flufenatsiinihydrokloridi; Flufenazin-dihydrochlorid; Flufenazin-hidroklorid; Flufenazinhydroklorid; Flufenazino hidrochloridas; Flufenazyny chlorowodorek; Fluphénazine, chlorhydrate de; Fluphenazine Dihydrochloride; Fluphenazini Dihydrochloridum; Fluphenazini hydrochloridum; Hidrocloruro de flufenazina.

Флуфеназина Гидрохлорид

$C_{22}H_{26}F_3N_3OS,2HCl$ = 510.4.

CAS — 146-56-5.

ATC — N05AB02.

ATC Vet — QN05AB02.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int.,* and *US.*

Ph. Eur. 6.2 (Fluphenazine Dihydrochloride). A white or almost white, crystalline powder. Freely soluble in water; slightly soluble in alcohol and in dichloromethane. A 5% solution in water has a pH of 1.9 to 2.4. Protect from light.

USP 31 (Fluphenazine Hydrochloride). A white or nearly white, odourless crystalline powder. Soluble 1 in 1.4 of water and 1 in 6.7 of alcohol; slightly soluble in acetone and in chloroform; practically insoluble in ether and in benzene. Store in airtight containers. Protect from light.

Adverse Effects and Treatment

As for Chlorpromazine, p.969. Fluphenazine is less likely to cause sedation, hypotension, or antimuscarinic effects but is associated with a higher incidence of extrapyramidal effects.

Convulsions. For mention of fluphenazine as one of the antipsychotics suitable for patients at risk of seizures, see p.969.

Effects on the liver. A patient developed jaundice 17 days after the first of 3 injections of a depot antipsychotic containing fluphenazine decanoate given over a 2-week period.[1] The patient developed indicators of severe liver toxicity, with extreme hyperbilirubinaemia and raised liver enzyme values, and remained very ill for the next 4 months. The patient showed cross-sensitivity to haloperidol but not to flupentixol.

See also under Chlorpromazine, p.971.

1. Kennedy P. Liver cross-sensitivity to antipsychotic drugs. *Br J Psychiatry* 1983; **143:** 312.

Overdosage. A patient who took about 30 fluphenazine hydrochloride 2.5-mg tablets was treated with gastric lavage.[1] Twenty hours after hospital admission he had difficulty in breathing due to spasm of the respiratory muscles; other very severe extrapyramidal adverse effects were also present. Muscle spasm was controlled by diazepam.

There were few adverse effects in a patient given intramuscular fluphenazine decanoate 50 mg every 4 hours, instead of the intended 4 weeks, to a total of 1050 mg.[2] About 3 weeks after the period of overdosage the patient had some degree of hypothermia and tachycardia, and after a further week parkinsonian signs appeared. No specific treatment was given.

1. Ladhani FM. Severe extrapyramidal manifestations following fluphenazine overdose. *Med J Aust* 1974; **2:** 26.
2. Cheung HK, Yu ECS. Effect of 1050 mg fluphenazine decanoate given intramuscularly over six days. *BMJ* 1983; **286:** 1016–17.

Precautions

As for Chlorpromazine, p.972. Fluphenazine may exacerbate depression and therefore it is contra-indicated in severely depressed patients.

Pregnancy. A neonate delivered to a mother who had received fluphenazine hydrochloride 10 to 20 mg daily throughout pregnancy had nasal congestion with severe rhinorrhoea, respiratory distress, vomiting, and extrapyramidal symptoms. Respiratory symptoms appeared to respond to pseudoephedrine.

1. Nath SP, *et al.* Severe rhinorrhea and respiratory distress in a neonate exposed to fluphenazine hydrochloride prenatally. *Ann Pharmacother* 1996; **30:** 35–7.

Interactions

As for Chlorpromazine, p.973.

Pharmacokinetics

Fluphenazine hydrochloride is absorbed after oral doses, and has a reported plasma half-life of 14.7 hours after oral doses. Fluphenazine decanoate and fluphenazine enantate are very slowly absorbed from the site of subcutaneous or intramuscular injection. They both gradually release fluphenazine into the body and are therefore suitable for use as depot injections. The plasma half-life of fluphenazine decanoate has been reported to be 6 to 9 days after intramuscular injection.

◊ References[1-4] to the pharmacokinetics of fluphenazine.

The plasma half-life of fluphenazine after a single dose was 14.7 hours in 1 patient given the hydrochloride orally and 14.9 and 15.3 hours in 2 patients given the hydrochloride by intramuscular injection.[1] The half-life was 3.6 and 3.7 days in 2 patients given the enantate intramuscularly and 9.6 and 6.8 days in 2 patients given the decanoate intramuscularly. Peak plasma-fluphenazine concentrations occurred earlier in patients given fluphenazine decanoate compared with those who received the enantate. Fluphenazine sulfoxide and 7-hydroxyfluphenazine were identified in the urine and faeces.

Uses and Administration

Fluphenazine is a phenothiazine with general properties similar to those of chlorpromazine (p.975). It has a piperazine side-chain. Fluphenazine is used in the treatment of psychiatric disorders including schizophrenia (p.955), mania (see Bipolar Disorder, p.372), severe anxiety (p.952), and behavioural disturbances (p.954). Fluphenazine is given as the hydrochloride by mouth or sometimes by intramuscular injection; for both routes, doses are expressed in terms of fluphenazine hydrochloride. The longer-acting decanoate or enantate esters of fluphenazine are given by intramuscular or sometimes subcutaneous injection; for both esters, doses are expressed in terms of the ester.

The usual initial *oral* dose of the hydrochloride for the treatment of schizophrenia, mania, and other **psychoses** is 2.5 to 10 mg daily in two or three divided doses; the dose is then increased according to response up to a usual maximum of 20 mg daily, although higher doses have occasionally been given. Dosage may subsequently be reduced to a usual maintenance dose of 1 to 5 mg daily. A lower initial dose of 1 to 2.5 mg daily, increased according to response up to a maximum of 10 mg daily, is recommended in the elderly. Treatment is sometimes started with an initial *intramuscular* injection of 1.25 mg of the hydrochloride adjusted thereafter according to response. The usual initial intramuscular daily dose is 2.5 to 10 mg given in divided doses every 6 to 8 hours. In general the required parenteral doses of fluphenazine hydrochloride have been found to be about one-third to one-half of those given orally. When symptoms are controlled, oral maintenance therapy may be substituted.

The long-acting decanoate or enantate esters of fluphenazine are usually given by deep intramuscular injection and are used mainly for the *maintenance* treatment of patients with schizophrenia or other chronic psychoses. The onset of action is usually within 1 to 3 days of injection and significant effects on psychosis are usually evident within 2 to 4 days. An initial dose of fluphenazine decanoate 12.5 mg (6.25 mg in the elderly) is given intramuscularly. Subsequent adjustments in the amounts and the dosage interval should be made according to the patient's response; the amounts required may range from 12.5 to 100 mg and the intervals required may range from 2 weeks to 5 or 6 weeks. Lower doses may be possible in some patients (see Schizophrenia, below). If doses greater than 50 mg are considered necessary, cautious increments should be made in steps of 12.5 mg. The enantate ester of fluphenazine has been given in a similar dose range at intervals of 1 to 3 weeks.

Fluphenazine hydrochloride has also been given *orally* in initial doses of 1 mg twice daily, increased if necessary to 2 mg twice daily, for the short-term adjunctive management of severe **anxiety** or **behavioural disturbances**.

Schizophrenia. References[1-3] to fluphenazine decanoate in schizophrenia (p.955) indicating that low doses (10 mg or less every 2 weeks) may be effective in some patients. Use of standard doses at greater intervals (6 weeks) has also been tried.[4] A systematic review of the use of depot fluphenazine in schizophrenia found little advantage over oral use in terms of compliance.[5] Another systematic review[6] considered that although oral fluphenazine is inexpensive and widely available, other drugs may be preferable because of its adverse effects.

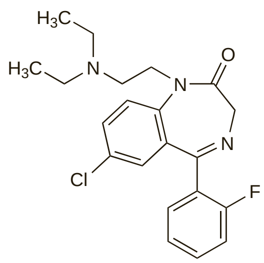
Flurazepam *(BAN, rINN)*

Fluratsepaami; Flurazépam; Flurazepamum. 7-Chloro-1-(2-diethylaminoethyl)-5-(2-fluorophenyl)-1,3-dihydro-1,4-benzodiazepin-2-one.

Флуразепам

$C_{21}H_{23}ClFN_3O$ = 387.9.
CAS — 17617-23-1.
ATC — N05CD01.
ATC Vet — QN05CD01.



Pharmacopoeias. In *Jpn.*

Flurazepam Monohydrochloride *(BANM, rINNM)*

Fluratsepaamimonohydrokloridi; Flurazepam hydrochlorid; Flurazépam, monochlorhydrate de; Flurazepami Hydrochloridum; Flurazepami monohydrochloridum; Flurazepám-monohidroklorid; Flurazepammonohydroklorid; Flurazepamo monohidrochloridas; Monochidrocloruro de flurazepam.

Флуразепама Моногидрохлорид

$C_{21}H_{23}ClFN_3O,HCl$ = 424.3.
CAS — 36105-20-1.
ATC — N05CD01.
ATC Vet — QN05CD01.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*
Ph. Eur. 6.2 (Flurazepam Monohydrochloride). A white or almost white crystalline powder. Very soluble in water; freely soluble in alcohol. A 5% solution in water has a pH of 5.0 to 6.0. Protect from light.

Flurazepam Dihydrochloride *(BANM, rINNM)*

Dihidrocloruro de flurazepam; Flurazépam, Dichlorhydrate de; Flurazepam Hydrochloride *(USAN)*; Flurazepami Dihydrochloridum; NSC-78559; Ro-5-6901.

Флуразепама Дигидрохлорид

$C_{21}H_{23}ClFN_3O,2HCl$ = 460.8.
CAS — 1172-18-5.
ATC — N05CD01.
ATC Vet — QN05CD01.

Pharmacopoeias. In *Chin.* and *US.*
USP 31 (Flurazepam Hydrochloride). An off-white to yellow crystalline powder. Is odourless or has a slight odour. Soluble 1 in 2 of water, 1 in 4 of alcohol, 1 in 90 of chloroform, 1 in 3 of methyl alcohol, 1 in 69 of isopropyl alcohol, 1 in 5000 of ether and of petroleum spirit, and 1 in 2500 of benzene. A solution in water is acid to litmus. Store in airtight containers. Protect from light.

Dependence and Withdrawal

As for Diazepam, p.987.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987.

Effects on the liver. Reports of cholestatic jaundice after the use of flurazepam.[1,2]

2. Reynolds R, *et al.* Cholestatic jaundice induced by flurazepam hydrochloride. *Can Med Assoc J* 1981; **124:** 893–4.

Effects on taste. Flurazepam had been reported to cause dysgeusia.[1]

1. Willoughby JMT. Drug-induced abnormalities of taste sensation. *Adverse Drug React Bull* 1983 (June): 368–71.

Porphyria. Flurazepam has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Renal impairment. Five patients on maintenance haemodialysis developed encephalopathy attributed to flurazepam and diazepam.[1]

1. Taclob L, Needle M. Drug-induced encephalopathy in patients on maintenance haemodialysis. *Lancet* 1976; **ii:** 704–5.

Interactions

As for Diazepam, p.989.

Pharmacokinetics

Flurazepam is readily absorbed from the gastrointestinal tract. It undergoes extensive first-pass metabolism and is excreted in the urine, chiefly as conjugated metabolites. The major active metabolite is *N*-desalkylflurazepam, which is reported to have a half-life ranging from 47 to 100 hours or more.

Metabolism. The metabolism of flurazepam was studied in 4 healthy male subjects given 30 mg daily for 2 weeks.[1] A hydroxyethyl metabolite was present in the blood shortly after a dose. The *N*-desalkyl metabolite, the major metabolite in the blood, had a half-life ranging from 47 to 100 hours. Steady-state concentrations were reached after 7 to 10 days and were about 5 to 6 times greater than those observed on day 1. Results from a study in 3 patients indicated that some metabolism of flurazepam may occur in the small bowel mucosa.[2]

1. Kaplan SA, *et al.* Blood level profile in man following chronic oral administration of flurazepam hydrochloride. *J Pharm Sci* 1973; **62:** 1932–5.
2. Mahon WA, *et al.* Metabolism of flurazepam by the small intestine. *Clin Pharmacol Ther* 1977; **22:** 228–33.

Uses and Administration

Flurazepam is a long-acting benzodiazepine with general properties similar to those of diazepam (p.992). It is used as a hypnotic in the short-term management of insomnia (p.957). In the USA flurazepam is given as the dihydrochloride and doses are expressed in terms of this salt. Flurazepam dihydrochloride 30 mg is equivalent to about 25.3 mg of flurazepam. Doses of 15 to 30 mg orally at night are given. In the UK flurazepam is given as the monohydrochloride although doses are expressed in terms of the base; flurazepam monohydrochloride 32.8 mg is equivalent to about 30 mg of flurazepam. Doses equivalent to 15 to 30 mg of flurazepam at night are given. A maximum initial dose of 15 mg has been suggested in the UK and the USA for elderly or debilitated patients.

Preparations

BP 2008: Flurazepam Capsules;
USP 31: Flurazepam Hydrochloride Capsules.

Proprietary Preparations (details are given in Part 3)

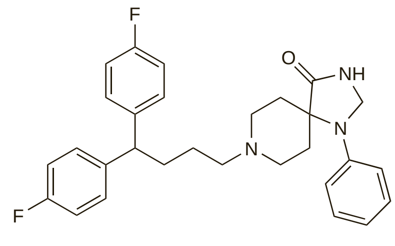
Fluspirilene *(BAN, USAN, rINN)*

Fluspirileeni; Fluspirilen; Fluspirilenas; Fluspirilène; Fluspirileno; Fluspirilenum; McN-JR-6218; R-6218. 8-[4,4-Bis(4-fluorophenyl)butyl]-1-phenyl-1,3,8-triazaspiro[4.5]decan-4-one.

Флуспирилен

$C_{29}H_{31}F_2N_3O$ = 475.6.
CAS — 1841-19-6.
ATC — N05AG01.
ATC Vet — QN05AG01.



Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Fluspirilene). A white or almost white powder. It exhibits polymorphism. Practically insoluble in water; slightly soluble in alcohol; soluble in dichloromethane. Protect from light.

Profile

Fluspirilene is a diphenylbutylpiperidine antipsychotic and has general properties similar to those of the phenothiazine, chlorpromazine (p.969). It is less likely to cause sedation. Fluspirilene has been given by deep intramuscular injection for the treatment of psychoses including schizophrenia (p.955). A usual initial dose is up to 2 mg weekly by deep intramuscular injection, increased according to response. Usual maintenance doses have ranged from 1 to 10 mg weekly although higher doses have been used in exceptional cases.

Adverse effects. References.

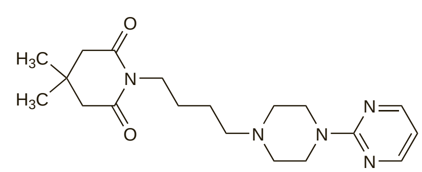
Gepirone Hydrochloride *(USAN, rINNM)*

BMY-13805-1; Gépirone, Chlorhydrate de; Gepironi Hydrochloridum; Hidrocloruro de gepirona; MJ-13805-1; Org-33062 (gepirone). 3,3-Dimethyl-*N*-{4-[4-(2-pyrimidinyl)-1-piperazinyl]butyl}glutarimide hydrochloride.

Гепирона Гидрохлорид

$C_{19}H_{29}N_5O_2,HCl$ = 395.9.
CAS — 83928-76-1 (gepirone); 83928-66-9 (gepirone hydrochloride).
ATC — N06AX19.
ATC Vet — QN06AX19.



(gepirone)

Profile

Gepirone is structurally related to buspirone (p.965). It has been investigated as the hydrochloride for the treatment of depression and anxiety disorders.

Action. Gepirone is a partial agonist at serotonin (hydroxytryptamine, 5-HT) receptors of the 5-HT_{1A} subtype. For reference to the actions and potential uses of such drugs, see Buspirone, p.966.

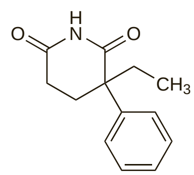
Glutethimide *(BAN, rINN)*

Glutéthimide; Glutethimidum; Glutetimid; Glutetimida; Glutetimide; Glutetimidi. 2-Ethyl-2-phenylglutarimide; 3-Ethyl-3-phenylpiperidine-2,6-dione.

Глутетимид

$C_{13}H_{15}NO_2$ = 217.3.
CAS — 77-21-4.
ATC — N05CE01.
ATC Vet — QN05CE01.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of glutethimide:
CIBAs; D; Doors; Goofers.

Profile

Glutethimide is a piperidinedione hypnotic and sedative with effects broadly similar to those of the barbiturates (see Amobarbital, p.961). It also has antimuscarinic properties. It has been given for the short-term management of insomnia but it has been superseded by other drugs.

Abuse. A warning of the hazards associated with the abuse of glutethimide in a combination with codeine termed 'loads'.[1]

1. Sramek JJ, Khajawall A. "Loads". *N Engl J Med* 1981; **305:** 231.

Porphyria. Glutethimide has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Preparations

Proprietary Preparations (details are given in Part 3)

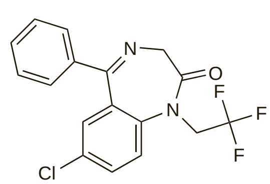
Multi-ingredient: ***Hung.:*** Tardyl†.

Halazepam *(BAN, USAN, rINN)*

Halatsepaami; Halazépam; Halazepamum; Sch-12041. 7-Chloro-1,3-dihydro-5-phenyl-1-(2,2,2-trifluoroethyl)-1,4-benzodiazepin-2-one.

Галазепам

$C_{17}H_{12}ClF_3N_2O$ = 352.7.
CAS — 23092-17-3.
ATC — N05BA13.
ATC Vet — QN05BA13.



Profile

Halazepam is a benzodiazepine with general properties similar to those of diazepam (p.986). It has been given for the short-term treatment of anxiety disorders (p.952) in usual oral doses of 20 to 40 mg every 6 to 8 hours.

Preparations

Proprietary Preparations (details are given in Part 3)

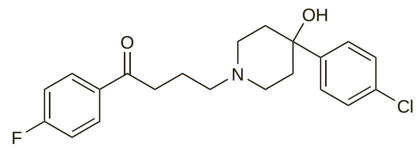
Port.: Pacinone; ***Spain:*** Alapryl.

Haloperidol *(BAN, USAN, rINN)*

Aloperidolo; Halopéridol; Haloperidoli; Haloperidolis; Haloperidolum; McN-JR-1625; R-1625. 4-[4-(4-Chlorophenyl)-4-hydroxypiperidino]-4′-fluorobutyrophenone.

Галоперидол

$C_{21}H_{23}ClFNO_2$ = 375.9.
CAS — 52-86-8.
ATC — N05AD01.
ATC Vet — QN05AD01.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Haloperidol). A white or almost white powder. Practically insoluble in water; slightly soluble in alcohol, in dichloromethane, and in methyl alcohol. Protect from light.

USP 31 (Haloperidol). A white to faintly yellowish amorphous or microcrystalline powder. Practically insoluble in water; soluble 1 in 60 of alcohol, 1 in 15 of chloroform, and 1 in 200 of ether. A saturated solution is neutral to litmus. Store in airtight containers. Protect from light.

Dilution. See Incompatibility, below.

Incompatibility. A precipitate formed after dilution of haloperidol (as the lactate) in sodium chloride 0.9% injection when the final haloperidol concentration was 1 mg/mL or higher.[1]

Undiluted haloperidol (5 mg/mL) injection has been reported to be incompatible with heparin sodium (diluted in sodium chloride 0.9% or glucose 5% injection),[2] sodium nitroprusside (diluted in glucose 5%),[1] cefmetazole sodium,[3] and diphenhydramine.[4] A mixture of equal volumes of sargramostim 10 micrograms/mL and haloperidol (as the lactate) 200 micrograms/mL resulted in a precipitate at 4 hours.[5]

1. Outman WR, Monolakis J. Visual compatibility of haloperidol lactate with 0.9% sodium chloride injection or injectable critical-care drugs during simulated Y-site injection. *Am J Hosp Pharm* 1991; **48:** 1539–41.
2. Solomon DA, Nasinnyk KK. Compatibility of haloperidol lactate and heparin sodium. *Am J Hosp Pharm* 1982; **39:** 843–4.
3. Hutchings SR, *et al.* Compatibility of cefmetazole sodium with commonly used drugs during Y-site delivery. *Am J Health-Syst Pharm* 1996; **53:** 2185–8.
4. Ukhun IA. Compatibility of haloperidol and diphenhydramine in a hypodermic syringe. *Ann Pharmacother* 1995; **29:** 1168–9.
5. Trissel LA, *et al.* Visual compatibility of sargramostim with selected antineoplastic agents, anti-infectives, or other drugs during simulated Y-site injection. *Am J Hosp Pharm* 1992; **49:** 402–6.

Stability. A combination of the stabilisers benzyl alcohol and vanillin could protect haloperidol from photodegradation.[1]

1. Thoma K, Klimek R. Photostabilisation of drugs in dosage forms without protection from packaging materials. *Int J Pharmaceutics* 1991; **67:** 169–75.

Haloperidol Decanoate *(BANM, USAN, rINNM)*

Decanoato de haloperidol; Halopéridol, décanoate d'; Haloperidoldekanoat; Haloperidol-dekanoát; Haloperidoli decanoas; Haloperidolidekanoaatti; Haloperidolio dekanoatas; R-13672.

Галоперидола Деканоат

$C_{31}H_{41}ClFNO_3$ = 530.1.
CAS — 74050-97-8.
ATC — N05AD01.
ATC Vet — QN05AD01.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Haloperidol Decanoate). A white or almost white powder. It melts at about 42°. Practically insoluble in water; very soluble in alcohol, in dichloromethane, and in methyl alcohol. Store at a temperature below 25°. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969. Haloperidol is less likely to cause sedation, hypotension, or antimuscarinic effects, but is associated with a higher incidence of extrapyramidal effects. Haloperidol should be used with great care in children and adolescents as they may be at increased risk of severe dystonic reactions; patients with hyperthyroidism may also be at increased risk.

Breast feeding. The American Academy of Pediatrics[1] considers that the use of haloperidol by mothers during breast feeding may be of concern, since there have been reports of decline in developmental scores in breast-fed infants. Licensed product information also reports that there have been isolated cases of extrapyramidal effects in breast-fed infants.

The concentration of haloperidol in breast milk of one mother given a mean daily dose of about 30 mg for 6 days was reported to be 5 nanograms/mL; on day 12 the concentration 9 hours after a 12-mg dose was 2 nanograms/mL.[2]

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/04/04)
2. Stewart RB, *et al.* Haloperidol excretion in human milk. *Am J Psychiatry* 1980; **137:** 849–50.

Convulsions. For mention of haloperidol as one of the antipsychotics suitable for patients at risk of seizures, see p.969.

Effects on the liver. Liver dysfunction with jaundice and eosinophilia developed in a 15-year-old male 4 weeks after starting haloperidol and benzatropine mesilate.[1] The drugs were stopped 2 weeks later but some symptoms lasted for 28 months. The reaction was suggestive of a drug-induced hypersensitivity reaction and haloperidol was the most likely cause. Haloperidol-induced liver injury was considered to be rare.

1. Dincsoy HP, Saelinger DA. Haloperidol-induced chronic cholestatic liver disease. *Gastroenterology* 1982; **83:** 694–700.

Overdosage. Symptoms of haloperidol overdosage in children have ranged from the expected, such as drowsiness, restlessness, confusion, marked extrapyramidal symptoms, and hypothermia,[1,2] to unexpected reactions such as bradycardia (possibly secondary to hypothermia)[1] and an episode of severe, delayed hypertension.[3]

Torsade de pointes has followed overdosage in adults (for references, see Effects on the Cardiovascular System under Chlorpromazine, p.970).

1. Scialli JVK, Thornton WE. Toxic reactions from a haloperidol overdose in two children: thermal and cardiac manifestations. *JAMA* 1978; **239:** 48–9.
2. Sinaniotis CA, *et al.* Acute haloperidol poisoning in children. *J Pediatr* 1978; **93:** 1038–9.
3. Cummingham DG, Challapalli M. Hypertension in acute haloperidol poisoning. *J Pediatr* 1979; **95:** 489–90.

Porphyria. Haloperidol is considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity.

Retroperitoneal fibrosis. Obstructive uropathy was noted in a 45-year-old woman given haloperidol 5 to 15 mg daily for 8 years.[1] Benzatropine was also taken during that time, and in the previous 5 years she had taken chlorpromazine and fluphenazine. A diagnosis of retroperitoneal fibrosis was made and was tentatively associated with long-term antipsychotic therapy.

1. Jeffries JJ, *et al.* Retroperitoneal fibrosis and haloperidol. *Am J Psychiatry* 1982; **139:** 1524–5.

Toxic encephalopathy. A report[1] of possible toxic encephalopathy after use of high intravenous doses of haloperidol. The patient, who had a history of bipolar disorder and cerebrovascular accident, had been given increasing intravenous doses of haloperidol (up to 270 mg daily) to control post-surgical agitation. The encephalopathy had resolved 8 days after stopping haloperidol.

1. Maxa JL, *et al.* Possible toxic encephalopathy following high-dose intravenous haloperidol. *Ann Pharmacother* 1997; **31:** 736–7.

Interactions

As for Chlorpromazine, p.973.

Haloperidol must be used with extreme caution in patients receiving lithium; an encephalopathic syndrome has been reported after their use together (see p.405).

Pharmacokinetics

Haloperidol is readily absorbed from the gastrointestinal tract. It is metabolised in the liver and is excreted in the urine and, via the bile, in the faeces; there is evidence of enterohepatic recycling. Owing to first-pass metabolism in the liver, plasma concentrations after oral doses are lower than those after intramuscular injection. Moreover, there is wide intersubject variation in plasma concentrations of haloperidol. In practice, however, no strong correlation has been found between plasma concentrations of haloperidol and its therapeutic effect. Paths of metabolism of haloperidol include oxidative *N*-dealkylation and reduction of the ketone group to form an alcohol known as reduced haloperidol. Haloperidol has been reported to have a plasma elimination half-life ranging from about 12 to 38 hours after oral doses. Haloperidol is about 92% bound to plasma proteins. It is widely distributed in the body and crosses the blood-brain barrier. Haloperidol is distributed into breast milk.

The decanoate ester of haloperidol is very slowly absorbed from the site of injection and is therefore suitable for depot injection. It is gradually released into the bloodstream where it is rapidly hydrolysed to haloperidol.

◊ References.

Metabolites. The clinical significance of the reduced metabolite of haloperidol has been much debated.[1,2] Its activity appears to be substantially less than that of the parent drug but there is some evidence for re-oxidation of reduced haloperidol to haloperidol.[1-3] Some studies suggest that nonresponders to haloperidol have elevated ratios of reduced haloperidol to haloperidol in the plasma, although other workers have reported contrary findings.[2] Pyridinium metabolites resulting from oxidation of haloperidol have been detected in the urine and there is concern that they may be neurotoxic in a manner similar to MPTP (see Parkinsonism, p.791), a compound which can induce irreversible parkinsonism.[4]

3. Ulrich S, *et al.* The relationship between serum concentration and therapeutic effect of haloperidol in patients with acute schizophrenia. *Clin Pharmacokinet* 1998; **34:** 227–63.

Uses and Administration

Haloperidol is a butyrophenone with general properties similar to those of the phenothiazine, chlorpromazine (p.975). It is an antipsychotic with actions most closely resembling those of phenothiazines with a piperazine side-chain.

Haloperidol is used in the treatment of various psychoses including schizophrenia (p.955) and mania (see Bipolar Disorder, p.372), and in behaviour disturbances (p.954), in Tourette's syndrome and severe tics (p.954), in intractable hiccups (p.976), and in severe anxiety (p.952), including for the sedation of patients in intensive care (p.957) or palliative care. Haloperidol has also been used for its antiemetic effect in the management of nausea and vomiting of various causes (p.1700).

Haloperidol is usually given orally or by injection as the base or intramuscularly as the long-acting decanoate ester. Some haloperidol preparations are prepared with the aid of lactic acid and may be stated to contain haloperidol lactate. Doses are expressed in terms of the equivalent amount of haloperidol. Haloperidol decanoate 141 mg is equivalent to about 100 mg of haloperidol. Dosages should be reduced in elderly or debilitated patients; a usual starting dose is half the normal adult dose. Doses at the lower end of the scale are also advised for adolescents.

The usual initial *oral* dose for the treatment of **psychoses** and associated behavioural disorders is 0.5 to 5 mg two or three times daily. In severe or resistant psychoses up to 30 mg daily is recommended in the UK, whereas in the USA doses of up to 100 mg daily are allowed; doses above 100 mg daily have rarely been used. The dose should be reduced gradually according to response. Maintenance doses as low as 3 to 10 mg daily may be sufficient. A suitable initial oral dose for children is 25 to 50 micrograms/kg daily in 2 divided doses, increased cautiously, if necessary. A maximum daily dose of 10 mg has been recommended in the UK but in the USA the suggested maximum daily dose is 150 micrograms/kg as the manufacturer has stated that there is little evidence of behaviour improvement with daily doses of more than 6 mg.

For the control of acute psychotic conditions, haloperidol may be given *intramuscularly* in doses of 2 to 10 mg; subsequent doses may be given hourly, until symptoms are controlled, although dosage intervals of 4 to 8 hours may be adequate, up to a maximum of 18 mg daily. For the emergency control of very severely disturbed patients, an initial intramuscular dose of no more than 18 mg is recommended. The *intravenous* route may also be used.

In patients already stabilised on an oral dose of haloperidol and requiring long-term therapy the long-acting decanoate ester may be given by *deep intramuscular* injection. The usual initial dose is the equivalent of 10 to 20 times the total daily oral dose of haloperidol, up to a maximum of 100 mg; if more than 100 mg is required for an initial dose the excess should be given after 3 to 7 days. Subsequent doses, usually given every 4 weeks, may be increased in steps of 50 mg to up to 300 mg or more, according to the patient's requirements, both dose and dose interval being adjusted as required.

In the management of **nausea and vomiting** haloperidol has been given in a dose of 0.5 to 2 mg by *intramuscular* injection; alternatively, an *oral* dose of 1 mg daily may be given. In palliative care haloperidol 1.5 mg may be given orally once or twice daily, increased if necessary to 5 to 10 mg daily given in divided doses; alternatively, it may be given by *subcutaneous* infusion (via a syringe driver) in doses of 2.5 to 10 mg over 24 hours. The *intravenous* route has also been used.

A starting *oral* dose of 0.5 to 1.5 mg three times daily has been suggested for the management of **Tourette's syndrome** and severe **tics**. Up to about 30 mg daily may be needed in Tourette's syndrome, although requirements vary considerably and the dose must be very carefully adjusted to obtain the optimum response; a maintenance dose of 4 mg daily is effective for most patients.

For intractable **hiccups** a suggested *oral* dose is 1.5 mg given 3 times daily adjusted according to response.

An *oral* dose of 500 micrograms twice daily has been used as adjunctive treatment in the short-term management of severe **anxiety disorders**.

In palliative care, haloperidol has been given in an *oral* dose of 1 to 3 mg every 8 hours for the treatment of **restlessness and confusion**. It may also be given as a *subcutaneous* infusion in a dose of 5 to 15 mg over 24 hours.

Ballism. Dopamine-blocking antipsychotics such as haloperidol may sometimes be needed for the management of patients with ballism (p.953) when symptoms are severe.

Chorea. For a discussion of the management of various choreas, including mention of the use of haloperidol, see p.953.

Dystonia. Antipsychotics such as phenothiazines, haloperidol, or pimozide are sometimes useful in the treatment of idiopathic dystonia (p.809) in patients who have failed to respond to other drugs. However, they often act non-specifically and there is the risk of adding drug-induced extrapyramidal disorders to the dystonia being treated (see Extrapyramidal Disorders under Adverse Effects of Chlorpromazine, p.971).

Schizophrenia. Systematic reviews[1,2] of the use of haloperidol for schizophrenia (p.955) concluded that it appears to be of similar efficacy to chlorpromazine although it is associated with a high incidence of extrapyramidal adverse effects. An earlier systematic review[3] considered that the limited evidence did not indicate any advantages of giving haloperidol in doses greater than 7.5 mg daily to patients with uncomplicated acute schizophrenia.

3. Waraich PS, *et al.* Haloperidol dose for the acute phase of schizophrenia. Available in The Cochrane Database of Systematic Reviews; Issue 2. Chichester: John Wiley; 2002 (accessed 19/03/08).

Sneezing. Report[1] of a patient whose intractable sneezing was controlled by haloperidol given in doses of up to 5 mg twice daily. Symptoms recurred when treatment was stopped after 5 weeks but responded again to 5 mg three times daily. On gradual reduction of dosage over 6 months the patient had no recurrence and had remained symptom-free after 6 months without medication.

Stuttering. Stuttering (stammering) is a disorder that affects the fluency of speech. Developmental stuttering usually occurs in early childhood and is more common in boys than girls. While stuttering may cease in some children after only a few months, it may become a chronic condition in others. Stuttering that starts during adulthood is rarer and may be the result of a neurological insult. It should also be remembered that stuttering may be drug induced. While stuttering may be greatly improved with intensive speech training the effectiveness of other forms of management such as hypnosis, psychotherapy, counselling, and drug therapy has been largely unconvincing.[1] Although many drugs have been used to treat stuttering a review of the literature[2] indicated that there were few adequate studies of their efficacy. Haloperidol was considered to be the most well studied drug and its efficacy had been shown by several double-blind placebo-controlled studies. However, most patients needed to continue taking haloperidol to maintain improvement but few did so because of its adverse effects. Double-blind studies have on the whole failed to confirm reports of benefit for drugs such as bethanechol, beta blockers, and calcium-channel blockers although isolated patients may have marked improvement. Other drugs that have been studied and which might be of benefit include clomipramine,[3] SSRIs,[4] and atypical antipsychotics[4] such as olanzapine and risperidone; local anaesthetics and injections of botulinum toxin have also been tried.

4. Costa D, Kroll R. Stuttering: an update for physicians. *Can Med Assoc J* 2000; **162:** 1849–55.

Taste disorders. For reference to the use of haloperidol in the treatment of taste disorders, see Chlorpromazine, p.977.

Tourette's syndrome. Many patients with Tourette's syndrome (p.954) do not require medication but when treatment is needed dopamine antagonists such as the antipsychotics haloperidol or pimozide are most commonly used. They often decrease the frequency and severity of tics and may improve any accompanying behavioural disturbances. However, superiority of either drug in terms of efficacy or adverse effects has not been clearly demonstrated.[1,2] Because of the potential for acute and long-term adverse effects it is usually recommended that doses are titrated to be as low as possible; the aim of treatment is not necessarily to control symptoms completely. Medication can often be stopped after a few years.

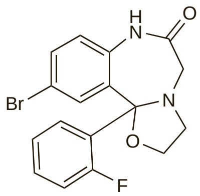
Haloxazolam *(rINN)*

Haloxazolamum. 10-Bromo-11b-(2-fluorophenyl)-2,3,7,11b-tetrahydrooxazolo[3,2-*d*][1,4]benzodiazepin-6(5*H*)-one.

Галоксазолам

$C_{17}H_{14}BrFN_2O_2$ = 377.2.

CAS — 59128-97-1.



Pharmacopoeias. In *Jpn.*

Profile

Haloxazolam is a benzodiazepine with general properties similar to those of diazepam (p.986). It has been given orally as a hypnotic in the short-term management of insomnia.

Hexobarbital *(BAN, rINN)*

Enhexymalum; Enimal; Heksobarbitaali; Heksobarbitalis; Hexobarbitál; Hexobarbitalum; Hexobarbitone; Methexenyl; Methylcyclohexenylmethyl-barbitursäure; Methylhexabarbital. 5-(Cyclohex-1-enyl)-1,5-dimethylbarbituric acid.

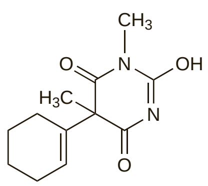
Гексобарбитал

$C_{12}H_{16}N_2O_3$ = 236.3.

CAS — 56-29-1.

ATC — N01AF02; N05CA16.

ATC Vet — QN01AF02; QN05CA16.



NOTE. The name ciclobarbital (see Cyclobarbital, p.986) has sometimes been applied to hexobarbital.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Hexobarbital). A white or almost white, crystalline powder. Very slightly soluble in water; sparingly soluble in alcohol. Forms water-soluble compounds with alkali hydroxides and carbonates and with ammonia.

Hexobarbital Sodium *(BANM, rINNM)*

Enhexymalnatrium; Hexenalum; Hexobarbital sódico; Hexobarbital Sodique; Hexobarbitalum Natricum; Hexobarbitone Sodium; Natrii Hexobarbitalum; Sodium Hexobarbital; Soluble Hexobarbitone. Sodium 5-(cyclohex-1-enyl)-1,5-dimethylbarbiturate.

Натрий Гексобарбитал

$C_{12}H_{15}N_2NaO_3$ = 258.2.

CAS — 50-09-9.

ATC — N01AF02; N05CA16.

ATC Vet — QN01AF02; QN05CA16.

Profile

Hexobarbital is a barbiturate with the general properties of amobarbital (p.961). It has been used as a hypnotic and sedative but barbiturates are no longer considered appropriate for such purposes.

Preparations

Proprietary Preparations (details are given in Part 3)
Hung.: Novopan†.

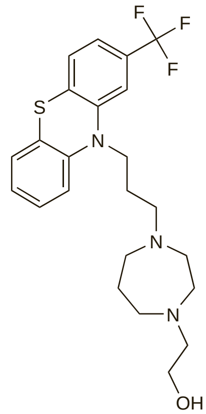
Homofenazine Hydrochloride *(rINNM)*

D-775 (homofenazine); HFZ (homofenazine); Hidrocloruro de homofenazina; Homofénazine, Chlorhydrate d'; Homofenazini Hydrochloridum. 2-{Hexahydro-4-[3-(2-trifluoromethylphenothiazin-10-yl)propyl]-1,4-diazepin-1-yl}ethanol dihydrochloride.

Гомофеназина Гидрохлорид

$C_{23}H_{28}F_3N_3OS,2HCl$ = 524.5.

CAS — 3833-99-6 (homofenazine); 1256-01-5 (homofenazine hydrochloride).



(homofenazine)

Profile

Homofenazine hydrochloride is a phenothiazine with general properties similar to those of chlorpromazine (p.969). It has been used in the management of neuropsychiatric disorders.

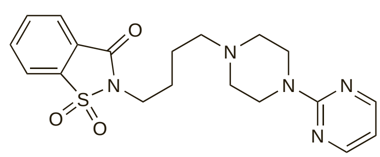
Ipsapirone Hydrochloride *(BANM, USAN, rINNM)*

Bay-q-7821; Hidrocloruro de ipsapirona; Ipsapirone, Chlorhydrate d'; Ipsapironi Hydrochloridum; TVX-Q-7821. 2-[4-(4-Pyrimidin-2-ylpiperazin-1-yl)butyl]-1,2-benzothiazol-3(2*H*)-one 1,1-dioxide hydrochloride.

Ипсапирона Гидрохлорид

$C_{19}H_{23}N_5O_3S,HCl$ = 437.9.

CAS — 95847-70-4 (ipsapirone); 92589-98-5 (ipsapirone hydrochloride).



(ipsapirone)

Profile

Ipsapirone is structurally related to buspirone (p.965). It has been investigated as the hydrochloride for the treatment of anxiety disorders and depression.

Action. Ipsapirone is a partial agonist at serotonin (hydroxytryptamine, 5-HT) receptors of the $5\text{-}HT_{1A}$ subtype. For reference to the actions and potential uses of such drugs, see Buspirone, p.966.

Ketazolam *(BAN, USAN, rINN)*

Ketatsolaami; Kétazolam; Ketazolamum; U-28774. 11-Chloro-8,12b-dihydro-2,8-dimethyl-12b-phenyl-4*H*-[1,3]oxazino[3,2-*d*][1,4]benzodiazepine-4,7(6*H*)-dione.

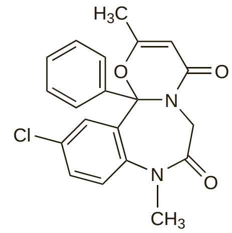
Кетазолам

$C_{20}H_{17}ClN_2O_3$ = 368.8.

CAS — 27223-35-4.

ATC — N05BA10.

ATC Vet — QN05BA10.



Profile

Ketazolam is a long-acting benzodiazepine with general properties similar to those of diazepam (p.986). It is given in the short-term treatment of anxiety (p.952) in usual oral doses of 15 to 60 mg daily, either in divided doses or as a single dose at night. Reduced doses may be required in elderly or debilitated patients.

Levomepromazine *(BAN, USAN, rINN)*

CL-36467; CL-39743; Levomepromatsiini; Levomepromazin; Levomepromazina; Lévomépromazine; Levomepromazinum; Methotrimeprazine; RP-7044; SKF-5116; XP-03. (−)-*NN*-Dimethyl-3-(2-methoxyphenothiazin-10-yl)-2-methylpropylamine; 3-(2-Methoxyphenothiazin-10-yl)-2-methylpropyldimethylamine.

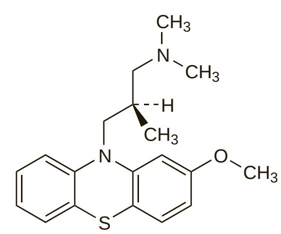
Левомепромазин

$C_{19}H_{24}N_2OS$ = 328.5.

CAS — 60-99-1.

ATC — N05AA02.

ATC Vet — QN05AA02.



Pharmacopoeias. In *US.* Also in *BP(Vet).*

BP(Vet) 2008 (Levomepromazine). A white or slightly cream-coloured crystalline powder. Practically insoluble in water; slightly soluble in alcohol; freely soluble in ether. Protect from light.

USP 31 (Methotrimeprazine). A fine white, practically odourless, crystalline powder. Soluble 1 in 10 of water, of alcohol, and of methyl alcohol, and 1 in 2 of chloroform; freely soluble in ether; sparingly soluble in alcohol at 25° but freely soluble in boiling alcohol. Store at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Levomepromazine Hydrochloride

(BANM, USAN, rINNM)

Hidrocloruro de levomepromazina; Levomepromatsiinihydrokloridi; Levomepromazin hydrochlorid; Lévomépromazine, chlorhydrate de; Levomepromazin-hidroklorid; Levomepromazinhydroklorid; Levomepromazini hydrochloridum; Levomepromazino hidrochloridas; Lewomepromazyny chlorowodorek; Methotrimeprazine Hydrochloride.

Левомепромазина Гидрохлорид

$C_{19}H_{24}N_2OS,HCl$ = 364.9.

CAS — 4185-80-2; 1236-99-3.

ATC — N05AA02.

ATC Vet — QN05AA02.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Levomepromazine Hydrochloride). A white or very slightly yellow, slightly hygroscopic crystalline powder. It deteriorates on exposure to air and light. Freely soluble in water and in alcohol. Store in airtight containers. Protect from light.

Incompatibility. Levomepromazine hydrochloride is reported to be incompatible with alkaline solutions.

Levomepromazine Maleate *(BANM, USAN, rINNM)*

Levomepromatsiinimaleaatti; Levomepromazin maleinát; Lévomépromazine, maléate de; Levomepromazini maleas; Levomepromazinmaleat; Levomepromazin-maleát; Levomepromazino maleatas; Lewomepromazyny maleinian; Maleato de levomepromazina; Methotrimeprazine Hydrogen Maleate; Methotrimeprazine Maleate.

Левомепромазина Малеат

$C_{19}H_{24}N_2OS,C_4H_4O_4$ = 444.5.

CAS — 7104-38-3.

ATC — N05AA02.

ATC Vet — QN05AA02.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*

Ph. Eur. 6.2 (Levomepromazine Maleate). A white or slightly yellowish crystalline powder. It deteriorates when exposed to air and light. Slightly soluble in water and in alcohol; sparingly soluble in dichloromethane. The supernatant of a 2% dispersion in water has a pH of 3.5 to 5.5. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969, although it may be more sedating. See also Adverse Effects of Antihistamines, p.561.

Levomepromazine may cause severe orthostatic hypotension, and patients taking large initial doses, patients over 50 years of age, or those given injections, should be lying down. Children are very susceptible to the hypotensive and sedative effects of levomepromazine.

Interactions

As for Chlorpromazine, p.973.

Antidepressants. Although *MAOIs* have been used with phenothiazines without untoward effects, the use of levomepromazine with MAOIs should probably be avoided as this combination has been implicated in 2 fatalities.[1,2]

2. McQueen EG. New Zealand committee on adverse drug reactions: fourteenth annual report 1979. *N Z Med J* 1980; **91:** 226–9.

Pharmacokinetics

◊ In a study involving 5 psychiatric patients peak plasma concentrations of levomepromazine were noted 1 to 4 hours after oral doses and 30 to 90 minutes after injection into the gluteal muscle.[1] About 50% of an oral dose reached the systemic circulation. Although the metabolite levomepromazine sulfoxide could not be detected after a single intramuscular injection, it was found in concentrations higher than unmetabolised levomepromazine after single and multiple oral dosage, both substances reaching a steady state in the plasma within 7 days of starting multiple-dose oral therapy. Fluctuations in plasma concentration during multiple-dose oral therapy indicated that until the correlation between acute adverse effects and peak plasma concentration of levomepromazine had been further studied the total daily dose should be divided into 2 or 3 portions when larger oral doses of levomepromazine are used.

1. Dahl SG. Pharmacokinetics of methotrimeprazine after single and multiple doses. *Clin Pharmacol Ther* 1976; **19:** 435–42.

Half-life. In 8 psychiatric patients given levomepromazine 50 to 350 mg daily the plasma half-life showed wide variation, from 16.5 to 77.8 hours, and did not correlate with the dose given.[1]

1. Dahl SG, *et al*. Pharmacokinetics and relative bioavailability of levomepromazine after repeated administration of tablets and syrup. *Eur J Clin Pharmacol* 1977; **11:** 305–310.

Uses and Administration

Levomepromazine is a phenothiazine with pharmacological activity similar to that of both chlorpromazine (p.975) and promethazine (p.589). It has antihistaminic actions (p.561) as well as CNS effects resembling those of chlorpromazine. It is also reported to have analgesic activity. It is used in the treatment of various psychoses including schizophrenia (p.955), as an analgesic for moderate to severe pain usually in non-ambulatory patients, and for premedication (p.1780). It is also used in palliative care for the control of symptoms such as restlessness, agitation, and as an adjunct to opioid analgesia, as well as being an effective broad-spectrum antiemetic in nausea and vomiting (p.1700).

Levomepromazine is also used in veterinary medicine.

Levomepromazine is given orally as the maleate or the hydrochloride or by injection as the hydrochloride. In the UK, doses such as those given below are expressed in terms of the appropriate salt. However, in some countries, the dose of levomepromazine may be expressed in terms of the base. The embonate has also been used. Care is required in elderly patients because of the risk of severe hypotension; if levomepromazine is given to such patients reduced doses may be necessary.

The usual initial oral dose of levomepromazine maleate for the treatment of **schizophrenia** is 25 to 50 mg daily; the daily dosage is usually divided into 3 portions with a larger portion taken at night. Doses of 100 to 200 mg have been given to non-ambulant patients increased gradually up to 1 g daily if necessary. Children are very susceptible to the hypotensive and sedative effects of levomepromazine: a suggested oral dose for a 10-year-old is 12.5 to 25 mg of the maleate daily in divided doses; a dose of 37.5 mg daily should not be exceeded.

When used in **palliative care** as an adjunct to analgesics in the management of severe terminal **pain** and for the control of **nausea and vomiting**, levomepromazine maleate may be given orally in a dose of 12.5 to 50 mg every 4 to 8 hours. The *BNF* also includes an oral dose of levomepromazine maleate 6 to 25 mg daily given in 1 or 2 divided doses for the management of nausea and vomiting where first-line antiemetics have proved inadequate. Alternatively 12.5 to 25 mg of levomepromazine hydrochloride may be given intramuscularly every 6 to 8 hours but patients should remain in bed for at least the first few doses; doses of up to 50 mg have been given for severe agitation. Levomepromazine hydrochloride may also be given intravenously in similar doses after dilution with an equal volume of sodium chloride 0.9% injection. Alternatively it may be given, suitably diluted with sodium chloride 0.9% injection, by continuous subcutaneous infusion via a syringe driver; doses range from a total of 25 to 200 mg daily although lower doses of 5 to 25 mg daily may also be effective against nausea and vomiting. Experience with parenteral use of levomepromazine hydrochloride in children is limited but a dose of 100 to 400 micrograms/kg daily by continuous intravenous or subcutaneous infusion has been suggested for children aged 1 month and over in the management of nausea and vomiting in palliative care; it has also been used in the treatment of restlessness and confusion in palliative care in a dose of 0.35 to 3 mg/kg daily by continuous subcutaneous infusion in those aged 1 year and over.

Levomepromazine hydrochloride given intramuscularly has been used in some countries for the control of acute pain, as a **premedicant**, and for postoperative analgesia. In some countries levomepromazine is also licensed for use as an **anxiolytic** and **sedative**, and in the management of other types of pain, including **labour pain**.

Pain. As levomepromazine appears to possess intrinsic analgesic activity in addition to its antiemetic and antipsychotic actions it has been used for the symptomatic control of restlessness and vomiting and as an adjunct to opioid analgesics in pain control (see Choice of Analgesic, p.2) in terminally ill patients.

Loprazolam Mesilate *(BANM, rINNM)*

HR-158; Loprazolam, Mésilate de; Loprazolam Mesylate; Loprazolam Methanesulphonate; Loprazolami Mesilas; Mesilato de loprazolam; RU-31158. 6-(2-Chlorophenyl)-2,4-dihydro-2-(4-methylpiperazin-1-ylmethylene)-8-nitroimidazo[1,2-*a*][1,4]benzodiazepin-1-one methanesulphonate monohydrate.

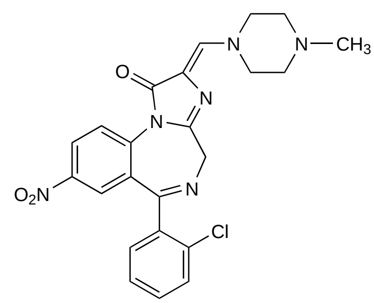
Лопразолама Мезилат

$C_{23}H_{21}ClN_6O_3,CH_4O_3S,H_2O$ = 579.0.

CAS — 61197-73-7 (loprazolam); 70111-54-5 (anhydrous loprazolam mesilate).

ATC — N05CD11.

ATC Vet — QN05CD11.



(loprazolam)

Pharmacopoeias. In *Br.*

BP 2008 (Loprazolam Mesilate). A yellow crystalline powder. Slightly soluble in water, in alcohol, and in chloroform; very slightly soluble in ether.

Dependence and Withdrawal

As for Diazepam, p.987.

◊ For the purpose of withdrawal regimens, 0.5 to 1 mg of loprazolam is considered equivalent to about 5 mg of diazepam.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987.

Porphyria. Loprazolam is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Interactions

As for Diazepam, p.989.

Pharmacokinetics

◊ References.

2. Dorling MC, Hindmarch I. Pharmacokinetic profile of loprazolam in 12 young and 12 elderly healthy volunteers. *Drugs Exp Clin Res* 2001; **27:** 151–9.

Uses and Administration

Loprazolam is an intermediate-acting benzodiazepine with general properties similar to those of diazepam (p.992).

Loprazolam mesilate is usually used for its hypnotic properties in the short-term management of insomnia (p.957), in usual oral doses equivalent to 1 mg of loprazolam at night. Dosage may be increased to up to 2 mg if necessary. A starting dose of 0.5 mg increased to a maximum of 1 mg may be appropriate for elderly or debilitated patients.

Preparations

BP 2008: Loprazolam Tablets.

Proprietary Preparations (details are given in Part 3)

Arg.: Dormonoct; ***Belg.:*** Dormonoct; ***Fr.:*** Havlane; ***Ger.:*** Sonin; ***Neth.:*** Dormonoct; ***Port.:*** Dormonoct; ***S.Afr.:*** Dormonoct; ***Spain:*** Somnovit.

Lorazepam *(BAN, USAN, rINN)*

Loratsepaami; Lorazépam; Lorazepám; Lorazepamas; Lorazepamum; Wy-4036. 7-Chloro-5-(2-chlorophenyl)-1,3-dihydro-3-hydroxy-1,4-benzodiazepin-2-one.

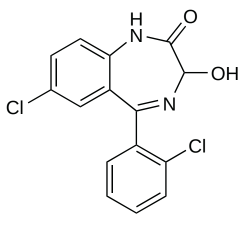
Лоразепам

$C_{15}H_{10}Cl_2N_2O_2$ = 321.2.

CAS — 846-49-1.

ATC — N05BA06.

ATC Vet — QN05BA06.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of lorazepam:
Benzo; Somnios.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Lorazepam). A white or almost white, crystalline powder. It exhibits polymorphism. Practically insoluble in water; sparingly soluble in alcohol; sparingly or slightly soluble in dichloromethane. Store in airtight containers. Protect from light.

USP 31 (Lorazepam). A white or practically white, practically odourless powder. Insoluble in water; sparingly soluble in alcohol; slightly soluble in chloroform. Store in airtight containers. Protect from light.

Incompatibility. Visual incompatibility has been noted with lorazepam and sargramostim[1] or aztreonam.[2]

1. Trissel LA, *et al.* Visual compatibility of sargramostim with selected antineoplastic agents, anti-infectives, or other drugs during simulated Y-site injection. *Am J Hosp Pharm* 1992; **49:** 402–6.
2. Trissel LA, Martinez JF. Compatibility of aztreonam with selected drugs during simulated Y-site administration. *Am J Health-Syst Pharm* 1995; **52:** 1086–90.

Solubility. The solubility of lorazepam in fluids for intravenous use (water, glucose injection, lactated Ringer's injection, and sodium chloride injection) was greatest in glucose injection (5%) at 62 micrograms/mL and lowest in sodium chloride injection (0.9%) at 27 micrograms/mL;[1] these differences in solubility appeared to be pH related. Commercial injections are reported to contain polyethylene glycol in propylene glycol to overcome this poor solubility. However, precipitation has been noted[2] in solutions prepared by dilution of lorazepam injection with sodium chloride injection (0.9%) to a concentration of 500 micrograms/mL. One group of workers[3] have reported that they had overcome such problems with precipitation by using glucose injection (5%) as a diluent and by avoiding final concentrations of lorazepam between 0.08 mg/mL and 1 mg/mL. It was suggested that the propylene glycol in the mixture might account for the unusual concentration effect. Such recommendations have been adopted by another group[4] although they observed that precipitation occurred if a formulation of lorazepam containing 4 mg/mL was used to prepare the injection; no precipitation was noted when a formulation containing 2 mg/mL was used. The group also commented that, in the USA, licensed product information for lorazepam injection advises that admixtures should be prepared with the 2 mg/mL formulation only.

6. Martens HJ, *et al.* Sorption of various drugs in polyvinyl chloride, glass, and polyethylene-lined infusion containers. *Am J Hosp Pharm* 1990; **47:** 369–73.

Dependence and Withdrawal

As for Diazepam, p.987.

◊ For the purpose of withdrawal regimens, 500 micrograms of lorazepam may be considered equivalent to about 5 mg of diazepam.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987. Pain and a sensation of burning have occurred following injection of lorazepam.

Breast feeding. The American Academy of Pediatrics[1] considers that, although the effect of lorazepam on breast-fed infants is unknown, its use by mothers during breast feeding may be of concern since anxiolytic drugs do appear in breast milk and thus could conceivably alter CNS function in the infant both in the short and long term.

Free lorazepam concentrations in the breast milk of 4 mothers ranged from 8 to 9 nanograms/mL four hours after receiving a 3.5-mg oral dose.[2] This represented about 15 to 26% of the concentration in plasma, and was probably sufficiently low to cause no adverse effects in breast-fed infants.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/04/04)
2. Summerfield RJ, Nielsen MS. Excretion of lorazepam into breast milk. *Br J Anaesth* 1985; **57:** 1042–3.

Effects on the blood. A case of pancytopenia associated with oral lorazepam was reported[1] in 1988; only 5 instances of thrombocytopenia and none of leucopenia had been reported to the UK CSM or the UK manufacturers over the previous 13 years.

1. El-Sayed S, Symonds RP. Lorazepam induced pancytopenia. *BMJ* 1988; **296:** 1332.

Effects on fluid and electrolyte homoeostasis. Inappropriate secretion of antidiuretic hormone related to ingestion of lorazepam was considered to be the cause of hyponatraemia in an 81-year-old woman.[1]

1. Engel WR, Grau A. Inappropriate secretion of antidiuretic hormone associated with lorazepam. *BMJ* 1988; **297:** 858.

Effects on the nervous system. For reference to extrapyramidal disorders associated with use of lorazepam, see Diazepam, p.988.

The elderly. For discussion of the need for reduced dosage of benzodiazepines in elderly patients, including mention of lorazepam, see Diazepam, p.989.

Formulation. There have been reports of toxicity, presumed to be due to polyethylene glycol[1,2] or propylene glycol,[3] after prolonged parenteral use of lorazepam; polyethylene glycol in propylene glycol is included as a solubiliser in lorazepam solutions. Diarrhoea in an infant given large enteral doses of lorazepam or diazepam solutions may have been due to the combined osmotic effect of polyethylene glycol and propylene glycol in these preparations.[4]

1. Laine GA, *et al.* Polyethylene glycol nephrotoxicity secondary to prolonged high-dose intravenous lorazepam. *Ann Pharmacother* 1995; **29:** 1110–4.
2. Tayar J *et al.* Severe hyperosmolar metabolic acidosis due to a large dose of intravenous lorazepam. *N Engl J Med* 2002; **346:** 1253–4.
3. Seay RE, *et al.* Possible toxicity from propylene glycol in lorazepam infusion. *Ann Pharmacother* 1997; **31:** 647–8. Woycik CL, Walker PC. Correction and comment: possible toxicity from propylene glycol in injectable drug preparations. *ibid.*: 1413.
4. Marshall JD, *et al.* Diarrhea associated with enteral benzodiazepine solutions. *J Pediatr* 1995; **126:** 657–9.

Hepatic impairment. Lorazepam is contra-indicated in severe hepatic impairment; patients with mild to moderate impairment may require reduced doses. Although the elimination half-life of lorazepam was increased in 13 patients with alcoholic cirrhosis compared with 11 control subjects, this was not associated with an impairment in systemic plasma clearance.[1] With the exception of a modest decrease in the extent of plasma protein binding, acute viral hepatitis had no effect on the disposition kinetics of lorazepam.

1. Kraus JW, *et al.* Effects of aging and liver disease on disposition of lorazepam. *Clin Pharmacol Ther* 1978; **24:** 411–19.

Local reactions. Of 40 patients given a single intravenous dose of lorazepam 4 mg three had local thrombosis 2 to 3 days later and 6 had local thrombosis 7 to 10 days later.[1] The incidence was lower than in those given diazepam [in solution].

1. Hegarty JE, Dundee JW. Sequelae after the intravenous injection of three benzodiazepines—diazepam, lorazepam, and flunitrazepam. *BMJ* 1977; **2:** 1384–5.

Interactions

As for Diazepam, p.989.

Pharmacokinetics

Lorazepam is readily absorbed from the gastrointestinal tract after oral doses, with a bioavailability of about 90%; peak plasma concentrations are reported to occur about 2 hours after an oral dose. The absorption profile after intramuscular injection is similar to that after oral dosage.

Lorazepam is about 85% bound to plasma proteins. It crosses the blood-brain barrier and the placenta; it is also distributed into breast milk. Lorazepam is metabolised in the liver to the inactive glucuronide, and excreted in urine. The elimination half-life has been reported to range from about 10 to 20 hours.

CNS. In a study involving 6 healthy subjects, peak plasma-lorazepam concentrations were reached 5 minutes after the end of a one-minute intravenous injection.[1] CNS effects, as measured by EEG activity, were not maximal until 30 minutes after injection; they declined to baseline values slowly over 5 to 8 hours in a similar manner to plasma concentrations. In contrast, CNS effects of diazepam were maximal immediately after the injection. They also declined more rapidly than lorazepam, but again in a similar way to plasma concentrations. Studies in *mice* suggested that the slow onset of action of lorazepam that has been reported by some is at least partly explained by a delay in passage from systemic blood into brain tissue.

1. Greenblatt DJ, *et al.* Kinetic and dynamic study of intravenous lorazepam; comparison with intravenous diazepam. *J Pharmacol Exp Ther* 1989; **250:** 134–40.

Uses and Administration

Lorazepam is a short-acting benzodiazepine with general properties similar to those of diazepam (p.992). It is used in the short-term treatment of anxiety disorders (p.952), as a hypnotic in the short-term management of insomnia (p.957), and as an anticonvulsant in the management of status epilepticus (p.469). When used in the treatment of status epilepticus lorazepam has a prolonged antiepileptic action and may be the preferred initial treatment if intravenous access is available. It is also used for its sedative and amnestic properties in premedication and as an adjunct in regimens for the control of nausea and vomiting associated with cancer chemotherapy (p.1700).

Lorazepam is usually given orally or by injection as the base although the pivalate is available for oral use in some countries. Sublingual tablets are used in some countries in doses similar to those for standard tablets. The intramuscular route is usually only used when oral or intravenous dosage is not possible. Injections should usually be diluted before use; intravenous injections should be given at a rate of not more than 2 mg/minute into a large vein. Lorazepam should be given in reduced dosage to elderly or debilitated patients; half the usual adult dose, or less, may be sufficient.

The usual oral dose of lorazepam for the treatment of **anxiety disorders** is 1 to 6 mg daily in 2 or 3 divided doses with the largest dose taken at night; up to 10 mg daily has been given. A dose of 25 to

30 micrograms/kg may be given by injection every 6 hours for acute anxiety. Lorazepam has also been used for **panic attacks**. A suggested dose in the *BNF* is 3 to 5 mg daily. A single oral dose of 1 to 4 mg at bedtime may be given for **insomnia** associated with anxiety. However, the MHRA in the UK advises against the use of oral daily doses of lorazepam above 4 mg for anxiety and phobia, and 2 mg for insomnia.

For **premedication** an oral dose of 2 to 3 mg may be given the night before the operation; the *BNF* suggests that this may be followed if necessary the next morning by a smaller dose. Alternatively, 2 to 4 mg may be given 1 to 2 hours before an operation. In the UK, although lorazepam tablets are not licensed for premedication of *children* under 5 years of age, the *BNFC* suggests that 50 to 100 micrograms/kg (maximum of 4 mg) may be given orally at least 1 hour before an operation to those aged 1 month to 12 years; the same dose may also be given the night before, in addition to, or to replace the dose before, the operation. Lorazepam may also be given parenterally for premedication; a dose of 50 micrograms/kg may be given 30 to 45 minutes before the operation if given intravenously or 1 to 1½ hours before if given intramuscularly. Again, although unlicensed in the UK for premedication of children under 12 years of age, the *BNFC* suggests that 50 to 100 micrograms/kg (maximum of 4 mg) may be given by slow intravenous injection to those aged 1 month to 18 years.

In the management of **status epilepticus** 4 mg may be given as a single intravenous dose; the *BNF* suggests that this may be repeated once after 10 minutes if seizures recur. A dose of 2 mg has been suggested for *children* by one manufacturer (*Wyeth*). Alternatively, the *BNFC* suggests that neonates and children up to 12 years of age may be given 100 micrograms/kg (maximum of 4 mg) as a single dose sublingually, rectally, or by slow intravenous injection; this may be repeated once after 10 minutes if necessary.

In patients receiving modestly emetogenic chemotherapy, lorazepam 1 to 2 mg orally may be added to antiemetic therapy with domperidone or metoclopramide, for the prophylaxis of **nausea and vomiting**. The addition of lorazepam may be helpful in the prevention of anticipatory symptoms because of its sedative and amnestic effects.

Disturbed behaviour. For a discussion of the management of behaviour disturbances associated with various psychotic disorders and the value of benzodiazepines, see p.954.

Pharmacopoeias. In *US.*
USP 31 (Loxapine Succinate). A white to yellowish, odourless, crystalline powder. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969.

Other adverse effects reported include nausea and vomiting, seborrhoea, dyspnoea, ptosis, headache, paraesthesia, facial flush, weight gain or loss, and polydipsia.

Abuse. There has been a report of 3 cases of loxapine succinate abuse.[1]

1. Sperry L, *et al*. Loxapine abuse. *N Engl J Med* 1984; **310:** 598.

Effects on carbohydrate metabolism. Reversible nonketotic hyperglycaemia, coma, and delirium developed in a patient receiving loxapine 150 mg daily in addition to lithium therapy.[1] Symptoms improved on stopping loxapine, but subsequently recurred when the patient was given amoxapine. The causative agent may have been 7-hydroxyamoxapine, a common metabolite of both amoxapine and loxapine.

1. Tollefson G, Lesar T. Nonketotic hyperglycemia associated with loxapine and amoxapine: case report. *J Clin Psychiatry* 1983; **44:** 347–8.

Mania. A patient, initially diagnosed as having schizophrenia, developed manic symptoms after receiving loxapine.[1] The diagnosis was revised to schizoaffective disorder but it was suspected that loxapine had a role in the emergence of the affective symptoms. As loxapine shares common metabolites with the antidepressant amoxapine it was suggested that an antidepressant effect might have precipitated the manic symptoms.

1. Gojer JAC. Possible manic side-effects of loxapine. *Can J Psychiatry* 1992; **37:** 669–70.

Overdosage. An 8-year-old child was treated with activated charcoal within 30 minutes of being given 375 mg of loxapine by accident.[1] The child became drowsy and was asleep but arousable 1 hour after ingestion. The degree of sedation appeared to peak after 3.75 hours and the child was discharged about 20 hours after ingestion.

1. Tarricone NW. Loxitane overdose. *Pediatrics* 1998; **101:** 496.

Porphyria. Loxapine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Interactions

As for Chlorpromazine, p.973.

Pharmacokinetics

Loxapine is readily absorbed from the gastrointestinal tract; peak plasma concentrations occur within 1 to 2 hours. It is very rapidly and extensively metabolised and there is evidence for a first-pass effect. It is mainly excreted in the urine, in the form of its conjugated metabolites, with smaller amounts appearing in the faeces as unconjugated metabolites; a substantial proportion of a dose is excreted in the first 24 hours. The major metabolites of loxapine are the active 7- and 8-hydroxyloxapine, which are conjugated to the glucuronide or sulfate; other metabolites include hydroxyloxapine-*N*-oxide, loxapine-*N*-oxide, and hydroxydesmethylloxapine (hydroxyamoxapine). Loxapine is widely distributed and is thought, on the basis of *animal* studies, to cross the placenta and be distributed into breast milk.

Uses and Administration

Loxapine is a dibenzoxazepine with general properties similar to those of the phenothiazine, chlorpromazine (p.975). It is given orally as the succinate and by intramuscular injection as the base in the treatment of psychoses including schizophrenia. Doses are expressed in terms of the base; loxapine succinate 34 mg is equivalent to about 25 mg of loxapine.

The usual oral dose is 20 to 50 mg daily initially, in 2 divided doses, increased according to response over the next 7 to 10 days to 60 to 100 mg daily or more, in 2 to 4 divided doses; the maximum recommended dose is 250 mg daily. Maintenance doses are usually in the range of 20 to 60 mg daily, in divided doses. For the control of acute conditions it is given by intramuscular injection in daily doses of up to 300 mg in 2 or 3 divided doses. Reduced dosage may be required in elderly patients.

Loxapine has also been given orally and by intramuscular injection as the hydrochloride.

Disturbed behaviour. For a discussion of the use and limitations of antipsychotics such as loxapine in patients with disturbed behaviour, see p.954.

References.

1. Carlyle W, *et al*. Aggression in the demented patient: a double-blind study of loxapine versus haloperidol. *Int J Clin Psychopharmacol* 1993; **8:** 103–8.

Schizophrenia. A brief review of loxapine[1] found no conclusive evidence that it was particularly effective in patients with paranoid schizophrenia (p.955). A subsequent systematic review considered that the limited evidence did not indicate a clear difference in its effects from other antipsychotics.[2]

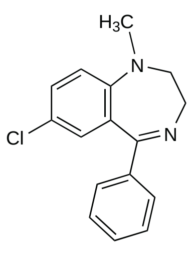
Медазепам

$C_{16}H_{15}ClN_2$ = 270.8.
CAS — 2898-12-6.
ATC — N05BA03.
ATC Vet — QN05BA03.



Pharmacopoeias. In *Jpn.*

Medazepam Hydrochloride *(USAN)*

Medazepam, hidrocloruro de; Ro-5-4556.

$C_{16}H_{15}ClN_2,HCl$ = 307.2.
CAS — 2898-11-5.
ATC — N05BA03.
ATC Vet — QN05BA03.

Profile

Medazepam is a long-acting benzodiazepine with properties similar to those of diazepam (p.986). It has been given for the short-term treatment of anxiety disorders (p.952). A usual oral dose is 10 to 30 mg daily in divided doses; in severe conditions up to 60 mg daily has been given. Reduced doses should be given to elderly or debilitated patients.

Preparations

Medetomidine Hydrochloride *(BANM, USAN, rINNM)*

Hidrocloruro de medetomidina; Medetomidiinihydrokloridi; Médétomidine, Chlorhydrate de; Medetomidinhydroklorid; Medetomidini Hydrochloridum; MPV-785. (±)-4-[1-(2,3-Xylyl)ethyl]imidazole monohydrochloride.

Медетомидина Гидрохлорид

$C_{13}H_{16}N_2,HCl$ = 236.7.
CAS — 86347-15-1 (medetomidine hydrochloride); 86347-14-0 (medetomidine).

Profile

Medetomidine is an α_2-adrenoceptor agonist with sedative, muscle relaxant, and analgesic properties. It is used as the hydrochloride in veterinary medicine.

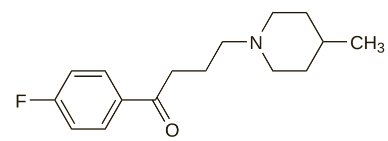
Its isomer dexmedetomidine (p.986) is used as the hydrochloride in intensive care.

Melperone Hydrochloride *(BANM, rINNM)*

FG-5111; Flubuperone Hydrochloride; Hidrocloruro de melperona; Melperon Hidroklorür; Melpérone, Chlorhydrate de; Melperoni Hydrochloridum; Methylperone Hydrochloride. 4′-Fluoro-4-(4-methylpiperidino)butyrophenone hydrochloride.

Мелперона Гидрохлорид

$C_{16}H_{22}FNO,HCl$ = 299.8.
CAS — 3575-80-2 (melperone); 1622-79-3 (melperone hydrochloride).
ATC — N05AD03.
ATC Vet — QN05AD03.



(melperone)

Profile

Melperone is a butyrophenone with general properties similar to those of haloperidol (p.1000). It is given as the hydrochloride by mouth or by intramuscular injection for the management of psychoses such as schizophrenia (p.955) and in disturbed behaviour (p.954); doses are expressed as the hydrochloride. A usual oral dose is up to 400 mg daily in divided doses. In acute conditions it may be given intramuscularly in doses of 25 to 100 mg repeated to a usual maximum of 200 mg daily.

Cardiac arrhythmias. Melperone has been reported to have class III electrophysiologic and antiarrhythmic activity[1,2] but its clinical use as an antiarrhythmic would be limited by a high incidence of adverse effects.[2] For a discussion of the cardiovascular effects of antipsychotics in general, see under Chlorpromazine, p.970.

1. Møgelvang JC, *et al*. Antiarrhythmic properties of a neuroleptic butyrophenone, melperone, in acute myocardial infarction. *Acta Med Scand* 1980; **208:** 61–4.
2. Hui WKK, *et al*. Melperone: electrophysiologic and antiarrhythmic activity in humans. *J Cardiovasc Pharmacol* 1990; **15:** 144–9.

Pharmacokinetics. References.

1. Köppel C, *et al*. Gas chromatographic-mass spectrometric study of urinary metabolism of melperone. *J Chromatogr Biomed Appl* 1988; **427:** 144–50.

Schizophrenia. References[1-3] to the use of melperone in schizophrenia. It has been suggested that melperone should be considered as an atypical antipsychotic in view of the low incidence of extrapyramidal effects associated with its use.

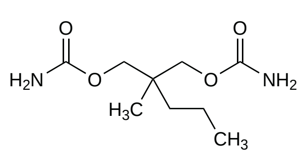
Meprobamate *(BAN, rINN)*

Meprobamaatti; Meprobamát; Meprobamat; Meprobamatas; Méprobamate; Meprobamato; Meprobamatum; Meprotanum. 2-Methyl-2-propyltrimethylene dicarbamate.

Мепробамат

$C_9H_{18}N_2O_4$ = 218.3.
CAS — 57-53-4.
ATC — N05BC01.
ATC Vet — QN05BC01.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of meprobamate: Miltown; Mother's little helper; Uncle Miltie.

Pharmacopoeias. In *Eur.* (see p.vii), *US*, and *Viet.*

Ph. Eur. 6.2 (Meprobamate). A white or almost white, crystalline or amorphous powder. Slightly soluble in water; freely soluble in alcohol.

USP 31 (Meprobamate). A white powder having a characteristic odour. Slightly soluble in water; freely soluble in alcohol and in acetone; practically insoluble or insoluble in ether. Store in airtight containers.

Dependence and Withdrawal

As for the barbiturates (see Amobarbital, p.962).

Adverse Effects and Treatment

Drowsiness is the most frequent adverse effect of meprobamate. Other effects include nausea, vomiting, diarrhoea, paraesthesia, weakness, and CNS effects such as headache, paradoxical excitement, dizziness, ataxia, and disturbances of vision. There may be hypotension, tachycardia, and cardiac arrhythmias. Hypersensitivity reactions occur occasionally. These may be limited to skin rashes, urticaria, and purpura or may be more severe with angioedema, bronchospasm, or anuria. Erythema multiforme or Stevens-Johnson syndrome, and exfoliative or bullous dermatitis have been reported.

Blood disorders including agranulocytosis, eosinophilia, leucopenia, thrombocytopenia, and aplastic anaemia have occasionally been reported.

Overdosage with meprobamate produces symptoms similar to those of barbiturate overdosage (see Amobarbital, p.962), and is managed similarly.

Overdosage. Two children aged 2 and 2.5 years recovered with conservative management alone after overdosage of meprobamate with bendroflumethiazide despite measured plasma-meprobamate concentrations of 170 and 158 micrograms/mL, respectively.[1] Although it had been recommended that haemoperfusion should be considered at plasma-meprobamate concentrations above 100 micrograms/mL, the authors considered that experience with adults suggested haemoperfusion should normally only be considered at plasma concentrations above 200 micrograms/mL.

1. Dennison J, *et al*. Meprobamate overdosage. *Hum Toxicol* 1985; **4:** 215–17.

Precautions

Meprobamate should be used with caution in patients with hepatic or renal impairment, depression, muscle weakness, and, as with all sedatives, in patients with impaired respiratory function. Meprobamate should be given with care to elderly or debilitated patients. Meprobamate may induce seizures in patients with a history of epilepsy.

Meprobamate may cause drowsiness; affected patients should not drive or operate machinery.

Breast feeding. The *BNF* considers that the use of meprobamate should be avoided in breast feeding mothers as concentrations in milk may exceed maternal plasma concentrations fourfold and may cause drowsiness in the infant.

Porphyria. Meprobamate has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. Studies on the use of meprobamate during pregnancy.

1. Milkovich L, van den Berg BJ. Effects of prenatal meprobamate and chlordiazepoxide hydrochloride on human embryonic and fetal development. *N Engl J Med* 1974; **291:** 1268–71.
2. Crombie DL, *et al*. Fetal effects of tranquilizers in pregnancy. *N Engl J Med* 1975; **293:** 198–9.
3. Hartz SC, *et al*. Antenatal exposure to meprobamate and chlordiazepoxide in relation to malformations, mental development, and childhood mortality. *N Engl J Med* 1975; **292:** 726–8.

Interactions

The sedative effects of meprobamate are enhanced by CNS depressants including alcohol. Meprobamate is capable of inducing hepatic microsomal enzyme systems involved in drug metabolism: the metabolism of other drugs may be enhanced if given concurrently.

Pharmacokinetics

Meprobamate is readily absorbed from the gastrointestinal tract and peak plasma concentrations occur 1 to 3 hours after ingestion. Meprobamate is widely distributed. It is extensively metabolised in the liver and is excreted in the urine mainly as an inactive hydroxylated metabolite and its glucuronide conjugate. About 10% of a dose is excreted unchanged. Meprobamate has a half-life reported to range from about 6 to 17 hours, although this may be prolonged after chronic use.

It diffuses across the placenta and appears in breast milk at concentrations of up to 4 times those in the maternal plasma.

Uses and Administration

Meprobamate is a carbamate with hypnotic, sedative, and some muscle relaxant properties, although in therapeutic doses its sedative effect rather than a direct action may be responsible for muscle relaxation. It has been used in the short-term treatment of anxiety disorders (p.952) and also for the short-term management of insomnia (p.957) but has largely been superseded by other drugs. Meprobamate has sometimes been used, alone or with an analgesic, in the management of muscle spasm (p.1887) and painful musculoskeletal disorders but such use is no longer considered appropriate.

The usual anxiolytic dose is 400 mg orally three or four times daily to a maximum of 2.4 g daily. In elderly patients, no more than half the usual adult dose has been suggested.

Preparations

USP 31: Meprobamate Oral Suspension; Meprobamate Tablets.

$C_{21}H_{26}N_2OS_2,C_6H_6O_3S$ = 544.7.
CAS — 32672-69-8 (mesoridazine besilate).
ATC — N05AC03.
ATC Vet — QN05AC03.

Pharmacopoeias. In *US.*

USP 31 (Mesoridazine Besylate). A white to pale yellowish powder having not more than a faint odour. Soluble 1 in 1 of water, 1 in 11 of alcohol, 1 in 3 of chloroform, and 1 in 6300 of ether; freely soluble in methyl alcohol. pH of a freshly prepared 1 in 100 solution is between 4.2 and 5.7. Store in airtight containers. Protect from light.

Profile

Mesoridazine is a phenothiazine with general properties similar to those of chlorpromazine (p.975). It has a piperidine side-chain and is a metabolite of thioridazine (p.1031). Mesoridazine has usually been given as the besilate, orally or by intramuscular injection.

Mesoridazine has been shown to prolong the QT interval in a dose-related manner which increases the risk of life-threatening arrhythmias such as torsade de pointes and sudden death; consequently its use in schizophrenia has been restricted. Details of these restrictions are given under Precautions of Thioridazine, the parent drug of mesoridazine (see p.1031). Its use in other psychiatric disorders was abandoned after it was felt that there was an unacceptable balance of risks and benefits as a result of its cardiotoxic potential, and it is no longer available in many countries.

Breast feeding. The American Academy of Pediatrics[1] considers that, although the effect of mesoridazine on breast-fed infants is unknown, its use by mothers during breast feeding may be of concern since antipsychotic drugs do appear in breast milk and thus could conceivably alter CNS function in the infant both in the short and long term.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/04/04)

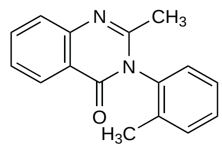
Methaqualone *(BAN, USAN, rINN)*

CI-705; CN-38703; Metacualona; Metakvalon; Metakvalonas; Metakvaloni; Methachalonum; Methakvalon; Méthaqualone; Methaqualonum; QZ-2; R-148; TR-495. 2-Methyl-3-*o*-tolylquinazolin-4-(3*H*)-one.

Метахалон

$C_{16}H_{14}N_2O$ = 250.3.
CAS — 72-44-6 (methaqualone); 340-56-7 (methaqualone hydrochloride).
ATC — N05CM01.
ATC Vet — QN05CM01.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of methaqualone:
300's; 714; 714s; Bandits; Beiruts; Blou Bulle; Blue Balls; Blue bulls; Disco biscuits; Down and dirtys; Drunfos; Drunken Monkey; Ewings; Flamingos; Flowers; Four-strokes; Fuckers; Genuines; Germans; Golfsticks; Gorilla Biscuits; Humbles; Joe Fridays; Knoppies; Lemmon 714; Lemons; Lennons; Lewds; Lizards; Loss-of-memory; Love drug; Lovers; Ludes; Luds; Lula; Magwheels; Pressouts; Pupumala; Q; Qua; Quaa; Quaalude; Quaaludes; Quaass; Quack; Quad; Quads; Quas; Seven fourteens; Shiny Tops; Soaper; Sopor; Sopors; Sporos; Strawberries; Super Sopors; Supers; Supper; Three hundreds; Vitamin Q; Wagon Wheels; Wallbangers; Whore pills.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Methaqualone). A white or almost white, crystalline powder. Very slightly soluble in water; soluble in alcohol; dissolves in dilute sulfuric acid. Protect from light.

Profile

Methaqualone is a quinazoline derivative with hypnotic and sedative properties. It has been given orally in the short-term management of insomnia but the use of methaqualone for this purpose is no longer considered appropriate. It has also been given with diphenhydramine for an enhanced effect.

Methaqualone has been withdrawn from the market in many countries because of problems with abuse.

Adverse effects and symptoms of overdosage are similar to those of barbiturates (see Amobarbital, p.962) although cardiac and respiratory depression reportedly occur less frequently.

Abuse. Although oral abuse of methaqualone has greatly declined in developed countries after the widespread withdrawal of the tablets, smoking of (usually illicitly manufactured) methaqualone, generally in combination with cannabis and tobacco, is a major public health problem in South Africa, and some other parts of Africa and India. Although diazepam has been used to manage dependence, controlled studies to inform the management of the condition are lacking.[1]

1. McCarthy G, *et al.* Treatment for methaqualone dependence in adults. Available in The Cochrane Database of Systematic Reviews; Issue 2. Chichester: John Wiley; 2005 (accessed 11/05/06).

Preparations

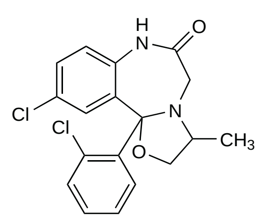
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Switz.:*** Toquilone compositum†.

Mexazolam *(rINN)*

CS-386; Methylcloxazolam; Mexazolamum. 10-Chloro-11b-(2-chlorophenyl)-2,3,7,11b-tetrahydro-3-methyloxazolo[3,2-*d*][1,4]benzodiazepin-6(5*H*)-one.

Мексазолам

$C_{18}H_{16}Cl_2N_2O_2$ = 363.2.
CAS — 31868-18-5.



Profile

Mexazolam is a benzodiazepine with general properties similar to those of diazepam (p.986). It has been given by mouth for its anxiolytic and sedative properties.

Preparations

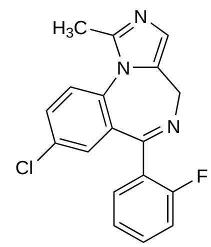
Proprietary Preparations (details are given in Part 3)
Port.: Sedoxil.

Midazolam *(BAN, rINN)*

Midatsolaami; Midazolám; Midazolamas; Midazolamum; Ro-21-3971. 8-Chloro-6-(2-fluorophenyl)-1-methyl-4*H*-imidazo[1,5-*a*][1,4]benzodiazepine.

Мидазолам

$C_{18}H_{13}ClFN_3$ = 325.8.
CAS — 59467-70-8.
ATC — N05CD08.
ATC Vet — QN05CD08.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Midazolam). A white or yellowish crystalline powder. Practically insoluble in water; freely soluble in alcohol and in acetone; soluble in methyl alcohol.

Midazolam Hydrochloride *(BANM, USAN, rINNM)*

Hidrocloruro de midazolam; Midazolam, Chlorhydrate de; Midazolami Hydrochloridum; Ro-21-3981/003.

Мидазолама Гидрохлорид

$C_{18}H_{13}ClFN_3,HCl$ = 362.2.
CAS — 59467-96-8.
ATC — N05CD08.
ATC Vet — QN05CD08.

Incompatibility. The visual compatibility of midazolam hydrochloride with a range of drugs was studied over a period of 4 hours.[1] A white precipitate was formed immediately with dimenhydrinate, pentobarbital sodium, perphenazine, prochlorperazine edisilate, and ranitidine hydrochloride. Similar incompatibility has been reported[2,3] with furosemide, thiopental, and parenteral nutrition solutions. Other workers[4] have reported that a precipitate is formed with midazolam hydrochloride if the resultant mixture has a pH of 5 or more.

1. Forman JK, Souney PF. Visual compatibility of midazolam hydrochloride with common preoperative injectable medications. *Am J Hosp Pharm* 1987; **44:** 2298–9.
2. Chiu MF, Schwartz ML. Visual compatibility of injectable drugs used in the intensive care unit. *Am J Health-Syst Pharm* 1997; **54:** 64–5.
3. Trissel LA, *et al.* Compatibility of parenteral nutrient solutions with selected drugs during simulated Y-site administration. *Am J Health-Syst Pharm* 1997; **54:** 1295–300.
4. Swart EL, *et al.* Compatibility of midazolam hydrochloride and lorazepam with selected drugs during simulated Y-site administration. *Am J Health-Syst Pharm* 1995; **52:** 2020–2.

Stability. Licensed product information states that solutions of midazolam hydrochloride in sodium chloride 0.9%, glucose 5%, or glucose 4% with sodium chloride 0.18% are stable at room temperature for up to 24 hours, and similar solutions containing the equivalent of 0.5 mg/mL of the base were stable for 36 days[1] when stored in glass bottles at temperatures of 4° to 6°, 24° to 26°, and 39° to 41°. Other workers[2] found that a solution containing midazolam hydrochloride equivalent to 1 mg/mL of the base in sodium chloride 0.9% was stable for at least 10 days when stored in PVC bags. The product information advises against admixture with Compound Sodium Lactate Intravenous Infusion (Hartmann's solution) as the potency of midazolam is reduced.

1. Pramar YV, *et al.* Stability of midazolam hydrochloride in syringes and i.v. fluids. *Am J Health-Syst Pharm* 1997; **54:** 913–15.
2. McMullin ST, *et al.* Stability of midazolam hydrochloride in polyvinyl chloride bags under fluorescent light. *Am J Health-Syst Pharm* 1995; **52:** 2018–20.

Midazolam Maleate *(BANM, USAN, rINNM)*

Maleato de midazolam; Midazolam, Maléate de; Midazolami Maleas; Ro-21-3981/001.

Мидазолама Малеат

$C_{18}H_{13}ClFN_3,C_4H_4O_4$ = 441.8.
CAS — 59467-94-6.
ATC — N05CD08.
ATC Vet — QN05CD08.

Dependence and Withdrawal

As for Diazepam, p.987.

◊ Withdrawal symptoms occurred[1] in 2 children after stopping midazolam, which had been used for sedation during mechanical ventilation.

1. van Engelen BGM, *et al.* Benzodiazepine withdrawal reaction in two children following discontinuation of sedation with midazolam. *Ann Pharmacother* 1993; **27:** 579–81.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987. There have been reports of life-threatening adverse respiratory and cardiovascular events occurring after use of midazolam; when giving midazolam the precautions given below should be observed to lessen the risk of such reactions. Pain, tenderness, and thrombophlebitis have occurred after injection of midazolam. Hiccups have been reported.

Incidence of adverse effects. Death due to respiratory depression, hypotension, or cardiac arrest has been reported in patients given intravenous midazolam for conscious sedation.[1] Within about 6 months of its introduction in the USA in May 1986, 13 fatalities due to cardiorespiratory depression had been reported (higher doses were used initially in the USA than those in the UK). By January 1988, 66 deaths had been reported, although in November 1987 the adult dosage recommendation had been reduced to 70 micrograms/kg and to 50 micrograms/kg for elderly patients. Fatalities have also occurred in the UK [where the dose is 70 micrograms/kg, reduced in the elderly] with 4 deaths reported to the UK CSM by November 1987.

While it appears that midazolam and diazepam produce very similar degrees of hypoventilation and oxygen desaturation when used in equivalent doses,[2] the sedative end-point does appear to be reached more abruptly with midazolam.[3] Appropriate precautions should therefore be taken:

- facilities for resuscitation should always be available when intravenous midazolam is used
- respiratory and cardiac function should be monitored continuously
- the dose of midazolam should be carefully titrated against the response of the patient and the product recommendations concerning dosage rate be observed
- particular care, including a reduction in midazolam dosage, is required in patients also receiving opioid analgesics, in the elderly and children, and in patients with compromised cardiorespiratory function
- similar warnings apply to the use of oral midazolam where it is available

The availability of the benzodiazepine antagonist, flumazenil, should not be an encouragement to use larger doses of midazolam.[1]

Since endoscopy of the upper gastrointestinal tract can itself reduce oxygen saturation, some workers have advocated the prophylactic use of nasal oxygen during this procedure for those patients at particular risk as outlined above.

Breast feeding. The American Academy of Pediatrics[1] considers that, although the effect of midazolam on breast-fed infants is unknown its use by mothers during breast feeding may be of concern since psychotropic drugs do appear in breast milk and thus could conceivably alter CNS function in the infant both in the short and long term.

Midazolam could not be detected in breast milk from 11 mothers the morning after either the first or the fifth nightly 15-mg oral dose.[2] Additional study of 2 mothers found that midazolam and its hydroxy-metabolite disappeared rapidly from milk with undetectable concentrations at 4 hours. The mean milk to plasma ratio for midazolam was 0.15 in 6 paired samples.

Children. An intravenous bolus injection of midazolam in children already receiving intravenous morphine after cardiac surgery produced an undesirable transient fall in cardiac output.[1] It was suggested that for patients already receiving other drugs that provide sedation the use of midazolam in the early postoperative period should be limited to a continuous infusion. Similarly, it has been recommended[2] that bolus intravenous doses of midazolam should be avoided in neonates due to the occurrence of hypotension.

The initial dosage of midazolam used for continuous intravenous sedation may need to be reduced in critically ill children under 3 years of age since the plasma clearance of midazolam appears to be reduced in these patients.[3]

Effects on mental function. For discussion of the adverse effects of benzodiazepines on mental function, including reports of sexual fantasies in women sedated with intravenous midazolam, see Diazepam, p.987.

Effects on the nervous system. For reference to acute dystonia associated with use of midazolam, see Diazepam, p.988.

ENCEPHALOPATHY. For a report of prolonged use of midazolam with fentanyl being associated with encephalopathy in infants sedated under intensive care, see Diazepam, p.988.

MYOCLONUS. Myoclonic twitching of all four limbs was noted[1] in 6 of 102 neonates who received a continuous intravenous infusion of midazolam at a rate of 30 to 60 micrograms/kg per hour. Myoclonus ceased a few hours after stopping the infusion and never recurred. No ictal activity was detected in EEGs recorded during the myoclonus.

1. Magny JF, *et al.* Midazolam and myoclonus in neonate. *Eur J Pediatr* 1994; **153:** 389–90.

The elderly. Sedation with midazolam in elderly subjects needed only about half the dose necessary to produce comparable effects in younger subjects.[1] Pharmacodynamic differences due to age suggested an increase in sensitivity of the CNS to midazolam in the elderly subjects.

1. Albrecht S, *et al.* The effect of age on the pharmacokinetics and pharmacodynamics of midazolam. *Clin Pharmacol Ther* 1999; **65:** 630–9.

Hepatic impairment. For the precautions to be observed in patients with impaired liver function, see under Pharmacokinetics, below.

Renal impairment. Five patients with severe renal impairment experienced prolonged sedation when given midazolam; this was attributed to accumulation of conjugated metabolites.[1]

1. Bauer TM, *et al.* Prolonged sedation due to accumulation of conjugated metabolites of midazolam. *Lancet* 1995; **346:** 145–7.

Interactions

As for Diazepam, p.989.

Pharmacokinetics

Absorption of midazolam is rapid, peak plasma concentrations being achieved within 20 to 60 minutes of a dose, depending on the route. Extensive first-pass metabolism results in a low systemic bioavailability after oral doses. Bioavailability is higher, but variable, after intramuscular injection; figures of more than 90% are often cited.

Midazolam is lipophilic at physiological pH. It crosses the placenta and is distributed into breast milk (but see above). Midazolam is about 96% bound to plasma proteins.

Midazolam usually has a short elimination half-life of about 2 hours although half-lives longer than 7 hours have been reported in some patients. The half-life of midazolam is also prolonged in neonates, in the elderly, and in patients with liver disorders.

Midazolam is metabolised in the liver via the cytochrome P450 isoenzyme CYP3A4. The major metabolite, 1-hydroxymidazolam (alpha-hydroxymidazolam) has some activity; its half-life is less than 1 hour. Midazolam metabolites are excreted in the urine, mainly as glucuronide conjugates.

Children. In a study[1] of the pharmacokinetics of midazolam in children the bioavailability of a dose of 0.15 mg/kg was 100, 87, 27, and 18% when given by the intravenous, intramuscular, oral, and rectal routes, respectively. The oral bioavailability was reduced to 16 and 15% after increasing the dose to 0.45 and 1 mg/kg, respectively. There was bioequivalence between the 0.15 mg/kg intramuscular dose and the 0.45 mg/kg oral dose from 45 to 120 minutes after dosage. Absorption from the rectal route gave lower serum-midazolam concentrations than the oral route at the 0.15 mg/kg dose.

Midazolam appears to be absorbed rapidly when given intranasally to children with mean maximum plasma concentrations being achieved within about 12 minutes;[2-4] values of 30% and 55% have been reported for the bioavailability[3,4] but methods to optimise nasal delivery have resulted in higher bioavailability in studies in adults (see below). A study comparing intranasal, intravenous, and rectal dosage of midazolam in children found that plasma concentrations from 45 minutes after intranasal and intravenous doses were similar; those after rectal doses were consistently less than after these other 2 routes.[2] Possible reasons suggested by the authors for this included the effect that the wide interindividual variations in rectal pH may have had on the absorption of midazolam.

Another study has investigated the relationship between intravenous dose and plasma-midazolam concentrations in children.[5]

Half-life. Data collected from 7 studies involving 90 subjects has suggested that the prolonged midazolam half-lives reported in a small number of patients are secondary to increases in the volume of distribution and not a result of alterations in clearance and metabolism.[1] Prolongation of the half-life of midazolam has been reported[2] in 2 patients after sustained infusion for status epilepticus.

1. Wills RJ, *et al.* Increased volume of distribution prolongs midazolam half-life. *Br J Clin Pharmacol* 1990; **29:** 269–72.
2. Naritoku DK, Sinha S. Prolongation of midazolam half-life after sustained infusion for status epilepticus. *Neurology* 2000 **54:** 1366–8.

Intranasal administration. Plasma concentrations of midazolam sufficient to induce conscious sedation are rapidly attained after intranasal doses.[1] Although bioavailability of up to 55% had previously been obtained in children after intranasal use (see above), slow administration and other methods to optimise nasal delivery had resulted in a bioavailability of 83% in adults.[2,3]

Liver disorders. The pharmacokinetics of midazolam in patients with advanced cirrhosis of the liver were characterised by an increase in oral systemic bioavailability[1] and by a decrease in clearance with consequent prolongation of elimination half-life.[1,2] Dosage may need to be reduced. However, metabolism of midazolam has been found in the anhepatic period of liver transplantation indicating extrahepatic metabolism (see below).

Metabolism. For a discussion of the metabolism of benzodiazepines, see Diazepam, p.992. Midazolam appears to be metabolised by at least 3 different cytochrome P450 isoenzymes found in the liver and in the kidney.[1] Variations in the activity of these enzymes might account for some of the interindividual differences in pharmacokinetics and pharmacodynamics seen with midazolam.[2] However, a study[3] in patients undergoing liver transplantation has indicated that the small intestine is a significant site for the first-pass metabolism of midazolam, metabolism presumably being catalysed by the cytochrome P450 isoenzyme CYP3A4 found in intestinal mucosa.

1. Wandel C, *et al.* Midazolam is metabolized by at least three different cytochrome P450 enzymes. *Br J Anaesth* 1994; **73:** 658–61.

Uses and Administration

Midazolam is a short-acting benzodiazepine with general properties similar to those of diazepam (p.992), except that it has a more potent amnestic action. It is mainly used for sedation (p.956) in minor surgical or investigative procedures and in intensive care, for premedication, and for induction of general anaesthesia. It is also used as a hypnotic in the short-term management of insomnia. When midazolam is used as a premedicant or for conscious sedation, onset of sedation occurs at about 15 minutes after intramuscular injection reaching a peak at 30 to 60 minutes, and within about 3 to 5 minutes after intravenous injection. When given intravenously as an anaesthetic induction agent, anaesthesia is induced in about 2 to 2.5 minutes; onset of action is more rapid when premedication with an opioid analgesic has been given.

Since the sedative end-point is reached abruptly with midazolam, dosage must be titrated carefully against the response of the patient; lower doses of midazolam are required when it is used with opioid analgesics. Respiratory and cardiac function should be monitored continuously, and facilities for resuscitation should always be available. It is advisable to keep the patient supine during intravenous use and throughout the procedure. The doses given below are, except where specified, the usual adult doses: midazolam should be given in reduced doses to **elderly** or **debilitated patients**.

Midazolam is used as the hydrochloride for oral, parenteral, and rectal dosage; the maleate may also be given orally. All doses are given in terms of the base; midazolam hydrochloride 8.3 mg or midazolam maleate 10.2 mg are both equivalent to about 7.5 mg of midazolam.

A usual total **sedative** dose for dental and minor surgical and other procedures ranges from 2.5 to 7.5 mg (about 70 micrograms/kg) *intravenously*; an initial dose of 2 mg over 30 seconds has been suggested, with further incremental doses of 0.5 to 1 mg at intervals of 2 minutes if required until the desired end-point is reached. In the USA a suggested initial dose of up to 2.5 mg is given intravenously over at least 2 minutes and repeated if necessary after an additional 2 minutes or more to a usual maximum total dose of 5 mg.

Sedation in children aged 6 months and over may be achieved orally. A single *oral* dose of 250 to 500 micrograms/kg, up to a maximum of 20 mg, is recommended although younger patients (6 months to less than 6 years) may require up to 1 mg/kg. If the *intravenous* route is more suitable, doses of 50 to 100 micrograms/kg up to a total dose of 600 micrograms/kg (but not exceeding 6 mg) are recommended in children aged 6 months to 5 years; children aged 6 to 12 years may be given 25 to 50 micrograms/kg up to a total dose of 400 micrograms/kg (or a maximum of 10 mg). Initial doses should be given over 2 to 3 minutes and an additional interval of at least 2 minutes is recommended before giving further doses. In some countries including the UK, the injection may be used *rectally* for sedation in children over 6 months of age; doses range from 300 to 500 micrograms/kg as a single dose. The injection solution may be diluted with Water for Injections up to a total volume of 10 mL if the volume is too small. The *intramuscular* route should only be used in children in exceptional cases as such injections are painful; usual doses ranging from 50 to 150 micrograms/kg have been suggested for intramuscular use in children aged 1 to 15 years. In the UK, although midazolam is not licensed for sedation of children under 6 months of age, the *BNFC* suggests that it may be given orally or intravenously to those aged 1 month and over in doses similar to those used in children aged 6 months and over (see above). Although also unlicensed, it further suggests that midazolam may be given *buccally* to children 6 months to 10 years of age in doses of 200 to 300 micrograms/kg (maximum of 5 mg); those aged 10 to 18 years may be given 6 to 7 mg (maximum of 8 mg if weighing 70 kg or over). The injection solution has been given *intranasally* to children aged 1 month and over; however, severe irritation of the nasal mucosa may occur (see Administration, below) and use of this route is not recommended in the *BNFC*.

Patients in **intensive care** who require continuous sedation (p.957) can be given midazolam by *intravenous infusion*. An initial loading dose of 30 to 300 micrograms/kg may be given by intravenous infusion over 5 minutes to induce sedation; in the USA a lower dose of 10 to 50 micrograms/kg is recommended. The maintenance dose required varies considerably but a dose of between 20 and 200 micrograms/kg per hour has been suggested. The loading dose should be reduced or omitted, and the maintenance dose reduced, for patients with hypovolaemia, vasoconstriction, or hypothermia. The need for continuous infusion should be reassessed on a daily basis to reduce the risk of accumulation and prolonged recovery. Sedation can also be achieved by giving intermittent *intravenous bolus injections* of midazolam; doses of 1 to 2 mg may be given, and repeated, until the desired level of sedation has been reached.

Midazolam is also used in children in intensive care who require sedation. In those aged over 6 months, an initial loading dose of 50 to 200 micrograms/kg is given by *slow intravenous injection*; maintenance doses are given as an intravenous infusion and range from 60 to 120 micrograms/kg per hour. Neonates with a gestational age of greater than 32 weeks and infants aged up to 6 months may be given midazolam by intravenous infusion in a dose of 60 micrograms/kg per hour; neonates with a gestational age of less than 32 weeks should be started on 30 micrograms/kg per hour. Loading doses are not recommended in infants aged under 6 months.

Abrupt withdrawal should be avoided after prolonged use.

Midazolam is given *intramuscularly* as a **premedicant** about 20 to 60 minutes before surgery. The usual dose is about 5 mg; doses range from 70 to 100 micrograms/kg. Children aged 6 months and over may be premedicated with *oral* midazolam in similar doses to those used for sedation (see above). The *rectal* route is used for premedication in some countries; total doses recommended in the UK in children aged over 6 months range from 300 to 500 micrograms/kg. The *intramuscular* route is also licensed in children aged 1 to 15 years in doses of 80 to 200 micrograms/kg; however, as before, this route should only be used in exceptional circumstances.

The usual dose of midazolam for **induction of anaesthesia** (p.1780) is about 150 to 200 micrograms/kg by slow *intravenous injection* in premedicated patients and at least 300 micrograms/kg in those who have not received a premedicant. Additional doses may be needed to complete induction; up to 600 micrograms/kg has been used in resistant cases. Further incremental doses of midazolam of about 25% of the induction dose have also been given as a component of the regimens used for the maintenance of anaesthesia during short surgical procedures. A dose of 150 micrograms/kg has been recommended for the induction of anaesthesia in children over 7 years of age; however, the *BNFC* notes that such use is rare and suggests a maximum total dose of 500 micrograms/kg (not exceeding 25 mg) in those aged up to 18 years.

Midazolam is also given for sedation in **combined anaesthesia** by *intravenous injection* in a dose of 30 to 100 micrograms/kg repeated as required or by *intravenous infusion* in a dose of 30 to 100 micrograms/kg every hour.

Midazolam maleate is also given *orally* for the short-term management of **insomnia**; the usual dose is the equivalent of midazolam 7.5 to 15 mg at night.

Administration. The rectal,[1] intranasal,[1-5] buccal,[6-8] and sublingual[1,9] routes have all been proposed as alternatives to parenteral use of midazolam.

Intranasal midazolam has caused intense burning, irritation, and lachrymation on instillation, and use of a lidocaine nasal spray has been advocated before giving midazolam to children.[10] The use of midazolam spray intranasally in adults would be impractical and uncomfortable because of the large volume required. It has therefore been tried as a nebulised solution.[11]

INTRATHECAL. See Pain, below.

Conversion and dissociative disorders. For reference to the use of midazolam in the diagnosis of conversion disorders, such as hysterical paralysis, see p.993.

Convulsions. Benzodiazepines such as diazepam or lorazepam given parenterally are often tried first to control status epilepticus (p.469). Midazolam has been used as an alternative.[1] It may be of value when intravenous access is difficult as effective concentrations of midazolam can be obtained after intramuscular injection.[2,3] The *BNF* considers it to be the benzodiazepine of choice when a continuous subcutaneous infusion is required for the control of convulsions, such as in palliative care, and states that it may be given in an initial dose of 20 to 40 mg every 24 hours. Intravenous midazolam has been used in some centres[4] for status epilepticus refractory to diazepam, lorazepam, or phenytoin but reviews of the literature[5] reveal that evidence of efficacy is limited mainly to uncontrolled studies and anecdotal reports.

The intranasal[6,7] and buccal[8] routes have also been used for the management of seizures, and UK guidelines[9] consider buccal midazolam an alternative to rectal diazepam for initial management of status epilepticus in the home setting or where intravenous access is not possible. In addition, a recent study[10] found that buccal midazolam was more effective than rectal diazepam for treatment of children with seizures in the hospital setting and did not appear to increase the risk of respiratory depression. The *BNF* states that a dose of midazolam 10 mg, repeated once if necessary, may be given by the buccal route to adults and children aged over 10 years.

The *BNFC* suggests giving a single buccal dose of 300 micrograms/kg to neonates. It suggests giving the following buccal doses, which may be repeated once if necessary, according to age: 1 to 6 months, 300 micrograms/kg (maximum of 2.5 mg); 6 months to 1 year, 2.5 mg; 1 to 5 years, 5 mg; 5 to 10 years, 7.5 mg. Alternatively, 1 microgram/kg per minute by continuous intravenous infusion may be given to neonates, children, and adolescents after an initial loading dose of 150 to 200 micrograms/kg. This may be increased by 1 microgram/kg per minute every 15 minutes until the seizure is controlled or until a maximum of 5 micrograms/kg per minute is reached.

Disturbed behaviour. For a discussion of the palliative treatment of terminal restlessness with benzodiazepines such as midazolam, see p.954.

Dyspnoea. Midazolam has been suggested[1] as an alternative to chlorpromazine in patients with advanced cancer and intractable dyspnoea (p.104) to relieve air hunger and to sedate dying patients who have unrelieved distress. Suggested[2] initial doses are 2.5 to 5 mg subcutaneously or 10 mg given by infusion over a period of 24 hours, increased as necessary. It may be combined successfully with morphine.[3]

3. Navigante AH, *et al.* Midazolam as adjunct therapy to morphine in the alleviation of severe dyspnea perception in patients with advanced cancer. *J Pain Symptom Manage* 2006; **31:** 38–47.

Hiccup. For the management of intractable hiccups see under Chlorpromazine, p.976. Midazolam given intravenously or subcutaneously has been reported[1] to have been effective in 2 patients with metastatic cancer who had hiccups unresponsive to conventional treatment. However, it has been noted[1,2] that benzodiazepines such as midazolam may exacerbate or precipitate hiccups.

2. Rousseau P. Hiccups. *South Med J* 1995; **88:** 175–81.

Insomnia. For discussion of the management of insomnia including limitations on the use of benzodiazepines and a recommendation that the period of treatment with midazolam should be limited to 2 weeks, see p.957.

References.

1. Monti JM, *et al.* The effect of midazolam on transient insomnia. *Eur J Clin Pharmacol* 1993; **44:** 525–7.

Pain. The conventional use of benzodiazepines in pain management is as muscle relaxants to relieve pain associated with skeletal muscle spasm (see under Choice of Analgesic, p.2). Midazolam has been studied[1-5] for use as an intrathecal analgesic but efficacy has been inconsistent.

Premedication and sedation. Midazolam is used as a premedicant (p.1780) and as a sedative for therapeutic and investigative procedures such as dental treatment (p.956) and endoscopy (see below). It is also used to provide continuous sedation in patients in intensive care (p.957) although a systematic review has raised concerns about such use in neonates.

ENDOSCOPY. Intravenous benzodiazepines such as diazepam or midazolam are often the preferred drugs for sedation in patients undergoing endoscopy (p.956). They are sometimes used with opioid analgesics for sedation.[1]

A reduced dose of midazolam was required for endoscopy when it was given as a bolus intravenous injection rather than as a slow intravenous titration. A study in 788 patients undergoing endoscopy found that a mean dose of 4.65 mg of midazolam given as a bolus intravenous injection was safe and effective in patients under 70 years of age whereas a mean dose of 1.89 mg was sufficient for patients over 70 years of age.[2] Furthermore, topical pharyngeal anaesthesia was not required with these doses of midazolam. Intravenous boluses were also easier to give and associated with less oxygen desaturation than titrating the dose.[3] Another study found that even lower doses of midazolam (35 micrograms/kg) were effective as premedication before gastroscopy, and were associated with fewer complications than higher doses (70 micrograms/kg).[4]

Intranasal[5] and oral[6] midazolam have also been tried for sedation before endoscopy, particularly in children.

Molindone Hydrochloride *(BANM, USAN, rINNM)*

EN-1733A; Hidrocloruro de molindona; Molindone, Chlorhydrate de; Molindoni Hydrochloridum. 3-Ethyl-1,5,6,7-tetrahydro-2-methyl-5-(morpholinomethyl)indol-4-one hydrochloride.

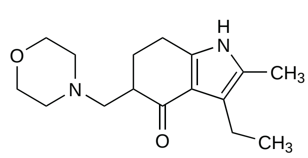
Молиндона Гидрохлорид

$C_{16}H_{24}N_2O_2,HCl = 312.8.$

CAS — 7416-34-4 (molindone); 15622-65-8 (molindone hydrochloride).

ATC — N05AE02.

ATC Vet — QN05AE02.



(molindone)

Pharmacopoeias. In *US.*

USP 31 (Molindone Hydrochloride). pH of a 1% solution in water is between 4.0 and 5.0. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969. Molindone hydrochloride is less likely to cause hypotension than chlorpromazine, and extrapyramidal effects may be frequent but less severe. The incidence of sedation is intermediate between that of chlorpromazine and of phenothiazines with a piperazine side-chain. Weight gain or loss may occur, but weight loss appears to be more prominent (see p.970).

Effects on the liver. A report of hepatotoxicity, associated with a flu-like syndrome, in a patient given molindone.[1] Symptoms and liver-enzyme values returned to normal on stopping the drug and recurred on rechallenge with low doses. The effect was probably due to a hypersensitivity reaction.

1. Bhatia SC, *et al.* Molindone and hepatotoxicity. *Drug Intell Clin Pharm* 1985; **19:** 744–6.

Interactions

As for Chlorpromazine, p.973.

Pharmacokinetics

Molindone is readily absorbed after oral doses, with peak concentrations of unchanged molindone occurring within about 1.5 hours. It is rapidly and extensively metabolised and a large number of metabolites have been identified. It is excreted in the urine and faeces mainly as metabolites and less than 2 to 3% as unchanged drug. The pharmacological effect from a single oral dose is reported to last for 24 to 36 hours.

◊ References.

1. Zetin M, *et al.* Bioavailability of oral and intramuscular molindone hydrochloride in schizophrenic patients. *Clin Ther* 1985; **7:** 169–75.

Uses and Administration

Molindone is an indole derivative with general properties similar to those of the phenothiazine, chlorpromazine (p.975). It is given as the hydrochloride for the treatment of psychoses including schizophrenia (p.955).

The usual oral dose of molindone hydrochloride is 50 to 75 mg daily initially, increased in 3 or 4 days to 100 mg daily; in severe or resistant conditions doses of up to 225 mg daily may be required. The maintenance dose can range from 15 to 225 mg daily according to severity of symptoms. The daily dose is usually divided into 3 or 4 portions.

Molindone should be given in reduced dosage to elderly or debilitated patients.

Psychiatric disorders. A systematic review[1] found that, based on limited data, molindone appeared to be effective in schizophrenia and other severe psychoses but evidence of differences from other classical antipsychotics was lacking.

1. Bagnall A, *et al.* Molindone for schizophrenia and severe mental illness. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2007 (accessed 19/03/08).

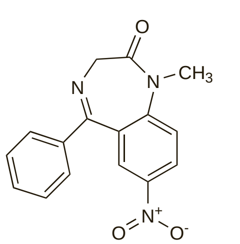
Nimetazepam *(rINN)*

Menifazepam; Nimétazépam; Nimetazepamum; S-1530. 1,3-Dihydro-1-methyl-7-nitro-5-phenyl-1,4-benzodiazepin-2-one.

Ниметазепам

$C_{16}H_{13}N_3O_3$ = 295.3.
CAS — 2011-67-8.



Profile

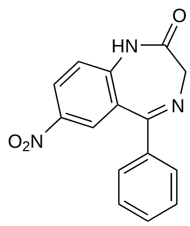
Nimetazepam is a benzodiazepine with the general properties of diazepam (p.986). It has been given orally for the short-term management of insomnia. It appears to have been subject to abuse, especially in South East Asia.

Nitrazepam *(BAN, USAN, rINN)*

Nitratsepaami; Nitrazépam; Nitrazepám; Nitrazepamas; Nitrazepamum; NSC-58775; Ro-4-5360; Ro-5-3059. 1,3-Dihydro-7-nitro-5-phenyl-2*H*-1,4-benzodiazepin-2-one.

Нитразепам

$C_{15}H_{11}N_3O_3$ = 281.3.
CAS — 146-22-5.
ATC — N05CD02.
ATC Vet — QN05CD02.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of nitrazepam:
Don; Moggies; Moogles; Nitro's; The Don.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, and *Jpn.*

Ph. Eur. 6.2 (Nitrazepam). A yellow, crystalline powder. Practically insoluble in water; slightly soluble in alcohol. Protect from light.

Dependence and Withdrawal

As for Diazepam, p.987.

◊ For the purpose of withdrawal regimens, 5 mg of nitrazepam may be considered equivalent to about 5 mg of diazepam.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987.

Effects on the digestive system. Two children given nitrazepam as part of their antiepileptic therapy developed drooling, eating difficulty, and aspiration pneumonia; symptoms improved in one patient when the dosage of nitrazepam was reduced.[1] Manometric studies indicated that the onset of normal cricopharyngeal relaxation in swallowing was delayed in these patients until after hypopharyngeal contraction, resulting in impaired swallowing and spillover of material into the trachea. Other workers[2] have found similar effects on swallowing and cricopharyngeal relaxation in children given nitrazepam. The deaths of 6 epileptic children under 5 years of age who were treated with nitrazepam have been reported.[3] Three of the deaths were unexpected, and in view of the previous reports of swallowing difficulties and aspiration, it was recommended that the use of nitrazepam in young children be restricted to those in whom seizure control fails to improve with other antiepileptics. Another study[4] also found an apparently increased risk of death, especially in young patients with intractable epilepsy, associated with nitrazepam therapy.

1. Wyllie E. *et al.* The mechanism of nitrazepam-induced drooling and aspiration. *N Engl J Med* 1986; **314:** 35–8.
2. Lim HCN, *et al.* Nitrazepam-induced cricopharyngeal dysphagia, abnormal esophageal peristalsis and associated bronchospasm: probable cause of nitrazepam-related sudden death. *Brain Dev* 1992; **14:** 309–14.
3. Murphy JV, *et al.* Deaths in young children receiving nitrazepam. *J Pediatr* 1987; **111:** 145–7.
4. Rintahaka PJ, *et al.* Incidence of death in patients with intractable epilepsy during nitrazepam treatment. *Epilepsia* 1999; **40:** 492–6.

Porphyria. Nitrazepam has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for Diazepam, p.989.

Pharmacokinetics

Nitrazepam is fairly readily absorbed from the gastrointestinal tract, although there is some individual variation. It is about 87% bound to plasma proteins. It crosses the blood-brain and the placental barriers and traces are found in breast milk. Nitrazepam is metabolised in the liver, mainly by nitroreduction followed by acetylation; none of the metabolites possess significant activity. It is excreted in the urine in the form of its metabolites (free or conjugated) with only small amounts of a dose appearing unchanged. Up to about 20% of an oral dose is found in the faeces. Mean elimination half-lives of 24 to 30 hours have been reported.

Distribution into breast milk. A mean milk-to-plasma ratio of 0.27 was obtained after giving nitrazepam 5 mg for 5 nights to 9 puerperal women.[1] The accumulation of nitrazepam in milk over the study period was similar to that in plasma.

1. Matheson I, *et al.* Midazolam and nitrazepam in the maternity ward: milk concentrations and clinical effects. *Br J Clin Pharmacol* 1990; **30:** 787–93.

Hepatic impairment. The pharmacokinetics of intravenous nitrazepam in 12 patients with cirrhosis of the liver has been compared with 9 healthy subjects aged 22 to 49 years and 8 healthy elderly subjects aged 67 to 76 years.[1] The mean elimination half-life of nitrazepam was 26 hours in young and 38 hours in elderly subjects, the difference, which was not significant, being chiefly due to the greater volume of distribution in elderly subjects. Although there was also no significant difference between young and elderly subjects in percentage of unbound nitrazepam (13.0 and 13.9% respectively) there was a substantially higher unbound fraction in the patients with cirrhosis, the mean value being 18.9%, and clearance of unbound nitrazepam was reduced relative to healthy subjects.

1. Jochemsen R, *et al.* Effect of age and liver cirrhosis on the pharmacokinetics of nitrazepam. *Br J Clin Pharmacol* 1983; **15:** 295–302.

Metabolism. Although the acetylation of the reduced metabolite of nitrazepam has been reported to be controlled by acetylator phenotype,[1] no significant differences between either half-life or residual effects of nitrazepam were observed in slow and fast acetylators.[2]

1. Karim AKMB, Price Evans DA. Polymorphic acetylation of nitrazepam. *J Med Genet* 1976; **13:** 17–19.
2. Swift CG, *et al.* Acetylator phenotype, nitrazepam plasma concentrations and residual effects. *Br J Clin Pharmacol* 1980; **9:** 312P–313P.

Uses and Administration

Nitrazepam is an intermediate-acting benzodiazepine with general properties similar to those of diazepam (p.992). It is used as a hypnotic in the short-term management of insomnia (p.957) and is reported to act in 30 to 60 minutes to produce sleep lasting for 6 to 8 hours. Nitrazepam has also been used in epilepsy, notably for infantile spasms (see below).

The usual oral dose for insomnia is 5 mg at night, although 10 mg may be required in some patients. Elderly or debilitated patients should not be given more than half of the normal adult dose.

Epilepsy. Benzodiazepines are sometimes employed in the management of epilepsy (p.465), but their long-term use is limited by problems of sedation, dependence, and tolerance to the antiepileptic effects. Nitrazepam has perhaps been most useful in the treatment of infantile spasms (as for example in West's syndrome) and the so-called infantile myoclonic seizures. The *BNFC* suggests that those aged from 1 month to 2 years may be given initial oral doses of 125 micrograms/kg twice daily, adjusted according to response over 2 to 3 weeks to 250 micrograms/kg twice daily (maximum 500 micrograms/kg, but not exceeding 5 mg, twice daily); the same total daily dose may also be given in 3 divided doses. There has been concern, however, over swallowing difficulties with subsequent aspiration and reports of unexpected death associated with the use of nitrazepam in young children (see Effects on the Digestive System under Adverse Effects, above).

Preparations

BP 2008: Nitrazepam Oral Suspension; Nitrazepam Tablets.

Proprietary Preparations (details are given in Part 3)

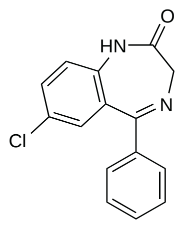
Nordazepam (rINN)

A-101; Demethyldiazepam; Desmethyldiazepam; *N*-Desmethyldiazepam; Nordazépam; Nordazepamum; Nordiazepam; Ro-5-2180. 7-Chloro-1,3-dihydro-5-phenyl-2*H*-1,4-benzodiazepin-2-one.

Нордазепам

$C_{15}H_{11}ClN_2O$ = 270.7.
CAS — 1088-11-5.
ATC — N05BA16.
ATC Vet — QN05BA16.



Profile

Nordazepam is a long-acting benzodiazepine with the general properties of diazepam (p.986). It is the principal active metabolite of a number of benzodiazepines and has a half-life of 2 to 5 days. It is given in oral doses of up to 15 mg daily for the short-term treatment of anxiety disorders (p.952) and insomnia (p.957).

Porphyria. Nordazepam is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals* or *in-vitro* systems.

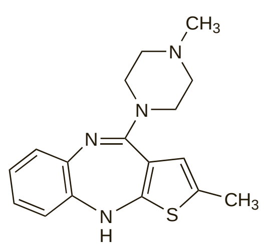
Olanzapine (BAN, USAN, rINN)

LY-170053; Olantsapiini; Olanzapin; Olanzapina; Olanzapinum. 2-Methyl-4-(4-methyl-1-piperazinyl)-10*H*-thieno[2,3-*b*][1,5]benzodiazepine.

Оланзапин

$C_{17}H_{20}N_4S$ = 312.4.
CAS — 132539-06-1.
ATC — N05AH03.
ATC Vet — QN05AH03.



Stability. A suspension of olanzapine 1 mg/mL, made by crushing olanzapine tablets and suspending the powder in a syrup-based mixture containing carboxymethylcellulose preserved with methyl hydroxybenzoate and propyl hydroxybenzoate (Guy's Hospital paediatric base formula), was considered to be stable for 2 weeks when stored in a refrigerator.[1]

1. Harvey EJ, *et al.* The preparation and stability of a liquid olanzapine preparation for oral administration in hospitals. *Pharm J* 2000; **265:** 275–6.

Adverse Effects, Treatment, and Precautions

Although olanzapine may share some of the adverse effects seen with the classical antipsychotics (see Chlorpromazine, p.969), the incidence and severity of such effects may vary. The most frequent adverse effects with olanzapine are somnolence and weight gain; hyperprolactinaemia is also common, but usually asymptomatic. Increased appetite, dizziness, fatigue, elevated plasma glucose, triglyceride, and liver enzyme values, eosinophilia, oedema, orthostatic hypotension, and mild transient antimuscarinic effects such as constipation and dry mouth are also relatively common. More severe abnormalities of glucose homoeostasis are uncommon; severe hyperglycaemia, or exacerbation of pre-existing diabetes, sometimes leading to ketoacidosis, coma, or death, has occurred. Clinical monitoring for hyperglycaemia has been recommended, especially in patients with or at risk of developing diabetes. Clinical monitoring of plasma lipids and weight have also been recommended.

Olanzapine is associated with a low incidence of extrapyramidal effects, including tardive dyskinesia, although these effects may be more likely at high doses and in the elderly; the risk of tardive dyskinesia also increases with long-term use. Neuroleptic malignant syndrome has been reported rarely.

Patients receiving olanzapine intramuscularly should be closely observed for 2 to 4 hours for hypotension, bradyarrhythmia, and hypoventilation. Olanzapine should not be given intramuscularly to patients with a history of cardiovascular disease or following heart surgery; caution is recommended when giving olanzapine by mouth to such patients and to those with cerebrovascular disease or conditions predisposing to hypotension. It is recommended that blood pressure is periodically assessed in elderly patients.

The antimuscarinic effects of olanzapine contra-indicate its use in patients with angle-closure glaucoma; caution is also advised in those with conditions such as benign prostatic hyperplasia or paralytic ileus. Olanzapine is also not recommended in Parkinson's disease since its use has commonly been associated with an increase in parkinsonian symptoms and hallucinations. It should be used with caution in patients with hepatic impairment, or a history of blood dyscrasias, bone marrow depression, or myeloproliferative disease. Seizures are rare with olanzapine but it should be used with care in those with a history of seizures or with conditions that lower the seizure threshold.

Olanzapine may affect the performance of skilled tasks such as driving.

Withdrawal symptoms, including sweating, tremor, anxiety, and nausea and vomiting, have occurred rarely when olanzapine has been stopped abruptly; a gradual dose reduction may be appropriate when stopping olanzapine.

Breast feeding. From a study[1] of the distribution of olanzapine into breast milk in 7 breast feeding women taking a median dose of 7.5 mg daily, it was estimated that the weight-adjusted median dose ingested by the breast-fed infants was 1.02% of the maternal dose. Olanzapine was not detected in the plasma of the 6 infants from whom a sample was taken; no adverse effects were observed in all 7 infants. However, UK licensed product information states that at steady state the estimated mean exposure of breast-fed infants of mothers taking olanzapine would be 1.8% of the maternal dose and recommends that patients should not breast feed if they are taking olanzapine.

Dementia. For details of a possibly increased risk of mortality in elderly patients with dementia given olanzapine and other atypical antipsychotics, see under Risperidone, p.1024.

Effects on the blood. A review[1] has described 11 reports of olanzapine-associated haematotoxicity that included 3 cases of agranulocytosis, 6 of neutropenia, and 2 of leucopenia. In most cases, the haematotoxicity developed within the first month of treatment and patients recovered after olanzapine withdrawal. There was a history of clozapine-associated haematotoxicity in 5 patients. It was suggested that white blood cell counts should be monitored periodically during olanzapine treatment.

Olanzapine has also apparently delayed recovery of granulocyte counts in patients with clozapine-induced granulocytopenia who were switched to olanzapine before blood counts had returned to the normal range.[2]

There have been case reports[3,4] of thrombocytopenia associated with olanzapine treatment. In one report,[3] the patient improved on stopping olanzapine but subsequently had a similar episode associated with benzatropine therapy. In another report,[4] an elderly patient with pre-existing idiopathic thrombocytopenic purpura died from bleeding complications due to thrombocytopenia associated with olanzapine treatment; the patient's plasma concentration of olanzapine was reported to be 10 times the usual mean therapeutic value.

Effects on body temperature. Olanzapine has been associated with occasional reports of hypothermia. In one report[1] body temperature fell as low as 33.4° over several days in a woman receiving olanzapine for bipolar disorder. The patient, who also had subclinical hypothyroidism, was asymptomatic, and body temperature returned to normal once olanzapine was stopped; it was unclear whether the endocrine abnormalities had contributed to the condition.

1. Blass DM, Chuen M. Olanzapine-associated hypothermia. *Psychosomatics* 2004; **45:** 135–9.

Effects on body-weight. The increased risk of weight gain with some atypical antipsychotics is discussed under Adverse Effects of Clozapine, p.981.

Effects on the cardiovascular system. Two of 3 elderly patients who developed venous thromboembolism shortly after starting treatment with olanzapine also had symptoms of pulmonary embolism.[1] There have been 2 further isolated cases[2,3] of pulmonary embolism associated with olanzapine therapy; it had been reported in a 28-year-old man[2] and in a 22-year-old man[3] after 10 weeks and after 6 months of olanzapine therapy, respectively. Both patients recovered and were switched to another atypical antipsychotic.

Effects on the nervous system. A 31-year-old woman with a complicated medical history suffered three generalised tonic-clonic seizures after 13 days of therapy with olanzapine.[1] She recovered after treatment with phenytoin. Another patient with Huntington's disease also suffered a severe generalised tonic-clonic seizure following treatment with olanzapine 30 mg daily for 1 month.[2] Olanzapine was continued but carbamazepine was added; there was no recurrence of the seizure.

2. Bella VL, Piccoli F. Olanzepine-induced tardive dyskinesia. *Br J Psychiatry* 2003; **182:** 81–2.

Mania. Although olanzapine is used in the treatment of bipolar disorder, it has been associated with reports of mania in both schizophrenic and bipolar patients.[1-4] A report sponsored by the manufacturers noted that no association was seen in pooled data from 2 placebo-controlled studies involving 254 bipolar patients.[5]

Overdosage. A 2⁄-year-old boy was found sleeping and difficult to arouse after taking one or two 7.5-mg olanzapine tablets.[1] His reported symptoms included agitation, aggressive behaviour, miosis, hypersalivation, tachycardia, and ataxia; he recovered after 24 hours. Symptoms suggestive of diabetes insipidus, together with mild CNS depression, have also been reported,[2] in an adolescent who took 75 mg of olanzapine with a small quantity of prazepam. The polyuria responded to desmopressin. A review[3] identified 29 fatalities associated with olanzapine overdose, but evidence of a direct causative relationship was limited.

4. Manson AJ, *et al.* Low-dose olanzapine for levodopa induced dyskinesias. *Neurology* 2000; **55:** 795–9.

Pregnancy. The manufacturer has reviewed both prospective and retrospective cases of pregnancies that have been exposed to olanzapine treatment.[1] Of the 37 prospective pregnancies, there were 14 therapeutic abortions (with no reported abnormality in the fetus), 3 spontaneous abortions (again with no reported abnormality in the fetus), and 1 still-birth. The remaining 19 pregnancies included 16 normal births without complications and 1 premature birth; the 2 other births were complicated by post-term deliveries. Eleven retrospective cases were also identified and included 2 cases of major malformation (dysplastic kidney and Down's syndrome), 1 case of fetal death following an overdose by the mother, and 1 case each of neonatal convulsion and sudden infant death. For comments on the use of some atypical antipsychotics, including olanzapine, during pregnancy, see under Precautions of Clozapine, p.983.

1. Goldstein DJ, *et al.* Olanzapine-exposed pregnancies and lactation: early experience. *J Clin Psychopharmacol* 2000; **20:** 399–403.

Speech disorders. Although olanzapine may be used in the treatment of stuttering, it has also been associated with reports of the development of the disorder, see under Uses and Administration, below.

Interactions

The central effects of other CNS depressants, including alcohol, may be enhanced by olanzapine. Olanzapine may antagonise the effects of dopaminergics. Neutropenia may be more common when olanzapine is given with valproate. Use with valproate or lithium has also been associated with an increased incidence of tremor, dry mouth, increased appetite, and weight gain.There is a theoretical risk of QT prolongation when olanzapine is given with other drugs that are known to cause this effect.

Drugs that induce hypotension, bradycardia, or respiratory depression should be used with caution in patients given intramuscular olanzapine. Parenteral benzodiazepine treatment should be given at least 1 hour after intramuscular olanzapine as it is recommended that they are not given together.

The metabolism of olanzapine is mediated to some extent by the cytochrome P450 isoenzyme CYP1A2. Use with drugs that inhibit, induce, or act as a substrate to this isoenzyme may affect plasma concentrations of olanzapine and a dose adjustment of olanzapine may be required. The CYP1A2 inhibitor fluvoxamine significantly inhibits the metabolism of olanzapine. The clearance of olanzapine is increased by tobacco smoking and carbamazepine.

Valproate. In a study of 4 patients, valproate reduced plasma concentrations of olanzapine by 32.3 to 78.8% (mean 53.6%).[1]

1. Bergemann N, *et al.* Valproate lowers plasma concentrations of olanzapine. *Pharmacopsychiatry* 2005; **38:** 44.

Pharmacokinetics

Olanzapine is well absorbed from the gastrointestinal tract after oral doses but undergoes considerable first-pass metabolism. Peak plasma concentrations are achieved about 5 to 8 hours after oral doses and about 15 to 45 minutes after an intramuscular dose. Olanzapine is about 93% bound to plasma proteins. It is extensively metabolised in the liver, primarily by direct glucuronidation and by oxidation mediated through the cytochrome P450 isoenzymes CYP1A2, and, to a lesser extent, CYP2D6. The 2 major metabolites 10-*N*-glucuronide and 4′-*N*-desmethyl olanzapine appear to be inactive. About 57% of a dose is excreted in the urine, mainly as metabolites, and about 30% appears in the faeces. The mean plasma elimination half-life has been variously reported to be about 30 to 38 hours; half-lives tend to be longer in female than in male patients. Olanzapine is distributed into breast milk.

Uses and Administration

Olanzapine is a thienobenzodiazepine atypical antipsychotic. It has affinity for serotonin, muscarinic, histamine (H_1), and adrenergic (α_1) receptors as well as various dopamine receptors.

Olanzapine is used for the management of schizophrenia and for the treatment of moderate to severe mania associated with bipolar disorder.

In the UK, the usual initial oral dose for **schizophrenia** is 10 mg daily as a single dose; thereafter dosage adjustments may be made according to response at intervals of not less than 24 hours to within the range of 5 to 20 mg daily. In the USA, the starting dose is 5 to 10 mg daily and it is recommended that dosage adjustments beyond 10 mg daily are made at intervals of not less than 1 week; the daily dosage should be adjusted in steps of 5 mg. However, it is recommended that doses above 10 mg daily should be given only after clinical reassessment.

For the treatment of **acute mixed or manic episodes** in bipolar disorder, a recommended initial oral dose is 10 or 15 mg daily as monotherapy or 10 mg if given as part of combination therapy; the daily dosage may be adjusted in steps of 5 mg if necessary, at intervals of not less than 24 hours to a dose of between 5 and 20 mg daily. If a response is achieved, therapy may continue at the same dosage to prevent recurrence. For **prevention of recurrence** in patients whose manic episodes have responded previously to olanzapine, the recommended starting dose is 10 mg daily.

For the **rapid control of agitation and disturbed behaviour** in patients with schizophrenia or mania, olanzapine may be given intramuscularly in an initial dose of 5 to 10 mg followed by 5 to 10 mg as required after 2 hours. Not more than 3 injections should be given in any 24-hour period and the maximum daily dose, including olanzapine given orally, should not exceed 20 mg. Injections may be given for up to a maximum of 3 days but transfer to oral therapy should be started as soon as possible.

The metabolism of olanzapine might be slower in female, elderly, or non-smoking patients; if more than one of these factors is present, a lower initial dose (e.g. 5 mg daily if given orally) and a more gradual dose escalation should be considered. The intramuscular dose should be reduced by half in the elderly. See below for doses in patients with hepatic or renal impairment.

Administration in hepatic or renal impairment. A starting dose of 5 mg daily of olanzapine orally or by intramuscular injection may be necessary for patients with renal or hepatic impairment; for patients with moderate hepatic insufficiency, the starting dose should only be increased with caution.

Bipolar disorder. Olanzapine is of benefit for the treatment of mania, with or without psychosis, in patients with bipolar disorder (p.372), and the use of atypical antipsychotics in the management of such patients is increasing. However, there have been individual case reports of olanzapine-induced mania (see above).

There is also increasing interest in the use of olanzapine for the depressive phase of bipolar disorder, and for other forms of resistant depression. In some countries olanzapine is available as a fixed-dose combination with fluoxetine for use in the former condition.

Nausea and vomiting. For mention of the use of olanzapine as a second-line drug to control nausea and vomiting in palliative care see p.1700.

Parkinsonism. Olanzapine is associated with a relatively low incidence of extrapyramidal disorders and has been studied[1] for use in the treatment of psychosis in patients with Parkinson's disease (see Disturbed Behaviour, p.954). However, there have been a number of reports of adverse effects including exacerbation of the movement disorder (see Parkinsonism, under Precautions, above).

1. Wolters EC, *et al.* Olanzapine in the treatment of dopaminomimetic psychosis in patients with Parkinson's disease. *Neurology* 1996; **47:** 1085–7.

Psychiatric disorders. The main treatment for *post-traumatic stress disorder* (p.953) is psychotherapy but adjunctive olanzapine may be used in patients refractory to psychotherapy and/or drug treatment with antidepressants. Olanzapine has also been tried for the control of *aggression* in children with autism and conduct disorder (see Disturbed Behaviour, p.954).

Schizophrenia. Studies suggest that olanzapine is as effective as haloperidol against positive symptoms of schizophrenia (p.955) and more effective against negative symptoms in the short-term and possibly in the long-term,[1-5] although a systematic review considered the evidence equivocal.[6] Quality of life has also been judged to be greater in patients treated with olanzapine.[7] In comparative studies, extrapyramidal adverse effects have been less frequent with olanzapine than haloperidol and fewer patients have discontinued treatment with olanzapine. There are relatively few published comparisons with other atypical antipsychotics, but one systematic review[8] concluded that there was little to differentiate between olanzapine and risperidone apart from their adverse effects; risperidone was particularly associated with movement disorders and sexual dysfunction while olanzapine induced rapid weight gain. Another study has suggested that olanzapine is not inferior to clozapine.[9] Olanzapine's efficacy in the treatment of patients with refractory schizophrenia remains to be determined; a small, randomised study found it to be no more effective than haloperidol.[10]

Tourette's syndrome. When drug treatment is required for tics and behavioural disturbances in Tourette's syndrome (see Tics, p.954) haloperidol or pimozide are commonly used but atypical antipsychotics, including olanzapine, are increasingly being tried.[1-4]

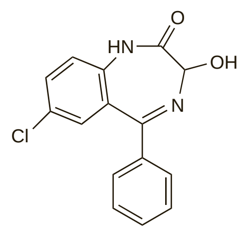
$C_{15}H_{11}ClN_2O_2$ = 286.7.

CAS — 604-75-1.

ATC — N05BA04.

ATC Vet — QN05BA04.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Oxazepam). A white or almost white crystalline powder. Practically insoluble in water; slightly soluble in alcohol. Protect from light.

USP 31 (Oxazepam). A creamy-white to pale yellow, practically odourless powder. Practically insoluble in water; soluble 1 in 220 of alcohol, 1 in 270 of chloroform, and 1 in 2200 of ether. pH of a 2% suspension in water is between 4.8 and 7.0.

Dependence and Withdrawal

As for Diazepam, p.987.

◊ For the purpose of withdrawal regimens, 15 mg of oxazepam is considered equivalent to about 5 mg of diazepam.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987.

Hepatic impairment. All benzodiazepines should be used with caution in patients with hepatic impairment, but short-acting ones such as oxazepam may be preferred.

Seven patients with acute viral hepatitis, 6 with cirrhosis of the liver, and 16 age-matched healthy control subjects took a single dose of oxazepam 15 or 45 mg orally.[1] Urinary excretion rates and plasma elimination patterns were unaltered in patients with acute and chronic parenchymal liver disease. Oxazepam 15 mg orally was also given three times daily for 2 weeks to 2 healthy subjects and to 2 patients with cirrhosis and did not appear to accumulate in any of the four.

1. Shull HJ, *et al.* Normal disposition of oxazepam in acute viral hepatitis and cirrhosis. *Ann Intern Med* 1976; **84:** 420–5.

Porphyria. Oxazepam is considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity.

Renal impairment. Pharmacokinetic studies suggest that, in general, the dosage of oxazepam does not need adjusting in patients with renal impairment.[1-3]

1. Murray TG, *et al.* Renal disease, age, and oxazepam kinetics. *Clin Pharmacol Ther* 1981; **30:** 805–9.
2. Busch U, *et al.* Pharmacokinetics of oxazepam following multiple administration in volunteers and patients with chronic renal disease. *Arzneimittelforschung* 1981; **31:** 1507–11.
3. Greenblatt DJ, *et al.* Multiple-dose kinetics and dialyzability of oxazepam in renal insufficiency. *Nephron* 1983; **34:** 234–8.

Thyroid disorders. There was a reduction in half-life and an increase in the apparent oral clearance of oxazepam in 7 hyperthyroid patients.[1] In 6 hypothyroid patients there was no overall change in oxazepam elimination, although 5 of the 6 complained of drowsiness despite a relatively low dose (15 mg).

1. Scott AK, *et al.* Oxazepam pharmacokinetics in thyroid disease. *Br J Clin Pharmacol* 1984; **17:** 49–53.

Interactions

As for Diazepam, p.989.

Pharmacokinetics

Oxazepam is well absorbed from the gastrointestinal tract and reaches peak plasma concentrations about 2 hours after ingestion. It crosses the placenta and has been detected in breast milk. Oxazepam is about 85 to 97% bound to plasma proteins and has been reported to have an elimination half-life ranging from about 3 to 21 hours. It is largely metabolised to the inactive glucuronide which is excreted in the urine.

Pregnancy. The placental passage of oxazepam and its metabolism in 12 women given a single dose of oxazepam 25 mg during labour has been studied.[1] Oxazepam was readily absorbed and peak plasma concentrations were in the same range as those reported in healthy males and non-pregnant females given the same dose, although the plasma half-life (range 5.3 to 7.8 hours in 8 subjects studied) was shorter than that reported for non-pregnant subjects. Oxazepam was detected in the umbilical vein of all 12 patients with the ratio between umbilical to maternal vein concentration of oxazepam reaching a value of about 1.35 and remaining constant beyond a dose-delivery time of 3 hours. All of the babies had a normal Apgar score value. The oxazepam plasma half-life in the newborns was about 3 to 4 times that of the mothers, although in 3 the plasma concentration of oxazepam conjugate rose during the first 6 to 10 hours after delivery indicating the ability of the neonate to conjugate oxazepam.

1. Tomson G, *et al*. Placental passage of oxazepam and its metabolism in mother and newborn. *Clin Pharmacol Ther* 1979; **25:** 74–81.

Uses and Administration

Oxazepam is a short-acting benzodiazepine with general properties similar to those of diazepam (p.992). It is used in the short-term management of anxiety disorders (p.952) and insomnia (p.957) associated with anxiety. Oxazepam is also used for the control of symptoms associated with alcohol withdrawal (p.1626). Oxazepam is usually given as the base but the hemisuccinate has been used in some multi-ingredient preparations.

The usual oral dose of oxazepam for the treatment of anxiety or for control of symptoms of alcohol withdrawal is 15 to 30 mg three or four times daily. A suggested initial dose for elderly or debilitated patients is 10 mg three times daily increased if necessary up to 10 to 20 mg three or four times daily. For the treatment of insomnia associated with anxiety oxazepam 15 to 25 mg may be given one hour before retiring; up to 50 mg may occasionally be necessary.

Administration in renal impairment. For a suggestion that dosage adjustment of oxazepam may not be necessary in patients with renal impairment, see Renal Impairment, above.

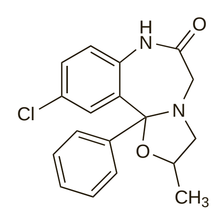
Oxazolam *(rINN)*

Oxazolamum; Oxazolazepam. 10-Chloro-2,3,7,11b-tetrahydro-2-methyl-11b-phenyloxazolo[3,2-*d*][1,4]benzodiazepin-6(5*H*)-one.

Оксазолам

$C_{18}H_{17}ClN_2O_2$ = 328.8.

CAS — 24143-17-7.



Pharmacopoeias. In *Jpn.*

Profile

Oxazolam is a long-acting benzodiazepine with general properties similar to those of diazepam (p.986). It has been given by mouth for the short-term treatment of anxiety disorders.

Oxazolam has also been used as a premedicant in general anaesthesia.

Oxypertine (BAN, USAN, rINN)

Oksipertiini; Oxipertin; Oxipertina; Oxypertinum; Win-18501-2. 5,6-Dimethoxy-2-methyl-3-[2-(4-phenylpiperazin-1-yl)ethyl]-indole.

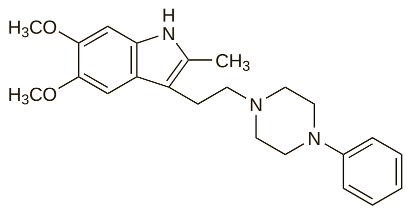
Оксипертин

$C_{23}H_{29}N_3O_2$ = 379.5.

CAS — 153-87-7 (oxypertine); 40523-01-1 (oxypertine hydrochloride).

ATC — N05AE01.

ATC Vet — QN05AE01.



Profile

Oxypertine is an indole derivative with general properties similar to those of the phenothiazine, chlorpromazine (p.969). It has been given orally in the treatment of psychoses including schizophrenia, mania, and disturbed behaviour, and in severe anxiety.

Paliperidone (USAN, rINN)

9-Hydroxyrisperidone; Paliperidona; Palipéridone; Paliperidonum; RO-76477. (±)-3-{2-[4-(6-Fluoro-1,2-benzisoxazol-3-yl)piperidino]ethyl}-6,7,8,9-tetrahydro-9-hydroxy-2-methyl-4*H*-pyrido[1,2-*a*]pyrimidin-4-one.

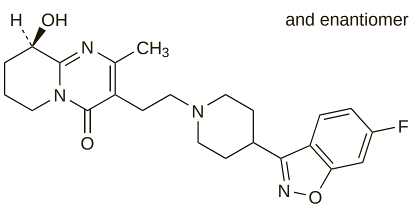
Палиперидон

$C_{23}H_{27}FN_4O_3$ = 426.5.

CAS — 144598-75-4.

ATC — N05AX13.

ATC Vet — QN05AX13.



and enantiomer

Paliperidone Palmitate (USAN, rINNM)

Palipéridone, Palmitate de; Paliperidoni Palmitas; Palmitato de paliperidona; RO-92670. (9*RS*)-3-{2-[4-(6-Fluoro-1,2-benzisoxazol-3-yl)piperidin-1-yl]ethyl}-2-methyl-4-oxo-6,7,8,9-tetrahydro-4*H*-pyrido[1,2-*a*]pyrimidin-9-yl hexadecanoate.

Палиперидона Палмитат

$C_{39}H_{57}FN_4O_4$ = 664.9.

CAS — 199739-10-1.

Profile

Paliperidone is a benzisoxazole derivative and is the major active metabolite of the atypical antipsychotic risperidone (p.1024). It is reported to be an antagonist at dopamine D_2, serotonin (5-HT_2), adrenergic (α_1 and α_2), and histamine (H_1) receptors. It is used in the treatment of schizophrenia.

The recommended oral dose of paliperidone is 6 mg once daily as a modified-release preparation; doses may range from 3 to 12 mg daily. US licensed product information recommends that dose increases are made in small steps of 3 mg at intervals of more than 5 days.

For details of dose reductions in patients with renal impairment, see below.

Paliperidone palmitate is being developed as a long-acting intramuscular formulation.

Administration in renal impairment. The plasma concentrations of paliperidone are increased in patients with renal impairment. The usual oral daily dosage (see above) should therefore be adjusted according to creatinine clearance (CC).

In the UK, licensed product information recommends the following doses:

- CC 50 to 80 mL/minute: initially 3 mg once daily, may be increased thereafter according to response and tolerance
- CC 30 to 50 mL/minute: 3 mg once daily
- CC 10 to 30 mL/minute: initially 3 mg on alternate days which may be increased thereafter to 3 mg once daily after clinical reassessment

However, US licensed product information recommends the following maximum doses:

- CC 50 to 80 mL/minute: 6 mg once daily
- CC 10 to 50 mL/minute: 3 mg once daily

Paliperidone has not been studied in patients with a CC of less than 10 mL/minute; UK product information does not recommend its use in such patients.

Paraldehyde

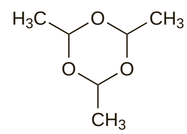
Paracetaldehyde; Paraldehid; Paraldehidas; Paraldehído; Paraldehit; Paraldehyd; Paraldéhyde; Paraldehydi; Paraldehydum. The trimer of acetaldehyde; 2,4,6-Trimethyl-1,3,5-trioxane.

$(C_2H_4O)_3$ = 132.2.

CAS — 123-63-7.

ATC — N05CC05.

ATC Vet — QN05CC05.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Paraldehyde). A colourless or slightly yellow, transparent liquid. It solidifies on cooling to form a crystalline mass. It may contain a suitable amount of an antoxidant. Relative density 0.991 to 0.996. F.p. is 10° to 13°; not more than 10% distils below 123° and not less than 95% below 126°. Soluble in water but less soluble in boiling water; miscible with alcohol and with volatile oils. Store in small well-filled airtight containers. Protect from light.

USP 31 (Paraldehyde). A colourless transparent liquid with a strong characteristic, but not unpleasant or pungent, odour. It is subject to oxidation to form acetic acid. It may contain a suitable stabiliser. Specific gravity is about 0.99. It has a congealing temperature of not lower than 11° and distils completely between 120° and 126°. Soluble 1 in 10 of water v/v, but only 1 in 17 of boiling water v/v; miscible with alcohol, with chloroform, with ether, and with volatile oils. Store in well-filled airtight containers of not more than 30 mL at a temperature not exceeding 25°. Protect from light. It must not be used more than 24 hours after opening the container.

Incompatibility. Paraldehyde exerts a solvent action upon rubber, polystyrene, and styrene-acrylonitrile copolymer and should not be given in plastic syringes made with these materials.

An evaluation of the compatibility of paraldehyde with plastic syringes and needle hubs concluded that, if possible, all-glass syringes should be used with paraldehyde.[1] Needles with plastic hubs could be used. Polypropylene syringes with rubber-tipped plastic plungers (*Plastipak*), or glass syringes with natural rubber-tipped plastic plungers (*Glaspak*) were acceptable only for the immediate administration or measurement of paraldehyde doses.

1. Johnson CE, Vigoreaux JA. Compatibility of paraldehyde with plastic syringes and needle hubs. *Am J Hosp Pharm* 1984; **41:** 306–8.

Stability. Paraldehyde decomposes on storage, particularly after the container has been opened. Partly decomposed paraldehyde is **dangerous** if given. It must not be used if it has a brownish colour or a sharp penetrating odour of acetic acid.

Dependence and Withdrawal

Prolonged use of paraldehyde may lead to dependence, especially in alcoholics. Features of dependence and withdrawal are similar to those of barbiturates (see Amobarbital, p.962).

Adverse Effects and Treatment

Paraldehyde decomposes on storage and deaths from corrosive poisoning have followed the use of such material. Paraldehyde has an unpleasant taste and imparts a smell to the breath; it may cause skin rashes.

Oral or rectal use of paraldehyde may cause gastric or rectal irritation. Intramuscular injection is painful and associated with tissue necrosis, sterile abscesses, and nerve damage. Intravenous use is extremely hazardous since it may cause pulmonary oedema and haemorrhage, hypotension and cardiac dilatation, and circulatory collapse; thrombophlebitis is also associated with intravenous use.

Overdosage results in rapid laboured breathing owing to damage to the lungs and to acidosis. Nausea and vomiting may follow an overdose by mouth. Respiratory depression and coma as well as hepatic and renal damage may occur. Treatment is as for barbiturate overdose (see Amobarbital, p.962).

Precautions

Paraldehyde should not be given to patients with gastric disorders and it should be used with caution, if at all, in patients with bronchopulmonary disease or hepatic impairment. It should not be given rectally in the presence of colitis. Old paraldehyde must never be used.

Paraldehyde must be well diluted before oral or rectal use; if it is deemed essential to give paraldehyde intravenously it must be well diluted and given very slowly with extreme caution (see also Adverse Effects, above and Uses, below). Intramuscular injections may be given undiluted but care should be taken to avoid nerve damage. Plastic syringes should be avoided (see Incompatibility, above).

Interactions

The sedative effects of paraldehyde are enhanced by CNS depressants such as alcohol, barbiturates, and other sedatives. A few case reports suggest that disulfiram may enhance the toxicity of paraldehyde; use together is not recommended.

Pharmacokinetics

Paraldehyde is generally absorbed readily, although absorption is reported to be slower after rectal than after oral or intramuscular doses. It is widely distributed and has a reported half-life of 4 to 10 hours. About 80% of a dose is metabolised in the liver probably to acetaldehyde, which is oxidised by aldehyde dehydrogenase to acetic acid. Unmetabolised drug is largely excreted unchanged through the lungs; only small amounts appear in the urine. It crosses the placental barrier and is distributed into breast milk.

Uses and Administration

Paraldehyde is a hypnotic and sedative with antiepileptic effects. However, because of the hazards associated with its use, its tendency to react with plastic, and the risks associated with its deterioration, it has largely been superseded by other drugs. It is still occasionally used to control status epilepticus (p.469) resistant to conventional treatment. Given rectally or intramuscularly it causes little respiratory depression and is therefore useful where facilities for resuscitation are poor.

At low temperature it solidifies to form a crystalline mass. If it solidifies, the whole should be liquefied before use.

A usual dose for adults is 10 to 20 mL given rectally as a 10% solution in sodium chloride 0.9% solution or diluted with 1 or 2 parts of oil. Doses of 5 to 10 mL are also occasionally given intramuscularly up to a maximum of 20 mL daily with not more than 5 mL being given at any one site. In the UK it is licensed for intramuscular use in children; however, the *BNFC* advocates use of the rectal route instead, diluted as above. Recommended single daily doses by either route are:

- up to 3 months, 0.5 mL (the *BNFC* suggests a single rectal dose of 0.4 mL/kg (maximum of 0.5 mL) in those under 1 month)
- 3 to 6 months, 1 mL
- 6 to 12 months, 1.5 mL
- 1 to 2 years, 2 mL
- 3 to 5 years, 3 to 4 mL
- 6 to 12 years, 5 to 6 mL

Paraldehyde has been given by slow intravenous infusion in specialist centres with intensive care facilities but this route is not usually recommended; it must be diluted in sodium chloride 0.9% before use.

Paraldehyde has been given orally; it should always be well diluted to avoid gastric irritation.

Preparations

BP 2008: Paraldehyde Injection.

Proprietary Preparations (details are given in Part 3)
USA: Paral.

Penfluridol (BAN, USAN, rINN)

McN-JR-16341; Penfluridoli; Penfluridolum; R-16341. 4-(4-Chloro-3-trifluoromethylphenyl)-1-[3-(*p,p'*-difluorobenzhydryl)propyl]piperidin-4-ol.

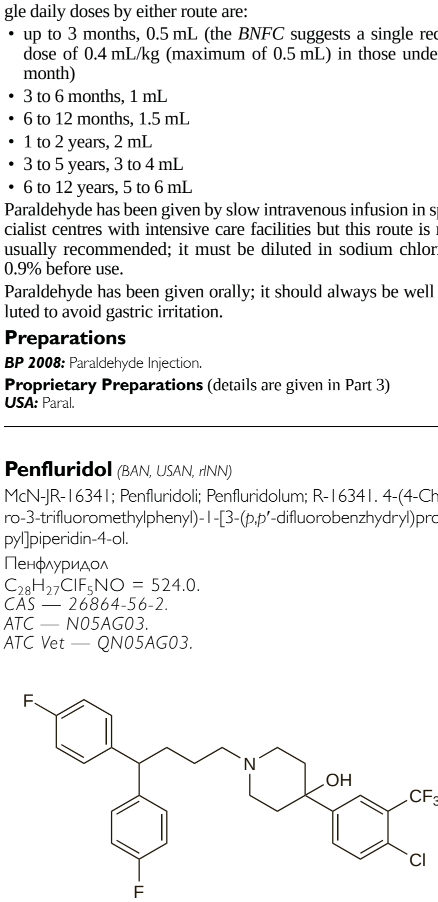
Пенфлуридол

$C_{28}H_{27}ClF_5NO$ = 524.0.

CAS — 26864-56-2.

ATC — N05AG03.

ATC Vet — QN05AG03.



Pharmacopoeias. In *Chin.*

Profile

Penfluridol is a diphenylbutylpiperidine antipsychotic and shares the general properties of the phenothiazine, chlorpromazine (p.969). After oral doses it has a prolonged duration of action that lasts for about a week. It is used in the treatment of psychoses including schizophrenia (p.955).

The usual oral dose of penfluridol for the treatment of chronic psychoses is 20 to 60 mg once a week. Doses of up to 250 mg once a week may be required in severe or resistant conditions.

Schizophrenia. A systematic review[1] concluded that penfluridol appears to have a similar efficacy and adverse effects profile to other classical antipsychotics used in the treatment of schizophrenia (p.955). The authors also suggested that penfluridol, in a weekly oral dose of 40 to 80 mg, is a suitable alternative, particularly for patients who do not respond to daily oral medication or adapt well to depot drugs.

1. Soares BGO, Lima MS. Penfluridol for schizophrenia. Available in The Cochrane Database of Systematic Reviews; Issue 2. Chichester: John Wiley; 2006 (accessed 19/03/08).

Sodium 5-ethyl-5-(1-methylbutyl)barbiturate.

Натрий Пентобарбитал

$C_{11}H_{17}N_2NaO_3$ = 248.3.

CAS — 57-33-0.

ATC — N05CA01.

ATC Vet — QN05CA01.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Pentobarbital Sodium). A white or almost white, hygroscopic, crystalline powder. Very soluble in water. A 10% solution in water has a pH of 9.6 to 11.0 when freshly prepared. Store in airtight containers.

USP 31 (Pentobarbital Sodium). White, crystalline granules or white powder. Is odourless or has a slight characteristic odour. Very soluble in water; freely soluble in alcohol; practically insoluble in ether. pH of a 10% solution in water is between 9.8 and 11.0. Solutions decompose on standing, the decomposition being accelerated at higher temperatures. Store in airtight containers.

Incompatibility. Pentobarbital may be precipitated from preparations containing pentobarbital sodium, depending on the concentration and pH. Pentobarbital sodium has, therefore, been reported to be incompatible with many other drugs particularly acids and acidic salts.

Dependence and Withdrawal

As for Amobarbital, p.962.

Adverse Effects, Treatment, and Precautions

As for Amobarbital, p.962.

Interactions

As for Amobarbital, p.962.

Pharmacokinetics

Pentobarbital is well absorbed from the gastrointestinal tract after oral or rectal doses, and is reported to be about 60 to 70% bound to plasma proteins. The elimination half-life appears to be dose-dependent and reported values have ranged from 15 to 50 hours. Pentobarbital is metabolised in the liver, mainly by hydroxylation, and excreted in the urine mainly as metabolites.

Uses and Administration

Pentobarbital is a barbiturate that has been used as a hypnotic and sedative. It has general properties and uses similar to those of amobarbital (p.962). It has been used as a sedative and in the short-term management of insomnia (p.957) but barbiturates are not considered appropriate for such purposes. Pentobarbital sodium has also been used for premedication in anaesthetic procedures (p.1780), but barbiturates for pre-operative sedation have been replaced by other drugs. Pentobarbital is usually given as the sodium salt, although pentobarbital itself and its calcium salt have both been used.

A usual oral dose of pentobarbital sodium for insomnia was 100 to 200 mg, given at bedtime. Usual parenteral doses for other indications were 150 to 200 mg as a single intramuscular dose or 100 mg by slow intravenous injection.

Cerebrovascular disorders. For reference to the use of barbiturate-induced coma in the management of patients with cerebral ischaemia, see under Thiopental, p.1796. See also p.1181 for reference to the use of barbiturates in the management of raised intracranial pressure.

Status epilepticus. General anaesthesia may be used to control refractory tonic-clonic status epilepticus (p.469). A short-acting barbiturate such as thiopental is usually used, but pentobarbital has been used similarly.

Preparations

BP 2008: Pentobarbital Tablets;

Perazine Dimalonate

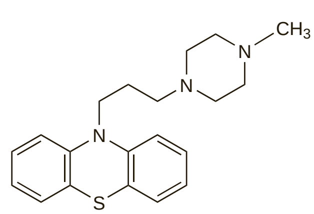
P-725 (perazine); Pemazine Dimalonate; Perazina, dimalonato de. 10-[3-(4-Methylpiperazin-1-yl)propyl]phenothiazine dimalonate.

$C_{20}H_{25}N_3S,2C_3H_4O_4$ = 547.6.

CAS — 84-97-9 (perazine); 14777-25-4 (perazine dimalonate).

ATC — N05AB10.

ATC Vet — QN05AB10.



(perazine)

Pharmacopoeias. *Pol.* includes only an injection of the dimalonate. It also includes a monograph for Perazine Dimaleate.

Profile

Perazine dimalonate is a phenothiazine with general properties similar to those of chlorpromazine (p.969) and is used for the treatment of psychotic conditions. It has a piperazine side-chain. It is given orally as the dimalonate although doses are expressed in terms of the base; perazine dimalonate 40.3 mg is equivalent to about 25 mg of perazine. Usual doses are the equivalent of 50 to 600 mg of the base daily; up to 1000 mg daily has been given in resistant cases. It has also been given intramuscularly.

Perazine dimaleate given orally has been used similarly.

Adverse effects. A report of 5 patients receiving perazine dimalonate who developed acute axonal neuropathies of superficial nerve fibres after exposure to sunlight.[1]

1. Roelcke U, *et al.* Acute neuropathy in perazine-treated patients after sun exposure. *Lancet* 1992; **340:** 729–30.

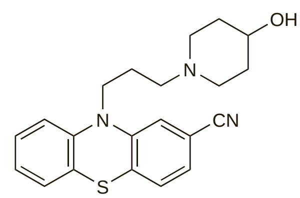
Перициазин

$C_{21}H_{23}N_3OS$ = 365.5.

CAS — 2622-26-6.

ATC — N05AC01.

ATC Vet — QN05AC01.



Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969. Sedation and orthostatic hypotension may be marked.

Interactions

As for Chlorpromazine, p.973.

Uses and Administration

Pericyazine is a phenothiazine with general properties similar to those of chlorpromazine (p.975). It has a piperidine side-chain. It is used in the treatment of psychoses including schizophrenia (p.955) and disturbed behaviour (p.954), and in the short-term management of severe anxiety (p.952).

Pericyazine is usually given as the base but the mesilate and tartrate have also been used.

The usual oral dose for the treatment of severe anxiety, agitation, aggression, or impulsive behaviour is 15 to 30 mg daily given in 2 divided doses, the larger amount in the evening. In schizophrenia and severe psychoses initial doses of 75 mg daily may be given in divided doses, increased if necessary, at weekly intervals by increments of 25 mg, to a maximum of 300 mg daily.

A recommended initial oral dose in children aged over 1 year is 500 micrograms daily for a child weighing 10 kg; for heavier children this initial dose may be increased by 1 mg for each additional 5 kg, to a maximum total of 10 mg daily. Thereafter the dose may be gradually increased according to response but the daily maintenance dose should not exceed twice the initial dose.

Elderly patients should be given reduced doses: a recommended initial dose is 5 to 10 mg daily for anxiety or disturbed behaviour and 15 to 30 mg daily for schizophrenia or psychosis, both in divided doses.

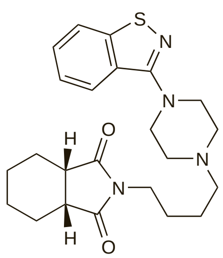
Perospirone Hydrochloride *(rINNM)*

Hidrocloruro de perospirona; Pérospirone, Chlorhydrate de; Perospironi Hydrochloridum; SM-9018. *cis-N*-{4-[4-(1,2-Benzisothiazol-3-yl)-1-piperazinyl]butyl}-1,2-cyclohexanedicarboximide hydrochloride.

Пероспирона Гидрохлорид

$C_{23}H_{30}N_4O_2S,HCl = 463.0.$

CAS — 150915-41-6 (perospirone); 129273-38-7 (perospirone hydrochloride).



(perospirone)

Profile

Perospirone is an antipsychotic used in the treatment of schizophrenia. Although it has been described as an atypical antipsychotic, the incidence of extrapyramidal effects may be rather higher than is usually seen with atypical drugs such as clozapine (p.981). Perospirone hydrochloride is given in usual oral doses of 12 to 48 mg daily in 3 divided doses.

$C_{28}H_{38}ClN_3O_2S = 516.1.$

CAS — 17528-28-8.
ATC — N05AB03.
ATC Vet — QN05AB03.

Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969. Perphenazine has been associated with a lower frequency of sedation, but a higher incidence of extrapyramidal effects.

Breast feeding. The American Academy of Pediatrics[1] considers that, although the effect of perphenazine on breast-fed infants is unknown, its use by mothers during breast feeding may be of concern since antipsychotics do appear in breast milk and thus could conceivably alter CNS function in the infant both in the short and long term.

The distribution of perphenazine into breast milk was studied[2] in a mother who was receiving oral perphenazine 24 mg daily, later reduced to 16 mg daily. Breast feeding was started after it was estimated that a breast-fed infant would ingest about 0.1% of a maternal dose. Treatment with perphenazine lasted for 3.5 months and during this period the child thrived normally and no drug-induced symptoms were seen.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/04/04)

Interactions

As for Chlorpromazine, p.973.

Pharmacokinetics

Perphenazine is well absorbed after oral doses and undergoes some first-pass metabolism, resulting in a relative bioavailability of about 60 to 80%. Peak plasma concentrations are achieved between 1 to 3 hours after ingestion. It is widely distributed and crosses the placenta. Perphenazine is extensively metabolised; up to 70% is excreted in the urine mainly as metabolites, with about 5% being excreted in the faeces. The plasma elimination half-life of perphenazine is between 9 and 12 hours. Perphenazine decanoate and perphenazine enantate are slowly absorbed from the site of intramuscular injection. They gradually release perphenazine into the body and are therefore suitable for use as depot injections.

◊ Perphenazine 5 or 6 mg given intravenously had a plasma half-life from 8.4 to 12.3 hours in a study of 4 schizophrenic patients and 4 healthy subjects.[1] Plasma-perphenazine concentrations varied considerably 3 to 5 hours after dosing; this was followed by an exponential elimination phase. Plasma concentrations were undetectable after a 6-mg oral dose in 4 healthy subjects and only low plasma concentrations of its sulfoxide metabolite could be detected; this was attributed to a marked first-pass effect. Systemic availability was also variable and poor in 4 schizophrenic patients given perphenazine 12 mg three times daily. However, it was considered that oral therapy should be given at 8-hour intervals. Intramuscular injection of perphenazine enantate 50 or 100 mg every 2 weeks gave plasma-perphenazine concentrations similar to those after continuous oral dosage, but high initial absorption in the first 2 to 3 days was associated with serious CNS adverse effects.

1. Hansen CE, *et al.* Clinical pharmacokinetic studies of perphenazine. *Br J Clin Pharmacol* 1976; **3:** 915–23.

Metabolism. In a study in 12 healthy subjects there was a clear difference in the disposition of a single oral dose of perphenazine between poor and extensive hydroxylators of debrisoquine.[1]

1. Dahl-Puustinen M-L, *et al.* Disposition of perphenazine is related to polymorphic debrisoquin hydroxylation in human beings. *Clin Pharmacol Ther* 1989; **46:** 78–81.

Uses and Administration

Perphenazine is a phenothiazine with general properties similar to those of chlorpromazine (p.975). It has a piperazine side-chain. It is used in the treatment of various psychoses including schizophrenia (p.955) and mania (see Bipolar Disorder, p.372) as well as disturbed behaviour (p.954) and in the short-term, adjunctive management of severe anxiety (p.952). Perphenazine is also used for the management of postoperative or chemotherapy-induced nausea and vomiting (p.1700) and for the treatment of intractable hiccup (p.976).

Perphenazine is usually given orally and sometimes by intramuscular or intravenous injection as the base. Long-acting decanoate or enantate esters of perphenazine, available in some countries, are given by intramuscular injection.

The usual initial oral dose for the treatment of **schizophrenia, mania, and other psychoses** is 4 mg three times daily. The dose is adjusted according to response up to a usual maximum of 24 mg daily, although up to 64 mg daily has occasionally been used in hospitalised patients. Similar doses have been used for the management of **severe agitated or violent behaviour** or in **severe anxiety**. Perphenazine has sometimes been used in preparations with tricyclic antidepressants such as amitriptyline in the treatment of anxiety with depression.

For the **control of nausea and vomiting** the usual oral dose is 4 mg three times daily but up to 8 mg three times daily may be required.

Perphenazine may be given by deep *intramuscular* injection for control of acute psychotic symptoms or for severe nausea and vomiting. An initial dose of 5 or 10 mg is followed, if necessary, by 5 mg every 6 hours to a maximum of 15 to 30 mg daily.

Perphenazine, diluted to a concentration of 500 micrograms/mL in sodium chloride 0.9%, is occasionally given by *intravenous* injection in divided doses, not more than 1 mg being given every 1 to 2 minutes; the maximum intravenous dose is 5 mg. The intravenous route is usually reserved for the control of severe vomiting or intractable hiccup. Perphenazine has also been given by slow infusion.

The long-acting decanoate or enantate esters of perphenazine are given by deep intramuscular injection in doses ranging from about 50 to 300 mg of ester given at intervals of 2 to 4 weeks.

Perphenazine and its esters should be given in reduced doses to the elderly but it should be noted that they are not indicated for the management of agitation and restlessness in these patients.

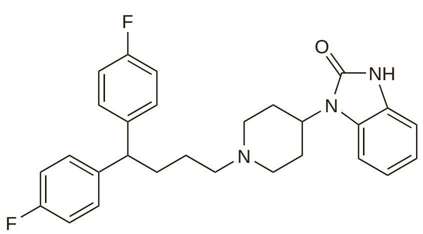
Пимозид

$C_{28}H_{29}F_2N_3O$ = 461.5.
CAS — 2062-78-4.
ATC — N05AG02.
ATC Vet — QN05AG02.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Pimozide). A white or almost white powder. Practically insoluble in water; slightly soluble in alcohol; soluble in dichloromethane; sparingly soluble in methyl alcohol. Protect from light.

USP 31 (Pimozide). A white crystalline powder. Insoluble in water; soluble 1 in 1000 of alcohol, of ether, and of methyl alcohol, 1 in 100 of acetone, 1 in 10 of chloroform, and 1 in more than 1000 of 0.1N hydrochloric acid. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969.

Extrapyramidal effects may be more common than with chlorpromazine but pimozide may be less likely to cause sedation, hypotension, or antimuscarinic effects.

Ventricular arrhythmias and other ECG abnormalities, such as prolongation of the QT interval and T-wave changes, have been associated with the use of pimozide; an ECG should therefore be performed before, and repeated periodically during, treatment. If repolarisation changes appear or arrhythmias develop, the need for continuing treatment should be reviewed; the dose of pimozide should be reduced or, if the QT interval exceeds 500 milliseconds, therapy should be withdrawn. Pimozide is contra-indicated in patients with pre-existing prolongation of the QT interval, or a family history of congenital QT prolongation, and in patients with a history of cardiac arrhythmias. Electrolyte disturbances such as hypokalaemia or hypomagnesaemia in patients receiving pimozide may lead to cardiotoxicity.

Effects on the cardiovascular system. The UK CSM has received reports of ventricular arrhythmias and other ECG abnormalities such as prolongation of the QT interval and T-wave changes associated with the use of pimozide.[1,2] In August 1990 they had received 13 reports of sudden unexpected death since 1971; many of these patients had no evidence of pre-existing cardiac disease, and 7 were under 30 years of age. Five of the 13 were also taking other antipsychotics. Most cases were associated with doses greater than 20 mg daily and many had had the dose increased rapidly, possibly resulting in substantial tissue accumulation. By February 1995 the CSM had received a total of 40 reports (16 fatal) of serious cardiac reactions most of which involved arrhythmias.

See also under Chlorpromazine, p.970.

2. CSM/MCA. Cardiac arrhythmias with pimozide (Orap). *Current Problems* 1995; **21:** 2. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2015618&RevisionSelectionMethod=LatestReleased (accessed 16/05/06)

Interactions

As for Chlorpromazine, p.973. The risk of arrhythmias with pimozide may be increased by other drugs that prolong the QT interval including some antiarrhythmics, other antipsychotics (including depot preparations), tricyclic antidepressants, the antihistamines terfenadine and astemizole, antimalarials, and cisapride; use together should be avoided. Use with drugs that induce electrolyte disturbances, such as diuretics, should also be avoided.

The use of pimozide with drugs that inhibit the cytochrome P450 isoenzyme CYP3A4 is contra-indicated; the resultant decrease in the metabolism of pimozide may lead to increased plasma concentrations and hence greater risk of cardiac arrhythmias. CYP3A4 inhibitors include the macrolide antibacterials such as clarithromycin, erythromycin, and troleandomycin; the azole antifungals including itraconazole and ketoconazole; the HIV-protease inhibitors; the NNRTIs; nefazodone, and zileuton. The metabolism of pimozide may also be inhibited by grapefruit juice and use together should be avoided.

Pimozide is also metabolised by CYP2D6, albeit to a lesser extent, and *in vitro* data indicate that the CYP2D6 inhibitor quinidine may reduce the metabolism of pimozide; UK licensed product information contra-indicates the use of such inhibitors with pimozide. The isoenzyme CYP1A2 may also be involved in the metabolism of pimozide and consequently there is a theoretical possibility of interactions with CYP1A2 inhibitors.

Pimozide should also not be used with SSRIs such as citalopram, escitalopram, paroxetine, and sertraline.

Antibacterials. Sudden deaths have occurred in patients given pimozide and *clarithromycin*, see p.973.

Pharmacokinetics

More than half of an oral dose of pimozide is reported to be absorbed. It undergoes significant first-pass metabolism. Peak plasma concentrations have been reported after 4 to 12 hours and there is a considerable interindividual variation in the concentrations achieved. Pimozide is metabolised in the liver mainly by *N*-dealkylation and excreted in the urine and faeces in the form of metabolites and unchanged drug. Metabolism is mediated mainly by the cytochrome P450 isoenzyme CYP3A4 and to a lesser extent by CYP2D6; CYP1A2 may also be involved. Pimozide has a mean elimination half-life of about 55 hours, although half-lives of up to 150 hours have been noted in some patients.

Uses and Administration

Pimozide is a diphenylbutylpiperidine antipsychotic and is structurally similar to the butyrophenones. It is a long-acting antipsychotic with general properties similar to those of the phenothiazine, chlorpromazine (p.975), although it also has some calcium-blocking activity. Pimozide is given orally in the management of psychoses including schizophrenia, paranoid states, and monosymptomatic hypochondria (p.954) and in Tourette's syndrome. An ECG should be performed in all patients before starting treatment with pimozide (see Adverse Effects, Treatment, and Precautions, above).

In **schizophrenia**, treatment is usually begun with a dose of 2 mg daily (the *BNFC* suggests 1 mg in those aged 12 to 18 years), adjusted thereafter according to response in increments of 2 to 4 mg at intervals of not less than 1 week. A maximum daily dose of 20 mg should not be exceeded. It is usually given as a single daily dose.

In **monosymptomatic hypochondria** and **paranoid psychoses**, the initial dose is 4 mg daily adjusted as above to a maximum daily dose of 16 mg.

Pimozide treatment should start at half the usual initial dosage in elderly patients.

In the USA, pimozide is used for the treatment of **Tourette's syndrome** in an initial dose of 1 to 2 mg daily in divided doses; children may be given 50 micrograms/kg daily initially. Dosage may be increased gradually to a maximum of 10 mg daily or 200 micrograms/kg daily; data are limited in children under 12 years of age. Although not licensed in the UK for the treatment of Tourette's syndrome, the *BNFC* suggests that children aged from 2 to 12 years may be given 1 to 4 mg daily and those aged from 12 to 18 years, 2 to 10 mg daily.

Chorea. Antipsychotics such as pimozide have some action against choreiform movements (p.953) as well as being of use to control the behavioural disturbances of Huntington's chorea.

References.

1. Shannon KM, Fenichel GM. Pimozide treatment of Sydenham's chorea. *Neurology* 1990; **40:** 186.

Dystonia. Antipsychotics such as phenothiazines, haloperidol, or pimozide are sometimes useful in the treatment of idiopathic dystonia (p.809) in patients who have failed to respond to other drugs.[1] In very severe dystonia combination therapy may be required. Pimozide in gradually increasing doses up to 12 mg daily with tetrabenazine and trihexyphenidyl is sometimes effective. However, antipsychotics often act non-specifically and there is the risk of adding drug-induced extrapyramidal disorders to the dystonia being treated (see Extrapyramidal Disorders under Adverse Effects of Chlorpromazine, p.971).

1. Marsden CD, Quinn NP. The dystonias. *BMJ* 1990; **300:** 139–44.

Schizophrenia. A systematic review[1] concluded that pimozide appears to be of similar efficacy to other classical antipsychotics in the treatment of schizophrenia (p.955). There was no evidence that it was particularly useful for those with delusional disorders or with mainly negative symptoms.

1. Rathbone J, McMonagle T. Pimozide for schizophrenia or related psychoses. Available in The Cochrane Database of Systematic Reviews; Issue 3. Chichester: John Wiley; 2007 (accessed 20/03/08).

Taste disorders. For reference to the use of pimozide in the treatment of taste disorders, see Chlorpromazine, p.977.

Tourette's syndrome. Tourette's syndrome (see Tics, p.954) is a disorder characterised by motor and vocal tics and behavioural disturbances. Many patients with Tourette's syndrome do not require medication but when treatment is needed dopamine antagonists such as the antipsychotics haloperidol or pimozide[1,2] have been most commonly used. They often decrease the frequency and severity of tics and may improve any accompanying behavioural disturbances. However, superiority of either drug in terms of efficacy or adverse effects has not been clearly demonstrated. Because of the potential for acute and long-term adverse effects it is usually recommended that doses are titrated to as low as possible; the aim of treatment is not necessarily to control symptoms completely. Medication can often be stopped after a few years.

Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969.

Effects on mental function. Manic symptoms developed in a schizophrenic patient given pipotiazine palmitate. Symptoms recurred on rechallenge.[1]

1. Singh AN, Maguire J. Pipothiazine palmitate induced mania. *BMJ* 1984; **289:** 734.

Pharmacokinetics

Pipotiazine palmitate is very slowly absorbed from the site of intramuscular injection. It gradually releases pipotiazine into the body and is therefore suitable for use as a depot injection.

Uses and Administration

Pipotiazine is a phenothiazine with general properties similar to those of chlorpromazine (p.975). It has a piperidine side-chain. It is used in the treatment of schizophrenia (p.955) and other psychoses. Pipotiazine is given orally as the base and by deep intramuscular injection as the palmitate ester; oral doses are expressed as the base and parenteral doses are expressed as the ester.

A usual oral dose of pipotiazine for the treatment of psychoses is 5 to 20 mg daily in a single dose; in severe psychoses higher doses have been given for brief periods, up to 60 mg daily being permitted in some countries.

The long-acting palmitate ester of pipotiazine is given by deep intramuscular injection. An initial test dose of 25 mg is followed by a further 25 to 50 mg after 4 to 7 days. The dosage is then adjusted in increments of 25 to 50 mg according to response every 4 weeks. Usual maintenance doses of 50 to 100 mg are given at average intervals of 4 weeks; the maximum recommended dose in the UK is 200 mg every 4 weeks.

Pipotiazine should be given in reduced dosage to elderly patients; a starting dose of 5 to 10 mg has been suggested for pipotiazine palmitate intramuscular injections.

Schizophrenia. A systematic review[1] concluded that depot pipotiazine palmitate appeared to be no different in terms of efficacy or adverse effects to other antipsychotics given orally or by depot injection.

Prazepam *(BAN, USAN, rINN)*

Pratsepaami; Prazépam; Prazepám; Prazepamas; Prazepamum; W-4020. 7-Chloro-1-(cyclopropylmethyl)-1,3-dihydro-5-phenyl-2*H*-1,4-benzodiazepin-2-one.

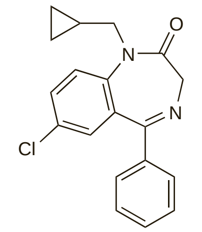
Празепам

$C_{19}H_{17}ClN_2O$ = 324.8.

CAS — 2955-38-6.

ATC — N05BA11.

ATC Vet — QN05BA11.



Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*

Ph. Eur. 6.2 (Prazepam). A white to almost white crystalline powder. Practically insoluble in water; sparingly soluble in dehydrated alcohol; freely soluble in dichloromethane. Protect from light.

Profile

Prazepam is a long-acting benzodiazepine with general properties similar to those of diazepam (p.986). After oral doses, prazepam undergoes extensive first-pass metabolism in the liver to oxazepam (p.1014) and desmethyldiazepam (nordazepam, p.1012). Desmethyldiazepam is largely responsible for the pharmacological activity of prazepam. The usual oral dose for the short-term treatment of anxiety disorders (p.952) is 30 mg daily as a single nightly dose or in divided doses; in severe conditions up to 60 mg daily has been given. In elderly or debilitated patients, treatment should start with a daily dose of no more than 15 mg.

Breast feeding. The American Academy of Pediatrics[1] considers that, although the effect of prazepam on breast-fed infants is unknown, its use by mothers during breast feeding may be of concern since anxiolytic drugs do appear in breast milk and thus could conceivably alter CNS function in the infant both in the short and long term.

The ratio of desmethyldiazepam in plasma to that in breast milk of 5 women given prazepam 20 mg three times daily for 3 days was 9.6 from measurements 12 hours after the last dose.[2] It was estimated that a breast-fed infant of a mother on continuous prazepam therapy would ingest the equivalent of about 4% of the daily maternal dose.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Prochlorperazine Maleate). A white or pale yellow, crystalline powder. Very slightly soluble in water and in alcohol. A freshly prepared saturated solution in water has a pH of 3.0 to 4.0. Protect from light.

USP 31 (Prochlorperazine Maleate). A white or pale yellow, practically odourless, crystalline powder. Practically insoluble in water; soluble 1 in 1200 of alcohol; slightly soluble in warm chloroform. Its saturated solution is acid to litmus. Store in airtight containers. Protect from light.

Prochlorperazine Mesilate (BANM, rINNM)

Chlormeprazine Mesylate; Mesilato de proclorperazina; Prochlorpemazine Mesylate; Prochlorperazine Dimethanesulphonate; Prochlorpérazine, mésilate de; Prochlorperazine Mesylate; Prochlorperazine Methanesulphonate; Prochlorperazini mesilas; Prochlorperazini Mesylas.

Прохлорперазина Мезилат

$C_{20}H_{24}ClN_3S,2CH_3SO_3H$ = 566.2.

CAS — 5132-55-8.

ATC — N05AB04.

ATC Vet — QN05AB04.

Pharmacopoeias. In *Br.*

BP 2008 (Prochlorperazine Mesilate). A white or almost white, odourless or almost odourless powder. Very soluble in water; sparingly soluble in alcohol; slightly soluble in chloroform; practically insoluble in ether. A 2% solution in water has a pH of 2.0 to 3.0. Protect from light.

Incompatibility. Incompatibility has been reported between the edisilate or mesilate salts of prochlorperazine and several other compounds: these include aminophylline, amphotericin B, ampicillin sodium, aztreonam, some barbiturates, benzylpenicillin salts, calcium gluconate, cefalotin sodium, cefmetazole sodium, chloramphenicol sodium succinate, chlorothiazide sodium, dimenhydrinate, heparin sodium, hydrocortisone sodium succinate, midazolam hydrochloride, and some sulfonamides. Incompatibility between prochlorperazine edisilate and morphine sulfate has been attributed to phenol present in some formulations of the opioid.[1,2] Incompatibility has been reported on dilution of prochlorperazine edisilate injection with sodium chloride injection containing methyl hydroxybenzoate and propyl hydroxybenzoate as preservatives.[3] The problem did not occur with unpreserved sodium chloride or when benzyl alcohol was used as preservative. Prochlorperazine mesilate syrup has been reported to be incompatible with magnesium trisilicate mixture.[4]

3. Jett S, *et al.* Prochlorperazine edisylate incompatibility. *Am J Hosp Pharm* 1983; **40:** 210.
4. Greig JR. Stemetil syrup and magnesium trisilicate. *Pharm J* 1986; **237:** 504.

Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969. Prochlorperazine may cause less sedation and fewer antimuscarinic effects but extrapyramidal effects may be more frequent.

Severe dystonic reactions have followed the use of prochlorperazine, particularly in children and adolescents. It should therefore be used with extreme care in children. In addition, in the UK, parenteral use in children is not recommended.

Local irritation has occurred after the use of buccal tablets of prochlorperazine maleate.

Effects on the cardiovascular system. Hypertension has been reported[1] in a few patients given prochlorperazine intravenously for prophylaxis of cisplatin-induced nausea and vomiting.

1. Roche H, *et al.* Hypertension and intravenous antidopaminergic drugs. *N Engl J Med* 1985; **312:** 1125–6.

Effects on the mouth. Reports of ulceration and soreness of the lip and tongue have been associated with use of prochlorperazine maleate oral tablets.[1,2] The erosive cheilitis resolved after withdrawal of prochlorperazine and recurred on rechallenge.

1. Duxbury AJ, *et al.* Erosive cheilitis related to prochlorperazine maleate. *Br Dent J* 1982; **153:** 271–2.
2. Reilly GD, Wood ML. Prochlorperazine—an unusual cause of lip ulceration. *Acta Derm Venereol (Stockh)* 1984; **64:** 270–1.

Interactions

As for Chlorpromazine, p.973.

Pharmacokinetics

◊ The pharmacokinetics of prochlorperazine were studied in 8 healthy subjects after doses of 6.25 and 12.5 mg intravenously, and 25 mg by mouth.[1] There was a marked interindividual variation in pharmacokinetics after intravenous doses but no evidence of dose-dependent pharmacokinetics; mean terminal half-lives were 6.8 hours for the higher and 6.9 hours for the lower dose. The apparent volume of distribution was very high and plasma clearance values were apparently greater than liver plasma flow, suggesting that the liver may not be the only site of metabolism. After oral doses, prochlorperazine concentrations were detectable in only 4 of the 8 subjects, due in part to a low bioavailability but also to the lack of sensitivity of the high-pressure liquid chromatographic assay used. The time to peak plasma concentration varied from 1.5 to 5 hours, and the peak concentrations varied from 1.6 to 7.6 nanograms/mL. Bioavailability was estimated to range from 0 to 16%. A low bioavailability due to high first-pass metabolism would be expected because of the high plasma clearance of prochlorperazine.

1. Taylor WB, Bateman DN. Preliminary studies of the pharmacokinetics and pharmacodynamics of prochlorperazine in healthy volunteers. *Br J Clin Pharmacol* 1987; **23:** 137–42.

Buccal route. Both single- and multiple-dose studies indicated that bioavailability of prochlorperazine maleate was greater after buccal doses than when given orally.[1,2] Doses of 3 mg twice daily by the buccal route and 5 mg three times daily by mouth produced similar steady-state plasma-prochlorperazine concentrations.[1]

Uses and Administration

Prochlorperazine is a phenothiazine antipsychotic with general properties similar to those of chlorpromazine (p.975). It has a piperazine side-chain. Prochlorperazine and its salts are widely used in the prevention and treatment of nausea and vomiting (p.1700) including that associated with migraine or drug-induced emesis. They are also used for the short-term symptomatic relief of vertigo (p.565) as occurs in Ménière's disease (p.564) or labyrinthitis, and in the management of schizophrenia (p.955), mania (see Bipolar Disorder, p.372), and other psychoses. Prochlorperazine has been used as an adjunct in the short-term management of severe anxiety (p.952).

Prochlorperazine maleate is generally administered by the oral or buccal routes, while prochlorperazine edisilate and mesilate are given orally or parenterally. The base has been given rectally.

Depending on the country or the manufacturer, doses of prochlorperazine are expressed either as the base or the salt. Prochlorperazine edisilate 7.5 mg, prochlorperazine maleate 8.1 mg, or prochlorperazine mesilate 7.6 mg are equivalent to about 5 mg of prochlorperazine. Most doses in the UK are expressed in terms of the maleate or mesilate, while most doses in the USA are expressed in terms of the base. As a result there is a disparity in the dosage recommendations for these countries, with the doses in the USA tending to be higher.

Reduced dosage may be required in elderly patients.

For **nausea and vomiting** doses are as follows:

- in the UK, the usual *oral* dose for prevention is 5 to 10 mg of the maleate or mesilate (roughly equivalent to about 3 to 6.5 mg of the base) 2 or 3 times daily
- for the treatment of nausea and vomiting, recommended UK doses are 20 mg of the maleate or mesilate *orally* or 12.5 mg of the mesilate by deep *intramuscular* injection; further doses, preferably orally, are given if necessary. The recommended *buccal* dose of prochlorperazine maleate for this indication is 3 to 6 mg twice daily
- in the USA, the *oral* dose for the control of nausea and vomiting is the equivalent of 5 or 10 mg of the base (as edisilate or maleate) given 3 or 4 times daily; alternatively the equivalent of 10 mg of the base twice daily or 15 mg once daily of the base (both as the maleate) may be taken as modified-release capsules. The recommended *intramuscular* dosage is the equivalent of 5 to 10 mg of the base (as edisilate) given every 3 to 4 hours if necessary, up to a total of 40 mg of the base daily. The *rectal* dose is 25 mg of the base given twice daily. In the management of severe nausea and vomiting the equivalent of 2.5 to 10 mg of prochlorperazine (as the edisilate) may be given by slow *intravenous* injection or infusion at a rate not exceeding 5 mg/minute; doses should not exceed 40 mg daily

For treatment of **psychoses** the following doses have been given:

- in the UK, prochlorperazine maleate or mesilate may be given in an *oral* dose of 12.5 mg twice daily for 7 days adjusted gradually to 75 to 100 mg daily according to response; some patients may be maintained on doses of 25 to 50 mg daily. The equivalent of prochlorperazine mesilate 12.5 to 25 mg two or three times daily may be given by deep *intramuscular* injection
- in the USA, prochlorperazine is given as the maleate or edisilate in usual initial *oral* doses equivalent to 5 or 10 mg of the base 3 or 4 times daily adjusted according to response up to a maximum of 150 mg of base daily. In acute disturbances it may be given by deep *intramuscular* injection as the edisilate in doses equivalent to 10 to 20 mg of the base and repeated every 2 to 6 hours if necessary

There are similar discrepancies with **children's doses**. Owing to the risk of severe extrapyramidal reactions, prochlorperazine should be used with extreme caution in children; it is not recommended for very young children or those weighing less than 10 kg. Where use in children is unavoidable, UK licensed product information has suggested that 250 micrograms/kg of the maleate or mesilate may be given orally 2 or 3 times daily to children aged 1 year and over for the prevention and treatment of nausea and vomiting; the intramuscular route is considered unsuitable. However, the *BNFC* suggests giving intramuscular doses, repeated up to 3 times daily if necessary, according to age as follows: 2 to 5 years, 1.25 to 2.5 mg; 5 to 12 years, 5 to 6.25 mg.

In the USA oral, rectal, and intramuscular routes have all been advocated for children aged 2 years and over. The usual oral or rectal antiemetic dose ranges up to 7.5 mg of the base or its equivalent daily in children weighing 10 to 13 kg; in children 14 to 17 kg, up to 10 mg daily; from 18 to 39 kg, up to 15 mg daily. Higher doses have been given for psychoses. The suggested intramuscular dose for children in the USA is the equivalent of about 130 micrograms/kg of base given as a single deep intramuscular injection of the edisilate.

Oral doses of 5 to 10 mg of the maleate or mesilate (or, in the USA, the equivalent of 5 mg of the base) up to 3 or 4 times daily have been used for short-term adjunctive management of **severe anxiety disorders**. A modified-release preparation may be given in doses similar to those used in nausea and vomiting.

Prochlorperazine is also used in the UK in the treatment of **vertigo** including that due to Ménière's disease. It is given *orally* in doses of 15 to 30 mg of the maleate or mesilate daily in divided doses; after several weeks the dose may be gradually reduced to 5 to 10 mg daily. The recommended *buccal* dose of prochlorperazine maleate for this indication is 3 to 6 mg twice daily.

Headache. Some phenothiazines such as prochlorperazine have been used in the control of the symptoms of severe migraine (see p.976). In comparative studies[1,2] prochlorperazine appears to have been more effective in relieving migraine headache and nausea and vomiting than metoclopramide when these drugs were given parenterally. Intravenous prochlorperazine was shown to be effective in aborting intractable migraine in children in a small uncontrolled study.[3]

Промазина Гидрохлорид

$C_{17}H_{20}N_2S,HCl$ = 320.9.
CAS — 53-60-1.
ATC — N05AA03.
ATC Vet — QN05AA03.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Promazine Hydrochloride). A white or almost white, slightly hygroscopic, crystalline powder. Very soluble in water, in alcohol, and in dichloromethane. A freshly prepared 5% solution in water has a pH of 4.2 to 5.2. Protect from light.

USP 31 (Promazine Hydrochloride). A white or slightly yellow, practically odourless, crystalline powder. It oxidises upon prolonged exposure to air and acquires a pink or blue colour. Soluble 1 in 3 of water; freely soluble in chloroform. pH of a 1 in 20 solution is between 4.2 and 5.2. Store in airtight containers. Protect from light.

Incompatibility. Incompatibility has been reported between promazine hydrochloride and several other compounds: these include aminophylline, some barbiturates, benzylpenicillin potassium, chlortetracycline, chlorothiazide sodium, dimenhydrinate, heparin sodium, hydrocortisone sodium succinate, phenytoin sodium, prednisolone sodium phosphate, and sodium bicarbonate.

Sorption. A study[1] of drug loss from intravenous delivery systems reported an 11% loss of promazine hydrochloride from solution when infused for 7 hours via a plastic infusion set, and a 59% loss after infusion for one hour from a glass syringe through silastic tubing. Loss was negligible after infusion for 1 hour from a system comprising a glass syringe with polyethylene tubing.

1. Kowaluk EA, *et al.* Interactions between drugs and intravenous delivery systems. *Am J Hosp Pharm* 1982; **39:** 460–7.

Stability. A study of the stability of promazine diluted to a 0.1% infusion in sodium chloride 0.9% or glucose 5% found that solutions in glucose 5% remained stable for up to 6 days at 4°, and at room temperature, provided they were stored in the dark.[1] However, with sodium chloride 0.9% as the diluent, deterioration of promazine was observed 24 hours after preparation, even when stored in the dark, and after 8 hours when exposed to light. Temperature had no effect on degradation rate.

1. Tebbett IR, *et al.* Stability of promazine as an intravenous infusion. *Pharm J* 1986; **237:** 172–4.

Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969.

Pregnancy. An increased incidence of neonatal jaundice coincided with the increased use of promazine.[1] A decrease in the incidence of jaundice was noted 3 months after the total withdrawal of the drug from the hospital although restriction of its use during labour had no impact.

1. John E. Promazine and neonatal hyperbilirubinaemia. *Med J Aust* 1975; **2:** 342–4.

Interactions

As for Chlorpromazine, p.973.

Pharmacokinetics

The pharmacokinetics of promazine appear to be generally similar to those of chlorpromazine (p.975).

Uses and Administration

Promazine is a phenothiazine with general properties similar to those of chlorpromazine (p.975). It has relatively weak antipsychotic activity and is not generally used for the management of psychoses. It is mainly used for the short-term management of agitated or disturbed behaviour (p.954). It has also been given for the alleviation of nausea and vomiting (p.1700). Promazine is given as the hydrochloride by mouth, intramuscularly, or by slow intravenous injection. Promazine has also been given by mouth as the embonate.

For the treatment of **agitated behaviour**, promazine is given in doses equivalent to 100 to 200 mg of the hydrochloride 4 times daily by mouth or 50 mg by intramuscular injection repeated if necessary after 6 to 8 hours. It has also been given by slow intravenous injection in concentrations not exceeding 25 mg/mL, for severely agitated hospitalised patients.

An oral dose of 25 to 50 mg every 4 to 6 hours has been given for the control of **nausea and vomiting**; it has also been given by intramuscular injection for this indication.

Promazine should be given in reduced dosage to elderly or debilitated patients; 25 mg orally of the hydrochloride initially, increasing, if necessary, to 50 mg four times daily has been suggested for the control of agitation and restlessness; for intramuscular injection, a dose of 25 mg may be sufficient.

Hiccup. Promazine hydrochloride has been used in some countries for the treatment of intractable hiccup. A protocol for the management of intractable hiccups may be found under Chlorpromazine, p.976.

(prothipendyl)

Profile

Prothipendyl is an azaphenothiazine with general properties similar to those of chlorpromazine (p.969). It is given as the hydrochloride in oral doses of 40 to 80 mg two to four times daily for the treatment of psychoses and agitation, and as an adjunct to analgesics in the treatment of severe pain. Prothipendyl hydrochloride may also be given by injection.

Preparations

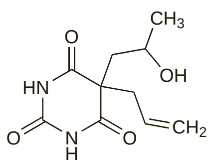
Proprietary Preparations (details are given in Part 3)
Austria: Dominal; ***Belg.:*** Dominal; ***Ger.:*** Dominal.

Proxibarbal *(rINN)*

HH-184; Proksybarbal; Proxibarbalum; Proxibarbital. 5-Allyl-5-(2-hydroxypropyl)barbituric acid.

Проксибарбал

$C_{10}H_{14}N_2O_4$ = 226.2.
CAS — 2537-29-3.
ATC — N05CA22.
ATC Vet — QN05CA22.



Pharmacopoeias. In *Pol.*

Profile

Proxibarbal is a barbiturate with general properties similar to those of amobarbital (p.961). It has been used as a sedative in the management of anxiety disorders. It has also been used in the treatment of headache. However, barbiturates are not considered appropriate in the management of these conditions. Proxibarbal has been associated with severe hypersensitivity-induced thrombocytopenia.

Preparations

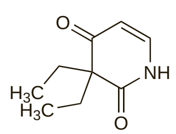
Proprietary Preparations (details are given in Part 3)
Hung.: Vasalgin.

Pyrithyldione *(rINN)*

Didropyridinum; NU-903; Piritildiona; Pyrithyldionum; Pyrityldion; Pyrityylidioni. 3,3-Diethylpyridine-2,4(1*H*,3*H*)-dione.

Пиритильдион

$C_9H_{13}NO_2$ = 167.2.
CAS — 77-04-3.
ATC — N05CE03.
ATC Vet — QN05CE03.



Profile

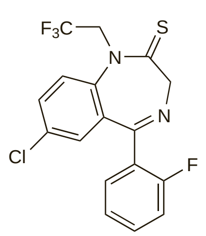
Pyrithyldione has been given in preparations with diphenhydramine in the short-term management of insomnia but there have been reports of agranulocytosis associated with the use of this combination.

Quazepam *(BAN, USAN, rINN)*

Kvatsepaami; Kvazepam; Quazépam; Quazepamum; Sch-16134. 7-Chloro-5-(2-fluorophenyl)-1,3-dihydro-1-(2,2,2-trifluoroethyl)-1,4-benzodiazepine-2-thione.

Квазепам

$C_{17}H_{11}ClF_4N_2S$ = 386.8.
CAS — 36735-22-5.
ATC — N05CD10.
ATC Vet — QN05CD10.



Pharmacopoeias. In *US.*
USP 31 (Quazepam). Off-white to yellowish powder.

Dependence and Withdrawal

As for Diazepam, p.987.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987.

Breast feeding. The American Academy of Pediatrics[1] considers that, although the effect of quazepam on breast-fed infants is unknown, its use by mothers during breast feeding may be of concern since psychotropic drugs do appear in breast milk and thus could conceivably alter CNS function in the infant both in the short and long term.

However, a study in 4 women given a single 15-mg dose of quazepam found that only about 0.1% of the dose was excreted over 48 hours in breast milk, as quazepam and its 2 major metabolites.[2]

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/04/04)
2. Hilbert JM, *et al.* Excretion of quazepam into human breast milk. *J Clin Pharmacol* 1984; **24:** 457–62.

Interactions

As for Diazepam, p.989.

Pharmacokinetics

Quazepam is readily absorbed from the gastrointestinal tract after oral doses, peak plasma concentrations being reached in about 2 hours. It is metabolised extensively in the liver. The principal active metabolites are 2-oxoquazepam and *N*-desalkyl-2-oxoquazepam (*N*-desalkylflurazepam) which have elimination half-lives of about 39 and 73 hours respectively, compared with a half-life of 39 hours for quazepam. Further hydroxylation occurs and quazepam is excreted in urine and faeces mainly as conjugated metabolites.

Quazepam and its two active metabolites are more than 95% bound to plasma proteins. Quazepam and its metabolites are distributed into breast milk.

Uses and Administration

Quazepam is a long-acting benzodiazepine with general properties similar to those of diazepam (p.992). It is given as a hypnotic in the short-term management of insomnia (p.957), in an initial oral dose of 15 mg at night; in elderly or debilitated patients and some other patients this can be reduced to 7.5 mg.

Preparations

USP 31: Quazepam Tablets.

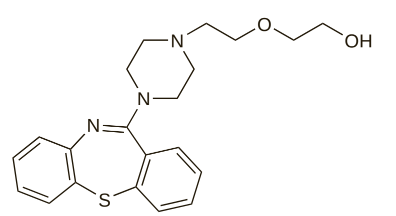
ATC — N05AH04.
ATC Vet — QN05AH04.



(quetiapine)

Adverse Effects, Treatment, and Precautions

Although quetiapine may share some of the adverse effects seen with the classical antipsychotics (see Chlorpromazine, p.969), the incidence and severity of such effects may vary. Quetiapine has been associated with a low incidence of extrapyramidal symptoms but tardive dyskinesia may occur after long-term treatment. Rises in prolactin concentrations may be less than with chlorpromazine.

The most frequent adverse effects with quetiapine are somnolence and dizziness. Mild asthenia, anxiety, fever, rhinitis, peripheral oedema, constipation, dyspepsia, dry mouth, and raised liver enzyme values are also relatively common. Orthostatic hypotension associated with dizziness, tachycardia, and syncope has been reported, particularly during initial dose-titration. Prolongation of QT interval is rarely significant with quetiapine. Hyperglycaemia and exacerbation of pre-existing diabetes have been reported rarely. Clinical monitoring for hyperglycaemia has been recommended, especially in patients with, or at risk of developing, diabetes. Weight gain, particularly during early treatment, has also been noted. Neuroleptic malignant syndrome is rare with quetiapine. Leucopenia, neutropenia, and eosinophilia have also been reported. Other adverse effects have included rises in plasma-triglyceride and cholesterol concentrations, and reduced plasma-thyroid hormone concentrations. There have been rare reports of seizures, hypersensitivity reactions including angioedema, and priapism.

Asymptomatic changes in the lens of the eye have occurred in patients during long-term treatment with quetiapine; cataracts have developed in *dogs* during chronic dosing studies. In the USA, it is recommended that patients should have an eye examination to detect cataract formation when starting therapy with quetiapine and every 6 months during treatment.

Quetiapine should be used with caution in patients with hepatic or renal impairment, with cardiovascular disease or other conditions predisposing to hypotension, with cerebrovascular disease, or with a history of seizures or conditions that lower the seizure threshold.

When quetiapine is used for the depressive phase in bipolar disorder, patients should be closely monitored during early therapy until significant improvement in depression is observed because suicide is an inherent risk in depressed patients. For further details, see under Bipolar Disorder, p.372.

Quetiapine may affect the performance of skilled tasks including driving.

Gradual withdrawal of quetiapine is recommended because of the risk of withdrawal symptoms, including nausea, vomiting, insomnia, and rebound psychoses, with abrupt cessation.

Breast feeding. In a case report[1] of a mother receiving quetiapine 200 mg daily by mouth, the maximum concentration of the drug in breast milk an hour after the dose was reported to be 62 micrograms/litre; the mean concentration over 6 hours was 13 micrograms/litre. The authors concluded that the breast-fed infant would ingest, at maximum, the daily equivalent of 0.43% of the weight-adjusted maternal dose. Follow-up at 4.5 months reported no adverse effects in the infant, who had been breast fed from 8 weeks of age.

Licensed product information recommends that patients receiving quetiapine should not breast feed.

1. Lee A, *et al.* Excretion of quetiapine in breast milk. *Am J Psychiatry* 2004; **161:** 1715–16.

Dementia. The FDA[1] has issued advice against the use of atypical antipsychotics in the treatment of behavioural problems in elderly patients with dementia after analysis of placebo-controlled studies showed an increased risk of mortality with certain drugs of this class, including quetiapine; most of the deaths appeared due to cardiovascular events or infection. See also under Risperidone, p.1024.

1. FDA. FDA issues public health advisory for antipsychotic drugs used for treatment of behavioral disorders in elderly patients (issued 11th April, 2005). Available at: http://www.fda.gov/bbs/topics/ANSWERS/2005/ANS01350.html (accessed 30/05/05)

Effects on the blood. There have been reports of leucopenia,[1] neutropenia,[2] and pancytopenia[3] associated with quetiapine therapy; all 3 patients improved when the drug was stopped. Thrombotic thrombocytopenic purpura has also been reported in a patient who received quetiapine on 2 separate occasions 2 years apart.[4] From December 1997 to October 2006, Health Canada[5] had received 11 reports of thrombocytopenia associated with quetiapine, 6 of which were associated with quetiapine alone. In one of these 6 cases, thrombocytopenia recurred 3 months after restarting quetiapine, which had stopped for 1 month.

Effects on lipid metabolism. The increased risk of hyperlipidaemia with some atypical antipsychotics is discussed under Adverse Effects of Chlorpromazine, p.970. See also Effects on Carbohydrate Metabolism under Adverse Effects of Clozapine, p.981.

Effects on the pancreas. From December 1997 to October 2006, Health Canada[1] had received 9 reports of pancreatitis associated with quetiapine, 5 of which were associated with quetiapine alone. One patient was reported to have developed severe haemorrhagic pancreatitis, and another, necrotising pancreatitis. One report described pancreatitis occurring on two separate occasions in the patient.

1. Health Canada. Quetiapine: pancreatitis and thrombocytopenia. *Can Adverse React News* 2007; **17** (2): 1–2. Available at: http://www.hc-sc.gc.ca/dhp-mps/alt_formats/hpfb-dgpsa/pdf/medeff/carn-bcei_v17n2_e.pdf (accessed 09/04/08)

Effects on the respiratory system. Hyperventilation and respiratory alkalosis have been reported with quetiapine use.[1] Acute respiratory failure developed[2] in a 92-year-old woman with a history of chronic obstructive pulmonary disease who was given a single 50-mg dose of quetiapine.

1. Shelton PS, *et al.* Hyperventilation associated with quetiapine. *Ann Pharmacother* 2000; **34:** 335–7.
2. Jabeen S, *et al.* Acute respiratory failure with a single dose of quetiapine fumarate. *Ann Pharmacother* 2006; **40:** 559–62.

Mania. Although it is used in the treatment of bipolar disorder, quetiapine has been associated with mania. In one report, a 26-year-old man with schizophrenia developed manic symptoms after starting treatment with quetiapine; the symptoms resolved when quetiapine was withdrawn.[1]

1. Lykouras L, *et al.* Manic symptoms associated with quetiapine treatment. *Eur Neuropsychopharmacol* 2003; **13:** 135–6.

Overdosage. Hypotension, tachycardia, and somnolence were the main clinical events seen in a patient who had taken an overdose of 3 g of quetiapine.[1] Tachycardia of an unexpectedly long duration was also noted. Management was symptomatic, including maintenance of fluids. Asymptomatic prolongation of the QT interval was seen in another patient who had taken a 2-g overdose of quetiapine.[2] Her treatment regimen also included risperidone, and the authors warned that considerable QT interval prolongation may occur when patients overdose on quetiapine while taking therapeutic doses of risperidone.

A subsequent report[3] has described a case series of 18 patients who took from 500 mg to 24 g of quetiapine either alone (6 patients) or with other drugs (12). Quetiapine overdosage was primarily associated with CNS and respiratory depression and sinus tachycardia. Four of the 18 patients required mechanical ventilation but no deaths occurred. The corrected QT interval, but not the QT interval, was prolonged, but apart from sinus tachycardia no patient had a dysrhythmia. Seizures occurred in 2 patients and delirium in 3. The patient who took 24 g of quetiapine was found to have had a peak blood concentration of 20.48 micrograms/mL. She had presented 1.5 hours after ingestion and was intubated and treated with gastric lavage followed by activated charcoal. About 2.5 hours later she had a generalised tonic-clonic seizure. The patient was discharged after 40 hours without sequelae. Another analysis[4] considered 14 cases of overdose, the amounts varying from 1.2 to 18 g; there appeared to be no correlation between the amount taken and the serum concentration, nor was severity of intoxication necessarily correlated with greater intake. Toxicity was generally mild, with tachycardia and somnolence as the main presenting symptoms; there were no fatalities.

Pregnancy. For comments on the use of some atypical antipsychotics, including quetiapine, during pregnancy, see under Precautions of Clozapine, p.983.

Interactions

The central effects of other CNS depressants, including alcohol, may be enhanced by quetiapine. Quetiapine should be used with caution in patients also receiving antihypertensives or drugs that prolong the QT interval. Quetiapine may antagonise the actions of dopaminergics such as levodopa.

CYP3A4 is the main isoenzyme responsible for cytochrome P450-mediated metabolism of quetiapine and caution is advised when quetiapine is used with potent inhibitors of CYP3A4 such as erythromycin, fluconazole, itraconazole, and ketoconazole; lower doses of quetiapine should be used when given with such drugs. Conversely, enzyme inducers such as carbamazepine and phenytoin may decrease the plasma concentrations of quetiapine, and higher doses of quetiapine may be necessary. Thioridazine has also been reported to increase the clearance of quetiapine.

Antibacterials. In a study involving 19 Chinese patients with schizophrenia taking quetiapine 200 mg twice daily, adding *erythromycin* 500 mg three times daily increased the maximum plasma concentration, area under the concentration-time curve, and terminal elimination half-life of quetiapine by 68, 129, and 92%, respectively. Reductions in plasma concentrations of the metabolites of quetiapine suggested that erythromycin had probably inhibited quetiapine's metabolism by the cytochrome P450 isoenzyme CYP3A4. Modification of dosage was recommended in this patient group taking these two drugs together.[1]

1. Li K-Y, *et al.* Effect of erythromycin on metabolism of quetiapine in Chinese suffering from schizophrenia. *Eur J Clin Pharmacol* 2005; **60:** 791–5.

Antipsychotics. For a report of asymptomatic QT prolongation associated with quetiapine in a patient also receiving *risperidone*, see under Overdosage, above.

Pharmacokinetics

Quetiapine is well absorbed after oral doses and widely distributed throughout the body. Peak plasma concentrations are reached in about 1.5 hours. It is about 83% bound to plasma proteins. Quetiapine is extensively metabolised in the liver by sulfoxidation mediated mainly by the cytochrome P450 isoenzyme CYP3A4 and by oxidation. It is excreted mainly as inactive metabolites with about 73% of a dose appearing in the urine and about 20% in the faeces. The elimination half-life has been reported to be about 6 to 7 hours.

It is distributed into breast milk.

Uses and Administration

Quetiapine fumarate is a dibenzothiazepine atypical antipsychotic. It is reported to have affinity for serotonin ($5\text{-}HT_2$), histamine (H_1), and adrenergic (α_1 and α_2) receptors as well as dopamine D_1 and D_2 receptors. Quetiapine is used in the treatment of schizophrenia and of bipolar disorder.

Quetiapine is given orally as the fumarate although doses are expressed in terms of the base; 28.8 mg of quetiapine fumarate is equivalent to about 25 mg of quetiapine.

The usual initial daily dose in **schizophrenia** is the equivalent of 50 mg of the base on day one. In the UK, 100 mg is given on day two, 200 mg on day three, and 300 mg on day four; daily doses are given in 2 divided doses. The dosage is then adjusted according to response to a usual range of 300 to 450 mg daily, although 150 mg daily may be adequate for some patients; the maximum recommended dose is 750 mg daily. In the USA, the usual initial daily dose is increased on days two and three in increments of 50 to 150 mg, as tolerated, to a target of 300 to 400 mg daily by day four. The daily dose on the first day is given in 2 divided doses, but may be given in 3 divided doses thereafter. The daily dosage may be further adjusted as necessary in steps of 50 to 100 mg at intervals of not less than 2 days to a usual range similar to that in the UK. A modified-release preparation of quetiapine is also available in some countries for once-daily dosing up to the equivalent of 800 mg daily of the base.

In the treatment of acute manic episodes associated with **bipolar disorder**, the initial dose is 50 mg twice daily on day one, 100 mg twice daily on day two, 150 mg twice daily on day three, and 200 mg twice daily on day four. The dose may then be adjusted according to response to a usual range of 400 to 800 mg daily, although, in some patients, 200 mg daily may be adequate. Increments in dosage should be no greater than 200 mg daily. Quetiapine is also licensed in the USA for use in the depressive phase of bipolar disorder. The initial dose is 50 mg once daily at bedtime increased to 100 mg on day two, 200 mg on day three, and 300 mg on day four. The dose may be further increased to 400 mg on day five and 600 mg on day eight, if necessary. In the USA, quetiapine is also licensed for the maintenance treatment of bipolar disorder as an adjunct to lithium or valproate; patients should be continued on the dose that controlled their initial symptoms.

Quetiapine should be given in reduced doses to the elderly; a recommended starting dose is 25 mg daily, which may be increased every day in increments of 25 to 50 mg according to response; the effective dose range is likely to be lower than in younger adults. Reduced doses are also recommended in patients with hepatic or renal impairment, see below.

Administration in hepatic or renal impairment. Quetiapine should be given in reduced doses to patients with hepatic impairment; a recommended initial oral dose is 25 mg daily, increased in steps of 25 to 50 mg daily according to response. UK licensed product information also recommends a similar dose reduction in patients with renal impairment.

Bipolar disorder. Quetiapine is of benefit for the treatment of mania in patients with bipolar disorder (p.372) and the use of atypical antipsychotics in the management of such patients is increasing. However, there have been individual case reports of quetiapine-induced mania (see above). In some countries, quetiapine is also licensed for use in the depressive phase of bipolar disorder.

Schizophrenia. A systematic review[1] noted that, although quetiapine is effective for the treatment of schizophrenia, it appeared comparable with classical antipsychotics and risperidone.

The incidence of extrapyramidal effects was lower with quetiapine therapy but the risk of dry mouth and somnolence was higher. Quetiapine was not found to benefit negative symptoms.

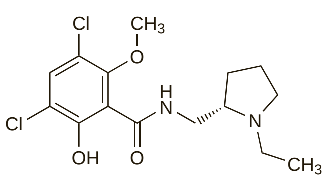
CAS — 84225-95-6 (raclopride); 98185-20-7 (raclopride tartrate).



Profile

Raclopride is a substituted benzamide related to sulpiride (p.1028). It has been investigated for the treatment of psychoses. Since it binds selectively and with high affinity to D_2 dopaminergic receptors, raclopride labelled with carbon-11 has been tried as a tracer in computerised tomographic studies of neurological disorders associated with dysfunction of brain D_2 dopaminergic receptors.

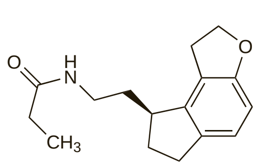
ATC Vet — QN05CH02.



Profile

Ramelteon is a melatonin receptor agonist used as a hypnotic in the management of insomnia (p.957), particularly in patients who have difficulty falling asleep. The usual oral dose is 8 mg taken within 30 minutes of bedtime; it should not be taken with or immediately after a high-fat meal. Ramelteon is not recommended for patients with severe hepatic impairment; it should be used with caution in those with moderate impairment.

Ramelteon is metabolised mainly via the cytochrome P450 isoenzyme CYP1A2 and consequently, it should not be used with fluvoxamine, a potent inhibitor of this isoenzyme; it should also be used with caution in patients taking other drugs that inhibit this isoenzyme.

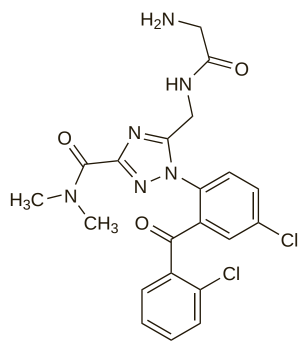
CAS — 99593-25-6 (rilmazafone); 85815-37-8 (anhydrous rilmazafone hydrochloride).



(rilmazafone)

Profile

Rilmazafone hydrochloride is a hypnotic and sedative used in the short-term treatment of insomnia in usual oral doses of 1 to 2 mg at bedtime; it is also used in similar doses as a premedicant.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Risperidone). A white or almost white powder. It exhibits polymorphism. Practically insoluble in water; sparingly soluble in alcohol; freely soluble in dichloromethane; dissolves in dilute acid solutions. Protect from light.

USP 31 (Risperidone). A white or almost white powder. Practically insoluble in water; sparingly soluble in alcohol; soluble in dichloromethane.

Adverse Effects, Treatment, and Precautions

Although risperidone may share some of the adverse effects seen with the classical antipsychotics (see Chlorpromazine, p.969), the incidence and severity of such effects may vary. Risperidone is reported to be less likely to cause sedation or extrapyramidal effects (see also Uses and Administration, below) but agitation may occur more frequently. Other common adverse effects include insomnia, anxiety, and headache. Dyspepsia, nausea and vomiting, abdominal pain, constipation, blurred vision, sexual dysfunction including priapism, urinary incontinence, rash and other allergic reactions, drowsiness, concentration difficulties, dizziness, fatigue, and rhinitis have been reported less commonly. In addition to orthostatic hypotension, hypertension has been reported infrequently. Other adverse effects with risperidone include cerebrovascular accidents, tachycardia, weight gain, oedema, increased liver enzyme values, and decreases in neutrophil or thrombocyte counts. Risperidone may cause dose-dependent increases in prolactin levels. In rare cases, hyperglycaemia and exacerbation of pre-existing diabetes mellitus have also been reported. Clinical monitoring for hyperglycaemia has been recommended, especially in patients with or at risk of developing diabetes. Other rare effects include seizures, body temperature dysregulation, hyponatraemia, neuroleptic malignant syndrome, and tardive dyskinesia.

Risperidone should be used with caution in patients with cardiovascular disease, including conditions associated with QT prolongation, or conditions predisposing to hypotension. Caution is also recommended in patients with a history of or at risk of developing cerebrovascular disease, in patients with Parkinson's disease or epilepsy, and in patients with hepatic or renal impairment.

Risperidone may affect the performance of skilled tasks such as driving.

Gradual withdrawal of risperidone is recommended because of the risk of withdrawal symptoms, including sweating, nausea and vomiting, and rebound psychosis, with abrupt cessation.

Breast feeding. From the study of concentrations of risperidone and its active metabolite, 9-hydroxyrisperidone, in the breast milk of a mother receiving 6 mg daily by mouth, it was estimated that a breast-fed infant would ingest the daily equivalent of 4.3% (as risperidone equivalents) of the weight-adjusted maternal dose.[1] Later case reports[2] of 3 women receiving risperidone 3 mg daily, 4 mg daily, and 1.5 mg daily, by mouth, estimated that a breast-fed infant would receive the daily equivalent of 2.3%, 2.8%, and 4.7%, respectively, of the weight-adjusted maternal dose. Where breast feeding occurred, in the latter 2 cases, no adverse effects were reported in the breast-fed infants; risperidone and 9-hydroxyrisperidone were not detected in the plasma of either infant.

Licensed product information states that patients receiving risperidone should not breast feed; the US information also recommends that patients should not breast feed for at least 12 weeks after intramuscular injection.

Dementia. After analysis of data from controlled studies there was evidence that the use of risperidone in elderly patients with dementia appeared to be associated with an increased risk of cerebrovascular adverse effects such as stroke and transient ischaemic attacks. In 4 studies, involving 764 such patients treated with risperidone, there were 29 cases of cerebrovascular adverse events (4 fatal) versus 7 cases (1 fatal) in 466 patients given placebo. Postmarketing data for elderly dementia patients, representing over 2.4 million patient-years of exposure, included 37 cases, of which 16 were fatal.[1]

The UK CSM[2] have therefore recommended that risperidone should not be used to treat behavioural problems in elderly patients with dementia. Similarly, the CSM[2] and the EMEA[3] have recommended that olanzapine should not be used to treat behavioural problems or dementia-related psychosis in elderly patients with dementia after analysis of placebo-controlled studies revealed a threefold increase in cerebrovascular adverse effects including stroke and a twofold increase in all-cause mortality. It was considered[2] that the risk may not be confined to use in dementia and should be considered relevant to any patient with a history of stroke or transient ischaemic attack or other risk factors for cerebrovascular disease, including hypertension, diabetes, current smoking, or atrial fibrillation. The FDA[4] has also issued advice against the use of all atypical antipsychotics in the treatment of behavioural problems in elderly patients with dementia. Their advice was based on an unpublished analysis of 17 placebo-controlled studies involving aripiprazole, olanzapine, quetiapine, or risperidone use in elderly demented patients with behavioral disorders: the analysis found that 15 studies showed an increase in the mortality rate in the drug-treated group compared to the placebo-treated patients. A total of 5106 patients were included in these studies, and a 1.6- to 1.7-fold increase in mortality was seen; most of the deaths appeared due to cardiovascular events or infection. Another published meta-analysis[5] of placebo-controlled studies also had similar findings.

However, 2 large retrospective population-based studies in the elderly (1 involving 10 385 patients given atypicals and 1015 given classical antipsychotics,[6] the other involving 17 845 given atypicals and 14 865 given classical antipsychotics[7]), suggested that use of atypical antipsychotics was not associated with a statistically significant increased risk of stroke compared with the classical drugs.

For further discussion of the problems associated with the use of antipsychotics in disturbed behaviour in the elderly, see p.954.

Effects on lipid metabolism. The increased risk of hyperlipidaemia with some atypical antipsychotics is discussed under Adverse Effects of Chlorpromazine, p.970. See also Effects on Carbohydrate Metabolism under Adverse Effects of Clozapine, p.981.

Effects on the liver. There has been a report of 2 cases of hepatotoxicity associated with risperidone.[1] An idiosyncratic reaction to risperidone was suspected in another patient who developed hepatotoxicity after receiving only 2 doses of risperidone.[2]

1. Fuller MA, *et al.* Risperidone-associated hepatotoxicity. *J Clin Psychopharmacol* 1996; **16:** 84–5.
2. Phillips EJ, *et al.* Rapid onset of risperidone-induced hepatotoxicity. *Ann Pharmacother* 1998; **32:** 843.

Effects on the skin. A patient developed facial and periorbital oedema 2 weeks after her dose of risperidone reached 6 mg daily.[1] The oedema subsided when the dose was halved but recurred shortly after it was again increased to 6 mg. She had previously had a similar reaction to lithium and there was also a family history of angioedema.

1. Cooney C, Nagy A. Angio-oedema associated with risperidone. *BMJ* 1995; **311:** 1204.

Extrapyramidal disorders. In reports of 3 cases of tardive dystonia associated with oral risperidone therapy,[1,2] onset ranged from 3 to 8 months after starting the drug. Dyskinesia has also been reported 5 days after the withdrawal of oral risperidone and citalopram therapy.[3] In another report,[4] three patients receiving risperidone orally developed early-onset tardive dyskinesia despite the addition of antimuscarinic therapy with biperiden or trihexyphenidyl. Extrapyramidal adverse effects have also been reported within 24 hours of intramuscular risperidone injection.[5] However, the incidence of extrapyramidal effects (p.971) is generally lower with atypical than classical antipsychotics.

Overdosage. A 3⁄-year-old child developed extrapyramidal symptoms after accidental ingestion of a single 4-mg tablet of risperidone.[1] The child was initially treated with gastric lavage, activated charcoal, and sorbitol; extrapyramidal symptoms responded to treatment with diphenhydramine and the child recovered completely. The need to monitor for and treat hypotension after overdosage with risperidone was highlighted in a report[2] of a 15-year-old girl who took 40 mg of risperidone. A 72-year-old woman receiving risperidone 6 mg daily was found unconscious, hypotensive, and hypothermic.[3] Other reported symptoms include first-degree heart block, prolonged QT interval, and respiratory arrest; she recovered after supportive treatment.

Interactions

The central effects of other CNS depressants, including alcohol, may be enhanced by risperidone. Risperidone may also enhance the effects of antihypertensives. There may be an increased risk of QT prolongation when risperidone is given with other drugs that are known to cause this effect. Risperidone may antagonise the actions of levodopa and other dopaminergics.

Carbamazepine has been shown to decrease the antipsychotic fraction (risperidone plus 9-hydroxyrisperidone) of risperidone and a similar effect may be seen with other enzyme inducers. Fluoxetine may increase the plasma concentrations of the antipsychotic fraction by raising the concentration of risperidone. Dose adjustment of risperidone may be necessary in such situations.

Antiepileptics. For the effect of risperidone on *valproate*, see p.511.

Antipsychotics. For a report suggesting that risperidone might increase plasma concentrations of *clozapine*, see p.984. For a report of asymptomatic QT prolongation associated with *quetiapine* in a patient also receiving risperidone, see under Overdosage of Quetiapine, p.1023.

Antivirals. Dystonia and worsening of tremors were reported 1 week after adding *indinavir* and *ritonavir* to treatment with risperidone in a patient with AIDS;[1] he recovered once all 3 drugs were withdrawn and following treatment with clonazepam. An early exposure to risperidone, indinavir, and ritonavir had not resulted in any extrapyramidal adverse effects. The authors considered this to reflect the patient's relatively short exposure to risperidone at the time.

1. Kelly DV, *et al.* Extrapyramidal symptoms with ritonavir/indinavir plus risperidone. *Ann Pharmacother* 2002; **36:** 827–30.

Pharmacokinetics

Risperidone is readily absorbed after oral doses, peak plasma concentrations being reached within 1 to 2 hours. It is extensively metabolised in the liver by hydroxylation to its main active metabolite, 9-hydroxyrisperidone (paliperidone, p.1015); oxidative *N*-dealkylation is a minor metabolic pathway. Hydroxylation is mediated by the cytochrome P450 isoenzyme CYP2D6 and is the subject of genetic polymorphism. Excretion is mainly in the urine and, to a lesser extent, in the faeces. Risperidone and 9-hydroxyrisperidone are about 90% and 77% bound to plasma proteins, respectively. Both are distributed into breast milk.

Metabolism. Although the hydroxylation of risperidone is subject to genetic polymorphism, the pharmacokinetics and effects of the active antipsychotic fraction (risperidone plus 9-hydroxyrisperidone) have been reported to vary little between extensive and poor metabolisers.[1] A mean value of 19.5 hours has been reported for the terminal elimination half-life of the active fraction following oral doses of risperidone.[1]

1. Huang M-L, *et al.* Pharmacokinetics of the novel antipsychotic agent risperidone and the prolactin response in healthy subjects. *Clin Pharmacol Ther* 1993; **54:** 257–68.

Uses and Administration

Risperidone is a benzisoxazole atypical antipsychotic, reported to be an antagonist at dopamine D_2, serotonin ($5\text{-}HT_2$), adrenergic (α_1 and α_2), and histamine (H_1) receptors. It is given orally for the treatment of schizophrenia and other psychoses and in the short-term treatment of acute manic or mixed episodes associated with bipolar disorder. In the USA, risperidone is used similarly in children and also for the treatment of irritability associated with autistic disorder; for further details see Administration in Children and Disturbed Behaviour, below. Risperidone may also be given by deep intramuscular injection for maintenance therapy in patients with schizophrenia or other psychoses tolerant to oral antipsychotics.

For **schizophrenia**, the usual initial oral dose of risperidone is 2 mg daily; this may be increased to 4 mg daily on the second day, and subsequently adjusted as required in steps of 1 or 2 mg according to tolerance, at intervals of not less than 24 hours. Most patients benefit from doses of 4 to 6 mg daily. Risperidone may be given once daily or in 2 divided doses. Extrapyramidal symptoms may be more likely with doses above 10 mg daily; US licensed product information does not recommend daily doses above 6 mg if divided into 2 doses, although higher doses are permitted if given as a single dose. The maximum recommended dose is 16 mg daily.

An initial oral dose of 500 micrograms twice daily slowly increased in steps of 500 micrograms twice daily, if necessary, to a dose of 1 to 2 mg twice daily is recommended for elderly or debilitated patients. Above doses of 1.5 mg twice daily, increases should be made at intervals of at least 1 week.

The long-acting formulation of risperidone should be given by deep intramuscular injection every 2 weeks. Patients with no history of risperidone use should be given risperidone orally for several days to assess tolerability. Treatment may then be started as follows:

- patients not stabilised on oral risperidone: 25 mg every 2 weeks
- patients stabilised on oral risperidone for at least 2 weeks in doses of 4 mg daily or less: 25 mg every 2 weeks
- patients stabilised on oral risperidone for at least 2 weeks in doses above 4 mg daily: 37.5 mg every 2 weeks
- elderly patients should be given a maximum of 25 mg every 2 weeks

Oral risperidone should be continued for the first 3 weeks after the first injection.

Dose increases of 12.5 mg may be considered at least 4 weeks after the previous adjustment up to a maximum of 50 mg every 2 weeks; the clinical effects of a dose adjustment may not be seen for at least 3 weeks after the change.

For the treatment of **mania** in bipolar disorder, a recommended initial oral dose is 2 to 3 mg once daily. Dosage adjustments of 1 mg daily may be made at intervals of not less than 24 hours up to a total of 6 mg daily. The initial dosage regimen in elderly or debilitated patients should be reduced as for schizophrenia (see above).

Reduced doses are recommended in patients with hepatic or renal impairment, see below.

Action. Risperidone is described as an atypical antipsychotic; although it has a lower propensity to produce parkinsonism, dystonias and akathisias have been reported.[1] (See also Extrapyramidal Disorders, above.) The traditional hypothesis is that antipsychotics work through inhibition of dopamine D_2 receptors and that extrapyramidal adverse effects result from blockade of D_2 receptors in the striatum (see p.975). Like clozapine, risperidone has a high affinity for 5-HT_2 receptors and, like haloperidol, it has a high affinity for dopamine D_2 receptors. Risperidone also binds to alpha-adrenergic and histamine H_1 sites. It is unclear whether risperidone's antipsychotic effect is due to activity at dopamine D_2 receptors or at another site. It has been suggested[1] that other potent effects of risperidone may be counterbalancing the D_2 activity to produce its atypicality.

1. Kerwin RW. The new atypical antipsychotics: a lack of extrapyramidal side-effects and new routes in schizophrenia research. *Br J Psychiatry* 1994; **164:** 141–8.

Administration in children. In the USA, risperidone is licensed for the treatment of schizophrenia in adolescents aged 13 to 17 years, for the short-term treatment of acute manic or mixed episodes associated with bipolar disorder in children and adolescents aged 10 to 17 years, and for the treatment of irritability associated with autistic disorder in those aged 5 to 16 years.

For **schizophrenia** or **mania**, an initial oral dose of 500 micrograms is given once daily in the morning or in the evening. This may be increased in steps of 0.5 or 1 mg according to tolerance, at intervals of not less than 24 hours, to a dose of 3 mg daily for schizophrenia or 2.5 mg daily for mania. The maximum recommended dose for both indications is 6 mg daily. The total daily dose may be given in 2 divided doses to those who experience persistent somnolence.

For the treatment of **irritability associated with autistic disorder**, the following oral doses are given once daily or in 2 divided doses according to body-weight:

- under 20 kg: the usual initial daily dose is 250 micrograms; this may be increased to 500 micrograms daily after at least 4 days and subsequently adjusted as required in steps of 250 micrograms, generally at intervals of no less than 2 weeks. The maximum recommended dose is 1 mg daily. Caution should be exercised with dosage for children who weigh less than 15 kg
- 20 kg and over: the usual initial daily dose is 500 micrograms; this may be increased to 1 mg daily after at least 4 days and subsequently adjusted as required in steps of 500 micrograms, generally at intervals of no less than 2 weeks. The maximum recommended dose is 2.5 mg daily in those weighing over 20 kg and 3 mg daily in those over 45 kg
- For those who experience persistent somnolence, the total daily dose may be given as a single dose at bedtime, or in 2 divided doses, or in a reduced dose

For further details on the use of risperidone in children with autism see Disturbed Behaviour, below.

Risperidone is not licensed in the UK for use in children aged under 15 years; however, the *BNFC* suggests that it may be used in those aged 12 years and over for the oral treatment of acute and chronic psychoses. Doses are similar to those used in the treatment of schizophrenia in adults (see above). The *BNFC* also suggests that risperidone may be used, under specialist supervision, in children over 5 years of age for the short-term treatment of severe aggression in autism; doses are similar to those licensed for autistic disorders in the USA.

Administration in hepatic or renal impairment. The recommended initial oral dose of risperidone in patients with renal or hepatic impairment is 500 micrograms twice daily; this may be slowly increased in steps of 500 micrograms twice daily, if necessary, to a dose of 1 to 2 mg twice daily. Above doses of 1.5 mg twice daily, increases should be made at intervals of at least 1 week.

Patients with schizophrenia who tolerate an oral dose of risperidone of at least 2 mg daily may be switched to the long-acting formulation of risperidone; a dose of 25 mg by deep intramuscular injection every 2 weeks is recommended. Alternatively, an initial dose of 12.5 mg by deep intramuscular injection may be given.

AIDS. Risperidone was used successfully to control HIV- or AIDS-related psychosis in 21 patients, some of whom also had manic symptoms.[1] No extrapyramidal symptoms were reported during treatment. However, for reports suggesting that risperidone can induce or exacerbate manic symptoms in patients with schizoaffective disorders, see under Mania in Adverse Effects, above. For an interaction between risperidone and antiretroviral therapy in a patient with AIDS, see under Interactions, above.

1. Singh AN, *et al.* Treatment of HIV-related psychotic disorders with risperidone: a series of 21 cases. *J Psychosom Res* 1997; **42:** 489–93.

Anxiety disorders. Although there have been anecdotal reports[1,2] of improvement after the addition of risperidone to treatment in patients with obsessive-compulsive disorder refractory to conventional treatment, there has also been a report[3] of a patient whose obsessive-compulsive behaviour recurred when he was treated with risperidone for tardive dyskinesia.

1. Jacobsen FM. Risperidone in the treatment of affective illness and obsessive-compulsive disorder. *J Clin Psychiatry* 1995; **56:** 423–9.
2. McDougle CJ, *et al.* Risperidone addition in fluvoxamine-refractory obsessive-compulsive disorder: three cases. *J Clin Psychiatry* 1995; **56:** 526–8.
3. Remington G, Adams M. Risperidone and obsessive-compulsive symptoms. *J Clin Psychopharmacol* 1994; **14:** 358–9.

Bipolar disorder. Risperidone is of benefit for the treatment of mania, including in patients with bipolar disorder (p.372), and the use of atypical antipsychotics in the management of such patients is increasing. However, there have been individual case reports of risperidone-induced mania (see above).

Disturbed behaviour. Although risperidone has been used for the management of behavioural disturbances[1,2] in **elderly patients with dementia** (p.954), such use is no longer recommended, see Dementia, under Adverse Effects, above. Furthermore, despite anecdotal reports[3] of efficacy in patients with Lewy-body dementia, other reports[4] suggest that these patients are likely to be just as sensitive to risperidone as to classical antipsychotics (see the Elderly in Precautions for Chlorpromazine, p.973).

There is evidence[5-10] that risperidone may be effective in reducing behavioural disturbances in **children with autism** (see Disturbed Behaviour, p.954), but it appears to have little effect on core symptoms, and it has been pointed out that the marked hyperprolactinaemia induced by risperidone could lead to hypogonadism, and deleterious effects on adolescent bones.[11] A systematic review[12] concluded that risperidone may be of some benefit for symptoms such as hyperactivity, irritability, repetition, and social withdrawal although this must be weighed against the risk of adverse effects, notably weight gain. The authors noted that only 3 studies were analysed, including 1 that was carried out in adults, and the data available were limited; further studies were considered warranted. Nonetheless, in some countries, including the USA, risperidone is licensed for the treatment of irritability associated with autistic disorder in children and adolescents aged 5 to 16 years; for details of doses see Administration in Children, above.

Dystonias. Antipsychotics are sometimes useful in the treatment of idiopathic dystonia (p.809) in patients who have failed to respond to treatment with levodopa or antimuscarinics, but, as with classical antipsychotics, there is the risk of adding drug-induced extrapyramidal effects to the dystonia. Risperidone has been reported to be of benefit in a few patients with idiopathic segmental dystonia partly insensitive to haloperidol.[1]

1. Zuddas A, Cianchetti C. Efficacy of risperidone in idiopathic segmental dystonia. *Lancet* 1996; **347:** 127–8.

Parkinsonism. There have been conflicting reports of the use of risperidone as an antipsychotic in a small number of patients with Parkinson's disease (see also Disturbed Behaviour, p.954). While some patients found that risperidone ameliorated levodopa-induced hallucinations without worsening extrapyramidal symptoms,[1,2] others reported that risperidone produced a substantial worsening of symptoms.[2,3]

1. Meco G, *et al.* Risperidone for hallucinations in levodopa-treated Parkinson's disease patients. *Lancet* 1994; **343:** 1370–1.

3. Ford B, *et al.* Risperidone in Parkinson's disease. *Lancet* 1994; **344:** 681.

Schizophrenia. Risperidone is claimed to produce a relatively low incidence of extrapyramidal effects and to have efficacy against both positive and negative symptoms of schizophrenia. Most of the earlier studies compared risperidone with haloperidol but, of these, some of the major studies[1-3] were criticised for potential methodological flaws[4,5] and it was difficult to determine any difference in efficacy including effect on negative symptoms. A later systematic review[6] suggested that risperidone's benefits over haloperidol or other classical antipsychotics were marginal; although it did appear to reduce the risk of extrapyramidal effects compared with haloperidol, the latter produces a relatively high incidence of such effects. Furthermore, the risk of extrapyramidal effects with risperidone appears to be dose-dependent:[7] although similar to that for placebo overall, at doses of more than 10 mg the risk appears to approach that associated with haloperidol. In a more recent double-blind randomised study[8] the relapse rate after at least 2 years of treatment in patients with first-episode psychosis, who had initially responded to relatively small daily doses of risperidone (mean modal 3.3 mg) or haloperidol (2.9 mg), was 42% (82 of 197 patients) and 55% (111 of 203), respectively. The median time to relapse was also longer for risperidone (466 days) when compared with haloperidol (205 days). In the few comparative studies with other atypical antipsychotics, risperidone has appeared to be of similar efficacy to clozapine.[9] However, another systematic review[10] concluded that such equivalence with clozapine cannot be assumed. For a systematic review of studies comparing risperidone with olanzapine, see p.1013. There is insufficient evidence to indicate whether risperidone is effective for treatment-resistant or poorly responsive patients but there is some evidence that patients stabilised on risperidone may be less likely to relapse.[11] A systematic review[12] of the use of the long-acting injectable formulation of risperidone in schizophrenia considered that, although it might offer the advantage of better compliance, there was little evidence of benefit over oral use.

Stuttering. Risperidone 0.5 to 2 mg daily was found to be of benefit in the management of stuttering in a placebo-controlled study[1] involving 16 patients but there has also been a case report[2] of a patient whose stuttering returned during treatment with risperidone.

Tourette's syndrome. When drug treatment is required for tics and behavioural disturbances in Tourette's syndrome (see Tics, p.954) haloperidol or pimozide are commonly used but atypical antipsychotics, especially risperidone, are being increasingly tried.[1-3]

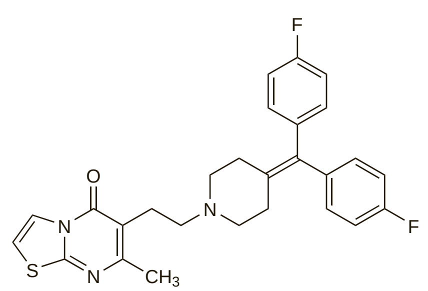
Ritanserin *(BAN, USAN, rINN)*

R-55667; Ritanserina; Ritansérine; Ritanserinum. 6-{2-[4-(4,4′-Difluorobenzhydrylidene)piperidino]ethyl}-7-methyl[1,3]thiazolo[3,2-*a*]pyrimidin-5-one.

Ритансерин

$C_{27}H_{25}F_2N_3OS = 477.6.$
CAS — 87051-43-2.



Profile

Ritanserin is a serotonin antagonist that has been studied in a variety of disorders including anxiety disorders, depression, and schizophrenia. It is reported to have little sedative action.

Action. Ritanserin is a relatively selective antagonist at serotonin (5-hydroxytryptamine, 5-HT) receptors of the 5-HT_2 subtype, although it also has appreciable affinity for 5-HT_{1C} receptors.[1] Unlike ketanserin (p.1320), it does not block α_1-adrenergic receptors. Ritanserin has anxiolytic activity; it also hastens the onset of slow-wave sleep although sleep may be impaired on withdrawal.

Ritanserin may interfere with platelet function[2,3] but has been reported to have no significant effect on blood pressure, blood flow, or heart rate in patients with hypertension.[2,4] Features characteristic of class III antiarrhythmic activity have also been noted.[2]

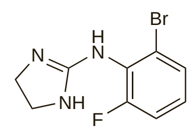
3. Wiesbeck GA, *et al.* The effects of ritanserin on mood, sleep, vigilance, clinical impression, and social functioning in alcohol-dependent individuals. *Alcohol Alcohol* 2000; **35:** 384–9.

Romifidine *(BAN, rINN)*

Romifidiini; Romifidin; Romifidina; Romifidinum; STH-2130. 2-Bromo-6-fluoro-*N*-(1-imidazolin-2-yl)aniline.

Ромифидин

$C_9H_9BrFN_3 = 258.1.$
CAS — 65896-16-4.
ATC Vet — QN05CM93.



Profile

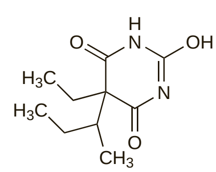
Romifidine is an α_2-adrenoceptor agonist with sedative, muscle relaxant, and analgesic properties and is used in veterinary medicine.

Secbutabarbital *(rINN)*

Butabarbital; Butabarbitone; Secbutabarbitalum; Secbutobarbital *(BAN)*; Secbutobarbitone. 5-*sec*-Butyl-5-ethylbarbituric acid.

Секбутабарбитал

$C_{10}H_{16}N_2O_3 = 212.2.$
CAS — 125-40-6.



NOTE. Butabarbital should be distinguished from Butobarbital (p.967).

Pharmacopoeias. In *US.*

USP 31 (Butabarbital). A white, odourless, crystalline powder. Very slightly soluble in water; soluble in alcohol, in chloroform, in ether, and in aqueous solutions of alkali hydroxides and carbonates. Store in airtight containers.

Secbutabarbital Sodium *(rINNM)*

Butabarbital Sodium; Natrii Secbutabarbitalum; Secbutabarbital sódico; Secbutabarbital Sodique; Secbutobarbital Sodium *(BANM)*; Secbutobarbitone Sodium; Secumalnatrium; Sodium Butabarbital. Sodium 5-*sec*-butyl-5-ethylbarbiturate.

Натрий Секбутабарбитал

$C_{10}H_{15}N_2NaO_3 = 234.2.$
CAS — 143-81-7.

Pharmacopoeias. In *US.*

USP 31 (Butabarbital Sodium). A white powder. Soluble 1 in 2 of water, 1 in 7 of alcohol, and 1 in 7000 of chloroform; practically insoluble in absolute ether. pH of a 10% solution in water is between 10.0 and 11.2. Store in airtight containers.

Profile

Secbutabarbital is a barbiturate with general properties similar to those of amobarbital (p.961). It was used as a hypnotic and sedative although barbiturates are no longer considered appropriate for such purposes. For the short-term management of insomnia (p.957) it was usually given as the sodium salt in oral doses of 50 to 100 mg at night; as a sedative 15 to 30 mg has been given 3 or 4 times daily. Secbutabarbital base has also been given.

Preparations

USP 31: Butabarbital Sodium Elixir; Butabarbital Sodium Tablets.

Proprietary Preparations (details are given in Part 3)
USA: Butisol.

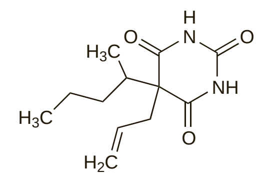
Multi-ingredient: *USA:* Butibel; Phenazopyridine Plus; Urelief Plus; ***Venez.:*** Butropina; Eumidral.

Secobarbital *(rINN)*

Meballymal; Quinalbarbitone; Sécobarbital; Secobarbitalum; Secobarbitone; Sekobarbitaali. 5-Allyl-5-(1-methylbutyl)barbituric acid.

Секобарбитал

$C_{12}H_{18}N_2O_3 = 238.3.$
CAS — 76-73-3.
ATC — N05CA06.
ATC Vet — QN05CA06; QN51AA02.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of secobarbital:
F-40s; Marshmallow reds; M&Ms; Mexican reds; Pink ladies; Pink lady; Pinks; RDs; Red birds; Red bullets; Red devil; Red devils; Red dolls; Red lillies; Reds; Seccies; Seccy; Seco; Seggy.

Pharmacopoeias. In *US.*

USP 31 (Secobarbital). A white amorphous or crystalline odourless powder. Very slightly soluble in water; freely soluble in alcohol, in ether, and in solutions of fixed alkali hydroxides and carbonates; soluble in chloroform; soluble 1 in 8.5 of 0.5N sodium hydroxide. A saturated solution in water has a pH of about 5.6. Store in airtight containers.

Secobarbital Sodium *(BAN, rINNM)*

Meballymalnatrium; Natrii Secobarbitalum; Quinalbarbitone Sodium; Secobarbital sódico; Sécobarbital Sodique; Secobarbitalum Natricum; Secobarbitone Sodium. Sodium 5-allyl-5-(1-methylbutyl)barbiturate.

Натрий Секобарбитал

$C_{12}H_{17}N_2NaO_3 = 260.3.$
CAS — 309-43-3.
ATC — N05CA06.
ATC Vet — QN05CA06.

Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Secobarbital Sodium). A white odourless hygroscopic powder. Very soluble in water; soluble in alcohol; practically insoluble in ether. pH of a 10% solution in water is between 9.7 and 10.5. Solutions decompose on standing, heat accelerating the decomposition. Store in airtight containers.

Incompatibility. Secobarbital may be precipitated from preparations containing secobarbital sodium depending on the concentration and pH. Secobarbital sodium has, therefore, been reported to be incompatible with many other drugs, particularly acids and acidic salts.

Dependence and Withdrawal

As for Amobarbital, p.962.

Adverse Effects, Treatment, and Precautions

As for Amobarbital, p.962.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving secobarbital, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding. However, for the view that barbiturates should not be used in women who are breast feeding, see under Amobarbital, p.962.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/04/04)

Industrial exposure. Exposure to secobarbital sodium among 6 workers in the pharmaceutical industry resulted in absorption of substantial amounts of the drug, with blood concentrations approaching those expected after a therapeutic dose.[1] There continued to be evidence of absorption, despite protective masks to reduce inhalation, and it appeared that substantial absorption was taking place through the skin.

1. Baxter PJ, *et al.* Exposure to quinalbarbitone sodium in pharmaceutical workers. *BMJ* 1986; **292:** 660–1.

Porphyria. Secobarbital has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for Amobarbital, p.962.

Pharmacokinetics

Secobarbital is well absorbed from the gastrointestinal tract after oral doses and is reported to be about 46 to 70% bound to plasma proteins. The mean elimination half-life is reported to be 28 hours. It is metabolised in the liver, mainly by hydroxylation, and excreted in urine as metabolites and a small amount of unchanged drug.

Uses and Administration

Secobarbital is a barbiturate that has been used as a hypnotic and sedative. It has general properties similar to those of amobarbital (p.962). As a hypnotic in the short-term management of insomnia (p.957) it was usually given in an oral dose of 100 mg of the sodium salt at night, but barbiturates are no longer considered appropriate for such use.

Secobarbital sodium has also been given orally or by intramuscular or intravenous injection for premedication in anaesthetic procedures (p.1780) but barbiturates for pre-operative sedation have been replaced by other drugs.

Preparations

USP 31: Secobarbital Elixir; Secobarbital Sodium and Amobarbital Sodium Capsules; Secobarbital Sodium Capsules; Secobarbital Sodium for Injection; Secobarbital Sodium Injection.

Proprietary Preparations (details are given in Part 3)
UK: Seconal; ***USA:*** Seconal.

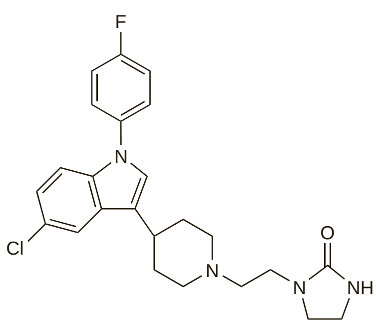
Multi-ingredient: ***Port.:*** Vesparax†; ***UK:*** Tuinal; ***USA:*** Tuinal.

Sertindole *(BAN, USAN, rINN)*

Lu-23-174; Sertindol; Sertindoli; Sertindolum. 1-(2-{4-[5-Chloro-1-(*p*-fluorophenyl)indol-3-yl]piperidino}ethyl)-2-imidazolidinone.

Сертиндол

$C_{24}H_{26}ClFN_4O$ = 440.9.
CAS — 106516-24-9.
ATC — N05AE03.
ATC Vet — QN05AE03.



Adverse Effects, Treatment, and Precautions

Although sertindole may share some of the adverse effects seen with the classical antipsychotics (see Chlorpromazine, p.969), the incidence and severity of such effects may vary. Sertindole is associated with a low incidence of extrapyramidal adverse effects and does not appear to cause sedation. Prolactin elevation may be less frequent. The most common adverse effects with sertindole are peripheral oedema, rhinitis, dyspnoea, sexual dysfunction, dizziness, dry mouth, orthostatic hypotension, weight gain, and paraesthesia. Hyperglycaemia, convulsions, and tardive dyskinesia are uncommon.

Marketing of sertindole has been restricted because of cardiac arrhythmias and sudden cardiac deaths associated with its use (see below). Since sertindole has been associated with prolongation of the QT interval, usually during the first 3 to 6 weeks of treatment, it is recommended that patients should have an ECG before the start of therapy and periodically during treatment. Patients with pre-existing prolongation of the QT interval or a family history of congenital QT prolongation should not be given sertindole and sertindole should be stopped if such prolongation occurs during treatment. In addition, sertindole is contra-indicated in patients with a history of cardiovascular disease, heart failure, cardiac hypertrophy, arrhythmias, or bradycardia. Certain medications may also increase the risk (see Interactions, below).

Sertindole should not be given to patients with uncorrected hypokalaemia or hypomagnesaemia. Baseline serum potassium and magnesium screening should be performed before starting sertindole therapy in patients who are at risk of significant electrolyte disturbances. Serum potassium should be monitored in patients with electrolyte disturbances, vomiting or diarrhoea, or receiving diuretics during sertindole treatment. It is also recommended that blood pressure should be monitored during dose titration and in early maintenance therapy.

Sertindole is contra-indicated in patients with severe hepatic impairment. It should be used with caution in the elderly and in patients with Parkinson's disease, mild to moderate hepatic impairment, or a history of seizures.

Sertindole may affect the performance of skilled tasks including driving.

Gradual withdrawal of sertindole is recommended because of the risk of withdrawal symptoms such as sweating, nausea and vomiting, and rebound psychosis, with abrupt cessation.

Dementia. The FDA has issued advice against the use of atypical antipsychotics in the treatment of behavioural problems in elderly patients with dementia after analysis of placebo-controlled studies showed an increased risk of mortality with certain drugs in this class. See under Risperidone, p.1024.

Effects on body-weight. The increased risk of weight gain with some atypical antipsychotics is discussed under Adverse Effects of Clozapine, p.981.

Effects on carbohydrate metabolism. The increased risk of glucose intolerance and diabetes mellitus with some atypical antipsychotics, and recommendations on monitoring, are discussed under Adverse Effects of Clozapine, p.981.

Effects on the cardiovascular system. Prolongation of the QT interval is said by the manufacturer to be common in patients given sertindole, with the effect being greater at the upper end of the dose range. In addition, the QT interval is prolonged to a greater extent than that seen with some other antipsychotics. QT interval prolongation is a known risk factor for the development of serious arrhythmias such as torsade de pointes although such arrhythmias are uncommon with sertindole.

In evidence presented to the FDA it was reported that as of 1st June 1996 there had been 27 deaths, 16 due to adverse cardiac events, among the 2194 patients given sertindole in clinical studies.[1] By the end of November 1998, the UK CSM was aware of 36 suspected adverse drug reactions with a fatal outcome, 9 of which originated in the UK.[2] There had also been 13 reports of serious but non-fatal cardiac arrhythmias in the UK. Although not all the fatalities were related to sudden cardiac events, at the time the CSM considered that, given the number of serious arrhythmias and sudden cardiac deaths, the risk-benefit ratio of sertindole was no longer favourable. The drug was withdrawn from the market in the UK and subsequently in a number of other countries, although it remained available on a named-patient basis. However, in 2001, the issue was re-evaluated by the CSM and the European advisory body, the Committee on Proprietary Medicinal Products, and it was recommended that sertindole could be reintroduced in Europe under certain restrictions.[3] Initially sertindole should only be prescribed to patients enrolled in clinical studies to ensure that they are carefully selected and monitored. In the UK, sertindole was remarketed in September 2002.

2. CSM/MCA. Suspension of availability of sertindole (Serdolect). *Current Problems* 1999; **25:** 1. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2023233&RevisionSelectionMethod=LatestReleased (accessed 16/05/06)
3. CSM/MCA. Restricted re-introduction of the atypical antipsychotic sertindole (Serdolect) (issued 10th September, 2002). Available at: http://www.mhra.gov.uk/Safetyinformation/Safetywarningsalertsandrecalls/Safetywarningsandmessagesformedicines/CON019523 (accessed 21/08/08)

Effects on lipid metabolism. The increased risk of hyperlipidaemia with some atypical antipsychotics is discussed under Adverse Effects of Chlorpromazine, p.970. See also Effects on Carbohydrate Metabolism under Adverse Effects of Clozapine, p.981.

Pregnancy. For comments on the use of some atypical antipsychotics during pregnancy, see under Precautions of Clozapine, p.983.

Interactions

The risk of arrhythmias with sertindole may be increased by other drugs that prolong the QT interval and use together should be avoided. Sertindole should be given with caution with drugs that produce electrolyte disturbances; monitoring of serum potassium is recommended if given with potassium-depleting diuretics.

Sertindole may antagonise the effects of dopaminergics.

Sertindole is extensively metabolised by the cytochrome P450 isoenzymes of the group CYP3A and by CYP2D6. The use of potent inhibitors of CYP3A such as indinavir, itraconazole, and ketoconazole with sertindole is contra-indicated. Minor increases in sertindole plasma concentrations have been noted in patients also given macrolide antibacterials or calcium-channel blockers which also inhibit CYP3A; however, despite the small increase, the use of these CYP3A4 inhibitors with sertindole is not recommended. Fluoxetine and paroxetine, potent inhibitors of CYP2D6, have increased plasma concentrations of sertindole by a factor of 2 to 3 and lower maintenance doses of sertindole may be required. In contrast, enzyme inducers such as rifampicin, carbamazepine, phenytoin, and phenobarbital may decrease sertindole plasma levels by a factor of 2 to 3; in such cases, higher doses of sertindole may be required.

Pharmacokinetics

Sertindole is slowly absorbed with peak concentrations occurring about 10 hours after oral doses. It is about 99.5% bound to plasma proteins and readily crosses the placenta. Sertindole is extensively metabolised in the liver by the cytochrome P450 isoenzymes CYP2D6 and CYP3A. There is moderate interindividual variation in the pharmacokinetics of sertindole due to polymorphism in the isoenzyme CYP2D6. Poor metabolisers, deficient in this isoenzyme, may have plasma concentrations of sertindole 2 to 3 times higher than other patients. The two major metabolites, dehydrosertindole and norsertindole, appear to be inactive. Sertindole and its metabolites are excreted slowly, mainly in the faeces with a minor amount appearing in the urine. The mean terminal half-life is about 3 days.

Uses and Administration

Sertindole is an atypical antipsychotic that is an antagonist at central dopamine (D_2), serotonin (5-HT_2), and adrenergic (α_1) receptors. It is used in the treatment of schizophrenia (p.955) in patients who are unable to tolerate at least one other antipsychotic. In addition, sertindole should only be prescribed to patients enrolled in clinical studies to ensure adequate monitoring, especially regular ECG measurements (see Adverse Effects, above).

Sertindole is given in an initial oral dose of 4 mg once daily, increased gradually in steps of 4 mg every 4 or 5 days to a usual maintenance dose of 12 to 20 mg once daily. The maximum dose is 24 mg daily. Slower dose titration and lower maintenance doses are advisable for the elderly and patients with mild to moderate hepatic impairment.

If therapy is interrupted for 1 week or more, the dose of sertindole should be re-titrated. An ECG should also be undertaken before re-starting sertindole.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *Jpn.*
Ph. Eur. 6.2 (Sulpiride). A white or almost white crystalline powder. Practically insoluble in water; slightly soluble in alcohol and in dichloromethane; sparingly soluble in methyl alcohol. It dissolves in dilute solutions of mineral acids and in alkali hydroxides.

Levosulpiride *(rINN)*

Levosulpirida; Lévosulpiride; Levosulpiridum; Levosulpride; L-Sulpiride.

Левосульпирид

$C_{15}H_{23}N_3O_4S$ = 341.4.
CAS — 23672-07-3.
ATC — N05AL07.
ATC Vet — QN05AL07.

Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969.

Sleep disturbances, overstimulation, and agitation may occur. Extrapyramidal effects appear to be as frequent as with chlorpromazine but have usually been mild. It has been suggested that sulpiride is less likely to cause tardive dyskinesia but good evidence of any important difference is lacking. Sulpiride is less likely to cause sedation than chlorpromazine and antimuscarinic effects are minimal. Cardiovascular effects such as hypotension are generally rare although they may occur with overdosage.

Sulpiride should be given with care to manic or hypomanic patients in whom it may exacerbate symptoms.

Breast feeding. Sulpiride may be distributed into breast milk and the *BNF* recommends that its use should be avoided in mothers wishing to breast feed.

On the fifth day after starting D-sulpiride, DL-sulpiride, or L-sulpiride in a dose of 50 mg twice daily, mean concentrations of sulpiride in breast milk from 45 women were 840, 850, and 810 nanograms/mL respectively.[1]

1. Polatti F. Sulpiride isomers and milk secretion in puerperium. *Clin Exp Obstet Gynecol* 1982; **9:** 144–7.

Effects on the cardiovascular system. Sulpiride 100 mg by mouth caused an attack of hypertension in 6 of 26 hypertensive patients; in 4 it induced a rise in urinary excretion of vanillylmandelic acid and catecholamines.[1] A transient rise in blood pressure and catecholamines after sulpiride occurred in 3 patients who were found to have a phaeochromocytoma; another patient probably had a phaeochromocytoma. The means by which sulpiride provoked hypertension were not known but appeared to be due to a noradrenergic effect. Sulpiride should be avoided during the treatment of phaeochromocytoma, and prescribed with great care in hypertensive patients.

1. Corvol P, *et al*. Poussées hypertensives déclenchées par le sulpiride. *Sem Hop Paris* 1974; **50:** 1265–9.

Porphyria. Sulpiride is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Renal impairment. For the precautions to be observed in patients with impaired renal function, see under Uses and Administration, below.

Interactions

As for Chlorpromazine, p.973

Gastrointestinal drugs. Giving sulpiride with therapeutic doses of *sucralfate* or an *antacid* containing aluminium and magnesium hydroxides to 6 healthy subjects reduced the mean oral bioavailability of sulpiride by 40 and 32%, respectively.[1] When sulpiride was given 2 hours after the antacid or sucralfate (each in 2 subjects), bioavailability was reduced by about 25%. This interaction was expected to be clinically significant, and it was recommended that sulpiride should be given before, rather than with or after, sucralfate or antacids.

1. Gouda MW, *et al*. Effect of sucralfate and antacids on the bioavailability of sulpiride in humans. *Int J Pharmaceutics* 1984; **22:** 257–63.

Pharmacokinetics

Sulpiride is slowly absorbed from the gastrointestinal tract; peak plasma concentrations are attained 3 to 6 hours after ingestion. Bioavailability is low and subject to interindividual variation. It is rapidly distributed to the tissues but passage across the blood-brain barrier is poor. Sulpiride is about 40% bound to plasma proteins and is reported to have a plasma half-life of about 8 to 9 hours. It is excreted in the urine and faeces, mainly as unchanged drug. Sulpiride is distributed into breast milk.

Uses and Administration

Sulpiride is a substituted benzamide antipsychotic that is reported to be a selective antagonist of central dopamine (D_2, D_3, and D_4) receptors. It is also claimed to have mood elevating properties.

Sulpiride is mainly used in the treatment of psychoses such as schizophrenia (below). It has also been given in the management of Tourette's syndrome (below), anxiety disorders (p.952), depression (p.373), vertigo (p.565), and benign peptic ulceration (below). Levosulpiride, the L-isomer of sulpiride, has been used similarly to sulpiride.

In the treatment of **schizophrenia** in adults and children aged 14 years and over, initial oral doses of 200 to 400 mg of sulpiride are given twice daily, increased if necessary up to a maximum of 1.2 g twice daily in patients with mainly positive symptoms or up to a total of 800 mg daily in patients with mainly negative symptoms. Patients with mixed positive and negative symptoms, with neither predominating, are given usual doses of 400 to 600 mg twice daily. Lower initial doses have been recommended in elderly patients, subsequently adjusted as required.

Sulpiride is also given in some countries by intramuscular injection, in usual doses ranging from 200 to 800 mg daily.

Dosage adjustment is advised in patients with renal impairment (see below).

Administration in renal impairment. A single intravenous dose of sulpiride 100 mg was given to 6 healthy subjects with normal renal function (creatinine clearance greater than 90 mL/minute) and to 3 groups of 6 patients each with creatinine clearances (CC) in the ranges of 30 to 60, 10 to 30, and less than 10 mL/minute.[1] There was a progressive diminution in the rate of elimination and an increase in half-life with decreasing renal function. The mean plasma elimination half-lives were 5.90, 11.02, 19.27, and 25.96 hours in the 4 groups, respectively.

In the UK it has been recommended that the oral dose be reduced according to CC as follows:

- CC 30 to 60 mL/minute: two-thirds of the usual dose, or prolong dosage interval by a factor of 1.5
- CC 10 to 30 mL/minute: half the usual dose, or double dosage interval
- CC less than 10 mL/minute: one-third of the usual dose, or triple dosage interval

However, the *BNF* suggests that sulpiride should be avoided if CC is less than 10 mL/minute.

1. Bressolle F, *et al.* Pharmacokinetics of sulpiride after intravenous administration in patients with impaired renal function. *Clin Pharmacokinet* 1989; **17:** 367–73.

Chorea. Antipsychotics have some action against choreiform movements (p.953) as well as being of use to control the behavioural disturbances of Huntington's chorea. Although sulpiride was found to have produced an overall reduction in abnormal movements in 11 patients with Huntington's chorea when compared with placebo in a double-blind study[1] there was generally no accompanying functional improvement and patients with mild disease tended to worsen when taking sulpiride.

1. Quinn N, Marsden CD. A double blind trial of sulpiride in Huntington's disease and tardive dyskinesia. *J Neurol Neurosurg Psychiatry* 1984; **47:** 844–7.

Gastrointestinal disorders. Although sulpiride is used in some countries as an adjunct in the treatment of peptic ulcer disease (p.1702) it is not among the more usual drugs used for this indication. Efficacy has also been claimed for sulpiride or levosulpiride in a variety of other gastrointestinal disorders, including irritable bowel disease (p.1699), decreased gastrointestinal motility (p.1694), and nausea and vomiting (p.1700), but again they are not among the drugs usually considered for use in these conditions.

Lactation induction. Drug therapy has been used occasionally to stimulate lactation in breast-feeding mothers, although mechanical stimulation of the nipple remains the primary method. Dopamine antagonists such as sulpiride can produce modest increases in breast milk production[1-3] although metoclopramide has been more widely used (see p.2003). However, there is concern about the adverse effects of these drugs. As sulpiride appears in breast milk and may be associated with adverse effects in the infant it has been recommended that it should not be used to enhance milk production.[4,5]

5. Lasich AJ. Sulpiride and breastfeeding. *S Afr Med J* 2005; **95:** 624–6.

Schizophrenia. A systematic review[1] of the use of sulpiride for schizophrenia (p.955) or serious mental illness concluded that while sulpiride might be as effective as the classical antipsychotics for schizophrenia and appeared to produce few adverse effects, evidence of its value for treating negative symptoms was lacking. Comparisons with the atypical antipsychotic drugs were also lacking.

1. Soares B, *et al.* Sulpiride for schizophrenia. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 1999 (accessed 21/08/08).

Tourette's syndrome. When drug treatment is needed for tics and behavioural disturbances in Tourette's syndrome (p.954) dopamine antagonists such as the antipsychotics haloperidol or pimozide are most commonly used but sulpiride has also been tried.[1] Although unlicensed in the UK for the treatment of Tourette's syndrome, the *BNFC* has suggested that oral doses of sulpiride 50 to 400 mg twice daily may be given to those aged from 2 to 12 years, and 100 to 400 mg twice daily to adolescents aged from 12 to 18 years.

Sultopride Hydrochloride *(rINNM)*

Hidrocloruro de sultoprida; LIN-1418; Sultopride, Chlorhydrate de; Sultopridi Hydrochloridum. *N*-(1-Ethylpyrrolidin-2-ylmethyl)-5-ethylsulphonyl-2-methoxybenzamide hydrochloride.

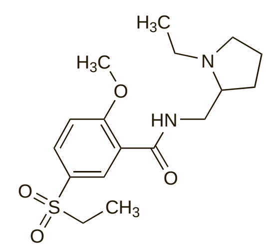
Сультоприда Гидрохлорид

$C_{17}H_{26}N_2O_4S,HCl = 390.9.$

CAS — 53583-79-2 (sultopride); 23694-17-9 (sultopride hydrochloride).

ATC — N05AL02.

ATC Vet — QN05AL02.



(sultopride)

Profile

Sultopride is a substituted benzamide with general properties similar to those of sulpiride (above). It is used in psychoses such as schizophrenia (p.955). It has also been used in the emergency management of agitation in psychotic or aggressive patients. It is given as the hydrochloride but doses are expressed in terms of the base; sultopride hydrochloride 441 mg is equivalent to about 400 mg of sultopride.

For acute and chronic psychoses it may be given in oral doses of 400 to 800 mg daily; it may also be given intramuscularly.

Ventricular arrhythmias, including torsade de pointes, have been reported. It has been recommended that sultopride should not be used in patients with bradycardia.

Porphyria. Sultopride is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

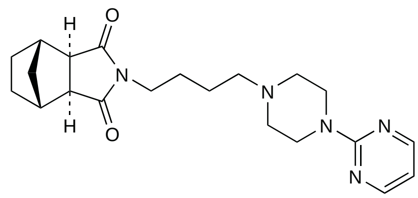
Тандоспирона Цитрат

$C_{21}H_{29}N_5O_2,C_6H_8O_7$ = 575.6.

CAS — 87760-53-0 (tandospirone); 112457-95-1 (tandospirone citrate).



(tandospirone)

Profile

Tandospirone, a partial agonist at serotonin (5-HT) receptors of the 5-HT_{1A} subtype, is an anxiolytic structurally related to buspirone (p.965). It also has antidepressant actions. Tandospirone citrate is given in usual oral doses of 30 mg daily in 3 divided doses up to a maximum of 60 mg daily.

Temazepam *(BAN, USAN, rINN)*

ER-115; 3-Hydroxydiazepam; K-3917; Ro-5-5345; Tematsepaami; Témazépam; Temazepám; Temazepamas; Temazepamum; Wy-3917. 7-Chloro-1,3-dihydro-3-hydroxy-1-methyl-5-phenyl-1,4-benzodiazepin-2-one.

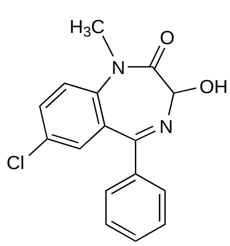
Темазепам

$C_{16}H_{13}ClN_2O_2$ = 300.7.

CAS — 846-50-4.

ATC — N05CD07.

ATC Vet — QN05CD07.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of temazepam:
Beans; Egg; Eggs; Jellies; Knockout Pills; Mazzies; Oranges; Rugby Balls; Temazies; Temmies; Terms; Wobbly jellies.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Temazepam). A white or almost white crystalline powder. Practically insoluble in water; sparingly soluble in alcohol; freely soluble in dichloromethane. Protect from light.

USP 31 (Temazepam). A white or nearly white crystalline powder. Very slightly soluble in water; sparingly soluble in alcohol. Protect from light.

Dependence and Withdrawal

As for Diazepam, p.987.

◊ For the purpose of withdrawal regimens, 10 mg of temazepam may be considered equivalent to about 5 mg of diazepam.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987.

Abuse. Liquid-filled temazepam *capsules* (known on the street as 'eggs') were widely abused on the illicit drugs market, the liquid gel lending itself to intravenous injection.[1] This formulation was, therefore, replaced in a number of countries by tablets or by semi-solid gel-filled capsules, which were intended to be difficult to inject even after heating or diluting the gel in various solvents.[2] In spite of this there is evidence of intravenous or intra-arterial abuse of these capsules,[3-5] and there are reports of ischaemia, in some cases necessitating amputation.[6-8] The *tablets* may also be liable to abuse; there has been a report of death after intravenous injection of a solution containing crushed temazepam tablets.[9] The manufacturers of a temazepam *elixir* considered that, because of its viscosity and its low strength relative to the liquid in the capsules, it had a low potential for intravenous abuse.[10] Nonetheless, there have been reports[3] of some drug abusers injecting large quantities of diluted elixir.

For mention of rhabdomyolysis associated with abuse of temazepam, see Effects on Skeletal Muscle, under Diazepam, p.988.

10. Drake J, Ballard R. Misuse of temazepam. *BMJ* 1988; **297:** 1402.

Breast feeding. The American Academy of Pediatrics[1] considers that, although the effect of temazepam on breast-fed infants is unknown, its use by mothers during breast feeding may be of concern since psychotropic drugs do appear in breast milk and thus could conceivably alter CNS function in the infant both in the short and long term.

Temazepam was detected in breast milk in only one of 10 mothers given temazepam as a bedtime sedative;[2] temazepam was given in a dose of 10 to 20 mg and milk concentrations were measured about 15 hours after a dose. The authors considered that breast-fed neonates would ingest negligible amounts of temazepam.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/04/04)
2. Lebedevs TH, *et al.* Excretion of temazepam in breast milk. *Br J Clin Pharmacol* 1992; **33:** 204–6.

Effects on the skin. Generalised lichenoid drug eruption that had persisted for 5 months in an elderly patient receiving therapy including temazepam resolved within 10 days of stopping the benzodiazepine.[1] Bullous eruptions associated with temazepam overdose have also been reported.[2]

1. Norris P, Sounex TS. Generalised lichenoid drug eruption associated with temazepam. *BMJ* 1986; **293:** 510.
2. Verghese J, Merino J. Temazepam overdose associated with bullous eruptions. *Acad Emerg Med* 1999; **6:** 1071.

Hepatic impairment. All benzodiazepines should be used with caution in patients with hepatic impairment, and licensed product information in the UK advises that temazepam should be avoided in severe cases. However, short-acting benzodiazepines such as temazepam may pose less risk in patients with hepatic impairment; in a study of 15 patients with cirrhosis and 16 healthy subjects, liver disease had no significant effect on the pharmacokinetic parameters or pattern of elimination of temazepam.[1]

1. Ghabrial H, *et al.* The effects of age and chronic liver disease on the elimination of temazepam. *Eur J Clin Pharmacol* 1986; **30:** 93–7.

Interactions

As for Diazepam, p.989.

Pharmacokinetics

Temazepam is fairly readily absorbed from the gastrointestinal tract, although the exact rate of absorption depends on the formulation. It is about 96% bound to plasma proteins. Mean elimination half-lives of about 8 to 15 hours or longer have been reported. It is excreted mainly in the urine in the form of its inactive glucuronide conjugate together with small amounts of the demethylated derivative, oxazepam, also in conjugated form.

Absorption and plasma concentration. Various oral temazepam formulations have been available worldwide. These included powder-filled hard gelatin capsules, liquid-filled soft gelatin capsules, semi-solid gel-filled soft gelatin capsules, and an elixir. There has been considerable debate over the comparative absorption profiles of temazepam from these formulations which have, in some cases, been modified over the years. It should be noted that pharmacokinetic studies of temazepam do not always clearly state the formulation used.

Temazepam 30 mg was given as a premedicant to 80 patients undergoing surgery in the form of capsules [type not stated] or elixir.[1] Mean peak plasma concentrations of about 800 nanograms/mL occurred 30 minutes after a dose of either formulation although there was wide interindividual variation in plasma concentrations. The evidence corresponded with previous suggestions that a plasma concentration of about 250 nanograms/mL or more was required to ensure sedation. The presence or absence of anxiety did not influence the absorption of the preparations.

1. Hosie HE, Nimmo WS. Temazepam absorption in patients before surgery. *Br J Anaesth* 1991; **66:** 20–4.

Distribution into CSF. A study in 13 male patients showed a correlation between the unbound concentration of temazepam in plasma and the amount of temazepam detected in CSF.[1] The mean CSF to total plasma temazepam concentration ratio was 5.2.

1. Badcock NR. Plasma and cerebrospinal fluid concentrations of temazepam following oral drug administration. *Eur J Clin Pharmacol* 1990; **38:** 153–5.

Metabolism. References.

1. Locniskar A, Greenblatt DJ. Oxidative versus conjugative biotransformation of temazepam. *Biopharm Drug Dispos* 1990; **11:** 499–506.

Sex differences. The elimination half-life was significantly longer at 16.8 hours among 17 women given temazepam 30 mg compared with 12.3 hours among 15 men.[1] The total clearance was also lower among women. After correction for differences in protein binding, unbound clearance was still lower in women than men but there was no significant effect of age on this parameter. Time to peak plasma concentration and volume of distribution were not affected by the age or sex of the subjects.

1. Divoll M, *et al.* Effect of age and gender on disposition of temazepam. *J Pharm Sci* 1981; **70:** 1104–7.

Uses and Administration

Temazepam is a short-acting benzodiazepine with general properties similar to those of diazepam (p.992). It is used as a hypnotic in the short-term management of insomnia (p.957) and for premedication before surgical or investigative procedures (p.1780).

A usual oral dose for insomnia is 10 to 20 mg at night; exceptionally, doses up to 40 mg may be required. For premedication the usual oral dose is 20 to 40 mg given half to one hour beforehand. The *BNFC* states that children aged 1 year and over may be given 1 mg/kg orally for premedication, to a maximum total dose of 30 mg.

Temazepam should be given in reduced dosage to elderly or debilitated patients; one-half the usual adult dose, or less, may be sufficient.

Administration. For reference to the various formulations of oral temazepam that have been used, see Abuse under Adverse Effects, Treatment, and Precautions, above.

Administration in the elderly. In a small study[1] a 7.5-mg dose of temazepam was found to be adequate for the short-term management of insomnia in elderly patients.

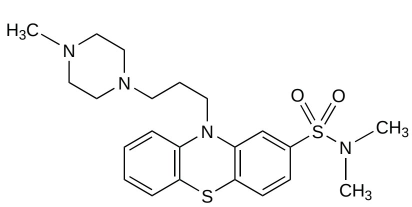
ATC Vet — QN05AB08.



(thioproperazine)

Pharmacopoeias. In *Fr.*

Profile

Thioproperazine is a phenothiazine with general properties similar to those of chlorpromazine (p.969). It has a piperazine side-chain. It is used in the treatment of schizophrenia (p.955), mania (see Bipolar Disorder, p.372), and other psychoses. Thioproperazine is given as the mesilate although doses are expressed in terms of the base; thioproperazine mesilate 7.2 mg is equivalent to about 5 mg of thioproperazine. Initial daily doses of 5 mg are given orally, increased as necessary; the usual effective dosage is 30 to 40 mg daily. In severe or resistant cases daily doses of 90 mg or more have been given.

$C_{21}H_{26}N_2S_2,HCl$ = 407.0.

CAS — 130-61-0.

ATC — N05AC02.

ATC Vet — QN05AC02.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Thioridazine Hydrochloride). A white or almost white, crystalline powder. Freely soluble in water and in methyl alcohol; soluble in alcohol. A 1% solution in water has a pH of 4.2 to 5.2. Protect from light.

USP 31 (Thioridazine Hydrochloride). A white to slightly yellow granular powder having a slight odour. Freely soluble in water, in chloroform, and in methyl alcohol; insoluble in ether. pH of a 1% solution in water is between 4.2 and 5.2. Store in airtight containers. Protect from light.

Incompatibility. For a warning about incompatibility between thioridazine hydrochloride solution (*Mellaril; Novartis, USA*) and carbamazepine suspension (*Tegretol; Novartis, USA*), see p.471.

Adverse Effects and Treatment

As for Chlorpromazine, p.969.

Thioridazine has been associated with a higher incidence of antimuscarinic effects, but lower incidence of extrapyramidal effects than chlorpromazine. It may also be less sedating. However, it is more likely to induce hypotension and there is an increased risk of cardiotoxicity and dose-related prolongation of the QT interval. Because of this and the consequent danger of life-threatening arrhythmias such as torsade de pointes and sudden death, its use has been restricted (see Precautions, and Uses and Administration, below). Sexual dysfunction also appears to be more frequent with thioridazine.

Pigmentary retinopathy characterised by reduced visual acuity, brownish colouring of vision, and impairment of night vision has been seen particularly in patients taking large doses.

Effects on the cardiovascular system. Between 1964 and 2001, the UK CSM received 42 reports of suspected heart rate and rhythm disorders associated with thioridazine.[1] There were 21 fatalities reported out of 39 cases where the outcome was known.

See also under Chlorpromazine, p.970.

1. Committee on Safety of Medicines/Medicines Control Agency. QT interval prolongation with antipsychotics. *Current Problems* 2001; **27:** 4. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON007458&RevisionSelectionMethod=LatestReleased (accessed 12/05/06)

Hypersensitivity. Pruritus and erythematous rash on the genitals of a woman after sexual intercourse were found to be due to thioridazine present in the seminal fluid of her husband, who was taking 100 mg daily at night.[1]

1. Sell MB. Sensitization to thioridazine through sexual intercourse. *Am J Psychiatry* 1985; **142:** 271–2.

Overdosage. Rhabdomyolysis has been reported in a patient after overdosage with thioridazine.[1] Twenty-four hours after taking 9.4 g of thioridazine the patient presented with difficulty in moving and speaking. On examination he had swelling and tenderness over his upper arms, thighs, and calves. Ataxia and transient dysarthria were attributed to generalised muscle weakness. Other effects were consistent with antimuscarinic effects of thioridazine. He had no signs of neuroleptic malignant syndrome but his urine contained myoglobin. The patient was treated with gastric lavage, activated charcoal, and rehydration. Serum biochemistry returned to normal over 1 week and the muscle tenderness and weakness disappeared.

1. Nankivell BJ, *et al.* Rhabdomyolysis induced by thioridazine. *BMJ* 1994; **309:** 378.

Precautions

As for Chlorpromazine, p.972. Thioridazine should not be used in patients with clinically significant cardiac disorders, uncorrected hypokalaemia or other electrolyte imbalance, with known or suspected QT prolongation or a family history of QT prolongation, or with a history of ventricular arrhythmias including torsade de pointes. Use is also contra-indicated in patients known to have reduced activity of the cytochrome P450 isoenzyme CYP2D6, which is responsible for thioridazine metabolism. Use with drugs liable to interfere with the metabolism of thioridazine, with other drugs known to prolong the QT interval, and with drugs likely to cause electrolyte imbalance should also be avoided (see under Interactions, below).

For all patients starting thioridazine it is recommended that a baseline ECG and electrolyte screening are performed. An ECG should also be repeated before each dose increase, 1 week after the maximum therapeutic dose has been reached, and at 6-monthly intervals in those who continue treatment. Serum electrolyte concentrations should also be monitored periodically during treatment and any imbalance corrected.

Porphyria. Thioridazine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for Chlorpromazine, p.973. The metabolism of thioridazine is mediated by the cytochrome P450 isoenzyme CYP2D6; thioridazine itself is also an inhibitor of CYP2D6. Therefore, there is the potential for interactions between thioridazine and other drugs that inhibit or act as a substrate for this enzyme; such drugs should not be given with thioridazine. Some examples include antiarrhythmics, certain antidepressants including the SSRIs and tricyclics, certain antipsychotics, beta blockers, HIV-protease inhibitors, and opioids.

Use with other drugs known to prolong the QT interval such as class IA and class III antiarrhythmics, tricyclic antidepressants, and some other antipsychotics should also be avoided, as should use with those drugs known to cause electrolyte imbalance.

Pharmacokinetics

The pharmacokinetics of thioridazine appear to be generally similar to those of chlorpromazine (p.975). Thioridazine is metabolised by the cytochrome P450 isoenzyme CYP2D6. Its main active metabolite is mesoridazine (p.1007); another metabolite, sulforidazine, also has some activity. Thioridazine and its active metabolites are reported to be highly bound to plasma proteins (more than 95%). The plasma half-life of thioridazine has been estimated to be about 4 to 10 hours. It also crosses the placenta and is distributed into breast milk.

2. Axelsson R, Mårtensson E. Serum concentration and elimination from serum of thioridazine in psychiatric patients. *Curr Ther Res* 1976; **19:** 242–65.

Metabolism. In 10 psychiatric patients stabilised on thioridazine, therapy was replaced by equipotent doses of the side-chain sulfoxide (mesoridazine) and side-chain sulfone (sulforidazine) metabolites of thioridazine.[1] Both metabolites were shown to have an antipsychotic effect, the dose of each required being about two-thirds that of thioridazine. The serum half-lives were thioridazine 21 hours, mesoridazine 16 hours, and sulforidazine 13 hours. Apathy, depression, and restlessness gradually developed during treatment with the 2 metabolites and they could not be used for any length of time. Extrapyramidal symptoms, hypersalivation, and drowsiness were more common with the metabolites; 2 patients had epileptic seizures, and 1 receiving sulforidazine developed probable cholestatic jaundice.

There is some evidence that the metabolism of thioridazine is influenced by debrisoquine hydroxylation phenotype.[2] A single-dose study in 19 healthy male subjects demonstrated slower formation of mesoridazine, and hence higher serum-thioridazine concentrations in poor debrisoquine hydroxylators compared with extensive hydroxylators. Formation of thioridazine ring-sulfoxide appeared to be compensatorily increased in slow hydroxylators.

1. Axelsson R. On the serum concentrations and antipsychotic effects of thioridazine, thioridazine side-chain sulfoxide and thioridazine side-chain sulfone, in chronic psychotic patients. *Curr Ther Res* 1977; **21:** 587–605.
2. von Bahr C, *et al.* Plasma levels of thioridazine and metabolites are influenced by the debrisoquin hydroxylation phenotype. *Clin Pharmacol Ther* 1991; **49:** 234–40.

Uses and Administration

Thioridazine is a phenothiazine with general properties similar to those of chlorpromazine (p.975). It has a piperidine side-chain and, unlike chlorpromazine, has little antiemetic activity.

The use of thioridazine has been restricted to the treatment of schizophrenia (p.955) in patients who fail to show an adequate response to treatment with other antipsychotics. Its use in other psychiatric disorders was abandoned after it was felt that there was an unacceptable balance of risks and benefits as a result of its cardiotoxic potential; it has been withdrawn in some countries, including the UK.

For all patients starting thioridazine it is recommended that a baseline ECG and electrolyte screening are performed. An ECG should also be repeated before each dose increase, 1 week after the maximum therapeutic dose has been reached, and at 6-monthly intervals in those who continue treatment. Serum electrolyte concentrations should also be monitored periodically during treatment and any imbalance corrected.

Thioridazine is given orally as the hydrochloride or the base, and doses may be expressed in terms of either. In some countries, doses of oral liquid preparations have been given in terms of the base, whereas those of the tablets have been given as the hydrochloride. In the USA, all doses are given in terms of the hydrochloride. Thioridazine 22.8 mg is equivalent to about 25 mg of thioridazine hydrochloride.

In the treatment of schizophrenia thioridazine hydrochloride should be started at the usual dose of 50 to 100 mg three times daily and slowly titrated upwards to a maximum of 800 mg daily if necessary; doses should be reduced once effective control is achieved. The daily dosage range is 200 to 800 mg, which may be given in 2 to 4 divided doses. It has been recommended that increases in doses should be no more than 100 mg weekly.

Thioridazine should be given in lower initial doses to patients with a low body-mass or those with hepatic or renal impairment; dosage increases should also be more gradual.

In those patients who require withdrawal of thioridazine, the dose should be gradually reduced over 1 to 2 weeks to avoid symptoms such as gastrointestinal disorders, dizziness, anxiety, and insomnia that are sometimes seen after abruptly stopping high-dose or long-term treatment.

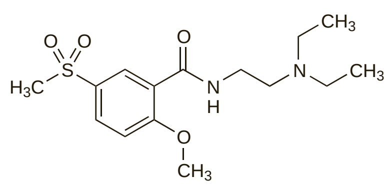
$C_{15}H_{24}N_2O_4S,HCl = 364.9.$

CAS — 51012-32-9 (tiapride); 51012-33-0 (tiapride hydrochloride).

ATC — N05AL03.

ATC Vet — QN05AL03.



(tiapride)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Tiapride Hydrochloride). A white or almost white crystalline powder. Very soluble in water; slightly soluble in dehydrated alcohol; soluble in methyl alcohol. A 5% solution in water has a pH of 4.0 to 6.0.

Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969.

Effects on the cardiovascular system. Torsade de pointes developed after a single dose of tiapride in an elderly patient with cardiac disease, a known risk factor for such arrhythmias.[1]

1. Iglesias E, *et al.* Tiapride-induced torsade de pointes. *Am J Med* 2000; **109:** 509.

Interactions

As for Chlorpromazine, p.973.

Pharmacokinetics

Tiapride is rapidly absorbed after oral doses and peak plasma concentrations occur after 1 to 2 hours. It is excreted largely unchanged in the urine. The plasma half-life is reported to range from 3 to 4 hours. It is thought to be distributed into breast milk on the basis of *animal* studies.

◊ The steady-state pharmacokinetics of tiapride have been studied in 5 elderly patients with tardive dyskinesia, and in 2 patients with Huntington's chorea.[1] All patients received tiapride 100 mg three times daily by mouth for 7 days. The mean peak plasma concentration of tiapride was 1.47 micrograms/mL, achieved a mean of 1.4 hours after dosing, and the mean elimination half-life was 3.8 hours. These values did not differ significantly from those previously reported in younger healthy subjects, although renal clearance was slightly lower in these patients. About half of the dose of tiapride was excreted unchanged by the kidneys; a metabolite, probably *N*-monodesethyltiapride was detected in the urine but its identity was not confirmed.

1. Roos RAC, *et al*. Pharmacokinetics of tiapride in patients with tardive dyskinesia and Huntington's disease. *Eur J Clin Pharmacol* 1986; **31:** 191–4.

Uses and Administration

Tiapride is a substituted benzamide with general properties similar to those of sulpiride (p.1028).

It is usually given as the hydrochloride in the management of behavioural disorders and to treat dyskinesias. Doses are expressed in terms of the equivalent amount of base; tiapride hydrochloride 222.2 mg is equivalent to about 200 mg of tiapride. Oral doses of 200 to 400 mg daily are usually given, although higher daily doses have been used, particularly in the management of dyskinesias. Tiapride hydrochloride has also been given by intramuscular or intravenous injection.

Disturbed behaviour. For a discussion of the management of disturbed behaviour including limitations on the use of antipsychotics, see p.954.

References.

1. Gutzmann H, *et al.* Measuring the efficacy of psychopharmacological treatment of psychomotoric restlessness in dementia: clinical evaluation of tiapride. *Pharmacopsychiatry* 1997; **30:** 6–11.
2. Allain H, *et al.* Double blind study of tiapride versus haloperidol and placebo in agitation and aggressiveness in elderly patients with cognitive impairment. *Psychopharmacology (Berl)* 2000; **148:** 361–6.

Extrapyramidal disorders. Tiapride has been tried in the treatment of antipsychotic-induced tardive dyskinesia (p.971), but, as with all antipsychotics, improvement may only be short-term.

Tiapride has also been tried in the treatment of Tourette's syndrome (p.954).

For reference to the use of tiapride in suppressing the adverse effects of levodopa on respiration, see p.806.

CHOREA. Antipsychotics have some action against choreiform movements as well as being of use to control the behavioural disturbances of Huntington's chorea, and tiapride has been quite widely used for this purpose. For a discussion of the management of various choreas, see p.953.

References.

2. Deroover J, *et al.* Tiapride versus placebo: a double-blind comparative study in the management of Huntington's chorea. *Curr Med Res Opin* 1984; **9:** 329–38.

Substance dependence. An early review[1] concluded that the role of tiapride in acute *alcohol* withdrawal (p.1626) was likely to be limited as patients at risk of severe reactions would still require adjunctive therapy for the control of hallucinations and seizures. Following detoxification, tiapride appeared to help, to some degree, to alleviate distress, improve abstinence and drinking behaviour, and facilitate reintegration within society.[2] Interest in its use with carbamazepine continues.[3-5]

Тиотиксена Гидрохлорид

$C_{23}H_{29}N_3O_2S_2,2HCl,2H_2O = 552.6.$

CAS — 58513-59-0 (anhydrous tiotixene hydrochloride); 49746-04-5 (anhydrous tiotixene hydrochloride, Z-isomer); 22189-31-7 (tiotixene hydrochloride dihydrate); 49746-09-0 (tiotixene hydrochloride dihydrate, Z-isomer).

ATC — N05AF04.

ATC Vet — QN05AF04.

Pharmacopoeias. In *US*, which permits both the dihydrate and the anhydrous form.

USP 31 (Thiothixene Hydrochloride). It is anhydrous ($C_{23}H_{29}N_3O_2S_2,2HCl = 516.5$) or contains two molecules of water of hydration. A white or practically white crystalline powder having a slight odour. Soluble 1 in 8 of water, 1 in 270 of dehydrated alcohol, and 1 in 280 of chloroform; practically insoluble in acetone, in ether, and in benzene. Store in airtight containers. Protect from light.

Stability. A combination of the stabilisers hydroxyquinoline sulfate and vanillin could protect tiotixene from photodegradation.[1]

1. Thoma K, Klimek R. Photostabilization of drugs in dosage forms without protection from packaging materials. *Int J Pharmaceutics* 1991; **67:** 169–75.

Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969. Tiotixene is less likely to cause sedation but extrapyramidal effects are more frequent.

Interactions

As for Chlorpromazine, p.973.

Pharmacokinetics

◊ In 15 adequately controlled schizophrenic patients receiving oral tiotixene 15 to 60 mg daily in 2, 3, or 4 divided doses, plasma concentrations were found to be in the relatively narrow range of 10 to 22.5 nanograms/mL 126 to 150 minutes after the last daily dose despite the fourfold difference in dosage.[1] Investigations in a further 5 patients indicated that peak plasma concentrations were obtained about 1 to 3 hours after a dose, indicating rapid absorption with an absorption half-time of about 30 minutes. There was an early plasma half-life of about 210 minutes and a late half-life of about 34 hours; resurgence of drug concentrations in some subjects might have been due to enterohepatic recycling.

1. Hobbs DC, *et al*. Pharmacokinetics of thiothixene in man. *Clin Pharmacol Ther* 1974; **16:** 473–8.

Metabolism. There has been a study[1] indicating that tiotixene may induce its own metabolism.

1. Bergling R, *et al*. Plasma levels and clinical effects of thioridazine and thiothixene. *J Clin Pharmacol* 1975; **15:** 178–86.

Uses and Administration

Tiotixene is a thioxanthene antipsychotic with general properties similar to those of the phenothiazine, chlorpromazine (p.975). It has a piperazine side-chain. It is used in the treatment of psychoses including schizophrenia (p.955). Tiotixene is given orally as the base or hydrochloride and by intramuscular injection as the hydrochloride. Doses are expressed in terms of the base. Tiotixene 1 mg is equivalent to about 1.2 mg of tiotixene hydrochloride.

The usual initial oral dose is 2 mg three times daily (or 5 mg twice daily in more severe conditions) gradually increasing to 20 to 30 mg daily if necessary; once-daily dosage may be adequate. In severe or resistant psychoses doses of up to 60 mg daily may be given. The usual initial intramuscular dose is 4 mg two to four times daily increased if necessary to a maximum of 30 mg daily.

Tiotixene should be given in reduced dosage to elderly or debilitated patients.

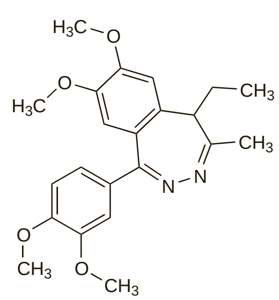
Tofisopam *(rINN)*

EGYT-341; Tofisopaami; Tofisopamum; Tofizopam. 1-(3,4-Dimethoxyphenyl)-5-ethyl-7,8-dimethoxy-4-methyl-5*H*-2,3-benzodiazepine.

Тофизопам

$C_{22}H_{26}N_2O_4$ = 382.5.
CAS — 22345-47-7.
ATC — N05BA23.
ATC Vet — QN05BA23.



Pharmacopoeias. In *Jpn.*

Profile

Tofisopam is a 2,3-benzodiazepine related structurally to the 1,4-benzodiazepines such as diazepam (p.986) and sharing some of the same actions. It is reported, however, to be largely lacking in the sedative, anticonvulsant, and muscle relaxant properties of the conventional benzodiazepines. Tofisopam has been given orally in the short-term treatment of anxiety disorders. The *R*-(+)-isomer, dextofisopam, is under investigation in the treatment of irritable bowel syndrome.

Proprietary Preparations (details are given in Part 3)
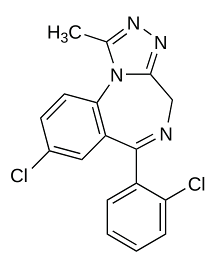
Multi-ingredient: ***Rus.:*** Tempalgin (Темпалгин); Tempanginol (Темпангинол).

Triazolam *(BAN, USAN, rINN)*

Clorazolam; Triatsolaami; Triazolamum; U-33030. 8-Chloro-6-(2-chlorophenyl)-1-methyl-4*H*-[1,2,4]triazolo[4,3-*a*][1,4]benzodiazepine.

Триазолам

$C_{17}H_{12}Cl_2N_4$ = 343.2.
CAS — 28911-01-5.
ATC — N05CD05.
ATC Vet — QN05CD05.



Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Triazolam). A white to off-white, practically odourless, crystalline powder. Practically insoluble in water and in ether; soluble 1 in 1000 of alcohol, 1 in 25 of chloroform, and 1 in 600 of 0.1N hydrochloric acid.

Dependence and Withdrawal

As for Diazepam, p.987.

Adverse Effects and Treatment

As for Diazepam, p.987.

Effects on the liver. A 44-year-old man developed severe pruritus with jaundice which subsequently proved fatal. Liver histology showed intense cholestasis. Triazolam was considered to be the most likely cause.[1]

1. Cobden I, *et al*. Fatal intrahepatic cholestasis associated with triazolam. *Postgrad Med J* 1981; **57:** 730–1.

Effects on mental function. The effects of triazolam on mental function have been controversial since van der Kroef first described in 1979 a range of symptoms including anxiety, amnesia, depersonalisation and derealisation, depression, paranoia, and severe suicidal tendencies that he had seen in 25 patients and attributed to triazolam.[1] This led to suspension of triazolam in the Netherlands (re-approved in 1990) and removal of the 1-mg tablet from other markets. Continued reporting of similar symptoms of cognitive impairment with triazolam resulted in withdrawal of the 500-microgram dosage form in several countries in 1987 and 1988 and in a gradual reduction of recommended dosage from 1 mg at night down to 125 to 250 micrograms at night. Triazolam was withdrawn from the UK[2] and some other markets in 1991. Opinion still remains divided over the adverse effects of triazolam, the main issues being its propensity to cause adverse effects relative to other benzodiazepines and whether its risk-benefit ratio is acceptable to justify its continued use.[3,4]

Others[5] have reviewed spontaneous adverse effects reported to the FDA in the USA for triazolam, temazepam, and flurazepam. Daytime sedation was noted with all three, but triazolam caused more agitation, confusion, hallucinations, and amnesia. Such effects occurred frequently with the 250-microgram dose as well as with the 500-microgram dose. Similar results were obtained after analysis of reports for triazolam and temazepam in the first 7 years of marketing, although the possibility that selection factors were producing higher reporting rates for triazolam could not be entirely excluded.[6] A study[7] gave triazolam 500 micrograms, lormetazepam 2 mg, or placebo, to groups of 40 patients for 25 nights and observed the greatest frequency of daytime anxiety, panic, derealisation, and paranoia with triazolam. Another[8] found a greater total number of reports of memory impairment or amnesia after nightly doses of triazolam 500 micrograms compared with temazepam 30 mg. Triazolam also impaired delayed, but not immediate, memory recall. Similar cases of memory impairment occurring with triazolam at doses of 125 and 250 micrograms have reportedly been submitted to the UK CSM.[2] The emergence of daytime symptoms after more than a few days' treatment with triazolam could be attributed to rebound or withdrawal phenomena occurring as a result of rapid elimination of the drug.

As regards the risk-benefit ratio of triazolam some workers have questioned the hypnotic efficacy of the drug at a dose of 250 micrograms and consider that reduction of the dose has decreased efficacy more than adverse effects.[3]

In defence of triazolam, the FDA and the manufacturers (*Upjohn*) have considered epidemiological studies which, unlike the FDA spontaneous reporting scheme, have been unable to demonstrate a substantial difference in its adverse effects compared with other benzodiazepines except, perhaps, in the incidence of amnesia.[9] Retrospective studies[10,11] claiming similar findings have been the subject of criticism.[12-14] Other workers have cited studies indicating benefit of triazolam 250 micrograms for the treatment of insomnia.[15] A review by the US Institute of Medicine found that triazolam was safe when given in a dose of 250 micrograms daily for 7 to 10 days but called for studies of lower doses and of long-term use.[16]

Precautions

As for Diazepam, p.988.

Hepatic impairment. Cirrhosis decreased the apparent oral clearance of triazolam to an extent depending on the severity of the liver disease.[1] An initial dose of 125 micrograms was suggested for patients with severe liver dysfunction. It was suggested that the relative lack of effect that mild to moderate cirrhosis had on the metabolism of oral triazolam might be due to some first-pass metabolism occurring in the intestinal wall.[2]

1. Kroboth PD, *et al*. Nighttime dosing of triazolam in patients with liver disease and normal subjects: kinetics and daytime effects. *J Clin Pharmacol* 1987; **27:** 555–60.
2. Robin DW, *et al*. Triazolam in cirrhosis: pharmacokinetics and pharmacodynamics. *Clin Pharmacol Ther* 1993; **54:** 630–7.

Renal impairment. Peak plasma-triazolam concentrations were lower in 11 dialysis patients compared with 11 controls.[1] It was postulated that a relatively high basal gastric acid secretion in dialysis patients could result in hydrolysis and opening of the ring structure of triazolam effectively reducing its systemic availability. Giving an antacid could reverse this effect. Renal failure had no other effect on the pharmacokinetics of triazolam which could probably be given in usual doses.

1. Kroboth PD, *et al.* Effects of end stage renal disease and aluminium hydroxide on triazolam pharmacokinetics. *Br J Clin Pharmacol* 1985; **19:** 839–42.

Interactions

As for Diazepam, p.989.

Pharmacokinetics

Triazolam is rapidly and nearly completely absorbed from the gastrointestinal tract, peak plasma concentrations being achieved within 2 hours of an oral dose. Triazolam has a plasma elimination half-life ranging from 1.5 to 5.5 hours. It is reported to be about 89% bound to plasma proteins. Hydroxylation of triazolam in the liver is mediated by the cytochrome P450 isoenzyme CYP3A4. Triazolam is excreted in the urine mainly in the form of its conjugated metabolites with only small amounts appearing unchanged.

Uses and Administration

Triazolam is a short-acting benzodiazepine with general properties similar to those of diazepam (p.992). It is used as a hypnotic in the short-term management of insomnia (p.957) in oral doses of 125 to 250 micrograms at night for no more than 2 weeks; doses of up to 500 micrograms at night have been used for resistant cases but these may be associated with an increased risk of severe adverse effects (see Effects on Mental Function, above). Initial doses of 125 micrograms at night have been suggested for elderly or debilitated subjects, increased up to a maximum of 250 micrograms only if necessary.

Administration in hepatic or renal impairment. See under Precautions, above.

Preparations

USP 31: Triazolam Tablets.

Triclofos Sodium *(BANM, USAN, rINNM)*

Natrii Triclofosum; Sch-10159; Sodium Triclofos; Triclofós sódico; Triclofos Sodique. Sodium 2,2,2-trichloroethyl hydrogen orthophosphate.

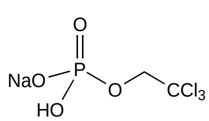
Натрий Триклофос

$C_2H_3Cl_3NaO_4P$ = 251.4.

CAS — 306-52-5 (triclofos); 7246-20-0 (triclofos sodium).

ATC — N05CM07.

ATC Vet — QN05CM07.



Pharmacopoeias. In *Br.* and *Jpn.*

BP 2008 (Triclofos Sodium). A white or almost white, odourless or almost odourless, hygroscopic powder. Freely soluble in water; slightly soluble in alcohol; practically insoluble in ether. A 2% solution in water has a pH of 3.0 to 4.5.

Dependence and Withdrawal, Adverse Effects, Treatment, and Precautions

As for Cloral Hydrate, p.979 but causes fewer gastrointestinal disturbances. Also, triclofos sodium is not corrosive to skin and mucous membranes.

Interactions

As for Cloral Hydrate, p.979.

Pharmacokinetics

Triclofos sodium is rapidly hydrolysed to trichloroethanol, peak serum concentrations being achieved within about one hour after oral dosage. For the pharmacokinetics of trichloroethanol, see Cloral Hydrate, p.979.

Uses and Administration

Triclofos sodium has hypnotic and sedative actions similar to those of cloral hydrate (p.979) but it is more palatable and causes less gastric irritation. It is used similarly in the short-term management of insomnia (p.957) and for sedation of children before painless procedures; however, its use as a hypnotic, particularly in children, is now limited.

The usual adult dose as a hypnotic is 1 to 2 g orally at night. A suggested hypnotic dose for children 1 month to 1 year of age is 25 to 30 mg/kg; children aged 1 to 5 years may be given single doses of 250 to 500 mg, and children aged 6 to 12 years may be given single doses of 0.5 to 1 g. Although not licensed in the UK for sedation of children before painless procedures, the *BNFC* suggests that those aged 1 month to 18 years may be given 30 to 50 mg/kg (maximum of 2 g) 45 to 60 minutes before the procedure; up to 100 mg/kg (maximum of 2 g) may be used with respiratory monitoring.

Preparations

BP 2008: Triclofos Oral Solution.

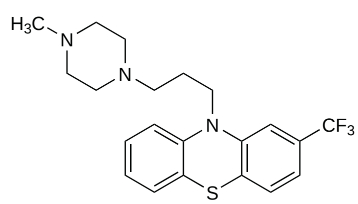
Трифлуоперазина Гидрохлорид

$C_{21}H_{24}F_3N_3S,2HCl$ = 480.4.

CAS — 117-89-5 (trifluoperazine); 440-17-5 (trifluoperazine hydrochloride).

ATC — N05AB06.

ATC Vet — QN05AB06.



(trifluoperazine)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Trifluoperazine Hydrochloride). A white to pale yellow, hygroscopic, crystalline powder. Freely soluble in water; soluble in alcohol; practically insoluble in ether. A 10% solution in water has a pH of 1.6 to 2.5. Protect from light.

USP 31 (Trifluoperazine Hydrochloride). A white to pale yellow, practically odourless, crystalline powder. Soluble 1 in 3.5 of water, 1 in 11 of alcohol, and 1 in 100 of chloroform; insoluble in ether and in benzene. pH of a 1 in 20 solution is between 1.7 and 2.6. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969. Trifluoperazine is less likely to cause sedation, hypotension, hypothermia, or antimuscarinic effects but is associated with a higher incidence of extrapyramidal effects particularly when the daily dose exceeds 6 mg.

Breast feeding. The American Academy of Pediatrics[1] considers that, although the effect of trifluoperazine on breast-fed infants is unknown, its use by mothers during breast feeding may be of concern since antipsychotic drugs do appear in breast milk and thus could conceivably alter CNS function in the infant both in the short and long term.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 29/04/04)

Interactions

As for Chlorpromazine, p.973.

Pharmacokinetics

Trifluoperazine hydrochloride is readily absorbed from the gastrointestinal tract after oral doses; peak plasma concentrations are attained 1.5 to 6 hours after ingestion and bioavailability is subject to interindividual variation. It is highly bound to plasma proteins. The elimination of trifluoperazine is multiphasic and the terminal half-life is about 22 hours. The major metabolite is the possibly active *N*-oxide. Other metabolites include the sulfoxide and the 7-hydroxy derivative. Trifluoperazine is distributed into breast milk.

Uses and Administration

Trifluoperazine is a phenothiazine antipsychotic with general properties similar to those of chlorpromazine (p.975). It has a piperazine side-chain.

Trifluoperazine is used in the treatment of a variety of psychiatric disorders including schizophrenia (p.955), severe anxiety (p.952), and disturbed behaviour (p.954). It is also used for the control of nausea and vomiting (p.1700).

Trifluoperazine is given as the hydrochloride but doses are expressed in terms of the base. Trifluoperazine 1 mg is equivalent to about 1.2 mg of trifluoperazine hydrochloride. A modified-release preparation is also available in some countries. Trifluoperazine should be given in reduced dosage to elderly or debilitated patients.

The usual initial *oral* dose for the treatment of schizophrenia and other **psychoses** is 2 to 5 mg twice daily, gradually increased to a usual range of 15 to 20 mg daily; in severe or resistant psychoses daily doses of 40 mg or more have been given. For the control of acute psychotic symptoms it may be given by deep *intramuscular* injection in a dose of 1 to 2 mg, repeated if necessary every 4 to 6 hours; more than 6 mg daily is rarely required. The initial oral dose for use in *children* is up to 5 mg daily in divided doses adjusted according to age, body-weight, and response, or 1 mg given once or twice daily by intramuscular injection.

For the control of **nausea and vomiting** the usual adult *oral* dose is 1 or 2 mg twice daily; up to 6 mg daily may be given in divided doses. *Children* aged 3 to 5 years may be given up to 1 mg daily in divided doses; this may be increased to a maximum of 4 mg daily in children aged 6 to 12 years.

When used as an adjunct in the short-term management of **severe anxiety disorders** doses are similar to those used for the control of nausea and vomiting.

Schizophrenia. A systematic review[1] of the use of trifluoperazine for schizophrenia (p.955) concluded that it appeared to be of similar efficacy to other commonly used classical antipsychotics with a similar profile of adverse effects. However, there did not appear to be good evidence for claims that it was effective for schizophrenia at low doses.

Pharmacopoeias. In *US.*

USP 31 (Triflupromazine Hydrochloride). A white to pale tan crystalline powder having a slight characteristic odour. Soluble 1 in less than 1 of water and of alcohol and 1 in 1.7 of chloroform; soluble in acetone; insoluble in ether. Store in glass containers. Protect from light.

Profile

Triflupromazine hydrochloride is a phenothiazine with general properties similar to those of chlorpromazine (p.969). It is used mainly in the management of psychoses (p.954) and the control of nausea and vomiting (p.1700). Triflupromazine hydrochloride is usually given by injection but in some countries oral preparations are available.

In the management of psychosis, the usual dose is 60 to 150 mg daily by intramuscular injection. For the control of nausea and vomiting 5 to 15 mg is given intramuscularly and repeated after 4 hours if necessary up to a maximum of 60 mg daily; a dose of 1 mg to a maximum total daily dose of 3 mg may be given intravenously.

A suggested intramuscular dose for children over 2⁄ years of age is 200 to 250 micrograms/kg daily up to a maximum of 10 mg daily.

Reduced doses should be used in elderly or debilitated patients.

Preparations

USP 31: Triflupromazine Hydrochloride Injection; Triflupromazine Hydrochloride Tablets; Triflupromazine Oral Solution.

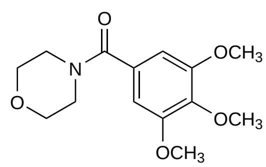
Trimetozine (USAN, rINN)

Abbott-22370; NSC-62939; PS-2383; Trimetozina; Trimétozine; Trimetozinum. 4-(3,4,5-Trimethoxybenzoyl)morpholine.

Триметоцин

$C_{14}H_{19}NO_5$ = 281.3.
CAS — 635-41-6.



Profile

Trimetozine has been used for its sedative properties.

Preparations

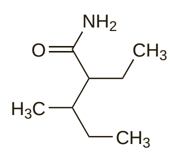
Proprietary Preparations (details are given in Part 3)
Hung.: Trioxazin.

Valnoctamide (USAN, rINN)

McN-X-181; NSC-32363; Valnoctamida; Valnoctamidum. 2-Ethyl-3-methylvaleramide.

Вальноктамид

$C_8H_{17}NO$ = 143.2.
CAS — 4171-13-5.
ATC — N05CM13.
ATC Vet — QN05CM13.



Profile

Valnoctamide, an isomer of valpromide (p.508), has been given orally in the treatment of anxiety disorders.

◊ References.

1. Bialer M, *et al.* Pharmacokinetics of a valpromide isomer, valnoctamide, in healthy subjects. *Eur J Clin Pharmacol* 1990; **38:** 289–91.
2. Barel S, *et al.* Stereoselective pharmacokinetic analysis of valnoctamide in healthy subjects and in patients with epilepsy. *Clin Pharmacol Ther* 1997; **61:** 442–9.

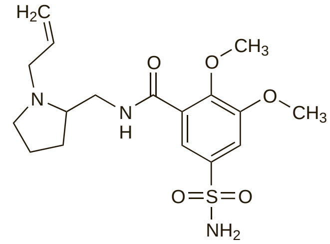
Interactions. For a discussion of the potential interaction between carbamazepine and valnoctamide, see Antiepileptics, p.474.

Veralipride (rINN)

Veraliprida; Véralipride; Veralipridum. *N*-[(1-Allyl-2-pyrrolidinyl)methyl]-5-sulphamoyl-2-veratramide.

Вералиприд

$C_{17}H_{25}N_3O_5S$ = 383.5.
CAS — 66644-81-3.
ATC — N05AL06.
ATC Vet — QN05AL06.



Profile

Veralipride is a substituted benzamide antipsychotic. It has been used in the treatment of cardiovascular and psychological symptoms associated with the menopause; the usual oral dose is 100 mg daily for 20 days repeated at intervals of 7 to 10 days. Preparations of veralipride have now been withdrawn from the market in some countries because of the opinion that there is an unacceptable balance of risks and benefits; adverse effects such as anxiety, depression, and tardive dyskinesia have been associated with veralipride, both during and after treatment.

Menopausal disorders. HRT with oestrogens is the mainstay of treatment for acute symptoms associated with the menopause (see p.2077) but when it is considered to be unsuitable a variety of other drugs including veralipride have been tried.[1] It has also been tried with raloxifene in postmenopausal women.[2] However, treatment with veralipride has been associated with extrapyramidal adverse effects.[3,4]

1. Young RL, *et al.* Management of menopause when estrogen cannot be used. *Drugs* 1990; **40:** 220–30.
2. Morgante G, *et al.* Veralipride administered in combination with raloxifene decreases hot flushes and improves bone density in early postmenopausal women. *Gynecol Endocrinol* 2004; **18:** 194–8.
3. Masmoudi K, *et al.* Troubles extrapyramidaux sous véralipride (Agréal), traitement symptomatique des bouffées de chaleur: à propos de 17 cas. *Rev Med Interne* 2005; **26:** 453–7.
4. Raja M, Azzoni A. Tardive dyskinesia after long-term veralipride treatment. *J Neuropsychiatr Clin Neurosci* 2005; **17:** 252–3.

Porphyria. Veralipride is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

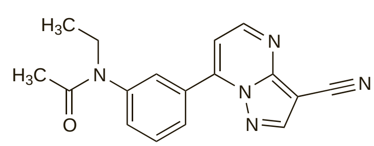
Zaleplon (BAN, USAN, rINN)

CL-284846; L-846; LJC-10846; Tsaleploni; ZAL-846; Zaleplón; Zaléplone; Zaleplonum. 3′-(3-Cyanopyrazolo[1,5-*a*]pyrimidin-7-yl)-*N*-ethylacetanilide.

Залеплон

$C_{17}H_{15}N_5O$ = 305.3.
CAS — 151319-34-5.
ATC — N05CF03.
ATC Vet — QN05CF03.



Dependence and Withdrawal

As for Diazepam, p.987.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987. Zaleplon should be used with caution and in reduced doses in patients with hepatic impairment, and should be avoided where this is severe.

Treatment of overdose is largely supportive. Activated charcoal may be given orally to patients who present within one hour of ingestion of more than 50 mg zaleplon by adults, or 1 mg/kg by children, provided that the airway can be protected. Flumazenil may be considered in cases of severe CNS depression.

◊ References.

1. Israel AG, Kramer JA. Safety of zaleplon in the treatment of insomnia. *Ann Pharmacother* 2002; **36:** 852–9.

Abuse. In a controlled study in healthy patients with a history of drug abuse, zaleplon was shown to have a comparable abuse potential to that of the benzodiazepine, triazolam.[1]

1. Rush CR, *et al.* Zaleplon and triazolam in humans: acute behavioral effects and abuse potential. *Psychopharmacology (Berl)* 1999; **145:** 39–51.

Breast feeding. Licensed product information for zaleplon advises that it should not be given to breast-feeding mothers since, although only a small amount is excreted into breast milk, the effect on the nursing infant is not known.

Zaleplon was detected in the breast milk of 5 women who had been given a 10-mg dose.[1] The milk-to-plasma concentration ratio for zaleplon was about 0.5.

1. Darwish M, *et al.* Rapid disappearance of zaleplon from breast milk after oral administration to lactating women. *J Clin Pharmacol* 1999; **39:** 670–4.

Effects on mental function. For reports of adverse effects on mental function, such as complex sleep-related behaviours, associated with some hypnotics including zaleplon, see under Zolpidem, below.

Hypersensitivity. For mention of anaphylactoid reactions associated with some hypnotics including zaleplon, see under Zolpidem, below.

Interactions

As for Diazepam, p.989. Zaleplon is primarily metabolised by aldehyde oxidase and use with inhibitors of this enzyme, such as cimetidine, may result in increased plasma concentrations of zaleplon (see Uses and Administration, below). Zaleplon is also partly metabolised by the cytochrome P450 isoenzyme CYP3A4 and, consequently, caution is advised when zaleplon is given with drugs that are substrates for, or potent inhibitors of, this isoenzyme. Cimetidine is also an inhibitor of CYP3A4 and thus inhibits both the primary and secondary metabolic pathways of zaleplon.

Use with rifampicin or other potent enzyme-inducing drugs may accelerate the metabolism of zaleplon and reduce its plasma concentrations.

Pharmacokinetics

Zaleplon is rapidly absorbed from the gastrointestinal tract with peak plasma concentrations reached in about one hour after oral dosage. A heavy meal or one with a high-fat content delays absorption and reduces peak concentrations. Bioavailability is about 30% due to significant first-pass hepatic metabolism. Zaleplon is metabolised primarily by aldehyde oxidase to form 5-oxo-zaleplon and, to a lesser extent, by the cytochrome P450 isoenzyme CYP3A4 to desethylzaleplon, which is further metabolised by aldehyde oxidase to 5-oxo-desethylzaleplon. The plasma-elimination half-life of zaleplon is about 1 hour. About 70% of a dose is excreted in the urine as these inactive metabolites or their glucuronides; less than 1% is excreted unchanged. About 17% of a dose is eliminated in the faeces, mainly as 5-oxo-zaleplon. Zaleplon is distributed into breast milk.

2. Drover D, *et al.* Pharmacokinetics, pharmacodynamics, and relative pharmacokinetic/pharmacodynamic profiles of zaleplon and zolpidem. *Clin Ther* 2000; **22:** 1443–61.
3. Drover DR. Comparative pharmacokinetics and pharmacodynamics of short-acting hypnosedatives: zaleplon, zolpidem and zopiclone. *Clin Pharmacokinet* 2004; **43:** 227–38.

Uses and Administration

Zaleplon is a pyrazolopyrimidine with similar sedative properties to the benzodiazepines (see Diazepam, p.992). It is used as a hypnotic in the short-term management of insomnia. Zaleplon has a rapid onset and short duration of action. The usual oral dose is 10 mg at bedtime although US product information notes that occasional patients may require 20 mg. Elderly or debilitated patients or those also taking cimetidine should be given 5 mg. For dosages in patients with hepatic impairment, see below.

Administration in hepatic impairment. The oral dose of zaleplon should be reduced to 5 mg at bedtime in patients with mild to moderate hepatic impairment; it should not be given to those with severe impairment.

Insomnia. Zaleplon is a pyrazolopyrimidine hypnotic. Although not related structurally to the benzodiazepines it appears to act by binding selectively to the benzodiazepine type I receptor (BZ1- or ω_1-receptors) on the GABA subtype A complex. Zaleplon reduces sleep latency but has little effect on sleep duration; it is rapidly absorbed and eliminated and consequently residual effects the next day are said to be minimal. These characteristics make it best suited for the treatment of patients with insomnia (p.957) who have difficulty falling asleep; zaleplon can either be taken at bedtime or during the night if a patient has trouble falling back to sleep, provided they are assured of at least 4 hours uninterrupted sleep.

CAS — 199191-69-0.
ATC — N05AE04.
ATC Vet — QN05AE04.

Adverse Effects, Treatment, and Precautions

Although ziprasidone may share some of the adverse effects seen with the classical antipsychotics (see Chlorpromazine, p.969), the incidence and severity of such effects may vary. Frequent adverse effects with ziprasidone include somnolence, rash or urticaria, gastrointestinal disturbances, dizziness, flu-like symptoms, hypertension, headache, agitation, confusion, and dyspnoea. Orthostatic hypotension may be a problem, particularly when starting treatment. Ziprasidone may increase prolactin levels and weight gain has also been noted. Sexual dysfunction has been reported infrequently. Extrapyramidal symptoms may occur, and tardive dyskinesia may develop with prolonged use. There have also been infrequent or rare cases of cholestatic jaundice, hepatitis, seizures, blood dyscrasias including leucopenia and thrombocytopenia, and hyperlipidaemia. Hyperglycaemia occurs uncommonly with ziprasidone. Clinical monitoring for hyperglycaemia has been recommended, especially in patients with, or at risk of, developing diabetes.

Ziprasidone has been associated with dose-related prolongation of the QT interval. Because of this and the consequent danger of life-threatening arrhythmias such as torsade de pointes and sudden death, its use is contra-indicated in patients with a history of QT prolongation or cardiac arrhythmias, with recent acute myocardial infarction, or with decompensated heart failure. Certain medications may also increase the risk (see Interactions, below). Baseline serum potassium and magnesium screening should be performed in patients who are at risk of significant electrolyte disturbances and hypokalaemia or hypomagnesaemia should be corrected before starting ziprasidone therapy. Serum electrolytes should be monitored in patients who start diuretic therapy during ziprasidone treatment. Patients receiving ziprasidone who have symptoms that might indicate torsade de pointes (e.g. dizziness, palpitations, or syncope) should be further evaluated.

Ziprasidone should be used with caution in patients with a history of seizures or in conditions that lower the seizure threshold, cardiovascular or cerebrovascular disease, or conditions which predispose to hypotension. Since intramuscular injections are formulated with cyclodextrin, which is cleared by renal filtration, the manufacturer recommends caution in patients with renal impairment.

Ziprasidone may affect the performance of skilled tasks including driving.

Dementia. The FDA[1] has issued advice against the use of atypical antipsychotics, including ziprasidone, in the treatment of behavioural problems in elderly patients with dementia after analysis of placebo-controlled studies showed an increased risk of mortality with certain drugs of this class. See under Risperidone, p.1024.

1. Food and Drug Administration. FDA issues public health advisory for antipsychotic drugs used for treatment of behavioral disorders in elderly patients (issued 11/04/05). Available at: http://www.fda.gov/bbs/topics/ANSWERS/2005/ANS01350.html (accessed 30/05/05)

Effects on body-weight. The increased risk of weight gain with some atypical antipsychotics is discussed under Adverse Effects of Clozapine, p.981.

Effects on carbohydrate metabolism. The increased risk of glucose intolerance and diabetes mellitus with some atypical antipsychotics, and recommendations on monitoring, are discussed under Adverse Effects of Clozapine, p.981.

Effects on lipid metabolism. The increased risk of hyperlipidaemia with some atypical antipsychotics is discussed under Adverse Effects of Chlorpromazine, p.970. See also Effects on Carbohydrate Metabolism under Adverse Effects of Clozapine, p.981.

Extrapyramidal disorders. There have been reports[1-3] of tardive dyskinesia associated with ziprasidone therapy; onset ranged from 2 to 34 months after starting the drug. Acute dystonia has also been reported[4,5] with ziprasidone. However, the incidence of extrapyramidal adverse effects (p.971) is generally lower with atypical than classical antipsychotics.

1. Rosenquist KJ, *et al.* Tardive dyskinesia and ziprasidone. *Am J Psychiatry* 2002; **159:** 1436.
2. Keck ME, *et al.* Ziprasidone-related tardive dyskinesia. *Am J Psychiatry* 2004; **161:** 175–6.
3. Ananth J, *et al.* Tardive dyskinesia in 2 patients treated with ziprasidone. *J Psychiatry Neurosci* 2004; **29:** 467–9.
4. Ziegenbein M, *et al.* Ziprasidone-induced Pisa syndrome after clozapine treatment. *J Neuropsychiatr Clin Neurosci* 2003; **15:** 458–9.
5. Mason MN, *et al.* Ziprasidone-induced acute dystonia. *Am J Psychiatry* 2005; **162:** 625–6.

Mania. Although it is used in the treatment of bipolar disorder, ziprasidone has been associated with reports of mania in bipolar patients, see under Uses and Administration, below.

Neuroleptic malignant syndrome. Neuroleptic malignant syndrome (NMS— p.972) has been associated with ziprasidone;[1] however, the patient had also received lithium, a drug that has been associated with NMS.

1. Borovicka MC, *et al.* Ziprasidone- and lithium-induced neuroleptic malignant syndrome. *Ann Pharmacother* 2006; **40:** 139–42.

Pregnancy. For comments on the use of some atypical antipsychotics, including ziprasidone, during pregnancy, see under Precautions of Clozapine, p.983.

US licensed drug information states that ziprasidone demonstrated possible teratogenic effects in some *animals*; it was noted that there are no adequate and well-controlled studies in human pregnancy. Ziprasidone should only be used if the benefits to the mother outweigh the risks to the fetus.

Interactions

Use of ziprasidone with other drugs known to prolong the QT interval is contra-indicated because of the increased risk of arrhythmias. Monitoring of serum electrolytes is recommended if ziprasidone is given with diuretics.

The metabolism of ziprasidone is mediated by the cytochrome P450 isoenzyme CYP3A4. Therefore, there is the potential for interactions between ziprasidone and other drugs that induce, inhibit, or act as a substrate for this enzyme.

Ziprasidone may enhance the effects of other CNS depressants and certain antihypertensives; it may antagonise the effects of levodopa and dopaminergics.

Pharmacokinetics

Ziprasidone is well absorbed from the gastrointestinal tract with peak plasma concentrations being reached 6 to 8 hours after oral doses. The presence of food may double the absorption. Following intramuscular injection, peak plasma concentrations are reached within 1 hour. Plasma protein binding is about 99%. Ziprasidone is extensively metabolised by aldehyde oxidase (about 66% of a dose) and by the cytochrome P450 isoenzyme CYP3A4. The mean terminal elimination half-life has been reported to be about 7 hours after oral dosage and about 2 to 5 hours after intramuscular dosage. Ziprasidone is excreted mainly as metabolites in the faeces (about 66%) and urine (about 20%); less than 5% of a dose appears as unchanged drug.

3. Preskorn SH. Pharmacokinetics and therapeutics of acute intramuscular ziprasidone. *Clin Pharmacokinet* 2005; **44:** 1117–33.

Uses and Administration

Ziprasidone is an atypical antipsychotic reported to have affinity for adrenergic (α_1), histamine (H_1), and serotonin (5-HT_2) receptors as well as dopamine (D_2) receptors. It is used for the treatment of schizophrenia and in acute manic or mixed episodes associated with bipolar disorder. Ziprasidone is given by mouth usually as the hydrochloride; it is also given parenterally as the mesilate. Doses are expressed in terms of the base; ziprasidone hydrochloride 11.3 mg or ziprasidone mesilate 13.6 mg are each equivalent to about 10 mg of ziprasidone.

For the treatment of **schizophrenia**, ziprasidone hydrochloride is given in an initial oral dose of 20 mg twice daily with food. Doses may be increased if necessary at intervals of not less than 2 days up to 80 mg twice daily. For maintenance, doses as low as 20 mg twice daily may be effective.

For acute agitation in patients with schizophrenia, ziprasidone may be given as the mesilate by intramuscular injection. The recommended dose is 10 to 20 mg as required, up to a maximum of 40 mg daily for 3 consecutive days. Doses of 10 mg may be given every 2 hours and doses of 20 mg may be given every 4 hours. Patients should be switched to oral therapy as soon as possible.

For the treatment of **mania**, ziprasidone hydrochloride is given in an initial oral dose of 40 mg twice daily with food. The dose should be increased to 60 or 80 mg twice daily on the second day of treatment and subsequently adjusted according to tolerance.

Bipolar disorder. Ziprasidone is effective in the management of acute mania in patients with bipolar disorder[1] but it may also be associated with the induction of mania or hypomania in such patients.[2]

1. Keck PE, *et al.* Ziprasidone in the treatment of acute bipolar mania: a three-week, placebo-controlled, double-blind, randomized trial. *Am J Psychiatry* 2003; **160:** 741–8.
2. Baldassano CF, *et al.* Ziprasidone-associated mania: a case series and review of the mechanism. *Bipolar Disord* 2003; **5:** 72–5.

Schizophrenia. A systematic review[1] of the effectiveness and safety of ziprasidone in patients with schizophrenia (p.955) found that from the limited data available ziprasidone was as effective as haloperidol; it was less likely to provoke extrapyramidal disorders but appeared to cause more nausea and vomiting, and pain at the site of injection. Comparisons with other atypical antipsychotics were lacking. A comparative study[2] of intramuscular ziprasidone with intramuscular haloperidol also found a favourable outcome in patients with acute psychoses.

1. Bagnall A, *et al.* Ziprasidone for schizophrenia and severe mental illness. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2000 (accessed 20/10/05).
2. Brook S, *et al.* Intramuscular ziprasidone compared with intramuscular haloperidol in the treatment of acute psychosis. *J Clin Psychiatry* 2000; **61:** 933–41.

Tourette's syndrome. When drug treatment is required for tics and behavioural disturbances in Tourette's syndrome (p.954), haloperidol or pimozide are commonly used but atypical antipsychotics such as ziprasidone are increasingly being tried.[1]

1. Sallee FR, *et al.* Ziprasidone treatment of children and adolescents with Tourette's syndrome: a pilot study. *J Am Acad Child Adolesc Psychiatry* 2000; **39:** 292–9.

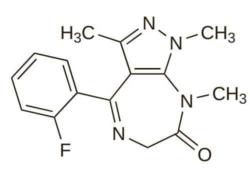
Zolazepam Hydrochloride *(BANM, USAN, rINNM)*

CI-716; Hidrocloruro de zolazepam; Zolazépam, Chlorhydrate de; Zolazepami Hydrochloridum. 4-(*o*-Fluorophenyl)-6,8-dihydro-1,3,8-trimethylpirazole[3,4-e][1,4]diazepin-7(1*H*)-one monohydrochloride.

Золазепама Гидрохлорид

$C_{15}H_{15}FN_4O,HCl$ = 322.8.

CAS — 31352-82-6 (zolazepam); 33754-49-3 (zolazepam hydrochloride).



(zolazepam)

Pharmacopoeias. In *US* for veterinary use only.

USP 31 (Zolazepam Hydrochloride). A white to off-white crystalline powder. Freely soluble in water and in 0.1N hydrochloric acid; slightly soluble in chloroform; practically insoluble in ether; soluble in methyl alcohol. pH of a 10% solution in water is between 1.5 and 3.5. Store in airtight containers.

Profile

Zolazepam hydrochloride is a benzodiazepine with general properties similar to those of diazepam (p.992). It is used with tiletamine (p.1796) for general anaesthesia in veterinary medicine.

Zolpidem Tartrate *(BANM, USAN, rINNM)*

SL-80.0750 (zolpidem); SL-80.0750-23N; Tartrato de zolpidem; Tsolpideemitartraatti; Zolpidem Hemitartrate; Zolpidem, tartrate de; Zolpidemi tartras; Zolpidemo tartratas; Zolpidem-tartarát; Zolpidemtartrat; Zolpidemu winian. *N,N*-Dimethyl-2-(6-methyl-2-*p*-tolylimidazo[1,2-*a*]pyridin-3-yl)acetamide hemitartrate.

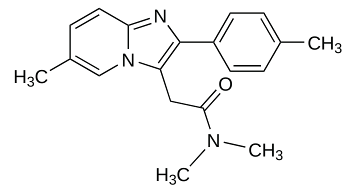
Золпидема Тартрат

$(C_{19}H_{21}N_3O)_2,C_4H_6O_6$ = 764.9.

CAS — 82626-48-0 (zolpidem); 99294-93-6 (zolpidem tartrate).

ATC — N05CF02.

ATC Vet — QN05CF02.



(zolpidem)

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of zolpidem tartrate: Sleepeasy; Tic-Tacs.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Zolpidem Tartrate). A white or almost white hygroscopic crystalline powder. Slightly soluble in water; practically insoluble in dichloromethane; sparingly soluble in methyl alcohol. Store in airtight containers. Protect from light.

Dependence and Withdrawal

As for Diazepam, p.987.

Withdrawal symptoms. A 37-year-old man, who increased his dose from 10 mg to 130 mg daily over 2 months, had a generalised tonic-clonic seizure after zolpidem was abruptly stopped.[1] The patient recovered after being started on a benzodiazepine dosage tapering programme. Symptoms attributed to daytime abstinence after excessive night-time doses have been reported[2] in 2 patients and included anxiety, tremor, sweating, nausea, gastric and abdominal pain, swallowing difficulties, tachycardia, and tachypnoea. The patients had increased their doses because of the development of tolerance to the hypnotic effect but had begun to experience muscle twitches and myoclonic jerks.

1. Gilbert DL, Staats PS. Seizure after withdrawal from supratherapeutic doses of zolpidem tartrate, a selective omega I benzodiazepine receptor agonist. *J Pain Symptom Manage* 1997; **14:** 118–20.
2. Cavallaro R, *et al.* Tolerance and withdrawal with zolpidem. *Lancet* 1993; **342:** 374–5.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987.

Treatment of overdose is largely supportive. Activated charcoal may be given orally within one hour of ingestion of 100 mg zolpidem or more by adults, or more than 5 mg by children. Alternatively, gastric lavage may be considered in adults if they present within 1 hour of a potentially life-threatening overdose. Flumazenil may be considered in cases of severe CNS depression (see also Overdosage, below).

◊ Reviews.

1. Darcourt G, *et al.* The safety and tolerability of zolpidem—an update. *J Psychopharmacol* 1999; **13:** 81–93.

Abuse. Zolpidem abuse has been reported;[1,2] effects noted include a paradoxical stimulant effect when taking large doses of zolpidem. Tolerance may also develop. Intravenous abuse has also been reported.[3]

3. Brunelle E, *et al.* Zolpidem: intravenous misuse in drug abusers. *Addiction* 2005; **100:** 1377–8.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving zolpidem, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding.

In 5 women given a 20-mg dose of zolpidem, the amount of drug excreted in breast milk after 3 hours ranged between 0.76 and

3.88 micrograms, which represented 0.004 to 0.019% of the dose.[2] No detectable (below 0.5 nanograms/mL) zolpidem was found in subsequent milk samples.

Effects on the liver. Hepatitis developed on 2 separate occasions in a 53-year-old woman after the use of zolpidem for insomnia.[1]

1. Karsenti D, *et al.* Hepatotoxicity associated with zolpidem treatment. *BMJ* 1999; **318:** 1179.

Effects on mental function. Psychotic reactions, which may not subsequently be recalled, have been reported in patients taking therapeutic doses of zolpidem.[1-4] Somnambulism has also been reported with zolpidem.[5,6] Other complex sleep-related behaviours, such as eating or driving while asleep, have been reported with zaleplon,[7] zolpidem,[6,7] and zopiclone. Such behaviour is more likely to occur when these drugs are taken with alcohol or other CNS depressants, or when taken in doses exceeding the recommended maximum. It is not clear if there are differences in risk with individual drugs; however, as a precautionary measure, the FDA[8] had requested for labelling changes that highlight these adverse effects to be made to all hypnotics marketed in the USA.

Hypersensitivity. Rare cases of angioedema involving the tongue, glottis, or larynx have been reported after the first or subsequent doses of hypnotics such as eszopiclone, zaleplon, zolpidem, and zopiclone; additional symptoms suggestive of anaphylaxis have also developed in some patients.

Overdosage. A retrospective analysis of 344 cases of acute overdosage with zolpidem reported to the Paris Poison Center and the manufacturers *Synthelabo* has been published.[1] The ingested dose, where known, ranged from 10 to 1400 mg, and the most common adverse effect was drowsiness (in 89 patients). Other adverse effects probably associated with the overdosage included coma in 4 patients and vomiting in 7. Recovery was usually rapid when overdosage involved only zolpidem. It was recommended that patients who had ingested more than 100 mg of zolpidem should undergo gastric lavage and should be monitored for at least 12 hours (see also above). Although it has been shown that flumazenil[2] can effectively antagonise the CNS effects of zolpidem the authors of this analysis[1] found that in general it was not required.

2. Patat A, *et al.* Flumazenil antagonizes the central effects of zolpidem, an imidazopyridine hypnotic. *Clin Pharmacol Ther* 1994; **56:** 430–6.

Interactions

As for Diazepam, p.989.

Antidepressants. A 16-year-old girl who had been taking *paroxetine* 20 mg daily for 3 days began to hallucinate and became disorientated one hour after taking zolpidem 10 mg at night. The delirium cleared spontaneously 4 hours later without treatment.[1] When questioned, at least one other of the author's patients receiving this combination reported transient visual hallucinations. Other isolated cases of visual hallucinations have been reported in patients taking zolpidem with antidepressants including *bupropion*, *desipramine*, *fluoxetine*, *sertraline*, and *venlafaxine*.[2]

2. Elko CJ, *et al.* Zolpidem-associated hallucinations and serotonin reuptake inhibition: a possible interaction. *J Toxicol Clin Toxicol* 1998; **36:** 195–203.

Antiepileptics. A 47-year-old man with a history of bipolar disorder, who was receiving citalopram and zolpidem, had episodes of somnambulism after he was also given *valproic acid* for treatment of manic symptoms.[1] The episodes stopped on withdrawal of valproic acid and returned on rechallenge. An interaction between zolpidem and valproic acid was suspected (but somnambulism has also been associated with zolpidem alone, see Effects on Mental Function, above).

For the suggestion that *carbamazepine* and *phenytoin* may interact with zolpidem, see Rifampicin, below.

1. Sattar SP, *et al.* Somnambulism due to probable interaction of valproic acid and zolpidem. *Ann Pharmacother* 2003; **37:** 1429–33.

Antifungals. Use of *ketoconazole* with zolpidem has resulted in increased plasma concentrations, and an enhanced sedative effect, of zolpidem, albeit only modest.[1] The use of zolpidem with *fluconazole*[1] or *itraconazole*[1,2] has resulted in small, non-significant changes in the pharmacokinetics and sedative effects of zolpidem.

1. Greenblatt DJ, *et al.* Kinetic and dynamic interaction study of zolpidem with ketoconazole, itraconazole, and fluconazole. *Clin Pharmacol Ther* 1998; **64:** 661–71.
2. Luurila H, *et al.* Effect of itraconazole on the pharmacokinetics and pharmacodynamics of zolpidem. *Eur J Clin Pharmacol* 1998; **54:** 163–6.

Antivirals. HIV-protease inhibitors such as *ritonavir* may increase plasma concentrations of zolpidem with a risk of extreme sedation and respiratory depression; use together is possible provided the patient is carefully monitored for excessive sedative effects.

Rifampicin. Rifampicin reduced the hypnotic effect of zolpidem in a study in 8 healthy female subjects.[1] The area under the curve for zolpidem was reduced by 73% after rifampicin and the peak plasma concentration by 58%. The elimination half-life of zolpidem was reduced from 2.5 to 1.6 hours. Similar effects could be expected with other potent inducers of the cytochrome P450 isoenzyme CYP3A4 such as carbamazepine and phenytoin.

1. Villikka K, *et al.* Rifampin reduces plasma concentrations and effects of zolpidem. *Clin Pharmacol Ther* 1997; **62:** 629–34.

Pharmacokinetics

Zolpidem is rapidly absorbed from the gastrointestinal tract after oral doses, peak plasma concentrations being reached within 3 hours. Zolpidem undergoes first-pass metabolism and an absolute bioavailability of about 70% has been reported. Zolpidem has an elimination half-life of about 2.5 hours and is about 92% bound to plasma proteins. It is metabolised primarily by the cytochrome P450 isoenzyme CYP3A4; the inactive metabolites of zolpidem are excreted in the urine and faeces. Zolpidem is distributed into breast milk.

Uses and Administration

Zolpidem tartrate is an imidazopyridine that is reported to have similar sedative properties to the benzodiazepines (see Diazepam, p.992), but minimal anxiolytic, muscle relaxant, and anticonvulsant properties. It has a rapid onset and short duration of action, and is used as a hypnotic in the short-term management of insomnia. The usual oral dose is 10 mg taken immediately before retiring. In elderly or debilitated patients, treatment should be limited to a dose of 5 mg at night. Doses should also be reduced in patients with hepatic impairment, see below. A modified-release formulation of zolpidem tartrate is also available.

Administration in hepatic impairment. In patients with hepatic impairment, treatment with immediate-release formulations of zolpidem tartrate should be started with a dose of 5 mg at night; the dose may be increased to 10 mg, if necessary, in those under 65 years. UK licensed product information contraindicates the use of zolpidem in patients with severe impairment.

Catatonia. Anecdotal reports[1,2] suggesting that zolpidem may be a useful test in the diagnosis of catatonia.

1. Thomas P, *et al.* Test for catatonia with zolpidem. *Lancet* 1997; **349:** 702.

Insomnia. Zolpidem is an imidazopyridine with strong sedative actions, but only minor anxiolytic, muscle relaxant, or anticonvulsant properties. Some degree of amnesia has been reported. Zolpidem appears to act by binding to the benzodiazepine receptor component of the GABA receptor complex. It has, however, a selective affinity for the subtype of benzodiazepine receptors prevalent in the cerebellum (BZ1- or ω_1-receptors) as opposed to those more commonly found in the spinal cord (BZ2- or ω_2-receptors) or in the peripheral tissues (BZ3- or ω_3-receptors). Zolpidem has a rapid onset and short duration of hypnotic action and at usual doses decreases time to sleep onset and increases duration of sleep with little apparent effect on sleep stages (see Insomnia, p.957). Reviews agree that clinical studies have shown zolpidem to have hypnotic activity superior to placebo and generally similar to comparative benzodiazepines. Although it does not appear to produce rebound insomnia to any great extent, there appears to be little evidence that zolpidem offers any advantage over short-acting benzodiazepines in terms of residual effects the next day, or its potential to induce tolerance or withdrawal symptoms or dependence (see also under Dependence and Withdrawal, above).

Parkinsonism. Although preliminary findings[1] in 10 patients suggested that zolpidem might improve symptoms of Parkinson's disease concern has been expressed[2] over the risk of falls associated with zolpidem-induced drowsiness and the serious consequences for these patients. Benefit has also been reported[3] in the treatment of antipsychotic-induced parkinsonism in one patient with symptoms of repetitive persistent gross tremors of the hands.

Zopiclone *(BAN, rINN)*

27267-RP; Tsopikloni; Zopiclona; Zopiclonum; Zopiklon; Zopiklonas. 6-(5-Chloro-2-pyridyl)-6,7-dihydro-7-oxo-5*H*-pyrrolo[3,4-*b*]pyrazin-5-yl 4-methylpiperazine-1-carboxylate.

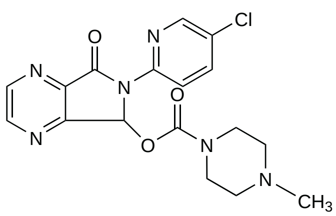
Зопиклон

$C_{17}H_{17}ClN_6O_3$ = 388.8.

CAS — 43200-80-2.

ATC — N05CF01.

ATC Vet — QN05CF01.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of zopiclone: Zoppies.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Zopiclone). A white or slightly yellowish powder. Practically insoluble in water and in alcohol; sparingly soluble in acetone; freely soluble in dichloromethane. It dissolves in dilute mineral acids. Protect from light.

Dependence and Withdrawal

As for Diazepam, p.987.

◊ There have been reports[1,2] of zopiclone dependence and associated withdrawal symptoms on dosage reduction or cessation of use. However, a 67-year-old man who increased his dosage of zopiclone up to 337.5 mg daily to treat insomnia without apparent adverse effects, had his zopiclone withdrawn without severe complications over 4 weeks using drug and cognitive therapy.[3] A WHO expert committee[4] considered in 2006 that the likelihood of zopiclone abuse was low and not great enough to warrant international control.

4. WHO. WHO expert committee on drug dependence: thirty-fourth report. *WHO Tech Rep Ser 942* 2006. Also available at: http://libdoc.who.int/trs/WHO_TRS_942_eng.pdf (accessed 06/08/08)

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987. A bitter or metallic taste in the mouth has been the most frequently reported adverse effect with zopiclone.

Treatment of overdose is largely supportive. Activated charcoal may be given orally within one hour of ingestion of more than 150 mg zopiclone by adults, or 1.5 mg/kg by children. Alternatively gastric lavage may be considered in adults if they present within 1 hour of a potentially life-threatening overdose. Flumazenil has been used in cases of severe CNS depression (see also Overdosage, below).

Incidence of adverse effects. In a French postmarketing survey[1] of 20 513 patients treated with zopiclone the most commonly reported adverse events were bitter taste (3.6%), dry mouth (1.6%), difficulty arising in the morning (1.3%), sleepiness (0.5%), nausea (0.5%) and nightmares (0.5%). The UK CSM[2] had received 122 reports of adverse reactions to zopiclone over a period of about one year since the product's introduction in November 1989. A fifth of these were neuropsychiatric reactions, a proportion similar to that found with other hypnotics. Many of these reactions were potentially serious and involved hallucinations (3 auditory and 2 visual), amnesia (4 cases), and behavioural disturbances (10, including 3 cases of aggression). Most reactions started immediately or shortly after the first dose and improved rapidly on stopping the drug. Three patients had difficulty in stopping treatment, 2 because of withdrawal symptoms and one due to repeated rebound insomnia. The CSM considered that, although differing structurally from the benzodiazepines, zopiclone has the same potential for adverse psychiatric reactions, including dependence. As with the benzodiazepines it should be reserved for patients with severe sleep disturbance and its duration of use limited to 28 days; care should also be taken in the elderly, those who have a history of previous psychiatric illness, or who are prone to drug abuse.

1. Allain H, *et al.* Postmarketing surveillance of zopiclone in insomnia: analysis of 20,513 cases. *Sleep* 1991; **14:** 408–13.
2. Committee on Safety of Medicines. Zopiclone (Zimovane) and neuro-psychiatric reactions. *Current Problems 30* 1990.

Abuse. For a report of zopiclone abuse see under Dependence and Withdrawal, above.

Administration. Results in 9 healthy subjects given zopiclone indicated a significant delay in onset of action when the drug was taken in the supine, as opposed to the standing, position; this was associated with a prolongation of more than 20 minutes in the lag time before absorption began.[1] In order to obtain a rapid and complete hypnotic effect from zopiclone the tablet should be swallowed in the standing position.

1. Channer KS, *et al.* The effect of posture at the time of administration on the central depressant effects of the new hypnotic zopiclone. *Br J Clin Pharmacol* 1984; **18:** 879–86.

Driving. For reference to the increased risk of road-traffic accidents for drivers taking zopiclone, see p.988.

Effects on mental function. For reports of adverse effects on mental function, such as complex sleep-related behaviours, associated with some hypnotics including zopiclone, see under Zolpidem, above.

Hepatic impairment. Zopiclone was given in a dose of 7.5 mg to 7 cirrhotic patients and 8 healthy subjects; a further 2 cirrhotic patients received 3.75 mg.[1] Mean peak plasma concentrations were similar in healthy subjects and those with hepatic impairment following equivalent doses but time to peak plasma concentration was 4 hours in the latter as compared with 2 hours in the healthy subjects. Elimination was greatly prolonged in cirrhotic patients, in whom the mean plasma half-life was 8.53 hours compared with 3.5 hours. The CNS-depressant effects of zopiclone were delayed in the cirrhotic patients in a way consistent with the pharmacokinetic changes. There was also some evidence of an increased response in these patients. The authors recommended caution when giving zopiclone to patients with severe hepatic disease; licensed product information contra-indicates the use of zopiclone in such patients.

1. Parker G, Roberts CJC. Plasma concentrations and central nervous system effects of the new hypnotic agent zopiclone in patients with chronic liver disease. *Br J Clin Pharmacol* 1983; **16:** 259–65.

Hypersensitivity. For mention of anaphylactoid reactions associated with some hypnotics including zopiclone, see under Zolpidem, above.

Overdosage. Consciousness was rapidly regained after intravenous flumazenil was given to a patient who had taken an overdosage of zopiclone.[1] However, fatalities after zopiclone overdose have also been reported.[2,3]

1. Ahmad Z, *et al.* Diagnostic utility of flumazenil in coma with suspected poisoning. *BMJ* 1991; **302:** 292.
2. Boniface PJ, Russell SGG. Two cases of fatal zopiclone overdose. *J Anal Toxicol* 1996; **20:** 131–3.
3. Meatherall RC. Zopiclone fatality in a hospitalized patient. *J Forensic Sci* 1997; **42:** 340–3.

Interactions

As for Diazepam, p.989. Use with rifampicin or other potent inducers of the cytochrome P450 isoenzyme CYP3A4, such as carbamazepine or phenytoin, is likely to reduce the effects of zopiclone.

Antibacterials. In a study in healthy subjects *erythromycin* increased the rate of absorption of zopiclone and prolonged its elimination.[1] In another study[2] in 8 healthy subjects *rifampicin* was associated with an 82% reduction in the area under the curve for zopiclone. The peak plasma concentration of zopiclone was reduced from 76.9 to 22.5 nanograms/mL and the elimination half-life from 3.8 to 2.3 hours.

1. Aranko K, *et al.* The effect of erythromycin on the pharmacokinetics and pharmacodynamics of zopiclone. *Br J Clin Pharmacol* 1994; **38:** 363–7.
2. Villikka K, *et al.* Concentrations and effects of zopiclone are greatly reduced by rifampicin. *Br J Clin Pharmacol* 1997; **43:** 471–4.

Pharmacokinetics

Zopiclone is rapidly absorbed and widely distributed after oral doses. It has an elimination half-life of 3.5 to 6.5 hours and is reported to be about 45 to 80% bound to plasma proteins. Zopiclone is extensively metabolised in the liver; the 2 major metabolites, the less active zopiclone *N*-oxide and the inactive *N*-desmethylzopiclone, are excreted mainly in the urine. About 50% of a dose is converted by decarboxylation to inactive metabolites, which are partly eliminated via the lungs as carbon dioxide. Only about 5% of a dose appears unchanged in the urine and about 16% appears in the faeces. Excretion of zopiclone in the saliva may explain reports of a bitter taste. It is also distributed into breast milk.

◊ Reviews.

1. Fernandez C, *et al.* Clinical pharmacokinetics of zopiclone. *Clin Pharmacokinet* 1995; **29:** 431–41.
2. Drover DR. Comparative pharmacokinetics and pharmacodynamics of short-acting hypnosedatives: zaleplon, zolpidem and zopiclone. *Clin Pharmacokinet* 2004; **43:** 227–38.

Distribution into breast milk. Zopiclone was distributed into breast milk in 12 women in concentrations about half those in plasma.[1] The calculated dose that would be received by a neonate was 1.5 micrograms/kg, corresponding to 1.2% of the maternal dose.

1. Matheson I, *et al.* The excretion of zopiclone into breast milk. *Br J Clin Pharmacol* 1990; **30:** 267–71.

Uses and Administration

Zopiclone is a cyclopyrrolone with similar sedative, anxiolytic, muscle relaxant, amnestic, and anticonvulsant properties to those of the benzodiazepines (see Diazepam, p.992). Like diazepam, its actions are mediated by enhancement of the activity of gamma-aminobutyric acid (GABA) in the brain. Zopiclone is reported to bind to the benzodiazepine receptor component of the GABA receptor complex but at a different site to the benzodiazepines. It has a short duration of action.

Zopiclone is used as a hypnotic in the short-term management of insomnia. The usual oral dose is 7.5 mg before bed. In elderly patients, treatment should start with a dose of 3.75 mg before bed. Reduced doses are also recommended in patients with hepatic or renal impairment, see below.

Eszopiclone, the (+)-isomer of zopiclone, is used similarly (see p.995).

Administration in hepatic or renal impairment. In those with renal impairment or mild to moderate hepatic impairment, treatment with zopiclone should start with an oral dose of 3.75 mg before bed. It should not be given to patients with severe hepatic impairment.

Insomnia. Zopiclone has a similar pharmacological and pharmacokinetic profile to the short-acting benzodiazepines. It is claimed to initiate sleep rapidly, without reduction of total rapid-eye-movement (REM) sleep, and then sustain it with preservation of normal slow-wave sleep (see Insomnia, p.957). It is generally considered to be as effective as a hypnotic as the benzodiazepines. Rebound insomnia has occurred but does not appear to be common. Residual effects the next day may be less pronounced after zopiclone than after short-acting benzodiazepines but there appears to be little evidence that zopiclone offers any clinical advantage in terms of its potential to induce tolerance, withdrawal symptoms, or dependence. For recommendations of the UK CSM concerning its use as a hypnotic, see Incidence of Adverse Effects, above.

Zotepine *(BAN, rINN)*

Zotepina; Zotépine; Zotepinum. 2-[(8-Chlorodibenzo[*b,f*]-thiepin-10-yl)oxy]-*N,N*-dimethylethylamine.

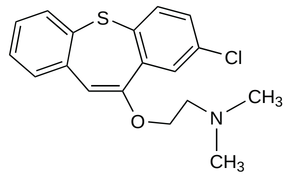
Зотепин

$C_{18}H_{18}ClNOS = 331.9$.

CAS — 26615-21-4.

ATC — N05AX11.

ATC Vet — QN05AX11.



Adverse Effects, Treatment, and Precautions

Although zotepine may share some of the adverse effects seen with the classical antipsychotics (see Chlorpromazine, p.969), the incidence and severity of such effects may vary. Common adverse effects include asthenia, headache, hypotension and, less commonly, orthostatic hypotension, tachycardia, gastrointestinal disturbances, elevated liver enzyme values, leucopenia, agitation, anxiety, dizziness, insomnia, somnolence, rhinitis, sweating, and blurred vision. Other less common adverse effects include thrombocytopenia, hyperglycaemia, hyperlipidaemia, convulsions, sexual dysfunction, and urinary incontinence. Extrapyramidal symptoms have been reported and tardive dyskinesia may occur with prolonged therapy. Neuroleptic malignant syndrome has been reported rarely. Prolactin levels may be increased and weight gain has been noted.

Zotepine can prolong the QT interval and patients with pre-existing prolongation of the QT interval should not be given the drug. It should be used with caution in patients at risk of developing arrhythmias; in such patients an ECG should be performed before starting treatment. Electrolytes should also be measured and any imbalance corrected. Monitoring of ECG and electrolytes should be continued during treatment especially at each dose increase. Zotepine may also increase the heart rate and, consequently, it should be used with care in patients with angina pectoris due to coronary artery disease. Caution is also recommended in patients with other cardiovascular disorders such as severe hypertension.

Zotepine has uricosuric properties and should not be given to patients with acute gout or a history of nephrolithiasis; it should be used with caution in patients with a history of gout or hyperuricaemia. Zotepine lowers the seizure threshold and should not be used in patients with a personal or family history of epilepsy unless the potential benefit outweighs the risk of convulsions. It has antimuscarinic actions and should be used with caution in patients with disorders such as benign prostatic hyperplasia, urinary retention, angle-closure glaucoma, and paralytic ileus. It should also be used with caution in patients with hepatic impairment; in such patients, weekly monitoring of liver function is recommended for at least the first 3 months of therapy. Zotepine may exacerbate the symptoms of Parkinson's disease. It should be used with caution in patients with tumours of the adrenal medulla such as phaeochromocytoma or neuroblastoma.

Zotepine may affect the performance of skilled tasks including driving.

Gradual withdrawal of zotepine is recommended because of the risk of withdrawal symptoms such as sweating, nausea and vomiting, and rebound psychosis, with abrupt cessation.

Dementia. The FDA has issued advice against the use of atypical antipsychotics in the treatment of behavioural problems in elderly patients with dementia after analysis of placebo-controlled studies showed an increased risk of mortality with certain drugs of this class. See under Risperidone, p.1024.

Effects on body-weight. The increased risk of weight gain with some atypical antipsychotics is discussed under Adverse Effects of Clozapine, p.981.

Effects on carbohydrate metabolism. The increased risk of glucose intolerance and diabetes mellitus with some atypical antipsychotics, and recommendations on monitoring, are discussed under Adverse Effects of Clozapine, p.981.

Effects on lipid metabolism. The increased risk of hyperlipidaemia with some atypical antipsychotics is discussed under Adverse Effects of Chlorpromazine, p.970. See also under Adverse Effects of Clozapine, p.981.

Pregnancy. For comments on the use of some atypical antipsychotics during pregnancy, see under Precautions of Clozapine, p.983.

Interactions

Zotepine may enhance the effects of other CNS depressants and antimuscarinics. The risk of seizures is particularly increased when zotepine is given with high doses of other antipsychotics and the combination is not recommended. Additive hypotensive effects may theoretically occur with antihypertensives and some anaesthetic drugs; however its α-blocking actions might reduce the effects of methyldopa or clonidine.

The risk of arrhythmias with zotepine may be increased by use with other drugs that prolong the QT interval or cause hypokalaemia. Use of zotepine with fluoxetine or diazepam may lead to increased plasma concentrations of zotepine.

Pharmacokinetics

Zotepine is well absorbed from the gastrointestinal tract after oral doses with peak plasma concentrations being achieved 2 to 3 hours later. It undergoes extensive first-pass metabolism to the equipotent metabolite norzotepine and inactive metabolites. CYP1A2 and CYP3A4 are the major cytochrome P450 isoenzymes involved in the metabolism of zotepine. Plasma protein binding of zotepine and norzotepine is 97%. Zotepine is excreted mainly in the urine and faeces as inactive metabolites and has an elimination half-life of about 14 hours. It is thought to be distributed into breast milk on the basis of studies in *rats*.

Uses and Administration

Zotepine is an atypical antipsychotic that, in addition to its antagonist action at central dopamine (D_1 and D_2) receptors, binds to serotonin ($5\text{-}HT_2$), adrenergic (α_1), and histamine (H_1) receptors and also inhibits noradrenaline reuptake. It is given in the treatment of schizophrenia in an initial oral dose of 25 mg three times daily; this is increased according to response, at intervals of 4 days, to a maximum of 100 mg three times daily. There is an appreciable increase in the incidence of seizures at total daily doses above the recommended maximum of 300 mg. For elderly patients, the recommended starting dose is 25 mg given twice daily, increased gradually up to a maximum of 75 mg twice daily. Doses should also be reduced in patients with hepatic or renal impairment, see below.

Administration in hepatic or renal impairment. For patients with renal or hepatic impairment, the recommended initial oral dose of zotepine is 25 mg given twice daily increased gradually up to a maximum of 75 mg twice daily.

Schizophrenia. A systematic review[1] of short-term studies of zotepine for schizophrenia (p.955) concluded tentatively that it was as effective as classical antipsychotics and might be of benefit in patients with negative symptoms; in addition, it seemed less likely to provoke extrapyramidal disorders. Comparisons with atypical antipsychotics were too scanty for a meaningful comparison to be drawn.

Preparations

Proprietary Preparations (details are given in Part 3)

Austria: Nipolept; ***Cz.:*** Zoleptil; ***Ger.:*** Nipolept; ***Indon.:*** Lodopin; ***Jpn:*** Lodopin; ***Port.:*** Zoleptil; ***UK:*** Zoleptil.

Zuclopenthixol *(BAN, rINN)*

AY-62021 (clopenthixol or clopenthixol hydrochloride); *Z*-Clopenthixol; *cis*-Clopenthixol; α-Clopenthixol; N-746 (clopenthixol or clopenthixol hydrochloride); NSC-64087 (clopenthixol); Tsuklopentiksoli; Zuclopenthixolum; Zuclopentixol; Zuklopentixol. (*Z*)-2-{4-[3-(2-Chloro-10*H*-dibenzo[*b,e*]thiin-10-ylidene)propyl]piperazin-1-yl}ethanol.

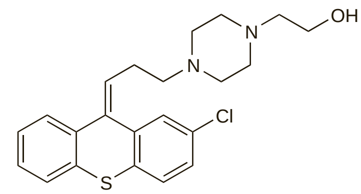
Зуклопентиксол

$C_{22}H_{25}ClN_2OS = 401.0$.

CAS — 53772-83-1 (zuclopenthixol); 982-24-1 (clopenthixol).

ATC — N05AF05.

ATC Vet — QN05AF05.



NOTE. Clopenthixol (*BAN, INN, USAN*) is the racemic mixture.

Zuclopenthixol Acetate *(BANM, rINNM)*

Acetato de zuclopentixol; Zuclopenthixol, Acétate de; Zuclopenthixoli Acetas; Zuklopentiksol Asetat.

Зуклопентиксола Ацетат

$C_{24}H_{27}ClN_2O_2S = 443.0$.

CAS — 85721-05-7.

ATC — N05AF05.

ATC Vet — QN05AF05.

Pharmacopoeias. In *Br.*

BP 2008 (Zuclopenthixol Acetate). A yellowish, viscous oil. Very slightly soluble in water; very soluble in alcohol, in dichloromethane, and in ether. Store at a temperature not exceeding –20°. Protect from light.

Zuclopenthixol Decanoate *(BANM, rINNM)*

Decanoato de zuclopentixol; Tsuklopentiksolidekanoaatti; Zuclopenthixol, décanoate de; Zuclopenthixoli decanoas; Zuklopenthixol-dekanoát; Zuklopentiksol Dekanoat; Zuklopentiksolio dekanoatas; Zuklopentixoldekanoat; Zuklopentyksolu dekanonian.

Зуклопентиксола Деканоат

$C_{32}H_{43}ClN_2O_2S = 555.2$.

CAS — 64053-00-5.

ATC — N05AF05.

ATC Vet — QN05AF05.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Zuclopenthixol Decanoate). A yellow viscous oily liquid. Very slightly soluble in water; very soluble in alcohol and in dichloromethane. Store under an inert gas in airtight containers at a temperature not exceeding –20°. Protect from light.

Zuclopenthixol Hydrochloride *(BANM, rINNM)*

Hidrocloruro de zuclopentixol; Zuclopenthixol, Chlorhydrate de; Zuclopenthixol Dihydrochloride; Zuclopenthixoli Hydrochloridum; Zuklopentiksol Dihidroklorür.

Зуклопентиксола Гидрохлорид

$C_{22}H_{25}ClN_2OS,2HCl = 473.9$.

CAS — 58045-23-1.

ATC — N05AF05.

ATC Vet — QN05AF05.

Pharmacopoeias. In *Br.*

BP 2008 (Zuclopenthixol Hydrochloride). An off-white granular powder. Very soluble in water; sparingly soluble in alcohol; slightly soluble in chloroform; very slightly soluble in ether. A 1% solution in water has a pH of 2.0 to 3.0. Protect from light.

Stability. References.

1. Li Wan Po A, Irwin WJ. The photochemical stability of cis- and trans-isomers of tricyclic neuroleptic drugs. *J Pharm Pharmacol* 1980; **32:** 25–9.

Adverse Effects, Treatment, and Precautions

As for Chlorpromazine, p.969. Zuclopenthixol is less likely to cause sedation but extrapyramidal effects are more frequent.

Porphyria. Zuclopenthixol is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Interactions

As for Chlorpromazine, p.973.

Pharmacokinetics

Zuclopenthixol is absorbed after oral doses with peak plasma concentrations occurring 3 to 6 hours later. The biological half-life after oral doses is reported to be about 1 day. Paths of metabolism of zuclopenthixol include sulfoxidation, side-chain *N*-dealkylation, and glucuronic acid conjugation. It is mainly excreted in the faeces as unchanged drug and its *N*-dealkylated metabolite. Zuclopenthixol is about 98% bound to plasma proteins. It is widely distributed in the body and crosses the blood-brain barrier. Small amounts of drug or metabolites cross the placenta and are distributed into breast milk.

On intramuscular injection the acetate and decanoate esters of zuclopenthixol are hydrolysed to release zuclopenthixol. Zuclopenthixol acetate has a relatively quick onset of action after injection and a duration of action of 2 to 3 days. It is therefore useful for the control of acute psychotic symptoms while avoiding repeated injections. The decanoate has a much longer duration of action and is a suitable depot preparation for maintenance treatment.

Metabolism. Determination of metaboliser phenotype with regard to cytochrome P450 isoenzyme CYP2D6 appeared to be of limited value in patients receiving zuclopenthixol as interindividual variation appeared to be the main factor affecting dose to serum concentration ratios.[1]

1. Linnet K, Wiborg O. Influence of Cyp2D6 genetic polymorphism on ratios of steady-state serum concentration to dose of the neuroleptic zuclopenthixol. *Ther Drug Monit* 1996; **18:** 629–34.

Uses and Administration

Zuclopenthixol is a thioxanthene of high potency with general properties similar to the phenothiazine, chlorpromazine (p.975). It has a piperazine side-chain.

Zuclopenthixol is used for the treatment of schizophrenia (see below), mania (see Bipolar Disorder, p.372), and other psychoses. It may be particularly suitable for agitated or aggressive patients who may become overexcited with flupentixol. Zuclopenthixol hydrochloride is usually given orally with doses expressed in terms of the base; zuclopenthixol hydrochloride 11.8 mg is equivalent to about 10 mg of zuclopenthixol. Zuclopenthixol hydrochloride has also been given intramuscularly. Zuclopenthixol acetate and zuclopenthixol decanoate are given by deep intramuscular injection; doses are expressed in terms of the ester. The acetate ester has a rapid onset of action and a duration of action of 2 to 3 days; it is used as a 5% oily solution for the initial treatment of acute psychoses and for exacerbations of chronic psychoses. The longer-acting decanoate ester is used as a 20% oily solution for the maintenance treatment of chronic psychoses; a 50% solution is available for those requiring high doses.

- The usual initial *oral* dose of the hydrochloride for the treatment of **psychoses** is the equivalent of 20 to 30 mg of the base daily in divided doses; in severe or resistant cases up to 150 mg daily has been given. The usual maintenance dose is 20 to 50 mg daily.
- The usual dose of zuclopenthixol acetate is 50 to 150 mg by deep *intramuscular* injection repeated, if necessary, after 2 or 3 days. Some patients may need an additional injection between 1 and 2 days after the first dose.

  Zuclopenthixol acetate is not intended for maintenance treatment; no more than 4 injections should be given in a maximum course of 2 weeks and the total dose should not exceed 400 mg. When maintenance treatment is required, *oral* zuclopenthixol hydrochloride may be introduced 2 to 3 days after the last injection of zuclopenthixol acetate, or *intramuscular* injections of the decanoate (see below) begun with the last injection of the acetate.
- The long-acting decanoate should be given by deep *intramuscular* injection; treatment is usually started with a test dose of 100 mg. This may be followed after at least 1 week by a dose of 200 to 500 mg or more, every 1 to 4 weeks, adjusted according to response. Injection volumes greater than 2 mL should be divided between 2 separate injection sites. The maximum recommended dose of zuclopenthixol decanoate is 600 mg weekly.

Elderly or debilitated patients should be given reduced doses of zuclopenthixol. Licensed product information states that the dose of the hydrochloride or the decanoate may need to be reduced to one-quarter or one-half of the usual initial dose; in addition, the maximum single dose of the acetate should be limited to 100 mg.

Administration in hepatic or renal impairment. Licensed product information recommends that for zuclopenthixol acetate, half the normal recommended intramuscular dose should be used for patients with hepatic impairment; a dosage reduction is considered to be unnecessary in patients with renal impairment but where there is renal failure half the normal intramuscular dosage is recommended.

Schizophrenia. A systematic review[1] comparing zuclopenthixol decanoate with other depot antipsychotics considered that although it may induce more adverse effects, limited data suggested it might offer advantages such as lower relapse rates and increased acceptability in the treatment of schizophrenia (p.955) and similar serious mental illnesses. Similar reviews of the use of the acetate[2] or hydrochloride[3] found, however, that evidence of additional benefit over other antipsychotics was lacking.

This chapter describes the management of blood disorders including some anaemias, haemorrhagic disorders, and neutropenia. It covers blood, blood products and substitutes, and colloid plasma expanders; crystalloid plasma expanders are generally solutions of sodium chloride (p.1686) or glucose (p.1945) or both. Also included in the chapter are haemostatic drugs and erythropoietin and other colony-stimulating factors. The management of haematological malignancies is covered in the Antineoplastics chapter, p.635.

Haematopoiesis

In the embryo and fetus, the formation and development of blood cells occurs at various sites including the liver, spleen, thymus, lymph nodes, and bone marrow; from birth throughout the rest of life it occurs mainly in the bone marrow with a small amount occurring in the lymph nodes. The bone marrow contains pluripotent stem cells that differentiate into different types of progenitor cells (committed stem cells); these then mature into various types of blood cells under the influence of growth factors and hormones. The main cellular components of blood are red blood cells (erythrocytes), white blood cells (leucocytes), and platelets.

Erythrocyte production is stimulated by erythropoietin, a hormone released by the kidney in response to anaemia or hypoxia.

The leucocytes are classified according to their morphological appearance into granulocytes, lymphocytes, and monocytes. The granulocytes are further classified as neutrophils, eosinophils, and basophils, according to the characteristics of their cytoplasmic granules. The term polymorphonuclear leucocytes can be applied to granulocytes in general but applies in particular to neutrophils. Most lymphocytes are matured in the lymph nodes, thymus, and spleen, from bone marrow lymphocyte precursors. Lymphocytes enter the bloodstream via the lymphatics, but only a small proportion are present in the blood. Monocytes are released into the blood but then enter the tissues to become fixed tissue macrophages. The maturation of leucocytes is stimulated by granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and macrophage colony-stimulating factor (M-CSF).

Platelet maturation is stimulated by thrombopoietin.

Other growth factors involved at various stages of blood cell development include stem cell factor and interleukins-1, -3, -4, -5, -6, and -11.

The average blood cell counts in adults are:

- erythrocytes (men): 5.0×10^{12} cells/litre
- erythrocytes (women): 4.3×10^{12} cells/litre
- leucocytes: 7.0×10^{9} cells/litre (7000 cells/mm^3) but the value can vary markedly, even in the same individual at different times, from 4 to 11×10^{9} cells/litre. This total is made up of:
  - neutrophils (40 to 80%)
  - lymphocytes (20 to 40%)
  - monocytes (2 to 10%)
  - eosinophils (1 to 6%)
  - basophils (<1 to 2%)
- platelets: 150 to 450×10^{9} cells/litre (150 000 to 450 000 cells/mm^3)

Anaemias

Anaemia is usually understood to mean a lowering of haemoglobin concentration, red cell count, or packed cell volume to below 'normal' values, but the criteria for normality are difficult to establish. WHO's suggested definition of anaemia in populations living at around sea level is a haemoglobin concentration below:

- 13 g per 100 mL in men
- 12 g per 100 mL in women
- 11 g per 100 mL in pregnant women
- 12 g per 100 mL in children aged 12 to 14 years
- 11.5 g per 100 mL in children aged 5 to 11 years
- 11 g per 100 mL in children aged 6 to 59 months

However, because of individual variation, some apparently normal individuals have blood haemoglobin concentrations below these values, while others may be above these values and still be effectively anaemic.

Reduction in overall haemoglobin concentrations may be due to fewer red cells, with the cells retaining normal amounts of haemoglobin (normochromic anaemia), or the amount of haemoglobin in the cells may be reduced (hypochromic anaemia). Red cells themselves may be reduced in size (microcytic), enlarged (macrocytic), or normal in size (normocytic).

The immediate cause of anaemia may be decreased red cell production (due to defective proliferation and/or maturation of red cells from their precursors in bone marrow), increased red cell destruction (i.e. haemolysis), or loss of red cells from the circulation due to haemorrhage, either occult or overt. These conditions may occur due to underlying disease, nutritional deficiency, congenital disorders, or toxicity due to drugs or other substances and the cause must always be sought before an appropriate treatment can be determined.

The symptoms of anaemia are as variable as its causes but may include fatigue, pallor, dyspnoea, palpitations, headache, faintness or lightheadedness, tinnitus, anorexia and gastrointestinal disturbances, and loss of libido; tachycardia, heart failure, and retinal haemorrhage may occur in severe anaemia.

The treatment of anaemia depends upon its type and cause. Some of the principal types are classified in Table 1, below, and their management is discussed in more detail under the relevant headings. Sickle-cell disease and β-thalassaemia are discussed under Haemoglobinopathies.

Table 1. Types of anaemias.

Classification	Anaemia	Mean cell volume	Haemoglobin	Associated with
Microcytic	Iron-deficiency anaemia	Decreased (or normal in early stages)	Hypochromic	Blood loss, malabsorption, inadequate iron intake
	Hereditary sideroblastic anaemia	Decreased	Hypochromic	
	Thalassaemias	Decreased	Hypochromic	
Macrocytic	Megaloblastic anaemia	Increased	Normochromic	Vitamin B_{12} deficiency, folate deficiency (including drug induced)
	Acquired sideroblastic anaemia	Increased	Hypochromic	Alcoholism, drug or other toxicity
Normocytic	Normocytic-normochromic anaemia	Normal	Normochromic	Anaemia of chronic disorders, bone-marrow disorders (including aplastic anaemia), malignancy, renal failure, endocrine disorders, prematurity
Haemolytic	Haemolytic anaemia	Increased		Immune disorders, drug toxicity, hereditary disorders
	Sickle-cell anaemia

Aplastic anaemia

Aplastic anaemia is characterised by pancytopenia (a deficiency of all cellular elements of the blood) and hypoplasia of the bone marrow, with less than 25% of the marrow occupied by haematopoietic cells but without evident fibrosis or malignant infiltration. It is relatively rare, although it may be somewhat more common in the Far East, and is mainly seen in younger adults. Some forms, such as Fanconi's anaemia, are inherited but most are induced, for example by the effects of cytotoxic drugs or radiation, idiosyncratic reactions to other drugs, seronegative fulminant hepatitis, or auto-immune reactions. Since all cell lines are affected patients develop thrombocytopenia and neutropenia as well as anaemia, and symptoms include bleeding syndromes and infections as well as typical symptoms of anaemia. Paroxysmal nocturnal haemoglobinuria (see Haemolytic Anaemia, below), in which genetic mutation causes the production of abnormal blood cells and results in haemolysis, can be associated with aplastic anaemia.

Although spontaneous recovery has occurred, untreated aplastic anaemia is usually fatal. Management may be divided into supportive care and attempts to restore bone-marrow function with bone marrow transplantation or immunosuppression, and has been the subject of guidelines and reviews.[1-4]

Supportive care involves the prevention and treatment of infection (see Infections in Immunocompromised Patients, p.174), the control of haemorrhage with platelet concentrates, and where necessary, infusions of red blood cells (with platelets to prevent haemorrhage) for anaemia. Transfusions should be minimised in candidates for bone marrow transplant (see below).

In patients aged under 40 years with severe disease and with a suitable HLA-matched donor, **bone marrow transplantation** offers the prospect of long-term cure, and is considered the treatment of choice.[1-5] Ideally this should be performed early before the patient has received too many transfusions, which increase the risk of rejection, and before infection develops. Transfusion of cord blood from an HLA-identical sibling can also produce permanent engraftment, and may be associated with less acute graft-versus-host disease than bone marrow transplantation.[2] However, recent results have suggested that chronic graft-versus-host disease and overall survival may be worse when peripheral blood stem cells are used rather than bone marrow.[3]

In patients unsuitable for bone marrow transplantation, or where a suitable donor is not available, treatment with **immunosuppressants** may be tried. About 50% of patients are reported to respond to a course of antilymphocyte immunoglobulin within 3 months, and the addition of ciclosporin further improves response rates to between 60 and 80% and 5-year survival to between 75 and 90%.[1,2] However, one long-term study[6] providing follow-up data for 11 years has found no significant difference in survival between regimens of antilymphocyte immunoglobulin with or without ciclosporin.[6] Ciclosporin has been used alone but is less effective than antilymphocyte immunoglobulin.[1,3]

Despite these good rates of response with the addition of ciclosporin, relapse is not uncommon.[7] A second course of antilymphocyte immunoglobulin is recommended if there is no response, or there is relapse, after 3 months.[2] Ciclosporin is continued after a response has occurred and until the blood count has been stable for at least 6 months; it may then be slowly withdrawn, usually over many months and depending on blood counts.[2] Some patients may require continued therapy.[3,4]

Good response rates have been reported from combined regimens including a granulocyte colony-stimulating factor.[8] However, there are concerns about long-term use and the role of these factors is still under investigation.[2,3,9] There has been interest in the use of other haematopoietic growth factors including granulocyte-macrophage colony-stimulating factor, ancestim (stem cell factor), epoetin, interleukin-1, interleukin-3, and interleukin-6, either alone or with immunosuppression, but results have generally been poor or trials stopped because of toxicity, and so the use of these factors is not recommended.[2,9] However, short courses of granulocyte colony-stimulating factor may be considered for supportive therapy in neutropenic patients with severe systemic infections that are not responding to antibacterial or antifungal therapy.[2]

Oxymetholone was used extensively before the availability of antilymphocyte immunoglobulin and ciclosporin. It can increase the response to antilymphocyte immunoglobulin alone, but it can be hepatotoxic and causes virilisation, and is generally used for patients who have failed several courses of antilymphocyte immunoglobulin with ciclosporin, or where this regimen cannot be used.[2] Mycophenolate mofetil is under investigation in patients who are ineligible for bone marrow transplantation and refractory to standard immunosuppressive therapy.[2] Cyclophosphamide is commonly used in preparation for bone marrow transplantation and complete remission has also been reported with high-dose cyclophosphamide alone.[10,11] However, a randomised trial[12] of high-dose cyclophosphamide plus ciclosporin compared with conventional immunosuppression was stopped early when a higher mortality was observed in those receiving cyclophosphamide. Further follow-up[13] also found that relapse rates were no different. Nonetheless, cyclophosphamide continues to be of investigational interest.[4]

Responses to immunosuppressants are often partial, but this may be sufficient to free the patient from dependency on transfusions and intensive antibacterial cover, and is considered well worth achieving.[1,2] Nevertheless, the procedure is not curative; patients appear to retain some underlying defect in marrow function, and in the long term about 15% of them develop leukaemias or myelodysplasias.[1]

Children with severe aplastic anaemia are treated similarly to adults.[14] Although some reports have suggested that the response to immunosuppressant therapy may be lower in children under 5 years of age, others have shown the opposite. The choice of treatment in children may also need to take into account the potential long-term adverse effects of treatment, particularly with immunosuppressants or irradiation, on endocrine function, growth, fertility, and the development of secondary malignancies.

Older patients tend to be treated with immunosuppressant therapy rather than bone marrow transplantation.[2] A retrospective cohort study[15] that compared patients older than 50 years with younger patients found that more older patients had received ciclosporin alone, that the response to immunosuppression was independent of age at the time of treatment, and that although survival decreased with age deaths were similar to those in a general population and were not related to the type of treatment or the number of courses of treatment.

The outcome of **pregnancy** in women who had previously been treated for aplastic anaemia with an immunosuppressant regimen has been described.[16] Of 36 pregnancies, 22 were uncomplicated and 7 were complicated by relapse of aplastic anaemia; complications appeared to be more likely in women with low platelet counts and paroxysmal nocturnal haemoglobinuria. Rarely, aplastic anaemia can develop during pregnancy, and although the disease may remit spontaneously after termination or delivery, this does not occur in all cases.[17,18] Supportive care is the mainstay for management of aplastic anaemia during pregnancy, although the use of ciclosporin may be considered if transfusions are required.[2]

Patients with **non-severe aplastic anaemia** may require supportive therapy only. For those who do require immunosuppression there is less evidence on which to base treatment, but one prospective study[19] of patients with non-severe disease who had become transfusion-dependent reported that the combination of antilymphocyte immunoglobulin and ciclosporin produced a higher response rate with an earlier onset than ciclosporin alone. Although survival was no different between the groups, combination therapy was associated with less disease progression and a higher probability of disease-free survival.

Haemolytic anaemia

The normal life span of an erythrocyte is about 120 days; a haemolytic state is defined as a reduction in this mean life span due to premature destruction of red cells, either intravascularly, or more commonly after sequestration by the spleen or liver. Healthy bone marrow can compensate for even quite severe haemolysis by increased erythropoiesis; however, if the red cell survival-time is less than 15 days, or if the bone marrow is abnormal, or there is a deficiency of folate, iron, or other necessary nutrients, then compensation will be inadequate and haemolytic anaemia will result. In addition to typical symptoms of anaemia (above) patients frequently exhibit jaundice and splenomegaly, while the increased erythropoiesis results in reticulocytosis (elevated counts of immature red cells).

Haemolytic anaemias may be either congenital or acquired. The **congenital** disorders include:

- those due to membrane defects in the erythrocyte, such as spherocytosis or elliptocytosis
- those due to enzyme defects (including the various forms of glucose-6-phosphate dehydrogenase (G6PD) deficiency)
- those due to haemoglobin defects (haemoglobinopathies), including sickle-cell disease and β-thalassaemia (below)

The **acquired** haemolytic anaemias arise from numerous causes but may be divided into immune and non-immune types. The immune types include:

- some drug-induced haemolytic anaemias (including those produced by penicillins, rifampicin, and methyldopa)
- auto-immune haemolytic anaemia (further classified into warm or cold depending on the temperature at which the red cell antibodies are most active)
- paroxysmal nocturnal haemoglobinuria, resulting from complement-mediated red cell lysis
- haemolytic disease of the newborn (see p.2204)

The non-immune types include:

- haemolysis due to infections such as malaria
- chemically-induced haemolysis (due to a direct effect on the red cell rather than an immunologically-mediated one, and including the effects of toxins such as copper and arsenic as well as some snake venoms, and drugs such as amphotericin B, dapsone, and sulfasalazine)
- the effects of mechanical trauma

Treatment of haemolytic anaemia depends on the underlying cause, although general supportive measures (bed rest, transfusion if haemodynamic abnormalities make it necessary, and supplementation with folate) will be similar in all poorly-compensated patients. Well compensated haemolysis may require no treatment at all, although clearly elucidation and, where possible, removal of the cause is desirable.

Hereditary haemolytic disorders such as spherocytosis[1] mostly respond well to splenectomy, although milder forms may not require treatment. In patients with G6PD deficiency, treatment consists essentially of avoidance of drugs or foodstuffs likely to provoke haemolysis.

Acquired haemolytic anaemia is best treated by identification and where possible elimination of any underlying cause. Most drug-induced haemolytic anaemias respond rapidly to withdrawal of the offending substance.

Auto-immune haemolytic anaemias require treatment aimed at maintaining the patient and controlling haemolysis. Although treatment may need to be prolonged, in many patients with idiopathic disease antibodies eventually disappear or decrease to insignificant titres after months or years. The auto-immune haemolytic anaemias may be secondary to other disorders including leukaemias, lymphomas, and SLE; correction of the underlying disease often results in marked improvement of accompanying haemolysis.

In patients with warm auto-immune haemolytic anaemia treatment starts with corticosteroids.[2] A typical initial dose is prednisone or prednisolone 1 to 1.5 mg/kg by mouth daily. The onset of response is usually rapid and most patients demonstrate benefit within 10 to 14 days. The initial effective dose of corticosteroid should be continued until a satisfactory response has been obtained, and once there is haematologic stabilisation the dose may be gradually reduced. Many patients will require low-dose maintenance therapy. If symptoms do not respond to tolerable doses of corticosteroids splenectomy should be considered. Immunosuppressants such as azathioprine or cyclophosphamide may be considered in patients refractory to other therapy;

responses are reportedly variable, but they sometimes permit reduction of corticosteroid maintenance doses. There are some reports of benefit from the use of danazol and some cases have responded to rituximab. High-dose intravenous normal immunoglobulin may be used in some patients if the adverse effects of long-term corticosteroid or immunosuppressant therapy are severe. Plasma exchange may be useful for acute management of severe haemolysis while other therapies are taking effect.[2] Transfusion is problematic in these patients because of the difficulty in establishing compatibility between patient and donor.[3] Nonetheless, transfusion may be life-saving in acute disease, and the least incompatible blood should be used.

In patients with cold auto-immune haemolytic anaemias such as cold haemagglutinin disease it is additionally important to keep the patient warm.[2] Corticosteroids and splenectomy are generally of no benefit in these patients (although there may be a responsive subgroup), but treatment with chlorambucil 2 to 4 mg daily by mouth may produce a response. Blood transfusion should be avoided if possible, and if given it should be preferably via a warming coil and infused slowly. Rituximab has also been tried with some success in cold auto-immune haemolytic anaemia.

In paroxysmal nocturnal haemoglobinuria, red cells are more sensitive to complement-mediated lysis because of a deficiency in protective membrane proteins on the cell surface. Haemolysis may be accompanied by neutropenia, thrombocytopenia, and venous thrombosis, and in some patients there may be some overlap with aplastic anaemia, see above. Curative therapy for paroxysmal nocturnal haemoglobinuria is possible with allogeneic haematopoietic stem cell transplantation. More recently, eculizumab has become available; a monoclonal antibody directed at the complement protein C5, it inhibits terminal complement activation to reduce haemolysis and transfusion requirements.[4]

Iron-deficiency anaemia

For a discussion of iron deficiency anaemia and its management, see under Iron, p.1951.

Megaloblastic anaemia

For a discussion of megaloblastic anaemia and its management, see under Vitamin B_{12}, p.1982.

Normocytic-normochromic anaemia

Anaemias in which red cell size and cellular haemoglobin are not significantly different from normal (normocytic-normochromic anaemias) form a substantial proportion of all cases. Such anaemias are usually secondary to another disease and include:

- anaemia of chronic disorders (associated with chronic infection such as tuberculosis, malignancy, inflammatory disorders such as inflammatory bowel disease, polymyalgia rheumatica, rheumatoid arthritis, and SLE)
- anaemia of renal failure
- anaemia of prematurity
- anaemia associated with endocrine disorders such as hypothyroidism or hypopituitarism
- anaemias associated with primary bone-marrow failure (including aplastic anaemia, above, pure red cell aplasia, marrow fibrosis or infiltration as in myelodysplasia or leukaemia, and marrow failure associated with AIDS).

Iron-deficiency anaemia (p.1951), which is usually classified as microcytic and hypochromic may in fact be neither, particularly in the early stages, and should be differentiated from anaemia of chronic disease. The latter is also accompanied by changes in iron metabolism, notably sequestration of iron in reticuloendothelial cells: plasma iron is low but in contrast to iron deficiency the total iron binding capacity is reduced and serum ferritin is often increased.

The **treatment** of most of these anaemias is essentially that of the underlying disease. Blood transfusion has been given when anaemia is severe. In patients with anaemia of renal failure, which is due at least in part to decreased erythropoietin production by the damaged kidney, regular subcutaneous or intravenous injection of recombinant human erythropoietins (epoetins) can completely reverse the anaemia. Epoetins may also have a role in anaemia of prematurity and some drug-induced anaemias, and have been investigated in patients with the anaemia of chronic disease and some other normocytic-normochromic anaemias.

Sideroblastic anaemia

The sideroblastic anaemias are characterised by a population of hypochromic red cells in the presence of increased serum-iron concentrations, and abnormal erythroid precursors, known as ring sideroblasts, in the bone marrow. They are associated with abnormalities in porphyrin biosynthesis leading to diminished production of haem, and increased mitochondrial iron uptake. Sideroblastic anaemias may be of various types, and are classified as acquired or hereditary.

Acquired sideroblastic anaemia. Acquired sideroblastic anaemia may either be idiopathic, or secondary to either a drug or toxin (such as alcohol, isoniazid, chloramphenicol, or lead) or to a disease (including hypothyroidism, rheumatoid arthritis, haemolytic or megaloblastic anaemias, leukaemias, and lymphomas). The treatment of the secondary forms is essentially the treatment of the underlying disease or removal of the precipitating cause. The anaemia is usually mild and often macrocytic.

Patients with idiopathic disease usually have only mild anaemia, and most require no treatment. Although rarely suffering from vitamin B_6 deficiency a few patients will respond at least partially to high doses of pyridoxine by mouth, up to 400 mg daily, and a trial is considered worthwhile in all patients. If patients become symptomatic, transfusion may be required, but should be kept to a minimum because of the problems of iron overload. All patients with sideroblastic anaemia must have their serum-iron and -ferritin concentrations regularly monitored, and be given desferrioxamine by regular bolus injection when there is evidence of iron overload. The use of epoetins and granulocyte colony-stimulating factor is under investigation.

Hereditary sideroblastic anaemia. The hereditary forms of the disease appear to be sex-linked, and almost always manifest themselves in males. The anaemia may be more severe than in acquired sideroblastic anaemia, and is usually microcytic.

A trial of pyridoxine is considered worthwhile as some forms are responsive, but in many cases there is no benefit. Some patients develop gradually increasing iron loads, and may eventually develop haemosiderosis; to prevent this, regular venesection or the use of desferrioxamine are indicated if there is evidence of iron accumulation. Allogeneic bone marrow or haematopoietic stem cell transplantation is under investigation.

Haemoglobinopathies

Haemoglobinopathies are clinical abnormalities due to altered structure, function, or production of haemoglobin. Human haemoglobins are tetramers, constructed of 4 globin chains each enfolding an iron-containing haem moiety: two of these globins are of the 'α-like' types (globins α or ζ) and two are 'non-α' (types β, γ, δ, or ε). The normal major adult haemoglobin, haemoglobin A, comprises two α and two β chains, while the predominant fetal haemoglobin, haemoglobin F (also present in minute amounts in normal adults), is composed of two α and two γ globins. The erythroblast inherits two genes for the production of α globin and one for β globin production from each parent, and a mutation in a single α gene will therefore affect only 25% of the haemoglobin produced, whereas a single β mutation will affect 50%: the β-haemoglobinopathies, due to defective β globin production, are therefore more likely to produce symptoms, and the most widespread forms are the β-thalassaemias and sickle-cell disease, which are discussed below.

Sickle-cell disease

Sickle-cell disease is a haemoglobinopathy (see above) in which a structural abnormality in the β globin chain results in the formation of an abnormal haemoglobin, haemoglobin S. In the deoxygenated state haemoglobin S is less soluble and polymerises into rod-like fibres, and cells containing high concentrations of haemoglobin S subsequently become deformed into a sickle shape. Normal haemoglobins can be incorporated into the polymer but some, such as fetal haemoglobin (haemoglobin F), are not; increasing concentrations of these in the red cell reduce the rate of sickling.

The heterozygous form, sickle-cell trait, is generally asymptomatic except in conditions of extreme anoxia, although characteristic abnormalities of renal function (inadequate concentration of the urine) may be present. As with thalassaemia trait (see below) it is more common in populations of tropical origin, and has been postulated to offer a degree of protection against malaria. In the homozygous form a varying degree of haemolytic anaemia is present, accompanied by increased erythropoiesis. In addition to shortened survival, the decreased flexibility of the deformed erythrocytes can lead to occlusion of the microvasculature, and sickle-cell crisis. The latter may manifest as excruciating pain due to infarction of the blood supply to the bones, or infarction of other organs including lung, liver, kidney, penis (leading to priapism), and brain (stroke). An acute chest syndrome occurs in many patients, and may be fatal. It is a form of acute lung injury associated with infarction, fat embolism, and infection, and may progress to acute respiratory distress syndrome. Occasionally a large proportion of red cell mass may become trapped in the spleen or liver (sequestration crisis) with death due to gross anaemia. Chronic complications include skin ulceration, renal failure, retinal detachment, and increased susceptibility to infection.

Treatment of sickle-cell disease is essentially symptomatic.[1-5] Young children should receive prophylactic penicillin and pneumococcal vaccine, to reduce the risk of infection (see Spleen Disorders, p.194). Infection should be treated early, and folate supplementation given if necessary since the increased erythropoiesis resulting from chronic haemolysis may increase folate requirements.

Sickle-cell crisis requires hospitalisation, with the use of large volumes of intravenous fluids for dehydration, analgesia including opioids for pain (see p.9), and treatment of any concurrent infection. Oxygen should be given if the patient is hypoxaemic. Where crisis affects a vital organ with life-threatening or potentially disabling consequences partial exchange transfusion should be carried out promptly, as no other therapy exists. Where rapid enlargement of spleen or liver indicates a sequestration crisis, transfusion is also important to avoid fatal anaemia.

Maintenance transfusion is rarely indicated, although it may be given to patients who have already had a stroke; measures to avoid iron overload such as phlebotomy or desferrioxamine chelation are necessary in patients receiving regular transfusions. Prophylactic transfusions in children at high risk have been reported[6] to reduce the incidence of first stroke but the risks and benefits of treatment must be carefully considered. A further study[7] investigated whether prophylactic transfusions could be safely stopped after 30 months in children who had not had an overt stroke and who had reverted to low stroke risk. The study was stopped early when it was found that in those who stopped transfusions there was a significant return to high risk and that some patients had subsequently suffered a stroke. Splenectomy may be recommended in the management of recurrent splenic sequestration.

Research into specific therapy for sickling has produced some promising results. Because haemoglobin F is known to protect against sickling, considerable interest has centred on attempts to stimulate fetal haemoglobin production. Most studies have used hydroxycarbamide. Initial trials showed some elevation in mean fetal haemoglobin concentrations, but responses were very variable. However, a subsequent randomised controlled study in 299 patients[8] reported that therapy with hydroxycarbamide caused a 44% reduction in the median annual rate of painful crises. The beneficial effects did not become evident for several months. Observational follow-up of 233 patients in this group,[9] for up to 9 years, suggested that hydroxycarbamide also reduced mortality. Beneficial effects have also been reported in initial studies in children[10-12] and sustained benefits have been reported in longer-term cohort studies.[13,14] Results from a small study[15] in children suggested that hydroxycarbamide, with serial phlebotomy to reduce iron overload, may be an effective replacement for secondary stroke prophylaxis in patients who are unable to continue with long-term maintenance transfusions. Although one study,[14] in which some children had received hydroxycarbamide for up to 8 years, found no evidence of mutagenic changes or cases of malignancy, the potential toxicity of long-term therapy remains a concern. A short-chain fatty acid, butyric acid, which has a low order of toxicity, has been reported to stimulate fetal haemoglobin in patients with sickle-cell disease when given by infusion as arginine butyrate.[16] Promising results have also been reported in small studies[17] using oral sodium phenylbutyrate. Other drugs under investigation include clotrimazole, decitabine, inhaled nitric oxide, and the nonionic surfactant poloxamer 188. There is also some investigation into gene therapy.

As in thalassaemia (see below), bone marrow transplantation is potentially curative in a small minority of patients, but the indications for transplantation are much less well established.[18]

β-Thalassaemia

β-Thalassaemia is a haemoglobinopathy (above) that is due to a deficiency in β globin production accompanied by normal production of α globin chains that, in the absence of sufficient partner chains, are insoluble and precipitate out in erythrocytes and erythroid precursors as large cellular inclusions. These interfere with red cell maturation resulting in ineffective haematopoiesis, retard the passage of red cells from the bone marrow, and create a tendency for those red cells that do mature to be trapped and destroyed in the spleen. The condition is therefore characterised by a hypochromic, microcytic anaemia accompanied by haemolysis. In the heterozygous form, where only one of the β globin genes is affected (known as thalassaemia trait or thalassaemia minor) the anaemia is mild and clinically insignificant. There is some evidence that patients with this form of the disease experience a degree of protection from malaria, which may account for the more frequent distribution of the trait in the populations of areas such as the Mediterranean, parts of Africa, and Asia.

The more severe forms of the disease (known as thalassaemia intermedia if haemoglobin levels are high enough not to require regular transfusion, or thalassaemia major in transfusion-dependent patients) occur in homozygous patients who inherit a defective β globin gene from both parents. Severe anaemia develops in the first year of life as fetal haemoglobin production (which does not involve a β globin) is replaced by the production of adult haemoglobin. The anaemia stimulates erythropoietin production, and if not corrected massive proliferation of red cell precursors develops within, and eventually beyond, the bone marrow, resulting in recurrent bone fractures, deformity of the skull due to expansion of the marrow spaces, and compression of vital structures such as the spinal cord with consequent paresis. Other symptoms include splenomegaly and hypersplenism (resulting in neutropenia and thrombocytopenia), increased susceptibility to infection, and hypermetabolism which may lead to folate deficiency because of the increased folate requirement. If untreated, death in patients with thalassaemia major usually occurs by the 2nd or 3rd year.

Treatment. The mainstay of treatment for severe β-thalassaemia is regular blood transfusion to correct the anaemia. Transfusions should be started as early as possible in life once it is clear that anaemia is severe enough to warrant them. Various transfusion regimens have been used based on different pretransfusion haemoglobin concentrations.[1] The Thalassaemia International Federation[2] recommends regular blood transfusions, usually every 2 to 5 weeks, to maintain a pretransfusion haemoglobin concentration of 9 to 10.5 g per 100 mL. The post-transfusion concentration should not exceed 15 g per 100 mL. It is also recommended that patients should receive leucocyte-depleted packed red cells in order to minimise adverse reactions and platelet allo-immunisation (an immune response to donor platelets). Washed red cells may be used in patients who have repeated severe allergic transfusion reactions. The use of leucocyte-depleted red cells is also desirable in patients who are candidates for haematopoietic stem cell transplantation to reduce the risk of graft rejection and CMV reactivation.[1] An increase in transfusion requirements is a sign of hypersplenism, and splenectomy may be indicated depending on the state of iron overload. However, splenectomy should be avoided if possible below the age of 5 years because of the increased risk of infection.[2] For a discussion of antibacterial prophylaxis in splenectomised patients, see Spleen Disorders, p.194.

If anaemia is corrected by transfusion, growth and development proceed fairly normally in thalassaemic children. However, because the body lacks a mechanism for the excretion of excess iron, repeated transfusion invariably results in iron overload (p.1442), leading eventually to haemochromatosis. The consequences of haemochromatosis include liver dysfunction, endocrine dysfunction (failure of the adolescent growth spurt, hypogonadism, sometimes diabetes and hypothyroidism), and particularly heart disease (pericarditis, heart failure, and arrhythmias). If unchecked, the iron build-up usually leads to death (mainly through heart failure or arrhythmia) by the time patients reach their mid-20s. The accumulation of iron can be retarded by the chelator desferrioxamine and regular systemic use has been shown to improve survival in thalassaemic children,[2,3] and to protect against the cardiac complications of iron overload.[2-4] The greatest increase in iron excretion may be seen in patients given the drug by continuous subcutaneous infusion rather than intramuscular bolus. Continuous intravenous infusion may be considered in patients with severe iron overload or cardiac complications.[2] There is some suggestion that intensive desferrioxamine therapy can improve impaired organ function,[3] but it is considered preferable to begin chelation therapy as early as possible to try to prevent organ damage developing in the first place. In practice, desferrioxamine therapy is started after the first 10 to 20 transfusions or when the ferritin concentration rises above 1 mg/litre, usually at about 3 years of age.[2,5] If therapy is started before this age, careful monitoring of growth and bone development is recommended[2] and liver biopsy has been advocated.[3] Better iron excretion is achieved if patients are given ascorbic acid 100 to 200 mg daily in addition to desferrioxamine (but see under Interactions for Desferrioxamine, p.1440). Patients with thalassaemia may have increased folate requirements and folate supplementation may also be necessary. Although it is not yet certain how much chelation therapy will prolong survival the fact that a nearly normal iron balance can be achieved long term seems hopeful. Deferiprone has been used as an oral alternative to desferrioxamine,[6] but there are conflicting reports regarding its efficacy and safety in the longer term.[7,8] It may have a role in patients for whom desferrioxamine therapy is unsuitable.[2] Investigation of combination therapy using desferrioxamine with deferiprone is underway, as is the development of other oral chelators.[5]

In addition to the essentially symptomatic treatment of thalassaemia a very few patients may be candidates for bone marrow transplantation where suitable facilities and compatible donors exist; if transplantation is carried out before organ damage is marked, successfully transplanted patients are apparently cured and can lead a normal life.[9,10] Gene therapy is also under investigation.

An alternative approach using hydroxycarbamide in an attempt to stimulate fetal haemoglobin production and 'mop up' some of the excess α globin chains has been tried experimentally but results have been mixed. Results of an initial study in patients given butyric acid (as an arginine butyrate infusion) for the same purpose appeared more promising[11] although a subsequent study failed to show any benefit.[12] Mixed results have also been reported with the use of oral butyrate derivatives such as sodium phenylbutyrate[13] and isobutyramide.[14]

Haemostasis and Fibrinolysis

Haemostasis is the physiological response that occurs when blood vessels are damaged. It results in coagulation (formation of a blood clot) and thus arrests bleeding. The initial response is the formation of a plug of platelets, which adhere both to the injured tissue and to each other. The vessel injury, with factors released by the platelets, trigger a series of reactions (the coagulation 'cascade') mediated by proteins circulating in the plasma (blood clotting factors). This results in formation of an insoluble fibrin clot that reinforces the initial platelet plug. Regulatory mechanisms come into operation to prevent widespread coagulation. Lysis of the clot (fibrinolysis) then occurs when wound healing and tissue repair are underway.

Platelet aggregation. Platelets usually circulate in plasma in an inactive form. Contact with damaged endothelium causes them to become activated and to adhere to the site of injury. This adhesion is partly mediated by binding of von Willebrand factor, a plasma protein that also acts as a carrier for factor VIII, to a glycoprotein (termed GPIb) on the platelet membrane surface. Substances are secreted by the activated platelets which cause further platelet aggregation (adenosine diphosphate and thromboxane A_2) and vasoconstriction (serotonin and thromboxane A_2). Thromboxane A_2 secreted by platelets is derived from arachidonic acid.

- The enzyme cyclo-oxygenase is required for the synthesis of thromboxane A_2 and this enzyme is inhibited by the **antiplatelet drugs** aspirin and sulfinpyrazone. Aspirin binds irreversibly to the enzyme and therefore the antiplatelet effect lasts for the lifetime of the platelet. Sulfinpyrazone is a reversible inhibitor of the enzyme.

Platelet aggregation involves interaction of fibrinogen with a receptor, glycoprotein IIb/IIIa, on the platelet surface.

- Antiplatelet drugs such as abciximab act by blocking this receptor.

In addition to their action in forming the initial haemostatic plug, platelets are also involved in coagulation by providing a surface on which interactions between clotting factors take place, resulting in more efficient coagulation.

Coagulation. The series of reactions that results in formation of a fibrin clot may be conveniently considered as two pathways, the *intrinsic* pathway (triggered within the blood) and the *extrinsic* pathway (triggered by substances extraneous to the blood). While this distinction is useful for understanding *in-vitro* coagulation and is the basis for tests that are specific for each pathway (see below), the mechanism of *in-vivo* coagulation is not so segregated and factors appearing in one pathway are also necessary for reactions in the other pathway. The intrinsic and extrinsic pathways of coagulation and the *in-vivo* pathways are discussed further below and are represented in summary form in Figure 1, p.1047 and Figure 2, p.1048 respectively. Factors circulate in the blood in an inactive form and are activated by cleavage of peptide bonds. The numerals attached to the factors reflect the order in which they were discovered and not their importance or position in the chain of reaction. The letter 'a' after a factor name or number denotes the activated form. Factors involved in blood coagulation are listed in Table 2, below. Once the coagulation cascade is started, activated factors act in positive feedback mechanisms to amplify the activation steps thus producing rapid coagulation. Cofactors are necessary as they increase the speed of the reactions. Other components necessary for coagulation are calcium ions and a membrane surface. Calcium ions are required for nearly all the reactions. Many of the activation steps, notably those involving factors VII, IX, and X, take place on a membrane surface expressing tissue factor, or platelets. Factors bind to phospholipids on the membrane surface.

The *extrinsic* pathway begins when *tissue factor* (factor III) is released from damaged tissue. This forms a complex with *factor VII* and factor VIIa and directly activates *factor X*. The *intrinsic* pathway begins when blood comes into contact with a negatively charged surface. *Factor XII* interacts with high molecular weight kininogen (Fitzgerald factor) and prekallikrein (Fletcher factor) to produce *kallikrein*, which activates factor XII. The active factor XIIa then activates *factor XI*, which in turn activates *factor IX*. *Factor VIII* is activated by thrombin to factor VIIIa to act as a cofactor for factor IXa, which converts *factor X* to factor Xa. The extrinsic and intrinsic pathways therefore converge with the activation of factor X. *Factor V* is activated by thrombin to factor Va to be a cofactor for factor Xa, which converts prothrombin (*factor II*) to thrombin with the subsequent formation of a *fibrin* gel. *Factor XIII* is also activated by thrombin to factor XIIIa, which stabilises the fibrin gel to form a stable clot.

The dependence of many steps in the coagulation cascade on calcium ions allows coagulation *in vitro* to be blocked by the addition of calcium chelators, such as sodium citrate, to collected blood. When collected blood is tested for coagulation function, addition of calcium ions allows clotting to proceed. Tests of coagulation function include activated partial thromboplastin time (APTT), which is a measure of the activity of the intrinsic system, prothrombin time (PT), a measure of the activity of the extrinsic system, and thrombin clotting time, which measures the conversion of fibrinogen to fibrin.

The factors involved in triggering the *in-vitro intrinsic* pathway, that is prekallikrein, factor XII, and possibly factor XI, are probably not important in *in-vivo* blood coagulation as deficiency of any of these factors is not associated with a serious bleeding disorder. The important step in the clotting cascade *in vivo* is release of *tissue factor* (factor III) from damaged tissue. As has already been mentioned, tissue factor forms a complex with *factor VII* and factor VIIa that activates *factor X*. Factor Xa activates *prothrombin* resulting in formation of a *fibrin clot* which occurs as described above under the *in-vitro* systems. To enhance coagulation, various positive feedback mechanisms and other clotting factors operate to increase production of activated factors VII and X. For example, formation of factor VIIa is amplified by factor VIIa itself and by factor Xa. Formation of factor Xa is amplified by factor IXa produced by the action of thrombin on factor XI.

Regulation of coagulation. The process of blood coagulation is regulated to ensure that it remains localised at the site of injury and does not result in more widespread clotting. This is achieved by dilution of clotting factors in flowing blood, by rapid hepatic clearance of many activated factors or products, and by natural anticoagulant mechanisms, which include antithrombin III, protein C, and protein S (see Figure 2). *Antithrombin III* inhibits the serine protease clotting factors, that is, thrombin, IXa, Xa, XIa, and XIIa. Antithrombin III is activated by binding to glycosaminoglycans, such as heparan glycosaminoglycan and dermatan sulfate, present in vascular endothelium.

- Heparin and low-molecular-weight heparins act as **anticoagulants** by binding antithrombin III at a specific binding site and enhancing its inhibitory effect on the serine protease clotting factors. At therapeutic doses of heparin the factors inhibited are thrombin and factor Xa. Low-dose heparin, such as that given for the prophylaxis of thromboembolism, inhibits factor Xa. Very high doses of heparin have a direct inhibitory effect on antithrombin III. Heparinoids which lack the specific binding site for antithrombin III do not have the anticoagulant properties of heparin. Low-molecular-weight heparins have a higher ratio of anti-factor-Xa to antithrombin activity than heparin and therefore mainly inhibit factor Xa.

Proteins C and S are both vitamin K-dependent plasma proteins. Protein C circulates in plasma in an inactive form. It is activated by contact with thrombin that is bound to thrombomodulin, a receptor located on the surface of endothelial cells. Activated protein C inhibits factors Va and VIIIa and therefore slows blood clotting. Protein S acts as a cofactor in this inhibition.

Vitamin K is essential for the activities of factors II, VII, IX, and X. It is also essential for the activity of proteins C and S. These factors contain glutamic acid residues that undergo carboxylation in the liver, a reaction requiring reduced vitamin K as a cofactor. This carboxylation step allows the factors to bind calcium, a reaction necessary for their function in the clotting cascade.

- Deficiency of vitamin K or the use of **oral anticoagulants** (which are vitamin K antagonists) therefore impairs the function of these clotting factors. Oral anticoagulants have no effect on circulating clotting factors and thus the time required before the anticoagulant effect is seen depends on the individual clearance rate of the factor.

Fibrinolysis is the mechanism of clot dissolution. It is mediated by *plasminogen*, which circulates in plasma in an inactive form; conversion to its active form, *plasmin*, occurs when plasminogen binds to fibrin in the presence of a *plasminogen activator* (see Figure 2). Plasmin, a *proteolytic enzyme*, digests fibrin clots and hydrolyses other proteins, including factors II, V, VIII, and XII. As fibrin is lysed, plasmin is released which is inhibited by α_2-antiplasmin to prevent a systemic lytic state developing. There are two types of plasminogen activator, *tissue plasminogen activator* (tPA), which originates from the endothelium, and *urokinase*, which

Table 2. Proteins involved in blood coagulation and in fibrinolysis.

	Proteins	Synonyms
Blood coagulation	Factor I	Fibrinogen
	Factor II*	Prothrombin
	Factor III	Tissue thromboplastin; tissue factor
	Factor IV	Calcium ion
	Factor V	Ac-globulin; labile factor; proaccelerin
	Factor VI (unassigned)	
	Factor VII*	Proconvertin; SPCA; stable factor
	Factor VIII	Antihaemophilic factor; AHF
	Factor IX*	Christmas factor; plasma thromboplastin component; PTC
	Factor X*	Stuart factor; Stuart-Prower factor
	Factor XI	Plasma thromboplastin antecedent; PTA
	Factor XII	Hageman factor
	Factor XIII	Fibrin stabilising factor; FSF
	von Willebrand factor	Factor VIII-related antigen; vWF
	High molecular weight kininogen	HMWK; Fitzgerald factor
	Prekallikrein	Fletcher factor
Fibrinolysis	Plasminogen	
	Prourokinase	
	Tissue plasminogen activator	tPA
	Antithrombin III	Major antithrombin; AT-III; Heparin cofactor
	Protein C*	Autoprothrombin IIA; Factor XIV
	Protein S*

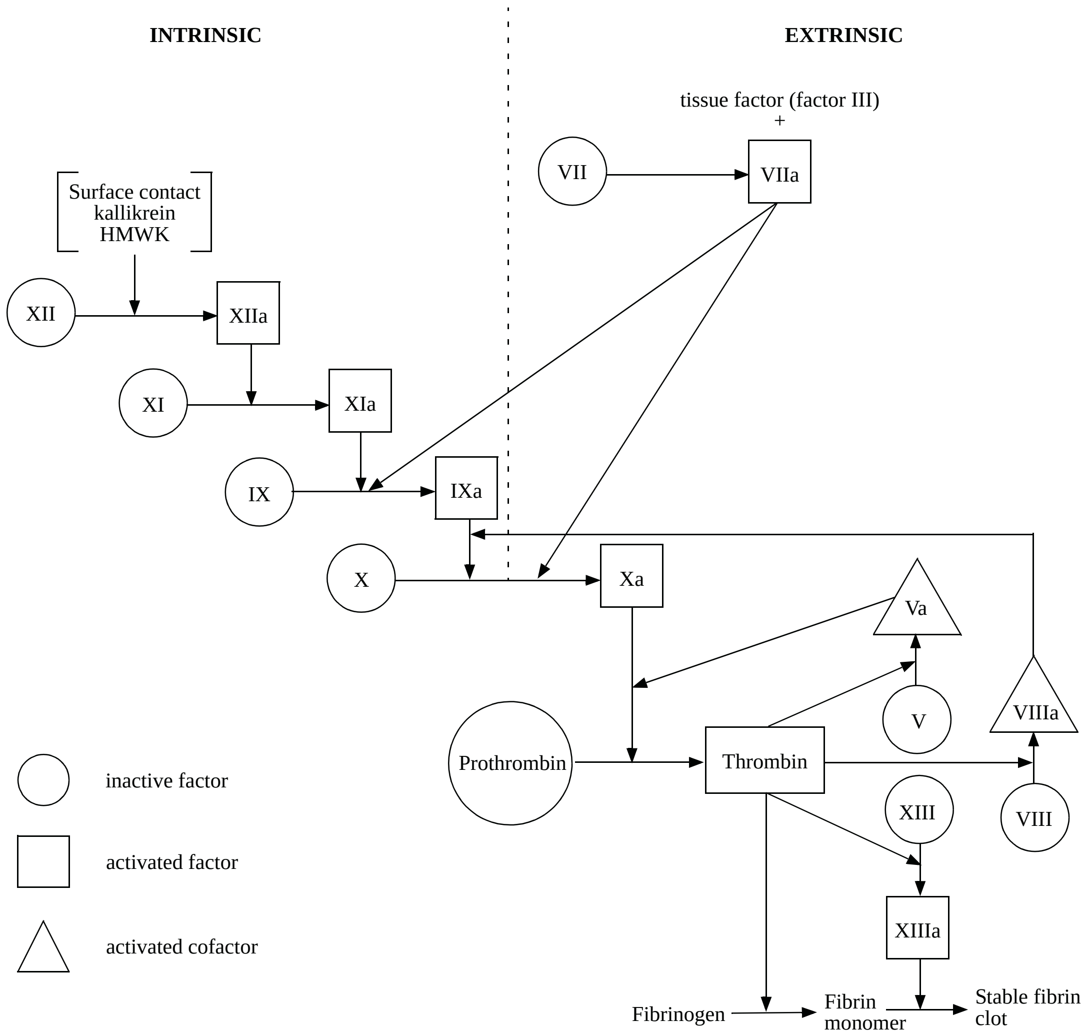
* denotes vitamin K-dependent factor

Figure 1. Simplified representation of in-vitro coagulation.



is activated from prourokinase. Activators of prourokinase include plasmin. Tissue plasminogen activator binds to fibrin and thus activates plasminogen bound to fibrin much more rapidly than circulating plasminogen; therefore the fibrinolytic action of tissue plasminogen activator is fibrin specific. Urokinase does not bind to fibrin, and therefore its fibrinolytic action is not fibrin specific, although it is activated by plasmin that is bound to fibrin. *In vivo*, fibrinolysis is almost entirely due to the activity of tissue plasminogen activator.

- The two types of plasminogen activator with their different modes of action provide the basis for the specificity of **thrombolytics** (the so-called 'clot specific' effect), which act by promoting the conversion of plasminogen to plasmin. The tissue plasminogen activators alteplase and tenecteplase are fibrin-specific thrombolytics, and streptokinase and urokinase are fibrin-nonspecific.
- The **antifibrinolytic drugs** aminocaproic acid and tranexamic acid act primarily by blocking the binding of plasminogen and plasmin to fibrin, thereby preventing the breakdown of fibrin clots.
- Aprotinin, an inhibitor of proteolytic enzymes, acts as a **haemostatic** by inhibiting the action of plasmin and therefore preventing the breakdown of fibrin clots. Other drugs acting as haemostatics include batroxobin, which is reported to promote the production of fibrin from fibrinogen, and etamsylate, which has a stabilising effect on the capillary wall. Drugs such as oxidised cellulose, calcium alginate, collagen, and gelatin act by providing a physical meshwork within which clotting can occur. Adrenaline, adrenalone, and noradrenaline produce haemostasis by causing vasoconstriction. Drugs with astringent properties such as alum and ferric chloride are also used for haemostasis.

The use of haemostatics may be considered when bleeding cannot be controlled by direct measures such as the application of pressure, suture or ligation, or electrocoagulation.

Dysfunction of the haemostatic mechanisms or the systems regulating haemostasis produces haemorrhagic disorders (acquired and inherited, see below) or thromboembolic (p.1187) disorders.

Acquired haemorrhagic disorders

Bleeding disorders sometimes arise due to disturbances in either clotting factors or platelets, or to vascular wall defects occurring as a result of a disease or a medical or surgical procedure. Disturbances and defects may also be drug-induced. In some conditions, including renal and liver disease, cardiopulmonary bypass procedures, or following massive blood transfusion, disturbances in many of the homoeostatic mechanisms occur simultaneously producing complex haemorrhagic disorders, sometimes referred to as complex acquired coagulopathies.

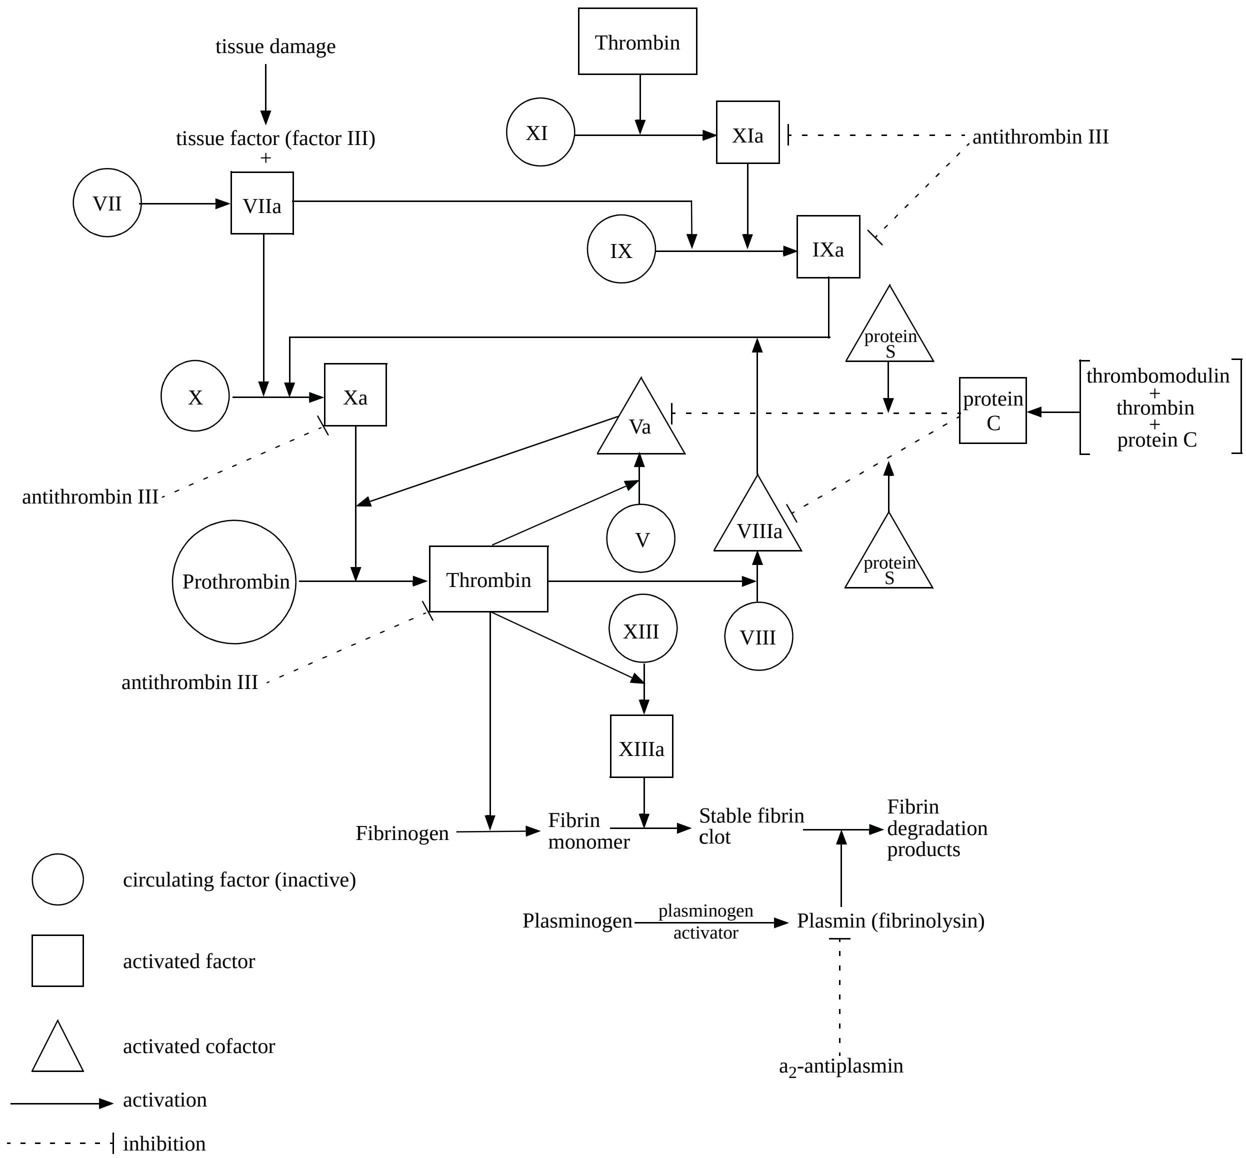
One of the commoner causes of haemorrhagic disorder caused by *disturbance of clotting factors* is overdose with heparin, oral anticoagulants, or thrombolytics. Different approaches are used in the management of overdose with these drugs, as discussed in Treatment of Adverse Effects under Heparin (p.1302), Warfarin Sodium (p.1426), and Streptokinase (p.1404).

Deficiencies in clotting factors may occur in several diseases. Vitamin K is essential for the activity of a number of clotting factors and plasma proteins (see Haemostasis and Fibrinolysis, above), and disorders that cause a deficiency of vitamin K can lead to impairment of these. Diseases of the small bowel and biliary tract can impair absorption of vitamin K, and liver disease reduces the production of clotting factors. Deficiency is generally treated by giving vitamin K, although this is not always effective in patients with liver diseases. Vitamin K is widely used for the prevention and treatment of neonatal vitamin K deficiency bleeding (p.1997). Examples of other acquired disorders that affect clotting factors but occur rarely include acquired haemophilia affecting factor VIII (see Haemophilias, below) and von Willebrand syndrome (see von Willebrand's Disease, below).

Low platelet concentrations can be associated with many other illnesses and increase the risk of bleeding; management is discussed in Thrombocytopenia, below.

Various drugs are used, or are under investigation, for their effect on *perioperative blood loss*.[1,2] Topical treatments such as fibrin glue, gelatin-based films and sponges, oxidised cellulose, and thrombin are used for a local haemostatic effect in surgical procedures. The antifibrinolytic drugs aprotinin, aminocaproic acid, and tranexamic acid are used to reduce bleeding and transfusion requirements in procedures such as liver transplantation and cardiac sur-

Figure 2. Simplified representation of *in-vivo* coagulation and fibrinolysis



gery involving cardiopulmonary bypass. Desmopressin is used in surgical patients with some congenital and acquired bleeding disorders, but in patients without pre-existing bleeding disorders it has not consistently been shown to be of benefit. Recombinant activated factor VII (eptacog alfa) is used in the management of bleeding in patients with haemophilia, but it is also under investigation in surgical patients with normal haemostasis.

Disseminated intravascular coagulation

Disseminated intravascular coagulation (DIC) is an acute or chronic syndrome resulting from an underlying condition that causes pathological stimulation of coagulation at some point in the coagulation pathway (above); thrombin generation triggered by uncontrolled tissue factor is probably the main factor in most cases. Causes include obstetric emergencies (placental abruption, amniotic fluid embolism), infection (bacterial septicaemia, viraemia), neoplasms, trauma (head injury, burns), venomous snake bites, transfusion of incompatible blood, liver disease, and various vascular causes.

Stimulation of coagulation leads to microvascular thrombosis that produces widespread tissue ischaemia and may lead to ischaemia of major organs. Simultaneously, secondary activation of the fibrinolytic system and consumption of coagulation factors produces bleeding, which is often the predominant manifestation. Symptoms are therefore very variable and include those of bleeding, such as spontaneous bruising, prolonged bleeding from intravenous puncture sites, and gastrointestinal and pulmonary haemorrhage, and those of thrombosis, such as acute renal failure, venous thromboembolism, skin necrosis, liver failure, cerebral infarction, acute respiratory distress, and coma. Some cases may be asymptomatic.

Treatment of DIC is aimed primarily at the underlying cause since the condition will not resolve until the underlying trigger is removed. Recovery is often fairly rapid once treatment is started. Supportive therapy to ensure adequate hydration and tissue oxygenation is also vital. These measures may be sufficient in patients with asymptomatic DIC. Most patients with symptomatic DIC also require therapy with plasma and platelets to replace coagulation factors and arrest bleeding. Coagulation factor concentrates such as fibrinogen concentrate or cryoprecipitate are not favoured, as they do not contain all coagulation factors and they may be contaminated with traces of activated coagulation factors, which can exacerbate the coagulation disorder in these patients. Heparin has been used in the management of DIC with the aim of switching off the coagulatory mechanisms. Although benefit has been shown with some underlying causes, heparin may worsen bleeding and its use in DIC is considered by some to be controversial. Where the risk of bleeding is relatively minor and thrombosis predominates, heparin may be appropriate. Other measures that have been tried in limited numbers of patients include use of a low-molecular-weight heparin. Concentrates of activated protein C, and more recently the recombinant form drotrecogin alfa (activated), have been used in DIC associated with severe sepsis and have improved coagulation abnormalities and mortality. Antithrombin III has also been used, but despite beneficial reports of use in sepsis-related DIC a large study found no benefit.

Haemophilias

The haemophilias are bleeding disorders caused by low concentrations of specific coagulation factors. Acquired haemophilia is rare and most patients have inherited forms. The most well known are haemophilia A (factor VIII deficiency) and haemophilia B (factor IX deficiency). Factor XI deficiency, originally called haemophilia C, is mentioned under Inherited Haemorrhagic Disorders, below.

Haemophilia A (classical haemophilia, factor VIII deficiency) is the most common of the serious hereditary bleeding disorders.[1] It is an X-linked recessive disorder and therefore, with rare exceptions, males are affected and females are carriers. The condition is due to deficiency of factor VIII and severity of bleeding is related to the residual factor level. The condition is severe when there is less than 1% of normal factor VIII activity, moderate when the factor VIII concentration is 1 to 5% of normal, and mild when the factor concentration is greater than 5%. Clots are slow to form and break up easily, and bleeding after trauma or surgery may be prolonged. In moderate and severe haemophilia A bleeding may occur into major joints producing long-term joint destruction, a major cause of morbidity in haemophilia. Other frequent sites of bleeding are large muscles, and renal and intestinal tracts. CNS haemorrhage may also occur, especially after trauma.

Treatment of bleeding episodes depends on the severity of the haemophilia.[1-4] Patients with moderate to mild haemophilia A can be satisfactorily treated with desmopressin,[5,6] which produces an increase in factor VIII and von Willebrand factor, and increases platelet adhesion and expression of tissue factor. Desmopressin also transiently stimulates plasma fibrinolytic activity, and it has been suggested that use with an antifibrinolytic, such as tranexamic acid, may inhibit this effect. However, there is no evidence for haemostatic improvement with this combination, although tranexamic acid itself is effective in the management of mucosal bleeding and during dental surgery.[5] Desmopressin is usually given intravenously. The subcutaneous route is an alternative but the maximum effect is slower. It can also be given intranasally, and this route is used by patients to treat themselves outside hospital. In patients with more severe haemophilia A, desmopressin is ineffective and treatment of bleeding episodes requires replacement of factor VIII. The amount given depends on the severity of bleeding.

Desmopressin and factor VIII preparations are also used for the *prevention of bleeding episodes* in situations where haemorrhage may be anticipated, for example before surgery or dental treatment;[7,8] patients with haemophilia A should also not be given intramuscular injections (because of potential muscle damage and bleeding into muscle) unless they are given during a period when the patient is covered by replacement factor. Prophylactic cover with an antifibrinolytic, such as tranexamic acid given orally (or, in dentistry, also topically as a mouthwash), may also be used and should be continued for 5 to 7 days after the procedure. Fibrin glue can also be useful in the control of local bleeding.[8]

An alternative method of management has been practised in Sweden since 1958 where *continuous prophylaxis* with factor VIII is given to patients with severe haemophilia A with the aim of preventing arthropathy. Therapy is started at 1 to 2 years of age and the factor VIII concentration is maintained at a level of at least 1% of normal. Patients who began receiving prophylaxis before the age of 2 have had almost no bleeding episodes and joints have remained normal for up to 16 years of follow-up.[9,10] This approach has subsequently been adopted in a number of other countries, although questions remain about the best age at which to start therapy, when to stop, the optimum dose, and effects on quality of life.[1,2,11]

There are various factor VIII preparations available that vary in activity and source.[4] Most products were previously derived from pooled donor plasma and were associated with transmission of viruses including HIV (leading to the subsequent development of AIDS), hepatitis B, and other hepatitis viruses. The introduction of products treated with heat or chemicals, and efforts to screen the donor material from which factor VIII is obtained, seem to have overcome problems with transmission of HIV and hepatitis B and C, although there is concern that non-lipid-enveloped viruses such as human parvovirus B19 and hepatitis A may still be transmitted. It is recommended that patients not already immune should be vaccinated against hepatitis A and B. There is some concern that variant Creutzfeldt-Jakob disease (vCJD) may be transmitted by plasma-derived clotting factor products, but there is no proof as yet that this has occurred. Factor VIII produced by recombinant DNA technology may avoid the dangers of possible viral transmission and is therefore the factor VIII preparation of choice (but see also Transmission of Infections under Factor VIII, p.1067). It has been suggested that high-purity plasma-derived factor VIII preparations slow the decline in CD4 count in haemophiliac patients who are HIV-positive, but this was based on the measurement of surrogate markers and the purity of clotting factor preparations has been found not to affect the development of AIDS. Factor VIII preparations are usually given by bolus injection, but there is increasing interest in the use of continuous infusion[2,11] because it can maintain a steady state of clotting factor concentrations and reduce the amount of concentrate used. Evidence from controlled studies is needed to confirm the perceived benefits of this method.

A serious complication of replacement therapy in haemophilia A is the development of *antibodies to factor VIII* (often called inhibitors). The reported incidence varies widely, up to about 30%. Antibodies are more likely to develop in young patients with severe haemophilia who receive continuous prophylaxis, but can also arise in patients with mild haemophilia, typically after intensive replacement therapy; some patients appear to have a genetic predisposition.[12] Antibody concentrations can be measured and may be classified as either low-titre or high-titre; patients are further described as low or high responders according to the increase in antibody production when given factor VIII.[13]

The management of acute bleeding episodes can be problematic in these patients, and depends on the characteristics of the antibodies.[12-14] Patients with low-titre low-responding antibodies are generally treated with high-dose factor VIII. Porcine factor VIII may be useful in high-titre or highly-responding patients at least in the short term, although with longer use antibodies to the porcine material can develop in turn. Otherwise, when high-titre highly-responding antibodies are present, bleeding episodes are managed with factor VIII inhibitor bypassing fraction, or recombinant factor VIIa, which bypass the factor VIII-dependent step in the coagulation cascade. The removal of antibodies by plasmapheresis, with or without extracorporeal immunoadsorption, followed by high-dose factor VIII, has been used in high-titre patients when other measures have failed.[14]

Attempts have been made to induce tolerance and eradicate the antibodies.[12,13,15] Regimens have used regular doses of factor VIII over prolonged periods, sometimes with immunosuppression by cyclophosphamide, immunomodulation by normal immunoglobulin, or extracorporeal immunoadsorption. The treatment of bleeding episodes during immune tolerance induction therapy can be difficult, requiring the use of factor VIII inhibitor bypassing fraction or recombinant factor VIIa.

A future development that may provide a clinical cure for haemophilia is *gene therapy*.[1,16] However, despite successful treatment in *animal* models, initial human trials for haemophilia A and B have shown no sustained responses.

Haemophilia B (factor IX deficiency; Christmas disease) is less common than haemophilia A. The classification and clinical features of this form are the same as for haemophilia A, but are related to a deficiency of factor IX. Treatment follows the same principles as for haemophilia A,[1-4] except that desmopressin does not affect factor IX concentrations and is therefore ineffective in haemophilia B. Bleeding episodes are treated with factor IX replacement, preferably using recombinant factor IX or plasma-derived highly purified factor IX preparations that do not contain other clotting factors. Low-purity factor IX preparations derived from plasma that contain other clotting factors in addition to factor IX (prothrombin complex concentrates) are associated with thromboembolic complications, particularly in patients with liver disease and others at increased risk of thromboembolism or disseminated intravascular coagulation. Fresh frozen plasma may be used in emergencies if specific factor IX products are unavailable. Antifibrinolytic drugs may be used in patients treated with purified factor IX preparations, but should be avoided in those given prothrombin complex concentrates because of the increased risk of thrombosis.[3] Continuous prophylaxis using factor IX preparations has also been used in haemophilia B.[9,10] As in patients with haemophilia A, vaccination against hepatitis A and hepatitis B is recommended for all haemophiliacs not already immune.

Antibody inhibitors of factor IX can be produced although the incidence of antibody formation is lower than that seen in haemophilia A. Acute bleeding episodes in these patients may be managed using recombinant factor VIIa.[1] Induction of tolerance has also been used for antibodies in haemophilia B, but the response is not as good as for haemophilia A and these patients appear to be at risk of anaphylaxis and nephrotic syndrome.[1,12]

As mentioned under haemophilia A, gene therapy is under investigation as a possible clinical cure.

Acquired haemophilia is a rare disease in which autoantibodies form against factor VIII.[17] In about 50% of cases, factor VIII autoantibodies are idiopathic; the rest are associated with other conditions including the postpartum period, malignancies, auto-immune diseases, and adverse drug reactions. The bleeding pattern is different to congenital haemophilia and usually occurs as bleeding in the skin or muscles, haematuria, haematemesis or melaena, and prolonged postpartum or postoperative bleeding; haemarthroses are relatively uncommon.

Treatment for acute episodes depends on the severity of bleeding and the antibody titre. Desmopressin is only effective in patients with low inhibitor titres. Large doses of plasma-derived or recombinant factor VIII may be effective, but the dose required to saturate the autoantibodies can be difficult to predict and therapy must be closely monitored to adjust dosage according to factor VIII concentrations. The use of porcine factor VIII concentrate is an alternative. A small number of patients have been managed with factor VIII inhibitor bypassing fraction or recombinant factor VIIa, and these may be used when the titre is very high or bleeding persists despite the use of factor VIII concentrates.

Up to a third of patients with acquired haemophilia have a spontaneous resolution of their autoantibodies. For other patients, treatment to eradicate or suppress the autoantibodies is often based on a corticosteroid, such as prednisone, given alone or combined with cyclophosphamide; evidence for the efficacy of such treatment is largely anecdotal however. Other combinations that have also been tried include a corticosteroid with azathioprine, or a corticosteroid with cyclophosphamide plus vincristine. Ciclosporin, alone or with a corticosteroid, has been used as a salvage therapy. Intravenous immunoglobulin has been tried, but any benefit is questionable. Similarly, plasmapheresis and immunoadsorption have been used, but their contribution to the success of treatment is difficult to assess because they are usually combined with immunosuppressive drug therapy. Factor VIII immune tolerance regimens are rarely, if ever, used in acquired haemophilia.

Inherited haemorrhagic disorders

Inherited disorders that lead to abnormal bleeding include platelet disorders and disturbances in clotting factors.

Inherited platelet disorders can affect platelet function, size, and number. Platelet function disorders include abnormalities in platelet receptors (such as Glanzmann's thrombasthenia), platelet granules (storage pool deficiencies), signal transduction pathways and granule release, and membrane phospholipids.[1,2] Treatment depends on the disorder, but in some conditions desmopressin or platelet transfusions are useful in the management of bleeding.[1] Inherited thrombocytopenias are discussed under Thrombocytopenia, below.

Inherited disorders that result in deficiencies or abnormalities of clotting factors can cause variable degrees of bleeding. The most common inherited disorders of clotting factors are haemophilias A and B (above) and von Willebrand disease (below). Other inherited disorders are rare[3] but include abnormalities of fibrinogen, deficiencies of the individual factors II, V, VII, X, XI (haemophilia C), XIII, and combined deficiencies of factors V and VIII, or of factors II, VII, IX, and X. Management depends on the clotting factors affected and the degree or risk of bleeding. In general, antifibrinolytics such as tranexamic acid may be adequate for control of mucosal bleeding and menorrhagia, and fibrin glue may be useful for local haemostasis. Severe bleeding requires the replacement of clotting factors, preferably using specific factor concentrates or recombinant factor products; fresh frozen plasma may be a suitable alternative when more specific products are not available. Vitamin K treatment may be considered in patients with deficiencies of vitamin K-dependent clotting factors (II, VII, IX, and X).

Neonatal intraventricular haemorrhage

Intraventricular haemorrhage, also referred to as periventricular or periventricular-intraventricular haemorrhage, is bleeding from vessels in or around the ventricles of the brain. It is the major cause of death in very low birth-weight neonates and can affect up to 60% of neonates weighing less than 1500 g. Intraventricular haemorrhage is rare in neonates over 32 weeks of gestation, since the vessels that bleed involute early in the third trimester. Intraventricular haemorrhage usually develops within the first 3 days of life. The haemorrhage may be graded from 1 to 4 according to severity, the higher numbered grades being the most severe and most likely to produce the long-term consequences of impaired motor and mental function. The aetiology is probably multifactorial and may include fluctuations in cerebral blood flow due to failure of autoregulatory mechanisms and tissue damage caused by oxygen free-radicals.

Once intraventricular haemorrhage has occurred **treatment** is supportive and includes correction of anaemia, hypotension, and acidaemia, and management of raised intracranial pressure.

As intraventricular haemorrhage is a major risk factor for impaired motor and mental development **prevention** is very important. Numerous interventions aim to reduce its incidence and include prevention of premature births, avoidance of hypercapnia, correction of major haemodynamic disturbances, and correction of coagulation abnormalities. Various drugs have also been tried including corticosteroids, etamsylate, indometacin, pancuronium, phenobarbital, vitamin E, and vitamin K. Some of these drugs have been given to the mother antenatally since the development of intraventricular haemorrhage may be related to perinatal events.

• Giving corticosteroids to pregnant women at risk of preterm delivery is recommended to prevent neonatal respiratory distress syndrome (p.1508) and may also reduce the incidence of intraventricular haemorrhage.[1] A review of data from 12 controlled studies involving antenatal corticosteroid use (primarily to prevent respiratory distress syndrome)[2] suggested that the risk of intraventricular haemorrhage was also reduced but this was based on limited data. Further studies[3-6] have supported this finding, although few have involved randomised doses of corticosteroids. The mechanism for the beneficial effect of corticosteroids is not clear but avoidance of neonatal hypotension has been suggested.[3]

• Etamsylate limits capillary bleeding through its action on hyaluronic acid and initial studies showed a reduction in intraventricular haemorrhage. A subsequent study[7] showed little evidence of benefit on short-term follow-up, although confidence intervals were wide. Follow-up[8] of these infants at 2 years of age found that etamsylate had not reduced the risk of death, impairment, or disability. Follow-up of another study[9] also found that despite a reported reduction in intraventricular haemorrhage with etamsylate, developmental outcome assessments at about 4 years of age showed that it had not reduced cerebral palsy compared with the control group.

• Indometacin may reduce cerebral blood flow as a result of vasoconstriction, reduce oxygen free-radical damage, and accelerate maturation of blood vessels around the ventricles. Early studies produced conflicting results but a later larger multicentre study[10] showed a reduction in both incidence and severity although there was an unusually large number of neonates with severe intraventricular haemorrhage in the control group.[11] A concern with the use of indometacin is the possibility that it may produce cerebral ischaemia due to its vasoconstrictor action and therefore increase the risk of developmental handicaps.[11] However, follow-up of the infants included in the multicentre study at the ages of 3 years,[12] 4.5 years,[13] and 8 years,[14] reported no adverse effects on cognitive or motor development. Further analysis of the data from this cohort has suggested that indometacin may reduce intraventricular haemorrhage in boys but have little effect in girls;[15] a true difference in effect between the sexes remains to be confirmed however. Another large multicentre study[16] also found that although indometacin reduced the incidence of severe haemorrhage, it did not improve survival without neurosensory impairment at 18 months. A subsequent systematic review[17] concluded that although indometacin prophylaxis reduced the rate of severe intraventricular haemorrhage, it did not improve the rate of survival free of neurosensory disability.

• Neuromuscular blockers, such as pancuronium, abolish non-synchronous respiration and therefore stabilise both cerebral and arterial blood flow velocity and some studies have shown a reduction in intraventricular haemorrhage in mechanically ventilated neonates (see Intensive Care, p.1901). However, other studies have produced conflicting results and routine use in all ventilated neonates is not recommended.

• Phenobarbital was also suggested to act by stabilising fluctuations in cerebral blood flow, and studies of use in neonates show similarly inconsistent results with many showing no benefit. A meta-analysis[18] concluded that postnatal phenobarbital could not be recommended as prophylaxis, and was associated with an increased need for mechanical ventilation. Initial studies of antenatal phenobarbital were more promising with a decrease in severity of haemorrhage being reported.[19] However, a larger randomised study[20] in 610 women failed to show any effect of antenatal phenobarbital on incidence or severity of intraventricular haemorrhage. An assessment of surviving infants who could be traced at about 20 months of age also found that antenatal phenobarbital had no apparent effect on neurodevelopmental outcome.[21] A concern with the use of phenobarbital in the perinatal period is that it may lower Apgar scores and produce respiratory depression. A meta-analysis[22] did not support the maternal use of phenobarbital.

• Vitamin E protects polyunsaturated fatty acids, and thus membranes, from oxidation. As oxygen free-radical damage may contribute to the development of intraventricular haemorrhage, vitamin E may have a role in its prevention. Results have been conflicting. A systematic review[23] of studies in preterm infants (gestational age less than 37 weeks or birth-weight less than 2500 g) found that vitamin E reduced the risk of intraventricular haemorrhage overall, but only reduced the risk of severe haemorrhage in surviving very low birth-weight infants (less than 1000 g). There was also a suggestion that intravenous vitamin E may have no effect compared with other dosage routes. However, the strength of these findings is limited and there was an increased risk of sepsis associated with vitamin E use, such that the role of supplementation with this vitamin has not been established in preterm infants.

• The activity of vitamin K-dependent coagulation factors is reduced in neonates and antenatal vitamin K in mothers has been tried as a means of preventing intraventricular haemorrhage. However, results of studies have not been promising. Most trials have been too small to produce conclusive results and a larger randomised controlled study[24] in 139 mothers failed to find any benefit from vitamin K prophylaxis. A subsequent systematic review[25] of 5 trials, including this one, also concluded that antenatal vitamin K use did not prevent intraventricular haemorrhage in preterm infants.

Plasma volume expansion using fresh frozen plasma or a plasma substitute has also been thought to reduce intraventricular haemorrhage by stabilising the circulation, but a prospective multicentre study found no evidence of reduction in haemorrhage[26] or subsequent death and disability[27] after the use of plasma or gelatin as volume expanders.

Thrombocytopenia

Platelet concentrations in healthy individuals range from 150×10^9 cells/litre to 450×10^9 cells/litre, and thrombocytopenia is often **defined** as a reduction in the number of circulating platelets to less than 150×10^9 cells/litre (150 000 cells/mm^3). As the platelet count falls the risk of bleeding increases, although spontaneous bleeding is uncommon unless the count falls below 10×10^9 cells/litre to 20×10^9 cells/litre, or there is an abnormality in platelet function. Thrombocytopenia can result from decreased production, increased destruction, or abnormal splenic sequestration of platelets.

There are a number of **congenital forms** of thrombocytopenia that can affect platelet size, number, and function. They range across a wide clinical spectrum from mild forms, which may only be discovered incidentally and do not require specific treatment, to severe forms that are associated with a high risk of bleeding and may ultimately require haematopoietic stem cell transplantation.[1]

Secondary thrombocytopenia can be associated with many other illnesses.[2] Decreased platelet production may occur in bone marrow diseases such as leukaemias and aplastic anaemia, some viral illnesses, chronic alcohol toxicity, and liver disease. Increased destruction of platelets occurs in many disorders including idiopathic thrombocytopenic purpura (p.1505), sepsis, disseminated intravascular coagulation (above), and thrombotic thrombocytopenic purpura and haemolytic-uraemic syndrome (see Thrombotic Microangiopathies, p.1076). Gestational thrombocytopenia[3] is a mild form that usually occurs in late pregnancy, in which platelet concentrations return to normal within 12 weeks after delivery. More severe thrombocytopenia may be caused by obstetric conditions including pre-eclampsia and HELLP (haemolysis, elevated liver enzymes, low platelets) syndrome. Neonatal thrombocytopenia[4] that is mild and of early onset (in the first 72 hours of life) may be secondary to placental insufficiency and reduced platelet production. More severe thrombocytopenia of later onset may result from platelet destruction associated with sepsis or necrotising enterocolitis. In neonatal allo-immune thrombocytopenia, maternal antibodies against fetal platelet antigens cross the placenta to cause disease ranging from mild self-limiting thrombocytopenia to neonatal intracranial haemorrhage. In neonatal auto-immune thrombocytopenia there is placental transfer of maternal platelet autoantibodies in mothers with conditions such as idiopathic thrombocytopenic purpura or SLE.

Drug-induced thrombocytopenia has been reported with many drugs.[5-9] Decreased platelet production can be caused by drugs that have a toxic effect on bone marrow, including many antineoplastics. Drugs that are often implicated in immune-mediated platelet destruction include anticonvulsants, cinchona alkaloid derivatives (quinine, quinidine), diuretics, disease-modifying antirheumatic drugs (penicillamine, gold salts), NSAIDs, and sulfonamides. The 2 types of heparin-induced thrombocytopenia have been well documented (see p.1302).

Treatment of thrombocytopenia is based on management of the underlying disorder where appropriate, or stopping the offending drug. Platelet infusions are used in the treatment of active bleeding or in thrombocytopenic patients who are at risk of bleeding. They should not be used when there is a thrombotic process such as in thrombotic thrombocytopenic purpura or heparin-induced thrombocytopenia. The platelet count at which infusion may be considered depends on various factors including the cause of thrombocytopenia, the presence of additional risk factors such as sepsis, the degree of bleeding, and whether the risk is related to surgery. For example, if there is active bleeding or invasive procedures are contemplated, platelet infusion may be used when the count is less than 50×10^9 cells/litre. In patients with no bleeding and no additional risk factors, a lower threshold of 5×10^9 cells/litre may be adequate.[2,10] Patients requiring long-term treatment may develop antibodies to HLA with repeated transfusions from random donors, which results in impaired responsiveness to subsequent transfusion; these patients should receive platelets obtained from a single donor for each transfusion, preferably HLA-matched.[2,10] In platelet refractoriness, when thrombocytopenia is a result of non-immune platelet destruction, treatment is problematic and although prophylactic platelet infusions may be given, it is not known whether this is effective.[10]

Oprelvekin (recombinant human interleukin-11) is a platelet growth factor that has recently been introduced for the prevention of severe antineoplastic-induced thrombocytopenia. Recombinant human thrombopoietin and the non-peptide thrombopoietin receptor agonist, eltrombopag, are also under investigation.

von Willebrand's disease

von Willebrand's disease (vWD)[1,2] is a congenital bleeding disorder caused by a deficiency or dysfunction of von Willebrand factor (vWF), a plasma protein that stimulates platelet aggregation and acts as a carrier for factor VIII to protect it from premature destruction. There is also a secondary deficiency of factor VIII, because of its dependence on vWF. There are 3 main phenotypes of vWD:

- type 1 is the most common and is characterised by mild to moderate deficiencies of vWF and factor VIII
- type 2 results in qualitative abnormalities of vWF, and is further divided into subtypes according to the defect
- type 3 is rare but is a severe bleeding disorder due to very low or undetectable plasma levels of vWF, with low but usually detectable concentrations of factor VIII.

The clinical presentation of vWD includes easy bruising and bleeding from mucosal surfaces, such as epistaxis; severely affected patients may suffer spontaneous soft-tissue bleeding resulting in haematomas and haemarthroses. Excessive and prolonged bleeding can occur after surgery, and women may experience excessive bleeding during menstruation and childbirth.[1,2]

Patients are usually only treated at the time of spontaneous bleeding or given prophylaxis before invasive procedures. Desmopressin transiently increases both vWF and factor VIII levels and is used in patients with type 1 disease. It is less likely to be effective in type 2 disease where vWF is dysfunctional, and it is generally contra-indicated in type 2B disease because the abnormal vWF that is released may induce platelet aggregation and thrombocytopenia. Type 3 disease does not respond to desmopressin because of the lack of vWF stores.[1,2]

Plasma concentrates that contain both vWF and factor VIII are used when desmopressin is not suitable. A concentrate that contains highly purified vWF, with very little factor VIII, is available in some countries. Very highly purified factor VIII preparations, or recombinant forms, should not be used; they do not contain appreciable amounts of vWF so the factor VIII therefore has a very short half-life, making it ineffective (but see also below, about the management of patients with alloantibodies). When haemorrhage is not controlled despite adequate factor VIII levels, platelet concentrates may be required.[1,2] Cryoprecipitate may be used as a source of clotting factors and vWF when other measures have failed, but it does not consistently correct bleeding time and has a higher risk of transfusion-transmitted infection.[2]

Some patients with type 3 disease who have received multiple transfusions develop alloantibodies that inactivate vWF and form circulating immune complexes. Further use of concentrates that contain vWF is contra-indicated because of the risk of anaphylaxis. There are a few reports of successful control of surgical bleeding in such patients by continuous infusion of recombinant forms of factor VIII and activated factor VII, which contain no vWF.[1,2]

Antifibrinolytic drugs, such as tranexamic acid or aminocaproic acid, may be sufficient in the management of less severe forms of mucosal bleeding, and are used as adjuncts to desmopressin or plasma concentrates in patients undergoing surgery.[1,2] Hormonal contraceptives can reduce bleeding in women with vWD and menorrhagia.[1,2]

Acquired von Willebrand syndrome is rare, and is usually associated with conditions such as lymphoproliferative and myeloproliferative diseases, cancers, auto-immune diseases, and hypothyroidism. Some drugs have been reported to cause an acquired von Willebrand syndrome, including ciprofloxacin and valproic acid. Depending on the underlying cause, vWF activity may be affected by accelerated clearance, reduced synthesis, or an inhibition of function. Management is based on treatment of the underlying cause, but specific options for treatment of bleeding include desmopressin, factor concentrates, and intravenous immunoglobulin.[1-3] Plasma exchange and extracorporeal immunoadsorption have also been used successfully.[2,3]

Neutropenia

A circulating neutrophil count below 1.5×10^9 cells/litre (1500 cells/mm^3) is usually regarded as abnormal and neutrophil counts below 0.5×10^9 cells/litre are associated with increased risk of infections. Neutropenia may be a result of reduced production, increased peripheral destruction, or increased peripheral pooling of neutrophils, and can be inherited or acquired.

Inherited forms of neutropenia are rare and include congenital agranulocytosis (Kostmann's syndrome: severe persistent neutropenia with frequent and severe infections that start in infancy) and cyclic neutropenia (fluctuating periods of neutropenia accompanied by fever, mouth ulceration, and serious infection).

Granulocyte colony-stimulating factors have been shown to reduce the incidence of severe infections and have improved substantially the quality of life of patients with congenital neutropenias although there are some concerns over their safety. As patients survive longer with such treatment they show an increased risk of developing myelodysplastic syndrome and leukaemia. However, it is unclear whether prolonged survival unmasks the natural course of the disease or whether granulocyte colony-stimulating factor further increases the risk of leukaemic transformation. Haematopoietic stem cell transplantation may be indicated for patients whose disease is refractory to colony-stimulating therapy or has transformed into myelodysplastic syndrome or leukaemia. Cyclic neutropenia is also managed with granulocyte colony-stimulating factor, but leukaemic transformation does not seem to occur in these patients.

There are many causes of **acquired** neutropenia. Drugs are a common cause, either by direct toxicity to the bone marrow, or by immune-mediated marrow suppression or peripheral destruction. Drugs that cause dose-related direct toxicity include cytotoxic and immunosuppressive drugs, flucytosine, ganciclovir, and zidovudine. Drugs that appear to cause neutropenia by immune-mediated mechanisms include sulfur-containing drugs (such as captopril, co-trimoxazole, and some antithyroid drugs), clozapine, penicillins, and cephalosporins. Patients with drug-induced neutropenia usually present with fever of sudden onset, sore throat, mouth ulcers, headache, and malaise. This condition is also known as **agranulocytosis**. Other causes of acquired neutropenia include serious bacterial and viral infections, radiotherapy, neoplasms that invade bone marrow, and some auto-immune disorders.

The management of acquired neutropenia includes the treatment of any contributory condition. Drug-induced neutropenia is usually managed by withdrawal of the offending drug. After an idiosyncratic reaction the implicated drug should not be given again, since abrupt neutropenia will usually be precipitated. Colony-stimulating factors can be used to manage drug-induced neutropenia.

In all neutropenic patients onset of fever is indicative of serious infection and is treated immediately with empirical antibacterial therapy as described on p.174.

Albumin ⊗

Albümin; Albúmina; Albumine; Albuminum.

ATC — B05AA01.

ATC Vet — QB05AA01; QV08DA01 (microspheres of human albumin).

Pharmacopoeias. Many pharmacopoeias have monographs, including *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Human Albumin Solution; Albumini Humani Solutio). An aqueous solution of protein obtained from the plasma of healthy donors; the plasma is tested for the absence of hepatitis B surface antigen and antibodies against HIV-1 and HIV-2 and hepatitis C virus. It is prepared as a concentrated solution containing 15 to 25% of total protein or as an isotonic solution containing 3.5 to 5% of total protein; not less than 95% of the total protein is albumin. A suitable stabiliser, such as sodium octanoate or *N*-acetyltryptophan or a combination of the two, may be added but no antimicrobial preservative is added. It contains not more than 160 mmol of sodium per litre and not more than 200 micrograms of aluminium per litre. The solution is sterilised by filtration and distributed aseptically into containers which are sealed to prevent contamination and maintained at 59° to 61° for not less than 10 hours. Finally, the containers are incubated for not less than 14 days at 30° to 32° or for not less than 4 weeks at 20° to 25° and examined visually for signs of microbial contamination. It should be stored in a colourless glass container and protected from light.

A clear, almost colourless, yellow, amber, or green slightly viscous liquid. A solution in sodium chloride 0.9% containing 1% protein has a pH of 6.7 to 7.3.

The BP 2008 gives Albumin and Human Albumin as approved synonyms.

USP 31 (Albumin Human). A sterile, nonpyrogenic, preparation of serum albumin obtained by fractionating material (blood, plasma, serum, or placentas) from healthy human donors, the source material being tested for the absence of hepatitis B surface antigen. It is made by a process that yields a product that is safe for intravenous use. It contains 4, 5, 20, or 25% of serum albumin and not less than 96% of the total protein is albumin. It may contain sodium acetyltryptophanate with or without sodium caprylate as a stabilising agent; it contains no added antimicrobial agent. It contains 130 to 160 mmol of sodium per litre. It is a practically odourless, moderately viscous, clear, brownish fluid. It should be stored in airtight containers.

Adverse Effects and Precautions

Adverse reactions to albumin infusion occur rarely and include nausea and vomiting, increased salivation, flushing, urticaria, hypotension, tachycardia, and febrile reactions. These effects usually respond to slowing or stopping the infusion. Allergic reactions, including severe anaphylactic shock, are possible. Rapid increases in circulatory volume can cause vascular overload, hypertension, haemodilution, and pulmonary oedema. Solutions containing albumin 20 or 25% are hyperosmotic and draw fluid from the extravascular compartment.

Infusion of albumin solutions is contra-indicated in patients with severe anaemia or heart failure. They should be given with caution to patients with hypertension or low cardiac reserve. Dehydrated patients may require additional fluids. Injured or postoperative patients should be observed carefully when given albumin as the rise in blood pressure may result in bleeding from previously undetected sites.

Human albumin preparations carry a risk of viral transmission. Manufacturing processes, including heating to about 60°, have reduced the risk of transmitting some viral infections.

Aluminium toxicity. Albumin solutions may contain appreciable amounts of aluminium. Marked increases in plasma-aluminium concentrations have been demonstrated in patients receiving large volumes by infusion and accumulation of aluminium may occur in patients with renal impairment.[1-3] In the UK albumin solutions with an aluminium content of less than 200 micrograms/litre are available for use in premature infants and patients undergoing dialysis.

Critically ill patients. Volume expansion with albumin (a colloid) has been widely used in critically ill patients, although its use had never been formally tested in large controlled studies. A systematic review based on available studies up to March 1998 (relatively small, old trials that recorded only a small number of deaths) suggested that albumin was of no benefit in critically ill patients with hypovolaemia, burns, or hypoalbuminaemia, and that it might be linked to increased mortality.[1] The authors of the review stressed that these results should be treated with caution but nevertheless called for an urgent reconsideration of the use of albumin in critically ill patients.

The review was severely criticised[2] and while it was recognised that albumin had probably been overused in the past it was considered that more studies were required to define the effect of albumin on mortality.[3-5] Another review[6] found that the use of albumin did not significantly affect mortality; this meta-analysis had broader criteria and included studies that were considered to be relevant but that had been excluded by the other review.

In response to this debate, albumin 4% was compared with sodium chloride 0.9% for resuscitation in a study of 6997 hypovolaemic patients in intensive care (the SAFE study).[7] This large, randomised, double-blind study found equivalent rates of death from any cause during the 28-day study period. Survival-time during the 28 days, length of stay in the intensive care unit and in hospital, time on mechanical inhalation or renal replacement therapy, and development of organ failure were also similar. Although these two fluids seem clinically equivalent in a heterogeneous population of patients in intensive care, further study of selected groups, such as those with trauma or severe sepsis, is required.

An update to the original 1998 review included the results of SAFE. The authors maintained that patients with burns (a group excluded from the large trial) or hypoproteinaemia might still be at risk of increased mortality, and although no longer suggesting a generally increased risk, concluded that there was no evidence that albumin reduced mortality in patients with hypovolaemia. Whether highly selected groups of critically ill patients might benefit is as yet unclear.[8]

Pharmacovigilance data reported to albumin suppliers over 3 years (1998 to 2000) has also been analysed.[9] During this period of heightened awareness about possible adverse effects of albumin, due to the publication of the 1998 review, a total of 1.62×10^7 doses of 40 g had been distributed. Serious adverse effects possibly or probably related to albumin were found to be rare, and no death was classified as probably related to albumin use.

On a broader level, debate continues about the relative merits and risks of such colloid solutions, compared with those of crystalloids such as glucose or sodium chloride solutions, in the management of hypovolaemia and shock (p.1183).

Dilution. If concentrated albumin solutions are to be diluted before use, a suitable solution such as sodium chloride 0.9% or glucose 5% must be used. Albumin 25% that was erroneously diluted with water to produce a hypo-osmolar albumin 5% solution has produced severe haemolysis and renal failure in patients undergoing plasmapheresis,[1,2] including a fatality in one patient.[3]

Transmission of infections. There has been concern that albumin preparations may carry a potential risk of transmission of viral and subviral particles, notably Creutzfeldt-Jakob disease. In 1993, *Pasteur-Mérieux* (one of the largest producers of blood products) withdrew all products containing albumin derived from placental blood[1] due to uncertainty regarding the adequacy of screening procedures for placentas as a source. It was considered that the agent responsible for Creutzfeldt-Jakob disease might be contained in placentas from women who have been treated with growth hormone derived from cadaver pituitaries. More recently, the production of blood products (including albumin) using plasma from UK donors has been phased out due to the possible risk of transmission of new variant Creutzfeldt-Jakob disease.

Uses and Administration

Albumin is the major protein involved in maintaining colloid osmotic pressure in the blood. It also binds a number of endogenous and exogenous substances including bilirubin, steroid hormones, and many, mainly acidic, drugs.

Albumin solutions are used for plasma volume replacement and to restore colloid osmotic pressure. They have been used in conditions such as burns, severe acute albumin loss, and acute hypovolaemic shock (p.1183). They are also used as an exchange fluid in therapeutic plasmapheresis. Concentrated albumin solutions are used in neonatal hyperbilirubinaemia associated with haemolytic disease of the newborn (p.2204). They have also been suggested for short-term management of hypoproteinaemia in hepatic disease and in diuretic-resistant patients with nephrotic syndrome but are of little value in chronic hypoproteinaemias.

Albumin may be included in diagnostic preparations such as those labelled with technetium-99m (p.2055) for use as radiopharmaceuticals in scanning of the heart, lung, liver, spleen, bone marrow, veins, and lymphatic system. Albumin labelled with iodine-125 (p.2054) is used to measure blood and plasma volumes, blood circulation, and cardiac output. A suspension of albumin microspheres with perflutren (p.1488) is available for enhancing cardiac ultrasound imaging.

Recombinant forms of human albumin have been developed as excipients for vaccines and other drug products, and for the treatment of hypoalbuminaemia and hypovolaemic shock.

Albumin solutions are usually available as 4.5% or 5% solutions, which are iso-osmotic with plasma, and as 20% or 25% solutions which are hyperosmotic with respect to plasma, and cause a movement of fluid from the extravascular to the intravascular compartment. These concentrated solutions may be used undiluted or may be diluted with a suitable solution, commonly sodium chloride 0.9% or glucose 5%. Adequate hydration should be maintained and electrolytes monitored in patients receiving hyperosmotic solutions of albumin.

The amount of albumin solution given will depend upon the clinical condition of the patient and the response to treatment. The following doses have been suggested:

- acute hypovolaemic shock: an initial dose of 25 g for adults (for example, 500 mL of a 5% solution or 100 mL of a 25% solution) and up to about 1 g/kg for children
- hypoproteinaemia: a maximum of 2 g/kg daily
- neonatal hyperbilirubinaemia: 1 g/kg before exchange transfusion

The rate of infusion should be adjusted according to the indication and patient response, but in general, suggested rates of infusion are up to 5 mL/minute (5% solution) or 1 to 2 mL/minute (20% solution). In plasmapheresis the albumin infusion rate should be adjusted according to the rate of removal.

Albumin solutions should not be used for parenteral nutrition.

CAS — 60-32-2.
ATC — B02AA01.
ATC Vet — QB02AA01.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Aminocaproic Acid). A white or almost white, crystalline powder or colourless crystals. Freely soluble in water; slightly soluble in alcohol. A 20% solution in water has a pH of 7.5 to 8.0.

USP 31 (Aminocaproic Acid). A fine, white, odourless or practically odourless, crystalline powder. Soluble 1 in 3 of water and 1 in 450 of methyl alcohol; slightly soluble in alcohol; practically insoluble in chloroform and in ether; freely soluble in acids and in alkalis. Its solutions are neutral to litmus. Store in airtight containers.

Adverse Effects

Adverse effects associated with aminocaproic acid include dose-related gastrointestinal disturbances, dizziness, tinnitus, headache, nasal and conjunctival congestion, and skin rashes. Aminocaproic acid may cause muscle damage. This has usually occurred with high doses given for prolonged periods; renal failure may develop. Thrombotic complications have been reported, although they are usually a consequence of inappropriate use. If aminocaproic acid is given by rapid intravenous injection it can produce hypotension, bradycardia, and arrhythmias. There have been reports of a few patients suffering from convulsions, dry ejaculation, or cardiac and hepatic damage.

Effects on the blood. Very high doses of aminocaproic acid (36 g or more daily) have been given intravenously in the management of subarachnoid haemorrhage (see Stroke, p.1185). One study[1] reported rebleeding and excessive intra-operative bleeding and suggested that this was due to an antiplatelet effect of the aminocaproic acid. However, a comment on this report[2] pointed out that any antiplatelet effect was independent of its antifibrinolytic action and that this effect could only aggravate rebleeding, if it occurs, rather than causing it. However, early surgical intervention is now used to manage subarachnoid haemorrhage, and in a series of 307 patients treated with high-dose short-term aminocaproic acid before early surgery it was found that, compared with older reports in the literature, there was a low rate of rebleeding without an apparent increase in adverse effects.[3]

1. Glick R, *et al.* High dose ε-aminocaproic acid prolongs the bleeding time and increases rebleeding and intraoperative hemorrhage in patients with subarachnoid hemorrhage. *Neurosurgery* 1981; **9:** 398–401.

3. Leipzig TJ, *et al.* Reducing the risk of rebleeding before early aneurysm surgery: a possible role for antifibrinolytic therapy. *J Neurosurg* 1997; **86:** 220–5.

Effects on the kidneys. Adverse renal effects of aminocaproic acid are rare but have included renal arterial thrombosis, glomerular capillary thrombosis, and renal pelvic or ureteral obstruction caused by upper urinary tract thrombosis.[1] Cases of acute renal failure associated with myopathy are described under Effects on the Muscles, below.

1. Manjunath G, *et al.* Epsilon-aminocaproic acid and renal complications: case report and review of the literature. *Clin Nephrol* 2002; **58:** 63–7.

Effects on the muscles. There have been cases of reversible myopathy,[1-4] associated with daily doses of aminocaproic acid ranging from 10 to 49 g and treatment durations of about 1 to 3 months. In some patients myoglobinuria or acute tubular necrosis also occurred. Suggested mechanisms for the reaction have included a direct dose-related effect on the muscle fibre[2] or a defect in aerobic energy provision induced by aminocaproic acid.[3]

2. Vanneste JAL, van Wijngaarden GK. Epsilon-aminocaproic acid myopathy. *Eur Neurol* 1982; **21:** 242–8.
3. Van Renterghem D, *et al.* Epsilon amino caproic acid myopathy: additional features. *Clin Neurol Neurosurg* 1984; **86:** 153–7.
4. Seymour BD, Rubinger M. Rhabdomyolysis induced by epsilon-aminocaproic acid. *Ann Pharmacother* 1997; **31:** 56–8.

Precautions

As for Tranexamic Acid, p.1081.

The range of adverse effects that have been noted with aminocaproic acid indicates that caution is required in patients with renal or cardiac disorders. Should treatment be prolonged, it is advisable to monitor creatine phosphokinase values for signs of muscle damage.

Renal impairment. High anion gap metabolic acidosis developed in a 65-year-old woman with sepsis and acute renal failure who received aminocaproic acid for a haemorrhagic coagulopathy.[1] The acidosis improved temporarily after haemodialysis and resolved on withdrawal of aminocaproic acid and systemic alkalinisation. Although the dose of aminocaproic acid had been reduced because of renal impairment, it was suggested that more conservative dosing and close monitoring may be indicated in such patients. Hyperkalaemia has been attributed to the use of aminocaproic acid in a few patients with chronic renal failure.[2]

1. Budris WA, *et al.* High anion gap metabolic acidosis associated with aminocaproic acid. *Ann Pharmacother* 1999; **33:** 308–11.
2. Nzerue CM, Falana B. Refractory hyperkalaemia associated with use of epsilon-aminocaproic acid during coronary bypass in a dialysis patient. *Nephrol Dial Transplant* 2002; **17:** 1150–1.

Interactions

Retinoids. Aminocaproic acid should be used with caution in patients receiving oral *tretinoin* (see Antifibrinolytics, p.1619).

Pharmacokinetics

Aminocaproic acid is readily absorbed when given orally and peak plasma concentrations are reached within 2 hours. It is widely distributed and is rapidly excreted in the urine, mainly unchanged, with a terminal elimination half-life of about 2 hours.

Uses and Administration

Aminocaproic acid is an antifibrinolytic used similarly to tranexamic acid (p.1081) in the treatment and prophylaxis of haemorrhage associated with excessive fibrinolysis. It has also been used in the prophylaxis of hereditary angioedema (below).

A plasma concentration of about 130 micrograms/mL is considered to be necessary for effective inhibition of fibrinolysis and the recommended dosage schedules are aimed at producing and maintaining this concentration for as long as is necessary. For the treatment and prophylaxis of **haemorrhage**, aminocaproic acid may be given orally in an initial dose of 4 to 5 g, followed by 1 to 1.25 g every hour. Alternatively, the same dose may be given intravenously as a 2% solution; the initial dose (4 to 5 g) should be given over one hour followed by a continuous infusion of 1 g/hour. Up to 8 hours of treatment is often sufficient. Should treatment need to be extended, then the maximum dose over 24 hours should not normally exceed 24 g.

In patients with **haemophilia** (p.1048) who undergo dental extraction, aminocaproic acid has been given in an initial dose of 6 g orally immediately after the procedure, followed by 6 g orally every 6 hours for up to 10 days.

Care is required when aminocaproic acid is used in patients with renal impairment and dosage should be reduced.

Hereditary angioedema. In the management of hereditary angioedema (p.1081), antifibrinolytic drugs may be used as an alternative to androgens for the prophylaxis of attacks. The usual oral dose of aminocaproic acid in such patients is 1 g three or four times daily. It has also been used intravenously for acute attacks, and anecdotal reports suggest it may be modestly helpful, but there is no published evidence suggesting significant benefit.[1]

Ancestim *(USAN, rINN)*

Ancestimum; r-metHuSCF; SCF; Stem Cell Factor. *N*-L-Methionyl-1–165-haematopoietic cell growth factor KL (human clone V19.8:hSCF162), dimer.

Анцестим
CAS — 163545-26-4.
ATC — L03AA12.
ATC Vet — QL03AA12.

Adverse Effects and Precautions

Injection site reactions commonly occur with the use of ancestim. Other skin reactions, including pruritus, rash, and urticaria, are less frequent. Systemic hypersensitivity reactions are also common and may be life-threatening. Premedication with antihistamines (both H_1- and H_2-antagonists) and an inhaled beta$_2$ agonist bronchodilator should be used, and the patient observed for at least an hour after ancestim is given. Tachycardia and respiratory symptoms including pharyngitis, dyspnoea, and cough, have also been reported.

Ancestim should not be given in the period from 24 hours before to 24 hours after a dose of cytotoxic chemotherapy or radiotherapy.

Uses and Administration

Ancestim is a recombinant human stem cell factor. It is used with filgrastim (p.1070) to mobilise peripheral blood progenitor cells that are to be collected by apheresis harvest and used for autologous transplantation. The dose of ancestim is 20 micrograms/kg daily by subcutaneous injection; the injections of ancestim and filgrastim must be given at separate sites.

Antithrombin III *(BAN, rINN)*

Antithrombin III Human; Antithrombine III; Antithrombinum III; Antitrombiini III; Antitrombin III; Antitrombina III; Antitrombina III humana; Antytrombina III; AT-III; Cofactor I de la heparina; Heparin Cofactor; Heparin Cofactor I; Major Antithrombin.

Антитромбин III
CAS — 52014-67-2.
ATC — B01AB02.
ATC Vet — QB01AB02.

Pharmacopoeias. Many pharmacopoeias have monographs, including *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Human Antithrombin III Concentrate; Antithrombinum III Humanum Densatum). A preparation of a glycoprotein fraction obtained from human plasma that inactivates thrombin in the presence of an excess of heparin. The plasma is obtained from healthy donors and is tested for the absence of hepatitis B surface antigen and antibodies against HIV-1 and HIV-2 and hepatitis C virus. The method of preparation includes a step or steps that have been shown to remove or to inactivate known agents of infection. The antithrombin III concentrate is passed through a bacteria-retentive filter, distributed into sterile containers, and immediately frozen. The preparation is freeze-dried and the containers sealed under vacuum or in an atmosphere of inert gas. No antimicrobial preservative is added but a suitable stabiliser (such as albumin) is permitted. When reconstituted in the volume of solvent stated on the label, the resulting solution contains not less than 25 international units of antithrombin III per mL.

A white or almost white, hygroscopic, friable solid or powder. Store in airtight containers. Protect from light.

USP 31 (Antithrombin III Human). A glycoprotein, which is the major inhibitor of thrombin and other activated clotting factors, including factors IX, X, XI, and XII, and the cofactor through which heparin exerts its effect. It is obtained from human plasma of healthy donors who must, as far as can be ascertained, be free from detectable agents of infection transmissible by transfusion of blood or blood derivatives. The method of manufacturing includes steps that have been shown to remove or inactivate known agents of infection. The antithrombin III concentrate is passed through a bacteria-retentive filter, filled aseptically into its final, sterile containers, and immediately frozen. It is then freeze-dried, and the containers are closed under vacuum. No antimicrobial preservative is added at any stage of production. When reconstituted in the recommended volume of diluent, the pH is between 6.0 and 7.5, and the potency is not less than 25 USP units of antithrombin III per mL.

Store at a temperature of 2° to 8°, excursions permitted up to 25°. Protect from light.

Antithrombin Alfa *(USAN, rINN)*

Antithrombine Alfa; Antithrombinum Alfa; Antitrombina alfa; Human Antithrombin III from the milk of transgenic goats (glycoform alfa); Recombinant Human Antithrombin.

Антитромбин Альфа
CAS — 84720-88-7.

Units

The potency of antithrombin III is expressed in international units and preparations may be assayed using the second International Standard for antithrombin concentrate (1997); each ampoule contains 4.7 international units of functional activity and 5.1 international units of antigenic activity.

One USP unit is described as the amount of antithrombin III that forms a complex with 1 unit of thrombin at 25° in the presence of heparin at a pH of 8.4. Since assays of antithrombin III are carried out at 37°, it is unclear whether USP units and international units are precisely equivalent, but in practice US preparations, like those elsewhere, appear to have their potency defined in international units.

The potency of antithrombin alfa is also expressed in international units.

Adverse Effects and Precautions

Adverse effects of antithrombin III include flushing, headache, dizziness, chest tightness, nausea, a foul taste in the mouth, chills, and cramps. These can be controlled by slowing or stopping the infusion. Allergic reactions occur rarely.

Human plasma-derived antithrombin III preparations carry a risk of viral transmission. Manufacturing processes, including heating to about 60°, have reduced the risk of transmitting some viral infections. Antithrombin alfa is produced in the milk of transgenic goats, and should not be used in patients who are hypersensitive to goat proteins or goat milk components.

Uses and Administration

Antithrombin III is a protein in plasma; it is the major endogenous inhibitor of thrombin and other activated clotting factors including factors IX, X, XI, and XII (p.1045), and is the cofactor through which heparin (p.1303) exerts its effect. Genetic and acquired deficiency of antithrombin III occurs and is associated with susceptibility to thromboembolic disorders.

Human plasma-derived antithrombin III is given intravenously to patients with antithrombin III deficiency in the treatment of thromboembolism and for prophylaxis associated with surgical and obstetric procedures. The aim of therapy is to restore plasma-antithrombin III concentrations to at least 80% of normal. The dose, frequency, and duration of therapy are individualised for each patient taking into account the patient's pretreatment concentration and presence of active coagulation. A usual initial dose is about 30 to 50 international units/kg.

Antithrombin alfa is used similarly in the prophylaxis of venous thromboembolism in surgical patients with congenital antithrombin III deficiency. The dose is individualised, but a usual initial dose is about 20 to 25 international units/kg given as an intravenous infusion over 15 minutes, followed by a maintenance infusion of about 4 to 5 international units/kg per hour.

Septicaemia. Antithrombin III has been used in septicaemia (p.190) in an attempt to manage the pro-coagulant state that occurs. Initial small studies reported a reduction in mortality[1] but a large controlled study[2] (KyberSept) found that treatment with antithrombin III had no effect on 28-day mortality. A further small observational study and meta-analysis also found no benefit from the use of antithrombin III in septicaemia.[3] These studies had used antithrombin III for less than 7 days, and a small study[4] in surgical patients with septicaemia found that 14 days of treatment with antithrombin III did improve measures of coagulation and fibrinolysis, the changes being most evident in the second week of therapy. However, the study was not large enough to test effects on mortality. Subsequent analysis of data from the KyberSept study appeared to show that 28-day mortality was in fact reduced in patients who had not been given heparin as well as antithrombin III;[5] combined use increased the risk of bleeding and apparently decreased the benefits of treatment with antithrombin III.

Aprotinin *(BAN, USAN, rINN)*

Aprotiniini; Aprotinina; Aprotininas; Aprotinine; Aprotininum; Aprotynina; Bayer A-128; Riker 52G; RP-9921.

Апротинин

CAS — 9087-70-1.
ATC — B02AB01.
ATC Vet — QB02AB01.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Aprotinin). A polypeptide consisting of 58 amino acids that inhibits the activity of several proteolytic enzymes such as chymotrypsin, kallikrein (kallidinogenase), plasmin (fibrinolysin), and trypsin. It contains not less than 3 Ph. Eur. units/mg calculated with reference to the dried substance. An almost white, hygroscopic powder. Soluble in water and in isotonic solutions; practically insoluble in organic solvents. Store in airtight containers. Protect from light.

Ph. Eur. 6.2 (Aprotinin Concentrated Solution). A solution of aprotinin containing not less than 15 Ph. Eur. units/mL. A clear colourless solution. Store in airtight containers. Protect from light.

USP 31 (Aprotinin). A polypeptide consisting of a chain of 58 amino acid residues, which inhibits stoichiometrically the activity of several proteolytic enzymes such as chymotrypsin, kallikrein (kallidinogenase), plasmin (fibrinolysin), and trypsin. It is obtained from bovine tissues and purified by a suitable process, and is stored as a bulk solution or lyophilised powder. Its potency is not less than 3 USP units/mg calculated with reference to the dried substance.

The lyophilised powder should be stored in airtight containers at a temperature between 8° and 15°. Protect from light. The bulk solution should be stored in airtight containers at a temperature not exceeding 25°. Do not allow to freeze.

Incompatibility. Aprotinin is reported to be incompatible with corticosteroids, heparin, tetracyclines, and nutrient solutions containing amino acids or fat emulsions.

Units

The potency of aprotinin is expressed in terms of kallikrein (kallidinogenase) inactivator units (KIU) or of trypsin inactivation (Ph. Eur. units). One KIU is contained in 140 nanograms of aprotinin. One Ph. Eur. and one USP unit is equivalent to about 1800 KIU.

Potency has also been expressed in terms of plasmin inactivation (antiplasmin units).

Adverse Effects and Precautions

Aprotinin is usually well tolerated. Local thrombophlebitis can occur. Adverse effects including bronchospasm, hypotension, cardiac arrhythmias, gastrointestinal disturbances, and skin rashes are considered to be hypersensitivity reactions; anaphylaxis, including fatalities, has occurred. Licensed UK product information warns that the risk of anaphylactic reaction increases when re-exposure occurs within 6 months, but product information in the US extends this warning to contra-indicate the use of aprotinin for 12 months after a previous exposure. A test dose is recommended for all patients and the use of prophylactic histamine antagonists may be considered; a hypersensitivity reaction to the therapeutic dose of aprotinin can still occur even after an uneventful test dose. There have been reports of renal dysfunction and reversible renal failure in patients given aprotinin during open-heart surgery with extracorporeal circulation; the risk may be increased in patients with pre-existing renal impairment or risk factors for altered renal function. For further details of an increased risk of cardiovascular and cerebrovascular events, renal failure, and death in patients undergoing surgery, see Haemorrhagic Disorders under Uses and Administration, below.

Disseminated intravascular coagulation. Fatal disseminated intravascular coagulation has been reported in a patient after the use of intraoperative autotransfusion and aprotinin during surgery.[1] Activation of the clotting system occurs during autotransfusion although this usually causes no systemic adverse effects. While there were other possible causes, it was suggested that aprotinin could have contributed to deposition of fibrin microthrombi in the microvasculature and prevented subsequent fibrinolysis.

1. Milne AA, *et al.* Disseminated intravascular coagulation after aortic aneurysm repair, intraoperative salvage autotransfusion, and aprotinin. *Lancet* 1994; **344:** 470–1.

Effects on coagulation tests. In patients receiving heparin, aprotinin may prolong the activated clotting time when measured by some methods, but this may not represent increased anticoagulation. It has been recommended that an alternative to the activated clotting time should be used to monitor heparin therapy when aprotinin is used concurrently.

It should also be noted that aprotinin injection and heparin injection are pharmaceutically incompatible.

Effects on the respiratory system. Acute respiratory distress syndrome developed in a 24-year-old male 2 hours after the start of an intravenous infusion of aprotinin for bleeding after tonsillectomy.[1] Mechanical ventilation was required for 4 days.

1. Vucicevic Z, Suskovic T. Acute respiratory distress syndrome after aprotinin infusion. *Ann Pharmacother* 1997; **31:** 429–32.

Hypersensitivity. Hypersensitivity reactions, including anaphylaxis, can occur with the use of aprotinin both on primary and secondary exposure. In a study[1] of 248 re-exposures to aprotinin in 240 patients undergoing cardiac surgery, there were 7 cases of anaphylactic reactions ranging from mild to severe with a higher incidence of reactions occurring in those patients re-exposed within 6 months of the previous dose. A review[2] of 124 reported reactions in 122 patients also found that reactions ranged from mild to severe, and that about half were life-threatening and 11 were fatal. The risk of reaction was greatest with re-exposure to aprotinin as this had been the situation in 80% of the cases, although there were 19 cases associated with the first use of aprotinin. The average risk of anaphylaxis was estimated to be 2.8% in re-exposed patients. Most reactions occurred within 6 months of previous exposure, and the risk was greatest in the first 3 months. Various diagnostic tests have been tried in an attempt to predict hypersensitivity risk. Aprotinin-specific serum-IgG was reported to be detectable in about 50% of patients who had received only one aprotinin treatment, but other tests such as preoperative skin testing were not found to be reliable.

A number of measures have been suggested in order to reduce the risk of hypersensitivity reactions to aprotinin, including the use of an intravenous test dose in all patients, but it must be noted that these also have the potential to trigger a reaction.[1] For patients who have previously received aprotinin it has been recommended that re-exposure should be avoided for at least 6 months,[1,2] that aprotinin-specific antibody screening should be done,[2] and that prophylactic histamine H_1- and H_2-antagonists should be given to ameliorate severe anaphylactic reactions[1] although there are reports of reactions occurring despite antihistamine and corticosteroid prophylaxis.[2] It has also been suggested that in cardiac surgery, aprotinin should only be given when cardiopulmonary bypass is available to assist resuscitation.[1,2]

There have also been rare reports of hypersensitivity reactions on re-exposure to aprotinin used locally as a component of fibrin sealant.[3,4] In one fatal case[4] the previous exposure to fibrin sealant had been 5 years before.

4. Oswald A-M, *et al.* Fatal intraoperative anaphylaxis related to aprotinin after local application of fibrin glue. *Anesthesiology* 2003; **99:** 762–3.

Interactions

Heparin. For comment on the use of aprotinin with heparin, see Effects on Coagulation Tests, above.

Neuromuscular blockers. For reports of apnoea when aprotinin was used with neuromuscular blockers, see p.1904.

Retinoids. Aprotinin should be used with caution in patients receiving oral *tretinoin* (see Antifibrinolytics, p.1619).

Pharmacokinetics

Aprotinin, being a polypeptide, is inactivated in the gastrointestinal tract. After intravenous use, it is excreted in the urine as inactive degradation products. The terminal elimination half-life is about 5 to 10 hours.

Renal impairment. The terminal elimination half-life of aprotinin was reported as 13.3 and 14.9 hours, respectively, in two patients with chronic renal impairment given aprotinin by intravenous infusion over 30 minutes.[1] A study[2] of cardiac surgical patients undergoing cardiopulmonary bypass also found that aprotinin clearance was reduced in those with renal impairment. The elimination half-life was about 20 hours in patients with end stage renal disease compared with about 8 hours in those with creatinine clearance greater than 50 mL/min.

1. Müller FO, *et al.* Pharmacokinetics of aprotinin in two patients with chronic renal impairment. *Br J Clin Pharmacol* 1996; **41:** 619–20.
2. O'Connor CJ, *et al.* The impact of renal dysfunction on aprotinin pharmacokinetics during cardiopulmonary bypass. *Anesth Analg* 1999; **89:** 1101–7.

Uses and Administration

Aprotinin is a haemostatic. It is an inhibitor of proteolytic enzymes including chymotrypsin, kallikrein (kallidinogenase), plasmin, and trypsin.

Aprotinin has been used to reduce blood loss and transfusion requirements in patients at increased risk of major blood loss during coronary artery bypass graft surgery with cardiopulmonary bypass. However, the marketing of aprotinin injection has been suspended worldwide because of a possible increased risk of death associated with its use in cardiac surgery (see Haemorrhagic Disorders, below). Nevertheless, it may be available in some countries, such as the USA, using a special access protocol. It has also been used in the treatment of hyperfibrinolytic haemorrhage associated with raised plasma concentrations of plasmin. Aprotinin is applied topically as a component of fibrin glues (p.1069).

It is recommended that because of the risk of hypersensitivity reactions an intravenous test dose of 10 000 KIU should be given to all patients at least 10 minutes before the therapeutic dose. All intravenous doses of aprotinin should be given through a central venous line.

In **coronary artery bypass graft surgery**, the test dose is followed by a loading dose given with the patient in a supine position, after induction of anaesthesia but before incision; 2 000 000 KIU is given intravenously over 20 to 30 minutes. The loading dose is followed by a continuous infusion of 500 000 KIU/hour until the end of the operation. An additional dose of 2 000 000 KIU is added to the prime volume of the extracorporeal circuit. In patients with septic endocarditis, a dose of 3 000 000 KIU is added to the prime volume of the circuit and the continuous infusion may be continued into the early postoperative period. The total amount of aprotinin used is usually no more than 7 000 000 KIU. A regimen using half the dose for loading, maintenance, and to prime the circuit, may be used in low-risk patients.

Haemorrhagic disorders. Aprotinin has been used in the treatment of life-threatening haemorrhage caused by raised plasma concentrations of plasmin. It has also been used in the treatment of severe bleeding arising from overdosage with thrombolytics (see Treatment of Adverse Effects under Streptokinase, p.1404).

Aprotinin has been used to reduce blood loss in patients undergoing surgery, particularly cardiac surgery involving cardiopulmonary bypass. This bypass procedure is complicated by a postperfusion syndrome that includes impairment of haemostasis and pulmonary dysfunction. Contributing factors include ischaemia reperfusion, surgical trauma, endotoxaemia, and blood contact with the artificial surfaces of the bypass apparatus. This syndrome has been interpreted as a 'whole body inflammatory response', and the beneficial effect of aprotinin has been attributed to an attenuation of this response. As well as its inhibitory effect on fibrinolysis, aprotinin is thought to have effects on the complement system, cytokines, neutrophil activation, and platelet function.[1,2] Aprotinin has reduced blood loss and transfusion requirements in patients undergoing both primary and repeat cardiac surgery.[1,3-6] The usual dosage regimen (as given in Uses and Administration, above) and low-dosage regimens (50% of the usual dose) appear to be equally effective, but regimens that use aprotinin only as a pump prime dose appear to be less effective.[1,5]

The safety of aprotinin in cardiac surgery has been questioned, however, because of the results of two observational studies. One analysis[7] of patient outcome after the use of aminocaproic acid, aprotinin, tranexamic acid, or no treatment, found that although the three drugs had reduced blood loss to a similar extent, aprotinin was associated with an increased risk of cardiovascular and cerebrovascular events (myocardial infarction, heart failure, stroke, or encephalopathy) and renal failure. Observational follow-up also found that aprotinin, but not aminocaproic acid or tranexamic acid, was associated with an increased risk of death in the 5 years after surgery.[8] In another study[9] that compared data from patients who had received either aprotinin or tranexamic acid, there was an increased risk of renal dysfunction associated with aprotinin, particularly in patients with abnormal pre-operative renal function. In response to these studies, the FDA recommended[10] that patients receiving aprotinin should be carefully monitored, and that physicians should consider limiting its use to situations where the clinical benefit of reduced blood loss is essential and outweighs the potential risks. The concerns raised by these studies and the FDA's recommendation prompted further analysis of data relating to the effects of aprotinin. A meta-analysis[5] that included studies in different types of surgery, although the majority were in cardiac surgery, found no increased risk of death, cardiovascular events, or renal failure. However, because the reporting of renal function was lacking for many studies, and therefore a potential for bias, the authors were not confident that a modest increase in risk could be ruled out. Another meta-analysis[11] that was limited to studies in cardiac surgery also found no increased risk of death or cardiovascular events with aprotinin. There was also no increase in the risk of dialysis-dependent renal failure, but high-dose aprotinin did increase the risk of renal dysfunction, compared with placebo. Two large retrospective studies, which attempted to account for confounding variables, were also undertaken in cohorts of patients who had undergone coronary artery bypass graft surgery. One study found that, compared with aminocaproic acid, aprotinin increased the risk of in-hospital death.[12] The other found increased in-patient renal dysfunction, and death at 30 days and 1 year, in patients given aprotinin compared with aminocaproic acid or no antifibrinolytic therapy. Survival estimates also found an association between aprotinin use and reduced survival for up to 10 years after surgery.[13] Preliminary data analysis from a randomised study (BART) also found an increased risk of death with aprotinin, compared with aminocaproic acid or tranexamic acid, and in November 2007, authorities such as the FDA[14] and EMEA[15] recommended that marketing of aprotinin injection be suspended.

Aprotinin has been used to reduce transfusion requirements during liver transplantation, by its effect on intra-operative hyperfibrinolysis.[16,17] However, concerns about an increased risk of thromboembolism in these patients has been raised.[18] A systematic review[19] of 23 studies using antifibrinolytic drugs, 18 of which used aprotinin, found no evidence of an increased risk of thromboembolic complications in liver transplant patients, but noted that the studies were underpowered and that identification of subgroups of patients at risk may have been missed. Aprotinin has also been used to reduce transfusion requirements during orthopaedic surgery.[20]

Pancreatitis. Aprotinin has been tried in the management of pancreatitis (p.2361) because of the postulated role of proteolytic enzymes in this condition. However, results have been largely disappointing.

Preparations

BP 2008: Aprotinin Injection;
USP 31: Aprotinin Injection.

Proprietary Preparations (details are given in Part 3)

Batroxobin *(rINN)*

Batroxobina; Batroxobine; Batroxobinum.

Батроксобин

CAS — 9039-61-6 (batroxobin); 9001-13-2 (haemocoagulase).
ATC — B02BX03.
ATC Vet — QB02BX03.

Profile

Batroxobin is an enzyme obtained from the venom of the viper *Bothrops atrox*. It has also been obtained from *Bothrops moojeni* and a similar preparation is derived from *Bothrops jararaca*.

Batroxobin is reported to act on fibrinogen to produce a fibrin monomer that can be converted by thrombin to a fibrin clot. It is used both as a haemostatic and, in larger doses, to induce a hypofibrinogen state in the management of thromboembolic disorders. When used as a haemostatic it is usually given with a factor-X activator; such a combined preparation is known as haemocoagulase (hemocoagulase). Batroxobin has been given parenterally or by local application.

Preparations

Proprietary Preparations (details are given in Part 3)
Austria: Defibrase; Reptilase; ***Fr.:*** Reptilase†; ***India:*** Reptilase; ***Ital.:*** Botropase†; ***Port.:*** Reptilase†.

Blood ⊗

Sangre.

Pharmacopoeias. Many pharmacopoeias have monographs, including *US.*

USP 31 (Whole Blood). It is blood that has been collected from suitable human donors under rigid aseptic precautions for transfusion or for further processing into one or more of its components for transfusion. It contains a citrate-based anticoagulant (Anticoagulant Citrate Dextrose Solution, Anticoagulant Citrate Phosphate Dextrose Solution, or Anticoagulant Citrate Phosphate Dextrose Adenine Solution).

Whole blood must be tested for syphilis, hepatitis B virus, human T-cell lymphotropic virus (HTLV) type I and type II, hepatitis C, and HIV. It should also be tested for blood group and rhesus factors, and for unexpected antibodies to red cell antigens.

One unit (dose) of whole blood contains a minimum of 50 g of haemoglobin. One unit of whole blood filtered for removal of leucocytes (Whole Blood, Leukocytes Reduced), contains less than 5×10^6 residual leucocytes.

Whole blood is stored in the original container or transferred to an equivalent one using a technique that does not compromise sterility. It should be stored at 1° to 6°, unless platelets are to be prepared, in which case the blood is stored for no longer than 8 hours after collection at room temperature.

Whole blood collected in Anticoagulant Citrate Dextrose Solution, Anticoagulant Citrate Phosphate Dextrose-Dextrose Solution, or in Anticoagulant Citrate Phosphate Dextrose-Dextrose Solution may be stored for up to 21 days at 1° to 6° after the blood has been drawn. Whole blood collected in Anticoagulant Citrate Phosphate Dextrose Adenine Solution may be stored for up to 35 days at 1° to 6°. If the hermetic seal of the container is broken during collection, preparation, or further processing, the expiry date is not later than 24 hours after the seal is broken (when blood is stored at 1° to 6°), but not to exceed the original expiry date of the unit.

It is a deep red, opaque liquid from which the corpuscles readily settle upon standing for 24 to 48 hours, leaving a clear, yellowish or pinkish supernatant layer of plasma.

The USP 31 gives the names ACD Whole Blood, CPD Whole Blood, CPDA-1 Whole Blood, and Heparin Whole Blood, which specify the anticoagulant used.

Adverse Effects

The rapid transfusion of large volumes of whole blood may overload the circulation and cause pulmonary oedema. Transfusion of very large volumes of citrated blood can lead to hypocalcaemia, although this is not usually a problem unless there is hepatic impairment or hypothermia. Hyperkalaemia may occur but on its own is rarely clinically significant. Hypothermia may result from rapid transfusion of large volumes of cooled blood and may, combined with hypocalcaemia, hyperkalaemia, and resultant acidosis, lead to cardiac toxicity. Disseminated intravascular coagulation may also occur in patients receiving large-volume transfusions. Repeated transfusions of blood, as in thalassaemia, may lead to iron overload.

The transfusion of incompatible blood causes haemolysis, possibly with renal failure. Pyrexia, rigors, and urticaria may be due to antibodies towards a number of blood components. Severe allergic reactions and anaphylaxis can occur. Delayed reactions may occur more than 24 hours after transfusion in patients in whom previous transfusion or pregnancy has induced sensitisation; these reactions are usually mild and manifest as fever, chills, fall in haemoglobin concentration, and haemoglobinuria.

Transmission of infections. The use of blood, blood components, or blood products has been associated with the transmission of viruses, most notably hepatitis B virus and HIV; other reports of transmission include CMV, hepatitis C and possibly other hepatitis viruses, HTLV-I and -II, and the agent causing Creutzfeldt-Jakob disease. Transmission of bacterial and parasitic diseases is also possible including syphilis, Chagas' disease, and malaria.

The main methods of minimising the risk of transmission of infection are by rigorous selection of blood donors and by microbiological screening tests. Contamination during collection and processing is minimised by using closed systems and by strict aseptic technique. Treatment of blood products with heat or chemicals can inactivate some organisms including some viruses, in particular HIV-1, but blood and blood components cannot be treated in either of these ways. Patients receiving multiple transfusions of pooled plasma products are at increased risk of contracting infections and can be offered immunological protection, for example hepatitis B vaccine.

Creutzfeldt-Jakob disease. While there is no proof that transmission of Creutzfeldt-Jakob disease by blood or blood products has occurred,[1] 3 cases have been reported of possible transmission of variant Creutzfeldt-Jakob disease (vCJD) by blood transfusion.[2-4] It is recognised that there is a need for further assessment of the potential risk of transmission of vCJD by such products.

A number of precautionary measures have been implemented in the UK to minimise transmission of vCJD by blood or tissues:[5]

- plasma is imported from outside the UK for fractionation to manufacture plasma derivatives
- leucocytes are removed from donated blood (leucodepletion) as it was thought that this would remove infectivity. However, *animal* studies have shown that this is not the case and that prion concentration in the blood is likely to be reduced by only about 40%[6]
- plasma is imported for clinical use in patients born after January 1996 (this date was chosen because it was considered that foods infected with bovine spongiform encephalopathy had been largely eliminated from the diet by this time[6])
- donations of blood, platelets, and live bone are not accepted from donors who themselves have received blood components since 1 January 1980, or from any donors who have received intravenous immunoglobulin prepared from UK plasma or who have undergone plasma exchange anywhere in the world

Concern at the risk of transmitting Creutzfeldt-Jakob disease by albumin prepared from placental blood has led to restriction on this source of albumin (see Transmission of Infections under Albumin, p.1052).

Effects on leucocytes. A study of 50 patients in an intensive care unit found that 45 of them developed leucocytosis after transfusion of packed red blood cells.[1] The leucocytosis, which was accounted for by neutrophils, occurred immediately after transfusion and persisted for 12 hours. A further study[2] of 96 critically ill patients found that leucocytosis commonly occurred in those who were not septic and had received unfiltered packed red cells. Mean white cell counts were increased significantly 2 hours after infusion, remained elevated for about 12 hours, and returned to baseline by 24 hours. In 11 patients who required more than one transfusion, the use of filtered packed red cells was not associated with leucocytosis. Concentrations of interleukin-8 were found to be raised in unfiltered blood after 4 weeks of storage, and were higher in the transfused blood that caused leucocytosis. The authors suggested that cytokines produced by leucocytes in stored blood might be responsible for leucocytosis in recipients of unfiltered packed red cells.

Effects on the lungs. A rare but life-threatening complication of transfusion of blood or other plasma-containing products is acute lung injury, often termed transfusion-related acute lung injury (TRALI). Symptoms develop during or within 6 hours of infusion and are those of acute respiratory distress syndrome[1-3] (p.1498). Treatment is the same as for acute respiratory distress of any cause but oxygen exchange usually begins to improve between 24 and 48 hours; if the patient survives there appear to be no long-term sequelae.[1] The presence of HLA-specific antileucocyte antibodies in plasma from multiparous female donors appears to play a role in starting the reaction;[1,3] such antibodies have also been identified in some implicated male donors.[2] Another mechanism, the neutrophil priming hypothesis, proposes that TRALI results from 2 independent events. The first event causes the recipient's neutrophils to be primed and is related to the recipient's condition; in the second event the infused blood product activates the primed neutrophils in the lung, which causes endothelial damage.[2,3]

Graft-versus-host disease. Acute graft-versus-host disease (see Haematopoietic Stem Cell Transplantation, p.1811) has been reported in both immunocompromised and immunocompetent patients after blood transfusion.[1] Symptoms include fever, rash, abnormal liver function tests, diarrhoea, and pronounced leucopenia and pancytopenia. The reaction can be severe and fatal.

High-risk immunocompromised groups include bone marrow transplant recipients, patients with congenital immunodeficiencies, fetuses receiving intra-uterine transfusions, patients with Hodgkin's disease, and patients treated with purine analogue drugs such as fludarabine. Patients at less risk include those with acute leukaemia, non-Hodgkin's lymphoma, solid tumours treated with intensive chemotherapy or radiotherapy, premature infants and those undergoing exchange transfusion, and solid organ transplant recipients.

Immunocompetent patients who share an HLA haplotype with HLA-homozygous blood donors also appear to be at increased risk. Such cases have been reported particularly in Japan, where practices have included the use of transfusions from blood relatives. There is also a high incidence of shared haplotype in the population.

Infusion of products containing viable lymphocytes appears to be responsible. Treatment of graft-versus-host disease associated with transfusion is largely ineffective and patients considered to be at risk should be given products depleted of viable lymphocytes by irradiation. Blood products depleted of leucocytes by filtration still contain a small percentage of viable leucocytes, and this should not be used as the sole method to prevent graft-versus-host disease.

Malignant neoplasms. It has been suggested that perioperative allogeneic blood transfusion is associated with an increase in the risk of recurrence, and decreased long-term survival, after resection of malignancy. This suggestion was based on retrospective observational studies, and was attributed to immunosuppressant effects of allogeneic blood. Randomised controlled trials have produced conflicting results, but a 1996 review[1] did not find a detrimental effect on the risk of cancer recurrence, and suggested that the findings of the observational studies probably resulted from the confounding effect of factors associated with the need for transfusion. A later meta-analysis[2] of 32 studies of perioperative transfusion in patients undergoing colorectal surgery concluded that the cancer recurrence rate was increased (odds ratio 1.68) in patients given transfusions. Risk factors associated with this increase were rectal disease, more advanced disease, and an increased number of transfused units. However, many of the included studies had small sample sizes, there was significant heterogeneity, and other possible surgery-related risk factors could not be evaluated, such that a causal association between the increased risk of cancer recurrence and transfusion could not be established. Other systematic reviews have come to different conclusions. A meta-analysis[3] of studies in patients undergoing resection of any type of solid tumour included only studies that used an active comparator (leucocyte-depleted or autologous blood). Only 8 studies met the inclusion criteria and the analysis provided no evidence of an increased risk of death or cancer recurrence in patients given allogeneic blood. The proposed detrimental immunosuppressive effect of perioperative allogeneic blood transfusion was studied in colorectal cancer patients given either allogeneic packed red cells (buffy coat removed) or leucocyte-depleted red cells.[4] Although the leucocyte count is reduced when the buffy coat is removed, more leucocytes are removed from leucocyte-depleted red cells, which should reduce any immunosuppressive effect. However, after 5 years there was no difference in survival or recurrence rates between the two groups. Survival was better for a third group of non-transfused patients, but this may be explained by a higher incidence of rectal cancer in the transfused groups, and the better clinical status of patients not requiring transfusion. A review[5] of individual studies and meta-analyses concluded that a causal relationship between allogeneic blood transfusion and solid cancer recurrence had not been proven. There was some evidence for transfusion-associated immunomodulation, but the mechanisms of effect and the specific constituents of allogeneic blood that mediate the effect remain unclear.

Epidemiological studies have reported an increase in the incidence of non-Hodgkin's lymphoma coinciding with the increase in the use of allogeneic blood transfusions since the 1950s. Proposed mechanisms have included transfusion-associated immunosuppression, transmission of oncogenic viruses, and blood donation by prelymphomatous donors.[6,7] Although some case-control studies have reported no association between blood transfusion and the development of non-Hodgkin's lymphoma,[8,9] others have reported a positive association, particularly for some subtypes of lymphoma.[10] Reviews[6,7] of these and other studies have found considerable disagreement between reports. This may result from biases in study design, confounding factors such as HIV infection, and lack of consensus on lymphoma classification.

Precautions

Whole blood should generally not be transfused unless the ABO and Rh groups of the patient's and the donor's blood have been verified and a compatibility check made between the patient's serum and the donor's red cells (see under Blood Groups, below).

The Rh group of the recipient should always be determined and ideally all patients should be transfused with blood of homologous Rh groups.

To reduce the possibility of cardiac arrest from cardiac hypothermia when large volumes are used or the blood is transfused rapidly, and to minimise postoperative shivering, stored blood should be carefully warmed to about 37° before transfusion.

Whole blood should not be given to patients with chronic anaemia who have a normal or elevated plasma volume.

Drugs should *not* be added to blood.

Transfusion of blood from donors who have recently been receiving drug treatment may be hazardous to the recipient.

◊ Guidelines[1-4] for accepting blood from donors who have been receiving drugs have been published.

Blood groups. The chief blood group systems are the ABO system and the Rhesus system.

In simple terms red blood cells carry on their surface genetically determined antigens. A person with antigen A, B, A plus B, or neither is classified as group A, B, AB, or O respectively. Such persons will have, in their serum, antibodies to B, A, neither, or both respectively—anti-B (β), anti-A (α), or anti-B plus anti-A ($\alpha + \beta$). Giving blood containing red cells from a person of group A to a person with anti-A results in agglutination or possibly haemolysis. For the determination of the ABO group the agglutinogens of the red cells and the agglutinins of the serum are determined by testing against known standards.

In the Rhesus system many persons carry an antigen (Rh-positive) which stimulates antibody formation in Rh-negative persons; subsequent exposure to Rh-positive blood causes haemolysis.

Many variants of these and other systems, are recognised.

Uses and Administration

Blood is a complex fluid with many functions including the maintenance of hydration of the tissues, maintenance of body temperature, and the transport within the body of gases, ions, nutrients, hormones, enzymes, antibodies, waste products of metabolism, and drugs.

The main components of blood are plasma, red blood cells (erythrocytes), white blood cells (leucocytes), and platelets (for further information on different blood cells and their formation, and average counts in adults, see Haematopoiesis, p.1042). Serum is the fluid which remains once blood or plasma has clotted; it is, in effect, plasma with fibrinogen removed.

Whole blood is used as a source of red cell concentrates, clotting factors, platelets, plasma and plasma fractions, and immunoglobulins, each of which has specific indications for use. Because of the risks involved in transfusing whole blood and the need for economy in its use, the appropriate blood component should be used whenever possible.

Whole blood may be used where replacement of plasma proteins as well as red blood cells is needed, for example after acute blood loss during surgery or severe haemorrhage. It may also be used to supplement the circulation during cardiac bypass surgery.

The amount of whole blood transfused and the rate at which it is given depend upon the patient's age and general condition, upon the state of their circulatory system, and upon the therapeutic indication for transfusion.

The expression 'unit of blood' generally represents a volume of about 510 mL, including anticoagulant. For blood preparations a unit generally refers to the quantity of a blood component obtained from 1 unit of whole blood. Specific units of activity are used for some blood components.

The haemoglobin concentration of the blood of the average adult is raised by about 1 g per 100 mL by the transfusion of 1 unit of whole blood.

Preparations

USP 31: Whole Blood.

Calcium Alginate

Alginato cálcico; E404.

CAS — 9005-35-0.
ATC — B02BC08.
ATC Vet — QB02BC08.

Profile

Calcium alginate is the calcium salt of alginic acid, a polyuronic acid composed of residues of D-mannuronic and L-guluronic acids. It may be obtained from seaweeds, mainly species of *Laminaria*. Calcium alginate is used as an absorbable haemostatic and for the promotion of wound healing (p.1585); it is also used in the form of a mixed calcium-sodium salt of alginic acid as a fibre made into a dressing or packing material. Calcium ions in the calcium alginate fibres are exchanged for sodium ions in the blood and exudate to form a hydrophilic gel.

Alginic acid and its calcium and sodium salts are widely used in the food industry.

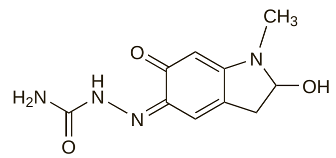
Carbazochrome *(rINN)*

AC-17; Adrenochrome Monosemicarbazone; Carbazochromum; Carbazocromo. 3-Hydroxy-1-methyl-5,6-indolinedione semicarbazone.

Карбазохром

$C_{10}H_{12}N_4O_3$ = 236.2.

CAS — 69-81-8 (carbazochrome); 13051-01-9 (carbazochrome salicylate); 51460-26-5 (carbazochrome sodium sulfonate).
ATC — B02BX02.
ATC Vet — QB02BX02.



Pharmacopoeias. *Jpn* includes Carbazochrome Sodium Sulfonate ($C_{10}H_{11}N_4NaO_5S,3H_2O$ = 376.3).

Profile

Carbazochrome, an oxidation product of adrenaline, has been given as a haemostatic. Carbazochrome sodium sulfonate may be given orally in doses ranging from 30 to 150 mg daily, in at least 3 divided doses. Parenteral doses of 10 mg may be given subcutaneously or intramuscularly, and up to 100 mg may be given intravenously. It has also been given as the dihydrate and as the salicylate.

Darbepoetin Alfa *(BAN, USAN, rINN)* ⊗

Darbepoetiinialfa; Darbepoetina alfa; Darbépoétine Alfa; Darbepoetinum Alfa; NESP; Novel Erythropoiesis Stimulating Protein. 30-L-Asparagine-32-L-threonine-87-L-valine-88-L-asparagine-90-L-threonineerythropoietin (human).

Дарбепоетин Альфа

CAS — 209810-58-2.
ATC — B03XA02.
ATC Vet — QB03XA02.

Adverse Effects and Precautions

As for Epoetins, p.1061.

Pharmacokinetics

On subcutaneous injection the bioavailability of darbepoetin alfa is about 37% and absorption is slow. It undergoes extensive metabolism, with terminal half-lives of 21 and 49 hours after intravenous and subcutaneous use respectively.

4. Heatherington AC, *et al.* Pharmacokinetics of darbepoetin alfa after intravenous or subcutaneous administration in patients with non-myeloid malignancies undergoing chemotherapy. *Clin Pharmacokinet* 2006; **45:** 199–211.

Uses and Administration

Darbepoetin alfa is an analogue of the endogenous protein hormone erythropoietin with similar properties to the epoetins (p.1062). It is used in the management of anaemia associated with chronic renal failure (see Normocytic-normochromic Anaemia, p.1044) and for anaemia caused by chemotherapy in patients with non-myeloid malignancies.

For **anaemia associated with chronic renal failure** in adults and children aged 11 years and older, the aim of treatment is to increase the haemoglobin concentration to 10 to 12 g per 100 mL. The rate of rise in haemoglobin should be gradual to minimise adverse effects such as hypertension; a rate not exceeding 2 g per 100 mL per month is suggested. Darbepoetin alfa is given by subcutaneous or intravenous injection in an initial dose of 450 nanograms/kg once weekly, as a single injection. In patients on haemodialysis, the intravenous route is recommended to reduce the risk of developing neutralising antibodies and pure red cell aplasia (see Effects on the Blood under Epoetins, p.1061). The dose should be adjusted at intervals of not less than 4 weeks, according to response, until the target haemoglobin concentration is achieved. In general, adjustments are made by increasing or decreasing the dose by about 25%. Maintenance doses may then be continued once weekly. Patients may be converted from weekly doses to once every 2 weeks, and should receive a dose that is equal to twice the dose that had been given once weekly. Alternatively, for patients who are not on dialysis, an initial dose of 750 nanograms/kg subcutaneously once every 2 weeks may be used, followed by dose adjustment. When the target haemoglobin concentration is achieved, a maintenance dose may be given once a month; this is equal to twice the dose that had been given once every 2 weeks.

For **anaemia in chemotherapy patients** with non-myeloid malignancies, darbepoetin alfa is given subcutaneously in an initial dose of 500 micrograms (6.75 micrograms/kg) once every 3 weeks; if the response is inadequate after 9 weeks, further therapy with darbepoetin alfa may not be effective. Alternatively, it may be given in an initial dose of 2.25 micrograms/kg once weekly. If the response is inadequate after 6 weeks, the dose may be increased to 4.5 micrograms/kg once weekly. Darbepoetin alfa should be stopped after the course of chemotherapy has finished, but it may be continued for up to 4 weeks in the UK. The rate of rise in haemoglobin should be gradual; a rate not exceeding 2 g per 100 mL per month, and a target haemoglobin of not more than 12 g per 100 mL, are suggested. Once the desired haemoglobin target has been reached, the dose should be reduced by 25 to 50% to maintain that level.

Dextran 1 *(BAN, rINN)* ⊗

Dekstraani 1; Dekstranas 1; Dextrán 1; Dextranum 1.

Декстран 1

CAS — 9004-54-0 (dextran).
ATC — B05AA05.
ATC Vet — QB05AA05.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Dextran 1 for Injection). A low-molecular-weight fraction of dextran, consisting of a mixture of isomalto-oligosaccharides. It is obtained by hydrolysis and fractionation of dextrans produced by fermentation of sucrose using a certain strain or substrains of *Leuconostoc mesenteroides*. The average relative molecular mass is about 1000.

A white or almost white, hygroscopic powder. Very soluble in water; very slightly soluble in alcohol.

USP 31 (Dextran 1). A low-molecular-weight fraction of dextran, consisting of a mixture of isomalto-oligosaccharides. It is obtained by controlled hydrolysis and fractionation of dextrans produced by fermentation of certain strains of *Leuconostoc mesenteroides*, in the presence of sucrose. It is a glucose polymer in

which the linkages between glucose units are almost exclusively α-1,6. Its weight average molecular weight is about 1000.
A white to off-white, hygroscopic powder. Very soluble in water; sparingly soluble in alcohol. pH of a 15% solution in water is between 4.5 and 7.0. Store at a temperature between 4° and 30°.

Profile

Dextran 1 is used to prevent severe anaphylactic reactions to infusions of dextran. It is reported to occupy the binding sites of dextran-reactive antibodies and so prevent the formation of large immune complexes with higher molecular weight dextrans.

Dextran 1 is given in usual doses of 20 mL of a solution containing 150 mg/mL by intravenous injection about 1 to 2 minutes before the infusion of the higher molecular weight dextran; the interval should not exceed 15 minutes. A suggested dose for children is 0.3 mL/kg. The dose of dextran 1 should be repeated if further infusions of dextran are required more than 48 hours after the initial dose.

Use. Two large multicentre studies (involving about 29 200 and 34 950 patients) have suggested that dextran 1 prevented anaphylactic reactions by hapten inhibition in a dose-dependent way.[1,2] It did not reduce the incidence of mild reactions, which are not generally mediated by antibodies. Another large study[3] comparing the effects of giving dextran 1 either 2 minutes before injection of dextran 40 or 70 or mixed with the injection, was stopped after the occurrence of 2 severe reactions in the admixture group. A comparison[4] of severe anaphylactic reactions to dextran infusion during the period 1983 to 1992 (when prophylaxis with dextran 1 was used) with reactions reported during the period 1975 to 1979 (no prophylaxis) found that the use of dextran 1 was associated with a 35-fold reduction in severe anaphylactic reactions to dextran infusion.

There were 21, 20, and 2 adverse reactions to dextran 1 in the first 3 studies respectively, including nausea, skin reactions, bradycardia, and hypotension. Apart from one patient, reactions to dextran 1 were mild and were considered to be of minor clinical importance. In the fourth study, adverse effects to dextran 1 were reported in about one case per 100 000 doses.

Dextran 40 *(BAN, USAN, rINN)* ⊗

Dekstraani 40; Dekstran 40; Dekstranas 40; Dextrán 40; Dextranum 40; LMD; LMWD; Low-molecular-weight Dextran; LVD.

Декстран 40
CAS — 9004-54-0 (dextran).
ATC — B05AA05.
ATC Vet — QB05AA05.

Pharmacopoeias. In *Chin.*, *Jpn*, and *US.*
Eur. (see p.vii) and *Jpn* describe Dextran 40 for Injection.
Ph. Eur. 6.2 (Dextran 40 for Injection). A mixture of polysaccharides, principally of the α-1,6-glucan type, obtained by hydrolysis and fractionation of dextrans produced by fermentation of sucrose using a certain strain or substrains of *Leuconostoc mesenteroides*. The average relative molecular mass is about 40 000.
A white or almost white powder. Very soluble in water; very slightly soluble in alcohol.
USP 31 (Dextran 40). It is derived by controlled hydrolysis and fractionation of polysaccharides elaborated by the fermentative action of certain strains of *Leuconostoc mesenteroides* on a sucrose substrate. It is a glucose polymer in which the linkages between glucose units are almost entirely of the α-1:6 type. Its weight average molecular weight is in the 35 000 to 45 000 range. A 10% solution in water has a pH of 4.5 to 7.0. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Incompatibility. Incompatibilities may arise from the slightly acid pH of dextran 40 preparations.

Adverse Effects, Treatment, and Precautions

As for Dextran 70, p.1059.

Rapid renal excretion of dextran 40 in patients with reduced urine flow can result in high urinary concentrations which increase urinary viscosity and may cause oliguria or acute renal failure. Therefore, infusions of dextran 40 are contra-indicated in renal disease with oliguria; should anuria or oliguria occur during treatment dextran 40 should be withdrawn. Dehydration should preferably be corrected before giving dextran 40. Dextran 40 can cause capillary oozing of wound surfaces.

Effects on the kidneys. Acute renal failure has been associated with dextran 40[1-4] and less frequently with dextran 70.[1] The mechanism of the effect is unclear but suggestions include an increase in plasma oncotic pressure that decreases filtration pressure in the glomerulus and hence decreases glomerular filtration rate,[2] obstruction within the tubules,[2,4] or a direct toxic effect on renal cells.[4] Plasmapheresis has been used successfully to remove dextran from the circulation.[2-4]

4. Vos SCB, *et al.* Acute renal failure during dextran-40 antithrombotic prophylaxis: report of two microsurgical cases. *Ann Plast Surg* 2002; **48:** 193–6.

Hypersensitivity. For reports of anaphylactic reactions associated with use of dextran 40, see Dextran 70, below, and Dextran 1, above.

Pharmacokinetics

After intravenous infusion dextran 40 is slowly metabolised to glucose. About 70% of a dose is excreted unchanged in the urine within 24 hours. A small amount is excreted into the gastrointestinal tract and eliminated in the faeces.

Uses and Administration

Dextran 40 is a plasma volume expander used in the management of hypovolaemic shock (p.1183). As a 10% solution, dextran 40 exerts a slightly higher colloidal osmotic pressure than plasma proteins and thus produces a greater expansion of plasma volume than dextrans of a higher molecular weight, although the expansion may have a shorter duration because of more rapid renal excretion. Dextran 40 also reduces blood viscosity and inhibits sludging or aggregation of red blood cells. It is used in the prophylaxis and treatment of postoperative thromboembolic disorders, in conditions where improved circulatory flow is required, and as a priming solution during extracorporeal circulation.

Dextran 40 is given by intravenous infusion as a 10% solution in sodium chloride 0.9% or glucose 5%. Doses depend on the clinical condition of the patient.

In **shock**, a maximum of 20 mL/kg during the first 24 hours has been recommended; the first 10 mL/kg may be given by rapid intravenous infusion. Doses of up to 10 mL/kg may be given daily thereafter for up to 5 days. Dehydration should preferably be corrected before dextran 40 is given.

In the treatment of **thromboembolic disorders** a suggested regimen is 500 to 1000 mL over 4 to 6 hours on the first day, then 500 mL over 4 to 6 hours on the next and subsequent alternate days for not more than 10 days.

For prophylaxis of postoperative thromboembolic disorders, 500 mL over 4 to 6 hours may be given during or at the end of surgery and the dose repeated on the next day; treatment may be continued in high risk patients on alternate days for up to 10 days.

Infants may be given up to 5 mL/kg and children up to 10 mL/kg.

A dose of 10 to 20 mL/kg has been added to extracorporeal perfusion fluids.

Dextran 40 is also an ingredient of artificial tears.

Post-dural puncture headache. Dextran 40 has been used in the treatment of post-dural puncture headache (p.1851) when other measures, including epidural autologous blood patch, have been ineffective. Reports[1-3] have described dextran 40 given in an epidural bolus dose of 20 mL. Sometimes this has been followed by a continuous epidural infusion of 3 to 4 mL/hour, and in these cases headache was relieved within 20 hours of starting the infusion.[1,2]

1. Aldrete JA. Persistent post-dural-puncture headache treated with epidural infusion of dextran. *Headache* 1994; **34:** 265–7.
2. Reynvoet MEJ, *et al.* Epidural dextran 40 patch for postdural puncture headache. *Anaesthesia* 1997; **52:** 886–8.
3. Souron V, Hamza J. Treatment of postdural puncture headaches with colloid solutions: an alternative to epidural blood patch. *Anesth Analg* 1999; **89:** 1333–4.

Thromboembolic disorders. Dextran 40 is only one of a variety of drugs that have been used for the prophylaxis of venous thromboembolism (p.1189) resulting from surgical operations such as hip replacement surgery. Dextran 40 may be used to prevent thromboembolic complications in some types of vascular surgery including carotid endarterectomy.[1]

Декстран 70
CAS — 9004-54-0 (dextran).
ATC — B05AA05.
ATC Vet — QB05AA05.

Pharmacopoeias. In *Chin.*, *Jpn*, and *US.*
Eur. (see p.vii) describes Dextran 70 for Injection.
Ph. Eur. 6.2 (Dextran 70 for Injection). A mixture of polysaccharides, principally of the α-1,6-glucan type, obtained by hydrolysis and fractionation of dextrans produced by fermentation of sucrose using a certain strain or substrains of *Leuconostoc mesenteroides*. The average relative molecular mass is about 70 000.
A white or almost white powder. Very soluble in water; very slightly soluble in alcohol.
USP 31 (Dextran 70). It is derived by controlled hydrolysis and fractionation of polysaccharides elaborated by the fermentative action of certain appropriate strains of *Leuconostoc mesenteroides* on a sucrose substrate. It is a glucose polymer in which the linkages between glucose units are almost entirely of the α-1:6 type. Its weight average molecular weight is in the 63 000 to 77 000 range. A 6% solution in water has a pH of 4.5 to 7.0. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Incompatibility. Incompatibilities may arise from the slightly acid pH of dextran 70 preparations.

Storage. Crystals may form in solutions of dextran if they are stored at low temperatures. These may be redissolved by warming for a short time.

Adverse Effects and Treatment

Infusions of dextrans may occasionally produce hypersensitivity reactions such as fever, nasal congestion, joint pains, urticaria, hypotension, and bronchospasm. Severe anaphylactic reactions occur rarely and may be fatal. Dextran-reactive antibodies have been detected in patients who have not previously received dextran. This may possibly be in response to dietary or bacterial polysaccharides. Nausea and vomiting have also been reported. These reactions are treated symptomatically after withdrawal of the dextran.

Dextran 1 (p.1058) may be used to block the formation of dextran-reactive antibodies and hence the hypersensitivity reactions.

Effects on the blood. A syndrome of acute hypotension, pulmonary oedema, coagulopathy, and anaemia, has occurred after the intra-uterine instillation of 32% solution of dextran 70 for hysteroscopy.[1] The volumes of solution that were used in 10 reported cases ranged from 300 to 1200 mL, and these large volumes may have contributed to the intravascular absorption of dextran. The pathogenesis and role of dextran in this syndrome are unclear but suggestions have included acute volume overload, direct alveolar endothelial damage, and release of tissue factors that promote fibrinolysis and a consumptive coagulopathy.

1. Ellingson TL, Aboulafia DM. Dextran syndrome: acute hypotension, noncardiogenic pulmonary edema, anemia, and coagulopathy following hysteroscopic surgery using 32% dextran 70. *Chest* 1997; **111:** 513–18.

Effects on the kidneys. For a report of acute renal failure associated with use of dextran 70, see Dextran 40, above.

Hypersensitivity. In a retrospective study of allergic reactions to dextran 40 and dextran 70 reported in Sweden from 1970 to 1979,[1] there were 478 reports of reactions, 458 of which were considered to be due to dextran, out of 1 365 266 infusions given. There was a male to female ratio of 1.5 to 1 for all reactions and a ratio of 3 to 1 for the most severe reactions. The mean age of the patients was higher in those with severe reactions. Of the 28 fatal reactions, 27 occurred within 5 minutes of the start of the infusion and 25 when less than 25 mL had been infused. Three of the fatal reactions occurred after a test dose of only 0.5 to 1 mL and it was strongly recommended that such test doses should not be used.

An anaphylactic reaction has also been reported[2] more than 75 minutes after intraperitoneal instillation. After successful symptomatic treatment symptoms recurred 20 minutes later, due to slow absorption of dextran from the peritoneal cavity. No further reaction occurred after removal of 200 mL of intraperitoneal fluid by culdocentesis.

Anaphylactoid reactions after BCG vaccination have been attributed to hypersensitivity to dextran in the formulation.[3]

The use of dextran 1 for the prevention of hypersensitivity reactions is discussed under that monograph (p.1058).

1. Ljungström K-G, *et al.* Adverse reactions to dextran in Sweden 1970–1979. *Acta Chir Scand* 1983; **149:** 253–62.
2. Borten M, *et al.* Recurrent anaphylactic reaction to intraperitoneal dextran 75 used for prevention of postsurgical adhesions. *Obstet Gynecol* 1983; **61:** 755–7.
3. Rudin C, *et al.* Anaphylactoid reaction to BCG vaccine containing high molecular weight dextran. *Eur J Pediatr* 1995; **154:** 941–2.

Precautions

Dextran infusions produce a progressive dilution of oxygen-carrying capacity, coagulation factors, and plasma proteins and may overload the circulation. They are therefore contra-indicated in patients with severe heart failure, bleeding disorders such as hypofibrinogenaemia or thrombocytopenia, or renal failure and should be used with caution in patients with renal impairment, haemorrhage, chronic liver disease, or those at risk of developing pulmonary oedema or heart failure. Central venous pressure should be monitored during the initial period of infusion to detect fluid overload. Also patients should be watched closely during the early part of the infusion period, and the infusion stopped immediately if signs of anaphylactic reactions appear. Infusions should also be stopped if there are signs of oliguria or renal failure. The haematocrit should not be allowed to fall below 30% and all patients should be observed for early signs of bleeding complications. The bleeding time may be increased especially in patients receiving large volumes of dextrans. Deficiency of coagulation factors should be corrected and fluid and electrolyte balance maintained. Dehydration should be corrected before or at least during dextran infusions, in order to maintain an adequate urine flow.

The anticoagulant effect of heparin may be enhanced by dextran.

The higher molecular weight dextrans may interfere with blood grouping and cross-matching of blood, while the lower molecular weight dextrans may interfere with some methods. Therefore, whenever possible, a sample of blood should be collected before giving the dextran infusion and kept frozen in case such tests become necessary.

The presence of dextran may interfere with the determination of glucose, bilirubin, or protein in blood.

Pharmacokinetics

After intravenous infusion dextrans with a molecular weight of less than 50 000 are excreted unchanged by the kidney. Dextrans with a molecular weight greater than 50 000 are slowly metabolised to glucose. Small amounts of dextrans are excreted into the gastrointestinal tract and eliminated in the faeces.

About 50% of dextran 70 is excreted unchanged in the urine within 24 hours.

Uses and Administration

Dextran 70 is a plasma volume expander used in the management of hypovolaemic shock (p.1183). As a 6% solution dextran 70 exerts a colloidal osmotic pressure similar to that of plasma proteins and thus produces less expansion of plasma volume than dextrans of a lower molecular weight, although the expansion may have a longer duration because of less rapid renal excretion. Dextran 70 also reduces blood viscosity, interferes with fibrin polymerisation, has an antiplatelet effect, and inhibits sludging or aggregation of red blood cells. It may be used in the prophylaxis of postoperative thromboembolic disorders (p.1189).

Dextran 70 is given by intravenous infusion as a 6% solution, usually in sodium chloride 0.9% or glucose 5%.

Doses depend on the severity of the plasma loss and on the degree of haemoconcentration.

In **shock**, the usual initial dose for rapid expansion of plasma volume is 500 to 1000 mL infused at a rate of 20 to 40 mL/minute. A suggested maximum dose is 20 mL/kg during the first 24-hour period and 10 mL/kg per day thereafter; treatment should not continue for longer than 3 days. Patients may also require blood, coagulation factors, and electrolytes. A hypertonic solution of 6% dextran 70 in sodium chloride 7.5% is also available for use as a plasma expander, given in a single intravenous dose of 250 mL over 2 to 5 minutes, followed by isotonic fluids as required.

For the prophylaxis of pulmonary embolism or venous **thrombosis** in moderate- to high-risk patients undergoing surgery, a dose of 500 to 1000 mL may be given over 4 to 6 hours either during or immediately after surgery. A dose of 500 mL should be given on the next day and in high-risk patients on subsequent alternate days for up to 2 weeks after the operation.

A 32% solution of dextran 70 has been instilled into the uterus in a dose of 50 to 100 mL as a rinsing and dilatation fluid to aid **hysteroscopy**.

Dextran 70 is also an ingredient of artificial tears.

Hypertonic solutions. There is some evidence to suggest that hypertonic solutions of dextran 70 in sodium chloride 7.5% may be an effective treatment option for hypovolaemic shock resulting from trauma.[1,2]

Dextran 75 *(BAN, USAN, rINN)* ⊗

Dextrán 75; Dextranum 75.

Декстран 75

CAS — 9004-54-0 (dextran).
ATC — B05AA05.
ATC Vet — QB05AA05.

Profile

Dextran 75 consists of dextrans (glucose polymers) of weight average molecular weight about 75 000 that are derived from the dextrans produced by the fermentation of sucrose by means of a certain strain of *Leuconostoc mesenteroides*.

Dextran 75 is a plasma volume expander with actions and uses similar to dextran 70 (p.1059). It is given by intravenous infusion as a 6% solution in sodium chloride 0.9% or glucose 5%.

Ecallantide *(USAN, rINN)*

DX-88; Ecalantida; Écallantide; Ecallantidum. Human plasma kallikrein-inhibitor (synthetic protein).

Экальлантид

CAS — 460738-38-9.

Profile

Ecallantide is a recombinant inhibitor of human plasma kallikrein. It is under investigation in the management of hereditary angioedema (p.1081).

◊ Reviews.

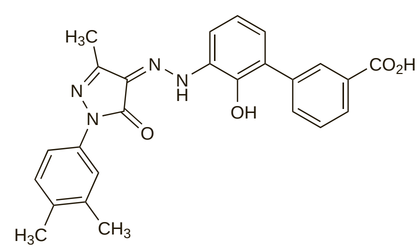
Eltrombopag *(rINN)*

Eltrombopagum. 3′-{(2*Z*)-2-[1-(3,4-Dimethylphenyl)-3-methyl-5-oxo-1,5-dihydro-4*H*-pyrazol-4-ylidene]diazanyl}-2′-hydroxybiphenyl-3-carboxylic acid.

Элтромбопаг

$C_{25}H_{22}N_4O_4$ = 442.5.
CAS — 496775-61-2.



Eltrombopag Olamine *(USAN, rINNM)*

Eltrombopag olamina; Eltrombopagum Olaminum; SB-497115-GR. 3′-{(2*Z*)-2-[1-(3,4-Dimethylphenyl)-3- methyl-5-oxo-1,5-dihydro-4*H*-pyrazol-4-ylidene]diazanyl}-2′-hydroxybiphenyl-3-carboxylic acid compound with 2-aminoethanol (1:2).

Элтромбопаг Оламин

$C_{25}H_{22}N_4O_4,2(C_2H_7NO)$ = 564.6.
CAS — 496775-62-3.

Profile

Eltrombopag is a non-peptide thrombopoietin receptor agonist. It is under investigation as a platelet growth factor given orally for the management of thrombocytopenia in patients with hepatitis C infection, and in idiopathic thrombocytopenic purpura.

Epoetins ⊗

Epoetinas.
ATC — B03XA01.
ATC Vet — QB03XA01.

Description. Erythropoietin is a glycosylated protein hormone and a haematopoietic growth factor produced primarily in the kidneys.

Erythropoietin for clinical use is produced by recombinant DNA technology and the name epoetin is often applied to such material. Epoetin alfa, epoetin beta, epoetin gamma, epoetin omega, and epoetin zeta are recombinant human erythropoietins derived from a cloned human erythropoietin gene. All have the same 165 amino acid sequence but differ in the glycosylation pattern. Epoetin delta is a recombinant human erythropoietin derived from a genetically engineered continuous human cell line. It has the same amino acid sequence and glycosylation pattern as human erythropoietin.

Pharmacopoeias. *Eur.* (see p.vii) includes Erythropoietin Concentrated Solution.

Ph. Eur. 6.2 (Erythropoietin Concentrated Solution). A clear or slightly turbid colourless solution, containing 0.05 to 1% of glycoproteins indistinguishable from naturally occurring human erythropoietin in terms of amino acid sequence and glycosylation pattern. It has a potency of not less than 100 000 units per mg of active substance. Store in airtight containers below −20° and avoid repeated freezing and thawing.

Epoetin Alfa *(BAN, USAN, rINN)* ⊗

EPO; Epoetina alfa; Époétine Alfa; Epoetinum Alfa. 1–165-Erythropoietin (human clone λHEPOFL13 protein moiety), glycoform α.

Эпоэтин Альфа
CAS — 113427-24-0.
ATC — B03XA01.
ATC Vet — QB03XA01.

Epoetin Beta *(BAN, USAN, rINN)* ⊗

BM-06.019; EPOCH; Epoetina beta; Époétine Bêta; Epoetinum Beta. 1–165-Erythropoietin (human clone λHEPOFL13 protein moiety), glycoform β.

Эпоэтин Бета
CAS — 122312-54-3.
ATC — B03XA01.
ATC Vet — QB03XA01.

Epoetin Delta *(USAN, rINN)* ⊗

Epoetina delta; Époétine Delta; Epoetinum Delta; GA-EPO; HMR-4396. 1–165-Erythropoietin (human HMR4396), glycoform δ.

Эпоэтин Дельта
CAS — 261356-80-3.
ATC — B03XA01.
ATC Vet — QB03XA01.

Epoetin Gamma *(BAN, rINN)* ⊗

BI-71.052; Epoetina gamma; Époétine Gamma; Epoetinum Gamma. 1–165-Erythropoietin (human clone λHEPOFL13 protein moiety), glycoform γ.

Эпоэтин Гамма
CAS — 130455-76-4.
ATC — B03XA01.
ATC Vet — QB03XA01.

Epoetin Omega *(rINN)* ⊗

Epoetina omega; Époétine Oméga; Epoetinum Omega. 1–165-Erythropoietin (human clone λHEPOFL13 protein moiety), glycoform ω.

Эпоэтин Омега
CAS — 148363-16-0.
ATC — B03XA01.
ATC Vet — QB03XA01.

Epoetin Zeta *(rINN)* ⊗

Epoetina Dseta; Époétine Zêta; Epoetinum Zeta. 1–165-Erythropoietin (human clone B03XA01), glycoform ζ.

Эпоэтин Цета
CAS — 604802-70-2.
ATC — B03XA01.
ATC Vet — QB03XA01.

Stability. Proprietary preparations of recombinant human erythropoietin may contain albumin or amino acids for stability. Use in neonates may necessitate making very dilute solutions. A study of the stability of epoetin alfa in various intravenous fluids[1] found that a minimum of 0.05% protein was required to prevent loss of drug from solutions containing epoetin alfa 0.1 units/mL. In another study,[2] 0.0125% albumin was sufficient to prevent loss of drug from a solution containing epoetin alfa 100 units/mL. Epoetin alfa was stable for up to 24 hours in a solution for enteral use in neonates, formulated to mimic amniotic fluid, which also contained filgrastim and electrolytes.[3] Epoetin alfa and filgrastim were stable for at least 24 hours when refrigerated and for at least 3 weeks when frozen. At room temperature epoetin alfa was stable for 24 hours and filgrastim was stable for 18 hours. Lowered epoetin alfa concentrations were thought to be due to adsorption to the plastic infusion bag or tubing, and this was overcome by priming the tubing.

Adverse Effects and Treatment

Adverse effects of epoetins include flu-like symptoms such as fever, chills, headache, arthralgias, myalgias, asthenia, dizziness, and tiredness, which occur especially at the start of treatment. Other effects include rashes, urticaria, nausea and vomiting, diarrhoea, hyperkalaemia, and reactions at the injection site. Severe hypersensitivity reactions have been reported rarely. Pure red cell aplasia associated with neutralising antibodies has also been reported rarely in patients with chronic renal failure. Modest increases in the platelet count within the normal range may occur during epoetin therapy.

Hypertension is common with the use of epoetins, particularly in patients with renal failure, and is associated with a rapid rise in haematocrit. Hypertensive crisis with encephalopathy and seizures has been reported, even in patients with initially normal or low blood pressure.

Reports of thromboembolism include myocardial ischaemia and infarction, transient ischaemic attacks and cerebrovascular accidents, deep-vein thrombosis, and pulmonary embolism. Shunt thromboses may occur in the arteriovenous fistulae of dialysis patients, and occlusion of the dialysis system is possible, due to an increased haematocrit.

Effects on the blood. The use of recombinant human erythropoietin has been associated with an increase in **thrombotic events**, including vascular access thrombosis in haemodialysis patients. A number of mechanisms have been proposed for this increase such as increased blood viscosity, effects on proteins involved in coagulation, activation of platelets and the endothelium, and a vasoconstrictor effect on vascular smooth muscle.[1]

Pure red cell aplasia has been reported rarely in patients with chronic renal failure after months to years of treatment with epoetin alfa; most patients have been found to have antibodies to epoetins.[2] There have also been a few cases in patients treated with epoetin beta.[3-5] A review[5] of cases reported between January 1988 and April 2004 found that the number peaked in 2001 and 2002, and decreased rapidly when changes were made to recommendations for storage, handling, and use of epoetin alfa preparations. The effect appeared to be brand specific[6-8] and associated particularly with the subcutaneous use of preparations containing polysorbate 80 as a stabiliser.[9] Other possible causes have been proposed including contamination with silicone lubricant used in pre-filled syringes or release of organic compounds from rubber plungers.[10] Subsequently, manufacturers have reported that cases of red cell aplasia with neutralising antibodies have also occurred in chronic renal failure patients treated with subcutaneous darbepoetin alfa.[11] They also warn that because of cross-reactivity, patients who develop antibody-mediated anaemia with either an epoetin or darbepoetin alfa should not be swapped to another erythropoietic protein.

Epoetin-induced red cell aplasia has been managed with withdrawal of the epoetin and treatment with immunosuppressants including corticosteroids, cyclophosphamide, and ciclosporin. Intravenous normal immunoglobulin has also been used. Kidney transplantation is reported to bring about a rapid recovery.[10,12]
