The currently available natriuretic peptides have short half-lives and have to be given parenterally. Other approaches to manipulating their effects have been investigated, including the use of atriopeptidase inhibitors (neutral endopeptidase inhibitors; neutral metalloendopeptidase inhibitors), such as candoxatrilat and ecadotril (sinorphan) to prolong the half-life of endogenous atrial natriuretic peptide. Compounds such as omapatrilat (p.1361) that inhibit both neutral endopeptidase and angiotensin-converting enzyme are also being studied.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics

Nebivolol is rapidly absorbed after oral doses. It is extensively metabolised in the liver by alicyclic and aromatic hydroxylation, *N*-dealkylation, and glucuronidation; the hydroxy metabolites are reported to be active. The rate of aromatic hydroxylation by cytochrome P450 isoenzyme CYP2D6 is subject to genetic polymorphism, and bioavailability and half-life vary widely. In fast metabolisers the elimination half-life of nebivolol is about 10 hours and that of the hydroxy metabolites is about 24 hours. Peak plasma concentrations of unchanged drug plus active metabolites are 1.3 to 1.4 times higher in slow metabolisers and the half-lives of nebivolol and its hydroxy metabolites are prolonged.

Nebivolol is about 98% bound to plasma proteins. It has high lipid solubility. It is excreted in the urine and faeces, almost entirely as metabolites. Nebivolol is distributed into breast milk in *animals*.

Uses and Administration

Nebivolol is a cardioselective beta blocker (p.1225). It has vasodilating activity, which appears to be due to a direct action on the endothelium, possibly involving nitric oxide release. It is reported to lack intrinsic sympathomimetic and membrane-stabilising activity.

Nebivolol is used in the management of hypertension (p.1171), and as an adjunct to standard therapy in patients aged 70 years and older with stable chronic heart failure (p.1165). It is given orally as the hydrochloride although doses are expressed in terms of the base; 5.45 mg of nebivolol hydrochloride is equivalent to about 5 mg of base.

In **hypertension** the usual initial dose of nebivolol is 5 mg once daily. US licensed product information allows the dose to be increased, if necessary, at intervals of 2 weeks, to a maximum dose of 40 mg once daily. Dosage reduction may be necessary in the elderly and in patients with hepatic or renal impairment (see below).

In **heart failure** the initial dose of nebivolol is 1.25 mg once daily. If tolerated, the dose should be doubled every 1 to 2 weeks up to a maximum of 10 mg once daily.

◊ Reviews.

1. Moen MD, Wagstaff AJ. Nebivolol: a review of its use in the management of hypertension and chronic heart failure. *Drugs* 2006; **66:** 1389–1409.

4. Prisant LM. Nebivolol: pharmacologic profile of an ultraselective, vasodilatory β -blocker. *J Clin Pharmacol* 2008; **48:** 225–39.

Administration in the elderly. UK licensed product information states that, for hypertension, patients over 65 years of age should be given an initial dose of 2.5 mg of nebivolol once daily, increased to 5 mg once daily if required.

Administration in hepatic impairment. UK licensed product information contra-indicates the use of nebivolol in patients with hepatic impairment. In the USA, licensed product information also contra-indicates nebivolol in severe hepatic impairment (Child-Pugh higher than class B) but patients with moderate hepatic impairment may be given nebivolol for hypertension in an initial oral dose of 2.5 mg once daily, increased with caution if required.

Administration in renal impairment. UK licensed product information states that in hypertension the initial dose of nebivolol should be reduced to 2.5 mg once daily in patients with renal impairment, increased to 5 mg once daily for maintenance if required. US licensed product information similarly recommends an initial dose of 2.5 mg once daily in patients with severe renal impairment (creatinine clearance below 30 mL/minute); the dose may be increased cautiously if required.

Nesiritide Citrate *(USAN, rINNM)* ⊗

Citrato de nesiritida; Nésiritide, Citrate de; Nesiritidi Citras.

Незиритида Цитрат

$C_{143}H_{244}N_{50}O_{42}S_4,xC_6H_8O_7$.

CAS — 124584-08-3 (nesiritide); 189032-40-4 (nesiritide citrate).

ATC — C01DX19.

ATC Vet — QC01DX19.

Incompatibility. The manufacturer states that nesiritide injection is physically and/or chemically incompatible with heparin, insulin, sodium etacrynate, bumetanide, enalaprilat, hydralazine, furosemide, and the preservative sodium metabisulfite. Nesiritide binds to heparin and should not be given through heparin-coated central catheters.

Adverse Effects and Precautions

The most common adverse effects of nesiritide relate to vasodilatation and include hypotension, headache, and dizziness. Nausea and vomiting, abdominal pain, back pain, angina pectoris, insomnia, and anxiety, have also been reported. Cardiac arrhythmias have occurred but may be associated with the underlying condition. Adverse effects on renal function have been reported. If hypotension occurs the infusion of nesiritide should be stopped or the dose reduced and general supportive measures should be used; the hypotension may persist for several hours.

Nesiritide should not be used as primary therapy in patients with cardiogenic shock or with hypotension. It is not recommended in patients with low cardiac filling pressures or in those for whom vasodilators are inappropriate, such as those with significant valvular stenosis, restrictive or obstructive cardiomyopathy, constrictive pericarditis, or pericardial tamponade.

Effects on the kidneys. Nesiritide has both haemodynamic and neurohormonal effects on the kidneys and has been reported to worsen renal function. A meta-analysis[1] found that nesiritide significantly increased the risk of worsening renal function in patients with acute heart failure, and there is some evidence[2] that this may be related to the duration of treatment. However, a randomised trial[3] in patients with acute heart failure and pre-existing renal impairment found that the effect of nesiritide on renal function was neutral.

1. Sackner-Bernstein JD, *et al.* Risk of worsening renal function with nesiritide in patients with acutely decompensated heart failure. *Circulation* 2005; **111:** 1487–91. Correction. *ibid.*; 2274.
2. Chow SL, *et al.* Effect of nesiritide infusion duration on renal function in acutely decompensated heart failure patients. *Ann Pharmacother* 2007; **41:** 556–61.

Effects on mortality. Although nesiritide improves haemodynamics in patients with acute decompensated heart failure, its effects on mortality are controversial.[1] A retrospective study[2] comparing nesiritide with inotrope therapy or glyceryl trinitrate in patients with acute decompensated heart failure found a similar risk of in-hospital mortality with nesiritide and glyceryl trinitrate, which was significantly lower than the risk with inotrope therapy. However, a meta-analysis[3] of controlled studies comparing nesiritide with non-inotrope control therapy found that there was a trend to higher mortality at 30 days in patients given nesiritide; the results were not statistically significant, but became so after correction of the number of deaths in one of the studies.[4] A later meta-analysis[5] also found a trend towards increased mortality with nesiritide at 30 days, but the results again were not statistically significant, and there was no difference in mortality between nesiritide and control patients at 180 days.

5. Arora RR, *et al.* Short and long-term mortality with nesiritide. *Am Heart J* 2006; **152:** 1084–90.

Interactions

The risk of hypotension may be increased in patients receiving nesiritide with other drugs that lower blood pressure.

Pharmacokinetics

Nesiritide is cleared from the circulation by 3 mechanisms: uptake into cells; proteolytic cleavage by endopeptidases; and excretion by the kidneys. It has a biphasic elimination, with a terminal elimination half-life of 18 minutes.

Uses and Administration

Nesiritide is a recombinant brain natriuretic peptide (see p.1347) used in the management of acutely decompensated heart failure (p.1165). It is given intravenously as the citrate, but dosage is expressed in terms of the base. The initial dose of nesiritide is 2 micrograms/kg by intravenous injection over 1 minute, followed by a maintenance infusion of 10 nanograms/kg per minute.

Heart failure. The use of nesiritide in acute decompensated heart failure (p.1165) has been reviewed.[1,2] It may be used for short-term treatment as an alternative to standard intravenous therapy with vasodilators, inotropes, or diuretics, and appears to have no proarrhythmic effects; however, its effects on mortality are controversial (see under Adverse Effects and Precautions, above) and its role in therapy remains unclear. There is some evidence from retrospective studies that it may be safely used in addition to standard therapy[3,4] and may have a role as a more prolonged treatment in patients awaiting cardiac transplantation.[5] Although nesiritide has also been given intermittently for outpatient management of chronic heart failure, this use is not currently recommended.[6]

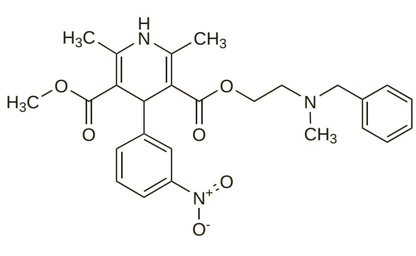
ATC — C08CA04.

ATC Vet — QC08CA04.



(nicardipine)

Pharmacopoeias. In *Chin.* and *Jpn.*

Incompatibility. The manufacturers recommend that a solution containing nicardipine hydrochloride 100 micrograms/mL is used for intravenous infusion. Suitable diluents are solutions of glucose or sodium chloride. Sodium bicarbonate and lactated Ringer's are incompatible with nicardipine infusion. Nicardipine hydrochloride (1 mg/mL in glucose 5%) has also been reported[1] to be visually incompatible with furosemide, heparin, and thiopental.

1. Chiu MF, Schwartz ML. Visual compatibility of injectable drugs used in the intensive care unit. *Am J Health-Syst Pharm* 1997; **54:** 64–5.

Adverse Effects, Treatment, and Precautions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1350).

Interactions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1352).

Pharmacokinetics

Nicardipine is rapidly and completely absorbed from the gastrointestinal tract but is subject to saturable first-pass hepatic metabolism. Bioavailability of about 35% has been reported after a 30-mg dose at steady state. The pharmacokinetics of nicardipine are non-linear due to the saturable first-pass hepatic metabolism and an increase in dose may produce a disproportionate increase in plasma concentration. There is also considerable interindividual variation in plasma-nicardipine concentrations. Nicardipine is more than 95% bound to plasma proteins. Nicardipine is extensively metabolised in the liver and is excreted in the urine and faeces, mainly as inactive metabolites. The terminal plasma half-life is about 8.6 hours, thus steady-state plasma concentrations are achieved after 2 to 3 days of dosing three times daily.

4. Porchet HC, Dayer P. Serum concentrations and effects of (±)-nicardipine compared with nifedipine in a population of healthy subjects. *Clin Pharmacol Ther* 1990; **48:** 155–60.

Uses and Administration

Nicardipine is a dihydropyridine calcium-channel blocker with actions and uses similar to nifedipine (p.1354). It is used in the management of hypertension (p.1171) and angina pectoris (p.1157).

Nicardipine hydrochloride is generally given orally although the intravenous route has been used for the short-term treatment of hypertension.

Oral doses of nicardipine hydrochloride are similar for both **hypertension** and **angina**. The initial dose is 20 mg three times daily and may be increased at intervals of at least 3 days until the required effect is achieved. The usual maintenance dose is 30 mg three times daily, but daily doses of between 60 and 120 mg in divided doses may be given. Modified-release preparations of nicardipine hydrochloride for dosage twice daily are also available.

Nicardipine hydrochloride may be given by slow intravenous infusion as a 100 micrograms/mL solution in the short-term treatment of hypertension. An initial infusion rate of 5 mg/hour is recommended, increased, as necessary, up to a maximum of 15 mg/hour and subsequently reduced to 3 mg/hour. For use in children, see below.

Reduced doses of nicardipine hydrochloride and longer dosing intervals may be necessary in patients with hepatic or renal impairment (see below).

◊ Reviews.

1. Curran MP, *et al.* Intravenous nicardipine: its use in the short-term treatment of hypertension and various other indications. *Drugs* 2006; **66:** 1755–82.

Administration in children. Intravenous infusion of nicardipine has been used in both infants and children for the management of hypertension. In studies[1-4] in children aged between 2 days and 17 years, initial doses ranged from 0.2 to 5 micrograms/kg per minute, with maintenance infusions of 0.15 to 6 micrograms/kg per minute. Adverse effects were rare; one study[4] reported adverse effects in 5 of 31 treatment courses, including tachycardia, flushing, palpitations, and hypotension. There has also been a report[5] of the successful use of intravenous infusion of nicardipine in 8 preterm infants (gestational age 28 to 36 weeks). Infusions were given at a dose of 0.5 to 2 micrograms/kg per minute and continued for periods of 3 to 36 days. No hypotension, oedema, or tachycardia were observed.

The *BNFC* suggests that neonates and children up to age 18 years may be given nicardipine hydrochloride by continuous intravenous infusion for the management of hypertensive crises. The initial dose is 500 nanograms/kg per minute, adjusted according to response; the usual maintenance dose is 1 to 4 micrograms/kg per minute, with a maximum dose of 250 micrograms/minute.

5. Gouyon JB, *et al.* Intravenous nicardipine in hypertensive preterm infants. *Arch Dis Child* 1997; **76:** F126–F127.

Administration in hepatic or renal impairment. Reduced doses of nicardipine hydrochloride and longer dosing intervals may be necessary in patients with hepatic or renal impairment. The US manufacturers recommend an initial dose of 20 mg twice daily by mouth in patients with hepatic impairment.

Cerebrovascular disorders. Nicardipine has been reported to increase cerebral blood flow[1] and use by various routes has been investigated for possible benefit in haemorrhagic[2-5] and ischaemic stroke[6,7] (p.1185), although nimodipine (p.1357) is the dihydropyridine calcium-channel blocker usually used. Nicardipine has also been tried[8] in patients with cerebrovascular insufficiency. However, studies have produced inconclusive results.

Niceritrol *(BAN, rINN)*

Nicéritrol; Niceritrolum; Nikeritroli; PETN. Pentaerythritol tetranicotinate; 2,2-Bis(hydroxymethyl)propane-1,3-diol tetranicotinate.

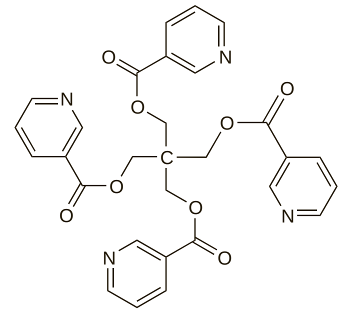
Ницеритрол

$C_{29}H_{24}N_4O_8 = 556.5.$

CAS — 5868-05-3.

ATC — C10AD01.

ATC Vet — QC10AD01.



NOTE. The synonym PETN has been applied to both niceritrol and pentaerithrityl tetranitrate.

Pharmacopoeias. In *Jpn.*

Profile

Niceritrol, an ester of pentaerythritol and nicotinic acid, has general properties similar to those of nicotinic acid (p.1957), to which it is slowly hydrolysed. Niceritrol has been used as a lipid regulating drug in hyperlipidaemias and as a vasodilator in the treatment of peripheral vascular disease.

Nicorandil *(BAN, USAN, rINN)*

Nicorandilum; SG-75. *N*-[2-(Nitroxy)ethyl]-3-pyridinecarboxamide.

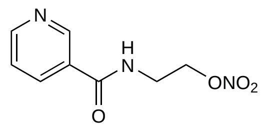
Никорандил

$C_8H_9N_3O_4$ = 211.2.

CAS — 65141-46-0.

ATC — C01DX16.

ATC Vet — QC01DX16.



Pharmacopoeias. In *Jpn.*

Adverse Effects and Precautions

Adverse effects reported with nicorandil are headache (which is usually transitory and seen at the start of therapy), cutaneous vasodilatation and flushing, nausea, vomiting, dizziness, and weakness. Rarely reported effects include myalgia, skin rashes, and oral ulceration, and there have been very rare reports of angioedema and hepatic function abnormalities. A reduction in blood pressure and/or an increase in heart rate may occur with high doses.

Nicorandil is contra-indicated in patients with cardiogenic shock, left ventricular failure with low filling pressures, and hypotension. In patients with hypovolaemia, low systolic blood pressure, acute pulmonary oedema, or acute myocardial infarction with acute left ventricular failure and low filling pressures, nicorandil should preferably be avoided but may be used with caution.

Incidence of adverse effects. Postmarketing surveillance for nicorandil was carried out by prescription-event monitoring[1] of 13 620 patients, and showed that adverse reactions occurred in 175. The most frequent was headache, occurring in 58 patients, mainly in the first month of treatment. Unspecified adverse effects occurred in 36 patients. Other effects included dizziness (19), nausea (17), malaise (13), palpitations (8), flushing and vomiting (6 each), and lassitude (4). Rare adverse effects included 3 cases each of angioedema and photosensitivity.

1. Dunn N, *et al.* Safety profile of nicorandil—prescription-event monitoring (PEM) study. *Pharmacoepidemiol Drug Safety* 1999; **8:** 197–205.

Ulceration. Nicorandil has been associated with ulceration of mucosal surfaces. Painful, large aphthous ulcers on the *tongue* and *oral mucosa* have been reported[1-3] in patients receiving nicorandil for angina. The ulcers were usually resistant to treatment but all healed when nicorandil was withdrawn. Colchicine or thalidomide treatment has improved ulcers associated with nicorandil in a few patients, but relapse occurred when the colchicine or thalidomide was stopped.[3] However, a large study[4] casts some doubt on the evidence for a causal link between nicorandil and oral ulceration, although it was suggested that this could be further investigated.

Anal ulceration has been reported[5-7] in patients taking nicorandil. Healing of the ulcers occurred in those patients in whom nicorandil was withdrawn.

Multiple ulcers of the upper and lower *gastrointestinal tract*, in addition to oral and anal ulceration, have been reported[8] in a patient taking nicorandil; all of the ulcers healed when nicorandil was stopped. There have also been several cases of *peristomal* ulceration, which resolved after stopping nicorandil.[9]

Perivulval ulceration has also been reported, and in 1 case was associated with a *cutaneous* ulcer.[10] Another patient[11] developed both perianal and leg ulcers, both of which improved rapidly when nicorandil was stopped.

Interactions

Nicorandil should not be used with phosphodiesterase type-5 inhibitors such as sildenafil as the hypotensive effect of nicorandil may be significantly enhanced.

Pharmacokinetics

Nicorandil is well absorbed from the gastrointestinal tract and maximum plasma concentrations are achieved 30 to 60 minutes after oral doses. Metabolism is mainly by denitration and about 20% of a dose is excreted in the urine mainly as metabolites. The elimination half-life is about 1 hour. Nicorandil is only slightly bound to plasma proteins.

Uses and Administration

Nicorandil is a nitrate derivative of nicotinamide (p.1957) and acts as a vasodilator. It is a potassium-channel opener (p.1155) providing vasodilatation of arterioles and large coronary arteries and its nitrate component produces venous vasodilatation through stimulation of guanylate cyclase. It thus reduces both preload and afterload, and improves coronary blood flow.

Nicorandil is given orally for prevention and long-term treatment of **angina pectoris**, including reduction of the risk of acute coronary events in high-risk patients (p.1157). The usual initial oral dose is 10 mg twice daily (or 5 mg twice daily in patients susceptible to headache), increased as necessary to a maximum of 30 mg twice daily; the usual therapeutic dose is in the range of 10 to 20 mg twice daily.

Nicorandil is also given intravenously in the management of **unstable angina** and **acute heart failure** (p.1165). For unstable angina, a solution containing 100 to 300 micrograms/mL is given by intravenous infusion in a dose of 2 mg/hour, adjusted according to response, to a maximum dose of 6 mg/hour. For acute heart failure, a solution containing 400 to 2500 micrograms/mL is used; the usual dose is 200 micrograms/kg given by intravenous injection over 5 minutes, followed by continuous intravenous infusion at a dose of 200 micrograms/kg per hour. The dosage should be adjusted according to response, within the range of 50 to 200 micrograms/kg per hour.

Ischaemic heart disease. A large multicentre double-blind randomised placebo-controlled study[1] suggested that nicorandil, in addition to its anti-anginal effects, may have cardioprotective properties. The incidence of major coronary events, particularly unplanned admission for chest pain, was significantly reduced in patients with stable angina at high risk of future adverse events. Nicorandil may mimic the mechanism of ischaemic pre-conditioning, whereby a brief period of ischaemia makes the myocardium resistant to damage from a further episode,[2] but it is not clear how much this mechanism contributes to its effects. There is some evidence[3-7] that nicorandil improves outcomes when given at the time of percutaneous coronary intervention, although a large study[8] in patients with myocardial infarction failed to confirm a benefit. It has been suggested[5] that an antioxidant effect may be part of the mechanism involved.

Nicotinyl Alcohol *(BAN, USAN)*

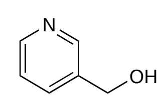
3-Hydroxymethylpyridine; Nicotinic Alcohol; Nicotinílico, alcohol; NSC-526046; NU-2121; 3-Pyridinemethanol; β-Pyridylcarbinol; Ro-1-5155. 3-Pyridylmethanol.

C_6H_7NO = 109.1.

CAS — 100-55-0.

ATC — C04AC02; C10AD05.

ATC Vet — QC04AC02; QC10AD05.



Nicotinyl Alcohol Tartrate *(BANM)*

Alcohol nicotinílico, tartrato de; Nicotinyl Tartrate. 3-Pyridylmethanol hydrogen (2*R*,3*R*)-tartrate.

$C_6H_7NO,C_4H_6O_6$ = 259.2.

CAS — 6164-87-0.

ATC — C04AC02; C10AD05.

ATC Vet — QC04AC02; QC10AD05.

Pharmacopoeias. In *Br.*

BP 2008 (Nicotinyl Alcohol Tartrate). A white or almost white, odourless or almost odourless, crystalline powder. Freely soluble in water; slightly soluble in alcohol; practically insoluble in chloroform and in ether. A 5% solution in water has a pH of 2.8 to 3.7.

Profile

Nicotinyl alcohol is a vasodilator and lipid regulating drug with general properties similar to those of nicotinic acid (p.1957), to which it is partly hydrolysed.

Nicotinyl alcohol has been given orally, as the tartrate, in the management of peripheral vascular disease, and has also been used in Ménière's disease and in hyperlipidaemias.

Preparations

BP 2008: Nicotinyl Alcohol Tablets.

Proprietary Preparations (details are given in Part 3)
Indon.: Cetacol; ***Pol.:*** Nicotol†.

Multi-ingredient: ***Braz.:*** Lipofacton.

Nifedipine *(BAN, USAN, rINN)*

Bay-a-1040; Nifedipiini; Nifedipin; Nifedipina; Nifedipinas; Nifédipine; Nifedipino; Nifedipinum. Dimethyl 1,4-dihydro-2,6-dimethyl-4-(2-nitrophenyl)pyridine-3,5-dicarboxylate.

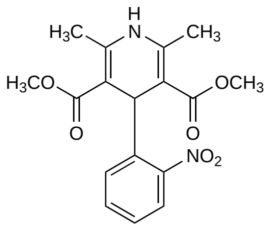
Нифедипин

$C_{17}H_{18}N_2O_6$ = 346.3.

CAS — 21829-25-4.

ATC — C08CA05.

ATC Vet — QC08CA05.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Nifedipine). A yellow crystalline powder. Practically insoluble in water; sparingly soluble in dehydrated alcohol; freely soluble in acetone. When exposed to daylight or to certain wavelengths of artificial light it is converted to a nitrosophenylpyridine derivative, while exposure to ultraviolet light leads to formation of a nitrophenylpyridine derivative. Solutions should be prepared in the dark or under light of wavelength greater than 420 nm, immediately before use. Protect from light.

USP 31 (Nifedipine). A yellow powder. Practically insoluble in water; soluble 1 in 10 of acetone. When exposed to daylight or to certain wavelengths of artificial light it is converted to a nitrosophenylpyridine derivative, while exposure to ultraviolet light leads to formation of a nitrophenylpyridine derivative. Store in airtight containers. Protect from light.

Stability. Yellow food colourings such as curcumin have been used[1] to slow photodegradation of nifedipine solutions. An extemporaneously prepared solution of nifedipine in a peppermint-flavoured vehicle was reported[2] to be stable for at least 35 days when stored in amber glass bottles.

Adverse Effects

The most common adverse effects of nifedipine are associated with its vasodilator action and often diminish on continued therapy. They include dizziness, flushing, headache, hypotension, peripheral oedema, tachycardia, and palpitations. Nausea and other gastrointestinal disturbances, increased micturition frequency, lethargy, eye pain, visual disturbances, and mental depression have also occurred. A paradoxical increase in ischaemic chest pain may occur at the start of treatment and in a few patients excessive fall in blood pressure has led to cerebral or myocardial ischaemia or transient blindness.

There have been reports of rashes (including erythema multiforme), fever, and abnormalities in liver function, including cholestasis, due to hypersensitivity reactions. Gingival hyperplasia, myalgia, tremor, and impotence have been reported.

Some tablets formulated for once-daily use are covered in a membrane which is not digested and may cause gastrointestinal obstruction; bezoars may rarely occur.

Overdosage may be associated with bradycardia and hypotension; hyperglycaemia, metabolic acidosis, and coma may also occur.

Nifedipine has been reported to be teratogenic in *animals*.

Effects on mortality. Since 1995 there have been reports and reviews that have implicated calcium-channel blockers (particularly short-acting nifedipine and high doses) in increasing cardiovascular[1] and overall mortality.[2] Possible links with cancer, haemorrhage, and depression and suicide are discussed separately (see Cancer Occurrence, Effects on the Blood, and Effects on Mental Function, below, respectively).

In response, the US National Heart, Lung, and Blood Institute issued a statement warning that short-acting nifedipine should be used with great caution (if at all), especially at higher doses, in the treatment of hypertension, angina, and myocardial infarction,[3] and in some countries short-acting nifedipine preparations have been withdrawn. However, there has been much debate and controversy over the reports that questioned the safety of calcium-channel blockers.[4-6]

A review by the WHO/ISH pointed out that much of the evidence for adverse effects comes from observational studies or small randomised studies and concluded that, as there was insufficient evidence to confirm either benefit or harm, recommendations on the management of angina, hypertension, and myocardial infarction should remain unchanged.[7] In addition, many of the studies that led to the negative reports used the older short-acting calcium-channel blockers. The calcium-channel blockers used now are largely modified-release formulations of short half-life blockers or are calcium-channel blockers with long half-lives.

Studies completed after the WHO/ISH review have generally failed to show any increase in mortality with calcium-channel blockers, although their effects on cardiovascular outcomes remain less clear. A placebo-controlled study (SYST-EUR) reported[8] a reduction in incidence of stroke and cardiovascular events in 4695 elderly patients treated with nitrendipine (and enalapril and hydrochlorothiazide in addition if necessary) for isolated systolic hypertension, while a retrospective cohort study[9] in post-myocardial infarction patients failed to show any increase in mortality after one year in those receiving calcium-channel blockers. Another cohort study[10] in patients with hypertension also found no overall increase in mortality with calcium-channel blockers, although there was a trend towards a higher rate with short-acting formulations. A meta-analysis[11] of randomised studies comparing calcium-channel blockers with other antihypertensives in patients with hypertension suggested that calcium-channel blockers were associated with an increased risk of major cardiovascular events (except stroke) although all-cause mortality was not increased. However, large, long-term studies have found no difference in cardiovascular outcomes or overall mortality in patients randomised to amlodipine or chlortalidone,[12] while a lower incidence of cardiovascular events was reported for amlodipine compared with atenolol.[13] A long-term study[14] of nifedipine added to standard therapy in patients with stable angina also found no increased mortality, and there was a reduced need for coronary interventions.

Carcinogenicity. An observational study carried out between 1988 and 1992 suggested that calcium-channel blockers were associated with an increased risk of cancer.[1] Subsequent studies have failed to support this finding.[2-7] A review by the WHO/ISH concluded that there is no good evidence that calcium-channel blockers increase cancer risk,[8] and the biological basis for an effect of calcium-channel blockers on cancer risk has also been questioned.[9] The large, long-term, randomised Antihypertensive and Lipid-Lowering treatment to prevent Heart Attack Trial (ALLHAT)[10] found no increase in the incidence of cancer in patients receiving a calcium-channel blocker (amlodipine) compared with those receiving a diuretic (chlortalidone).

Effects on the blood. Treatment with nifedipine significantly reduces platelet aggregation *in vitro*[1] and results indicating inhibition of platelet function in healthy subjects receiving oral (but not intravenous) nifedipine have been reported.[2,3] Thus, concern has been expressed[4] that calcium-channel blockers may have the potential to produce haemorrhagic complications in surgical patients (specifically, those undergoing coronary bypass surgery). Major surgical bleeding was associated with nimodipine in patients undergoing cardiac valve replacement,[5] although it has been used in other situations apparently without an increased risk of bleeding.[6]

Conflicting results have been reported with regard to the risk of gastrointestinal bleeding. A prospective cohort study in 1636 elderly hypertensive patients,[7] and a subsequent case-control study,[8] reported that calcium-channel blockers were associated with an increased risk of gastrointestinal haemorrhage compared with beta blockers. However, it was suggested[9] that this may have been due to a protective effect of beta blockers rather than an adverse effect of calcium-channel blockers, and another study[10] also suggested that the risk of gastrointestinal bleeding was not materially increased by calcium-channel blockers.

Calcium-channel blockers have also been associated with a number of blood dyscrasias; there have been case reports of aplastic anaemia with nifedipine,[11] and of thrombocytopenia with amlodipine[12] and with diltiazem.[13,14]

Effects on carbohydrate metabolism. There are reports of deterioration of diabetes,[1] reduction in glucose tolerance,[2] and development of diabetes[1,3] in patients given nifedipine. Nifedipine has also been reported to increase plasma-glucose concentrations.[3,4] However, other reports and studies have found no change in glucose tolerance in either diabetic or non-diabetic patients taking nifedipine.[5-10]

Effects on the ears. There have been isolated reports[1] of tinnitus associated with several calcium-channel blockers including nifedipine, nicardipine, nitrendipine, diltiazem, verapamil, and cinnarizine.

1. Narváez M, *et al.* Tinnitus with calcium-channel blockers. *Lancet* 1994; **343:** 1229–30.

Effects on the eyes. Individual reports have implicated nifedipine in the development of transient retinal ischaemia and blindness,[1] and of periorbital oedema.[2] In a postmarketing survey painful or stinging eyes were more common in patients receiving nifedipine (178 of 757 evaluable) than in those given captopril (45 of 289), although the cause was uncertain.[3] Nifedipine has also been suggested as a risk factor in the development of cataract,[4,5] but the numbers involved in this analysis are small[6] and it is possible that the risk, if it exists,[7] relates to hypertension rather than nifedipine treatment.[6]

Effects on the heart. The use of nifedipine has been associated with the development of various heart disorders in some patients. Complete heart block has been reported in an elderly patient who had previously developed heart block with verapamil,[1] and sudden circulatory collapse has been reported in 4 patients receiving nifedipine who underwent routine coronary bypass surgery.[2] One patient died despite all attempts at resuscitation.[2] However, probably the majority of reports have concerned the development or aggravation of cardiac ischaemia, up to and including frank myocardial infarction after use of short-acting nifedipine.[3-6] Such cases appear to be chiefly associated with a too-rapid fall in blood pressure after the use of sublingual nifedipine for hypertensive urgencies or emergencies,[5,6] or occur in patients with a history of ischaemic heart disease.[3,4]

For discussion of the effects of calcium-channel blockers on cardiovascular mortality, see above.

WITHDRAWAL. Exacerbation of coronary ischaemia and thrombosis of arteriovenous graft could have resulted from withdrawal of nifedipine in a patient.[1] Abrupt withdrawal of nisoldipine from 15 patients with stable angina pectoris after 6 weeks of therapy resulted in severe unstable angina in 2 patients and acute myocardial infarction in another.[2] It was postulated that the withdrawal effect could be due to an increase in sensitivity of vascular α_2 adrenoceptors to circulating adrenaline.

2. Mehta J, Lopez LM. Calcium-blocker withdrawal phenomenon: increase in affinity of alpha adrenoceptors for agonist as a potential mechanism. *Am J Cardiol* 1986; **58:** 242–6.

Effects on the kidneys. Calcium-channel blockers may be of benefit in various forms of kidney disorder (see under Uses and Administration, below). However, reversible deterioration in renal function without any appreciable accompanying decline in systemic arterial blood pressure has been reported[1] in 4 patients with underlying renal insufficiency receiving nifedipine,[1] and in another report[2] nifedipine increased urinary protein excretion and exacerbated renal impairment in 14 type 2 diabetic patients.

Excessive diuresis occurred in a patient given nifedipine for angina pectoris,[3] and nocturia in 9 patients referred for prostatic surgery was also attributed to nifedipine.[4]

Effects on the menstrual cycle. Menorrhagia in 2 women[1] and menstrual irregularity with heavy bleeding in another[2] have been reported in association with nifedipine treatment.

1. Rodger JC, Torrance TC. Can nifedipine provoke menorrhagia? *Lancet* 1983; **ii:** 460.
2. Singh G, *et al.* Can nifedipine provoke menorrhagia? *Lancet* 1983; **ii:** 1022.

Effects on mental function. Insomnia, hyperexcitability, pacing, agitation, and depression were reported[1] in a patient in association with nifedipine therapy. The symptoms disappeared within 2 days of withdrawal of nifedipine. Four further cases of major depression, which developed within a week of starting nifedipine and resolved within a week of stopping the drug, have been reported.[2]

Although 2 epidemiological studies suggested that calcium-channel blockers may promote suicide,[3] a subsequent study[4] found no evidence of an association between depression and the use of calcium-channel blockers, and the number of suicides was low. Further studies[5,6] have also failed to find an increased risk of suicide with calcium-channel blockers compared with other antihypertensive drugs.

Effects on the mouth. *GINGIVAL HYPERPLASIA.* A number of reports have implicated nifedipine in the development of gingival hyperplasia.[1-4] In most cases it has occurred about 1 to 6 months after starting therapy and has resolved after stopping nifedipine. A patient who had taken nifedipine for 12 years developed gingival hyperplasia shortly after the dosage of nifedipine was increased.[5] Amlodipine has also induced gingival overgrowth.[6] A study involving 115 patients given nifedipine, diltiazem, or verapamil for at least 3 months indicated that gingival hyperplasia is an important adverse effect that may occur with calcium-channel blockers in general.[7] Dihydropyridine calcium-channel blockers were among the most common drugs associated with reports of gingival hyperplasia in the Australian Adverse Drug Reactions Advisory Committee database.[8]

PAROTITIS. Acute swelling of the parotid glands occurred in a patient after sublingual administration of nifedipine.[1]

1. Bosch X, *et al.* Nifedipine-induced parotitis. *Lancet* 1986; **ii:** 467.

Effects on the neuromuscular system. Severe muscle cramps have been reported in a few patients taking nifedipine;[1,2] in one patient[2] the cramps were associated with widespread paraesthesia. Reversible myoclonic dystonia associated with nifedipine has been reported in a patient.[3] Severe rhabdomyolysis developed in a patient with a transplanted kidney who was receiving an intravenous infusion of nifedipine.[4] The patient recovered rapidly once the infusion was stopped. There has also been a report[5] of myopathy, myalgia, and arthralgia associated with amlodipine, and of arthralgia in a patient[6] receiving diltiazem.

Parkinsonism is a recognised adverse effect of flunarizine and cinnarizine, which have calcium-channel blocking properties (see Extrapyramidal Disorders under Flunarizine, p.580). It has also been reported with diltiazem (see p.1266) and with amlodipine.[7,8]

Effects on the oesophagus. Calcium-channel blockers decrease lower oesophageal sphincter pressure and have been used in oesophageal motility disorders (see below), but a retrospective cohort study[1] found that calcium-channel blockers may also precipitate or exacerbate gastro-oesophageal reflux disease.

1. Hughes J, *et al.* Do calcium antagonists contribute to gastro-oesophageal reflux disease and concomitant noncardiac chest pain? *Br J Clin Pharmacol* 2007; **64:** 83–9.

Effects on the peripheral circulation. An erythromelalgia-like eruption occurred in a patient 8 weeks after starting therapy with nifedipine. Symptoms included severe burning pain and swelling in the feet and lower legs, which were fiery red, tender, and warm to the touch. Symptoms resolved in 2 days when nifedipine was stopped.[1] Similar effects have been reported in other patients on nifedipine.[2-4] Erythromelalgia has also been reported with nicardipine.[5] This type of erythromelalgia may be termed secondary erythermalgia.[6]

Effects on the respiratory system. There have been some reports of pulmonary oedema being precipitated by nifedipine therapy in patients with aortic stenosis.[1,2] Nifedipine has also been reported to exacerbate impaired tissue oxygenation in patients with cor pulmonale secondary to obstructive airways disease.[3]

For a report of exacerbation of laryngeal oedema, see under Hypersensitivity, below.

3. Kalra L, Bone MF. Nifedipine and impaired oxygenation in patients with chronic bronchitis and cor pulmonale. *Lancet* 1989; **i:** 1135–6.

Effects on the skin and nails. The commonest skin reactions to nifedipine have been rash, pruritus, urticaria, alopecia, and exfoliative dermatitis;[1] there have been a few reports of erythema multiforme and the Stevens-Johnson syndrome.[1] Erythema multiforme occurred in a patient after substitution of amlodipine for nifedipine[2] and cross-sensitivity, manifest as a pruritic maculopapular rash, has been reported between amlodipine and diltiazem.[3] Generalised pruritus has been reported with amlodipine.[4] Other skin reactions that have been reported with nifedipine include severe photosensitivity reactions,[5] nonthrombocytopenic purpuric rashes,[6] and telangiectasias,[7] including photodistributed telangiectasias,[8] and pemphigoid nodularis.[9] Photodistributed telangiectasias have also been reported with amlodipine,[10,11] and in one case[10] recurred 3 years later. Amlodipine has also been associated[12] with a case of lichen planus.

For reference to erythromelalgia, see under Effects on the Peripheral Circulation, above.

Nail and periungual pigmentation developed[13] in a 75-year-old man 18 months after starting amlodipine; it was much improved 2 years after the drug was stopped.

Effects on taste. Distortion of taste and smell has been reported in 2 patients taking nifedipine,[1] but a large survey involving 922 patients receiving nifedipine and 343 taking captopril did not show any association of taste disturbances with nifedipine.[2] Sudden loss of taste has also been reported[3] in a patient who had been taking amlodipine for several years; the sense of taste returned when amlodipine was stopped, but taste loss recurred on rechallenge.

Gynaecomastia. Unilateral gynaecomastia developed in 3 men 4, 6, and 26 weeks after starting nifedipine therapy.[1]

1. Clyne CAC. Unilateral gynaecomastia and nifedipine. *BMJ* 1986; **292:** 380.

Haemorrhage. See Effects on the Blood, above.

Hypersensitivity. Nifedipine is associated with various hypersensitivity reactions including skin rashes and effects on the liver(see above).

Nifedipine, given sublingually, exacerbated laryngeal swelling that developed in a woman after the use of isosorbide dinitrate spray.[1]

1. Silfvast T, *et al.* Laryngeal oedema after isosorbide dinitrate spray and sublingual nifedipine. *BMJ* 1995; **311:** 232.

Oedema. Oedema of the feet and ankles is a common adverse effect of nifedipine and other dihydropyridine calcium-channel blockers. It occurs typically 2 or more weeks after starting treatment and is caused by pre-capillary arteriolar dilatation rather than fluid retention.[1] Evidence from a study in 10 diabetic subjects beginning nifedipine therapy, 5 of whom developed ankle oedema, suggested that nifedipine abolished the reflex vasoconstriction produced when the feet are below the level of the heart which is believed to prevent excessive fluid filtration into the tissues.[2]

The oedema may respond to simple measures such as elevation of the feet or to a reduction in dosage but if it persists the calcium-channel blocker should be withdrawn.[1]

Generalised oedema[3] and facial and upper extremity oedema[4] have been reported in patients taking amlodipine, but in both cases symptoms resolved on withdrawal of the drug.

Treatment of Adverse Effects

Activated charcoal may be given orally to adults or children who present within 1 hour of ingesting a potentially toxic overdose of nifedipine. Alternatively, gastric lavage may be considered in adults. Supportive and symptomatic care should be given. Hypotension may respond to placing the patient in the supine position with the feet raised; plasma expanders may be given, although cardiac overload should be avoided. If hypotension is not corrected, calcium should be given intravenously. The usual initial dose is 10 to 20 mL of 10% calcium gluconate given by slow intravenous injection or infusion; alternatively, up to 10 mL of 10% calcium chloride may be given. Glucagon may also be used. If hypotension persists, an intravenous sympathomimetic such as isoprenaline, dopamine, or noradrenaline may also be necessary. Bradycardia may be treated with atropine, isoprenaline, or cardiac pacing.

Dialysis is not useful as nifedipine is highly protein bound. Plasmapheresis may be beneficial.

Overdosage. The management of calcium-channel blocker overdosage is mainly supportive (see Treatment of Adverse Effects, above). Cardiovascular effects usually predominate and, although severe toxicity is more likely in overdosage with non-dihydropyridines such as verapamil or diltiazem, treatment of overdosage is similar for all calcium-channel blockers.[1-4] Prompt gastrointestinal decontamination, atropine to reverse bradycardia, and cardiovascular support with intravenous fluids, sympathomimetics, and possibly inotropes, are the mainstays of treatment. Intravenous calcium is also widely used, and high doses may be required; intravenous glucagon may also be given. Fampridine has been suggested[5] as a specific antagonist, and successful use of vasopressin[6] or terlipressin[7] has been reported in patients with resistant hypotension. There is also some evidence that high-dose insulin, with glucose if required to maintain normal blood-glucose concentrations, may be of benefit.[8-11]

Most reports of overdosage have been with verapamil (see p.1421). The following are some individual reports with nifedipine:

- Hypotension, tachycardia, and flushing, followed by hypokalaemia, were seen in a patient who took nifedipine 600 mg as modified-release tablets together with an overdose of paracetamol, but there was no evidence of heart block.[12] The patient was given calcium gluconate intravenously and subsequently activated charcoal and lactulose. Absorption of nifedipine was essentially complete 10 hours after ingestion. Potassium chloride was given orally to treat hypokalaemia and acetylcysteine was used to manage the paracetamol poisoning.
- Third-degree AV block, progressing to asystole, developed in a 14-month-old child who ingested about 800 mg of nifedipine.[13] During cardiopulmonary resuscitation a total of 700 mg of calcium chloride was given, together with atropine, adrenaline, and sodium bicarbonate. The stomach was subsequently emptied by gastric lavage and activated charcoal given. The patient remained tachycardic and hypotensive, with evidence of pulmonary oedema and hyperglycaemia, and was given intravenous electrolytes and dopamine infusions and assisted ventilation, together with treatment to control subsequent tonic-clonic seizures. She eventually made an apparently complete recovery apart from a moderate speech delay.

Precautions

Nifedipine should be used with caution in patients with hypotension, in patients whose cardiac reserve is poor, and in those with heart failure since deterioration of heart failure has been noted. Nifedipine should not be used in cardiogenic shock, in patients who have suffered a myocardial infarction in the previous 2 to 4 weeks, or in acute unstable angina. Nifedipine should not be used to treat an anginal attack in chronic stable angina. In patients with severe aortic stenosis nifedipine may increase the risk of developing heart failure. Sudden withdrawal of nifedipine might be associated with an exacerbation of angina. The dose may need to be reduced in patients with hepatic impairment.

Nifedipine should be stopped in patients who experience ischaemic pain after use.

Nifedipine is reported to be teratogenic in *animals* and may inhibit labour, but it has been used in hypertension in pregnancy (see Hypertension, under Uses and Administration, below).

Breast feeding. Nifedipine is distributed into breast milk[1,2] but the amount present is probably too small to be harmful. There have been no reports of any clinical effects in breast-fed infants whose mothers were receiving nifedipine and the American Academy of Pediatrics therefore considers[3] that it is usually compatible with breast feeding.

1. Ehrenkranz RA, *et al.* Nifedipine transfer into human milk. *J Pediatr* 1989; **114:** 478–80.

Diabetes mellitus. Nifedipine may modify insulin and glucose responses (see Effects on Carbohydrate Metabolism under Adverse Effects, above) calling for adjustments in antidiabetic therapy. Also some studies have suggested that nifedipine may worsen proteinuria and renal dysfunction in diabetic patients with some degree of renal insufficiency,[1,2] but other studies, (see Kidney Disorders under Uses and Administration, below), have suggested that nifedipine may have a beneficial effect on proteinuria.

Some studies have suggested that patients with diabetes mellitus[3,4] or impaired glucose metabolism[5] may be more susceptible to adverse cardiovascular effects of calcium-channel blockers. The calcium-channel blockers used in these studies were nisoldipine, amlodipine, and isradipine (long-acting or intermediate-acting calcium-channel blockers). However, two of the studies[3,4] compared the calcium-channel blocker with an ACE inhibitor and it has been suggested that ACE inhibitors may have a protective effect in patients with diabetes that is additional to their antihypertensive action. Thus, ACE inhibitors may be particularly beneficial in these patients rather than calcium-channel blockers being particularly harmful.[6]

Interference with laboratory estimations. Nifedipine may give falsely elevated spectrophotometric values of urinary vanillylmandelic acid; HPLC estimations are unaffected.

Porphyria. Nifedipine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Withdrawal. Sudden withdrawal of nifedipine might be associated with an exacerbation of angina.

For a report of life-threatening coronary vasospasm occurring after withdrawal of nifedipine before a revascularisation procedure, see under Effects on the Heart, in Diltiazem, p.1265.

Interactions

Nifedipine may enhance the antihypertensive effects of other antihypertensive drugs such as beta blockers although the combination is generally well tolerated. Enhanced antihypertensive effects may also be seen if used with drugs such as aldesleukin and antipsychotics that cause hypotension. Nifedipine may modify insulin and glucose responses (see Effects on Carbohydrate Metabolism, above) and therefore diabetic patients may need to adjust their antidiabetic treatment when receiving nifedipine. Nifedipine is extensively metabolised in the liver by the cytochrome P450 isoenzyme CYP3A4, and interactions may occur with other drugs, such as quinidine, sharing the same metabolic pathway, and with enzyme inducers, such as carbamazepine, phenytoin, and rifampicin, and enzyme inhibitors, such as cimetidine, erythromycin, and HIV-protease inhibitors.

Alcohol. A study involving 10 healthy subjects showed that the area under the concentration-time profile for nifedipine 20 mg was increased by 54% when taken orally with alcohol, and maximum pulse rate was achieved more rapidly, which was in line with *animal* and *in-vitro* studies suggesting that the metabolism of nifedipine is inhibited by alcohol.[1]

1. Qureshi S, *et al.* Nifedipine-alcohol interaction. *JAMA* 1990; **264:** 1660–1.

Antiarrhythmics. Nifedipine and *quinidine* probably have a common metabolic pathway in the liver and might be expected to interact if given concurrently. In one study,[1] quinidine appeared to inhibit nifedipine metabolism resulting in increased serum concentrations of nifedipine; quinidine concentrations were unchanged. However, conflicting effects on serum-quinidine concentrations have been reported, see p.1384.

1. Bowles SK, *et al.* Evaluation of the pharmacokinetic and pharmacodynamic interaction between quinidine and nifedipine. *J Clin Pharmacol* 1993; **33:** 727–31.

Antibacterials. The macrolide antibacterials are inhibitors of the cytochrome P450 isoenzyme CYP3A4 and may inhibit the metabolism of calcium-channel blockers. Two days after *clarithromycin* was started,[1] vasodilatory shock and heart block occurred in a 77-year-old man whose antihypertensive medication included nifedipine. Clarithromycin was continued and when his condition improved nifedipine was reintroduced at half the previous dose; his blood pressure was stable on discharge.

1. Gerónimo-Pardo M, *et al.* Clarithromycin–nifedipine interaction as possible cause of vasodilatory shock. *Ann Pharmacother* 2005; **39:** 538–42.

Antidiabetics. See Diabetes Mellitus under Precautions and Effects on Carbohydrate Metabolism under Adverse Effects, above.

Antiepileptics. The effects of dihydropyridine calcium-channel blockers may be reduced by enzyme-inducing antiepileptics such as *carbamazepine*, *phenobarbital*, and *phenytoin*.[1-4] In contrast, *sodium valproate* has been reported to increase plasma-nimodipine concentrations.[3]

For reports of an interaction between dihydropyridines and *phenytoin* resulting in raised serum-phenytoin concentration, see p.499.

3. Tartara A, *et al.* Differential effects of valproic acid and enzyme-inducing anticonvulsants on nimodipine pharmacokinetics in epileptic patients. *Br J Clin Pharmacol* 1991; **32:** 335–40.
4. Yasui-Furukori N, Tateishi T. Carbamazepine decreases antihypertensive effect of nilvadipine. *J Clin Pharmacol* 2002; **42:** 100–103.

Antifungals. Azole antifungals inhibit the cytochrome P450 enzyme system and may therefore interfere with metabolism of calcium-channel blockers. Two women who had been taking felodipine for about a year developed peripheral oedema a few days after starting treatment with *itraconazole*.[1] Plasma-felodipine concentrations were measured in one of the women before and during a subsequent course of itraconazole and increased considerably when the two drugs were used together. A similar interaction occurred when itraconazole therapy was started in a patient already taking nifedipine.[2] Potentiation of the effects of nifedipine by *fluconazole* has also been reported.[3]

1. Neuvonen PJ, Suhonen R. Itraconazole interacts with felodipine. *J Am Acad Dermatol* 1995; **33:** 134–5.
2. Tailor SAN, *et al.* Peripheral edema due to nifedipine-itraconazole interaction: a case report. *Arch Dermatol* 1996; **132:** 350–2.
3. Kremens B, *et al.* Loss of blood pressure control on withdrawal of fluconazole during nifedipine therapy. *Br J Clin Pharmacol* 1999; **47:** 707–8.

Antihistamines. Severe angina developed in a patient stabilised on nifedipine who took *terfenadine* 60 mg for seasonal allergy. The pain resolved within an hour or two.[1]

1. Falkenberg HM. Possible interaction report. *Can Pharm J* 1988; **121:** 294.

Antineoplastics. For reports of increased *vincristine* toxicity in children also receiving itraconazole and nifedipine concomitantly, see Antifungals under Interactions of Vincristine, p.787.

Antivirals. The HIV-protease inhibitors are known to inhibit the cytochrome P450 isoenzyme CYP3A4 and may therefore interfere with the metabolism of calcium-channel blockers. A woman stable on felodipine developed oedema[1] in both legs when she was given *nelfinavir* after a needle-stick injury. The oedema resolved on withdrawal of felodipine, and was attributed to inhibition of felodipine metabolism. A study[2] in healthy subjects found that *indinavir plus ritonavir* increased exposure to both amlodipine and diltiazem.

2. Glesby MJ, *et al.* Pharmacokinetic interactions between indinavir plus ritonavir and calcium channel blockers. *Clin Pharmacol Ther* 2005; **78:** 143–53.

Beta blockers. Although nifedipine is often used with beta blockers without untoward effects, heart failure has been reported in a few patients with angina who were given nifedipine and a beta blocker.[1,2] Severe hypotension has been reported in 1 of 15 angina patients given nifedipine and *atenolol*;[3] withdrawal of the beta blocker precipitated severe unstable angina in this patient. Severe hypotension in a patient was attributed to the use of nifedipine with *propranolol*, and was thought to have contributed to fatal myocardial infarction.[4]

4. Staffurth JS, Emery P. Adverse interaction between nifedipine and beta-blockade. *BMJ* 1981; **282:** 225.

Calcium-channel blockers. Plasma concentrations of nifedipine were increased in a study in 6 healthy subjects when pretreated with *diltiazem*; the elimination half-life of nifedipine was prolonged from 2.54 hours to 3.40 hours after pretreatment with diltiazem 30 mg daily and to 3.47 hours after 90 mg daily. The effect was probably due to reduced hepatic metabolism of nifedipine.[1] Nifedipine and diltiazem are reported to be metabolised by the same hepatic enzyme and, conversely, pretreatment with nifedipine has resulted in increased concentrations of diltiazem.[2]

2. Tateishi T, *et al.* The effect of nifedipine on the pharmacokinetics and dynamics of diltiazem: the preliminary study in normal volunteers. *J Clin Pharmacol* 1993; **33:** 738–40.

Digoxin. For the effect of nifedipine and other dihydropyridine calcium-channel blockers on digoxin, see p.1262.

Grapefruit juice. Grapefruit juice inhibits the cytochrome P450 isoenzyme CYP3A4, particularly in the intestinal wall, and has been shown to increase markedly the bioavailability of oral calcium-channel blockers;[1-3] calcium-channel blockers given intravenously appear to be unaffected.[4] The interaction may be less significant with calcium-channel blockers such as amlodipine that have a higher bioavailability,[5] but most calcium-channel blockers should not be taken orally at the same time as grapefruit juice.[6] A stereoselective effect has also been reported.[7]

Histamine H_2-antagonists. Pharmacokinetic studies have indicated that use of nifedipine with *cimetidine* can increase the bioavailability of nifedipine.[1-4] An increase in the area under the plasma concentration-time curve of between 77 and 92% has been reported.[2,3] Potentiation of the hypotensive effect of nifedipine by cimetidine was also shown in 7 hypertensive patients.[1] The mechanism of the interaction was thought to be due to inhibition of the cytochrome P450 system by cimetidine and thus inhibition of the metabolism of nifedipine.

Ranitidine was found to have little effect on the pharmacokinetics of nifedipine, although there was an increase in the bioavailability of nifedipine during use of ranitidine.[5] *Famotidine* has been reported not to interact with nifedipine.[6]

1. Kirch W, *et al.* Einfluß von cimetidin und ranitidin auf pharmakokinetik und antihypertensiven effekt von nifedipin. *Dtsch Med Wochenschr* 1983; **108:** 1757–61.

6. Kirch W, *et al.* Negative effects of famotidine on cardiac performance assessed by noninvasive hemodynamic measurements. *Gastroenterology* 1989; **96:** 1388–92.

Immunosuppressants. Flushing, paraesthesias, and rashes were reported in 2 patients given nifedipine 40 mg daily while taking *ciclosporin* for psoriasis.[1] A study in 8 psoriatic patients indicated that giving nifedipine with ciclosporin resulted in reduced recovery of the principal metabolite of nifedipine, presumably because ciclosporin reduced nifedipine metabolism through competition for the cytochrome P450 metabolising enzymes.

For reference to the effects of calcium-channel blockers on ciclosporin concentrations in blood, see p.1827. For the possible protective effect of nifedipine against ciclosporin-induced nephrotoxicity, see Transplantation under Uses and Administration, below.

For the effect of nifedipine on *tacrolimus*, see p.1845.

1. McFadden JP, *et al.* Cyclosporin decreases nifedipine metabolism. *BMJ* 1989; **299:** 1224.

Magnesium salts. Profound hypotension has been reported in 2 women in whom a single oral dose of nifedipine 10 mg was added to treatment with magnesium sulfate infusion for pre-eclampsia; both women were also receiving methyldopa.[1] Neuromuscular blockade has been reported in 2 women after use of nifedipine with intravenous magnesium sulfate. In one woman receiving nifedipine as a tocolytic, symptoms of neuromuscular blockade occurred immediately on injection of magnesium sulfate and resolved within 25 minutes of stopping the injection.[2] In another woman who was receiving a magnesium sulfate infusion for pre-eclampsia, symptoms developed 30 minutes after the second of 2 doses of nifedipine had been given and improved after receiving calcium gluconate injection.[3]

3. Ben-Ami M, *et al.* The combination of magnesium sulphate and nifedipine: a cause of neuromuscular blockade. *Br J Obstet Gynaecol* 1994; **101:** 262–3.

Melatonin. Melatonin may cause a reduction in blood pressure and might be expected to have additive effects if given with antihypertensives. However, in a study[1] in hypertensive patients taking nifedipine, giving melatonin led to an increase in both blood pressure and heart rate.

1. Lusardi P, *et al.* Cardiovascular effects of melatonin in hypertensive patients well controlled by nifedipine: a 24-hour study. *Br J Clin Pharmacol* 2000; **49:** 423–7.

Tobacco. In a study of the effects of cigarette smoking and the treatment of angina with nifedipine, propranolol, or atenolol, smoking was shown to have direct and adverse effects on the heart and to interfere with the efficacy of all 3 anti-anginal drugs, with nifedipine being the most affected.[1]

1. Deanfield J, *et al.* Cigarette smoking and the treatment of angina with propranolol, atenolol, and nifedipine. *N Engl J Med* 1984; **310:** 951–4.

Xanthines. For the effect of nifedipine on *theophylline*, see p.1144.

Pharmacokinetics

Nifedipine is rapidly and almost completely absorbed from the gastrointestinal tract, but undergoes extensive hepatic first-pass metabolism. Bioavailability of oral liquid-filled capsules is between 45 and 75%, but is lower for longer-acting formulations. Peak blood concentrations are reported to occur 30 minutes after oral doses of liquid-filled capsules.

Nifedipine is about 92 to 98% bound to plasma proteins. It is distributed into breast milk. It is extensively metabolised in the liver and 70 to 80% of a dose is excreted in the urine almost entirely as inactive metabolites. The half-life is about 2 hours after intravenous doses or oral liquid-filled capsules.

◊ General reviews.

1. Kelly JG, O'Malley K. Clinical pharmacokinetics of calcium antagonists: an update. *Clin Pharmacokinet* 1992; **22:** 416–33.

◊ The pharmacokinetics of nifedipine have been reviewed.[1] Studies have been complicated by the difficulty in preparing a stable intravenous formulation and the problems in developing a sufficiently sensitive and specific method of analysis. Nearly 100% of an oral dose of nifedipine is absorbed in the small intestine although the bioavailability from capsules is 45 to 68%. The rate of absorption from both oral and sublingual capsules varies widely among individuals: there has been a report that high plasma-nifedipine concentrations are achieved more rapidly if the capsule is bitten and swallowed than from standard oral and sublingual administration (but this is no longer recommended—see Hypertension, below). The absorption of nifedipine from tablets is slower than from capsules, with maximum plasma concentrations occurring at 1.6 to 4.2 hours compared with 0.5 to 2.17 hours, and absorption may still be occurring at 24 to 32 hours after a dose.

Nifedipine undergoes almost complete hepatic oxidation to 3 pharmacologically inactive metabolites which are excreted in the urine. It has been reported that after oral doses 30 to 40% of the amount absorbed is metabolised during the first pass through the liver. The elimination half-life of nifedipine is apparently dependent upon the dosage form in which it is given, with half-lives of 6 to 11 hours, 2 to 3.4 hours, and 1.3 to 1.8 hours measured after oral tablet, oral capsule, and intravenous doses respectively. The total systemic clearance of nifedipine from plasma ranges from 27 to about 66 litres/hour. Renal impairment does not substantially alter nifedipine pharmacokinetics.

1. Sorkin EM, *et al.* Nifedipine: a review of its pharmacodynamic and pharmacokinetic properties, and therapeutic efficacy, in ischaemic heart disease, hypertension and related cardiovascular disorders. *Drugs* 1985; **30:** 182–274.

Absorption. Although studies have indicated that the absorption of nifedipine may be affected by food the results appear to vary depending upon the preparation used. A reduction in peak plasma-nifedipine concentrations, and a delay in achieving them, was reported[1] when nifedipine *capsules* were given after a meal compared with 30 minutes before. In contrast, the bioavailability and maximum serum concentrations of nifedipine were markedly increased when a *modified-release tablet* (*Adalat L*) was given after a meal rather than fasting,[2] although another modified-release tablet (*Slofedipine*) showed delayed absorption when given after food.[3] A further tablet formulation (*Adalat OROS*) was unaffected by food,[3] while a *modified-release capsule* containing uncoated and enteric-coated granules (*Sepamit R*) was reported to have essentially the same bioavailability when taken before or after a meal.[4]

3. Schug BS, *et al.* The effect of food on the pharmacokinetics of nifedipine in two slow release formulations: pronounced lag-time after a high fat breakfast. *Br J Clin Pharmacol* 2002; **53:** 582–8.
4. Ueno K, *et al.* Effect of a light breakfast on the bioavailability of sustained-release nifedipine. *DICP Ann Pharmacother* 1991; **25:** 317–19.

Hepatic impairment. The pharmacokinetics of nifedipine were found to be considerably altered in 7 patients with liver cirrhosis.[1] Systemic plasma clearance was substantially reduced and the elimination half-life was considerably longer than in healthy subjects. In addition, systemic availability of oral nifedipine was much higher in patients with cirrhosis and was complete in 3 patients with surgical portacaval shunt. Patients with liver cirrhosis seemed to be more sensitive to the effects of nifedipine on diastolic blood pressure and heart rate, and this could be explained by the higher free drug concentrations observed. It was concluded that lower doses of nifedipine may be required in patients with liver cirrhosis, and the patient's response should be closely monitored.

1. Kleinbloesem CH, *et al.* Nifedipine: kinetics and hemodynamic effects in patients with liver cirrhosis after intravenous and oral administration. *Clin Pharmacol Ther* 1986; **40:** 21–8.

Interindividual variation. A study in 53 Dutch subjects found a bimodal distribution of plasma concentrations of nifedipine after a single oral dose; it was proposed that the higher plasma concentrations in 17% of subjects represented a slow metaboliser phenotype, with the majority of the population being fast metabolisers.[1] Although further studies[2,3] in European populations have not confirmed these results, a study in 12 Mexican subjects supported the concept of polymorphic metabolism, with 5 fast and 7 slow metabolisers, a much higher proportion of slow metabolisers than in the European studies.[4] Studies have also reported a markedly increased area under the concentration-time curve in South Asian,[5,6] Mexican,[7] and Nigerian[8] subjects compared with Caucasians. The difference did not appear to be due to diet.[5,6] The initial dose of nifedipine might need to be lower in these ethnic groups. Another population study[9] found that clearance was slower in blacks compared with whites, and in men compared with women; alcohol ingestion and smoking both also reduced nifedipine clearance.

Uses and Administration

Nifedipine is a dihydropyridine calcium-channel blocker (p.1154). It is a peripheral and coronary vasodilator, but, unlike the rate-limiting calcium-channel blockers verapamil or diltiazem, has little or no effect on cardiac conduction and negative inotropic activity is rarely seen at therapeutic doses. Use of nifedipine results primarily in vasodilatation, with reduced peripheral resistance, blood pressure, and afterload, increased coronary blood flow, and a reflex increase in heart rate. This in turn results in an increase in myocardial oxygen supply and cardiac output. Nifedipine has no antiarrhythmic activity. Nicardipine and newer dihydropyridines such as amlodipine, felodipine, isradipine, and lacidipine may be even more selective than nifedipine for vascular smooth muscle. Nimodipine acts particularly on cerebral blood vessels. Most of the dihydropyridine calcium-channel blockers (nifedipine and lacidipine are exceptions) are chiral compounds used as racemic mixtures.

Nifedipine is used in the management of hypertension; in the management of angina pectoris (p.1157), particularly when a vasospastic element is present, as in Prinzmetal's angina, but is not suitable for relief of an acute attack; and in the treatment of Raynaud's syndrome. Nifedipine has also been tried in numerous non-vascular disorders.

Nifedipine is usually given orally. It is available in several formulations. Liquid-filled capsules with a relatively rapid onset but short duration of action are given three times daily. This short-acting preparation is not recommended for the management of hypertension (see below). There are also tablets and capsules with a slower onset and longer duration of action, enabling twice-daily dosage; although these are often referred to by nomenclature implying extended or sustained release they should be distinguished from the true extended-release preparations available in some countries that allow dosage once daily.

Doses of nifedipine are dependent upon the formulation used; they may need to be reduced in the elderly or those with impaired liver function.

For **hypertension** a long-acting preparation of nifedipine may be given in doses of 10 to 40 mg twice daily, or 20 to 90 mg once daily, depending on the preparation used.

For **angina pectoris**, nifedipine may be given as a long-acting preparation in a dose of 10 to 40 mg twice daily or 30 to 90 mg once daily, depending on the preparation. Alternatively, the liquid-filled capsules have been given in a dose of 5 to 20 mg three times daily, but longer-acting preparations are preferred.

Nifedipine has been given by injection via a coronary catheter for the treatment of coronary spasm during coronary angiography and balloon angioplasty. Blood pressure and heart rate should be monitored carefully.

In the management of **Raynaud's syndrome**, nifedipine may be given as liquid-filled capsules in a dose of 5 to 20 mg three times daily.

For the use of nifedipine in children, see below.

◊ General reviews.

2. Croom KF, Wellington K. Modified-release nifedipine: a review of the use of modified-release formulations in the treatment of hypertension and angina pectoris. *Drugs* 2006; **66:** 497–528.

Administration in children. Nifedipine has been used in the management of various disorders in children. The *BNFC* recommends the following oral doses:

Hypertension; angina in Kawasaki disease or progeria:
- age 1 month to 12 years: 200 to 300 micrograms/kg 3 times daily, increased to a maximum daily dose of 3 mg/kg or 100 mg
- age 12 to 18 years: 5 to 20 mg 3 times daily, increased to a maximum daily dose of 100 mg

Hypertensive crises:
- age 1 month to 18 years: 250 to 500 micrograms/kg as a single dose

Raynaud's syndrome:
- age 2 to 18 years: 2.5 to 10 mg 2 to 4 times daily; treatment should start with low doses at night, increased gradually to avoid postural hypotension

Neonatal hyperinsulinaemic hypoglycaemia:
- see below.

Use of nifedipine capsules for acute hypertension is no longer recommended in adults because of the risk of severe adverse effects related to precipitous reductions in blood pressure (see Effects on Mortality under Adverse Effects, above). Although there have been reports of adverse effects in children,[1-3] they may be less susceptible than adults, and the use of nifedipine capsules may still be appropriate. A study[4] in 12 children aged 6 to 15 years with acute severe hypertension reported that sublingual nifedipine in a mean dose of 240 micrograms/kg (range 180 to 320 micrograms/kg) was safe and effective. A retrospective study[1] in 117 children found that nifedipine safely reduced blood pressure, and that precipitous declines only occurred with doses higher than 250 micrograms/kg, while another retrospective study[2] in 166 children found that nifedipine in a mean dose of 300 micrograms/kg (range 40 to 1300 micrograms/kg) was generally safe, although children with acute CNS injury were at higher risk of neurological adverse effects.

Other routes that have been used include rectal[5] and intranasal,[6] but these are less established.

Atherosclerosis. The use of drugs that interfere with atherogenesis (the development of atheromas) has been suggested as a means of reducing diseases associated with atherosclerosis (p.1159). Calcium is thought to be necessary for several steps in atherogenesis and studies in *animals* have shown that calcium-channel blockers slow the development and progression of atherosclerotic lesions. However, studies in humans have been less convincing.[1] In a placebo-controlled study,[2] amlodipine had no demonstrable effect on angiographic progression of coronary atherosclerosis or the risk of major cardiovascular events although it was associated with fewer admissions to hospital for unstable angina and revascularisation. Similar results have been reported with nisoldipine.[3] In another study,[4] comparing lacidipine with a beta blocker, there was less progression of atherosclerosis in those receiving lacidipine and also a trend towards fewer cardiovascular events.

Calcium-channel blockers have also been tried in the prevention of restenosis after percutaneous coronary interventions. A meta-analysis[5] found that addition of calcium-channel blockers to standard therapy reduced the risk of restenosis and the occurrence of clinical events.

5. Dens J, *et al.* An updated meta-analysis of calcium-channel blockers in the prevention of restenosis after coronary angioplasty. *Am Heart J* 2003; **145:** 404–8.

Cardiomyopathies. Calcium-channel blockers may have a role in some forms of cardiomyopathy (p.1163). In *hypertrophic cardiomyopathy* verapamil is probably the calcium-channel blocker of choice (see p.1424). Nifedipine does not appear to reduce left ventricular outflow tract obstruction, and conflicting results have been found with respect to improvement in the diastolic function abnormality with this drug.[1] The use of calcium-channel blockers is not standard therapy in *dilated cardiomyopathy* although symptomatic improvement has been reported[2] with diltiazem.

Cough. Nifedipine has been reported to reduce the severity of cough induced by captopril,[1] possibly by inhibiting prostaglandin synthesis. For further details on cough associated with ACE inhibitors, see p.1194.

1. Fogari R, *et al.* Effects of nifedipine and indomethacin on cough induced by angiotensin-converting enzyme inhibitors: a double-blind, randomized, cross-over study. *J Cardiovasc Pharmacol* 1992; **19:** 670–3.

Hiccup. Hiccups (p.976) result from involuntary spasmodic contraction of the diaphragm. Intractable hiccups resolved completely with nifedipine 20 mg every 8 hours in a patient.[1] In a further 7 such patients,[2] nifedipine in doses of 20 to 80 mg daily stopped hiccups in 4 and improved them in another. Resolution of intractable hiccups has also been reported[3] in 2 patients given nimodipine; the drug was given orally in one patient and intravenously in the other.

For the treatment of hiccups in palliative care the *BNF* recommends nifedipine at a dose of 10 mg three times daily.

High-altitude disorders. Nifedipine lowers pulmonary artery pressure and is one of several drugs that are used in high-altitude disorders (p.1168), success being reported for both the treatment[1,2] and prevention[2,3] of symptoms of pulmonary oedema. In a study conducted at 4559 m above sea-level[1] nifedipine 10 mg sublingually and 20 mg as a modified-release dosage form was given to 6 subjects with symptoms of high-altitude pulmonary oedema. The sublingual dose was repeated if tolerated after 15 minutes and the subjects subsequently received modified-release nifedipine 20 mg every 6 hours while they remained at high altitude. Symptoms of high-altitude pulmonary oedema were relieved within 1 hour of beginning nifedipine and radiographic signs of oedema regressed during treatment despite remaining at high altitude for 36 hours and participating in mountaineering activities. Raised pulmonary arterial pressure was also reduced to control values by nifedipine. Successful treatment of pulmonary oedema in a climber at 6550 m has been described with doses of 20 mg every 8 hours for 36 hours and such doses also prevented the development of symptoms in 2 climbers who had taken nifedipine from the start of the climb.[2] Doses of 20 mg every 8 hours have been reported to allow rapid ascent to 4559 m without development of pulmonary oedema in 9 of 10 subjects who received nifedipine compared with 4 of 11 who received only placebo.[3] However, the point has been made that although it is reasonable that many climbers carry nifedipine in case of an attack, prophylactic nifedipine should not be considered an alternative to slow ascent and acclimatisation.[4]

Hyperinsulinaemic hypoglycaemia. Nifedipine may have effects on blood-glucose levels due to inhibition of insulin release[1] (see Effects on Carbohydrate Metabolism, under Adverse Effects, above). There have been reports[1-4] of the successful use of nifedipine to increase blood-glucose levels in infants with hyperinsulinaemic hypoglycaemia (see under Uses of Glucagon, p.1447), and it may have a role[5] as adjunctive therapy in such patients. The *BNFC* suggests that neonates with persistent hyperinsulinaemic hypoglycaemia may be given oral nifedipine in a dose of 100 to 200 micrograms/kg 4 times daily, increased to a maximum of 600 micrograms/kg 4 times daily if required.

Hypertension. Long-acting calcium-channel blockers are among the drug groups that may be used as first-line therapy in uncomplicated hypertension (p.1171); meta-analyses[1] and large studies[2] have shown them to be as safe and effective as other first-line antihypertensives and they are particularly recommended in older patients. Dihydropyridine calcium-channel blockers are also useful in patients who require combination therapy[3] and are particularly effective when given with a beta blocker or an ACE inhibitor. The use of short-acting calcium-channel blockers is not recommended since they may increase mortality (see under Adverse Effects, above).

Calcium-channel blockers may also be used in **hypertensive crises**, particularly in hypertensive urgencies where oral therapy is suitable. Nifedipine has been given sublingually, or by biting the capsule and swallowing the contents, but such use may cause dangerous hypotension and is no longer recommended. In hypertensive emergencies, where parenteral antihypertensives are required, intravenous nicardipine may be used. One study concluded that intravenous nicardipine was as effective as sodium nitroprusside in the treatment of postoperative hypertension.[4]

For **hypertension in pregnancy**, first-line treatment is usually methyldopa or a beta blocker but calcium-channel blockers may also be used. Nifedipine is reported to be teratogenic in *animals* and may inhibit labour, but it has been tried in a limited number of patients with pre-eclampsia. Although a high rate of caesarean deliveries, premature births, and small-for-date infants was reported[5] in patients given nifedipine as a second-line drug, assessment of the role of nifedipine is difficult because outcome is often poor in such severely compromised pregnancies.[6] Fetal nifedipine concentrations have been reported to be 75% of maternal values 2 to 3 hours after sublingual administration.[7] However, nifedipine in a single 20-mg oral dose lowered blood pressure without compromising blood flow in the fetus in 9 women in the third trimester with normal haemodynamics.[6] This is in line with other reports,[8] although there has also been a report[9] of severe hypotension and fetal distress after sublingual nifedipine administration. In a randomised controlled study,[10] nifedipine 10 to 30 mg sublingually followed by 10 mg as capsules by mouth every 6 hours increasing to 20 mg every 4 hours if necessary, was compared with hydralazine 12.5 mg intravenously as required followed by 20 to 30 mg orally every 6 hours, with added methyldopa if necessary. Both groups also received intravenous magnesium sulfate. Effective control of blood pressure was achieved in 23 of 24 patients given nifedipine compared with only 17 of 25 given hydralazine and 9 nifedipine patients achieved term delivery compared with only 2 of those receiving hydralazine. The average gestational age was greater in infants in the nifedipine group; hence these neonates weighed more and had fewer neonatal complications when compared with neonates from the hydralazine treated group.

Kidney disorders. Although nifedipine may adversely affect renal function (see under Adverse Effects, above) there is evidence that calcium-channel blockers may be of benefit in various forms of kidney disorder. Proteinuria is an important indicator of glomerular kidney disease (p.1504) of various causes and the effects of calcium-channel blockers on proteinuria and renal dysfunction have been studied in a variety of patients. Results have been mixed,[1-5] and it is not clear whether any protective effect of calcium-channel blockers on renal function is only due to their antihypertensive action or whether they also have additional effects. The benefits of ACE inhibitors in kidney disorders are much better established (see p.1199) and a study[6] in African American hypertensives was stopped early when treatment with ramipril was found to be superior to treatment with amlodipine. A further study[7] in patients with non-diabetic proteinuria found that addition of felodipine to ACE inhibitor therapy provided no additional benefit in terms of renal outcomes.

Nifedipine has also been used in the management of renal calculi (see below), and has been reported to protect against ciclosporin-induced nephrotoxicity in renal transplant patients (see Transplantation, below).

Migraine and cluster headache. Drugs with calcium-channel blocking activity have been given in the management of headaches considered to have a vascular component such as migraine (p.616) and cluster headache (p.616).

In migraine prophylaxis, of those drugs with calcium-channel blocking activity studied, flunarizine (p.580) has the best documented efficacy, and verapamil may be useful. Other calcium-channel blockers such as diltiazem, nifedipine, and nimodipine have been tried, but results have been conflicting. Verapamil has also been used successfully in patients with hemiplegic migraine, both intravenously to abort attacks,[1,2] and orally for prophylaxis.[2]

Beneficial effects have been reported[3-6] with calcium-channel blockers in the prevention of cluster headache during cluster periods. Verapamil appears to have been the most widely used. In one double-blind study it was found to be of similar efficacy to lithium[7] and appeared to produce fewer adverse effects. There have also been reports[8] of the successful use of nimodipine in patients with thunderclap headache.

Oesophageal motility disorders. Results from a number of studies have indicated that nifedipine, usually in doses of 10 to 20 mg sublingually, may be of benefit in patients with achalasia, reducing lower oesophageal sphincter pressure and producing some symptomatic improvement.[1-5] Nifedipine has a role when mechanical dilatation of the sphincter or surgery are not feasible (see Oesophageal Motility Disorders, p.1702).

Peripheral vascular disease. Vasospastic arterial disease (p.1178) is due to an inappropriate response to temperature, usually cold, when vasoconstriction and/or vasospasm occurs. The most important of these disorders is Raynaud's syndrome. Calcium-channel blockers have been of benefit in Raynaud's syndrome,[1] but it is not entirely clear which of their pharmacological actions is responsible. The most widely used and studied is nifedipine. Evidence of subjective benefit has been seen both in primary idiopathic disease[2-5] and in Raynaud's phenomenon secondary to systemic sclerosis,[3,4,6,7] systemic lupus erythematosus,[3,4] rheumatoid arthritis,[4] and cancer chemotherapy,[8] or associated with breastfeeding.[9-11] Objective improvement as demonstrated by evidence of improved digital blood flow has been demonstrated in some[5,6,12,13] but not all[7] studies. Doses have varied; 10 mg of nifedipine twice daily initially, increased after a week to a maximum of 20 mg twice daily has been suggested,[14] but in many studies doses of up to 60 mg daily have been used, although side-effects have proved intolerable in some patients given such doses.[7] A modified-release preparation has also been used[15] and may reduce the incidence of adverse effects.

Nifedipine in doses of 20 to 60 mg daily has also been reported to be of benefit in the treatment of another vasospastic condition, chilblains, both for established chilblains and in the prevention of relapse.[16]

Phaeochromocytoma. Pharmacological management of phaeochromocytoma (p.1179) is principally achieved by alpha-adrenergic blockade and tachycardia may subsequently be controlled by cautious addition of a beta blocker. There have also been some reports[1-4] of the use of nifedipine to treat cardiovascular symptoms in adults and children with phaeochromocytoma.

Premature labour. Although $beta_2$ agonists or magnesium are the drugs that have been most commonly used as tocolytics to postpone premature labour (p.2003), there is increasing interest in calcium-channel blockers such as nifedipine, either given alone or added to other tocolytics, as first-line drugs. Labour was successfully postponed in a patient given nifedipine 20 mg three times daily and oral terbutaline.[1] Terbutaline by subcutaneous injection was also occasionally necessary. Nifedipine was given from the twenty-sixth week of pregnancy for 55 days. A normal, healthy infant was delivered in the thirty-sixth week of pregnancy. In a study[2] in 20 patients, oral nifedipine 30 mg initially, then 20 mg every 8 hours, was more effective in suppressing premature labour than ritodrine given intravenously or no treatment. However, a similar study[3] in 33 patients found nifedipine to be no more effective than ritodrine infusion, although associated with a lower incidence of adverse effects. Similar results have been reported with nicardipine.[4] Meta-analyses[5,6] have concluded that nifedipine is at least as effective as $beta_2$ agonists and is associated with fewer maternal adverse effects, and this was supported by the results of further studies.[7,8] The larger[7] of these involved 185 women using oral nifedipine in an initial dose of up to 40 mg followed by 60 to 160 mg daily, reduced after 3 days to a maintenance dose of at least 20 mg 3 times daily. However, a systematic review[9] which examined 31 studies of the effectiveness of nifedipine in premature labour concluded that their overall quality was poor. Others[10] have expressed concern about the safety of calcium-channel blockers, reviewing cases of dyspnoea and pulmonary oedema in particular. They suggest that these drugs should not be used with intravenous beta agonists, that high doses should be avoided in women with cardiovascular compromise or multiple gestations, and that blood pressure and fetal heart rate should be monitored during use of short-acting preparations, which should not be chewed.

Pulmonary hypertension. Vasodilators have been tried in primary pulmonary hypertension (p.1179) on the premise that pulmonary vasoconstriction is an important component of the condition. Calcium-channel blockers are the most widely-used. Improved survival over a 5-year period has been noted in a study in patients treated with high doses of calcium-channel blockers (nifedipine or diltiazem).[1] However, treatment failures have occurred with nifedipine, and at least one death has been reported shortly after starting therapy.[2] Other reports have also stressed the potentially deleterious effects of nifedipine (or other vasodilator) therapy in pulmonary hypertension. Increased dyspnoea and a fall in arterial PO_2 have been reported in a patient with primary pulmonary hypertension given nifedipine, probably due to preferential vasodilatation of underventilated hypoxic tissues resulting in an increased physiological shunt.[3] Invasive investigations, notably blood-gas monitoring, are therefore recommended when giving nifedipine to these patients[2,3] and it has been advised that an acute response test should be performed before embarking on long-term treatment.[1]

Renal calculi. There is some interest in the possible use of drug treatment to ease the spontaneous passage of renal calculi (p.2181) in patients with uncomplicated lower ureteral stones. It has been suggested that the combination of a calcium-channel blocker (to reduce ureteral spasm) with a corticosteroid (to reduce oedema) may be useful. Small studies[1-3] have used modified-release preparations of nifedipine, given in oral doses of 30 mg daily for up to 28 days, with oral deflazacort 30 mg daily for up to 10 days. If the stone had not been expelled within 28 days, the patient was treated with extracorporeal shock wave lithotripsy or ureteroscopy. Treatment with nifedipine and deflazacort was found to improve the rate of stone expulsion and expulsion time, and to reduce analgesic requirements.

The use of a 10-day course of nifedipine and deflazacort has also been studied[4] as adjunctive therapy after lithotripsy. It was found to ease the passage of stone fragments, reduce analgesic requirements, and increase the number of patients who were stone-free after 45 days.

Tardive dyskinesia. Calcium-channel blockers have been tried in the treatment of tardive dyskinesia (see under Extrapyramidal Disorders, p.971). However, a systematic review[1] concluded that their effects are unclear and they should not be used.

1. Soares-Weiser K, Rathbone J. Calcium channel blockers for neuroleptic-induced tardive dyskinesia. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2004 (accessed 28/03/06).

Transplantation. The main adverse effect of ciclosporin is reversible, dose-related nephrotoxicity. There is some evidence that nifedipine may be of value in protecting against this effect. Retrospective analysis[1] of 106 ciclosporin-treated renal transplant patients found that patients receiving nifedipine for hypertension had better graft function, despite having shorter graft duration and therefore requiring higher dosage of ciclosporin, than hypertensive patients receiving other drug treatment. Subsequent studies have similarly reported improved graft function[2] in patients receiving nifedipine and suggest that graft survival is also improved.[3,4] A nephroprotective effect has also been reported with nitrendipine,[5] felodipine,[6] isradipine,[7] and with the non-dihydropyridine diltiazem (see p.1267), although a study[8] with nicardipine failed to demonstrate any improvement in graft function.

For a report of adverse effects attributed to reduced metabolism of nifedipine in patients taking ciclosporin, see Immunosuppressants, under Interactions, above.

Urticaria. Oral antihistamines are the main drugs used in the management of urticaria (p.1584). Addition of a calcium-channel blocker, such as nifedipine, has been suggested for patients unresponsive to treatment with oral antihistamines alone, but results have been mixed.[1,2]

Pharmacopoeias. In *Jpn.*

Profile

Nilvadipine is a dihydropyridine calcium-channel blocker with general properties similar to those of nifedipine (p.1350). It is used in the management of hypertension (p.1171). Nilvadipine is given orally, usually as a modified-release preparation, in a dose of up to 16 mg daily.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Nimodipine). A light yellow or yellow crystalline powder. It exhibits polymorphism. Practically insoluble in water; sparingly soluble in dehydrated alcohol; freely soluble in ethyl acetate. Exposure to ultraviolet light leads to formation of a nitrophenylpyridine derivative. Solutions should be prepared in the dark or under light of wavelength greater than 420 nm, immediately before use. Protect from light.

USP 31 (Nimodipine). A light yellow or yellow crystalline powder, affected by light. It exhibits polymorphism. Practically insoluble in water; sparingly soluble in alcohol; freely soluble in ethyl acetate. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Incompatibility. Licensed product information states that solutions of nimodipine are incompatible with some plastics, including PVC, and that the only plastics suitable for use are polyethylene and polypropylene.

Adverse Effects, Treatment, and Precautions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1350).

Nimodipine should be used with caution in patients with cerebral oedema or severely raised intracranial pressure.

Effects on the heart. Marked bradycardia developed in a patient with acute ischaemic stroke during treatment with nimodipine and was suspected to be related to the drug therapy.[1]

1. Fagan SC, Nacci N. Nimodipine and bradycardia in acute stroke—drug or disease? *DICP Ann Pharmacother* 1991; **25:** 247–9.

Interactions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1352).

Pharmacokinetics

Nimodipine is rapidly absorbed from the gastrointestinal tract after oral doses but undergoes extensive first-pass metabolism in the liver. The oral bioavailability is reported to be about 13%. Nimodipine is more than 95% bound to plasma proteins. It crosses the blood-brain barrier, but concentrations in CSF are lower than those in plasma. Nimodipine is extensively metabolised in the liver. It is excreted in faeces via the bile, and in urine, almost entirely as metabolites. The terminal elimination half-life is reported to be about 9 hours but the initial decline in plasma concentration is much more rapid, equivalent to a half-life of 1 to 2 hours.

Uses and Administration

Nimodipine is a dihydropyridine calcium-channel blocker that has the general properties of nifedipine (p.1354), but acts particularly on cerebral blood vessels. It is used in cerebrovascular disorders (see below), particularly in the prevention and treatment of ischaemic neurological deficits after aneurysmal subarachnoid haemorrhage.

To reduce the incidence and severity of neurological deficit after aneurysmal haemorrhage nimodipine is given orally in a dose of 60 mg every 4 hours. Treatment should begin within 4 days of onset of haemorrhage and should continue for 21 days. In patients with hepatic impairment the dose may be reduced (see below) and blood pressure should be closely monitored.

If cerebral ischaemia occurs or has already occurred, neurological deficit may be treated by intravenous infusion of nimodipine. It should be given via a bypass into a running intravenous infusion into a central vein. The initial dose should be nimodipine 1 mg/hour for 2 hours, increased (provided that no severe decrease in blood pressure occurs) to 2 mg/hour. The starting dose should be reduced to 500 micrograms/hour, or even lower if necessary, in patients weighing less than 70 kg and in those with unstable blood pressure; a similar reduction in dosage has been suggested in hepatic impairment, and blood pressure should be closely monitored. Treatment should be started as soon as possible and continued for at least 5 and no more than 14 days; if the patient has already received oral nimodipine, the total duration of nimodipine use should not exceed 21 days.

Administration in hepatic impairment. The clearance of nimodipine is reduced in patients with cirrhosis, and blood pressure should be closely monitored in such patients. US licensed product information recommends that the oral dose of nimodipine should be halved to 30 mg every 4 hours in patients with hepatic cirrhosis. Some manufacturers have also suggested a reduction in the initial intravenous dose to 500 micrograms or less per hour.

Cerebrovascular disorders. Nimodipine is used orally and intravenously in the prevention and treatment of ischaemic neurological deficits caused by arterial vasospasm after aneurysmal subarachnoid haemorrhage (see Stroke, p.1185), although the evidence for benefit after intravenous use is limited.[1] Nimodipine has also been used for traumatic subarachnoid haemorrhage,[2] but results have been mixed.[3,4] In addition to dilating cerebral blood vessels and improving cerebral blood flow, nimodipine may also prevent or reverse ischaemic damage to the brain by limiting transcellular calcium influx.

These effects have led to the investigation of nimodipine in other conditions associated with cerebral ischaemia. Studies[5,6] of nimodipine given orally after ischaemic stroke have produced conflicting results. A meta-analysis[7] of controlled studies suggested that nimodipine is beneficial if given within 12 hours of stroke onset but a further study[8] failed to confirm these findings. In a controlled study[9] of 155 patients suffering a cardiac arrest, nimodipine was given by intravenous infusion for 24 hours. Nimodipine had no effect on overall survival, although it did improve survival of patients in whom advanced life support was delayed for more than 10 minutes after arrest. Nimodipine has also been tried in dementia (p.362). Two multicentre studies[10] involving a total of 755 patients with dementia of vascular or degenerative origin given nimodipine for up to 6 months reported improvements in cognitive function and disability, and a systematic review[11] concluded that nimodipine could be of some benefit in patients with various forms of dementia.

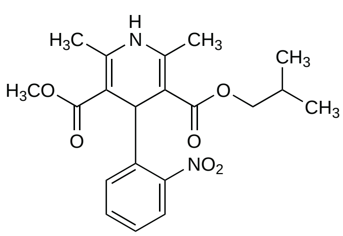
$C_{20}H_{24}N_2O_6$ = 388.4.
CAS — 63675-72-9.
ATC — C08CA07.
ATC Vet — QC08CA07.



Adverse Effects, Treatment, and Precautions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1350).

Interactions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1352).

Pharmacokinetics

Nisoldipine is well absorbed from the gastrointestinal tract after oral doses but undergoes rapid and extensive first-pass metabolism in the gut wall and liver and bioavailability has been reported to be only about 4 to 8%. About 60 to 80% of an oral dose is excreted in the urine and the remainder in the faeces, mainly as metabolites. The terminal elimination half-life is about 7 to 12 hours. Nisoldipine is more than 99% bound to plasma proteins.

◊ A study[1] in 11 patients given oral nisoldipine 10 mg once or twice daily indicated that the pharmacokinetics of nisoldipine could best be described by an open 2-compartment model. Peak plasma concentrations occurred 1 hour after a single oral dose, and varied greatly between the patients. The mean plasma elimination half-life was 11.4 hours after a single dose and 14.0 hours after repeated dosing, which was longer than had been previously reported, perhaps reflecting the greater sensitivity of the assay.

In another study oral, but not intravenous, nisoldipine increased liver blood flow in 10 healthy subjects and thus affected its own systemic availability.[2] Variations in liver blood flow may account for the interindividual variation in the pharmacokinetics of nisoldipine.

2. van Harten J, *et al.* Variability in the pharmacokinetics of nisoldipine as caused by differences in liver blood flow response. *J Clin Pharmacol* 1989; **29:** 714–21.

Uses and Administration

Nisoldipine is a dihydropyridine calcium-channel blocker with actions and uses similar to those of nifedipine (p.1354). It is used in the management of hypertension (p.1171) and angina pectoris (p.1157).

Nisoldipine is given orally usually as a modified-release preparation. Absorption is affected by food and the modified-release preparation should be taken on an empty stomach; it should not be taken with high fat meals. Doses are similar for both hypertension and angina. The initial dose is 10 mg once daily and the usual maintenance dose is 20 to 40 mg once daily.

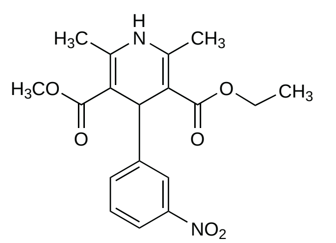
Nitrendipine *(BAN, USAN, rINN)*

Bay-e-5009; Nitrendipiini; Nitrendipin; Nitrendipinas; Nitrendipino; Nitrendipinum. Ethyl methyl 1,4-dihydro-2,6-dimethyl-4-(3-nitrophenyl)pyridine-3,5-dicarboxylate.

Нитрендипин

$C_{18}H_{20}N_2O_6$ = 360.4.
CAS — 39562-70-4.
ATC — C08CA08.
ATC Vet — QC08CA08.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *Jpn.*

Ph. Eur. 6.2 (Nitrendipine). A yellow crystalline powder. It exhibits polymorphism. Practically insoluble in water; sparingly soluble in dehydrated alcohol and in methyl alcohol; freely soluble in ethyl acetate. Exposure to ultraviolet light leads to formation of a nitrophenylpyridine derivative. Solutions should be prepared in the dark or under light of wavelength greater than 420 nm, immediately before use. Protect from light.

Adverse Effects, Treatment, and Precautions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1350).

Interactions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1352).

Pharmacokinetics

Nitrendipine is reported to be well absorbed after oral doses but undergoes extensive first-pass metabolism; the absolute oral bioavailability is reported to range from about 10 to 20%, depending in part on the dosage form. Nitrendipine is about 98% bound to plasma proteins. It is extensively metabolised in the liver and is excreted as metabolites, mainly in urine, with small amounts in the faeces. Although early studies reported a terminal elimination half-life of about 2 to 4 hours, later studies, using more sensitive assay procedures, have recorded values between about 10 and 22 hours.

Uses and Administration

Nitrendipine is a dihydropyridine calcium-channel blocker with actions similar to those of nifedipine (p.1354). It is used in the treatment of hypertension (p.1171).

The usual dose is 20 mg daily as a single oral dose or as 2 divided doses. The dose may be increased to 20 mg twice daily if necessary for the control of resistant hypertension. In the elderly, an initial dose of 10 mg daily should be used. The dose should also be reduced in hepatic impairment (see below).

Nitric Oxide *(USAN)*

Azote, monoxyde d'; Azoto oksidas; Azotu(II) tlenek; Kväveoxid; Mononitrogen Monoxide; Nitrogen Monoxide; Nitrogenii oxidum; Nitrogén-monoxid; OHM-11771; Oxid dusnatý; Óxido nítrico; Typpioksidi.

NO = 30.01.
CAS — 10102-43-9.
ATC — R07AX01.
ATC Vet — QR07AX01.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Nitric Oxide). A colourless gas that turns brown when exposed to air. At 20° and at a pressure of 101 kPa, 1 volume dissolves in about 21 volumes of water. Store compressed at a pressure not exceeding 2.5 MPa measured at 15° in suitable containers.

Adverse Effects

Inhaled nitric oxide may lead to the development of methaemoglobinaemia, particularly at higher doses. Although it is a selective pulmonary vasodilator, systemic hypotension may occur. Abrupt withdrawal of therapy may lead to a deterioration in oxygenation and the development of rebound pulmonary hypertension.

Nitrogen dioxide produced when nitric oxide combines with oxygen can cause acute lung injury; high concentrations of inhaled nitric oxide are directly irritant to the lungs.

◊ A potential complication of inhaled nitric oxide is methaemoglobinaemia but this is probably related to the dose; the risk does not appear to be increased during low-dose (20 ppm) therapy.[1] Another possible adverse event is an increased risk of bleeding due to inhibition of platelet aggregation.[2-5] Rebound pulmonary hypertension[6] and deterioration in oxygenation[7,8] have been reported in some children after stopping nitric oxide therapy. Severe systemic hypotension has also been reported[9] after starting therapy in a neonate with severe left ventricular dysfunction. Pulmonary oedema has been associated with the use of nitric oxide in 2 patients with CREST syndrome, a form of systemic sclerosis.[10] Motor neurone disease in a patient with alcoholism has been partly attributed[11] to the use of nitric oxide for pulmonary hypertension.

11. Tsai GE, Gastfriend DR. Nitric oxide-induced motor neuron disease in a patient with alcoholism. *N Engl J Med* 1995; **332:** 1036.

Precautions

Patients given inhaled nitric oxide should be monitored for methaemoglobinaemia and oxygenation. Inhaled nitric oxide and nitrogen dioxide levels should also be monitored. Treatment should not be stopped abruptly since rebound pulmonary hypertension and deterioration in oxygenation may occur.

The exposure of workers to nitric oxide and nitrogen dioxide should be limited.

Pharmacokinetics

Nitric oxide is absorbed systemically after inhalation but is rapidly inactivated by reaction with haemoglobin to form methaemoglobin and nitrate; it has a half-life of only a few seconds. It is excreted mainly in the urine as nitrate.

Uses and Administration

Nitric oxide is an endogenous chemical messenger that acts mainly by stimulating guanylate cyclase in smooth muscle to cause vasodilatation. It is also involved in platelet aggregation, neurotransmission, and the immune system, and possesses antimicrobial, antitumour, and antiviral activity.

Endogenous nitric oxide is now recognised to be the same substance as endothelium-derived relaxing factor (EDRF). It is synthesised from L-arginine by the enzyme, nitric oxide synthase, of which three isoforms have been identified. Constitutive isoforms occur in endothelial cells (such as in vascular endothelium, platelets, and the heart) and neuronal cells (in some central and peripheral neurones). Small amounts of nitric oxide are regularly produced by these systems. In contrast, an inducible isoform producing larger amounts of nitric oxide is expressed only after activation by external stimuli such as infection or inflammation. This inducible nitric oxide synthase may be expressed in many cells, including macrophages and cells in vascular smooth muscle, the heart, gastrointestinal tract, and liver.

Inhaled nitric oxide is a highly selective pulmonary vasodilator. It is used in the management of term and near-term neonates with hypoxic respiratory failure associated with pulmonary hypertension. It is also used as a diagnostic tool to test acute vasoreactivity in patients with pulmonary hypertension of various aetiologies, and is being studied in other bronchopulmonary disorders and in different age groups.

In the management of hypoxic respiratory failure in neonates, nitric oxide is given by inhalation in a usual concentration of 20 ppm. Doses have been titrated above and below this concentration but due to the risk of methaemoglobinaemia, doses above 20 ppm are not generally recommended. The concentration should be reduced gradually before stopping treatment.

ACUTE RESPIRATORY DISTRESS SYNDROME. Although inhalation of nitric oxide has been reported to improve oxygenation in patients with acute respiratory distress syndrome (p.1498), meta-analyses[1,2] have failed to confirm any significant mortality benefit, and there is some evidence[2] that nitric oxide increases the risk of renal dysfunction.

RESPIRATORY DISORDERS IN NEONATES. Inhaled nitric oxide is used in the management of hypoxic respiratory failure in term and near-term neonates.[1-3] It has also been studied in premature neonates.

Most studies have been in neonates with persistent pulmonary hypertension of the newborn (p.1179), although varying definitions have been used. A systematic review[4] of controlled studies in term and near-term neonates with hypoxic respiratory failure found that oxygenation was improved with inhaled nitric oxide, with a reduction in the need for extracorporeal membrane oxygenation, but no effect on mortality has been shown. A randomised trial[5] also found no mortality benefit when nitric oxide was started early in the disease process, although progression was slowed. Neonates with congenital diaphragmatic hernia (CDH), however, have not been shown to benefit,[6,7] and nitric oxide is not recommended in such patients,[4] although the optimal treatment of this condition is controversial; one study[8] suggested that inhaled nitric oxide may have a role in patients with CDH who develop late pulmonary hypertension. Another study[9] suggested that the improvement in oxygenation may not be sustained, and that neonates with pulmonary hypoplasia and dysplasia are less sensitive to nitric oxide.

The dose of nitric oxide found to be effective in most studies has been from 20 to 80 ppm. However, since nitric oxide is associated with dose-related toxicity, lower doses (1 to 2 ppm) have also been studied. One study[10] found no significant difference between high and low doses, but another study[11] found that low doses did not improve oxygenation and diminished the response to subsequent higher doses.

Inhaled nitric oxide has also been reported to improve oxygenation in premature neonates with hypoxic respiratory failure, but its use is not yet established.[12,13] A study[14] in premature infants with respiratory distress syndrome suggested that the incidence of chronic lung disease and death was reduced by nitric oxide, and an open study[15] in very premature infants who had already developed chronic lung disease also found an improvement in oxygenation with nitric oxide therapy. However, a systematic review[16] found that use of rescue nitric oxide therapy in severely ill infants was ineffective, and that late use to prevent chronic lung disease also had no effect. There was some evidence that early routine use in mildly sick infants might improve outcomes, but further studies were needed to identify those infants who were most likely to benefit.

There have been concerns that use of inhaled nitric oxide might adversely affect neurodevelopmental outcome more than conventional therapy particularly in premature infants, but follow-up studies have reported mixed results. Studies in term and near-term infants,[17-19] and in premature infants,[20] have found that use of nitric oxide has no effect on neurodevelopment, but there have also been reports of poor neurodevelopmental outcome[21] and of improved outcome.[22,23] Differences in study design make comparisons between studies difficult, and the effect on neurodevelopment remains to be confirmed.

Sickle-cell disease. Sickle-cell crisis due to vaso-occlusion is an acute complication of sickle-cell disease (p.1044), requiring hospitalisation, with the use of large volumes of intravenous fluids for dehydration, and analgesia including opioids for pain. Concentrations of nitric oxide metabolites and L-arginine have been found to be low in vaso-occlusive crisis and a study[1] in paediatric patients showed that inhaled nitric oxide may be of benefit.

Ph. Eur. 6.2 (Noradrenaline Tartrate; Noradrenaline Acid Tartrate BP 2008; Norepinephrine Acid Tartrate BP 2008). A white or almost white crystalline powder. Freely soluble in water; slightly soluble in alcohol. Store in airtight containers, or preferably, in a sealed tube under vacuum or an inert gas. Protect from light.

USP 31 (Norepinephrine Bitartrate). A white or faintly grey, odourless, crystalline powder. It slowly darkens on exposure to air and light. Soluble 1 in 2.5 of water and 1 in 300 of alcohol; practically insoluble in chloroform and in ether. Its solutions in water have a pH of about 3.5. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Incompatibility. Noradrenaline acid tartrate is strongly acidic in solution, and would be expected to be incompatible with drugs having an alkaline pH. Licensed product information in the UK states that solutions are reportedly incompatible with alkalis and oxidising agents, barbiturates, chlorphenamine, chlorothiazide, nitrofurantoin, novobiocin, phenytoin, sodium bicarbonate, sodium iodide, and streptomycin. Incompatibility with insulin has also been reported.[1]

CAS — 329-56-6.

ATC — C01CA03.

ATC Vet — QC01CA03.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Noradrenaline Hydrochloride; Norepinephrine Hydrochloride BP 2008). A white or brownish-white, crystalline powder. It becomes coloured on exposure to air and light. Very soluble in water; slightly soluble in alcohol. A 2% solution in water has a pH of 3.5 to 4.5. Store in airtight containers, or preferably, in a sealed tube under vacuum or an inert gas. Protect from light.

Adverse Effects

As for Sympathomimetics, p.1407. Noradrenaline is an extremely potent peripheral vasoconstrictor and its adverse effects include hypertension (possibly associated with reflex bradycardia), headache, and peripheral ischaemia, which may be severe enough to result in gangrene of the extremities. Extravasation may lead to severe phlebitis and sloughing.

Dental use. Severe headache,[1,2] including fatal cerebral haemorrhage,[1,3] has been reported after the use of lidocaine with noradrenaline 1 in 25 000 for dental anaesthesia. It was suggested[1-3] that preparations containing noradrenaline 1 in 25 000 should not be used, and that a concentration of 1 in 80 000 was to be preferred. However, in the UK the *Dental Practitioners' Formulary*[4] had stated that noradrenaline should not be used as a vasoconstrictor in local anaesthetic solutions since it presented no advantage over adrenaline and carried additional hazard.

1. Boakes AJ, *et al.* Adverse reactions to local anaesthetic/vasoconstrictor preparations: a study of the cardiovascular responses to Xylestesin and Hostacain-with-Noradrenaline. *Br Dent J* 1972; **133:** 137–40.

3. Okada Y, *et al.* Fatal subarachnoid haemorrhage associated with dental local anaesthesia. *Aust Dent J* 1989; **34:** 323–5.
4. *Dental Practitioners' Formulary.* 2002–2004. London: British Dental Association, British Medical Association, and the Royal Pharmaceutical Society of Great Britain; 2002. D6.

Treatment of Adverse Effects

As for Sympathomimetics, p.1407. If extravasation occurs, infiltration with phentolamine (see p.1370) as soon as possible, and certainly within 12 hours, may relieve pain and prevent tissue necrosis.

Precautions

As for Sympathomimetics, p.1407. Noradrenaline has mainly alpha-agonist properties and must be avoided in the presence of hypertension; blood pressure and infusion rate must be monitored frequently. Noradrenaline-induced cardiac arrhythmias are more likely in patients with hypoxia or hypercapnia.

Noradrenaline is a severe tissue irritant and only very dilute solutions should be used. It should be infused centrally or into a large vein if possible, and care should be taken to avoid extravasation.

Noradrenaline may reduce placental perfusion throughout pregnancy and some consider that it and similar vasoconstrictor sympathomimetics are best avoided; also in late pregnancy noradrenaline provokes uterine contractions which can result in fetal asphyxia.

Interactions

As for Sympathomimetics, p.1407. Severe hypertension may occur if noradrenaline is given to patients taking tricyclic antidepressants since tricyclics block the uptake of noradrenaline into nerve endings.

Pharmacokinetics

Like adrenaline (p.1204), noradrenaline is inactive when given orally, and it is rapidly inactivated in the body by similar processes. When given intravenously it is extensively metabolised and only small amounts are excreted unchanged in the urine.

Uses and Administration

Noradrenaline is a direct-acting catecholamine sympathomimetic (p.1408) with pronounced effects on alpha-adrenergic receptors; it also stimulates $beta_1$ receptors but has little effect on $beta_2$ receptors. It is the major neurotransmitter in postganglionic adrenergic neurones, and is stored in granules in the nerve axons. Some is also present in the adrenal medulla and is released with adrenaline.

The major effects of noradrenaline relate to its alpha-agonist properties. It causes peripheral vasoconstriction, leading to an increase in systolic and diastolic blood pressure, which is accompanied by reflex slowing of the heart rate. Blood flow is reduced in the kidneys, liver, skin, and usually skeletal muscle. Noradrenaline causes the pregnant uterus to contract; high doses liberate glucose from the liver and have other hormonal effects similar to those of adrenaline. Beta-stimulant effects of noradrenaline have a positive inotropic action on the heart, but there is little bronchodilator effect. It produces little stimulation of the CNS.

Noradrenaline is used for the emergency restoration of blood pressure in acute hypotensive states such as shock (p.1183). It has also been used in the management of cardiac arrest. Noradrenaline has been used in local anaesthesia to diminish the absorption and localise the effect of the local anaesthetic (p.1852) but adrenaline is now preferred (see also Dental use under Adverse Effects, above). Locally applied solutions have been used to control bleeding in upper gastrointestinal haemorrhage and similar disorders.

In **acute hypotensive states**, noradrenaline is used as the acid tartrate, or occasionally as the hydrochloride, but doses are expressed in terms of the base; noradrenaline acid tartrate 2 micrograms or noradrenaline hydrochloride 1.2 micrograms are equivalent to about 1 microgram of noradrenaline. It is given by intravenous infusion of a solution containing the equivalent of 4 micrograms of the base per mL in glucose 5%, or sodium chloride 0.9% and glucose 5%. To avoid tissue necrosis the infusion should be given through a central venous catheter or into a large vein high up in a limb, preferably the arm. Some sources have suggested that addition of phentolamine 5 to 10 mg/litre to the infusion may prevent sloughing, should extravasation occur, without affecting the vasopressor action. The infusion is usually given initially at a rate of 2 to 3 mL/minute (8 to 12 micrograms/minute) and adjusted according to the blood pressure response. Blood pressure is initially recorded every 2 minutes and the rate of infusion continuously monitored. The infusion must not be stopped suddenly but should be gradually withdrawn to avoid disastrous falls in blood pressure. The average maintenance dose is 0.5 to 1 mL/minute (2 to 4 micrograms/minute), but there is a wide variation and higher doses may be required. The concentration of the infusion may be altered according to clinical needs. Alternatively a solution containing the equivalent of 40 micrograms of the base per mL may be given at an initial rate of 0.16 to 0.33 mL/minute via a central venous catheter, using a syringe pump or drip counter.

Preparations

Olmesartan Medoxomil *(BAN, USAN, rINN)*

CS-866; Olmésartan Médoxomil; Olmesartán medoxomilo; Olmesartanum Medoxomilum; RNH-6270 (olmesartan). (5-Methyl-2-oxo-1,3-dioxol-4-yl) methyl ester of 4-(1-Hydroxy-1-methylethyl)-2-propyl-1-{[2′-(1*H*-tetrazol-5-yl)[1,1′-biphenyl]-4-yl]methyl}-1*H*-imidazole-5-carboxylic acid.

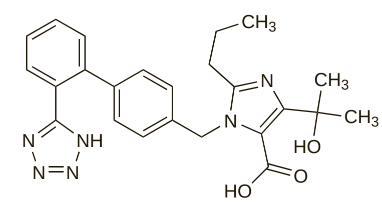
Ольмезартан Медоксомил

$C_{29}H_{30}N_6O_6 = 558.6.$

CAS — 144689-24-7 (olmesartan); 144689-63-4 (olmesartan medoxomil).

ATC — C09CA08.

ATC Vet — QC09CA08.



(olmesartan)

NOTE. The name olmesartan has been applied to both the base and to the medoxomil ester.

Adverse Effects and Precautions

As for Losartan Potassium, p.1326.

Interactions

As for Losartan Potassium, p.1327.

Pharmacokinetics

Olmesartan medoxomil is an ester prodrug that is hydrolysed during absorption from the gastrointestinal tract to the active form olmesartan. The absolute bioavailability is about 26%. Peak plasma concentrations of olmesartan occur about 1 to 2 hours after oral doses. Olmesartan is at least 99% bound to plasma proteins. It is excreted in the urine and the bile as olmesartan; about 35 to 50% of the absorbed dose is excreted in the urine and the remainder in the bile. The terminal elimination half-life is between 10 and 15 hours.

◊ References.

Uses and Administration

Olmesartan is an angiotensin II receptor antagonist with actions similar to those of losartan (p.1327). It is used in the management of hypertension (p.1171).

Olmesartan is given orally as the ester prodrug olmesartan medoxomil. After a dose the hypotensive effect lasts for 24 hours. Most of the hypotensive effect is apparent within 2 weeks after starting therapy and is maximal within about 8 weeks.

In hypertension, olmesartan medoxomil is given in a usual dose of 20 mg once daily, although in the UK an initial dose of 10 mg once daily is recommended. The dose may be increased to 40 mg once daily if required.

For doses in hepatic or renal impairment, see below.

10. Barrios V, Escobar C. Olmesartan medoxomil plus hydrochlorothiazide for treating hypertension. *Expert Opin Pharmacother* 2008; **9:** 129–36.

Administration in hepatic or renal impairment. Olmesartan is excreted in both urine and bile and raised plasma concentrations have been noted in patients with renal or hepatic impairment. In patients with *renal impairment*, licensed product information in the UK does not recommend the use of olmesartan in severe impairment (creatinine clearance (CC) below 20 mL/minute) since experience is limited, and the maximum dose in mild to moderate impairment (CC 20 to 60 mL/minute) is 20 mg once daily. Similarly, in patients with *hepatic impairment*, licensed product information in the UK does not recommend the use of olmesartan in severe impairment since there is no experience. Those with moderate hepatic impairment should be given an initial dose of 10 mg once daily and the maximum dose is 20 mg once daily.

Migraine. For reference to the use of angiotensin II receptor antagonists, including olmesartan, in the prophylaxis of migraine, see under Losartan, p.1328.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Omega-3-Acid Ethyl Esters 60). A mixture of ethyl esters of omega-3 acids. They are obtained by transesterification of the body oil of fat fish species coming from families such as Engraulidae, Carangidae, Clupeidae, Osmeridae, Salmonidae, and Scombridae. The acids consist of alpha-linolenic acid, moroctic acid, eicosatetraenoic acid, eicosapentaenoic acid (timnodonic acid), heneicosapentaenoic acid, clupanodonic acid, and docosahexaenoic acid (cervonic acid). The total amount of omega-3 acid ethyl esters, eicosapentaenoic acid ethyl esters, and docosahexaenoic acid ethyl esters should be stated on the label. For a total omega-3 acid ethyl ester content of 55%, the amount of eicosapentaenoic acid ethyl esters and docosahexaenoic acid ethyl esters together is not less than 50% and the content of eicosapentaenoic acid ethyl esters is not less than 40%; for a total omega-3 acid ethyl ester content of 60%, the amount of eicosapentaenoic acid ethyl esters and docosahexaenoic acid ethyl esters together is not less than 50% and the content of docosahexaenoic acid ethyl esters is not less than 40%; and for a total omega-3 acid ethyl ester content of 65%, the amount of eicosapentaenoic acid ethyl esters and docosahexaenoic acid ethyl esters together is not less than 50%, the content of eicosapentaenoic acid ethyl esters is not less than 25%, and the content of docosahexaenoic acid ethyl esters is not less than 20%. Tocopherol may be added as an antioxidant.

A light yellow liquid with a slight fish-like odour. Practically insoluble in water; very soluble in acetone, in dehydrated alcohol, in heptane, and in methyl alcohol. Store in airtight containers under inert gas. Protect from light.

Ph. Eur. 6.2 (Omega-3-Acid Ethyl Esters 90). A mixture of ethyl esters of omega-3 acids. They are obtained by transesterification of the body oil of fat fish species coming from families such as Engraulidae, Carangidae, Clupeidae, Osmeridae, Salmonidae, and Scombridae. The acids consist of alpha-linolenic acid, moroctic acid, eicosatetraenoic acid, eicosapentaenoic acid (timnodonic acid), heneicosapentaenoic acid, clupanodonic acid, and docosahexaenoic acid (cervonic acid). The total amount of omega-3 acid ethyl esters is not less than 90%, and that of both eicosapentaenoic acid ethyl esters and docosahexaenoic acid ethyl esters together is 80%; the content of eicosapentaenoic acid ethyl esters is not less than 40% and of docosahexaenoic acid ethyl esters is not less than 34%. Tocopherol may be added as an antioxidant.

A light yellow liquid with a slight fish-like odour. Practically insoluble in water; very soluble in acetone, in dehydrated alcohol, in heptane, and in methyl alcohol. Store in airtight containers under inert gas. Protect from light.

Omega-3 Marine Triglycerides

Deniz Kaynaklı Omega-3 Trigliseridler; Poisson (huile de) riche en acides oméga-3 (fish oil, rich in omega-3-acids); Saumon d'élevage, huile de (salmon oil, farmed); Triglicéridos marinos omega 3.

Омега-3 Триглицериды Морского Происхождения

NOTE. Omega-3 Marine Triglycerides (BAN) is a mixture of triglycerides of fatty acids from marine fish containing the equivalent of about 18% of eicosapentaenoic acid and 12% of docosahexaenoic acid. The content of triglycerides is not the same as that in Omega-3-Marine Triglycerides BP.

Pharmacopoeias. *Eur.* (see p.vii) includes Omega-3-Acid Triglycerides, Fish Oil, Rich in Omega-3-Acids, and Salmon Oil, Farmed. *US* includes Fish Oil containing Omega-3 Acids.

Ph. Eur. 6.2 (Omega-3-Acid Triglycerides; Omega-3 Acidorum Triglycerida; Omega-3-Marine Triglycerides). A mixture of mono-, di-, and triesters of omega-3 acids with glycerol, containing mainly triesters. They are obtained by esterification of concentrated and purified omega-3 acids with glycerol or by transesterification of the omega-3 acid ethyl esters with glycerol. The omega-3 acids are from the body oil of fatty fish species coming from families such as Engraulidae, Carangidae, Clupeidae, Osmeridae, Salmonidae, and Scombridae. The acids consist of alpha-linolenic acid, moroctic acid, eicosatetraenoic acid, eicosapentaenoic acid (timnodonic acid), heneicosapentaenoic acid, clupanodonic acid, and docosahexaenoic acid (cervonic acid). The total amount of omega-3 acids expressed as triglycerides is not less than 60% and that of both eicosapentaenoic acid and docosahexaenoic acid together, expressed as triglycerides, is not less than 45%. Tocopherol may be added as an antioxidant.

A pale yellow liquid. Practically insoluble in water; slightly soluble in dehydrated alcohol; very soluble in acetone and in heptane. Store in well-filled, airtight containers under inert gas. Protect from light.

Ph. Eur. 6.2 (Fish Oil, Rich in Omega-3-Acids; Piscis Oleum Omega-3 Acidis Abundans). The purified, winterised, and deodorised fatty oil obtained from fish of the families Engraulidae, Carangidae, Clupeidae, Scombridae, and Ammodytidae. The acids consist of alpha-linolenic acid, moroctic acid, eicosatetraenoic acid, eicosapentaenoic acid (timnodonic acid), heneicosapentaenoic acid, clupanodonic acid, and docosahexaenoic acid (cervonic acid). The minimum content, expressed as triglycerides, is eicosapentaenoic acid 13%, docosahexaenoic acid 9%, and total omega-3 acids 28%. Antoxidants may be added.

A pale yellow liquid. Practically insoluble in water; slightly soluble in dehydrated alcohol; very soluble in acetone and in heptane. Store in well-filled, airtight containers under inert gas. Protect from light.

Ph. Eur. 6.2 (Salmon Oil, Farmed; Salmonis Domestici Oleum). The purified fatty oil obtained from fresh farmed *Salmo salar.* The positional distribution (β(2)-acyl) is 60 to 70% for docosahexaenoic acid (cervonic acid), 25 to 35% for eicosapentaenoic acid (timnodonic acid), and 40 to 55% for moroctic acid. The sum of the contents of eicosapentaenoic acid and docosahexaenoic acid, expressed as triglycerides, is 10.0 to 28.0%. Authorised antoxidants may be added. A pale pink liquid. Practically insoluble in water; slightly soluble in dehydrated alcohol; very soluble in acetone and in heptane. Store in well-filled airtight containers under an inert gas. Protect from light.

USP 31 (Fish Oil containing Omega-3 Acids). The purified, winterised, and deodorised fatty oil obtained from fish of the families Engraulidae, Carangidae, Clupeidae, Osmeridae, Scombroidae, and Ammodytidae. The acids consist of alpha-linolenic acid, moroctic acid, eicosatetraenoic acid, eicosapentaenoic acid (EPA), heneicosapentaenoic acid, docosapentaenoic acid, and docosahexaenoic acid (DHA). It contains not less than 28% (w/w) of total omega-3 acids (expressed as free acids) consisting of not less than 13% of EPA and not less than 9% of DHA. Antoxidants may be added. A pale yellow liquid. Practically insoluble in water; slightly soluble in anhydrous alcohol; very soluble in acetone and in heptane. Store in airtight containers at a temperature of 20° to 25°, excursions permitted between 15° and 30°. It may be stored under vacuum or under an inert gas. Protect from light.

Adverse Effects and Precautions

The most common adverse effects of omega-3 fatty acid preparations are gastrointestinal disturbances, particularly at high doses, including nausea, eructation, vomiting, abdominal distension, diarrhoea, and constipation. There have been rare reports of acne and eczema. Moderate increases in hepatic transaminases have been reported in patients with hypertriglyceridaemia.

Preparations vary widely in concentration and purity. Some preparations contain significant amounts of vitamins A and D and long-term use could cause toxicity. There is a theoretical possibility of vitamin E deficiency with long-term use, although many preparations contain vitamin E as an antoxidant. Concern has been expressed over the high calorific value and cholesterol content of some preparations.

Omega-3 fatty acids have antithrombotic activity and should be given with caution to patients with haemorrhagic disorders or to those receiving anticoagulants or other drugs affecting coagulation. Hepatic function should be monitored in patients with hepatic impairment, particularly if receiving high doses. Caution may also be required in asthmatic patients sensitive to aspirin since omega-3 fatty acids may affect prostaglandin synthesis (but see Inflammatory and Auto-immune Disorders, below, for studies of fish oils in the management of asthma).

◊ Reviews.

Effects on the blood. Omega-3 fatty acids have antithrombotic effects and may increase bleeding. In a study[1] in adolescents with familial hypercholesterolaemia, epistaxis occurred in 8 of 11 patients treated with a fish oil supplement; prolonged bleeding time was noted in 3 patients. There have also been case reports of INR elevation and haematoma in patients taking fish oil preparations with antithrombotics (see Lipid Regulating Drugs under Interactions of Warfarin, p.1431), although controlled studies have failed to show an effect.

Effects on glucose metabolism. Although a deterioration in glycaemic control has been reported in diabetic patients taking omega-3 fatty acids and fish oil preparations, a meta-analysis[1] of studies in type 1 and type 2 diabetics, and a systematic review[2] of controlled studies in type 2 diabetics, both concluded that fish oils effectively lowered triglycerides without a deleterious effect on glycaemic control.

Uses and Administration

Omega-3 fatty acids are long-chain polyunsaturated fatty acids containing 18 to 22 carbon atoms and a varying number of double bonds, the first of which is in the n-3 position. They are essential fatty acids and must be obtained from the diet. They have an important role as eicosanoid precursors and as components of cell membranes; in humans, they compete with arachidonic acid, an omega-6 fatty acid precursor. Their actions in humans include a hypolipidaemic action (especially a reduction in plasma triglycerides), an anti-inflammatory action, and an antiplatelet effect. The main dietary omega-3 fatty acids are eicosapentaenoic acid and docosahexaenoic acid and are derived from marine fish; other omega-3 fatty acids found in fish oils (defined in terms of number of carbon atoms and number of double bonds) include alpha-linolenic acid, moroctic acid (C18:4), eicosatetraenoic acid (C20:4), heneicosapentaenoic acid (C21:5), and clupanodonic acid (C22:5). Alpha-linolenic acid is also found in some plant sources and is converted to a limited extent in the body to eicosapentaenoic acid and docosahexaenoic acid.

Fish oils and purified omega-3 fatty acid preparations are used in patients with severe hypertriglyceridaemia (see Hyperlipidaemias, p.1169) and for secondary prevention after myocardial infarction (see Cardiovascular Disorders below). They are also marketed as dietary supplements, and are used in preparations for parenteral nutrition.

The preparations available vary widely in purity and omega-3 fatty acid content, usually expressed in terms of eicosapentaenoic acid and docosahexaenoic acid; the fatty acids may be present as triglycerides or as ethyl esters. Typical oral doses of fish oil for the treatment of hypertriglyceridaemia are 5 g twice daily of a preparation containing 17% eicosapentaenoic acid and 11.5% docosahexaenoic acid, or 2 to 4 g daily of a preparation containing 46% eicosapentaenoic acid and 38% docosahexaenoic acid. For the secondary prevention of myocardial infarction, 1 g daily of a preparation containing 46% eicosapentaenoic acid and 38% docosahexaenoic acid may be given. Eicosapentaenoic acid ethyl ester may also be used alone in the treatment of hyperlipidaemia, and to improve the symptoms associated with arteriosclerosis obliterans.

Action. Interest in omega-3 fatty acids arose from observations that populations with a diet rich in marine fish oils generally have a low incidence of cardiovascular disease, while the incidence of asthma, psoriasis, and auto-immune diseases appears to be lower among Eskimos (Inuit) than in populations consuming a typical western diet (although the incidence of haemorrhagic stroke and epilepsy may be higher). Increased omega-3 fatty acid intake has been suggested to underlie these differences, and fish oil and other omega-3 preparations have therefore been promoted as dietary supplements, with benefit suggested for many conditions.

The beneficial health effects of omega-3 fatty acids have been attributed to their effects on eicosanoid balance, lipid metabolism, and cell membranes. Essential fatty acids of both the omega-3 and omega-6 series have an important role as components of cell membranes and as precursors of eicosanoids (prostaglandins, leukotrienes, and thromboxanes). Eicosanoids derived from omega-3 fatty acids generally have anti-inflammatory, antithrombotic, antiarrhythmic, and vasodilator effects, while those derived from omega-6 fatty acids tend to be pro-inflammatory and prothrombotic. Since omega-3 and omega-6 fatty acids compete for the same enzymatic pathways, increasing the intake of omega-3 fatty acids promotes the formation of anti-inflammatory and antithrombotic eicosanoids, and may have beneficial effects. Production of inflammatory cytokines such as interleukins and tumour necrosis factor alpha may also be affected.

For further information on the actions of omega-3 fatty acids in cardiovascular disorders, inflammatory and auto-immune disorders, malignant neoplasms, and neurological and psychiatric disorders, see below.

Cardiovascular disorders. Omega-3 fatty acids have a number of actions that are potentially beneficial for patients at risk of cardiovascular disease.[1-6] They have a hypolipidaemic effect due to inhibition of very-low-density lipoprotein (VLDL) synthesis in the liver, and this particularly reduces triglyceride concentrations.[7] Heart rate may be reduced,[8] and they also have an antiarrhythmic effect,[5] possibly due to a direct action on myocardial cells. Omega-3 fatty acids may also reduce blood pressure in hypertensive patients,[9] as well as increasing erythrocyte deformability and decreasing blood viscosity. They appear to stabilise atherosclerotic plaques,[10] and may reduce progression of atherosclerosis[11] and of restenosis after percutaneous coronary intervention.[12]

Despite these benefits, the role of dietary or supplementary omega-3 fatty acids for cardiovascular risk reduction (p.1164) remains controversial. Epidemiological studies have suggested that increased dietary fish intake is associated with a reduced risk of fatal coronary events,[13] and possibly also ischaemic stroke,[14,15] and there is also evidence for benefit with omega-3 fatty acid supplements, particularly for secondary prevention.[1-4,16] In the GISSI-Prevenzione study,[17] long-term use of omega-3 fatty acid supplements reduced the risk of fatal cardiovascular events in a large group of Italian post-infarction patients studied for 3.5 years,[17] while the JELIS investigators[18] reported a reduction in primary and secondary cardiovascular events in Japanese patients with hypercholesterolaemia. However, a systematic review[19] found no clear benefit from omega-3 fatty acids, whether dietary or supplemental, in people with or without cardiac risk factors.

Inflammatory and auto-immune disorders. Omega-3 fatty acids have effects on several immunological and inflammatory mediators[1,2] and have been tried in a number of inflammatory and auto-immune disorders. Beneficial effects have been reported in rheumatoid arthritis[3] (p.11) and in glomerular kidney disease[4-6] (p.1504), but results in kidney transplantation (p.1813) have been mixed, and systematic reviews[7,8] suggest no significant effect on rejection episodes or graft survival. Some studies have shown benefit in psoriasis (p.1583), both with oral[9,10] and with intravenous dosage,[11,12] but other studies found neither the oral[13] nor the topical[14] route to be effective. Variable benefit has been seen in inflammatory bowel disease[15] (p.1697) although this may relate to the different formulations used. In Crohn's disease, a systematic review found that enteric-coated formulations helped to maintain remission,[16] but a subsequent randomised study using a gelatin capsule formulation found no benefit.[17] Similarly, a systematic review found that conventional formulations were not of benefit in patients with ulcerative colitis.[18] Fish oils have also been tried in lung disorders, although systematic reviews have found little evidence of benefit in asthma;[19,20] in cystic fibrosis, limited benefit has been reported,[21] with one study[22] reporting that fish oil supplementation reduced the need for antibacterial treatment. Preliminary evidence[23] also suggests that omega-3 supplementation may reduce inflammatory markers and improve dyspnoea in chronic obstructive pulmonary disease.

Malignant neoplasms. There is some evidence that the incidence of cancer may be lower in populations with a high fish intake, and *animal* studies have suggested that omega-3 fatty acids may slow the progression of some cancers.[1] However, studies of omega-3 fatty acid intake and cancer incidence in humans have given conflicting results, and systematic reviews[2,3] have found no evidence of a beneficial effect. It has also been suggested that omega-3 fatty acids might be beneficial in patients with cancer cachexia, but a randomised study[4] found that eicosapentaenoic acid supplementation was less effective than megestrol acetate, and a systematic review[5] found insufficient evidence to establish whether eicosapentaenoic acid was more effective than placebo.

Neurological and psychiatric disorders. Omega-3 fatty acids concentrate in neuronal membranes and appear to have an important role in brain development and function. Supplementation during pregnancy and in infants has been investigated, but there is little evidence that maternal supplements improve neonatal outcomes,[1] and only limited evidence of a benefit on growth and neurodevelopment in preterm infants given milk formulas supplemented with both omega-3 and omega-6 fatty acids.[2,3] However, in older children with phenylketonuria treated with dietary restriction, omega-3 fatty acid supplements may improve motor skills.[4]

Omega-3 fatty acids have also been tried in the treatment of neurological and psychiatric disorders.[5,6] There appears to be a link between deficient fatty acid intake and mood disorders,[7] and there is reasonable evidence to support the use of omega-3 fatty acids as adjuncts in the treatment of depression, including possible benefit in the depressive symptoms of bipolar disorder, but further studies are needed to confirm this.[8-10] Benefit has been shown in schizophrenia, but results have been mixed and the role of omega-3 fatty acids is not established.[11] Some positive results have been reported in hyperactivity and in autism, but further studies are needed.[12] Omega-3 fatty acids have also been tried in dementia, but there is not yet sufficient evidence[13] to recommend them for prevention.

Eicosapentaenoic acid ethyl ester has been tried in Huntington's disease, and may improve motor function,[14] but this remains to be confirmed.

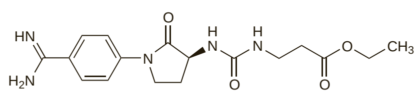
Orbofiban Acetate *(USAN, rINNM)*

Acetato de orbofibrán; CS-511; Orbofiban, Acétate d'; Orbofibani Acetas; SC-57099-B. *N*-{[(3*S*)-1-(*p*-Amidinophenyl)-2-oxo-3-pyrrolidinyl]carbamoyl}-β-alanine ethyl ester monoacetate quadrantihydrate.

Орбофибана Ацетат

$C_{17}H_{23}N_5O_4,C_2H_4O_2,¼H_2O$ = 426.0.
CAS — 163250-90-6 (orbofiban); 165800-05-5 (orbofiban acetate).



(orbofiban)

Profile

Orbofiban is a glycoprotein IIb/IIIa-receptor antagonist. It has been investigated as an oral antiplatelet drug in unstable angina and myocardial infarction but has been associated with an increase in mortality.

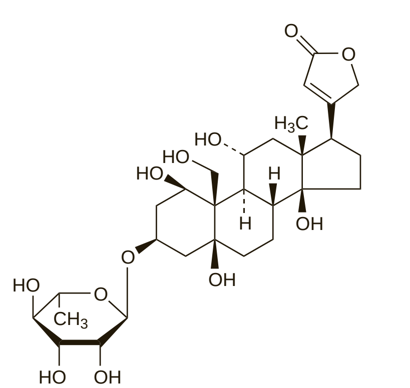
◊ References.

1. Cannon CP, *et al.* Oral glycoprotein IIb/IIIa inhibition with orbofiban in patients with unstable coronary syndromes (OPUS-TIMI 16) trial. *Circulation* 2000; **102:** 149–56.

Ouabain

Acocantherin; G-Strophanthin; Ouabaiini; Ouabain oktahydrát; Ouabaína; Ouabainas; Ouabaïne; Ouabainum; Ouabainum Octahydricum; Strophanthin-G; Strophanthinum; Strophanthoside-G; Uabaina; Ubaína. 3β-(α-L-Rhamnopyranosyloxy)-1β,5,11α,-14,19-pentahydroxy-5β,14β-card-20(22)-enolide octahydrate.

$C_{29}H_{44}O_{12},8H_2O$ = 728.8.
CAS — 630-60-4 (anhydrous ouabain); 11018-89-6 (ouabain octahydrate).
ATC — C01AC01.
ATC Vet — QC01AC01.



Pharmacopoeias. In *Eur.* (see p.vii) and *Viet.*

Ph. Eur. 6.2 (Ouabain). Colourless crystals or white or almost white, crystalline powder. Sparingly soluble in water and in dehydrated alcohol; practically insoluble in ethyl acetate. Protect from light.

Profile

Ouabain is a cardiac glycoside with positive inotropic activity that is obtained from the seeds of *Strophanthus gratus* or from the wood of *Acokanthera schimperi* or *A. ouabaio* (Apocynaceae). It has general properties similar to those of digoxin (p.1259) and may be used in the treatment of heart failure (p.1165). Ouabain is given orally in a dose of up to 24 mg daily; it has also been given intravenously.

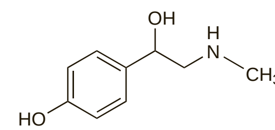
Preparations

Proprietary Preparations (details are given in Part 3)
Ger.: Strodival.

Oxedrine *(BAN)* ⊗

Oksedriini; Oxedrin; Oxedrinum; Sinefrina; Sympaethaminum; Synephrine; *p*-Synephrine. (*RS*)-1-(4-Hydroxyphenyl)-2-(methylamino)ethanol.

$C_9H_{13}NO_2$ = 167.2.
CAS — 94-07-5.
ATC — C01CA08; S01GA06.
ATC Vet — QC01CA08; QS01FB90; QS01GA06.



NOTE. Synephrine and *p*-synephrine have been used as synonyms for oxedrine. Care should be taken to avoid confusion with *m*-synephrine, which is phenylephrine (p.1568).

Oxedrine Hydrochloride *(BANM)* ⊗

Sinefrina, hidrocloruro de.

$C_9H_{13}NO_2,HCl$ = 203.7.
ATC — C01CA08; S01GA06.
ATC Vet — QC01CA08; QS01GA06.

Oxedrine Tartrate *(BANM)* ⊗

Aetaphen. Tartrat.; Aethaphenum Tartaricum; Oksedriinitartraatti; Oxedrini Tartras; Oxedrintartrat; Oxyphenylmethylaminoethanol Tartrate; Sinefrina Tartrato; Sinefrina, tartrato de; Synephrine Tartrate.

$(C_9H_{13}NO_2)_2,C_4H_6O_6$ = 484.5.
CAS — 16589-24-5 (oxedrine tartrate); 67-04-9 (±oxedrine tartrate).
ATC — C01CA08; S01GA06.
ATC Vet — QC01CA08; QS01GA06.

Profile

Oxedrine is a sympathomimetic (p.1407) given as the tartrate in the treatment of hypotensive states in oral doses of about 100 to 150 mg three times daily; it has also been given by subcutaneous, intramuscular, or intravenous injection.

Oxedrine is also used in eye drops as an ocular decongestant, usually as the tartrate in a concentration of 0.5% in combination preparations. The hydrochloride has also been used.

Preparations

Proprietary Preparations (details are given in Part 3)
Austria: Sympatol; ***Hong Kong:*** Ocuton; ***Hung.:*** Sympathomim; ***Ital.:*** Sympatol; ***Switz.:*** Sympalept.

Multi-ingredient: ***Austria:*** Dacrin; Pasuma-Dragees; ***Fr.:*** Dacryne; Dacryoboraline; Polyfra; Posine†; Sedacollyre; Uvicol.

Oxilofrine Hydrochloride *(rINNM)* ⊗

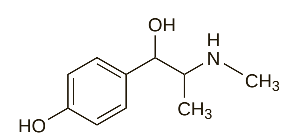
Оксилофрина Гидрохлорид

$C_{10}H_{15}NO_2,HCl$ = 217.7.
CAS — 942-51-8.



(oxilofrine)

Profile
Oxilofrine is a sympathomimetic (p.1407) related to ephedrine (p.1558). It is given orally as the hydrochloride in the treatment of hypotensive states in usual doses of 16 mg three times daily, although higher doses have been given. It has also been used in antitussive preparations.

Preparations
Proprietary Preparations (details are given in Part 3)
Austria: Carnigen; ***Ger.:*** Carnigen.

Multi-ingredient: ***Canad.:*** Cophylac.

Oxprenolol Hydrochloride
(BANM, USAN, rINNM) ⊗

Ba-39089; Hidrocloruro de oxiprenolol; Hidrocloruro de oxprenolol; Okspreonolol Hidroklorür; Oksprenololihydrokloridi; Oksprenololio hidrochloridas; Oksprenololu chlorowodorek; Oxprénolol, chlorhydrate d'; Oxprenolol hydrochlorid; Oxprenolol-hidroklorid; Oxprenololhydroklorid; Oxprenololi hydrochloridum; Oxyprenolol Hydrochloride. 1-(o-Allyloxyphenoxy)-3-isopropylaminopropan-2-ol hydrochloride.

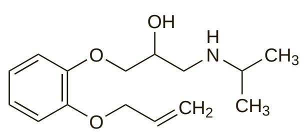
Окспренолола Гидрохлорид

$C_{15}H_{23}NO_3,HCl = 301.8.$

CAS — 6452-71-7 (oxprenolol); 6452-73-9 (oxprenolol hydrochloride).

ATC — C07AA02.

ATC Vet — QC07AA02.



(oxprenolol)

NOTE. Compounded preparations of oxprenolol hydrochloride may be represented by the following names:

- Co-prenozide (*BAN*)—oxprenolol hydrochloride 640 parts and cyclopenthiazide 1 part (w/w).

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US*. *Chin.* includes the base.

Ph. Eur. 6.2 (Oxprenolol Hydrochloride). A white or almost white, crystalline powder. Very soluble in water; freely soluble in alcohol. A 10% solution in water has a pH of 4.5 to 6.0. Protect from light.

USP 31 (Oxprenolol Hydrochloride). A white crystalline powder. Freely soluble in water, in alcohol, and in chloroform; sparingly soluble in acetone; practically insoluble in ether. A 10% solution in water has a pH of 4.0 to 6.0.

Adverse Effects, Treatment, and Precautions
As for Beta Blockers, p.1226.

Breast feeding. Oxprenolol is distributed into breast milk but the amount likely to be ingested by an infant is small (see under Pharmacokinetics, below). No adverse effects have been seen in breast-fed infants whose mothers were given oxprenolol and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 10/01/08)

Hypersensitivity. Oxprenolol-induced drug fever has been reported[1] in a patient and was confirmed by a challenge test.

1. Hasegawa K, *et al*. Drug fever due to oxprenolol. *BMJ* 1980; **281:** 27–8.

Overdosage. Rhabdomyolysis with myoglobinuria has been reported[1] as a complication of severe overdosage with oxprenolol.

1. Schofield PM, *et al*. Recovery after severe oxprenolol overdose complicated by rhabdomyolysis. *Hum Toxicol* 1985; **4:** 57–60.

Interactions
The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics
Oxprenolol is well absorbed from the gastrointestinal tract, but is subject to first-pass metabolism resulting in variable bioavailability (20 to 70%). Peak plasma concentrations occur about 1 or 2 hours after a dose. Oxprenolol is about 80% bound to plasma proteins. It crosses the placenta and is distributed into breast milk. It is moderately lipid-soluble and crosses the blood-brain barrier. Oxprenolol is metabolised in the liver and almost entirely excreted in the urine. An elimination half-life of 1 to 2 hours has been reported.

Pregnancy and breast feeding. The placental transfer of oxprenolol and its passage into breast milk was studied[1] in 32 pregnant women given a preparation containing oxprenolol and dihydralazine (*Trasipressol*). At delivery the mean maternal plasma concentration was 0.386 nanomoles/mL compared with 0.071 and 0.081 nanomoles/mL in plasma from the umbilical artery and vein respectively. Oxprenolol plasma concentrations in the newborn ranged from 0 to 0.186 nanomoles/mL during the first 24 hours of life. The concentrations of oxprenolol in breast milk 3 to 6 days after delivery ranged from 0 to 1.342 nanomoles/mL, and the milk to plasma concentration ratio was 0.45:1. Based on the highest milk concentration seen it was calculated that a breast-fed infant could receive, at a maximum, a daily dose at least 60 times less than an average adult daily dose (240 mg daily) for hypertension. In another study[2] in 12 women given oxprenolol, mean milk to plasma concentration ratios were 0.21:1 to 0.43:1, depending on dose.

1. Sioufi A, *et al*. Oxprenolol placental transfer, plasma concentrations in newborns and passage into breast milk. *Br J Clin Pharmacol* 1984; **18:** 453–6.
2. Fidler J, *et al*. Excretion of oxprenolol and timolol in breast milk. *Br J Obstet Gynaecol* 1983; **90:** 961–5.

Uses and Administration
Oxprenolol is a non-cardioselective beta blocker (p.1225). It is reported to possess intrinsic sympathomimetic and membrane-stabilising activity.

Oxprenolol is given orally as the hydrochloride in the management of hypertension (p.1171), angina pectoris (p.1157), and cardiac arrhythmias (p.1160). It is also used in anxiety disorders (p.952).

In **hypertension** oxprenolol hydrochloride is given in a usual dose of 80 to 160 mg daily in two or three divided doses. The dose may be increased at weekly or fortnightly intervals until a satisfactory response is achieved. The usual maximum dose is 320 mg daily although up to 480 mg daily has been given.

The usual dose for **angina pectoris** is 80 to 160 mg daily in two or three divided doses with a usual maximum of 320 mg daily.

For **cardiac arrhythmias** a dose of 40 mg daily to not more than 240 mg daily in two or three divided doses may be used.

To relieve **anxiety** in stressful situations oxprenolol hydrochloride is given in usual doses of 40 to 80 mg daily, either as a single dose or in two divided doses.

Modified-release preparations allowing once daily dosing are also available.

Preparations
BP 2008: Oxprenolol Tablets;
USP 31: Oxprenolol Hydrochloride Extended-release Tablets; Oxprenolol Hydrochloride Tablets.

Proprietary Preparations (details are given in Part 3)
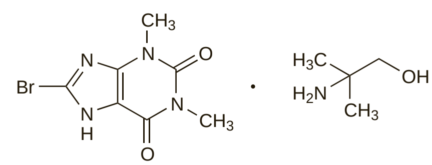
Austria: Ildamen; ***Cz.:*** Myofedrin†; ***Ger.:*** Ildamen†; Myofedrin†; ***India:*** Ildamen; ***Philipp.:*** Ildamen; ***Port.:*** Ildamen.

Pamabrom *(USAN)* ⊗

Pamabromo. 2-Amino-2-methylpropan-1-ol 8-bromotheophyllinate.

$C_4H_{11}NO,C_7H_7BrN_4O_2 = 348.2.$

CAS — 606-04-2.



Pharmacopoeias. In *US*.

Profile
Pamabrom is a weak diuretic that has been used, with analgesics and antihistamines, for symptomatic relief of the premenstrual syndrome.

Preparations
Proprietary Preparations (details are given in Part 3)
USA: Maximum Strength Aqua-Ban.

Multi-ingredient: ***Arg.:*** Everfem; ***Canad.:*** Extra Strength Multi-Symptom PMS Relief†; Midol PMS Extra Strength; Painaid PMF; Pamprin; Relievol PMS; Trendar PMS†; Tylenol Menstrual; ***Chile:*** Kitadol Periodo Menstrual; Minfaden; Predual; Tapsin Periodo Menstrual; ***Malaysia:*** Panadol Menstrual; ***Mex.:*** Femsedin Kutz; ***Singapore:*** Panadol Menstrual; ***USA:*** Fem-1†; Lurline PMS; Midol Pre-Menstrual Syndrome; Midol Teen Formula; Painaid PMF Premenstrual Formula; Pamprin; Premsyn PMS; Womens Tylenol Multi-Symptom Menstrual Relief.

Pamiteplase *(rINN)*

Pamiteplasa; Pamitéplase; Pamiteplasum; YM-866. 275-L-Glutamic acid-(1–91)-(174–527)-plasminogen activator (human tissue-type protein moiety).

Памитеплаза

CAS — 151912-42-4.

Profile
Pamiteplase is a thrombolytic related to alteplase (p.1207) used in acute myocardial infarction. It has been investigated in ischaemic stroke.

Preparations
Proprietary Preparations (details are given in Part 3)
Jpn: Solinase†.

Pantethine

Pantetina. (*R*)-*NN*′-[Dithiobis(ethyleneiminocarbonylethylene)]-bis(2,4-dihydroxy-3,3-dimethylbutyramide).

Пантетин

$C_{22}H_{42}N_4O_8S_2 = 554.7.$

CAS — 16816-67-4.

ATC — A11HA32.

ATC Vet — QA11HA32.

Pharmacopoeias. In *Jpn*.

Profile
Pantethine, a derivative of pantothenic acid (p.1959), is a component of coenzyme A. It is used as a lipid regulating drug in the

treatment of hyperlipidaemias (p.1169). The usual oral dose is 600 to 1200 mg daily in divided doses.

Pantethine is also used as a nutritional supplement.

Preparations

Proprietary Preparations (details are given in Part 3)
Hong Kong: Pantomin†; ***Ital.:*** Pantetina; ***Jpn:*** Pantosin; ***Spain:*** Liponet†; Obliterol†.

Multi-ingredient: ***Ital.:*** Carpantin†.

Pargyline Hydrochloride *(BANM, USAN, rINNM)*

A-19120; Hidrocloruro de pargilina; MO-911; NSC-43798; Pargyline, Chlorhydrate de; Pargylini Hydrochloridum. *N*-Methyl-*N*-2-propynylbenzylamine hydrochloride; Benzylmethylprop-2-ynylamine hydrochloride.

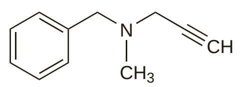
Паргилина Гидрохлорид

$C_{11}H_{13}N,HCl = 195.7.$

CAS — 555-57-7 (pargyline); 306-07-0 (pargyline hydrochloride).

ATC — C02KC01.

ATC Vet — QC02KC01.



(pargyline)

Profile

Pargyline hydrochloride is an MAOI (see Phenelzine Sulfate, p.415) that was formerly used in the treatment of moderate to severe hypertension.

Parnaparin Sodium *(BAN, rINN)*

OP-21-23; Parnapariininatrium; Parnaparin sodná sůl; Parnaparin Sodyum; Parnaparina sódica; Parnaparine sodique; Parnaparinnatrium; Parnaparin-nátrium; Parnaparino natrio druska; Parnaparinum natricum.

Парнапарин Натрий

CAS — 9041-08-1.

ATC — B01AB07.

ATC Vet — QB01AB07.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*

Ph. Eur. 6.2 (Parnaparin Sodium). It is prepared by hydrogen peroxide and cupric salt depolymerisation of heparin obtained from the intestinal mucosa of pigs and cattle. The majority of the components have a 2-*O*-sulfo-α-L-idopyranosuronic acid structure at the non-reducing end and a 2-*N*,6-*O*-disulfo-D-glucosamine structure at the reducing end of their chain. The mass-average molecular mass ranges between 4000 and 6000, with a characteristic value of about 5000. The mass percentage of chains lower than 3000 is not more than 30%. The degree of sulfation is 2.0 to 2.6 per disaccharide unit. Potency is not less than 75 units and not more than 110 units of anti-factor Xa activity per mg with reference to the dried substance, and the ratio of anti-factor Xa activity to anti-factor IIa (antithrombin) activity is between 1.5 and 3.0.

Profile

Parnaparin sodium is a low-molecular-weight heparin (p.1329) with anticoagulant activity used in the prevention of postoperative venous thromboembolism (p.1189); it has also been used in other thromboembolic disorders. For general surgical procedures it is given by subcutaneous injection in a dose of 3200 units 2 hours before the procedure, followed by 3200 units once daily for 7 days or until the patient is fully ambulant. For higher risk or orthopaedic patients a dose of 4250 units is given 12 hours before the procedure, followed by 4250 units 12 hours postoperatively and then once daily for 10 days.

For treatment of thromboembolism a dose of 6400 units may be given by subcutaneous injection for 7 to 10 days.

◊ References.

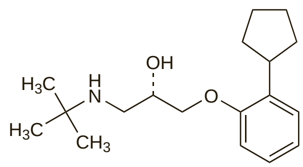
Пенбутолола Сульфат

$(C_{18}H_{29}NO_2)_2,H_2SO_4 = 680.9.$

CAS — 38363-40-5 (penbutolol); 38363-32-5 (penbutolol sulfate).

ATC — C07AA23.

ATC Vet — QC07AA23.



(penbutolol)

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US*.

Ph. Eur. 6.2 (Penbutolol Sulphate). A white or almost white, crystalline powder. Slightly soluble in water; practically insoluble in cyclohexane; soluble in methyl alcohol. Protect from light.

USP 31 (Penbutolol Sulfate). A white to off-white, crystalline powder. Soluble in water and in methyl alcohol. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics

Penbutolol is readily absorbed from the gastrointestinal tract and peak plasma concentrations occur about 1 to 3 hours after a dose. Penbutolol is 80 to 98% bound to plasma proteins. It has a high lipid solubility. It is extensively metabolised in the liver by hydroxylation and glucuronidation, the metabolites being excreted in the urine with only small amounts of unchanged penbutolol. A plasma elimination half-life of about 20 hours has been reported.

Renal impairment. Glucuronidation was considered more prominent than hydroxylation in the metabolism of penbutolol and its activity was not altered in patients with renal impairment.[1]

1. Bernard N, *et al.* Pharmacokinetics of penbutolol and its metabolites in renal insufficiency. *Eur J Clin Pharmacol* 1985; **29:** 215–19.

Uses and Administration

Penbutolol is a non-cardioselective beta blocker (p.1225). It is reported to possess some intrinsic sympathomimetic activity but lacks membrane-stabilising properties.

Penbutolol is used as the sulfate in the management of hypertension (p.1171). It may also be used in cardiac disorders such as angina pectoris (p.1157).

In **hypertension** penbutolol sulfate is given in an initial oral dose of 20 mg daily; the dose may be increased if necessary to 40 to 80 mg daily. Maximum antihypertensive efficacy is reported to occur within 2 weeks in patients given a dose of 20 mg daily but about 4 weeks may be required for maximum effect in patients given 10 mg daily.

Penbutolol sulfate has also been used in similar doses in cardiac disorders such as **angina**.

Preparations

USP 31: Penbutolol Sulfate Tablets.

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Ger.:*** Betarelix; Betasemid.

Pentaerithrityl Tetranitrate *(BAN, rINN)*

Erynite; Nitropentaerythrol; Nitropenthrite; Pentaérithrityle, Tétranitrate de; Pentaerithrityli Tetranitras; Pentaeritritilio tetranitratas; Pentaeritritol Tetranitrat; Pentaeritrit-tetranitrát; Pentaerityltetranitrat; Pentaeritrityylitetranitraatti; Pentaerythritol Tetranitrate; Pentaerythritolum Tetranitricum; Pentaerythrityl Tetranitrate; Pentaérythrityle, tétranitrate de; Pentaerythrityli tetranitras; Pentaerythrityl-tetranitrát; Pentaerytrityltetranitrat; Pentaerytrityylitetranitraatti; Pentaerytrytylu tetraazotan; Pentanitrol; PETN; Tetranitrato de pentaeritritilo. 2,2-Bis(hydroxymethyl)propane-1,3-diol tetranitrate.

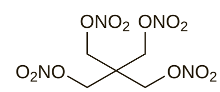
Пентаэритритила Тетранитрат

$C_5H_8N_4O_{12} = 316.1.$

CAS — 78-11-5.

ATC — C01DA05.

ATC Vet — QC01DA05.



NOTE. The synonym PETN has been applied to both niceritrol and pentaerithrityl tetranitrate.

Pharmacopoeias. *Chin.* and *Eur.* (see p.vii) include as diluted pentaerithrityl tetranitrate.

Ph. Eur. 6.2 (Pentaerithrityl Tetranitrate, Diluted). A mixture of pentaerithrityl tetranitrate with lactose monohydrate or mannitol. Its solubility depends on the diluent and its concentration. Protect from light and heat.

Undiluted pentaerithrityl tetranitrate is a white or slightly yellowish powder. Practically insoluble in water; slightly soluble in alcohol; soluble in acetone.

Handling. Undiluted pentaerithrityl tetranitrate can be exploded by percussion or excessive heat.

Profile

Pentaerithrityl tetranitrate is a vasodilator with general properties similar to those of glyceryl trinitrate (p.1296) but its duration of action is more prolonged.

It is used in angina pectoris (p.1157) in usual oral doses of up to 240 mg daily, in divided doses, before a meal. It is also given as modified-release preparations.

Pentaerithrityl trinitrate, an active metabolite of pentaerithrityl tetranitrate, has also been used clinically under the name pentrinitrol.

Pentosan Polysulfate Sodium *(BAN, USAN, rINN)*

Natrii pentosani polusulfas; Natrii Pentosani Polysulfas; Natriumpentosaanipolys Ulfaatti; Natriumpentosanpolysulfat; Pentosan Polysulphate Sodium; Pentosane polysulfate sodique; Pentosano polisulfato de sodio; PZ-68; Sodium Pentosan Polysulphate; Sodium Xylanpolysulphate; SP-54.

Натрия Пентозана Полисульфат

CAS — 37319-17-8; 116001-96-8.
ATC — C05BA04.
ATC Vet — QC05BA04.

Description. Pentosan polysulfate sodium is a mixture of linear polymers of β-1→4-linked xylose, usually sulfated at the 2- and 3-positions and occasionally (approximately 1 in every 4 residues) substituted at the 2-position with 4-*O*-methyl-α-D-glucuronic acid 2,3-*O*-sulfate. The average molecular weight lies between 4000 and 6000 with a total molecular weight range of 1000 to 40 000.

Adverse Effects and Precautions

As for Heparin, p.1301. Gastrointestinal disturbances may also occur.

Uses and Administration

Pentosan polysulfate sodium is a heparinoid with anticoagulant and fibrinolytic properties; it may also have hypolipidaemic and anti-inflammatory effects. It is used in thromboembolic disorders, although its anticoagulant effect is less than that of heparin. It is also used in the management of interstitial cystitis (see below) and has been tried in a number of other conditions, including variant Creutzfeldt-Jakob disease (see below). Pentosan polysulfate sodium has been used orally, parenterally, and topically.

In the management of interstitial cystitis, pentosan polysulfate sodium is given orally in a dose of 100 mg three times daily.

Cystitis. Pentosan polysulfate sodium has been used in inflammatory conditions of the bladder, including interstitial cystitis (p.2179) and is thought to act by enhancing the protective effect of mucins at the bladder surface.[1] Studies have differed concerning its efficacy in the treatment of interstitial cystitis and an analysis[2] of placebo-controlled trials concluded that pentosan polysulfate sodium was more effective in treating pain, urgency, and frequency, but that the difference was small. Any benefit is usually apparent within 3 to 6 months and only occurs in a minority of patients.[3] Pentosan polysulfate sodium was reported[4] to have minimal long-term efficacy in a group of patients with severe or refractory interstitial cystitis.

Pentosan polysulfate sodium has also been reported[5-7] to be useful in the control of radiation-induced haemorrhagic cystitis (p.2178).

7. Sandhu SS, *et al.* The management of haemorrhagic cystitis with sodium pentosan polysulphate. *BJU Int* 2004; **94:** 845–7.

Prostatitis. Pentosan polysulfate sodium is one of a number of drugs that have been tried in the management of prostatitis (p.2181). An improvement in symptoms was reported[1] in an uncontrolled study of oral pentosan polysulfate sodium in men with chronic prostatitis/chronic pelvic pain syndrome. A randomised study[2] using pentosan polysulfate sodium 300 mg three times daily found that symptoms were moderately or markedly improved at the end of the 16-week treatment period in more members of the active treatment group than in the group given placebo.

2. Nickel JC, *et al.* Pentosan polysulfate sodium therapy for men with chronic pelvic pain syndrome: a multicenter, randomized, placebo controlled study. *J Urol (Baltimore)* 2005; **173:** 1252–5.

Variant Creutzfeldt-Jakob disease. Variant Creutzfeldt-Jakob disease (vCJD) is a transmissible spongiform encephalopathy believed to be caused by infection of the nervous system with prions. Pentosan polysulfate sodium has been tried in small numbers of patients with vCJD, although there is little published research data. In 2003 the UK Department of Health[1] took advice from the CJD Therapy Advisory Group and the CSM; both groups considered that there was insufficient information on which to base prescribing regimens, and further work was needed.

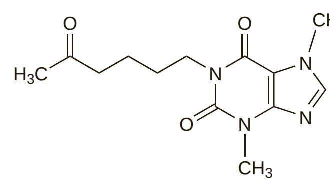
Pentoxifylline *(BAN, USAN, rINN)*

BL-191; Okspentifilin; Oxpentifylline; Pentoksifilin; Pentoksifilinas; Pentoksifylliini; Pentoxifilina; Pentoxifillin; Pentoxifylin; Pentoxifyllin; Pentoxifyllinum. 3,7-Dimethyl-1-(5-oxohexyl)xanthine.

Пентоксифиллин

$C_{13}H_{18}N_4O_3$ = 278.3.
CAS — 6493-05-6.
ATC — C04AD03.
ATC Vet — QC04AD03.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Pentoxifylline). A white or almost white crystalline powder. Soluble in water; sparingly soluble in alcohol; freely soluble in dichloromethane. Protect from light.

USP 31 (Pentoxifylline). A white to almost white crystalline powder. Soluble in water; sparingly soluble in alcohol; freely soluble in chloroform and in methyl alcohol; slightly soluble in ether.

Adverse Effects

Pentoxifylline can cause nausea, gastrointestinal disturbances, dizziness, and headache. Flushing, angina, palpitations, cardiac arrhythmias, and hypersensitivity reactions may also occur. Bleeding events have been reported rarely, usually in association with bleeding risk factors.

Overdosage with pentoxifylline may be associated with fever, faintness, flushing, hypotension, drowsiness, agitation, and seizures.

Haemorrhage. Three major bleeding episodes including 2 fatal cerebral haemorrhages were reported in a group of patients receiving pentoxifylline 400 mg three times daily together with acenocoumarol for intermittent claudication.[1] Gastrointestinal bleeding occurred in a 67-year-old patient with a history of duodenal ulcer after a single dose of pentoxifylline for optic neuropathy.[2]

1. APIC Study Group. Acenocoumarol and pentoxifylline in intermittent claudication: a controlled clinical study. *Angiology* 1989; **40:** 237–48.
2. Oren R, *et al.* Pentoxifylline-induced gastrointestinal bleeding. *DICP Ann Pharmacother* 1991; **25:** 315–16.

Overdosage. A 22-year-old woman who took pentoxifylline 4 to 6 g with suicidal intent experienced severe bradycardia and first- and second-degree AV block; other effects included nausea, vomiting, abdominal cramps, hypokalaemia, excitation, and insomnia.[1] She recovered after intensive supportive and symptomatic treatment.

1. Sznajder IJ, *et al*. First and second degree atrioventricular block in oxpentifylline overdose. *BMJ* 1984; **288:** 26.

Precautions

Pentoxifylline should be avoided in cerebral haemorrhage, extensive retinal haemorrhage, severe cardiac arrhythmias, and acute myocardial infarction. It should be used with caution in patients with ischaemic heart disease or hypotension. The dose of pentoxifylline may need to be reduced in patients with hepatic or renal impairment (see under Uses and Administration, below).

Porphyria. Pentoxifylline is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Interactions

Pentoxifylline may potentiate the effect of antihypertensives. High parenteral doses of pentoxifylline may enhance the action of insulin and oral hypoglycaemics in diabetic patients. Pentoxifylline should not be given with ketorolac as there is reported to be an increased risk of bleeding and/or prolongation of the prothrombin time. There may also be an increased risk of bleeding during use with meloxicam. Serum levels of theophylline may be raised by pentoxifylline.

Pharmacokinetics

Pentoxifylline is readily absorbed from the gastrointestinal tract but undergoes first-pass hepatic metabolism. Some metabolites are active. The apparent plasma half-life of pentoxifylline is reported to be 0.4 to 0.8 hours; that of the metabolites varies from 1.0 to 1.6 hours. In 24 hours most of a dose is excreted in the urine, mainly as metabolites, and less than 4% is recovered in the faeces. Elimination of pentoxifylline is decreased in elderly patients and patients with hepatic disease. Pentoxifylline and its metabolites are distributed into breast milk.

5. Paap CM, *et al.* Multiple-dose pharmacokinetics of pentoxifylline and its metabolites during renal insufficiency. *Ann Pharmacother* 1996; **30:** 724–9.

Uses and Administration

Pentoxifylline is a xanthine derivative used in the treatment of peripheral vascular disease (p.1178). Although often classified as a vasodilator, its primary action seems to be a reduction in blood viscosity, probably by effects on erythrocyte deformability and platelet adhesion and aggregation. It is reported to increase blood flow to ischaemic tissues and improve tissue oxygenation in patients with peripheral vascular disease and to increase oxygen tension in the cerebral cortex and in the cerebrospinal fluid; it has been used in cerebrovascular disorders. Pentoxifylline also inhibits production of the cytokine, tumour necrosis factor alpha (TNFα), and this property is under investigation in a number of diseases (see below).

In the treatment of peripheral vascular disease the usual oral dose is 400 mg three times daily in a modified-release formulation; this may be reduced to 400 mg twice daily for maintenance or if adverse effects are troublesome. Doses should be taken with meals to reduce gastrointestinal disturbances. In severe hepatic or renal impairment, doses may need to be reduced (see below). Beneficial effects may not be evident until after 2 to 8 weeks of treatment. Pentoxifylline may also be given parenterally.

Administration in hepatic and renal impairment. The elimination half-life of pentoxifylline and its metabolites is significantly prolonged in patients with hepatic cirrhosis,[1] and some metabolites have a prolonged half-life in renal impairment.[2] The UK manufacturers state that in patients with severely impaired hepatic function the dose of pentoxifylline may need to be reduced, while accumulation may occur in patients with severe renal impairment (creatinine clearance less than 30 mL/minute) who receive more than 400 mg once or twice daily.

Inhibition of tumour necrosis factor alpha. Pentoxifylline inhibits production of tumour necrosis factor alpha (TNFα), a cytokine that is implicated in the pathogenesis of many diseases, and investigative work with pentoxifylline is being, or has been, carried out in many such disorders. Studies have been performed in patients with alcoholic hepatitis,[1] cardiomyopathy,[2] cerebral malaria,[3,4] diabetic nephropathy,[5] leishmaniasis,[6,7] leprosy,[8,9] membranous nephropathy,[10] radiation-induced damage,[11-13] severe sepsis or septic shock,[14] recurrent aphthous stomatitis,[15-17] and various vasculitic syndromes, including Behçet's syndrome.[18] Pentoxifylline has also been tried for improving graft survival in kidney transplantation.[19,20] For mention of a possible benefit in sarcoidosis, see p.1512. Although promising results have been reported in some of these studies, the place of pentoxifylline in the overall management of these disorders remains to be established.

Perhexiline Maleate *(BANM, USAN, rINNM)*

Maleato de perhexilina; Perhexiline, Maléate de; Perhexilini Maleas; WSM-3978G. 2-(2,2-Dicyclohexylethyl)piperidine hydrogen maleate.

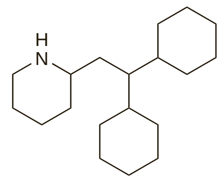
Пергексиллина Малеат

$C_{19}H_{35}N,C_4H_4O_4$ = 393.6.

CAS — 6621-47-2 (perhexiline); 6724-53-4 (perhexiline maleate).

ATC — C08EX02.

ATC Vet — QC08EX02.



(perhexiline)

Profile

Perhexiline maleate may be used in the long-term management of severe angina pectoris (p.1157) in patients who have not responded to other anti-anginal drugs. Its mode of action is complex.

The usual initial oral dose is 100 mg daily, subsequently either increased or decreased, as necessary, at intervals of 2 to 4 weeks; it is generally recommended not to give more than 300 mg daily although doses of 400 mg daily have been necessary in some patients. The maintenance of plasma-perhexiline concentrations between 0.15 and 0.60 micrograms/mL has been recommended.

Perhexiline occasionally produces severe adverse effects including peripheral neuropathy affecting all four limbs with associated papilloedema, severe and occasionally fatal hepatic toxicity, and metabolic abnormalities with marked weight loss, hypertriglyceridaemia, and profound hypoglycaemia. It is contra-indicated in patients with hepatic or renal impairment. Perhexiline should be used with caution in diabetic patients. Hepatic metabolism of perhexiline is mediated by the cytochrome P450 isoenzyme CYP2D6. Therefore caution is advised if perhexiline is used with other drugs that inhibit or are metabolised by this enzyme, and perhexiline toxicity has been reported with SSRIs such as fluoxetine or paroxetine.

Porphyria. Perhexiline is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals* or *in-vitro* systems.

ATC Vet — QC09AA04.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Perindopril *tert*-Butylamine; Perindopril Erbumine BP 2008). A white or almost white, slightly hygroscopic, crystalline powder. It exhibits polymorphism. Freely soluble in water and in alcohol; soluble or sparingly soluble in dichloromethane. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for ACE inhibitors, p.1193.

◊ In a postmarketing surveillance study[1] of 47 351 patients receiving perindopril for hypertension, no unexpected adverse effects were reported and serious reactions were rare; 1587 (6.3%) women and 782 (3.5%) men withdrew from therapy due to adverse effects.

Although a study[2] of perindopril use in patients with stable chronic heart failure reported no significant first-dose hypotension, there has been a case report[3] of ischaemic stroke, possibly associated with hypotension, after a single dose of perindopril in a patient with post-infarction heart failure. Standard precautions as for other ACE inhibitors (p.1195) should be followed when starting perindopril therapy.

3. Bagger JP. Adverse event with first-dose perindopril in congestive heart failure. *Lancet* 1997; **349:** 1671–2.

Interactions

As for ACE inhibitors, p.1196.

Pharmacokinetics

Perindopril acts as a prodrug of the diacid perindoprilat, its active form. After oral doses perindopril is rapidly absorbed with a bioavailability of about 65 to 75%. It is extensively metabolised, mainly in the liver, to perindoprilat and inactive metabolites including glucuronides. The presence of food is reported to reduce the conversion of perindopril to perindoprilat. Peak plasma concentrations of perindoprilat are achieved 3 to 4 hours after an oral dose of perindopril. Perindoprilat is about 10 to 20% bound to plasma proteins. Perindopril is excreted predominantly in the urine, as unchanged drug, as perindoprilat, and as other metabolites. The elimination of perindoprilat is biphasic with a distribution half-life of about 5 hours and an elimination half-life of 25 to 30 hours or longer, the latter half-life probably representing strong binding to angiotensin-converting enzyme. The excretion of perindoprilat is decreased in renal impairment. Both perindopril and perindoprilat are removed by dialysis.

Uses and Administration

Perindopril is an ACE inhibitor (p.1193). It is used in the treatment of hypertension (p.1171) and heart failure (p.1165). It is also used to reduce the risk of cardiovascular events in patients with stable ischaemic heart disease (see Cardiovascular Risk Reduction, p.1164).

Perindopril is converted in the body into its active metabolite perindoprilat. ACE inhibition is reported to occur within 1 hour of a dose, to be at a maximum at about 4 to 8 hours, and to be maintained for 24 hours. Perindopril is given orally as the erbumine salt and should be taken before food. In some countries perindopril is also available as the arginine salt; 5 mg of perindopril arginine is equivalent to about 4 mg of perindopril erbumine.

In the treatment of **hypertension** perindopril is given in an initial dose of 4 mg of the erbumine or 5 mg of the arginine salt once daily. Since there may be a precipitous fall in blood pressure in some patients when starting therapy with an ACE inhibitor, the first dose should preferably be given at bedtime. Hypotension is particularly likely in patients with renovascular hypertension, volume depletion, heart failure, or severe hypertension and in such patients the initial dose may be halved to 2 or 2.5 mg respectively once daily. Patients taking diuretics should have the diuretic withdrawn 2 or 3 days before perindopril is started and resumed later if required; if this is not possible, the initial dose may be halved similarly. The same lower initial dose may also be used in the elderly. The dose of perindopril may be increased according to response to a maximum of 8 mg of the erbumine or 10 mg of the arginine salt daily. In the USA a maximum dose of 16 mg of perindopril erbumine daily is allowed in uncomplicated hypertension.

In the management of **heart failure**, severe first-dose hypotension on introduction of an ACE inhibitor is common in patients on loop diuretics, but their temporary withdrawal may cause rebound pulmonary oedema. Thus treatment should be initiated with a low dose under close medical supervision. Perindopril is given in an initial dose of 2 mg of the erbumine or 2.5 mg of the arginine salt in the morning. The usual maintenance dose is 4 mg or 5 mg respectively daily.

In the management of patients with **ischaemic heart disease** perindopril is given in an initial dose of 4 mg (erbumine) or 5 mg (arginine) once daily for 2 weeks, then titrated up to a maintenance dose of 8 or 10 mg respectively once daily if tolerated. Elderly patients should be started on 2 or 2.5 mg once daily for the first week.

Dosage should be reduced in patients with impaired renal function (see below).

Administration in renal impairment. The dose of perindopril should be reduced in patients with renal impairment. UK licensed product information recommends the following doses:

- creatinine clearance (CC) between 30 and 60 mL/minute: 2 mg of the erbumine or 2.5 mg of the arginine salt daily
- CC between 15 and 30 mL/minute: 2 mg (erbumine) or 2.5 mg (arginine) on alternate days
- CC less than 15 mL/minute: 2 mg (erbumine) or 2.5 mg (arginine) on dialysis days.

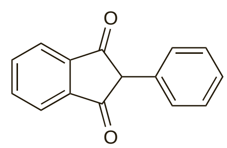
Phenindione *(BAN, rINN)*

Fenindion; Fenindiona; Fenindione; Fenindioni; Phénindione; Phenindionum; Phenylindanedione; Phenylinium. 2-Phenylindan-1,3-dione.

Фениндион

$C_{15}H_{10}O_2$ = 222.2.
CAS — 83-12-5.
ATC — B01AA02.
ATC Vet — QB01AA02.



Pharmacopoeias. In *Br.* and *Fr.*

BP 2008 (Phenindione). Soft, odourless or almost odourless, white or creamy-white crystals. Very slightly soluble in water; slightly soluble in alcohol and in ether; freely soluble in chloroform. Solutions are yellow to red.

Adverse Effects and Treatment

As for Warfarin Sodium, p.1425. However, phenindione and the other indanediones are generally more toxic than warfarin with hypersensitivity reactions involving many organs and sometimes resulting in death. Some of the reactions include skin rashes and exfoliative dermatitis, pyrexia, diarrhoea, vomiting, sore throat, liver and kidney damage, myocarditis, agranulocytosis, leucopenia, eosinophilia, and a leukaemoid syndrome.

Phenindione may discolour the urine pink or orange and this is independent of any haematuria. Taste disturbances have been reported.

Effects on the gastrointestinal tract. There have been cases of paralytic ileus, one fatal, associated with phenindione.[1,2]

1. Menon IS. Phenindione and paralytic ileus. *Lancet* 1966; **i:** 1421–2.
2. Nash AG. Phenindione and paralytic ileus. *Lancet* 1966; **ii:** 51–2.

Precautions

As for Warfarin Sodium, p.1426.

Phenindione is not recommended in pregnancy.

Breast feeding. Phenindione is distributed into breast milk, with reported concentrations[1] of 1 to 5 micrograms/mL after a single dose of 50 or 75 mg. A woman receiving phenindione 50 mg each morning and 50 and 25 mg on alternate nights breast-fed her infant son,[2] who required a herniotomy at 5 weeks. After surgery he had an enormous scrotal haematoma and oozing from the wound, and was found to have extended prothrombin and partial thromboplastin times. The American Academy of Pediatrics therefore considers[3] that phenindione should be given with caution to breast-feeding mothers.

Interactions

The interactions associated with oral anticoagulants are described in detail under warfarin (p.1427). Specific references to interactions involving phenindione can be found there under the headings for the following drug groups: analgesics; antibacterials; antifungals; antiplatelets; anxiolytic sedatives; gastrointestinal drugs; lipid regulating drugs; and sex hormones.

Pharmacokinetics

Phenindione is absorbed from the gastrointestinal tract. It crosses the placenta and is distributed into breast milk. Metabolites of phenindione excreted in the urine are responsible for any discoloration that may occur.

Uses and Administration

Phenindione is an oral indanedione anticoagulant with actions similar to those of warfarin (p.1432). It is used in the management of thromboembolic disorders (p.1187), but because of its higher incidence of severe adverse effects it is now rarely employed.

The usual initial dose of phenindione is 200 mg on the first day, 100 mg on the second day, and then maintenance doses of 50 to 150 mg daily according to coagulation tests.

Preparations

BP 2008: Phenindione Tablets.

Proprietary Preparations (details are given in Part 3)

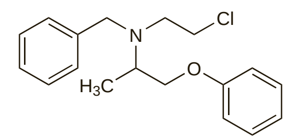
Phenoxybenzamine Hydrochloride

(BANM, rINNM)

Fenoksybenzaminy chlorowodorek; Hidrocloruro de fenoxibenzamina; Phénoxybenzamine, Chlorhydrate de; Phenoxybenzamini Hydrochloridum; SKF-688A. Benzyl(2-chloroethyl)(1-methyl-2-phenoxyethyl)amine hydrochloride.

Феноксибензамина Гидрохлорид

$C_{18}H_{22}ClNO,HCl$ = 340.3.
CAS — 59-96-1 (phenoxybenzamine); 63-92-3 (phenoxybenzamine hydrochloride).
ATC — C04AX02.
ATC Vet — QC04AX02.



(phenoxybenzamine)

Pharmacopoeias. In *Br., Chin.,* and *US.*

BP 2008 (Phenoxybenzamine Hydrochloride). A white or almost white, odourless or almost odourless, crystalline powder. Sparingly soluble in water; freely soluble in alcohol and in chloroform.

Adverse Effects and Treatment

The adverse effects of phenoxybenzamine are mainly due to its alpha-adrenoceptor blocking activity. They include orthostatic hypotension and dizziness, reflex tachycardia, nasal congestion, and miosis. Inhibition of ejaculation may occur. These effects may be minimised by using a low initial dose, and may diminish with continued use, but the hypotensive effect can be exaggerated by exercise, heat, a large meal, or alcohol ingestion. Other side-effects include dry mouth, decreased sweating, drowsiness, fatigue, and confusion. Gastrointestinal effects are usually slight. When phenoxybenzamine is given intravenously, idiosyncratic profound hypotension can occur within a few minutes of starting the infusion. Convulsions have been reported after rapid intravenous infusion of phenoxybenzamine.

Severe hypotension may occur in overdose and treatment includes support of the circulation by postural measures and parenteral fluid volume replacement. Sympathomimetics are considered to be of little value, and adrenaline is contra-indicated since it also stimulates beta receptors causing increased hypotension and tachycardia. Sources differ as to the value of noradrenaline in overcoming alpha-receptor blockade.

Phenoxybenzamine has been shown to be mutagenic in *in vitro* tests and carcinogenic in *rodents.*

Precautions

Phenoxybenzamine should be given with care to patients with heart failure, ischaemic heart disease, cerebrovascular disease, or renal impairment, and should be avoided if a fall in blood pressure would be dangerous. Phenoxybenzamine may aggravate the symptoms of respiratory infections.

The symbol † denotes a preparation no longer actively marketed

When given intravenously, phenoxybenzamine hydrochloride should always be diluted and given by infusion. Intravenous fluids must always be given beforehand to ensure an adequate circulating blood volume and to prevent a precipitous fall in blood pressure. Care should be taken to avoid extravasation. Contamination of the skin should also be avoided since contact sensitisation may occur.

Porphyria. Phenoxybenzamine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Interactions

Since phenoxybenzamine only blocks alpha receptors, leaving the beta receptors unopposed, use with drugs such as adrenaline that also stimulate beta receptors may enhance the cardiac-accelerating and hypotensive action of phenoxybenzamine.

Pharmacokinetics

Phenoxybenzamine is incompletely and variably absorbed from the gastrointestinal tract. After oral dosage the onset of action is gradual over several hours and persists for 3 or 4 days following a single dose. The maximum effect is attained in about 1 hour after an intravenous dose. The plasma half-life after intravenous dosage is about 24 hours. Phenoxybenzamine is metabolised in the liver and excreted in the urine and bile, but small amounts remain in the body for several days. The duration of action is thought to depend on the rate of synthesis of new alpha receptors following irreversible covalent bonding to existing alpha receptors by a reactive intermediate of phenoxybenzamine.

Uses and Administration

Phenoxybenzamine is a powerful alpha-adrenoceptor blocker (p.1153) with a prolonged duration of action; it binds covalently to alpha receptors in smooth muscle to produce an irreversible ('non-competitive') blockade. A single large dose of phenoxybenzamine can cause alpha-adrenoceptor blockade for 3 days or longer.

Phenoxybenzamine is used in the management of phaeochromocytoma (p.1179). It has also been employed in severe shock (p.1183) and in the treatment of urinary retention (p.2180).

Phenoxybenzamine is used as the hydrochloride. It is given orally or by intravenous infusion as a dilute solution.

In **phaeochromocytoma** it is used to control the hypertension associated with excessive catecholamine release during the pre-operative period and in patients whose tumours are inoperable. A beta blocker may also be given to control tachycardia, but not before alpha blockade has completely suppressed the pressor effects of the phaeochromocytoma. The usual initial oral dose of phenoxybenzamine hydrochloride is 10 mg once or twice daily, increased gradually, according to the patient's response, to a usual dose of 1 to 2 mg/kg daily in 2 divided doses. It may be given intravenously for operative cover in patients with phaeochromocytoma in a daily dose of 1 mg/kg in 200 mL of sodium chloride 0.9% infused over at least 2 hours. A similar intravenous dose in 200 to 500 mL of sodium chloride 0.9% has been given in the management of severe **shock**.

For **urinary retention** due to neurogenic bladder an oral dose of 10 mg twice daily has been given.

Preparations

BP 2008: Phenoxybenzamine Capsules;
USP 31: Phenoxybenzamine Hydrochloride Capsules.

Proprietary Preparations (details are given in Part 3)

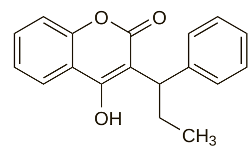
Phenprocoumon *(BAN, USAN, rINN)*

Fenprocomón; Fenprocumon; Fenprokumon; Fenprokumoni; Phenprocoumone; Phenprocoumonum; Phenylpropylhydroxycoumarin. 4-Hydroxy-3-(1-phenylpropyl)coumarin.

Фенпрокумон

$C_{18}H_{16}O_3$ = 280.3.
CAS — 435-97-2.
ATC — B01AA04.
ATC Vet — QB01AA04.



Adverse Effects, Treatment, and Precautions

As for Warfarin Sodium, p.1425.

Effects on the liver. A woman who had twice previously developed jaundice while taking phenprocoumon developed jaundice and parenchymal liver damage when, after some years, phenprocoumon was again given.[1] Other cases of phenprocoumon-associated liver damage have been reported.[2-4]

1. den Boer W, Loeliger EA. Phenprocoumon-induced jaundice. *Lancet* 1976; **i:** 912.
2. Slagboom G, Loeliger EA. Coumarin-associated hepatitis: report of two cases. *Arch Intern Med* 1980; **140:** 1028–9.
3. Cordes A, *et al.* Phenprocoumon-induziertes Leberversagen. *Dtsch Med Wochenschr* 2003; **128:** 1884–6.
4. Bulang T, *et al.* Akutes Leberversagen durch Phenprocoumon–drei Fallberichte. *Z Gastroenterol* 2004; **42:** 1055–8.

Interactions

The interactions associated with oral anticoagulants are discussed in detail under warfarin (p.1427). Specific references to interactions involving phenprocoumon can be found there under the headings for the following drug groups: analgesics; antiarrhythmics; antidepressants; antidiabetics; antigout drugs; antineoplastics; gastrointestinal drugs; lipid regulating drugs; and sex hormones.

Pharmacokinetics

Phenprocoumon is readily absorbed from the gastrointestinal tract and is extensively bound to plasma proteins. Metabolism is mediated partly by the cytochrome P450 isoenzyme CYP2C9, which shows genetic polymorphism. The half-life is 5 to 6 days. It is excreted in the urine and faeces as conjugated hydroxy metabolites and parent compound. Phenprocoumon is given as a racemic mixture; the *S*-isomer is more potent. The stereoisomers have different pharmacokinetics.

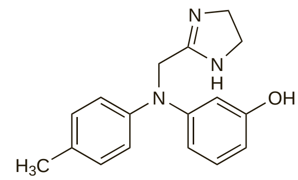
Phentolamine Mesilate *(BANM, rINNM)*

Fentolamiinimesilaatti; Fentolamin mesylát; Fentolaminmesilat; Fentolamin-mezilát; Fentolamino mesilatas; Mesilato de fentolamina; Phentolamine, mésilate de; Phentolamine Mesylate; Phentolamine Methanesulphonate; Phentolamini mesilas. 3-[*N*-(2-Imidazolin-2-ylmethyl)-*p*-toluidino]phenol methanesulphonate.

Фентоламина Мезилат

$C_{17}H_{19}N_3O,CH_4SO_3$ = 377.5.
CAS — 50-60-2 (phentolamine); 73-05-2 (phentolamine hydrochloride); 65-28-1 (phentolamine mesilate).
ATC — C04AB01; G04BE05.
ATC Vet — QC04AB01; QG04BE05.



(phentolamine)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Phentolamine Mesilate). A white or almost white, slightly hygroscopic, crystalline powder. Freely soluble in water and in alcohol; practically insoluble in dichloromethane. Store in airtight containers. Protect from light.

USP 31 (Phentolamine Mesylate). A white or off-white, odourless crystalline powder. Soluble 1 in 1 of water, 1 in 4 of alcohol, and 1 in 700 of chloroform. Its solutions in water have a pH of about 5 and slowly deteriorate. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects and Treatment

The adverse effects of phentolamine are primarily due to its alpha-adrenoceptor blocking activity and include orthostatic hypotension and tachycardia. Myocardial infarction and cerebrovascular spasm or occlusion have been reported occasionally, usually in association with marked hypotension; flushing, sweating, and feelings of apprehension may accompany hypotensive episodes. Anginal pain and arrhythmias have been reported rarely. Nausea, vomiting, and diarrhoea may also occur. Other side-effects include weakness, dizziness, flushing, and nasal congestion. Hypoglycaemia has been reported following overdosage.

Severe hypotension may occur in overdosage although phentolamine has a short duration of action. Treatment may include support of the circulation by postural measures and parenteral fluid volume replacement. Noradrenaline may be given cautiously to overcome alpha-adrenoceptor blockade. Adrenaline is contra-indicated since it also stimulates beta receptors causing increased hypotension and tachycardia.

When injected into the corpus cavernosum of the penis phentolamine has been associated with local pain; induration and fibrosis may occur with repeated use. Priapism has occurred.

Precautions

Phentolamine should not generally be given to patients with angina pectoris or other evidence of ischaemic heart disease. Care should be taken in patients with peptic ulcer disease, which may be exacerbated.

Interactions

Since phentolamine only blocks alpha receptors, use with drugs such as adrenaline may lead to severe hypotension and tachycardia due to unopposed beta-adrenoceptor stimulation.

Pharmacokinetics

After intravenous dosage, the half-life of phentolamine has been reported to be 19 minutes. It is extensively metabolised and about 13% of an intravenous dose is excreted unchanged in the urine.

Uses and Administration

Phentolamine is an alpha-adrenoceptor blocker (p.1153) which also has a direct action on vascular smooth muscle. It produces vasodilatation, an increase in cardiac output, and has a positive inotropic effect, but is reported to have little effect on the blood pressure of patients with essential hypertension. The alpha-receptor blocking action is reversible ('competitive') and non-selective, and the duration of effect is relatively short.

Phentolamine is given in the management of hypertensive crises, particularly those due to excessive catecholamine release associated with surgery for phaeochromocytoma (p.1179). It has been used for the differential diagnosis of phaeochromocytoma, but has largely been superseded by estimations of catecholamines in blood and urine.

Phentolamine is also used to prevent or treat dermal necrosis and sloughing associated with the intravenous infusion or extravasation of noradrenaline. It has been used in the treatment of erectile dysfunction (p.2179).

Phentolamine is given by injection as the mesilate.

In patients with hypertensive crises during surgery for **phaeochromocytoma**, a dose of 2 to 5 mg of phentolamine mesilate is given intravenously and repeated if necessary; blood pressure should be monitored. A dose of 1 mg intravenously is used for children. The intramuscular route may be used pre-operatively and for diagnostic procedures.

For prevention of **dermal necrosis** during intravenous infusion of noradrenaline, 10 mg of phentolamine mesilate is added to each litre of solution containing noradrenaline. For treatment of extravasation of noradrenaline, 5 to 10 mg of phentolamine mesilate in 10 mL of sodium chloride 0.9% is injected into the affected area.

For **erectile dysfunction**, phentolamine mesilate is given by injection into the corpora cavernosa of the penis. It is usually given with papaverine, but a preparation containing phentolamine with aviptadil (vasoactive intestinal peptide) may also be used. Phentolamine has also been tried orally.

Hyperhidrosis. Hyperhidrosis (p.1580) is usually treated with topical aluminium salts or topical antimuscarinics, but intradermal botulinum A toxin or procedures such as endoscopic transthoracic sympathectomy may be needed in severe cases. Phentolamine has been tried as an alternative. Improvement in symptoms has been reported[1] in 2 patients with generalised hyperhidrosis given 100 mg of phentolamine mesilate by intravenous infusion over 6 hours. Improvement lasted for 2 to 3 months and the infusion was repeated, in 1 patient several times.

1. McCleane G. The use of intravenous phentolamine mesilate in the treatment of hyperhidrosis. *Br J Dermatol* 2002; **146:** 533–4.

Pain. Sympathetic nerve block (p.1853) is used in a number of pain syndromes and usually involves injection of local anaesthetics. Phentolamine has been used as an alternative and beneficial results have been reported in pain associated with chronic pancreatitis,[1] pancreatic and other visceral cancers,[2,3] and chronic gastroparesis.[4]

Complete resolution of pain has also been reported in 2 patients with cutaneous leiomyomata given oral doxazosin.[5]

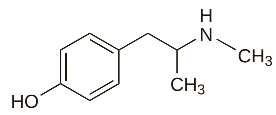
Pholedrine Sulfate *(rINNM)* ⊗

Isodrine Sulphate; Pholédrine, Sulfate de; Pholedrine Sulphate *(BANM)*; Pholedrini Sulfas; Sulfato de foledrina; Sympropaminum (pholedrine). 4-(2-Methylaminopropyl)phenol sulfate.

Фоледрина Сульфат

$(C_{10}H_{15}NO)_2,H_2SO_4$ = 428.5.
CAS — 370-14-9 (pholedrine); 6114-26-7 (pholedrine sulfate).



(pholedrine)

Profile

Pholedrine is a sympathomimetic (p.1407) used in the treatment of hypotensive states. It is usually given orally as the sulfate, often in combination with other drugs, and has also been included in preparations promoted for vascular disorders. Pholedrine eye drops have been used as an alternative to hydroxyamfetamine (p.2322) in the diagnosis of Horner's syndrome.

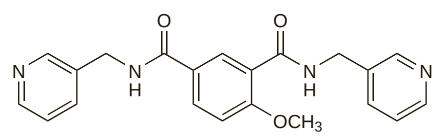
Preparations

Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Ger.:*** Adyston†; Zellaforte N Plus†; ***Switz.:*** Ortho-Maren retard.

Picotamide *(BAN)*

G-137; Picotamida; Picotamide, monohydrate de; Picotamid-monohidrát; Picotamidum monohydricum; Pikotamid monohydrát; Pikotamidimonohydraatti; Pikotamidmonohydrat; Pikotamido monohidratas. 4-Methoxy-*N*,*N*′-bis(3-pyridinylmethyl)-1,3-benzenedicarboxamide monohydrate.

$C_{21}H_{20}N_4O_3,H_2O$ = 394.4.
CAS — 32828-81-2 (anhydrous picotamide); 80530-63-8 (picotamide monohydrate).
ATC — B01AC03.
ATC Vet — QB01AC03.



Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Picotamide Monohydrate). A white or almost white, polymorphic, crystalline powder. Slightly soluble in water; soluble in dehydrated alcohol and in dichloromethane; dissolves in dilute mineral acids.

Profile

Picotamide is a thromboxane synthase inhibitor and thromboxane receptor antagonist with antiplatelet activity. It is given by mouth in thromboembolic disorders (p.1187) in initial doses of 900 to 1200 mg daily in divided doses, reducing to a maintenance dose of 300 to 600 mg daily.

ACE inhibitor-induced cough. Cough is a recognised adverse effect of ACE inhibitors and has been treated with a number of drugs (see p.1194). Picotamide led to the disappearance of cough in 8 of 9 patients receiving enalapril for hypertension,[1] suggesting that thromboxanes may be involved in the aetiology of ACE inhibitor-induced cough.

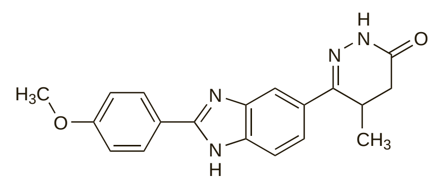
Pimobendan *(BAN, USAN, rINN)*

Pimobendaani; Pimobendán; Pimobendanas; Pimobendane; Pimobendanum; UDCG-115. 4,5-Dihydro-6-[2-(*p*-methoxyphenyl)-5-benzimidazolyl]-5-methyl-3(2*H*)-pyridazinone.

Пимобендан

$C_{19}H_{18}N_4O_2$ = 334.4.
CAS — 74150-27-9; 118428-36-7.
ATC Vet — QC01CE90.



Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Pimobendan). A white or slightly yellowish, hygroscopic powder. Practically insoluble in water; slightly soluble in acetone and in methyl alcohol; freely soluble in dimethylformamide. Store in airtight containers.

Profile

Pimobendan is a phosphodiesterase inhibitor with calcium-sensitising properties. It has positive inotropic and vasodilator activity and is used as an adjunct to standard therapy in the management of heart failure (p.1165). It is given orally in a dose of 1.25 to 2.5 mg twice daily.

Studies with other inotropic phosphodiesterase inhibitors have shown that their prolonged oral use can lead to an increased mortality rate.

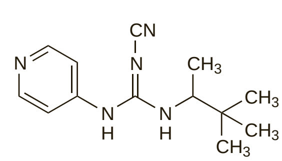
Jpn: Acardi.

Pinacidil *(USAN, rINN)*

P-1134; Pinacidilum; Pinasidiili. (±)-2-Cyano-1-(4-pyridyl)-3-(1,2,2-trimethylpropyl)guanidine.

Пинацидил

$C_{13}H_{19}N_5$ = 245.3.
CAS — 60560-33-0 (anhydrous pinacidil); 85371-64-8 (pinacidil monohydrate).
ATC — C02DG01.
ATC Vet — QC02DG01.



Profile
Pinacidil is a potassium-channel opener (p.1155) that produces direct peripheral vasodilatation of the arterioles. It has been used in the management of hypertension. It reduces blood pressure and peripheral resistance and produces fluid retention. Tachycardia and an increase in cardiac output occur mainly as a reflex response to the reduction in peripheral resistance.

◊ Reviews.

Pindolol *(BAN, USAN, rINN)* ⊗

LB-46; Pindololi; Pindololis; Pindololum; Prindolol; Prinodolol. 1-(Indol-4-yloxy)-3-isopropylaminopropan-2-ol.

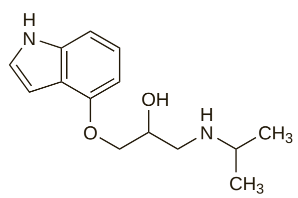
Пиндолол

$C_{14}H_{20}N_2O_2$ = 248.3.

CAS — 13523-86-9.

ATC — C07AA03.

ATC Vet — QC07AA03.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Pindolol). A white or almost white, crystalline powder. Practically insoluble in water; slightly soluble in methyl alcohol; dissolves in dilute mineral acids. Protect from light.

USP 31 (Pindolol). A white to off-white, crystalline powder with a faint odour. Practically insoluble in water; very slightly soluble in chloroform; slightly soluble in methyl alcohol. Protect from light.

Adverse Effects, Treatment, and Precautions
As for Beta Blockers, p.1226.

Effects on lipid metabolism. Beta blockers can affect plasma-lipid concentrations, although this may be less of a problem with those that have intrinsic sympathomimetic activity. For reference to the lack of effect of pindolol, see p.1227.

Tremor. Fine tremor in the extremities of 5 patients during pindolol therapy was considered to have been due to its partial agonist activity.[1]

1. Hod H, *et al*. Pindolol-induced tremor. *Postgrad Med J* 1980; **56:** 346–7.

Interactions
The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics
Pindolol is almost completely absorbed from the gastrointestinal tract and peak plasma concentrations are obtained about 1 to 2 hours after an oral dose. It has a bioavailability of about 87%. About 40 to 60% is reported to be bound to plasma proteins. It is moderately lipid-soluble. Pindolol crosses the placenta and is distributed into breast milk. It is only partially metabolised in the liver and is excreted in the urine both unchanged and in the form of metabolites. A plasma elimination half-life of 3 to 4 hours has been reported in healthy adults. The half-life may be prolonged in elderly hypertensive patients and in patients with renal or hepatic impairment.

Uses and Administration
Pindolol is a non-cardioselective beta blocker (p.1225). It is reported to have intrinsic sympathomimetic activity but little membrane-stabilising activity.

Pindolol is used in the management of hypertension (p.1171), angina pectoris (p.1157), cardiac arrhythmias (p.1160), and other cardiovascular disorders. It is also used in glaucoma (p.1873).

In **hypertension** pindolol is usually given initially in an oral dosage of 5 mg two or three times daily, or 15 mg once daily, subsequently increased according to response. The usual maintenance dose is 15 to 30 mg once daily, but up to 45 mg daily, as a single dose or in divided doses, may be required. Additional benefit is rarely obtained from doses higher than 45 mg daily, although doses up to 60 mg daily have been given.

The usual oral dose for **angina pectoris** is 2.5 to 5 mg up to three times daily; however, doses of up to 40 mg daily have been used.

Eye drops containing pindolol 1% are used in the management of **glaucoma**.

Pindolol has also been given intravenously in the management of cardiac arrhythmias.

Psychiatric disorders. In addition to its beta-blocking properties, pindolol is also a partial agonist at serotonin 5-HT_1-receptors and has been used to augment the effects of SSRIs in patients with depression (p.373). Results have been conflicting,[1] but a meta-analysis[2] found that the time to response was shorter in patients given pindolol with an SSRI, although there was no effect on long-term outcomes. Small studies have also reported positive effects with pindolol augmentation of SSRIs in obsessive-compulsive disorder[3] (p.952) and in panic disorder[4] (p.952), although no effect was seen in social phobia.[5] Another study[6] found that pindolol augmentation of antipsychotic therapy reduced aggression in patients with schizophrenia (p.955).

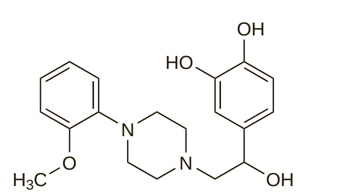
Pipratecol *(rINN)*

Pipratécol; Pipratecolum; 711-SE. 1-(3,4-Dihydroxyphenyl)-2-[4-(2-methoxyphenyl)piperazin-1-yl]ethanol.

Пипратекол

$C_{19}H_{24}N_2O_4$ = 344.4.

CAS — 15534-05-1.



Profile
Pipratecol is a vasodilator that has been given with raubasine (p.1386) in the treatment of cerebrovascular disorders.

Piretanide *(BAN, USAN, rINN)* ⊗

Hoe-118; Piretanid; Piretanida; Piretanidas; Pirétanide; Piretanidi; Piretanidum; S73-4118. 4-Phenoxy-3-(pyrrolidin-1-yl)-5-sulphamoylbenzoic acid.

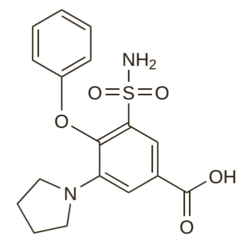
Пиретанид

$C_{17}H_{18}N_2O_5S$ = 362.4.

CAS — 55837-27-9.

ATC — C03CA03.

ATC Vet — QC03CA03.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Piretanide). A yellowish-white to yellowish powder. It exhibits polymorphism. Very slightly soluble in water; sparingly soluble in dehydrated alcohol. Protect from light.

Adverse Effects
As for Furosemide, p.1292. Muscle cramps have been reported after high doses of piretanide.

Precautions
Piretanide's precautions and contra-indications, which are dependent on its effects on fluid and electrolyte balance, are similar to those of the thiazide diuretics (see Hydrochlorothiazide, p.1309). Patients with impaired micturition or prostatic hyperplasia may develop retention of urine with piretanide.

Interactions
As for Furosemide, p.1293.

Pharmacokinetics
Piretanide has been reported to be almost completely absorbed after oral doses. It is extensively bound to plasma proteins, and is reported to have a half-life of about 1 hour after an oral dose.

◊ References.

1. Beermann B, Grind M. Clinical pharmacokinetics of some newer diuretics. *Clin Pharmacokinet* 1987; **13:** 254–66.

Uses and Administration
Piretanide is a loop diuretic with actions and uses similar to those of furosemide (p.1294). It is used for oedema, including that associated with heart failure (p.1165), in oral doses of 3 to 6 mg daily. In the treatment of hypertension (p.1171) it is given in a usual oral dose of 6 to 12 mg daily. The sodium salt is given by injection.

Plant Stanols and Sterols

Phytosterols.

Станолы и Стерины из Растений

Phytosterol

Fitosterolis; Fitoszterin; Fytosterol; Fytosteroli; Phytosterin; Phytostérol; Phytosterolum.

Фитостерин; Фитостерол

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Phytosterol). A natural mixture of sterols obtained from plants of the genera *Hypoxis*, *Pinus*, and *Picea*. It contains not less than 70% β-sitosterol, calculated with reference to the dried substance. A white or almost white powder. Practically insoluble in water; soluble in tetrahydrofuran; sparingly soluble in ethyl acetate. Store in airtight containers. Protect from light.

Sitostanol

Dihydro-β-sitosterol; Fucostanol; β-Sitostanol; Stigmastanol. (3β,5α)-Stigmastan-3-ol.

Ситостанол

$C_{29}H_{52}O = 416.7.$

CAS — 83-45-4.

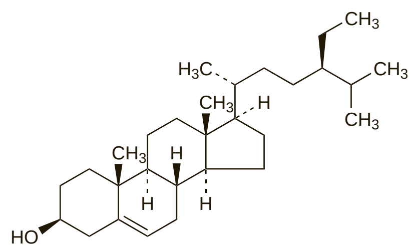
Sitosterol

β-Sitosterin; β-Sitosterol. (3β)-Stigmast-5-en-3-ol.

Ситостерин; Ситостерол

$C_{29}H_{50}O = 414.7.$

CAS — 83-46-5.



Profile

Stanols and sterols occur naturally in plants and are chemically related to cholesterol. The term phytosterol is used to describe both unsaturated plant sterols and their saturated (hydrogenated) counterparts, plant stanols (phytostanols). Sitosterol, campesterol, and stigmasterol are the commonest phytosterols; their respective stanols are found in lower amounts naturally, but can be produced by hydrogenation of sterols.

Dietary phytosterols have a cholesterol-lowering action; they reduce cholesterol absorption from the intestine and may also have other mechanisms. Sitosterol has been used as a lipid regulating drug, and both sterol and stanol esters (formed by esterification with unsaturated fatty acids) have been incorporated into margarines and other food products for use in the dietary management of hypercholesterolaemia. Sitosterol, sitostanol, and other phytosterols, are also used in nutritional supplements.

Sitosterol is also used in benign prostatic hyperplasia (p.2178), although its mechanism of action is not clear. It is given orally in usual initial doses of 20 mg three times daily.

There have been reports of bleeding complications associated with supplements containing phytosterols.

Policosanol

Поликосанол

CAS — 142583-61-7.

ATC — C10AX08.

ATC Vet — QC10AX08.

Octacosanol

Cluytyl Alcohol; Montanyl Alcohol; Octacosyl Alcohol. 1-Octacosanol.

Октакосанол

$C_{28}H_{58}O = 410.8.$

CAS — 557-61-9.

Profile

Policosanol is a mixture of higher primary aliphatic alcohols (fatty alcohols) derived from plant waxes such as sugar cane wax; it is also found in beeswax and in wheat-germ oil (p.2415). The main component is octacosanol. Policosanol appears to have cholesterol-lowering properties and has been used in the treatment of hypercholesterolaemias, although its benefit has been disputed. Both policosanol and octacosanol are used in nutritional supplements.

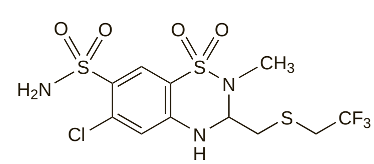
Политиазид

$C_{11}H_{13}ClF_3N_3O_4S_3 = 439.9.$

CAS — 346-18-9.

ATC — C03AA05.

ATC Vet — QC03AA05.



Pharmacopoeias. In *Br.*

BP 2008 (Polythiazide). A white or almost white, crystalline powder with an alliaceous odour. Practically insoluble in water and in chloroform; sparingly soluble in alcohol.

Adverse Effects, Treatment, and Precautions

As for Hydrochlorothiazide, p.1307.

Interactions

As for Hydrochlorothiazide, p.1309.

Pharmacokinetics

Polythiazide is fairly readily absorbed from the gastrointestinal tract. The estimated plasma elimination half-life is about 26 hours. More than 80% may be bound to plasma proteins. It is excreted mainly in the urine as unchanged polythiazide and metabolites.

◊ References.

1. Hobbs DC, Twomey TM. Kinetics of polythiazide. *Clin Pharmacol Ther* 1978; **23:** 241–6.

Uses and Administration

Polythiazide is a thiazide diuretic with actions and uses similar to those of hydrochlorothiazide (p.1310). It is given orally for hypertension (p.1171), and for oedema, including that associated with heart failure (p.1165).

Diuresis begins within about 2 hours of an oral dose, and lasts for 24 to 48 hours.

In the treatment of **hypertension** the usual dose is stated to be 2 to 4 mg daily, either alone or with other antihypertensives although doses of only 0.5 to 1 mg may be adequate. In the treatment of **oedema** the usual dose is 1 to 4 mg daily.

Preparations

BP 2008: Polythiazide Tablets.

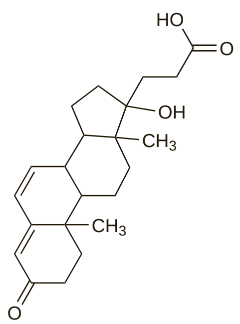
$C_{22}H_{29}KO_4$ = 396.6.

CAS — 4138-96-9 (canrenoic acid); 2181-04-6 (potassium canrenoate).

ATC — C03DA02.

ATC Vet — QC03DA02.



(canrenoic acid)

Pharmacopoeias. In *Jpn.*

Adverse Effects and Precautions

As for Spironolactone, p.1400. Irritation or pain may occur at the site of injection.

Effects on endocrine function. A lower incidence of gynaecomastia has been reported in patients with hepatic cirrhosis and ascites during use of potassium canrenoate than with equivalent doses of spironolactone,[1] and spironolactone-induced gynaecomastia disappeared when spironolactone was replaced by potassium canrenoate in a patient with hyperaldosteronism.[2] This suggests that metabolites other than canrenone (a common metabolite of both canrenoate and spironolactone thought to be responsible for their activity) or possibly spironolactone itself may be responsible for the anti-androgenic effects of spironolactone.[3,4]

1. Bellati G, Idéo G. Gynaecomastia after spironolactone and potassium canrenoate. *Lancet* 1986; **i:** 626.
2. Dupont A. Disappearance of spironolactone-induced gynaecomastia during treatment with potassium canrenoate. *Lancet* 1985; **ii:** 731.
3. Gardiner P. Spironolactone and potassium canrenoate metabolism. *Lancet* 1985; **ii:** 1432.
4. Overdiek JWPM, Merkus FWHM. Spironolactone metabolism and gynaecomastia. *Lancet* 1986; **i:** 1103.

Interactions

As for Spironolactone, p.1401.

Uses and Administration

Potassium canrenoate is a potassium-sparing diuretic with actions and uses similar to those of spironolactone (p.1401). Canrenone (p.1239) is a metabolite common to both drugs, but its contribution to the pharmacological action is unclear. Potassium canrenoate is used in the treatment of refractory oedema associated with heart failure (p.1165) or hepatic disease when an injectable aldosterone antagonist is required. It may be given in doses of 200 to 400 mg daily, increasing to 800 mg daily in exceptional cases; it is given by slow intravenous injection over a period of 2 to 3 minutes for each 200 mg or by intravenous infusion in glucose 5% or sodium chloride 0.9%.

Preparations

Proprietary Preparations (details are given in Part 3)

Prajmalium Bitartrate *(BAN, rINN)*

Bitartrato de prajmalio; GT-1012; NPAB; Prajmalii Bitartras; Prajmaline Bitartrate; Prajmalium, Bitartrate de. *N*-Propylajmalinium hydrogen tartrate.

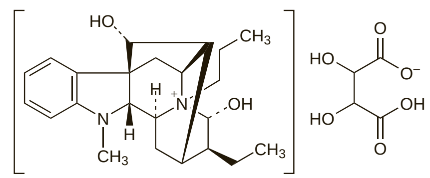
Праймалия Битартрат

$C_{23}H_{33}N_2O_2,C_4H_5O_6$ = 518.6.

CAS — 35080-11-6 (prajmalium); 2589-47-1 (prajmalium bitartrate).

ATC — C01BA08.

ATC Vet — QC01BA08.



Adverse Effects and Precautions

As for Ajmaline, p.1206.

Effects on the liver. Cholestatic jaundice associated with pruritus, chills, and eosinophilia[1] was attributed to an allergic reaction to prajmalium bitartrate in a patient 20 days after the start of treatment.

1. Rotmensch HH, *et al.* Cholestatic jaundice: an immune response to prajmalium bitartrate. *Postgrad Med J* 1980; **56:** 738–41.

Effects on mental state. Confusion and disorientation in time and place[1] occurred on 2 occasions in a 67-year-old man given prajmalium bitartrate 100 mg daily for the control of tachycardia; the confusion rapidly disappeared when prajmalium was withdrawn.

1. Lessing JB, Copperman IJ. Severe cerebral confusion produced by prajmalium bitartrate. *BMJ* 1977; **2:** 675.

Uses and Administration

Prajmalium is a class I antiarrhythmic (p.1153) and is the *N*-propyl derivative of ajmaline (p.1206). It is given orally as the bitartrate in the management of supraventricular and ventricular arrhythmias (p.1160) in initial doses of 60 to 80 mg daily. Maintenance doses of 20 to 40 mg daily in divided doses are used.

Sodium (3*R*,5*R*)-7-{(1*S*,2*S*,6*S*,8*S*,8a*R*)-1,2,6,7,8,8a-hexahydro-6-hydroxy-2-methyl-8-[(*S*)-2-methylbutyryloxy]-1-naphthyl}-3,5-dihydroxyheptanoate.

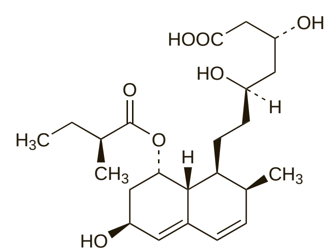
Натрий Правастатин

$C_{23}H_{35}O_7Na$ = 446.5.

CAS — 81093-37-0 (pravastatin); 81131-70-6 (pravastatin sodium).

ATC — C10AA03.

ATC Vet — QC10AA03.



(pravastatin)

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Pravastatin Sodium). A white to yellowish-white, hygroscopic, powder or crystalline powder. Freely soluble in water and in methyl alcohol; soluble in dehydrated alcohol. A 5% solution in water has a pH of 7.2 to 9.0. Store in airtight containers.

USP 31 (Pravastatin Sodium). A white to yellowish white hygroscopic powder. Freely soluble in water and in methyl alcohol; soluble in alcohol; practically insoluble in chloroform, in ether, and in ethyl acetate; very slightly soluble in acetonitrile. Store in airtight containers.

Adverse Effects and Precautions

As for Simvastatin, p.1390.

Interactions

The interactions of statins with other drugs are described under simvastatin (p.1392). Pravastatin is not significantly metabolised by the cytochrome P450 enzyme system and does not have the same interactions with enzyme inhibitors as simvastatin, although caution has been advised when such combinations are used. Increased plasma-pravastatin concentrations have been reported in some patients receiving ciclosporin and low doses should be used (see Uses and Administration, below).

Pharmacokinetics

Pravastatin is rapidly but incompletely absorbed from the gastrointestinal tract and undergoes extensive first-pass metabolism in the liver, its primary site of action. The absolute bioavailability of pravastatin is 17%. About 50% of the circulating drug is bound to plasma proteins. The plasma elimination half-life of pravastatin is 1.5 to 2 hours. About 70% of an oral dose of pravastatin is excreted in the faeces, as unabsorbed drug and via the bile, and about 20% is excreted in the urine.

◊ General reviews.

1. Quion JAV, Jones PH. Clinical pharmacokinetics of pravastatin. *Clin Pharmacokinet* 1994; **27:** 94–103.
2. Hatanaka T. Clinical pharmacokinetics of pravastatin: mechanisms of pharmacokinetic events. *Clin Pharmacokinet* 2000; **39:** 397–412.

Uses and Administration

Pravastatin, a 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor (or statin), is a lipid regulating drug with actions on plasma lipids similar to those of simvastatin (p.1394).

Pravastatin is used to reduce LDL-cholesterol, apolipoprotein B, and triglycerides, and to increase HDL-cholesterol in the treatment of hyperlipidaemias (p.1169), including hypercholesterolaemias, combined (mixed) hyperlipidaemia (type IIa or IIb hyperlipoproteinaemias), hypertriglyceridaemia (type IV), dysbetalipoproteinaemia (type III), and post-transplantation hyperlipidaemia. It is also used for cardiovascular risk reduction (p.1164), including primary prophylaxis in hypercholesterolaemic patients, and secondary prophylaxis, including prevention of stroke, in patients with clinically-evident ischaemic heart disease.

Pravastatin is given orally as the sodium salt; the usual dose is 10 to 40 mg of pravastatin sodium once daily at bedtime. The dose may be adjusted, according to response, at intervals of not less than 4 weeks. UK licensed product information states that the maximum dose is 40 mg once daily, but US licensed product information allows a maximum of 80 mg once daily in patients with hypercholesterolaemia. Low initial doses are recommended in patients with hepatic or renal impairment (see below).

In patients also taking *ciclosporin*, UK licensed product information recommends an initial dose of 20 mg once daily, but US licensed product information states an initial dose of 10 mg; dose increases should be made with caution.

For the use of pravastatin in children and adolescents, see below.

◊ General reviews.

2. Haria M, McTavish D. Pravastatin: a reappraisal of its pharmacological properties and clinical effectiveness in the management of coronary heart disease. *Drugs* 1997; **53:** 299–336.

Administration in children. In children with heterozygous familial hypercholesterolaemia, pravastatin sodium is licensed in doses of 10 to 20 mg once daily in those aged 8 to 13 years and 10 to 40 mg once daily in those aged 14 to 18 years. Short-term studies have suggested that pravastatin effectively reduces cholesterol and is safe in children with familial hypercholesterolaemia[1] and in children taking immunosuppressants after heart transplant,[2] although plasma concentrations may be higher in the latter group. A randomised controlled study[3] and a prospective study[4] have also found that pravastatin is effective and well tolerated in familial hypercholesterolaemia, and there is some evidence[3] that carotid intima media thickness (a marker of atherosclerosis) may be reduced.

Administration in hepatic or renal impairment. Patients with moderate or severe renal or significant hepatic impairment should be given pravastatin sodium in an initial dose of 10 mg daily, and the dose should be increased with caution.

Preparations

BP 2008: Pravastatin Tablets;
USP 31: Pravastatin Sodium Tablets.

Prazosin Hydrochloride

(BANM, USAN, rINNM)

CP-12299-1; Furazosin Hydrochloride; Hidrocloruro de prazosina; Pratsosiinihydrokloridi; Prazosin Hidroklorür; Prazosine, chlorhydrate de; Prazosin-hydrochlorid; Prazosinhydroklorid; Prazosini hydrochloridum; Prazozin-hidroklorid; Prazozino hidrochloridas. 2-[4-(2-Furoyl)piperazin-1-yl]-6,7-dimethoxyquinazolin-4-ylamine hydrochloride.

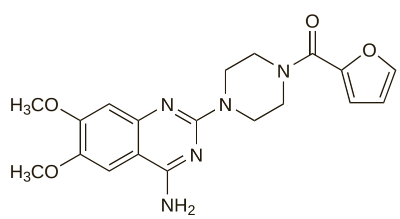
Празозина Гидрохлорид

$C_{19}H_{21}N_5O_4,HCl = 419.9.$

CAS — 19216-56-9 (prazosin); 19237-84-4 (prazosin hydrochloride).

ATC — C02CA01.

ATC Vet — QC02CA01.



(prazosin)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Prazosin Hydrochloride). A white or almost white powder. Very slightly soluble in water; slightly soluble in alcohol and in methyl alcohol; practically insoluble in acetone. Protect from light.

USP 31 (Prazosin Hydrochloride). A white to tan powder. Slightly soluble in water, in dimethylacetamide, in dimethylformamide, and in methyl alcohol; very slightly soluble in alcohol; practically insoluble in acetone and in chloroform. Store in airtight containers. Protect from light.

Adverse Effects

Prazosin hydrochloride can cause orthostatic hypotension which may be severe and produce syncope after the initial dose; it may be preceded by tachycardia. This reaction can be avoided by starting treatment with a low dose, preferably at night (see Uses and Administration, below). The hypotensive effects may be exaggerated by exercise, heat, or alcohol ingestion.

The more common adverse effects include dizziness, drowsiness, headache, lack of energy, nausea, and palpitations, and may diminish with continued prazosin therapy or with a reduction in dosage. Other adverse effects include oedema, chest pain, dyspnoea, constipation, diarrhoea, vomiting, depression and nervousness, sleep disturbances, vertigo, hallucinations, paraesthesia, nasal congestion, epistaxis, dry mouth, urinary frequency and incontinence, reddened sclera, blurred vision, tinnitus, abnormal liver enzyme values, pancreatitis, arthralgia, alopecia, lichen planus, skin rashes, pruritus, and diaphoresis. Impotence and priapism have also been reported.

◊ General reviews.

1. Carruthers SG. Adverse effects of α -adrenergic blocking drugs. *Drug Safety* 1994; **11:** 12–20.

Effects on the cardiovascular system. Orthostatic hypotension, preceded by tachycardia and sometimes producing syncope, is an established adverse effect of the initial dose of prazosin. Sinus bradycardia was associated with prazosin in a patient who had light headedness after each daily dose.[1]

1. Ball J. Symptomatic sinus bradycardia due to prazosin. *Lancet* 1994; **343:** 121.

Effects on the gastrointestinal tract. Faecal incontinence in a 52-year-old man receiving prazosin was exacerbated by haemorrhoidectomy and appeared to be due to diminished resting anal tone, presumably because of smooth muscle relaxation secondary to alpha-adrenoceptor blockade.[1] Symptoms ceased almost immediately on stopping the drug.

1. Holmes SAV, *et al.* Faecal incontinence resulting from α -adrenoceptor blockade. *Lancet* 1990; **336:** 685–6.

Effects on mental function. Psychiatric symptoms including confusion, paranoia, and hallucinations developed in 3 patients associated with prazosin treatment.[1] Two of the patients had chronic renal failure and the other had mild renal impairment. Acute psychosis has also been reported with doxazosin.[2]

1. Chin DKF, *et al.* Neuropsychiatric complications related to use of prazosin in patients with renal failure. *BMJ* 1986; **293:** 1347.
2. Evans M, *et al.* Drug induced psychosis with doxazosin. *BMJ* 1997; **314:** 1869.

Hypersensitivity. Urticaria and angioedema were attributed to prazosin in a 70-year-old woman.[1]

1. Ruzicka T, Ring J. Hypersensitivity to prazosin. *Lancet* 1983; **i:** 473–4.

Lupus erythematosus. One study has reported the formation of antinuclear antibodies in patients receiving prazosin,[1] but this is not in agreement with other reports,[2,3] and commentators consider the association unproven.[4] There is no evidence of the development of lupus erythematosus.[1]

1. Marshall AJ, *et al.* Positive antinuclear factor tests with prazosin. *BMJ* 1979; **1:** 165–6.
2. Wilson JD, *et al.* Antinuclear factor in patients on prazosin. *BMJ* 1979; **1:** 553–4.
3. Melkild A, Gaarder PI. Does prazosin induce formation of antinuclear factor? *BMJ* 1979; **1:** 620–1.
4. Kristensen BØ. Does prazosin induce formation of antinuclear factor? *BMJ* 1979; **1:** 621.

Urinary incontinence. There have been reports of urinary incontinence developing in patients receiving prazosin. Analysis[1] of 56 cases reported to the Australian Adverse Drug Reactions Advisory Committee indicated that typically symptoms appeared within 1 or 2 days of the start of therapy and persisted until the drug was withdrawn or the dose reduced. Both stress and urge incontinence occurred, sometimes in the same patient. Of the 56 patients, 51 were women and most were elderly. In a study[2] in women attending a hypertension clinic urinary incontinence was reported in 40.8% of 49 women receiving alpha blockers (prazosin, terazosin, or doxazosin) and in 16.3% of controls. Incontinence might be due to a reduction in urethral pressure induced by alpha-adrenoceptor blockade.

Interestingly, faecal incontinence has also been reported with prazosin—see Effects on the Gastrointestinal Tract, above.

1. Mathew TH, *et al.* Urinary incontinence secondary to prazosin. *Med J Aust* 1988; **148:** 305–6.
2. Marshall HJ, Beevers DG. α-Adrenoceptor blocking drugs and female urinary incontinence: prevalence and reversibility. *Br J Clin Pharmacol* 1996; **42:** 507–9.

Treatment of Adverse Effects

If overdosage with prazosin occurs activated charcoal should be given if the patient presents within 1 hour of ingestion. Severe hypotension may occur and treatment includes support of the circulation by postural measures and parenteral fluid volume replacement, and if necessary cautious intravenous infusion of a vasopressor. Prazosin is not removed by dialysis.

Precautions

Treatment with prazosin should be introduced cautiously because of the risk of sudden collapse following the initial dose. Extra caution is necessary in patients with hepatic or renal impairment and in the elderly.

Prazosin is not recommended for the treatment of heart failure caused by mechanical obstruction, for example aortic or mitral valve stenosis, pulmonary embolism, and restrictive pericardial disease. It should be used with caution in patients with angina pectoris. Prazosin may cause drowsiness or dizziness; patients so affected should not drive or operate machinery.

Cataract surgery. For a warning about intraoperative floppy iris syndrome during cataract surgery in patients taking alpha blockers, see Surgical Procedures under Precautions for Tamsulosin Hydrochloride, p.2197.

Cerebral haemorrhage. Hypotension with disturbance of consciousness[1] occurred in 3 patients with recent cerebral haemorrhage after an initial dose of prazosin 500 micrograms.

1. Lin M-S, Hsieh W-J. Prazosin-induced first-dose phenomenon possibly associated with hemorrhagic stroke: a report of three cases. *Drug Intell Clin Pharm* 1987; **21:** 723–6.

Tolerance. Although prazosin may be of initial benefit in patients with chronic heart failure, some studies[1,2] have reported the development of tolerance to its haemodynamic effects on prolonged therapy. This may be partly due to upregulation of $alpha_1$ adrenoceptors.[3]

1. Packer M, *et al*. Role of the renin-angiotensin system in the development of hemodynamic and clinical tolerance to long-term prazosin therapy in patients with severe chronic heart failure. *J Am Coll Cardiol* 1986; **7:** 671–80.
2. Bayliss J, *et al*. Clinical importance of the renin-angiotensin system in chronic heart failure: double blind comparison of captopril and prazosin. *BMJ* 1985; **290:** 1861–5.
3. Kersting F, *et al*. Preliminary evidence for the mechanism underlying the development of tolerance to prazosin in congestive heart failure: the α-agonistic properties of dobutamine unmasked by prazosin treatment. *J Cardiovasc Pharmacol* 1993; **21:** 537–43.

Interactions

The hypotensive effects of prazosin may be enhanced by use with diuretics and other antihypertensives, and by alcohol and other drugs that cause hypotension. The risk of first-dose hypotension may be particularly increased in patients receiving beta blockers or calcium-channel blockers.

Analgesics. *Indometacin* reduced prazosin-induced hypotension in 4 of 9 subjects.[1]

1. Rubin P, *et al*. Studies on the clinical pharmacology of prazosin II: the influence of indomethacin and of propranolol on the action and disposition of prazosin. *Br J Clin Pharmacol* 1980; **10:** 33–9.

Antidepressants and antipsychotics. A patient who was taking *amitriptyline* and *chlorpromazine* developed acute agitation on receiving prazosin.[1] The symptoms settled rapidly when prazosin was discontinued. Antidepressants and antipsychotics may enhance the hypotensive effect of prazosin and other alpha blockers.

1. Bolli P, Simpson FO. New vasodilator drugs for hypertension. *BMJ* 1974; **1:** 637.

Calcium-channel blockers. An enhanced hypotensive effect has been reported in normotensive subjects given prazosin and *verapamil* concurrently; the effect may be due in part to enhanced bioavailability of prazosin.[1] Markedly increased hypotensive responses have also been reported with combined use of prazosin and *nifedipine*,[2,3] although the validity of such reports has been questioned.[4]

1. Pasanisi F, *et al*. Combined alpha adrenoceptor antagonism and calcium channel blockade in normal subjects. *Clin Pharmacol Ther* 1984; **36:** 716–23.

Digoxin. For reference to the effect of prazosin on serum-digoxin concentrations, see under Digoxin, p.1261.

Pharmacokinetics

Prazosin is readily absorbed from the gastrointestinal tract with peak plasma concentrations occurring 1 to 3 hours after an oral dose. The bioavailability is variable and a range of 43 to 85% has been reported. Prazosin is highly bound to plasma proteins. It is extensively metabolised in the liver and some of the metabolites are reported to have hypotensive activity. It is excreted as the metabolites and 5 to 11% as unchanged prazosin mainly in the faeces via the bile. Less than 10% is excreted in the urine. Small amounts are distributed into breast milk. Its duration of action is longer than would be predicted from its relatively short plasma half-life of about 2 to 4 hours. Half-life is reported to be increased to about 7 hours in patients with heart failure.

The elderly. The bioavailability of prazosin was significantly reduced in the elderly, about 40% less unchanged drug reaching the systemic circulation compared with the young.[1] This was attributed to a reduction in the absorption from the gastrointestinal tract. The half-life was also prolonged in the elderly and this was associated with an increase in the volume of distribution at steady state. However, it was considered unlikely that these effects would have major clinical significance.

1. Rubin PC, *et al*. Prazosin disposition in young and elderly subjects. *Br J Clin Pharmacol* 1981; **12:** 401–4.

Protein binding. Although a study[1] found that prazosin was about 80 to 85% bound to serum albumin and only about 10 to 30% bound to α_1-acid glycoprotein *in vitro*, potential interactions between the binding proteins *in vivo* were not taken into account; binding to α_1-acid glycoprotein might be more significant in clinical practice. A subsequent study[2] indicated that variations in prazosin protein binding pre- and post-operatively were related to variations in concentration of the glycoprotein.

1. Brunner F, Müller WE. Prazosin binding to human α -acid glycoprotein (orosomucoid), human serum albumin, and human serum: further characterisation of the 'single drug binding site' of orosomucoid. *J Pharm Pharmacol* 1985; **37:** 305–9.
2. Sager G, *et al*. Binding of prazosin and propranolol at variable α -acid glycoprotein and albumin concentrations. *Br J Clin Pharmacol* 1989; **27:** 229–34.

Uses and Administration

Prazosin is an alpha blocker (p.1153) that acts by selective blockade of $alpha_1$-adrenoceptors. It is used in the management of hypertension (p.1171), in Raynaud's syndrome (see Peripheral Vascular Disease, below), and to relieve symptoms of urinary obstruction in benign prostatic hyperplasia (p.2178). It has also been used in heart failure (p.1165).

Prazosin produces peripheral dilatation of both arterioles and veins and reduction of peripheral resistance, usually without reflex tachycardia. It reduces both standing and supine blood pressure with a greater effect on the diastolic pressure. It is reported to have no effect on renal blood flow or glomerular filtration rate, and has little effect on cardiac output in hypertensive patients. In patients with heart failure, prazosin reduces both preload and afterload and produces an improvement in cardiac output, although tolerance may develop. In benign prostatic hyperplasia, prazosin may relieve the symptoms of urinary obstruction by reducing smooth muscle tone in the prostate and bladder neck.

Prazosin is given orally as the hydrochloride, but doses are usually expressed in terms of the base. Prazosin hydrochloride 1.1 mg is equivalent to about 1 mg of prazosin. After oral dosage the hypotensive effect is seen within 2 to 4 hours and persists for several hours. Full effects are seen after 4 to 6 weeks.

A low starting dose is given in the evening to lessen the risk of collapse which may occur in some patients after the first dose (see Adverse Effects, above). Doses may need to be reduced in the elderly and in patients with hepatic or renal impairment.

In **hypertension**, the usual initial dose in the UK is 500 micrograms two or three times daily for 3 to 7 days; if tolerated the dose may then be increased to 1 mg two or three times daily for a further 3 to 7 days, and thereafter gradually increased, according to the patient's response, to a usual maximum of 20 mg daily in divided doses. In the US the recommended starting dose is 1 mg two or three times daily and up to 40 mg daily in divided doses has been given; however, the usual maintenance dose is between 6 and 15 mg daily. Smaller doses may be required in patients also taking other antihypertensives. Modified-release preparations may allow once daily dosing.

In **Raynaud's syndrome** and in **benign prostatic hyperplasia** an initial dose of 500 micrograms twice daily may be given, increasing to a maintenance dose not exceeding 2 mg twice daily.

In **heart failure**, treatment has been started with 500 micrograms two to four times daily and increased gradually according to response; the usual maintenance dose has been 4 to 20 mg daily.

Erectile dysfunction. Prazosin has been given transurethrally with alprostadil[1] in the management of erectile dysfunction (p.2179).

1. Peterson CA, *et al*. Erectile response to transurethral alprostadil, prazosin and alprostadil-prazosin combinations. *J Urol (Baltimore)* 1998; **159:** 1523–8.

Familial Mediterranean fever. Familial Mediterranean fever (p.557) is usually treated with prophylactic colchicine, but its use may be limited by adverse effects. A Japanese man who had suffered from attacks for 16 years was treated[1] with prazosin 3 mg daily. There were no further attacks for more than a year after starting treatment, but stopping prazosin resulted in a recurrence.

1. Kataoka H, *et al*. Treating familial Mediterranean fever with prazosin hydrochloride. *Ann Intern Med* 1998; **129:** 424–5.

Muscle cramp. Skeletal muscle cramp may occur during haemodialysis, possibly due to activation of the sympathetic nervous system. Prazosin was reported[1] to reduce the incidence of cramp in 4 of 5 patients with frequent haemodialysis-associated muscle cramp. However, the increased incidence of hypotension reported might limit its use for this indication.

1. Sidhom OA, *et al*. Low-dose prazosin in patients with muscle cramps during hemodialysis. *Clin Pharmacol Ther* 1994; **56:** 445–51.

Peripheral vascular disease. Alpha blockers, including prazosin, may be used in the management of Raynaud's syndrome (see Vasospastic Arterial Disorders, p.1188). Studies of the benefits of prazosin have produced varying results. A short-term reduction in number and duration of attacks was reported in 5 of 7 patients given prazosin 2 mg daily but only 1 patient had complete relief from attacks and few could tolerate doses higher than 6 mg daily.[1] Improvements were not maintained during continued treatment for 2 months. Others[2,3] have reported benefit from prazosin 1 mg two or three times daily in the majority of patients, with one study suggesting greater benefit in Raynaud's disease (the primary, idiopathic form) than in secondary Raynaud's syndrome.[2] In a subsequent study, higher doses of prazosin (2 or 4 mg three times daily) were no more effective than 1 mg three times daily, and were associated with a significantly greater incidence of adverse effects.[4] A systematic review[5] concluded that prazosin was modestly effective in the treatment of Raynaud's syndrome secondary to scleroderma.

Post-traumatic stress disorder. Post-traumatic stress disorder (p.953) is usually treated with psychotherapy or drugs such as SSRIs. Increased $alpha_1$-adrenergic receptor activity may be a contributory factor, and several small studies have reported that treatment with prazosin improves nightmares and sleep disturbances in patients with this condition.[1,2] A reduction in nightmares occurred in 5 patients taking part in a small 6-week open-label study;[3] doses ranged from 1 mg at night to 2 mg night and morning. A similar improvement was found in a retrospective study[4] of combat veterans with chronic treatment-resistant symptoms, where doses of prazosin were increased gradually from 1 mg at night up to a maximum daily dose of 20 mg if required, and in a placebo-controlled study[5] in similar patients given doses of up to 15 mg at night. Another small study[6] and a case report[7] have also reported benefit; doses varied from 1 mg at night to 10 mg daily in 2 divided doses.

Renal calculi. For the potential use of alpha blockers to aid the passage of renal calculi, see under Uses of Tamsulosin Hydrochloride, p.2197.

Scorpion stings. Stings from the Indian red scorpion (*Mesobuthus tamulus*) are potentially fatal. The scorpion venom is a potent sympathetic stimulator resulting in high circulating catecholamines, hypertension, arrhythmias, pulmonary oedema, and circulatory failure. The efficacy of antivenom is questionable and treatment for cardiotoxicity is supportive (see p.2237). Prazosin, given orally, appears to be beneficial and has been suggested[1,2] as first-line treatment, except in cases of severe pulmonary oedema. Prazosin has also been used in other countries to treat stings by dangerous scorpion species.[3,4]

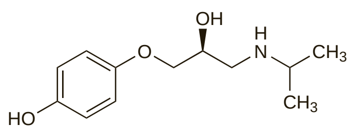
Prenalterol Hydrochloride *(BANM, USAN, rINNM)*

C-50005/A-Ba (racemate); CGP-7760B; H133/22; H-80/62 (racemate); Hidrocloruro de prenalterol; Prénaltérol, Chlorhydrate de; Prenalteroli Hydrochloridum. (*S*)-1-(4-Hydroxyphenoxy)-3-isopropylaminopropan-2-ol hydrochloride.

Преналътерола Гидрохлорид

$C_{12}H_{19}NO_3,HCl = 261.7.$
CAS — 57526-81-5 (prenalterol); 61260-05-7 (prenalterol hydrochloride).
ATC — C01CA13.
ATC Vet — QC01CA13.



(prenalterol)

Profile

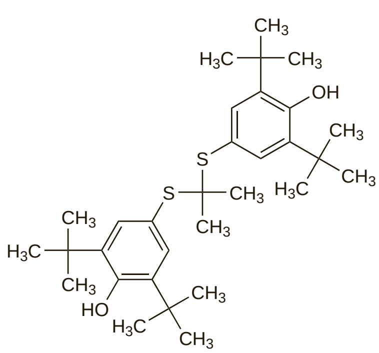
Prenalterol is a sympathomimetic (p.1407) with stimulant effects on $beta_1$ adrenoceptors. It has an inotropic action on the heart with relatively little chronotropic effect. Prenalterol hydrochloride has been given parenterally in the treatment of heart failure and shock. It has also been promoted for the reversal of beta blockade.

Probucol *(BAN, USAN, rINN)*

DH-581; Probucolum. 4,4′-(Isopropylidenedithio)bis(2,6-di-*tert*-butylphenol).

Пробукол

$C_{31}H_{48}O_2S_2 = 516.8.$
CAS — 23288-49-5.
ATC — C10AX02.
ATC Vet — QC10AX02.



Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Probucol). A white to off-white, crystalline powder. Insoluble in water; soluble in alcohol and in petroleum spirit; freely soluble in chloroform and in propyl alcohol. Protect from light.

Profile

Probucol is a lipid regulating drug that has been used in the treatment of hyperlipidaemias (p.1169). It lowers total plasma-cholesterol concentrations, mainly by reducing low-density lipoprotein (LDL)-cholesterol and high-density lipoprotein (HDL)-cholesterol concentrations but has little effect on triglyceride or very-low-density lipoprotein (VLDL)-cholesterol concentrations. It has also been used to prevent restenosis after reperfusion and revascularisation procedures (below), and in scleroderma.

Probucol prolongs the QT interval and has been associated with cardiac arrhythmias.

Reperfusion and revascularisation procedures. Restenosis is common after percutaneous coronary revascularisation procedures (p.1181) and various drugs have been tried for its prevention. Probucol, started a few weeks before the procedure, has been reported to reduce the rate of restenosis after coronary angioplasty,[1] and to reduce the need for repeat interventions,[1,2] although another study[3] found no effect.

1. Tardif J-C, *et al.* Probucol and multivitamins in the prevention of restenosis after coronary angioplasty. *N Engl J Med* 1997; **337:** 365–72.

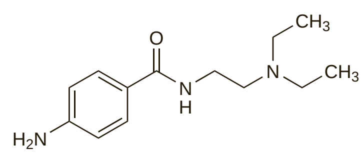
Procainamide Hydrochloride

(BANM, rINNM)

Hidrocloruro de procainimida; Novocainamidum; Procaïnamide, chlorhydrate de; Procainamidi Chloridum; Procainamidi hydrochloridum; Prokaiiniamidihydrokloridi; Prokainamid-hidroklorid; Prokainamid-hydrochlorid; Prokainamidhydroklorid; Prokainamido hidrochloridas; Prokainamidu chlorowodorek. 4-Amino-*N*-(2-diethylaminoethyl)benzamide hydrochloride.

Прокаинамида Гидрохлорид

$C_{13}H_{21}N_3O,HCl = 271.8.$
CAS — 51-06-9 (procainamide); 614-39-1 (procainamide hydrochloride).
ATC — C01BA02.
ATC Vet — QC01BA02.



(procainamide)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Procainamide Hydrochloride). A white or very slightly yellow, hygroscopic, crystalline powder. Very soluble in water; freely soluble in alcohol; slightly soluble in acetone. A 10% solution in water has a pH of 5.6 to 6.3. Store in airtight containers. Protect from light.

USP 31 (Procainamide Hydrochloride). A white to tan, odourless, crystalline powder. Very soluble in water; soluble in alcohol; slightly soluble in chloroform; very slightly soluble in ether and in benzene. A 10% solution in water has a pH of 5.0 to 6.5. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°.

Stability. Procainamide is more stable in neutral solutions such as sodium chloride, than in acidic solutions such as glucose, but patients requiring intravenous procainamide often have heart failure and cannot tolerate the sodium load associated with sodium chloride injections. The stability of procainamide in glucose 5% is improved by neutralising the glucose using sodium bicarbonate, or storing the admixture at 5°. The concentration of procainamide remained above 90% of the initial concentration for 24 hours if the glucose was first neutralised and this was considered more practical than refrigeration if extended stability was required.[1]

The compound formed by mixing procainamide hydrochloride with glucose 5% was shown to be a mixture of α- and β-glucosylamines[2] and about 10 to 15% of the procainamide was lost in this way after 10 hours at room temperature.

An oral liquid,[3] prepared from procainamide capsules, containing 5, 50, or 100 mg/mL of the hydrochloride was stable for at least 6 months when stored at 4° to 6°.

Adverse Effects

Cardiac effects occur particularly during intravenous use of procainamide and in overdose. Rapid intravenous dosage may result in severe hypotension, ventricular fibrillation, and asystole. High plasma concentrations are also associated with impaired cardiac conduction.

Hypersensitivity reactions to procainamide are common. Procainamide is a frequent cause of drug-induced SLE and the incidence has been reported to be as high as 30% during long-term use. Antinuclear antibodies may be detected in a high proportion of patients, but they do not necessarily develop the symptoms of SLE, which include arthralgia, arthritis, myalgia, pleural effusion, pericarditis, and fever. Agranulocytosis, eosinophilia, neutropenia, thrombocytopenia, and haemolytic anaemia have been reported. Other symptoms of hypersensitivity not necessarily related to SLE may also occur including hepatomegaly, angioedema, skin rashes, pruritus, urticaria, flushing, and hypergammaglobulinaemia.

Anorexia, nausea, vomiting, a bitter taste, and diarrhoea are more common with higher oral doses. Effects on the CNS such as mental depression, dizziness, and psychosis with hallucinations, have been reported.

Incidence of adverse effects. Out of 488 hospitalised patients in the Boston Collaborative Drug Surveillance Program who had received procainamide, 45 had acute adverse effects attributed to the drug.[1] Life-threatening reactions included heart block (3), tachyarrhythmias (2), and bradycardia and/or hypotension (2). Other reactions included gastrointestinal upsets (19), pyrexia (8), bradycardia and hypotension (5), tachyarrhythmias (3), heart block (1), eosinophilia (1), and urticaria (1).

1. Lawson DH, Jick H. Adverse reactions to procainamide. *Br J Clin Pharmacol* 1977; **4:** 507–11.

Effects on the blood. Adverse haematological effects reported during procainamide therapy include neutropenia,[1-3] agranulocytosis,[2-6] thrombocytopenia,[5] haemolytic anaemia,[7] and pancytopenia.[8] These disorders are usually reversible on withdrawing procainamide although some fatalities have been reported.[3,4] It has been suggested[2,6] that agranulocytosis or severe neutropenia is more likely in patients taking modified-release preparations, but others have found no difference in the incidence between modified-release and conventional-release preparations.[3] An increased risk of agranulocytosis with procainamide has been documented in one large study.[9] Although the precise estimate of excess risk could not be calculated, the order of magnitude was about 3 per million exposed for up to one week. This excess risk was low and of little relevance in the initial choice of therapy.

Effects on the gastrointestinal tract. Pseudo-obstruction of the bowel occurred in a diabetic patient when given procainamide both orally and intravenously. It was believed that the anticholinergic properties of procainamide, together with the diabetic state, contributed to the severe hypomotility of the gastrointestinal tract.[1]

1. Peterson AM, *et al.* Procainamide-induced pseudo-obstruction in a diabetic patient. *DICP Ann Pharmacother* 1991; **25:** 1334–5.

Effects on the heart. Procainamide prolongs the QT interval and has been associated with the development of torsade de pointes,[1,2] and fatal cardiovascular toxicity has been reported[3] in patients with renal impairment. Toxicity appears to be related to accumulation of the major metabolite, *N*-acetylprocainamide, and haemodialysis has been used to reduce plasma concentrations and control symptoms,[1,4] although its benefits have been disputed (see Dialysis, under Treatment of Adverse Effects,

The symbol † denotes a preparation no longer actively marketed

below). However, symptoms developed in 1 patient[2] despite plasma concentrations of both procainamide and *N*-acetylprocainamide being within the therapeutic range.

Effects on the liver. There have been reports of granulomatous hepatitis[1] and intrahepatic cholestasis[2,3] due to hypersensitivity reactions in patients taking procainamide. Fever and elevation of liver enzyme values also occurred. The reactions were reversible on withdrawing procainamide.

3. Chuang LC, *et al.* Possible case of procainamide-induced intrahepatic cholestatic jaundice. *Ann Pharmacother* 1993; **27:** 434–7.

Effects on mental function. Acute psychosis has been reported[1] in patients receiving therapy with procainamide.

1. Bizjak ED, *et al.* Procainamide-induced psychosis: a case report and review of the literature. *Ann Pharmacother* 1999; **33:** 948–51.

Effects on the muscles. Procainamide may affect neuromuscular transmission and there have been reports of severe generalised skeletal muscle weakness[1-3] in patients receiving procainamide. In 2 patients this was associated with respiratory failure[1,2] and developed shortly after starting therapy. Concentrations of procainamide and its *N*-acetyl metabolite exceeded the normal therapeutic ranges and rapid cycling peritoneal dialysis was used to remove the drug in 1 patient.[2] Adverse muscle symptoms are a feature of procainamide-induced lupus erythematosus (see below), but in such instances symptoms usually develop on long-term treatment.

3. Sayler DJ, DeJong DJ. Possible procainamide-induced myopathy. *DICP Ann Pharmacother* 1991; **25:** 436.

Lupus erythematosus. Procainamide is a well-known cause of drug-induced lupus erythematosus.[1,2] It occurs in about 20% of patients on long-term therapy,[2] although the majority of patients taking procainamide for more than 1 year have detectable antinuclear antibodies. There is some evidence[3] that slow acetylators are more likely to develop antibodies than rapid acetylators, and that the antibodies appear more rapidly in slow acetylators, but this may not correlate with the development of clinical symptoms.[4] The clinical syndrome may include fever, polyarthritis, arthralgia, myalgia, and pleuropulmonary and pericardial features, and is usually spontaneously reversible on withdrawal of procainamide.

Treatment of Adverse Effects

In overdosage with procainamide treatment is largely symptomatic and supportive. Activated charcoal may be considered if the patient presents within 1 hour of ingestion. The ECG, blood pressure, and renal function should be monitored. Supportive measures include correction of hypotension, assisted ventilation, and electrical pacing. Haemodialysis or haemoperfusion increase the elimination of procainamide and *N*-acetylprocainamide, see below.

SLE will normally respond to withdrawal of procainamide but corticosteroids may be required.

Dialysis. In the UK, the National Poisons Information Service does not recommend the use of haemodialysis or haemofiltration in the treatment of poisoning with class Ia antiarrhythmics. Nonetheless, both procainamide and *N*-acetylprocainamide are removed by haemodialysis, and there are reports[1-4] of the successful use of haemodialysis in patients with procainamide toxicity. However, toxicity has occurred in patients undergoing regular haemodialysis,[2,5,6] suggesting that some accumulation still takes place, and rebound increases in plasma concentrations have also been reported[4,7] after dialysis. Haemoperfusion[5,7] and haemofiltration[6] have also been used, and may be more effective. Peritoneal dialysis may also remove a small amount of procainamide and *N*-acetylprocainamide,[7] and there has been a report[8] of the successful use of rapid cycling peritoneal dialysis in a patient on maintenance peritoneal dialysis who developed procainamide-induced diaphragmatic paralysis.

Precautions

Procainamide is contra-indicated in heart block (unless the patient has a pacemaker) and in SLE, and should be used with caution in patients with myocardial damage or severe organic heart disease. The *BNF* considers that it should not be used in heart failure or hypotension. Patients with torsade de pointes may deteriorate if given procainamide. If procainamide is used to treat atrial tachycardia it may be necessary to pre-treat with digoxin. Procainamide should preferably not be used in patients with myasthenia gravis or digoxin toxicity. There may be cross-sensitivity between procaine and procainamide.

Accumulation of procainamide may occur in patients with heart failure or hepatic or renal impairment and dosage reduction may be necessary.

Blood counts and screening for lupus erythematosus and serum antinuclear factor should be carried out regularly during therapy.

Intravenous use of procainamide may lead to severe hypotension; it should be injected slowly and blood pressure and ECG should be monitored.

Breast feeding. There was evidence of accumulation of procainamide and *N*-acetylprocainamide in the breast milk of a woman taking procainamide 500 mg four times daily.[1] Milk and serum samples were obtained at three-hourly intervals for 15 hours. Mean serum concentrations of the drug and metabolite were found to be 1.1 and 1.6 micrograms/mL respectively; those in the milk were 5.4 and 3.5 micrograms/mL respectively. The mean milk:serum ratios were 4.3 (range 1.0 to 7.3) and 3.8 (range 1.0 to 6.2) respectively. However, it was considered that the amount ingested by the infant would not yield clinically significant serum concentrations. Although licensed product information states that procainamide should be avoided in breast-feeding women, there have been no reports of adverse effects in infants, and the American Academy of Pediatrics considers[2] that its use is therefore usually compatible with breast feeding.

Interactions

Procainamide may enhance the effects of antihypertensives, other antiarrhythmics and arrhythmogenic drugs, antimuscarinics, and neuromuscular blockers, and diminish those of parasympathomimetics, such as neostigmine. Procainamide is actively secreted by kidney tubules and interactions may occur with drugs secreted by the same pathway, such as cimetidine and trimethoprim.

Alcohol. The total body clearance of procainamide is increased by alcohol[1] and the elimination half-life reduced. The acetylation rate of procainamide is also increased resulting in a greater proportion of drug present as the active metabolite *N*-acetylprocainamide.

1. Olsen H, Mørland J. Ethanol-induced increase in procainamide acetylation in man. *Br J Clin Pharmacol* 1982; **13:** 203–8.

Antacids. Procainamide is adsorbed by some antacids and reduced bioavailability has been reported[1] in healthy subjects given procainamide with *kaolin-pectin*; the authors recommended that procainamide and adsorbents should not be used together.

1. Al-Shora HI, *et al.* Interactions of procainamide, verapamil, guanethidine and hydralazine with adsorbent antacids and antidiarrhoeal mixtures. *Int J Pharmaceutics* 1988; **47:** 209–13.

Antiarrhythmics. *Amiodarone* given orally alters the pharmacokinetic properties of an intravenous dose of procainamide,[1] decreasing clearance and prolonging the plasma elimination half-life. The dosage of intravenous procainamide should be reduced by 20 to 30% during concurrent use. Increased serum-procainamide concentrations have also been reported[2] in patients stabilised on oral procainamide who had amiodarone added to their therapy; the dosage of procainamide had to be reduced in some patients due to signs of toxicity. *Quinidine* has also been reported[3] to increase plasma-procainamide concentrations.

1. Windle J, *et al.* Pharmacokinetic and electrophysiologic interactions of amiodarone and procainamide. *Clin Pharmacol Ther* 1987; **41:** 603–10.
2. Saal AK, *et al.* Effect of amiodarone on serum quinidine and procainamide levels. *Am J Cardiol* 1984; **53:** 1264–7.
3. Hughes B, *et al.* Increased procainamide plasma concentrations caused by quinidine: a new drug interaction. *Am Heart J* 1987; **114:** 908–9.

Antibacterials. The renal clearance of procainamide and *N*-acetylprocainamide is reduced by *trimethoprim*[1,2] through competition for renal tubular secretion. Serum concentrations may be increased with a resulting increase in pharmacodynamic response. The fluoroquinolones *ciprofloxacin*,[3] *levofloxacin*,[3] and *ofloxacin*[4] have also been reported to reduce the renal clearance of procainamide.

4. Martin DE, *et al.* Effects of ofloxacin on the pharmacokinetics and pharmacodynamics of procainamide. *J Clin Pharmacol* 1996; **36:** 85–91.

Histamine H_2-antagonists. Histamine H_2-antagonists compete with other basic drugs for renal tubular secretion. *Cimetidine* reduces the renal clearance of procainamide and *N*-acetylprocainamide[1,2] and a dosage reduction may be necessary. Increases[3,4] and decreases[4] in renal and metabolic clearances of procainamide have occurred with *ranitidine*.

4. Rocci ML, *et al.* Ranitidine-induced changes in the renal and hepatic clearances of procainamide are correlated. *J Pharmacol Exp Ther* 1989; **248:** 923–8.

Pharmacokinetics

Procainamide is readily and almost completely absorbed from the gastrointestinal tract. It is widely distributed throughout the body and is only about 15 to 20% bound to plasma proteins. The therapeutic effect of procainamide has been correlated with plasma concentrations of about 3 to 10 micrograms/mL in most patients; progressively severe toxicity is noted at concentrations above 12 micrograms/mL.

Some procainamide undergoes acetylation in the liver to *N*-acetylprocainamide, which also has antiarrhythmic properties. The rate of acetylation of procainamide is genetically determined, there being slow and fast acetylators. Procainamide also undergoes hydrolysis in plasma to para-aminobenzoic acid.

Procainamide is excreted in the urine by active renal secretion, 30 to 70% as unchanged procainamide, with the remainder as *N*-acetylprocainamide and other metabolites. The elimination half-life of procainamide is 2.5 to 5 hours and that of its acetyl metabolite 6 to 7 hours. *N*-Acetylprocainamide may represent a significant fraction of the total drug in the circulation.

Procainamide crosses the placenta and is distributed into breast milk.

Bioavailability. Modified-release procainamide preparations have been shown[1] to produce similar steady-state serum concentrations of procainamide and *N*-acetylprocainamide when compared with equivalent total doses of immediate-release capsules. However, tablet matrices of a modified-release preparation have been recovered from the stools of a patient with diarrhoea[2] and 3.5 g of procainamide was recovered in these matrices over an 18-hour collection period; the patient had correspondingly low plasma-procainamide concentrations.

2. Bauer LA, *et al.* Influence of age, renal function and heart failure on procainamide clearance and n-acetylprocainamide serum concentrations. *Int J Clin Pharmacol Ther Toxicol* 1989; **27:** 213–16.

Hepatic impairment. In 20 healthy subjects and 20 patients with chronic liver disease given a single 500-mg oral dose of procainamide hydrochloride about 64 and 33% respectively of the dose was excreted in the urine within 6 hours.[1] Decreased procainamide acetylation in the patients compared with the control group was not correlated with the severity of liver disease, whereas decreased procainamide hydrolysis and increased procainamide-derived aminobenzoic acid acetylation appeared to be related to the degree of hepatic impairment. It was suggested that the decrease in excretion of procainamide and its metabolites in the urine of the patients with liver disease could be due to an impairment in oral absorption since renal function was within the normal range but the variations in acetylation and hydrolysis were related to hepatic function.

1. du Souich P, Erill S. Metabolism of procainamide and p-aminobenzoic acid in patients with chronic liver disease. *Clin Pharmacol Ther* 1977; **22:** 588–95.

Renal impairment. Procainamide and its active *N*-acetyl metabolite are mainly excreted in the urine and accumulation, particularly of the metabolite, may occur in renal impairment. A study[1] in 20 patients found that procainamide clearance correlated with renal function, and that the ratio of *N*-acetylprocainamide to procainamide in the serum increased as renal function declined. Fatal toxicity in patients with renal impairment and plasma-procainamide concentrations within the therapeutic range has been attributed[2] to accumulation of *N*-acetylprocainamide. Both procainamide and *N*-acetylprocainamide are removed by dialysis, although the benefit of these procedures has been disputed (see Dialysis under Treatment of Adverse Effects, above).

Uses and Administration

Procainamide is a class Ia antiarrhythmic (p.1153); it has properties similar to those of quinidine (p.1385).

Procainamide is usually reserved for the short-term management of severe or symptomatic ventricular arrhythmias (p.1160) such as those following myocardial infarction. It may also be used for cardioversion and management of atrial fibrillation.

Therapeutic effect is generally associated with plasma concentrations of 3 to 10 micrograms/mL. The dose of procainamide hydrochloride required will depend on the age, renal and hepatic function, and underlying cardiac condition of the patient: an adult with normal renal function generally requires up to 50 mg/kg daily in divided oral doses every 3 to 6 hours. Higher doses may be necessary for atrial arrhythmias. Modified-release preparations are available.

In an emergency and under continuous ECG and blood pressure monitoring, procainamide hydrochloride may be given intravenously. The injection should be diluted in glucose 5% to permit better control of the speed of injection, and should be given in doses of 100 mg every 5 minutes at a rate not exceeding 50 mg/minute until the arrhythmia has been suppressed or a maximum dose of 1 g has been reached. A response may be obtained after 100 to 200 mg has been given and more than 500 or 600 mg is not generally required. Alternatively, procainamide hydrochloride may be given by continuous infusion of 500 to 600 mg over 25 to 30 minutes. Therapeutic plasma concentrations may then be maintained by infusion at a rate of 2 to 6 mg/minute. When transferring to oral therapy, a period of about 3 to 4 hours should elapse between the last intravenous dose and the first oral dose.

Procainamide hydrochloride has also been given intramuscularly.

Procainamide hydrochloride may need to be given in reduced doses or at longer dosing intervals in the elderly and in patients with hepatic or renal impairment. For use in children, see below.

Acecainide (*N*-acetylprocainamide), the active metabolite of procainamide, has class III antiarrhythmic activity and has been used in ventricular arrhythmias.

Administration in children. In a study in 5 children treated with procainamide for various cardiac arrhythmias the mean elimination half-life was found to be 1.7 hours, and the plasma clearance was higher than that reported in adults.[1] In contrast the total serum clearance of procainamide in 3 neonates with supraventricular tachycardia was found to be similar to that in adults and the mean elimination half-life was 5.3 hours.[2] A loading dose of 10 to 12 mg/kg intravenously was given followed by a continuous infusion of 20 to 75 micrograms/kg per minute.

An oral dose of 15 to 50 mg/kg daily in 4 divided doses has been used in children.

Propafenone Hydrochloride

(BANM, USAN, rINNM)

Fenopraine Hydrochloride; Hidrocloruro de propafenona; Propafenon Hidroklorür; Propafénone, chlorhydrate de; Propafenon-hydrochlorid; Propafenonhydroklorid; Propafenoni hydrochloridum; Propafenonihydrokloridi; Propafenono hidrochloridas; SA-79; WZ-884642; WZ-884643. 2′-(2-Hydroxy-3-propylaminopropoxy)-3-phenylpropiophenone hydrochloride.

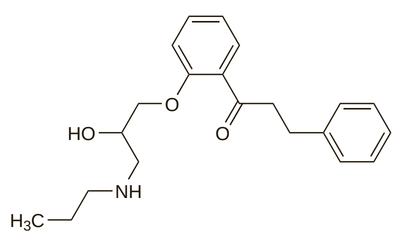
Пропафенона Гидрохлорид

$C_{21}H_{27}NO_3,HCl = 377.9.$

CAS — 54063-53-5 (propafenone); 34183-22-7 (propafenone hydrochloride).

ATC — C01BC03.

ATC Vet — QC01BC03.



(propafenone)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Propafenone Hydrochloride). Colourless crystals or a white or almost white powder. Slightly soluble in cold water; soluble in hot water and in methyl alcohol; practically insoluble in alcohol. A 0.5% solution in water has a pH of 5.0 to 6.2.

USP 31 (Propafenone Hydrochloride). A white powder. Soluble in hot water and in methyl alcohol; slightly soluble in alcohol and in chloroform; very slightly soluble in acetone; insoluble in ether and in toluene. A 0.5% solution in water has a pH of 5.0 to 6.2. Store in airtight containers at a temperature between 15° and 30°. Protect from light.

Adverse Effects

Propafenone can cause disturbances in cardiac conduction which can result in bradycardia, heart block, and sinus arrest. It may aggravate heart failure and may cause hypotension. In common with other antiarrhythmics, propafenone may induce or worsen arrhythmias in some patients.

Among the most common adverse effects are gastrointestinal intolerance, dry mouth, a bitter or metallic taste, dizziness, blurred vision, headache, and fatigue. Convulsions, blood dyscrasias, liver disorders, lupus erythematosus, skin rashes, impotence, and increased breathlessness and worsening of asthma have also been reported.

Effects on the heart. Propafenone may worsen ventricular arrhythmias and there have been reports[1,2] of fatal exacerbations occurring hours to days after starting treatment. Cardiovascular toxicity may also occur in overdosage.[3] Torsade de pointes has been reported[2,4,5] but appears to be less frequent than with class Ia antiarrhythmics.

5. Hii JT, *et al.* Propafenone-induced torsade de pointes: cross-reactivity with quinidine. *Pacing Clin Electrophysiol* 1991; **14:** 1568–70.

Effects on the liver. A review of liver injury secondary to propafenone therapy concluded that it is a rare occurrence and appears to be due to hepatocellular injury, cholestasis, or a combination.[1]

1. Spinler SA, *et al.* Propafenone-induced liver injury. *Ann Pharmacother* 1992; **26:** 926–8.

Effects on mental function. Delusions, hallucinations, and paranoia have been reported in an elderly patient after 2 doses of propafenone. The manufacturer had received reports of mania and psychosis.[1] Amnesia developed in a 61-year-old man 6 days after starting treatment with propafenone.[2] Symptoms resolved 6 to 7 hours after stopping the drug.

2. Jones RJ, *et al.* Probable propafenone-induced transient global amnesia. *Ann Pharmacother* 1995; **29:** 586–90.

Effects on the nervous system. Myoclonus has been reported in a patient receiving propafenone.[1] In another patient peripheral neuropathy developed 10 months after starting treatment but symptoms had resolved 6 months after stopping the drug.[2] There have also been reports of ataxia.[3]

1. Chua TP, *et al.* Myoclonus associated with propafenone. *BMJ* 1994; **308:** 113.

3. Odeh M, *et al.* Propafenone-induced ataxia: report of three cases. *Am J Med Sci* 2000; **320:** 151–3.

Lupus erythematosus. Symptoms of lupus erythematosus and raised antinuclear antibody titres were associated with propafenone therapy on 2 occasions in a 63-year-old woman.[1]

1. Guindo J, *et al.* Propafenone and a syndrome of the lupus erythematosus type. *Ann Intern Med* 1986; **104:** 589.

Precautions

Propafenone is contra-indicated in patients with uncontrolled heart failure, conduction disturbances including heart block unless controlled by artificial pacing, cardiogenic shock (unless arrhythmia-induced), severe bradycardia, or pronounced hypotension. It may alter the endocardial pacing threshold and adjustment may be necessary in patients with pacemakers.

Propafenone has beta-blocking activity and may exacerbate obstructive airways disease; it should be used with great caution in such disorders and is contra-indicated in severe disease. Propafenone may aggravate myasthenia gravis and should be avoided in patients with this condition. Electrolyte disturbances should be corrected before beginning treatment. Propafenone should be used with caution in patients with hepatic or renal impairment.

Pregnancy and breast feeding. Experience in a patient given propafenone throughout the last trimester of pregnancy indicated that despite transplacental diffusion propafenone could safely be used at this time without harm to the fetus. Propafenone and its metabolite were detected in breast milk at concentrations considered to represent a markedly subtherapeutic dose to an infant.[1]

1. Libardoni M, *et al.* Transfer of propafenone and 5-OH-propafenone to foetal plasma and maternal milk. *Br J Clin Pharmacol* 1991; **32:** 527–8.

Interactions

Propafenone is extensively metabolised by the cytochrome P450 enzyme system, mainly by the isoenzyme CYP2D6, although CYP1A2 and CYP3A4 are also involved. Interactions may therefore occur with other drugs that are metabolised by these enzymes. Plasma-propafenone concentrations may be reduced by enzyme inducers such as rifampicin; enzyme inhibitors, such as cimetidine, fluoxetine, quinidine, and HIV-protease inhibitors, may increase plasma-propafenone concentrations. Propafenone itself may alter the plasma concentrations of other drugs, including beta blockers, ciclosporin, desipramine, digoxin, theophylline, venlafaxine, and warfarin. The absorption of propafenone may be reduced by orlistat. There may be an increased risk of arrhythmias if propafenone is given with other antiarrhythmics or arrhythmogenic drugs.

Antiarrhythmics. *Quinidine* inhibits the hepatic metabolism of propafenone and has been reported[1] to increase plasma-propafenone concentrations in extensive metabolisers;[1] the plasma concentration of the active 5-hydroxy metabolite was reduced and that of the *N*-depropyl metabolite increased but there was no change in the clinical response. Another study,[2] however, found that quinidine increased the beta-blocking effect of propafenone in extensive metabolisers, and a study[3] in patients with refractory atrial fibrillation found that addition of quinidine to propafenone was as effective and possibly better tolerated than increasing the propafenone dose.

1. Funck-Brentano C, *et al.* Genetically-determined interaction between propafenone and low dose quinidine: role of active metabolites in modulating net drug effect. *Br J Clin Pharmacol* 1989; **27:** 435–44.
2. Mörike KE, Roden DM. Quinidine-enhanced beta-blockade during treatment with propafenone in extensive metabolizer human subjects. *Clin Pharmacol Ther* 1994; **55:** 28–34.
3. Lau C-P, *et al.* Control of paroxysmal atrial fibrillation recurrence using combined administration of propafenone and quinidine. *Am J Cardiol* 2000; **86:** 1327–32.

Antibacterials. *Rifampicin* has lowered steady-state plasma concentrations of propafenone with the reappearance of arrhythmia.[1]

1. Castel JM, *et al.* Rifampicin lowers plasma concentrations of propafenone and its antiarrhythmic effect. *Br J Clin Pharmacol* 1990; **30:** 155–6.

Histamine H_2-antagonists. *Cimetidine* has been reported[1] to raise plasma-propafenone concentrations. The mean steady-state concentration increased by 22% but the wide interindividual variability meant this change was not significant.

1. Pritchett ELC, *et al.* Pharmacokinetic and pharmacodynamic interactions of propafenone and cimetidine. *J Clin Pharmacol* 1988; **28:** 619–24.

Pharmacokinetics

Propafenone is readily and almost completely absorbed from the gastrointestinal tract. It is metabolised in the liver, largely by the cytochrome P450 isoenzyme CYP2D6, but also to a small extent by CYP1A2 and CYP3A4; the extent of metabolism is genetically determined. In subjects with the extensive metaboliser phenotype there is extensive first-pass metabolism to two active metabolites, 5-hydroxypropafenone and *N*-depropylpropafenone, and to other minor inactive metabolites. In the small proportion of subjects with the slow metaboliser phenotype (lacking CYP2D6) little or no 5-hydroxypropafenone is formed. The bioavailability of propafenone is dependent upon metaboliser phenotype but more importantly on dosage as the first-pass metabolism is saturable. In practice doses are high enough to compensate for differences in phenotype. Propafenone and its metabolites also undergo glucuronidation.

Propafenone is more than 95% protein bound.

Propafenone is excreted in the urine and faeces mainly in the form of conjugated metabolites. The elimination half-life is reported to be 2 to 10 hours in extensive metabolisers and 10 to 32 hours in slow metabolisers.

Propafenone crosses the placenta and is distributed into breast milk.

Uses and Administration

Propafenone is a class Ic antiarrhythmic (p.1153) with some negative inotropic and beta-adrenoceptor blocking activity. It is used in the management of supraventricular and ventricular arrhythmias.

Treatment should be started under close monitoring of the ECG and blood pressure. The usual initial oral dose of propafenone hydrochloride is 150 mg three times daily and this may be increased, if necessary, at intervals of 3 to 4 days up to a maximum of 300 mg three times daily. Reduced doses may be appropriate in patients weighing less than 70 kg and in the elderly; dose reduction may also be necessary in hepatic impairment (see below).

Propafenone hydrochloride is available in some countries as a modified-release preparation. It has also been given by slow intravenous injection or by infusion.

Administration in hepatic impairment. The clearance of propafenone may be reduced in hepatic impairment; careful monitoring is required and lower doses should be considered. US licensed product information states that the dose should be only 20 to 30% of that given in normal hepatic function.

Administration in renal impairment. A study[1] of the disposition of propafenone found that renal function did not affect the pharmacokinetics of propafenone or 5-hydroxypropafenone, and another study[2] suggested that propafenone could be used safely for atrial fibrillation in patients with chronic renal failure. Nevertheless, UK and US licensed product information states that caution is necessary if propafenone is given to patients with renal impairment.

Propafenone does not appear to be removed by haemofiltration.[3]

3. Seto W, *et al.* Propafenone disposition during continuous venovenous hemofiltration. *Ann Pharmacother* 1999; **33:** 957–9.

Cardiac arrhythmias. Propafenone is effective in many cardiac arrhythmias.[1,2] It may have a role in the management of supraventricular arrhythmias (see p.1160), including as a single oral loading dose for recent-onset atrial fibrillation.[3,4] It may also be used in ventricular arrhythmias, although in many cases non-pharmacological therapy is preferred. Successful use in children with various arrhythmias has also been reported.[5,6]

(propranolol)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Propranolol Hydrochloride). A white or almost white powder. Soluble in water and in alcohol.

USP 31 (Propranolol Hydrochloride). A white to off-white, odourless, crystalline powder. Soluble in water and in alcohol; slightly soluble in chloroform; practically insoluble in ether. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Stability. In aqueous solutions propranolol decomposes with oxidation of the isopropylamine side-chain, accompanied by a reduction in pH and discoloration of the solution. Solutions are most stable at pH 3 and decompose rapidly when alkaline.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Breast feeding. Propranolol is distributed into breast milk. A milk/plasma ratio range of 0.33 to 1.65 was reported in a study of 3 women.[1] It was calculated that the maximum dose likely to be ingested by a breast-fed infant would be less than 0.1% of the maternal dose. Other small studies[2,3] have reported similar results. No adverse effects have been seen in breast-fed infants whose mothers were given propranolol and the American Academy of Pediatrics considers[4] that it is therefore usually compatible with breast feeding.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics

Propranolol is almost completely absorbed from the gastrointestinal tract, but is subject to considerable hepatic-tissue binding and first-pass metabolism. Peak plasma concentrations occur about 1 to 2 hours after an oral dose. Plasma concentrations vary greatly between individuals. Propranolol has high lipid solubility. It crosses the blood-brain barrier and the placenta, and is distributed into breast milk. Propranolol is about 90% bound to plasma proteins. It is metabolised in the liver and at least one of its metabolites (4-hydroxypropranolol) is considered to be active, but the contribution of metabolites to its overall activity is uncertain. The metabolites and small amounts of unchanged drug are excreted in the urine. The plasma half-life of propranolol is about 3 to 6 hours. Propranolol is reported not to be significantly dialysable.

Pregnancy. A study in 6 pregnant patients (32 to 36 weeks' gestation) showed that the disposition of propranolol 120 mg orally and 10 mg intravenously was not altered in pregnancy compared with the postnatal period.[1] Another study[2] in 13 pregnant patients given propranolol to control hypertension showed that the pharmacokinetics of propranolol and most of its major metabolites were not altered during pregnancy. Samples at term[3] in 10 of the women showed that propranolol and all of its known metabolites were present in maternal plasma, cord plasma, and neonatal plasma. At delivery plasma protein binding of propranolol was reported as 87.5% in maternal plasma and 67.2% in cord plasma. Similar results for maternal and cord plasma protein binding have been reported by others.[4]

Uses and Administration

Propranolol is a non-cardioselective beta blocker (p.1225). It is reported to have membrane-stabilising properties, but does not possess intrinsic sympathomimetic activity.

Propranolol is used as the hydrochloride in the management of hypertension (p.1171), phaeochromocytoma (p.1179), angina pectoris (p.1157), myocardial infarction (p.1175), and cardiac arrhythmias (p.1160). It is also used in hypertrophic cardiomyopathy (p.1163). It is used to control symptoms of sympathetic overactivity in the management of hyperthyroidism (p.2165), anxiety disorders (p.952), and tremor (p.1231). Other indications include the prophylaxis of migraine (p.616) and of upper gastrointestinal bleeding in patients with portal hypertension (see Variceal Haemorrhage under Monoethanolamine Oleate, p.2346).

Propranolol hydrochloride is usually given orally. In **hypertension** it is given in initial doses of 40 to 80 mg twice daily increased as required to a usual range of 160 to 320 mg daily; some patients may require up to 640 mg daily. Propranolol is *not* suitable for the emergency treatment of hypertension; it should not be given intravenously in hypertension.

In **phaeochromocytoma**, patients treated surgically may be given 60 mg daily on the 3 days before the operation, always with alpha blockade. If the tumour is inoperable prolonged treatment may be given with a daily dose of 30 mg.

In **angina,** initial doses of propranolol hydrochloride 40 mg given 2 or 3 times daily are increased as required to a usual range of 120 to 240 mg daily. Some patients may require up to 320 mg daily.

Propranolol hydrochloride is given within 5 to 21 days of **myocardial infarction** in doses of 40 mg given four times daily for 2 or 3 days followed by 80 mg twice daily. Another regimen is to give 180 to 240 mg daily in divided doses.

Propranolol may be given in doses of 30 to 160 mg daily in divided doses in the long-term management of **cardiac arrhythmias**. For the emergency treatment of cardiac arrhythmias, propranolol hydrochloride may be given by slow intravenous injection over a period of 1 minute, in a dose of 1 mg, repeated if necessary every 2 minutes until a maximum total of 10 mg has been given in conscious patients and 5 mg in patients under anaesthesia. Patients receiving propranolol intravenously should be carefully monitored.

In **hypertrophic cardiomyopathy** the usual dose of propranolol hydrochloride is 10 to 40 mg given three or four times daily.

In **hyperthyroidism** propranolol hydrochloride is given in doses of 10 to 40 mg three or four times daily. If intravenous administration is necessary 1 mg is given over 1 minute, repeated at 2-minute intervals until a response is seen or to a maximum dose of 10 mg in conscious patients or 5 mg in patients under anaesthesia.

The dose for **anxiety** is 40 mg daily; this may be increased to 40 mg two or three times daily.

Essential tremor may be treated with 40 mg given two or three times daily; the dose can be increased at weekly intervals to 160 mg daily although doses up to 320 mg daily may be necessary.

An initial dose of 40 mg two or three times daily is used in **migraine** prophylaxis; the dose can be increased at weekly intervals up to 160 mg daily. Some patients have been given 240 mg daily.

In **portal hypertension,** propranolol hydrochloride should be given in initial doses of 40 mg twice daily; the dose may be increased as required up to 160 mg twice daily.

For the use of propranolol in children, see below.

Administration in children. Propranolol hydrochloride has been used both orally and intravenously in children, although it is not licensed for all indications. Suggested doses are:

for **hypertension**:
- neonates: 250 micrograms/kg orally three times daily, increased as required to a maximum of 2 mg/kg three times daily
- 1 month to 12 years: 0.25 to 1 mg/kg orally three times daily, increased as required to a maximum of 5 mg/kg daily in divided doses
- over 12 years: an adult dose (see above)

for **arrhythmias, phaeochromocytoma, and hyperthyroidism**:
- neonates: 250 to 500 micrograms/kg orally three times daily. *Alternatively* 20 to 50 micrograms/kg may be given intravenously three or four times daily, injected slowly with appropriate monitoring
- 1 month to 18 years: 250 to 500 micrograms/kg orally three or four times daily, adjusted according to response, to a maximum of 1 mg/kg four times daily or a total daily dose of 160 mg. *Alternatively* 25 to 50 micrograms/kg may be given intravenously three or four times daily, injected slowly with appropriate monitoring

for **prophylaxis of migraine**:
- children up to 12 years: 10 to 20 mg orally two or three times daily
- over 12 years: an adult dose (see above)

for **tetralogy of Fallot**, see below

Administration in hepatic impairment. A study of the disposition of oral propranolol at steady state in 9 normal subjects and 7 with cirrhosis found a mean threefold increase in unbound blood-propranolol concentrations in patients with cirrhosis when compared with the controls. Mean half-lives for the 2 groups were 11.2 and 4 hours respectively.[1] Another study of propranolol given as a single dose of a 20-mg tablet and as a 160-mg modified-release preparation daily for 7 days in 10 patients with cirrhosis and portal hypertension found higher plasma concentrations in patients with severe liver disease compared with those reported in normal controls.[2] Others have reported similar findings.[3]

In patients with severe liver disease, it has been suggested that propranolol therapy be started at a low dose such as 20 mg three times daily,[2] 80 mg of a modified-release preparation given once daily,[2] or 160 mg of a modified-release preparation given every other day.[3] Monitoring of beta blockade is essential; checking the heart rate[2] or exercise testing[3] have been suggested as suitable methods to assess the extent of beta blockade in patients with cirrhosis.

3. Calès P, *et al.* Pharmacodynamic and pharmacokinetic study of propranolol in patients with cirrhosis and portal hypertension. *Br J Clin Pharmacol* 1989; **27:** 763–70.

Administration in renal impairment. A study of the pharmacokinetics of propranolol in 11 patients with chronic renal insufficiency showed no impairment in the elimination kinetics of propranolol compared with 8 subjects with normal renal function.[1] Peak concentrations of propranolol reported in patients with chronic renal failure have been 2 to 3 times higher than those in patients receiving dialysis or in normal subjects.[1,2] Additional studies indicate that there is no pharmacokinetic reason to amend the dosage of propranolol in patients with renal impairment.[3]

Findings from a study in 8 patients on haemodialysis include a slight elevation of plasma-propranolol concentrations, no elevation of plasma concentration of 4-hydroxypropranolol, but extremely high plasma concentrations of other propranolol metabolites.[4]

4. Stone WJ, Walle T. Massive propranolol metabolite retention during maintenance hemodialysis. *Clin Pharmacol Ther* 1980; **28:** 449–55.

Tetralogy of Fallot. Beta blockers, particularly propranolol, have been used for the treatment[1] and prophylaxis[1-3] of cyanotic attacks in infants and children with tetralogy of Fallot and reversible right-ventricular outflow tract obstruction, although caution is required since bradycardia may develop.[4] Esmolol may be preferred during surgery.[5-7]

In the UK, licensed prescribing information allows an oral dose of propranolol hydrochloride of up to 1 mg/kg given 3 or 4 times daily. It may also be given intravenously in a dose of up to 100 micrograms/kg 3 or 4 times daily, injected slowly under ECG control.

The *BNFC* recommends the following doses:
- Neonates: 0.25 to 1 mg/kg orally 2 or 3 times daily, to a maximum of 2 mg/kg 3 times daily, or 15 to 20 micrograms/kg (maximum 100 micrograms/kg) intravenously, repeated every 12 hours if necessary
- Children aged 1 month to 12 years: 0.25 to 1 mg/kg orally 3 or 4 times daily, to a maximum of 5 mg/kg daily, or 15 to 20 micrograms/kg (maximum 100 micrograms/kg) intravenously, repeated every 6 to 8 hours if necessary.

2936; A-32686; Proscilaridina; Proscillaridiini; Proscillaridin A; Proscillaridine; Proscillaridinum; PSC-801. 14-Hydroxy-3β-(α-L-rhamnopyranosyloxy)-14β-bufa-4,20,22-trienolide.

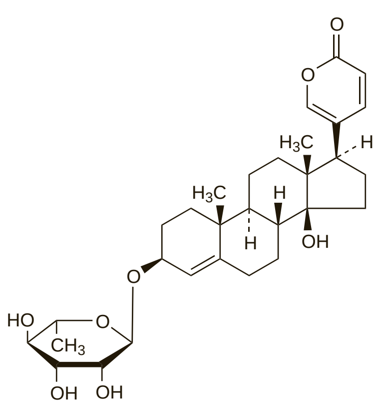
Просцилларидин

$C_{30}H_{42}O_8$ = 530.6.

CAS — 466-06-8.

ATC — C01AB01.

ATC Vet — QC01AB01.



Profile

Proscillaridin is a cardiac glycoside obtained from *Drimia maritima* (Liliaceae). It is a positive inotrope with general properties similar to those of digoxin (p.1259). It is reported to have a rapid onset and a short duration of action.

Proscillaridin is used in the treatment of heart failure (p.1165). It is given orally in usual initial and maintenance doses of 1 to 1.5 mg daily; maintenance doses may range from 0.75 to 2 mg daily as required.

Preparations

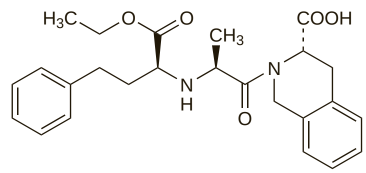
Хинаприла Гидрохлорид

$C_{25}H_{30}N_2O_5,HCl$ = 475.0.

CAS — 85441-61-8 (quinapril); 82586-55-8 (quinapril hydrochloride).

ATC — C09AA06.

ATC Vet — QC09AA06.



(quinapril)

Pharmacopoeias. In *US.*

USP 31 (Quinapril Hydrochloride). A white to off-white powder, with a pink cast at times. Freely soluble in aqueous solvents.

Suspension. Extemporaneous formulations of quinapril 1 mg/mL made by adding crushed Accupril tablets (*Pfizer, US*) to the following vehicles were found to be stable for 6 weeks when stored at 5°:

- *Kphos* 15% (*Beach, US*), *Bicitra* 15% (*Draxis Pharma, US*), *OraSweet* 70% (*Paddock, US*)
- *Kphos* 15%, *Bicitra* 15%, *OraSweet SF* 70%
- *Kphos* 15%, *Bicitra* 15%, simple syrup 70%

The suspension containing *OraSweet SF* was considered to be the formulation of choice.[1]

1. Freed AL, *et al.* The development and stability assessment of extemporaneous pediatric formulations of Accupril. *Int J Pharm* 2005;**304:** 135–44.

Adverse Effects, Treatment, and Precautions

As for ACE inhibitors, p.1193.

Breast feeding. After of a single dose of quinapril 20 mg in 6 women, quinapril was detected in the breast milk in a milk to plasma ratio of 0.12; no quinaprilat was detected.[1] It was estimated that the dose received by the infant would only be about 1.6% of the maternal dose.

1. Begg EJ, *et al.* Quinapril and its metabolite quinaprilat in human milk. *Br J Clin Pharmacol* 2001; **51:** 478–81.

Interactions

As for ACE inhibitors, p.1196.

Antibacterials. Quinapril has been reported to reduce the absorption of *tetracyclines* due to the presence of magnesium carbonate in the tablet formulation.

Pharmacokinetics

Quinapril acts as a prodrug of the diacid quinaprilat, its active metabolite. About 60% of an oral dose of quinapril is absorbed. Quinapril is metabolised mainly in the liver to quinaprilat and inactive metabolites. Peak plasma concentrations of quinaprilat are achieved within 2 hours of an oral dose of quinapril. Quinaprilat is about 97% bound to plasma proteins. After an oral dose, quinapril is excreted in the urine and faeces, as quinaprilat, other metabolites, and unchanged drug, with the urinary route predominating; up to 96% of an intravenous dose of quinaprilat is excreted in the urine. The effective half-life for accumulation of quinaprilat is about 3 hours after multiple doses of quinapril; a long terminal phase half-life of 25 hours may represent strong binding of quinaprilat to angiotensin-converting enzyme.

The pharmacokinetics of both quinapril and quinaprilat are affected by renal and hepatic impairment. Dialysis has little effect on the excretion of quinapril or quinaprilat.

Small amounts of quinapril are distributed into breast milk.

Uses and Administration

Quinapril is an ACE inhibitor (p.1193). It is used in the treatment of hypertension (p.1171) and heart failure (p.1165).

Quinapril is converted in the body to its active metabolite quinaprilat. The haemodynamic effects are seen within 1 hour of a single oral dose and the maximum effect occurs after about 2 to 4 hours, although the full effect may not develop for 1 to 2 weeks during chronic use. The haemodynamic action persists for about 24 hours, allowing once-daily dosing. Quinapril is given orally as the hydrochloride, but doses are expressed in terms of the base. Quinapril hydrochloride 10.8 mg is equivalent to about 10.0 mg of quinapril.

In the treatment of **hypertension** the initial dose is 10 mg of quinapril once daily. Since there may be a precipitous fall in blood pressure in some patients when starting therapy with an ACE inhibitor, the first dose should preferably be given at bedtime. An initial dose of 2.5 mg daily is recommended in the elderly, in patients with renal impairment, or in those taking a *diuretic*; if possible, the diuretic should be withdrawn 2 or 3 days before quinapril is started and resumed later if necessary.

The usual maintenance dose is 20 to 40 mg daily, as a single dose or divided into 2 doses, although up to 80 mg daily has been given.

In the management of **heart failure**, severe first-dose hypotension on introduction of an ACE inhibitor is common in patients on loop diuretics, but their temporary withdrawal may cause rebound pulmonary oedema. Thus treatment should begin with a low dose under close medical supervision. Quinapril is given in an initial dose of 2.5 mg daily. Usual maintenance doses range from 10 to 20 mg daily, as a single dose or divided into 2 doses; up to 40 mg daily has been given.

Quinaprilat may be given intravenously in patients unable to take quinapril orally; doses range from 1.25 to 10 mg twice daily.

Quinethazone *(BAN, rINN)* ⊗

Chinethazonum; Kinetatsoni; Kinetazon; Quinetazona; Quinéthazone; Quinethazonum. 7-Chloro-2-ethyl-1,2,3,4-tetrahydro-4-oxoquinazoline-6-sulphonamide.

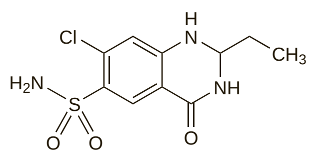
Хинетазон

$C_{10}H_{12}ClN_3O_3S$ = 289.7.

CAS — 73-49-4.

ATC — C03BA02.

ATC Vet — QC03BA02.



Profile

Quinethazone is a diuretic that is related chemically to metolazone and has properties similar to those of the thiazide diuretics (see Hydrochlorothiazide, p.1307). It has been used for oedema, including that associated with heart failure, and for hypertension.

Quinidine *(BAN)*

Chinidinum; Chinidyna; Kinidiini; Kinidin; Kinin; Quinidina. (8*R*,9*S*)-6′-Methoxycinchonan-9-ol; (+)-(α*S*)-α-(6-Methoxy-4-quinolyl)-α-[(2*R*,4*S*,5*R*)-(5-vinylquinuclidin-2-yl)]methanol.

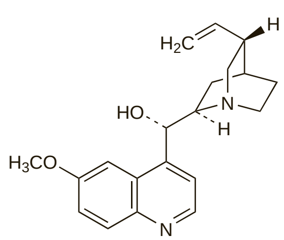
Хинидин

$C_{20}H_{24}N_2O_2$ = 324.4.

CAS — 56-54-2 (anhydrous quinidine); 63717-04-4 (quinidine dihydrate); 72402-50-7 (± quinidine).

ATC — C01BA01.

ATC Vet — QC01BA01.



Description. Quinidine is an isomer of quinine, obtained from the bark of species of *Cinchona* and their hybrids; it may also be obtained from *Remijia pedunculata*, or prepared from quinine.

Quinidine Bisulfate

Quinidina, bisulfato de; Quinidine Bisulphate *(BANM)*.

Хинидина Бисульфат

$C_{20}H_{24}N_2O_2,H_2SO_4$ = 422.5.

CAS — 747-45-5 (anhydrous quinidine bisulfate); 6151-39-9 (quinidine bisulfate tetrahydrate).

ATC — C01BA01.

ATC Vet — QC01BA01.

Pharmacopoeias. In *Br.*

BP 2008 (Quinidine Bisulphate). Colourless, odourless or almost odourless, crystals. It contains not more than 15% of hydroquinidine bisulfate. Freely soluble in water and in alcohol; practically insoluble in ether. A 1% solution in water has a pH of 2.6 to 3.6. Protect from light.

Quinidine Gluconate *(BANM)*

Quinidina, gluconato de; Quinidinium Gluconate.

Хинидина Глюконат

$C_{20}H_{24}N_2O_2,C_6H_{12}O_7$ = 520.6.

CAS — 7054-25-3.

ATC — C01BA01.

ATC Vet — QC01BA01.

Pharmacopoeias. In *US.*

USP 31 (Quinidine Gluconate). A white, odourless powder. It contains not more than 20% of hydroquinidine gluconate. Freely soluble in water; slightly soluble in alcohol. Store at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adsorption. More than 40% of a dose of quinidine gluconate was lost when the drug was given by intravenous infusion using a PVC infusion bag and tubing.[1]

1. Darbar D, *et al.* Loss of quinidine gluconate injection in a polyvinyl chloride infusion system. *Am J Health-Syst Pharm* 1996; **53:** 655–8.

Quinidine Polygalacturonate

Quinidina, poligalacturonato de. Quinidine poly(D-galacturonate) hydrate.

Хинидина Полигалактуронат

$C_{20}H_{24}N_2O_2,(C_6H_{10}O_7)_x,xH_2O$.

CAS — 27555-34-6 (anhydrous quinidine polygalacturonate); 65484-56-2 (quinidine polygalacturonate hydrate).

ATC — C01BA01.

ATC Vet — QC01BA01.

Quinidine Sulfate

Chinidin sulfát dihydrát; Chinidini sulfas; Chinidino sulfatas; Chinidinsulfate; Chinidinum Sulfuricum; Chinidyny siarczan; Kinidiinisulfaatti; Kinidin Sülfat; Kinidinsulfat; Kinidin-szulfát; Quinidina, sulfato de; Quinidine, sulfate de; Quinidine Sulphate *(BANM)*; Quinidini Sulfas; Quinidini Sulfas Dihydricus.

Хинидина Сульфат

$(C_{20}H_{24}N_2O_2)_2,H_2SO_4,2H_2O$ = 782.9.

CAS — 50-54-4 (anhydrous quinidine sulfate); 6591-63-5 (quinidine sulfate dihydrate).

ATC — C01BA01.

ATC Vet — QC01BA01.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Quinidine Sulphate). White or almost white, crystalline powder, or silky, colourless needles. It contains not more than 15% of hydroquinidine sulfate. Slightly soluble in water; soluble in boiling water and in alcohol; practically insoluble in acetone. A 1% solution in water has a pH of 6.0 to 6.8. Protect from light.

USP 31 (Quinidine Sulfate). Fine, needle-like, white crystals, frequently cohering in masses, or a fine, white powder. It is odourless and darkens on exposure to light. It contains not more than 20% of hydroquinidine sulfate. Its solutions are neutral or alkaline to litmus. Soluble 1 in 100 of water, 1 in 10 of alcohol, and 1 in 15 of chloroform; insoluble in ether. Protect from light.

Stability. Quinidine sulfate was reported[1] to be stable for up to 60 days in several extemporaneously prepared oral liquid formulations.

1. Allen LV, Erickson MA. Stability of bethanechol chloride, pyrazinamide, quinidine sulfate, rifampin, and tetracycline hydrochloride in extemporaneously compounded oral liquids. *Am J Health-Syst Pharm* 1998; **55:** 1804–9.

Adverse Effects and Treatment

Quinidine and its salts have both cardiac and non-cardiac adverse effects. Gastrointestinal irritation is common, with nausea, vomiting, and diarrhoea.

Hypersensitivity similar to that occurring with quinine may also occur and a test dose has been recommended (see Uses and Administration, below). Reactions include respiratory difficulties, urticaria, pruritus, skin rashes, purpura, thrombocytopenia and other blood dyscrasias, and, rarely, fever and anaphylaxis. Granulomatous hepatitis and a lupus-like syndrome have been reported.

Quinidine may give rise to cinchonism (see Quinine, p.612) with tinnitus, impaired hearing, visual disturbances, headache, confusion, vertigo, vomiting, and abdominal pain; it is usually associated with large doses, but may occur in idiosyncratic subjects given small doses.

Quinidine may induce hypotension, particularly in overdosage or if intravenous infusions are given too rapidly. It prolongs the QT interval and may precipitate ventricular arrhythmias, including torsade de pointes.

In quinidine overdosage, the cardiac symptoms of intoxication predominate. Quinidine is cumulative in action and inappropriately high plasma concentrations may induce ECG changes, heart block, asystole, ventricular tachycardia, ventricular fibrillation, syncope, seizures, coma, and sometimes death. Treatment of adverse effects and overdosage is symptomatic and supportive. Activated charcoal may be considered if the patient presents within 1 hour of ingestion.

◊ Reviews.

Effects on the blood. Quinidine-induced thrombocytopenia is not uncommon and it is one of the best documented cases of drug-dependent thrombocytopenia.[1] It appears to be a hypersensitivity reaction, with quinidine inducing the production of autoantibodies that cause platelet destruction. Highly specific quinidine-dependent antibodies have been detected in patients with thrombocytopenia, and may have a role in diagnosis.[2] The exact mechanism of the reaction is unclear but it is generally thought that binding of quinidine to the platelet surface induces antibody production;[1] alternatively, an antibody-quinidine complex may be formed, which is then deposited on the platelets.[1,3] The antigenic constituent of the platelet membrane may be glycoprotein Ib although other surface glycoproteins have also been implicated.[3,4]

Effects on the eyes. Corneal deposits resembling those found in keratopathy developed in a patient who had been taking quinidine for 2 years.[1] Symptoms had improved and both corneas had cleared completely within 2 months of stopping the drug.

A small number of patients have also been identified[2] who developed uveitis during quinidine treatment.

1. Zaidman GW. Quinidine keratopathy. *Am J Ophthalmol* 1984; **97:** 247–9.
2. Fraunfelder FW, Rosenbaum JT. Drug-induced uveitis: incidence, prevention and treatment. *Drug Safety* 1997; **17:** 197–207.

Effects on the joints. Quinidine has been associated with a number of rheumatic disorders.[1] It is a recognised, though uncommon, cause of drug-induced lupus (see below), but there have also been reports[2-4] of reversible, symmetrical polyarthritis developing in patients with no evidence of antinuclear antibodies. Symptoms were generally milder than in drug-induced lupus, and onset was more rapid; recovery occurred within a week of stopping quinidine and in some patients symptoms recurred on rechallenge. Polymyalgia rheumatica-like symptoms have also been reported.[1]

4. Naschitz JE, Yeshurun D. Quinidine and rheumatic syndromes. *Ann Intern Med* 1988; **109:** 248–9.

Effects on the liver. Hypersensitivity reactions involving the liver have been reported in about 2% of patients receiving quinidine.[1,2] The main clinical symptom is fever[1-3] but skin rash,[1-3] purpura,[2] and hepatomegaly[1] may also occur. Liver enzyme values are raised[1-4] and the platelet count may be reduced.[3] The reaction is reversible on withdrawing quinidine with fever resolving in about 48 hours and liver enzymes values returning to normal within about 2 weeks. Liver biopsy often shows granulomatous hepatitis,[1-3] but other inflammatory changes[2] and cholestatic jaundice[4] have been found.

4. Hogan DB, *et al.* Unusual hepatotoxic reaction to quinidine. *Can Med Assoc J* 1984; **130:** 973.

Effects on mental state. Gradually progressive cerebral dysfunction characterised by intermittent confusion, agitation, restlessness, personality change, and paranoid features occurred in a 62-year-old man who had taken quinidine for about 15 years.[1] Within 24 hours of stopping quinidine there was a marked improvement and after 5 days he had returned to normal with no cognitive deficits. It was considered that quinidine had precipitated or exacerbated the functional psychosis.

1. Johnson AG, *et al.* A functional psychosis precipitated by quinidine. *Med J Aust* 1990; **153:** 47–9.

Effects on the skin. Skin reactions reported with quinidine include exacerbation of psoriasis,[1] blue-grey pigmentation,[2] photosensitivity,[3] and fatal toxic epidermal necrolysis.[4] Purpuric bruising, attributed to inhalation of quinidine dust in the workplace, has also been reported.[5]

1. Harwell WB. Quinidine-induced psoriasis. *J Am Acad Dermatol* 1983; **9:** 278.

5. Salom IL. Purpura due to inhaled quinidine. *JAMA* 1991; **266:** 1220.

Hypoglycaemia. Mean plasma-insulin concentrations increased and mean plasma-glucose concentrations decreased in 8 healthy subjects and 10 patients with malaria given quinidine intravenously.[1] Profound hypoglycaemia occurred in 1 patient with cerebral malaria and acute renal failure. These effects were considered to be associated with stimulation of β-cell secretion of insulin by quinidine and it was concluded that hypoglycaemia may occur in any severely ill fasting patient given parenteral quinidine.

1. Phillips RE, *et al.* Hypoglycaemia and antimalarial drugs: quinidine and release of insulin. *BMJ* 1986; **292:** 1319–21.

Lupus erythematosus. There are several well-documented reports of quinidine-induced lupus erythematosus.[1-4] The syndrome involves polyarthritis with a positive antinuclear antibody test. Symptoms do not usually occur until several months after starting quinidine and resolve slowly on stopping the drug. A recurrence of lupus-like symptoms has occurred in patients with a previous reaction to procainamide.[2]

1. West SG, *et al.* Quinidine-induced lupus erythematosus. *Ann Intern Med* 1984; **100:** 840–2.

4. Cohen MG, *et al.* Two distinct quinidine-induced rheumatic syndromes. *Ann Intern Med* 1988; **108:** 369–71.

Oesophageal stricture. Oral quinidine is a recognised cause of oesophageal injury[1,2] and has been associated with ulceration and stricture formation.

1. McCord GS, Clouse RE. Pill-induced esophageal strictures: clinical features and risk factors for development. *Am J Med* 1990; **88:** 512–18.
2. Jaspersen D. Drug-induced oesophageal disorders: pathogenesis, incidence, prevention and management. *Drug Safety* 2000; **22:** 237–49.

Precautions

Quinidine is contra-indicated in complete heart block (unless the patient has a pacemaker). It should be used with extreme caution in patients with a prolonged QT interval or a history of torsade de pointes, incomplete heart block, uncompensated heart failure, myocarditis, or severe myocardial damage. Patients should be monitored closely for hypersensitivity reactions after the first dose and quinidine should not be given to those who develop a reaction or those with a history of hypersensitivity to quinidine, including patients who have previously developed thrombocytopenia with quinidine or quinine. Antiarrhythmic therapy with quinidine should be begun with extreme caution, if at all, during acute infections or fever as hypersensitivity reactions may be masked. Care is also required in patients with myasthenia gravis as quinidine can exacerbate the symptoms and may reduce the effectiveness of parasympathomimetic drugs.

When quinidine is used to treat atrial flutter or fibrillation, the reduction in AV block may result in a very rapid ventricular rate. This can be avoided by prior digitalisation or by use of a rate-limiting calcium-channel blocker or beta blocker. However, quinidine should be avoided in digitalis overdosage as markedly increased plasma concentrations of digoxin may occur.

Reduced dosage should be considered for the elderly, for patients with hepatic or renal impairment, and on the occasions when it is used in heart failure.

Breast feeding. A woman[1] receiving 2.1 g quinidine daily throughout pregnancy had milk and serum concentrations 5 days after delivery of 6.4 and 9.0 micrograms/mL respectively, giving a milk to serum ratio of 0.71. It was estimated that the amount of quinidine that would be ingested by an infant would be far below the therapeutic range for its weight. No adverse effects have been reported in infants and the American Academy of Pediatrics considers[2] that quinidine is therefore usually compatible with breast feeding.

1. Hill LM, Malkasian GD. The use of quinidine sulfate throughout pregnancy. *Obstet Gynecol* 1979; **54:** 366–8.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 10/07/07)

Pregnancy. In a report[1] on the use of quinidine sulfate by a woman throughout pregnancy, concentrations in the infant's serum at delivery were similar to the mother's although amniotic fluid concentrations were raised. The infant's weight, ECG, haemoglobin concentration, and platelet count were all found to be within normal limits.

1. Hill LM, Malkasian GD. The use of quinidine sulfate throughout pregnancy. *Obstet Gynecol* 1979; **54:** 366–8.

Interactions

Quinidine has the potential for both pharmacodynamic and pharmacokinetic interactions with many other drugs.

Use of quinidine with drugs that increase the QT interval or have arrhythmogenic effects should generally be avoided, since there is an increased risk of toxicity. Although quinidine is sometimes given with other antiarrhythmics, caution is required since there may be both pharmacodynamic and pharmacokinetic interactions (see below). Interactions may also occur with other drugs because of the antimuscarinic and alpha-adrenoceptor blocking properties of quinidine; potentiation of the effects of neuromuscular blockers has also been reported.

Quinidine is metabolised in the liver, mainly by the cytochrome P450 isoenzyme CYP3A4, and may interact with inhibitors or inducers of this isoenzyme. Rifampicin, phenobarbital, and phenytoin increase the metabolism of quinidine and increased doses may be required; HIV-protease inhibitors, which inhibit CYP3A4, may produce toxic concentrations of quinidine.

Urinary excretion of quinidine is dependent on urinary pH; drugs that increase urinary pH such as sodium bicarbonate, some antacids, and carbonic anhydrase inhibitors tend to increase the plasma concentration of quinidine since the proportion of nonionised drug in the urine is increased allowing greater renal tubular reabsorption.

Quinidine itself may also have effects on other drugs; it inhibits cytochrome P450 isoenzyme CYP2D6 and may affect drugs metabolised by this route. Examples of further drugs that may be affected by quinidine include oral anticoagulants, beta blockers, and digoxin; more details are given under the monographs for these drugs.

Antiarrhythmics. *Amiodarone* may increase the plasma concentration of quinidine, increasing the risk of toxicity; prolongation of the QT interval with torsade de pointes has been reported.[1] This is probably because amiodarone inhibits hepatic or renal clearance of quinidine or displaces quinidine from binding sites. If the two drugs are used together the dose of quinidine may need to be reduced and the patient should be closely monitored. *Verapamil* given intravenously has been reported[2] to cause severe hypotension in patients also taking quinidine by mouth. Studies *in vitro* suggest this is due to the additive blockade of α-adrenergic receptors by both drugs and the simultaneous blockade of calcium channels by verapamil; verapamil may also increase the plasma concentration of quinidine. Quinidine itself may increase the plasma concentration of some other antiarrhythmics (see Ajmaline, p.1206, Digoxin, p.1261, Disopyramide, p.1270, Flecainide Acetate, p.1289, Procainamide, p.1378, and Propafenone Hydrochloride, p.1380).

1. Lesko LJ. Pharmacokinetic drug interactions with amiodarone. *Clin Pharmacokinet* 1989; **17:** 130–40.
2. Maisel AS, *et al.* Hypotension after quinidine plus verapamil. *N Engl J Med* 1985; **312:** 167–70.

Antibacterials. Torsade de pointes has been reported[1] in a patient taking *erythromycin* with quinidine. Like quinidine, erythromycin prolongs the QT interval, and the effect may be greater if the drugs are given together;[2] there is also some evidence[3-5] that erythromycin reduces quinidine clearance.

1. Lin JC, Quasny HA. QT prolongation and development of torsades de pointes with the concomitant administration of oral erythromycin base and quinidine. *Pharmacotherapy* 1997; **17:** 626–30.
2. Stanford RH, *et al.* Effect of oral erythromycin on quinidine pharmacodynamics in healthy volunteers. *Pharmacotherapy* 1997; **17:** 1111.
3. Spinler SA, *et al.* Possible inhibition of hepatic metabolism of quinidine by erythromycin. *Clin Pharmacol Ther* 1995; **57:** 89–94.
4. Stanford RH, *et al.* Effect of oral erythromycin on quinidine pharmacokinetics in healthy volunteers. *Pharmacotherapy* 1998; **18:** 426–7.
5. Damkier P, *et al.* Effect of diclofenac, disulfiram, itraconazole, grapefruit juice and erythromycin on the pharmacokinetics of quinidine. *Br J Clin Pharmacol* 1999; **48:** 829–38.

Antifungals. *Ketoconazole* temporarily increased the plasma-quinidine concentration in a patient through reduced hepatic elimination.[1] Another antifungal that inhibits hepatic metabolism, *itraconazole*, has also been reported[2] to increase plasma-quinidine concentrations.

1. McNulty RM, *et al.* Transient increase in plasma quinidine concentrations during ketoconazole-quinidine therapy. *Clin Pharm* 1989; **8:** 222–5.
2. Kaukonen K-M, *et al.* Itraconazole increases plasma concentrations of quinidine. *Clin Pharmacol Ther* 1997; **62:** 510–17.

Beta blockers. Quinidine and beta blockers may have additive adverse effects, and pharmacokinetic interactions may also occur. Sinus bradycardia has been reported in a patient prescribed oral quinidine and *timolol* eye drops,[1] and orthostatic hypotension has occurred when quinidine was used with *atenolol*.[2] Use of quinidine or the beta blocker alone was well tolerated in each case with no adverse effects.

1. Dinai Y, *et al.* Bradycardia induced by interaction between quinidine and ophthalmic timolol. *Ann Intern Med* 1985; **103:** 890–1.
2. Manolis AS, Estes NAM. Orthostatic hypotension due to quinidine and atenolol. *Am J Med* 1987; **82:** 1083–4.

Calcium-channel blockers. *Nifedipine* has been reported[1] to reduce plasma-quinidine concentrations and increasing the dose of quinidine to up to 20 mg/kg failed to increase the plasma concentration. Withdrawal of nifedipine resulted in a doubling of the quinidine concentration. A pharmacokinetic and pharmacodynamic study in healthy subjects, however, failed to show that modified-release *felodipine* or nifedipine had any effect on quinidine disposition.[2] Another study in healthy subjects suggested that quinidine may inhibit nifedipine metabolism.[3] *Diltiazem* has also been reported[4] to decrease the clearance and increase the half-life of quinidine in healthy subjects, although it was noted that another study had failed to show any interaction.

For the effects of *verapamil* used with quinidine, see Antiarrhythmics, above.

4. Laganière S, *et al.* Pharmacokinetic and pharmacodynamic interactions between diltiazem and quinidine. *Clin Pharmacol Ther* 1996; **60:** 255–64.

Diuretics. *Carbonic anhydrase inhibitors* increase urinary pH and may increase plasma-quinidine concentrations by increasing renal tubular reabsorption. *Thiazides* and *loop diuretics* may increase the risk of arrhythmias by causing hypokalaemia. Arrhythmias occurred in 4 of 10 patients receiving *amiloride* when given quinidine,[1] possibly due to additive sodium-channel blockade.

1. Wang L, *et al.* Amiloride-quinidine interaction: adverse outcomes. *Clin Pharmacol Ther* 1994; **56:** 659–67.

Histamine H_2-antagonists. *Cimetidine* inhibits the hepatic metabolism of quinidine and increases in plasma concentration and half-life with a reduction in clearance have been reported.[1-3]

1. Hardy BG, *et al.* Effect of cimetidine on the pharmacokinetics and pharmacodynamics of quinidine. *Am J Cardiol* 1983; **52:** 172–5.
2. Kolb KW, *et al.* Effect of cimetidine on quinidine clearance. *Ther Drug Monit* 1984; **6:** 306–12.
3. MacKichan JJ, *et al.* Effect of cimetidine on quinidine bioavailability. *Biopharm Drug Dispos* 1989; **10:** 121–5.

Pharmacokinetics

Quinidine is rapidly absorbed from the gastrointestinal tract; the time to peak plasma concentration depends on the salt and formulation but is about 2 hours for quinidine sulfate immediate-release tablets. Bioavailability is variable, owing to first-pass metabolism in the liver.

Quinidine is metabolised in the liver, mainly by the cytochrome P450 isoenzyme CYP3A4, to a number of metabolites, at least some of which are pharmacologically active. It is excreted in the urine, mainly in the form of its metabolites. The proportion excreted unchanged is dependent on urinary pH; in acidic urine about 20% is excreted as unchanged quinidine but in alkaline urine this is reduced to about 5% due to increased renal tubular reabsorption.

Quinidine is widely distributed throughout the body and is 80 to 90% bound to plasma proteins including α_1-acid glycoprotein. It has a plasma half-life of about 6 to 8 hours but this may show wide variation. Its therapeutic effect has been correlated with plasma concentrations of about 1 to 6 micrograms/mL, depending on the assay method used; older methods that do not differentiate quinidine from its metabolites may give misleading results.

Quinidine crosses the placenta and is distributed into breast milk. Only small amounts are removed by haemodialysis.

◊ Considerable intersubject and intrasubject variability in the pharmacokinetics of quinidine has been noted;[1] in one study the half-life ranged from about 1 to 16 hours regardless of whether the drug was given as a tablet, capsule, oral solution, or intramuscular injection. There may also be considerable variations in absorption depending upon the formulation and the salt used.[2,3] The effect of food on absorption is not clear.[4,5] The heart condition being treated or associated with the arrhythmia may alter quinidine's pharmacokinetics[6,7] as may the age of the patient.[8-10] Hepatic impairment may affect protein binding and prolong quinidine's half-life.[11] Protein binding increases in patients with renal impairment, although it returns to normal during dialysis procedures.[12] Accumulation of quinidine metabolites may occur in patients with renal dysfunction.[13-15]

Uses and Administration

Quinidine is a class Ia antiarrhythmic (p.1153). It also has antimuscarinic and alpha-adrenoceptor blocking properties. Quinidine is used in the management of supraventricular and ventricular arrhythmias, including cardioversion and maintenance of sinus rhythm in atrial fibrillation, but other drugs or methods are usually preferred.

Quinidine is an isomer of quinine and may be used as an alternative to quinine in the treatment of malaria when quinine is not immediately available.

Quinidine is usually given orally and various salts have been used, including the bisulfate, the gluconate, the polygalacturonate, and the sulfate. Strengths of preparations and doses used may be expressed in terms of the salt actually contained in the preparation, but are commonly expressed as the equivalent amount of anhydrous quinidine base or quinidine sulfate dihydrate. Quinidine bisulfate (anhydrous) 260 mg, quinidine gluconate (anhydrous) 321 mg, quinidine sulfate (dihydrate) 241 mg, and quinidine sulfate (anhydrous) 230 mg are each equivalent to about 200 mg of quinidine (anhydrous).

For the management of **cardiac arrhythmias**, a typical dose of *quinidine sulfate dihydrate* is 200 to 400 mg three or four times daily, adjusted according to response; an initial test dose of 200 mg has been recommended for detecting hypersensitivity. Modified-release preparations may be preferred for maintenance.

Quinidine has also been given parenterally but absorption after intramuscular injection is erratic and incomplete, and intravenous use is associated with a risk of severe hypotension. If parenteral use is necessary for acute conversion of supraventricular or ventricular arrhythmias, *quinidine gluconate* may be given by intravenous infusion at a rate no faster than 250 micrograms/kg per minute; most patients respond to a total dose of less than 5 mg/kg, but up to 10 mg/kg may be given if required. ECG and blood pressure should be monitored throughout the infusion.

For the use of quinidine in the management of **malaria**, see below.

◊ General references.

Cardiac arrhythmias. Quinidine is a class Ia antiarrhythmic and has been used in the management of supraventricular and ventricular arrhythmias, but other drugs or non-pharmacological therapies are usually preferred (see Cardiac Arrhythmias, p.1160). Although use of quinidine may have increased after the CAST studies, which found an increased mortality with the use of encainide, flecainide, and moracizine in asymptomatic ventricular arrhythmias, a meta-analysis[1] of studies using quinidine for benign or potentially lethal ventricular arrhythmias found that it was associated with at least as high an incidence of adverse events, including death and early proarrhythmia, as the class Ic drugs flecainide and propafenone. Another meta-analysis[2] found that quinidine was more effective than placebo in maintaining sinus rhythm after cardioversion of atrial fibrillation, but again total mortality was increased.

Quinidine has been used[3] in patients with Brugada syndrome, a congenital channelopathy that predisposes to ventricular arrhythmias, and may have a role as an alternative to an implantable cardioverter defibrillator.

3. Belhassen B, *et al.* Efficacy of quinidine in high-risk patients with Brugada syndrome. *Circulation* 2004; **110:** 1731–7.

Congenital myasthenia. Although quinidine may exacerbate the symptoms of myasthenia gravis and should be used with great caution in such patients, beneficial responses have been reported in patients with the slow-channel congenital myasthenic syndrome (see p.630).

Hiccup. Quinidine is one of several drugs that have been tried in intractable hiccups. For details of a protocol for the control of hiccups see Chlorpromazine, p.976.

Malaria. Quinidine may be more potent than quinine as an antimalarial but it is more likely to cause cardiac toxicity and hypersensitivity and WHO[1,2] has recommended that parenteral formulations of quinidine should only be used when parenteral quinine or artemisinin derivatives are not immediately available. In these situations intravenous infusions of quinidine could be used to begin treatment for severe chloroquine-resistant malaria. Patients should be transferred to oral therapy with quinine as soon as possible to complete a 7-day course; alternatively a single oral treatment of pyrimethamine-sulfadoxine may be given.

In the USA, the CDC[3,4] have recommended parenteral quinidine gluconate as the drug of choice for the treatment of complicated falciparum malaria, but only because of the lack of availability of parenteral quinine.

Quinidine is given intravenously as the gluconate and doses have been expressed in terms of the base or salt; it should be given under close control, preferably with continuous ECG monitoring and frequent measurements of blood pressure. Regimens used include one[1,5] where the equivalent of 15 mg of the base per kg is infused over 4 hours as a loading dose followed by the equivalent of 7.5 mg of the base per kg every 8 hours as infusions over 4 hours; the patient should be transferred to an oral form of antimalarial as soon as possible. An alternative regimen[6] consists of a loading dose of 10 mg of quinidine gluconate per kg given by intravenous infusion over a period of 1 to 2 hours followed by a constant intravenous infusion of 20 micrograms/kg per minute for a maximum of 72 hours or until oral therapy with quinine can be instituted to complete a total 3-day course of treatment. It is generally recommended that loading doses should not be used if the patient has received quinine or quinidine within the previous 24 hours or mefloquine within the preceding 7 days.

The overall management of malaria is discussed in the chapter on Antimalarials, p.594.

Ramipril *(BAN, USAN, rINN)*

Hoe-498; Ramipriili; Ramiprilis; Ramiprilum. (2*S*,3a*S*,6a*S*)-1-{*N*-[(*S*)-1-Ethoxycarbonyl-3-phenylpropyl]L-alanyl}perhydrocyclopenta[*b*]pyrrole-2-carboxylic acid.

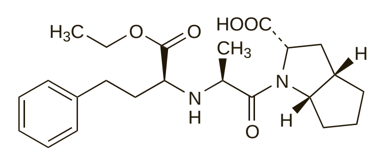
Рамиприл

$C_{23}H_{32}N_2O_5$ = 416.5.

CAS — 87333-19-5.

ATC — C09AA05.

ATC Vet — QC09AA05.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Ramipril). A white or almost white, crystalline powder. Sparingly soluble in water; freely soluble in methyl alcohol. Protect from light.

USP 31 (Ramipril). A white to almost white, crystalline powder. Sparingly soluble in water; freely soluble in methyl alcohol. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for ACE inhibitors, p.1193.

Interactions

As for ACE inhibitors, p.1196.

Pharmacokinetics

Ramipril acts as a prodrug of the diacid ramiprilat, its active metabolite. After oral doses at least 50 to 60% is absorbed. Ramipril is metabolised in the liver to ramiprilat; other metabolites are inactive. Peak plasma concentrations of ramiprilat are achieved 2 to 4 hours after an oral dose of ramipril. Ramiprilat is about 56% bound to plasma proteins. After oral doses ramipril is excreted primarily in the urine, as ramiprilat, other metabolites, and some unchanged drug. About 40% of an oral dose appears in the faeces; this may represent both biliary excretion and unabsorbed drug. The effective half-life for accumulation of ramiprilat is 13 to 17 hours after multiple doses of ramipril 5 to 10 mg, but is much longer for doses of 1.25 to 2.5 mg daily; the difference relates to the long terminal half-life associated with saturable binding to the angiotensin-converting enzyme. The clearance of ramiprilat is reduced in renal impairment.

Uses and Administration

Ramipril is an ACE inhibitor (p.1193). It is used in the treatment of hypertension (p.1171), heart failure (p.1165), and after myocardial infarction (p.1175) to improve survival in patients with clinical evidence of heart failure. It is also used to reduce the risk of cardiovascular events in patients with certain risk factors (see Cardiovascular Risk Reduction, p.1164).

Ramipril owes its activity to ramiprilat to which it is converted after oral doses. The haemodynamic effects are seen within 1 to 2 hours of a single oral dose and the maximum effect occurs after about 3 to 6 hours, although the full effect may not develop for several weeks during chronic dosing. The haemodynamic effect is maintained for at least 24 hours, allowing once-daily dosing.

In the treatment of **hypertension** an initial oral dose of 1.25 mg once daily is given. Since there may be a precipitous fall in blood pressure when starting therapy with an ACE inhibitor, the first dose should preferably be given at bedtime. Patients taking diuretics should, if possible, have the diuretic stopped 2 to 3 days before starting ramipril, and resumed later if necessary. The usual maintenance dose is 2.5 to 5 mg daily as a single dose, although up to 10 mg daily may be required. In the USA an initial dose of 2.5 mg once daily in hypertensive patients not taking a diuretic and a maintenance dose of 2.5 to 20 mg daily, as a single dose or in two divided doses, have been suggested.

In the management of **heart failure**, severe first-dose hypotension on introduction of an ACE inhibitor is common in patients on loop diuretics, but their temporary withdrawal may cause rebound pulmonary oedema. Thus treatment should begin with a low dose under close medical supervision; high doses of diuretics should be reduced before starting ramipril. Ramipril is given in an initial dose of 1.25 mg once daily. The usual maximum dose is 10 mg daily; doses of 2.5 mg or more daily may be taken in 1 or 2 divided doses.

After **myocardial infarction**, treatment with ramipril may be started in hospital 3 to 10 days after the infarction at a usual initial dose of 2.5 mg twice daily, increased after two days to 5 mg twice daily. The usual maintenance dose is 2.5 to 5 mg twice daily.

For the **prophylaxis of cardiovascular events** in patients considered to be at high risk, ramipril is given in an initial dose of 2.5 mg once daily. The dose should be increased, if tolerated, to 5 mg once daily after 1 week, then to the usual maintenance dose of 10 mg once daily after a further 3 weeks. In patients with hypertension or recent myocardial infarction it may also be given in divided doses.

A reduction in dosage of ramipril may be necessary in patients with impaired hepatic or renal function (see below).

Administration in hepatic or renal impairment. The UK licensed product information states that in patients with hepatic impairment, or renal impairment with a creatinine clearance of less than 30 mL/minute, the initial dose of ramipril should not exceed 1.25 mg daily. In hepatic impairment higher doses should be used with caution. In renal impairment the maintenance dose should not exceed 5 mg daily; for those with a creatinine clearance of less than 10 mL/minute, the maintenance dose should not exceed 2.5 mg daily.

Ranolazine Hydrochloride *(USAN, rINNM)*

Hidrocloruro de ranolazina; Ranolazine, Chlorhydrate de; Ranolazini Hydrochloridum; RS-43285.

Ранолазина Гидрохлорид

$C_{24}H_{33}N_3O_4$,2HCl = 500.5.

CAS — 95635-56-6.

ATC — C01EB18.

ATC Vet — QC01EB18.

Adverse Effects and Precautions

Adverse effects most commonly seen with ranolazine are nausea, constipation, dizziness, and headache. Palpitations, tinnitus, vertigo, dry mouth, abdominal pain, vomiting, peripheral oedema, and dyspnoea have also been reported. Rarely reported effects include bradycardia, haematuria, paraesthesia, hypotension, and blurred vision.

Dose-related prolongation of the QT interval may occur; ranolazine is therefore contra-indicated in patients with pre-existing QT prolongation, and in those at increased risk of QT prolongation, including patients with hepatic impairment (Child-Pugh classes A to C) and those taking interacting drugs (see Interactions, below). Blood pressure may be increased in patients with severe renal impairment and should be monitored regularly.

Interactions

Ranolazine is primarily metabolised by the P450 isoenzyme CYP3A and should not be given with other drugs that are potent or moderately potent inhibitors of this enzyme, such as ketoconazole, diltiazem, macrolide antibacterials, HIV protease inhibitors, and grapefruit juice or grapefruit products. Simvastatin is also metabolised by this enzyme and plasma concentrations are reported to be doubled when given with ranolazine. Ranolazine is an inhibitor of CYP2D6 and drugs metabolised by this enzyme, such as tricyclic antidepressants or some antipsychotics, may need dose reductions. Ranolazine is both a substrate for, and inhibitor of, P-glycoprotein, and the dose of other substrates, such as digoxin, may need reducing.

Pharmacokinetics

Absorption of ranolazine is highly variable with peak plasma concentrations occurring about 2 to 5 hours after an oral dose of the modified-release preparation. Ranolazine is extensively metabolised in the gastrointestinal tract and liver. Four main metabolites have been identified. Protein binding of ranolazine is about 62%. About 75% of a dose is excreted in the urine with the remainder in the faeces, with less than 5% as unchanged drug. The apparent terminal half-life for the modified-release preparation of ranolazine is 7 hours, and steady state occurs within 3 days.

◊ Reviews.

1. Jerling M. Clinical pharmacokinetics of ranolazine. *Clin Pharmacokinet* 2006; **45:** 469–91.

Uses and Administration

Ranolazine is an antianginal drug. Its mechanism of action is unclear but may involve inhibition of the late sodium current in cardiac myocytes; it also inhibits fatty acid oxidation, but this does not appear to occur at therapeutic plasma concentrations. It is used for the treatment of angina pectoris (p.1157) in patients who have not responded satisfactorily to other antianginals and should be given as an adjunct to standard therapy. It is given in a modified-release form in an initial oral dose of 500 mg twice daily, increasing to a maximum of 1 g twice daily if necessary.

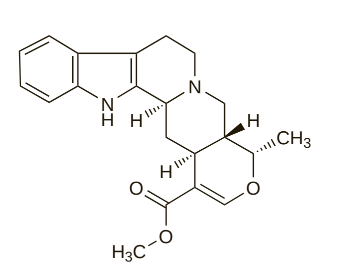
Raubasine

Ajmalicine; Alkaloid F; Raubasiini; Raubasin; Raubasina; Raubasinum; δ-Yohimbine. Methyl 16,17-didehydro-19α-methyl-18-oxayohimban-16-carboxylate.

$C_{21}H_{24}N_2O_3$ = 352.4.

CAS — 483-04-5.



Pharmacopoeias. In *Chin.*

Profile

Raubasine is an alkaloid obtained from *Rauwolfia serpentina* (Apocynaceae). It is a vasodilator related chemically to reserpine (p.1387) and has been given orally and by injection in peripheral and cerebral vascular disorders.

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Lamuran.

Multi-ingredient: ***Austria:*** Defluina; ***Fr.:*** Duxil†; Iskedyl; ***Hong Kong:*** Duxaril; ***Philipp.:*** Duxaril; ***Port.:*** Duxil; Transoxyl†; ***Singapore:*** Duxaril; ***Spain:*** Duxor†; ***Thai.:*** Duxaril; Iso-Triraupin†.

Rauwolfia Serpentina

Chotachand; Rauwolfia; Rauwolfia; Rauwolfiae Radix; Rauwolfiawurzel.

CAS — 8063-17-0 (rauwolfia).
ATC — C02AA04.

Pharmacopoeias. In *Ger.* and *US.*

USP 31 (Rauwolfia Serpentina). The dried roots of *Rauwolfia serpentina* (Apocynaceae). It contains not less than 0.15% of reserpine-rescinnamine group alkaloids calculated as reserpine. Store at 15° to 30° in a dry place.

Profile

Rauwolfia serpentina contains numerous alkaloids, the most active as hypotensive agents being the ester alkaloids, reserpine and rescinnamine. Other alkaloids present have structures related to reserpic acid, but are not esterified, and include ajmaline (rauwolfine), ajmalinine, ajmalicine, isoajmaline (isorauwolfine), serpentine, rauwolfinine, and sarpagine. The actions of rauwolfia serpentina are those of its alkaloids and it has been used for the same purposes as reserpine, p.1387. It has been given orally as the powdered whole root.

Rauwolfia vomitoria has also been used.

A crude form of rauwolfia serpentina has been used in India for centuries as preparations such as Sarpagandha, in the treatment of insomnia and certain forms of mental illness.

Preparations

USP 31: Rauwolfia Serpentina Tablets.

Proprietary Preparations (details are given in Part 3)

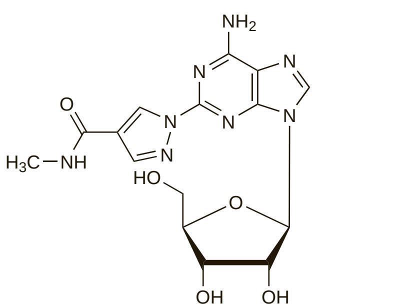
Multi-ingredient: ***Ger.:*** Hyperforat-forte†; ***Rus.:*** Speman Forte (Спеман Форте); ***Spain:*** Rulun; ***USA:*** Rauzide†.

Regadenoson *(BAN, USAN, rINN)*

CVT-3146; Régadénoson; Regadenosón; Regadenosonum. 1-(6-Amino-9-β-D-ribofuranosyl-9*H*-purin-2-yl)-*N*-methyl-1*H*-pyrazole-4-carboxamide monohydrate.

Регаденозон

$C_{15}H_{18}N_8O_5,H_2O = 408.4.$
CAS — 313348-27-5 (regadenoson); 875148-45-1 (regadenoson monohydrate).



Adverse Effects, Treatment, and Precautions

As for Adenosine, p.1202. Regadenoson may be used with caution in patients with asthma or chronic obstructive pulmonary disease.

Interactions

As for Adenosine, p.1202.

Pharmacokinetics

After intravenous injection of regadenoson, peak plasma concentrations are reached within 1 to 4 minutes and decline in a multi-exponential fashion. The initial half-life is about 2 to 4 minutes, followed by an intermediate stage with a half-life of about 30 minutes, during which the pharmacodynamic effect is lost; the half-life during the terminal phase is about 2 hours. Regadenoson does not appear to be metabolised; about 57% of a dose is excreted unchanged in the urine.

◊ References.

1. Gordi T, *et al.* A population pharmacokinetic/pharmacodynamic analysis of regadenoson, an adenosine A -receptor agonist, in healthy male volunteers. *Clin Pharmacokinet* 2006; **45:** 1201–12.
2. Gordi T, *et al.* Regadenoson pharmacokinetics and tolerability in subjects with impaired renal function. *J Clin Pharmacol* 2007; **47:** 825–33.

Uses and Administration

Regadenoson has similar properties to adenosine (p.1202) but has a greater selectivity for the adenosine A_{2A}-receptor. It is a coronary vasodilator and increases coronary blood flow and is used to provide a pharmacological stress as an adjunct to radionuclide myocardial perfusion imaging. It is given intravenously in a single dose of 400 micrograms by rapid injection over about 10 seconds, followed by 5 mL of sodium chloride 0.9%; the radionuclide should be given 10 to 20 seconds after the sodium chloride.

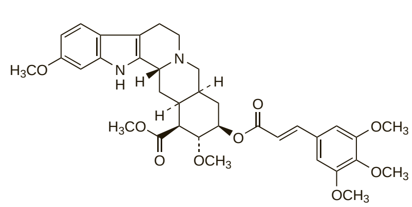
Rescinnamine *(BAN, rINN)*

Rescinamina; Rescinnamin; Rescinnaminum; Resinnamiini. Methyl-*O*-(3,4,5-trimethoxycinnamoyl)reserpate.

Ресциннамин

$C_{35}H_{42}N_2O_9 = 634.7.$
CAS — 24815-24-5.
ATC — C02AA01.
ATC Vet — QC02AA01.



Profile

Rescinnamine is an ester alkaloid isolated from the root of *Rauwolfia serpentina* or *R. vomitoria*. It has properties similar to those described under reserpine (below) and has been used in the treatment of hypertension.

Preparations

Proprietary Preparations (details are given in Part 3)

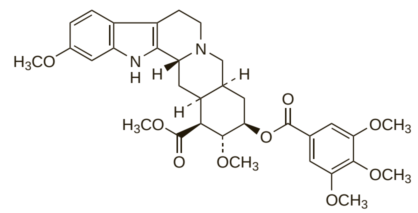
Multi-ingredient: ***Thai.:*** Iso-Triraupin†.

Reserpine *(BAN, rINN)*

Reserpiini; Reserpin; Reserpina; Réserpine; Reserpinum; Reszerpin; Rezerpin; Rezerpina; Rezerpinas. Methyl 11,17α-dimethoxy-18β-(3,4,5-trimethoxybenzoyloxy)-3β,20α-yohimbane-16β-carboxylate; Methyl *O*-(3,4,5-trimethoxybenzoyl)reserpate.

Резерпин

$C_{33}H_{40}N_2O_9 = 608.7.$
CAS — 50-55-5.
ATC — C02AA02.
ATC Vet — QC02AA02.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Reserpine). It occurs as small, white to slightly yellow crystals or a crystalline powder. It darkens slowly on exposure to light. Practically insoluble in water; very slightly soluble in alcohol. Protect from light.

USP 31 (Reserpine). A white or pale buff to slightly yellowish, odourless, crystalline powder. It darkens slowly on exposure to light, but more rapidly when in solution. Insoluble in water; soluble 1 in 1800 of alcohol and 1 in 6 of chloroform; freely soluble in acetic acid; very slightly soluble in ether; slightly soluble in benzene. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Stability. Reserpine is unstable in the presence of alkalis, particularly when the drug is in solution.

Adverse Effects

Adverse effects commonly include nasal congestion, headache and CNS symptoms including depression, drowsiness, dizziness, lethargy, nightmares, and symptoms of increased gastrointestinal tract motility including diarrhoea, abdominal cramps, and, at higher doses, increased gastric acid secretion. Respiratory distress, cyanosis, anorexia, and lethargy may occur in infants whose mothers have taken reserpine before delivery.

Higher doses may cause flushing, bradycardia, severe depression which may lead to suicide, and extrapyramidal effects. Hypotension, coma, convulsions, respiratory depression, and hypothermia also occur in overdosage. Hypotension is also more common in patients after a cerebrovascular accident.

Breast engorgement and galactorrhoea, gynaecomastia, increased prolactin concentrations, decreased libido, impotence, sodium retention, oedema, decreased or increased appetite, weight gain, miosis, dry mouth, sialorrhoea, dysuria, rashes, pruritus, and thrombocytopenic purpura have also been reported.

Large doses of reserpine have been shown to be tumorigenic in *rodents*. Several reports have suggested an association between reserpine and the development of neoplasms of the breast (see below) but other surveys have failed to confirm this.

Neoplasms of the breast. Although early studies suggested that the incidence of breast cancer was up to 3 to 4 times greater in hypertensive women treated with rauwolfia preparations than in control groups, analysis[1] of both prospective trials and case-control studies found only a low-grade association between use of rauwolfia preparations and risk of malignancy.

1. Grossman E, *et al.* Antihypertensive therapy and the risk of malignancies. *Eur Heart J* 2001; **22:** 1343–52.

Treatment of Adverse Effects

Withdrawal of reserpine or reduction of the dosage causes the reversal of many adverse effects although mental disorders may persist for months and hypotensive effects may persist for weeks after the cessation of treatment. If overdosage occurs activated charcoal may be considered within 1 hour of ingestion. Treatment is generally supportive and symptomatic. Severe hypotension may respond to placing the patient in the supine position with the feet raised. Direct-acting sympathomimetics may be effective for treatment of severe hypotension, but should be given with caution. The patient must be observed for at least 72 hours.

Precautions

Reserpine should not be used in patients with depression or a history of depression, with active peptic ulcer disease or ulcerative colitis, or in patients with Parkinson's disease. It should also be avoided in phaeochromocytoma.

It should be used with caution in debilitated or elderly patients, and in the presence of cardiac arrhythmias, myocardial infarction, renal insufficiency, gallstones, epilepsy, or allergic conditions such as bronchial asthma.

Reserpine is contra-indicated in patients having ECT and an interval of at least 7 to 14 days should be allowed between the last dose of reserpine and the start of any ECT.

It is probably not necessary to stop reserpine during anaesthesia, although the effects of CNS depressants may be enhanced by reserpine.

Interactions

Patients taking reserpine may be hypersensitive to adrenaline and other direct-acting sympathomimetics, which should not be given except to antagonise reserpine. The effects of indirect-acting sympathomimetics such as ephedrine may be decreased by reserpine. The hypotensive effects of reserpine are enhanced by thiazide diuretics and other antihypertensives. Reserpine may cause excitation and hypertension in patients receiving MAOIs. Use of digitalis or quinidine with reserpine may cause cardiac arrhythmias. Reserpine may enhance the effects of CNS depressants.

Antiparkinsonian drugs. For the inhibitory effect of reserpine on the antiparkinsonian actions of *levodopa,* see Antihypertensives, p.807.

Pharmacokinetics

Reserpine is absorbed from the gastrointestinal tract with a bioavailability of 50%. It is extensively metabolised and is excreted slowly in the urine and faeces. In the first 4 days, about 8% is excreted in the urine, mainly as metabolites, and about 60% in the faeces, mainly unchanged. Reserpine crosses the placenta and the blood-brain barrier and also appears in breast milk.

Uses and Administration

Reserpine is an alkaloid obtained from the roots of certain species of *Rauwolfia* (Apocynaceae), mainly *Rauwolfia serpentina* and *R. vomitoria,* or by synthesis. The material obtained from natural sources may contain closely related alkaloids.

Reserpine is an antihypertensive drug that causes depletion of noradrenaline stores in peripheral sympathetic nerve terminals and depletion of catecholamine and serotonin stores in the brain, heart, and many other organs resulting in a reduction in blood pressure, bradycardia, and CNS depression. The hypotensive effect is mainly due to a reduction in cardiac output and a reduction in peripheral resistance. Cardiovascular reflexes are partially inhibited, but orthostatic hypotension is rarely a problem at the doses used in hypertension. When given orally the full effect is only reached after several weeks of treatment and persists for up to 6 weeks after treatment is stopped.

Reserpine has been used in the management of hypertension (p.1171) and in chronic psychoses (p.954) such as schizophrenia. It has also been used in the treatment of Raynaud's syndrome (see Vasospastic Arterial Disorders, p.1188).

In **hypertension**, reserpine may be given orally in an initial dose of up to 500 micrograms daily for about 2 weeks, subsequently reduced to the lowest dose necessary to maintain the response; some sources recommend an initial dose of 50 to 100 micrograms. A maintenance dose of about 100 to 250 micrograms daily may be adequate and 500 micrograms should not normally be exceeded. To reduce adverse effects and tolerance smaller doses of reserpine may be used with a thiazide diuretic.

Reserpine has been used in chronic **psychoses** in daily doses of up to 1 mg.

Preparations

USP 31: Reserpine and Chlorothiazide Tablets; Reserpine and Hydrochlorothiazide Tablets; Reserpine Elixir; Reserpine Injection; Reserpine Tablets; Reserpine, Hydralazine Hydrochloride, and Hydrochlorothiazide Tablets.

Reteplase *(BAN, USAN, rINN)*

BM-06.022; Reteplaasi; Reteplas; Reteplasa; Rétéplase; Reteplasum; rPA. 173-L-Serine-174-L-tyrosine-175-L-glutamine-173–527-plasminogen activator (human tissue-type).

Ретеплаза

$C_{1736}H_{2653}N_{499}O_{522}S_{22}$ = 39571.1.

CAS — 133652-38-7.

ATC — B01AD07.

ATC Vet — QB01AD07.

Description. Reteplase is a nonglycosylated protein produced by recombinant DNA technology. It consists of selected domains of human tissue plasminogen activator.

Incompatibility. Reteplase may precipitate out of solution if it is given with heparin in the same intravenous line.[1] Reteplase and heparin must therefore be given separately; if a single intravenous line is used it must be flushed thoroughly with sodium chloride 0.9% or with glucose 5% before, and after, reteplase injection.

1. Committee on Safety of Medicines/Medicines Control Agency. Reteplase (Rapilysin): incompatibility with heparin. *Current Problems* 2000; **26:** 5. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON007462&RevisionSelectionMethod=LatestReleased (accessed 20/06/06)

Adverse Effects, Treatment, and Precautions

As for Streptokinase, p.1402. Allergic reactions may be less likely to occur with reteplase than with streptokinase.

Interactions

As for Streptokinase, p.1404.

Pharmacokinetics

Based on fibrinolytic activity, reteplase is reported to have an initial half-life of about 14 minutes and a terminal half-life of 1.6 hours in patients with myocardial infarction.

Uses and Administration

Reteplase is a thrombolytic drug. It converts plasminogen to plasmin, a proteolytic enzyme which has fibrinolytic effects. The mechanisms of fibrinolysis are discussed further under Haemostasis and Fibrinolysis on p.1045. Reteplase has some fibrin specificity (see Thrombolytics, p.1156).

Reteplase is used similarly to streptokinase (p.1404) in acute myocardial infarction (p.1175). It is given intravenously as soon as possible after the onset of symptoms. The dose is 10 units given by slow intravenous injection (but over not more than 2 minutes), and this dose of 10 units is repeated once, 30 minutes after the start of the first injection.

◊ General references.

4. Simpson D, *et al.* Reteplase: a review of its use in the management of thrombotic occlusive disorders. *Am J Cardiovasc Drugs* 2006; **6:** 265–85.

Catheters and cannulas. Reteplase has been used[1] successfully to clear thrombi in central venous catheters. A single dose of 0.4 units of reteplase was given as a 1 unit/mL solution, further diluted to the volume required to fill the catheter. The minimum dwell time was 30 minutes and the solution was aspirated after treatment. A second dose of 0.4 units was given if necessary.

Reviparin Sodium *(BAN, rINN)*

Repariininatrium; Reviparina sódica; Réviparine Sodique; Reviparinnatrium; Reviparinum Natricum.

Ревипарин Натрий

CAS — 9041-08-1.

ATC — B01AB08.

ATC Vet — QB01AB08.

Description. Reviparin sodium is prepared by nitrous acid depolymerisation of heparin obtained from the intestinal mucosa of pigs. The majority of the components have a 2-*O*-sulfo-α-L-idopyranosuronic acid structure at the non-reducing end and a 6-*O*-sulfo-2,5-anhydro-D-mannitol structure at the reducing end of their chain. The mass-average molecular mass ranges between 3150 and 5150 with a characteristic value of about 4150. The degree of sulfation is about 2.1 per disaccharide unit.

Units

As for Low-molecular-weight Heparins, p.1329.

Adverse Effects, Treatment, and Precautions

As for Low-molecular-weight Heparins, p.1329.

Severe bleeding with reviparin sodium may be reduced by the slow intravenous injection of protamine sulfate; about 1.2 mg of protamine sulfate is stated to inhibit the effect of 100 units of reviparin sodium.

Interactions

As for Low-molecular-weight Heparins, p.1329.

Pharmacokinetics

Reviparin sodium is absorbed after subcutaneous administration with a bioavailability of about 95%. Peak plasma concentrations are reached after about 3 hours. Reviparin sodium is excreted mainly in the urine; the elimination half-life is about 3 hours.

Uses and Administration

Reviparin sodium is a low-molecular-weight heparin (p.1329) with anticoagulant activity. It is used in the prevention and treatment of venous thromboembolism (p.1189) and has been used to prevent coagulation during haemodialysis.

Doses are expressed in terms of anti-factor Xa activity (anti-Xa units) although different values may be encountered in the literature depending upon the reference preparation used.

In the prophylaxis of venous thromboembolism during surgery, reviparin sodium is given subcutaneously in a dose of 1432 units once daily, with the first dose given 2 hours before surgery.

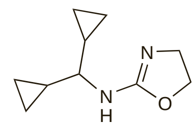
Рильменидина Фосфат

$C_{10}H_{16}N_2O,H_3PO_4$ = 278.2.

CAS — 54187-04-1 (rilmenidine); 85409-38-7 (rilmenidine phosphate).

ATC — C02AC06.

ATC Vet — QC02AC06.



(rilmenidine)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Rilmenidine Dihydrogen Phosphate). A white or almost white powder. Freely soluble in water; slightly soluble in alcohol; practically insoluble in dichloromethane.

Profile

Rilmenidine is a centrally acting antihypertensive that appears to act through stimulation of central imidazoline receptors and also has alpha$_2$-adrenoceptor agonist activity. It has general properties similar to those of clonidine (p.1247), but is reported to cause less sedation and central adverse effects. In the management of hypertension (p.1171) it has been given as the phosphate, but doses are expressed in terms of the base. Rilmenidine phosphate 1.5 mg is equivalent to about 1 mg of rilmenidine. The dose is 1 mg daily, as a single oral dose; this may be increased if necessary, after 1 month, to 2 mg daily in divided doses.

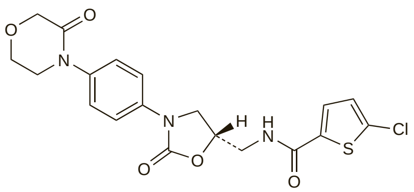
Rivaroxaban *(USAN, rINN)*

Bay-59-7939; Rivaroxabán; Rivaroxabanum. 5-Chloro-*N*-({(5*S*)-2-oxo-3-[4-(3-oxomorpholin-4-yl)phenyl]-1,3-oxazolidin-5-yl}methyl)thiophene-2-carboxamide.

Ривароксабан

$C_{19}H_{18}ClN_3O_5S = 435.9.$

CAS — 366789-02-8.



Profile

Rivaroxaban is an oral direct inhibitor of activated factor X that is under investigation in thromboembolic disorders.

Rosuvastatin Calcium *(BANM, USAN, rINNM)*

Calcii Rosuvastatinum; Rosuvastatina calcica; Rosuvastatine Calcique; S-4522; ZD-4522 (rosuvastatin). (*E*)-(3*R*,5*S*)-7-{4-(4-Fluorophenyl)-6-isopropyl-2-[methyl(methylsulfonyl)amino]pyrimidin-5-yl}-3,5-dihydroxyhept-6-enoic acid calcium (2:1).

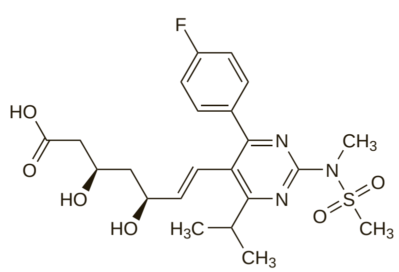
Кальций Розувастатин

$(C_{22}H_{27}FN_3O_6S)_2Ca = 1001.1.$

CAS — 287714-41-4 (rosuvastatin); 147098-20-2 (rosuvastatin calcium).

ATC — C10AA07.

ATC Vet — QC10AA07.



(rosuvastatin)

Adverse Effects and Precautions

As for Simvastatin, p.1390. Systemic exposure to rosuvastatin may be higher in Asian patients (see Ethnicity under Pharmacokinetics, below) and lower doses are advised in Asians and in other patients at high risk of myopathy (see Uses and Administration, below).

Incidence of adverse effects. An analysis[1] of adverse effects reported to the FDA in the first year of marketing found that rosuvastatin was significantly more likely to be associated with severe adverse effects than some other statins. However, further analyses of data from clinical studies[2] and post-marketing studies[3,4] suggest that the risk of adverse effects is similar for all the statins. Another observational study[5] with a median treatment period of 9.8 months found that rosuvastatin was generally well tolerated, although 17.5% of patients stopped taking the drug, with myalgia being the most common reason. Abnormal liver function tests were more common in patients taking higher doses.

5. Kasliwal R, *et al.* Safety profile of rosuvastatin: results of a prescription-event monitoring study of 11 680 patients. *Drug Safety* 2007; **30:** 157–70.

Interactions

The interactions of statins with other drugs are described under simvastatin, p.1392. Rosuvastatin undergoes limited metabolism, principally by the cytochrome P450 isoenzyme CYP2C9, and may not have the same interactions with enzyme inhibitors as simvastatin. However, increased plasma-rosuvastatin concentrations have been reported with ciclosporin, HIV-protease inhibitors, and, to a lesser extent, with gemfibrozil, and such combinations should be avoided. If they must be given together, lower doses of rosuvastatin should be used (see Uses and Administration, below); in UK licensed product information, rosuvastatin is contra-indicated with ciclosporin.

Pharmacokinetics

Rosuvastatin is incompletely absorbed from the gastrointestinal tract, with an absolute bioavailability of about 20%. Peak plasma concentrations are achieved about 5 hours after an oral dose. It is taken up extensively by the liver, its primary site of action, and undergoes limited metabolism, mainly by the cytochrome P450 isoenzyme CYP2C9. It is about 90% bound to plasma proteins. The plasma elimination half-life of rosuvastatin is about 19 hours. About 90% of an oral dose of rosuvastatin appears in the faeces, including absorbed and non-absorbed drug, and the remainder is excreted in the urine; about 5% of a dose is excreted unchanged in urine.

Ethnicity. A pharmacokinetic study[1] found that plasma exposure to rosuvastatin and its metabolites was significantly higher in Asian (Chinese, Malay, or Indian) than in Caucasian subjects and lower doses should be used (see Uses and Administration, below).

1. Lee E, *et al.* Rosuvastatin pharmacokinetics and pharmacogenetics in white and Asian subjects residing in the same environment. *Clin Pharmacol Ther* 2005; **78:** 330–41.

Uses and Administration

Rosuvastatin, a hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitor (or statin), is a lipid regulating drug with actions on plasma lipids similar to those of simvastatin (p.1394). It is used to reduce LDL-cholesterol, apolipoprotein B, and triglycerides, and to increase HDL-cholesterol in the management of hyperlipidaemias (p.1169), including primary hypercholesterolaemia (type IIa), mixed dyslipidaemia (type IIb), and hypertriglyceridaemia (type IV), as well as in patients with homozygous familial hypercholesterolaemia. It is also used to reduce the progression of atherosclerosis.

Rosuvastatin is given orally as the calcium salt, although doses are expressed in terms of the base; 10.4 mg of rosuvastatin calcium is equivalent to about 10 mg of base.

The usual initial dose of rosuvastatin is 5 or 10 mg once daily, depending on plasma-cholesterol concentrations, cardiovascular risk factors, and risk factors for adverse effects. The maintenance dose ranges from 5 to 40 mg once daily, although the 40-mg dose is reserved for patients with high cardiovascular risk who do not achieve their target cholesterol concentration at lower doses and who do not have risk factors for adverse effects. Specific dosage recommendations vary; for dosage in renal impairment, see below.

UK licensed product information recommends an initial dose of 5 or 10 mg once daily; elderly patients, Asians, and those at risk of myopathy should be given the 5-mg dose. The dose may be increased at intervals of 4 weeks, if necessary, to a usual maximum of 20 mg once daily. A higher dose of 40 mg once daily may be given under specialist supervision in severe hypercholesterolaemia, but should not be given to patients at high risk of myopathy, including those receiving fibrates, and Asian patients; use with *ciclosporin* is contra-indicated.

US licensed product information recommends a usual initial dose of 10 mg once daily. However, a lower initial dose of 5 mg once daily may be adequate and is recommended for patients at risk of myopathy, including Asian patients; patients with marked hypercholesterolaemia, such as those with homozygous familial hypercholesterolaemia, may be started on 20 mg once daily. The dose should be adjusted after 2 to 4 weeks, to a usual maximum of 20 mg once daily; a dose of 40 mg once daily may be necessary in some patients. Patients receiving *ciclosporin* may be given a maximum of 5 mg once daily, and in those receiving *gemfibrozil* or *ritonavir-boosted lopinavir* the maximum dose is 10 mg once daily; dosage increases should be made with caution in Asian patients.

Administration in renal impairment. Patients with renal impairment have an increased risk of developing myopathy and statins should be used with caution, particularly in higher doses. In severe renal impairment plasma-rosuvastatin concentrations may be increased and dosage reduction may be necessary.

UK licensed product information recommends the following oral doses according to creatinine clearance (CC):

- CC 30 to 60 mL/minute: initial oral dose of 5 mg once daily and a maximum dose of 20 mg once daily
- CC below 30 mL/minute: contra-indicated

In the USA usual doses (see above) are allowed in moderate impairment but an initial dose of 5 mg once daily and a maximum dose of 10 mg once daily is recommended in those with CC below 30 mL/minute per 1.73 m^2.

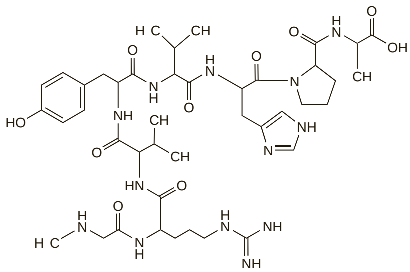
Saralasin Acetate *(BANM, USAN, rINNM)*

Acetato de sarasalina; P-113; Saralasine, Acétate de; Saralasini Acetas; The acetate of 1-Sar-8-Ala-angiotensin II. The hydrated acetate of Sar-Arg-Val-Tyr-Val-His-Pro-Ala; [1-(*N*-Methylglycine)-5-L-valine-8-L-alanine]-angiotensin II acetate hydrate.

Саралазина Ацетат

$C_{42}H_{65}N_{13}O_{10},xCH_3COOH,xH_2O$ = 912.0 (saralasin).
CAS — 34273-10-4 (saralasin); 54194-01-3 (anhydrous saralasin); 39698-78-7 (saralasin acetate hydrate).



(saralasin)

Profile

Saralasin acetate is a competitive antagonist of angiotensin II and thus blocks its pressor action. It is also a partial agonist and causes a transient initial rise in blood pressure. Saralasin has a short half-life and has been used in the differential diagnosis of renovascular hypertension but its use has largely been superseded.

Sarpogrelate Hydrochloride *(rINNM)*

Hidrocloruro de sarpogrelato; MCI-9042; Sarpogrélate, Chlorhydrate de; Sarpogrelati Hydrochloridum. (±)-2-(Dimethylamino)-1-{[o-(*m*-methoxyphenethyl)phenoxy]methyl}ethyl hydrogen succinate hydrochloride.

Сарпогрелата Гидрохлорид

$C_{24}H_{31}NO_6,HCl$ = 466.0.
CAS — 125926-17-2 (sarpogrelate); 135159-51-2 (sarpogrelate hydrochloride).

Profile

Sarpogrelate is a serotonin 5-HT_2-receptor antagonist used as an inhibitor of platelet aggregation in thromboembolic disorders. It is given for occlusive arterial disease (see Peripheral Vascular Disease, p.1178) in oral doses of 100 mg of the hydrochloride three times daily.

Preparations

Proprietary Preparations (details are given in Part 3)
Jpn: Anplag.

Saruplase *(BAN, rINN)*

Prourokinase, Non-glycosylated; Recombinant Human Single-Chain Urokinase-type Plasminogen Activator; Saruplasa; Saruplasum; scuPA. Prourokinase (enzyme-activating) (human clone pUK4/pUK18), non-glycosylated.

Саруплаза

$C_{2031}H_{3121}N_{585}O_{601}S_{31}$ = 46343.1.
CAS — 99149-95-8.
ATC — B01AD08.
ATC Vet — QB01AD08.

NOTE. The term prourokinase has been used for both saruplase and nasaruplase (p.1346).

Profile

Saruplase is a thrombolytic drug. It is a urokinase-type plasminogen activator with a single chain structure prepared via recombinant DNA technology and is converted to urokinase (p.1420) in the body by plasmin. It also has some intrinsic plasminogen-activating properties. Saruplase has been investigated in acute myocardial infarction.

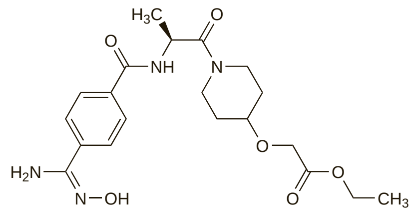
Sibrafiban *(BAN, USAN, rINN)*

G-7333; Ro-48-3657/001; Sibrafibán; Sibrafibanum. Ethyl (*Z*)-[(1-{*N*-[(*p*-hydroxyamidino)benzoyl]-L-alanyl}-4-piperidyl)oxy]acetate.

Сибрафибан

$C_{20}H_{28}N_4O_6$ = 420.5.
CAS — 172927-65-0.



Profile

Sibrafiban is a glycoprotein IIb/IIIa-receptor antagonist. It has been investigated as an oral antiplatelet drug in unstable angina and myocardial infarction but results have been disappointing.

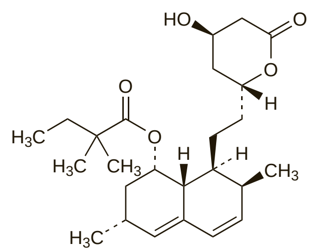
Simvastatin *(BAN, USAN, rINN)*

L-644128-000U; MK-733; Simvastatiini; Simvastatina; Simvastatinas; Simvastatine; Simvastatinum; Sinvinolina; Synvinolin; Szimvasztatin; Velastatin; Velastatina. (1*S*,3*R*,7*S*,8*S*,8a*R*)-1,2,3,7,8,8a-Hexahydro-3,7-dimethyl-8-{2-[(2*R*,4*R*)-tetrahydro-4-hydroxy-6-oxo-2*H*-pyran-2-yl]ethyl}-1-naphthyl 2,2-dimethylbutyrate.

Симвастатин

$C_{25}H_{38}O_5$ = 418.6.
CAS — 79902-63-9.
ATC — C10AA01.
ATC Vet — QC10AA01.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Simvastatin). A white or almost white crystalline powder. Practically insoluble in water; freely soluble in alcohol; very soluble in dichloromethane. Store under nitrogen in airtight containers. Protect from light.

USP 31 (Simvastatin). A white to off-white powder. Practically insoluble in water; freely soluble in alcohol, in chloroform, and in methyl alcohol; sparingly soluble in propylene glycol; very slightly soluble in petroleum spirit. Store at a temperature between 15° and 30°, or at 2° to 8°.

Adverse Effects

The commonest adverse effects of therapy with simvastatin and other statins are gastrointestinal disturbances. Other adverse effects reported include headache, skin rashes, dizziness, blurred vision, insomnia, and dysgeusia. Reversible increases in serum-aminotransferase concentrations may occur and liver function should be monitored (see Precautions, below). Hepatitis and pancreatitis have been reported. Hypersensitivity reactions including anaphylaxis and angioedema have also occurred. Myopathy, characterised by myalgia and muscle weakness and associated with increased creatine phosphokinase concentrations, has been reported, especially in patients also taking ciclosporin, fibric acid derivatives, or nicotinic acid. Rarely, rhabdomyolysis with acute renal failure may develop.

Incidence of adverse effects. By February 1992 the UK CSM had received 738 reports of adverse effects associated with simvastatin,[1] from an estimated 257 000 prescriptions. Abnormal hepatic function and myalgia were 2 of the most frequently reported reactions, with 36 and 48 reports respectively, including 5 reports of hepatitis and 2 of jaundice. Other muscle effects included 3 reports of myositis, 10 of myopathy, and 7 reports of asymptomatic increases in serum creatine kinase concentrations. Gastrointestinal adverse effects accounted for 20% of the reports; skin, neurological and musculoskeletal effects for 15% each; psychiatric effects for 10%; liver effects for 7%; and visual effects for 4%. A systematic review[2] of data from clinical studies confirmed that the risk of liver transaminase elevation was increased by statins but there was no significant increase in the incidence of myalgia (reported in about 15% of patients), creatine kinase elevation (0.9%), or rhabdomyolysis (0.2%), compared with placebo. The incidence of adverse effects may be greater with high-dose therapy.[3,4]

Carcinogenicity. For discussion of the effects of statins on the risk of cancer, see Malignant Neoplasms under Uses, below.

Effects on the blood. *Thrombocytopenia* has been reported rarely with statin therapy. Serious thrombocytopenic purpura has occurred with simvastatin, with the onset ranging from 1 or 2 days[1,2] to 11 or 12 months[3,4] after starting treatment. Platelet counts improved after stopping simvastatin in each case, although most patients were given corticosteroids, immunoglobulins, or plasma exchange. There has also been a similar report with atorvastatin,[5] which recurred on rechallenge; the patient had previously taken simvastatin without developing thrombocytopenia, suggesting an idiosyncratic reaction.

A case of *haemolytic anaemia* has been reported[6] in a patient taking lovastatin; no adverse effect was seen when the patient was given simvastatin.

Statins have effects on coagulation and fibrinolysis but these are generally beneficial (see Action under Uses, below); there have been rare reports of *ocular haemorrhage*,[7] but the association with statins is not established.

7. Fraunfelder FW. Ocular hemorrhage possibly the result of HMG-CoA reductase inhibitors. *J Ocul Pharmacol Ther* 2004; **20:** 179–82.

Effects on the eyes. Studies in *animals* have suggested that some statins could cause cataracts, but this has not been confirmed in humans. Although a study[1] with lovastatin found lens opacities in 13 of 101 patients after treatment for 18 weeks, no deterioration in visual function was found in 11 of these who continued lovastatin and were followed up for an average of 26 months from the start of treatment. Similarly, no differences were found in the development of lens opacities or in changes in visual acuity between patients treated with lovastatin for 48 weeks and patients taking placebo in a study of 8245 patients.[2] A large case-control study[3] found no evidence that use of therapeutic statin doses was associated with the development of cataracts, although the risk did appear to be increased in patients taking simvastatin with erythromycin. Further observational studies have suggested that statins may have beneficial effects; in one study[4] there was no effect on the overall incidence of cataract but the risk of developing nuclear cataract appeared to be decreased, while another study[5] reported a reduction in the overall incidence but this was not significant for any specific cataract type.

For mention of ocular haemorrhage in patients taking statins, see above.

Effects on the hair. Between its introduction in Australia and 1993, 16 cases of alopecia associated with the use of simvastatin had been reported to the Adverse Drug Reactions Advisory Committee.[1] Most cases involved either excessive hair loss or hair thinning, although 2 cases of hair loss in patches and 1 resembling alopecia areata were reported. Onset occurred between 3 days and 15 months after starting therapy. Progressive hair loss has also been reported[2] in a woman within 6 weeks of commencing atorvastatin; the hair regrew when atorvastatin was stopped but alopecia recurred when therapy was restarted 5 months later.

1. Anonymous. Simvastatin and alopecia. *Aust Adverse Drug React Bull* 1993; **12:** 7.
2. Segal AS. Alopecia associated with atorvastatin. *Am J Med* 2002; **113:** 171.

Effects on the kidneys. *Proteinuria* was reported in 10 patients taking simvastatin 40 mg daily.[1] The protein loss was of a pattern typical for increased glomerular permeability. In 2 patients proteinuria disappeared when simvastatin was withdrawn and recurred on its subsequent reintroduction. However, there is also some evidence that statins may improve proteinuria (see Kidney Disorders under Uses, below).

Acute tubulointerstitial *nephritis* developed[2] in a patient receiving high-dose therapy with rosuvastatin. It resolved over 3 weeks when rosuvastatin was stopped, but recurred 2 weeks after rechallenge. A similar reaction was noted with atorvastatin, but improved with dose reduction, and the patient was finally stabilised on simvastatin without a further recurrence.

Renal failure due to rhabdomyolysis has been reported rarely (see under Effects on Skeletal Muscle, below).

1. Deslypere JP, *et al.* Proteinuria as complication of simvastatin treatment. *Lancet* 1990; **336:** 1453.
2. van Zyl-Smit R, *et al.* Renal tubular toxicity of HMG-CoA reductase inhibitors. *Nephrol Dial Transplant* 2004; **19:** 3176–9.

Effects on the liver. Statins cause dose-related increases in liver enzymes but the incidence appears to be low with low to moderate doses[1] and serious hepatic effects appear to be rare.[2] Although monitoring of liver function tests is advised, the value of routine assessment has been questioned.[3] There is some evidence[4] that the incidence of hepatic reactions may be higher with fluvastatin than with other statins, but this is not yet established.

There have also been case reports[5-7] of cholestasis in patients receiving statins.

Effects on the lungs. Interstitial lung disorders, including hypersensitivity pneumonitis, have been reported with a number of statins.[1-4] In some cases the condition improved when the statin was stopped[2] but treatment with corticosteroids and immunosuppressants was required in some patients[1-4] and progressive disease and fatalities have occurred.[4]

Effects on mental function. There have been conflicting reports of the effects of statins on mental function, and a number of adverse psychiatric reactions have been reported with statins and with other lipid regulating drugs, although the exact association is unclear.

There have been a few case reports of *depressive symptoms* developing in patients treated with pravastatin[1] or simvastatin.[2] The symptoms appeared during the first few weeks or months of treatment. However, randomised studies investigating the effects of lowering cholesterol on mental function have found no effect on mood disorders (with simvastatin[3]) or psychological well-being (with lovastatin[4] or pravastatin[5]), and epidemiological studies have suggested that use of statins may be associated with improved psychological status[6] and a reduction in the risk of depression and suicide.[7]

Impairment of cognitive function has been reported with statins. In the study using lovastatin,[4] reductions in some measures of cognitive function were noted, and similar results were found in a study using simvastatin.[8] New onset cognitive impairment in a patient a week after starting simvastatin resolved when the drug was stopped but recurred on rechallenge with a lower dose,[9] while analyses of reports to adverse drug reaction reporting databases[10,11] have found a number of cases of memory loss in patients receiving statins, some of which were confirmed by rechallenge. However, clinical studies have not found statins to have an adverse effect on cognition, and there is epidemiological evidence that use of statins may reduce the incidence of dementia (see under Uses, below). A study with atorvastatin[12] also found beneficial effects on cognitive function.

Other psychiatric effects that have been noted in reports to another adverse drug reaction reporting database[13] include 5 cases of aggressive reactions, all of which resolved when the statin was stopped.

Effects on the nervous system. Treatment with statins may be associated with the development of peripheral neuropathy,[1] although the reaction appears to be rare. Up to 2005, the Australian Adverse Drug Reactions Advisory Committee had received 281 reports[2] of both sensory and sensorimotor peripheral neuropathies associated with statins. Time to onset of symptoms ranged from after the first dose to 4.5 years. Recovery was seen on withdrawal in about half of the cases, including in some diabetics, and there were some reports of positive rechallenge. In 21 cases symptoms persisted at the time of reporting, up to 8 months after the statin was stopped, and in a further 2 reports the symptoms were unresolved after 3 and 5 years respectively. Similar patterns have been noted elsewhere.[3] A case-control study[4] found that the risk of neuropathy was substantially increased in users of statins although the number of cases was small, and the authors concluded that the benefits of therapy generally outweighed the risks.

Upper motor neurone lesions similar to amyotrophic lateral sclerosis have also been reported in patients taking statins,[5] although the association is not yet confirmed.

Effects on the pancreas. Statins may cause pancreatitis but the incidence appears to be low,[1,2] and a case-control study[3] failed to support a strong association.

Effects on sexual function. There have been reports of *erectile dysfunction* in some men receiving statins. Five men receiving simvastatin developed impotence,[1] which resolved when fluvastatin was substituted in 4 of them. In another case,[2] impotence occurred in a patient receiving lovastatin, and recurred when therapy was changed to pravastatin. Up to 1995, the Australian Adverse Drug Reactions Advisory Committee[3] had received 28 reports of impotence associated with simvastatin, which had recurred on rechallenge in 4 cases. A report[4] from the French and Spanish drug monitoring systems, and an observational study[5] in high-risk cardiovascular patients, supported the association between statins and erectile dysfunction, and a systematic review[6] came to similar conclusions. However, it has been pointed out[7] that the increased risk of sexual dysfunction with statins in the Scandinavian Simvastatin Survival Study was not statistically significant, and there has also been a small study[8] suggesting that atorvastatin may improve erectile function in men with hyperlipidaemia as the only risk factor.

Decreased libido has also been reported with statins. Serum-testosterone concentrations were measured in 2 of 8 patients reported to the Netherlands Pharmacovigilance Centre and were found to be low;[9] they rose after the statin was stopped.

Testicular pain has been reported[10] in a 54-year-old patient 7 months after starting lovastatin. The pain resolved when lovastatin was stopped, but recurred with both simvastatin and atorvastatin. The mechanism for the reaction was unclear.

There has also been a report[11] of a *low sperm count* in a patient receiving lovastatin.

Gynaecomastia occurred in a patient 6 months after changing from simvastatin to atorvastatin.[12] Symptoms improved when atorvastatin was stopped and did not recur when treatment with simvastatin was restarted.

Effects on skeletal muscle. The association between muscle disorders and statins is well known.[1-8] Mild *myalgia* is relatively common, but *myositis* and *myopathy,* with elevation of creatine kinase, may also occur. *Rhabdomyolysis,*[9,10] which involves severe muscle damage, substantial elevation of creatine kinase and myoglobulinuria leading to renal impairment, occurs more rarely, but has resulted in fatalities. Muscle toxicity is dose-related and the risk appears to be broadly similar with all of the currently-marketed statins;[5,6,11] the incidence with cerivastatin was found to be considerably higher and this led to its withdrawal worldwide in 2001. Patients with complex medical problems, including renal impairment and possibly endocrine disorders such as hypothyroidism, may be at increased risk of muscle toxicity; drug interactions may also contribute (see below). Myopathy has been reported with other lipid regulating drugs, particularly fibrates, and the risk may be increased in patients with severe hyperlipidaemia who require combination therapy; careful monitoring is required if statins and fibrates are used together.[6,12] The UK CSM[1] and a joint committee of the American College of Cardiology, American Heart Association, and National Heart, Lung and Blood Institute,[6] have both advised that patients treated with statins should consult their doctor if they develop muscle pain, tenderness, or weakness and that treatment should be stopped if muscle toxicity occurs or is suspected clinically or if creatine phosphokinase is markedly raised or progressively rising. If continued therapy is required, the dose may be reduced or another statin or alternative lipid regulating drug may be tried, although the risk of recurrent muscle problems appears quite high.[10] An algorithm for diagnosis and management of statin-associated myalgia has been suggested.[13]

The mechanism by which statins cause muscle toxicity is not clear, but it has been suggested that depletion of ubidecarenone concentrations may be involved.[14] Although positive results have been reported with ubidecarenone supplementation[15] evidence of benefit is limited and it is not generally recommended.[16]

Other muscular disorders that have been reported in patients receiving statins include *dermatomyositis* and *polymyositis,*[17] and *myasthenia gravis.*[18-20]

Effects on sleep patterns. Changes to sleep patterns have been reported with lipophilic statins such as lovastatin[1-3] and simvastatin,[4] but appear to be less common with pravastatin,[1] possibly because it is hydrophilic and less likely to penetrate the brain. However, a large placebo-controlled study[5] found that simvastatin had no effect on sleep patterns, and smaller studies assessing sleep using questionnaires[6] or polysomnography,[7-9] have found no significant effects with any of the statins, although some patients appeared to have underlying sleep disorders.

Nightmares and sleep disturbances in a patient taking simvastatin and metoprolol resolved when treatment was changed to pravastatin and atenolol.[10] There has been a report of nightmares with atorvastatin, which resolved when the drug was stopped but recurred on rechallenge.[11]

Precautions

Statins should not be given to patients with active liver disease. Liver function should be assessed before starting treatment and subsequently when clinically indicated; additional assessment after 3 months and before and after dosage increases has been advised for some statins, particularly when high doses are given. Statins should not be used in patients who already have unexplained persistently raised serum-aminotransferase concentrations and should be stopped if marked or persistent increases in serum-aminotransferase concentrations occur. They should be avoided during pregnancy since there is a possibility that they could interfere with fetal sterol synthesis; there have been a number of reports of congenital abnormalities associated with statins (see Pregnancy, below). Statins may cause myopathy and rhabdomyolysis, especially at higher doses, and they should be used with caution in patients at risk of rhabdomyolysis, and particularly in patients taking drugs that increase plasma concentrations of the statin (see Interactions, below); the statin should be stopped if creatine phosphokinase increases significantly or if myopathy is diagnosed.

Statins should be used with caution in patients with renal impairment as the risk of myopathy is increased. Dose reduction may be required for statins that are excreted by the kidney and for those with a particularly high risk of myopathy (see Administration in Renal Impairment under Uses of the individual drugs for further details).

Children. For discussion of concerns relating to the use of statins in children, see Administration in Children under Uses, below.

Porphyria. Simvastatin is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Pregnancy. Statins are generally contra-indicated in pregnancy since there is a possibility that they might affect fetal sterol synthesis whereas the risk to the mother from stopping treatment temporarily is usually very low. Evidence that statins have adverse effects on the fetus, however, is limited. Studies based on postmarketing surveillance[1,2] or pregnancy registry data[3] have generally found that the frequency and range of congenital anomalies reported was similar to that expected in the general population. However, reviews of case reports[4,5] found that the incidence of CNS defects and limb anomalies was higher than expected, suggesting a possible adverse effect of statin exposure; 1 of the 5 cases reported as a CNS defect was later found to have cardiac anomalies only.[6]

Interactions

The most serious consequence of drug interactions with simvastatin and other statins is the development of myopathy or rhabdomyolysis. Drugs that can cause myopathy when given alone increase the risk of myopathy with all statins; these drugs include fibric acid derivatives (fibrates or gemfibrozil), and nicotinic acid. The risk of myopathy is also increased by drugs that increase the plasma concentrations of statins, by inhibiting their metabolism or by inhibiting their uptake into the liver. Since the statins have different metabolic pathways, these interactions depend on the individual drug concerned. Simvastatin is metabolised by the cytochrome P450 isoenzyme CYP3A4, as are atorvastatin and lovastatin, and interactions may occur with drugs that inhibit this enzyme, including ciclosporin, itraconazole, ketoconazole, erythromycin, clarithromycin, telithromycin, HIV-protease inhibitors, nefazodone, danazol, amiodarone, and verapamil; there may also be a similar interaction with grapefruit juice. Such combinations should be used with caution, if at all, and dose reduction may be advised (see Uses and Administration, below); UK licensed product information contra-indicates the use of simvastatin in patients receiving potent CYP3A4 inhibitors. Fluvastatin is metabolised mainly by CYP2C9, while pravastatin and rosuvastatin are not significantly metabolised; interactions specific to these statins are discussed on p.1290, p.1374, and p.1389, respectively.

Statins may also have effects on other drugs. Bleeding and increases in prothrombin time have been reported in patients taking simvastatin or other statins with coumarin anticoagulants.

Antiarrhythmics. *Amiodarone* is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and may increase plasma concentrations of statins metabolised by this enzyme, increasing the risk of toxicity. There have been reports[1-3] of myopathy and rhabdomyolysis in patients taking amiodarone and simvastatin (in some cases with other CYP3A4 inhibitors), and a pharmacokinetic study[4] found that amiodarone increased plasma-simvastatin concentrations in healthy subjects. High doses of simvastatin are not recommended in patients taking amiodarone (see Uses and Administration, below).

An asymptomatic increase in serum aminotransferases in a patient receiving rosuvastatin and amiodarone may have been the result of an interaction between the drugs.[5]

Antibacterials. *Erythromycin* and other *macrolides* are inhibitors of the cytochrome P450 isoenzyme CYP3A4 and may increase plasma concentrations and the risk of myopathy with some statins. Increased plasma concentrations of simvastatin have been reported with erythromycin,[1] and increased plasma concentrations of atorvastatin have been found with erythromycin[2] and *clarithromycin*,[3] but not with *azithromycin*.[3] There have been reports of myopathy or rhabdomyolysis in patients receiving simvastatin with clarithromycin,[4] and in patients receiving lovastatin with azithromycin,[5] clarithromycin,[5] or erythromycin.[6]

Rifampicin, an inducer of CYP2C9 and CYP3A4, may reduce the bioavailability of fluvastatin, and has also been reported to reduce the plasma concentration of simvastatin[7] and atorvastatin.[8]

There have been reports of rhabdomyolysis in patients receiving atorvastatin[9] or simvastatin[10] with *fusidic acid*.

1. Kantola T, *et al.* Erythromycin and verapamil considerably increase serum simvastatin and simvastatin acid concentrations. *Clin Pharmacol Ther* 1998; **64:** 177–82.

Anticoagulants. For reports of bleeding and increased prothrombin time in patients receiving oral anticoagulants with statins, see Lipid Regulating Drugs, p.1431.

Antidepressants. Myositis and rhabdomyolysis, with raised liver enzyme values, have been reported[1-4] in patients given simvastatin with *nefazodone*; in one case[3] the reaction appeared to be precipitated by the addition of azithromycin. Increased creatine kinase concentrations also occurred in a patient given pravastatin with nefazodone.[5]

A study[6] in healthy subjects found that *St John's wort* reduced the plasma concentration of simvastatin but had no effect on pravastatin.

1. Jacobson RH, *et al.* Myositis and rhabdomyolysis associated with concurrent use of simvastatin and nefazodone. *JAMA* 1997; **277:** 296.
2. Thompson M, Samuels S. Rhabdomyolysis with simvastatin and nefazodone. *Am J Psychiatry* 2002; **159:** 1607.

6. Sugimoto K-i, *et al.* Different effects of St John's Wort on the pharmacokinetics of simvastatin and pravastatin. *Clin Pharmacol Ther* 2001; **70:** 518–24.

Antifungals. *Itraconazole* and *ketoconazole* are inhibitors of the cytochrome P450 isoenzyme CYP3A4 and may increase plasma concentrations and the risk of myopathy with some statins. Raised plasma concentrations of simvastatin,[1,2] lovastatin,[3,4] and atorvastatin[5] have been reported with itraconazole, whereas the effect on pravastatin,[1] rosuvastatin,[6] or fluvastatin[4] appears to be minimal. Myopathy and rhabdomyolysis have been reported with simvastatin and itraconazole[2,7] or ketoconazole,[8] and with lovastatin and itraconazole.[9] *Fluconazole* inhibits CYP2C9 and has been reported[10] to increase the plasma concentration of fluvastatin. There has also been a report[11] of rhabdomyolysis in a patient taking fluconazole and simvastatin.

Antiplatelet drugs. For discussion of a possible interaction between statins and clopidogrel, see p.1250

Antivirals. *HIV-protease inhibitors* are inhibitors of the cytochrome P450 isoenzyme CYP3A4 and may affect the metabolism of simvastatin and other statins. Studies have shown increased plasma concentrations of both simvastatin and atorvastatin with *nelfinavir*,[1] and with *ritonavir-boosted saquinavir*,[2] whereas the plasma concentration of pravastatin was reduced with ritonavir-boosted saquinavir.[2] Rhabdomyolysis has been reported[3] in a patient taking simvastatin when ritonavir was added to her therapy. Although rosuvastatin is not significantly metabolised, increased plasma concentrations have been reported with *ritonavir-boosted lopinavir*.[4,5]

There has also been a report[6] of rhabdomyolysis in a patient receiving atorvastatin with the non-nucleoside reverse transcriptase inhibitor *delavirdine*.

Efavirenz is an inducer of CYP3A4 and a study in healthy subjects[7] found that it could reduce plasma concentrations of atorvastatin and simvastatin; plasma concentrations of pravastatin were also reduced, although it is not metabolised by CYP3A4.

1. Hsyu P-H, *et al.* Pharmacokinetic interactions between nelfinavir and 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors atorvastatin and simvastatin. *Antimicrob Agents Chemother* 2001; **45:** 3445–50.

Calcium-channel blockers. Calcium-channel blockers may increase plasma concentrations of some statins, probably by inhibition of the cytochrome P450 isoenzyme CYP3A4. Pharmacokinetic studies have reported increased plasma concentrations of simvastatin with *verapamil*,[1] and with *diltiazem*,[2] and of lovastatin with diltiazem;[3] the small increase with simvastatin and *lacidipine* was not considered clinically relevant.[4]

The interaction between statins and diltiazem has also been reported in patients. A retrospective study[5] found that the cholesterol-lowering effect of simvastatin was greater in patients who were also receiving diltiazem, and there have also been reports[6-8] of rhabdomyolysis, associated with hepatitis in 1 case,[6] in patients receiving simvastatin and diltiazem together. Rhabdomyolysis[8,9] and hepatitis[9] have also been reported in patients receiving atorvastatin with diltiazem.

1. Kantola T, *et al.* Erythromycin and verapamil considerably increase serum simvastatin and simvastatin acid concentrations. *Clin Pharmacol Ther* 1998; **64:** 177–82.

Colchicine. For reports of additive muscle toxicity with statins and colchicine, see Cardiovascular Drugs under Interactions of Colchicine, p.556.

Danazol. Rhabdomyolysis has been reported[1] in a patient receiving lovastatin with a number of other drugs; it was considered that an interaction with danazol was the most likely cause. A similar reaction has been reported[2] with simvastatin.

1. Dallaire M, Chamberland M. Rhabdomyolyse sévère chez un patient recevant lovastatine, danazol et doxycycline. *Can Med Assoc J* 1994; **150:** 1991–4.
2. Andreou ER, Ledger S. Potential drug interaction between simvastatin and danazol causing rhabdomyolysis. *Can J Clin Pharmacol* 2003; **10:** 172–4.

Endothelin receptor antagonists. *Bosentan* is an inducer of the cytochrome P450 isoenzyme CYP3A4 and has been reported[1] to reduce plasma-simvastatin concentrations in healthy subjects.

1. Dingemanse J, *et al.* Investigation of the mutual pharmacokinetic interactions between bosentan, a dual endothelin receptor antagonist, and simvastatin. *Clin Pharmacokinet* 2003; **42:** 293–301.

Fruit juices. *Grapefruit juice* inhibits the cytochrome P450 isoenzyme CYP3A4 and studies using concentrated grapefruit juice have reported increased plasma concentrations of simvastatin,[1] lovastatin,[2] and atorvastatin.[3] A study[4] using less concentrated grapefruit juice found only minimal effect on the activity of lovastatin, but the conclusions of this study have been criticised;[5] studies using normal strength grapefruit juice have found considerable increases in plasma concentrations of atorvastatin[6] and simvastatin.[7] There is also a case report[8] of a woman receiving simvastatin who developed symptoms of rhabdomyolysis 4 days after she started eating one grapefruit each day. Statins that are not significantly metabolised by CYP3A4, such as pitavastatin[6] and pravastatin,[3,9] do not appear to be affected.

Rhabdomyolysis has also been reported[10] in a patient taking rosuvastatin and ezetimibe when he started drinking *pomegranate juice* regularly.

Immunosuppressants. Myopathy and rhabdomyolysis have been reported in patients receiving atorvastatin,[1] lovastatin,[2-4] or simvastatin[5-7] with immunosuppressant regimens including *ciclosporin*. The mechanism of the interaction may be additive toxicity, since both statins and ciclosporin are known to cause myopathy, but effects on plasma concentrations may also be involved. Pharmacokinetic studies have shown that ciclosporin increases the plasma concentrations of atorvastatin,[8,9] fluvastatin,[10,11] lovastatin,[12] pravastatin,[12,13] rosuvastatin,[14] and simvastatin.[15] For the effects of statins on plasma-ciclosporin concentrations, see p.1827.

Levothyroxine. For reference to the effect of lovastatin and simvastatin in patients receiving levothyroxine, see Lipid Regulating Drugs, p.2173.

Lipid regulating drugs. Myopathy and myositis are recognised adverse effects of both statins and fibric acid derivatives, including *fibrates* and *gemfibrozil*, and the risk is increased if they are given together. There has also been a report[1] of both hepatotoxicity and rhabdomyolysis in a patient given a statin and gemfibrozil together. The interaction between gemfibrozil and statins may also have a pharmacokinetic basis; studies have shown increased plasma concentrations of atorvastatin,[2] lovastatin,[3] pravastatin,[4] rosuvastatin,[5] and simvastatin[6] when given with gemfibrozil.

Myopathy has also been reported[7,8] in patients given statins with *nicotinic acid*, although a study[9] of adverse effects reported to the FDA found no increase in reports for lovastatin given with nicotinic acid compared with either drug alone.

For reports of increased hepatotoxicity when statins were given with *ezetimibe* see Effects on the Liver, p.1284.

Proton pump inhibitors. There is a report[1] of rhabdomyolysis causing AV block in a patient receiving atorvastatin when *esomeprazole* and clarithromycin were added to her treatment. As symptoms started before the introduction of clarithromycin, it was thought that a possible contributory mechanism for the interaction was a reduction in the first-pass metabolism of atorvastatin due to the inhibition of p-glycoprotein by esomeprazole.

1. Sipe BE, *et al.* Rhabdomyolysis causing AV blockade due to possible atorvastatin, esomeprazole, and clarithromycin interaction. *Ann Pharmacother* 2003; **37:** 808–11.

Ranolazine. A study[1] in healthy subjects showed that ranolazine moderately increased plasma concentrations of simvastatin but it was not thought that the interaction would be clinically significant.

1. Jerling M, *et al.* Studies to investigate the pharmacokinetic interactions between ranolazine and ketoconazole, diltiazem, or simvastatin during combined administration in healthy subjects. *J Clin Pharmacol* 2005; **45:** 422–33.

Pharmacokinetics

Simvastatin is absorbed from the gastrointestinal tract and must be hydrolysed to its active β-hydroxyacid form. Other active metabolites have been detected and a number of inactive metabolites are also formed. Simvastatin is a substrate for the cytochrome P450 isoenzyme CYP3A4 and undergoes extensive first-pass metabolism in the liver, its primary site of action. Less than 5% of the oral dose has been reported to reach the circulation as active metabolites. Both simvastatin and its β-hydroxyacid metabolite are about 95% bound to plasma proteins. Simvastatin is mainly excreted in the faeces via the bile as metabolites. About 10 to 15% is recovered in the urine, mainly in inactive forms. The half-life of the active β-hydroxyacid metabolite is 1.9 hours.

Genetic variation. The pharmacokinetics of statins are influenced not only by metabolising enzymes but also by their affinity for organ-specific transporter proteins responsible for their uptake and efflux from cells, in particular in the intestine and liver.[1,2] Statins differ not only in their affinity for cytochrome P450 isoenzymes, but also in their affinity for transporter proteins such as organic anion transporting polypeptides (OATPs) and P-glycoprotein (multi-drug resistance 1; MDR1). Both metabolising enzymes and transporter proteins may be subject to ethnic and genetic variation, and it has been suggested that this may explain some of the variability in the efficacy and the risk of adverse effects in different populations.

2. Tirona RG. Ethnic differences in statin disposition. *Clin Pharmacol Ther* 2005; **78:** 311–16.

Uses and Administration

Simvastatin is a lipid regulating drug; it is a competitive inhibitor of 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase), the rate-determining enzyme for cholesterol synthesis. Inhibition of HMG-CoA reductase leads to reduced cholesterol synthesis in the liver and lower intracellular cholesterol concentrations; this stimulates an increase in low-density-lipoprotein (LDL)-cholesterol receptors on hepatocyte membranes, thereby increasing the clearance of LDL from the circulation. HMG-CoA reductase inhibitors (also called statins) reduce total cholesterol, LDL-cholesterol, and very-low-density lipoprotein (VLDL)-cholesterol concentrations in plasma. They also tend to reduce triglycerides and to increase high-density lipoprotein (HDL)-cholesterol concentrations.

Simvastatin is used to reduce LDL-cholesterol, apolipoprotein B, and triglycerides, and to increase HDL-cholesterol in the treatment of hyperlipidaemias (p.1169). It is used in hypercholesterolaemias, combined (mixed) hyperlipidaemia (type IIa or IIb hyperlipoproteinaemias), hypertriglyceridaemia (type IV), and primary dysbetalipoproteinaemia (type III), and may also be used as adjunct therapy in patients with homozygous familial hypercholesterolaemia who have some LDL-receptor function. Simvastatin is also used for cardiovascular risk reduction (p.1164).

Simvastatin is given orally and doses range from 5 to 80 mg daily. For the treatment of **hyperlipidaemias**, the usual initial dose is 10 to 20 mg in the evening; an initial dose of 40 mg may be used in patients who require a large reduction in cholesterol or who are at high cardiovascular risk. The dose may be adjusted at intervals of not less than 4 weeks up to a maximum of 80 mg once daily in the evening. Patients with homozygous familial hypercholesterolaemia may be treated with 40 mg once daily in the evening, or 80 mg daily in 3 divided doses of 20 mg, 20 mg, and an evening dose of 40 mg.

For **cardiovascular risk reduction** in high-risk patients, such as those with atherosclerotic cardiovascular disease or diabetes mellitus, the usual dose is 20 to 40 mg once daily. Patients who are at moderate risk may be given a dose of 10 mg once daily.

The dose of simvastatin should be reduced in patients at risk of myopathy, including patients with severe renal impairment (see below). For patients taking drugs that interact with simvastatin, dose reduction is also advised, as follows:

- patients taking *ciclosporin* or *danazol*, initial dose 5 mg once daily and maximum dose 10 mg once daily
- patients taking *gemfibrozil* or other *fibrates*, or *nicotinic acid*, maximum dose 10 mg once daily
- patients taking *amiodarone* or *verapamil*, maximum dose 20 mg once daily
- patients taking *diltiazem*, maximum dose 40 mg once daily

For the use of simvastatin in children, see below.

Action. The effects of statins on *plasma lipids* are well established.[1-4] Their primary action is to inhibit 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, the rate-limiting enzyme in cholesterol synthesis. Cholesterol is an important precursor for synthesis of a number of substances by the liver, and reduced intracellular concentrations stimulate an increase in the expression of low-density lipoprotein (LDL) receptors in the liver. This leads to increased uptake of LDL-cholesterol from the plasma into liver cells, with a subsequent reduction in both LDL and total cholesterol. Triglycerides are also decreased, due to decreased synthesis of very-low-density lipoprotein (VLDL), while high-density lipoprotein (HDL)-cholesterol is either modestly increased or unchanged, leading to an improvement in the LDL:HDL ratio. An effect on LDL-cholesterol may also occur independent of the effect on receptors; some statins have been shown to lower LDL-cholesterol in patients with homozygous familial hypercholesterolaemia, despite their lack of functional LDL receptors. Statins generally provide a greater reduction in LDL-cholesterol than other classes of lipid regulating drugs, but where large reductions are required combination therapy may be necessary. Statins have been used with bile-acid binding resins and with ezetimibe; they have also been given with fibrates or nicotinic acid, although the increased risk of adverse effects needs to be considered. Cholesterol synthesis in the liver peaks during the early morning (midnight to 3 a.m.) and there is some evidence that statins with short half-lives, such as simvastatin, should be taken in the evening.[5]

Statins have a number of additional (pleiotropic) actions,[1-4,6,7] although whether these contribute to their cardiovascular effects is controversial.[8] In *atherosclerosis* they have beneficial effects on endothelial function, which may be partly independent of their effect on lipids, and also appear to stabilise atherosclerotic plaques. A number of studies[9,10] have also shown that statins reduce concentrations of C-reactive protein (CRP), a marker of inflammation that is raised in atherosclerosis, and there is some evidence that the reduction in CRP is independently associated with a reduction in cardiovascular events[11] and regression of atherosclerotic lesions,[12] although results have been mixed in a related condition, calcific aortic stenosis.[13] Statins have a number of actions that may be beneficial in *heart failure*,[14] but detrimental effects are also possible and their role specifically for heart failure is unclear.[15] Evidence from cohort studies[16-18] suggests statins may improve mortality in heart failure, and analyses of cardiovascular risk reduction studies[19,20] also suggest benefit. However, a randomised study[21] of rosuvastatin in patients with heart failure of ischaemic origin failed to show an effect on mortality, although there were fewer hospitalisations in patients given the active drug. Statins may also have *antihypertensive*[22] and *antiarrhythmic* effects; they reduce the incidence of atrial fibrillation,[23] and have also been associated with a reduced risk of ventricular arrhythmias,[24,25] although this requires confirmation. Beneficial effects have also been reported on some measures of *haemostasis*,[26] and a reduced incidence of venous thromboembolism has been noted in some studies.[27]

Statins also appear to have anti-inflammatory and immunomodulatory actions and these may contribute to their beneficial effects. There is evidence from epidemiological studies that they reduce the risk of bacterial infections, although this has been attributed to a 'healthy-user' effect,[28,29] and they may also reduce mortality in patients with sepsis.[29] Benefit has also been reported in *rheumatoid arthritis* and other inflammatory arthropathies.[30-33] In patients with *organ transplantation*, both cardiovascular and immunomodulatory actions may be of benefit (see below). However, the use of statins in these diseases remains to be confirmed.

For discussion of the use of statins in other non-cardiovascular disorders, including dementia, kidney disorders, malignant neoplasms, and osteoporosis, see below.

Administration in children. The management of hyperlipidaemias in children and adolescents is controversial and is usually reserved for those with familial hyperlipidaemias who have a high risk of premature cardiovascular disease. Dietary measures and bile-acid binding resins have traditionally been first-line therapy in children, but may be poorly tolerated or inadequate. Studies with statins in children aged 8 to 18 years with familial hypercholesterolaemia have shown[1,2] that they effectively lower total cholesterol and low-density lipoprotein (LDL)-cholesterol and they are now increasingly preferred where drug therapy is indicated.[3,4] However, there have been concerns about the potential adverse effects of statins on growth and sexual development, since these patients require life-long treatment. Although this does not appear to be a problem, most studies have been relatively short-term, and longer follow-up is needed to confirm statin safety.[3,4] Preliminary evidence suggests that statins may also be effective in children with hyperlipidaemia related to nephrotic syndrome[5] or organ transplantation.[3,4]

US licensed product information for simvastatin allows its use in children aged 10 to 17 years with familial heterozygous hypercholesterolaemia in an initial oral dose of 10 mg at night, increased at intervals of 4 weeks as required to a maximum dose of 40 mg daily. A placebo-controlled study[6] in 173 such children found that simvastatin given orally in a dose of up to 40 mg daily for 48 weeks effectively reduced LDL-cholesterol and was well tolerated, with no effect on growth or sexual development.

The *BNFC* recommends the following doses for children with hyperlipidaemia:

- age 5 to 10 years: initial dose 5 mg at night, increased if necessary at intervals of at least 4 weeks to a maximum dose of 20 mg at night
- age 10 to 18 years: initial dose 10 mg at night, increased if necessary at intervals of at least 4 weeks to a maximum dose of 40 mg at night

Doses should be reduced in children who are taking drugs that may interact with simvastatin (see Interactions, above).

Administration in renal impairment. Statins appear to be safe and effective in patients with dyslipidaemia and renal impairment, and there is some evidence that they may have beneficial effects on renal function (see Kidney Disorders, below). However, patients with severe renal impairment may be at increased risk of developing myopathy or rhabdomyolysis and lower doses may be appropriate in such patients. Dose reduction may also be needed for statins that are excreted by the kidneys.

Simvastatin does not undergo significant renal excretion and no dose modification is required in patients with mild or moderate renal impairment. However, in patients with severe renal impairment the recommended initial dose is 5 mg once daily and doses above 10 mg once daily should be used with caution.

Cardiovascular risk reduction. Lipid regulating drugs have an important role in cardiovascular risk reduction (p.1164), and statins are widely used for both primary and secondary prevention. The rationale for their use has been the established link between hypercholesterolaemia and atherosclerosis, but they may have additional actions that contribute to their effect (see Action, above). The efficacy of statins in reducing cardiovascular events has been established in a wide range of patient groups and is generally believed to be a class effect, although outcome studies have not been performed for all the statins in every case.

In patients with established ischaemic heart disease, statins reduce the risk of further cardiovascular events, and also reduce both cardiovascular and overall mortality.[1] Statins shown to be effective for secondary prevention in large, randomised studies include simvastatin,[2] pravastatin,[3,4] and fluvastatin.[5,6] For primary prevention in patients at high risk but without prior cardiovascular events, statins similarly reduce the risk of cardiovascular events, although an effect on mortality has not been shown.[7] Benefit has been established in studies using pravastatin,[8,9] lovastatin,[10] simvastatin,[11] and atorvastatin;[12] the negative results of the ALLHAT-LLT study[13] with pravastatin were attributed to the substantial use of statins in the control group.

Although the main benefit of statins is to reduce mortality and major coronary events, there may also be a reduction in the incidence[14-17] and severity[18] of stroke (although there may be an increase in haemorrhagic stroke[16]), and the incidence of peripheral vascular disease;[19] some studies have also shown a reduction in coronary[19,20] and peripheral[19,21] ischaemic symptoms. Observational studies have suggested that statins may also reduce postoperative mortality in patients with high cardiovascular risk undergoing surgery, although this remains to be confirmed,[22] and there is some evidence that statins may reduce the risk of myocardial damage in patients undergoing percutaneous interventions,[23] although they have not been shown to affect restenosis.[24,25] Early use of statins may also have a role in patients with acute coronary syndromes; one meta-analysis[26] found no evidence of benefit at 1 or 4 months after the initial event, but another[27] reported a reduction in cardiovascular events with statin therapy for 6 months or longer, and some studies[28] have suggested earlier benefit with high-dose regimens.

The main effect of statins appears to relate to their action on lipid concentrations, and increased benefit has been reported[29] with the use of intensive lipid lowering regimens, including a reduction in mortality in patients with acute coronary syndromes.[30] However, studies have shown that statins improve outcomes in patients with both raised[8,26] and average[3,4,10,12] cholesterol concentrations, and meta-analyses[31,32] have concluded that the absolute benefit of statin treatment depends on both the initial cardiovascular risk and the degree of cholesterol reduction achieved. Most benefit has been reported in patients at the highest risk; subgroups in whom particular benefit has been reported include patients with metabolic syndrome compared with those without,[33] and diabetics compared with non-diabetics,[34] although a study[35] with atorvastatin in diabetics undergoing haemodialysis found no benefit. Early studies included mainly middle-aged men, but later studies[11] and meta-analyses[9,31] have confirmed that statins also improve outcomes in women and in the elderly. Observational studies[36,37] have confirmed that these benefits extend to the clinical situation.

Statins differ in potency,[38-40] but evidence that they differ in efficacy for cardiovascular risk reduction when given at comparable lipid-lowering doses is limited.[41] Patients who do not achieve target lipid concentrations or who experience adverse effects with one statin may find an alternative statin effective and tolerable, although recurrence of myalgia is not uncommon.[42]

Dementia. There is conflicting evidence on the link between statin use and dementia. Epidemiological studies have reported[1,2] that the prevalence of dementia (p.362) is lower in patients taking statins, although it has been suggested that this may be due to bias in prescribing.[3] (Prevalence may also be reduced in patients taking fibrates.[2]) Some longitudinal studies have reported[4,5] that statins also reduce the incidence of dementia, but others have found no evidence of a reduction in risk,[6-8] and it has been suggested[6] that inappropriate analysis may explain the positive results. Prospective, randomised trials are therefore needed to determine their role, if any, in the prevention of dementia.[3]

There is also some evidence that statins[9-11] and other lipid regulating drugs[11] may reduce the progression of cognitive decline in patients with dementia, although the effect has generally been small. However, negative effects on mental function have been reported with some statins (see under Adverse Effects, above) and their use in the management of dementia is not established.

Kidney disorders. Although proteinuria has been reported with statins (see Effects on the Kidney under Adverse Effects, above) there is also some evidence that statins modestly reduce the progression of proteinuria and loss of renal function.[1-4] However, further studies are required to confirm these effects.

Malignant neoplasms. Although studies in *animals* suggest[1] that statins could be carcinogenic, evidence for a detrimental effect in humans is limited, and some studies have suggested that statins may be protective. Low plasma-cholesterol concentrations have been associated with cancer, and an increased incidence of cancer was reported in a randomised study of pravastatin for cardiovascular risk reduction in elderly patients,[2] although this was attributed to chance. Conversely, several observational studies have reported[3-7] that statins reduce the incidence of cancer, although the effect has generally been small. A number of meta-analyses have been performed and have generally found no association between the use of statins and the incidence of cancer. Analyses including only randomised studies[8,9] have found no significant effect on overall risk, although follow-up may not have been long enough in most studies to be conclusive; there is also little evidence of a protective effect for specific cancers.[10-12] However, another large cohort study[13] in elderly patients found no evidence that statins either increased or reduced the risk, and longer follow-up in a randomised study[14] using simvastatin also found no significant effect.

Organ and tissue transplantation. Cardiovascular disease is an important cause of morbidity and mortality after organ transplantation and statins are useful for cardiovascular risk reduction in these patients. They may also have immunomodulatory effects and have reduced the risk of rejection in some studies.[1] A meta-analysis of patients who had undergone heart transplantation (p.1812) considered that treatment with a statin within 3 months of transplantation reduced allograft rejection with haemodynamic compromise and reduced 1-year mortality;[2] it was calculated that one life was saved for every 8.5 treated heart transplant patients. There is some tentative evidence that statin therapy may also reduce acute rejection and the development of obliterative bronchiolitis in patients who have undergone lung transplantation (p.1815),[3] although prospective controlled studies are lacking.

Osteoporosis. Statins appear to have effects on bone metabolism and preliminary studies[1,2] have suggested that some statins may increase bone mineral density. However, the clinical relevance of any effect is unclear.[3] Several case-control studies[4-6] have also suggested that use of statins may protect against fractures, but another case-control study[7] and an observational study[8] failed to support such an association. A review[9] of 4 further observational studies found that the risk of fracture was lower in women taking statins, but analysis of data from randomised studies of statins for cardiovascular disease[10,11] failed to confirm any effect, and controlled studies are needed[3,12] to confirm the role of statins in the management of osteoporosis (p.1084).

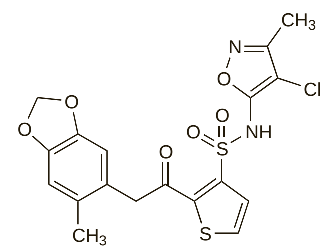
Sitaxentan Sodium *(rINNM)*

Natrii Sitaxentanum; Sitaxentán sódico; Sitaxentan Sodique; Sitaxsentan Sodium; TBC-11251 (sitaxentan or sitaxentan sodium). *N*-(4-Chloro-3-methyl-5-isoxazolyl)-2-{[4,5-(methylenedioxy)-*o*-tolyl]acetyl}-3-thiophenesulfonamide sodium.

Натрий Ситаксентан

$C_{18}H_{14}ClN_2NaO_6S_2 = 476.9.$

CAS — 184036-34-8 (sitaxentan); 210421-74-2 (sitaxentan sodium).



(sitaxentan)

Adverse Effects

As for Bosentan, p.1235. Increases in INR and prolongation of the prothrombin time have also been reported.

Sitaxentan is teratogenic in *rats.*

Precautions

As for Bosentan, p.1235. Sitaxentan is contra-indicated in patients with mild to severe hepatic impairment (Child-Pugh Class A to C).

Although, like bosentan, sitaxentan is teratogenic in *rats* and similar precautions apply, its effects on combined oral contraceptives may differ (see Interactions below).

Interactions

Sitaxentan is both an inhibitor of and a substrate for the cytochrome P450 isoenzyme CYP2C9 and interactions may therefore occur with other drugs that are either metabolised by, or inhibit, this isoenzyme. Plasma concentrations of oral anticoagulants such as warfarin may be increased.

Use with ciclosporin is contra-indicated as plasma concentrations of sitaxentan are greatly increased (see below).

Sitaxentan has increased exposure to ethinylestradiol and norethisterone in those taking oral contraceptives and may possibly increase the associated risk of thromboembolism.

Ciclosporin. Licensed product information for sitaxentan states that its concentration was increased sixfold when given with ciclosporin 3.5 mg/kg twice daily. Although the mechanism of action is unknown it has been postulated that sitaxentan sodium is a substrate for the organic anion transporting polypeptide (OATP) transporter protein and should therefore be used with caution with other, more potent, OATP inhibitors.

Pharmacokinetics

Sitaxentan sodium is absorbed after oral doses with peak plasma concentrations being achieved within 1 to 4 hours. Its absolute bioavailability is 70 to 100%. A high-fat meal delays the rate of absorption but does not affect the extent. Sitaxentan is more than 99% bound to plasma proteins, mainly albumin.

Sitaxentan is highly metabolised by the cytochrome P450 isoenzymes CYP2C9 and CYP3A4 to weakly active metabolites. About 50 to 60% of a dose is excreted in the urine with the remainder appearing in the faeces; less than 1% is excreted unchanged. Sitaxentan has a terminal elimination half-life of 10 hours and steady state is achieved within about 6 days.

Uses and Administration

Sitaxentan is an endothelin receptor antagonist (p.1155) with similar actions to bosentan (p.1235), although it has a higher selectivity for the endothelin ET_A-receptor. It is used in the management of pulmonary hypertension functional class III (p.1179). It is also being investigated in the management of heart failure.

In the treatment of pulmonary hypertension sitaxentan sodium is given orally in a dose of 100 mg once daily. Alternate therapy should be considered if there is no response after 12 weeks but a further 12 weeks of treatment may be tried.

(anhydrous sodium nitroprusside)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Sodium Nitroprusside). Reddish-brown crystals or powder. Freely soluble in water; slightly soluble in alcohol. Protect from light.

USP 31 (Sodium Nitroprusside). Reddish-brown, practically odourless crystals or powder. Freely soluble in water; slightly soluble in alcohol; very slightly soluble in chloroform; insoluble in benzene. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Incompatibility. Sodium nitroprusside has been reported to be visually incompatible with cisatracurium besilate[1] and with levofloxacin[2] during simulated Y-site administration.

1. Trissel LA, *et al.* Compatibility of cisatracurium besylate with selected drugs during simulated Y-site administration. *Am J Health-Syst Pharm* 1997; **54:** 1735–41.
2. Saltsman CL, *et al.* Compatibility of levofloxacin with 34 medications during simulated Y-site administration. *Am J Health-Syst Pharm* 1999; **56:** 1458–9.

Stability in solution. Solutions of sodium nitroprusside decompose when exposed to light and must be protected during infusion by wrapping the container with aluminium foil or some other light-proof material. Nitroprusside will react with minute quantities of organic and inorganic substances forming highly coloured products. If this occurs the solution should be discarded. Solutions should not be used more than 24 hours after preparation.

The instability of sodium nitroprusside solutions has been the subject of considerable investigation. Although stated to be more stable in acid than in alkaline solution,[1] a later study[2] found that whereas the initial light-induced darkening of a 1% solution was independent of pH, further degradation leading to the development of a blue precipitate required an acid pH. If protected from light by wrapping in aluminium foil, sodium nitroprusside 50 or 100 micrograms/mL was found to be stable in 5% glucose, lactated Ringer's, and normal saline solutions for 48 hours.[3] In clinical practice the infusion container should be opaque or protected with foil, but an amber giving set may be used, to allow visual monitoring.[4,5]

Various substances have been reported to increase the stability of nitroprusside solutions, including dimethyl sulfoxide,[6] glycerol,[1] sodium citrate,[1] and other salts with anionic chelating potential such as sodium acetate or phosphate.[1] In contrast sodium bisulfite and the hydroxybenzoates are reported to reduce stability.[1]

Adverse Effects

Sodium nitroprusside rapidly reduces blood pressure and is converted in the body to cyanide and then thiocyanate. Its adverse effects can be attributed mainly to excessive hypotension and excessive cyanide accumulation; thiocyanate toxicity may also occur, especially in patients with renal impairment. Intravenous infusion of sodium nitroprusside may produce nausea and vomiting, apprehension, headache, dizziness, restlessness, perspiration, palpitations, retrosternal discomfort, abdominal pain, and muscle twitching, but these effects may be reduced by slowing the infusion rate.

An excessive amount of cyanide in plasma (more than 80 nanograms/mL), because of overdosage or depletion of endogenous thiosulfate (which converts cyanide to thiocyanate *in vivo*), may result in tachycardia, sweating, hyperventilation, arrhythmias, and profound metabolic acidosis. Metabolic acidosis may be the first sign of cyanide toxicity. Methaemoglobinaemia may also occur.

Adverse effects attributed to thiocyanate include tinnitus, miosis, and hyperreflexia; confusion, hallucinations, and convulsions have also been reported.

Other adverse effects include thrombocytopenia and phlebitis.

Effects on the blood. *THROMBOCYTOPENIA.* Platelet counts decreased in 7 of 8 patients with heart failure 1 to 6 hours after intravenous infusion of nitroprusside was started.[1] The counts began to return to normal 24 hours after the infusion was stopped.

1. Mehta P, *et al.* Nitroprusside lowers platelet count. *N Engl J Med* 1978; **299:** 1134.

Effects on the gastrointestinal tract. Five out of 38 patients who were given sodium nitroprusside intravenously for controlled hypotension during surgery developed symptoms of adynamic ileus postoperatively.[1] The symptoms could have been secondary to intestinal ischaemia due to diminished mesenteric arterial blood flow. However, other explanations have been proposed including sympathetic stimulation[2,3] or the concomitant use of opioid analgesics.[4]

1. Chen JW, *et al.* Adynamic ileus following induced hypotension. *JAMA* 1985; **253:** 633.
2. Gelman S. Adynamic ileus following induced hypotension. *JAMA* 1985; **254:** 1721.

4. Lemmo J, Karnes J. Adynamic ileus following induced hypotension. *JAMA* 1985; **254:** 1721.

Effects on intracranial pressure. A significant increase in intracranial pressure while the mean blood pressure was 80 or 90% of initial values was reported[1] in 14 normocapnic patients given an infusion of sodium nitroprusside to produce controlled hypotension prior to neurosurgery; values reverted towards normal at mean blood pressures of 70% of controls. A similar but insignificant trend occurred in 5 hypocapnic patients. In another report[2] a rise in intracranial pressure was noted after the use of nitroprusside in a patient with Reye's syndrome.

1. Turner JM, *et al.* Intracranial pressure changes in neurosurgical patients during hypotension induced with sodium nitroprusside or trimetaphan. *Br J Anaesth* 1977; **49:** 419–24.
2. Griswold WR, *et al.* Nitroprusside-induced intracranial hypertension. *JAMA* 1981; **246:** 2679–80.

Phlebitis. Acute transient phlebitis has occurred after infusion of sodium nitroprusside.[1]

1. Miller R, Stark DCC. Acute phlebitis from nitroprusside. *Anesthesiology* 1978; **49:** 372.

Treatment of Adverse Effects

Adverse effects due to excessive hypotension may be treated by slowing or stopping the infusion.

For details of the treatment of cyanide poisoning see Hydrocyanic Acid, p.2045. Thiocyanate can be removed by dialysis.

Precautions

Sodium nitroprusside should not be used in the presence of compensatory hypertension (for example, in arteriovenous shunts or coarctation of the aorta). It should be used with caution, if at all, in patients with hepatic impairment, and in patients with low plasma-cobalamin concentrations or Leber's optic atrophy. It should also be used with caution in patients with impaired renal or pulmonary function and with particular caution in patients with impaired cerebrovascular circulation. Thiocyanate, a metabolite of sodium nitroprusside, inhibits iodine binding and uptake and sodium nitroprusside should be used with caution in patients with hypothyroidism. The blood-thiocyanate concentration should be monitored if treatment continues for more than 3 days and should not exceed 100 micrograms/mL although toxicity may be apparent at lower thiocyanate concentrations. Thiocyanate concentrations do not reflect cyanide toxicity and cyanide concentrations should also be monitored; the blood concentration of cyanide should not exceed 1 microgram/mL and the serum concentration should not exceed 80 nanograms/mL. The acid–base balance should also be monitored. Care should be taken to ensure that extravasation does not occur. Sodium nitroprusside should not be withdrawn abruptly due to the risk of rebound effects.

Aortic stenosis. Vasodilators such as sodium nitroprusside are usually contra-indicated in conditions where cardiac outflow is obstructed since cardiac output cannot increase to compensate for the fall in blood pressure. However, a study[1] in patients with aortic stenosis and severe left ventricular dysfunction found that sodium nitroprusside was well tolerated and that it rapidly and markedly improved cardiac function.

1. Khot UN, *et al.* Nitroprusside in critically ill patients with left ventricular dysfunction and aortic stenosis. *N Engl J Med* 2003; **348:** 1756–63.

Pregnancy. Although there are concerns that nitroprusside given to the mother might produce cyanide toxicity in the fetus, a systematic review[1] was unable to find sufficient evidence to determine the risk.

1. Sass N, *et al.* Does sodium nitroprusside kill babies? A systematic review. *Sao Paulo Med J* 2007; **125:** 108–11.

Tachyphylaxis. Tachyphylaxis to sodium nitroprusside was associated with high plasma concentrations of cyanide without metabolic acidosis in 3 patients undergoing hypotensive anaesthesia.[1]

1. Cottrell JE, *et al.* Nitroprusside tachyphylaxis without acidosis. *Anesthesiology* 1978; **49:** 141–2.

Withdrawal. Rebound haemodynamic changes, including hypertension and increased heart rate, occurred 10 to 30 minutes after stopping intravenous sodium nitroprusside infusion in 20 patients with heart failure.[1] The changes generally resolved spontaneously within 1 to 3 hours and produced only minimal exacerbation of symptoms in most patients, although 3 developed pulmonary oedema 20 to 30 minutes after stopping the infusion, needing restarting of nitroprusside in 2 cases. A study[2] investigating a possible mechanism for this effect found that plasma-renin concentrations were increased during infusion of nitroprusside and remained elevated for 30 minutes after the infusion was stopped. It was suggested that this persistence of elevated plasma-renin concentrations after clearance of short-lived nitroprusside may be responsible for the rebound effects.

1. Packer M, *et al.* Rebound hemodynamic events after the abrupt withdrawal of nitroprusside in patients with severe chronic heart failure. *N Engl J Med* 1979; **301:** 1193–7.
2. Cottrell JE, *et al.* Rebound hypertension after sodium nitroprusside-induced hypotension. *Clin Pharmacol Ther* 1980; **27:** 32–6.

Interactions

Enhanced hypotension should be expected if sodium nitroprusside is used with other antihypertensives or drugs that produce hypotension.

Alteplase. Sodium nitroprusside infusion prolonged the fibrinolytic activity of alteplase when given to *animals*; use of nitrovasodilators with alteplase may be responsible for the enhanced bleeding tendency seen in some patients on thrombolytic therapy.[1]

1. Korbut R, *et al.* Prolongation of fibrinolytic activity of tissue plasminogen activator by nitrovasodilators. *Lancet* 1990; **335:** 669.

Pharmacokinetics

Sodium nitroprusside is rapidly metabolised to cyanide in erythrocytes and smooth muscle and, *in vivo*, this is followed by the release of nitric oxide, the active metabolite. Cyanide is further metabolised in the liver to thiocyanate, which is slowly excreted in the urine; this metabolism is mediated by the enzyme rhodanase and requires the presence of thiosulfate. The plasma half-life of thiocyanate is reported to be about 3 days, but may be much longer in patients with renal impairment.

◊ Reviews.

1. Schulz V. Clinical pharmacokinetics of nitroprusside, cyanide, thiosulphate and thiocyanate. *Clin Pharmacokinet* 1984; **9:** 239–51.

Uses and Administration

Sodium nitroprusside is a short-acting hypotensive drug with a duration of action of 1 to 10 minutes. It produces peripheral vasodilatation and reduces peripheral resistance by a direct action on both veins and arterioles. It has been termed a nitrovasodilator because it releases nitric oxide *in vivo*. Its effects appear within a few seconds of intravenous infusion. Sodium nitroprusside is used in the treatment of hypertensive crises (p.1171) and to produce controlled hypotension during general anaesthesia. It has also been used to reduce preload and afterload in severe heart failure (p.1165) including that associated with myocardial infarction (p.1175).

It is given by continuous intravenous infusion of a solution containing 50 to 200 micrograms/mL. A controlled infusion device must be used. The solution should be prepared immediately before use by dissolving sodium nitroprusside in glucose 5% and then diluting with glucose 5%; the solution must be protected from light during infusion. Blood pressure should be monitored closely and care should be taken to prevent extravasation. In general, treatment should not continue for more than 72 hours. If required for several days concentrations of cyanide should be monitored; the blood concentration should not exceed 1 microgram/mL and the serum concentration should not exceed 80 nanograms/mL. Thiocyanate concentrations in blood should also be measured if infusion continues for more than 72 hours and should not exceed 100 micrograms/mL. Since rebound hypertension has been reported when sodium nitroprusside is withdrawn, the infusion should be tailed off gradually over 10 to 30 minutes.

For **hypertensive crises** in patients not receiving antihypertensive drugs, an initial dose of 0.3 to 1.5 micrograms/kg per minute may be given, increasing gradually under close supervision until the desired reduction in blood pressure is achieved. The average dose required to maintain the blood pressure 30 to 40% below the pretreatment diastolic blood pressure is 3 micrograms/kg per minute and the usual dose range is 0.5 to 6 micrograms/kg per minute. Lower doses should be used in patients already receiving other antihypertensives. The maximum recommended rate is about 8 micrograms/kg per minute in the UK, and 10 micrograms/kg per minute in the USA; infusions at these rates should be used for no longer than 10 minutes and should be stopped after 10 minutes if there is no response. If there is a response, sodium nitroprusside should ideally be given for only a few hours to avoid the risk of cyanide toxicity. Treatment with an oral antihypertensive should be introduced as soon as possible.

For the **induction of hypotension** during anaesthesia a maximum dose of 1.5 micrograms/kg per minute is recommended.

In **heart failure** an initial dose of 10 to 15 micrograms/minute has been used, increasing by 10 to 15 micrograms/minute every 5 to 10 minutes according to response. The usual dosage range is 10 to 200 micrograms/minute and the dose should not exceed 280 micrograms/minute (or 4 micrograms/kg per minute).

Sodium nitroprusside has also been used as a reagent for detecting ketones in urine.

Administration in children. Although experience is more limited than with adults, sodium nitroprusside has been successfully used in infants and children. Continuous infusion of nitroprusside at a rate of 2 to 4 micrograms/kg per minute for 28 days was reported[1] in an 11-year-old child with refractory hypertension, without any signs of thiocyanate toxicity. In a series of 58 neonates with cardiovascular disorders or respiratory distress syndrome,[2] sodium nitroprusside was given in a usual initial dose of 250 to 500 nanograms/kg per minute, and the rate was then repeatedly doubled at intervals of 15 to 20 minutes until the desired effect was achieved, adverse effects supervened, or it was judged ineffective. The maximum rate did not exceed 6 micrograms/kg per minute. Infusion of sodium nitroprusside in doses of 0.5 to 8 micrograms/kg per minute to produce controlled reduction of blood pressure has also been reported[3] in 28 children with hypertensive crises; 16 had also received labetalol.[3]

Sotalol Hydrochloride

(BANM, USAN, rINNM) ⊗

Hidrocloruro de sotalol; MJ-1999; Sotalol, chlorhydrate de; Sotalol Hidroklorür; *d,l*-Sotalol Hydrochloride; Sotalol-hydrochlorid; Sotalolhydroklorid; Sotaloli hydrochloridum; Sotalolihydrokloridi; Sotalolio hidrochloridas; Szotalol-hidroklorid. 4′-(1-Hydroxy-2-isopropylaminoethyl)methanesulphonanilide hydrochloride.

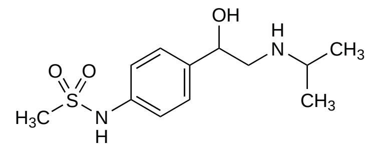
Соталола Гидрохлорид

$C_{12}H_{20}N_2O_3S,HCl$ = 308.8.

CAS — 3930-20-9 (sotalol); 959-24-0 (sotalol hydrochloride).

ATC — C07AA07.

ATC Vet — QC07AA07.



(sotalol)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Sotalol Hydrochloride). A white or almost white powder. Freely soluble in water; soluble in alcohol; practically insoluble in dichloromethane. A 5% solution in water has a pH of 4.0 to 5.0. Protect from light.

USP 31 (Sotalol Hydrochloride). A white to off-white powder. Freely soluble in water; soluble in alcohol; very slightly soluble in chloroform.

Stability. Suspensions of sotalol hydrochloride 5 mg/mL made using either commercially available or extemporaneously prepared vehicles were found[1] to be stable for up to 3 months when stored at 4° or 25°. Prolonged storage at 25° was not recommended, however, because of the risk of microbial growth.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Torsade de pointes has been reported in patients given sotalol, usually due to prolongation of the QT interval. The QT interval should be monitored: extreme caution is required if the QT interval exceeds 500 milliseconds and sotalol should be stopped or the dose reduced if the QT interval exceeds 550 milliseconds. As hypokalaemia or hypomagnesaemia may predispose patients to arrhythmias, serum-electrolyte concentrations should be monitored before and during treatment with sotalol.

Sotalol should be used with caution in renal impairment (see under Uses and Administration, below) and is contra-indicated in patients whose creatinine clearance is less than 10 mL/minute.

Breast feeding. Sotalol is distributed into breast milk and milk to serum ratios have been reported[1-3] to range from 2.2 to 8.8. In one report[2] it was calculated that a breast-fed infant might ingest 20 to 23% of a maternal dose; however, no bradycardia was noted in the infant in this study. The American Academy of Pediatrics states[4] that there have been no reports of clinical effects in breast-fed infants whose mothers were receiving sotalol and that therefore it may be considered to be usually compatible with breast feeding.

Interactions

There is an increased risk of precipitating ventricular arrhythmias if sotalol is given with other drugs that prolong the QT interval, and use with the following drugs is therefore not recommended: class Ia antiarrhythmics (including disopyramide, procainamide, and quinidine), amiodarone, phenothiazine antipsychotics, tricyclic antidepressants, certain antihistamines (astemizole or terfenadine), cisapride, erythromycin, halofantrine, pentamidine, quinolones, sultopride, and vincamine. Caution is required if sotalol is given with drugs that cause electrolyte disturbances, such as diuretics, since this also increases the risk of arrhythmias.

Other interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics

Sotalol is almost completely absorbed from the gastrointestinal tract and peak plasma concentrations are obtained about 2 to 4 hours after a dose. The plasma elimination half-life is about 10 to 20 hours. Sotalol has low lipid solubility. Very little is metabolised and it is excreted unchanged in the urine. Binding to plasma proteins is reported to be low. It crosses the placenta and is distributed into breast milk; concentrations in milk may be higher than those in maternal serum (see Breast Feeding, above). Only small amounts are reported to cross the blood-brain barrier and enter the CSF. Sotalol is removed by dialysis.

Pregnancy. The systemic clearance of sotalol in 6 healthy women after an intravenous dose was significantly higher during pregnancy than in the postnatal period, and the mean elimination half-life was shorter (6.6 versus 9.3 hours), although the latter difference was not significant.[1] Clearance after an oral dose was also higher during pregnancy than afterwards, but half-lives (10.9 versus 10.3 hours) and mean bioavailability were similar. The changes were probably due to alterations in renal function in the antenatal period.

In a study[2] of transplacental therapy, sotalol was found to cross the placenta easily and completely, with steady-state plasma concentrations similar in mother and fetus. Sotalol accumulated in the amniotic fluid but not in the fetus; it was not associated with fetal growth restriction.

Uses and Administration

Sotalol is a non-cardioselective beta blocker (p.1225). It is reported to lack both intrinsic sympathomimetic and membrane-stabilising properties. In addition to the class II antiarrhythmic activity of beta blockers, sotalol lengthens the duration of the action potential resulting in class III antiarrhythmic activity. For a classification and explanation of antiarrhythmic activity, see p.1153.

Sotalol is used in the management of ventricular and supraventricular arrhythmias (p.1160). Because of its proarrhythmic effects, it is usually reserved for severe or life-threatening arrhythmias, and it should not be used in patients with asymptomatic ventricular arrhythmias. Although it was formerly used for its beta-blocking effects in the management of angina pectoris, hypertension, and myocardial infarction, it is no longer recommended for these indications because of the risk of precipitating arrhythmias.

Sotalol is given as the hydrochloride. Treatment should be started in hospital with suitable monitoring facilities. The QT interval should be assessed before the start of treatment and whenever the dosage is adjusted (see Precautions above); plasma-electrolyte concentrations and renal function should also be monitored. The dose should be reduced in patients with renal impairment (see below).

The usual initial oral dose of sotalol hydrochloride is 80 mg daily, as a single dose or in two divided doses. The dosage is then individualised according to response, and doses are increased gradually allowing 2 or 3 days between increments. US licensed product information recommends a higher initial dose of 80 mg twice daily and this should not be increased for at least 3 days. Most patients respond to doses of 160 to 320 mg daily (usually given in two divided doses). Some patients with ventricular arrhythmias may require doses as high as 640 mg daily.

Sotalol may be given intravenously to control acute arrhythmias, to substitute for oral therapy, and for programmed electrical stimulation. To control acute arrhythmias, sotalol hydrochloride is given in a dose of 20 to 120 mg (500 to 1500 micrograms/kg) intravenously over 10 minutes. This dose may be repeated every 6 hours if necessary. To substitute for oral therapy an intravenous infusion of 200 to 500 micrograms/kg per hour may be used. The total daily dose should not exceed 640 mg. For programmed electrical stimulation (to test antiarrhythmic efficacy) an initial dose of 1.5 mg/kg is given over 10 to 20 minutes, followed by an intravenous infusion of 200 to 500 micrograms/kg per hour.

Sotalol is used as a racemic mixture; *d*-sotalol (dexsotalol; (+)-sotalol) has also been investigated as an antiarrhythmic but development was stopped when it was found to increase mortality (see Action, below).

Action. Sotalol is used as the racemic mixture of the two stereoisomers, *d*-sotalol (dexsotalol; (+)-sotalol) and *l*-sotalol ((–)-sotalol). A comparison of the effects of *d*-sotalol and racemic sotalol in 6 healthy subjects[1] showed that the beta-blocking activity resided almost entirely in the *l*-isomer, while the effects on the QT interval, which are consistent with type III antiarrhythmic activity, appear to be due to both isomers. A study in 8 healthy subjects also showed a lack of beta blockade by *d*-sotalol.[2] This would suggest that the electrophysiological effects of sotalol are unrelated to its beta-blocking properties. *d*-Sotalol has been investigated as an antiarrhythmic.[3] However, a preliminary placebo-controlled study in patients with myocardial infarction at high risk of arrhythmia due to impaired left ventricular function was terminated early when increased mortality was seen in the treatment group.[4,5]

Administration in children. Sotalol has been used to treat both ventricular and supraventricular arrhythmias in children aged from newborn to adolescent;[1-3] it appears to be effective and well-tolerated, although proarrhythmic effects may occur. Neonates may be more sensitive to the QT-prolonging effects of sotalol[3] and lower doses may be appropriate. In the UK, the *BNFC* recommends the following oral doses of sotalol hydrochloride:

- Neonates: initial dose 1 mg/kg twice daily, increased as necessary every 3 to 4 days to a maximum of 4 mg/kg twice daily
- Children aged 1 month to 12 years: initial dose 1 mg/kg twice daily, increased as necessary every 2 to 3 days to a maximum of 4 mg/kg twice daily (maximum total dose 80 mg twice daily)

Licensed product information in the USA recommends doses of sotalol hydrochloride based on body surface area. Children aged 2 years and over may be given an initial dose of 30 mg/m^2 three times daily, increased as necessary at intervals of at least 36 hours to a maximum of 60 mg/m^2 three times daily. For children under 2 years of age the dose should be further reduced, and nomograms are available providing age-specific recommendations.

In children with refractory supraventricular tachycardia, sotalol has been given with flecainide; in a study[4] in children aged under 1 year, doses used ranged from 100 to 250 mg/m^2 daily of sotalol and from 40 to 150 mg/m^2 daily of flecainide.

Sotalol has also been used transplacentally to treat fetal tachycardias, including atrial flutter and supraventricular tachycardia. It may be effective as second-line therapy in addition to digoxin,[5] and has also been used first-line.[6,7] However, one retrospective study[6] of 21 fetuses given sotalol transplacentally found that it was more effective in atrial flutter than in supraventricular tachycardia; mortality was also higher in fetuses with supraventricular tachycardia, and the authors therefore suggested that sotalol should only be used in resistant cases.

Administration in renal impairment. Sotalol is excreted mainly unchanged by the kidneys and may accumulate in renal impairment. The usual daily dosage (see above) should therefore be reduced, either by decreasing the size of each dose, or by increasing the interval between doses. UK licensed product information for oral or intravenous sotalol recommends the following doses based on creatinine clearance (CC):

- CC 30 to 60 mL/minute: half usual dose
- CC 10 to 30 mL/minute: quarter usual dose
- CC less than 10 mL/minute: not recommended

Dosage recommendations in the USA depend on both the indication and CC, and incremental increases should not be made until 5 or 6 doses have been given. In the treatment of ventricular arrhythmias, licensed product information for oral sotalol recommends that in renal impairment doses should be given at the following intervals:

- CC 30 to 59 mL/minute: every 24 hours
- CC 10 to 29 mL/minute: every 36 to 48 hours
- CC less than 10 mL/minute: dosage should be individualised

For the treatment of atrial fibrillation, the same dosage intervals are recommended but sotalol is contra-indicated if CC is less than 40 mL/minute.

In a study of 10 hypertensive patients with varying degrees of renal impairment,[1] the apparent first-order elimination rate constant and plasma clearance of sotalol correlated with glomerular filtration rate. Another study[2] compared kinetics in patients with normal renal function, renal impairment, and renal failure. Elimination half-lives of 8.1 and 24.2 hours were reported in patients with CC above 39 mL/minute and between 8 and 38 mL/minute, respectively. It was suggested that an increase in the dosage interval to 48 or 72 hours may be necessary to compensate for longer half-lives. Caution is required when sotalol is used in patients on dialysis; a half-life of 33.9 hours was reported in patients with renal failure but this fell to 5.8 hours during dialysis which removed about 43% of sotalol.

Ph. Eur. 6.2 (Spirapril Hydrochloride Monohydrate). A white or almost white, fine crystalline powder. Very slightly soluble in water; slightly soluble in acetonitrile; practically insoluble in dichloromethane; soluble in methyl alcohol. Store in airtight containers. Protect from light.

Profile

Spirapril is an ACE inhibitor (p.1193) that is used in the management of hypertension (p.1171). It owes its activity to the diacid spiraprilat, to which it is converted after oral doses. It is given orally as the hydrochloride in a usual maintenance dose of 6 mg once daily.

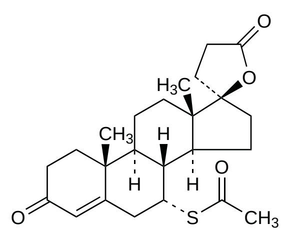
Spironolactone *(BAN, rINN)* ⊗

Espironolactona; SC-9420; Spirolactone; Spironolactonum; Spironolakton; Spironolaktonas; Spironolaktoni. 7α-Acetylthio-3-oxo-17α-pregn-4-ene-21,17β-carbolactone; (7α,17α)-7-(Acetylthio)-17-hydroxy-3-oxo-pregn-4-ene-21-carboxylic acid γ-lactone.

Спиронолактон

$C_{24}H_{32}O_4S$ = 416.6.
CAS — 52-01-7.
ATC — C03DA01.
ATC Vet — QC03DA01.



NOTE. Compounded preparations of spironolactone may be represented by the following names:

- Co-flumactone (*BAN*)—spironolactone and hydroflumethiazide in equal parts (w/w)
- Co-spironozide (*PEN*)—spironolactone and hydrochlorothiazide.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*
Ph. Eur. 6.2 (Spironolactone). A white or yellowish-white powder. Practically insoluble in water; soluble in alcohol. It exhibits polymorphism. Protect from light.
USP 31 (Spironolactone). A light cream-coloured to light tan, crystalline powder with a faint to mild mercaptan-like odour. Practically insoluble in water; soluble in alcohol and in ethyl acetate; freely soluble in chloroform and in benzene; slightly soluble in methyl alcohol and in fixed oils.

Stability. There was no appreciable loss of spironolactone from extemporaneously prepared suspensions of spironolactone, 2.5, 5 and 10 mg/mL, in a cherry syrup after storage for 2 weeks at 5° or 30° or at ambient room temperature under intense fluorescent light.[1] Degradation was less than 5% for samples stored for 4 weeks, but was more noticeable in suspensions with a higher initial concentration. There were no changes in colour or odour. Bacterial and fungal counts were well within acceptable limits after 4 weeks at 30°.

1. Mathur LK, Wickman A. Stability of extemporaneously compounded spironolactone suspensions. *Am J Hosp Pharm* 1989; **46:** 2040–2.

Adverse Effects

Spironolactone may give rise to headache and drowsiness, and gastrointestinal disturbances, including cramp and diarrhoea. Ataxia, mental confusion, and skin rashes have been reported as adverse effects. Gynaecomastia is not uncommon and in rare cases breast enlargement may persist. Other endocrine disorders include hirsutism, deepening of the voice, menstrual irregularities, and impotence. Transient increases in blood-urea-nitrogen concentrations may occur and mild acidosis has been reported. Spironolactone has been shown to cause tumours in *rats*.

Spironolactone may cause hyponatraemia and hyperkalaemia.

Incidence of adverse effects. A survey found that of 788 patients given spironolactone 164 developed adverse effects.[1] These included hyperkalaemia in 8.6%, dehydration in 3.4%, hyponatraemia in 2.4%, gastrointestinal disorders in 2.3%, neurological disorders in 2%, rash, and gynaecomastia. Hyperkalaemia was associated with renal impairment and the use of potassium supplements: only 2.8% of nonuraemic patients not receiving potassium chloride developed hyperkalaemia, while 42.1% of those with marked uraemia and treated with potassium chloride became hyperkalaemic.

In a study[2] of 54 patients (53 female, 1 male) taking spironolactone 200 mg daily for hirsutism or acne adverse effects were reported in 91%.[2] Menstrual disturbances occurred in 72% of patients, breast tenderness in 39%, dry skin in 39%, and breast enlargement in 24%. Other adverse effects included nausea and vomiting, dizziness, headache, drowsiness, and skin rashes. Two patients developed a chloasma-like pigmentation of the face. The gynaecological effects were reduced in patients taking oral contraceptives.

2. Hughes BR, Cunliffe WJ. Tolerance of spironolactone. *Br J Dermatol* 1988; **118:** 687–91.

Carcinogenicity. Breast cancer was reported in 5 patients taking spironolactone and hydrochlorothiazide for prolonged periods[1] although it was suggested[2] that the association with spironolactone therapy was unlikely to be causal.

Although the *rat* may not be an appropriate model for determining long-term safety in man,[3,4] evidence of carcinogenicity in this species prompted the UK CSM to limit the product licences of spironolactone-containing products to exclude use in essential hypertension or idiopathic oedema.[5]

2. Whitling AM, *et al.* Spironolactone-induced agranulocytosis. *Ann Pharmacother* 1997; **31:** 582–5.

Effects on electrolyte balance. *CALCIUM.* A report[1] suggested that spironolactone may have a calcium-sparing effect, in addition to its well known potassium-sparing properties.

1. Puig JG, *et al.* Hydrochlorothiazide versus spironolactone: long-term metabolic modifications in patients with essential hypertension. *J Clin Pharmacol* 1991; **31:** 455–61.

POTASSIUM. There have been reports[1-3] of severe hyperkalaemia in patients taking spironolactone, including patients with renal impairment and those with a high potassium intake from either dietary sources or potassium supplements. In the Boston Collaborative Drug Surveillance Program[4] hyperkalaemia was reported in 42.1% of patients with uraemia taking spironolactone and receiving potassium supplements compared with 2.8% of those without uraemia and not receiving potassium supplements. Two deaths were attributed to hyperkalaemia in patients taking spironolactone and potassium chloride. Potassium supplements should be avoided in patients receiving spironolactone, and plasma-potassium concentrations should be carefully monitored in those with renal impairment.

4. Greenblatt DJ, Koch-Weser J. Adverse reactions to spironolactone: a report from the Boston Collaborative Drug Surveillance Program. *JAMA* 1973; **225:** 40–3.

Effects on endocrine function. Spironolactone has been associated with disturbances of endocrine function. The most prominent in men is gynaecomastia which appears to be related to both dose and duration of treatment. Incidences of 62%[1] and 100%[2] have been reported. Gynaecomastia has also been accompanied by impotence.[3,4] The effects are generally reversible on stopping treatment. Reversal of male-pattern baldness has also been reported.[5]

In women symptoms include breast enlargement and tenderness.[6] The incidence of menstrual abnormalities may be high: unspecified disturbances have been reported in 33 of 53 women,[6] secondary amenorrhoea in 6 of 9,[7] and secondary and primary amenorrhoea in 1 and 2 patients, respectively.[8] The incidence of gynaecological disturbances has been found to be lower in women taking oral contraceptives.[6]

The mechanism of the effects of spironolactone on the endocrine system is unclear. Some workers[9] suggested that although spironolactone affects testosterone synthesis, the more likely explanation was its anti-androgenic action, and reduction in 17-hydroxylase activity. Others[10] found an alteration in the testosterone/oestrogen ratio due to an increase in testosterone clearance and increased peripheral conversion to estradiol. In addition, spironolactone is reported to inhibit binding of dihydrotestosterone to receptors.

Effects on lipid metabolism. Unlike thiazide diuretics, spironolactone appeared not to increase serum-cholesterol concentrations in a study of 23 patients.[1]

1. Ames RP, Peacock PB. Serum cholesterol during treatment of hypertension with diuretic drugs. *Arch Intern Med* 1984; **144:** 710–14.

Effects on the liver. Hepatotoxicity characterised by cholestatic lesions has been reported in a patient receiving spironolactone.[1] Only one other published case of spironolactone-associated hepatotoxicity was known to the authors.

1. Renkes P, *et al.* Spironolactone and hepatic toxicity. *JAMA* 1995; **273:** 376–7.

Effects on the skin. Lichen-planus-like skin eruptions developed in a 62-year-old woman who was taking digoxin, propranolol, diazepam, spironolactone, and iron tablets.[1] Flares of the lichen-planus-like eruption seemed to be associated with use of spironolactone and there was evidence of resolution when spironolactone was withdrawn. Cutaneous vasculitis was associated with spironolactone on 3 occasions in an 80-year-old man.[2] A chloasma-like pigmentation of the face was reported in 2 patients receiving spironolactone for hirsutism or acne.[3]

3. Hughes BR, Cunliffe WJ. Tolerance of spironolactone. *Br J Dermatol* 1988; **118:** 687–91.

Hypersensitivity. Eosinophilia and a rash developed in 2 patients with alcoholic cirrhosis while taking spironolactone.[1]

1. Wathen CG, *et al.* Eosinophilia associated with spironolactone. *Lancet* 1986; **i:** 919–20.

Precautions

Spironolactone should not be used in patients with hyperkalaemia or severe renal impairment. It should be used with care in patients who are at increased risk of developing hyperkalaemia; such patients include the elderly, those with diabetes mellitus, and those with some degree of renal or hepatic impairment. It should also be given with care to patients likely to develop acidosis. Serum electrolytes and blood-urea-nitrogen should be measured periodically.

Breast feeding. The concentration of canrenone was measured[1] in the serum and milk of a breast-feeding woman taking 25 mg of spironolactone four times daily. The milk to serum concentration ratios of canrenone at 2 and 14.5 hours after a dose of spironolactone were 0.72 and 0.51 respectively, and it was estimated that the amount of canrenone ingested by the infant would be 0.2% of the mother's daily dose of spironolactone. The serum potassium and sodium levels of the infant were in the normal range. The American Academy of Pediatrics[2] considers that spironolactone is therefore usually compatible with breast feeding.

Diabetes mellitus. Severe hyperkalaemia was reported in a type 1 diabetic woman with hyporeninaemic hypoaldosteronism given spironolactone.[1]

1. Large DM, *et al.* Hyperkalaemia in diabetes mellitus—potential hazards of coexisting hyporeninaemic hypoaldosteronism. *Postgrad Med J* 1984; **60:** 370–3.

Interference with laboratory estimations. Spironolactone and canrenoate can interfere with some assays for plasma-digoxin concentrations.[1-3] However, spironolactone may also produce actual changes in digoxin concentrations (see p.1262) and results of assays should be interpreted with caution.

1. Yosselson-Superstine S. Drug interferences with plasma assays in therapeutic drug monitoring. *Clin Pharmacokinet* 1984; **9:** 67–87.
2. Foukaridis GN. Influence of spironolactone and its metabolite canrenone on serum digoxin assays. *Ther Drug Monit* 1990; **12:** 82–4.
3. Steimer W, *et al.* Intoxication due to negative canrenone interference in digoxin drug monitoring. *Lancet* 1999; **354:** 1176–7.

Porphyria. Spironolactone has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

There is an increased risk of hyperkalaemia if spironolactone is given with potassium supplements or with other potassium-sparing diuretics. Hyperkalaemia may occur as well in patients also given ACE inhibitors, angiotensin II receptor antagonists, NSAIDs, ciclosporin, or trilostane. In patients given spironolactone with NSAIDs or ciclosporin the risk of nephrotoxicity may also be increased. Diuretics may reduce the excretion of lithium and increase the risk of lithium toxicity. Hyponatraemia may occur in patients taking a potassium-sparing diuretic with a thiazide; this risk may be increased in patients given chlorpropamide. Spironolactone may reduce the ulcer-healing properties of carbenoxolone. As with other diuretics, spironolactone may enhance the effects of other antihypertensive drugs and may reduce vascular responses to noradrenaline.

ACE inhibitors and angiotensin II receptor antagonists. Severe hyperkalaemia has been reported in patients given spironolactone with ACE inhibitors or angiotensin II receptor antagonists and fatalities have occurred. In a study[1] of 44 patients taking such combinations for heart failure who were admitted to hospital with life-threatening hyperkalaemia, 37 required haemodialysis and 2 developed fatal complications. In another group[2] of 25 patients given spironolactone with ACE inhibitors who were admitted with severe hyperkalaemia, 2 died and 4 others developed severe cardiac arrhythmias. Advanced age, renal impairment or diabetes mellitus were risk factors for hyperkalaemia in both studies. It was suggested that combinations of spironolactone with ACE inhibitors or angiotensin II receptor antagonists should be used with caution in such patients and that they should not be given doses of spironolactone above 25 mg daily.

Aspirin. Aspirin has been shown to produce substantial reductions in sodium excretion[1] in healthy subjects taking spironolactone and to reduce the excretion of spironolactone's active metabolite, canrenone.[2] However, use of aspirin in hypertensive patients[3] did not alter the effect of spironolactone on blood pressure, serum electrolytes, blood urea nitrogen, or plasma-renin activity.

Mitotane. For a report of the inhibition of the action of mitotane by spironolactone, see p.753.

Warfarin. For reference to the interaction between warfarin and spironolactone, see p.1430.

Pharmacokinetics

Spironolactone is well absorbed from the gastrointestinal tract, with a bioavailability of about 90%. It is about 90% bound to plasma proteins.

Spironolactone is metabolised extensively to a number of metabolites including canrenone and 7α-thiomethylspirolactone, both of which are pharmacologically active. The major metabolite may be 7α-thiomethylspirolactone, although it is uncertain to what extent the actions of spironolactone are dependent on the parent compound or its metabolites.

Spironolactone is excreted mainly in the urine and also in the faeces, in the form of metabolites. Spironolactone or its metabolites may cross the placental barrier, and canrenone is distributed into breast milk.

Uses and Administration

Spironolactone, a steroid with a structure resembling that of the natural adrenocortical hormone aldosterone, acts on the distal portion of the renal tubule as a competitive antagonist of aldosterone. It acts as a potassium-sparing diuretic, increasing sodium and water excretion and reducing potassium excretion.

Spironolactone is reported to have a relatively slow onset of action, requiring 2 or 3 days for maximum effect, and a similarly slow diminishment of action over 2 or 3 days on stopping.

Spironolactone is used in the management of heart failure, both to treat refractory oedema and in lower doses as an adjunct to standard therapy (see below). It is also used for refractory oedema associated with cirrhosis of the liver (with or without ascites, p.1159), or the nephrotic syndrome, and in ascites associated with malignancy. It is frequently given with the thiazides, furosemide, or similar diuretics, where it adds to their natriuretic but diminishes their kaliuretic effects, hence conserving potassium in those at risk from hypokalaemia. Diuretic-induced hypokalaemia and its management, including the role of potassium-sparing diuretics, is discussed under Effects on the Electrolyte Balance in the Adverse Effects of Hydrochlorothiazide, p.1308. It has been used in the treatment of essential hypertension (in lower doses than for oedema), but in the UK is no longer recommended for use in either essential hypertension or idiopathic oedema; doubts have been expressed over its safety during long-term administration.

Spironolactone is also used in the diagnosis and treatment of primary hyperaldosteronism (below).

Other conditions in which spironolactone has been tried on the basis of its anti-androgenic properties include hirsutism, particularly in the polycystic ovary syndrome.

In the treatment of **oedema**, spironolactone is usually given in an initial oral dose of 100 mg daily, subsequently adjusted as necessary; some patients may require doses of up to 400 mg daily. In hepatic cirrhosis with ascites and oedema, patients with a urinary sodium/potassium ratio greater than 1 may be given an initial dose of spironolactone 100 mg daily while patients with a ratio of less than 1 may be given initial doses of 200 to 400 mg daily.

Spironolactone is given in doses of 400 mg daily in the presumptive diagnosis of primary **hyperaldosteronism**; in doses of 100 to 400 mg daily for the preoperative management of hyperaldosteronism; and in the lowest effective dosage for long-term maintenance therapy in the absence of surgery.

Suggested doses of spironolactone for children range from 1 to 3 mg/kg daily, in divided doses.

Potassium supplements should not be given with spironolactone.

Acne. Spironolactone has been used for its anti-androgenic properties in some cases of acne (p.1577) where standard therapy is unsuccessful. Beneficial responses to oral therapy have been reported in patients with acne from both open[1] and placebo-controlled[2,3] studies. Topical application has been tried[4,5] but response has been variable. It is possible that the vehicle may affect the response. In women, spironolactone may be useful when treatment with an oestrogen is contra-indicated.

Alopecia. Anti-androgens have a role in the treatment of hirsutism (see below) but have also been used in patients with androgenetic alopecia (p.1577), and there is some evidence that spironolactone may be effective.[1]

1. Sinclair R, *et al.* Treatment of female pattern hair loss with oral antiandrogens. *Br J Dermatol* 2005; **152:** 466–73.

Bartter's syndrome. Spironolactone may be used to reduce potassium wasting in patients with Bartter's syndrome (p.1670).

Bronchopulmonary dysplasia. Bronchopulmonary dysplasia (p.1500) is a major cause of chronic lung disease in infants. Treatment often involves the use of corticosteroids. Additional supportive therapy has included the use of diuretics such as furosemide (p.1294); results with hydrochlorothiazide or spironolactone have been more ambiguous (p.1310).

Heart failure. Drug therapy of heart failure (p.1165) is based on the use of diuretics, ACE inhibitors, cardiac glycosides, beta blockers, and vasodilators. Spironolactone has been used as a diuretic for refractory oedema, but it also has an additional role as an aldosterone antagonist.[1,2] Although the precise neurohormonal mechanisms leading to the development of heart failure are still not clear, there is evidence that raised levels of aldosterone may contribute to the pathophysiology.[3,4] ACE inhibitor therapy suppresses aldosterone production but this effect is not complete and the use of spironolactone with ACE inhibitors has therefore been studied. In the Randomized Aldactone Evaluation Study (RALES)[5] in patients with severe heart failure, addition of spironolactone in a dose of 25 to 50 mg daily to therapy with ACE inhibitors and loop diuretics reduced the risk of death or hospitalisation,[5] and the use of spironolactone should therefore be considered in such patients.[6-8] A small study[9] has also shown benefit in patients with less severe heart failure. However, use of spironolactone with ACE inhibitors may lead to hyperkalaemia and careful monitoring of potassium concentrations is required[10,11] (see Interactions, above). A retrospective analysis[12] of heart failure patients found that over 10% had to stop spironolactone because of hyperkalaemia, and a further 10% stopped because of worsening renal function. Risk factors were advanced age and higher baseline plasma-potassium concentrations.

High-altitude disorders. Acetazolamide is generally the drug of choice for prophylaxis of high-altitude disorders (p.1168). Anecdotal reports[1-4] and a small-scale double-blind study[5] suggested that spironolactone could be useful in preventing acute mountain sickness, although a deterioration in pulmonary function despite spironolactone prophylaxis has been noted in a patient.[6]

Hirsutism. Hirsutism (p.2089) is frequently treated with anti-androgens, usually cyproterone or spironolactone. Spironolactone in doses of 50 to 200 mg daily has produced both subjective and objective improvement in hirsutism in patients with idiopathic hirsutism or polycystic ovary syndrome,[1-4] and its use has been reviewed.[5] It is preferably used with oral contraceptives,[6,7] to improve efficacy and avoid the menstrual irregularity and to avoid the risk of feminisation to a male fetus. Most studies have involved premenopausal women and it has been suggested[4,8] that spironolactone would be useful in women in whom cyproterone is contra-indicated or not tolerated. A randomised study (not placebo-controlled) found spironolactone 100 mg daily and cyproterone 100 mg daily to be equally effective,[9] while a systematic review[10] of the use of spironolactone in hirsutism concluded that it was significantly more effective than both cyproterone and finasteride for up to 12 months after treatment.

Hyperaldosteronism. Hyperaldosteronism (aldosteronism) is a disorder characterised by mineralocorticoid excess due to high circulating levels of aldosterone.[1-4] Mineralocorticoid excess due to other mineralocorticoids is rare. Primary hyperaldosteronism is usually caused by an aldosterone-producing adenoma (Conn's syndrome) or primary adrenal hyperplasia. Other causes include aldosterone-producing adrenal carcinoma, and glucocorticoid-suppressible hyperaldosteronism.

Secondary hyperaldosteronism is more common and results from conditions in which there is activation of the renin-angiotensin-aldosterone system, including diuretic therapy, and oedematous conditions such as heart failure, hepatic cirrhosis, and nephrotic syndrome. Bartter's syndrome (p.1670) also results in hyperaldosteronism.

Most patients with primary hyperaldosteronism are asymptomatic, although they may present with signs or symptoms of mineralocorticoid excess (p.1490). Diagnosis often follows the incidental discovery of hypokalaemia. Symptomatic hypokalaemia (p.1669) may develop in some patients, particularly those taking diuretics.

Diagnosis is confirmed by the presence of raised plasma and urinary aldosterone concentrations. However, the concentrations may be affected by serum-potassium concentration, posture, and time of day, and interpretation may be difficult. The plasma aldosterone:renin ratio may also be measured. In primary hyperaldosteronism the aldosterone concentration is raised but renin is suppressed, although this does not necessarily prove the diagnosis; in secondary hyperaldosteronism both are raised. Radiological and nuclear imaging are useful for further differentiating between adenoma and hyperplasia.

Hyperaldosteronism due to an aldosterone-producing adenoma is usually treated surgically. The aldosterone antagonist spironolactone may be given pre-operatively to lower the blood pressure and normalise the serum potassium. In patients who are not suitable for surgery, long-term medical management involves spironolactone, initially in high doses but reduced to the lowest dose for maintenance. If spironolactone is not tolerated, amiloride may be used as an alternative, but high doses are required. There has also been a report[5] of the successful use of eplerenone, another aldosterone antagonist; gynaecomastia had developed with spironolactone but resolved when treatment was changed to eplerenone. Trilostane, an adrenal suppressant, has been used to inhibit aldosterone synthesis.

In primary adrenal hyperplasia surgery is not usually effective and medical management with spironolactone or amiloride is required. Additional antihypertensive therapy may also be needed. Glucocorticoid-suppressible hyperaldosteronism, also known as familial hyperaldosteronism type I (FH-I), is a rare autosomal dominant form and may be treated with dexamethasone. However, this may not control the blood pressure and spironolactone or amiloride may be required in addition.

In secondary hyperaldosteronism the underlying condition should be treated, but spironolactone may be of benefit as part of the therapy.

Precocious puberty. Spironolactone (as an anti-androgen) and testolactone were given to boys with familial precocious puberty (p.2081) for periods of up to 18 months. Rates of growth and bone maturation were restored to normal during combination therapy but not with either drug given alone.[1] However, after further treatment for 2 to 4.2 years there was a diminishing response manifested by the recurrence of clinical features of puberty and an increase in the bone maturation rate.[2] Addition of deslorelin appeared to restore the control of puberty,[2] and in a long-term study[3] growth rate remained normal for 6 years.

Premenstrual syndrome. Spironolactone has been used for its diuretic and anti-androgenic properties in premenstrual syndrome (p.2099).

Preparations

BP 2008: Spironolactone Tablets;
USP 31: Spironolactone and Hydrochlorothiazide Tablets; Spironolactone Tablets.

Proprietary Preparations (details are given in Part 3)
Arg.: Aldactone; Drimux A; Espimax; Expal; Lanx; Modulactone; Normital; Osiren†; Rediun-E; ***Austral.:*** Aldactone; Spiractin; ***Austria:*** Aldactone; Spirobene; Spirohexal; Spirono; ***Belg.:*** Aldactone; Docspirono; Spirotop; ***Braz.:*** Aldactone; Aldosterin†; Espirolona; Spiroctan; ***Canad.:*** Aldactone; Novo-Spiroton; ***Chile:*** Alizar; Cardactona; ***Cz.:*** Spirolone†; Uractone†; Verospiron; Xenalon†; ***Denm.:*** Hexalacton; Spirix; Spiron; ***Fin.:*** Aldactone; Spiresis; Spirix; ***Fr.:*** Aldactone; Flumach; Practon; Spiroctan; Spironone; ***Ger.:*** Aldactone; Aquareduct†; duraspiron†; Jenaspiron; Osyrol; Spiro; Spirobeta; Spirogamma; Spirono; Verospiron; ***Gr.:*** Aldactone; Uridactone†; ***Hong Kong:*** Aldactone; ***Hung.:*** Huma-Spiroton; Spirolone†; Spiron; Verospiron; ***India:*** Aldactone; ***Indon.:*** Aldactone; Carpiaton; Letonal; Spirola; ***Irl.:*** Aldactone; ***Israel:*** Aldactone; Aldospirone; Spironol; ***Ital.:*** Aldactone; Spiroderm†; Spirolang; Uractone; ***Mex.:*** Aldactone; Biolactona; Quimolactona†; Vivitar; ***Neth.:*** Aldactone; ***Norw.:*** Aldactone; Spirix; ***NZ:*** Aldactone†; Spirotone; ***Philipp.:*** Aldactone; ***Pol.:*** Spironol; Verospiron; ***Port.:*** Aldactone; Aldonar; Nefrolactona†; ***Rus.:*** Aldactone (Альдактон)†; Verospiron (Верошпирон); ***S.Afr.:*** Aldactone; Spiractin; ***Singapore:*** Aldactone; Uractonum; ***Spain:*** Aldactone; ***Swed.:*** Aldactone; Spirix; Spiroscand†; ***Switz.:*** Aldactone; Primacton; Xenalon; ***Thai.:*** Aldactone; Altone; Berlactone†; Hyles; Pondactone; Spironex†; ***Turk.:*** Aldacton; ***UK:*** Aldactone; Spirospare†; ***USA:*** Aldactone; ***Venez.:*** Aldactone; Spiroctan†.

Staphylokinase

Estafiloquinasa.

Profile

Staphylokinase is a thrombolytic derived from *Staphylococcus aureus*. Recombinant and modified forms are under investigation for the treatment of thromboembolic disorders, including acute myocardial infarction.

Streptokinase *(BAN, rINN)*

Estreptoquinasa; Plasminokinase; Sterptokinasum; Streptokinaasi; Streptokinas; Streptokinasum; Sztreptokináz.

Стрептокиназа

CAS — 9002-01-1.
ATC — B01AD01.
ATC Vet — QB01AD01.

Pharmacopoeias. *Eur.* (see p.vii) includes a concentrated solution.

Ph. Eur. 6.2 (Streptokinase Concentrated Solution; Streptokinasi Solutio Concentrata). A preparation of a protein obtained from culture filtrates of certain strains of haemolytic *Streptococcus* group C. It has the property of combining with human plasminogen to form plasminogen activator. The potency is not less than 510 international units per microgram of nitrogen. A clear, colourless liquid. pH 6.8 to 7.5. Store in airtight containers at a temperature of –20°. Protect from light.

Stability. The incorporation of albumin in commercial preparations of streptokinase has reduced the incidence of flocculation with streptokinase solutions. However, flocculation has occurred with small volumes prepared with sodium chloride 0.9% in sterilised glass containers apparently because of residual acid buffers that remain in empty evacuated containers after sterilisation.[1]

1. Thibault L. Streptokinase flocculation in evacuated glass bottles. *Am J Hosp Pharm* 1985; **42:** 278.

Units

The potency of streptokinase is expressed in international units and preparations are assayed using the second International Standard (1989).

The Christensen unit is the quantity of streptokinase that will lyse a standard blood clot completely in 10 minutes and is equivalent to the international unit.

Adverse Effects

In common with other thrombolytics streptokinase may cause haemorrhage, particularly from puncture sites; severe internal bleeding has occurred and may be difficult to control. Streptokinase is antigenic, and allergic reactions ranging from rashes to rarer anaphylactoid and serum-sickness-like symptoms have occurred. Fever, sometimes high, and associated symptoms such as chills and back or abdominal pain are quite frequent. Nausea and vomiting may occur. There have been a few reports of Guillain-Barré syndrome.

Streptokinase infusion may be associated with hypotension, both direct or as a result of reperfusion; bradycardia and arrhythmias may also occur due to reperfusion. The break-up of existing clots may occasionally produce emboli elsewhere; pulmonary embolism and acute renal failure due to cholesterol embolisation have been reported.

Back pain. Streptokinase infusion has been associated with the development of very severe low back pain, which resolves within a few minutes of stopping the infusion, and may be severe enough to warrant opioid analgesia.[1-4] The back pain may represent a hypersensitivity reaction. Providing that the pain is controlled and that dissecting aortic aneurysm is not suspected, it may still be possible to complete the streptokinase infusion.[4,5] Alternatively, immediate substitution with a different thrombolytic has been suggested.[6]

There have also been a few reports of low back pain associated with anistreplase infusion.[7,8]

Effects on the blood. Although falls in the haemoglobin value of patients receiving thrombolytics are most likely to be due to blood loss from haemorrhage, there has been a report of a patient who had signs of haemolytic anaemia after intravenous infusion of streptokinase.[1] In a subsequent test *in vitro* the patient's serum caused strong agglutination of streptokinase-treated red blood cells, supporting the view that streptokinase was responsible for the haemolysis.

1. Mathiesen O, Grunnet N. Haemolysis after intravenous streptokinase. *Lancet* 1989; **i:** 1016–17.

Effects on the eyes. Acute uveitis[1,2] and iritis,[3,4] associated with transient renal impairment in one patient,[3] have followed treatment of myocardial infarction with intravenous streptokinase. In one case uveitis was associated with serum sickness[2] and in all of them hypersensitivity to streptokinase was suspected.

1. Kinshuck D. Bilateral hypopyon and streptokinase. *BMJ* 1992; **305:** 1332.

4. Gray MY, Lazarus JH. Iritis after treatment with streptokinase. *BMJ* 1994; **309:** 97.

Effects on the kidneys. Transient proteinuria has been reported after use of streptokinase. In some patients proteinuria and renal impairment have developed about 7 days after thrombolytic therapy and have been associated with a syndrome resembling serum sickness,[1,2] suggesting a delayed hypersensitivity reaction; a similar case in a patient receiving anistreplase was associated with Henoch-Schönlein-like vasculitis.[3] These delayed reactions should be distinguished from the transient and apparently self-limiting proteinuria that has been reported in some patients in the first 24 to 72 hours after beginning streptokinase.[4,5] Proteinuria within the first 24 hours has been attributed to deposition of an immune complex in the glomeruli,[6] although haemodynamic and neurohormonal changes associated with acute myocardial infarction may be responsible since proteinuria has occurred in patients not receiving thrombolytic therapy.[7,8]

Streptokinase infusion has also been associated with acute oliguric acute renal failure due to acute tubular necrosis, apparently as a result of hypotension during the infusion, in a patient with existing renovascular narrowing.[9] Interestingly, it has been pointed out that a variant streptokinase may be the pathogenic agent in glomerulonephritis occurring after *Streptococcus pyogenes* infection.[10]

Renal failure has developed as a consequence of streptokinase-induced cholesterol embolism, see under Embolism, below.

Effects on the liver. Raised serum-alanine aminotransferase values, and in some cases raised aspartate aminotransferase activity, were seen more frequently in 95 patients who received streptokinase than in 94 given placebo as part of a study in patients with myocardial infarction.[1] The mechanism for the raised aminotransferase activity was not clear; a concomitant rise in γ-glutamyltransferase activity and bilirubin concentration suggested an hepatic source.

For references to rupture of the liver occurring during treatment with streptokinase, see Haemorrhage, below.

1. Maclennan AC, *et al.* Activities of aminotransferases after treatment with streptokinase for acute myocardial infarction. *BMJ* 1990; **301:** 321–2.

Effects on the nervous system. There have been a few reports of Guillain-Barré syndrome after treatment with streptokinase.[1-4] Whether streptokinase was the cause is not certain although its antigenic properties do suggest that induction of an immunological reaction might be responsible.[3]

For discussion of cerebrovascular effects of streptokinase, see Haemorrhage, below.

4. Taylor BV, *et al.* Guillain-Barré syndrome complicating treatment with streptokinase. *Med J Aust* 1995; **162:** 214–15.

Effects on the respiratory system. Fatal acute respiratory distress syndrome occurred in a patient given streptokinase for pulmonary embolism.[1] It was suggested that streptokinase may have caused the pulmonary injury by altering vascular permeability due to generation of fibrinolytic products or via reperfusion oedema.

1. Martin TR, *et al.* Adult respiratory distress syndrome following thrombolytic therapy for pulmonary embolism. *Chest* 1983; **83:** 151–3.

Effects on the skin. Rashes may occur as an allergic reaction to streptokinase. For a report of skin necrosis possibly associated with cholesterol embolisation, see Embolism, below.

Embolism. Thrombolytic therapy has occasionally and paradoxically been associated with further embolism. This may be due to clots that break away from the treated thrombus, or to cholesterol crystals released after removal of fibrin from atheromatous plaques by thrombolysis.

Fatal pulmonary embolism has been reported,[1] apparently due to breakaway from a deep-vein thrombus under treatment. However, comparative studies have suggested that there is no evidence of a higher rate of such complications with streptokinase than with heparin.[2] When they do occur a good clinical response is usually seen to continued streptokinase.[2] Complications due to multiple microemboli were reported[3] in 7 of 475 consecutive patients treated with streptokinase or anistreplase for acute myocardial infarction. The sites of embolism were the legs (in 4) and brain (in 3); one patient apparently had systemic effects with skin infarction and renal impairment. Five of the 7 patients died. There has also been a report[4] of acute peripheral arterial thromboembolism in a patient given alteplase for ischaemic stroke.

Cholesterol embolisation can have many clinical manifestations depending on the location of the emboli. A classic presentation is livedo reticularis, gangrenous lower extremities, and acute renal failure.[5,6] Symptoms may appear within a few hours of starting thrombolytic treatment,[7] although in some cases they may not become evident for several days.[8-11]

Haemorrhage. Haemorrhage is a common adverse effect of thrombolytic therapy, and the problem and its management have been reviewed.[1] Thrombolytics are used to lyse pathological thrombi, but can also produce a 'lytic state' due to depletion of the natural plasmin inhibitor α_2-antiplasmin by excess plasmin production; they may also cause lysis of thrombi required for haemostasis.

Haemorrhage is a particular risk where there is existing or concomitant trauma. More than 70% of bleeding episodes occur at vascular puncture sites,[1] so invasive procedures should be avoided if possible; if catheterisation is considered essential meticulous care of the vascular puncture site is necessary. Bleeding or severe bruising in patients receiving thrombolytic therapy have also been associated with intramuscular injection of analgesics,[2] the use of an automatic blood-pressure measuring machine,[3] a pre-existing prosthetic abdominal aortic graft,[4] and recent dental extraction.[5] Other disease states may also contribute: haemospermia has been reported after thrombolysis in a patient with mild prostatic symptoms,[6] haemorrhagic bullae have been reported in a patient with lichen sclerosus et atrophicus,[7] and diabetic patients are at risk of retinal haemorrhage if they have diabetic retinopathy,[8] although any increase in risk seems to be small.[9] A review of the GUSTO-I Study[10] (40 903 patients) identified older age, low body-weight, female sex, and African ancestry as other factors that increased the risk of haemorrhage.

Intracranial haemorrhage leading to stroke is the most serious bleeding complication with thrombolytics, and has a high mortality. Assessment of data from national registries and large-scale trials has identified a number of risk factors for intracranial haemorrhage, including those mentioned above for overall haemorrhage, hypertension on admission, a history of stroke, and thrombolysis with current alteplase regimens.[11-14] The benefits and risks must be assessed for each patient and thrombolytic therapy should still be given to the elderly and to those with hypertension if the expected benefits are great. Intracranial haemorrhage is a particular concern with the use of thrombolytics for the treatment of ischaemic stroke. In the NINDS study, using alteplase, clinical outcome appeared to be improved despite an increased incidence of symptomatic intracerebral haemorrhage. Subgroup analysis[15] suggested that severe neurological deficit, brain oedema, and mass effect, before treatment, were risks associated with the increased incidence of haemorrhage.

Fibrin-specific thrombolytics such as alteplase were developed in the hope that they would have less systemic effect than fibrin-nonspecific thrombolytics such as streptokinase and therefore cause less bleeding. However, studies that have assessed comparative bleeding rates have failed to confirm this, although the use of adjunctive antithrombotics and different dose regimens makes comparison difficult. In GUSTO-I,[10] the bleeding rate with alteplase plus intravenous heparin was lower than with streptokinase plus intravenous heparin, but was similar to that with streptokinase plus subcutaneous heparin. However, the rate of intracranial haemorrhage was higher with alteplase.[16] In ASSENT-2,[17] which compared bolus doses of the highly fibrin-specific thrombolytic tenecteplase with front-loaded alteplase, tenecteplase produced fewer major non-cerebral bleeds than alteplase but the rates of intracranial haemorrhage were nearly identical. Although a meta-analysis[18] suggested that rates of intracranial haemorrhage may be higher with bolus thrombolytics, others have suggested that this may not be a problem with newer bolus regimens.[19]

Other bleeding complications reported with thrombolytics include rupture of the spleen[20,21] and liver,[22] and rupture of a follicle has been reported in a menstruating woman.[23] Rupture of the heart with fatal consequences has been reported, although thrombolytics do not appear to increase the overall risk of cardiac rupture following myocardial infarction,[24] except possibly for early rupture in women.[25]

Diffuse alveolar haemorrhage has been reported[26] in a patient treated with streptokinase after myocardial infarction. Intrapleural use was associated with life-threatening haemorrhage in empyema following cardiac surgery,[27] and with fatal haemorrhage in a case of aortic dissection misdiagnosed as empyema.[28]

Hypersensitivity. Streptokinase is a bacterial protein and has antigenic activity. The formation of streptokinase-neutralising antibodies may reduce the efficacy of subsequent doses and increase the risk of hypersensitivity reactions.

In a series of 25 patients given intravenous streptokinase for myocardial infarction, titres of streptokinase-neutralising antibodies rose from a mean neutralisation capacity of 0.16 million units before treatment to a mean of 25.54 million units 2 weeks after treatment, the highest individual titre being 93 million units. After 12 weeks the neutralisation capacity was still sufficient in 24 patients to have neutralised a standard 1.5-million unit dose of streptokinase. After 17 to 34 weeks titres were still high enough in 18 of 20 patients examined to neutralise at least half a standard dose.[1] As these results indicate, giving standard doses of streptokinase within up to a year of a previous course may lead to reduced effect. Thus, the period in which it should not be repeated is usually between 5 days and 12 months post infarction (see Precautions, below). However, high titres of neutralising antibodies persisting for up to 7.5 years after use of streptokinase have been reported.[2-4] Since readministration also increases the risk of hypersensitivity reactions, it has been suggested[2,5] that repeat courses should not be given within 4 or more years, and that if a repeat course is needed a non-antigenic thrombolytic such as alteplase or urokinase should be used until it is known whether or not high *in-vitro* titres affect efficacy. Increased titres of streptokinase-neutralising antibodies have also been measured in patients given topical streptokinase for wounds.[6]

Anistreplase also appears susceptible to neutralisation by streptokinase antibodies.[7]

Plasmacytosis,[8,9] serum-sickness,[8,10,11] rhabdomyolysis,[12] renal impairment (see Effects on the Kidneys, above), uveitis and iritis (see Effects on the Eyes, above), arthritis,[13] and anaphylaxis[14-17] have been reported in patients receiving streptokinase and are thought to represent hypersensitivity reactions, in some cases perhaps due to previous exposure to streptococcal antigens during infection. Back pain (see above) may also represent a hypersensitivity reaction. In some patients there may be a delay of between 1 and 10 days before appearance of the reaction.[18] The incidence of severe hypersensitivity reactions is probably fairly low, however; in the GISSI study anaphylaxis was reported in only 7 of 5860 patients although other hypersensitivity reactions leading to withdrawal of streptokinase were reported in 99 patients, with a further 42 such reactions after completion of the infusion.[15] Some episodes of apparent anaphylaxis seen with streptokinase may be fibrinolysin-mediated rather than antibody-antigen reactions. Alteplase, which is considered non-antigenic, produced an anaphylactoid reaction in a patient who had a history of atopy.[19] Fibrinolysin, which activates complement cascade and the kinin system, is formed in quantity after the use of a thrombolytic. In most patients these effects are clinically insignificant, but in those who are strongly atopic there is the possibility of precipitating an anaphylactoid reaction.

Treatment of Adverse Effects

Allergic reactions may require treatment with antihistamines and corticosteroids, which have sometimes been given prophylactically. Anaphylaxis requires the use of adrenaline (for further details, see p.1205).

Severe haemorrhage not controlled by local pressure requires the streptokinase infusion to be stopped. Tranexamic acid, aminocaproic acid, or aprotinin may be of benefit. Packed red blood cells may be preferable to whole blood for replacement therapy; factor VIII preparations may also be given. Volume expansion may be necessary, but the use of dextrans should be avoided because of their platelet-inhibiting properties.

Precautions

Streptokinase should be used with great care, if at all, in patients at increased risk of bleeding, or those in whom haemorrhage is likely to prove particularly dangerous. It should thus be avoided in patients with active internal bleeding or a recent history of peptic ulcer disease, oesophageal varices, ulcerative colitis or other bleeding gastrointestinal lesions, in patients with pancreatitis, in patients with subacute bacterial endocarditis, in patients with coagulation defects including those due to liver or kidney disease, or after recent surgery, childbirth, or trauma. It should not be given to patients at increased risk of cerebral bleeding including those with severe hypertension, haemorrhage or recent stroke, or to patients with cerebral neoplasm. It should not be given in pregnancy, particularly in the first 18 weeks because of the risk of placental separation and it has been suggested that it should not be used during heavy vaginal bleeding.

Invasive procedures, including intramuscular injections, should be avoided during, and immediately before and after, streptokinase therapy as they may increase the risk of bleeding; care should be taken when physically handling patients. Streptokinase should also be used with care in elderly patients. Patients with mitral stenosis associated with atrial fibrillation are more likely to have left heart thrombus which may lead to cerebral embolism after thrombolytic therapy. Although there is a theoretical risk of retinal bleeding in patients with diabetic retinopathy the benefits of treatment generally outweigh the risk.

Anti-streptokinase antibodies are formed after streptokinase use, with antibody titres rising abruptly after about 5 days. These antibodies may cause resistance or hypersensitivity to subsequent doses of streptokinase. Therefore, further doses of streptokinase should not be given in the period between 5 days and 12 months after the initial dose (even longer periods have been suggested, see Hypersensitivity, under Adverse Effects, above); if thrombolytic therapy is required in this period an alternative non-antigenic drug should be used. High titres of anti-streptokinase antibodies may also occur in patients after some streptococcal infections such as streptococcal pharyngitis or acute rheumatic fever or in those with acute glomerulonephritis secondary to streptococcal infections; in such patients there may be resistance to streptokinase or a reduced effect.

Administration. Overinfusion of streptokinase may occur if a drop-counting infusion pump is employed.[1] This arises as a result of flocculation of the streptokinase solution producing translucent fibres that affect the drop-forming mechanism so increasing the drop size.

For a comment on the incidence of flocculation in streptokinase solutions, see Stability, above.

1. Schad RF, Jennings RH. Overinfusions of streptokinase. *Am J Hosp Pharm* 1982; **39:** 1850.

Aortic dissection. A report of 4 cases of the inappropriate use of streptokinase in patients with aortic dissection misdiagnosed as myocardial infarction.[1] Thrombolytics are likely to extend aortic dissection and adversely affect the outcome. Of the 2 patients who died, one, who would have been suitable for early operation, died through the delay caused by impaired clotting. Although early intervention with thrombolytics may be of major benefit in acute myocardial infarction it is important that accurate differential diagnosis takes place to exclude conditions such as aortic dissection and prevent avoidable deaths.

For a report of fatal haemorrhage with streptokinase used in aortic dissection misdiagnosed as empyema, see Haemorrhage under Adverse Effects, above.

1. Butler J, *et al.* Streptokinase in acute aortic dissection. *BMJ* 1990; **300:** 517–19.

Cardiopulmonary resuscitation. Thrombolytics are not recommended after prolonged or traumatic cardiopulmonary resuscitation because of the risk of haemorrhage. However, studies[1,2] in patients given cardiopulmonary resuscitation for cardiac arrest associated with acute myocardial infarction have suggested that thrombolytics are generally safe and that any increase in bleeding complications is outweighed by the benefits of thrombolysis.

1. Cross SJ, *et al.* Safety of thrombolysis in association with cardiopulmonary resuscitation. *BMJ* 1991; **303:** 1242.
2. Kurkciyan I, *et al.* Major bleeding complications after cardiopulmonary resuscitation: impact of thrombolytic treatment. *J Intern Med* 2003; **253:** 128–35.

Pregnancy. Thrombolytics are generally contra-indicated in pregnancy. However there are a few reports of their use and these have been briefly reviewed.[1] In most cases, thrombolytics were given at 28 weeks of pregnancy or later to patients with deep-vein thrombosis, pulmonary embolism, or prosthetic valve thrombosis. There were some reports of favourable maternal and fetal outcomes although therapy was associated with maternal haemorrhage, including spontaneous abortion and minor vaginal bleeding, especially when given near the time of delivery. There was one report of placental abruption with fetal death.

Interactions

Oral anticoagulants, heparin, and antiplatelet drugs such as aspirin are often used with streptokinase, but may increase the risk of haemorrhage. The risk may also be increased with dextrans, and with other drugs that affect coagulation or platelet function.

Pharmacokinetics

Streptokinase is rapidly cleared from the circulation after intravenous use. Clearance is biphasic with the initial and more rapid phase being due to specific antibodies. A half-life of 23 minutes has been reported for the streptokinase-activator complex.

Uses and Administration

Streptokinase is a thrombolytic drug derived from various streptococci. It rapidly activates endogenous plasminogen, indirectly by means of a streptokinase-plasminogen complex, to plasmin (see Fibrinolysin, p.1287), which has fibrinolytic effects and can dissolve intravascular blood clots. The mechanisms of fibrinolysis are discussed further under Haemostasis and Fibrinolysis on p.1045. Streptokinase affects circulating, unbound plasminogen as well as fibrin-bound plasminogen and thus may be termed a fibrin-nonspecific thrombolytic (see p.1156).

Streptokinase is given by intravenous or sometimes intra-arterial infusion in the treatment of thromboembolic disorders such as myocardial infarction (p.1175), peripheral arterial thromboembolism (below), and venous thromboembolism (deep-vein thrombosis and pulmonary embolism) (p.1189). It has also been tried in ischaemic stroke (below), although alteplase is generally preferred. Streptokinase may be used to clear cannulas and shunts and is used topically with streptodornase to clear clots and purulent matter.

In acute **myocardial infarction** streptokinase is usually given intravenously as a single dose of 1.5 million units infused over 1 hour as soon as possible after the onset of symptoms. Streptokinase has also been given in a suitable dose by intracoronary infusion but coronary catheterisation with the aid of angiography is required, thus restricting use to suitably equipped centres.

In the treatment of **pulmonary embolism** and other **arteriovenous occlusions** an initial loading dose of streptokinase, normally 250 000 units infused intravenously over 30 minutes, is given to overcome any resistance due to circulating antibodies. This is followed by infusion of a maintenance dose of 100 000 units/hour for 24 to 72 hours, depending on the condition to be treated; for central retinal thrombosis, 12 hours may be adequate. Treatment should be controlled by monitoring the thrombin clotting time, which should be maintained at 2 to 4 times normal values. Since thrombolytic activity rapidly fades when the infusion stops, streptokinase treatment is generally followed after 3 to 4 hours by intravenous heparin infusion, and then oral anticoagulation, to prevent re-occlusion.

Streptokinase, as a solution containing 250 000 units in 2 mL is used to clear occluded cannulas; 1000 units/mL has been used to clear shunts of occluding thrombi.

Administration in children. There are limited data on the use of systemic thrombolytic therapy for arterial or venous thromboembolism in children and various dosage regimens have been used, based on case studies. The most widely used drugs are streptokinase and alteplase. For streptokinase, the Eighth American College of Chest Physicians (ACCP) Consensus Conference on Antithrombotic Therapy[1] suggests a loading dose of 2000 units/kg to be given intravenously, followed by continuous infusion of 2000 units/kg per hour for 6 to 12 hours. In the UK, the *BNFC* suggests a loading dose of 2500 to 4000 units/kg over 30 minutes, followed by infusion of 500 to 1000 units/kg per hour, continued until reperfusion occurs, up to a maximum of 3 days.

Alteplase may be preferred because of its fibrin specificity and low immunogenicity. The dose of alteplase suggested by the ACCP is 100 to 600 micrograms/kg per hour by continuous intravenous infusion over 6 hours, while the dose recommended by the *BNFC* is 100 to 500 micrograms/kg per hour for 3 to 6 hours. The use of alteplase to clear occluded catheters in children is discussed on p.1208.

Empyema and pleural effusion. Thoracic empyema is treated with antibacterials and pleural drainage. Efficient removal of fluid may be impaired by fibrinous clots within the pleural cavity. Intrapleural instillation of streptokinase (100 000 to 750 000 units in up to 100 mL of sodium chloride 0.9%) has been reported to be effective in small series of patients[1-4] and there have been reports of the successful use of alteplase[5-7] and urokinase.[4,8] However, a double-blind trial[9] involving 454 patients found no benefit with streptokinase, and the role of thrombolytics remains unclear. A meta-analysis[10] found no evidence of benefit, although a systematic review[11] suggested that thrombolytics may reduce the need for surgical intervention. Intrapleural streptokinase has also been used successfully in a few patients with malignant multiloculated pleural effusion resistant to standard pleural drainage.[12]

Intrapericardial instillation of thrombolytics has been tried in a few patients with pericardial empyema to prevent the development of constrictive pericarditis.[13,14]

Intracardiac thrombosis. Thrombosis of prosthetic heart valves (see p.1187) is usually treated surgically, but thrombolytics have also been used. In a study[1] of patients with left-sided prosthetic valve thrombosis, thrombolytic therapy was found to be more successful than surgery, especially in those who were critically ill; most patients were given streptokinase. Another retrospective study[2] in which patients were given streptokinase, urokinase, or alteplase, concluded that thrombolytics were effective but embolic and haemorrhagic complications might limit their use.

Ischaemic heart disease. Thrombolytics such as alteplase, streptokinase, and urokinase have an established role in the early management of acute myocardial infarction (p.1175). Myocardial infarction is caused by coronary artery occlusion, usually due to thrombosis, and thrombolytics are given intravenously to break up the thrombus or clot and restore the patency of the coronary artery, thereby limiting infarct size and irreversible damage to the myocardium. Reduction of ECG abnormalities and modification of ventricular remodelling may also contribute to their effect. Other antithrombotics, in particular aspirin and heparin, are given as adjunctive therapy.

Several large studies have established that thrombolytics can preserve left ventricular function and improve short-term and 1-year mortality figures;[1,2] benefit has been maintained in 5-year[3] and 10-year[4,5] follow-up studies. Benefit is greatest with early treatment. Trials such as the GISSI-1 study[6] and the ISIS-2 study[7] helped to establish that mortality is reduced if thrombolytics are given within 6 hours of the onset of symptoms[8] and further studies provided evidence[9,10] that patients presenting within 12 hours should receive a thrombolytic. Use after 12 hours has been associated with an increase in adverse effects,[8] and is usually reserved for patients with evidence of ongoing ischaemia. Prehospital thrombolysis is feasible and reduces the time to thrombolysis and short-term mortality.[11] Five-year follow-up of one study[12] has suggested that there is also a beneficial effect on long-term mortality.

Choice of thrombolytic depends on factors such as cost, method of administration, and contra-indications. Although streptokinase has been the most widely used, several large studies have compared clinical benefit in terms of improved left ventricular function and mortality and have shown no difference between streptokinase and other thrombolytics, including saruplase,[13] the tissue plasminogen activator alteplase,[14] anistreplase,[15] and reteplase[16] in overall efficacy. In the GUSTO-I study,[17] accelerated or 'front loaded' alteplase (that is, rapid intravenous dosage over 1⁄ hours rather than the conventional 3 hours) was more effective than streptokinase, although the study was criticised for not comparing like with like. On the other hand, alteplase might be associated with a greater risk of stroke than streptokinase.[18] Studies comparing bolus injections of reteplase with accelerated alteplase (GUSTO-III)[19] and tenecteplase with alteplase (ASSENT-2)[20] have also found no difference in mortality rate.

The overall effectiveness of thrombolytics is limited by persistent coronary occlusion, re-occlusion, and bleeding complications. Different thrombolytic regimens, such as bolus injections of reteplase, and combinations of thrombolytics, for example alteplase with streptokinase and alteplase with saruplase, have been investigated in attempts to improve patency rates. However, there has been concern that adverse effects may be higher with bolus injection. A study[21] comparing double-bolus alteplase with accelerated alteplase was terminated early when excess deaths were found in the group receiving bolus injections, and a subsequent meta-analysis[22] found a higher incidence of intracranial haemorrhage associated with bolus doses of various thrombolytics. Although use of thrombolytics before percutaneous coronary intervention (PCI) does not appear to be beneficial, a small study[23] has suggested that intracoronary streptokinase given immediately after PCI may improve microvascular reperfusion; however, there was no effect on clinical outcomes.

Thrombolytics have also been tried in other acute coronary syndromes, including unstable angina and non-ST elevation myocardial infarction (p.1157). Although small-scale studies reported some benefit the results were variable, and an overview[8] of trials in patients with suspected myocardial infarction, which included some patients with unstable angina, found that there was no mortality benefit in patients without ST elevation. In 2 studies that investigated alteplase (the TIMI-IIIB study[24] with 1473 patients) and anistreplase (the UNASEM study[25] involving 159 patients), thrombolysis failed to improve outcome and was associated with an excess of bleeding complications. Thrombolytic therapy is therefore not recommended for patients with unstable angina or non-ST elevation myocardial infarction.

Peripheral arterial thromboembolism. Thrombolytics including streptokinase may be used in the management of peripheral arterial thromboembolism (p.1178). Streptokinase has been injected intravenously or intra-arterially directly into the clot as an alternative to surgical treatment of the occlusion. It has also been infused intra-arterially to remove distal clots during surgery. The *intravenous* dose generally used is 250 000 units over 30 minutes followed by 100 000 units/hour. A lower dose of 5000 units/hour has been used *intra-arterially* directly into the clot[1] and for removal of distal clots during surgery streptokinase has been given intra-arterially in a dose of 100 000 units over 30 minutes or as five bolus doses of 20 000 units at 5-minute intervals.[2]

Stroke. Stroke (p.1185) is normally considered a contra-indication to the use of thrombolytics, and clearly they would be inappropriate in acute haemorrhagic stroke. However, when stroke is associated with thrombotic occlusion there is evidence, as with myocardial infarction, that a degree of neuronal recovery is possible if the occlusion is reversed sufficiently quickly, and thrombolytics may therefore have a role in some patients with acute ischaemic stroke.

Early studies with intravenous thrombolytics in acute *ischaemic stroke* suggested a reduction in early death, although subsequent randomised trials produced disappointing results, with the exception of one with alteplase given within 3 hours of the onset of stroke (NINDS—National Institute of Neurological Disorders and Stroke rt-PA Stroke Trial).[1] The studies using streptokinase—MAST-E (Multicentre Acute Stroke Trial-Europe),[2] ASK (Australian Streptokinase Trial),[3] and MAST-I (Multicentre Acute Stroke Trial-Italy)[4,5]—were terminated before completion because of adverse outcomes (intracranial bleeding and increased mortality) in the treatment groups, particularly in those receiving therapy more than 3 hours after stroke onset.[3] The study investigating alteplase given within 6 hours of the onset of symptoms (ECASS I—European Cooperative Acute Stroke Study)[6] reported that, although some patients might benefit, overall alteplase was associated with higher mortality rates and an increase in some intracranial bleeding (parenchymal haemorrhage). In the NINDS randomised study,[1] alteplase given within 3 hours of the onset of ischaemic stroke appeared to improve clinical outcome despite an increased incidence of symptomatic intracerebral haemorrhage. Patients treated with alteplase were more likely to have minimal or no disability 3 months after stroke,[1] and this benefit was maintained at 12 months.[7] However, there was no difference in mortality or rate of recurrence of stroke. A second ECASS study (ECASS II)[8] that hoped to confirm the early findings of the NINDS study failed to confirm a statistical benefit for alteplase over placebo and found no significant differences between patients who received alteplase within 3 hours or between 3 and 6 hours. A review[9] of several studies confirmed that alteplase needed to be given early, and preferably within 90 minutes, if it was to be effective.

On the basis of the NINDS study, alteplase given within 3 hours of the onset of ischaemic stroke is now recommended for selected patients in most guidelines on stroke management.[10-14] Despite their own disappointing results, the ECASS II investigators reached a similar conclusion. However, these recommendations have been criticised.[15,16] It has been pointed out[17,18] that very few patients will be eligible for treatment with alteplase, since the time of onset of symptoms is often uncertain and in many patients more than 3 hours elapses before a definite diagnosis of ischaemic stroke is made. In addition, the NINDS study[1] excluded patients with severe stroke and those taking anticoagulants. The rationale for exclusion of patients with severe stroke is that haemorrhagic transformation is more likely to occur with large areas of infarction.[17] However, size of infarct is difficult to identify by CT scanning.[17] Anticoagulants or antiplatelets are also contra-indicated in the first 24 hours after use of alteplase. The poor results obtained in studies using streptokinase have led to recommendations that streptokinase should be avoided in ischaemic stroke,[13] although an overview of thrombolytic studies[18] suggested that it may not be worse than alteplase and that the apparent hazards of streptokinase may be accounted for by differences in trial design (for example use with anticoagulants) and in patient population. Thus, while alteplase can be considered for those few patients meeting the entry criteria for the NINDS study, a systematic review[19] concluded that further large studies are required to establish more clearly the overall role of thrombolytics in acute ischaemic stroke. Studies of the use of alteplase outside the setting of a clinical trial have had mixed results.[20-22] However, an observational study[23] found that alteplase was safe and effective when used in accordance with guidelines, while another study[24] found that it could be used in elderly patients (80 years-of-age and older), a group normally excluded from clinical trials.

Intra-arterial thrombolytics may have advantages over intravenous use and may be used in selected patients.[12-14] Studies with nasaruplase[25] and urokinase[26] have suggested benefit up to 6 hours after stroke due to middle cerebral artery occlusion, and use of intra-arterial thrombolytics may therefore be considered in such patients.[12-14] Intra-arterial thrombolytics are also used in basilar artery occlusion, although evidence to support this is limited;[12,13,27] intravenous alteplase may be an alternative.[28] Combined use of intravenous and intra-arterial alteplase,[29] as well as use of adjunctive therapies such as therapeutic ultrasound[30] or antithrombotics, are under investigation but do not yet have an established role.[13]

Intravenous thrombolytics have no role in the management of acute *haemorrhagic stroke*, but they have been given locally to facilitate the aspiration of haematomas in both intracerebral[31] and subarachnoid haemorrhage. Small studies with urokinase have shown benefit in patients with intraventricular haemorrhage.

Strophanthin-K

Estrofantina; Kombé Strophanthin; Strophanthin; Strophanthoside-K.

CAS — 11005-63-3.

NOTE. Do not confuse with K-strophanthin-α which is Cymarin.

Pharmacopoeias. In *Chin.*

Profile

Strophanthin-K is a cardiac glycoside or a mixture of cardiac glycosides from strophanthus, the seeds of *Strophanthus kombe* (Apocynaceae) or other spp., adjusted by admixture with a suitable diluent such as lactose so as generally to possess 40% of the activity of anhydrous ouabain.

Strophanthin-K is a positive inotrope with general properties similar to those of digoxin (p.1259). It is poorly absorbed from the gastrointestinal tract but may be given intravenously in maintenance doses of 125 to 250 micrograms daily in the management of heart failure (p.1165).

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Kombetin.

Suleparoid *(rINNM)*

Heparan Sulfate; Heparan Sulphate; Heparitin Sulfate; Suléparoïde; Suleparoide; Suleparoidum.

Сулепароид

CAS — 9050-30-0.

Suleparoid Sodium *(rINN)*

Heparan Sulfate Sodium; Sodium Heparitin Sulphate; Suleparoide sódico; Suléparoïde Sodique; Suleparoidum Natricum.

Сулепароид Натрий

CAS — 57459-72-0.

Profile

Suleparoid is a naturally occurring glycosaminoglycan given orally in the management of thromboembolic disorders; it is also used topically. Suleparoid sodium is a component of danaparoid sodium (p.1255).

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Aremin; Arteven; Clarema; Hemovasal; Leparan†; Spatix†; Tavidan; Vas; Vasorema†.

Multi-ingredient: ***Ital.:*** Osmogel.

Sulodexide *(rINN)*

KRX-101; Sulodexida; Sulodexidum. Glucurono-2-amino-2-deoxyglucoglucan sulfate.

Сулодексид

CAS — 57821-29-1.
ATC — B01AB11.
ATC Vet — QB01AB11.

Profile

Sulodexide is a heparinoid consisting of a mixture of low-molecular-weight heparin and dermatan sulfate. It is used as a hypolipidaemic and antithrombotic and has been given orally and parenterally for peripheral vascular disease and cerebrovascular disease. It is also included in preparations used topically for local vascular inflammation and soft-tissue disorders. Sulodexide has also been investigated for the treatment of diabetic nephropathy.

Sympathomimetics ⊗

Adverse Effects

Sympathomimetics may produce a wide range of adverse effects, generally resembling the effect of excessive stimulation of the sympathetic nervous system. These effects are mediated by the different types of adrenergic receptor, and the effects of individual drugs depend to a large extent on their relative activity at the different receptors, as well as the body's homoeostatic response. While many sympathomimetics are relatively selective for specific receptors, this depends on the dose, and at higher doses most have effects on all receptors.

Central effects may occur with all sympathomimetics and include anxiety, fear, restlessness, insomnia, confusion, irritability, headache, and psychotic states; dyspnoea, weakness, anorexia, nausea, and vomiting are also common. Although some sympathomimetics have direct effects, others do not cross the blood-brain barrier and their central effects appear to be a somatic response.

The most important adverse effects of the sympathomimetics are those that affect the cardiovascular system. Palpitations, tachycardia, and arrhythmias mainly result from stimulation of cardiac beta receptors, and there is also an increase in cardiac contractility; this may result in angina or cardiac arrest.

The effects on blood vessels depend on the relative effects at alpha and beta receptors, since most blood vessels have both. Stimulation of alpha receptors produces vasoconstriction, with resultant hypertension, and this may be severe enough to lead to cerebral haemorrhage or pulmonary oedema, particularly in overdosage. There may also be reflex bradycardia. Conversely, hypotension, with dizziness and fainting, and flushing, may occur due to beta$_2$-induced vasodilatation, and may contribute to tachycardia.

Alpha-mediated vasoconstriction causes cold extremities, since blood vessels supplying the skin and mucosa have only alpha receptors; this may lead to gangrene, particularly when sympathomimetics are infiltrated into digits. Extravasation similarly may cause tissue necrosis and sloughing. Topical application to mucosal surfaces also causes vasoconstriction, pain, and irritation; hypoxia may lead to rebound mucosal congestion.

Other effects include mydriasis, difficulty in micturition and urinary retention, piloerection, sweating, and increased salivation, all of which result from alpha$_1$ stimulation. Hypokalaemia and muscle tremor may occur as a result of beta$_2$ stimulation, although tremor may also occur as a somatic response. Effects on the uterus are complex and depend on the stage of the menstrual cycle; labour may be inhibited by beta$_2$ stimulation. Hyperglycaemia may occur due to complex metabolic effects, and lactic acidosis has also been reported.

Effects on the heart. The heart has mainly beta$_1$ adrenoceptors and cardiac arrhythmias are most likely with beta$_1$ agonists; increased mortality has been reported with the use of beta agonists in heart failure (see Ibopamine, p.1312). A review[1] of vasopressor sympathomimetics, which are mainly used for their alpha-agonist properties, concluded that dopamine and adrenaline were associated with the highest risk, mainly of dose-related sinus tachycardia and ventricular arrhythmias. However, the clinical significance of most arrhythmias occurring with dopamine was considered questionable; supraventricular or ventricular arrhythmias with adrenaline were most likely in patients receiving general anaesthesia or with underlying disorders of cardiac conduction. The risk with noradrenaline was uncertain, though there are few clinical reports, while phenylephrine and methoxamine were thought unlikely to cause problems. Overall the frequency of serious problems with this class of drugs did not seem to be high, and benefits outweighed the risks in most patients.

Sympathomimetics may cause myocardial ischaemia, particularly in patients with ischaemic heart disease, and severe cardiovascular effects have occurred with the use of dobutamine for cardiac stress testing (see Diagnosis and Testing, p.1272). In addition, myocardial infarction has been reported in an 11-year-old boy treated with nebulised racepinefrine for symptoms of croup,[2] and there have also been reports of myocardial ischaemia associated with adrenaline overdosage (see p.1203).

Topical use. Systemic effects may occasionally follow the local or topical use of sympathomimetics, for example as eye drops for the treatment of glaucoma.[1] Psychiatric effects including hallucinations and paranoia have also occurred after both proper and improper use of sympathomimetics in decongestant preparations.[2]

2. Anonymous. Drugs that cause psychiatric symptoms. *Med Lett Drugs Ther* 1993; **35:** 65–70.

Treatment of Adverse Effects

Most sympathomimetics have a short duration of action and treatment of adverse effects is mainly supportive; if given by infusion, stopping it or reducing the rate will be sufficient in many cases. A rapidly-acting alpha blocker, such as phentolamine, may be given to reverse alpha$_1$-mediated effects such as hypertension, while a beta blocker may be given for beta$_1$-mediated effects such as cardiac arrhythmias. In severe hypertension, rapidly-acting vasodilators such as glyceryl trinitrate have also been used.

In the case of extravasation of an alpha agonist, or injection into a digit, an alpha blocker such as phentolamine should be given as soon as possible to prevent tissue necrosis and ischaemic damage.

Non-catecholamine sympathomimetics may have a longer duration of action and adverse effects, particularly hypertension, may be prolonged.

Precautions

Sympathomimetics should be used with caution in patients with cardiovascular disorders, who may have an increased susceptibility to their effects. Particular care is needed in patients with cardiac arrhythmias, ischaemic heart disease, or hypertension. All sympathomimetics should generally be avoided in severe hypertension, although alpha agonists are particularly hazardous; they should also be used with caution in patients with occlusive vascular disease, who are at increased risk of peripheral ischaemia. Beta$_1$ agonists are a particular hazard in tachycardia. Sympathomimetics with beta$_2$ effects should be used with caution in obstructive cardiomyopathy and other disorders where a reduction in total peripheral resistance could be harmful.

Sympathomimetics should be avoided in phaeochromocytoma. Caution is also needed in patients with hyperthyroidism, who may be at increased risk of effects on the heart; elevated thyroid hormone concentrations may also enhance adrenoceptor sensitivity. Diabetics and elderly patients have a high incidence of atherosclerotic disease and may also be at higher risk; the effects of sympathomimetics on blood glucose should also be considered.

Alpha agonists in particular should be used with caution in angle-closure glaucoma, as well as in patients with prostate disorders, who may be at increased risk of urinary retention. Sympathomimetics with vasoconstrictor effects may reduce placental perfusion and should possibly be avoided in pregnancy; adrenaline and others with beta$_2$-mediated effects may also inhibit labour.

If sympathomimetics are used for circulatory support, hypovolaemia, metabolic acidosis, and hypoxia or hypercapnia should be corrected either before starting the sympathomimetic or while it is being given. Blood pressure should be monitored regularly during treatment.

Interactions

Interactions with sympathomimetics are complex and may be hazardous; they result mainly from their pharmacological actions at alpha and beta receptors.

Increased cardiac effects may occur with drugs that increase the sensitivity of the myocardium to beta$_1$ agonists; hazardous arrhythmias may occur with volatile anaesthetics, particularly cyclopropane or halothane. Caution is also required with thyroid hormones, and with drugs that affect cardiac conduction, such as cardiac glycosides and antiarrhythmics.

All sympathomimetics affect blood pressure and should be used with caution with antihypertensive drugs or drugs that cause hypotension, particularly those whose action involves the sympathetic nervous system. Direct-acting sympathomimetics with alpha-agonist actions specifically reverse the hypotensive effect of adrenergic neurone blockers such as guanethidine, and severe hypertension may result. There are also complex interactions between both alpha and beta blockers and sympathomimetics, particularly those that have actions at both types of receptor. Alpha blockers antagonise the effects at alpha receptors but leave the beta-mediated effects unopposed, leading to an increased risk of hypotension and tachycardia. Beta blockers, especially those that are non-selective, antagonise the effects at beta receptors but leave the alpha-mediated effects unopposed, increasing the risk of hypertension and reflex bradycardia. They also antagonise the bronchodilating effects of beta$_2$ agonists. Severe anaphylaxis in patients taking non-cardioselective beta blockers may not respond to adrenaline (see below).

Hazardous interactions resulting in severe hypertension may occur with MAOIs (including RIMAs) and sympathomimetics, especially those that have indirect actions, since MAOIs increase the amount of noradrenaline stored in adrenergic nerve endings. Sympathomimetics for which the risk is particularly high include dexamfetamine, dopamine, dopexamine, ephedrine, isometheptene, mephentermine, metaraminol, methylphenidate, phentermine, phenylephrine, phenylpropanolamine, and pseudoephedrine. The effects of direct-acting sympathomimetics such as adrenaline and noradrenaline may also be slightly enhanced. For additional warnings see under Phenelzine (p.418) and Moclobemide (p.411).

Tricyclic antidepressants block the inactivation of adrenaline and noradrenaline by uptake into the nerve endings and may increase their effect; hypertension and arrhythmias may occur. Conversely, the effect of indirectly-acting sympathomimetics could theoretically be reduced by tricyclics, although there is little clinical evidence that this occurs. There is also no evidence that an interaction occurs when local anaesthetic solutions containing adrenaline or noradrenaline are used in patients taking MAOIs or tricyclics, although great care needs to be taken to avoid inadvertent intravenous injection of these local anaesthetic preparations.

Interactions may also occur between sympathomimetics and drugs that have similar or opposing effects through non-adrenergic mechanisms. Sympathomimetics with central actions may potentiate the effects of CNS stimulants, while the vasoconstrictor and pressor effects of alpha agonists may be enhanced by drugs with similar effects, such as ergot alkaloids or oxytocin. Beta$_2$-mediated hypokalaemia may be potentiated by other drugs that cause potassium loss, including corticosteroids, potassium-depleting diuretics, and aminophylline or theophylline; patients given high doses of beta$_2$ agonists with such drugs should have their plasma-potassium concentration monitored (see Interactions of Salbutamol, p.1132). Hypokalaemia may also contribute to the increased susceptibility to cardiac arrhythmias caused by digoxin and other cardiac glycosides.

Antiparkinsonian drugs. Additive cardiovascular toxicity may occur when some sympathomimetics are given with antiparkinsonian drugs such as *levodopa* (see p.808) and *bromocriptine* (see p.800). Severe hypertension may also occur with some sympathomimetics and *selegiline* (see p.818), possibly due to inhibition of peripheral monoamine oxidase.

Beta blockers. The interactions between beta blockers and sympathomimetics are complex and depend on the selectivity of both drugs. Patients given adrenaline (including the low doses used with local anaesthetics) while taking non-selective beta blockers such as *propranolol* can develop raised blood pressure due to alpha-mediated vasoconstriction, followed by reflex bradycardia, and occasionally cardiac arrest;[1] the bronchodilator effects of adrenaline and other beta$_2$ agonists are also inhibited. In contrast, cardioselective beta blockers such as *metoprolol*, have minimal effects on blood pressure and heart rate since they only inhibit the beta$_1$- mediated effects, leaving the beta$_2$-mediated vasodilatation to balance the vasoconstrictor effect. However, beta blockers that also have alpha-blocking effects, such as *carvedilol*, may cause hypotension since only the beta$_2$-induced vasodilatation remains; such an interaction has been reported with dobutamine.[2] Low doses of cardioselective beta blockers do not appear to interfere with sympathomimetic (isoprenaline)-induced bronchodilatation,[3] although the effect of larger doses is uncertain.

Propranolol has also been shown to inhibit the favourable pressor and bronchodilator responses to adrenaline when given for anaphylaxis.[4] Thus, patients on long-term treatment with some non-cardioselective beta blockers who develop anaphylaxis may be relatively refractory to adrenaline.

4. Newman BR, Schultz LK. Epinephrine-resistant anaphylaxis in a patient taking propranolol hydrochloride. *Ann Allergy* 1981; **47:** 35–7.

General anaesthetics. Anaesthesia may sensitise the myocardium to the effects of sympathomimetics, increasing the risk of arrhythmias, and fatalities have been attributed to the use of adrenaline with *halothane* anaesthesia.[1] It has been suggested[2] that the use of adrenaline for haemostasis during surgery is a particular risk, although use of a low dose may be safe in patients anaesthetised with *cyclopropane*, *halothane*, or similar volatile anaesthetics; other factors likely to increase the irritability of the myocardium, such as carbon-dioxide retention, hypoxia, or the use of cocaine, should be avoided.[2,3] For *halothane* or *trichloroethylene* anaesthesia a maximum strength for the adrenaline solution of 1 in 100 000, given at a rate not exceeding 10 mL in any 10-minute period or 30 mL in 1 hour, has been recommended;[3] this may also apply for cyclopropane, although the risk of arrhythmias is higher.[3] Other volatile anaesthetics generally appear to carry less risk.

Theophylline. For discussion of possible interactions between sympathomimetics with beta-agonist actions and theophylline, see p.1145.

Vasodilators. Paradoxical hypotension may occur when sympathomimetics with both alpha- and beta-agonist properties are given with *tolazoline*, and there has been a report[1] of fatal hypotension in a patient given tolazoline and dopamine together. The mechanism of the interaction appears to be antagonism of the alpha-mediated vasoconstrictor effect of the sympathomimetic by the alpha-blocking effects of tolazoline, leaving the vasodilator effects unopposed.

1. Carlon GC. Fatal association of tolazoline and dopamine. *Chest* 1979; **76:** 336.

Actions and Uses

Sympathomimetics have actions that mimic the effects of stimulation of postganglionic (adrenergic) nerves. They include the endogenous catecholamines adrenaline, noradrenaline, and dopamine, and other drugs that directly stimulate adrenergic receptors, as well as drugs that have an indirect action by stimulating the release of noradrenaline from storage vesicles in adrenergic nerve endings. Phenylephrine is an example of a direct-acting sympathomimetic, whereas ephedrine and many other sympathomimetics have both direct and indirect effects.

The endogenous sympathomimetics are catecholamines, consisting of a catechol portion (characterised by hydroxy groups at adjacent positions on a benzene ring) and an aliphatic amine portion. Adrenaline and noradrenaline both have direct actions on adrenergic receptors, whereas dopamine has direct and indirect actions, as well as stimulating specific dopamine receptors. Although sympathetic nerves are generally termed adrenergic, the principal neurotransmitter is actually noradrenaline; it also acts as a neurotransmitter in the CNS. The major physiological role of adrenaline is metabolic. Dopamine is an important neurotransmitter within the CNS, but also has a role peripherally within the renal, mesenteric, and coronary vasculature.

Adrenergic receptors are classified as either alpha or beta receptors, and these are subdivided into a number of types. Dopamine receptors are a distinct group of receptors that are mainly found in the CNS, and at least 5 subtypes are known (see p.791); D$_1$ receptors also occur in some vascular beds. The effects of adrenergic stimulation depend on the location and activity of the receptors:

- alpha$_1$ receptors are found primarily in blood vessels, as well as in the skin, eye, bladder, uterus, and liver. Stimulation leads to vasoconstriction, particularly in the vessels of the skin and mucosa, abdominal viscera, and kidney; this results in an increase in blood pressure, sometimes with compensatory reflex bradycardia. Alpha$_1$ stimulation also results in contraction of other smooth muscle, including the urinary sphincter and the uterus, and induces mydriasis in the eye
- alpha$_2$ receptors are mainly found presynaptically. Stimulation appears to play a role in feedback inhibition of neurotransmitter release and may be involved in the inhibition of intestinal activity; it also plays a role in the inhibition of insulin secretion
- beta$_1$ receptors are found predominantly in the heart. Stimulation produces an increase in the rate and force of contraction, increased conduction velocity, and greater automaticity
- beta$_2$ receptors are mainly found in blood vessels and the lung, as well as in the uterus, the gastrointestinal tract, the liver, and the ciliary body of the eye. Stimulation leads to vasodilatation, bronchodilatation, uterine relaxation, and a decrease in gastrointestinal motility; it also results in release of insulin and enhances gluconeogenesis and glycogenolysis
- beta$_3$ receptors are found in fat cells and are thought to have a role in lipolysis and thermogenesis; they have also been found in the heart, uterus, and bladder but their role is not clear
- D$_1$ receptors are found in the renal, mesenteric, and coronary vascular beds. Stimulation leads to vasodilatation

Sympathomimetics differ in their relative affinity for each type of receptor, and also in whether they have direct or indirect actions (see Table 5, below). Their effects generally reflect these characteristics, although both may depend on the dose. Feedback mechanisms and the homoeostatic response of the body are also important. The specific effects of the different sympathomimetics are described in more detail in the individual monographs.

The endogenous catecholamines all have a very short action and are inactive by mouth; they are also highly polar and do not cross the blood-brain barrier. Other sympathomimetics are analogues of catecholamines but generally have a longer duration of action and are orally active; many also cross the blood-brain barrier and have central effects. For example, dexamfetamine has marked central stimulant effects, while the seemingly paradoxical antihypertensive action of alpha$_2$ agonists such as clonidine may be due to central effects that outweigh their effects in vascular smooth muscle.

The differing characteristics of the sympathomimetics mean that they are used in a wide range of disorders. Those with alpha$_1$-agonist effects are mainly used to increase the blood pressure in hypotensive disorders and in shock (p.1183). Some alpha agonists, such as phenylephrine (p.1568), are also applied topically to produce vasoconstriction of mucosal surfaces and are used for the symptomatic relief of nasal congestion and in eye disorders; they may also be used as mydriatics. Alpha$_2$ agonists are used as central antihypertensives (see Clonidine, p.1247), or in the treatment of glauco-

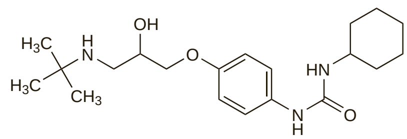
ma (see Apraclonidine, p.1877). Beta$_1$ agonists are mainly used for their inotropic actions in acute heart failure and shock, while beta$_2$ agonists such as salbutamol (p.1131) are used for their bronchodilator effects and as uterine relaxants in premature labour. Sympathomimetics with mainly CNS effects may be used as central stimulants (see Dexamfetamine, p.2153).

Talinolol *(rINN)* ⊗

Talinololum. (±)-1-{*p*-[3-(*tert*-Butylamino)-2-hydroxypropoxy]-phenyl}-3-cyclohexylurea.

Талинолол

$C_{20}H_{33}N_3O_3$ = 363.5.
CAS — 57460-41-0.
ATC — C07AB13.
ATC Vet — QC07AB13.



Profile

Talinolol is a cardioselective beta blocker (p.1225). It is given orally in the management of hypertension (p.1171) and other cardiovascular disorders, in doses of up to 300 mg daily. It has also been given intravenously.

Preparations

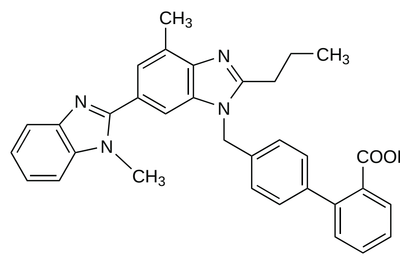
Telmisartan *(BAN, USAN, rINN)*

BIBR-277; BIBR-277-SE; Telmisartaani; Telmisartán; Telmisartanum. 4′-{[4-Methyl-6-(1-methyl-2-benzimidazolyl)-2-propyl-1-benzimidazolyl]methyl}-2-biphenylcarboxylic acid.

Тельмизартан

$C_{33}H_{30}N_4O_2$ = 514.6.
CAS — 144701-48-4.
ATC — C09CA07.
ATC Vet — QC09CA07.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Telmisartan). A white or slightly yellowish, crystalline powder. Practically insoluble in water; slightly soluble in methyl alcohol; sparingly soluble in dichloromethane. it dissolves in 1M sodium hydroxide. It exhibits polymorphism.

Adverse Effects and Precautions

As for Losartan Potassium, p.1326. Telmisartan should be used with caution in patients with hepatic impairment or biliary obstruction.

◊ References.

1. Michel MC, *et al.* Safety of telmisartan in patients with arterial hypertension : an open-label observational study. *Drug Safety* 2004; **27:** 335–44.

Interactions

As for Losartan Potassium, p.1327.

Digoxin. Telmisartan may increase serum concentrations of digoxin (see Angiotensin II Receptor Antagonists under Interactions of Digoxin, p.1261) but the interaction is probably not clinically significant.

Pharmacokinetics

Telmisartan is rapidly absorbed from the gastrointestinal tract; the absolute oral bioavailability is dose-dependent and is about 42% after a 40-mg dose and 58% after a 160-mg dose. Peak plasma concentrations of telmisartan are reached about 0.5 to 1 hour after an oral dose. Telmisartan is over 99% bound to plasma proteins. It is excreted almost entirely in the faeces via bile, mainly as unchanged drug. The terminal elimination half-life of telmisartan is about 24 hours.

◊ References.

1. Stangier J, *et al.* Absorption, metabolism, and excretion of intravenously and orally administered [C]telmisartan in healthy volunteers. *J Clin Pharmacol* 2000; **40:** 1312–22.

Uses and Administration

Telmisartan is an angiotensin II receptor antagonist with actions similar to those of losartan (p.1327). It is used in the management of hypertension (p.1171).

Telmisartan is given orally. After a dose the hypotensive effect peaks within 3 hours and persists for at least 24 hours. The maximum hypotensive effect occurs within about 4 to 8 weeks after starting therapy.

In hypertension, telmisartan is given in an initial dose of 40 mg once daily. This may be increased, if necessary, to a maximum dose of 80 mg once daily. Lower doses should be considered in patients with hepatic or renal impairment (see below).

6. Francischetti EA, *et al.* Treatment of hypertension in individuals with the cardiometabolic syndrome: role of an angiotensin II receptor blocker, telmisartan. *Expert Rev Cardiovasc Ther* 2008; **6:** 289–303.

Administration in hepatic or renal impairment. Giving telmisartan to patients with hepatic impairment resulted in an increase in bioavailability and a reduction in clearance compared with healthy subjects.[1] Although telmisartan was well tolerated, it was suggested that lower doses should be considered in patients with hepatic impairment. In the UK telmisartan is contra-indicated in severe hepatic impairment and a maximum dose of 40 mg once daily is recommended for patients with mild to moderate impairment

Telmisartan appears to be well tolerated in patients with renal impairment, including those on dialysis.[2] However, in the UK, an initial dose of 20 mg once daily is recommended for patients with severe renal impairment or on haemodialysis.

As for Streptokinase, p.1404

Pharmacokinetics

After intravenous injection in patients with acute myocardial infarction, tenecteplase has a biphasic clearance from plasma with an initial half-life of 20 to 24 minutes and a terminal phase half-life of 90 to 130 minutes. It is cleared mainly by hepatic metabolism.

◊ Reviews.

1. Tanswell P, *et al.* Pharmacokinetics and pharmacodynamics of tenecteplase in fibrinolytic therapy of acute myocardial infarction. *Clin Pharmacokinet* 2002; **41:** 1229–45.

Uses and Administration

Tenecteplase is a thrombolytic drug. It converts plasminogen to plasmin, a proteolytic enzyme that has fibrinolytic effects. The mechanisms of fibrinolysis are discussed further under Haemostasis and Fibrinolysis on p.1045. Tenecteplase is a fibrin-specific thrombolytic (see p.1156).

Tenecteplase is used similarly to streptokinase (p.1404) in acute myocardial infarction (p.1175). It is given intravenously as a single bolus dose over 5 to 10 seconds as soon as possible after the onset of symptoms. The dose is based on body-weight and ranges from 30 mg in patients less than 60 kg to a maximum of 50 mg in those 90 kg or above.

Tenitramine

Tenitramina. *NNN′N′*-Tetrakis(2-hydroxyethyl)ethylenediamine tetranitrate.

$C_{10}H_{20}N_6O_{12}$ = 416.3.
CAS — 21946-79-2.
ATC — C01DA38.
ATC Vet — QC01DA38.

Profile

Tenitramine is a vasodilator with general properties similar to those of glyceryl trinitrate (p.1296) that has been used in angina pectoris (p.1157).

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Tenitran†.

Teprotide *(BAN, USAN, rINN)*

BPF_{9a}; L-Pyroglutamyl-L-tryptophyl-L-prolyl-L-arginyl-L-prolyl-L-glutaminyl-L-isoleucyl-L-prolyl-L-proline; SQ-20881; Teprotida; Téprotide; Teprotidum; 2-L-Tryptophan-3-de-L-leucine-4-de-L-proline-8-L-glutaminebradykinin potentiator B. 5-oxo-Pro-Trp-Pro-Arg-Pro-Gln-Ile-Pro-Pro.

Тепротид

$C_{53}H_{76}N_{14}O_{12}$ = 1101.3.
CAS — 35115-60-7.

Profile

Teprotide is a nonapeptide originally found in the venom of *Bothrops jararaca*, a South American pit-viper. It is an ACE inhibitor with a short duration of action and has been given parenterally as an investigational tool.

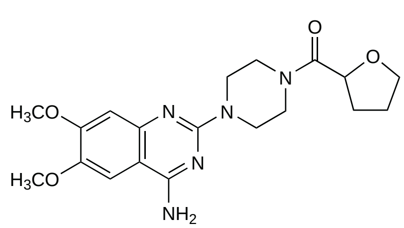
Terazosin Hydrochloride

(BANM, USAN, rINNM)

Abbott-45975; Hidrocloruro de terazosina; Teratsosiinihydrokloridi; Terazosin Hidroklorür; Térazosine, chlorhydrate de; Terazosinhydroklorid; Terazosini hydrochloridum. 1-(4-Amino-6,7-dimethoxyquinazolin-2-yl)-4-(tetrahydro-2-furoyl)piperazine hydrochloride dihydrate; 6,7-Dimethoxy-2-[4-(tetrahydrofuran-2-carbonyl)piperazin-1-yl]quinazolin-4-ylamine hydrochloride dihydrate.

Теразозина Гидрохлорид

$C_{19}H_{25}N_5O_4,HCl,2H_2O$ = 459.9.
CAS — 63590-64-7 (terazosin); 63074-08-8 (anhydrous terazosin hydrochloride); 70024-40-7 (terazosin hydrochloride dihydrate).
ATC — G04CA03.
ATC Vet — QG04CA03.



(terazosin)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Terazosin Hydrochloride Dihydrate). White or slightly yellow, crystalline powder. Sparingly soluble in water; very slightly soluble in alcohol; slightly soluble in methyl alcohol; practically insoluble in acetone. A 2% solution in water has a pH of 3.0 to 5.0. Protect from light.

USP 31 (Terazosin Hydrochloride). A white to pale yellow, crystalline powder. soluble in water and in methyl alcohol; freely soluble in isotonic saline solution; slightly soluble in alcohol and in 0.1N hydrochloric acid; practically insoluble in acetone and in hexanes; very slightly soluble in chloroform. Store in airtight containers at a temperature between 20° and 25°.

Adverse Effects, Treatment, and Precautions

As for Prazosin Hydrochloride, p.1375.

Urinary incontinence. For reference to urinary incontinence associated with terazosin, see under Adverse Effects of Prazosin Hydrochloride, p.1375.

Interactions

As for Prazosin Hydrochloride, p.1376.

Pharmacokinetics

Terazosin is rapidly and almost completely absorbed from the gastrointestinal tract after oral doses; the bioavailability is reported to be about 90%. Peak plasma concentrations are achieved in about 1 hour. Terazosin is 90 to 94% protein bound. It is metabolised in the liver; one of the metabolites is reported to possess antihypertensive activity. The half-life in plasma is about 12 hours. Terazosin is excreted in faeces via the bile, and in the urine, as unchanged drug and metabolites.

Uses and Administration

Terazosin is an alpha$_1$-adrenoceptor blocker (p.1153) with actions similar to those of prazosin (p.1376), but a longer duration of action.

It is used in the management of hypertension (p.1171) and in benign prostatic hyperplasia (p.2178) to relieve symptoms of urinary obstruction.

Terazosin is given orally as the hydrochloride, but doses are usually expressed in terms of the base. Terazosin hydrochloride 1.2 mg is equivalent to about 1 mg of terazosin. After oral doses its hypotensive effects are seen within 15 minutes and may last for up to 24 hours, permitting once daily dosage.

To avoid the risk of collapse which may occur in some patients after the first dose the initial dose for both hypertension and benign prostatic hyperplasia is 1 mg of terazosin at bedtime, increasing gradually at intervals of 7 days according to the patient's response. For **hypertension** the usual maintenance dose is 2 to 10 mg once daily and the usual maximum dose is 20 mg daily in a single dose or two divided doses. For **benign prostatic hyperplasia** the usual maintenance dose is 5 to 10 mg once daily.

CAS — 6964-20-1.

ATC — C10AX03.

ATC Vet — QC10AX03.

Profile

Tiadenol is a lipid regulating drug used in the treatment of hyperlipidaemias (p.1169). The usual oral dose is 1.2 to 2.4 g daily in divided doses.

Preparations

Proprietary Preparations (details are given in Part 3)

Fr.: Fonlipol.

Ticlopidine Hydrochloride

(BANM, USAN, rINNM)

4-C-32; 53-32C; Hidrocloruro de ticlopidina; Ticlopidine, chlorhydrate de; Ticlopidini hydrochloridum; Tiklopidiinihydrokloridi; Tiklopidin Hidroklorür; Tiklopidinhidroklorid; Tiklopidin-hydrochlorid; Tiklopidinhydroklorid; Tiklopidino hidrochloridas. 5-(2-Chlorobenzyl)-4,5,6,7-tetrahydrothieno[3,2-*c*]pyridine hydrochloride.

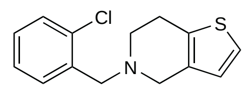
Тиклопидина Гидрохлорид

$C_{14}H_{14}ClNS,HCl = 300.2.$

CAS — 55142-85-3 (ticlopidine); 53885-35-1 (ticlopidine hydrochloride).

ATC — B01AC05.

ATC Vet — QB01AC05.



(ticlopidine)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *Jpn.*

Ph. Eur. 6.2 (Ticlopidine Hydrochloride). A white or almost white, crystalline powder. Sparingly soluble in water and in dehydrated alcohol; very slightly soluble in ethyl acetate. A 2.5% solution in water has a pH of 3.5 to 4.0.

Adverse Effects and Precautions

Gastrointestinal disturbances, skin rashes, and bleeding are the most commonly reported adverse effects associated with ticlopidine therapy. Blood dyscrasias, including neutropenia, thrombotic thrombocytopenic purpura, and aplastic anaemia, have also occurred. There have been reports of hepatitis and cholestatic jaundice. Blood-lipid concentrations may increase during long-term therapy.

Ticlopidine should not be given to patients with haematopoietic disorders such as neutropenia or thrombocytopenia, haemorrhagic diathesis or other haemorrhagic disorders associated with a prolonged bleeding time, or conditions with an increased risk of bleeding such as peptic ulcer disease, acute cerebral haemorrhage, or severe liver dysfunction. Full blood counts should be performed before starting treatment and every 2 weeks during the first 3 months of therapy. If ticlopidine is stopped during this period, a full blood count should be performed within 2 weeks of stopping treatment. Consideration should be given to stopping ticlopidine therapy 10 to 14 days before elective surgery.

Effects on the blood. Severe *neutropenia* or *agranulocytosis* may occur in about 1% of patients given ticlopidine[1] and fatal infection has been reported.[2] Neutropenia usually develops within the first 3 months of therapy and is reversible on stopping ticlopidine, but there has been a report[3] of a delayed reaction that occurred 18 days after ticlopidine was stopped. Isolated *thrombocytopenia* occurs in about 0.4% of patients and *thrombotic thrombocytopenic purpura*, sometimes fatal, has occurred.[1,4-7] Conversely, good results have been achieved with ticlopidine as a treatment for thrombotic thrombocytopenic purpura,[8,9] but it should only be used with extreme caution.[10] Aplastic anaemia has also occurred rarely with ticlopidine.[1,11]

Clopidogrel has also been associated with blood dyscrasias. Up to August 2004, the Australian Adverse Drug Reactions Advisory Committee (ADRAC)[12] had received 80 reports of blood dyscrasias associated with clopidogrel, although ticlopidine was associated with a much higher rate of reports. Individual cases of thrombotic thrombocytopenic purpura and haemolytic uraemic syndrome,[13-16] aplastic anaemia,[17] leucopenia,[18] and acquired haemophilia A,[19] have also been reported. However the most frequently reported adverse effect of clopidogrel, as with other antithrombotics, is bleeding, particularly when given with other drugs affecting coagulation; ADRAC had received 130 reports of haemorrhagic events, leading to fatalities in 18 cases.[12]

19. Haj M, *et al.* Acquired haemophilia A may be associated with clopidogrel. *BMJ* 2004; **329:** 323.

Effects on the gastrointestinal tract. Diarrhoea is a common adverse effect of ticlopidine therapy; it usually occurs during the first few months of therapy and resolves within 1 to 2 weeks without stopping therapy. However, there has been a report[1] of diarrhoea and weight loss of 2 months duration that first presented 2 years after ticlopidine was started; diarrhoea resolved when ticlopidine was withdrawn.

1. Mansoor GA, Aziz K. Delayed chronic diarrhea and weight loss possibly due to ticlopidine therapy. *Ann Pharmacother* 1997; **31:** 870–2.

Effects on the joints. Acute arthritis associated with a diffuse rash developed in a patient shortly after starting treatment with ticlopidine.[1] Both the rash and the arthritis resolved on withdrawal, and it was suggested that a hypersensitivity reaction might be involved. One case of polyarthritis and 3 cases of arthralgia associated with ticlopidine had been reported to the UK CSM up to March 2001. Two cases of acute arthritis have also been reported[2] with clopidogrel; symptoms developed 2 to 3 weeks after starting treatment and resolved after stopping.

1. Dakik HA, *et al.* Ticlopidine associated with acute arthritis. *BMJ* 2002; **324:** 27.
2. Garg A, *et al.* Clopidogrel associated with acute arthritis. *BMJ* 2000; **320:** 483.

Effects on the kidneys. A reversible deterioration in renal function has been reported in patients given ticlopidine after coronary stent implantation.[1,2] There has also been a report[3] of membranous nephropathy with nephrotic syndrome in a patient receiving clopidogrel.

1. Elsman P, Zijlstra F. Ticlopidine and renal function. *Lancet* 1996; **348:** 273–4.
2. Virdee M, *et al.* Ticlopidine and renal function. *Lancet* 1996; **348:** 1031–2.
3. Tholl U, *et al.* Clopidogrel and membranous nephropathy. *Lancet* 1999; **354:** 1443–4.

Effects on the liver. Cholestatic hepatitis has been reported in patients receiving ticlopidine and is usually reversible when ticlopidine is stopped.[1-3] However, there have been reports of persistent cholestasis after ticlopidine withdrawal.[4,5] A case of granulomatous hepatitis has also been reported.[6] Clopidogrel was substituted for ticlopidine in a patient who had developed raised liver enzymes during ticlopidine treatment;[7] liver enzyme values returned to normal during continued clopidogrel therapy. However, there has been a report[8] of hepatotoxicity with clopidogrel.

1. Cassidy LJ, *et al.* Probable ticlopidine-induced cholestatic hepatitis. *Ann Pharmacother* 1995; **29:** 30–2.
2. Pérez-Balsa AM, *et al.* Hepatotoxicity due to ticlopidine. *Ann Pharmacother* 1998; **32:** 1250–1.

5. Mambelli E, *et al.* Severe ticlopidine-induced cholestatic syndrome. *Blood Purif* 2007; **25:** 441–5.
6. Ruiz-Valverde P, *et al.* Ticlopidine-induced granulomatous hepatitis. *Ann Pharmacother* 1995; **29:** 633–4.
7. Zeolla MM, Carson JJ. Successful use of clopidogrel for cerebrovascular accident in a patient with suspected ticlopidine-induced hepatotoxicity. *Ann Pharmacother* 1999; **33:** 939–41.
8. Willens HJ. Clopidogrel-induced mixed hepatocellular and cholestatic liver injury. *Am J Ther* 2000; **7:** 317–18.

Effects on the lungs. Bronchiolitis obliterans-organising pneumonia developed in a 76-year-old woman receiving ticlopidine and prednisone for temporal arteritis.[1] The condition resolved over several months when ticlopidine was withdrawn.

1. Alonso-Martinez JL, *et al.* Bronchiolitis obliterans-organizing pneumonia caused by ticlopidine. *Ann Intern Med* 1998; **129:** 71–2.

Interactions

Ticlopidine should be used with caution in patients receiving other drugs, such as anticoagulants and antiplatelets, that increase the risk of bleeding. Ticlopidine is an inhibitor of cytochrome P450, including the isoenzymes CYP2C19, CYP2D6, and CYP2B6, and may inhibit the metabolism of other drugs that are metabolised by this route. The clearance of ticlopidine may be reduced by cimetidine. Corticosteroids may antagonise the effect of ticlopidine on bleeding time.

Anticoagulants. Use of ticlopidine with anticoagulants may increase the risk of bleeding. However, ticlopidine has been reported to antagonise the effect of *acenocoumarol* (see Antiplatelets under Interactions of Warfarin, p.1429).

Antiepileptics. For a report of acute *phenytoin* toxicity in a well-stabilised patient following addition of ticlopidine, see p.500.

Xanthines. For reference to the effect of ticlopidine on *theophylline* half-life, see p.1145.

Pharmacokinetics

Ticlopidine is rapidly and almost completely absorbed from the gastrointestinal tract. It is about 98% bound to plasma proteins. The terminal half-life during chronic dosing is reported to be about 30 to 50 hours. Ticlopidine is extensively metabolised in the liver. About 60% of a dose is excreted in the urine as metabolites and 25% in the faeces.

◊ References.

2. Buur T, *et al.* Pharmacokinetics and effect of ticlopidine on platelet aggregation in subjects with normal and impaired renal function. *J Clin Pharmacol* 1997; **37:** 108–15.

Uses and Administration

Ticlopidine hydrochloride is a thienopyridine antiplatelet drug used in thromboembolic disorders (p.1187). It appears to act by inhibiting adenosine diphosphate-mediated platelet aggregation. It may be given prophylactically as an alternative to aspirin in patients at risk of thrombotic stroke (p.1185) and in the management of intermittent claudication (see Peripheral Vascular Disease, p.1178) and ischaemic heart disease. It is also licensed as an adjunct to aspirin for the prevention of subacute stent occlusion after intracoronary stenting (but see Reperfusion and Revascularisation Procedures, below). Ticlopidine may also be used to prevent occlusion and platelet loss during extracorporeal circulatory procedures.

In the prevention of thrombotic **stroke**, and in **intermittent claudication**, ticlopidine hydrochloride is given orally in a dose of 250 mg twice daily, with meals. For the prevention of subacute stent occlusion after **intracoronary stenting** ticlopidine hydrochloride is given in a dose of 250 mg twice daily for 4 weeks, starting at the time of stent placement.

Regular haematological monitoring is required during ticlopidine therapy (see Adverse Effects and Precautions, above).

Reperfusion and revascularisation procedures. Coronary stents are widely used as an adjunct to angioplasty to prevent acute vessel closure and to reduce restenosis (see Reperfusion and Revascularisation Procedures, p.1181). Subacute thrombosis is a major complication of their use and patients were initially treated with an aggressive combination of anticoagulants and antiplatelets. However, it is now generally recognised that antiplatelet drugs alone are adequate in most patients.

Early studies[1-4] found that ticlopidine for 4 to 6 weeks after stenting, given with long-term aspirin, was at least as effective as an oral anticoagulant with aspirin, with some studies showing benefit in terms of thrombosis[1,4] or bleeding complications.[1] However, the risk of neutropenia limits the use of ticlopidine, and clopidogrel is now generally preferred, although there is some evidence[5] that shorter courses of ticlopidine (2 weeks) may be acceptable.

Ticlopidine has also been reported[6] to improve the long-term patency of saphenous vein bypass grafts used to treat peripheral vascular disease in the legs.

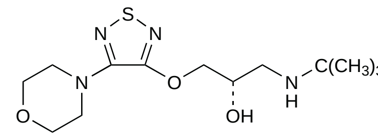
CAS — 26839-75-8 (timolol); 91524-16-2 (timolol hemihydrate); 26921-17-5 (timolol maleate).

ATC — C07AA06; S01ED01.

ATC Vet — QC07AA06; QS01ED01.



(timolol)

NOTE. TIM is a code approved by the BP 2008 for use on single unit doses of eye drops containing timolol maleate where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Timolol Maleate). A white or almost white, crystalline powder or colourless crystals. Soluble in water and in alcohol. A 2% solution in water has a pH of 3.8 to 4.3. Protect from light.

USP 31 (Timolol Maleate). A white to practically white, odourless or practically odourless powder. Soluble in water, in alcohol, and in methyl alcohol; sparingly soluble in chloroform and in propylene glycol; insoluble in cyclohexane and in ether. A 2% solution in water has a pH of 3.8 to 4.3.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Breast feeding. Timolol is distributed into breast milk. After instillation of timolol 0.5% eye drops twice daily, concentrations of timolol in breast milk of a woman were about 6 times greater than those in serum, the values being 5.6 and 0.93 nanograms/mL respectively.[1] In a study[2] in patients given oral timolol 5 mg three times daily, the mean concentration in breast milk was 15.9 nanograms/mL, and the ratio of milk to plasma concentrations was 0.8; a similar ratio was found at higher doses, and the authors considered that the amount ingested by an infant would not be important. No adverse effects were seen in these studies and the American Academy of Pediatrics considers[3] that timolol is therefore usually compatible with breast feeding.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Antivirals. US licensed product information for *ritonavir* warns that ritonavir may increase concentrations of timolol and that the dose of timolol may need to be reduced if used together.

Pharmacokinetics

Timolol is almost completely absorbed from the gastrointestinal tract but is subject to moderate first-pass metabolism. Peak plasma concentrations occur about 1 to 2 hours after a dose. Low concentrations are also found in plasma after use as eye drops. Timolol has low to moderate lipid solubility. Protein binding is reported to be low. Timolol crosses the placenta and is distributed into breast milk. A plasma half-life of 4 hours has been reported. Timolol is extensively metabolised in the liver, the metabolites being excreted in the urine with some unchanged timolol. Timolol is not removed by haemodialysis.

Metabolism. Timolol appears to be metabolised[1] by the cytochrome P450 isoenzyme CYP2D6 and studies[2-4] have shown that it is influenced by genetic polymorphism.

1. Volotinen M, *et al*. Timolol metabolism in human liver microsomes is mediated principally by CYP2D6. *Drug Metab Dispos* 2007; **35:** 1135–41.
2. McGourty JC, *et al*. Pharmacokinetics and beta-blocking effects of timolol in poor and extensive metabolizers of debrisoquin. *Clin Pharmacol Ther* 1985; **38:** 409–13.

4. Lennard MS, *et al*. Timolol metabolism and debrisoquine oxidation polymorphism: a population study. *Br J Clin Pharmacol* 1989; **27:** 429–34.

Uses and Administration

Timolol is a non-cardioselective beta blocker (p.1225). It is reported to lack intrinsic sympathomimetic and membrane-stabilising activity.

Timolol is used as the maleate in the management of glaucoma (p.1873), hypertension (p.1171), angina pectoris (p.1157), and myocardial infarction (p.1175). It is also used in the prophylactic treatment of migraine (p.616). The hemihydrate is also used.

Eye drops containing timolol maleate or hemihydrate equivalent to 0.25 and 0.5% of timolol are instilled twice daily to reduce **raised intra-ocular pressure** in open-angle **glaucoma** and ocular hypertension. Once-daily use may suffice when the intra-ocular pressure has been controlled. Gel-forming eye drops are also available that are instilled once daily.

For other indications timolol is given orally. In **hypertension** timolol maleate is usually given in initial doses of 10 mg daily, increased according to response at intervals of 7 or more days. Usual maintenance doses are 10 to 40 mg daily, but doses up to 60 mg daily may be required in some patients; doses above 30 mg daily should be given in 2 equally divided doses.

In **angina pectoris** the initial dose is 5 mg twice daily, increased at intervals of 3 or more days by 10 mg daily. Most patients respond to 35 to 45 mg daily in divided doses, but some patients may require up to 60 mg daily.

In patients who have had a **myocardial infarction** timolol maleate is given in initial doses of 5 mg twice daily for 2 days, starting 7 to 28 days after infarction, and increased subsequently in the absence of any contra-indicating adverse effects, to 10 mg twice daily.

Doses of 10 to 20 mg daily of timolol maleate are used in the prophylaxis of **migraine**.

Reduced doses may be required in renal or hepatic impairment.

Preparations

BP 2008: Timolol Eye Drops; Timolol Tablets;
USP 31: Timolol Maleate and Hydrochlorothiazide Tablets; Timolol Maleate Ophthalmic Solution; Timolol Maleate Tablets.

Tinzaparin Sodium *(BAN, USAN, rINN)*

Tintsapariininatrium; Tinzaparin sodná sůl; Tinzaparin Sodyum; Tinzaparina sódica; Tinzaparine sodique; Tinzaparinnatrium; Tinzaparin-nátrium; Tinzaparino natrio druska; Tinzaparinum natricum.

Тинзапарин Натрий

CAS — 9041-08-1.

ATC — B01AB10.

ATC Vet — QB01AB10.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Tinzaparin Sodium). It is prepared by enzymatic depolymerisation, using heparinase from *Flavobacterium heparinum*, of heparin obtained from the intestinal mucosa of pigs. The majority of the components have a 2-*O*-sulfo-4-enepyranosuronic acid structure at the non-reducing end and a 2-*N*,6-*O*-disulfo-D-glucosamine structure at the reducing end of their chain. The mass-average relative molecular mass ranges between 5500 and 7500, with a characteristic value of about 6500. The mass percentage of chains lower than 2000 is not more than 10%. The degree of sulfation is 1.8 to 2.5 per disaccharide unit.

The potency is not less than 70 units and not more than 120 units of anti-factor Xa activity per mg with reference to the dried substance and the ratio of anti-factor Xa activity to anti-factor IIa (antithrombin) activity is between 1.5 and 2.5.

Units

As for Low-molecular-weight Heparins, p.1329.

Adverse Effects, Treatment, and Precautions

As for Low-molecular-weight Heparins, p.1329.

Severe bleeding with tinzaparin sodium may be reduced by the slow intravenous injection of protamine sulfate; 1 mg of protamine sulfate is stated to inhibit the effects of 100 units of tinzaparin sodium.

Interactions

As for Low-molecular-weight Heparins, p.1329.

Pharmacokinetics

Tinzaparin sodium is absorbed after subcutaneous injection with a bioavailability of about 90%. Peak plasma activity is reached within 4 to 6 hours. The elimination half-life is about 90 minutes but detectable anti-factor Xa activity persists for up to 24 hours.

Uses and Administration

Tinzaparin sodium is a low-molecular-weight heparin (p.1329) with anticoagulant properties. It is used in the prevention and treatment of venous thromboembolism (p.1189) and to prevent clotting during extracorporeal circulation.

For *prophylaxis* of **venous thromboembolism** tinzaparin sodium is given by subcutaneous injection in a variety of dosage regimens.

- For patients undergoing general surgical procedures 3500 units of tinzaparin sodium are given 2 hours before the procedure, followed by 3500 units once daily for 7 to 10 days.
- In patients at high risk, such as those undergoing orthopaedic surgery, a dose of 50 units/kg has been recommended; alternatively, a dose of 4500 units may be given 12 hours before surgery, followed by 4500 units once daily.

For the *treatment* of venous thromboembolism tinzaparin sodium is given in a dose of 175 units/kg by subcutaneous injection once daily for at least 6 days and until adequate oral anticoagulation is established.

For prevention of clotting in the extracorporeal circulation during **haemodialysis**, tinzaparin sodium may be given into the arterial side of the dialyser or intravenously. The dialyser may be primed with 500 to 1000 mL sodium chloride 0.9% containing 5000 units tinzaparin sodium/litre. For dialysis sessions lasting less than 4 hours a single dose of 2000 to 2500 units tinzaparin sodium is given; for longer sessions an initial dose of 2500 units is followed by an infusion of 750 units/hour.

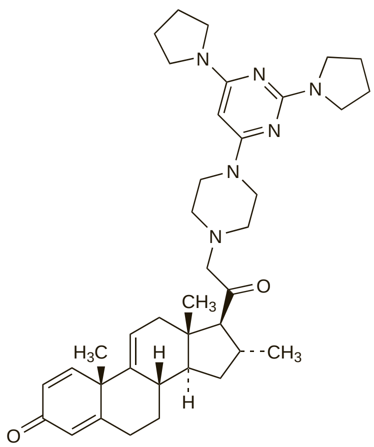
ATC — N07XX01.

ATC Vet — QN07XX01.



(tirilazad)

Profile

Tirilazad, a lazaroid, is an inhibitor of lipid peroxidation thought to have a cytoprotective effect against radicals produced in response to tissue trauma. It has been used in the prevention of secondary tissue damage in subarachnoid haemorrhage. It has also been investigated in spinal cord injuries, head injuries, and ischaemic stroke.

Tirofiban Hydrochloride

(BANM, USAN, rINNM)

Hidrocloruro de tirofibán; L-700462; MK-383; MK-0383; Tirofiban, Chlorhydrate de; Tirofiban Hidroklorür; Tirofibani Hydrochloridum. *N*-(Butylsulfonyl)-4-[4-(4-piperidyl)butoxy]-L-phenylalanine hydrochloride monohydrate.

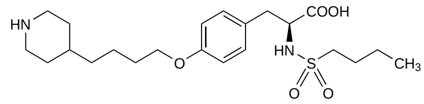
Тирофибана Гидрохлорид

$C_{22}H_{36}N_2O_5S,HCl,H_2O$ = 495.1.

CAS — 144494-65-5 (tirofiban); 142373-60-2 (anhydrous tirofiban hydrochloride); 150915-40-5 (tirofiban hydrochloride monohydrate);.

ATC — B01AC17.

ATC Vet — QB01AC17.



(tirofiban)

Adverse Effects

Bleeding is the most common adverse effect of tirofiban. Other side-effects include nausea, headache, fever, rashes and other hypersensitivity reactions, and thrombocytopenia.

Effects on the blood. References[1,2] to tirofiban-associated thrombocytopenia.

1. Mulot A, *et al.* Practical approach to the diagnosis and management of thrombocytopenia associated with tirofiban treatment. *Am J Hematol* 2004; **77:** 67–71.
2. Patel S, *et al.* Profound thrombocytopenia associated with tirofiban: case report and review of literature. *Angiology* 2005; **56:** 351–5.

Precautions

As for Abciximab, p.1192.

Pharmacokinetics

After stopping an infusion of tirofiban, the antiplatelet effect persists for about 4 to 8 hours. The plasma half-life is about 2 hours. Tirofiban is not highly bound to plasma proteins; the unbound fraction in plasma is about 35%. Tirofiban is eliminated largely unchanged in the urine, with some biliary excretion in the faeces. Tirofiban is removed by haemodialysis.

◊ Reviews.

1. Kondo K, Umemura K. Clinical pharmacokinetics of tirofiban, a nonpeptide glycoprotein IIb/IIIa receptor antagonist: comparison with the monoclonal antibody abciximab. *Clin Pharmacokinet* 2002; **41:** 187–95.

Uses and Administration

Tirofiban hydrochloride is an antiplatelet drug that reversibly inhibits binding of fibrinogen to the glycoprotein IIb/IIIa receptors of platelets. It is given with heparin and aspirin for the management of unstable angina, both in patients managed medically and in those undergoing percutaneous coronary procedures. Tirofiban is used as the hydrochloride, but the dose is expressed in terms of the base; 110 nanograms of tirofiban hydrochloride monohydrate is equivalent to 100 nanograms of tirofiban base.

Tirofiban is given intravenously, at an initial rate of 400 nanograms/kg per minute for 30 minutes, and then continued at 100 nanograms/kg per minute. The recommended duration of treatment is at least 48 hours. Tirofiban infusion may be continued during coronary angiography, and should be maintained for 12 to 24 hours after angioplasty or atherectomy. The entire duration of treatment should not exceed 108 hours.

The dose of tirofiban should be reduced in patients with renal impairment (see below).

Administration in renal impairment. Patients with renal impairment (creatinine clearance less than 30 mL/minute) should receive half the usual infusion dose of tirofiban.

Ischaemic heart disease. Patients with acute coronary syndromes may be treated either medically or with percutaneous coronary interventions such as angioplasty or stenting. Tirofiban, given with heparin and aspirin, has been tried as adjunctive therapy. A study[1] comparing tirofiban with heparin in the **medical management** of unstable angina (p.1157) or non-Q-wave myocardial infarction reported an initial benefit, at 2 days, of reduced risk of refractory ischaemia, myocardial infarction, or death with tirofiban. This benefit was not maintained at 7 or 30 days after treatment, although a further analysis[2] found that the risk of death or myocardial infarction at 30 days was reduced in patients with raised troponin I concentrations who received tirofiban. In another study,[3] the combination of heparin and tirofiban also reduced the risk of refractory ischaemia, myocardial infarction, or death, compared with heparin alone, and benefit was maintained at 6 months. About half of these patients also underwent revascularisation procedures or surgery if required.

Tirofiban has also been studied in patients undergoing **interventional therapy** (see Reperfusion and Revascularisation Procedures, p.1181), but results have been mixed. The RESTORE trial[4] found short-term benefit with tirofiban as an adjunct to heparin in patients undergoing angioplasty or atherectomy for acute coronary syndromes (unstable angina or myocardial infarction), but this was not maintained at 30 days and there was no effect on restenosis after 6 months. However, another study using a higher loading dose found a reduced rate of clinical events in patients given tirofiban, both early after the procedure and on longer-term follow-up,[5] and an observational study[6] in patients with acute myocardial infarction also found improved outcomes. Pretreatment with tirofiban for 24 to 48 hours before intervention was found to improve angiographic outcomes compared with periprocedural treatment,[7] but there was no difference in clinical events at 30 days. In patients undergoing planned interventions, tirofiban was found to improve outcomes compared with placebo;[8] another study found that it was less effective than abciximab at 30 days,[9] although this difference was no longer apparent after 6 months.[10]

Tocainide *(BAN, USAN, rINN)*

Tocainida; Tocaïnide; Tocainidum; Tokainid; Tokainidi; W-36095. 2-Aminopropiono-2′,6′-xylidide.

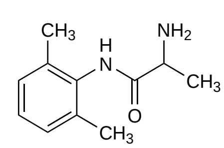
Токаинид

$C_{11}H_{16}N_2O$ = 192.3.

CAS — 41708-72-9.

ATC — C01BB03.

ATC Vet — QC01BB03.



Tocainide Hydrochloride *(BANM, rINNM)*

Hidrocloruro de tocainida; Tocaïnide, Chlorhydrate de; Tocainidi Hydrochloridum.

Токаинида Гидрохлорид

$C_{11}H_{16}N_2O,HCl = 228.7.$

CAS — 35891-93-1.

ATC — C01BB03.

ATC Vet — QC01BB03.

Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Tocainide Hydrochloride). A fine, white, odourless powder. Freely soluble in water and in alcohol; practically insoluble in chloroform and in ether.

Profile

Tocainide is a class Ib antiarrhythmic (p.1153) with similar properties to mexiletine (p.1339); like mexiletine it is structurally related to lidocaine (p.1862). Tocainide hydrochloride has been given orally and intravenously in the management of ventricular arrhythmias but severe haematological and pulmonary toxicity limit its use.

Tolazoline Hydrochloride *(BANM, rINNM)*

Benzazoline Hydrochloride; Hidrocloruro de tolazolina; Tolazol. Hydrochlor.; Tolazoline, Chlorhydrate de; Tolazolini Hydrochloridum; Tolazolinium Chloratum. 2-Benzyl-2-imidazoline hydrochloride.

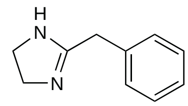
Толазолина Гидрохлорид

$C_{10}H_{12}N_2,HCl = 196.7.$

CAS — 59-98-3 (tolazoline); 59-97-2 (tolazoline hydrochloride).

ATC — C04AB02; M02AX02.

ATC Vet — QC04AB02; QM02AX02.



(tolazoline)

NOTE. Do not confuse with benazoline (see Metizoline, p.1565), which is a sympathomimetic vasoconstrictor, or with benazolin, which is a herbicide.

Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Tolazoline Hydrochloride). A white to off-white, crystalline powder. Its solutions are slightly acid to litmus. Soluble 1 in less than 1 of water, 1 in 2 of alcohol, 1 in 3 of chloroform, and 1 in 10 000 of ether. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Adverse Effects

Adverse effects of tolazoline include piloerection, headache, flushing, tachycardia, cardiac arrhythmias, tingling, chilliness, shivering, sweating, nausea, vomiting, diarrhoea, and epigastric pain. Orthostatic hypotension or marked hypertension may occur, especially with large doses. Tolazoline stimulates gastric acid and may exacerbate peptic ulcer disease. Oliguria, haematuria, myocardial infarction, gastrointestinal haemorrhage, thrombocytopenia and other blood dyscrasias have been reported.

Intra-arterial injection has been followed by a burning sensation in the limb.

Effects in the neonate. Hypochloraemic metabolic alkalosis,[1] acute renal failure,[2] and duodenal perforation[3] have been reported in neonates given tolazoline.

1. Adams JM, *et al.* Hypochloremic metabolic alkalosis following tolazoline-induced gastric hypersecretion. *Pediatrics* 1980; **65:** 298–300.
2. Trompeter RS, *et al.* Tolazoline and acute renal failure in the newborn. *Lancet* 1981; **i:** 1219.
3. Wilson RG, *et al.* Duodenal perforation associated with tolazoline. *Arch Dis Child* 1985; **60:** 878–9.

Treatment of Adverse Effects

In the event of overdosage hypotension is best treated by keeping the patient recumbent with the head lowered. If necessary the circulation may be maintained by infusion of suitable electrolyte solutions. Hypotension may be treated with ephedrine. Adrenaline is not suitable for the reversal of hypotension induced by alpha blockers since it may activate the hypotension by stimulating beta receptors.

Precautions

Tolazoline should not be given to patients with hypotension and when used for peripheral vascular disease should be avoided in ischaemic heart disease or after a cerebrovascular accident. Since tolazoline stimulates gastric secretion of hydrochloric acid it may activate stress ulcers and may cause significant hypochloraemic alkalosis. Pretreatment of infants with antacids may prevent gastrointestinal bleeding, although use of intravenous ranitidine is not recommended (see below under Interactions). Tolazoline should not be used in the presence of peptic ulcer disease and should be used with caution in patients with mitral stenosis.

Interactions

Tolazoline should not be used with sympathomimetics such as adrenaline since the hypotensive effect may be potentiated due to unopposed beta-adrenoceptor stimulation. Tolazoline may cause a disulfiram-like reaction if given with alcohol.

Ranitidine. Intravenous ranitidine reversed the falls in pulmonary and systemic vascular resistances in 12 children who had been given tolazoline as a pulmonary vasodilator.[1]

1. Bush A, *et al.* Cardiovascular effects of tolazoline and ranitidine. *Arch Dis Child* 1987; **62:** 241–6.

Sympathomimetics. For a report of fatal hypotension associated with the use of tolazoline with *dopamine*, see Vasodilators under the Interactions of Sympathomimetics, p.1408.

Pharmacokinetics

Tolazoline is absorbed from the gastrointestinal tract. It is more rapidly absorbed after intramuscular injection. An elimination half-life in neonates of 3 to 13 hours has been reported after intravenous use, although it may be as high as about 40 hours and is inversely related to urine output. Tolazoline is rapidly excreted in the urine, largely unchanged.

Uses and Administration

Tolazoline hydrochloride is a vasodilator that has a direct dilator action on the peripheral blood vessels. It has some alpha-adrenoceptor blocking activity and also stimulates smooth muscle in the gastrointestinal tract, increases gastrointestinal secretion, can cause mydriasis, and has a stimulant effect on the heart.

Tolazoline hydrochloride is used intravenously to reduce pulmonary artery pressure in persistent pulmonary hypertension in neonates with persistent fetal circulation (see below). It has been used orally and by subcutaneous, intramuscular, intravenous, or slow intra-arterial injection in the treatment of peripheral vascular disease. It has also been given in some ophthalmic conditions.

Pulmonary hypertension. Tolazoline and other vasodilators have been tried in persistent pulmonary hypertension in the newborn (p.1179) in an attempt to induce selective pulmonary vasodilatation and improve gas exchange. The response is variable and often unsuccessful due to concomitant systemic hypotension, a failure to achieve or sustain pulmonary vasodilatation, and adverse effects, and other therapies such as high-frequency oscillatory ventilation, extracorporeal membrane oxygenation, and inhaled nitric oxide are now more widely used.

The loading dose for pulmonary hypertension in neonates that has been recommended by licensed product information is 1 to 2 mg/kg over 5 to 10 minutes by intravenous infusion; this is then followed by doses of up to 1 to 2 mg/kg per hour. Infants with reduced urine output may require lower maintenance doses. The high incidence of adverse effects has, however, led to several studies investigating the use of lower doses. One group suggested that a loading dose of 500 micrograms/kg given intravenously followed by a continuous infusion of 500 micrograms/kg per hour was more appropriate and safer than standard doses.[1] In a retrospective study[2] of extremely preterm infants (mean gestational age 24 weeks) with severe hypoxaemia (possibly attributable to persistent pulmonary hypertension), tolazoline was given as a slow bolus infusion, with most patients receiving a dose of 0.5 to 1 mg/kg; some required further doses.

Tolazoline has also been given via the endotracheal route,[3,4] although as it is acid in solution it may contribute to alveolar injury. In a study[4] of 12 neonates with gestational age ranging from 25 to 42 weeks, endotracheal tolazoline at doses from 1 to 2.5 mg/kg was found to cause no adverse systemic effects.

The *BNFC* gives a dose of 1 mg/kg by slow intravenous injection, followed by 200 micrograms/kg per hour by infusion if necessary. It warns that doses in excess of 300 micrograms/kg per hour are associated with cardiotoxicity and renal failure. A suggested dose for endotracheal use is 200 micrograms/kg diluted in 0.5 to 1 mL of sodium chloride 0.9%.

Torasemide *(BAN, rINN)* ⊗

AC-4464; BM-02015; Torasemid; Torasemid bezvodý; Torasemid, vattenfri; Torasemida; Torasémide; Torasémide anhydre; Torasemidi; Torasemidi, vedetön; Torasemidum; Torasemidum anhydricum; Torazemidas, bevandenis; Torsemide *(USAN)*. 1-Isopropyl-3-(4-*m*-toluidinopyridine-3-sulphonyl)urea.

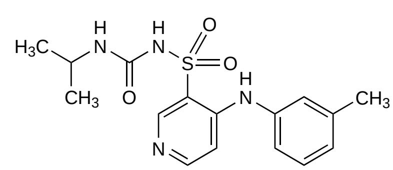
Торасемид

$C_{16}H_{20}N_4O_3S = 348.4.$

CAS — 56211-40-6 (torasemide); 72810-59-4 (torasemide sodium).

ATC — C03CA04.

ATC Vet — QC03CA04.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Torasemide, Anhydrous). A white or almost white powder. It exhibits polymorphism. Practically insoluble in water; slightly soluble in alcohol. It is sparingly soluble in dilute solu-

tions of alkali hydroxides and slightly soluble in dilute acids. Protect from light.
USP 31 (Torsemide). A white to off-white, crystalline powder. Practically insoluble in water and in ether; slightly soluble in alcohol, in methyl alcohol, in 0.1N sodium hydroxide, and in 0.1N hydrochloric acid; very slightly soluble in acetone and in chloroform.

Adverse Effects and Precautions

As for Furosemide, p.1292.

Interactions

As for Furosemide, p.1293.

Pharmacokinetics

Torasemide is well absorbed from the gastrointestinal tract. Peak serum concentrations are achieved within 1 hour of oral doses. Torasemide is metabolised by the cytochrome P450 isoenzyme CYP2C9, which shows genetic polymorphism. Metabolism takes place in the liver and inactive metabolites are excreted in the urine. The elimination half-life of torasemide is about 3.5 hours. Torasemide is extensively bound to plasma proteins. In patients with heart failure both hepatic and renal clearance are reduced. In patients with renal impairment, the renal clearance is reduced but total plasma clearance is not significantly altered.

◊ References.

2. Vormfelde SV, *et al.* CYP2C9 polymorphisms and the interindividual variability in pharmacokinetics and pharmacodynamics of the loop diuretic drug torsemide. *Clin Pharmacol Ther* 2004; **76:** 557–66.

Uses and Administration

Torasemide is a loop diuretic with actions similar to those of furosemide (p.1294).

Torasemide is used for oedema associated with heart failure (p.1165), including pulmonary oedema, and with renal and hepatic disorders. It is also used in the treatment of hypertension (p.1171), either alone or with other antihypertensives.

Diuresis after oral use starts within 1 hour, reaches a maximum in about 1 to 2 hours, and lasts for up to 8 hours; after intravenous injection its effects are evident within 10 minutes but like oral use can last up to 8 hours.

In the treatment of **oedema** the usual oral dose is 5 mg once daily increased according to response to 20 mg once daily; doses of up to 40 mg daily have been required in some patients. Torasemide may also be given intravenously in usual initial doses of 10 to 20 mg daily. Higher doses may sometimes be necessary, especially in oedema of renal origin; the dose should be increased stepwise as necessary to a maximum of 200 mg daily, although doses should not exceed 40 mg daily in patients with hepatic cirrhosis.

In the treatment of **hypertension** torasemide is given in initial oral doses of 2.5 to 5 mg daily; US licensed product information allows the dose to be increased to 10 mg daily if required, although UK licensed product information suggests that doses above 5 mg are unlikely to produce additional benefit.

Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Trandolapril). A white or almost white powder. Practically insoluble in water; sparingly soluble in dehydrated alcohol; freely soluble in dichloromethane. Protect from light.

Adverse Effects, Treatment, and Precautions

As for ACE inhibitors, p.1193.

Interactions

As for ACE inhibitors, p.1196.

Pharmacokinetics

Trandolapril acts as a prodrug of the diacid trandolaprilat, its active metabolite. After oral doses of trandolapril the bioavailability of trandolaprilat is 40 to 60%. Trandolapril is metabolised in the liver to trandolaprilat and to some inactive metabolites. Peak plasma concentrations of trandolaprilat are achieved 4 to 6 hours after an oral dose of trandolapril. Trandolaprilat is more than 80% bound to plasma proteins. About 33% of an oral dose of trandolapril is excreted in the urine, mainly as trandolaprilat; the rest is excreted in the faeces. The effective half-life for accumulation of trandolaprilat is 16 to 24 hours after multiple doses of trandolapril.

Impaired renal function decreases the excretion of trandolaprilat. Trandolaprilat is removed by haemodialysis.

◊ References.

1. Bevan EG, *et al.* Effect of renal function on the pharmacokinetics and pharmacodynamics of trandolapril. *Br J Clin Pharmacol* 1993; **35:** 128–35.

Uses and Administration

Trandolapril is an ACE inhibitor (p.1193). It is used in the treatment of hypertension (p.1171) and in left ventricular dysfunction following myocardial infarction (p.1175).

Trandolapril owes its activity to trandolaprilat to which it is converted after oral doses. The haemodynamic effects are seen about 1 hour after an oral dose and the maximum effect occurs after 8 to 12 hours. The haemodynamic action lasts for at least 24 hours, allowing once-daily dosing.

In the treatment of **hypertension** the initial oral dose is 500 micrograms once daily. Since there may be a precipitous fall in blood pressure in some patients when starting therapy with an ACE inhibitor, the first dose should preferably be given at bedtime. In patients already taking a diuretic, the diuretic should be stopped, if possible, 2 to 3 days before starting trandolapril and resumed later if necessary. In patients with co-existing heart failure treatment with trandolapril should begin under close medical supervision. The usual maintenance dose for hypertension is 1 to 2 mg once daily, although up to 4 mg daily may be given, as a single dose or in 2 divided doses.

In **myocardial infarction**, treatment with trandolapril may be started 3 days after the infarction in an initial dose of 500 micrograms once daily, gradually increased to a maximum of 4 mg once daily.

A reduction in dosage may be necessary in patients with renal impairment (see below).

3. Køber L, *et al.* A clinical trial of the angiotensin-converting-enzyme inhibitor trandolapril in patients with left ventricular dysfunction after myocardial infarction. *N Engl J Med* 1995; **333:** 1670–6.
4. Peters DC, *et al.* Trandolapril: an update of its pharmacology and therapeutic use in cardiovascular disorders. *Drugs* 1998; **56:** 871–93.

Administration in renal impairment. The initial dose of trandolapril in patients with renal impairment should not exceed 500 micrograms daily. UK licensed product information states that the maximum maintenance dose should be 2 mg daily in patients with a creatinine clearance of less than 10 mL/minute.

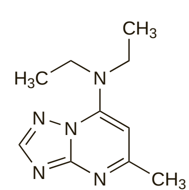
Trapidil *(BAN, rINN)*

AR-12008; Tarpidil; Trapidiili; Trapidilis; Trapidilum. 7-Diethylamino-5-methyl-1,2,4-triazolo[1,5-*a*]pyrimidine.
Трапидил
$C_{10}H_{15}N_5$ = 205.3.
CAS — 15421-84-8.
ATC — C01DX11.
ATC Vet — QC01DX11.



Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*

Ph. Eur. 6.2 (Trapidil). A white or almost white crystalline powder. Freely soluble in water; soluble in dehydrated alcohol and in dichloromethane. Protect from light.

Profile

Trapidil is a vasodilator and an inhibitor of platelet aggregation. It is also an antagonist of platelet-derived growth factor. It is used orally in the management of ischaemic heart disease in doses of 400 to 600 mg daily, in divided doses; doses of up to 600 mg daily may be used to prevent restenosis after angioplasty (but see below). Ischaemic heart disease is discussed under Atherosclerosis (p.1159) and the treatment of its clinical manifestations is described under Angina Pectoris (p.1157) and Myocardial Infarction (p.1175).

1. Harder S, *et al.* Pharmacokinetics of trapidil, an antagonist of platelet derived growth factor, in healthy subjects and in patients with liver cirrhosis. *Br J Clin Pharmacol* 1996; **42:** 443–9.

Angioplasty and stenting. Although angiographic studies[1-3] have found that trapidil reduces the rate of restenosis after balloon angioplasty (see Reperfusion and Revascularisation Procedures, p.1181), no effect on clinical outcomes[3] has been shown. Studies investigating the use of trapidil after coronary stenting[3,4] have shown no benefit in terms of restenosis or clinical events, and it was concluded that trapidil is not indicated for this purpose.

Treprostinil *(USAN, rINN)*

LRX-15; Tréprostinil; Treprostinilo; Treprostinilum; Treprostinol; 15AU81; U-62840; UT-15. ({(1*R*,2*R*,3a*S*,9a*S*)-2,3,3a,4,9,9a-Hexahydro-2-hydroxy-1-[(3*S*)-3-hydroxyoctyl]-1*H*-benz[*f*]inden-5-yl}oxy)acetic acid.

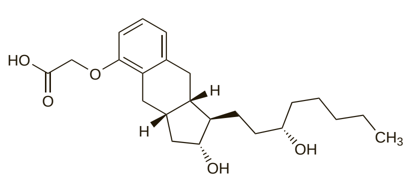
Трепростинил

$C_{23}H_{34}O_5$ = 390.5.

CAS — 81846-19-7.

ATC — B01AC21.

ATC Vet — QB01AC21.



Treprostinil Sodium *(rINNM)*

Natrii Treprostinilum; Tréprostinil Sodique; Treprostinilo sódico.

Натрий Трепростинил

$C_{23}H_{33}NaO_5$ = 412.5.

CAS — 289480-64-4.

ATC — B01AC21.

ATC Vet — QB01AC21.

Adverse Effects and Precautions

Infusion site pain and reactions, including erythema, induration, and rash, are the most common adverse effects reported during subcutaneous infusion of treprostinil. Other effects include headache, nausea, diarrhoea, jaw pain, oedema, vasodilatation, dizziness, hypotension, and pruritus.

Abrupt cessation of the infusion should be avoided, because symptoms of pulmonary hypertension may worsen. Treprostinil should be used with caution in hepatic impairment.

Interactions

Since treprostinil is a vasodilator and inhibitor of platelet aggregation, care should be taken in patients receiving other vasodilators or anticoagulants.

Pharmacokinetics

Treprostinil sodium is rapidly and completely absorbed after subcutaneous injection. It is metabolised by the liver and eliminated with a terminal half-life of about 4 hours. About 80% of a dose is excreted in the urine, mainly as metabolites.

4. McSwain CS, *et al.* Dose proportionality of treprostinil sodium administered by continuous subcutaneous and intravenous infusion. *J Clin Pharmacol* 2008; **48:** 19–25.

Uses and Administration

Treprostinil, a vasodilator and platelet aggregation inhibitor, is an analogue of the prostaglandin epoprostenol (prostacyclin; p.1279). Treprostinil sodium is given by continuous subcutaneous infusion in the treatment of pulmonary hypertension (p.1179); if this route cannot be tolerated, treprostinil sodium may be given by continuous infusion through a central venous catheter. Doses are calculated in terms of treprostinil: treprostinil sodium 1.32 nanograms is equivalent to about 1.25 nanograms of treprostinil. The infusion is started with a dose equivalent to treprostinil 1.25 nanograms/kg per minute; if this is not tolerated the dose should be halved. The infusion rate can be increased according to patient response, by increments of up to 1.25 nanograms/kg per minute each week for the first 4 weeks, followed by increases of up to 2.5 nanograms/kg per minute each week. There is limited experience with doses above 40 nanograms/kg per minute. The dose of treprostinil should be reduced in hepatic impairment, see below.

Inhaled treprostinil is under investigation in pulmonary hypertension, and intravenous use has been investigated for intermittent claudication.

9. Channick RN, *et al.* Safety and efficacy of inhaled treprostinil as add-on therapy to bosentan in pulmonary arterial hypertension. *J Am Coll Cardiol* 2006; **48:** 1433–7.

Administration in hepatic impairment. Clearance of treprostinil is reduced in patients with hepatic impairment. The manufacturers recommend that the initial dose should be 0.625 nanograms/kg per minute, and should be increased cautiously, in mild to moderate impairment. Treprostinil has not been studied in severe hepatic impairment.

Triamterene *(BAN, USAN, rINN)* ⊗

NSC-77625; SKF-8542; Triamtereeni; Triamterén; Triamteren; Triamterenas; Triamtérène; Triamtereno; Triamterenum; Triantereno. 6-Phenylpteridine-2,4,7-triamine; 2,4,7-Triamino-6-phenylpteridine.

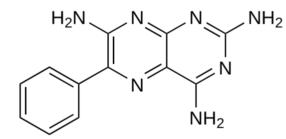
Триамтерен

$C_{12}H_{11}N_7$ = 253.3.

CAS — 396-01-0.

ATC — C03DB02.

ATC Vet — QC03DB02.



NOTE. Compounded preparations of triamterene may be represented by the following names:

- Co-triamterzide (*BAN*)—triamterene 2 parts and hydrochlorothiazide 1 part (w/w)
- Co-triamterzide (*PEN*)—triamterene and hydrochlorothiazide.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Triamterene). A yellow, crystalline powder. Very slightly soluble in water and in alcohol. Protect from light.

USP 31 (Triamterene). A yellow, odourless, crystalline powder. Practically insoluble in water, in chloroform, in ether, in benzene, and in dilute alkali hydroxides; very slightly soluble in alcohol, in acetic acid, and in dilute mineral acids; soluble 1 in 30 of formic acid and 1 in 85 of 2-methoxyethanol. Store in airtight containers. Protect from light.

Adverse Effects

As for Amiloride Hydrochloride, p.1209. Triamterene has also been reported to cause photosensitivity reactions, increases in uric acid concentrations, and blood dyscrasias. Renal calculi may occur in susceptible patients, and megaloblastic anaemia has been reported in patients with depleted folic acid stores such as those with hepatic cirrhosis. Reversible renal failure, due either to acute interstitial nephritis or to an interaction with NSAIDs (see under Interactions, below) has occurred.

Incidence of adverse effects. In a postmarketing surveillance study of 70 898 patients[1] taking triamterene with hydrochlorothiazide the most common adverse effects were fatigue, dizziness, and nausea. Adverse effects necessitated withdrawal in 8.1% of patients. A subgroup analysis of 21 731 patients[2] indicated that hyperkalaemia was more common in elderly patients and in those with diabetes mellitus.

1. Hollenberg NK, Mickiewicz CW. Postmarketing surveillance in 70,898 patients treated with a triamterene/hydrochlorothiazide combination (Maxzide). *Am J Cardiol* 1989; **63:** 37B–41B.
2. Hollenberg NK, Mickiewicz CW. Hyperkalemia in diabetes mellitus: effect of a triamterene-hydrochlorothiazide combination. *Arch Intern Med* 1989; **149:** 1327–30.

Effects on the blood. There have been case reports of pancytopenia associated with triamterene therapy.[1,2] Some patients had hepatic cirrhosis and the antifolate activity of triamterene was considered responsible.[2]

1. Castellano G, *et al.* Pancitopenia aguda y megaloblastosis medular durante el tratemiento con triamterene de la ascitis causada por cirrosis hepática: aportación de dos casos. *Gastroenterol Hepatol* 1983; **6:** 540–4.
2. Remacha A, *et al.* Triamterene-induced megaloblastosis: report of two new cases, and review of the literature. *Biol Clin Hematol* 1983; **5:** 127–34.

Effects on the kidneys. There have been a number of reports[1-4] of renal calculi containing triamterene or its metabolites, generally in patients also taking hydrochlorothiazide. An abnormal urinary sediment was described which was thought to represent precipitated triamterene.[5] These observations were expanded in a crossover study:[6] abnormal urinary sediment was seen in 14 of 26 patients taking triamterene but in none taking amiloride. Triamterene and its metabolites were identified by others in 181 of 50 000 renal calculi.[7] Triamterene either formed the nucleus of the stone or was deposited with calcium oxalate or uric acid. One-third of the 181 stones were entirely or mainly composed of triamterene and its metabolites and it was suggested that supersaturation of the urine with these substances could provide suitable nuclei for the crystallisation of calcium oxalate.[8] However, other workers were unable to confirm this and suggested that triamterene and its metabolites could become incorporated into the protein matrix of existing stones.[9] In addition, an epidemiological study[10] found no evidence that triamterene use was associated with an increased incidence of renal stones. Some authors[11] have therefore considered that there was not enough evidence to contra-indicate the drug in patients with a history of recurrent renal calculi.

Deposition of triamterene in the urine may also play a part in the development of interstitial nephritis, which was diagnosed in 4 patients also taking hydrochlorothiazide, over a period of 4 years.[6]

Triamterene has also been associated with transient decline in renal function and the development of renal failure.[12,13] Several mechanisms may be responsible including interstitial nephritis, intrarenal obstruction by crystalline deposits, and an interaction with NSAIDs (see under Interactions, below).[13] Elderly patients may be particularly at risk.[12]

13. Sica DA, Gehr TWB. Triamterene and the kidney. *Nephron* 1989; **51:** 454–61.

Effects on the skin. Photodermatitis has been reported in a patient taking triamterene.[1] Pseudoporphyria, possibly associated with exposure to sunlight, occurred in a patient with vitiligo during treatment with triamterene and hydrochlorothiazide.[2]

1. Fernández de Corres L, *et al.* Photodermatitis from triamterene. *Contact Dermatitis* 1987; **17:** 114–15.
2. Motley RJ. Pseudoporphyria due to Dyazide in a patient with vitiligo. *BMJ* 1990; **300:** 1468.

Precautions

As for Amiloride Hydrochloride, p.1209. Triamterene should also be given with caution to patients with hyperuricaemia or gout, or a history of renal calculi. Patients with depleted folic acid stores such as those with hepatic cirrhosis may be at increased risk of megaloblastic anaemia.

Triamterene may interfere with the fluorescent measurement of quinidine. It may slightly colour the urine blue.

Interactions

As for Amiloride Hydrochloride, p.1209.

Digoxin. For a report of the effect of triamterene on digoxin, see p.1262.

Dopaminergics. For a report of increased *amantadine* toxicity associated with hydrochlorothiazide and triamterene, see p.793.

NSAIDs. There have been several reports of renal failure in patients taking triamterene and NSAIDs.[1,2] Both types of drug are nephrotoxic and in combination the effect appears to be additive.[3-5] It has been suggested that the suppression of urinary prostaglandins by NSAIDs could potentiate the nephrotoxic effects of triamterene.[1]

NSAIDs may also antagonise the diuretic action of triamterene.[6]

6. Webster J. Interactions of NSAIDs with diuretics and β-blockers: mechanisms and clinical implications. *Drugs* 1985; **30:** 32–41.

Pharmacokinetics

Triamterene is variably but fairly rapidly absorbed from the gastrointestinal tract. The bioavailability has been reported to be about 50%. The plasma half-life has been reported to be about 2 hours. It is estimated to be about 60% bound to plasma proteins. It is extensively metabolised and is mainly excreted in the urine in the form of metabolites with some unchanged triamterene. Triamterene crosses the placenta and may be distributed into breast milk.

Uses and Administration

Triamterene is a weak diuretic with potassium-sparing properties which has actions and uses similar to those of amiloride (p.1210). It produces a diuresis in about 2 to 4 hours, with a duration of 7 to 9 hours. The full therapeutic effect may be delayed until after several days of treatment.

Triamterene adds to the natriuretic but diminishes the kaliuretic effects of other diuretics. It is mainly used, as an adjunct to thiazide diuretics such as hydrochlorothiazide and loop diuretics such as furosemide, to conserve potassium in those at risk from hypokalaemia during the treatment of refractory oedema associated with hepatic cirrhosis, heart failure (p.1165), and the nephrotic syndrome. It is also used with other diuretics in the treatment of hypertension (p.1171).

When triamterene is given alone in the treatment of **oedema**, the oral dosage range is 150 to 250 mg daily, given in 2 divided doses, after breakfast and lunch. Doses may be given on alternate days for maintenance therapy. More than 300 mg daily should not be given.

Smaller doses are used initially when other diuretics are also given. When used with hydrochlorothiazide, for example, in the treatment of **hypertension**, an initial dose of 50 mg of triamterene daily may be used.

Potassium supplements should not be given.

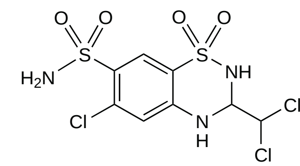
Trichlormethiazide *(rINN)* ⊗

Trichlorméthiazide; Trichlormethiazidum; Triclormetiazida; Trikloorimetiatsidi; Triklormetiazid. 6-Chloro-3-dichloromethyl-3,4-dihydro-2*H*-1,2,4-benzothiadiazine-7-sulphonamide 1,1-dioxide.

Трихлорметиазид

$C_8H_8Cl_3N_3O_4S_2$ = 380.7.
CAS — 133-67-5.
ATC — C03AA06.
ATC Vet — QC03AA06.



Pharmacopoeias. In *Jpn* and *US.*

USP 31 (Trichlormethiazide). A white or practically white, crystalline powder, odourless or with a slight characteristic odour. Soluble 1 in 1100 of water, 1 in 48 of alcohol, 1 in 5000 of chloroform, 1 in about 4 of dimethylformamide, 1 in about 9 of dioxan, and 1 in 1400 of ether; freely soluble in acetone; soluble in methyl alcohol.

Profile

Trichlormethiazide is a thiazide diuretic with properties similar to those of hydrochlorothiazide (p.1307). It is given orally for oedema, including that associated with heart failure (p.1165), and for hypertension (p.1171).

Diuresis begins about 2 hours after an oral dose, and lasts about 24 hours.

In the treatment of oedema the usual dose is 1 to 4 mg daily or intermittently. In the treatment of hypertension the usual dose is 2 to 4 mg daily, either alone, or with other antihypertensives. In some patients 1 mg daily may be adequate. In children over 6 months of age a dose of 70 micrograms/kg daily in one or two doses has been used.

Preparations

USP 31: Trichlormethiazide Tablets.

Proprietary Preparations (details are given in Part 3)
USA: Diurese†; Metahydrin†; Naqua†.

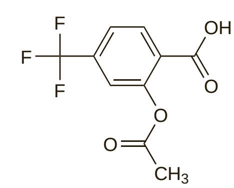
Multi-ingredient: ***Fin.:*** Uretren Comp; ***Ger.:*** Esmalorid†; ***Spain:*** Rulun; ***USA:*** Metatensin†.

Triflusal *(BAN, rINN)*

Triflusaali; Triflusalis; Triflusalum; Trifluzál; UR-1501. 2-Acetoxy-4-trifluoromethylbenzoic acid; *O*-Acetyl-4-(trifluoromethyl)salicylic acid.

Трифлусал

$C_{10}H_7F_3O_4$ = 248.2.
CAS — 322-79-2.
ATC — B01AC18.
ATC Vet — QB01AC18.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Triflusal). A white or almost white crystalline powder. Practically insoluble in water; very soluble in dehydrated alcohol; freely soluble in dichloromethane. Store in airtight containers at a temperature not exceeding 25°.

Profile

Triflusal is an inhibitor of platelet aggregation used in the management of thromboembolic disorders (p.1187) in usual oral doses of 300 to 900 mg daily.

◊ References.

Trimetaphan Camsilate *(BAN, rINN)*

Cansilato de trimetafán; Méthioplégium; Trimetaphan Camphorsulfonate; Trimétaphan, Camsilate de; Trimetaphan Camsylate; Trimetaphani Camsilas; Trimetaphani Camsylas; Trimethaphan Camsylate. (+)-1,3-Dibenzylperhydro-2-oxothieno-[1′,2′:1,2]thieno[3,4-*d*]-imidazol-5-ium 2-oxobornane-10-sulfonate; 4,6-Dibenzyl-4,6-diaza-1-thioniatricyclo[$6.3.0.0^{3,7}$]undecan-5-one 2-oxobornane-10-sulfonate.

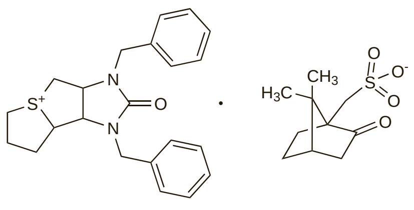
Триметафана Камзилат

$C_{22}H_{25}N_2OS,C_{10}H_{15}O_4S$ = 596.8.

CAS — 7187-66-8 (trimetaphan); 68-91-7 (trimetaphan camsilate).

ATC — C02BA01.

ATC Vet — QC02BA01.



Incompatibility. Trimetaphan is incompatible with thiopental sodium, gallamine triethiodide, iodides, bromides, and strongly alkaline solutions.

Adverse Effects and Treatment

The adverse effects of trimetaphan are mainly due to ganglionic blockade. A reduction in gastrointestinal motility may cause constipation and, on prolonged use, paralytic ileus. Urinary retention, cycloplegia, mydriasis, tachycardia, precipitation of angina, and gastrointestinal disturbances such as anorexia, nausea, or vomiting, may occur. Orthostatic hypotension may be severe. Rapid intravenous infusion can result in respiratory arrest. Other adverse effects include raised intra-ocular pressure, dry mouth, hypoglycaemia, hypokalaemia, fluid retention, weakness, urticaria, and itching. Trimetaphan crosses the placenta and can cause paralytic or meconium ileus in the neonate.

If severe hypotension occurs, trimetaphan should be stopped and the patient positioned with the head lower than the feet. A vasopressor may be given cautiously if necessary.

Effects on the eyes. Although trimetaphan may increase intra-ocular pressure, a sudden and dramatic reduction of intra-ocular pressure to very low levels was noted in 5 patients undergoing surgery when the systolic blood pressure was reduced to 60 mmHg with trimetaphan infusion.[1]

1. Dias PLR, *et al.* Effect on the intraocular pressure of hypotensive anaesthesia with intravenous trimetaphan. *Br J Ophthalmol* 1982; **66:** 721–4.

Precautions

Trimetaphan should be avoided in patients with asphyxia or respiratory insufficiency, uncorrected anaemia, shock or hypovolaemia, severe arteriosclerosis, severe ischaemic heart disease, or pyloric stenosis and should only be used with extreme caution in those with hepatic or renal impairment, degenerative disease of the CNS, Addison's disease, prostatic hyperplasia, glaucoma, cerebral or coronary vascular insufficiency, and diabetes. It should be used with care in elderly or debilitated patients and should be avoided in pregnancy. Owing to a histamine-liberating effect it should be used with caution in allergic subjects.

Interactions

Trimetaphan should be used with caution in patients being treated with other antihypertensives, drugs that depress cardiac function, or muscle relaxants, and in those taking NSAIDs or corticosteroids. The hypotensive effect is enhanced by general and spinal anaesthetics. Adrenaline should not be infiltrated locally at the site of incision when trimetaphan is being given since this may antagonise the effect of trimetaphan.

Neuromuscular blockers. For a reference to possible potentiation of neuromuscular blockade by trimetaphan, see Ganglion Blockers, under Interactions of Atracurium, p.1904.

Uses and Administration

Trimetaphan is a ganglion blocker that inhibits the transmission of nerve impulses in both sympathetic and parasympathetic ganglia. The sympathetic blockade produces peripheral vasodilatation. Trimetaphan also has a direct vasodilator effect on peripheral blood vessels. It has been used for inducing controlled hypotension during surgical procedures; it acts rapidly to produce a hypotensive response which persists for about 10 to 15 minutes. Trimetaphan has also been used for the emergency treatment of hypertensive crises (p.1171), especially in the presence of pulmonary oedema or acute dissecting aortic aneurysms. However, sodium nitroprusside is now preferred.

Trimetazidine Hydrochloride *(BANM, rINNM)*

Hidrocloruro de trimetazidina; Trimetatsidiinidihydrokloridi; Trimetazidin Hidroklorür; Trimetazidindihidroklorid; Trimetazidindihydrochlorid; Trimetazidindihydroklorid; Trimétazidine, Chlorhydrate de; Trimétazidine, dichlorhydrate de; Trimetazidine Dihydrochloride; Trimetazidini dihydrochloridum; Trimetazidini Hydrochloridum; Trimetazidino hidrochloridas; Trimetazine Hydrochloride. 1-(2,3,4-Trimethoxybenzyl)piperazine dihydrochloride.

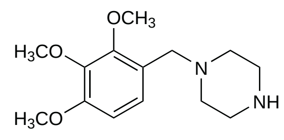
Триметазидина Гидрохлорид

$C_{14}H_{22}N_2O_3,2HCl$ = 339.3.

CAS — 5011-34-7 (trimetazidine); 13171-25-0 (trimetazidine hydrochloride).

ATC — C01EB15.

ATC Vet — QC01EB15.



(trimetazidine)

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*

Ph. Eur. 6.2 (Trimetazidine Dihydrochloride; Trimetazidine Hydrochloride BP 2008). A slightly hygroscopic, white or almost white crystalline powder. Freely soluble in water; sparingly soluble in alcohol. Store in airtight containers.

Profile

Trimetazidine hydrochloride is used in angina pectoris (p.1157) and in ischaemia of neurosensorial tissues as in Ménière's disease (p.564); 40 to 60 mg is given daily by mouth in divided doses.

◊ References.

Effects on the nervous system. Eight elderly patients aged between 72 and 94 years were reported[1] to have developed signs of parkinsonism while taking trimetazidine; the parkinsonism regressed completely when the drug was stopped. A retrospective study[2] found that adverse effects on motor function, including parkinsonism, gait disorders, and tremor, occurred in 56 of 130 patients taking trimetazidine and were more common in older patients.

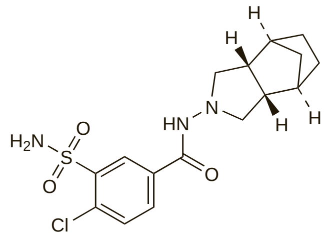
Tripamide *(USAN, rINN)* ⊗

ADR-033; E-614; Tripamida; Tripamidum. 4-Chloro-*N*-(*endo*-hexahydro-4,7-methanoisoindolin-2-yl)-3-sulphamoylbenzamide.

Трипамид

$C_{16}H_{20}ClN_3O_3S$ = 369.9.

CAS — 73803-48-2.



Profile

Tripamide is a diuretic structurally related to indapamide. It is used in the treatment of hypertension.

Preparations

Proprietary Preparations (details are given in Part 3)
Thai.: Normonal.

Urapidil *(BAN, rINN)*

B-66256M; Urapidiili; Urapidilum. 6-[3-(4-*o*-Methoxyphenylpiperazin-1-yl)propylamino]-1,3-dimethyluracil.

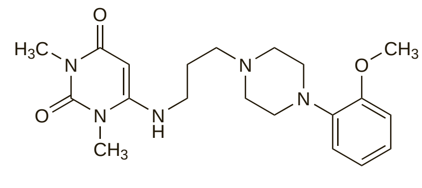
Урапидил

$C_{20}H_{29}N_5O_3$ = 387.5.

CAS — 34661-75-1.

ATC — C02CA06.

ATC Vet — QC02CA06.



Pharmacopoeias. In *Jpn.*

Urapidil Hydrochloride *(BANM, rINNM)*

Hidrocloruro de urapidil; Urapidil, Chlorhydrate d'; Urapidili Hydrochloridum.

Урапидила Гидрохлорид

$C_{20}H_{29}N_5O_3,HCl$ = 423.9.

CAS — 64887-14-5.

ATC — C02CA06.

ATC Vet — QC02CA06.

Adverse Effects and Precautions

Urapidil is reported to be well-tolerated, with adverse effects generally transient and most frequent at the beginning of therapy. Dizziness, nausea, headache, fatigue, orthostatic hypotension, palpitations, nervousness, pruritus, and allergic skin reactions have been reported.

It should be used with care in elderly patients and those with severe hepatic impairment. Intravenous urapidil should not be used in patients with aortic stenosis.

Urinary incontinence. Enuresis was reported[1] to be associated with the use of urapidil in 2 elderly patients.

1. Jonville A-P, *et al.* Urapidil and enuresis. *Lancet* 1992; **339:** 688.

Pharmacokinetics

After oral doses urapidil is rapidly absorbed with a reported bioavailability of 70 to 80%. It is reported to be about 80% bound to plasma proteins. Urapidil is extensively metabolised in the liver, mainly by hydroxylation, and excreted mostly in urine, as metabolites and 10 to 20% of unchanged drug. The elimination half-life is reported to be about 4.7 hours when given orally as capsules and about 2.7 hours after intravenous dosage.

◊ Reviews.

1. Kirsten R, *et al.* Clinical pharmacokinetics of urapidil. *Clin Pharmacokinet* 1988; **14:** 129–40.

Uses and Administration

Urapidil is an antihypertensive drug that is reported to block peripheral $alpha_1$ adrenoceptors (see Alpha Blockers, p.1153) and to have central actions. It produces a reduction in peripheral resistance and a fall in systolic and diastolic blood pressure, usually without reflex tachycardia.

Urapidil is used in the management of hypertension (p.1171), including hypertensive crises.

Urapidil is given orally as the base and intravenously as the hydrochloride, but doses are usually expressed in terms of the base. Urapidil hydrochloride 10.94 mg is equivalent to about 10 mg of urapidil. Urapidil fumarate has also been given orally.

In hypertension doses of 30 to 90 mg are given twice daily by mouth. In hypertensive crises a suggested regimen is to give an initial dose of 25 mg by slow intravenous injection over 20 seconds, repeated if necessary after 5 minutes. This may be followed by a dose of 50 mg after a further 5 minutes if the response is still inadequate. Treatment should continue with a maintenance infusion of 9 to 30 mg/hour once the blood pressure is sufficiently reduced.

Urokinase *(BAN, USAN, rINN)*

Urokinaasi; Urokinas; Urokinasa; Urokinasum; Ürokinaz; Urokináz; Urokinazė; Uroquinasa.

Урокиназа

CAS — 9039-53-6.

ATC — B01AD04.

ATC Vet — QB01AD04.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *Jpn.*

Ph. Eur. 6.2 (Urokinase). An enzyme isolated from human urine that activates plasminogen. It consists of a mixture of low (33 000) and high (54 000) molecular mass forms, the high molecular mass form being predominant. The potency is not less than 70 000 international units per mg of protein. A white or almost white, amorphous powder. Soluble in water. Store in airtight containers at a temperature not exceeding 8°. Protect from light.

Stability. Solutions of urokinase containing 2500 to 25 000 units/mL were found to be stable in single-use syringes when stored at −30° for 30 days and also when stored frozen for 7 days, thawed, and refrozen for a further 23 days.[1]

1. Dedrick SC, Ramirez-Rico J. Potency and stability of frozen urokinase solutions in syringes. *Am J Health-Syst Pharm* 2004; **61:** 1586–9.

Units

The potency of urokinase is expressed in international units. Preparations are assayed using the first International Reference Preparation (1968), a mixture of low-molecular-weight and high-molecular-weight urokinases. The first International Standard for high-molecular-weight urokinase was established in 1989 for use with preparations of this type of urokinase.

Potency used to be expressed in Ploug or Plough units or in CTA units, but these now appear to be obsolete.

Adverse Effects, Treatment, and Precautions

As for Streptokinase, p.1402. Serious allergic reactions may be less likely to occur with urokinase than with streptokinase.

Hypersensitivity. Allergic reactions are considered to be less frequent with urokinase than with streptokinase. However, in a series of 6 patients who had previously been treated with streptokinase,[1] thrombolytic therapy with urokinase for recurrent myocardial infarction was associated with rigors in 4 patients, 2 of whom also developed bronchospasm. None of the patients had any history of atopy.

1. Matsis P, Mann S. Rigors and bronchospasm with urokinase after streptokinase. *Lancet* 1992; **340:** 1552.

Transmission of infection. Some preparations of urokinase are produced in cultures of human cells and there is a risk of transmission of infection associated with their use.

Interactions

As for Streptokinase, p.1404.

Pharmacokinetics

After intravenous infusion urokinase is cleared rapidly from the circulation by the liver. A plasma half-life of up to 20 minutes has been reported.

Uses and Administration

Urokinase is a thrombolytic produced by the kidney and found in human urine. It directly converts plasminogen to plasmin, a proteolytic enzyme with fibrinolytic effects. The mechanisms of fibrinolysis are discussed further under Haemostasis and Fibrinolysis on p.1045. Urokinase affects circulating, unbound plasminogen as well as fibrin-bound plasminogen and thus may be termed a fibrin-nonspecific thrombolytic (see p.1156).

Urokinase is used similarly to streptokinase (p.1404) in the management of thromboembolic disorders including venous thromboembolism (pulmonary embolism and deep-vein thrombosis; p.1189) and peripheral arterial thromboembolism (p.1178). It is also used to clear occluded catheters and cannulas. Urokinase has been used in myocardial infarction and for clearing clots after haemorrhage within the eye.

In the treatment of **venous thromboembolism**, urokinase is given by intravenous infusion in an initial dose of 4400 units/kg over 10 minutes. This is followed by 4400 units/kg per hour for 12 hours in pulmonary embolism, and for 12 to 24 hours in deep-vein thrombosis. Alternatively, patients with pulmonary embolism may be given a bolus injection of 15 000 units/kg into the pulmonary artery; the injection may be repeated, with the dose adjusted according to plasma-fibrinogen concentration, up to 3 times in 24 hours.

In the treatment of **peripheral arterial thromboembolism**, a solution containing urokinase 2000 units/mL is infused into the clot via a catheter at a rate of 4000 units/minute for 2 hours. Angiography should then be performed and, if flow has not resumed, the catheter should be advanced into the occluded vessel and the infusion continued at the same rate for a further 2 hours. The procedure may be repeated, if necessary, up to 4 times. Once blood flow is re-established, the catheter should be partially withdrawn and infusion continued at a rate of 1000 units/minute until the remaining clot has lysed; a dose of 500 000 units given over 8 hours is usually sufficient.

For **clearing occluded intravenous catheters or cannulas**, 5000 to 25 000 units of urokinase dissolved in 2 mL of sodium chloride 0.9% may be instilled into the device and clamped off for up to 4 hours; the lysate is then aspirated and the procedure repeated if necessary. Alternatively, a solution of 5000 units of urokinase in 200 mL of sodium chloride 0.9% may be infused into the device over 30 minutes.

Catheters and cannulas. For reference to the use of urokinase to maintain patency of long-term venous access devices, see under Uses for Alteplase, p.1208.

Valsartan *(BAN, USAN, rINN)*

CGP-48933; Valsartaani; Valsartán; Valsartanum. *N*-[*p*-(*o*-1*H*-Tetrazol-5-ylphenyl)benzyl]-*N*-valeryl-L-valine; *N*-Pentanoyl-*N*-[2′-(1*H*-tetrazol-5-yl)biphenyl-4-ylmethyl]-L-valine.

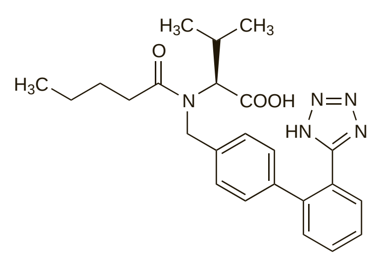
Вальзартан

$C_{24}H_{29}N_5O_3$ = 435.5.

CAS — 137862-53-4.

ATC — C09CA03.

ATC Vet — QC09CA03.



Pharmacopoeias. In *US.*

USP 31 (Valsartan). Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°.

Suspension. The US licensed product information provides the following method for making 160 mL of a suspension containing valsartan 4 mg/mL:

- add 80 mL of *Ora-Plus* (*Paddock, USA*) to an amber glass bottle containing eight 80-mg tablets (*Diovan, Novartis*) and shake for at least 2 minutes
- allow to stand for at least 1 hour then shake again for at least 1 minute
- add 80 mL of *Ora-Sweet SF* (*Paddock, USA*) to the bottle and shake for at least 10 seconds

The suspension can be stored for 30 days at or below 30° or for up to 75 days at 2° to 8°.

Adverse Effects and Precautions

As for Losartan Potassium, p.1326. Valsartan should be used with caution in patients with hepatic impairment, cirrhosis, or biliary obstruction.

Interactions

As for Losartan Potassium, p.1327.

Pharmacokinetics

Valsartan is rapidly absorbed after oral doses, with a bioavailability of about 23%. Peak plasma concentrations of valsartan occur 2 to 4 hours after an oral dose. It is between 94 and 97% bound to plasma proteins. Valsartan is not significantly metabolised and is excreted mainly via the bile as unchanged drug. The terminal elimination half-life is about 5 to 9 hours. Following an oral dose about 83% is excreted in the faeces and 13% in urine.

◊ References.

2. Prasad PP, *et al.* Pharmacokinetics of multiple doses of valsartan in patients with heart failure. *J Cardiovasc Pharmacol* 2002; **40:** 801–7.

Uses and Administration

Valsartan is an angiotensin II receptor antagonist with actions similar to those of losartan (p.1327). It is used in the management of hypertension (p.1171), to reduce cardiovascular mortality in patients with left ventricular dysfunction after myocardial infarction (p.1175), and in the management of heart failure (see under Losartan Potassium, p.1327).

Valsartan is given orally. After a dose the hypotensive effect occurs within 2 hours, reaches a peak within 4 to 6 hours, and persists for over 24 hours. The maximum hypotensive effect is achieved within 2 to 4 weeks.

In **hypertension**, valsartan is given in an initial dose of 80 mg once daily. This may be increased, if necessary, to 160 mg once daily; the maximum dose is 320 mg once daily. A lower initial dose of 40 mg once daily may be used in elderly patients over 75 years, and in those with intravascular volume depletion.

In **heart failure,** valsartan is given in an initial dose of 40 mg twice daily. The dose should be increased, as tolerated, to 160 mg twice daily.

In patients who have had **myocardial infarction**, valsartan may be started as early as 12 hours after the infarction in clinically stable patients, in an initial dose of 20 mg twice daily; the dose may be doubled at intervals over the next few weeks up to 160 mg twice daily if tolerated.

Valsartan should be used with caution in patients with hepatic or renal impairment and dose reduction may be required (see below).

◊ Reviews.

1. Markham A, Goa KL. Valsartan: a review of its pharmacology and therapeutic use in essential hypertension. *Drugs* 1997; **54:** 299–311.
2. Ripley TL. Valsartan in chronic heart failure. *Ann Pharmacother* 2005; **39:** 460–9.
3. Mistry NB, *et al.* The angiotensin receptor antagonist valsartan: a review of the literature with a focus on clinical trials. *Expert Opin Pharmacother* 2006; **7:** 575–81.
4. Bissessor N, White H. Valsartan in the treatment of heart failure or left ventricular dysfunction after myocardial infarction. *Vasc Health Risk Manag* 2007; **3:** 425–30.

Administration in children. Valsartan may be used for hypertension in children aged 6 to 16 years. US licensed product information recommends an initial dose of 1.3 mg/kg once daily (up to a maximum of 40 mg). The dose should be adjusted according to response, but doses above 2.7 mg/kg daily have not been studied. A suspension formulation may be used (see Suspension, above) but exposure to valsartan may be higher with the suspension than with tablets. There is no experience with valsartan in children with renal impairment (creatinine clearance below 30 mL/minute per 1.73 m^2) and it should therefore not be used in such children.

Administration in hepatic or renal impairment. The elimination of valsartan may be reduced in patients with hepatic impairment or biliary obstruction and it should be used with caution, if at all, in such patients; dose reductions may be required. In the UK, valsartan is contra-indicated in patients with severe hepatic impairment, cirrhosis, or biliary obstruction. In mild to moderate hepatic impairment an initial dose of 40 mg once daily and a maximum dose of 80 mg once daily is recommended for hypertension, and the dose after myocardial infarction should not generally exceed 80 mg twice daily.

Lower doses of valsartan may also be considered in patients with renal impairment. In the UK, an initial dose of 40 mg once daily is recommended for the treatment of hypertension in patients with moderate or severe renal impairment (creatinine clearance less than 20 mL/minute). Doses may need to be reduced in patients with heart failure or after myocardial infarction if renal function deteriorates.

Preparations

USP 31: Valsartan and Hydrochlorothiazide Tablets.

Proprietary Preparations (details are given in Part 3)
Arg.: Alpertan; Diovan; Redutensil†; Sarval; Simultan; ***Austria:*** Angiosan; Diovan; ***Belg.:*** Diovane; ***Braz.:*** Diovan; Tareg†; ***Canad.:*** Diovan; ***Chile:*** Tareg; Valaplex; Vartalan; ***Cz.:*** Diovan; Sarton†; Valsacor; ***Denm.:*** Diovan; ***Fin.:*** Diovan; ***Fr.:*** Nisis; Tareg; ***Ger.:*** Cordinate; Diovan; Provas; ***Gr.:*** Dalzad; Diovan; ***Hong Kong:*** Diovan; ***Hung.:*** Diovan; Varexan; ***India:*** Diovan; Starval; ***Indon.:*** Diovan; ***Irl.:*** Diovan; ***Israel:*** Diovan; ***Ital.:*** Rixil; Tareg; Valpression; ***Jpn:*** Diovan; ***Malaysia:*** Diovan; ***Mex.:*** Diovan; ***Neth.:*** Diovan; ***Norw.:*** Diovan; ***Philipp.:*** Diovan; ***Pol.:*** Diovan; ***Port.:*** Diovan; Tareg; ***Rus.:*** Diovan (Диован); ***S.Afr.:*** Diovan; Tareg; ***Singapore:*** Diovan; ***Spain:*** Diovan; Kalpress; Miten; Vals; ***Swed.:*** Diovan; ***Switz.:*** Diovan; Provas; ***Thai.:*** Diovan; ***Turk.:*** Diovan; ***UK:*** Diovan; ***USA:*** Diovan; ***Venez.:*** Alsart; Diovan; Vasaten.

Verapamil Hydrochloride

(BANM, USAN, rINNM)

CP-16533-1 (verapamil); D-365 (verapamil); Hidrocloruro de verapamilo; Iproveratril Hydrochloride; Verapamiilihydrokloridi; Vérapamil, chlorhydrate de; Verapamil Hidroklorür; Verapamil-hidroklorid; Verapamil-hydrochlorid; Verapamilhydroklorid; Verapamili hydrochloridum; Verapamilio hidrochloridas. 5-[*N*-(3,4-Dimethoxyphenethyl)-*N*-methylamino]-2-(3,4-dimethoxyphenyl)-2-isopropylvaleronitrile hydrochloride.

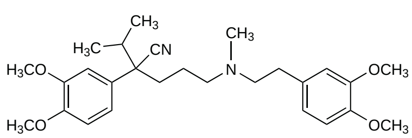
Верапамила Гидрохлорид

$C_{27}H_{38}N_2O_4,HCl = 491.1.$

CAS — 52-53-9 (verapamil); 152-11-4 (verapamil hydrochloride).

ATC — C08DA01.

ATC Vet — QC08DA01.



(verapamil)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Verapamil Hydrochloride). A white or almost white, crystalline powder. Soluble in water; sparingly soluble in alcohol; freely soluble in methyl alcohol. A 5% solution in water has a pH of 4.5 to 6.0. Protect from light.

USP 31 (Verapamil Hydrochloride). A white or practically white, practically odourless, crystalline powder. Soluble in water; sparingly soluble in alcohol; freely soluble in chloroform; practically insoluble in ether. A 5% solution in water has a pH of 4.5 to 6.5. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Incompatibility. Verapamil hydrochloride will precipitate in alkaline solutions. There have been reports of incompatibility with solutions of aminophylline,[1] nafcillin sodium,[2] and sodium bicarbonate.[3]

1. Johnson CE, *et al.* Compatibility of aminophylline and verapamil in intravenous admixtures. *Am J Hosp Pharm* 1989; **46:** 97–100.
2. Tucker R, Gentile JF. Precipitation of verapamil in an intravenous line. *Ann Intern Med* 1984; **101:** 880.
3. Cutie MR. Verapamil precipitation. *Ann Intern Med* 1983; **98:** 672.

Adverse Effects

Treatment with verapamil is generally well tolerated, but adverse effects connected with its pharmacological effects on cardiac conduction can arise and may be particularly severe in patients with previous myocardial damage or hypertrophic cardiomyopathies. Adverse effects on the heart include bradycardia, AV block, worsening heart failure, and transient asystole. These effects are more common with parenteral than with oral therapy.

The most troublesome non-cardiac adverse effect is constipation. Nausea may occur but is less frequently reported. Other adverse effects include hypotension, dizziness, flushing, headaches, fatigue, dyspnoea, and peripheral oedema. There have been reports of skin reactions and some cases of abnormal liver function and hepatotoxicity. Gingival hyperplasia has occurred. Gynaecomastia has been reported rarely.

In overdosage there may be severe cardiotoxicity and profound hypotension.

Carcinogenicity. See under Adverse Effects of Nifedipine, p.1350.

Effects on the cardiovascular system. For discussion of the possibility that calcium-channel blockers might be associated with increased cardiovascular mortality, see Effects on Mortality, under Adverse Effects of Nifedipine, p.1350.

Verapamil has vasodilating properties and negative inotropic activity and may cause adverse cardiovascular effects with worsening of arrhythmias. As discussed under Precautions (below) certain cardiac disorders put the patient at risk of severe toxicity.

Effects on the ears. There have been isolated reports[1] of tinnitus associated with several calcium-channel blockers including nifedipine, nicardipine, nitrendipine, diltiazem, verapamil, and cinnarizine.

1. Narváez M, *et al.* Tinnitus with calcium-channel blockers. *Lancet* 1994; **343:** 1229–30.

Effects on the endocrine system. Hyperprolactinaemia has been reported[1-4] in patients receiving verapamil, and in a few cases[2,3] patients have also had galactorrhoea.

Hyperglycaemia, metabolic acidosis, hyperkalaemia, and bradycardia have occurred[5] after a single dose of modified-release verapamil in a non-diabetic patient who had previously tolerated regular verapamil.

Verapamil has been reported not to affect the release of calcitonin,[6] thyroxine, tri-iodothyronine, thyrotrophin (TSH), follicle-stimulating hormone (FSH), luteinising hormone (LH), or testosterone when given orally;[1] however, intravenous use has been reported to have an inhibitory effect on the release of FSH, LH, and TSH.[7]

Effects on the gastrointestinal tract. For a report of intestinal pseudo-obstruction related to verapamil use, see under Adverse Effects of Diltiazem, p.1265.

Effects on the liver. Elevated serum concentrations of liver enzymes and bilirubin have been reported during verapamil therapy.[1-5] Clinical symptoms of hepatotoxicity such as abdominal pain, fever, darkened urine, and malaise have also occurred.[2-5] These reactions might have been due to a hypersensitivity reaction and were reversible on stopping verapamil.

Effects on the mouth. Gingival hyperplasia[1] and oral mucosal injury[2] have been associated with verapamil therapy. A study involving 115 patients who had received nifedipine, diltiazem, or verapamil for at least 3 months indicated that gingival hyperplasia is an important adverse effect that may occur with calcium-channel blockers in general.[3]

3. Steele RM, *et al.* Calcium antagonist-induced gingival hyperplasia. *Ann Intern Med* 1994; **120:** 663–4.

Effects on the nervous system. There has been a report[1] of 3 patients who complained of unusual perceptual symptoms, described as painful coldness and numbness or bursting feelings, especially in the legs, while taking oral verapamil.

1. Kumana CR, Mahon WA. Bizarre perceptual disorder of extremities in patients taking verapamil. *Lancet* 1981; **i:** 1324–5.

Effects on the neuromuscular system. Movement disorders, including acute dystonia,[1] myoclonic dystonia,[2] myoclonus,[3,4] and parkinsonism,[5,6] have occurred in patients receiving verapamil. However, there have also been reports of the successful use of verapamil in refractory movement disorders (see below).

1. Pina MA, *et al.* Verapamil and acute dystonia. *J Clin Pharm Ther* 1998; **23:** 79–80.

6. Padrell MD, *et al.* Verapamil-induced parkinsonism. *Am J Med* 1995; **99:** 436.

Effects on the peripheral circulation. Secondary erythermalgia, a vasospastic arterial disorder that may be caused by vasoactive drugs, has been reported[1,2] in patients taking verapamil. Symptoms included burning pain, swelling, and erythema of the hands[2] and feet,[1,2] and resolved when verapamil was stopped. Similar reactions have been reported with nifedipine and other calcium-channel blockers (see p.1351).

2. Hart JJ. Painful, swollen, and erythematous hands and feet. *Arthritis Rheum* 1996; **39:** 1761–2.

Effects on the respiratory tract. A patient with a history of bronchial asthma developed symptoms of acute asthma after use of a modified-release verapamil preparation;[1] it was possible that excipients, notably alginate, may have been responsible for the reaction.

1. Ben-Noun L. Acute asthma associated with sustained-release verapamil. *Ann Pharmacother* 1997; **31:** 593–5.

Effects on sexual function. In a group of 14 men taking verapamil, 3 reported impotence;[1] in 1 patient normal sexual function returned when verapamil was stopped, but impotence recurred on rechallenge.

1. King BD, *et al.* Impotence during therapy with verapamil. *Arch Intern Med* 1983; **143:** 1248–9.

Effects on the skin and hair. The commonest skin reactions to verapamil have been rash, pruritus, alopecia, and urticaria;[1] there have been a few reports of erythema multiforme, the Stevens-Johnson syndrome, and exfoliative dermatitis.[1] Hypertrichosis, over many parts of the body, has been reported in a male patient within about 1 month of starting verapamil therapy.[2] In a female patient who had been prematurely grey for about 40 years use of verapamil caused portions of the hair to regrow in its original natural black colour.[3]

Haemorrhage. See Effects on the Blood under Adverse Effects of Nifedipine, p.1350.

Overdosage. See under Treatment of Adverse Effects, below.

Treatment of Adverse Effects

As for Nifedipine, p.1352, but see also below.

Verapamil is not removed by dialysis.

Overdosage. The consequences and treatment of overdosage with verapamil are similar to those with other calcium-channel blockers (see Treatment of Adverse Effects under Nifedipine, p.1352), although death and life-threatening complications may be more common with non-dihydropyridines such as verapamil; a number of fatalities have occurred.[1]

Individual reports of overdosage with verapamil have included:

- A patient[2] who took 3.2 g of verapamil developed bradycardia and hypotension, which responded to intravenous calcium gluconate injection. A continuous infusion of calcium gluconate was given for 12 hours to maintain sinus rhythm. The blood-verapamil concentration measured 5 hours after ingestion was 4 micrograms/mL.

- A patient[3] presented with loss of consciousness, severe hypotension, and bradycardia up to 18 hours after taking at least 1.2 g of verapamil. Treatment with glucagon, prenalterol, and atropine was unsuccessful, and there was a minimal response to intravenous calcium gluconate. Dobutamine and isoprenaline were given to maintain the blood pressure and mechanical ventilation was required for 24 hours, during which time metabolic acidosis and hyperglycaemia developed. The patient survived with cerebral anoxic damage.
- A patient[4] who had taken an unknown amount of verapamil developed cyanosis, undetectable blood pressure, and complete heart block. There was some response to sympathomimetics and calcium gluconate, although pacing was necessary to reverse the bradycardia. However, hypotension unresponsive to sympathomimetics developed after an episode of asystole and the patient died 19 hours after admission. The serum-verapamil concentration 12 hours after admission was 3 micrograms/mL.
- Haematemesis occurred in a patient[5] who took 3.2 g of verapamil; gastric ulceration was found on gastroscopy 12 hours after admission.

Overdosage with modified-release preparations of verapamil may result in prolonged toxicity of delayed onset.[6] Conventional-release preparations may also produce prolonged toxicity; elimination half-life was reported to be prolonged to 15 hours and peak plasma concentrations delayed to 6 to 7 hours in a 59-year-old man after ingestion of 2.4 g of verapamil.[7] Rate-limiting absorption at high doses was considered to be the cause.

Although severe toxicity usually relates to acute verapamil overdosage, similar symptoms have also been reported with chronic toxicity. Long-term treatment with verapamil 240 mg daily[8] in a patient with cirrhosis of the liver led to loss of consciousness, cardiogenic shock, cyanosis, hypotension, severe acidosis, hyperkalaemia, hypothermia, and renal failure. The patient recovered after treatment with high doses of dopamine, noradrenaline, sodium bicarbonate, and sodium chloride.

Precautions

Verapamil is contra-indicated in hypotension, cardiogenic shock, marked bradycardia, and uncompensated heart failure. It is also contra-indicated in second- or third-degree AV block, and in the sick-sinus syndrome, unless a pacemaker is fitted. There is an increased incidence of adverse cardiac effects in patients with hypertrophic cardiomyopathy. In patients with atrial flutter or fibrillation and an accessory pathway with anterograde conduction, for example Wolff-Parkinson-White syndrome, verapamil may induce severe ventricular tachycardia and it is usually contra-indicated in such patients.

Special care is required in using verapamil as an antiarrhythmic in infants as they may be more susceptible to verapamil-induced arrhythmias.

Doses of verapamil should be reduced in patients with hepatic impairment.

Sudden withdrawal of verapamil might be associated with exacerbation of angina.

Breast feeding. Verapamil concentrations in breast milk similar to those found in plasma have been reported[1] in a woman taking verapamil 80 mg four times daily. The maximum concentration measured in breast milk was 300 nanograms/mL. However, the average concentration in milk in another woman[2] taking 80 mg three times daily was 23% of that in serum. The serum concentration of verapamil in the breast-fed child was 2.1 nanograms/mL during treatment and undetectable 38 hours after the last maternal dose. In another patient[3] taking the same dose, the average steady-state concentrations of verapamil and norverapamil in milk were, respectively, 60% and 16% of the concentration in plasma, with the ratio between milk and plasma varying during a dosage interval. It was estimated that the infant received less than 0.01% of the mother's dose, and no verapamil or norverapamil could be detected in the plasma of the infant. No adverse effects have been seen in breast-feeding infants, and the American Academy of Pediatrics considers[4] that verapamil is therefore usually compatible with breast feeding.

Muscular disorders. Sudden respiratory failure was believed to have been precipitated by intravenous verapamil therapy in a patient with Duchenne's muscular dystrophy.[1]

1. Zalman F, *et al.* Acute respiratory failure following intravenous verapamil in Duchenne's muscular dystrophy. *Am Heart J* 1983; **105:** 510–11.

Porphyria. Verapamil has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Wolff-Parkinson-White Syndrome. Patients with atrial flutter or fibrillation and an accessory pathway, such as those with Wolff-Parkinson-White syndrome, may be at increased risk of developing ventricular tachycardia if AV-blocking drugs such as verapamil are used, since conduction across the anomalous pathway may be increased. Ventricular fibrillation and severe hypotension have been reported[1] after the use of intravenous verapamil 5 to 10 mg in patients with the Wolff-Parkinson-White syndrome.

1. McGovern B, *et al.* Precipitation of cardiac arrest by verapamil in patients with Wolff-Parkinson-White syndrome. *Ann Intern Med* 1986; **104:** 791–4.

Interactions

Verapamil should be used with caution with drugs that have antiarrhythmic or beta-blocking effects; the use of intravenous verapamil with a beta blocker is especially hazardous (see below). Verapamil is extensively metabolised in the liver and interactions may occur with drugs that inhibit or enhance hepatic metabolism. Grapefruit juice may cause increased plasma concentrations of verapamil. Verapamil can itself affect the pharmacokinetics of other drugs, particularly by inhibition of the cytochrome P450 isoenzyme CYP3A4 and by effects on P-glycoprotein. Drugs affected include carbamazepine, ciclosporin, digoxin, midazolam, simvastatin, and theophylline; the plasma concentration of alcohol may also be increased. For details of these interactions, see under the individual drug monographs.

Analgesics. For a possible interaction of verapamil with *aspirin*, see under Antiplatelets, below.

Antiarrhythmics. Verapamil may have pharmacodynamic and pharmacokinetic interactions with other antiarrhythmics. Cardiogenic shock and asystole occurred in 2 patients receiving *flecainide* when verapamil was added to their therapy.[1] Verapamil given intravenously has been reported to cause severe hypotension in patients also receiving oral *quinidine*;[2] both drugs block alpha-adrenoceptors and verapamil may also increase the plasma concentration of quinidine.

1. Buss J, *et al.* Asystole and cardiogenic shock due to combined treatment with verapamil and flecainide. *Lancet* 1992; **340:** 546.
2. Maisel AS, *et al.* Hypotension after quinidine plus verapamil: possible additive competition at alpha-adrenergic receptors. *N Engl J Med* 1985; **312:** 167–70.

Antibacterials. Acute verapamil toxicity manifested by complete heart block has been reported in a patient after the use of *ceftriaxone* and *clindamycin*.[1] Displacement of verapamil from binding sites was postulated as the probable mechanism of action. *Rifampicin* is an enzyme-inducing drug and has been reported[2,3] to reduce plasma-verapamil concentrations. A verapamil dose of 1.92 g was required to control supraventricular tachycardia in a patient also taking rifampicin[3] and when rifampicin was withdrawn the plasma-verapamil concentration 9 days later was almost four times higher. A patient taking propranolol and verapamil developed symptomatic bradycardia a few days after starting treatment with *clarithromycin* and on another occasion after starting treatment with *erythromycin*.[4] Inhibition of verapamil metabolism by the antibacterials was proposed as the mechanism for the interaction. A further case of severe hypotension and bradycardia has also been reported[5] in a patient shortly after beginning therapy with clarithromycin and verapamil, and similar effects were seen[6] in a patient 2 days after starting *telithromycin*. A case of complete heart block has been reported[7] in a patient aged 79 taking verapamil, one week after erythromycin was added to her therapy, probably due to mutual inhibition of hepatic metabolism of both drugs.

7. Goldschmidt N, *et al.* Compound cardiac toxicity of oral erythromycin and verapamil. *Ann Pharmacother* 2001; **35:** 1396–9.

Antiepileptics. *Phenobarbital* is a hepatic enzyme-inducing drug and has been reported[1] to increase the clearance of oral and intravenous verapamil and to reduce oral bioavailability in healthy subjects. Plasma protein binding of verapamil was also reduced. Dosage adjustment of verapamil may be needed in patients also taking phenobarbital. Marked reduction in verapamil concentrations has also occurred with *phenytoin*.[2]

For a report of neurotoxicity in patients given verapamil with *carbamazepine*, see Calcium-channel Blockers, under Interactions of Carbamazepine, p.475.

1. Rutledge DR, *et al.* Effects of chronic phenobarbital on verapamil disposition in humans. *J Pharmacol Exp Ther* 1988; **246:** 7–13.
2. Woodcock BG, *et al.* A reduction in verapamil concentrations with phenytoin. *N Engl J Med* 1991; **325:** 1179.

Antiplatelets. Calcium-channel blockers can inhibit platelet function (see Effects on the Blood under Adverse Effects of Nifedipine, p.1350). Use of verapamil and *aspirin* in an 85-year-old man was considered to be the cause of ecchymoses and retroperitoneal bleeding that developed about 3 weeks after starting treatment with the combination.[1]

Anxiolytics. For the effect of verapamil on plasma-*buspirone* concentrations, see p.966.

Benzodiazepines. For the effects of verapamil on the pharmacokinetics of *midazolam*, see Calcium-channel Blockers, p.990.

Beta blockers. Oral verapamil and beta blockers have been used together in the treatment of angina and hypertension but both drugs have cardiodepressant activity and the combination, if used at all, must be used with extreme caution; bradycardia, heart block, and left ventricular failure have been reported.[1-4] Bradycardia has also been reported[5] in a patient treated with *timolol* eye drops and oral verapamil. Patients with severe ischaemic heart disease or heart failure are particularly at risk.[6] The risks are increased with intravenous verapamil, and it has been suggested[6] that treatment with beta blockers should be stopped at least 24 hours before giving verapamil by this route; the interaction is particularly hazardous when both verapamil and beta blockers are given intravenously, and such combinations are not recommended.

Verapamil may also affect the pharmacokinetics of some beta blockers (see Calcium-channel Blockers, under Interactions of Beta Blockers, p.1229).

6. McInnes GT. Interactions that matter: calcium blockers. *Prescribers' J* 1988; **28:** 60–4.

Calcium salts. Calcium salts antagonise the pharmacological response to verapamil and other calcium-channel blockers and are given intravenously to treat their adverse effects (see Treatment of Adverse Effects under Nifedipine, p.1352). Recurrence of atrial fibrillation has occurred[1] during maintenance verapamil treatment when calcium adipinate and calciferol were given orally.

1. Bar-Or D, Yoel G. Calcium and calciferol antagonise effect of verapamil in atrial fibrillation. *BMJ* 1981; **282:** 1585–6.

Everolimus. For the effect of verapamil on everolimus, see p.1834.

Histamine H_2-antagonists. Studies in healthy subjects using single doses of verapamil after pretreatment with *cimetidine* for up to 8 days have produced conflicting results. The pharmacokinetics of intravenous verapamil were unaltered by cimetidine in some studies,[1,2] but a 21% reduction in clearance and a 50% increase in the elimination half-life were also reported.[3] The pharmacokinetics of oral verapamil were unchanged in one study[2] but two others[1,4] reported a significant increase in bioavailability. Although one of these studies[1] found the interaction had no clinical effects, the other[4] reported an increased clinical effect in 5 of 6 subjects. The interaction with cimetidine appears to be stereoselective since the oral bioavailability of the *S*-enantiomer increased by 35% and that of the *R*-enantiomer by 15%.[4] The clinical significance of this interaction in patients and during long-term verapamil treatment is unknown, but cimetidine should be used with caution in patients receiving verapamil.

Lithium. Verapamil may have effects on neuromuscular function (see under Adverse Effects, above) and neurotoxicity has occurred[1-4] in patients receiving lithium after the addition of verapamil to their therapy, despite serum-lithium concentrations (where reported[1,2,4]) remaining in the therapeutic range. Verapamil has also been reported to decrease serum-lithium concentrations.[5]

5. Weinrauch LA, *et al.* Decreased serum lithium during verapamil therapy. *Am Heart J* 1984; **108:** 1378–80.

St John's wort. A study in healthy subjects[1] found that repeated doses of St John's wort significantly reduced the plasma concentrations of both the *R*- and *S*-isomers of verapamil, probably due to induction of the cytochrome P450 isoenzyme CYP3A4.

1. Tannergren C, *et al.* St John's wort decreases the bioavailability of *R*- and *S*-verapamil through induction of the first-pass metabolism. *Clin Pharmacol Ther* 2004; **75:** 298–309.

Theophylline. For the effects of verapamil on the pharmacokinetics of theophylline, see Calcium-channel Blockers, p.1144.

Pharmacokinetics

Verapamil is about 90% absorbed from the gastrointestinal tract, but is subject to considerable first-pass metabolism in the liver and the bioavailability is only about 20%.

Verapamil exhibits bi- or tri-phasic elimination kinetics and is reported to have a terminal plasma half-life of 2 to 8 hours after a single oral dose or after intravenous dosage. With repeated oral doses half-life increases to 4.5 to 12 hours. Verapamil acts within 5 minutes when given intravenously and within 1 to 2 hours when given orally; peak plasma concentrations occur 1 to 2 hours after an oral dose. There is considerable interindividual variation in plasma concentrations.

Verapamil is about 90% bound to plasma proteins. It is extensively metabolised in the liver to at least 12 metabolites of which norverapamil has been shown to have some activity. About 70% of a dose is excreted by the kidneys in the form of its metabolites but about 16% is excreted in the bile into the faeces. Less than 4% is excreted unchanged. Verapamil crosses the placenta and is distributed into breast milk.

The elderly. Studies[1-3] comparing the pharmacokinetics and pharmacodynamics of verapamil in elderly (61 years and older) and young subjects have found that clearance and elimination half-life are increased in older subjects, and increased plasma concentrations have also been reported. However, there may also be changes in the response to verapamil in older subjects that are not directly related to the plasma concentration.

Metabolism. Verapamil is extensively metabolised in the liver to a number of metabolites, and several cytochrome P450 isoenzymes appear to be involved. An *in-vitro* study[1] has suggested that the main isoenzymes responsible for the metabolism of both enantiomers of verapamil are CYP3A4, CYP3A5, and CYP2C8, and that the same isoenzymes are involved in the further metabolism of norverapamil. However, since CYP2C8 generally makes up only a small part of the cytochrome P450 content of the liver, it was considered that this would have little significance for potential drug interactions. In contrast to some previous reports, the isoenzymes CYP1A2 and CYP2C9 were not found to be involved to any great extent.

1. Tracy TS, *et al.* Cytochrome P450 isoforms involved in metabolism of the enantiomers of verapamil and norverapamil. *Br J Clin Pharmacol* 1999; **47:** 545–52.

Stereospecificity. Verapamil is used as a racemic mixture. It has been shown[1] that *S*-verapamil is 3.3 times more potent than the racemic mixture and 11 times more potent than *R*-verapamil. Thus it was concluded that the cardiac effects of verapamil are related not to the total plasma-verapamil concentration but to the concentration of the *S*-isomer, and conventional plasma concentration monitoring will be of little value in establishing therapeutic plasma concentrations during multiple oral dosing.

A series of studies have been carried out to determine whether differences in the pharmacokinetics of the *R*- and *S*-isomers of verapamil could account for observed differences in the plasma concentration-response curve after oral and intravenous doses. When given intravenously, there were pronounced differences in the pharmacokinetics and protein binding of the 2 isomers;[2] the volume of distribution and total systemic clearance of *S*-verapamil were much higher than those of the *R*-isomer although the terminal half-life was similar. After oral doses of a mixture of *R*- and *S*-verapamil, plasma concentrations of the *R*-isomer were found to be substantially higher than those of the more potent *S*-isomer,[3] suggesting stereospecific first-pass hepatic metabolism and accounting for the apparent lower potency of verapamil when given orally. The proportion of *S*-isomer also depends on the oral formulation; modified-release formulations produce lower proportions of *S*-isomer in plasma than conventional formulations.[4]

Uses and Administration

Verapamil is a phenylalkylamine calcium-channel blocker (p.1154) and a class IV antiarrhythmic (p.1153). It slows conduction through the AV node, and thus slows the increased ventricular response rate that occurs in atrial fibrillation and flutter. Its anti-anginal effect is mainly due to coronary and peripheral vasodilatation, although it also inhibits coronary artery spasm; the decrease in peripheral vascular resistance reduces the work of the heart, which has a sparing effect on myocardial intracellular oxygen consumption. The decrease in peripheral vascular resistance may also explain its antihypertensive effect. Verapamil is used in the control of supraventricular arrhythmias and in the management of angina pectoris and hypertension. It may also be used in the management of myocardial infarction.

Verapamil may be given intravenously or orally, as the hydrochloride; doses are expressed in terms of verapamil hydrochloride.

In the acute management of supraventricular **arrhythmias** it is given intravenously, preferably under continuous ECG and blood pressure monitoring. The initial dose is 5 to 10 mg by slow intravenous injection over 2 to 3 minutes. If necessary, licensed product information in the UK allows a second dose of 5 mg to be given 5 to 10 minutes after the first; in the USA, a second dose of 10 mg may be given after 30 minutes.

Oral doses for the treatment of supraventricular arrhythmias are 120 to 480 mg daily in 3 or 4 divided doses, according to the severity of the condition and the patient's response.

In the management of **angina pectoris,** the usual oral dose is 120 mg three times daily; some patients with angina of effort may respond to 80 mg three times daily, but this lower dose is not likely to be effective in angina at rest or Prinzmetal's variant angina. Modified-release preparations may be given in doses of up to 480 mg daily.

In **hypertension** the usual initial oral dose is 240 mg daily, in 2 or 3 divided doses, adjusted according to response; doses of up to 480 mg daily have been used. Modified-release preparations may be given in similar daily doses.

In the secondary prevention of **myocardial infarction**, verapamil hydrochloride is given as a modified-release oral preparation, started at least 1 week after acute infarction (in patients without heart failure), in a dose of 360 mg daily in divided doses.

Doses of verapamil should be reduced in patients with hepatic impairment (see below).

For doses of verapamil in children with supraventricular arrhythmias or hypertension, see below.

◊ General reviews.

2. Prisant LM. Verapamil revisited: a transition in novel drug delivery systems and outcomes. *Heart Dis* 2001; **3:** 55–62.

Administration in children. Verapamil may be used for the treatment of supraventricular arrhythmias and hypertension in children, although great care is needed, especially in infants (see Precautions, above).

Intravenous doses of verapamil hydrochloride for supraventricular arrhythmias are as follows:

- children up to 1 year of age, 100 to 200 micrograms/kg
- 1 to 15 years, 100 to 300 micrograms/kg (to a maximum dose of 5 mg)

The dose should be given over at least 2 minutes and may be repeated after 30 minutes if necessary; doses at the lower end of the range may be adequate and the injection should be stopped when a response has been obtained.

Oral doses for supraventricular arrhythmias or for hypertension are:

- children up to 2 years of age, 20 mg two or three times daily
- 2 years and over, 40 to 120 mg two or three times daily according to age and response

Administration in the elderly. For a discussion of the effects of increasing age on verapamil, see under Pharmacokinetics, above.

Administration in hepatic impairment. Verapamil is extensively metabolised in the liver and should be used with caution in hepatic impairment; US licensed product information recommends that oral doses for patients with severe hepatic impairment should be reduced to about one-third of the usual dose (see above).

In a study[1] of patients with liver cirrhosis steady-state plasma concentrations of verapamil were double those seen in patients with normal liver function after intravenous doses and 5 times the normal concentration when given orally. The elimination half-life was prolonged about fourfold after oral or intravenous doses, suggesting that steady-state plasma concentration will not be reached in patients with liver cirrhosis until about 56 hours after therapy has started.

1. Somogyi A, *et al.* Pharmacokinetics, bioavailability and ECG response of verapamil in patients with liver cirrhosis. *Br J Clin Pharmacol* 1981; **12:** 51–60.

Administration in renal impairment. The pharmacokinetics and pharmacodynamic effects of verapamil are not significantly altered by renal impairment[1] and dosage adjustment is not considered to be necessary. The elimination of verapamil is not altered by haemodialysis,[1,2] haemofiltration,[2] or peritoneal dialysis[2] and no dosage supplement is required in patients undergoing these procedures.

Amaurosis fugax. For a report of the use of verapamil in patients with amaurosis fugax, see under Uses and Administration of Nifedipine, p.1354.

Bipolar disorder. Although lithium and valproate are the mainstays of therapy in bipolar disorder (p.372) many other drugs have been tried, including verapamil.[1] Beneficial responses to verapamil at doses up to 480 mg daily have been reported,[2-4] although a review[5] concluded that there is limited support for its use. Verapamil has also been used with lithium, but there may be an increased risk of neurotoxicity (see under Interactions, above).

Box jellyfish sting. Stings by the box jellyfish (*Chironex fleckeri*) (p.2220) can be fatal because of the effects of the venom on the cardiovascular and respiratory systems and on the kidneys. Studies in *rodents* have reported a beneficial effect of intravenous verapamil in the treatment of box jellyfish envenomation, and use in patients with serious box-jellyfish stings has been recommended.[1] However, it has also been suggested[2] that the lack of evidence for benefit and the potential for adverse effects means that use of verapamil should be limited to extreme cases only.

Cardiac arrhythmias. Verapamil has an established role in the management of supraventricular cardiac arrhythmias (p.1160). It is used for rate control in atrial fibrillation and flutter, and may also be used in paroxysmal supraventricular tachycardia. It has been successfully used with digoxin for transplacental therapy in fetal atrial flutter or supraventricular tachycardia,[1,2] although caution is necessary if it is used in infants since they may be particularly susceptible to its adverse effects (see Precautions, above).

2. Simpson JM, Sharland GK. Fetal tachycardias: management and outcome of 127 consecutive cases. *Heart* 1998; **79:** 576–81.

Cardiomyopathies. Verapamil has an established role as a negative inotrope in the management of patients with *hypertrophic cardiomyopathy*,[1,2] although it is usually reserved for patients in whom beta blockers either fail to control symptoms or are not tolerated. It may improve symptoms and exercise tolerance; although a crossover study[3] failed to show an improvement in exercise capacity with verapamil or the beta blocker nadolol, most patients preferred drug treatment to placebo and there was an apparent improvement in quality of life with verapamil. Verapamil may also be useful for rate control in patients with hypertrophic cardiomyopathy and chronic atrial fibrillation. However, there is no evidence that it reduces the incidence of sudden cardiac death, and serious adverse effects have been reported,[4] especially in patients with severe outflow obstruction. Patients with hypertrophic cardiomyopathy appear to be particularly susceptible to conduction disturbances associated with verapamil, and this may worsen hypotension and outflow obstruction.

Dilated cardiomyopathy is treated similarly to heart failure and calcium-channel blockers are not usually used, although some benefit has been reported with diltiazem (see p.1267).

For a discussion of the management of cardiomyopathies in general, see p.1163.

Kidney disorders. Calcium-channel blockers may be of benefit in various forms of kidney disorder (see Nifedipine, p.1355), although studies with verapamil have suggested that it is less effective than the ACE inhibitor trandolapril in patients with non-diabetic renal disease,[1] and that it does not prevent the development of renal disease in type 2 diabetics.[2] There is some evidence that verapamil may reduce the nephrotoxicity associated with certain drugs, including ciclosporin (see Transplantation, below), and the aminoglycoside gentamicin.[3]

Malignant neoplasms. Verapamil has been shown to reverse multidrug resistance to antineoplastics in cultured cells and in *animal* studies,[1] but studies in which verapamil was added to therapy for small cell lung cancer[2] or multiple myeloma[3] failed to show any benefit. See p.643 for a discussion of resistance to antineoplastics.

Migraine and cluster headache. For reference to the use of calcium-channel blockers, including verapamil, in the management of migraine and cluster headache, see under Nifedipine, p.1355.

Movement disorders. Verapamil has been associated with the development of various movement disorders (see under Adverse Effects, above) but there have also been case reports[1,2] of its successful use in refractory movement disorders, including severe tardive dyskinesia. However, a systematic review[3] concluded that evidence for the use of verapamil or other calcium-channel blockers in tardive dyskinesia is limited and they are not generally recommended.

The usual management of tardive dyskinesia is discussed under the Adverse Effects of Chlorpromazine, p.971.

Myocardial infarction. Calcium-channel blockers are not routinely used in either the acute or long-term treatment of myocardial infarction (p.1175), although some benefit has been reported with non-dihydropyridines. Diltiazem, started within 24 to 72 hours of the onset of infarction and continued for up to 14 days, has been reported to protect against re-infarction and refractory angina in patients recovering from acute non-Q-wave infarction.[1] A pilot study[2] of intravenous diltiazem as an adjunct to thrombolysis in acute myocardial infarction also suggested a reduction in recurrent ischaemia; diltiazem was given intravenously for 48 hours, beginning at the same time as the thrombolytic, then continued orally for 4 weeks. However, a study[3] with verapamil, started on admission to hospital, found no effect on mortality at 6 months, and there was a suggestion that very early use (within 6 hours of symptom onset) was detrimental. A later study[4] reported that early use of verapamil in patients receiving thrombolysis improved outcome at 90 days. Benefit has also been shown[5] with use of intracoronary verapamil to terminate post-reperfusion arrhythmias. For use of verapamil in patients receiving percutaneous coronary intervention see Reperfusion and Revascularisation Procedures, below.

Although they are not standard therapy, diltiazem and verapamil may be used for long-term management in selected patients without heart failure. In a study by the Multicenter Diltiazem Postinfarction Trial (MDPIT) research group,[6] diltiazem (target dose 240 mg daily) reduced 1-year mortality and re-infarction rates in patients without left ventricular dysfunction, but increased such adverse events in those with left ventricular dysfunction. Re-analysis of the study provided further evidence that diltiazem should be avoided in postinfarction patients with left ventricular dysfunction.[7] Another study[8] in patients with acute myocardial infarction treated with thrombolysis found no reduction in mortality with diltiazem started 36 to 96 hours after infarction and continued for up to 6 months, although the incidence of non-fatal cardiac events was reduced. Patients with heart failure were excluded from the trial. In the DAVIT II study[9] late intervention with verapamil (started in the second week after admission) reduced overall mortality, cardiac events, and re-infarction although another study[10] found only a benefit in re-infarction rate and not in overall mortality.

Peyronie's disease. Verapamil has been used by intraplaque injection for the treatment of Peyronie's disease.[1,2] Pain, curvature, and erectile dysfunction were all improved. A systematic review[2] of 19 studies involving plaque injection therapy for Peyronie's disease, of which 4 used verapamil, noted that although the results of these suggested that injection was safe and effective in mild to moderate Peyronie's disease, the quality of studies was generally poor and its efficacy needed to be verified. Verapamil has also been given by iontophoresis, but again benefits remain unclear. A study[3] comparing verapamil and dexamethasone with lidocaine reported considerable improvement in plaque volume, penile curvature, and pain in the group given verapamil and dexamethasone, while patients given lidocaine had a transient improvement in pain but no change in plaque volume or curvature. However, a study[4] comparing verapamil with sodium chloride as placebo reported some improvement with both treatments, with no difference between the groups.

Reperfusion and revascularisation procedures. Percutaneous coronary intervention is widely used in the management of patients with acute myocardial infarction and angina pectoris, and adjunctive drug treatment has an important role in reducing complications and improving outcome (see p.1181). Intracoronary verapamil may be used to treat vasospasm[1] and has also been used to treat[2,3] and prevent[4,5] the 'no-reflow' phenomenon. However, transient heart block occurred in some patients given verapamil prophylactically,[5] and this may limit its use.

There is also some evidence that verapamil may reduce the incidence of restenosis after coronary[6] or peripheral[7] percutaneous interventions.

Transplantation. Ciclosporin is widely used in transplantation to prevent rejection but its use is limited by its nephrotoxicity. Dihydropyridine calcium-channel blockers (see under Uses of Nifedipine, p.1356) and diltiazem (p.1267) have been reported to reduce ciclosporin-associated nephrotoxicity, and there is some evidence that verapamil may have a similar effect. Studies in renal[1,2] and heart or lung[3] transplant recipients suggested that verapamil can improve outcomes in patients receiving ciclosporin. Most studies have found that verapamil prevents ciclosporin-induced deterioration in renal function, despite increasing plasma-ciclosporin concentrations,[1,2] and there is also evidence[2] that graft survival may be improved. The beneficial effect of verapamil may be related to its ability to protect cells from ischaemia, selective vasodilatation of the afferent renal arterioles, or inherent immunosuppressive properties; its effect on plasma-ciclosporin concentrations may also be involved, either directly[1,2] or by allowing reduction of the ciclosporin dose.[3] However, one study[4] found that use of verapamil with ciclosporin resulted in higher serum-creatinine concentrations in patients given verapamil, with no reduction in the incidence of rejection, and careful monitoring is necessary if the drugs are used together. A higher incidence of severe infections has also been reported[5] in renal transplant patients given verapamil and ciclosporin; the authors suggested that if a rapid increase in plasma-ciclosporin concentrations was required, improved formulations of ciclosporin should be used rather than verapamil.

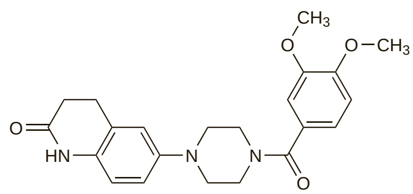
Vesnarinone *(USAN, rINN)*

OPC-8212; Vesnarinona; Vesnarinonum. 1-(1,2,3,4-Tetrahydro-2-oxo-6-quinolyl)-4-veratroylpiperazine.

Веснаринон

$C_{22}H_{25}N_3O_4 = 395.5.$

CAS — 81840-15-5.



Profile

Vesnarinone is a phosphodiesterase inhibitor with positive inotropic activity that has been tried orally in the management of heart failure.

Adverse effects. Studies with other inotropic phosphodiesterase inhibitors have shown that their prolonged oral use can lead to an increased mortality rate. In a multicentre study of vesnarinone,[1] doses of 120 mg daily resulted in increased mortality whereas 60 mg daily for 6 months was associated with lower morbidity and mortality. Reversible neutropenia occurred in 2.5% of the patients given 60 mg daily. However, in a subsequent larger study,[2] increased mortality was also reported with doses of 30 and 60 mg daily.

Warfarin Sodium *(BANM, rINNM)*

Natrii Warfarinum; Sodium Warfarin; Varfariininatrium; Varfarin Sodyum; Varfarino natrio druska; Warfarin sodná sůl; Warfarina sódica; Warfarine sodique; Warfarinnatrium; Warfarin-nátrium; Warfarinum natricum. The sodium salt of 4-hydroxy-3-(3-oxo-1-phenylbutyl)coumarin ; Sodium 2-oxo-3-[(1*RS*)-3-oxo-1-phenylbutyl]-2*H*-1-benzopyran-4-olate.

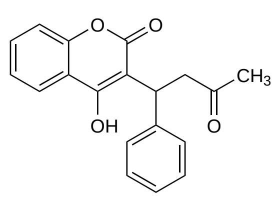
Натрий Варфарин

$C_{19}H_{15}NaO_4 = 330.3.$

CAS — 81-81-2 (warfarin); 2610-86-8 (warfarin potassium); 129-06-6 (warfarin sodium).

ATC — B01AA03.

ATC Vet — QB01AA03.



(warfarin)

NOTE. The use of the term warfarin sodium in *Martindale* should generally be taken to include the sodium clathrate. Until 1991 the BP, like the USP, allowed the use of either warfarin sodium or warfarin sodium clathrate in the definition of warfarin sodium.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int.*, and *US.*

Chin., Int., and *US* permit either warfarin sodium or warfarin sodium clathrate. *Eur.* has a separate monograph for warfarin sodium clathrate (see below).

Jpn includes Warfarin Potassium.

Ph. Eur. 6.2 (Warfarin Sodium). A white or almost white, hygroscopic, amorphous powder. Very soluble in water and in alcohol; soluble in acetone; very slightly soluble in dichloromethane. A 1% solution in water has a pH of 7.6 to 8.6. Store in airtight containers. Protect from light.

USP 31 (Warfarin Sodium). A white, odourless, amorphous solid or a crystalline clathrate which is discoloured by light. Very soluble in water; freely soluble in alcohol; very slightly soluble in chloroform and in ether. A 1% solution in water has a pH of 7.2 to 8.3. Protect from light.

Adsorption. Studies carried out for periods of 24 hours to 3 months found some adsorption of warfarin sodium by PVC when dissolved in 0.9% sodium chloride solution[1,2] or in 5% glucose solution.[3] In one of these studies,[1] adsorption was decreased by buffering the solution from its initial pH of 6.7 to a pH of 7.4. The second study[2] could demonstrate no adsorption onto polyethylene-lined or glass infusion containers.

2. Martens HJ, *et al.* Sorption of various drugs in polyvinyl chloride, glass, and polyethylene-lined infusion containers. *Am J Hosp Pharm* 1990; **47:** 369–73.
3. Moorhatch P, Chiou WL. Interactions between drugs and plastic intravenous fluid bags: part i: sorption studies on 17 drugs. *Am J Hosp Pharm* 1974; **31:** 72–8.

Incompatibility. Solutions of warfarin sodium have been reported to be incompatible with adrenaline hydrochloride, amikacin sulfate, metaraminol tartrate, oxytocin, promazine hydrochloride, and tetracycline hydrochloride. Visual incompatibility has been reported[1] with solutions of warfarin sodium mixed with solutions of aminophylline, bretylium tosilate, ceftazidime, cimetidine hydrochloride, ciprofloxacin lactate, dobutamine hydrochloride, esmolol hydrochloride, gentamicin sulfate, labetalol hydrochloride, metronidazole hydrochloride, or vancomycin hydrochloride. Haze was also reported after 24 hours with sodium chloride 0.9%.

1. Bahal SM, *et al.* Visual compatibility of warfarin sodium injection with selected medications and solutions. *Am J Health-Syst Pharm* 1997; **54:** 2599–2600.

Warfarin Sodium Clathrate *(BANM)*

Varfariininatriumklatraatti; Varfarino natrio druskos klatratas; Warfarin sodná sůl klatrát; Warfarina sódica, clatrato de; Warfarine sodique clathrate; Warfarinnatriumklatrat; Warfarin-nátrium-klatrát; Warfarinum natricum clathratum. The clathrate of warfarin sodium with isopropyl alcohol in the molecular proportions 2 to 1 respectively.

ATC — B01AA03.

ATC Vet — QB01AA03.

NOTE. The use of the term warfarin sodium in *Martindale* should generally be taken to include the sodium clathrate. Until 1991 the BP, like the USP, allowed the use of either warfarin sodium or warfarin sodium clathrate in the definition of warfarin sodium.

Pharmacopoeias. In *Eur.* (see p.vii).

Chin., Int., and *US* permit either warfarin sodium or warfarin sodium clathrate.

Ph. Eur. 6.2 (Warfarin Sodium Clathrate). A white or almost white, crystalline powder. Very soluble in water; freely soluble in alcohol; soluble in acetone; very slightly soluble in dichloromethane. A 1% solution in water has a pH of 7.6 to 8.6. Store in airtight containers. Protect from light.

Warfarin sodium clathrate contains about 92% of warfarin sodium.

Adverse Effects

The major risk from warfarin therapy is of haemorrhage from almost any organ of the body with the consequent effects of haematomas as well as anaemia. Although good control of warfarin anticoagulation is essential in preventing haemorrhage, bleeding has occurred at therapeutic international normalised ratio (INR) values. In such cases the possibility of an underlying cause such as renal or alimentary tract disease should be investigated. Skin necrosis, and purple discoloration of the toes (due to cholesterol embolisation) have occasionally occurred. Hypersensitivity reactions are extremely rare. Other effects not necessarily associated with haemorrhage include alopecia, fever, nausea, vomiting, diarrhoea, skin reactions, jaundice, hepatic dysfunction, and pancreatitis.

Warfarin is a recognised teratogen. Given in the first trimester of pregnancy it can cause a fetal warfarin syndrome or warfarin embryopathy characterised by bone stippling (chondrodysplasia punctata) and nasal hypoplasia. CNS abnormalities may develop after use in any trimester but appear most likely when used in the second or third trimester. Use of warfarin during pregnancy has been associated with an increased rate of abortion and still-birth, although this may, in part, be the consequence of an underlying maternal condition. Use in the late stages of pregnancy is associated with fetal haemorrhage. Reported incidences of the above complications have varied; one estimate is that if a coumarin anticoagulant is taken during pregnancy, one-sixth of pregnancies will result in an abnormal liveborn infant, and one-sixth will result in abortion or still-birth.

Effects on the blood. The incidence and risk of haemorrhage during long-term oral anticoagulation has been studied in patients in clinical trials[1,2] and in population-based studies.[1,3-7] The risk of bleeding was generally higher with more intense anticoagulation and in the presence of other risk factors, but the relationship with age was less clear. Some studies have shown higher rates of bleeding in elderly patients, but others have not; the risk of intracranial bleeding, however, does seem to be higher in the elderly.[2,6,7] Although cumulative risk of bleeding was related to duration of anticoagulation therapy, risk may be highest early in the course.[2]

Withdrawal of warfarin therapy may lead to rebound hypercoagulability and it has been suggested[8] that warfarin should be withdrawn gradually, although there is no clinical evidence to support this.

Effects on the bones. Vitamin K is involved in bone metabolism and vitamin K deficiency is associated with an increased risk of osteoporotic fractures. It has been suggested, therefore, that patients on long-term treatment with those oral anticoagulants that are vitamin K antagonists may be at increased risk of osteoporosis and fractures. However, two large observational studies in older women have produced conflicting results. A prospective study[1] of both users and nonusers of warfarin found that warfarin was not associated with decrease in bone density or increase in fracture rates. A retrospective study[2] reported an association between long-term anticoagulant use and increased risk of vertebral and rib fractures, compared with the general population. Overall, however, the risk of any fracture was not significantly increased.

3. Zimbelman J, *et al.* Unusual complications of warfarin therapy: skin necrosis and priapism. *J Pediatr* 2000; **137:** 266–8.

Effects on the skin and hair. Skin and soft-tissue necrosis is a rare but well-established adverse effect of coumarin anticoagulants.[1-4] It is characterised by a localised, painful skin lesion, initially erythematous or haemorrhagic in appearance, that becomes bullous and eventually culminates in gangrenous necrosis. Fatalities have occurred. Areas of increased subcutaneous fat such as breast, thigh, and buttocks have most often been involved. The aetiology appears to be thrombotic but the exact pathophysiology is not known. Patients with protein C deficiency appear to be at highest risk. Treatment with coumarin anticoagulants should be stopped if skin lesions appear and vitamin K should be given to reverse their effect. Heparin should be given to provide anticoagulation. Fresh frozen plasma or protein C concentrates may also have a role in reversing the condition. Surgical intervention is usually required if necrosis does develop.

Other skin reactions have also been reported with coumarins. Vasculitis affecting both legs developed in a 74-year-old woman a few weeks after starting treatment with acenocoumarol for deep-vein thrombosis and pulmonary embolism.[5] Acenocoumarol treatment was stopped and the skin lesions steadily improved over 15 days. However, the skin lesions reappeared a few hours after re-exposure to a single dose of acenocoumarol. The patient had also been taking amiodarone which may have contributed to the reaction. Henoch-Schönlein purpura was reported[6] in a 76-year-old woman 2 months after she started treatment with acenocoumarol; it resolved rapidly after the drug was withdrawn.

Increased shedding of telogen hair has been stated to occur in patients given coumarin anticoagulants.[7]

Treatment of Adverse Effects

The methods used to manage bleeding and/or excessive anticoagulation during warfarin therapy, or after warfarin overdosage, depend upon the degree of bleeding, the value of the international normalised ratio (INR), and the degree of thromboembolic risk.

For patients **over-anticoagulated** on warfarin, the *British Society for Haematology* recommends the following:

- in cases where the INR is 0.5 above the target value but less than 6.0, warfarin should be reduced in dose or withdrawn until the INR falls to below 5.0
- if the INR is greater than 6.0 but less than 8.0 and there is no bleeding or only minor bleeding, warfarin should be temporarily withheld until the INR falls to below 5.0
- for an INR greater than 8.0 use of phytomenadione (vitamin K_1) should also be considered if there are other risk factors for bleeding; typical doses of phytomenadione are 0.5 mg intravenously or up to 2.5 mg orally using the intravenous preparation. (The *BNF* allows 5 mg orally for more complete reversal of anticoagulation.)
- if there is any major bleeding warfarin should be stopped and phytomenadione given in a dose of 5 or 10 mg, preferably by slow intravenous injection. A concentrate of factors II, VII, IX, and X should also be given. The dose of concentrate should be calculated based on 50 units of factor IX/kg. If no concentrate is available fresh frozen plasma should be infused (about one litre for an adult), but may not be as effective. Higher doses of phytomenadione have been used (see Over-anticoagulation, p.1997); however phytomenadione takes several hours to act and large doses may reduce the response to resumed therapy with anticoagulants for a week or more.

US guidelines from the *American College of Chest Physicians* are as follows:

- if the INR is above therapeutic range but below 5.0, without significant bleeding, warfarin should be reduced in dose or stopped until the INR falls to therapeutic range
- for an INR of 5.0 or over but less than 9.0, warfarin should be stopped. If the patient is at increased risk of bleeding, phytomenadione 1 to 2.5 mg should be given orally, or up to 5 mg orally for more complete reversal of anticoagulation
- if the INR is 9.0 or above with no significant bleeding, warfarin should be stopped and phytomenadione 2.5 to 5 mg may be given orally
- if there is any major bleeding, warfarin should be stopped and phytomenadione 10 mg given by slow intravenous injection, with fresh plasma, concentrates of factors II, VII, IX, and X, or recombinant factor VIIa.

If bleeding occurs unexpectedly at therapeutic INR values, the possibility of an underlying cause such as renal or alimentary tract disease should be investigated.

See under Effects on the Skin and Hair, above, for the management of skin and soft tissue necrosis.

For **poisoning** in individuals not taking anticoagulant therapy, the *UK National Poisons Information Service* recommends that those who have ingested more than 250 micrograms/kg of warfarin or who have an INR greater than 6.0, should be given phytomenadione 10 to 20 mg orally or intravenously. If there is active bleeding, factor concentrate or fresh frozen plasma should also be given.

Precautions

Warfarin should not be given to patients who are haemorrhaging. In general it should not be given to patients at serious risk of haemorrhage, although it has been used with very careful control; patients at risk include those with haemorrhagic blood disorders, peptic ulcer disease, severe wounds (including surgical wounds), cerebrovascular disorders, and bacterial endocarditis. Consideration should be given to stopping warfarin a few days before an invasive procedure and using an alternative form of antithrombotic therapy. Severe hepatic and renal impairment as well as severe hypertension are considered by some to be contra-indications. Pregnancy is also generally considered to be a contra-indication, especially in the first trimester and during the late stages of pregnancy (see Adverse Effects, above).

Many factors may affect anticoagulant control with warfarin. These include vitamin K status, thyroid status, renal function, bioavailability differences between warfarin preparations, factors affecting absorption of warfarin, genetic variation in warfarin metabolism (see below), and drug interactions. Such factors may be responsible for apparent resistance to warfarin and a few patients have displayed hereditary resistance. Dosage alterations should be guided by regular monitoring of oral anticoagulant therapy and clinical status. Patients should carry anticoagulant treatment booklets.

◊ A discussion of factors affecting the anticoagulant effect of warfarin sodium.[1]

1. Shetty HGM, *et al.* Clinical pharmacokinetic considerations in the control of oral anticoagulant therapy. *Clin Pharmacokinet* 1989; **16:** 238–53.

Breast feeding. Drug concentrations were measured[1] in the plasma and milk of 13 women receiving 2 to 12 mg of warfarin daily. Plasma concentrations varied from 1.6 to 8.5 micromoles/litre but none was detectable in the breast milk or in the plasma of the 7 infants who were breastfed (limit of detection 0.08 micromoles/litre). No anticoagulant effect was found in the 3 breast-fed infants tested. In another report[2] of 2 women (dose of warfarin not specified), no evidence of the drug was found in the milk of one mother, and no anticoagulant effect was found in either infant. The American Academy of Pediatrics considers[3] that warfarin is therefore usually compatible with breast feeding.

Genetic variation. The response to warfarin and dosing requirements vary widely between individuals and between different racial groups.[1] Factors involved include age, indication for anticoagulation, diet, and use of interacting drugs, but much of the variability appears to be related to genetic polymorphism. Two genes appear to be particularly important: the gene for the cytochrome P450 isoenzyme CYP2C9, the major enzyme involved in warfarin metabolism; and the gene for vitamin K epoxide reductase (VKOR), which is involved in the synthesis of clotting factors and is the major target for warfarin and other coumarin anticoagulants.[2] Although polymorphisms in either gene may affect dose requirements, patients with variant alleles for both genes appear to be particularly sensitive to warfarin;[3] initial variability in response may be more strongly associated with VKOR.[4] Identification of affected patients by genetic testing may be used to guide initial warfarin dosage, and a dosage algorithm has been suggested, although it requires validation.[5] Similar effects have also been noted with other coumarins, including acenocoumarol[6] and phenprocoumon.[7]

Interactions

Many compounds interact with warfarin and other oral anticoagulants. Details of these interactions are given below for all oral anticoagulants with different groups of drugs; if the anticoagulant is other than warfarin, then its identity is specified. The major interactions are summarised in the tables, below.

Drugs generally recognised as diminishing the effects of oral anticoagulants are included in the following list. Further information on the interactions with these drugs and others where the interaction is not so well recognised is provided in the referenced section below.

acetomenaphthone	ethchlorvynol
alcohol (chronic ingestion without liver impairment)	glutethimide
aminoglutethimide	griseofulvin
barbiturates	nafcillin
bosentan	phytomenadione
carbamazepine	rifampicin
dichloralphenazone	St John's wort

Drugs recognised or generally reported as enhancing oral anticoagulants are included in the following list. Further information on the interactions with these drugs and others where the interaction is not so well recognised is provided in the referenced section below.

alcohol (acute ingestion or chronic ingestion with liver impairment)	ethylestrenol
allopurinol	fluconazole
amiodarone	glucagon
aspirin	itraconazole
cefamandole	ketoconazole
chloramphenicol	metronidazole
cimetidine	miconazole
clofibrate	norethandrolone
cloral hydrate	NSAIDs
co-trimoxazole	oxymetholone
danazol	quinidine
dextropropoxyphene	stanozolol
dextrothyroxine	sulfinpyrazone
dipyridamole	tamoxifen
disulfiram	telithromycin
erythromycin	thyroid agents
etacrynic acid	tramadol
	triclofos sodium

Interactions of a pharmacodynamic nature occurring with one anticoagulant may well apply to another but this may not be the case with pharmacokinetic interactions. Many food and herbal preparations also have the potential to interact with oral anticoagulants; some are discussed below.

An interaction may be due to increased or decreased anticoagulant metabolism; with warfarin some interacting drugs such as cimetidine, co-trimoxazole, or phenylbutazone have a selective effect on its stereoisomers. Altered absorption may sometimes play a part, as with colestyramine. Displacement of oral anticoagulants from plasma protein binding sites has been reported with many drugs, including some analgesics. Not all reports that have recorded an alteration in the pharmacokinetics of the anticoagulant have, however, shown a corresponding change in clinical response.

Interference with the coagulation process may be responsible for the increased risk of haemorrhage when aspirin, clofibrate, or thyroid hormones are used with anticoagulants. Many other compounds, such as asparaginase, some contrast media, epoprostenol, streptokinase, and urokinase also carry this risk; while interactions between these compounds and anticoagulants are not discussed further below, the possibility of an increased risk of haemorrhage should be considered when they are used together.

Where there is a risk of serious haemorrhage from an interaction, then use of both drugs is best avoided. In other instances the anticoagulant activity should be carefully monitored so as to increase or decrease the anticoagulant dose as required. Critical periods are when patients stabilised on an anticoagulant start treatment with an interacting drug, or when patients stabilised on a regimen of an interacting drug and anticoagulant have the interacting drug withdrawn. Depending on the mechanism of the interaction, the clinical response to the interaction may be rapid or may take some days. Interactions involving displacement from plasma protein binding sites are often transient. Some interacting drugs do not produce predictable effects; there have for instance been reports of increased as well as decreased anticoagulant activity with disopyramide, phenytoin, quinidine, and oral contraceptives. Another problem occurs with dipyridamole; it can cause bleeding when given to patients taking anticoagulants but without any changes in the measures used for anticoagulant control.

Alcohol. Alcohol has a variable effect on warfarin. Heavy regular drinkers may have a diminished effect, perhaps through enzyme induction, although the effect of warfarin may be increased in the presence of liver impairment; acute ingestion has enhanced the effect of warfarin. A moderate alcohol intake is generally not considered to cause problems.

Analgesics and NSAIDs. All NSAIDs should be used with caution or not at all in patients on warfarin. Many NSAIDs inhibit platelet function to some extent and have an irritant effect on the gastrointestinal tract, so increasing the risk of haemorrhage. Furthermore, some NSAIDs increase the hypoprothrombinaemic effect of warfarin, possibly by an intrinsic effect on coagulation or by displacement of warfarin from plasma protein-binding sites. Many studies have compared the relative displacing action of a range of NSAIDs *in vitro*, but such studies cannot easily be extrapolated to the clinical situation. Changes in plasma concentration of unbound warfarin resulting from displacement from plasma protein-binding sites are usually transient and are most likely to occur in the first few weeks after an NSAID is added to or withdrawn from warfarin therapy; monitoring of anticoagulant therapy is, therefore, most critical during this period.

High doses of *aspirin* and some other *salicylates* enhance the hypoprothrombinaemic effect of warfarin and should generally be avoided in patients on oral anticoagulant therapy. Low-dose aspirin with warfarin may have a role in some patients but the risk of gastrointestinal bleeding is increased. The possibility of an interaction with topical salicylates should also be considered.[1,2]

Use of *phenylbutazone* with warfarin has led to serious haemorrhage and should be avoided. Phenylbutazone affects the metabolism of the *R*- and *S*- isomers of warfarin in complex and different ways with the net effect of enhancing its anticoagulant activity.[3] Related drugs such as *oxyphenbutazone*, *azapropazone*,[4-6] and *feprazone*[7] behave similarly and should also be avoided.

For the following NSAIDs there are a few studies or isolated reports suggesting that they may enhance the hypoprothrombinaemic effect of warfarin or other specified oral anticoagulant: *diflunisal* (with acenocoumarol[8] or warfarin[9]), *flurbiprofen* (with acenocoumarol),[10] *indometacin*,[11,12] *ketoprofen*,[13] *meclofenamate sodium*,[14] *mefenamic acid*,[15] *piroxicam*, (with warfarin[16] or acenocoumarol[17]), *sulindac*,[18,19] *tiaprofenic acid* (with acenocoumarol),[20] and *tolmetin sodium*.[21] In many cases the result of concomitant therapy was an increased prothrombin time which may or may not be clinically significant; in other cases haemorrhage occurred. It should also be noted that for many of the above NSAIDs, perhaps particularly indometacin, there are studies (not cited) in which no enhancement of warfarin activity was found. NSAIDs with an apparently minimal effect on warfarin activity include *etodolac*, *ibuprofen*, and *naproxen*.

Interactions have also been reported with NSAIDs that are selective inhibitors of cyclo-oxygenase-2. As with other NSAIDs, some studies (not cited) have shown a lack of interaction between warfarin and *celecoxib*, but there have been several reports[22-25] of an increase in the INR with concomitant therapy and bleeding has occurred in some patients.[24] Increases in INR have also been reported in studies[25,26] of warfarin with *rofecoxib*; and there have also been reports of bleeding.[27] A small increase in INR was also reported[28] with *etoricoxib* in healthy subjects but was thought unlikely to be of clinical significance in most patients.

In view of the above considerations, *paracetamol* is recommended as the general analgesic and antipyretic of choice in patients on oral anticoagulant therapy. However, caution should be observed since, although it has no effect on the gastric mucosa or on platelet function, some studies (with warfarin, anisindione, dicoumarol, or phenprocoumon)[29,30] and isolated reports[31] have found an increased risk of bleeding in patients taking regular doses of paracetamol while on an oral anticoagulant. An increase in INR has also been reported[32] in a controlled study of the use of paracetamol in patients stabilised on warfarin. Increased monitoring of anticoagulant therapy may be appropriate for those also taking paracetamol regularly.

Opioid analgesics do not generally cause problems. However, there have been reports of enhanced anticoagulant activity in patients given *tramadol* with warfarin[33,34] including 2 deaths from haemorrhagic stroke,[34] and also with phenprocoumon,[35] although a randomised, double-blind, placebo-controlled study[36] in 19 patients failed to find evidence of an interaction between phenprocoumon and tramadol. *Co-proxamol*, a combination of *dextropropoxyphene* and paracetamol, has increased the effect of warfarin.[37-39] *Co-codamol*, a combination of *codeine* and paracetamol, has also enhanced warfarin activity.[40]

Amongst other analgesics, *glafenine* has been reported to possibly enhance the activity of phenprocoumon.[41] *Phenazone*, an inducer of enzyme metabolism, reduces plasma concentrations of warfarin and, in contrast with most other analgesics, may necessitate an increase in warfarin dosage.[42]

Antiarrhythmics. *Amiodarone* has been shown in several studies to increase the activity of warfarin[1-5] and acenocoumarol,[6,7] probably through inhibition of metabolism. The potentiating effect of amiodarone has been reported to persist for up to 4 months after its withdrawal.[1] Phenprocoumon has been reported to be either unaffected[8] or potentiated[9] by amiodarone. Isolated reports with *disopyramide*[10] and *quinidine*[11] have suggested that these drugs can enhance the anticoagulant effect of warfarin. In 7 patients on warfarin or dicoumarol treated with disopyramide or quinidine, however, all but one needed a small increase in the weekly anticoagulant dose suggesting that the antiarrhythmic had reduced the anticoagulant effect.[12] Since the effect was observed after conversion of atrial fibrillation to sinus rhythm an involvement of haemodynamic factors was postulated. Several studies (not cited) have failed to show an effect of quinidine on warfarin. There are also reports indicating that *propafenone*[13] and *moracizine*[14] can enhance warfarin.

Antibacterials. Several antibacterials have been involved in interactions with warfarin. Only a few reports are of serious effects and it is unlikely that any of the drugs need to be contra-indicated with warfarin; careful control should suffice.

Most of the drugs enhance the effects of warfarin. Apart from possible effects on the metabolism or plasma-protein binding of warfarin, some antibacterials may interfere with platelet function or with the bacterial synthesis of vitamin K in the gastrointestinal tract and thus have an anticoagulant effect of their own. This is generally considered unlikely to be of clinical significance except, perhaps, in patients with an inadequate vitamin K intake. Fever itself may increase the catabolism of clotting factors and exaggerate a potential antibacterial-warfarin interaction.

There are several reports of an enhanced warfarin response with *co-trimoxazole*; stereospecific inhibition of warfarin metabolism is probably responsible.[1] The interaction is generally attributed to the *sulfamethoxazole* moiety and there are isolated reports suggesting that the activity of warfarin (or other specified oral anticoagulant) may be enhanced by other sulfonamides including *sulfafurazole*,[2] *sulfamethizole*,[3] and *sulfaphenazole* (with phenindione).[4]

There are several reports of potentiation of the effects of warfarin by *erythromycin* or its salts; inhibition of warfarin metabolism probably occurs. Although no clinically-significant increase in prothrombin time was found in 8 non-infected patients, the potential for an interaction was recognised.[5] An enhanced response to warfarin has also been reported with *azithromycin*,[6,7] with *roxithromycin*,[8] which included reports of spontaneous bleeding, and with *telithromycin*,[9,10] including a case of mild haemoptysis.[9] *Clarithromycin* may potentiate the effect of acenocoumarol[11] and of warfarin,[12] although other factors may also have been involved in this case.

Cefamandole has been reported to enhance the hypoprothrombinaemic response to warfarin.[13,14] Interference with vitamin K synthesis in the gastrointestinal tract and/or liver has been implicated. Related cephalosporins with an *N*-methylthiotetrazole side-chain such as *cefmetazole*, *cefmenoxime*, *cefoperazone*, and *latamoxef* may be expected to behave similarly although there appear to be no reports of an interaction. *Cefazolin*, which has a similar side-chain, may also enhance the effect of warfarin to some extent.[14]

There have been reports of increased activity of warfarin (or other specified oral anticoagulant) by quinolone antibacterials including *nalidixic acid* (with warfarin[15,16] or acenocoumarol[17]), *ciprofloxacin*,[18-20] *gatifloxacin*,[20,21] *levofloxacin*,[20,22] *moxifloxacin*,[20,23] *norfloxacin*,[20,24] and *ofloxacin*,[25,26] although for some of these there are also studies indicating no effect (not cited). *Enoxacin* has been reported to decrease the clearance of *R*-warfarin but not *S*-warfarin; no prolongation of prothrombin time occurred.[27]

There are isolated reports suggesting an enhanced effect of warfarin (or other specified oral anticoagulant) with *aminosalicylic acid*,[28] *benzylpenicillin*,[29] *chloramphenicol* (with dicoumarol),[30] *doxycycline*,[31] *isoniazid*,[32] and *neomycin*.[33] Prothrombin times might be prolonged by broad-spectrum antibacterials such as *ampicillin*, and there has been a report[34] of an increased INR and haematuria in a patient taking warfarin with amoxicillin and clavulanic acid. Manufacturers' warnings of potentiation of warfarin by *aztreonam*, *trimethoprim*, and *tetracyclines* other than doxycycline appear to have only a theoretical basis. *Metronidazole* is discussed under Antiprotozoals, below.

Rifampicin diminishes the effect of warfarin by induction of metabolising enzymes in the liver. There are several reports of a similar effect with *nafcillin*[35-37] and with *dicloxacillin sodium*.[38,39]

Antidepressants. *Amitriptyline* and *nortriptyline* have been reported to prolong the half-life of dicoumarol in healthy subjects.[1,2] The few reports investigating the effect of tricyclic antidepressants on warfarin have not been able to conclude that a significant interaction exists. *Mianserin* and phenprocoumon have been reported not to interact.[3]

The *BNF* considers that there is a possible risk of increased warfarin activity with *SSRIs*; increased warfarin activity has been reported in a few patients taking *fluoxetine*,[4] in a patient taking *fluvoxamine*,[5] and another taking the SNRI *duloxetine*.[6] There has also been a report of increased anticoagulant activity in a patient taking acenocoumarol and *citalopram*.[7]

An increase in the dose of warfarin has been required by patients also taking *trazodone*.[8,9]

Antidiabetics. There have been a few early instances of *tolbutamide* enhancing the activity of dicoumarol.[1] However, this effect has not been seen in later studies involving dicoumarol,[1-3] warfarin,[2] and phenprocoumon,[4] although one study did find altered dicoumarol pharmacokinetics.[3] An absence of effect has been documented for phenprocoumon and *insulin*, *glibenclamide*, or *glibornuride*,[4] but there is a report of glibenclamide enhancing the effect of warfarin.[5]

There has been an isolated report of bleeding in a patient taking *phenformin* and warfarin.[6] *Metformin* has been reported to diminish phenprocoumon activity.[7]

An enhanced response to warfarin has been reported in a patient receiving *troglitazone*.[8]

Coumarin anticoagulants may increase the hypoglycaemic effect of *sulfonylureas* (see p.462).

Antiepileptics. Barbiturates such as *phenobarbital* and *primidone* diminish the activity of warfarin and other coumarins through increased metabolism. *Carbamazepine* is reported to have a similar effect.[1,2] Reports of the effect of *phenytoin* on anticoagulants do not provide a clear picture. There are reports of phenytoin enhancing the effects of warfarin[3,4] and a report of initial enhancement followed by decreased anticoagulant action.[5] Phenytoin has been reported to diminish the effect of dicoumarol.[6] Addition of *felbamate* has been reported[7] to necessitate a reduction in warfarin dosage. In another patient there was a transient increase in response to warfarin when *valproic acid* was started.[8] Valproate also inhibits platelet function and caution is required with warfarin and other anticoagulants.

For the effect of oral anticoagulants on phenytoin, see p.498.

Antifungals. *Griseofulvin* has been reported to diminish the activity of warfarin.[1-3] There are several reports indicating that *miconazole*, given either systemically or topically as the oral gel, may enhance the activity of oral anticoagulants (warfarin, ethyl biscoumacetate, acenocoumarol, phenindione, and tioclomarol).[4-11] Absorption of miconazole after intravaginal use may have enhanced the activity of acenocoumarol in 2 patients;[12] it enhanced the activity of warfarin[13] in another. Studies in healthy subjects given a single warfarin dose[14,15] support case reports[16-18] suggesting that *fluconazole* may increase the anticoagulant activity of warfarin. There are isolated reports of the potentiation of warfarin by *itraconazole*[19] and *ketoconazole*,[20] and of unspecified coumarins by topical *bifonazole* or *econazole*.[21] There has been a case report of a reduction in the effect of warfarin by *terbinafine*,[22] although a study[23] in healthy subjects found no clinically significant interaction, and others[24] considered that no interaction usually occurs. A case of potentiation of warfarin by terbinafine has also been reported;[25] the authors speculate that concomitant cimetidine may have contributed to the interaction by increasing plasma-terbinafine concentrations.

Antigout drugs. The two drugs in this group mostly implicated in interactions with anticoagulants are allopurinol and sulfinpyrazone.

With *allopurinol* there are conflicting reports of patients experiencing no interaction or an enhanced anticoagulant effect with dicoumarol,[1] phenprocoumon,[2] or warfarin.[3,4]

Interactions with *sulfinpyrazone* have usually involved warfarin and, apart from a case of a mixed response,[5] have involved increased anticoagulant activity, sometimes with haemorrhage, so calling for careful control. It is still not clear how sulfinpyrazone exerts its effect, but studies point to a stereoselective effect on warfarin metabolism where the *S*-isomer's metabolic clearance is inhibited;[6] sulfinpyrazone also affects platelets. Sulfinpyrazone has also enhanced the anticoagulant activity of acenocoumarol.[7] A significant interaction with phenprocoumon appears unlikely.[8]

Probenecid has accelerated the elimination of a single dose of phenprocoumon without effect on the prothrombin time.[9]

Benziodarone has been reported to enhance the effects of warfarin, diphenadione, ethyl biscoumacetate, and acenocoumarol, but not of dicoumarol, phenindione, or phenprocoumon.[10] A further study[11] confirmed that benziodarone could increase the half-life of ethyl biscoumacetate, but also found that the effect of phenprocoumon was enhanced. A study[12] of *benzbromarone*, which is structurally related to benziodarone, concluded that it enhanced the effect of warfarin by inhibition of the cytochrome P450 isoenzyme CYP2C9, leading to a stereoselective inhibition of the metabolism of warfarin.

11. Verstraete M, *et al.* Dissimilar effect of two anti-anginal drugs belonging to the benzofuran group on the action of coumarin derivatives. *Arch Int Pharmacodyn Ther* 1968; **176:** 33–41.
12. Takahashi H, *et al.* Potentiation of anticoagulant effect of warfarin caused by enantioselective metabolic inhibition by the uricosuric agent benzbromarone. *Clin Pharmacol Ther* 1999; **66:** 569–81.

Antihistamines. There has been a report[1] of a raised INR and severe epistaxis in a patient after the addition of *cetirizine* to long-term acenocoumarol.

1. Berod T, Mathiot I. Probable interaction between cetirizine and acenocoumarol. *Ann Pharmacother* 1997; **31:** 122.

Antimalarials. The ingestion of large amounts of tonic water by 2 patients necessitated a reduction in warfarin dosage. The enhanced effect was attributed to the *quinine* content of the tonic water.[1] A woman stabilised on warfarin developed haematuria and a high prothrombin ratio after taking *proguanil* for malaria prophylaxis.[2]

1. Clark DJ. Clinical curio: warfarin and tonic water. *BMJ* 1983; **286:** 1258.
2. Armstrong G, *et al.* Warfarin potentiated by proguanil. *BMJ* 1991; **303:** 789.

Antimuscarinics. There have been 2 cases reported[1] of *tolterodine* enhancing the effect of warfarin. It was stated that the manufacturers of tolterodine were aware of 6 reports of a possible interaction with warfarin.

1. Colucci VJ, Rivey MP. Tolterodine–warfarin drug interaction. *Ann Pharmacother* 1999; **33:** 1173–6.

Antineoplastics. There have been several reports of interactions between warfarin and antineoplastics. No clear picture emerges from these reports which is not surprising considering that antineoplastics are often given in combination and that they can exert their own haematological effects. *Cyclophosphamide* for instance has been associated with an increase in warfarin's activity when given with *methotrexate* and *fluorouracil*,[1] but with a decrease when given with non-antineoplastic drugs.[2] An increase in the activity of warfarin and mucous membrane bleeding occurred in a patient who had 4 courses of fluorouracil and folic acid at weekly intervals.[3] The patient was also taking indometacin. Warfarin dosage had to be reduced in 5 patients given fluorouracil-based antineoplastic regimens.[4] An increase in the effect of warfarin has been reported when given with fluorouracil and levamisole (see Levamisole, below). *Capecitabine* increases plasma-warfarin concentrations[5] and there have been reports of increased warfarin activity,[5-7] in 1 case resulting in gastrointestinal bleeding;[6] licensed product information for capecitabine states that altered coagulation parameters and bleeding have also occurred with phenprocoumon. There have been 2 cases reported[8] where *trastuzumab* enhanced the effect of warfarin. *Etoposide* with *vindesine*[9] or with *carboplatin*,[10] *ifosfamide* with *mesna*,[11] and *tamoxifen*[12-14] have all produced an increased anticoagulant effect. *Aminoglutethimide* has led to decreased activity of warfarin or acenocoumarol,[15,16] probably due to increased warfarin metabolism. Licensed product information for the antiandrogen *flutamide* states that increases in prothrombin time have been reported after starting flutamide therapy in patients on long-term warfarin. *In vitro* data indicate a similar reaction is likely with *bicalutamide*. *Mercaptopurine*[17] and *mitotane*[18] have also decreased warfarin activity. Licensed product information for *vorinostat* states that prolongation of prothrombin time has been seen when the drug is given with coumarin derivatives; prothrombin time and INR should be monitored in patients given both drugs.

Antiplatelets. The interaction between anticoagulants and *dipyridamole* is unusual as bleeding can occur without any alteration in prothrombin times; special care is therefore required. This interaction has involved a small number of patients taking dipyridamole and warfarin or phenindione;[1] inhibition of platelet function by dipyridamole has been implicated. However, in general it does not appear to increase the risk of bleeding.[2]

Paradoxically, addition of *ticlopidine* was found to significantly increase acenocoumarol requirements.[3]

Antithyroid drugs. See Thyroid and Antithyroid Drugs, below.

Antivirals. Reductions in dosage of either warfarin[1] or acenocoumarol[2] were necessary in 2 patients receiving *interferon alfa* for hepatitis C. The interactions may have been due to decreased metabolism of the anticoagulant. A similar need for a reduced warfarin dose had also been noted in other patients taking *interferon alfa-2b* or *interferon beta*.[1] However, in a patient taking interferon alfa-2b with *ribavirin*,[3] the warfarin dose needed to be increased, probably due to the interaction between ribavirin and warfarin.

An enhanced response to warfarin has been reported[4] in a patient taking *saquinavir.* The mechanism may involve competitive inhibition of warfarin metabolism and might also occur with other HIV-protease inhibitors. However, a decreased response to warfarin seemed to be caused by *ritonavir* when it was added to the multidrug therapy of a patient.[5] Ritonavir has also been reported to decrease the response to acenocoumarol.[6]

Up to October 2005 there had been 19 reports[7] received by the Canadian health authorities (Health Canada) of enhanced response to warfarin between 1 and 11 days after starting *oseltamivir.* The increased INR ranged from 3.2 to 10.9; however, there was not enough information to be certain of causality. In 3 other cases there was a decrease in INR on the addition of oseltamivir.

Anxiolytic sedatives, hypnotics, and antipsychotics. *Barbiturates*, by inducing liver metabolism, can reduce the activity of anticoagulants; *glutethimide* has a similar action. The *benzodiazepines* do not generally have any effect although there is the rare report of increased or decreased activity.

Although there is a report suggesting that *cloral hydrate* may decrease the effect of dicoumarol by enzyme induction,[1] other studies and experience indicate an increase in the anticoagulant activity of warfarin.[2-4] However, the increase is only transient and is probably the result of displacement of warfarin from plasma protein binding sites by the metabolite trichloroacetic acid.[2] *Triclofos sodium* appears to increase the activity of warfarin in a similar way.[5]

Reduced anticoagulant activity has been reported with *dichloralphenazone*,[6,7] *ethchlorvynol* (with dicoumarol),[8] and *haloperidol* (with phenindione).[9] Compounds such as *meprobamate* and *methaqualone* appear to have no effect.

Beta blockers. Beta blockers, particularly those with a high lipid solubility such as propranolol, may inhibit the metabolism of warfarin.[1] Although a number of studies have shown pharmacokinetic interactions between some beta blockers and oral anticoagulants, no effect on anticoagulant activity has generally been found. However, possible potentiation of the effect of warfarin by *propranolol*[2] has been reported.

Central stimulants. *Methylphenidate* has been reported both to increase the half-life of ethyl biscoumacetate,[1] and to have no effect on its half-life or anticoagulant activity.[2] *Prolintane* had no effect.[2]

1. Garrettson LK, *et al.* Methylphenidate interaction with both anticonvulsants and ethyl biscoumacetate: a new action of methylphenidate. *JAMA* 1969; **207:** 2053.
2. Hague DE, *et al.* The effect of methylphenidate and prolintane on the metabolism of ethyl biscoumacetate. *Clin Pharmacol Ther* 1971; **12:** 259–62.

Chamomile. A 70-year-old woman stabilised on warfarin developed multiple internal haemorrhages after she increased her use of chamomile lotion and consumption of chamomile tea to 4 or 5 times per day.[1] The interaction was considered to be due to the coumarin constituent of chamomile.

1. Segal R, Pilote L. Warfarin interaction with Matricaria chamomilla. *Can Med Assoc J* 2006; **174:** 1281–2.

Chinese herbal remedies. There have been a number of reports of increased anticoagulation in patients taking Chinese herbal remedies with warfarin.[1-6] The remedies have ranged from single ingredient herbal preparations to complex multi-ingredient products, sometimes sold under the same brand name but with very different compositions.

Corticosteroids and corticotropin. Corticosteroids are associated with an increase in blood coagulability, but their extensive use with anticoagulants, and very few reports of interaction, suggests that any problems are rare. However, there are some reports of corticosteroids or corticotropin either enhancing[1-3] or diminishing[4] the effects of anticoagulants. A retrospective study[5] in patients on long-term warfarin therapy given short courses of oral corticosteroids found that in most cases (29 of 32) there was an increase in INR, suggesting that careful monitoring is required.

5. Hazlewood KA, *et al.* Effect of oral corticosteroids on chronic warfarin therapy. *Ann Pharmacother* 2006; **40:** 2101–6.

Cough suppressants. An increase in the activity of warfarin has been reported in patients taking *noscapine*[1,2] or *oxolamine*.[3] A subsequent study[3] suggested that the dose of warfarin should be reduced by 50% if oxolamine was started.

Cranberry. Between 1999 and 2003 the UK CSM[1] had received 5 reports suggesting an interaction between warfarin and cranberry juice. In 3 patients the activity of warfarin had been potentiated and one of them had died. In the other patients the INR was either reduced or unstable. By 2004 there had been 7 further reports of suspected interactions and the CSM advised[2] patients to avoid cranberry juice and other cranberry products while taking warfarin. However. despite case reports suggesting an increase in warfarin activity, the potential for a pharmacokinetic effect has been questioned,[3] and pharmacokinetic studies[4,5] have failed to confirm an interaction.

Dermatological drugs. A patient's warfarin dose had to be increased when he started treatment with *etretinate*.[1]

1. Ostlere LS, *et al.* Reduced therapeutic effect of warfarin caused by etretinate. *Br J Dermatol* 1991; **124:** 505–10.

Dietary supplements. There have been reports of an increased INR in patients taking warfarin and dietary supplements containing *glucosamine* and *chondroitin*,[1,2] and the UK CHM advises[3] that patients on warfarin should not take glucosamine. A similar effect has been reported[4] with *poliglusam*.

1. Rozenfeld V, *et al.* Possible augmentation of warfarin effect by glucosamine-chondroitin. *Am J Health-Syst Pharm* 2004; **61:** 306–7.

Disulfiram. Two reports suggesting that disulfiram enhances the activity of warfarin[1,2] were confirmed by a study in 8 healthy subjects.[3] Although inhibition of liver enzymes by disulfiram was considered responsible,[3] a later study[4] suggested that disulfiram acts directly on the liver to increase hypoprothrombinaemia. This interaction is complicated by the variable effects of alcohol on warfarin (see above). Special care is therefore called for when these drugs are used together.

1. Rothstein E. Warfarin effect enhanced by disulfiram. *JAMA* 1968; **206:** 1574–5.
2. Rothstein E. Warfarin effect enhanced by disulfiram (Antabuse). *JAMA* 1972; **221:** 1052–3.
3. O'Reilly RA. Interaction of sodium warfarin and disulfiram (Antabuse) in man. *Ann Intern Med* 1973; **78:** 73–6.
4. O'Reilly RA. Dynamic interaction between disulfiram and separated enantiomorphs of racemic warfarin. *Clin Pharmacol Ther* 1981; **29:** 332–6.

Diuretics. *Etacrynic acid* has been reported to enhance the activity of warfarin.[1] *Chlortalidone*[2] and *spironolactone*[3] have both been associated with a reduction in warfarin's activity in healthy subjects and it has been suggested that this might be a consequence of the diuresis concentrating the circulating clotting factors. However, *bumetanide*, *furosemide*, and the *thiazides* appear to have no effect on warfarin.

1. Petrick RJ, *et al.* Interaction between warfarin and ethacrynic acid. *JAMA* 1975; **231:** 843–4.
2. O'Reilly RA, *et al.* Impact of aspirin and chlorthalidone on the pharmacodynamics of oral anticoagulant drugs in man. *Ann N Y Acad Sci* 1971; **179:** 173–86.
3. O'Reilly RA. Spironolactone and warfarin interaction. *Clin Pharmacol Ther* 1980; **27:** 198–201.

Endothelin receptor antagonists. A study in healthy subjects[1] showed that *bosentan* decreased the anticoagulant effect of warfarin; a case report[2] confirmed this.

1. Weber C, *et al.* Effect of the endothelin-receptor antagonist bosentan on the pharmacokinetics and pharmacodynamics of warfarin. *J Clin Pharmacol* 1999; **39:** 847–54.
2. Murphey LM, Hood EH. Bosentan and warfarin interaction. *Ann Pharmacother* 2003; **37:** 1028–31.

Gastrointestinal drugs. Antacids may or may not interact with warfarin. *Bismuth carbonate* and *magnesium trisilicate* for example have been reported to reduce warfarin's absorption,[1] but *aluminium hydroxide* has been observed to have no effect on warfarin or dicoumarol.[2] *Psyllium*[3] and *magnesium hydroxide*[2] have also been reported to have no effect on warfarin, but the latter has increased the plasma concentrations of dicoumarol.[2]

There have been occasional reports of *sucralfate* diminishing the effect of warfarin.[4-6]

Histamine H_2-antagonists have been widely studied. There are several reports indicating that *cimetidine* can enhance the anticoagulant effect of warfarin and haemorrhage has occurred. A number of studies show that cimetidine can increase the plasma concentration and half-life of warfarin and that there is a selective inhibitory effect on the metabolism of its *R*-isomer.[7-10] Not all these studies have, however, found an increase in prothrombin time. The effect of cimetidine on warfarin appears to be dose-dependent[7] and to be subject to interindividual variation;[9,10] careful monitoring is needed. Limited evidence suggests that cimetidine has a similar effect on the metabolism of acenocoumarol[11,12] and phenindione[11] but not of phenprocoumon.[13] Studies with *ranitidine* have generally been unable to show an effect on the metabolism of warfarin,[10,14] although in one study warfarin clearance was reduced.[7] There is a case report suggesting that potentiation of warfarin by ranitidine may occasionally occur.[15]

One study has suggested that *omeprazole* could inhibit the metabolism of *R*-warfarin although a clinically significant effect was unlikely.[16] No evidence of an interaction was found in a retrospective study[17] of patients on acenocoumarol and omeprazole. Similarly, *pantoprazole* appears to have no effect on the pharmacokinetics or pharmacodynamics of warfarin[18] or phenprocoumon.[19]

A marked increase in the effect of warfarin has been reported in a patient when *cisapride* was added.[20]

A study[21] in healthy subjects found that *aprepitant* caused a small decrease in plasma concentration of the more active *S*-isomer of warfarin and there was also a decrease in INR.

A reduction in the response to warfarin with development of venous thrombosis has been reported in a patient receiving *mesalazine*,[22] and in another patient receiving *sulfasalazine*.[23]

Ginkgo biloba. There is a report[1] of a woman stabilised on warfarin for 5 years who suffered an intracerebral haemorrhage 2 months after starting *Ginkgo biloba*, possibly due to the additive effect of the latter's antiplatelet activity. However, a study[2] in healthy subjects found no evidence that ginkgo affected warfarin pharmacokinetics or coagulation.

1. Matthews MK. Association of Ginkgo biloba with intracerebral hemorrhage. *Neurology* 1998; **50:** 1933–4.
2. Jiang X, *et al.* Effect of ginkgo and ginger on the pharmacokinetics and pharmacodynamics of warfarin in healthy subjects. *Br J Clin Pharmacol* 2005; **59:** 425–32.

Ginseng. A reduction in the response to warfarin was reported[1] in a patient after taking a ginseng preparation. A study[2] in healthy subjects also found a small reduction in response.

1. Janetzky K, Morreale AP. Probable interaction between warfarin and ginseng. *Am J Health-Syst Pharm* 1997; **54:** 692–3.
2. Yuan C-S, *et al.* American ginseng reduces warfarin's effect in healthy patients: a randomized, controlled trial. *Ann Intern Med* 2004; **141:** 23–7.

Glucagon. A dose-dependent enhancement of warfarin's anticoagulant activity has been reported with glucagon.[1]

1. Koch-Weser J. Potentiation by glucagon of the hypoprothrombinemic action of warfarin. *Ann Intern Med* 1970; **72:** 331–5.

Glucosamine. See Dietary Supplements, above.

Immunosuppressants. Severe bleeding occurred in a patient on long-term warfarin after stopping *azathioprine*,[1] while another patient[2] required an increased dose of warfarin when it was given with azathioprine.

There have been a few case reports of interaction between warfarin or acenocoumarol and *ciclosporin*, in which the dose of the anticoagulant or ciclosporin or both needed to be altered (see Anticoagulants under Interactions of Ciclosporin, p.1827).

There has been a report[3] of *leflunomide* enhancing the effects of warfarin, causing gross haematuria after the second dose; the patient's INR rose from 3.4 to 11. It was stated that the UK CSM had received 4 reports of increased INR with leflunomide up to the end of 2002.

3. Lim V, Pande I. Leflunomide can potentiate the anticoagulant effect of warfarin. *BMJ* 2002; **325:** 1333. Correction. *ibid.* 2003; **326:** 432.

Leukotriene antagonists. *Zafirlukast* is reported to decrease the clearance of *S*-warfarin.[1] Licensed product information for zafirlukast states that it probably inhibits the cytochrome P450 isoenzyme CYP2C9 which is involved in the metabolism of warfarin. Prothrombin time may be significantly prolonged when zafirlukast is added and warfarin dosage should be adjusted accordingly.

A study[2] of *montelukast* and warfarin found no significant interaction between the two drugs.

2. Van Hecken, *et al.* Effect of montelukast on the pharmacokinetics and pharmacodynamics of warfarin in healthy volunteers. *J Clin Pharmacol* 1999; **39:** 495–500.

Levamisole. An increased INR has been reported[1] in a patient taking chronic warfarin therapy after addition of *levamisole* and fluorouracil, possibly due to inhibition of warfarin metabolism. Interactions between warfarin and other fluorouracil-containing regimens have been reported (see Antineoplastics, above) but levamisole might also be involved. In a second patient, a similar reaction was reported[2] after levamisole and fluorouracil and an episode of bleeding subsequently occurred after levamisole alone.

2. Wehbe TW, Warth JA. A case of bleeding requiring hospitalization that was likely caused by an interaction between warfarin and levamisole. *Clin Pharmacol Ther* 1996; **59:** 360–2.

Lipid regulating drugs. Fibrates have been reported to interact with coumarin anticoagulants. *Clofibrate* can enhance the activity of warfarin, sometimes to the point of haemorrhage. The mechanism of this interaction is not clear, but it does not appear to be a pharmacokinetic effect. Similar enhancement of activity has been reported with clofibrate and dicoumarol or phenindione. *Bezafibrate* has been reported to enhance the effect of phenprocoumon[1] and warfarin,[2] and *fenofibrate*[3] and *gemfibrozil*[4] have been reported to enhance the effect of warfarin, although a study[5] in healthy subjects found that gemfibrozil slightly decreased plasma-warfarin concentrations.

Interactions may also occur between statins and coumarin anticoagulants,[6] although there have been conflicting reports in some cases. Hypoprothrombinaemia and bleeding has been reported in 2 patients on warfarin given *lovastatin*.[7] An increased response to warfarin has also been reported[6,8,9] in a number of patients taking *fluvastatin*. A study[10] with *rosuvastatin* and warfarin reported an increased INR in healthy subjects and in patients on long-term warfarin therapy, although another study[11] found no effect. However, there have been reports of haematoma and raised INR in patients after addition of rosuvastatin to long-term therapy with warfarin[12] or acenocoumarol.[13] An increased response to warfarin has been observed with *simvastatin*,[14] including a fatal cerebral haemorrhage in a patient who was changed from atorvastatin to simvastatin,[15] and potentiation of the effect of acenocoumarol by simvastatin has also been reported.[16] However, the INR in another patient on long-term warfarin remained stable on the addition of simvastatin.[17] Licensed product information for *pravastatin* states that no change in warfarin activity has been seen in patients given both drugs, but there has been a report[18] of bleeding in a patient taking fluindione when pravastatin was added. In a study[19] of 46 patients on warfarin who had been converted from pravastatin to simvastatin, the mean INR increased, but the median weekly warfarin dose did not differ significantly and no episodes of bleeding were reported.

Dextrothyroxine increases the anticoagulant effect of warfarin sodium[20,21] and dicoumarol.[22]

Colestyramine has reduced warfarin's serum concentration[23] and half-life[24] as well as its activity.[23,24] The mechanisms of this interaction include binding of warfarin to colestyramine and reduced absorption;[23] the enterohepatic recycling of warfarin may also be interrupted.[24] Phenprocoumon's activity has also been reduced by colestyramine.[25] However, colestyramine can also reduce vitamin K absorption, and this may result in hypoprothrombinaemia and bleeding.

Use of *omega-3 fatty acids* (as fish oil preparations) in patients taking warfarin and other antithrombotics has been associated with INR elevation[26] and subdural haematoma.[27] However, controlled studies in patients taking fish oil and warfarin[28,29] have failed to show an effect on bleeding episodes or bleeding time.

Benfluorex[30] and *colestipol*[31] have been reported not to interact with phenprocoumon.

Menthol. A significant decrease in INR was reported[1] in a patient stabilised on warfarin when he started using a menthol cough preparation.

1. Kassebaum PJ, *et al.* Possible warfarin interaction with menthol cough drops. *Ann Pharmacother* 2005; **39:** 365–7.

Pesticides. Chlorinated insecticides diminished the activity of warfarin in a patient.[1]

1. Jeffery WH, *et al.* Loss of warfarin effect after occupational insecticide exposure. *JAMA* 1976; **236:** 2881–2.

Piracetam. Piracetam caused an increase in prothrombin time in a patient who had been stabilised on warfarin.[1]

1. Pan HYM, Ng RP. The effect of Nootropil in a patient on warfarin. *Eur J Clin Pharmacol* 1983; **24:** 711.

Sex hormones. There have been reports of steroids with anabolic or androgenic properties enhancing the activity of anticoagulants to the point of haemorrhage. Reports have covered *oxymetholone* and warfarin[1-3] or acenocoumarol;[4] *stanozolol* and warfarin[5,6] or dicoumarol;[7] *ethylestrenol* and phenindione;[8] *norethandrolone* and dicoumarol;[9] *methyltestosterone* and phenprocoumon;[10] and *danazol* and warfarin.[11-13] The manufacturer of *oxandrolone* states that an 80 to 85% reduction in warfarin dose was needed when oxandrolone was added to treatment. The mechanism of this interaction is not clear although it is considered that it is not caused by altered pharmacokinetics. Steroids with a 17-α-alkyl substituent appear to be most involved, but there has been a report of topically applied testosterone, which does not have such a substituent, enhancing warfarin.[14]

A retrospective study[15] of women receiving anticoagulant therapy who were started on *HRT* found that *tibolone* enhanced the effect of warfarin and of phenindione, possibly due to its androgenic properties.

Oral contraceptives have also been implicated in interactions. However, while the effects of dicoumarol were diminished by a combined oral contraceptive,[16] those of acenocoumarol were enhanced by other preparations.[17] Combined oral contraceptives have increased the clearance of phenprocoumon without altering the anticoagulant effect.[18] There has also been a report[19] of a single course of *levonorgestrel* for emergency contraception increasing the effect of warfarin.

St John's wort. St John's wort has been reported to reduce the anticoagulant effect of warfarin.[1]

1. Yue Q-Y, *et al.* Safety of St John's wort (Hypericum perforatum). *Lancet* 2000; **355:** 576–7.

Thyroid and antithyroid drugs. Since response to oral anticoagulants is dependent on thyroid status an interaction between oral anticoagulants and thyroid or antithyroid drugs might be expected. Thyroid compounds do enhance the activity of oral anticoagulants possibly by increased metabolism of clotting factors. Dextrothyroxine is discussed under Lipid Regulating Drugs, above. Antithyroid compounds have not, however, been reported to diminish the effect of anticoagulants and paradoxically *propylthiouracil* has been reported to have caused hypoprothrombinaemia (see Effects on the Blood, under Carbimazole, p.2168). However, in a patient given *thiamazole* for Grave's disease, the response to warfarin varied depending on his thyroid status and thiamazole dose.[1]

1. Busenbark LA, Cushnie SA. Effect of Graves' disease and methimazole on warfarin anticoagulation. *Ann Pharmacother* 2006; **40:** 1200–3.

Tobacco. Although tobacco smoking may increase warfarin clearance,[1] an appreciable effect on anticoagulant activity appears unlikely.[1,2] However, there has been a report[3] of an increase in INR in a patient receiving warfarin when he stopped smoking.

3. Colucci VJ, Knapp JF. Increase in international normalized ratio associated with smoking cessation. *Ann Pharmacother* 2001; **35:** 385–6.

Ubidecarenone. Decreased INR values and reduced effect of warfarin has been reported[1] in 3 patients given ubidecarenone.

1. Spigset O. Reduced effect of warfarin caused by ubidecarenone. *Lancet* 1994; **344:** 1372–3.

Vaccines. There have been a few reports of increased prothrombin time and bleeding in warfarin-stabilised patients after *influenza vaccination*. Studies investigating this possible interaction have found only a small or inconsistent increase in warfarin activity[1,2] or no effect.[3-5] One study suggested that influenza vaccine decreases rather than increases the prothrombin time.[6] In a group of patients on long-term acenocoumarol therapy, influenza vaccination had no effect on acenocoumarol activity.[7]

Vitamins. Since vitamin K reverses the effects of oral anticoagulants, it is not surprising that there have been reports of *acetomenaphthone* and *phytomenadione* reducing anticoagulant activity, or of foods or nutritional preparations containing vitamin K compounds doing the same.

Occasional reports of *ascorbic acid* reducing the activity of warfarin[1,2] have not been confirmed in subsequent studies.[3,4] There have also been isolated reports suggesting that *vitamin E* may enhance the activity of warfarin[5] or dicoumarol,[6] although no effect was found in a study[7] of patients receiving warfarin and vitamin E.

Pharmacokinetics

Warfarin sodium is readily absorbed from the gastrointestinal tract; it can also be absorbed through the skin. It is extensively bound to plasma proteins and its plasma half-life is about 37 hours. It crosses the placenta but does not occur in significant quantities in breast milk. Warfarin is used as a racemic mixture; the *S*-isomer is more potent. The *R*- and *S*-isomers are both metabolised in the liver. The *S*-isomer is metabolised more rapidly than the *R*-isomer, mainly by the cytochrome P450 isoenzyme CYP2C9, which shows genetic polymorphism; other isoenzymes are also involved in the metabolism of the *R*-isomer. The stereoisomers may be affected differently by other drugs (see Interactions, above). Metabolites, with negligible or no anticoagulant activity, are excreted in the urine following reabsorption from the bile.

Uses and Administration

Warfarin is a coumarin anticoagulant used in the treatment and prophylaxis of thromboembolic disorders (p.1187). It acts by depressing the hepatic vitamin K-dependent synthesis of coagulation factors II (prothrombin), VII, IX, and X, and of the anticoagulant protein C and its cofactor protein S. For an explanation of the coagulation cascade, see Haemostasis and Fibrinolysis, p.1045. Since warfarin acts indirectly, it has no effect on existing clots. Also as the coagulation factors involved have half-lives ranging from 6 to 60 hours, several hours are required before an effect is observed. A therapeutic effect is usually apparent by 24 hours, but the peak effect may not be achieved until 2 or 3 days after a dose; the overall effect may last for 5 days.

Warfarin is used in the prevention and treatment of venous thromboembolism (deep-vein thrombosis and pulmonary embolism, p.1189). If an immediate effect on blood coagulation is required, heparin should be given intravenously or subcutaneously to cover the first 2 to 3 days. Warfarin therapy may be begun with, or shortly after, initial heparin treatment. Warfarin is also used for the prevention of systemic thromboembolism and ischaemic stroke in some patients with atrial fibrillation (p.1160), prosthetic heart valves (see Valvular Heart Disease, p.1187), or who have suffered a myocardial infarction (p.1175). It may also have a role in the prevention of myocardial infarction and in the management of stroke or transient ischaemic attacks (p.1185). Antiplatelet drugs may be given concomitantly.

Some patients may show a hereditary resistance to warfarin. Warfarin is a potent rodenticide although resistance has been reported in *rats*.

Administration and dosage. Warfarin is equally effective either orally or intravenously, but is usually given orally. Dosage must be determined individually as discussed below under Control of Anticoagulant Therapy. When rapid anticoagulation is required, an initial dose of warfarin sodium 10 mg may be given on the first day, although in many cases an initial dose of 5 mg daily is adequate; initial doses of less than 5 mg daily may be used in elderly patients and in those at increased risk of bleeding (see Precautions, above). Subsequent doses depend on the results of coagulation tests, but maintenance doses usually range from 3 to 9 mg daily. If necessary the same dose may be given by slow intravenous injection. Doses of warfarin sodium should be given at the same time each day. Theoretically, stopping warfarin abruptly may result in rebound hypercoagulability with risk of thrombosis. Therefore some clinicians tail off long-term treatment over several weeks but the need for this is unclear and the *British Society for Haematology* suggests that treatment may be stopped abruptly. Anticoagulant treatment booklets should be carried by patients.

Warfarin has also been given as the potassium salt; warfarin-deanol has been tried.

Control of oral anticoagulant therapy. Treatment with oral anticoagulants must be monitored to ensure that the dose is providing the required effect on the vitamin-K-dependent clotting factors; too small a dose provides inadequate anticoagulation, too large a dose puts the patient at risk of haemorrhage. This monitoring is commonly carried out by checking the clotting property of the patient's plasma using a suitable preparation of thromboplastin and a source of calcium. The time taken for the clot to form due to the effect of the thromboplastin preparation on prothrombin is known as the prothrombin time (PT). The prothrombin time ratio (PTR) is the prothrombin time of the patient's plasma divided by that for a standard plasma sample.

So that there is some consistency in prothrombin time ratios measured at different times or at different laboratories, it is now common practice for the manufacturer or control laboratory to calibrate their batches of thromboplastin against the international reference preparation. This calibration produces an international sensitivity index (ISI) appropriate to that thromboplastin. The laboratory measuring the clotting capacity of a sample of plasma is thus able to convert the prothrombin time ratio to an international normalised ratio (INR) using the sensitivity index through the formula

$$\text{INR} = \text{PTR}^{(\text{ISI})}$$

Thus a prothrombin time ratio of 2.0 obtained with a thromboplastin with a declared international sensitivity index of 1.5 would be converted to an international normalised ratio of 2.8. An international normalised ratio is therefore equivalent to a prothrombin time ratio carried out using the primary international reference preparation of thromboplastin.

This method of standardisation has taken over from methods involving use of a standard reagent such as the British or Manchester comparative thromboplastin. Preparations of thromboplastin derived from *rabbit* brain have superseded or are superseding those from human brain because of the dangers of viral transmission; a recombinant human form is also available.

Recommended target values or ranges of international normalised ratio for patients receiving anticoagulant treatment or cover for various conditions or procedures are given by the *British Society for Haematology* in the UK and the *American College of Chest Physicians*.

These are given in Table 6, below. An INR within 0.5 units of the target value in the UK is generally considered satisfactory. In the USA it is recommended that the INR be maintained at the mid-level of the range. An INR less than 2.0 generally represents inadequate anticoagulation and an INR above 4.5 represents greater risk of haemorrhage.

Measurements should be carried out before treatment and then daily or on alternate days in the early stages of treatment. Once the dose has been established and the patient well stabilised the measurement can be made at greater but regular intervals, for example every 8 weeks; allowances should be made for any events that might influence the activity of the anticoagulant. Self-monitoring may be appropriate in some patients.

Administration and dosage. Algorithms and guidelines have been developed for beginning anticoagulant therapy, based on the method of Fennerty *et al.*[1] Although a loading dose of 10 mg daily for 2 days (depending on the INR) has been widely used, lower doses may be more appropriate, especially in hospitalised patients at greater risk of over-anticoagulation. Studies[2-4] comparing warfarin loading doses of 5 and 10 mg found that for both groups a therapeutic INR in the range of 2.0 to 3.0 was reached in most patients by day 5 of treatment. Although a study of outpatients with venous thromboembolism[5] found that a therapeutic INR was achieved 1.4 days sooner with the larger loading dose, the nomogram used was not designed for inpatients.

In situations where rapid anticoagulation is not necessary, loading doses may not be required and treatment should begin with the estimated maintenance dose. Studies[6,7] have found that the maintenance dose decreases with age and is lower in women than in men, and lower initial doses are therefore recommended in the elderly. Regimens that have been suggested include warfarin in a dose of 4 mg daily for 3 days, then adjusted according to the INR,[8] or, for patients requiring anticoagulation prophylaxis, 2 mg daily for 2 weeks followed by weekly adjustment using an algorithm until the target INR is reached.

Administration in infants and children. Increasing numbers of infants and children are receiving anticoagulants for prophylaxis and treatment of thromboembolism. Doses of warfarin and therapeutic INR ranges have been adapted from adult therapy but cohort studies[1,2] of paediatric patients have found that warfarin requirements may be affected by a number of factors including age, and the use of infant formulas supplemented with vitamin K. Recommendations[3] for the use of oral anticoagulants in children have been published.

3. Monagle P, *et al.* Antithrombotic therapy in neonates and children: American College of Chest Physicians evidence-based clinical practice guidelines (8th edition). *Chest* 2008; **133** (suppl): 887S–968S.

Catheters and cannulas. For mention of the use of oral anticoagulants to prevent thrombosis in patients with indwelling infusion devices, see Heparin Sodium, p.1304.

Connective tissue and muscular disorders. Warfarin has been proposed to treat subcutaneous calcium deposition (calcinosis cutis) in patients with dermatomyositis, but its value is disputed, see Polymyositis and Dermatomyositis, p.1510.

Table 6. Recommended International Normalised Ratios (INR).

	INR	Condition or procedure
UK	2.5	Pulmonary embolism; deep-vein thrombosis; recurrence of venous thromboembolism when no longer on warfarin; symptomatic inherited thrombophilia; venous thromboembolism associated with antiphospholipid syndrome; atrial fibrillation; mural thrombus; cardiomyopathy; bioprosthetic heart valves.
	2.5 or 3.0	Cardioversion (higher INR may be appropriate before procedure); some mechanical prosthetic heart valves.
	3.5	Recurrence of venous thromboembolism when on warfarin; some mechanical prosthetic heart valves.
US	2.0 to 3.0	Prophylaxis of venous thromboembolism in high-risk surgical patients; treatment of venous thrombosis and pulmonary embolism; prophylaxis of systemic embolism in patients with atrial fibrillation, valvular heart disease, bioprosthetic heart valves or some mechanical prosthetic heart valves; prevention of recurrent myocardial infarction in patients receiving aspirin.
	2.5 to 3.5	Prophylaxis in patients with some mechanical prosthetic heart valves.
	3.0 to 4.0	Prevention of recurrent myocardial infarction in patients not receiving aspirin; systemic embolism in patients with some mechanical heart valves.

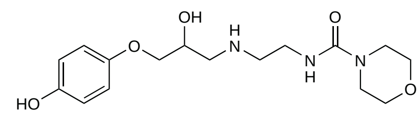
Xamoterol Fumarate *(BANM, USAN, rINNM)*

Fumarato de xamoterol; ICI-118587; Ksamoterolfumarat; Ksamoterolifumaraatti; Xamotérol, Fumarate de; Xamoteroli Fumaras. *N*-{2-[2-Hydroxy-3-(4-hydroxyphenoxy)propylamino]-ethyl}morpholine-4-carboxamide fumarate.

Ксамотерола Фумарат

$(C_{16}H_{25}N_3O_5)_2,C_4H_4O_4 = 794.8.$
CAS — 81801-12-9 (xamoterol); 90730-93-1 (xamoterol fumarate).
ATC — C01CX07.
ATC Vet — QC01CX07.



(xamoterol)

Profile

Xamoterol is a beta-adrenoceptor partial agonist with a selective action on beta$_1$ receptors. As a partial agonist it exerts mainly agonist activity at rest and under conditions of low sympathetic drive which results in improved ventricular function and increased cardiac output; during exercise and during conditions of increased sympathetic drive, such as that occurring in severe heart failure, xamoterol exerts beta-blocking activity. It therefore has the properties of both sympathomimetics (see p.1407) and beta blockers (see p.1225).

Xamoterol has been used in the management of chronic mild heart failure but was associated with deterioration and an excess of deaths in those with more severe disease. It has also been used in orthostatic hypotension secondary to autonomic failure.

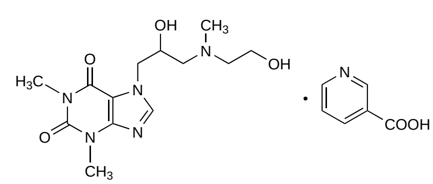
ATC Vet — QC04AD02.



Pharmacopoeias. In *Chin.* and *Pol.*

Profile

Xantinol nicotinate is a vasodilator with general properties similar to those of nicotinic acid (p.1957), to which it is slowly hydrolysed. Xantinol nicotinate is used in the management of peripheral (p.1178) and cerebral vascular disorders (p.1165) and in hyperlipidaemias (p.1169). Oral doses of up to 3 g daily may be given. It has also been given by intramuscular or slow intravenous injection.

Adverse Effects, Treatment, and Precautions

As for Hydrochlorothiazide, p.1307.

Effects on electrolyte balance. Although reductions in plasma-potassium concentrations with xipamide have been shown to be on average comparable with those produced by thiazide and loop diuretics at equipotent doses,[1] there have been several reports of marked hypokalaemia in individual patients. Asymptomatic hypokalaemia was reported in 4 of 5 patients[2] (serum-potassium concentrations of less than 3.4 mmol/litre) and in 3 of 13 patients[3] (serum-potassium concentrations of less than 3.0 mmol/litre). Severe hypokalaemia resulting in ventricular arrhythmias has been reported after xipamide used alone[4] or with indapamide.[5] Profound electrolyte disturbances with altered consciousness and ventricular extrasystoles occurred in a patient taking digoxin after the addition of xipamide for 10 days.[6] A case of hypokalaemic periodic paralysis associated with xipamide use has also been reported.[7]

7. Boulton AJM, Hardisty CA. Hypokalaemic periodic paralysis precipitated by diuretic therapy and minor surgery. *Postgrad Med J* 1982; **58:** 106–7.

Hepatic impairment. For a recommendation that xipamide should be given with caution to patients with liver disease, see under Pharmacokinetics, below.

Interactions

As for Hydrochlorothiazide, p.1309.

Pharmacokinetics

Xipamide has been reported to be well absorbed from the gastrointestinal tract. Absorption is fairly rapid with peak plasma concentrations occurring within 1 or 2 hours of oral doses. It is 99% bound to plasma proteins, and is excreted in the urine, partly unchanged and partly in the form of the glucuronide metabolite. It is reported to have a plasma half-life of about 5 to 8 hours. In patients with renal impairment excretion in the bile becomes more prominent.

◊ References.

1. Beermann B, Grind M. Clinical pharmacokinetics of some newer diuretics. *Clin Pharmacokinet* 1987; **13:** 254–66.

Hepatic impairment. Xipamide was present in the plasma and in ascitic fluid in patients with liver cirrhosis in proportion to the protein content of the respective compartments.[1] The amount of drug excreted into the urine was much greater in patients with liver disease than in healthy control subjects. This was attributed to a diminution in hepatic elimination, which could result in significant effects on the clinical response to xipamide. Thus patients with cholestasis could have an enhanced response to xipamide. On the other hand cirrhotic patients with the hepatorenal syndrome may be resistant to diuretics. Xipamide should be used with caution in patients with liver disease.

1. Knauf H, *et al.* Xipamide disposition in liver cirrhosis. *Clin Pharmacol Ther* 1990; **48:** 628–32.

Renal impairment. After single oral and intravenous doses of xipamide 20 mg the drug appeared to be completely absorbed from the gastrointestinal tract.[1] The mean elimination half-life in healthy subjects was 7 hours and two-thirds of the clearance was by extrarenal routes. There was some accumulation in patients with chronic renal failure, with a calculated elimination half-life of 9 hours in end-stage renal disease.

1. Knauf H, Mutschler E. Pharmacodynamics and pharmacokinetics of xipamide in patients with normal and impaired kidney function. *Eur J Clin Pharmacol* 1984; **26:** 513–20.

Uses and Administration

Xipamide is a diuretic, structurally related to indapamide, with actions and uses similar to those of the thiazide diuretics (see Hydrochlorothiazide, p.1310). It is given orally for hypertension (p.1171), and for oedema, including that associated with heart failure (p.1165).

Diuresis begins about 1 or 2 hours after an oral dose, reaches a peak at 4 to 6 hours, and lasts for about 12 hours.

In the treatment of **hypertension** the usual dose is 20 mg daily as a single morning dose, either alone, or with other antihypertensives. In some patients a dose of 10 mg daily may be adequate. In the treatment of **oedema** the usual initial dose is 40 mg daily, subsequently reduced to 20 mg daily, according to response; in resistant cases 80 mg daily may be required.

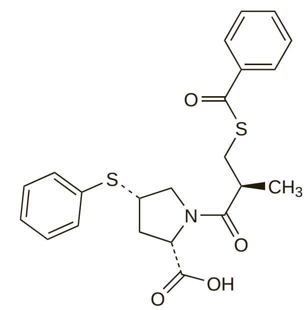
$C_{44}H_{44}CaN_2O_8S_4 = 897.2.$

CAS — 81872-10-8 (zofenopril); 81938-43-4 (zofenopril calcium).

ATC — C09AA15.

ATC Vet — QC09AA15.



(zofenopril)

Profile

Zofenopril is an ACE inhibitor (p.1193) that is used in the management of hypertension (p.1171) and myocardial infarction (p.1175). It owes its activity to the active metabolite zofenoprilat (SQ-26333) to which it is converted after oral doses. It is given orally in a usual daily maintenance dose of 30 to 60 mg of the calcium salt, as a single dose or in two divided doses.

Chelators Antidotes and Antagonists

The drugs included in this chapter act in a variety of ways to counter the toxic effects of exogenous and endogenous substances in the body. They are therefore used in the management of poisoning and overdosage, to protect against the toxicity of drugs such as antineoplastics, and in the management of metabolic disorders such as Wilson's disease where toxic substances accumulate.

The main groups of drugs used include:

- antagonists, such as the opioid antagonist naloxone, that compete with the poison for receptor sites. Other antagonists act by blocking substances that mediate the effects of the toxin; atropine (p.1219) acts in this way
- chelators and other drugs that form complexes with the toxin. This may reduce absorption of the toxin from the gastrointestinal tract, inactivate or reduce the activity of the toxin, or increase its elimination
- drugs that affect the metabolism of the toxin. Some antidotes, such as fomepizole in methyl alcohol poisoning, act by reducing the rate of metabolism to a toxic metabolite; alcohol (p.1625) has a similar action. Others, such as methionine and glutathione, promote the formation of inactive metabolites; acetylcysteine (p.1548) also acts in this way
- drugs that bypass the effect of the toxin. Calcium folinate (p.1943) is used for this purpose in methotrexate overdosage.

Acute poisoning

In the management of suspected acute poisoning it is often impossible to determine the identity of the poison or the size of the dose received with any certainty. Moreover, few poisons have specific antidotes or methods of elimination, and the mainstay of treatment for patients with suspected acute poisoning is therefore supportive and symptomatic therapy; in many cases nothing further is required. Symptoms of acute poisoning are frequently non-specific, particularly in the early stages. Maintenance of the airway and ventilation is the most important initial measure; other treatment, for example for cardiovascular or neurological symptoms, may be added as appropriate. Patients who are unconscious or who have respiratory depression may be given naloxone, particularly if opioid overdosage is a possibility. Some centres also recommend the routine administration of glucose to all unconscious patients since hypoglycaemia may be a cause of unconsciousness, although blood glucose measurements should be obtained first where facilities are immediately available; thiamine may be given in addition since glucose may precipitate Wernicke's encephalopathy.

Specific antidotes are available for a number of poisons and are the primary treatment where there is severe poisoning with a known toxin. They may be life-saving in such cases but their use is not without hazard and in many situations they are not necessary; their use does not preclude relevant supportive treatment.

Measures to reduce or prevent the absorption of the poison are widely advocated. For inhalational poisoning the victim is removed from the source of poisoning. Some toxins, in particular pesticides, may be absorbed through the skin, and clothing should be removed and the skin thoroughly washed to avoid continued absorption. Caustic substances are removed from the skin or eyes with copious irrigation. However, for orally ingested poisons the best method for gastrointestinal decontamination remains controversial.

Activated charcoal adsorbs a wide range of toxins and is often given to reduce absorption from the gastrointestinal tract. A single dose is generally effective, particularly if it is given within one hour of ingestion, although delayed use may be beneficial for modified-release preparations or for drugs that slow gastrointestinal transit time, such as those with antimuscarinic properties. Charcoal is generally well tolerated, although vomiting is common and there is a risk of aspiration if the airway is not adequately protected. Repeated doses may be of use to eliminate some substances even after systemic absorption has occurred.

Active removal of poisons from the stomach by induction of emesis or gastric lavage has been widely used, but there is little evidence to support its role (see under Ipecacuanha, p.1563). Induction of emesis with an emetic such as syrup of ipecacuanha has been used but is no longer recommended for either the home or hospital situation since there is no evidence that it improves outcomes and it may increase the risk of aspiration. If used at all, it should only be in fully conscious patients, where a potentially toxic amount has been ingested within the previous hour, and where other measures are unavailable or inappropriate. Emesis should not be induced if the poison is corrosive or petroleum based, nor if the poison is removable by treatment with activated charcoal. Gastric lavage may occasionally be indicated for ingestion of non-caustic poisons that are not absorbed by activated charcoal, but only if less than one hour has elapsed since ingestion; it should not be attempted if the airway is not adequately protected.

Whole-bowel irrigation using a non-absorbable osmotic agent such as a macrogol has also been used, particularly for substances that pass beyond the stomach before being absorbed, such as iron preparations or enteric-coated or modified-release formulations, but its role is not established.

Techniques intended to promote the elimination of poisons from the body, such as haemodialysis or haemoperfusion, are only of value for a limited number of poisons in a few severely poisoned patients. Forced diuresis is no longer recommended, although alkalinisation of the urine using sodium bicarbonate infusion may have a role for selected poisons. Repeated oral doses of activated charcoal may be as effective as these more invasive methods for some drugs that undergo enterohepatic or enteroenteric recycling.

Poisons Information Centres exist in many countries and should be consulted for more detailed information in specific situations.

Activated Charcoal

Aktif Kömür; Aktiivihiili; Aktivált szén; Aktyvintosios anglys; Carbo activatus; Carbo Medicinalis; Carbón activado; Charbon activé; Decolorising Charcoal; Kol, aktivt; Medicinal Charcoal; Uhlí aktivní; Węgiel leczniczy.

ATC — A07BA01.
ATC Vet — QA07BA01.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Charcoal, Activated). It is obtained from vegetable matter by suitable carbonisation processes intended to confer a high adsorption power. A black, light powder free from grittiness. Practically insoluble in all usual solvents. It adsorbs not less than 40% of its own weight of phenazone, calculated with reference to the dried substance. Store in airtight containers.

USP 31 (Activated Charcoal). The residue from the destructive distillation of various organic materials, treated to increase its adsorptive power. A fine, black, odourless, tasteless powder, free from gritty matter. The USP 31 has tests for adsorptive power in respect of alkaloids and dyes.

Adverse Effects and Precautions

Activated charcoal is relatively non-toxic when given by mouth but gastrointestinal disturbances such as vomiting, constipation, or diarrhoea have been reported. It may colour the faeces black. Activated charcoal should be used with caution in patients at risk of gastrointestinal obstruction as it may reduce gastrointestinal motility.

Haemoperfusion with activated charcoal has produced various adverse effects including platelet aggregation, charcoal embolism, thrombocytopenia, haemorrhage, hypoglycaemia, hypocalcaemia, hypothermia, and hypotension.

Care is needed if activated charcoal is used in patients receiving specific oral antidotes such as methionine (see Interactions, below). As with any treatment given by mouth for poisoning the risk of aspiration should be considered in drowsy or comatose patients.

Effects on the gastrointestinal tract. Gastrointestinal adverse effects are the main complication of oral activated charcoal. Vomiting may occur and is a risk factor for pulmonary aspiration (see Effects on the Lungs, below). Although some preparations may cause diarrhoea, activated charcoal may reduce gastrointestinal motility and multiple doses have been associated with intestinal obstruction or faecal impaction,[1-4] in some cases leading to ulceration[5] or perforation;[6] overdosage with drugs that reduce gastrointestinal motility may increase the risk.[2,3,6] Two cases of pseudo-obstruction, one of which was fatal, have also been reported[7] after the use of activated charcoal and sorbitol with opioid sedation for theophylline poisoning. In another report,[8] severe peritonitis developed in a patient given oral activated charcoal following gastric lavage; charcoal was found in the peritoneum, although the site of perforation could not be detected. Acute appendicitis has also been reported after multiple doses of activated charcoal.[9]

Effects on the lungs. Vomiting after oral activated charcoal for acute poisoning has been associated with pulmonary aspiration of gastric contents, sometimes with fatal results.[1-3] Vomiting may be related to the formulation used and may be increased with sorbitol-containing preparations,[4] although a study in children[5] failed to confirm this. The use of a cuffed endotracheal tube has been recommended for any patient with impaired laryngeal reflexes to prevent aspiration;[3] however, there have been reports of aspiration despite a protected airway, including a case of obstructive laryngitis in a child.[6] Acute[7] and chronic[8] pulmonary toxicity has also been reported after accidental administration of charcoal into the lung due to misplacement of the nasogastric tube.

Interactions

Activated charcoal has the potential to reduce the absorption of many drugs from the gastrointestinal tract and simultaneous oral therapy should therefore be avoided. In the management of acute poisoning, concurrent medication should be given parenterally. Care is needed if a specific oral antidote such as methionine is given since adsorption of the antidote may decrease its effectiveness; it has been recommended that activated charcoal should be cleared from the stomach or avoided if oral antidotes are to be used.

Uses and Administration

Activated charcoal can adsorb a wide range of plant and inorganic poisons and many drugs including salicylates, paracetamol, barbiturates, and tricyclic antidepressants; when given orally it reduces their systemic absorption from the gastrointestinal tract and is therefore used in the treatment of acute oral poisoning. It is of no value for poisoning by strong acids, alkalis, or other corrosive substances and its adsorptive capacity is too low to be of use in poisoning with iron salts, cyanides, lithium, malathion, clofenotane, and some organic solvents such as methyl alcohol or ethylene glycol. Adsorption characteristics can be influenced by the charcoal's particle size, thus different responses may be obtained with different preparations.

Activated charcoal is given by mouth usually as a slurry in water. A usual adult dose for reduction of absorption is 50 g, but higher doses have been used. Children 1 to 12 years old may be given 25 to 50 g and infants under 1 year 1 g/kg. For maximum efficacy, activated charcoal should be given as soon as possible (within 1 hour) after ingestion of the toxic compound. However, it may be effective several hours after poisoning with certain drugs that slow gastric emptying. In the case of drugs that undergo enterohepatic or enteroenteric recycling (e.g. phenobarbital and theophylline) *repeated doses* of activated charcoal are of value in enhancing faecal elimination. Adult doses for repeated administration in active elimination have varied but typically 50 g may be given every 4 hours or 25 g every 2 hours. Doses in children and infants are similar to those used above for reduction of absorption and may be given every 4 to 6 hours. Administration may also be via a nasogastric tube.

Mixtures such as 'universal antidote' that contained activated charcoal, magnesium oxide, and tannic acid should not be used; activated charcoal alone is more effective and tannic acid may cause hepatotoxicity.

In treatment of poisoning using charcoal haemoperfusion, activated charcoal is used to remove drugs from the bloodstream. Where available, it may be of value in acute severe poisoning by drugs such as the barbiturates, glutethimide, or theophylline when other intensive measures fail to improve the condition of the patient.

Activated charcoal is used in dressings for ulcers and suppurating wounds (p.1585) to reduce malodour and may improve the rate of healing.

Activated charcoal has been used as a marker of intestinal transit and has also been tried in the treatment of flatulence. Both activated charcoal and vegetable charcoal (wood charcoal; carbo ligni) are included in preparations for various gastrointestinal disorders.

Technical grades of activated charcoal have been used as purifying and decolorising agents, for the removal of residual gases in low-pressure apparatus, and in respirators as a protection against toxic gases.

Administration. Activated charcoal is most commonly given as a slurry in water but this is often unpalatable because of the colour, gritty taste, lack of flavour, and difficulty in swallowing.[1] Flavourings and other excipients are often added in an attempt to improve palatability, although the effect of any additives on the adsorptive capacity of charcoal needs to be considered. Studies *in vitro* or in healthy subjects indicated that some foods such as ice cream, milk, and cocoa might inhibit the adsorptive capacity of activated charcoal, whereas starches and jams appeared to have no effect.[2,3] Carmellose has improved palatability although it might also reduce adsorptive capacity.[4-6] Saccharin sodium, sucrose, or sorbitol may be suitable additives,[7] although there may be problems associated with sorbitol-containing products (see under Poisoning, below). Chocolate syrup has also been used but the sweetness and flavour may disappear after a few minutes of contact with the activated charcoal.[1] A more recent study[8] of charcoal use in children with suspected poisoning found no evidence that use of flavourings improved the success of administration.

Poisoning. The management of acute poisoning is discussed on p.1435. The use of a *single oral dose* of activated charcoal has become a widespread method of preventing the absorption of ingested compounds and may be superior to gastric emptying. The American Academy of Clinical Toxicology (AACT) and the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT) consider[1] that activated charcoal may be used if a patient presents within 1 hour of ingesting a potentially toxic amount of a poison known to be adsorbed by charcoal. There are insufficient data to support general use beyond 1 hour after ingestion.[1-3] In addition, *multiple oral doses* of activated charcoal have been found to enhance the elimination of some drugs and toxic substances even after systemic absorption. Mechanisms by which activated charcoal may increase drug elimination from the body include interruption of the enterohepatic circulation of drugs excreted into the bile, reduction of the reabsorption of drugs which diffuse or are actively secreted into the intestines, and increased elimination of the drug via the gastrointestinal tract when given with a laxative to decrease gastrointestinal transit time, although the practice of using charcoal with a laxative has been questioned.[4-6] Repeated oral doses of activated charcoal may therefore be considered for compounds that undergo enterohepatic or enteroenteric circulation, have a small volume of distribution, are not extensively bound to plasma proteins, and have a low endogenous clearance. Following a review of the literature[6] the AACT and EAPCCT recommended that multiple doses of charcoal should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline. Anecdotal reports and studies in acutely poisoned patients indicate that a technique of giving multiple doses of charcoal may offer an alternative to charcoal haemoperfusion or haemodialysis. However, while activated charcoal is generally well tolerated, major complications do occasionally occur, including pulmonary aspiration and bowel obstruction.[7] Also, use of multiple doses of charcoal preparations containing sorbitol or sodium bicarbonate can result in increased vomiting[8] or in electrolyte disturbances.[4,9,10]

HAEMOPERFUSION. Haemoperfusion involves the passage of blood through an adsorbent material such as activated charcoal or synthetic hydrophobic polystyrene resins that can retain certain drugs and toxic agents. Early problems with charcoal haemoperfusion such as charcoal embolism, marked thrombocytopenia, fibrinogen loss, and pyrogen reactions have been largely overcome by purification procedures and by coating the carbon with biocompatible polymers. However, transient falls in platelet count, leucocyte count, and circulatory concentrations of clotting factors, calcium, glucose, urea, creatinine, and urate have been reported during haemoperfusion. While there is no substitute for supportive measures, haemoperfusion can significantly reduce the body burden of certain compounds with a low volume of distribution within 4 to 6 hours in some severely poisoned patients; haemoperfusion is not effective for drugs or poisons with very large volumes of distribution.

Porphyria. Activated charcoal may be used as part of the management of erythropoietic protoporphyria, one of the non-acute porphyrias (p.1448). It acts as a sorbent in the gut lumen, interrupting the enterohepatic recycling of protoporphyrin. It may also have a role in congenital erythropoietic porphyria, a very rare porphyria. In a patient[1] with photomutilation due to this condition, activated charcoal 30 g given orally every 3 hours for 36 hours reduced the plasma-porphyrin concentration to normal values by 20 hours and was more effective than colestyramine or red cell transfusion. After discontinuation of activated charcoal, plasma-porphyrin concentrations rose rapidly to near pretreatment levels within 10 days. Long-term treatment with oral charcoal over a 9-month period produced a clinical remission with low concentrations of plasma and skin porphyrin and an absence of photocutaneous activity. The optimal dose was determined to be 60 g three times daily. However, exacerbation after an initial period of remission has been reported in another patient[2] and total lack of efficacy in a third.[3]

Activated charcoal has also been tried in variegate porphyria, but a study[4] in 8 patients found that oral charcoal led to clinical and biochemical deterioration with an increase in skin lesions and in urinary and plasma porphyrins.

Pruritus. Activated charcoal has been tried in pruritus (p.1582) associated with renal failure. In a double-blind crossover study,[1] activated charcoal 6 g daily by mouth for 8 weeks was more effective than placebo in relieving generalised pruritus in 11 patients undergoing maintenance haemodialysis. Another study[2] found that activated charcoal completely relieved pruritus in 10 of 23 haemodialysis patients, with a partial response in a further 10; treatment was generally well tolerated.

Amifostine *(BAN, USAN, rINN)*

Amifostiini; Amifostin; Amifostina; Amifostinum; Ethiofos; Gammaphos; NSC-296961; WR-2721. *S*-[2-(3-Aminopropylamino)ethyl] dihydrogen phosphorothioate.

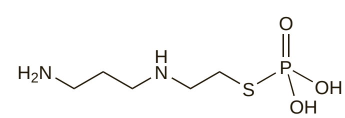
Амифостин

$C_5H_{15}N_2O_3PS = 214.2.$

CAS — 20537-88-6 (amifostine); 63717-27-1 (amifostine monohydrate).

ATC — V03AF05.

ATC Vet — QV03AF05.



Pharmacopoeias. *US* includes the trihydrate.

USP 31 (Amifostine). The trihydrate is a white crystalline powder. Freely soluble in water. pH of a 5% solution in water is between 6.5 and 7.5. Store in airtight containers at a temperature of 2° to 8°. Protect from light.

Incompatibility. Amifostine has been reported[1] to be physically incompatible with aciclovir sodium, amphotericin B, cefoperazone sodium, chlorpromazine hydrochloride, cisplatin, ganciclovir sodium, hydroxyzine hydrochloride, miconazole, minocycline hydrochloride, and prochlorperazine edisilate during simulated Y-site administration.

1. Trissel LA, Martinez JF. Compatibility of amifostine with selected drugs during simulated Y-site administration. *Am J Health-Syst Pharm* 1995; **52:** 2208–12.

Adverse Effects, Treatment, and Precautions

Amifostine may cause a transient reduction, usually in systolic, or, less frequently, in diastolic blood pressure. However, more pronounced reductions in blood pressure may occur and transient loss of consciousness has been reported very rarely. To minimise hypotension, patients should be adequately hydrated before treatment begins and should be in a supine position. Amifostine is contra-indicated in patients who are hypotensive or dehydrated. Patients taking antihypertensive drugs should discontinue treatment 24 hours before starting amifostine. Arterial blood pressure must be monitored during the amifostine infusion and if systolic blood pressure decreases significantly, the infusion must stop. It may be continued if blood pressure returns to normal within 5 minutes.

Nausea and vomiting are frequently reported and concurrent antiemetic therapy is recommended.

Amifostine reduces serum-calcium concentrations, although clinical hypocalcaemia has occurred only very rarely in patients who received multiple doses of amifostine within 24 hours. Serum-calcium concentrations should be monitored in patients at risk of hypocalcaemia.

Other adverse effects include flushing, chills, somnolence, hiccups, and sneezing. Hypersensitivity reactions and anaphylactoid reactions have been reported. Skin rashes may occur and there have been reports of more severe skin reactions including Stevens-Johnson syndrome and toxic epidermal necrolysis, in some cases resulting in fatality.

Administration of amifostine over a longer period than the recommended 15 minutes is associated with a higher incidence of adverse effects.

Effects on the skin. Amifostine has been associated with severe skin reactions, including Stevens-Johnson syndrome[1,2] and toxic epidermal necrolysis,[1,2] and fatalities have occurred.[2] The reactions appear to be more common in patients receiving radiotherapy.[2]

1. Lale Atahan I, *et al*. Two cases of Stevens-Johnson syndrome: toxic epidermal necrolysis possibly induced by amifostine during radiotherapy. *Br J Dermatol* 2000; **143:** 1072–3.
2. Boccia R, *et al*. Assessment and management of cutaneous reactions with amifostine administration: findings of the ethyol (amifostine) cutaneous treatment advisory panel (ECTAP). *Int J Radiat Oncol Biol Phys* 2004; **60:** 302–9.

Pharmacokinetics

Amifostine is rapidly cleared from the plasma after intravenous administration and is dephosphorylated by alkaline phosphatase to the active metabolite WR-1065, a free thiol compound. The elimination half-life of amifostine after a 15-minute infusion is less than 10 minutes. About 6% or less of a dose is excreted in the urine.

Uses and Administration

Amifostine, an aminothiol compound, is a cytoprotective agent. It is converted in the body to its active metabolite WR-1065, which protects noncancerous cells against the toxic effects of antineoplastics and ionising radiation. It is used in patients with advanced ovarian cancer to reduce neutropenia-related infection associated with cyclophosphamide and cisplatin therapy and, in patients with advanced solid tumours of non-germ cell origin, to reduce the cumulative renal toxicity associated with repeated cisplatin use. It is also used to reduce the incidence of xerostomia (dry mouth) in patients undergoing radiation therapy for head and neck cancer. Amifostine is under investigation in ameliorating the adverse effects of other antineoplastics and in the treatment of myelodysplasia.

In chemotherapy, amifostine is given by intravenous infusion over 15 minutes starting no more than 30 minutes before the antineoplastic therapy. The dose in adults is 910 mg/m^2 once daily. Subsequent doses should be reduced to 740 mg/m^2 in patients unable to tolerate the full dose. A dose of 740 mg/m^2 is also recommended for the reduction of renal toxicity of cisplatin if doses of cisplatin of less than 100 mg/m^2 are used.

In the prevention of xerostomia, amifostine is given in a dose of 200 mg/m^2 daily as a 3-minute intravenous infusion started 15 to 30 minutes before radiotherapy.

Cytoprotection. WR-1065, the active metabolite of amifostine, readily enters non-malignant cells where it deactivates cytotoxics such as alkylating and platinum-containing antineoplastics and protects against the effects of ionising radiation.[1-3] The cytoprotective effects of amifostine are reported to be selective for normal cells and not to interfere with the cytotoxic effects of antineoplastics and radiation on malignant cells. Several factors contribute to this selectivity, including the lower alkaline phosphatase content of malignant cells compared with normal cells, and the lower pH of malignant tissues, both of which decrease the formation and uptake of WR-1065 by malignant cells.[2,3]

Benefit has been reported with amifostine in various malignancies and the American Society of Clinical Oncology currently recommends[4] that its use may be considered in patients receiving cisplatin- or alkylating agent-based chemotherapy, and in patients receiving radiation therapy in the head and neck region. Although it is usually given intravenously, there is some evidence[5,6] that the subcutaneous route may be effective and may be associated with fewer adverse effects.

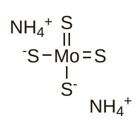
Ammonium Tetrathiomolybdate

Tetratiomolibdato de amonio.
$(NH_4)_2MoS_4$ = 260.3.
CAS — 15060-55-6.



Profile

Ammonium tetrathiomolybdate is a chelator that aids the elimination of copper from the body. It is under investigation in the treatment of Wilson's disease.

Wilson's disease. Ammonium tetrathiomolybdate forms a complex with protein and copper. When it is taken with food it blocks the intestinal absorption of copper, and when given between meals it combines with albumin- and caeruloplasmin-bound copper. Ammonium tetrathiomolybdate is under investigation for the initial reduction of copper levels in patients with Wilson's disease (p.1459); it may be particularly suitable for patients with neurological symptoms.[1] Bone marrow depression[1,2] and raised liver enzymes[1] have been reported; both have responded to temporary withdrawal or dose reduction.

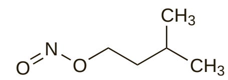
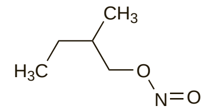
Amyli Nitris; Amylis Nitris; Amylium Nitrosum; Amylnitrit; Amyylinitriitti; Azotito de Amilo; Isoamyl Nitrite; Isopentyl Nitrite; Nitrito de amilo; Pentanolis Nitris.
$C_5H_{11}NO_2$ = 117.1.
ATC — V03AB22.
ATC Vet — QV03AB22.



and



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of amyl nitrite:
60 second trip; Aimes; Aimies; Ames; Amys; Boppers; Hard on; Pearls; Poppers; Sixty second trip; Snappers; Whiffenpoppers.

Pharmacopoeias. In *Jpn* and *US.*

USP 31 (Amyl Nitrite). A mixture of the nitrite esters of 3-methyl-1-butanol and 2-methyl-1-butanol. A clear, yellowish liquid having a peculiar, ethereal, fruity odour. It is very flammable. It is volatile even at low temperatures. B.p. about 96°. Practically insoluble in water; miscible with alcohol and with ether. Store in a cool place in airtight containers. Protect from light.

Stability. Amyl nitrite is liable to decompose with evolution of nitrogen, particularly if it has become acid in reaction.

Adverse Effects, Treatment, and Precautions

Amyl nitrite inhalation commonly causes flushing, headache, and dizziness; nausea and vomiting, hypotension, restlessness, and tachycardia may also occur. Overdosage may result in cyanosis, syncope, dyspnoea, and muscular weakness, due to vasodilatation and methaemoglobinaemia. Methylthioninium chloride may be required for severe methaemoglobinaemia but should not be used if cyanide poisoning is suspected since cyanide may be displaced.

Amyl nitrite may increase intra-ocular and intracranial pressure and should be used with caution in patients with glaucoma, recent head trauma, or cerebral haemorrhage.

Abuse. Volatile nitrites (commonly known as 'poppers'), including amyl, butyl, or isobutyl nitrite, have been abused in the belief that they expand creativity, stimulate music appreciation, promote a sense of abandon in dancing, and intensify sexual experience.[1,2]

Inhalation causes headache, tachycardia, syncope, acute psychosis, increased intra-ocular pressure, transient hemiparesis, methaemoglobinaemia, coma, and, rarely, sudden death. Haemolytic anaemia has also been reported;[3-5] in some subjects, Heinz body formation has been detected.[3] Methaemoglobinaemia may be severe,[6] and has also been reported after ingestion of volatile nitrites.[7-10] Symptoms are similar to those of hypoxia[9] and may be reversed by methylthioninium chloride.[6-10]

Amyl nitrite inhalation has led to severe and extensive contact dermatitis around the face with secondary spread elsewhere on the body.[11]

11. Bos JD, *et al*. Allergic contact dermatitis to amyl nitrite ('poppers'). *Contact Dermatitis* 1985; **12:** 109.

Handling and storage. Amyl nitrite is very flammable and must not be used where it may be ignited.

Uses and Administration

Amyl nitrite is rapidly absorbed on inhalation and has been used in the immediate treatment of patients with definite cyanide poisoning (p.2045) to induce the formation of methaemoglobin, which combines with the cyanide to form non-toxic cyanmethaemoglobin. The value of such treatment has been questioned since only low levels of methaemoglobin are formed, but other mechanisms may also be important. A suggested procedure has

The symbol † denotes a preparation no longer actively marketed

been to give amyl nitrite by inhalation for up to 30 seconds every minute until other measures can be instituted. It has also been suggested for use in the management of hydrogen sulfide poisoning (p.1690).

Amyl nitrite has an action similar to that of glyceryl trinitrate (p.1297) and used to be given by inhalation for the relief of acute attacks of angina pectoris but is seldom used now.

Homoeopathy. Amyl nitrite has been used in homoeopathic medicines under the following names: Amyl nitrosum; Am. nit.

Preparations

USP 31: Amyl Nitrite Inhalant.

Proprietary Preparations (details are given in Part 3)

AST-120

CAS — 90597-58-3.

Profile

AST-120 is an adsorbent consisting of spherical microcrystalline carbonaceous particles with oxygen complex including surface oxides. It is given orally to delay the progression of chronic renal failure by removing uraemic toxins and their precursors from the gastrointestinal tract. It is also under investigation in gastrointestinal disorders.

◊ References.

Preparations

Proprietary Preparations (details are given in Part 3)

Jpn: Kremezin.

Atipamezole *(BAN, USAN, rINN)*

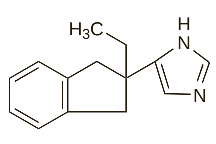
Atipamezol; Atipamézole; Atipamezolum; MPV-1248. 4-(2-Ethyl-2-indanyl)imidazole.

Атипамезол

$C_{14}H_{16}N_2$ = 212.3.

CAS — 104054-27-5.

ATC Vet — QV03AB90.



Atipamezole Hydrochloride *(BANM, rINNM)*

Atipametsolihydrokloridi; Atipamézole, Chlorhydrate d'; Atipamezolhydroklorid; Atipamezoli Hydrochloridum; Hidrocloruro de atipamezol.

Атипамезола Гидрохлорид

$C_{14}H_{16}N_2$,HCl = 248.8.

CAS — 104075-48-1.

Profile

Atipamezole is a selective alpha$_2$-adrenergic receptor antagonist that is used as the hydrochloride in veterinary medicine to reverse the sedative effects of medetomidine.

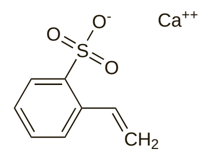
Calcium Polystyrene Sulfonate

Calcium Polystyrene Sulphonate; Poliestirenosulfonato cálcico; Polistiren Sülfonat Kalsiyum.

CAS — 37286-92-3.

ATC — V03AE01.

ATC Vet — QV03AE01.



Pharmacopoeias. In *Br.* and *Jpn.*

BP 2008 (Calcium Polystyrene Sulphonate). A cream to light brown, fine powder. The calcium content is not less than 6.5% and not more than 9.5%, calculated with reference to the dried substance. Each g exchanges not less than 1.3 mmol and not more than 2.0 mmol of potassium, calculated with reference to the dried substance. Practically insoluble in water and in alcohol. Store in airtight containers.

Adverse Effects and Precautions

As for Sodium Polystyrene Sulfonate, p.1465. Sodium overloading is not a problem with calcium polystyrene sulfonate, but calcium overloading and hypercalcaemia may occur. It should therefore be avoided in patients with conditions such as hyperparathyroidism, multiple myeloma, sarcoidosis, or metastatic carcinoma who may present with renal failure together with hypercalcaemia. Patients should be monitored for electrolyte disturbances, especially hypokalaemia and hypercalcaemia.

Effects on the lungs. An elderly man who died from cardiac arrest was found at autopsy to have bronchopneumonia associated with inhalation of calcium polystyrene sulfonate;[1] the resin had been given by mouth to treat hyperkalaemia.

1. Chaplin AJ, Millard PR. Calcium polystyrene sulphonate: an unusual cause of inhalation pneumonia. *BMJ* 1975; **3:** 77–8.

Interactions

As for Sodium Polystyrene Sulfonate, p.1465. Calcium ions are released from the resin in the gastrointestinal tract and this may reduce the absorption of tetracycline given by mouth.

Uses and Administration

Calcium polystyrene sulfonate, the calcium salt of sulfonated styrene polymer, is a cation-exchange resin that exchanges calcium ions for potassium ions and other cations in the gastrointestinal tract. It is used similarly to sodium polystyrene sulfonate (p.1465) to enhance potassium excretion in the treatment of hyperkalaemia (p.1669) and may be preferred to the sodium resin in patients who cannot tolerate an increase in their sodium load. It is estimated that 1 g of calcium polystyrene sulfonate could bind 1.3 to 2 mmol of potassium but it is unlikely that such figures could be achieved in practice.

It is given orally, in a dose of 15 g three or four times daily, as a suspension in water or syrup or as a sweetened paste. It should not be given in fruit juices that have a high potassium content. A dose for children is 1 g/kg daily in divided doses for acute hyperkalaemia, reduced to a maintenance dose of 500 mg/kg daily in divided doses; the oral route is not recommended for neonates.

When oral administration is difficult, calcium polystyrene sulfonate may be given rectally as an enema. The usual daily dose is 30 g given as a suspension in 100 mL of 2% methylcellulose '450' and 100 mL of water and retained, if possible, for at least 9 hours. Initial therapy may involve both oral and rectal routes. Following retention of the enema the colon should be irrigated to remove the resin. Children and neonates may be given rectal doses similar to the oral doses suggested for children.

Preparations

Proprietary Preparations (details are given in Part 3)

Deferasirox *(USAN, rINN)*

CGP-72670; Déférasirox; Deferasiroxum; ICL-670; ICL-670A. 4-[3,5-Bis(2-hydroxyphenyl)-1*H*-1,2,4-triazol-1-yl]benzoic acid.

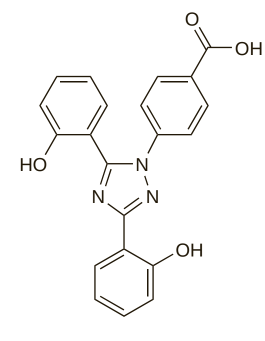
Деферазирокс

$C_{21}H_{15}N_3O_4$ = 373.4.

CAS — 201530-41-8.

ATC — V03AC03.

ATC Vet — QV03AC03.



Adverse Effects and Precautions

The commonest adverse effects with deferasirox are dose-related gastrointestinal disorders, such as nausea, vomiting, diarrhoea, and abdominal pain; diarrhoea may be more common in young children. Skin rashes are also common and may respond to a reduction in dose. Other adverse effects include headache, pyrexia, and cough.

Dose-dependent increases in serum creatinine are common and proteinuria may also occur; there have been reports of acute renal failure, including fatalities. Serum creatinine should be measured before starting deferasirox, and renal function should be assessed weekly for the first month (particularly in patients with risk factors for renal disease) and for a month after dosage increases, then monthly thereafter; tests for proteinuria should also be performed monthly. The dose should be reduced or treatment stopped if persistent increases in serum creatinine occur.

Liver enzyme values may increase in patients receiving deferasirox, and cases of hepatitis have occurred; gallstones and related biliary disorders have also been reported. Liver enzymes should be monitored monthly and treatment should be stopped if persistent increases occur.

As with other iron chelators, hearing loss and visual disorders, including cataracts, have occurred. Audiological and ophthalmological tests should be performed before starting deferasirox and then every 12 months. Serum ferritin should be measured monthly. In children, annual assessment of growth and development is also recommended.

There have been rare reports of blood disorders, some of which have been fatal, including agranulocytosis, neutropenia, and thrombocytopenia, in patients taking deferasirox. Blood counts should be monitored regularly.

Interactions

Deferasirox should not be given with aluminium-containing antacids since there is a possibility that it may chelate aluminium.

Pharmacokinetics

Deferasirox is absorbed from the gastrointestinal tract and peak plasma concentrations occur about 1.5 to 4 hours after ingestion. The absolute bioavailability is about 70% but is increased in the presence of food. Deferasirox is about 99% bound to plasma proteins, mainly albumin. It is metabolised by glucuronidation and is excreted mainly in the faeces via bile, as metabolites and as unchanged drug; there is a possibility that enterohepatic recycling may occur. About 8% of a dose is excreted in the urine. The mean elimination half-life is about 8 to 16 hours.

Uses and Administration

Deferasirox is an orally active iron chelator that is used in the management of chronic iron overload (p.1442) due to blood transfusion. It is available as tablets that are made into a suspension immediately before use. The usual initial dose in adults and children 2 years of age and older is 20 mg/kg once daily, taken on an empty stomach at least 30 minutes before food. Serum ferritin should be monitored monthly and the dose should be adjusted every 3 to 6 months as necessary. The maximum recommended dose is 30 mg/kg daily.

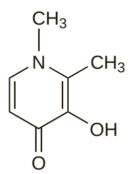
Deferiprone *(BAN, rINN)*

CP-20; Deferipron; Deferiprona; Défériprone; Deferiproni; Deferipronum; Dimethylhydroxypyridone; L1. 1,2-Dimethyl-3-hydroxypyrid-4-one; 3-Hydroxy-1,2-dimethyl-4-pyridone.

Дефериприон

$C_7H_9NO_2$ = 139.2.
CAS — 30652-11-0.
ATC — V03AC02.
ATC Vet — QV03AC02.



Adverse Effects and Precautions

Deferiprone has been shown to cause neutropenia and should not be used in neutropenic patients; the neutrophil count should be monitored weekly and treatment should be stopped if neutropenia develops. Agranulocytosis has also occurred. Patients should be advised to seek immediate medical attention if symptoms indicative of infection such as fever, sore throat, or flu-like symptoms occur.

Gastrointestinal disorders such as diarrhoea, nausea, vomiting, and abdominal pain are common during deferiprone treatment and may require a temporary reduction in dose. A reddish-brown discoloration of the urine is also common. Other adverse effects that have been reported include arthralgia and increased liver enzymes. Deferiprone may reduce plasma-zinc concentrations and zinc supplements may be required.

Deferiprone is teratogenic in *animals* and should not be used during pregnancy. Women of child-bearing potential should be advised to use contraceptive measures during treatment with deferiprone.

Caution is advised in patients with hepatic or renal impairment.

Effects on the blood. Agranulocytosis, in some cases fatal, has been reported in association with deferiprone use.[1,2]

1. Henter J-I, Karlén J. Fatal agranulocytosis after deferiprone therapy in a child with Diamond-Blackfan anemia. *Blood* 2007; **109:** 5157–9.
2. Anonymous. Deferiprone: agranulocytosis and neurological disorders. *Prescrire Int* 2007; **16:** 72.

Overdosage. Neurological disorders were reported by the manufacturer and the French pharmacovigilance authorities in 2 children aged 7 and 9 who had been treated with deferiprone doses at 2 ⁄ times the highest recommended dose of 100 mg/kg daily. The children were treated for 1 and 2 years, respectively, and developed nystagmus, gait disorders, ataxia, dystonia, and, in one case, psychomotor retardation. These disorders gradually improved after deferiprone was stopped.[1]

1. Agence française de sécurité sanitaire des produits de santé/Laboratoires Chiesi, France. Risque d'agranulocytoses fatales et de troubles neurologiques lors de l'utilisation de Ferriprox (défériprone) (issued 1st September, 2006). Available at: http://agmed.sante.gouv.fr/htm/10/filltrpsc/lp060901.pdf (accessed 27/09/07)

Interactions

Deferiprone chelates trivalent metal ions and could interact with aluminium-containing preparations; it should not be given with aluminium-containing antacids. Due to the risk of additive toxicity, use with drugs that may cause neutropenia or agranulocytosis is not recommended.

Pharmacokinetics

Deferiprone is rapidly absorbed from the gastrointestinal tract with peak serum concentrations occurring 45 to 60 minutes after an oral dose; absorption may be slowed in the presence of food and peak serum concentrations may be reduced. Deferiprone is metabolised to an inactive glucuronide metabolite and is excreted primarily in the urine, mainly as the metabolite and the iron-deferiprone complex, with a small amount of unchanged drug. The elimination half-life is about 2 to 3 hours.

Uses and Administration

Deferiprone is an orally active iron chelator used in the treatment of iron overload in patients with thalassaemia for whom desferrioxamine is unsuitable or ineffective. It may be given by mouth in doses of 25 mg/kg three times daily. Doses above 100 mg/kg daily are not recommended. For use in children, see Administration in Children, below.

◊ Reviews.

3. Hoffbrand AV. Deferiprone therapy for transfusional iron overload. *Best Pract Res Clin Haematol* 2005; **18:** 299–317.
4. Piga A, *et al*. Deferiprone: new insight. *Ann N Y Acad Sci* 2005; **1054:** 169–74.

Administration in children. UK licensed product information states that there are limited data on the use of deferiprone in children between 6 and 10 years of age, and no data on use in children below 6. Australian licensed product information states that limited data exist for children between the ages of 2 and 10 but that the effects of deferiprone on growth are unknown. Licensed doses in children are calculated by weight on the same basis as adults (see Uses and Administration, above).

Thalassaemia. Patients with thalassaemia receiving regular blood transfusions commonly develop iron overload requiring use of iron chelators. Deferiprone was developed as an oral alternative to desferrioxamine, but its role has been controversial. See Thalassaemia under Uses of Desferrioxamine, p.1442, for further information.

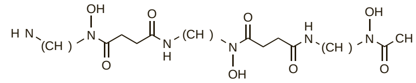
Дефероксамина Мезилат

$C_{25}H_{48}N_6O_8,CH_3SO_3H$ = 656.8.
CAS — 70-51-9 (desferrioxamine); 138-14-7 (desferrioxamine mesilate); 1950-39-6 (desferrioxamine hydrochloride).
ATC — V03AC01.
ATC Vet — QV03AC01.



(desferrioxamine)

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*
Ph. Eur. 6.2 (Deferoxamine Mesilate; Desferrioxamine Mesilate BP 2008). A white or almost white powder. Freely soluble in water; very slightly soluble in alcohol; slightly soluble in methyl alcohol. A freshly prepared 10% solution in water has a pH of 3.7 to 5.5. Store at 2° to 8°. Protect from light.
USP 31 (Deferoxamine Mesylate). A white to off-white powder. Freely soluble in water; slightly soluble in methyl alcohol. pH of a 1% solution in water is between 4.0 and 6.0. Store in airtight containers.

Incompatibility. Licensed product information states that desferrioxamine solutions are incompatible with heparin.

Adverse Effects and Treatment

Rapid intravenous injection of desferrioxamine may cause flushing, urticaria, hypotension, and shock. Local pain may occur with subcutaneous or intramuscular injections and pruritus, erythema, and swelling have occurred after prolonged subcutaneous use. Gastrointestinal disorders, dysuria, fever, allergic skin rashes, tachycardia, cardiac arrhythmias, convulsions, and leg cramps have been reported. Visual disturbances, including retinal changes, and hearing loss may occur and may be reversible if desferrioxamine is withdrawn. Cataract formation has also been reported. Desferrioxamine therapy may retard growth in very young children.

The adverse effects of desferrioxamine generally respond to dosage reduction. In acute overdosage desferrioxamine may be removed by haemodialysis.

◊ Reviews of the adverse effects of desferrioxamine.

1. Bentur Y, *et al*. Deferoxamine (desferrioxamine): new toxicities for an old drug. *Drug Safety* 1991; **6:** 37–46.

Effects on the blood. A patient with end-stage renal disease developed reversible thrombocytopenia on 3 separate occasions after intravenous infusions of desferrioxamine for dialysis osteomalacia.[1] Acute fatal aplastic anaemia occurred in a 16-year-old girl with thalassaemia after high intravenous doses of desferrioxamine (80 mg/kg daily) for 20 days.[2]

1. Walker JA, *et al*. Thrombocytopenia associated with intravenous desferrioxamine. *Am J Kidney Dis* 1985; **6:** 254–6.
2. Sofroniadou K, *et al*. Acute bone marrow aplasia associated with intravenous administration of deferoxamine (desferrioxamine). *Drug Safety* 1990; **5:** 152–4.

Effects on the ears and eyes. Lens opacities, retinal pigmentary changes and other retinal abnormalities, and ocular disturbances including loss of colour vision, night blindness, decreased visual acuity, and field defects, have been reported in patients receiving long-term or high-dose treatment with desferrioxamine.[1-4] The incidence appears to be about 30%, although individual studies have reported widely differing rates; in 2 studies long-term use of desferrioxamine was associated with symptomatic or asymptomatic ocular changes in 4% (2 of 52)[5] and 66% (10 of 15)[6] of patients respectively.

Sensorineural hearing impairment has also been reported,[5,7-12] and in one study[13] was attributed to desferrioxamine in 29% of patients (22 of 75). Tinnitus has been reported in a few patients.[11,14]

The mechanism by which desferrioxamine causes neurotoxicity is unclear. Some studies[8,15] have found an association with dose, suggesting a direct toxic effect of desferrioxamine; other studies[6,16] have suggested that depletion of trace metals, particularly zinc or copper, may be involved. Both ophthalmic and auditory abnormalities can improve when desferrioxamine is withdrawn,[1,3,5-10] although sometimes the effects may be irreversible[17] or recovery may only be partial.[8,9] There has also been a report[18] of improvement following use of zinc supplements.

Effects on growth rate. Growth retardation has been noted in thalassaemic children undergoing desferrioxamine therapy.[1,2] Growth retardation was related to dose[1,2] and inversely related to iron stores.[1] It was greater in those who started receiving desferrioxamine at the start of transfusion therapy at about 9 months old than in those who started desferrioxamine once iron accumulation was established, after about 3 years. A sharp increase in growth velocity was reported in 15 patients with low ferritin levels after a 50% reduction in desferrioxamine dose.[1]

Effects on the kidneys. Intensive treatment with intravenous infusions of desferrioxamine has been associated[1,2] with acute decreases in renal function, and it has been suggested[3] that nephrotoxicity could be related to the high doses used; acute renal failure has also been reported[4,5] after intravenous overdosage of desferrioxamine. However, other studies[6,7] have also found reductions in renal function associated with more usual subcutaneous dosage regimens.

Effects on the lungs. Pulmonary complications, including fatal acute respiratory distress syndrome, have been reported in patients given prolonged or high-dose intravenous desferrioxamine. A pulmonary syndrome with tachypnoea, hypoxaemia, reduced pulmonary function, and evidence of diffuse interstitial fibrosis and inflammation, has been reported[1,2] with high doses, possibly associated with a hypersensitivity reaction. There has also been a report[3] of fatal acute respiratory distress syndrome in 4 patients given intravenous desferrioxamine for 65 to 92 hours; toxicity was attributed to the prolonged infusion since no pulmonary complications had been noted with desferrioxamine given for less than 24 hours. Subsequent correspondence, however, suggested alternative explanations for the pulmonary injury including the use of doses above the daily maximum,[4] as well as inadequate desferrioxamine therapy.[5]

Effects on the skin. Desferrioxamine may be used in the management of porphyria cutanea tarda (see p.1448). However, lesions resembling porphyria cutanea tarda developed in 3 patients during long-term therapy with desferrioxamine for aluminium toxicity.[1] The lesions worsened on exposure to sun and resolved when treatment was completed. It was also possible that the lesions were associated with aluminium accumulation. Alopecia was noted in 1 patient but an association with desferrioxamine could not be established.

1. McCarthy JT, *et al.* Clinical experience with desferrioxamine in dialysis patients with aluminium toxicity. *Q J Med* 1990; **74:** 257–76.

Hypersensitivity. Individual cases of anaphylactoid reactions have been reported with desferrioxamine given by various parenteral routes, and desensitisation has been carried out successfully in some patients.[1-4] Immunological studies have suggested that the reaction may be pseudo-allergic in nature;[2-4] 4 patients who were unable to tolerate subcutaneous desferrioxamine due to severe hypersensitivity reactions were successfully treated with high-dose intravenous therapy.[5]

Effects on the lungs have also been attributed to hypersensitivity (see above).

Precautions

Desferrioxamine should be used with caution in patients with renal impairment since the metal complexes are excreted by the kidneys; in those with severe renal impairment dialysis increases elimination. The desferrioxamine-iron complex may colour the urine reddish-brown.

Desferrioxamine may exacerbate aluminium-related encephalopathy and precipitate seizures. Prophylactic treatment with antiepileptics such as clonazepam has been suggested for patients judged to be at risk.

An increased susceptibility to infection, particularly with *Yersinia* species, has been reported in patients with iron overload treated with desferrioxamine. Severe fungal infections have also been reported, mainly in patients undergoing dialysis. If infection is suspected, treatment with desferrioxamine should be stopped and appropriate antimicrobial treatment given.

Skeletal fetal anomalies have occurred in *animals*.

The urinary excretion of iron should be regularly monitored during treatment and periodic ophthalmological and audiological examinations are recommended for patients on long-term therapy. Monitoring of cardiac function is also recommended for patients receiving combined treatment with ascorbic acid (see also under Interactions, below).

Inappropriately high dosage in children with low ferritin levels may retard growth and therefore regular checks on height and weight are recommended for children.

Aluminium encephalopathy. Desferrioxamine may be used in the management of aluminium-associated encephalopathy, but has also been associated with precipitation or exacerbation of dementia,[1-3] with some fatal outcomes,[1] in dialysis patients with aluminium overload. It has been suggested[2] that the effect could be dose related. Desferrioxamine mobilises stored aluminium and may therefore increase plasma-aluminium concentrations, leading to toxicity. Use of a low dose of desferrioxamine (for example, 10 mg/kg) shortly before dialysis, in addition to charcoal haemoperfusion, has been recommended.[1] However, exacerbation of aluminium encephalopathy has also been reported[3] after the low dose of 500 mg twice weekly.

Diagnostic tests. *In vitro* and *animal* studies[1] have suggested that desferrioxamine could interfere with estimations of total iron-binding capacity. It may also interfere with colorimetric iron assays.

Desferrioxamine also binds gallium and has been reported[2-4] to distort the results of gallium-67 imaging studies.

Infection susceptibility. *Yersinia enterocolitica* is one of the most iron-dependent of all microbes and the risk of infection is increased in patients with iron overload. Use of exogenous iron-binding compounds (siderophores) such as desferrioxamine, may increase the ability of *Y. enterocolitica* to take up iron and may contribute to the increased risk of infection. Infections due to *Y. enterocolitica* (p.174) have been reported in patients receiving desferrioxamine for acute iron overdosage[1] or for chronic iron overload.[2-5] Severe infection with *Y. pseudotuberculosis* has also been reported in a thalassaemic patient on long-term desferrioxamine therapy.[6]

Treatment with desferrioxamine may also increase susceptibility to mucormycosis. Infections have occurred both in patients with iron overload disorders[7,8] and in those who do not have excessive iron stores.[9-11] A review[8] of 26 cases of mucormycosis in patients undergoing treatment revealed that 23 patients died; in 19 cases the diagnosis was only made at necropsy and only 9 patients received potentially effective treatment (surgery and/or amphotericin B). The organisms responsible were *Rhizopus* species in 13 cases and *Cunninghamella bertholletiae* in 3. In another review of 24 cases of mucormycosis in patients on dialysis,[12] at least 21 were receiving desferrioxamine; infection was fatal in 21 of the 24 patients.

In view of the serious nature of these infections it is important that they should be recognised and treated promptly. It has been suggested that a short course of a suitable antibacterial could be given as prophylaxis to young children from areas with a high incidence of yersiniosis who require treatment with desferrioxamine.[13]

Pregnancy. Desferrioxamine has been associated with fetal abnormalities in *animals*, and is generally only recommended in pregnancy if the benefits are considered to outweigh the risks. A review[1] of pregnancy outcome following iron overdose found that of 66 patients reported to the UK Teratology Information Service, 35 of whom had received desferrioxamine, 7 gave birth to infants with malformations (severe in one). However, in each case overdosage had occurred after the first trimester and the malformations therefore could not be directly related to either iron or desferrioxamine. It was concluded that treatment of iron overdose with desferrioxamine should not be withheld solely on the grounds of pregnancy. Long-term use of desferrioxamine has also been reported in pregnant patients with thalassaemia; a case report[2] and review of the literature found no evidence of teratogenicity despite use at various stages of gestation, suggesting that desferrioxamine may be given to the mother if necessary.

Interactions

Desferrioxamine is usually given parenterally and thus drug interactions due to chelation with oral metal ions are not a problem.

Ascorbic acid. Ascorbic acid is often given in addition to desferrioxamine to patients with iron overload to achieve better iron excretion. However, early on in treatment when there is excess tissue iron there is some evidence that ascorbic acid may worsen the iron toxicity, particularly to the heart. Thus, ascorbic acid should not be given for the first month after starting desferrioxamine treatment.

Phenothiazines. Neurological symptoms including loss of consciousness occurred in 2 patients given *prochlorperazine* during desferrioxamine therapy,[1] possibly due to synergistic effects on iron mobilisation. UK licensed product information therefore advises that they should not be used together.

Pharmacokinetics

Desferrioxamine mesilate is poorly absorbed from the gastrointestinal tract. After parenteral administration, desferrioxamine forms chelates with metal ions, which are then excreted in the urine; it is also metabolised, primarily in the plasma. The iron-desferrioxamine chelate is excreted in the urine and bile. Desferrioxamine is absorbed during peritoneal dialysis if added to the dialysis fluid. It is also removed by dialysis.

Uses and Administration

Desferrioxamine is a chelator that has a high affinity for ferric iron. When given by injection it forms a stable water-soluble iron-complex (ferrioxamine) that is readily excreted in the urine and in bile. Desferrioxamine appears to remove both free iron and bound iron from haemosiderin and ferritin but not from haemoglobin, transferrin, or cytochromes. It is estimated that 100 mg of desferrioxamine mesilate could bind about 8.5 mg of iron but it is unlikely that such a figure could be achieved in practice. Desferrioxamine also has an affinity for other trivalent metal ions including aluminium and theoretically 100 mg of the mesilate could bind 4.1 mg of aluminium.

Desferrioxamine increases the excretion of iron from the body and is used in conditions associated with chronic iron overload (such as the iron storage disorders haemochromatosis and haemosiderosis and after repeated blood transfusions as in thalassaemia) and in acute iron poisoning. It has been used as eye drops in the management of ocular siderosis and corneal rust stains. It is also used to reduce aluminium overload in patients with end-stage renal failure on maintenance dialysis.

Desferrioxamine is used as the mesilate and may be given by subcutaneous or intravenous infusion, by intramuscular injection, or intraperitoneally. It has been given orally in acute iron poisoning but this is no longer generally recommended (see Iron Poisoning, below).

In the treatment of **chronic iron overload**, the dosage and route of administration should be determined for each patient by monitoring urinary iron excretion, with the aim of normalising serum-ferritin concentrations. Continuous subcutaneous infusions, preferably with the aid of a small portable infusion pump, are particularly convenient for ambulant patients and are more effective than intramuscular injections. Continuous intravenous infusion has been recommended for patients incapable of continuing subcutaneous infusions or for those with cardiac problems secondary to iron overload. An initial daily dose of desferrioxamine mesilate 500 mg may be given by subcutaneous infusion or intravenous infusion, increasing until a plateau of iron excretion is reached. The usual effective dose range is 20 to 60 mg/kg daily. Subcutaneous infusions are given 3 to 7 times a week depending on the degree of iron overload, usually over 8 to 12 hours, but infusion over 24 hours may be necessary in some patients. For intramuscular injection, an initial dose of 0.5 to 1 g daily as 1 or 2 injections has been used, with the maintenance dose determined by response. It has been suggested that in addition to intramuscular treatment, up to 2 g of desferrioxamine mesilate should be given by intravenous infusion for each unit of blood transfused, at a rate not more than 15 mg/kg per hour at the time of each blood transfusion. Desferrioxamine should be given separately from the blood. Ascorbic acid supplements can enhance the excretion of iron, but, to reduce the risk of toxicity, should not be started until 1 month after starting desferrioxamine treatment (see under Interactions, above). Ascorbic acid is given in doses of up to 200 mg daily for adults or 50 to 200 mg daily for children; it also enhances iron absorption and should therefore be given separately from food.

Desferrioxamine has been used as a *diagnostic test* for iron storage disease in patients with normal renal function by injecting 500 mg of the mesilate intramuscularly and estimating the excretion of iron in the urine collected over the next 6 hours; an excretion of more than 1 mg of iron is suggestive of iron storage disease and more than 1.5 mg can be regarded as pathological.

In the treatment of **acute iron poisoning**, desferrioxamine is usually given by intravenous infusion, particularly in patients who are symptomatic. However, US licensed product information advises intramuscular injection unless the patient is in shock, due to the risk of adverse effects with the intravenous route. The dose should be adjusted according to the severity of the poisoning, preferably as indicated by the serum-iron concentration and total iron binding capacity, if available, although chelation therapy should be started in patients with significant symptoms without waiting for the results of blood concentrations. In the UK, the usual initial dose of desferrioxamine mesilate is 15 mg/kg per hour by slow intravenous infusion, reducing after 4 to 6 hours to provide a total dose not exceeding 80 mg/kg in 24 hours, although larger doses may be tolerated. Alternatively, it may be given intramuscularly as a single dose of 2 g for adults or 1 g for children. In the USA, an initial dose of 1 g is given, either intravenously at a maximum rate of 15 mg/kg per hour, or by intramuscular injection; subsequent doses of 500 mg may be given, by infusion over 4 to 12 hours or intramuscularly at intervals of 4 to 12 hours, to a maximum of 6 g in 24 hours.

In the treatment of **aluminium overload** in patients with end-stage renal failure, those undergoing maintenance haemodialysis or haemofiltration may be given desferrioxamine mesilate 5 mg/kg once a week by slow intravenous infusion during the last hour of a dialysis session, or 5 hours before dialysis in patients with more severe overload. In patients on peritoneal dialysis (CAPD or CCPD), desferrioxamine mesilate 5 mg/kg may be given once a week, by slow intravenous infusion, subcutaneously, intramuscularly, or intraperitoneally (the recommended route) before the final exchange of the day. For the *diagnosis* of aluminium overload, desferrioxamine mesilate 5 mg/kg is given by slow intravenous infusion during the last hour of haemodialysis. An increase in serum-aluminium concentration above baseline of more than 150 nanograms/mL (measured at the start of the next dialysis session) suggests aluminium overload.

Eye drops containing desferrioxamine mesilate 10% have been used for the treatment of ocular siderosis and corneal rust stains.

Administration. Compliance may be a problem with standard parenteral desferrioxamine regimens in patients with chronic iron overload. The oral,[1-3] rectal,[4] and intranasal[5] routes have therefore been tried as alternatives, but results have generally been disappointing. Twice-daily subcutaneous bolus injection has also been reported,[6-9] although the volume of the injection may be a limiting factor.[9]

Intraperitoneal desferrioxamine may be used to reduce aluminium levels in patients receiving peritoneal dialysis for chronic renal failure. Good results have also been reported[10] in a patient with haemochromatosis complicated by cirrhosis and cardiomyopathy, in whom a chronic peritoneal dialysis catheter was used to control ascites and to give desferrioxamine.

Aluminium overload. Desferrioxamine is an effective aluminium chelator and may have a role in both acute and chronic aluminium toxicity.

Accumulation of aluminium may be a particular problem in patients with chronic renal failure and has been implicated in renal osteodystrophy and dialysis dementia, as well as in other conditions, see Aluminium p.2254. The main sources in patients with renal failure are aluminium-containing phosphate binders and the use of tap water with a high aluminium content in the preparation of dialysis fluids. Acute aluminium toxicity is less common, but may occur following exposure to soluble aluminium salts.

Use of alternative phosphate binders (see Renal Osteodystrophy, p.1086) and limits on the aluminium concentration of dialysis fluids reduce the exposure to aluminium in patients with chronic renal failure, but desferrioxamine may also be used to remove aluminium that has already accumulated. The desferrioxamine-aluminium chelate (aluminoxamine) is removed by haemoperfusion and by haemodialysis,[1] and also by peritoneal dialysis, although the amount removed may be much less, and desferrioxamine has been used successfully to treat aluminium overload in dialysis patients. It has also been used with dialysis in acute toxicity.

In patients with *dialysis encephalopathy*, increased aluminium excretion and clinical improvement has been reported[2,3] in patients given desferrioxamine in doses of up to 6 g once a week via the arterial line during the first 2 hours of haemodialysis.[2,3] A study[4] of 11 patients with dialysis encephalopathy found that 5 patients who were treated with deionised or reverse-osmosis water alone died, whereas of 6 who were also given desferrioxamine 6 to 10 g intravenously each week at dialysis, 4 showed clinical improvement. Substantial improvement in early aluminium encephalopathy has been achieved in a patient on continuous ambulatory peritoneal dialysis by using intraperitoneal desferrioxamine.[5] Another small study[6] found that desferrioxamine improved psychomotor function in haemodialysis patients with impaired cerebral function but no clinical encephalopathy, who had only mildly elevated plasma-aluminium concentrations; desferrioxamine was given 3 times weekly during dialysis. Improvement in acute encephalopathy related to alum bladder irrigation has also been reported.[7] However, use of desferrioxamine may also exacerbate encephalopathy and caution is required (see Aluminium Encephalopathy, under Precautions, above).

Desferrioxamine has produced rapid clinical improvement in patients with *dialysis-related bone disease*.[8-10] In some studies[9,10] this has been associated with a reduction in the aluminium content of bone; others[8] have reported clinical improvement with no apparent effect on bone aluminium. Diagnosis of aluminium-related bone disease may require bone biopsy, but some studies have suggested that measurement of plasma-aluminium concentrations after a desferrioxamine infusion may also be used. Some studies reporting positive results[9,11] have used relatively high doses of desferrioxamine (40 mg/kg) with plasma-aluminium measured 24 to 44 hours later; a study[10] using a lower dose of desferrioxamine (28.5 mg/kg) and measuring plasma aluminium 5 hours later found similar increases in patients both with and without bone-aluminium accumulation. However, others have reported[12] that lower doses of desferrioxamine (5 or 10 mg/kg) are adequate when combined with measurement of serum-parathyroid hormone concentrations.

Desferrioxamine therapy has also produced beneficial results in *dialysis patients with anaemia*[13-15] and has also been found to reverse aluminium-induced resistance to erythropoietin.[16,17]

Prurigo nodularis in chronic aluminium overload has responded to desferrioxamine, with resolution of itch and skin lesions.[18]

Iron overload. Chronic iron overload can be caused by inappropriately increased gastrointestinal absorption, by grossly excessive oral intake over long periods, or by parenteral administration of iron, for example from transfused blood.[1,2] Excess iron is stored in the form of ferritin and haemosiderin. The term *haemosiderosis* is applied to the accumulation of haemosiderin in body tissues without associated tissue damage; *haemochromatosis* refers to a chronic disease state in which iron overload leads to tissue damage, mainly in the heart, liver, and pancreas. Primary or hereditary haemochromatosis is caused by a genetic defect in iron metabolism that results in excessive gastrointestinal absorption of iron. The treatment of choice for primary haemochromatosis is phlebotomy,[1-7] but chelation therapy may be needed in patients with anaemia, hypoproteinaemia, or severe cardiac disease. Neonatal haemochromatosis is a rare condition of unknown cause and results in fetal death or severe liver injury. Antoxidants and iron chelators may improve prognosis,[8] but many infants require liver transplantation. Maternal treatment with normal immunoglobulins has also been reported[9] to reduce the severity of recurrent neonatal haemochromatosis. Secondary or acquired haemochromatosis is commonly associated with chronic anaemias, in particular thalassaemia, in which excessive iron uptake due to disordered erythropoiesis and excess iron from repeated blood transfusions contribute to iron overload.[1,2] These patients generally require iron chelation, usually with parenteral desferrioxamine although oral iron chelators such as deferasirox and deferiprone have also been used (see below).

THALASSAEMIA. Patients homozygous for β-thalassaemia (p.1045) have severe anaemia requiring regular blood transfusions. As a consequence of this treatment iron overload develops and the excessive deposition of iron in the myocardium usually results in these patients dying in their second or third decade from arrhythmias or cardiac failure. Iron chelators such as desferrioxamine are therefore used to retard the accumulation of iron.

Desferrioxamine has been shown to prevent complications and improve survival in thalassaemic patients given regular systemic therapy.[1-3] There is also some evidence that impaired organ function might improve with intensive therapy. The liver is the main site of iron accumulation in iron overload, and a reduction in liver-iron concentrations and improvement in liver function has been reported[4] in patients with transfusional iron overload treated with desferrioxamine 2 to 4 g by slow subcutaneous infusion over 12 hours on 6 nights a week. However, in another study[5] improvement in the degree of hepatic fibrosis was seen after 3 to 5 years in only 2 of 7 patients given desferrioxamine up to 85 mg/kg daily by subcutaneous injection, despite reductions in iron concentrations. Preservation or possibly improvement in cardiac function has also been reported,[6-8] although cardiac disease continues to be the main cause of death in patients with thalassaemia. Although initial studies used intramuscular treatment, increased iron excretion is seen with continuous subcutaneous infusion, and this is usually the preferred route. However, compliance may be a problem, and is a major determinant of the effectiveness of treatment.[2] Intensive intravenous therapy, using continuous infusion devices, has been used successfully[9] in patients inadequately treated with subcutaneous desferrioxamine, and good results have also been reported[10,11] with intermittent intravenous infusions. Subcutaneous bolus injection has also been used (see Administration, above) although it may not be tolerated in all patients. Better iron excretion may be achieved if patients are given ascorbic acid 100 to 200 mg daily in addition to desferrioxamine (but see under Interactions, above). The most appropriate time to start desferrioxamine is not clear. Beginning chelation therapy before puberty could help to ensure normal sexual development in patients with thalassaemia major.[12] Other studies[1,2] have reported that initiation of therapy before severe iron overload develops, and maintenance of low serum-ferritin concentrations, prevents cardiac disease and improves prognosis, suggesting that chelation therapy should be started as early as possible, to prevent organ damage developing. However, desferrioxamine has been associated with adverse effects on growth (see Effects on Growth Rate, above) and it is usual to delay therapy until children are about 3 years of age, when iron overload becomes significant, although earlier treatment may be required in some cases.[3]

Alternatives to desferrioxamine have also been investigated. Deferiprone, which is given orally, effectively reduces iron overload,[13] but its long-term benefits are controversial. A study[14] in patients with thalassaemia reported progression of hepatic fibrosis in patients given deferiprone, although another study[15] was unable to confirm these findings. Other studies[16,17] have suggested that deferiprone may be superior to desferrioxamine in reducing cardiac complications. A systematic review[18] found no evidence to change treatment recommendations that indicate deferiprone for use in those for whom desferrioxamine is contra-indicated or ineffective; the authors acknowledged that there is a need for more research. Good results have been reported[19] with a combination of desferrioxamine and deferiprone, but the safety and efficacy of this regimen remains to be confirmed. Deferasirox, another oral iron chelator, is also used.

Iron poisoning. Despite the frequency of acute poisoning with iron preparations, no universally accepted treatment protocol exists. Diagnosis relies primarily on the history and clinical symptoms, although it is often difficult to determine the amount of iron ingested, and clinical assessment can be misleading since patients may exhibit mild symptoms despite having ingested potentially toxic quantities of iron. Measurement of the serum-iron concentration is useful in assessing the severity of poisoning but may not be immediately available, and does not always correlate with the severity of symptoms. Measurement of total iron binding capacity (TIBC) has been used but may be misleading and is no longer recommended.

Other tests that have been used include the desferrioxamine challenge test, in which desferrioxamine 50 mg/kg (to a maximum dose of 1 g) is given intramuscularly; if free iron is present, ferrioxamine will be excreted in the urine imparting a classic 'vin rosé' colour. However, interpretation is difficult and a negative result does not rule out toxicity; the test is no longer generally recommended.

The initial stage of treatment involves intravenous fluids and other supportive care as appropriate, and this may be sufficient in mild poisoning. Gastric lavage may be performed to remove any unabsorbed iron from the gastrointestinal tract, but may not remove tablets effectively; whole-bowel irrigation is an alternative, particularly in patients suspected of ingesting modified-release preparations or those with radiographic evidence of unabsorbed tablets remaining after gastric lavage. Addition of desferrioxamine to the lavage fluid has been suggested but there is little evidence of efficacy and some concern over possible toxic effects of ferrioxamine, and it is not routinely recommended. Activated charcoal is not effective in iron poisoning.

Chelation therapy with desferrioxamine is indicated in severe poisoning, including patients with impaired consciousness, shock, hypotension, or severe acidosis; other signs of severe poisoning include leucocytosis. A serum-iron concentration above 5 micrograms/mL indicates severe poisoning, and is usually an indication for chelation, but patients with shock or coma should be treated without waiting for the results of serum-iron tests; patients with moderate poisoning (serum-iron concentration 3 to 5 micrograms/mL) may be given chelation therapy if they are symptomatic. There is no general agreement on the duration of chelation therapy; among the suggested end-points are the resolution of severe symptoms, disappearance of the vin rosé coloration of the urine, 24 hours after the disappearance of coloration, and reduction of serum-iron concentrations to the normal range.

Malaria. Following the suggestion that iron-deficiency anaemia may offer some protection against infections (see Infections in the Precautions for Iron, p.1950), desferrioxamine was tried in a few patients with malaria.[1,2] Any antimalarial effect of desferrioxamine was thought to be as a result of chelation of parasite-associated iron rather than reduction in body-iron concentrations in the patient. Desferrioxamine given intravenously was reported[3] to shorten the time to regain consciousness in children with cerebral malaria receiving standard therapy with intravenous quinine and oral pyrimethamine-sulfadoxine. However, in another study[4] there was no evidence of a beneficial effect on mortality when desferrioxamine was added to an antimalarial treatment regimen that included a loading dose of quinine.

Porphyria. The management of various forms of porphyria is discussed on p.1448. Desferrioxamine has been used to reduce serum-iron concentrations in porphyria cutanea tarda and may have a role if phlebotomy is contra-indicated. In a study of 25 patients with porphyria cutanea tarda,[1] subcutaneous infusion of desferrioxamine was found to be as effective as repeated phlebotomies in normalising porphyrin excretion and iron storage. Desferrioxamine was also used successfully to treat haemodialysis-related porphyria cutanea tarda in a 22-year-old man in whom venesection therapy was contra-indicated because of severe anaemia requiring multiple blood transfusion.[2] Each course of intravenous desferrioxamine therapy after the end of 3 haemodialysis sessions was accompanied by a marked decrease in plasma porphyrins, a sharp increase in haematocrit values, and a simultaneous improvement in skin lesions.

Dexrazoxane *(BAN, USAN, rINN)*

ADR-529; Dexrazoxano; Dexrazoxanum; ICRF-187; NSC-169780. (+)-(S)-4,4′-Propylenebis(piperazine-2,6-dione).

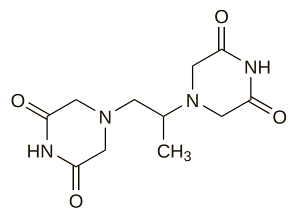
Дексразоксан

$C_{11}H_{16}N_4O_4$ = 268.3.

CAS — 24584-09-6.

ATC — V03AF02.

ATC Vet — QV03AF02.



Adverse Effects and Precautions

Dexrazoxane may add to the bone-marrow depression caused by antineoplastics and frequent complete blood counts are recommended during therapy. Although dexrazoxane protects against the cardiotoxic effects of anthracyclines, cardiac function should continue to be monitored when dexrazoxane is used. Pain on injection has been reported.

When used to reduce the cardiotoxicity of doxorubicin, licensed product information in the USA recommends that dexrazoxane should only be given to patients who have received a cumulative dose of doxorubicin of 300 mg/m^2 and who require continued use, since there is some evidence that dexrazoxane may reduce the efficacy of some antineoplastic regimens.

Patients with known liver function disorders should have their liver function assessed before receiving dexrazoxane for anthracycline extravasation.

Effects on the skin. Severe cutaneous and subcutaneous necrosis has been reported[1] in a patient who received dexrazoxane by infusion into a peripheral forearm vein, followed by intravenous injection of doxorubicin at a different site in the same arm. Local pain occurred during the dexrazoxane infusion but there was no evidence of extravasation.

1. Lossos IS, Ben-Yehuda D. Cutaneous and subcutaneous necrosis following dexrazoxane-CHOP therapy. *Ann Pharmacother* 1999; **33:** 253–4.

Pharmacokinetics

Dexrazoxane is mainly excreted in the urine as unchanged drug and metabolites. The elimination half-life is reported to be about 2 hours.

Uses and Administration

Dexrazoxane is the (+)-enantiomorph of the antineoplastic drug razoxane (p.767) and is a cytoprotective agent that is used to reduce the cardiotoxicity of doxorubicin and other anthracyclines (see p.713); it is also used in the management of anthracycline extravasation. It is hydrolysed to an active metabolite that is similar to edetic acid. This chelates iron within the cells and appears to prevent the formation of the anthracycline-iron complex that is thought to be responsible for cardiotoxicity.

Dexrazoxane is used to reduce the incidence and severity of cardiomyopathy associated with doxorubicin or epirubicin in patients with advanced or metastatic cancer who have previously received anthracyclines; in the USA, it is only licensed for use in women with metastatic breast cancer who have received a cumulative dose of doxorubicin of 300 mg/m^2 and who require continued use. It is given as the hydrochloride, by slow intravenous injection or rapid intravenous infusion, starting within 30 minutes before the anthracycline. The dose is expressed as the base. In the USA, the dose is calculated on a 10:1 ratio with doxorubicin; typically, 500 mg/m^2 of dexrazoxane is given for every 50 mg/m^2 of doxorubicin. In the UK the dose is calculated on a 20:1 ratio with doxorubicin and a 10:1 ratio with epirubicin. A reduction in dose may be required in patients with renal impairment (see below).

In patients with anthracycline extravasation, dexrazoxane is given intravenously into a large vein in an area other than that affected by the extravasation. It is given once daily for 3 days, by intravenous infusion over 1 to 2 hours, starting within 6 hours of extravasation; the dose should be given at about the same time each day. The usual dose is 1000 mg/m^2 on the first and second days, and 500 mg/m^2 on the third day; the maximum single dose for patients with a body-surface greater than 2 m^2 is 2000 mg.

Dexrazoxane is also being investigated for use in various other malignancies.

Administration in children. Doxorubicin has been used in the treatment of acute lymphoblastic leukaemia in children but cardiotoxicity may be a problem. A randomised study[1] in 206 children found that those given dexrazoxane with doxorubicin had fewer elevations of cardiac troponin T, a marker of myocardial damage, than those given doxorubicin alone, but longer follow-up was needed to assess effects on cardiac function and survival. Another study[2] in children with Hodgkin's disease suggested that use of dexrazoxane might increase the risk of secondary malignancies, but further analysis of the leukaemia study[3] found no evidence of such an effect.

3. Barry EV, *et al.* Absence of secondary malignant neoplasms in children with high-risk acute lymphoblastic leukemia treated with dexrazoxane. *J Clin Oncol* 2008; **26:** 1106–11.

Administration in renal impairment. Dexrazoxane is mainly excreted in the urine and the dose should be reduced in patients with renal impairment. A reduction of 50% is recommended for patients with a creatinine clearance below 40 mL/minute.

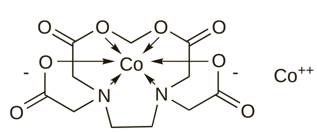
Dicobalt Edetate *(BAN, rINN)*

Cobalt Edetate; Cobalt EDTA; Cobalt Tetracemate; Dicobalti Edetas; Dikobolt Edetat; Édétate Dicobaltique; Edetato de dicobalto; Edetato dicobaltio. Cobalt [ethylenediaminetetra-acetato(4−)-*N*,*N*′,*O*,*O*′]cobalt(II).

Дикобальта Эдетат

$C_{10}H_{12}Co_2N_2O_8$ = 406.1.

CAS — 36499-65-7.



Adverse Effects and Precautions

Dicobalt edetate may cause hypotension, tachycardia, and vomiting. Anaphylactic reactions have occurred; oedema of the face and neck, sweating, chest pain, cardiac irregularities, and skin rashes have been reported. The adverse effects of dicobalt edetate are more severe in the absence of cyanide. Therefore, dicobalt edetate should not be given unless cyanide poisoning is definitely confirmed and poisoning is moderate or severe, that is, when consciousness is impaired.

Oedema. A patient with cyanide toxicity developed severe facial and pulmonary oedema after treatment with dicobalt edetate.[1] It has been suggested that when dicobalt edetate is used, facilities for intubation and resuscitation should be immediately available.

1. Dodds C, McKnight C. Cyanide toxicity after immersion and the hazards of dicobalt edetate. *BMJ* 1985; **291:** 785–6.

Uses and Administration

Dicobalt edetate is a chelator used in the treatment of acute cyanide poisoning (p.2045). Its use arises from the property of cobalt salts to form a relatively non-toxic stable ion-complex with cyanide. Owing to its toxicity, dicobalt edetate should be used only in confirmed cyanide poisoning and never as a precautionary measure. Cyanide poisoning must be treated as quickly as possible. A suggested dose is 300 mg given by intravenous injection over about 1 minute, repeated if the response is inadequate; a further dose of 300 mg of dicobalt edetate may be given 5 minutes later if required. For less severe poisoning the injection should be given over 5 minutes. Each injection of dicobalt edetate may be followed immediately by 50 mL of glucose 50% intravenously to reduce toxicity, though the value of giving glucose has been questioned.

Digoxin-specific Antibody Fragments

Digoxin Immune Fab (Ovine); F(ab); Fragmentos de anticuerpos específicos antidigoxina.

ATC — V03AB24.

ATC Vet — QV03AB24.

Adverse Effects and Precautions

Allergic reactions to digoxin-specific antibody fragments have been reported rarely. Patients known to be allergic to sheep protein and patients who have previously received digoxin-specific antibody fragments are likely to be at greater risk of developing an allergic reaction. Blood pressure, ECG, and potassium concentrations should be monitored closely during and after use.

Uses and Administration

Digoxin-specific antibody fragments are derived from antibodies produced in sheep immunised to digoxin. Digoxin has greater affinity for the antibodies than for tissue-binding sites, and the digoxin-antibody complex is then excreted in the urine. Digoxin-specific antibody fragments are generally restricted to the treatment of life-threatening digoxin or digitoxin intoxication in which conventional treatment is ineffective. Successful treatment of lanatoside C poisoning has also been reported.

It is estimated that 38 mg of antibody fragments could bind about 500 micrograms of digoxin or digitoxin and the dose calculation is based on this estimate and the body-load of digoxin (based on the amount ingested or ideally from the steady-state plasma concentration). Administration is by intravenous infusion over a 30-minute period. If cardiac arrest is imminent the dose may be given as a bolus. In the case of incomplete reversal or recurrence of toxicity a further dose can be given. In patients considered to be at high risk of an allergic response an intradermal or skin scratch test may be performed.

◊ Clinical studies[1-3] and reviews[4] of the use of digoxin-specific antibody fragments have confirmed their effectiveness in the treatment of severe digitalis toxicity in the majority of patients. An initial response is usually seen within 30 minutes of the end of the infusion with a maximum response after 3 to 4 hours.[4] The main causes of treatment failure or partial response are incorrect diagnosis of digitalis intoxication, inadequate dosage of antibody fragments, and use in patients already moribund.[3,4] Few adverse reactions have been attributed to the use of digoxin-specific antibody fragments; a few cases of minor allergic reactions have been reported including erythema, facial swelling, urticaria, and rashes,[2,4] but no anaphylactic reactions have been reported.[1-4] Haemodynamic status normally improves, but withdrawal of the inotropic support provided by digoxin may produce a decline in cardiac function in some patients. There may be dramatic reductions in plasma potassium concentrations.

Treatment has been successful in patients with varying degrees of renal impairment.[2,4,5] Elimination of the antibody fragment-digoxin complex may be markedly delayed in severe renal impairment and prolonged monitoring may be required in such patients.[6] Measurement of free serum-digoxin concentrations may be useful.[7] Experience with digoxin-specific antibody fragments in a patient with chronic renal failure receiving haemodialysis has been reported.[8] The patient had a good clinical response but haemodialysis did not remove the antibody fragment-digoxin complex.

In patients with adequate renal function the half-life of the antibody fragment-digoxin complex has been reported[2] to be about 16 to 20 hours although longer half-lives have been reported.[9] It has been suggested[10] that giving digoxin-specific antibody fragments by infusion over 7 hours, after an initial loading dose, could be useful in ensuring adequate antibody concentrations are maintained to bind digoxin as it is released from tissue stores over a prolonged period.

Use of the antibody fragments has also been effective in children with severe digitalis intoxication.[11]

Digoxin-specific antibody fragments have also been used successfully in poisoning due to preparations containing toad venom,[12] or due to common or yellow oleander (see Oleander, p.2356).

Dimercaprol *(BAN, rINN)*

BAL; British Anti-Lewisite; Dimercaprolum; Dimerkaprol; Dimerkaproli; Dimerkaprolis. 2,3-Dimercaptopropan-1-ol.

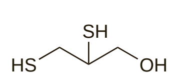
Димеркапрол

$C_3H_8OS_2$ = 124.2.

CAS — 59-52-9.

ATC — V03AB09.

ATC Vet — QV03AB09.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Dimercaprol). A clear colourless or slightly yellow liquid. Soluble in water and in arachis oil; miscible with alcohol and with benzyl benzoate. Store at 2° to 8° in well-filled airtight containers. Protect from light.

USP 31 (Dimercaprol). A colourless or practically colourless liquid, having a disagreeable, mercaptan-like odour. Soluble 1 in 20 of water; soluble in alcohol, in benzyl benzoate, and in methyl alcohol. Store at a temperature not exceeding 8° in airtight containers. Protect from light.

Adverse Effects and Treatment

The most consistent adverse effects produced by dimercaprol are hypertension and tachycardia. Other adverse effects include nausea, vomiting, headache, burning sensation of the lips, mouth, throat, and eyes, lachrymation and salivation, tingling of the extremities, a sensation of constriction in the throat and chest, muscle pains and muscle spasm, rhinorrhoea, conjunctivitis, sweating, restlessness, and abdominal pain. Transient reductions in the leucocyte count have also been reported. Pain may occur at the injection site and sterile abscesses occasionally develop. In children, fever commonly occurs and persists during therapy.

Adverse effects are dose-related, relatively frequent, and usually reversible. It has been suggested that ephedrine sulfate 30 to 60 mg, given by mouth 30 minutes before each injection of dimercaprol, may reduce adverse effects; antihistamines may alleviate some of the symptoms.

Precautions

Dimercaprol should be used with care in patients with hypertension or renal impairment. It should be discontinued, or continued with extreme caution, if acute renal insufficiency develops during therapy. Alkalinisation of the urine may protect the kidney during therapy by stabilising the dimercaprol-metal complex. Dimercaprol should not be used in patients with hepatic impairment unless due to arsenic poisoning. It should not be used in the treatment of poisoning due to cadmium, iron, or selenium as the dimercaprol-metal complexes formed are more toxic than the metals themselves.

G6PD deficiency. Haemolysis has been reported[1] during chelation therapy with dimercaprol and sodium calcium edetate for high blood-lead concentrations in 2 children with a deficiency of G6PD.

1. Janakiraman N, *et al*. Hemolysis during BAL chelation therapy for high blood lead levels in two G6PD deficient children. *Clin Pediatr (Phila)* 1978; **17:** 485–7.

Interactions

Iron supplements should not be given during dimercaprol therapy as toxic dimercaprol-metal complexes are formed.

Pharmacokinetics

After intramuscular injection, maximum blood concentrations of dimercaprol may be attained within 30 to 60 minutes. Dimercaprol is rapidly metabolised and the metabolites and dimercaprol-metal chelates are excreted in the urine and bile. Elimination is essentially complete within 4 hours of a single dose.

Uses and Administration

Dimercaprol is a chelator used in the treatment of acute poisoning by arsenic (p.2261), gold (p.123), and mercury (p.2342); it may also be used in the treatment of poisoning by antimony, bismuth, and possibly thallium. It is also used, with sodium calcium edetate, in acute lead poisoning (p.2332).

The sulfhydryl groups on dimercaprol compete with endogenous sulfhydryl groups on proteins such as enzymes to combine with these metals; chelation by dimercaprol therefore prevents or reverses any inhibition of the sulfhydryl enzymes by the metal and the dimercaprol-metal complex formed is readily excreted by the kidney. Since the complex may dissociate, particularly at acid pH, or be oxidised, the aim of treatment is to provide an excess of dimercaprol in body fluids until the excretion of the metal is complete.

Dimercaprol should be given by deep intramuscular injection and the injections should be given at different sites. The usual initial dose is up to 18 mg/kg daily in divided doses on the first day, reducing the daily dose and the frequency of injections over the subsequent days; a minimum interval of 4 hours between doses appears to reduce adverse effects. The individual dose is determined by severity of symptoms and the causative agent. Single doses should not generally exceed 3 mg/kg but single doses of up to 5 mg/kg may be required initially in patients with severe acute poisoning. Various dosage schedules are in use.

In the UK, adults may be given doses of 400 to 800 mg on the first day of treatment, 200 to 400 mg on the second and third days, and 100 to 200 mg on the fourth and subsequent days, all in divided doses; children may be given a similar dose per kg as for adults. Alternatively, the *BNF* recommends a dose for both adults and children of 2.5 to 3 mg/kg every 4 hours for 2 days, 2 to 4 times daily on the third day, then 1 to 2 times daily for 10 days or until recovery.

In the USA, a recommended schedule for severe arsenical or gold poisoning is 3 mg/kg given at 4-hourly intervals throughout the first 2 days, 4 times on the third day, and twice on each of the next 10 days. In milder cases, 2.5 mg/kg is given 4 times daily on each of the first 2 days, twice daily on the third day, and once daily on subsequent days for 10 days or until recovery.

Dimercaprol is also used with sodium calcium edetate (p.1462) in the treatment of lead poisoning and can be of particular value in the treatment of acute lead encephalopathy. Dimercaprol is usually started first, since sodium calcium edetate may cause lead to shift into the CNS. A suggested procedure is to give dimercaprol intramuscularly in an initial dose of 4 mg/kg, followed at 4-hourly intervals by dimercaprol 3 to 4 mg/kg intramuscularly and sodium calcium edetate; the sodium calcium edetate may be given either intravenously, or intramuscularly at a different site from the dimercaprol. Treatment may be continued for 2 to 7 days depending on the clinical response.

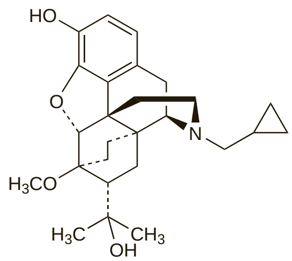
Diprénorphine, Chlorhydrate de; Diprenorphini Hydrochloridum; Hidrocloruro de diprenorfina; M-5050. (6*R*,7*R*,14*S*)-17-Cyclopropylmethyl-7,8-dihydro-7-(1-hydroxy-1-methylethyl)-6-*O*-methyl-6,14-ethano-17-normorphine hydrochloride; 2-[(−)-(5*R*,6*R*,7*R*,14*S*)-9a-Cyclopropylmethyl-4,5-epoxy-3-hydroxy-6-methoxy-6,14-ethanomorphinan-7-yl]propan-2-ol hydrochloride.

Дипренорфина Гидрохлорид

$C_{26}H_{35}NO_4,HCl = 462.0.$

CAS — 14357-78-9 (diprenorphine); 16808-86-9 (diprenorphine hydrochloride).

ATC Vet — QV03AB92.



(diprenorphine)

Pharmacopoeias. In *BP(Vet)*.

BP(Vet) 2008 (Diprenorphine Hydrochloride). A white or almost white crystalline powder. Sparingly soluble in water; slightly soluble in alcohol; very slightly soluble in chloroform; practically insoluble in ether. A 2% solution in water has a pH of 4.5 to 6.0. Protect from light.

Profile

Diprenorphine hydrochloride is an opioid antagonist used in veterinary medicine to reverse the effects of etorphine hydrochloride.

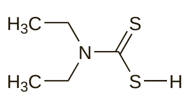
Ditiocarb Sodium *(rINN)*

DDTC; Dithiocarb Sodium; Ditiocarbe Sodique; Ditiocarbo sódico; Ditiocarbum Natricum; DTC; Sodium Diethyldithiocarbamate; Sodu dietyloditiokarbaminian; U-14624.

Дитиокарб Натрий

$C_5H_{10}NNaS_2 = 171.3.$

CAS — 148-18-5.



(ditiocarb)

Profile

Ditiocarb sodium is a chelator that has been used in nickel carbonyl poisoning. Disulfiram (p.2296), which is rapidly metabolised to ditiocarb, has been used as an alternative. Ditiocarb has also been used in the destruction of cisplatin wastes (see Handling and Disposal, p.699). It also has immunomodulating properties and has been investigated in HIV infection.

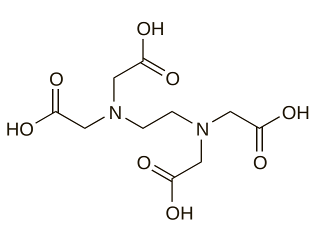
Edetic Acid *(BAN, rINN)*

Acide Édétique; Ácido edético; Acidum edeticum; Edathamil; Edetiinihappo; Edetinsyra; Edeto rūgštis; EDTA; Etiléndiamintetraecetsav; Kwas edetynowy; Kyselina edetová; Tetracemic Acid. Ethylenediaminetetra-acetic acid.

Эдетовая Кислота

$C_{10}H_{16}N_2O_8 = 292.2.$

CAS — 60-00-4.



Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF*.

Ph. Eur. 6.2 (Edetic Acid). A white or almost white, crystalline powder or colourless crystals. Practically insoluble in water and in alcohol. It dissolves in dilute solutions of alkali hydroxides. Protect from light.

USNF 26 (Edetic Acid). A white crystalline powder. Very slightly soluble in water; soluble in solutions of alkali hydroxides.

Incompatibility. Edetic acid and its salts chelate bivalent and trivalent metals and may affect the activity of drugs such as zinc insulin that contain such ions. Although edetates may enhance the antimicrobial efficacy of some disinfectants (see Chloroxylenol, p.1640), other preservatives may be inactivated. For reference to the inactivation of phenylmercuric salts by disodium edetate, see Incompatibility, under Phenylmercuric Nitrate, p.1657. For a report of edetates reducing the antimicrobial efficacy of thiomersal, see Incompatibility, p.1664.

Adverse Effects and Precautions

Edetic acid, used as a pharmaceutical excipient, is generally well tolerated. Adverse effects have been reported after inhalation of solutions containing edetic acid.

Asthma. Inhalation of an ipratropium nebuliser solution that contained edetic acid as one of the preservatives caused bronchoconstriction in 6 of 22 patients with asthma.[1] Inhalation of edetic acid alone produced dose-related bronchoconstriction that persisted for more than 1 hour.

1. Beasley CRW, *et al*. Bronchoconstrictor properties of preservatives in ipratropium bromide (Atrovent) nebuliser solution. *BMJ* 1987; **294:** 1197–8.

Blood testing. Pseudothrombocytopenia due to platelet clumping is a recognised complication of the use of edetates as anticoagulants for blood sampling and may lead to diagnostic errors.[1] The mechanism appears to be antibody-mediated. Alternative anticoagulants have been suggested.[1,2]

1. Bizzaro N. EDTA-dependent pseudothrombocytopenia: a clinical and epidemiological study of 112 cases, with 10-year follow-up. *Am J Hematol* 1995; **50:** 103–9.
2. Lippi U, *et al*. EDTA-induced platelet aggregation can be avoided by a new anticoagulant also suitable for automated complete blood count. *Haematologica* 1990; **75:** 38–41.

Uses

Edetic acid and its salts are chelators and are used in pharmaceutical manufacturing as well as having other industrial applications. They are also used as anticoagulants for blood taken for haematological investigations. Salts of edetic acid that are used clinically include sodium edetate (p.1463), sodium calcium edetate (p.1462), dicobalt edetate (p.1443), and sodium feredetate (p.1962).

Gallstones. Edetic acid has been suggested as a possible solvent for non-cholesterol gallstones (p.2409).

Preparations

Flumazenil *(BAN, USAN, rINN)*

Flumatseniili; Flumazénil; Flumazenilis; Flumazenilum; Flumazepil; Ro-15-1788; Ro-15-1788/000. Ethyl 8-fluoro-5,6-dihydro-5-methyl-6-oxo-4*H*-imidazo[1,5-*a*][1,4]benzodiazepine-3-carboxylate.

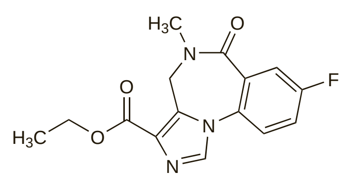
Флумазенил

$C_{15}H_{14}FN_3O_3 = 303.3.$

CAS — 78755-81-4.

ATC — V03AB25.

ATC Vet — QV03AB25.



Pharmacopoeias. In *Eur.* (see p.vii) and *US*.

Ph. Eur. 6.2 (Flumazenil). A white or almost white crystalline powder. Very slightly soluble in water; freely soluble in dichloromethane; sparingly soluble in methyl alcohol.

USP 31 (Flumazenil). A white to off-white powder. Practically insoluble in water; slightly soluble in acidic aqueous solutions. Store in airtight containers.

Adverse Effects and Precautions

The adverse effects experienced during use of flumazenil are generally due to the reversal of benzodiazepine effects and resemble benzodiazepine withdrawal symptoms (see p.987). Nausea, vomiting, dizziness, blurred vision, headache, and flushing may occur. Anxiety, fear, and agitation have been reported after too rapid reversal of sedation. There have been reports of seizures, especially in epileptics. Transient increases in blood pressure and heart rate have been observed. Hypersensitivity reactions have occurred rarely. Patients who have received benzodiazepines for prolonged periods are particularly at risk of experiencing withdrawal symptoms and rapid injection of flumazenil should be avoided in such patients.

Because of its short duration of action, patients given flumazenil to reverse benzodiazepine-induced sedation should be kept under close observation; further doses of flumazenil may be necessary. Flumazenil is contra-indicated in patients who are receiving benzodiazepines to control potentially life-threatening conditions and should not be given to epileptic patients who have been receiving benzodiazepines for a prolonged period to control seizures.

In cases of mixed overdose, flumazenil may unmask adverse effects of other psychotropic drugs. In particular, it should not be used in the presence of severe intoxication with tricyclic and related antidepressants.

Flumazenil should not be given to patients who have received neuromuscular blockers until the effects of neuromuscular blockade have fully cleared. Dosage should be adjusted individually; in high-risk or anxious patients, and after major surgery, it may be preferable to maintain some sedation during the early postoperative period. Flumazenil should be used with caution in patients with head injury since it may precipitate seizures or alter cerebral blood flow.

Careful titration of dosage is recommended in hepatic impairment.

◊ Cardiac arrhythmias,[1] sometimes preceded by tonic-clonic (grand mal) seizures[2,3] and occasionally fatal,[2] have been reported in several patients after the use of flumazenil for mixed overdoses with benzodiazepines and other psychotropics. Heart block has also been reported[4] after flumazenil use in a patient who had taken benzodiazepines, paracetamol, nifedipine, and atenolol. Death from refractory tonic-clonic seizures has been reported in a patient[5] after the use of flumazenil for a mixed overdose with a benzodiazepine and a tricyclic antidepressant.

Death from respiratory failure occurred in an 83-year-old woman after sedation with midazolam[6] despite use of flumazenil, although some[7] considered that this did not represent a failure by flumazenil to reverse the depressive effects on respiration of midazolam. Ventricular fibrillation followed by asystole and death has been reported in a patient given flumazenil during weaning from assisted ventilation (a period during which diazepam had been given).[8]

1. Short TG, *et al*. Ventricular arrhythmia precipitated by flumazenil. *BMJ* 1988; **296:** 1070–1.

8. Katz Y, *et al*. Cardiac arrest associated with flumazenil. *BMJ* 1992; **304:** 1415.

Effects on mental function. Although flumazenil is considered to lack agonist properties, a study[1] in healthy subjects found that intravenous flumazenil resulted in impairment of some measures of cognition and alertness. A severe acute psychotic disorder, which developed during treatment with flumazenil in a patient with hepatic encephalopathy, resolved when flumazenil was discontinued.[2]

1. Neave N, *et al*. Dose-dependent effects of flumazenil on cognition, mood, and cardio-respiratory physiology in healthy volunteers. *Br Dent J* 2000; **189:** 668–74.
2. Seebach J, Jost R. Flumazenil-induced psychotic disorder in hepatic encephalopathy. *Lancet* 1992; **339:** 488–9.

Pharmacokinetics

Flumazenil is well absorbed from the gastrointestinal tract but undergoes extensive first-pass hepatic metabolism and has a systemic bioavailability of about 20%. It is about 50% bound to plasma proteins. After intravenous administration it is extensively metabolised in the liver to the inactive carboxylic acid form, which is excreted mainly in the urine. The elimination half-life is about 40 to 80 minutes. In patients with hepatic impairment the clearance of flumazenil is decreased with a resultant prolongation of half-life.

Uses and Administration

Flumazenil is a benzodiazepine antagonist that acts competitively at CNS benzodiazepine receptors. It is used in anaesthesia and intensive care to reverse benzodiazepine-induced sedation; it may also be used to treat benzodiazepine overdosage (but see warnings in Precautions, above, and under Benzodiazepine Antagonism: Overdosage, below).

Flumazenil should be given by slow intravenous injection or infusion.

The usual initial dose for the reversal of benzodiazepine-induced sedation is 200 micrograms, followed at intervals of 60 seconds by further doses of 100 to 200 micrograms if required, to a maximum total dose of 1 mg or occasionally 2 mg (usual range, 0.3 to 1 mg); each dose should be given over 15 seconds, and further doses should only be given if an adequate response has not occurred 45 seconds after completion of the injection. If drowsiness recurs an intravenous infusion may be used, at a rate of 100 to 400 micrograms/hour, adjusted according to response. Alternatively, further doses of up to 1 mg, in boluses of 200 micrograms as above, may be given at 20-minute intervals to a maximum of 3 mg in one hour. Patients at risk from the effects of benzodiazepine reversal, such as those dependent on benzodiazepines, should receive smaller bolus injections of 100 micrograms. The dose for children is 10 micrograms/kg, repeated at 60-second intervals up to a maximum of 50 micrograms/kg or 1 mg, whichever is lower; doses are given intravenously over 15 seconds, with further doses if an adequate response has not occurred 45 seconds after completion of the injection, as for adults.

The usual initial dose for the management of benzodiazepine overdose is 200 micrograms given intravenously over 30 seconds. A further dose of 300 micrograms can be given after another 30 seconds and can be followed by doses of 500 micrograms at one-minute intervals if required, to a total dose of 3 mg or occasionally 5 mg. If a dose of up to 5 mg produces no response then further doses are unlikely to be effective. If symptoms of intoxication recur, repeated doses may be given at 20-minute intervals; not more than 1 mg should be given at any one time and not more than 3 mg in one hour. As before a slower rate of administration may be used for 'at risk' patients.

If signs of overstimulation occur during the use of flumazenil, then diazepam or midazolam may be given by slow intravenous injection.

Flumazenil labelled with carbon-11 has been used for studying GABA receptors by positron emission tomography.

4. Seger DL. Flumazenil—treatment or toxin. *J Toxicol Clin Toxicol* 2004; **42:** 209–16.

Benzodiazepine antagonism. Flumazenil is a specific benzodiazepine antagonist that binds competitively with benzodiazepine receptors, reversing the centrally mediated effects of benzodiazepines. Its effects are evident within a few minutes of intravenous injection, even after substantial doses of benzodiazepines, and last for up to 3 hours depending on the dose and on the characteristics of the benzodiazepine intoxication. In patients who have received benzodiazepines for prolonged periods, flumazenil may precipitate withdrawal symptoms.

SEDATION. Flumazenil reduces sedation and amnesia following the use of benzodiazepines for induction or maintenance of general anaesthesia, and in patients undergoing minor surgery or diagnostic procedures who are given benzodiazepines for conscious sedation.[1] Sedation may recur, particularly if long-acting benzodiazepines have been used, and there have been reports of increased analgesic requirements and anxiety following the use of flumazenil. Although flumazenil may antagonise the obvious effects of sedation, higher cognitive functions may still be impaired[2,3] and the patient may be unfit to be discharged safely unaccompanied. Flumazenil is usually given intravenously but reversal of sedation has also been reported[4] with oral use. Although experience with flumazenil in children is limited, it appears to be well tolerated and effective when used to reverse conscious sedation.[5] Flumazenil has also been used in intensive care to reverse sedation and assist in weaning from mechanical ventilation, but is not routinely recommended.

OVERDOSAGE. Flumazenil may be used as an adjunct in the management of benzodiazepine overdose including overdose involving multiple agents. However, its use may unmask the effects of other intoxicants,[6] and since benzodiazepine overdose is rarely lethal and may even protect against the toxicity of other drugs, flumazenil should be used with great caution in mixed overdose, particularly when involving tricyclic antidepressants.[7] Repeated doses of flumazenil may be required to maintain consciousness depending on the benzodiazepine responsible and the magnitude of the overdose; continuous infusion has also been used.[8,9]

Hepatic encephalopathy. Flumazenil has been tried in hepatic encephalopathy (p.1697) because of the suspected role of benzodiazepine-like agonists in the pathogenesis of the disorder.[1,2] However, benefits have generally been modest, and a meta-analysis[3] concluded that flumazenil did produce short-term improvement of hepatic encephalopathy but had no effect on recovery or survival; it might be considered for patients with chronic liver disease and hepatic encephalopathy but routine clinical use was not recommended.

3. Als-Nielsen B, *et al.* Benzodiazepine receptor antagonists for hepatic encephalopathy. Available in The Cochrane Database of Systematic Reviews; Issue 2. Chichester: John Wiley; 2004 (accessed 04/10/05).

Non-benzodiazepine antagonism. Although flumazenil is a specific benzodiazepine antagonist, it may also block the effects of other drugs that act via the benzodiazepine receptor, such as zopiclone and zolpidem. In a double-blind study[1] in healthy subjects, flumazenil rapidly antagonised clinical sedation induced by zolpidem, and a rapid response to flumazenil has been reported[2] in a patient who presented in a coma following mixed overdosage with zolpidem, alcohol, and prothipendyl. There have also been reports of flumazenil reversing coma associated with antihistamines,[3] carisoprodol,[4] gabapentin,[5] and promethazine.[6] Although reversal of alcohol-induced sedation has also been suggested, a controlled study[7] found no effect with flumazenil at a dose comparable to that used for benzodiazepine overdosage.

Fomepizole *(BAN, USAN, rINN)*

Fomepitsoli; Fomepizol; Fomépizole; Fomepizolum; 4-Methylpyrazole; 4-MP. 4-Methyl-1*H*-pyrazole.

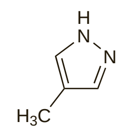
Фомепизол

$C_4H_6N_2$ = 82.10.

CAS — 7554-65-6.

ATC — V03AB34.

ATC Vet — QV03AB34.



Adverse Effects

The most frequent adverse effects associated with fomepizole are headache, nausea, dizziness, drowsiness, and taste disturbances. Abdominal pain, vomiting, diarrhoea, hypotension, tachycardia, hypersensitivity reactions, and raised hepatic enzymes have also been reported.

Pharmacokinetics

Fomepizole is absorbed from the gastrointestinal tract but is usually given intravenously. It is metabolised in the liver, primarily to 4-carboxypyrazole; the metabolites are excreted in the urine, with only a small amount of unchanged drug. After multiple doses, fomepizole induces its own metabolism by the cytochrome P450 enzyme system, significantly increasing the rate of elimination. Fomepizole is removed by dialysis.

Uses and Administration

Fomepizole is a competitive inhibitor of alcohol dehydrogenase. It is used for the treatment of poisoning by ethylene glycol (p.2300) or methyl alcohol (p.2024), which are converted to toxic metabolites by alcohol dehydrogenase. Fomepizole is given in a loading dose of 15 mg/kg followed by 10 mg/kg every 12 hours for 4 doses; the dose should then be increased to 15 mg/kg every 12 hours until serum concentrations of ethylene glycol or methyl alcohol are less than 20 mg/100 mL. All doses should be given by intravenous infusion over 30 minutes. In patients who also require haemodialysis, doses of fomepizole should be given every 4 hours during haemodialysis sessions.

Fomepizole has also been given similarly as the sulfate.

Fuller's Earth

Terra Fullonica; Tierra de Fuller.

CAS — 8031-18-3.

Profile

Fuller's earth consists largely of montmorillonite, a native hydrated aluminium silicate, with which very finely divided calcite (calcium carbonate) may be associated. It is an adsorbent and has been used in dusting powders, toilet powders, and lotions. Fuller's earth of high adsorptive capacity has been used in industry as a clarifying and filtering medium.

It has been used in the treatment of paraquat poisoning (p.2047), usually as a 15% suspension given in an initial oral dose of about 100 g, followed by further doses of about 50 g every 2 hours for 3 doses. Purgatives such as magnesium sulfate or mannitol have been given at the same time to promote emptying of the gut, but some suggest they should only be given with the first dose.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: *Braz.:* Camomila.

Glucagon *(BAN, rINN)*

Gliukagonas; Glucagón; Glucagonum; Glukagon; Glukagoni; HGF.
His-Ser-Gln-Gly-Thr-Phe-Thr-Ser-Asp-Tyr-Ser-Lys-Tyr-Leu-Asp-Ser-Arg-Arg-Ala-Gln-Asp-Phe-Val-Gln-Trp-Leu-Met-Asn-Thr.

Глюкагон

$C_{153}H_{225}N_{43}O_{49}S$ = 3482.7.

CAS — 16941-32-5.

ATC — H04AA01.

ATC Vet — QH04AA01.

Pharmacopoeias. In *US.*

USP 31 (Glucagon). A polypeptide hormone obtained from porcine and bovine pancreas glands. A fine, white or faintly coloured, practically odourless, crystalline powder. Soluble in dilute alkali and acid solutions; insoluble in most organic solvents. Store under nitrogen in airtight glass containers at a temperature of 2° to 8°.

Adverse Effects

Nausea and vomiting may occur after use of glucagon. Hypersensitivity reactions, abdominal pain, hypotension, tachycardia, and hypokalaemia have also been reported.

Precautions

Glucagon should generally not be given to patients with phaeochromocytoma since it can cause a release of catecholamines producing marked hypertension. Glucagon should be given with care to patients with insulinoma as it may induce hypoglycaemia due to its insulin-releasing effect. Glucagon was formerly used to diagnose phaeochromocytoma and insulinoma but this use has been largely abandoned. Caution is also required when it is being used as a diagnostic aid in diabetic patients or in elderly patients with heart disease.

Glucagon is not effective in patients with marked depletion of liver glycogen stores, as in starvation, adrenal insufficiency, alcohol-induced hypoglycaemia, or chronic hypoglycaemia. Oral carbohydrates should be given after glucagon to prevent the development of secondary hypoglycaemia.

Interactions

Warfarin. For a report of glucagon enhancing the anticoagulant effect of warfarin, see p.1431.

Pharmacokinetics

Glucagon has a plasma half-life of about 3 to 6 minutes but longer values have been reported in diabetics (see Bioavailability, below). It is inactivated in the liver, kidneys, and plasma.

Bioavailability. In a study[1] in healthy subjects and diabetic patients the bioavailability of glucagon given intranasally was about 30% of that after intramuscular injection. However, the mean value for the apparent half-life after intramuscular injection was 28.6 and 31.4 minutes respectively in the two groups, compared with 6.6 and 11.9 minutes for intravenous infusion, and 5.5 and 13.8 minutes when given intranasally, possibly due to slow release of glucagon from the injection site.

1. Pontiroli AE, *et al.* Pharmacokinetics of intranasal, intramuscular and intravenous glucagon in healthy subjects and diabetic patients. *Eur J Clin Pharmacol* 1993; **45:** 555–8.

Uses and Administration

Glucagon is an endogenous polypeptide hormone that is produced by the alpha cells of the pancreatic islets of Langerhans. It is a hyperglycaemic that mobilises glucose by activating hepatic glycogenolysis. It can to a lesser extent stimulate the secretion of pancreatic insulin. Glucagon for therapeutic use may be derived from animal sources but is now more commonly produced using recombinant DNA techniques. It is given as the hydrochloride, but doses are usually expressed as glucagon (note that 1 unit is equivalent to 1 mg of glucagon).

Glucagon is used in the treatment of severe hypoglycaemic reactions when the patient cannot take glucose by mouth and intravenous glucose is not feasible. It is given by subcutaneous, intramuscular, or intravenous injection in a dose of 1 mg (or 500 micrograms in patients under about 25 kg body-weight). If there is no response within 10 minutes, intravenous glucose should be given, although there is no contra-indication to repeating the dose of glucagon. Once the patient has responded sufficiently to take carbohydrate orally this should be given to restore liver glycogen stores and prevent secondary hypoglycaemia.

As glucagon reduces the motility of the gastrointestinal tract it is used as a diagnostic aid in gastrointestinal examinations. The route of administration and dose is dependent upon the diagnostic procedure. A dose of 1 to 2 mg intramuscularly has an onset of action of 4 to 15 minutes and a duration of effect of 10 to 40 minutes; 0.2 to 2 mg intravenously produces an effect within 1 minute that lasts for 5 to 25 minutes.

Glucagon possesses positive cardiac inotropic activity but is not generally considered suitable for heart failure. However, as it can bypass blocked beta receptors, it is used in the treatment of beta-blocker overdosage, see Cardiovascular Effects, below.

Intranasal preparations have been studied.

Cardiovascular effects. Glucagon has chronotropic and inotropic effects due to its ability to raise cyclic AMP concentrations independently of a response to catecholamines.[1] It is used in the management of beta-blocker overdosage (p.1227), although evidence of benefit is mainly anecdotal;[2] doses of 2 to 10 mg (or 50 to 150 micrograms/kg in children) by intravenous injection, followed by an infusion of 50 micrograms/kg per hour, have been suggested.

Glucagon may also have a role in anaphylactic shock (see under Adrenaline, p.1205), particularly in patients receiving beta blockers, in whom adrenaline may be less effective. A dramatic improvement in refractory hypotension during an anaphylactic reaction to contrast media was described in a 75-year-old man receiving beta blockers after intravenous glucagon.[3]

There has also been a report[4] of benefit with intravenous glucagon following calcium-channel blocker overdosage, but evidence from controlled studies is not available[2] and glucagon is not generally regarded as standard treatment for such patients.

4. Walter FG, *et al.* Amelioration of nifedipine poisoning associated with glucagon therapy. *Ann Emerg Med* 1993; **22:** 1234–7.

Diagnosis and testing. Glucagon stimulates secretion of growth hormone and cortisol (hydrocortisone) and has been used as a test of pituitary function in adults,[1-3] and in children.[4,5] It may be particularly suitable when first-line tests such as the insulin-tolerance test are contra-indicated.[3] The glucagon stimulation test should be used with caution in young children;[5] severe secondary hypoglycaemia and death has been reported[6] in a 2-year-old child after a glucagon test for growth hormone secretion.

Gastrointestinal disorders. The relaxant effect of glucagon on smooth muscle has been used to facilitate passage of swallowed foreign bodies[1] and impacted food boluses[2] that have become lodged in the lower oesophagus. However, a controlled trial[3] in children with impacted oesophageal coins found that glucagon was not effective.

Hypoglycaemia. Hypoglycaemia most commonly occurs in diabetic patients, particularly those receiving insulin therapy. Other rare causes include alcohol ingestion and tumours such as insulinomas. Neonatal hypoglycaemia occurs in small-for-gestational-age infants or infants of diabetic mothers. Persistent or recurrent hypoglycaemia in neonates is usually due to an endocrine or metabolic disorder, such as nesidioblastosis.

Glucose is the treatment of choice for **acute** hypoglycaemia since it corrects the problem at source. In patients who are unconscious or unable to take glucose orally, it may need to be given intravenously. Glucagon is an alternative in such situations, and first-line use has been suggested[1] since it is more convenient and easier to give than parenteral glucose, particularly in emergency situations. However, glucagon has a slower onset and may not always be effective, particularly where hepatic glycogen stores are depleted, such as in patients with alcohol-induced hypoglycaemia or with insulinoma. Low doses of glucagon have also been given prophylactically[2] in diabetic children at risk of developing hypoglycaemia due to gastrointestinal disorders or reduced oral intake.

Hypoglycaemia in neonates is usually managed by adjusting the enteral feeds or by giving parenteral glucose in symptomatic infants. Glucagon may be used if parenteral glucose is not effective or cannot be given.[3,4] In infants with persistent hyperinsulinaemic hypoglycaemia,[5] continuous infusion of glucagon has been used, although oral treatments such as diazoxide or chlorothiazide are usually preferred.

Intractable hypoglycaemia (such as that resulting from excessive endogenous insulin production from islet cell tumours or hyperplasia) is usually treated with diazoxide, but continuous infusion of glucagon has been used in patients with tumour-associated hypoglycaemia.[6,7]

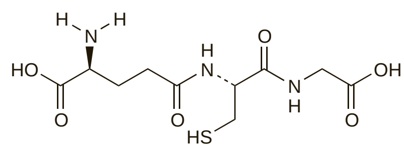
$C_{10}H_{17}N_3O_6S$ = 307.3.

CAS — 70-18-8.

ATC — V03AB32.

ATC Vet — QV03AB32.



Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*.

Ph. Eur. 6.2 (Glutathione). Fermentation product. A white or almost white, crystalline powder or colourless crystals. Freely soluble in water; very slightly soluble in alcohol and in dichloromethane. Protect from light.

Profile

Glutathione is an endogenous peptide with antoxidant and other metabolic functions. Glutathione and glutathione sodium are used to prevent neurotoxicity associated with cisplatin or oxaliplatin; they have also been used to prevent other adverse effects of antineoplastic and radiation therapy, as well as in a wide range of other disorders including poisoning with heavy metals and other compounds, liver disorders, corneal disorders, and eczema. Glutathione has also been tried in idiopathic pulmonary fibrosis and peripheral vascular disorders.

Antineoplastic toxicity. Glutathione has been reported to reduce the incidence of neurotoxicity induced by cisplatin therapy. In a double-blind, randomised trial[1] in 50 patients receiving cisplatin for advanced gastric cancer, glutathione significantly reduced the incidence of neuropathy assessed within one week of completing cisplatin therapy. There did not appear to be any reduction in cytotoxic activity. Similar benefit was observed in a randomised, double-blind, placebo-controlled trial involving 52 patients receiving oxaliplatin.[2]

Lung disorders. Glutathione is an important extracellular antoxidant in the lung and high concentrations are found in lung epithelial lining fluid. A deficiency of glutathione may contribute to the epithelial damage that occurs in various lung disorders, and treatment with nebulised glutathione has therefore been investigated. Small studies have found beneficial biochemical results in patients with cryptogenic fibrosing alveolitis (idiopathic pulmonary fibrosis)[1] and in cystic fibrosis,[2] but the clinical effects of these changes are not clear. Another study in cystic fibrosis[3] found no effect on oxidative markers after treatment for 2 weeks, but there was a small improvement in lung function. Benefit has also been reported[4] in a patient with emphysema. However, in a study[5] of patients with mild asthma, inhalation of glutathione solution was associated with bronchoconstriction, leading to cough or breathlessness in some patients, possibly due to sulfite formation.

Haem Derivatives

Heme Derivatives; Hemo, derivados del grupo.

ATC — B06AB01 (Haematin).

ATC Vet — QB06AB01 (haematin).

Profile

Haem is the iron protoporphyrin constituent of haemoglobin and is responsible for its colour and oxygen-carrying capacity. It is used in the management of porphyrias (below). Haem is given intravenously as its derivatives, although there is some confusion over their terminology. The names haematin (hematin) and haemin (hemin) have been used interchangeably although chemically haematin is the hydroxy derivative, formed by the reaction of haemin and sodium carbonate in solution. The arginine salt (haem arginate; haemin arginate; heme arginate) is reported to be more stable.

Haem arginate is used in the treatment of acute hepatic porphyrias, including acute intermittent porphyria, variegate porphyria, and hereditary coproporphyria. It is given by slow intravenous infusion in a dose of 3 mg/kg daily for 4 days, infused over at least 30 minutes. The maximum recommended dose is 250 mg daily. The course may be repeated, with close monitoring, in patients with an inadequate response.

Haematin is used intravenously for the amelioration of acute intermittent porphyria associated with the menstrual cycle in patients unresponsive to other therapy. It is given in a usual dose of 1 to 4 mg/kg daily for 3 to 14 days as an intravenous infusion over 10 to 15 minutes. In severe cases the dose may be repeated after 12 hours, but no more than 6 mg/kg should be given in any 24 hour period.

Phlebitis may occur after infusion of haem derivatives and they should be given into a large arm vein or central vein. Use of a filter is recommended due to the colour of the infusion.

Porphyrias. The porphyrias are a group of inherited and acquired disorders of haem biosynthesis in which defects in specific enzymes lead to the accumulation of haem precursors, including aminolevulinic acid, porphobilinogen, and porphyrins.[1-11] They are generally classified as acute or non-acute, reflecting their clinical presentation, or as hepatic or erythropoietic, depending on the site of the enzyme defect. The three most common forms are acute intermittent porphyria, porphyria cutanea tarda, and erythropoietic protoporphyria.

ACUTE PORPHYRIAS. These are inherited disorders characterised by the accumulation of porphyrin precursors, leading to acute attacks of neurovisceral symptoms. The most common form is *acute intermittent porphyria* (acute hepatic porphyria); *variegate porphyria* and *hereditary coproporphyria* are generally less common forms in which there is accumulation of both porphyrin precursors and porphyrins, leading to acute attacks with cutaneous symptoms similar to those seen in non-acute porphyrias (see below).

In acute porphyrias, some enzyme activity is present and the defect only becomes apparent when demand for hepatic haem is increased. Attacks are rare before puberty and the disorder may remain latent in many patients. The presenting symptom is most commonly severe abdominal pain; other gastrointestinal symptoms such as nausea and vomiting also occur, along with autonomic effects including hypertension, tachycardia, sweating, pallor, and pyrexia. Convulsions may occur at the peak of an attack and may persist between attacks. Neuropathy leads to weakness and paralysis and may progress rapidly to respiratory distress. Psychiatric symptoms are also common, particularly agitation, anxiety, and behavioural disturbances. Various factors can increase the demand for haem and attacks are usually precipitated by drugs, alcohol, steroid hormones, reduced caloric intake, or infection. They typically last for several days and are followed by complete recovery, although in some patients chronic abdominal pain may persist without other symptoms.

The primary management of an attack is to remove precipitants and to provide intensive support. *Symptomatic treatment* is complicated by the wide range of drugs that may precipitate porphyria. High doses of parenteral opioids may be required for pain; there is a danger of addiction occurring, but this is rare unless attacks are frequent or pain persists between attacks. Phenothiazines such as chlorpromazine are useful to control nausea and agitation and their sedative effect may also be beneficial. High doses of propranolol may be required for cardiovascular symptoms. Assisted ventilation may be necessary. Convulsions usually disappear as the attack resolves; management of patients who experience convulsions between attacks is a therapeutic problem since many antiepileptics are porphyrinogenic (see Porphyria, p.471). *Specific therapy* is aimed at suppressing the haem biosynthetic pathway, to prevent further accumulation of precursors. Haem, given as either haematin or haem arginate, is the most effective treatment and should be given as soon as possible after onset of the attack; it produces feedback suppression of the biosynthetic pathway. Tin-protoporphyrin, a haem oxygenase inhibitor, has been given with haem to prolong its action but is not commercially available. A high carbohydrate intake may also suppress haem precursor production and should be ensured in all patients, especially if haem is not immediately available; it is usually given orally to prevent fluid overload and exacerbation of hyponatraemia, but intravenous glucose may be required in patients who are vomiting. *Prevention* of attacks involves avoiding drugs that precipitate porphyria and maintaining an adequate carbohydrate intake. Gonadorelin analogues, such as buserelin, may have a role in preventing attacks related to the menstrual cycle. Long-term treatment with haem has been tried in patients with frequent attacks, although such use is not established.

NON-ACUTE PORPHYRIAS. These are characterised by the accumulation of porphyrins and usually present with cutaneous symptoms, although porphyrins also accumulate in the liver and liver damage commonly occurs. *Porphyria cutanea tarda* (cutaneous hepatic porphyria) is the most common form of porphyria. It is usually an acquired disorder and in most cases there is a history of moderate or heavy alcohol intake. There is usually a raised serum-iron concentration and use of oestrogen has also been implicated. The main clinical symptom is cutaneous photosensitivity leading to bullous dermatosis, pruritus, and skin fragility, in areas exposed to sunlight. *Management* involves protecting the skin from sunlight and trauma and avoiding causative agents such as alcohol and iron. Sunscreen preparations must be based on zinc oxide or titanium dioxide to be effective. Reduction of serum-iron concentrations by phlebotomy restores enzyme function and is effective in most patients; it should be carried out every 1 to 2 weeks until remission occurs, and may be required periodically for maintenance. Chloroquine and hydroxychloroquine have also been used and may be effective where phlebotomy is contra-indicated; they appear to act by complexing with porphyrins and increasing their excretion, but low doses are necessary to avoid exacerbating the condition. An alternative method of reducing serum-iron is with the iron chelator desferrioxamine, although it may be less effective than phlebotomy; it is usually reserved for patients unable to tolerate phlebotomy. In patients with renal failure who are too anaemic for phlebotomy and who cannot excrete chloroquine, erythropoietin may be used, and may be combined with desferrioxamine or low-volume phlebotomy.

Erythropoietic protoporphyria is a less common non-acute porphyria and is an inherited disorder leading to accumulation of protoporphyrin. Symptoms are cutaneous and there is an acute reaction to sunlight leading to urticaria, pruritus, swelling, redness, and a severe burning sensation; liver damage may also occur. *Management* involves protection of the skin, as for porphyria cutanea tarda. Betacarotene is widely used to increase tolerance to sunlight, although its efficacy is not established; canthaxanthin, another carotenoid, has also been used. Haem administration, as haematin or haem arginate, may be beneficial in suppressing protoporphyrin production. Colestyramine and activated charcoal reduce protoporphyrin levels by interrupting enterohepatic recycling; they also bind other porphyrins and may have a role in rare forms of porphyria such as *congenital erythropoietic porphyria*.

Lanthanum Carbonate *(USAN)*

Lanthanum carbonate (2:3) hydrate.

$La_2(CO_3)_3,xH_2O$ = 457.8 (anhydrous lanthanum carbonate).
CAS — 54451-24-0.
ATC — V03AE03.
ATC Vet — QV03AE03.

Adverse Effects and Precautions

The most common adverse effects with lanthanum carbonate are gastrointestinal disturbances, including nausea, vomiting, constipation, diarrhoea, dyspepsia, and abdominal pain. Only small amounts of lanthanum are absorbed from the gastrointestinal tract but some accumulation of lanthanum in bone has been reported; the clinical significance of this is unknown.

Ingestion of lanthanum carbonate may produce a radio-opaque appearance on abdominal radiography.

Uses and Administration

Lanthanum carbonate is a phosphate binder used for hyperphosphataemia (p.1669) in patients with chronic renal failure. It is given orally as the hydrate, but doses are expressed in terms of elemental lanthanum. The usual initial daily dose is 0.75 to 2.25 g of elemental lanthanum, given in divided doses with meals. The dose should be adjusted every 2 to 3 weeks until an acceptable serum-phosphate concentration is achieved; the usual maintenance dose is 1.5 to 3 g daily in divided doses, but up to 3.75 g daily has been given. The tablets should be chewed thoroughly before swallowing.

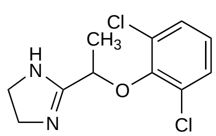
Lofexidine Hydrochloride *(BANM, USAN, rINNM)*

Ba-168; Hidrocloruro de lofexidina; Lofeksidin Hidroklorür; Lofexidine, Chlorhydrate de; Lofexidini Hydrochloridum; MDL-14042; MDL-14042A; RMI-14042A. 2-[1-(2,6-Dichlorophenoxy)ethyl]-2-imidazoline hydrochloride.

Лофексидина Гидрохлорид

$C_{11}H_{12}Cl_2N_2O,HCl$ = 295.6.
CAS — 31036-80-3 (lofexidine); 21498-08-8 (lofexidine hydrochloride).
ATC — N07BC04.
ATC Vet — QN07BC04.



(lofexidine)

Pharmacopoeias. In *Chin.*

Adverse Effects

Lofexidine has central alpha-adrenergic effects and may cause drowsiness, dryness of the mouth, throat, and nose, hypotension, and bradycardia; prolongation of the QT interval has also been reported. Sedation may occur following overdosage.

Sudden withdrawal of lofexidine may produce rebound hypertension.

Precautions

Lofexidine should be used with caution in patients with cerebrovascular disease, ischaemic heart disease including recent myocardial infarction, bradycardia, renal impairment, or a history of depression.

It may cause drowsiness and if affected, patients should not drive or operate machinery.

Withdrawal of lofexidine therapy should be gradual over 2 to 4 days or more to reduce the risk of rebound hypertension.

Interactions

Lofexidine may enhance the central depressant effects of sedatives, including alcohol. It may also enhance the effects of antihypertensives. Tricyclic antidepressants may reduce the efficacy of lofexidine.

Methadone. A 44-year-old opioid-dependent female receiving methadone had prolongation of the QT interval after a single 400-microgram dose of lofexidine.[1] The patient had previously had a normal QT while receiving methadone and it was suggested the effect might have been caused by the combination of the 2 drugs.

1. Schmittner J, *et al.* QT interval increased after single dose of lofexidine. *BMJ* 2004; **329:** 1075.

Pharmacokinetics

Lofexidine is absorbed from the gastrointestinal tract with peak plasma concentrations occurring after about 3 hours. It is extensively metabolised in the liver and excreted mainly in the urine. The elimination half-life is 11 hours.

Uses and Administration

Lofexidine is an $alpha_2$-adrenoceptor agonist structurally related to clonidine (p.1247). It has antihypertensive activity, but is used mainly in the control of opioid withdrawal symptoms.

In opioid withdrawal, lofexidine is given as the hydrochloride in an initial oral dose of 800 micrograms daily in divided doses. The dose may be increased gradually by 400 to 800 micrograms daily to a maximum of 2.4 mg daily; the maximum single dose should not exceed 800 micrograms. After 7 to 10 days, or longer in some cases, treatment is withdrawn gradually over at least 2 to 4 days.

Opioid dependence. A systematic review[1] of the use of $alpha_2$-adrenoceptor agonists in the management of opioid dependence (p.101) concluded that they were as effective as methadone, although patients stayed in treatment for longer with methadone and there were fewer adverse effects with methadone than with clonidine. Lofexidine was associated with less hypotension than clonidine and may therefore be preferred, particularly for outpatient treatment.

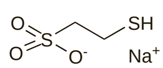
Mesna *(BAN, USAN, rINN)*

D-7093; Mesnum; NSC-113891; UCB-3983. Sodium 2-mercaptoethanesulphonate.

Месна

$C_2H_5NaO_3S_2$ = 164.2.
CAS — 19767-45-4.
ATC — R05CB05; V03AF01.
ATC Vet — QR05CB05; QV03AF01.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Mesna). A white or slightly yellow, hygroscopic, crystalline powder. Freely soluble in water; slightly soluble in alcohol; practically insoluble in cyclohexane. A 10% solution in water has a pH of 4.5 to 6.0. Store in airtight containers.

Incompatibility and stability. There was no evidence of degradation of mesna when stored in solution with ifosfamide in polyethylene infusion bags at room temperature for 7 hours[1] or in polypropylene syringes at room temperature or at 4° for 4 weeks.[2] However, in the latter study ifosfamide concentrations fell by about 3% after 7 days and 12% after 4 weeks at both temperatures. Another study[3] found that mixtures of mesna with cyclophosphamide in polyethylene infusion bags were stable for 48 hours at 4° and for 6 hours at room temperature.

Mesna has been reported to be incompatible with platinum compounds such as carboplatin and cisplatin.

1. Shaw IC, Rose JWP. Infusion of ifosphamide plus mesna. *Lancet* 1984; **i:** 1353–4.
2. Rowland CG, *et al.* Infusion of ifosfamide plus mesna. *Lancet* 1984; **ii:** 468.
3. Menard C, *et al.* Stability of cyclophosphamide and mesna admixtures in polyethylene infusion bags. *Ann Pharmacother* 2003; **37:** 1789–92.

Adverse Effects and Precautions

Adverse effects that may occur after use of mesna include gastrointestinal effects, headache, fatigue, limb pains, depression, irritability, hypotension (but see below), tachycardia, and skin rash. Bronchospasm has been reported after nebulisation.

Mesna may produce a false positive result in diagnostic tests for urinary ketones and may produce a false positive or false negative result in diagnostic tests for urinary erythrocytes.

Effects on blood pressure. Hypotension may occur with mesna; however, severe hypertension has also been reported[1] after use of mesna, either alone or with ifosfamide.

1. Gilleece MH, Davies JM. Mesna therapy and hypertension. *DICP Ann Pharmacother* 1991; **25:** 867.

Effects on the nervous system. For reports of severe encephalopathy in patients receiving mesna and ifosfamide, see p.732.

Hypersensitivity. Hypersensitivity reactions including rash, fever, nausea, facial and periorbital oedema, ulceration of mucous membranes, and tachycardia have been attributed to mesna.[1-4] Reactions may be more common in patients with autoimmune disorders; drug eruptions developed in 7 of 16 patients receiving mesna and cyclophosphamide for auto-immune disorders.[5] Five of these patients had a rash, with angioedema in 2 cases, and a pseudo-hypersensitivity reaction was diagnosed.

1. Lang E, Goos M. Hypersensitivity to mesna. *Lancet* 1985; **ii:** 329.
2. Seidel A, *et al.* Allergic reactions to mesna. *Lancet* 1991; **338:** 381.
3. Gross WL, *et al.* Allergic reactions to mesna. *Lancet* 1991; **338:** 381–2.
4. D'Cruz D, *et al.* Allergic reactions to mesna. *Lancet* 1991; **338:** 705–6.
5. Zonzits E, *et al.* Drug eruptions from mesna: after cyclophosphamide treatment of patients with systemic lupus erythematosus and dermatomyositis. *Arch Dermatol* 1992; **128:** 80–2.

Pharmacokinetics

Mesna is absorbed from the gastrointestinal tract. It is rapidly metabolised after oral or intravenous dosage to mesna disulfide (dimesna) and is excreted in the urine as both metabolite and unchanged drug; dimesna is reduced back to mesna, which is the active form, in the kidney. The half-lives of mesna and dimesna are reported to be about 20 minutes and 70 minutes respectively. After intravenous use, most of the dose is excreted in the urine within 4 hours. Mesna is about 70% bound to plasma proteins.

3. El-Yazigi A, *et al.* Pharmacokinetics of mesna and dimesna after simultaneous intravenous bolus and infusion administration in patients undergoing bone marrow transplantation. *J Clin Pharmacol* 1997; **37:** 618–24.

Uses and Administration

Mesna is used for the prevention of urothelial toxicity in patients being treated with the antineoplastics ifosfamide or cyclophosphamide. In the kidney, dimesna, the inactive metabolite of mesna, is reduced to free mesna. This has thiol groups that react with the metabolites of ifosfamide and cyclophosphamide, including acrolein, which are considered to be responsible for the toxic effects on the bladder.

The aim of mesna therapy is to ensure adequate levels of mesna in the urine throughout the period during which these toxic metabolites are present. The duration of mesna treatment should therefore equal that of the antineoplastic treatment plus the time taken for the concentration of antineoplastic metabolites in the urine to fall to non-toxic concentrations. Urinary output should be maintained and the urine monitored for haematuria and proteinuria throughout the treatment period. However, frequent emptying of the bladder should be avoided.

Mesna may be given intravenously or orally for the prevention of urothelial toxicity, the dosage and frequency depending on the antineoplastic regimen used. After oral use, availability of mesna in urine is about 50% of that after intravenous use and excretion in urine is delayed up to 2 hours and is more prolonged. The intravenous preparation may be given orally added to a flavoured drink; this mixture may be stored in a sealed container in a refrigerator for up to 24 hours. Alternatively, tablets are available.

Intravenous bolus antineoplastic regimens. If ifosfamide or cyclophosphamide is given as an intravenous bolus, the *intravenous dose of mesna* is 20% of the dose of the antineoplastic on a weight for weight basis given on 3 occasions over 15 to 30 minutes at intervals of 4 hours beginning at the same time as the antineoplastic injection; thus the total dose of mesna is equivalent to 60% of the antineoplastic given. This regimen is repeated each time the antineoplastic is used. Each individual dose of mesna may be increased to 40% of the dose of the antineoplastic and given 4 times at intervals of 3 hours for children and patients at high risk of urotoxicity; in such cases the total dose of mesna is equivalent to 160% of the antineoplastic given. The *oral dose of mesna* is 40% of the dose of the antineoplastic given on 3 occasions at intervals of 4 hours beginning 2 hours before the antineoplastic injection; thus a total dose of mesna equivalent to 120% of the antineoplastic is given. Alternatively, the initial dose of mesna may be given *intravenously* (20% of the dose of the antineoplastic), followed by two *oral doses* (each 40% of the dose of the antineoplastic) given 2 and 6 hours after the intravenous dose. Any of these regimens may be used if **cyclophosphamide** is given **orally**.

Intravenous infusion antineoplastic regimens. If the antineoplastic is given as an intravenous infusion over 24 hours, an initial *intravenous injection* of mesna as 20% of the total antineoplastic dose is followed by 100% of the total dose by intravenous infusion concurrently over 24 hours, followed by 60% by intravenous infusion over a further 12 hours (total dose 180% of the antineoplastic). The final 12-hour infusion may be replaced either by 3 intravenous injections each of 20% of the antineoplastic dose at intervals of 4 hours, the first injection being given 4 hours after the infusion has been stopped, or by *oral mesna* given in 3 doses each of 40% of the antineoplastic dose, the first dose being given when the 24-hour infusion is stopped, and the second and third doses being given 2 and 6 hours later.

Mesna is also used as a **mucolytic** in the management of some respiratory-tract disorders. The usual daily dose is 0.6 to 1.2 g given by a nebuliser; it may also be given by direct endotracheal instillation.

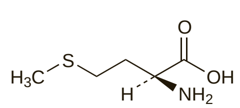
Methionine *(USAN, rINN)*

L-Metionina; M; Methionin; Méthionine; *S*-Methionine; L-Methionine; Methioninum; Metioniini; Metionin; Metionina; Metioninas. L-2-Amino-4-(methylthio)butyric acid.

Метионин

$C_5H_{11}NO_2S$ = 149.2.
CAS — 63-68-3.
ATC — V03AB26.
ATC Vet — QA05BA90; QG04BA90; QV03AB26.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US*.
Ph. Eur. 6.2 (Methionine). A white or almost white, crystalline powder or colourless crystals. Soluble in water; very slightly soluble in alcohol. A 2.5% solution in water has a pH of 5.5 to 6.5. Protect from light.
USP 31 (Methionine). White crystals having a characteristic odour. Soluble in water, in warm dilute alcohol, and in dilute mineral acids; insoluble in dehydrated alcohol, in acetone, in ether, and in benzene. pH of a 1% solution in water is between 5.6 and 6.1.

DL-Methionine

DL-Metionina; Methionin racemický; DL-Méthionine; DL-Methioninum; Methioninum Racemicum; DL-Metioniini; DL-Metionin; DL-Metionina; DL-Metioninas; Racemethionine *(USAN)*. DL-2-Amino-4-(methylthio)butyric acid.

$C_5H_{11}NO_2S$ = 149.2.
CAS — 59-51-8.
ATC — V03AB26.
ATC Vet — QV03AB26.

NOTE. The name methionine is often applied to DL-methionine.
Compounded preparations of DL-methionine may be represented by the following names:

- Co-methiamol *x/y* (*BAN*)—where *x* and *y* are the strengths in milligrams of DL-methionine and paracetamol respectively.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *Viet.*
Ph. Eur. 6.2 (DL-Methionine). An almost white crystalline powder or small flakes. Sparingly soluble in water; very slightly soluble in alcohol; dissolves in dilute acids and in dilute solutions of alkali hydroxides. A 2% solution in water has a pH of 5.4 to 6.1. Protect from light.

Adverse Effects and Precautions

Methionine may cause nausea, vomiting, drowsiness, and irritability. It should not be used in patients with acidosis. Methionine may aggravate hepatic encephalopathy in patients with established liver damage; it should be used with caution in patients with severe liver disease.

Interactions

Methionine may be adsorbed by activated charcoal and the effect of oral methionine may be reduced if they are given together.

Dopaminergics. For reference to the antagonism of the antiparkinsonian effect of *levodopa* by methionine, see Nutritional Agents, under Interactions of Levodopa, p.808.

Pharmacokinetics

Methionine is absorbed from the gastrointestinal tract. It is extensively metabolised to *S*-adenosylmethionine (ademetionine, p.2247), homocysteine, and other metabolites, and is excreted in the urine as an inorganic sulfate.

Uses and Administration

L-Methionine is an essential amino acid and is therefore included in amino-acid solutions used for parenteral nutrition (p.1923).

Methionine also enhances the synthesis of glutathione and is used as an alternative to acetylcysteine in the treatment of paracetamol poisoning to prevent hepatotoxicity (see p.108). The literature relating to the use of methionine in paracetamol poisoning is, in general, imprecise as to the form of methionine used. In the UK, the usual dose of DL-methionine is 2.5 g by mouth every 4 hours for 4 doses starting less than 10 to 12 hours after ingestion of the paracetamol. Children under 6 years old may be given 1 g every 4 hours for 4 doses. Methionine has also been given intravenously. Preparations containing both methionine and paracetamol have been formulated for use in situations where overdosage may occur. However, the issue of whether methionine should be routinely added to paracetamol preparations is contentious for medical and ethical reasons.

Methionine has also been given orally to lower urinary pH and as an adjunct in the treatment of liver disorders. It has also been used in the assessment of hyperhomocysteinaemia.

Acetylmethionine has also been used.

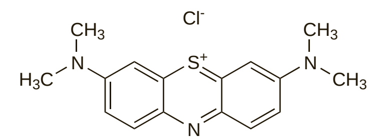
Метилтиониния Хлорид

$C_{16}H_{18}ClN_3S,3H_2O$ = 373.9.
CAS — 61-73-4 (anhydrous methylthioninium chloride); 7220-79-3 (methylthioninium chloride trihydrate).
ATC — V03AB17; V04CG05.
ATC Vet — QV03AB17; QV04CG05.



NOTE. *Commercial methylthioninium chloride may consist of the double chloride of tetramethylthionine and zinc, and is not suitable for medicinal use.*

Pharmacopoeias. In *Chin.* and *US*; in *Eur.* (see p.vii) (as xH_2O); in *Int.* (as anhydrous or $3H_2O$).
Ph. Eur. 6.2 (Methylthioninium Chloride). A dark blue, crystalline powder with a copper-coloured sheen, or green crystals with a bronze-coloured sheen. Soluble in water; slightly soluble in alcohol. Store in airtight containers. Protect from light.
USP 31 (Methylene Blue). Dark green crystals or crystalline powder with a bronze-like lustre. Is odourless or practically so. Solutions in water or alcohol are deep blue in colour. Soluble 1 in 25 of water and 1 in 65 of alcohol; soluble in chloroform. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Adverse Effects and Precautions

After high intravenous doses, methylthioninium chloride may cause nausea, vomiting, abdominal and chest pain, headache, dizziness, mental confusion, profuse sweating, dyspnoea, and hypertension; methaemoglobinaemia and haemolysis may occur. Haemolytic anaemia and hyperbilirubinaemia have been reported in neonates after intra-amniotic injection. Oral use may cause gastrointestinal disturbances and dysuria.

Methylthioninium chloride should not be injected subcutaneously as it has been associated with isolated cases of necrotic abscesses. It should not be given by intrathecal injection as neural damage has occurred. Methylthioninium chloride should be used with caution in patients with severe renal impairment and is contra-indicated in patients with G6PD deficiency (see Uses, below). Methylthioninium chloride is used to treat methaemoglobinaemia but in large doses it can itself produce methaemoglobinaemia and methaemoglobin concentration should therefore be closely monitored during treatment. Methylthioninium chloride should not be used to treat methaemoglobinaemia induced by sodium nitrite during the treatment of cyanide poisoning, since cyanide binding will be reduced with resultant increased toxicity. It has also been contra-indicated in methaemoglobinaemia due to chlorate poisoning because of the risk that the more toxic hypochlorite may be formed, although several authorities consider its use to treat methaemoglobinaemia in severe chlorate poisoning appropriate.

Methylthioninium chloride imparts a blue colour to saliva, urine, faeces, and skin, which may hinder a diagnosis of cyanosis.

Aniline poisoning. It has been suggested[1] that methylthioninium chloride should be used with caution in the treatment of aniline-induced methaemoglobinaemia since it may precipitate Heinz body formation and haemolytic anaemia. Methylthioninium chloride may reduce methaemoglobin concentrations, but repeated doses could aggravate haemolysis without further reducing methaemoglobinaemia.

1. Harvey JW, Keitt AS. Studies of the efficacy and potential hazards of methylene blue therapy in aniline-induced methaemoglobinaemia. *Br J Haematol* 1983; **54:** 29–41.

Pregnancy. Although intra-amniotic injection of methylthioninium chloride has been used to diagnose premature rupture of fetal membranes or to identify separate amniotic sacs in twin pregnancies, there have been several reports of haemolytic anaemia (Heinz-body anaemia) and hyperbilirubinaemia in neonates who had been exposed to methylthioninium chloride in the amniotic cavity.[1-5] In most cases, exchange transfusions and/or phototherapy were required to control the jaundice; in 1 case phototherapy led to a phototoxic reaction.[5] It has therefore been suggested[3,6] that the use of methylthioninium chloride for detecting premature rupture of the membranes should be avoided.

Multiple ileal occlusions have been reported in babies born to mothers who had twin pregnancies and who had received methylthioninium chloride by amniocentesis;[4,7,8] in some cases it was possible to determine that methylthioninium chloride had been injected into the amniotic sac of the affected twin. Analysis of data from the EUROCAT registries[9] for 1980 to 1988, which surveyed pregnancy outcomes in 11 countries, found a slightly higher risk of ileal and jejunal atresia or stenosis in twins regardless of whether they had received methylthioninium chloride, but the use of methylthioninium chloride was rare and no increased risk could be shown in babies exposed to it. A subsequent review[6] from the Centers for Disease Control and Prevention concluded that the epidemiological evidence for the teratogenicity of methylthioninium chloride was quite strong and advised that it should not be used for midtrimester amniocentesis.

A further difficulty in using methylthioninium chloride by amniocentesis for the diagnosis of premature rupture of the membranes is that the resultant staining of the skin and mucous membranes of the neonate hinders assessment of hypoxia, including the use of pulse oximetry.[10]

Interactions

Serotonergic drugs. Methylthioninium chloride has been associated with CNS toxicity when given intravenously as a visualising agent for thyroid or parathyroid surgery in patients who had recently received serotonergic drugs such as *bupropion, buspirone, clomipramine, mirtazapine, SSRIs,* or *venlafaxine*.[1] The MHRA in the UK therefore recommends that methylthioninium chloride should be avoided in patients recently treated with such drugs.

1. MHRA/CHM. Methylthioninium chloride (methylene blue): CNS toxicity with serotonergic drugs. *Drug Safety Update* 2008; **1** (6): 5–6. Available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2033510&RevisionSelectionMethod=LatestReleased (accessed 19/07/08)

Pharmacokinetics

Methylthioninium chloride is absorbed from the gastrointestinal tract. It is believed to be reduced in the tissues to leucomethylene blue, which is slowly excreted, mainly in the urine, with some unchanged drug.

Uses and Administration

Methylthioninium chloride is a thiazine dye that is used in the treatment of methaemoglobinaemia; it is also used as an antiseptic and in diagnostic procedures.

In patients with methaemoglobinaemia, therapeutic doses of methylthioninium chloride can lower the levels of methaemoglobin in the red blood cells. It activates a normally dormant reductase enzyme system, which reduces the methylthioninium chloride to leucomethylene blue and in turn is able to reduce methaemoglobin to haemoglobin. However, in large doses methylthioninium chloride can itself produce methaemoglobinaemia and methaemoglobin concentration should therefore be closely monitored during treatment. Methylthioninium chloride is not effective for the treatment of methaemoglobinaemia in patients with G6PD deficiency as these patients have a diminished capacity to reduce methylthioninium chloride to leucomethylene blue; it is also potentially harmful as patients with G6PD deficiency are particularly susceptible to the haemolytic anaemias induced by methylthioninium chloride.

In the treatment of acute methaemoglobinaemia, such as in nitrite poisoning, methylthioninium chloride is given intravenously as a 1% solution in doses of 1 to 2 mg/kg injected over a period of several minutes. A repeat dose may be given after one hour if required. It may be of some value in inherited methaemoglobinaemia; doses of up to 300 mg daily by mouth have been used.

Methylthioninium chloride has a mildly antiseptic action and has been given orally in doses of 65 to 130 mg three times daily in minor urinary-tract infections and to prevent the formation of urinary oxalate stones. It is also included in some preparations intended for application to the eye, mouth and pharynx, and skin.

Methylthioninium chloride is also used as a bacteriological stain, as a dye in diagnostic procedures such as fistula detection and the diagnosis of ruptured amniotic membranes (but see Pregnancy under Adverse Effects and Precautions, above), and for the delineation of certain body tissues during surgery, in particular the parathyroid glands. It is also used for viral photoinactivation in some plasma products. The blue colour can be removed from the skin with hypochlorite solution. Methylthioninium chloride was formerly used in a renal-function test.

Dementia. The aggregation of tau protein filaments in the brain is believed to be associated with the development of cognitive symptoms in Alzheimer's disease (see Dementia, p.362). Methylthioninium chloride, which is thought to dissolve and prevent such aggregations, is under investigation in the management of Alzheimer's disease.

Glutaric aciduria. Glutaric aciduria type II is a metabolic disorder associated with a deficiency of electron-transferring flavoproteins involved in the metabolism of amino acids and fatty acids. Treatment may involve diets low in fats and protein, and some success has been reported with riboflavin. Methylthioninium chloride may also be of benefit since it may act as an electron acceptor, and a response has been seen in an infant[1] with neonatal glutaric aciduria type II. An association has also been noted between encephalopathy due to ifosfamide neurotoxicity (see Effects on the Nervous System under Adverse Effects of Ifosfamide, p.732) and glutaric aciduria, possibly due to inhibition of electron transport by a metabolite of ifosfamide. Methylthioninium chloride has therefore been tried for both treatment and prevention of ifosfamide neurotoxicity, and successful results have been reported;[2-4] however, its role remains unclear.[5]

Hypotension. Excess nitric oxide production leading to peripheral vasodilatation may be involved in the pathogenesis of hypotension associated with a number of conditions and it has been suggested that methylthioninium chloride, which is a guanylate cyclase inhibitor, may block the effects of nitric oxide and increase blood pressure in such cases. Studies[1,2] in patients with septic shock, including 5 neonates[3] with refractory hypotension assumed to be due to sepsis, have suggested that methylthioninium chloride increases blood pressure and improves tissue oxygenation, although no mortality benefit has been demonstrated.

There have also been reports of the successful use of methylthioninium chloride in patients with anaphylactic shock,[4] hypotension associated with haemodialysis,[5] vasoplegia after cardiac surgery,[6] and severe hepatopulmonary syndrome,[7] all of which may involve increased nitric oxide production. However, the role of methylthioninium chloride in these conditions is not established.

The usual management of shock is discussed on p.1183; anaphylactic shock should be treated with adrenaline, as discussed on p.1205.

Ifosfamide encephalopathy. See Glutaric Aciduria, above.

Methaemoglobinaemia. Methaemoglobinaemia is a rare disorder of the blood in which there is an increase in the proportion of haemoglobin present in the oxidised form. Inherited methaemoglobinaemia may be due either to a deficiency of methaemoglobin reductase or to a structural abnormality of haemoglobin. Acquired methaemoglobinaemia may be caused by drugs[1] or chemicals that oxidise haemoglobin, including nitrates and nitrites, sodium nitroprusside, dapsone, sulfonamides, phenacetin, and some local anaesthetics such as prilocaine; it may occur as a result of direct administration or occupational[2] or environmental exposure. Exposure to low doses over long periods may lead to chronic methaemoglobinaemia whereas large doses may lead to an acute effect.

Methaemoglobinaemia has a profound effect on oxygen transport by the blood; there is an increase in oxygen affinity leading to reduced tissue delivery and varying degrees of cyanosis. The presence of symptoms depends upon the degree and rapidity of methaemoglobin formation. Chronic mild methaemoglobinaemia is generally well tolerated although patients may appear cyanotic. Acute methaemoglobinaemia, particularly where methaemoglobin levels exceed 20%, is associated with dyspnoea, headache, malaise, giddiness, and altered mental state; methaemoglobin levels above 50% may lead to vascular collapse, coma, and death.

Patients with inherited methaemoglobinaemia are usually asymptomatic but treatment may be given for cosmetic purposes to reduce the cyanotic skin colour. Patients with reductase deficiency generally respond to oral therapy with drugs that promote the reduction of methaemoglobin to haemoglobin, such as ascorbic acid, riboflavin, or methylthioninium chloride; methylthioninium chloride may also be given intravenously. Patients with structural abnormalities of haemoglobin do not respond. In acquired methaemoglobinaemia the causative agent should be identified and removed. Chronic or mild cases may not require treatment but acute symptomatic methaemoglobinaemia may be life-threatening and patients should be given intravenous methylthioninium chloride, along with oxygen and other supportive therapy as required. Toxicity is uncommon with methylthioninium chloride but it should not be used for methaemoglobinaemia due to the use of nitrites for cyanide poisoning since increased toxicity may result (for debate about its use after chlorate poisoning, see Adverse Effects and Precautions, above). Severe methaemoglobinaemia may require exchange transfusion; exchange transfusion with haemodialysis is the treatment of choice in patients with acute methaemoglobinaemia and haemolysis. Hyperbaric oxygen therapy has also been suggested in severe cases. Ascorbic acid is not useful in the acute situation since it acts too slowly but it may be of benefit where maintenance therapy is required.

2. Bradberry SM. Occupational methaemoglobinaemia: mechanisms of production, features, diagnosis and management including the use of methylene blue. *Toxicol Rev* 2003; **22:** 13–27.

ADMINISTRATION. In acute methaemoglobinaemia, methylthioninium chloride is usually given by intravenous bolus injection, but repeated doses may be needed and continuous intravenous infusion has also been used. Methylthioninium chloride was given at a dose of 7.5 to 10 mg/hour for 43 hours to control methaemoglobinaemia after dapsone poisoning.[1] The patient had responded to two bolus doses of 100 mg but methaemoglobinaemia had subsequently increased again owing to the long half-life of dapsone. Additional therapy included repeated doses of activated charcoal. A dosing schedule for methylthioninium chloride of 1 to 2 mg/kg as a bolus followed by a continuous infusion at an initial rate of 100 to 150 micrograms/kg per hour was suggested.

1. Dawson AH, Whyte IM. Management of dapsone poisoning complicated by methaemoglobinaemia. *Med Toxicol Adverse Drug Exp* 1989; **4:** 387–92.

Priapism. Priapism is usually treated with corporal aspiration or intracavernosal vasoconstrictors (see under Uses of Metaraminol, p.1333). There have been reports[1-4] of the successful use of intracavernosal methylthioninium chloride, particularly in patients with drug-induced priapism; it is thought to act by blocking the vasodilator effects of nitric oxide. However, penile necrosis has occurred[5] after the use of methylthioninium chloride and it should probably be avoided in patients with corporal fibrosis; aspiration of methylthioninium chloride about 5 minutes after injection has been suggested.[2,3]

Milk Thistle

Cardo mariano; Chardon marie (milk-thistle fruit); Lady's Thistle; Maarianohdakkeenhedelmä (milk-thistle fruit); Margainių vaisiai (milk-thistle fruit); Marian Thistle; Mariatistelfrukt (milk-thistle fruit); Mariendistel; Plod ostropestřece mariánského (milk-thistle fruit); Silybi mariani fructus (milk-thistle fruit); St Mary's Thistle.
CAS — 84604-20-6 (milk thistle extract).

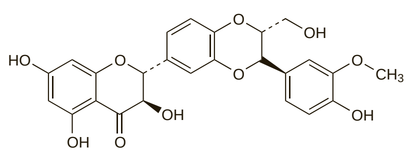
Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Milk-Thistle Fruit). The mature fruit, devoid of the pappus, of *Silybum marianum*. It contains not less than 1.5% of silymarin expressed as silibinin (dried drug). Protect from light.

USP 31 (Milk Thistle). The dried ripe fruit of *Silybum marianum* (Asteraceae), the pappus having been removed. It contains not less than 2% of silymarin, calculated as silibinin, on the dried basis. Store in airtight containers. Protect from light.

Silibinin *(rINN)*

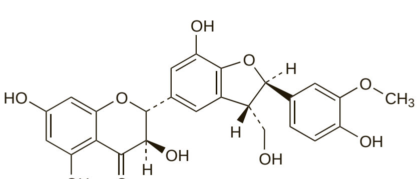
Silibinina; Silibinine; Silibininum; Silybin; Silybum Substance E_6; Silybinina. 3,5,7-Trihydroxy-2-[3-(4-hydroxy-3-methoxyphenyl)-2-(hydroxymethyl)-1,4-benzodioxan-6-yl]-4-chromanone.
Силибинин
$C_{25}H_{22}O_{10}$ = 482.4.
CAS — 22888-70-6.



NOTE. The name silymarin has been used for both a mixture of silibinin, silicristin, and silidianin, and for silibinin alone.

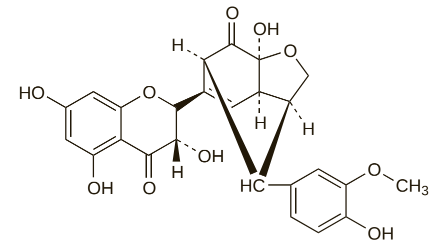
Silicristin *(rINN)*

Silicristina; Silicristine; Silicristinum; Silikrystyna; Silychristin. 2-[2,3-Dihydro-7-hydroxy-2-(4-hydroxy-3-methoxyphenyl)-3-(hydroxymethyl)-5-benzofuranyl]-3,5,7-trihydroxy-4-chromanone.
Силикристин
$C_{25}H_{22}O_{10}$ = 482.4.
CAS — 33889-69-9.



Silidianin *(rINN)*

Silidianina; Silidianine; Silidianinum; Silydianin. (+)-2,3α,3aα,7a-Tetrahydro-7aα-hydroxy-8(*R**)-(4-hydroxy-3-methoxyphenyl)-4-(3α,5,7-trihydroxy-4-oxo-2β-chromanyl)-3,6-methanobenzofuran-7(6α*H*)-one.
Силидианин
$C_{25}H_{22}O_{10}$ = 482.4.
CAS — 29782-68-1.



Silymarin

Silimarina; Silymarinum. A mixture of the isomers silibinin, silicristin, and silidianin.
CAS — 65666-07-1.
ATC — A05BA03.
ATC Vet — QA05BA03.

Profile

Milk thistle (*Silybum marianum*; *Carduus marianus*) is used in herbal medicine, mainly for gastrointestinal and hepatobiliary disorders. The fruit contains the active principle silymarin, a mixture of flavonolignans including the isomers silibinin, silicristin, and silidianin, of which silibinin is the major component. Silymarin is claimed to be a free radical scavenger and to have hepatoprotectant properties; it has been used in various liver disorders, as well as to prevent hepatotoxicity associated with poisoning. In *Amanita phalloides* poisoning (p.2349) both silymarin and silibinin (as the disodium dihemisuccinate salt) have been used.

Milk thistle is usually given as a standardised extract containing mainly silymarin, although the herb and fruit have also been used; the strength of the extract is expressed in terms of silymarin or silibinin, although the exact equivalence is not always clear. It is usually given orally since silymarin is poorly water-soluble and therefore unsuitable for intravenous use. A typical oral dose of up to 140 mg of silymarin two or three times daily has been suggested for hepatic disorders. Disodium silibinin dihemisuccinate is water-soluble and is given intravenously; the usual dose in *Amanita phalloides* poisoning is equivalent to silibinin 20 mg/kg daily, given by intravenous infusion in 4 divided doses.

Amanita poisoning. Silymarin and silibinin have been found to be effective in preventing hepatotoxicity after amanita poisoning.[1-3]

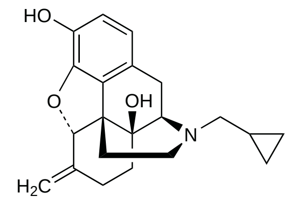
Nalmefene *(BAN, USAN, rINN)*

6-Desoxy-6-methylene-naltrexone; JF-1; Nalméfène; Nalmefeno; Nalmefenum; Nalmetrene; ORF-11676. 17-(Cyclopropylmethyl)-4,5α-epoxy-6-methylenemorphinan-3,14-diol.
Налмефен
$C_{21}H_{25}NO_3$ = 339.4.
CAS — 55096-26-9.



Nalmefene Hydrochloride *(BANM, rINNM)*

Hidrocloruro de nalmefeno; Nalméfène, Chlorhydrate de; Nalmefeni Hydrochloridum; Nalmetrene Hydrochloride.
Налмефена Гидрохлорид
$C_{21}H_{25}NO_3,HCl$ = 375.9.
CAS — 58895-64-0.

Adverse Effects

Nausea, vomiting, tachycardia, hypertension, fever, and dizziness have been reported with therapeutic doses of nalmefene. At higher doses or in patients later found to be physically dependent on opioids, symptoms suggestive of opioid withdrawal have been noted; these have included abdominal cramps, chills, dysphoria, myalgia, and joint pain.

Precautions

As for Naloxone, p.1453.

Incremental doses of nalmefene should be given slowly in patients with renal impairment.

Pharmacokinetics

Nalmefene is absorbed after oral doses but bioavailability is not complete owing to significant first-pass metabolism. It is metabolised in the liver, mainly to the inactive glucuronide, and is excreted in the urine. Some of the dose is excreted in the faeces and it may undergo enterohepatic recycling. The plasma elimination half-life is reported to be about 10 hours.

Uses and Administration

Nalmefene is a derivative of naltrexone and is a specific opioid antagonist with actions and uses similar to those of naloxone (p.1454), but with a longer duration of action. It is given as the hydrochloride but doses are expressed in terms of the base. Nalmefene hydrochloride 111 micrograms is equivalent to about 100 micrograms of nalmefene. It is usually given intravenously for a rapid onset of action; subcutaneous or intramuscular administration is also effective but has a slower onset. Nalmefene has also been given orally.

For the reversal of postoperative central depression due to the use of opioids, nalmefene is given intravenously, at a concentration of 100 micrograms/mL, in an initial dose of 250 nanograms/kg. Further doses of 250 nanograms/kg may be given at intervals of 2 to 5 minutes until the desired level of opioid reversal is reached; cumulative doses above 1 microgram/kg do not provide additional benefit. In patients with an increased cardiovascular risk a concentration of 50 micrograms/mL and doses and increments of 100 nanograms/kg are recommended.

In the management of known or suspected opioid overdosage, nalmefene is given intravenously at a concentration of 1 mg/mL. An initial dose of 500 micrograms per 70 kg is recommended, followed by a second dose of 1 mg per 70 kg after 2 to 5 minutes if necessary. If a total dose of 1.5 mg per 70 kg is not effective then additional doses are unlikely to have an effect. If the patient is suspected of being physically dependent on opioids an initial test dose of 100 micrograms per 70 kg is recommended; if there is no evidence of withdrawal symptoms within 2 minutes the usual dosage may be used.

Although nalmefene has a longer duration of action than naloxone, all patients should be closely observed and if respiratory depression does recur, the dose of nalmefene should be titrated as above to avoid over-reversal of opioid effects.

Alcohol withdrawal and abstinence. For mention of the use of nalmefene in the adjunctive management of patients with alcohol dependence, see under Naltrexone, p.1456.

Pruritus. It has been suggested that because central opioid receptors modulate itch, an opioid antagonist might be useful in pruritus (p.1582). A systematic review[1] found that opioid antagonists are effective in opioid-induced pruritus, and a number have also been reported to be of benefit in pruritus of other causes.

Rapid improvement of severe pruritus was reported after a single oral dose of *nalmefene* 10 or 20 mg in a double-blind study of 80 patients with either chronic urticaria or atopic dermatitis.[2] Pruritus was almost completely eliminated in up to 60% of patients receiving nalmefene. Adverse effects occurred in 67% of patients and included dizziness or lightheadedness, fatigue, and nausea. In another study,[3] 14 patients with resistant pruritus secondary to cholestatic liver disease were treated with oral nalmefene for 2 to 26 months. The initial dose was 2 mg twice daily and the dose was increased gradually as necessary. Although 13 of the patients reported some amelioration of pruritus, 5 found that increasing doses were required to produce any benefit, and in 3 tolerance appeared to develop.

Continuous infusion of *naloxone* 200 nanograms/kg per minute was reported to reduce perception of pruritus and scratching activity in a double-blind study of 29 patients with pruritus due to cholestasis,[4] although the role of continuous infusion in long-term management may be limited.

Benefit has been reported with oral *naltrexone* 50 mg daily in pruritus of various origins,[5] as well as in patients with cholestatic pruritus.[6,7] In uraemic pruritus, conflicting results have been reported;[8,9] a subsequent study[10] suggested that naltrexone might be of benefit in selected patients.

Preparations

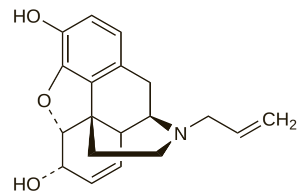
Proprietary Preparations (details are given in Part 3)
Mex.: Nocarex; ***USA:*** Revex.

Nalorphine *(BAN, rINN)*

Nalorfiini; Nalorfin; Nalorfina; Nalorphinum. (−)-(5*R*,6*S*)-9a-Allyl-4,5-epoxymorphin-7-en-3,6-diol; 17-Allyl-17-normorphine.

Налорфин

$C_{19}H_{21}NO_3$ = 311.4.
CAS — 62-67-9.
ATC — V03AB02.
ATC Vet — QV03AB02.



Nalorphine Hydrobromide *(BANM, rINNM)*

Hidrobromuro de nalorfina; Nalorphine, Bromhydrate de; Nalorphini Hydrobromidum.

Налорфина Гидробромид

$C_{19}H_{21}NO_3,HBr$ = 392.3.
ATC — V03AB02.
ATC Vet — QV03AB02.

Pharmacopoeias. In *Chin.*

Nalorphine Hydrochloride *(BANM, rINNM)*

Hidrocloruro de nalorfina; Nalorphine, Chlorhydrate de; Nalorphini Hydrochloridum; Nalorphinium Chloride.

Налорфина Гидрохлорид

$C_{19}H_{21}NO_3,HCl$ = 347.8.
CAS — 57-29-4.
ATC — V03AB02.
ATC Vet — QV03AB02.

Pharmacopoeias. In *US.*
USP 31 (Nalorphine Hydrochloride). Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects and Precautions

As for Naloxone (below). Nalorphine also has some opioid agonist properties and adverse effects such as drowsiness, respiratory depression, miosis, dysphoria, and lethargy may occur if it is given to patients who have not received opioids.

Uses and Administration

Nalorphine is an opioid antagonist with properties similar to those of naloxone (below); in addition it also possesses some agonist properties. It has been used as the hydrobromide or hydrochloride in the treatment of opioid-induced respiratory depression; it reverses severe opioid-induced respiratory depression but may exacerbate respiratory depression such as that induced by alcohol or other non-opioid central depressants.

Preparations

USP 31: Nalorphine Hydrochloride Injection.

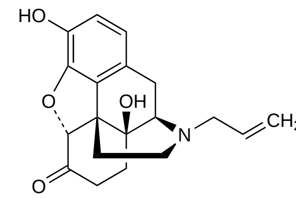
Naloxone Hydrochloride

(BANM, USAN, rINNM)

N-Allylnoroxymorphone Hydrochloride; Cloridrato de Naloxona; EN-15304; Hidrocloruro de naloxona; Nalokson Hidroklorür; Naloksonihydrokloridi; Naloksono hidrochloridas; Naloksonu chlorowodorek dwuwodny; Naloxone, Chlorhydrate de; Naloxone (chlorhydrate de) dihydraté; Naloxon-hidroklorid; Naloxon-hydrochlorid; Naloxonhydroklorid; Naloxoni Hydrochloridum; Naloxoni hydrochloridum dihydricum. 17-Allyl-6-deoxy-7,8-dihydro-14-hydroxy-6-oxo-17-normorphine hydrochloride dihydrate; (−)-(5*R*,14*S*)-9a-Allyl-4,5-epoxy-3,14-dihydroxymorphinan-6-one hydrochloride dihydrate.

Налоксона Гидрохлорид

$C_{19}H_{21}NO_4,HCl,2H_2O$ = 399.9.
CAS — 465-65-6 (naloxone); 357-08-4 (anhydrous naloxone hydrochloride); 51481-60-8 (naloxone hydrochloride dihydrate).
ATC — V03AB15.
ATC Vet — QV03AB15.



(naloxone)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.* Forms specified may be anhydrous, dihydrate, or both.
Ph. Eur. 6.2 (Naloxone Hydrochloride Dihydrate; Naloxone Hydrochloride BP 2008). It contains two molecules of water of hydration. A white or almost white, hygroscopic, crystalline powder. Freely soluble in water; soluble in alcohol; practically insoluble in toluene. Store in airtight containers. Protect from light.
USP 31 (Naloxone Hydrochloride). It is anhydrous or contains two molecules of water of hydration. A white to slightly off-white powder. Soluble in water, in dilute acids, and in strong alkali; slightly soluble in alcohol; practically insoluble in chloroform and in ether. Its aqueous solution is acidic. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Incompatibility. Infusions of naloxone hydrochloride should not be mixed with preparations containing bisulfite, metabisulfite, long-chain or high-molecular-weight anions, or solutions with an alkaline pH.

Adverse Effects

Nausea and vomiting have occurred with naloxone. Some adverse effects may be associated with opioid withdrawal. There have been individual reports of hypotension, hypertension, cardiac arrhythmias, and pulmonary oedema, generally in patients given naloxone postoperatively. Seizures have also been reported infrequently.

◊ Hypertension,[1,2] pulmonary oedema,[3] and cardiac arrhythmias including ventricular tachycardia and fibrillation[4] have been reported after the postoperative use of naloxone, generally in patients with pre-existing heart disease undergoing cardiac surgery. However, there have also been reports in healthy patients,[5,6] including some fatalities.[5]

Hypotension, bradycardia, and precipitation of focal seizures have been reported in patients given high-dose naloxone for acute ischaemic stroke.[7]

Ventricular fibrillation has been observed in an opioid addict given naloxone to reverse the effects of diamorphine.[8] However, this patient was later shown to have hepatic cirrhosis and alcoholic cardiomyopathy and the National Poisons Information Service in London noted that it had never been informed of such a suspected adverse reaction despite being contacted in about 800 cases of opioid poisoning each year.[9] In a later report severe adverse effects were noted in 6 of 453 subjects given naloxone to reverse diamorphine intoxication.[10] The effects were: asystole (1 case), generalised convulsions (3), pulmonary oedema (1), and violent behaviour (1).

Precautions

Naloxone should be used with caution in patients physically dependent on opioids, or who have received large doses of opioids, as an acute withdrawal syndrome may be precipitated (see Dependence and Withdrawal under Opioid Analgesics, p.101). Naloxone crosses the placenta and a withdrawal syndrome may be precipitated in neonates of opioid-dependent mothers.

Caution is required in patients with cardiac disease or those receiving cardiotoxic drugs.

The duration of action of some opioids exceeds that of naloxone; patients should therefore be carefully observed after administration in case of relapse.

Pharmacokinetics

Naloxone is absorbed from the gastrointestinal tract but it is subject to considerable first-pass metabolism. It is metabolised in the liver, mainly by glucuronide conjugation, and excreted in the urine. It has a plasma half-life of about 1 hour after parenteral administration. Naloxone crosses the placenta.

Pregnancy and the neonate. A study in 30 mothers given a single intravenous dose of naloxone during the second stage of labour, indicated that naloxone rapidly crossed the placental barrier so that some therapeutic effect might be anticipated in most neonates.[1] Placental transfer in 7 further mothers given naloxone intramuscularly was considered to be too variable for therapeutic purposes.

In 12 neonates given naloxone hydrochloride 35 or 70 micrograms intravenously via the umbilical vein, the mean plasma half-life was 3.53 or 2.65 hours respectively.[2] These half-lives were 2 to 3 times longer than those reported for adults, possibly due to a diminished ability of the newborn to metabolise drugs by conjugation with glucuronic acid. Mean peak plasma concentrations of 8.2 nanograms/mL or 13.7 nanograms/mL in those given 35 or 70 micrograms respectively, were reached within 40 minutes but this time was very variable, and in 5 neonates peak concentrations were reached within 5 minutes. Naloxone hydrochloride 200 micrograms intramuscularly in 17 further neonates produced peak concentrations of 7.4 to 34.6 nanograms/mL at 0.5 to 2 hours.

Uses and Administration

Naloxone is a specific opioid antagonist that acts competitively at opioid receptors. It is an effective antagonist of opioids that possess agonist or mixed agonist-antagonist activity although larger doses may be needed for compounds with the latter activity. It is used to reverse opioid central depression, including respiratory depression, induced by natural or synthetic opioids in the treatment of known or suspected opioid overdosage, postoperatively after the use of opioids during surgery, and in neonates when opioid analgesics have been given to the mother during labour.

Naloxone hydrochloride is usually given intravenously for a rapid onset of action, which occurs within 2 minutes. The onset of action is only slightly less rapid when it is given intramuscularly or subcutaneously. Other routes, including the endotracheal, have also been used. The duration of action of naloxone is dependent on the dose and route; it is usually reported to be several hours, but may be much shorter, in the region of 1 hour or less.

In the treatment of known or suspected **opioid overdosage**, the initial dose of naloxone hydrochloride is 0.4 to 2 mg given intravenously and repeated if necessary at intervals of 2 to 3 minutes. If no response has been seen after a total dose of 10 mg then the diagnosis of overdosage with drugs other than opioids should be considered. If the patient is suspected of being physically dependent on opioids the dose may be reduced to 100 to 200 micrograms to avoid precipitating withdrawal symptoms. If the intravenous route is not feasible the intramuscular or subcutaneous route can be used.

Naloxone hydrochloride may also be used **postoperatively** to reverse central depression resulting from the use of opioids during surgery. For adults, a dose of 100 to 200 micrograms may be given intravenously at intervals of 2 to 3 minutes, titrated for each patient in order to obtain an optimum respiratory response while maintaining adequate analgesia.

All patients receiving naloxone should be closely observed as the duration of action of many opioids exceeds that of naloxone and repeated doses may be required. Alternatively, to sustain opioid antagonism, an intravenous infusion may be used. Dosage regimens have not been well established, and the rate of infusion must be titrated according to the patient's response. Some have recommended an infusion of 60% of the initial dose per hour, diluted to a concentration of 200 micrograms/mL in glucose. Others have suggested an initial intravenous loading dose of 400 micrograms, followed by a continuous infusion at an initial rate of 400 micrograms/hour. Alternatively, an intravenous loading dose of 5 micrograms/kg has been suggested, followed by a continuous infusion of 2.5 micrograms/kg per hour.

For doses in children, see Administration in Children, below.

Some opioid analgesics have been formulated with naloxone hydrochloride to reduce their potential for parenteral abuse, or as a substitution treatment for opioid dependence. Naloxone hydrochloride has also been used cautiously in small doses to diagnose opioid dependence by precipitating the withdrawal syndrome (see below and under Naltrexone, p.1455).

Administration in children. In the treatment of known or suspected **opioid overdosage** in children, licensed product information recommends an initial dose of naloxone hydrochloride of 10 micrograms/kg intravenously, followed, if necessary, by a larger dose of 100 micrograms/kg. If the intravenous route is not feasible the intramuscular or subcutaneous route can be used.

For **acute respiratory depression induced by opioids** the Committee on Drugs of the American Academy of Pediatrics has recommended a dose for naloxone of 100 micrograms/kg by the intramuscular, intravenous, or intratracheal routes for neonates, including premature infants, to the age of 5 years or 20 kg body-weight; absorption may be erratic after intramuscular use. They advocated that children over 5 years or 20 kg should be given a *minimum* of 2 mg. These doses may be repeated as necessary to maintain opioid reversal.[1,2] The Committee noted that these higher dose recommendations were based partly on the concern that 10 micrograms/kg might not provide optimal opiate reversal in some infants, and that it was felt that the higher doses posed no increased risk.[3] The American Heart Association guidelines for paediatric advanced life support gave the same doses as the Committee for children to the age of 5 years or 20 kg body-weight, but stated that those aged over 5 years or 20 kg be given a dose of 2 mg, without specifying this as a minimum.[4] The use of injections containing 20 micrograms/mL of naloxone hydrochloride is no longer recommended because of the fluid load involved at these doses, especially in small neonates.[1] It has been noted that specialists differ in their dosage of naloxone;[5] a study in the USA found that paediatric intensive care and emergency medicine physicians tended to use 100 micrograms/kg up to a *maximum* initial dose of 2 mg.

In contrast, anaesthesiologists have tended to use initial doses of 10 to 20 micrograms naloxone, regardless of body-weight;[5] the American Academy of Pediatrics states that lower initial doses of 10 micrograms/kg may be considered for other clinical situations such as **respiratory depression during pain management**.[2] Licensed product information states that for **postoperative use**, initial doses of 5 to 10 micrograms may be given intravenously at 2 to 3 minute intervals until the desired response is obtained.

Opioid-induced depression in **neonates** resulting from the use of opioid analgesics in the mother during labour may be reversed by giving naloxone hydrochloride 10 micrograms/kg to the infant by intravenous, intramuscular, or subcutaneous injection, repeated at intervals of 2 to 3 minutes if necessary. Alternatively, a single intramuscular dose of about 60 micrograms/kg may be given at birth for a more prolonged action. Naloxone should be given with caution to the infants of opioid dependent mothers since withdrawal symptoms can result.

Eating disorders. Endogenous opioids may have a role in the pathophysiology of eating disorders,[1] thus opioid antagonists such as naloxone and naltrexone have been tried in their management. However, their role appears to be limited and they do not form part of the usual management of these conditions.

1. de Zwaan M, Mitchell JE. Opiate antagonists and eating behavior in humans: a review. *J Clin Pharmacol* 1992; **32**; 1060–72.

Non-opioid overdosage. Naloxone antagonises the action of exogenous and endogenous opioids. This may explain the varying responses reported to naloxone used in the treatment of overdosage with non-opioids, some of which may modulate endogenous opioids.

Benefit has been reported[1] with naloxone in valproate overdosage, although the evidence is based on case reports. There have also been case reports suggesting benefit in overdosage with camylofin,[2] chlorpromazine,[3] and ibuprofen.[4] A study[5] with midazolam in healthy subjects found that naloxone did not reverse respiratory depression, although there had been earlier reports of benefit in coma due to benzodiazepines.

Naloxone has been used for clonidine intoxication, but retrospective reviews[6,7] have concluded that responses are inconsistent, and there have been reports of hypertension. A lack of response has also been reported[8] in brimonidine overdosage. There has been a report[9] of the successful use of naloxone after captopril overdosage.

Naloxone may also be of benefit in overdosage with drugs that are structurally related to opioids, including apomorphine,[10] dextromethorphan,[11] and loperamide.[12]

Pruritus. For reference to the use of opioid antagonists, including naloxone, in the management of pruritus, see under Nalmefene, p.1453

Reversal of opioid effects. Naloxone is used postoperatively to reverse central depression resulting from the use of opioids during surgery. However, the beneficial analgesic effects of the opioids may also be reversed, and the increasing use of short-acting intravenous opioid analgesics should reduce the need for its use.

In patients receiving longer-term opioids, naloxone has been reported to alleviate some of their adverse effects without loss of therapeutic efficacy. Naloxone reversed respiratory depression in a patient given intrathecal morphine,[1] and urinary retention in 3 patients after epidural morphine,[2] without reversing analgesia. However, a study[3] in patients receiving extradural fentanyl found that naloxone failed to relieve urinary retention whereas pain scores rapidly increased. Naloxone given intravenously has been shown to reverse the delay in gastric emptying induced by opioid analgesics in healthy subjects[4] and in women during labour.[5] Continuous intravenous infusion of naloxone reduced the incidence of adverse effects in patients receiving morphine by patient-controlled analgesia for postoperative pain.[6] Pain control was not compromised and the lower dose of naloxone used (250 nanograms/kg hourly as opposed to 1 microgram/kg hourly) appeared to have an opioid-sparing effect. In patients receiving long-term opioids, oral naloxone in a daily dose equivalent to 20 to 40% of the daily opioid dose relieved opioid-induced constipation without compromising analgesic control.[7,8] Doses equivalent to 10% or less of the opioid dose were ineffective.[9] However, other studies[10] have found adverse effects even at low doses of naloxone, and the optimum dose remains unclear. Methylnaltrexone, a related opioid antagonist is also used for the reversal of opioid-induced constipation (see p.1747).

DIAGNOSTIC USE. Naloxone is used to reverse opioid effects in the diagnosis of opioid overdose, although some workers have recommended that it should only be used in patients with clinical signs of opioid overdose.[1]

Naloxone has also been used in the diagnosis of opioid dependence. It has been given intravenously to precipitate withdrawal symptoms, but methods that do not induce acute withdrawal have also been investigated. Pupillary dilatation in response to topical naloxone solution (naloxone eye drops) has been suggested as a useful method, but varying results have been reported depending on the strength of the solution used. A study[2] using naloxone hydrochloride solution 1 mg/mL distinguished patients with a physical dependence from non-dependent patients who had received opioids on a single occasion as pre-operative medication, but this response was not confirmed in another study[3] using naloxone 400 micrograms/mL solution. Another study[4] reported that a 2 mg/mL solution of naloxone hydrochloride gave useful results in an outpatient setting. However, there has been a report[5] of withdrawal syndrome and pupillary dilatation in 4 opioid dependent subjects after instillation of naloxone solution 40 mg/mL.

5. Sanchez-Ramos JR, Senay EC. Ophthalmic naloxone elicits abstinence in opioid-dependent subjects. *Br J Addict* 1987; **82:** 313–15.

OPIOID OVERDOSAGE. Naloxone is usually given intravenously in opioid overdosage but may also be given intramuscularly if intravenous access is not available. Alternative routes have also been tried; a study[1] using intranasal naloxone found that it was effective for prehospital management of suspected opioid overdosage, although response was slower than with intramuscular injection.

1. Kelly A-M, *et al.* Randomised trial of intranasal versus intramuscular naloxone in prehospital treatment for suspected opioid overdose. *Med J Aust* 2005; **182:** 24–7.

Shock. Endogenous opioids may have a role in the pathophysiology of shock but studies investigating naloxone for the treatment of shock have produced contradictory results. A systematic review[1] concluded that naloxone does increase blood pressure in various forms of shock, but no significant effect on mortality was shown. US licensed product information has noted that the optimal dose and duration of therapy with naloxone have not been established, and that caution should be exercised before its use, particularly in patients with underlying pain or who have previously received opioids and may have developed opioid tolerance.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Naltrexone Hydrochloride). A white or almost white, very hygroscopic, powder. Freely soluble in water; slightly soluble in alcohol; practically insoluble in dichloromethane. Store in airtight containers. Protect from light.

USP 31 (Naltrexone Hydrochloride). Store in airtight containers.

Adverse Effects

Difficulty in sleeping, loss of energy, anxiety, dysphoria, abdominal pain, nausea, vomiting, reduction in appetite, joint and muscle pain, and headache may occur with naltrexone. Dizziness, constipation, diarrhoea, skin rashes, and reduced potency and ejaculatory difficulties have also been reported. Some adverse effects may be associated with opioid withdrawal. Thrombocytopenic purpura has occurred rarely. High doses may cause hepatocellular injury. Injection site reactions, including abscesses and tissue necrosis, have been reported with use of the intramuscular preparation.

Effects on the liver. Increased liver enzyme values were reported in 6 of 40 obese patients given naltrexone 50 or 100 mg daily for 8 weeks.[1] Five of the 6 patients had minimally abnormal liver function before naltrexone was given and liver function tests returned to baseline values or better on stopping naltrexone.

Raised transaminase levels were noted in 5 of 26 obese patients after 3 weeks of treatment with naltrexone 300 mg daily; transaminase activity returned to normal when treatment was stopped.[2]

1. Atkinson RL, *et al.* Effects of long-term therapy with naltrexone on body weight in obesity. *Clin Pharmacol Ther* 1985; **38:** 419–22.
2. Mitchell JE. Naltrexone and hepatotoxicity. *Lancet* 1986; **i:** 1215.

Effects on the muscles. Asymptomatic rhabdomyolysis has been reported[1] in a patient receiving naltrexone; the condition resolved when naltrexone was withdrawn.

1. Zaim S, *et al.* Rhabdomyolysis associated with naltrexone. *Ann Pharmacother* 1999; **33:** 312–3.

Precautions

Naltrexone should be avoided in patients receiving opioids therapeutically, or in those misusing them, as an acute withdrawal syndrome may be precipitated (see Dependence and Withdrawal under Opioid Analgesics, p.101). Withdrawal symptoms may develop within 5 minutes and last up to 48 hours. Naltrexone should be discontinued at least 48 hours before elective surgery involving opioid analgesia. For further precautions when using naltrexone as an adjunct in the treatment of opioid dependence, see Uses and Administration, below.

When analgesia is required, larger doses than usual of opioids will be needed and there is an increased risk of respiratory depression and other adverse effects.

Naltrexone should be used with caution in patients with hepatic impairment and is contra-indicated in patients with acute hepatitis or hepatic failure. Regular monitoring of hepatic function has been recommended. Naltrexone should be given with caution to patients with renal impairment.

Pharmacokinetics

Naltrexone is well absorbed from the gastrointestinal tract but is subject to considerable first-pass metabolism and may undergo enterohepatic recycling. It is extensively metabolised in the liver and the major metabolite, 6-β-naltrexol, may also possess weak opioid antagonist activity. Maximum plasma concentrations of naltrexone and 6-β-naltrexol are achieved in about 1 hour and naltrexone is about 20% bound to plasma proteins at therapeutic doses. The elimination half-life of naltrexone is approximately 4 hours and that of 6-β-naltrexol about 13 hours. Naltrexone and its metabolites are excreted mainly in the urine. Less than 1% of an oral dose of naltrexone is excreted unchanged.

Hepatic impairment. A study[1] in 11 patients with hepatic cirrhosis found that the systemic availability of naltrexone was significantly increased, particularly in those with decompensated disease.

1. Bertolotti M, *et al.* Effect of liver cirrhosis on the systemic availability of naltrexone in humans. *J Hepatol* 1997; **27:** 505–511.

Uses and Administration

Naltrexone is a specific opioid antagonist with actions similar to those of naloxone (p.1454); however, it is more potent than naloxone and has a longer duration of action. It is used in the management of opioid dependence and alcohol dependence, and has also been investigated in other addictive disorders.

Naltrexone is used as the hydrochloride as an aid to maintaining abstinence after opioid withdrawal in detoxified, formerly **opioid-dependent** patients. Naltrexone treatment should not be started until the patient has been detoxified and abstinent from opioids for at least 7 to 10 days because of the risk of acute withdrawal; abstinence should be verified by analysis of the patient's urine. A *naloxone challenge test* should then be performed to confirm the absence of opioid dependence, as follows: naloxone hydrochloride 200 micrograms is given intravenously and the patient observed for 30 seconds for evidence of withdrawal symptoms; if none occur, a further dose of 600 micrograms is given and the patient observed for 30 minutes. A confirmatory rechallenge with naloxone hydrochloride 1.6 mg intravenously may be considered if results are ambiguous. Sources in the USA suggest a naloxone challenge test with a single dose of 800 micrograms given subcutaneously as an alternative to the intravenous route.

Once a negative naloxone challenge test has been obtained, naltrexone hydrochloride is given orally to maintain abstinence. Treatment may be initiated with a dose of 25 mg. If no signs of opioid withdrawal occur subsequent doses may be increased to 50 mg daily. The usual maintenance dose of naltrexone hydrochloride is 350 mg weekly given as 50 mg daily, but the dosing interval may be lengthened to improve compliance; for example, doses of 100 mg on Monday and Wednesday and 150 mg on Friday may be effective, and various other intermittent dosage regimens have been used. Patients should be carefully counselled and warned that attempts to overcome the opioid blockade with large doses of opioids could result in fatal opioid intoxication.

Naltrexone hydrochloride is also used as an adjunct in the management of **alcohol dependence** at a recommended oral dose of 50 mg daily. Alternatively, naltrexone (as the base) may be given as a modified-release intramuscular injection in a dose of 380 mg once every 4 weeks.

The symbol † denotes a preparation no longer actively marketed

Alcohol withdrawal and abstinence. Naltrexone may be of use as an adjunct to psychotherapy in maintaining abstinence after alcohol withdrawal in patients with alcohol dependence (p.1626). Two systematic reviews[1,2] have concluded that oral naltrexone is safe and effective for the short-term treatment of alcohol dependence, although there is less evidence for long-term benefit. However, since the risk of relapse is particularly high early after alcohol withdrawal, treatment for at least 3 to 6 months has been recommended.[2,3] Compliance with oral naltrexone may be a problem,[1,2] and promising results[4,5] have been reported with a long-acting intramuscular injection given monthly.

Naltrexone appears to be more effective at reducing the amount of alcohol consumed than producing complete abstinence;[1] reports[6] from patients who continued to drink during therapy suggest that naltrexone may reduce the pleasure associated with drinking, possibly by blocking the effect of endorphins released as a result of alcohol consumption.

Although naltrexone does not appear to be hepatotoxic at the oral dosage of 50 mg daily used for alcohol dependence, caution is recommended in patients with liver disease;[3] careful monitoring is recommended if it is given with disulfiram since hepatotoxicity could potentially be increased.

Other opioid antagonists have also been studied. Preliminary results[7,8] suggest that nalmefene may also be effective, although there is insufficient evidence to recommend its use.[2]

Autism. Autistic disorders have been linked with abnormalities in the endogenous opioid system and there is some evidence[1] that naltrexone may be of benefit in children with autism, especially in those with self-injurious behaviour.

1. ElChaar GM, *et al.* Efficacy and safety of naltrexone use in pediatric patients with autistic disorder. *Ann Pharmacother* 2006; **40:** 1086–95.

Opioid dependence. *MAINTENANCE.* Naltrexone is a long-acting, non-addictive oral opioid antagonist. It can be effective in maintaining abstinence in opioid addicts after detoxification, but compliance with therapy is difficult to maintain because although it blocks the euphoriant effects of opioids it does not block the craving for narcotics. It is thus most effective in highly motivated addicts with good sociological and psychological support to discourage impulsive use of opioids. Subcutaneous formulations have also been used but have been associated with serious complications (see Rapid Detoxification, below).

For a discussion of the management of opioid dependence, see p.101.

RAPID DETOXIFICATION. Naltrexone has been used in various regimens for rapid detoxification;[1,2] opioid withdrawal may be achieved in only a few days, although benefits for long-term outcome are not yet established. It has also been used for ultrarapid detoxification under anaesthesia, although a systematic review[3] concluded that the risks outweighed the benefits of using opioid antagonists in such procedures. A later study[4] also failed to support the use of such a regimen. After detoxification, patients may be given oral naltrexone for maintenance; subcutaneous formulations of naltrexone have also been used in an attempt to improve compliance, although serious complications, including deaths, have been reported[5-7] with their use.

Obidoxime Chloride *(USAN, rINN)*

Cloruro de obidoxima; LüH6; Obidoxime, Chlorure d'; Obidoximi Chloridum. 1,1′-[Oxybis(methylene)]bis[4-(hydroxyimino)methyl]pyridinium dichloride.

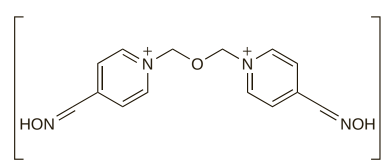
Обидоксима Хлорид

$C_{14}H_{16}Cl_2N_4O_3$ = 359.2.

CAS — 7683-36-5 (obidoxime); 114-90-9 (obidoxime chloride).

ATC — V03AB13.

ATC Vet — QV03AB13.



Profile

Obidoxime chloride is a cholinesterase reactivator with similar actions and uses to pralidoxime (p.1460). It is given with atropine in the treatment of organophosphorus poisoning in a usual initial dose of 250 mg (4 mg/kg) by slow intravenous injection. This may be followed by intravenous infusion of 750 mg over 24 hours, continued until the concentration of organophosphate is below critical levels; alternatively, repeated doses of 4 to 8 mg/kg may be given at intervals of 2 to 4 hours. It has also been given by intramuscular injection.

Penicillamine *(BAN, USAN, rINN)*

Penicilamin; Penicilamina; Penicilaminas; Penicillamin; Pénicillamine; D-Penicillamine; Penicillaminum; Penicylamina; Penisilamin; Penisillamiini. D-3,3-Dimethylcysteine; D-3-Mercaptovaline.

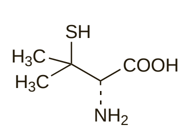
Пеницилламин

$C_5H_{11}NO_2S$ = 149.2.

CAS — 52-67-5 (penicillamine); 2219-30-9 (penicillamine hydrochloride).

ATC — M01CC01.

ATC Vet — QM01CC01.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Penicillamine). A white or almost white, crystalline powder. Freely soluble in water; slightly soluble in alcohol. A 1% solution in water has a pH of 4.5 to 5.5.

USP 31 (Penicillamine). A white or practically white, crystalline powder having a slight characteristic odour. Freely soluble in water; slightly soluble in alcohol; insoluble in chloroform and in ether. pH of a 1% solution in water is between 4.5 and 5.5. Store in airtight containers.

Adverse Effects and Treatment

Adverse effects of penicillamine are frequent. Gastrointestinal disturbances including anorexia, nausea, and vomiting may occur; oral ulceration and stomatitis have been reported and impaired taste sensitivity is common.

Skin rashes occurring early in treatment are commonly allergic and may be associated with pruritus, urticaria, and fever; they are usually transient but temporary drug withdrawal and use of corticosteroids or antihistamines may be required. Lupus erythematosus and pemphigus have been reported. A Stevens-Johnson-like syndrome has been observed during penicillamine treatment. Prolonged use of high doses may affect skin collagen and elastin, resulting in increased skin friability, eruptions resembling elastosis perforans serpiginosa, and a late rash or acquired epidermolysis bullosa (penicillamine dermatopathy) that may necessitate dosage reduction or discontinuation.

Haematological adverse effects have included thrombocytopenia and, less frequently, leucopenia; these are usually reversible, but agranulocytosis and aplastic anaemia have occurred and fatalities have been reported. Haemolytic anaemia has also occurred.

Proteinuria occurs frequently and in some patients may progress to glomerulonephritis or nephrotic syndrome. Penicillamine-induced haematuria is rare but normally requires immediate discontinuation.

Other adverse effects associated with penicillamine include Goodpasture's syndrome, bronchiolitis and pneumonitis, myasthenia gravis, polymyositis (rarely with cardiac involvement), intrahepatic cholestasis, and pancreatitis.

Incidence of adverse effects. References describing the range and incidence of adverse effects associated with of D-penicillamine.[1-3] The L- or DL-forms are much more toxic.[4]

4. Kean WF, *et al.* Chirality in antirheumatic drugs. *Lancet* 1991; **338:** 1565–8.

Effects on the blood. Of the 18 deaths ascribed to penicillamine reported to the UK CSM between January 1964 and December 1977, 14 were apparently due to blood disorders, at least 7 of them being marrow aplasias. The myelotoxicity of penicillamine was reviewed in 10 patients with confirmed or suspected marrow depression during penicillamine treatment for rheumatoid arthritis or scleroderma; 6 died.[1]

An incidence of 12 to 27% has been reported for penicillamine-induced thrombocytopenia in patients with rheumatoid arthritis, possibly due to bone-marrow suppression and a reduced platelet-production rate.[2]

There have been isolated reports[3-5] of thrombotic thrombocytopenic purpura attributed to the use of penicillamine, with some fatalities.

5. Trice JM, *et al.* Thrombotic thrombocytopenic purpura during penicillamine therapy in rheumatoid arthritis. *Arch Intern Med* 1983; **143:** 1487–8.

Effects on the breasts. Breast enlargement has been reported both in women[1-5] and in men[6] taking penicillamine and may be a rare adverse effect. In some patients breast enlargement was prolonged with poor resolution and others required surgery.

Danazol has been used successfully to treat penicillamine-induced breast gigantism.[2-4]

6. Reid DM, *et al.* Reversible gynaecomastia associated with D-penicillamine in a man with rheumatoid arthritis. *BMJ* 1982; **285:** 1083–4.

Effects on the gastrointestinal tract. There have been isolated reports of acute colitis in patients taking penicillamine.[1,2] Ileal ulceration and stenosis in a patient with Wilson's disease was considered to be related to elastosis probably resulting from long-term penicillamine therapy.[3]

1. Hickling P, Fuller J. Penicillamine causing acute colitis. *BMJ* 1979; **2:** 367.
2. Grant GB. Penicillamine causing acute colitis. *BMJ* 1979; **2:** 555.
3. Wassef M, *et al.* Unusual digestive lesions in a patient with Wilson's disease treated with long-term penicillamine. *N Engl J Med* 1985; **313:** 49.

Effects on the heart. For reports of heart block, Stokes-Adams syndrome, and fatal myocarditis in patients taking penicillamine, see Polymyositis under Effects on the Muscles and the Neuromuscular System, below.

Effects on the kidneys. Proteinuria associated with penicillamine[1] has usually occurred within 4 to 18 months of starting therapy, although onset can be later. A greater incidence has been found in patients with rheumatoid arthritis and cystinuria than in those with Wilson's disease. The severity varies; proteinuria of nephrotic proportions usually develops rapidly but resolves on drug withdrawal. Minimal change, mesangioproliferative, and membranous nephropathy have all been associated with penicillamine; progressive glomerulonephritis has been observed in a few patients with features of Goodpasture's syndrome (see Effects on the Respiratory System, below).

Although there is some evidence of a relationship between nephropathy and penicillamine dose and its rate of increase,[1] a study of 33 rheumatoid arthritis patients with penicillamine-induced nephropathy found no correlation with the dose or duration of treatment.[2] Appreciable proteinuria could still be detected 12 months after stopping penicillamine in 40% of these patients, but subsequently resolved in those whose proteinuria was solely related to penicillamine.

Penicillamine was successfully reintroduced and continued for at least 13 months in 5 patients with rheumatoid arthritis who had developed proteinuria during the first course of therapy. Proteinuria did not recur.[3] Another study[4] in 8 patients with proteinuria but no oedema suggested that penicillamine could be safely continued; proteinuria resolved in 5 of the patients during continued therapy.

Corticosteroids have been used in patients developing rapidly progressive glomerulonephritis[5] but may be unnecessary and potentially hazardous in patients who develop nephrotic syndrome.[2]

Effects on the liver. Penicillamine has been associated with hepatotoxicity. A case report and review of the literature[1] described 9 patients, all of whom had liver function profiles consistent with intrahepatic cholestasis; 1 patient died of acute renal failure but the others improved rapidly after drug withdrawal. In a later report,[2] a 72-year-old man with rheumatoid arthritis developed jaundice about 4 weeks after starting penicillamine therapy. Liver biopsy indicated a slight degree of cholangitis with eosinophils in the portal tracts and severe predominantly intrahepatocellular cholestasis. Jaundice cleared within 3 weeks of stopping penicillamine and liver enzyme values approached normal after 6 weeks. However, in another case[3] cholestasis persisted despite withdrawal of penicillamine and the patient died of sepsis 14 months later. Monitoring of liver function and eosinophil counts in the early weeks of penicillamine therapy has been recommended.[1]

3. Jacobs JWG, *et al.* Fatal cholestatic hepatitis caused by -penicillamine. *Br J Rheumatol* 1994; **33:** 770–3.

Effects on the muscles and the neuromuscular system. Neuromyotonia,[1] and profound sensory and motor neuropathy that responded to pyridoxine supplementation,[2] have occurred in patients taking penicillamine. Low back pain with fever and rash has also been reported;[3] back pain and fever recurred on rechallenge. It was suggested that an allergic mechanism was involved.

3. Bannwarth B, *et al.* Low back pain associated with penicillamine. *BMJ* 1991; **303:** 525.

Myasthenia. Myasthenia gravis is a well recognised, though uncommon, complication of long-term penicillamine therapy, particularly in patients with rheumatoid arthritis or other auto-immune disorders.[1-5] Symptoms are similar to those seen with spontaneous myasthenia gravis and include ptosis and diplopia, and generalised weakness, occasionally affecting the respiratory muscles. The onset of symptoms usually occurs within 6 to 7 months but may be delayed for a number of years. Myasthenic symptoms usually resolve spontaneously once penicillamine is withdrawn, but some patients require anticholinesterase therapy. Acetylcholine receptor antibodies have been reported in 75% or more of affected patients.[2,3] Several reports have suggested a genetic tendency to penicillamine-induced myasthenia, and an association with HLA antigens DR1 and Bw35 has been found in some studies,[1,4] although others[5] have not replicated these findings.

Polymyositis. Penicillamine therapy has been associated rarely with polymyositis and dermatomyositis.[1-5] Cardiac complications may occur: at least 2 deaths have resulted from myocarditis,[1] and complete heart block[1,3,6] and severe Stokes-Adams attacks[3] have been reported. It is possible that some patients may have a genetically determined susceptibility to this complication.[4]

Effects on the respiratory system. Pulmonary haemorrhage associated with progressive renal failure has been reported[1,2] with penicillamine and has generally been classified as Goodpasture's syndrome, although patients usually lack anti-glomerular basement membrane antibodies; an immune-complex mechanism has also been suggested.[1] There have been rare reports of obliterative bronchiolitis in patients with rheumatoid arthritis treated with penicillamine.[3-6]

Upper respiratory tract disorders have also been reported. A 76-year-old patient taking penicillamine developed rhinitis, bilateral blepharitis, and pemphigus foliaceus;[7] the rhinitis and blepharitis resolved when penicillamine was withdrawn. In addition, 2 patients with lower respiratory symptoms also developed persistent sinusitis,[6] which required surgery.

Effects on the skin. Penicillamine-induced skin lesions have been reviewed.[1] Reactions include those resulting from interference with collagen and elastin (see below); those associated with auto-immune mechanisms such as pemphigus, pemphigoid, lupus erythematosus, and dermatomyositis; and those classified as acute sensitivity reactions including macular or papular eruptions and urticaria. The effects on collagen and elastin tend to occur only after prolonged use of high doses, as in patients with Wilson's disease or cystinuria, whereas patients with diseases characterised by altered immune systems, such as rheumatoid arthritis, are more prone to develop the antibody-related adverse skin reactions. Acute hypersensitivity reactions tend to occur early in treatment, usually within the first 7 to 10 days, and appear not to be dose-related. Lichenoid reactions, stomatitis, nail changes, and adverse effects on hair have also occurred.

1. Levy RS, *et al.* Penicillamine: review and cutaneous manifestations. *J Am Acad Dermatol* 1983; **8:** 548–58.

Interference with collagen and elastin. Long-term, high-dose treatment with penicillamine can interfere with elastin and collagen production giving rise to increased skin friability, haemorrhagic lesions, miliary papules, and excessive wrinkling and laxity of the skin.[1] Penicillamine dermatopathy, characterised by wrinkling and purpura over bony prominences, has been described.[2] In addition, lesions resembling pseudoxanthoma elasticum have been reported.[3,4] Abnormal elastic tissue has also been reported in patients taking low doses of penicillamine (less than 1 g daily), not only in the skin but also in joint capsules,[5] and elastosis perforans serpiginosa has been reported[6,7] in 2 patients. In all these cases, histological findings generally show damage to elastic fibres giving them a typical appearance described as 'lumpy-bumpy' or 'bramble-bush'.

For reports of cutis laxa in neonates, see Pregnancy under Precautions, below.

Lichen planus. There have been rare reports of lichen planus in patients with primary biliary cirrhosis taking penicillamine,[1,2] although the role of penicillamine has been questioned. Oral lichen planus associated with penicillamine has also been reported[3] in patients with rheumatoid arthritis.

1. Powell FC, Rogers RS. Primary biliary cirrhosis, penicillamine, and lichen planus. *Lancet* 1981; **ii:** 525.

3. Blasberg B, *et al.* Lichenoid lesions of the oral mucosa in rheumatoid arthritis patients treated with penicillamine. *J Rheumatol* 1984; **11:** 348–51.

Pemphigus. Bullous skin disorders are established adverse effects of penicillamine and appear to have an auto-immune basis.[1] Pemphigus-spectrum disorders have been most commonly reported, including pemphigus vulgaris, pemphigus foliaceus, herpetiform pemphigus, pemphigus erythematosus, benign mucous membrane pemphigoid, cicatricial pemphigoid, and combined pemphigus and pemphigoid features.

1. Bialy-Golan A, Brenner S. Penicillamine-induced bullous dermatoses. *J Am Acad Dermatol* 1996; **35:** 732–42.

Psoriasiform eruptions. Two patients with rheumatoid arthritis developed psoriasiform eruptions during penicillamine treatment.[1] In 1 patient the eruption resolved when penicillamine was stopped but worsened when treatment was restarted.

1. Forgie JC, Highet AS. Psoriasiform eruptions associated with penicillamine. *BMJ* 1987; **294:** 1101.

Scleroderma. Penicillamine has been used in the treatment of scleroderma and systemic sclerosis (see under Uses, below). However, scleroderma, with evidence of pulmonary involvement, developed in a 14-year-old boy with Wilson's disease who had been treated with penicillamine for 11 years[1] and the suitability of penicillamine for this indication has therefore been questioned.

1. Miyagawa S, *et al.* Systemic sclerosis-like lesions during long-term penicillamine therapy for Wilson's disease. *Br J Dermatol* 1987; **116:** 95–100.

Toxic epidermal necrolysis. A 56-year-old woman developed agranulocytosis and toxic epidermal necrolysis 7 weeks after starting therapy with penicillamine 250 mg daily for primary biliary cirrhosis.[1] Severe toxic epidermal necrolysis has also been reported[2] in a woman taking penicillamine for Wilson's disease.

Genetic factors. There is evidence that some patients may have a genetically determined increased susceptibility to the adverse effects of penicillamine. Several studies have suggested that rheumatoid arthritis patients with a poor capacity for producing sulfoxides may be more susceptible to the toxic effects of penicillamine.[1,2] Patients with primary biliary cirrhosis also appear to have poor sulfoxidation capacity,[3] and this may contribute to their high incidence of adverse reactions to penicillamine, although no association between penicillamine toxicity and sulfoxidation status was found in a study of 20 such patients.[4]

Several studies have also suggested that certain histocompatibility antigens may increase susceptibility to penicillamine toxicity. An increased incidence of adverse reactions was noted[2] in patients with HLA-DR3, while other studies have shown associations between proteinuria and HLA antigens B8 and DR3,[5,6] myasthenia gravis and Bw35 and DR1,[7] thrombocytopenia and HLA antigens DR4,[5,6] A1,[5] and C4BQO,[5] and polymyositis or dermatomyositis and HLA antigens B18, B35, and DR4.[8] However, not all studies have reported the same associations, and the clinical usefulness of sulfoxidation testing or HLA-typing is not established.[6,9]

Systemic lupus erythematosus. A syndrome resembling lupus erythematosus developed in 6 women with long-standing severe rheumatoid arthritis while being treated with penicillamine;[1] this represented a frequency of penicillamine-induced lupus erythematosus of about 2%. All 6 had developed previous cutaneous reactions to gold therapy. A case of bullous systemic lupus erythematosus associated with penicillamine has also been reported.[2]

1. Chalmers A, *et al*. Systemic lupus erythematosus during penicillamine therapy for rheumatoid arthritis. *Ann Intern Med* 1982; **97:** 659–63.
2. Condon C, *et al.* Penicillamine-induced type II bullous systemic lupus erythematosus. *Br J Dermatol* 1997; **136:** 474–5.

Precautions

Penicillamine is contra-indicated in patients with lupus erythematosus or a history of penicillamine-induced agranulocytosis, aplastic anaemia, or severe thrombocytopenia. It should be used with care in patients with mild renal impairment and is contra-indicated in patients with moderate or severe renal impairment.

Penicillamine should not be given with other drugs capable of causing similar serious haematological or renal adverse effects, for example gold salts, chloroquine or hydroxychloroquine, or immunosuppressive drugs. Penicillamine is a degradation product of penicillin and patients who are allergic to penicillin may show cross-sensitivity to penicillamine although this appears to be rare.

Patients need to be carefully monitored for adverse effects. In particular full blood counts and urinalysis should be carried out; one recommendation is to perform blood counts weekly or fortnightly, and urinalysis weekly, for the first 2 months of treatment and after any change in dosage, and monthly thereafter. Treatment should be withdrawn if there is a fall in white cell or platelet count, or if progressive or serious proteinuria or haematuria occur. Liver function tests at 6-monthly intervals have also been recommended and renal function should be monitored.

Pyridoxine 25 mg daily may be given to patients on long-term therapy, especially if they are on a restricted diet, since penicillamine increases the requirement for this vitamin.

A reduced dose of penicillamine has been suggested for patients undergoing surgery (see Anaesthesia and Surgery, below).

Anaesthesia and surgery. Penicillamine may delay wound healing due to its effects on collagen and elastin and it has been suggested that the dose should be reduced to 250 mg daily for 6 weeks before surgery and during the postoperative period until healing has taken place.

The effects of penicillamine on muscle function should also be considered in patients requiring anaesthesia; a 57-year-old woman[1] with penicillamine-induced myasthenia developed prolonged postoperative apnoea, necessitating artificial ventilation.

1. Fried MJ, Protheroe DT. D-Penicillamine induced myasthenia gravis: its relevance for the anaesthetist. *Br J Anaesth* 1986; **58:** 1191–3.

Pregnancy. Penicillamine teratogenicity has been reviewed.[1] Evidence of the embryotoxicity of maternal penicillamine exposure in *animal* studies had been confirmed in humans by 5 reports of cutis laxa in neonates of mothers who had taken penicillamine during pregnancy; 3 further reports of intra-uterine brain injury were less characteristic. Nevertheless most pregnancy outcomes were normal. No birth defects had been reported when penicillamine was discontinued in early pregnancy. It is generally recommended that women receiving penicillamine for Wilson's disease should continue throughout pregnancy since the benefits outweigh the risks. However, in other conditions, particularly where there are safer alternatives, discontinuation of penicillamine is advised.

1. Rosa FW. Teratogen update: penicillamine. *Teratology* 1986; **33:** 127–31.

Interactions

Penicillamine forms chelates with metal ions and oral absorption may be reduced if it is given with iron or other metals, antacids, or food. Penicillamine should be taken on an empty stomach and it has been recommended that there should be an interval of at least 2 hours between taking penicillamine and iron supplements. Additive toxicity may occur if penicillamine is given with drugs that have adverse renal or haematological effects (see Precautions, above).

Antacids or food. In a single-dose study in 6 healthy subjects, penicillamine given orally immediately after food or a dose of an antacid mixture (aluminium hydroxide, magnesium hydroxide, and simeticone), resulted in plasma concentrations of penicillamine that were 52% and 66%, respectively, of those obtained in a fasting state. Results suggested that the reduction in plasma-penicillamine concentrations was associated with decreased absorption.[1] Another study[2] showed that the reduction of penicillamine plasma concentrations produced by aluminium- and magnesium-containing antacids did not occur with sodium bicarbonate, and thus the interaction was probably a result of chelation rather than a pH effect.

2. Ifan A, Welling PG. Pharmacokinetics of oral 500 mg penicillamine: effect of antacids on absorption. *Biopharm Drug Dispos* 1986; **7:** 401–5.

Diazepam. For a report of exacerbation of intravenous diazepam-induced phlebitis by oral penicillamine, see under Diazepam, p.991.

Gold. There have been conflicting reports on the effect of previous gold therapy on the subsequent development of penicillamine toxicity in patients with rheumatoid arthritis.

Some studies[1,2] have suggested that adverse effects with penicillamine may be more common in patients who have previously reacted adversely to gold, but others[3,4] have found no correlation. One study[5] found that although the overall incidence of adverse effects with penicillamine appeared unaffected by prior gold therapy, bone-marrow depression and rashes were more common in those previously treated with gold. It has been suggested[2] that the interaction occurs due to mobilisation of gold from the tissues by penicillamine, and an interval of at least 6 months between gold and penicillamine in patients with prior gold toxicity was recommended. However, another report[6] found that the interval between gold and penicillamine had no influence on the development of toxicity and suggested that there might be a common genetic susceptibility in certain patients. A patient who had experienced myasthenia with penicillamine had a recurrence with gold therapy,[7] but another study[4] found no evidence that the adverse effects of gold were increased in those with prior penicillamine toxicity.

Insulin. Unexplained hypoglycaemia in 2 patients with type 1 diabetes occurred 6 to 8 weeks after penicillamine treatment for rheumatoid arthritis was started.[1] Both patients required a reduction in their insulin dose. A possible immunological mechanism has been proposed.[1,2]

1. Elling P, Elling H. Penicillamine, captopril, and hypoglycemia. *Ann Intern Med* 1985; **103:** 644–5.
2. Becker RC, Martin RG. Penicillamine-induced insulin antibodies. *Ann Intern Med* 1986; **104:** 127–8.

Iron. Plasma-penicillamine concentrations were reduced to 35% when penicillamine was given after a dose of ferrous sulfate in healthy subjects.[1] Patients stabilised on penicillamine while on oral iron therapy were considered unlikely to respond fully to penicillamine and would be exposed to a large increase in penicillamine absorption with possible adverse reactions if the iron was stopped.[2]

1. Osman MA, *et al.* Reduction in oral penicillamine absorption by food, antacid, and ferrous sulfate. *Clin Pharmacol Ther* 1983; **33:** 465–70.
2. Harkness JAL, Blake DR. Penicillamine nephropathy and iron. *Lancet* 1982; **ii:** 1368–9.

Probenecid. Probenecid may reduce the beneficial effects of penicillamine in cystinuria, and it has been suggested[1] that hyperuricaemic cystinuric patients should not be given both drugs.

1. Yu T-F, *et al*. Studies on the metabolism of D-penicillamine and its interaction with probenecid in cystinuria and rheumatoid arthritis. *J Rheumatol* 1984; **11:** 467–70.

Pharmacokinetics

Penicillamine is rapidly but variably absorbed from the gastrointestinal tract and reaches peak concentrations in the blood within 1 to 3 hours. It is reported to be more than 80% bound to plasma proteins. It undergoes some metabolism in the liver, to *S*-methyl penicillamine, and is excreted primarily in the urine, mainly as disulfides, along with some *S*-methyl penicillamine and unchanged drug; a small amount may be excreted in the faeces. Elimination is biphasic with an initial elimination half-life of about 1 to 3 hours followed by a slower phase, suggesting gradual release from tissues.

◊ Reviews.

1. Netter P, *et al.* Clinical pharmacokinetics of D-penicillamine. *Clin Pharmacokinet* 1987; **13:** 317–33.

Uses and Administration

Penicillamine is a chelator that aids the elimination from the body of certain heavy-metal ions, including copper, lead, and mercury, by forming stable soluble complexes with them that are readily excreted by the kidney. It is used in the treatment of Wilson's disease (to promote the excretion of copper), in heavy-metal poisoning such as lead poisoning, in cystinuria (to reduce urinary concentrations of cystine), in severe active rheumatoid arthritis, and in chronic active hepatitis.

Penicillamine is given orally and should be taken on an empty stomach. A low initial dose increased gradually to the minimum optimal maintenance dosage may reduce the incidence of adverse effects as well as provide closer control of the condition being treated.

In the treatment of **Wilson's disease**, a dose of 1.5 to 2 g daily in divided doses may be given initially. The optimal dosage to achieve a negative copper balance should be determined initially by regular analysis of 24-hour urinary copper excretion and subsequently by monitoring free copper in the serum. A maintenance dose of 0.75 to 1 g daily may be adequate once control is achieved and should be continued indefinitely; UK licensed product information recommends that a maintenance dose of 2 g daily should not be continued for more than a year. In children, a suggested dose is up to 20 mg/kg daily (minimum 500 mg daily) in divided doses. A dose of 20 mg/kg daily is suggested for the elderly.

In the management of **lead poisoning**, penicillamine may be given in doses of 1 to 1.5 g daily in divided doses until urinary lead is stabilised at less than 500 micrograms/day. Children and the elderly may be given 20 mg/kg daily in divided doses.

In **cystinuria**, doses of penicillamine are adjusted according to cystine concentrations in the urine. For the *treatment* of cystinuria and cystine calculi, the dose is usually in the range of 1 to 4 g daily in divided doses; a suggested dose for children is 30 mg/kg daily in divided doses. For the *prevention* of cystine calculi, lower doses of 0.5 to 1 g at bedtime may be given. An adequate fluid intake is essential to maintain urine flow when penicillamine is used for cystinuria.

In the treatment of **severe active rheumatoid arthritis**, an initial dose of penicillamine 125 to 250 mg daily is increased gradually by the same amount at intervals of 4 to 12 weeks. Remission is usually achieved with maintenance doses of 500 to 750 mg daily in divided doses, but up to 1.5 g daily may be required. Improvement may not occur for several months; US licensed product information suggests that penicillamine should be discontinued if there is no response after treatment for 3 to 4 months with 1 to 1.5 g daily; in the UK, a trial for 12 months is suggested. After remission has been sustained for 6 months an attempt may be made gradually to reduce the dose by 125 to 250 mg daily every 3 months but relapse may occur. Lower doses may be required in the elderly who may be more susceptible to developing adverse effects. Initial doses of 125 mg daily are recommended, gradually increased to a maximum of 1 g daily if necessary. In children the maintenance dose is 15 to 20 mg/kg daily; a suggested initial dose is 2.5 to 5 mg/kg daily increased gradually at 4-week intervals.

In the management of **chronic active hepatitis**, penicillamine may be given after liver function tests have indicated that the disease has been controlled by corticosteroids. The initial dose is 500 mg daily in divided doses, increased gradually over 3 months to 1.25 g daily, while at the same time reducing the corticosteroid dose.

Acetylpenicillamine has been used in mercury poisoning.

Chronic active hepatitis. Penicillamine has been tried in chronic active hepatitis (p.1501) as an alternative to prolonged corticosteroid maintenance therapy once control of the disease is achieved. The dose of penicillamine is increased over several months to a suitable maintenance dose and, at the same time, the corticosteroid dose is decreased.

Cystinuria. Cystinuria is an inherited disorder of renal amino-acid excretion in which there is excessive excretion of cystine (cysteine disulfide), along with ornithine, lysine, and arginine. The low solubility of cystine leads to the formation of cystine stones in the kidney, resulting in pain, haematuria, renal obstruction, and infection. Treatment is primarily aimed at reducing the urinary concentration of cystine to below its solubility limit of 300 to 400 mg/litre at neutral pH. Patients with cystinuria excrete 400 to 1200 mg cystine daily and should be advised to drink at least 3 litres of water daily, including at night, to maintain a dilute urine. Cystine is more soluble in alkaline urine and urinary alkalinisers such as sodium bicarbonate, sodium citrate, or potassium citrate may be used; however, high doses are required and calcium stone formation may be promoted. Penicillamine may also be used, particularly in patients where these measures are ineffective or not tolerated; it complexes with cysteine to form a more soluble mixed disulfide, therefore reducing cystine excretion, preventing cystine stone formation, and promoting the gradual dissolution of existing stones. Adverse effects are common and tiopronin, which has a similar action, may be used as an alternative. Surgical removal may be necessary for established stones but lithotripsy is not very effective.

Lead poisoning. Penicillamine may be used to treat asymptomatic lead intoxication and to achieve desirable tissue-lead concentrations in patients with symptomatic lead poisoning once they have received treatment with sodium calcium edetate and dimercaprol (see p.2332).

Primary biliary cirrhosis. Copper accumulation in the liver has been noted in patients with primary biliary cirrhosis (see under Ursodeoxycholic Acid,p.2408) and therapy with penicillamine to reduce liver-copper concentrations has been studied. Despite good preliminary results, most studies have found it to be ineffective and any benefit appears to be offset by the high incidence of adverse effects.[1,2]

2. Gong Y, *et al.* D-penicillamine for primary biliary cirrhosis. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2004 (accessed 04/04/06).

Retinopathy of prematurity. Penicillamine has been investigated for the prophylaxis of retinopathy of prematurity (p.1994) in infants considered to be at risk, and a systematic review of 2 such studies considered that there was evidence for a reduced incidence of acute retinopathy.[1] Further studies were considered justified, with careful attention to possible adverse effects.

1. Phelps DL, *et al.* D-Penicillamine for preventing retinopathy of prematurity in preterm infants. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2001 (accessed 04/10/05).

Rheumatoid arthritis. Penicillamine is one of a diverse group of disease-modifying antirheumatic drugs that have been used in rheumatoid arthritis (p.11) in an attempt to suppress the rate of cartilage erosion or alter the course of the disease. However, early enthusiasm for penicillamine has been tempered by a high incidence of adverse effects.[1] During long-term therapy as many as 50% of patients taking penicillamine have been reported to stop treatment because of adverse effects.[2] Low doses of penicillamine to reduce the incidence of adverse effects have been tried and while doses as low as 125 mg daily have been claimed to be effective in some patients, a 36-week multicentre double-blind study[3] involving 225 patients concluded that a dose of penicillamine 500 mg daily was only slightly more effective than placebo. A dose of 125 mg daily was not significantly different from either the 500-mg dose or placebo. However, a 5-year open study[4] comparing penicillamine in doses up to 500 mg daily with hydroxychloroquine, sodium aurothiomalate, or auranofin found penicillamine to be as effective as the other drugs and well tolerated, with 53% of the patients randomised to penicillamine still receiving it at 5 years, as opposed to about 30 to 35% of those randomised to other drugs.

Scleroderma. Penicillamine affects the cross-linking of collagen,[1] and observational studies[2,3] have suggested that it may be of benefit in scleroderma (p.1817), and perhaps in some visceral manifestations of systemic sclerosis. A randomised study[4] comparing a conventional dose of penicillamine (up to 1 g daily) with a very low dose (125 mg on alternate days) found no difference in outcome, but there were more adverse effects with the higher dose. Although the lower dose was not expected to be effective, the skin score improved significantly in both groups; however, there was insufficient evidence to attribute this to use of penicillamine, and its role in scleroderma remains to be established.

For a report of sclerodermatous lesions in a patient taking penicillamine for Wilson's disease, see Scleroderma, under Effects on the Skin, above.

Wilson's disease. Wilson's disease, or hepatolenticular degeneration, is a rare autosomal disorder of copper accumulation.[1-5] Excretion of excess copper, which normally occurs via the bile, is impaired and total body copper progressively increases. The excess copper accumulates in the liver, brain, and other organs including the kidneys and corneas, and eventually causes tissue damage.

Effective treatment of Wilson's disease involves the use of copper-reducing drugs to establish a negative copper balance. This prevents deposition of more copper and also mobilises excess copper that has already been deposited making it available for excretion. Once negative copper balance has been achieved, maintenance treatment must be continued lifelong. Dietary restriction of copper is not generally considered to be an important part of the treatment of Wilson's disease, although patients may be advised to avoid copper-rich foods, such as liver and shellfish, during the first year of treatment and to restrict their consumption thereafter. Symptomatic recovery from copper overload occurs slowly, but is usually complete if treatment is started early enough, and a normal life expectancy can be achieved. However, once irreversible organ damage such as liver cirrhosis has occurred, treatment can only prevent further deterioration; those presenting with end-stage liver disease do not benefit from copper-reducing therapy, and liver transplantation is necessary (although successful medical treatment has been reported in children). The drugs used to reduce copper concentrations in the treatment of Wilson's disease are penicillamine, trientine, and zinc. Ammonium tetrathiomolybdate, an investigational drug, may also be used.

Penicillamine reduces copper concentrations in several ways. Its main action is to chelate circulating copper, which is then excreted in the urine. In addition, penicillamine reduces the affinity of copper for proteins and polypeptides, allowing removal of copper from tissues. It also induces hepatic synthesis of metallothionein, a protein that combines with copper to form a non-toxic product. *Trientine* is a less potent copper chelator than penicillamine; it competes for copper bound to serum albumin and increases copper excretion. *Zinc* induces synthesis of metallothionein in the intestine so that absorption of copper from the gastrointestinal tract is blocked. It is usually given as the acetate as this form is less irritating to the stomach than the sulfate. *Ammonium tetrathiomolybdate* forms a complex with protein and copper. When it is given with food it blocks the intestinal absorption of copper, and when taken between meals it combines with albumin- and caeruloplasmin-bound copper.

CHOICE OF DRUG. Penicillamine is generally regarded as the drug of choice for the initial management of Wilson's disease as it produces a rapid reduction in copper levels. However, it may initially exacerbate neurological symptoms (possibly due to transiently increased brain and blood copper concentrations) and some practitioners therefore suggest starting with zinc; zinc is less suitable in those requiring rapid reduction of copper levels as it has a slow onset of action. Trientine, which may also exacerbate neurological symptoms, is principally used in patients intolerant of penicillamine. Ammonium tetrathiomolybdate is under investigation for the initial reduction of copper levels; it may be particularly suitable for patients with neurological symptoms.

Once a negative copper balance is achieved, maintenance therapy must be continued for life. Penicillamine, trientine, and zinc are all used for maintenance treatment. Patients taking penicillamine are also given pyridoxine to prevent deficiency (see Precautions, above). The adverse effects of penicillamine may be a problem during long-term use and zinc, which has low toxicity, is often preferred. Zinc is also used in patients in the asymptomatic stage of the disease.

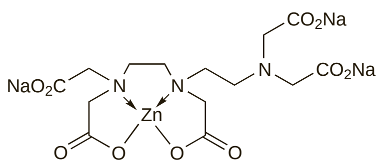
Zinc Trisodium Pentetate *(rINNM)*

Pentétate de Zinc Trisodique; Pentetate Zinc Trisodium; Pentetato zinc y trisodio; Trisodium Zinc Diethylenetriaminepentaacetate; Zinci Trinatrii Pentetas; Zn-DTPA (zinc pentetate or zinc trisodium pentetate).

Цинка Тринатрия Пентетат

$C_{14}H_{18}N_3Na_3O_{10}Zn$ = 522.7.

CAS — 65229-17-6 (zinc pentetate); 125833-02-5 (zinc trisodium pentetate).



Adverse Effects and Precautions

Adverse effects that have been reported with calcium or zinc trisodium pentetate include headache, nausea and diarrhoea, and injection-site reactions. Bronchospasm has occurred after inhalation. Pentetates chelate trace metals and supplements may be needed with long-term use. Serum-electrolytes should be monitored during use. Pentetates should be used with caution in patients with haemochromatosis since fatalities have been reported.

Uses and Administration

Pentetic acid and its salts are chelators with the general properties of the edetates (see Edetic Acid, p.1445). Calcium trisodium pentetate is used in the treatment of poisoning by heavy metals; both calcium trisodium pentetate and zinc trisodium pentetate are used for poisoning with radioactive metals such as plutonium, americium, and curium.

In heavy-metal poisoning, calcium trisodium pentetate has been given in a dose of 1 g daily by intravenous infusion for 3 to 5 days, with further treatment, if necessary, after an interval of 3 days.

For poisoning with plutonium and similar radioactive metals, either calcium trisodium pentetate or zinc trisodium pentetate may be used. Calcium trisodium pentetate is more effective within the first 24 hours and is preferred for the initial dose; however, zinc depletion may occur and if further chelation is required treatment should be continued with zinc trisodium pentetate if possible. The usual dose is 1 g of either calcium or zinc trisodium pentetate once daily, by slow intravenous injection over 3 to 4 minutes or by intravenous infusion. Treatment is usually continued for 5 days and then modified depending on the estimated radioactive body burden. For patients with poisoning by inhalation only, the calcium trisodium pentetate or zinc trisodium pentetate may be given by nebulisation.

Pentetates, labelled with metallic radionuclides, are used in nuclear medicine (see Indium-111, p.2054, and Technetium-99m, p.2056).

Thalassaemia. Iron overload in patients with thalassaemia (p.1045) is usually treated with desferrioxamine, but auditory toxicity can result. Calcium pentetic acid has been used as an alternative. A study[1] in 5 patients in whom desferrioxamine had to be withdrawn because of high-tone deafness found that the pentetate was as effective as desferrioxamine and hearing improved during treatment. Oral zinc supplements were necessary to maintain adequate plasma-zinc concentrations.

Pharmacopoeias. In *It.*

Adverse Effects

Use of pralidoxime may be associated with drowsiness, dizziness, disturbances of vision, nausea, tachycardia, headache, hyperventilation, and muscular weakness. Tachycardia, laryngospasm, and muscle rigidity have been attributed to giving pralidoxime intravenously at too rapid a rate. Large doses of pralidoxime may cause transient neuromuscular blockade.

Precautions

Pralidoxime should be used cautiously in patients with renal impairment; a reduction in dosage may be necessary. Caution is also required in giving pralidoxime to patients with myasthenia gravis as it may precipitate a myasthenic crisis. Pralidoxime should not be used to treat poisoning by carbamate pesticides.

When atropine and pralidoxime are given together, the signs of atropinisation may occur earlier than might be expected when atropine is used alone.

Pharmacokinetics

Pralidoxime is not bound to plasma proteins, does not readily pass into the CNS, and is rapidly excreted in the urine, partly unchanged and partly as a metabolite. The elimination half-life is about 1 to 3 hours.

Uses and Administration

Pralidoxime is a cholinesterase reactivator. It is used as an adjunct to, but *not* as a substitute for, atropine in the treatment of poisoning by certain cholinesterase inhibitors. Its main indication is in poisoning due to organophosphorus insecticides or related compounds (see p.2047). These compounds phosphorylate and consequently inactivate cholinesterase, causing acetylcholine accumulation and muscle paralysis. Pralidoxime acts principally to reactivate cholinesterase, restoring the enzymatic destruction of acetylcholine at the neuromuscular junction and relieving muscle paralysis. However, concomitant use of atropine is required to counteract directly the adverse effects of acetylcholine accumulation, particularly at the respiratory centre. Pralidoxime is not equally antagonistic to all organophosphorus anticholinesterases as reactivation is dependent on the nature of the phosphoryl group and the rate at which inhibition becomes irreversible. It is not effective in the treatment of poisoning due to phosphorus, inorganic phosphates, or organophosphates without anticholinesterase activity. It has usually been contra-indicated in the treatment of poisoning by carbamate insecticides (including carbaryl poisoning) as it may increase toxicity (see p.2037). The use of pralidoxime has been suggested for the treatment of overdosage by anticholinesterase drugs, including those used to treat myasthenia gravis such as neostigmine; however, it is only slightly effective and its use is not generally recommended.

Pralidoxime is usually given as the chloride or mesilate but the iodide and metilsulfate salts have also been used. Doses are usually expressed in terms of the salts.

Pralidoxime may be given by slow intravenous injection over 5 to 10 minutes, by intravenous infusion over 15 to 30 minutes, or by subcutaneous or intramuscular injection; it has also been given orally.

In the treatment of **organophosphorus poisoning** pralidoxime should be given as soon as possible. After about 24 hours it becomes less effective since cholinesterase inactivation usually becomes irreversible after this time; however, patients with severe poisoning may occasionally respond up to 36 hours or longer after exposure, depending on the organophosphate involved. Injections of *atropine* should be given intravenously or intramuscularly and repeated as necessary until the patient shows signs of atropine toxicity; atropinisation should then be maintained for 48 hours or more. Large amounts of atropine may be required.

See under Atropine Sulfate, p.1221, for details of dosages. As soon as the effects of atropine become apparent, 1 to 2 g of *pralidoxime* chloride, iodide, or mesilate, should be given intramuscularly or intravenously and repeated after 1 hour and then every 8 to 12 hours if necessary. Alternatively, the *BNF* recommends pralidoxime chloride in an initial dose of 30 mg/kg given by intravenous infusion over 20 minutes, or by intravenous injection over at least 5 minutes if pulmonary oedema is present or infusion cannot be given; the initial dose is then followed by intravenous infusion at a rate of 8 mg/kg per hour. In some countries, auto-injectors are available for emergency use containing pralidoxime, either alone or combined with atropine and/or avizafone, a prodrug of diazepam. Typical doses are 600 mg of pralidoxime chloride or 500 mg of pralidoxime mesilate given intramuscularly up to 3 times, depending on symptoms. Another alternative, in severe poisoning, is the use of a continuous infusion of 200 to 500 mg/hour, titrated against response. A maximum dose of 12 g in 24 hours has been suggested. The dose of pralidoxime may need to be reduced in patients with renal impairment.

Treatment should preferably be monitored by the determination of blood-cholinesterase concentrations and clinical symptoms. Patients should be closely observed for at least 24 hours after resolution of symptoms.

Other oximes with cholinesterase-reactivating properties that have been used similarly include asoxime chloride (p.1438), obidoxime chloride (p.1456), and trimedoxime bromide (p.1467).

Organophosphorus poisoning. Oximes such as pralidoxime are widely used in poisoning with organophosphate *pesticides*. Although benefit has been shown in *animal* studies, reviews[1,2] have pointed out that there is little good evidence from human studies to support their use and that randomised controlled studies are needed to confirm their efficacy and safety, as well as the optimum regimens to use. A randomised study[3] in patients with moderately severe poisoning with organophosphorus pesticides found that a continuous infusion of pralidoxime iodide 1 g/hour for 48 hours was more effective than a dose of 1 g every 4 hours.

Cholinesterase reactivators such as the oximes have also been used for poisoning with organophosphate *nerve agents*. Studies in *animals* have suggested that the efficacy of the different oximes depends on the organophosphate involved; asoxime (p.1438) and HLö-7 may be more effective than pralidoxime or obidoxime for poisoning with nerve agents, particularly for soman poisoning.[4]

Протамина Сульфат

CAS — 9009-65-8.
ATC — V03AB14.
ATC Vet — QV03AB14.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Protamine Sulphate). A mixture of the sulfates of basic peptides prepared from the sperm or roe of suitable species of fish, usually from the families Clupeidae or Salmonidae. A white or almost white hygroscopic powder. Sparingly soluble in water; practically insoluble in alcohol. Store in airtight containers.

USP 31 (Protamine Sulfate). A purified mixture of simple protein principles obtained from the sperm or testes of suitable species of fish. Store at 2° to 8° in airtight containers.

Adverse Effects and Precautions

Intravenous injections of protamine, particularly if given rapidly, may cause hypotension, bradycardia, and dyspnoea. A sensation of warmth, transitory flushing, nausea and vomiting, and lassitude may also occur.

Hypersensitivity reactions can occur; patients at risk include diabetics who have received protamine-insulin preparations, those who have previously received protamine (including those who have undergone procedures such as coronary angioplasty or cardiopulmonary bypass surgery where protamine is frequently used), and those allergic to fish. Protamine is a constituent of sperm and men who are infertile or who have had a vasectomy may also be at increased risk since they may have antibodies to protamine. Anaphylactoid reactions have been reported.

Protamine has an anticoagulant effect when given in the absence of heparin.

When repeated doses of protamine are used to neutralise large doses of heparin, rebound bleeding which responds to further doses of protamine, may occur. Clotting parameters should be closely monitored in patients receiving such prolonged therapy.

◊ In a report on 4 patients given protamine sulfate after cardiac surgery to neutralise the effect of heparin, severe adverse reactions including marked hypotension, vascular collapse, and pulmonary oedema were described.[1] Previous reports of similar reactions to protamine were reviewed. A total of 17 patients had immediate anaphylactic reactions; in 1 patient a complement-dependent IgG antibody-mediated reaction had been demonstrated and 3 patients tested for allergy to protamine had positive skin tests. In 15 of these 17 patients there was evidence of previous exposure to protamine; those with a high risk of sensitisation included leucapheresis donors who had received the drug, diabetics using insulin containing protamine, and patients with fish allergy. Suspected reactions to protamine occurred in a further 10 patients after cardiac surgery. However, these reactions were characterised by severe vascular damage, manifested as noncardiogenic pulmonary oedema or persistent hypotension, and onset was delayed for 30 minutes to several hours. Evidence suggested that these reactions were not antibody mediated; only 2 of 7 evaluable patients had previous exposure. All patients required aggressive therapy.

In a review of the toxicity of protamine,[2] adverse cardiovascular responses were considered to be of 3 types: transient hypotension related to rapid drug administration, occasional anaphylactoid responses, and rarely, catastrophic pulmonary vasoconstriction.

2. Horrow JC. Protamine: a review of its toxicity. *Anesth Analg* 1985; **64:** 348–61.

Uses and Administration

Protamine is a basic protein that combines with heparin to form a stable inactive complex. Protamine is used to neutralise the anticoagulant action of heparin in the treatment of haemorrhage resulting from severe heparin or low-molecular-weight heparin overdosage. It is also used to neutralise the effect of heparin given before surgery and during extracorporeal circulation as in dialysis or cardiac surgery. Protamine is used in some insulin preparations to prolong the effects of insulin. Protamine is usually given as the sulfate, although the hydrochloride may also be used.

Protamine sulfate is given by slow intravenous injection over a period of about 10 minutes. The dose is dependent on the amount of heparin to be neutralised and ideally should be titrated against the coagulability of the patient's blood. Protamine has weak anticoagulating properties and if given in gross excess its anticoagulant action could be significant. As heparin is being continuously excreted the dose should be reduced if more than 15 minutes have elapsed since intravenous heparin injection; for example, if protamine sulfate is given 30 minutes after heparin the dose may be reduced to about one-half. Alternative regimens may be necessary if heparin has been given subcutaneously or by continuous intravenous infusion. Not more than 50 mg of protamine sulfate should be injected for any one dose; patients should be carefully monitored as further doses may be required.

For *unfractionated heparin* the Ph. Eur. 6.2 specifies that 1 mg of either protamine hydrochloride or protamine sulfate precipitates not less than 100 units of heparin, assayed against a specific reference batch of heparin sodium. One UK manufacturer has stated that each mg of protamine sulfate will usually neutralise the anticoagulant effect of at least 80 international units of heparin (lung) or at least 100 international units of heparin (mucous). In the USA stated values are that each mg of protamine sulfate neutralises about 90 USP units of heparin (lung) or about 115 USP units of heparin (mucous).

For *low-molecular-weight heparins*, protamine neutralises the anti-thrombin activity but only partially neutralises the anti-factor-Xa effect; 1 mg of protamine is stated to inhibit the effects of:

- 71 units of bemiparin sodium
- 80 to 120 units of certoparin sodium
- 100 units of dalteparin sodium
- 1 mg (100 units) of enoxaparin sodium
- 82 units of reviparin sodium
- 100 units of tinzaparin sodium

Haemorrhagic disorders. Endogenous production of heparin-like substances may, rarely, be responsible for some bleeding disorders. It has been suggested that protamine could be useful as a diagnostic aid *in vitro* and could be given intravenously for transient control of bleeding in such patients.[1,2]

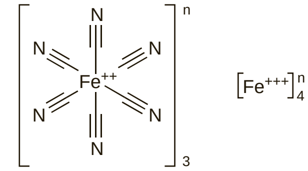
Prussian Blue

Azul de Prusia; Berlin Blue; CI Pigment Blue 27; Colour Index No. 77510; Ferric Ferrocyanide; Ferric Hexacyanoferrate (II); Insoluble Prussian Blue; Prussian Blue Insoluble *(USAN)*.

$Fe_4[Fe(CN)_6]_3$ = 859.2.

CAS — 14038-43-8 (insoluble Prussian blue); 12240-15-2 (soluble Prussian blue); 25869-00-5 (soluble Prussian blue).
ATC — V03AB31.
ATC Vet — QV03AB31.



NOTE. Prussian blue is available in a number of forms and it is not always clear from the literature which form is being referred to. CI Pigment Blue 27 has been used for both insoluble ferric hexacyanoferrate (II) (Colour Index No. 77510) and the soluble potassium, sodium, or ammonium ferric hexacyanoferrate (II) salts

Profile

Prussian blue is used in the treatment of thallium poisoning (see p.2400) and for known or suspected internal contamination with radiocaesium. When given orally it forms a non-absorbable complex with thallium or caesium in the gastrointestinal tract and increases their elimination from the body; it may also bind other elements and patients should be monitored for electrolyte imbalances. Prussian blue may cause constipation and a fibre-based laxative is recommended.

The usual dose of Prussian blue is 250 to 300 mg/kg daily, or up to 20 g daily for an adult, given in divided doses either by mouth or by nasogastric or duodenal tube. In the USA, a lower dose of 3 g three times daily for adults, or 1 g three times daily for children, has been recommended. For thallium poisoning, treatment should continue until the urinary excretion of thallium falls to 500 micrograms or less per 24 hours, the urine or blood concentration is less than 10 micrograms/L, or no thallium can be detected in the faeces. For radiocaesium contamination, a minimum of 30 days treatment should be given.

ATC Vet — QV03AE02.

Sevelamer Hydrochloride *(BANM, USAN, rINNM)*

GT16-026A; Hidrocloruro de sevelámero; Sévélamer, Chlorhydrate de; Sevelameri Hydrochloridum. Allylamine polymer with 1-chloro-2,3-epoxypropane hydrochloride.

Севеламера Гидрохлорид

CAS — 182683-00-7.
ATC — V03AE02.
ATC Vet — QV03AE02.

NOTE. The name sevelamer has been used for both sevelamer and sevelamer hydrochloride.

Adverse Effects and Precautions

The most common adverse effects associated with sevelamer are diarrhoea, nausea and vomiting, constipation, headache, cough and other respiratory symptoms, dizziness, hypotension or hypertension, peripheral oedema, pain, and fever. Flatulence, pharyngitis, skin rashes, and pruritus have also occurred; intestinal obstruction and ileus have been reported.

Sevelamer is contra-indicated in patients with hypophosphataemia and in bowel obstruction. Patients with renal impairment may develop hypocalcaemia or hypercalcaemia, and serum-calcium concentrations should be monitored. Serum-chloride concentrations should also be monitored during treatment with sevelamer.

Interactions

Sevelamer has been reported to reduce the bioavailability of ciprofloxacin and should not be taken at the same time. It may also affect the bioavailability of other drugs and should be given at least 3 hours before or 1 hour after drugs for which a reduction in bioavailability could be clinically significant.

Uses and Administration

Sevelamer is a phosphate binder used for hyperphosphataemia in patients with chronic renal failure on haemodialysis. It is given orally as either the carbonate or the hydrochloride. The initial dose is 0.8 to 1.6 g of sevelamer carbonate or sevelamer hydrochloride three times daily with each meal, depending on the severity of hyperphosphataemia. Doses should then be adjusted according to plasma-phosphate concentrations; the usual maintenance dose is from 0.8 to 4 g with each meal.

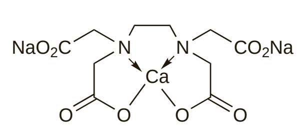
Натрия Кальция Эдетат

$C_{10}H_{12}CaN_2Na_2O_8,xH_2O$ = 374.3 (anhydrous).

CAS — 62-33-9 (anhydrous sodium calcium edetate); 23411-34-9 (sodium calcium edetate hydrate).



NOTE. Do not confuse with sodium edetate; see Inappropriate Administration under Sodium Edetate, p.1464.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., US,* and *Viet.*

Ph. Eur. 6.2 (Sodium Calcium Edetate). A white or almost white, hygroscopic, powder. Freely soluble in water; practically insoluble in alcohol. A 20% solution in water has a pH of 6.5 to 8.0. Store in airtight containers. Protect from light.

USP 31 (Edetate Calcium Disodium). White, slightly hygroscopic, odourless, crystalline powder or granules. Freely soluble in water. pH of a 20% solution in water is between 6.5 and 8.0. Store in airtight containers.

Adverse Effects

Sodium calcium edetate is nephrotoxic and may cause renal tubular necrosis. Nausea, diarrhoea, and abdominal cramp may also occur. Thrombophlebitis has followed intravenous infusion and may be related to the concentration of the injection. Pain at the intramuscular injection site has been reported. Other adverse effects that have been reported include fever, malaise, headache, myalgia, histamine-like responses such as sneezing, nasal congestion, and lachrymation, skin eruptions, transient hypotension, and ECG abnormalities.

Sodium calcium edetate chelates zinc within the body and zinc deficiency has been reported. Displacement of calcium from sodium calcium edetate may lead to hypercalcaemia.

Effects on the kidneys. Of 130 children with lead poisoning who received chelation therapy with sodium calcium edetate (25 mg/kg intramuscularly every 12 hours) and dimercaprol (3 mg/kg intramuscularly every 4 hours) for a total of 5 days, 21 developed clinical evidence of nephrotoxicity and in 4 severe oliguric acute renal failure began 1 or 2 days after chelation therapy was discontinued.[1] Nephrotoxicity was probably attributable to the use of sodium calcium edetate.

1. Moel DI, Kumar K. Reversible nephrotic reactions to a combined 2,3-dimercapto-l-propanol and calcium disodium ethylenediaminetetraacetic acid regimen in asymptomatic children with elevated blood lead levels. *Pediatrics* 1982; **70:** 259–62.

Precautions

Sodium calcium edetate should be used with caution, if at all, in patients with renal impairment. Daily urinalysis to monitor proteinuria and haematuria and regular monitoring of renal and hepatic function has been recommended.

Sodium calcium edetate can chelate several endogenous metals, including zinc, and may increase their excretion; therapy should be intermittent to prevent severe deficiency developing and monitoring of zinc levels may be required (see below).

Sodium calcium edetate should not be given orally in the treatment of lead poisoning as it has been suggested that absorption of lead may be increased as a result.

◊ Sodium calcium edetate 500 mg/m^2 was given by deep intramuscular injection every 12 hours for 5 days to 10 children with asymptomatic lead poisoning.[1] Blood-lead concentrations decreased to about 58% of the pretreatment values after 5 days and were essentially unchanged for up to 60 hours after the last dose. Sodium calcium edetate also produced a marked fall in the mean plasma-zinc concentration but this rebounded rapidly after the end of treatment. Mean urinary-lead excretion increased about 21-fold during the first 24 hours of therapy and urinary-zinc excretion increased about 17-fold. Sodium calcium edetate had little effect on the plasma concentrations or urinary excretion of copper. The results suggested that careful monitoring of zinc was required during treatment with sodium calcium edetate.

1. Thomas DJ, Chisolm JJ. Lead, zinc and copper decorporation during calcium disodium ethylenediamine tetraacetate treatment of lead-poisoned children. *J Pharmacol Exp Ther* 1986; **239:** 829–35.

Pharmacokinetics

Sodium calcium edetate is poorly absorbed from the gastrointestinal tract. It distributes primarily to the extracellular fluid and does not penetrate cells. It is not significantly metabolised; after intravenous injection about 50% of a dose is excreted in the urine in 1 hour and over 95% in 24 hours.

Uses and Administration

Sodium calcium edetate is the calcium chelate of disodium edetate and is a chelator used in the treatment of lead poisoning (see Treatment of Adverse Effects under Lead, p.2332). It mobilises lead from bone and tissues and aids elimination from the body by forming a stable, water-soluble, lead complex which is readily excreted by the kidneys. It may be used as a diagnostic test for lead poisoning but measurement of blood-lead concentrations is generally preferred.

Sodium calcium edetate is also a chelator of other heavy-metal polyvalent ions, including chromium. A cream containing sodium calcium edetate 10% has been used in the treatment of chrome ulcers and skin sensitivity reactions due to contact with heavy metals.

Sodium calcium edetate is also used as a pharmaceutical excipient and as a food additive.

In the treatment of lead poisoning, sodium calcium edetate may be given by intramuscular injection or by intravenous infusion. The intramuscular route may be preferred in patients with lead encephalopathy and increased intracranial pressure in whom excess fluids must be avoided, and also in children, who have an increased risk of incipient encephalopathy. Sodium calcium edetate may initially aggravate the symptoms of lead toxicity due to mobilisation of stored lead and it has often been given with dimercaprol (p.1444) in patients who are symptomatic; the first dose of dimercaprol should preferably be given at least 4 hours before the sodium calcium edetate.

For intravenous infusion, 1 g of sodium calcium edetate should be diluted with 250 to 500 mL of glucose 5% or sodium chloride 0.9%; a concentration of 3% should not be exceeded. The infusion should be given over a period of at least 1 hour. In the UK, the usual dose is 60 to 80 mg/kg daily given in two divided doses. In the USA, a dose of 1000 mg/m^2 daily is suggested for asymptomatic adults and children; a daily dose of 1500 mg/m^2 may be used in patients with symptomatic poisoning. Treatment is given for up to 5 days, repeated if necessary after an interval of at least 2 days. Any further treatment with sodium calcium edetate should then not be given for at least 7 days.

Alternatively, the same daily dose of sodium calcium edetate may be given intramuscularly in 2 to 4 divided doses as a 20% solution. Intramuscular injection of sodium calcium edetate is painful and it is recommended that preservative-free procaine hydrochloride should be added to a concentration of 0.5 to 1.5% to minimise pain; alternatively, lidocaine may be added to a concentration of 0.5%.

As excretion is mainly renal, an adequate urinary flow must be established and maintained during treatment. Doses should be reduced in patients with renal impairment (see below).

Administration in renal impairment. The dose of sodium calcium edetate should be reduced in patients with renal impairment. It has been suggested that the dose is halved and given once daily in moderate impairment, and that smaller and less frequent doses are given if renal impairment is severe.

Sodium Cellulose Phosphate

Cellulose Sodium Phosphate *(USAN)*; Celulosa, fosfato sódico de.

CAS — 9038-41-9; 68444-58-6.

ATC — V03AG01.

ATC Vet — QV03AG01.

Pharmacopoeias. In *US.*

USP 31 (Cellulose Sodium Phosphate). It is prepared by the phosphorylation of alpha cellulose. A free-flowing, cream-coloured, odourless, powder. Insoluble in water, in dilute acids, and in most organic solvents. The pH of a filtrate of a 5% mixture in water is between 6.0 and 9.0. The inorganic bound phosphate content is not less than 31.0% and not more than 36.0%; the free phosphate content is not more than 3.5%; and the sodium content is not less than 9.5% and not more than 13.0%, all calculated on the dried basis. The calcium binding capacity, calculated on the dried basis, is not less than 1.8 mmol per g.

Adverse Effects and Precautions

Diarrhoea and other gastrointestinal disturbances have been reported.

Sodium cellulose phosphate should not be given to patients with primary or secondary hyperparathyroidism, hypomagnesaemia, hypocalcaemia, bone disease, or enteric hyperoxaluria. It should be used cautiously in pregnant women and children, since they have high calcium requirements.

Patients should be monitored for electrolyte disturbances. Uptake of sodium and phosphate may increase and sodium cellulose phosphate should not be given to patients with renal failure or conditions requiring a restricted sodium intake such as heart failure. Theoretically, long-term treatment could result in calcium deficiency; regular monitoring of calcium and parathyroid hormone has therefore been recommended. Sodium cellulose phosphate is not a totally selective exchange resin and the intestinal absorption of other dietary cations may be reduced; magnesium deficiency has been reported but may be corrected by dosage reduction or oral magnesium supplements. Urinary excretion of oxalate may increase and dietary restriction of oxalate intake may be necessary.

◊ Potential complications of long-term sodium cellulose phosphate therapy include secondary hyperparathyroidism and bone disease; deficiency of magnesium, copper, zinc, and iron; and hyperoxaluria. A study in 18 patients[1] with absorptive hypercalciuria and recurrent renal stones indicated that these complications could largely be avoided if use was confined to those with absorptive hypercalciuria (hypercalciuria, intestinal hyperabsorption of calcium, and normal or suppressed parathyroid function), if the dose was adjusted so as not to reduce intestinal calcium absorption or urinary calcium subnormally (the optimal maintenance dose in most patients was 10 g daily), if oral magnesium supplements were provided, and if a moderate dietary restriction of calcium and oxalate was imposed. There was no evidence of zinc, copper, or iron deficiency.

1. Pak CYC. Clinical pharmacology of sodium cellulose phosphate. *J Clin Pharmacol* 1979; **19:** 451–7.

Interactions

Sodium cellulose phosphate binds with calcium and other cations. Use with calcium or magnesium salts, including cation-donating antacids or laxatives, may reduce its efficacy. Magnesium supplements are often required in patients receiving sodium cellulose phosphate but should be given at least one hour before or after any dose of the resin since the absorption of the magnesium may otherwise be impaired.

Uses and Administration

Sodium cellulose phosphate, the sodium salt of the phosphate ester of cellulose, is a cation-exchange resin that exchanges sodium ions for calcium and other divalent cations. When given orally, it binds calcium ions within the stomach and intestine to form a non-absorbable complex which is excreted in the faeces. Theoretically a 5-g dose will bind about 350 mg calcium. It is used in the treatment of absorptive hypercalciuria type I with recurrent formation of calcium-containing renal calculi (p.2181), usually with a moderate dietary calcium restriction. Sodium cellulose phosphate is also used in the treatment of hypercalcaemia associated with osteopetrosis, sarcoidosis, and vitamin D intoxication, and in idiopathic hypercalcaemia of infancy, although other more effective agents are usually used (see Vitamin D-mediated Hypercalcaemia, p.1668).

The usual initial dose is 15 g daily by mouth in 3 divided doses with meals reducing to 10 g daily for maintenance. A suggested dose for children is 10 g daily (but see Adverse Effects and Precautions, above). The powder may be taken dispersed in water or sprinkled onto food. Oral magnesium supplements equivalent to about 60 or 90 mg (about 2.4 or 3.6 mmol) of elemental magnesium twice daily have been recommended for patients taking daily doses of sodium cellulose phosphate 10 or 15 g respectively. The magnesium supplement should not be given simultaneously with sodium cellulose phosphate.

Sodium cellulose phosphate has also been used for the investigation of calcium absorption.

Tetrasodium Edetate

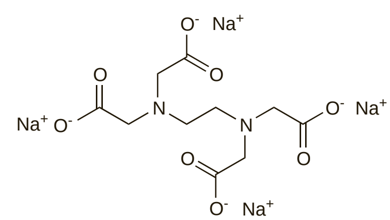
Edetate Sodium *(USAN)*.

$C_{10}H_{12}N_2Na_4O_8$ = 380.2.

CAS — 64-02-8.

ATC — S01XA05.

ATC Vet — QS01XA05.



Incompatibility. See under Edetic Acid, p.1445.

Adverse Effects and Treatment

In common with other edetates (see Sodium Calcium Edetate, p.1462), sodium edetate may cause gastrointestinal effects such as nausea, vomiting, and diarrhoea. Pain at the site of injection and thrombophlebitis may also occur. Other adverse effects include fever, headache, skin rashes, hypotension, and hyperuricaemia; nephrotoxicity has also been reported, particularly following overdosage.

Hypocalcaemia can occur, particularly if sodium edetate is infused too rapidly or in too concentrated a solution and tetany, convulsions, respiratory arrest, and cardiac arrhythmias may result.

The rate of infusion should be decreased if signs of muscle reactivity occur. The infusion should be discontinued if tetany occurs and should only be restarted cautiously after plasma ionised and total calcium concentrations indicate a need for further treatment and tetany has stopped. Calcium supplements may be given intravenously for hypocalcaemia but should be used with extreme caution in patients with tetany, particularly in digitalised patients since the effect of the digitalis may be reversed.

Inappropriate administration. There have been fatalities in both children and adults when they were given sodium edetate instead of *sodium calcium edetate* (p.1462), which is a chelator used for the treatment of lead poisoning.[1,2] The FDA had received reports of 11 deaths associated with the use of sodium edetate over the period 1971 to 2007;[3] in 5 cases, sodium edetate was given instead of sodium calcium edetate, and in 2 cases, sodium edetate was given instead of *etomidate* (p.1783). In some cases, confusion had arisen due to the use of the term EDTA in prescribing the drug. The FDA has subsequently recommended that the full product name be used, and that prescribers should consider including the indication for use on the prescription.[2]

3. FDA. Questions and answers on edetate disodium (marketed as Endrate and generic products) (issued 16th January 2008). Available at: http://www.fda.gov/cder/drug/infopage/edetate_disodium/QA.htm (accessed 25/01/08)

Precautions

Sodium edetate is contra-indicated in patients with renal impairment and should be used with caution in patients with hypokalaemia, tuberculosis, impaired cardiac function, diabetes mellitus, or a history of seizures. Plasma-electrolyte concentrations, particularly ionised calcium, and renal function should be monitored regularly; daily urinalysis is also recommended. Sodium edetate is irritant to the tissues and must be diluted before infusion; the recommended rate should not be exceeded.

Uses and Administration

Sodium edetate is a chelator with a high affinity for calcium, with which it forms a stable, soluble complex that is readily excreted by the kidneys. It has been given intravenously, as the disodium and trisodium salts, in the emergency treatment of hypercalcaemia (p.1668); it has also been used to control digitalis-induced cardiac arrhythmias, although less toxic agents are generally preferred (p.1260). It is also used topically to treat calcium deposits in the eye.

Sodium edetate also chelates other polyvalent metals but, unlike sodium calcium edetate, which is saturated with calcium, it is not used for the treatment of heavy metal poisoning since hypocalcaemia rapidly develops.

In the treatment of hypercalcaemia, injections containing varying amounts of disodium and trisodium edetate are used. In the UK, the trisodium salt is generally used. A dose of up to 70 mg/kg daily has been suggested for adults; children may be given up to 60 mg/kg daily. It should be given by slow intravenous infusion over 2 to 3 hours and each gram of trisodium edetate should be diluted with 100 mL of glucose 5% or sodium chloride 0.9%. In the USA, disodium edetate is given in an adult dose of 50 mg/kg in 24 hours by slow intravenous infusion; the maximum daily dose is 3 g. Children may be given 40 to 70 mg/kg in 24 hours. The injection should be diluted with 500 mL of sodium chloride 0.9% or glucose 5% for adults or to a concentration not greater than 3% for children, and infused over 3 hours or more, preferably 4 to 6 hours. The dosage may be repeated for a further 4 days followed by a two-day interval before subsequent courses of treatment. If necessary, up to fifteen doses may be given in total.

Sodium edetate is used in the treatment of calcium deposits from calcium oxide or calcium hydroxide burns of the eye and in the treatment of calcified corneal opacities, either by topical application after removing the appropriate area of corneal epithelium or by iontophoresis. Irrigation has also been suggested for zinc chloride injury to the eye, but treatment may be ineffective unless started within 2 minutes. In the UK, a 0.4% solution of the trisodium salt is used for topical application to the eye; in the USA, a 0.35 to 1.85% solution of the disodium salt has been suggested.

Sodium edetates are also used in cleaners for contact lenses and as antoxidant synergists in cosmetic and pharmaceutical preparations.

Atherosclerosis. Calcium is thought to be necessary for several steps in atherogenesis and removal of calcium from atherosclerotic plaques using a chelator such as disodium edetate has been tried in patients with atherosclerosis (p.1159). However, reports of beneficial clinical responses are largely anecdotal or from small, short-term, or uncontrolled clinical studies; a meta-analysis[1] of controlled trials concluded that there was insufficient evidence of benefit or harm, and a further randomised trial[2] in patients with coronary heart disease found no benefit with sodium edetate treatment. In addition, adverse effects are common with chelation therapy, and fatalities have been reported;[3] literature reviews[4,5] considering both uncontrolled and controlled studies have concluded that in view of the potential toxicity of such treatment it should be considered obsolete.

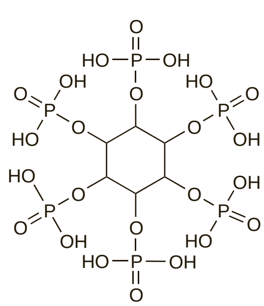
Sodium Fytate *(rINNM)*

Fitato sódico; Fytate de Sodium; Natrii Fytas; Phytate Sodium *(USAN)*; Sodium Phytate; SQ-9343. The nonasodium salt of *myo*-inositol hexakis(dihydrogen phosphate); Sodium cyclohexanehexyl(hexaphosphate).

Натрий Фэитат

$C_6H_9Na_9O_{24}P_6$ = 857.9.

CAS — 83-86-3 (fytic acid); 7205-52-9 (sodium fytate).



(fytic acid)

Profile

Sodium fytate reacts with calcium in the gastrointestinal tract to form non-absorbable calcium fytate which is excreted in the faeces. Sodium fytate has been used in a similar manner to sodium cellulose phosphate (p.1463) to reduce the absorption of calcium from the gut in the treatment of hypercalciuria. It also binds other metals; fytic acid has been used as an antoxidant, and as an adjunct in topical preparations for hyperpigmentation disorders.

Sodium fytate labelled with technetium-99m (p.2055) has been used intravenously for imaging of the liver.

Sodium Nitrite

Dusitan sodný; E250; Natrii nitris; Natrio nitritas; Natrium Nitrosum; Natriumnitriitti; Natriumnitrit; Nátrium-nitrit; Nitrito sódico; Sodium, nitrite de; Sodu azotyn; Sodyum Nitrit.

$NaNO_2$ = 69.00.

CAS — 7632-00-0.

ATC — V03AB08.

ATC Vet — QV03AB08.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Sodium Nitrite). Hygroscopic, colourless crystals or mass, or yellowish rods. Freely soluble in water; soluble in alcohol. Store in airtight containers.

USP 31 (Sodium Nitrite). A white to slightly yellow granular powder, or white or practically white, opaque fused masses or sticks. It is deliquescent in air. Soluble 1 in 1.5 of water; sparingly soluble in alcohol. Its solutions are alkaline to litmus. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°.

Adverse Effects

Sodium nitrite may cause nausea and vomiting, abdominal pain, dizziness, headache, flushing, cyanosis, tachypnoea, and dyspnoea; vasodilatation resulting in syncope, hypotension, and tachycardia may occur. Overdosage may result in cardiovascular collapse, coma, convulsions, and death. Ionised nitrites readily oxidise haemoglobin to methaemoglobin, causing methaemoglobinaemia.

Sodium nitrite is a precursor for the formation of nitrosamines, many of which are carcinogenic in *animals*, but a relationship with human cancer has not been established.

Methaemoglobinaemia. Severe methaemoglobinaemia has been reported after the consumption of nitrite-contaminated meat,[1,2] as well as following inadvertent ingestion of sodium nitrite.[3,4]

1. Walley T, Flanagan M. Nitrite-induced methaemoglobinaemia. *Postgrad Med J* 1987; **63:** 643–44.
2. Kennedy N, *et al.* Faulty sausage production causing methaemoglobinaemia. *Arch Dis Child* 1997; **76:** 367–8.
3. Finan A, *et al.* Methaemoglobinaemia associated with sodium nitrite in three siblings. *BMJ* 1998; **317:** 1138–9.
4. Anonymous. Methemoglobinemia following unintentional ingestion of sodium nitrite—New York, 2002. *MMWR* 2002; **51:** 639–42.

Treatment of Adverse Effects

When toxicity results from the ingestion of nitrites, treatment is supportive and symptomatic; oxygen and methylthioninium chloride may be required for methaemoglobinaemia although methylthioninium chloride should not be given if cyanide poisoning is suspected since cyanide may be displaced. Exchange transfusion may be considered when methaemoglobinaemia is severe.

Uses and Administration

Sodium nitrite is used with sodium thiosulfate in the treatment of cyanide poisoning (p.2045). Sodium nitrite produces methaemoglobinaemia and it is thought that cyanide ions combine with the methaemoglobin to produce cyanmethaemoglobin, thus protecting cytochrome oxidase from the cyanide ions; however, other mechanisms may have a significant role. As the cyanmethaemoglobin slowly dissociates, the cyanide is converted to relatively non-toxic thiocyanate and is excreted in the urine. Sodium thiosulfate provides an additional source of sulfur for this reaction and this accelerates the process.

The usual dosage regimen in adults is 300 mg of *sodium nitrite* (10 mL of a 3% solution) given intravenously over 5 to 20 minutes followed by 12.5 g of *sodium thiosulfate* (50 mL of a 25% solution or 25 mL of a 50% solution) given intravenously over a period of about 10 minutes. A suggested dosage regimen in children is about 4 to 10 mg/kg of *sodium nitrite*, given as a 3% solution (0.13 to 0.33 mL/kg), to a maximum of 300 mg (10 mL), followed by about 400 mg/kg of *sodium thiosulfate*, as a 25 or 50% solution (1.65 mL/kg of a 25% solution) to a maximum of 12.5 g (50 mL of a 25% solution). The methaemoglobin concentration should not be allowed to exceed 30 to 40%. If symptoms of cyanide toxicity recur, the injections of nitrite and thiosulfate may be repeated after 30 minutes at half the initial doses.

Sodium nitrite has also been suggested in the treatment of hydrogen sulfide poisoning (see p.1690).

Sodium nitrite has been used as a rust inhibitor, for example in instrument disinfectants. It is also used as a preservative in foods such as cured meats but should not be used in food for infants under the age of 3 months due to the risk of methaemoglobinaemia. Potassium nitrite is also used as a food preservative.

Sodium Polystyrene Sulfonate

Natrii polystyrenesulfonas; Natrii Polystyrensulfonas; Natrio polistirensulfonatas; Natriumpolystyreenisulfonaatti; Natriumpolystyrensulfonat; Natrium-polystyrensulfonát; Poliestirenosulfonato sódico; Polystyrène sulfonate sodique; Sodium Polystyrene Sulphonate.

CAS — 9003-59-2; 9080-79-9; 25704-18-1.

ATC — V03AE01.

ATC Vet — QV03AE01.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US*.

Ph. Eur. 6.2 (Sodium Polystyrene Sulphonate). An almost white to light brown powder. It contains 9.4 to 11.0% of sodium, calculated with reference to the dried substance. Each g exchanges 2.8 mmol to 3.4 mmol of potassium, calculated with reference to the dried substance. Practically insoluble in water, in alcohol, and in dichloromethane. Store in airtight containers.

USP 31 (Sodium Polystyrene Sulfonate). A golden brown, fine, odourless powder containing not more than 10% of water. The sodium content is not less than 9.4% and not more than 11.5%, calculated on the anhydrous basis. Each g exchanges not less than 110 mg and not more than 135 mg of potassium, calculated on the anhydrous basis. Insoluble in water.

Adverse Effects

Anorexia, nausea, vomiting, constipation, and occasionally diarrhoea may develop during treatment with sodium polystyrene sulfonate. Constipation may be severe; large doses in elderly patients and in children may result in faecal impaction and gastrointestinal concretions have occurred after oral use in neonates. If necessary a mild laxative may be used to prevent or treat constipation (but see Precautions, below, for laxatives that should be avoided).

Serious potassium deficiency can occur with sodium polystyrene sulfonate and signs of severe hypokalaemia may include irritability, confusion, ECG abnormalities, cardiac arrhythmias, and severe muscle weakness. Like other cation-exchange resins, sodium polystyrene sulfonate is not totally selective and its use may result in other electrolyte disturbances such as hypocalcaemia. Significant sodium retention may also occur, especially in patients with renal impairment, and may lead to heart failure.

Effects on the gastrointestinal tract. Colonic necrosis, including some fatalities, has been reported[1-3] after use of enemas containing sodium polystyrene sulfonate in sorbitol. Studies in *animals*[1] suggested that use of sorbitol was a contributory factor, although failure to irrigate the colon adequately, as recommended by the manufacturer, was also suggested[4,5] as a possible cause. Both colonic[6] and upper gastrointestinal necrosis[7] have also been reported after oral or nasogastric sodium polystyrene sulfonate with sorbitol, and there has also been a report[8] of colonic necrosis with oral sodium polystyrene sulfonate alone.

7. Abraham SC, *et al.* Upper gastrointestinal tract injury in patients receiving kayexalate (sodium polystyrene sulfonate) in sorbitol: clinical, endoscopic, and histopathologic findings. *Am J Surg Pathol* 2001; **25:** 637–44.
8. Cheng ES, *et al.* Colonic necrosis and perforation following oral sodium polystyrene sulfonate (Resonium A /Kayexelate) in a burn patient. *Burns* 2002; **28:** 189–90.

Effects on the lungs. Particles of sodium polystyrene sulfonate were found at autopsy in the lungs of 3 patients who had taken the resin orally and were associated with acute bronchitis and bronchopneumonia in 2 and with early bronchitis in the third.[1] It was suggested that, where possible, it may be preferable to give sodium polystyrene sulfonate rectally, but if it has to be given orally the patient should be positioned carefully to avoid aspiration.

1. Haupt HM, Hutchins GM. Sodium polystyrene sulfonate pneumonitis. *Arch Intern Med* 1982; **142:** 379–81.

Precautions

Sodium polystyrene sulfonate should not be given orally to neonates, and is contra-indicated by any route in neonates with reduced gut motility or in any patient with obstructive bowel disease. Care is also needed with rectal use in neonates and children in order to avoid impaction of the resin. Treatment should be discontinued if clinically significant constipation develops. Although sorbitol has been recommended for the prophylaxis and treatment of constipation, there have been reports of colonic necrosis in patients receiving this combination (see Effects on the Gastrointestinal Tract, above) and licensed product information advises against the use of sorbitol with polystyrene sulfonates. Magnesium-containing laxatives are also contra-indicated (see Interactions, below).

Patients receiving sodium polystyrene sulfonate should be monitored for electrolyte disturbances, especially hypokalaemia. Since serum concentrations may not always reflect intracellular potassium deficiency, symptoms of hypokalaemia should also be watched for and the decision to stop treatment assessed individually.

Use of sodium polystyrene sulfonate can result in sodium overloading and it should be used cautiously in patients with renal failure or conditions requiring a restricted sodium intake, such as heart failure and severe hypertension; calcium polystyrene sulfonate (p.1438) may be preferred in these patients.

The possible effects of sodium polystyrene sulfonate on serum electrolytes should be considered when interpreting diagnostic measurements.

After use of sodium polystyrene sulfonate retention enemas, the colon should be irrigated to ensure removal of the resin.

Interactions

Sodium polystyrene sulfonate is not totally selective for potassium and may also bind other cations. When given orally with cation-donating antacids and laxatives such as magnesium hydroxide, aluminium hydroxide, or calcium carbonate, competition for binding sites may reduce the potassium-lowering effect of the resin. In addition, particularly in patients with renal impairment, metabolic alkalosis may develop due to binding of the cation by the resin; this prevents neutralisation of bicarbonate ions in the small intestine. Seizures have been reported due to metabolic alkalosis in a patient given magnesium hydroxide with sodium polystyrene sulfonate and use of magnesium-containing laxatives should therefore be avoided.

Ion-exchange resins may also bind other drugs, reducing their absorption. Drugs that have been affected include levothyroxine (see p.2173) and lithium salts.

Hypokalaemia may exacerbate the adverse effects of digoxin and sodium polystyrene sulfonate should be used with caution in patients receiving cardiac glycosides.

Uses and Administration

Sodium polystyrene sulfonate, the sodium salt of sulfonated styrene copolymer with divinylbenzene, is a cation-exchange resin that exchanges sodium ions for potassium ions and other cations in the gastrointestinal tract when given orally or rectally. The exchanged resin is then excreted in the faeces. Each gram of resin exchanges about 3 mmol of potassium *in vitro*, and about 1 mmol *in vivo*.

Sodium polystyrene sulfonate is used to enhance potassium excretion in the treatment of hyperkalaemia, including that associated with anuria or severe oliguria (caution is required due to the sodium content). An effect may not be evident for several hours or longer, and in severe hyperkalaemia, where a rapid effect is required, other measures must also be considered (see p.1669).

Serum-electrolyte concentrations should be monitored throughout treatment and doses given according to response.

The usual oral dose is 15 g up to four times daily as a suspension in water or syrup or as a sweetened paste. It should not be given in fruit juices that have a high potassium content. A suggested oral dose for children is 1 g/kg daily in divided doses for acute hyperkalaemia, reduced to a maintenance dose of 500 mg/kg daily; the oral route is not recommended for neonates.

When oral use is difficult, sodium polystyrene sulfonate may be given rectally as an enema. The usual daily dose is 30 g given as a suspension in 100 mL of 2% methylcellulose '450' and 100 mL of water and retained, if possible, for at least 9 hours; higher doses, shorter retention times, and alternative vehicles have also been used. After retention of the enema the colon should be irrigated to remove the resin. Initial therapy may involve both oral and rectal routes. Children and neonates may be given rectal doses similar to the oral doses suggested for children; particular care is needed with rectal use in children as excessive dosage or inadequate dilution could result in impaction of resin.

Other polystyrene sulfonate resins include calcium polystyrene sulfonate (p.1438), which is used similarly to the sodium resin and potassium polystyrene sulfonate (p.1460), which has been used in the treatment of hypercalciuria. Aluminium polystyrene sulfonate, ammonium polystyrene sulfonate, and magnesium polystyrene sulfonate have all occasionally been used.

Sodium Thiosulfate

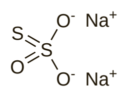
Disodium Thiosulfate Pentahydrate; Hiposulfito sódico; Natrii thiosulfas; Natrii Thiosulfas Pentahydricus; Natrio tiosulfatas; Natrium Thiosulfuricum; Natriumtiosulfaatti; Natriumtiosulfat; Nátrium-tioszulfát; Sodium Hyposulphite; Sodium, thiosulfate de; Sodium Thiosulphate; Sodu tiosiarczan; Sodyum Tiyosülfat; Thiosíran sodný pentahydrát; Tiosulfato sódico.

$Na_2S_2O_3,5H_2O$ = 248.2.

CAS — 7772-98-7 (anhydrous sodium thiosulfate); 10102-17-7 (sodium thiosulfate pentahydrate).

ATC — V03AB06.

ATC Vet — QV03AB06.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Sodium Thiosulphate). Colourless transparent crystals; efflorescent in dry air. It dissolves in its own water of crystallisation at about 49°. Very soluble in water; practically insoluble in alcohol. A 10% solution in water has a pH of 6.0 to 8.4. Store in airtight containers.

USP 31 (Sodium Thiosulfate). Large, colourless crystals, or a coarse, crystalline powder. Is deliquescent in moist air and effloresces in dry air at temperatures exceeding 33°. Soluble 1 in 0.5 of water; insoluble in alcohol. Its solutions are neutral or faintly alkaline to litmus. Store in airtight containers.

Incompatibility. Sodium thiosulfate may reduce the activity of some preservatives, including bronopol (p.1633), phenylmercuric salts (see Phenylmercuric Nitrate, p.1657), and thiomersal (p.1664).

Stability. Solutions of sodium thiosulfate 50% stored in air developed cloudiness or a deposit after autoclaving.[1] Addition of sodium phosphate 0.5% or 1.2% improved stability but solutions became cloudy or developed a deposit after 12 and 6 weeks respectively at 25°. Solutions containing sodium bicarbonate 0.5% became cloudy or developed a deposit after 12 weeks at 25°. No significant improvement in stability was obtained when the concentration of sodium thiosulfate was reduced to 30% or 15%, or when the injection was sealed under nitrogen.

1. Anonymous. Sodium thiosulphate injection–effect of additives on stability. *PSGB Lab Rep* P/75/3 1975.

Adverse Effects

Apart from osmotic disturbances sodium thiosulfate is relatively non-toxic. Large oral doses have a cathartic action.

Pharmacokinetics

Sodium thiosulfate is poorly absorbed from the gastrointestinal tract. After intravenous injection it is distributed throughout the extracellular fluid and rapidly excreted in the urine.

◊ An intravenous infusion of sodium thiosulfate 12 g/m^2 was given over 6 hours to 8 patients receiving intraperitoneal antineoplastic therapy.[1] The thiosulfate was rapidly eliminated, 95% being excreted within 4 hours of stopping the infusion; on average only 28.5% of the dose was recovered unchanged in the urine. The mean plasma elimination half-life was 80 minutes.

1. Shea M, *et al.* Kinetics of sodium thiosulfate, a cisplatin neutralizer. *Clin Pharmacol Ther* 1984; **35:** 419–25.

Uses and Administration

Sodium thiosulfate is used in the treatment of cyanide poisoning (p.2045). Sodium thiosulfate may be effective alone in less severe cases of cyanide poisoning, but it is often used with sodium nitrite (p.1464).

Sodium thiosulfate acts as a sulfur-donating substrate for the enzyme rhodanese, which catalyses the conversion of cyanide to relatively non-toxic thiocyanate, and thus accelerates the detoxification of cyanide.

The usual dosage regimen in adults is 300 mg of *sodium nitrite* (10 mL of a 3% solution) given intravenously over 5 to 20 minutes followed by 12.5 g of *sodium thiosulfate* (50 mL of a 25% solution or 25 mL of a 50% solution) given intravenously over a period of about 10 minutes. A suggested dosage regimen in children is about 4 to 10 mg/kg of *sodium nitrite*, given as a 3% solution (0.13 to 0.33 mL/kg) to a maximum of 300 mg (10 mL), followed by about 400 mg/kg of *sodium thiosulfate*, as a 25 or 50% solution (1.65 mL/kg of a 25% solution) to a maximum of 12.5 g (50 mL of a 25% solution). The methaemoglobin concentration should not be allowed to exceed 30 to 40%. If symptoms of cyanide toxicity recur, the injections of nitrite and thiosulfate may be repeated after 30 minutes at half the initial doses.

Sodium thiosulfate is used as an isotonic 4% solution in the management of extravasation of chlormethine and has been tried in the management of extravasation of some other antineoplastics (but see below).

Sodium thiosulfate has been used for its antifungal properties. Sodium thiosulfate and magnesium thiosulfate are included in mixed preparations for a variety of disorders.

Antineoplastic toxicity. Sodium thiosulfate may be used in the management of extravasation of chlormethine and some other antineoplastics (although this is a contentious area, see p.640). It is also used to inactivate some antineoplastics before disposal.

Sodium thiosulfate, given by intravenous infusion, has also been investigated for reducing the systemic toxicity of some antineoplastics. It has been reported to reduce the incidence of nephrotoxicity associated with intraperitoneal cisplatin (see Prophylaxis under Effects on the Kidneys, p.699) and to reduce hearing loss associated with carboplatin (see Effects on the Ears, p.693).

Bromate poisoning. Sodium thiosulfate has been used in the treatment of bromate poisoning[1,2] although its clinical efficacy is unclear;[3] it is thought to act by reducing bromate to the less toxic bromide ion, but evidence is lacking.[3,4] Although it has been given orally, this is no longer recommended since toxic sulfide may be formed.[4] However, intravenous sodium thiosulfate may have a role in some clinical circumstances.[4,5]

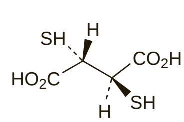
Succimer *(BAN, USAN, rINN)*

DIM-SA; DMSA; Succimère; Succímero; Succimero; Succimerum; Suksimeeri. *meso*-2,3-Dimercaptosuccinic acid; (R^*,S^*)-2,3-Dimercapto-butanedioic acid.

Сукцимер

$C_4H_6O_4S_2$ = 182.2.

CAS — 304-55-2.



Pharmacopoeias. In *Chin.*

Adverse Effects and Precautions

Succimer may cause gastrointestinal disorders, skin rashes, increases in serum transaminase, flu-like symptoms, drowsiness, and dizziness. Mild to moderate neutropenia has been reported in some patients and regular full blood counts are recommended during therapy. Succimer should be used with caution in patients with renal impairment or a history of hepatic disease.

Pharmacokinetics

Succimer is rapidly but incompletely absorbed after oral doses. It undergoes rapid and extensive metabolism and is excreted mainly in the urine with small amounts excreted in the bile and via the lungs.

1. Dart RC, *et al.* Pharmacokinetics of meso-2,3-dimercaptosuccinic acid in patients with lead poisoning and in healthy adults. *J Pediatr* 1994; **125:** 309–16.

Uses and Administration

Succimer is a chelator structurally related to dimercaprol (p.1444). It forms water-soluble chelates with heavy metals and is used in the treatment of lead poisoning. It has also been used in the treatment of poisoning with arsenic or mercury.

Succimer, labelled with a radionuclide, is used in nuclear medicine.

In the treatment of lead poisoning, succimer is given orally in a dose of 10 mg/kg or 350 mg/m^2 every 8 hours for 5 days then every 12 hours for an additional 14 days. The course of treatment may be repeated if necessary, usually after an interval of not less than 2 weeks.

Lead poisoning. Succimer is an effective lead chelator[1] and is used in the management of lead poisoning (see Treatment of Adverse Effects under Lead, p.2332). Succimer is also used in children with chronic lead exposure, and various dosage regimens have been studied.[2] It is generally only indicated if blood-lead concentrations are greater than 45 micrograms per 100 mL;[3] although short-term studies[4] in children with lower concentrations have shown effective reduction of blood lead, no effect on neurodevelopmental outcome has been shown in follow-up studies[5,6] and treatment of such children remains controversial.

6. Dietrich KN, *et al.* Effect of chelation therapy on the neuropsychological and behavioral development of lead-exposed children after school entry. *Pediatrics* 2004; **114:** 19–26.

Mercury poisoning. Succimer, given orally, increases the renal excretion of mercury and may be used in mercury poisoning (see Treatment of Adverse Effects under Mercury, p.2342). In patients with renal impairment, the succimer-mercury chelate may accumulate, and alternative methods have been tried. Extracorporeal infusion of succimer into the arterial blood line during haemodialysis, a procedure known as extracorporeal regional complexing haemodialysis, produced a substantial clearance of mercury in an anuric patient following intoxication with inorganic mercury.[1] Clearance was about ten times greater than that achieved with haemodialysis after intramuscular dimercaprol.

Adverse Effects and Precautions

Tiopronin has similar adverse effects and precautions to those of penicillamine (p.1456).

Incidence of adverse effects. In a study of 140 patients[1] with rheumatoid arthritis receiving long-term treatment with tiopronin, adverse effects necessitated withdrawal of treatment in 56 patients (40%). The majority of adverse effects occurred within the first 6 months of treatment. The most common were those affecting the skin and mucous membranes (46 patients) including stomatitis, pruritus, erythema, and 1 case of pemphigus. Proteinuria developed in 5 patients and nephrotic syndrome in 3. Haematological disorders developed in 13 patients. Gastrointestinal disorders and ageusia were also reported.

In another study of 74 patients[2] with rheumatoid arthritis adverse effects were reported in 32 patients (43%) and necessitated withdrawal in 24%. The most common adverse effects were ageusia (21%), mucocutaneous lesions (16%), and gastrointestinal disturbances (14%). Haematological disorders occurred in 5 patients and proteinuria in 3 patients.

In a comparative study in 200 patients,[3] treatment was withdrawn due to toxicity in 27% of patients taking tiopronin and 21% of patients treated with gold.

1. Sany J, *et al.* Etude de la tolérance à long terme de la thiopronine (Acadione) dans le traitement de la polyarthrite rhumatoïde: a propos de 140 cas personnels. *Rev Rhum* 1990; **57:** 105–11.
2. Ehrhart A, *et al.* Effets secondaires dus au traitement par la tiopronine de 74 polyarthrites rhumatoïdes. *Rev Rhum* 1991; **58:** 193–7.
3. Ferraccioli GF, *et al.* Long-term outcome with gold thiosulphate and tiopronin in 200 rheumatoid patients. *Clin Exp Rheumatol* 1989; **7:** 577–81.

Effects on the blood. Haematological disorders including leucopenia or thrombocytopenia have been reported during long-term studies of tiopronin. Isolated cases of agranulocytosis[1] and bone marrow aplasia[2] have also occurred.

See also Incidence of Adverse Effects, above.

1. Corda C, *et al.* Thiopronin-induced agranulocytosis. *Therapie* 1990; **45:** 161.
2. Taillan B, *et al.* Aplasie médullaire au cours d'une polyarthrite rhumatoïde traitée par tiopronine. *Rev Rhum* 1990; **57:** 443–4.

Effects on the kidneys. Proteinuria developed in 3 patients 4 to 14 months after starting treatment with tiopronin for cystinuria.[1] None of the patients had clinical symptoms of nephrotic syndrome. Renal biopsies in 2 patients demonstrated membranous glomerulonephritis. Proteinuria disappeared in all 3 patients 4 to 5 months after tiopronin was discontinued. However, there was histological evidence of irreversible changes and signs of progressive glomerular lesions in 1 patient.

1. Lindell A, *et al.* Membranous glomerulonephritis induced by 2-mercaptopropionylglycine (2-MPG). *Clin Nephrol* 1990; **34:** 108–15.

Effects on the skin. Mucocutaneous lesions are among the most common adverse effects of tiopronin (see Incidence of Adverse Effects, above). Reversible lichenoid eruptions have been reported[1] in a patient after treatment with tiopronin for 2 years, and may have been due to an immunological reaction to the sulfhydryl group. Lesions resembling pemphigus have also been reported in a few patients[2,3] and may require treatment with a corticosteroid or other immunosuppressant.

1. Kurumaji Y, Miyazaki K. Tiopronin-induced lichenoid eruption in a patient with liver disease and positive patch test reaction to drugs with sulfhydryl group. *J Dermatol* 1990; **17:** 176–81.

Pharmacokinetics

Tiopronin is absorbed from the gastrointestinal tract. Up to 48% of the dose is reported to be excreted in the urine during the first 4 hours and up to 78% by 72 hours.

◊ References.

1. Carlsson SM, *et al.* Pharmacokinetics of intravenous 2-mercaptopropionylglycine in man. *Eur J Clin Pharmacol* 1990; **38:** 499–503.
2. Carlsson MS, *et al.* Pharmacokinetics of oral tiopronin. *Eur J Clin Pharmacol* 1993; **45:** 79–84.

Uses and Administration

Tiopronin is a sulfhydryl compound and chelator with properties similar to those of penicillamine (p.1458). It is given orally in the management of cystinuria, in conjunction with adequate hydration and alkalinisation of the urine, in usual doses of 0.8 to 1 g daily in divided doses. The dose should be adjusted according to the urinary cystine concentration; up to 2 g daily has been given. Tiopronin should be given on an empty stomach. Tiopronin is used in similar doses in rheumatoid arthritis. It has been used in hepatic disorders and heavy-metal poisoning, and has been given by inhalation as a mucolytic in respiratory disorders. It may also be given by intravenous or intramuscular injection.

The sodium salt has also been used.

Cystinuria. Tiopronin may be used as an alternative to penicillamine in the management of cystinuria (p.1459). A multicentre study[1] in 66 patients with cystine nephrolithiasis found that addition of tiopronin in doses of up to 2 g daily (mean 1.193 g) to standard alkali and fluid therapy significantly reduced urinary-cystine concentrations and the rate of new stone formation. Adverse effects were similar to those reported with penicillamine. In the 49 patients who had previously received penicillamine, 41 had adverse effects with penicillamine, requiring cessation of therapy in 34, whereas 37 had adverse effects with tiopronin, requiring drug withdrawal in 15. In the remaining 17 patients, 11 had adverse effects with tiopronin and 1 discontinued treatment because of proteinuria. However, of the 34 patients who had been unable to tolerate penicillamine, 22 were able to continue treatment with tiopronin.

1. Pak CYC, *et al.* Management of cystine nephrolithiasis with alpha-mercaptopropionylglycine. *J Urol (Baltimore)* 1986; **136:** 1003–8.

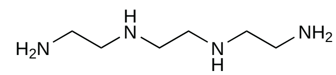
Триентина Дигидрохлорид

$C_6H_{18}N_4,2HCl$ = 219.2.

CAS — 112-24-3 (trientine); 38260-01-4 (trientine dihydrochloride).



(trientine)

Pharmacopoeias. In *US.*

USP 31 (Trientine Hydrochloride). A white to pale yellow crystalline powder. Freely soluble in water; slightly soluble in alcohol; insoluble in chloroform and in ether; soluble in methyl alcohol. pH of a 1% solution in water is between 7.0 and 8.5. Store under an inert gas in airtight containers at 2° to 8°. Protect from light.

Adverse Effects and Precautions

Trientine may cause nausea and skin rashes; duodenitis and colitis have also been reported. Iron deficiency may occur; if iron supplements are given an interval of at least 2 hours between the doses of trientine and iron has been recommended. Recurrence of symptoms of SLE has been reported in a patient who had previously reacted to penicillamine.

Interactions

Chelation of trientine with metal ions in the diet or in mineral supplements may impair the absorption of both. Trientine should not be taken with mineral supplements and should be taken at least 1 hour apart from food, other drugs, or milk, to reduce the likelihood of absorption being affected. Iron supplements should be taken at least 2 hours before or after trientine.

Uses and Administration

Trientine is a copper chelator used in a similar way to penicillamine in the treatment of Wilson's disease (p.1459). It tends to be used in patients intolerant of penicillamine.

Trientine dihydrochloride is given orally, preferably on an empty stomach. In the USA, the usual initial dose for adults is 0.75 to 1.25 g daily in 2 to 4 divided doses; this may be increased to a maximum of 2 g daily if required. In children, the usual initial dose is 500 to 750 mg daily, increased if necessary to a maximum dose of 1.5 g daily. In the UK, a dose of 1.2 to 2.4 g daily, in 2 to 4 divided doses, has been recommended for adults; children may be given an initial dose of 0.6 to 1.5 g daily.

Preparations

USP 31: Trientine Hydrochloride Capsules.

Proprietary Preparations (details are given in Part 3)

USA: Syprine.

Trimedoxime Bromide *(rINN)*

Bromuro de trimedoxima; Dipyroxime; TMB-4; Trimédoxime, Bromure de; Trimedoximi Bromidum. 1,1′-Trimethylenebis[4-formylpyridinium bromide]dioxime.

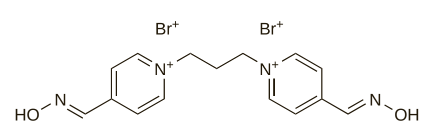
$C_{15}H_{18}Br_2N_4O_2$ = 446.1.

CAS — 56-97-3.



NOTE. Do not confuse with Trimedoxine, a range of veterinary antibacterial preparations.

Profile

Trimedoxime bromide is a cholinesterase reactivator given with atropine in the treatment of organophosphorus poisoning.

◊ References.

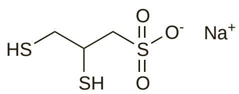
1. Kozer E, *et al.* Pediatric poisoning from trimedoxime (TMB4) and atropine automatic injectors. *J Pediatr* 2005; **146**: 41–4.

Unithiol

DMPS; Unithiolum; Unitiol; Unitioli. Sodium 2,3-dimercaptopropanesulfonate .

$C_3H_7NaO_3S_3$ = 210.3.

CAS — 4076-02-2.



Profile

Unithiol is a chelator structurally related to dimercaprol (p.1444). It is water soluble and reported to be less toxic than dimercaprol. Unithiol is used in the treatment of poisoning by heavy metals including arsenic, lead, and inorganic and organic mercury compounds; it has also been used in poisoning with chromium or cadmium, although its efficacy is not established.

Unithiol is given orally in doses of 100 mg three or four times daily in chronic poisoning. In acute poisoning, a dose of 1.2 to 2.4 g by mouth, in divided doses over 24 hours, has been suggested. It may also be given parenterally in patients with severe toxicity; a suggested intravenous dose is 3 to 5 mg/kg every 4 hours, reducing the frequency after 1 to 2 days and then changing to oral therapy.

◊ Reviews.

2. Aposhian HV, *et al.* Mobilization of heavy metals by newer, therapeutically useful chelating agents. *Toxicology* 1995; **97:** 23–38.

Arsenic poisoning. Complete recovery, without renal or neurological sequelae, has been reported[1,2] following the use of unithiol in patients with potentially lethal acute arsenic poisoning; haemodialysis was also used in 1 patient.[2] Increased urinary arsenic excretion, with some improvement in clinical symptoms, has also been reported[3,4] with unithiol in chronic arsenic toxicity.

1. Moore DF, *et al.* Acute arsenic poisoning: absence of polyneuropathy after treatment with 2,3-dimercaptopropanesulphonate (DMPS). *J Neurol Neurosurg Psychiatry* 1994; **57:** 1133–5.
2. Kruszewska S, *et al.* The use of haemodialysis and 2,3 propanesulphonate (DMPS) to manage acute oral poisoning by lethal dose of arsenic trioxide. *Int J Occup Med Environ Health* 1996; **9:** 111–115.

Lead poisoning. Unithiol may be used in lead poisoning, although other chelators are generally preferred (see Treatment of Adverse Effects under Lead, p.2332). In a study of 12 children[1] it reduced lead concentrations in blood but did not affect the concentrations of copper or zinc in plasma, although the urinary excretion of lead, copper, and zinc was increased during treatment.

1. Chisolm JJ, Thomas DJ. Use of 2,3-dimercaptopropane-1-sulfonate in treatment of lead poisoning in children. *J Pharmacol Exp Ther* 1985; **235:** 665–9.

Mercury poisoning. Unithiol is used in poisoning with mercury and mercury salts (see Treatment of Adverse Effects under Mercury, p.2342) and has been given by various routes. In 7 patients with poisoning due to mercury vapour or mercuric oxide, unithiol 100 mg given twice daily by mouth for up to 15 days enhanced urinary elimination of mercury;[1] the urinary elimination of copper and zinc was also increased in most patients and 2 developed skin rashes. A dose of 5 mg/kg intramuscularly three times daily, reduced to once daily by the third day of treatment, effectively reduced the half-life of mercury in the blood after poisoning with methylmercury.[2] A patient with severe mercuric chloride poisoning was treated successfully with unithiol given intravenously for 4 weeks, then orally for 3 weeks.[3] Unithiol has also been used with haemofiltration in patients with inorganic mercury poisoning and acute renal failure.[4,5]

5. Dargan PI, *et al.* Case report: severe mercuric sulphate poisoning treated with 2,3-dimercaptopropane-1-sulphonate and haemodiafiltration. *Crit Care* 2003; **7:** R1–R6.

Wilson's disease. Unithiol 200 mg twice daily[1] was used successfully to maintain cupriuresis in a 13-year-old boy with Wilson's disease (p.1459) after he developed systemic lupus during treatment with penicillamine and with trientine dihydrochloride. Unithiol was started in 2 similar patients[1] but both withdrew from treatment, one because of fever and a fall in leucocyte count after a test dose and the other because of intense nausea and taste impairment.

Cz.: Dimaval; ***Ger.:*** Dimaval; Mercuval.

Colouring Agents

Colouring agents have long been used in foods and cosmetics in an attempt to improve the appearance of the product or subject. They are also used in medicinal preparations for several reasons. These include improving their acceptability to patients, giving drug formulations a distinctive appearance to help identification and prevent counterfeiting, and increasing the stability of light-sensitive drugs. This chapter describes colouring agents used in medicines and some used in foods, cosmetics, and some medical devices including contact lenses. Most countries restrict the nature and extent of colouring agents used for such purposes. Matters of concern that have received considerable publicity include sensitivity reactions (see Tartrazine, p.1473) and hyperactive behaviour in children (see below).

Colouring agents can be broadly categorised into synthetic dyes and into natural agents (such as canthaxanthin, caramel, carmine, chlorophyll, cochineal, saffron, and turmeric, all of which are described in this chapter). Other compounds that may be used as cosmetic colours or food colours (and which are themselves natural pigments of foodstuffs) are anthocyanins (E163) and carotenoids. In this latter group are included bixin and norbixin which are obtained from annatto, capsanthin (E160c) which is an extract of paprika, carotenes (E160a) (see Betacarotene, p.1930), lycopene (E160d), beta-apo-8′-carotenal (E160e), and the ethyl ester of beta-apo-8′-carotenoic acid (E160f); lutein (E161b), like canthaxanthin, can be classified either as a carotenoid or as a xanthophyll.

Other agents described elsewhere in *Martindale* that may be used as food colours include aluminium (p.2254), gold (p.2316), indigo carmine (p.2324), patent blue V (p.2363), riboflavin (p.1977), silver (p.2387), and titanium dioxide (p.1617).

Hyperactivity. The role of foods and food additives in hyperactive behaviour (p.2148) has been debated for many years.

A meta-analysis[1] sought to evaluate whether artificial food colours (including carmoisine, sunset yellow, and tartrazine) contribute to the symptomatology of childhood hyperactivity in children already diagnosed with hyperactive syndromes. For the primary analysis only double-blind placebo-controlled trials were evaluated. Overall, the results supported the hypothesis that such food colours promote hyperactivity in hyperactive children as measured on behavioural ratings. However, caution was advised about making any clinical recommendations. The restrictions needed for a colour-free diet may be too much of a burden on the children and their families. Also, there is a need to find out more about the biology of artificial food colours and to ascertain whether responses depend on an allergic or pharmacological mechanism. A further study[2] in a more general population of children also found that mixtures of food additives including food colourings were associated with an increase in hyperactivity, although the European Food Safety Authority considered[3] that the results of the study were not conclusive enough to necessitate a change in the approved daily intakes for the additives involved.

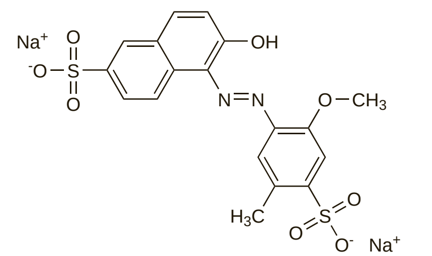
CAS — 25956-17-6.



Profile

Allura red AC is used as a colouring agent in drugs, cosmetics, and foodstuffs.

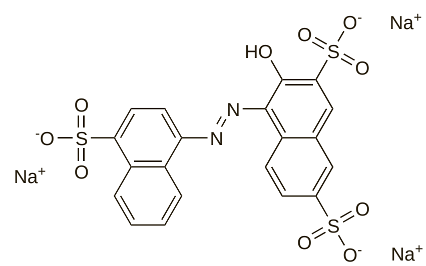
Amaranth

Amarant; Amaranto; Bordeaux S; CI Acid Red 27; CI Food Red 9; Colour Index No. 16185; E123; formerly FD & C Red No. 2; Naphtol Rot S. It consists mainly of trisodium 3-hydroxy-4-(4-sulphonato-1-naphthylazo)naphthalene-2,7-disulphonate.

Амарант

$C_{20}H_{11}N_2Na_3O_{10}S_3$ = 604.5.

CAS — 915-67-3.



NOTE. The name amaranth is also used to refer to a number of species of plant in the genus *Amaranthus*, some of which have been used as a source of dyes.

Profile

Amaranth is used as a colouring agent in medicines, foodstuffs, and cosmetics.

Carcinogenicity. Although some evidence of carcinogenicity was found in early *animal* studies, subsequent work failed to confirm these findings and in the UK amaranth is considered suitable for use as a food colour.[1]

1. MAFF. Food advisory committee: final report on the review of the colouring matter in food regulations 1973. *FdAC/REP/4*. London: HMSO, 1987.

Annatto

CI Natural Orange 4; Colour Index No. 75120; E160(b).

Аннато

CAS — 1393-63-1.

Bixin

E160(b). Methyl (9-*cis*)-hydrogen-6,6′-diapo-ψ,ψ-carotenedioate.

Биксин

$C_{25}H_{30}O_4$ = 394.5.

CAS — 6983-79-5.

Norbixin

E160(b). 6,6′-Diapo-ψ,ψ-carotenedioic acid.

Норбиксин

$C_{24}H_{28}O_4$ = 380.5.

CAS — 542-40-5.

Profile

Annatto is a colouring agent extracted from the seeds of *Bixa orellana*. It and its derivatives, the carotenoids bixin and norbixin, are used to colour foods, drugs, and cosmetics.

Bixin and norbixin exist in both *cis-* and *trans-* forms, with the *cis-* forms being the major colouring components.

Hypersensitivity. Hypersensitivity reactions to annatto have been reported rarely. A single case of anaphylaxis has been reported in a male patient, after consumption of cereal coloured with annatto.[1] Sensitivity was confirmed with a skin test. The design of several oral challenge studies using annatto has been criticised in a literature review.[2] However, the authors of the review acknowledge that annatto may cause rare but severe reactions in some patients, and may worsen the symptoms of patients with recurrent urticaria.

Beetroot Red

Beet Red; E162; Rojo de remolacha.

Свекольный Красный

CAS — 7659-95-2 (betanine).

Profile

Beetroot red is obtained from the roots of red beets, *Beta vulgaris* var. *rubra* (Chenopodiaceae). The main colouring principle consists of betacyanins of which betanine is the main constituent. Beetroot red is used as a colouring agent for drugs, foodstuffs, and cosmetics.

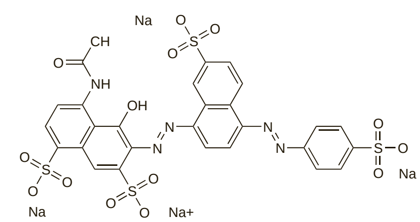
Black PN

Brilliant Black BN; Brilliant Black PN; CI Food Black 1; Colour Index No. 28440; E151; Negro brillante BN; Negro PN; Noir Brillant BN. It consists mainly of tetrasodium 4-acetamido-5-hydroxy-6-[7-sulphonato-4-(4-sulphonatophenylazo)-1-naphthylazo]naphthalene-1,7-disulphonate.

Бриллиантовый Чёрный PN; Чёрный Блестящий PN

$C_{28}H_{17}N_5Na_4O_{14}S_4$ = 867.7.

CAS — 2519-30-4.



Profile

Black PN is used as a colouring agent in medicines, cosmetics, and foods.

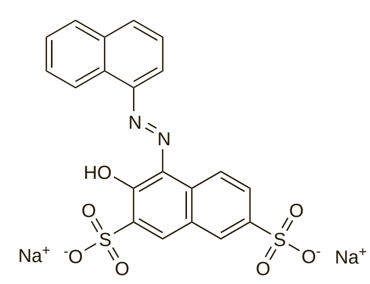
Bordeaux B

Azorubrum; Burdeos B; CI Acid Red 17; Colour Index No. 16180. It consists mainly of disodium 3-hydroxy-4-(1-naphthylazo)naphthalene-2,7-disulphonate.

Кислотный Бордо

$C_{20}H_{12}N_2Na_2O_7S_2$ = 502.4.

CAS — 5858-33-3.



Profile

Bordeaux B was formerly used as a colouring agent for medicines and foods but has been replaced by other colours.

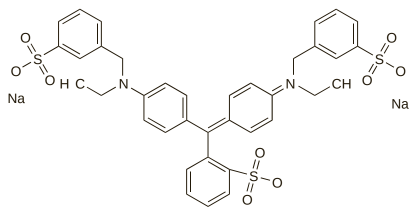
Brilliant Blue FCF

Azul brillante FCF; Blue EGS; CI Acid Blue 9; CI Food Blue 2; Colour Index No. 42090; E133; FD & C Blue No. 1; Patent Blue AC. Disodium 4′,4″-bis(*N*-ethyl-3-sulphonatobenzylamino)triphenylmethylium-2-sulphonate.

Бриллиантовый Голубой FCF; Синий Блестящий FCF

$C_{37}H_{34}N_2Na_2O_9S_3$ = 792.8.

CAS — 3844-45-9.



Profile

Brilliant blue FCF is used as a colouring agent in medicines, cosmetics, and foodstuffs. The parent compound, brilliant blue, is under investigation as a stain in ophthalmology.

Enteral feeds. Blue colourings such as brilliant blue FCF have been added to enteral feeds to aid the detection of pulmonary aspiration but such use has been associated with toxic effects. Blue discoloration of the skin, initially attributed to cyanosis, has been reported[1] in a child who received a large quantity of brilliant blue FCF as a colouring in an enteral feed. Abnormal systemic absorption of the dye has also been reported[2] in 2 critically ill patients, both of whom subsequently died. As of September 2003 the FDA was aware of 20 cases of blue discoloration of body fluids and skin associated with the use of blue dyes, including 12 fatalities.[3] Most cases occurred in patients with a history of sepsis, suggesting that altered intestinal permeability could be a factor.

Brown FK

Chocolate Brown FK; CI Food Brown 1; E154; Marrón FK. A mixture of 6 azo dyes: sodium 2′,4′-diaminoazobenzene-4-sulphonate; sodium 2′,4′-diamino-5′-methylazobenzene-4-sulphonate; disodium 4,4′-(4,6-diamino-1,3-phenylenebisazo) dibenzenesulphonate; disodium 4,4′-(2,4-diamino-1,3-phenylenebisazo) dibenzenesulphonate; disodium 4,4′-(2,4-diamino-5-methyl-1,3-phenylenebisazo) dibenzenesulphonate; trisodium 4,4′,4″-(2,4-diaminobenzene-1,3,5-triazo)tribenzenesulphonate.

Коричневый FK

CAS — 8062-14-4.

Profile

Brown FK is used as a colouring agent for foodstuffs.

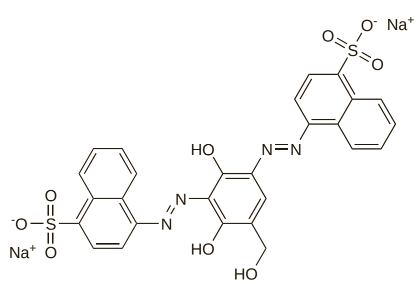
Brown HT

Chocolate Brown HT; CI Food Brown 3; Colour Index No. 20285; E155; Marrón HT. Disodium 4,4′-(2,4-dihydroxy-5-hydroxymethyl-1,3-phenylenebisazo)di(naphthalene-1-sulphonate).

Коричневый HT

$C_{27}H_{18}N_4Na_2O_9S_2$ = 652.6.

CAS — 4553-89-3.



Profile

Brown HT is used as a colouring agent for drugs and foodstuffs.

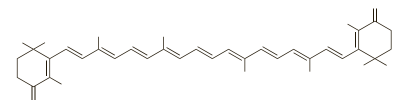
Canthaxanthin

Cantaxantina; Canthaxanthinum; CI Food Orange 8; Colour Index No. 40850; E161(g); Kantaksantiini; Kantaxantin. β,β-Carotene-4,4′-dione.

Кантаксантин

$C_{40}H_{52}O_2$ = 564.8.

CAS — 514-78-3.



Profile

Canthaxanthin is a carotenoid but unlike betacarotene or β-apo-8′-carotenal it has no vitamin A activity. It has selected uses as a food colouring and is given to salmon, trout, and poultry to colour their flesh, and to laying hens to colour the yolks of their eggs. It is also used to colour drugs and cosmetics.

Canthaxanthin has also been given orally to produce an artificial suntan, and as an adjunct to betacarotene in the management of erythropoietic protoporphyria (see Porphyrias under Haem Derivatives, p.1448). Such use has led to retinal deposits and in some cases to impairment of vision.

Adverse effects. Canthaxanthin has been associated with retinal changes involving accumulation of bright yellow particles around the macula ('gold speck' maculopathy), and alterations in eye function and visual deterioration have occurred.[1,2] Although these reports have related to oral use either for the production of an artificial tan by means of pigment deposition in the skin or for the medical treatment of erythropoietic protoporphyria, there has been concern about the use of canthaxanthin as a food colouring, and it was suggested that it should be restricted to use as a feed additive for farmed salmon and trout in order to produce a coloration of the fish flesh.[1] The results of long-term toxicity studies in *animals* have led to concern[2] about the potential for hepatotoxicity. However, subsequent studies failed to confirm hepatotoxicity in humans and it is now allowed as a food colouring,[3] although its uses are restricted in some countries.

There has also been a report of fatal aplastic anaemia in a patient who took canthaxanthin in order to produce an artificial tan.[4]

Preparations

Proprietary Preparations (details are given in Part 3)

Arg.: Bronzearte.

Multi-ingredient: ***Arg.:*** Bronsul; Sol Bronce Vital.

Caramel

Burnt Sugar; Caramelo; Sacch. Ust.; Saccharum Ustum.

Жжёный Сахар; Сахарный Колер

CAS — 8028-89-5.

Pharmacopoeias. In *USNF.*

USNF 26 (Caramel). A concentrated solution of the product obtained by heating sugar or glucose until the sweet taste is destroyed and a uniform dark brown mass results, a small amount of alkali or of alkaline carbonate or a trace of mineral acid being added while heating. It is a thick, dark brown liquid, having the characteristic odour of burnt sugar, and a pleasant bitter taste. One part dissolved in 1000 parts of water yields a clear solution having a distinct yellowish-orange colour. The colour of this solution is not changed and no precipitate is formed after exposure to sunlight for 6 hours. When spread as a thin layer on a glass plate, it appears homogeneous, reddish-brown, and transparent. Miscible with water; immiscible with ether, with chloroform, with acetone, with petroleum spirit, and with benzene; soluble in dilute alcohol up to 55%. Store in airtight containers.

Profile

Caramels are used in foods, drugs, and cosmetics to produce pale yellow to dark brown colours. They have no calorific value. They are complex mixtures of compounds prepared by heating carbohydrates (food-grade sweeteners consisting of glucose, fructose, or polymers of these) either alone or in the presence of acids or alkalis (food-grade citric or sulfuric acids or calcium, potassium, or sodium hydroxides, or mixtures of these). The caramels can be classified according to the reactants used in the manufacturing process:

Class I (E150a, plain caramel, spirit caramel, or caustic caramel); no ammonium or sulfite compounds are used.

Class II (E150b or caustic sulfite caramel); sulfite compounds used but not ammonium compounds.

Class III (E150c, ammonia caramel, or beer caramel); ammonium compounds used but not sulfite compounds

Class IV (E150d, sulfite ammonia caramel, or soft-drink caramel); both ammonium and sulfite compounds used.

Some caramels also have flavouring properties.

Carbazole Violet

Colour Index No. 51319; Pigment Violet 23. 8,18-Dichloro-5,15-diethyl-5,15-dihydrodiindolo(3,2-*b*:3′,2′-*m*)triphenodioxazine.

Фиолетовый Карбазол

$C_{34}H_{22}Cl_2N_4O_2$ = 589.5.

CAS — 6358-30-1.

Profile

Carbazole violet is a colouring agent used in cosmetics and contact lenses.

Carmine

Carmín; CI Natural Red 4; Cochineal Carmine; Colour Index No. 75470; E120.

Кармин

CAS — 1390-65-4.

Profile

Carmine is an aluminium lake of the colouring matter of cochineal (p.1471). It contains carminic acid, an anthraquinone glycoside. Unless precautions are taken during manufacture and transport to prevent contamination, carmine may be infected with salmonella micro-organisms.

Carmine and some of its salts are used as colouring agents in medicines, foodstuffs, and cosmetics.

Carmine passes through the gastrointestinal tract unchanged and has been used as a faecal 'marker'.

Hypersensitivity. By February 2004 the FDA was aware of 35 cases of hypersensitivity to carmine, carminic acid, or cochineal extract published in the scientific and medical literature and/or reported directly to the FDA. Hypersensitivity reactions to carmine, carminic acid, or cochineal extract included contact dermatitis (4 cases), urticaria/angioedema (9), occupational asthma (10), and systemic anaphylaxis (12). In more than half of these reports, there was evidence of an IgE-mediated diagnostic response. The adverse effects included allergic reactions to foods containing carmine and cochineal extract, occupational asthma from exposure to carmine, and allergic reactions to topically applied cosmetics containing carmine.

The FDA concluded that carmine and cochineal extract may cause potentially severe allergic responses and proposed that food and cosmetic labelling be enhanced; a declaration of inactive ingredients in drugs was already in force.[1]

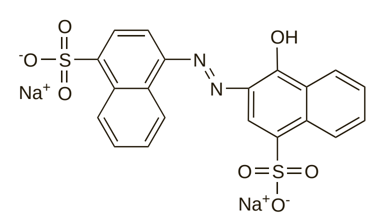
Carmoisine

Azorrubina; Azorubine; Carmoisina; CI Food Red 3; Colour Index No. 14720; E122. It consists mainly of disodium 4-hydroxy-3-(4-sulphonato-1-naphthylazo)naphthalene-1-sulphonate.

Кармуазин

$C_{20}H_{12}N_2Na_2O_7S_2$ = 502.4.

CAS — 3567-69-9.



Profile

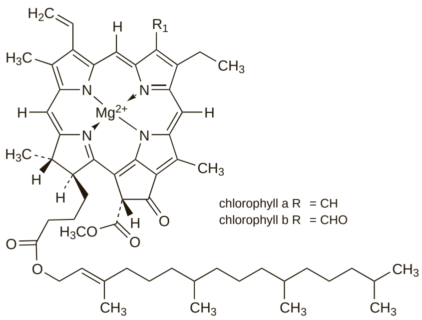
Carmoisine is used as a colouring agent in foods, medicines, and cosmetics. It has also been investigated clinically as a stain, to aid visualisation of malignant neoplasms of the skin during surgery.

Chlorophyll

CI Natural Green 3; Clorofila; Colour Index No. 75810; E140 (chlorophylls or chlorophyllins).

Хлорофилл

CAS — 479-61-8 (chlorophyll a); 519-62-0 (chlorophyll b).



Chlorophyllin Copper Complex Sodium

Clorofilina cúprica, complejo sódico de.

Медного Комплекса Хлорофиллина Натриевая Соль

Pharmacopoeias. In *US.*

USP 31 (Chlorophyllin Copper Complex Sodium). It contains sodium salts of copper-chelated chlorophyll derivatives, but no artificial colouring. Store in airtight containers. Protect from light.

Profile

Chlorophyll is a green photosynthetic pigment found in plants, algae, and cyanobacteria (blue-green algae). There are four closely related forms of chlorophyll. Chlorophyll a ($C_{55}H_{72}MgN_4O_5$ = 893.5) and chlorophyll b ($C_{55}H_{70}MgN_4O_6$ = 907.5) are found in plants and some types of algae; chlorophyll c, further subdivided into chlorophyll c1 ($C_{35}H_{30}MgN_4O_5$ = 610.9) and chlorophyll c2 ($C_{35}H_{28}MgN_4O_5$ = 608.9), is found in some types of algae; and chlorophyll d ($C_{54}H_{70}MgN_4O_6$ = 895.5) is found in some types of algae and in cyanobacteria.

Oil-soluble chlorophyll derivatives. Replacement of the magnesium atom in the chlorophylls by 2 hydrogen atoms using dilute mineral acids produces olive-green water-insoluble phaeophytins. Copper phaeophytins (sometimes called copper chlorophyll complex; E141) can be formed; these are more stable to acids and to light than the chlorophylls.

Water-soluble chlorophyll derivatives. When the chlorophylls are hydrolysed with alkali, phytyl alcohol and methyl alcohol are split off and green water-soluble chlorophyllins are formed as the potassium or sodium salts. Similar water-soluble compounds can be prepared in which the magnesium is replaced by copper to give copper chlorophyllin complex (E141).

Chlorophylls and chlorophyllins, as well as the copper complexes of these compounds, are used mainly as colouring agents, in foods, medicines, and cosmetics.

Chlorophyll is used clinically, as an external application in the treatment of wounds and ulcers, and as a mouthwash. There is no clear evidence that it accelerates healing but it is considered to have a deodorant action. Chlorophyllin and copper chlorophyllin complex are used similarly. Chlorophyll is also used as a dietary supplement.

Preparations

Proprietary Preparations (details are given in Part 3)
USA: Chloresium; Derifil; Pals.

CI Solvent Yellow 18

CI Food Yellow 12; Colour Index No. 12740. 4-[(2,4-Dimethylphenyl)azo]-2,4-dihydro-5-methyl-2-phenyl-3*H*-pyrazol-3-one.

$C_{18}H_{18}N_4O$ = 306.4.

CAS — 6407-78-9.

Profile

CI Solvent Yellow 18 is a colouring agent used in contact lenses.

CI Vat Orange 1

Colour Index No. 59105. Dibromo-dibenzo (b,def) chrysene-7,14-dione.

CI Кубовый Оранжевый 1

$C_{24}H_{10}Br_2O_2$ = 490.1.
CAS — 1324-11-4.

Profile

CI Vat Orange 1 is a colouring agent used in contact lenses.

Citranaxanthin

Citranaxantina; Elbli.

$C_{33}H_{44}O$ = 456.7.
CAS — 3604-90-8.

Profile

Citranaxanthin is a colouring agent used in animal feeds, to colour the fat of poultry and the egg-yolks of laying hens. It has vitamin A activity.

Citrus Red 2

CI Solvent Red 80; Colour Index No. 12156. 1-(2,5-Dimethoxyphenylazo)-2-naphthol.

Цитрусовый Красный 2

$C_{18}H_{16}N_2O_3$ = 308.3.
CAS — 6358-53-8.

Profile

Citrus Red 2 is a colouring agent used in foods.

Cochineal

CI Natural Red 4; Coccionella; Coccus; Coccus Cacti; Cochinilla; Colour Index No. 75470; E120.

Кошениль

CAS — 1343-78-8.

Pharmacopoeias. In *Br.*

BP 2008 (Cochineal). The dried female insect, *Dactylopius coccus* containing eggs and larvae. It has a characteristic odour. It complies with a test for contamination with *Escherichia coli* and salmonellae.

Profile

Cochineal, which is a source of carmine, is used as a red colouring agent in food, medicines, and cosmetics.

There have been reports of sensitivity reactions including anaphylaxis, after use of products containing cochineal (see Hypersensitivity in Carmine, p.1470).

Homoeopathy. Cochineal has been used in homoeopathic medicines under the following names: Coccus cacti; Dactylopius coccus; Coc. c.

Curcumin

Colour Index No. 75300; Curcumina; E100; Kurkum; Kurkumina; Turmeric Yellow. 1,7-Bis(4-hydroxy-3-methoxyphenyl)hepta-1,6-diene-3,5-dione.

Куркумин

$C_{21}H_{20}O_6$ = 368.4.
CAS — 458-37-7.

Profile

Curcumin is the main colouring component of turmeric (p.1473). It is used as a colouring agent for drugs, foodstuffs, and cosmetics. It is also thought to be responsible for many of the pharmacological properties for which turmeric is under investigation (see p.1473).

Preparations

Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***India:*** Well-Beeing†; ***Ital.:*** Depatox.

Eosin

CI Acid Red 87; Colour Index No. 45380; D & C Red No. 22; Eosin Y; Eosina; Éosine Disodique. The disodium salt of 2′,4′,5′,7′-tetrabromofluorescein .

Эозин

$C_{20}H_6Br_4Na_2O_5$ = 691.9.
CAS — 548-26-5; 17372-87-1.
ATC — D08AX02.
ATC Vet — QD08AX02.

Pharmacopoeias. In *Fr.*

Profile

Eosin has been incorporated in solution-tablets to give a distinctive colour to solutions prepared from them. It is also used in cosmetics.

Eosin has been used as a topical antiseptic in nappy rash, burns and other skin conditions, although other drugs are usually preferred.

Adverse effects. Contact dermatitis to eosin was seen relatively frequently between the 1920s and 1940s when it was a common colour in lipsticks. Fewer reports of hypersensitivity have occurred since then: changing fashions in cosmetic colours have reduced use of eosin and, if used, a purer grade and lower concentrations are now usually employed. However, cases of dermatitis after topical application of antiseptic preparations containing eosin were noted in the 1980s and 1990s. One report[1] suggested that an impurity might be responsible but another[2] implicated eosin itself after patch tests were performed with various products and pure tetrabromofluorescein.

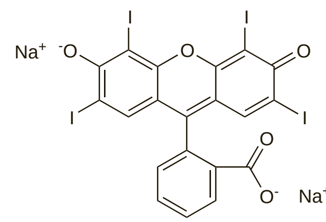
1. Tomb RR. Allergic contact dermatitis from eosin. *Contact Dermatitis* 1991; **24:** 27–9.
2. Koch P, *et al.* Allergic contact dermatitis from purified eosin. *Contact Dermatitis* 1995; **32:** 92–5.

Erythrosine

CI Food Red 14; Colour Index No. 45430; E127; Eritrosin BS; Eritrosina; Erythrosine BS; Erythrosine Sodium; FD & C Red No. 3. The monohydrate of the disodium salt of 2′,4′,5′,7′-tetraiodofluorescein .

Эритрозин

$C_{20}H_6I_4Na_2O_5,H_2O$ = 897.9.
CAS — 568-63-8 (anhydrous erythrosine sodium); 16423-68-0 (anhydrous erythrosine sodium); 49746-10-3 (erythrosine sodium monohydrate).



(anhydrous erythrosine sodium)

Profile

Erythrosine is used as a colouring agent for medicines, foods, and cosmetics. It is also used as a disclosing agent for plaque on teeth.

◊ Although early *animal* studies had indicated that erythrosine might have an adverse effect on the thyroid gland, a review[1] of the evidence and later studies, suggested that erythrosine was not genotoxic or mutagenic and was suitable for use as a food colour. Similarly, no evidence was found to support restricting its use in pharmaceutical products.[2]

1. MAFF. Food advisory committee: final report on the review of the colouring matter in food regulations 1973. *FdAC/REP/4.* London: HMSO, 1987.
2. European Commission. Opinion on toxicological data on colouring agents for medicinal products: erythrosin, adopted by the Scientific Committee on Medicinal Products and Medical Devices on 21 October 1998. Preparations

Proprietary Preparations (details are given in Part 3)
Arg.: Revelplac; ***Austral.:*** Disclo-Gel; Disclo-Tabs; ***UK:*** Ceplac.
Multi-ingredient: ***Arg.:*** Revelplac 2001.

Ferric Oxide

Demir Oksitler; E172 (iron oxides or hydroxides); Hierro, óxido de.

Оксид Железа

CAS — 51274-00-1; 1309-37-1.

Pharmacopoeias. *Chin.* includes red, black, brown, purple, and yellow ferric oxide. *It.* includes both red and yellow ferric oxide. *USNF* allows the basic colours of red or yellow ferric oxide or mixtures of these.

USNF 26 (Ferric Oxide). A powder exhibiting two basic colours (red and yellow), or other shades produced on blending the basic colours. Insoluble in water and in organic solvents; dissolves in hydrochloric acid upon warming, a small amount of insoluble residue usually remaining.

Profile

Ferric oxide is used for colouring medicines, contact lenses, cosmetics, and foodstuffs.

Preparations

Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Port.:*** Filter Oil Free†.

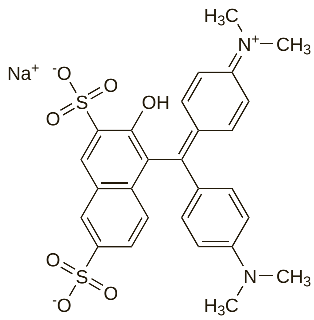
Green S

Acid Brilliant Green BS; Acid Green S; CI Food Green 4; Colour Index No. 44090; E142; Lissamine Green; Verde Brillante BS; Verde Lisamina; Verde S; Wool Green B; Yeşil S. Sodium 1-[4-dimethylamino-α-(4-dimethyliminiocyclohexa-2,5-dienylidene)benzyl]-2-hydroxynaphthalene-3,6-disulphonate.

Зелёный S

$C_{27}H_{25}N_2NaO_7S_2 = 576.6.$

CAS — 3087-16-9.



Profile

Green S is used as a colouring agent in medicines, cosmetics, and foodstuffs.

◊ Studies in *animals* indicated that there is some absorption of green S and caecal enlargement but it was considered that there is a very large margin of safety between the highest estimated human intake of green S of 130 micrograms daily and the level at which changes were seen in *animal* studies (500 mg/kg daily). It was recommended that the use of green S in food is acceptable.[1]

1. MAFF. Food advisory committee: final report on the review of the colouring matter in food regulations 1973. *FdAC/REP/4.* London: HMSO, 1987.

Logwood

CI Natural Black 1; Colour Index No. 75290.

Кампешевое Дерево (*Haematoxylon campechianum*)

CAS — 8005-33-2.

Profile

Logwood extract is a colouring agent derived from the logwood tree, *Haematoxylum (Haematoxylon) campechianum*. The logwood extract haematoxylin is used mainly as a histological stain. It is also used for colouring non-absorbable sutures.

Orange B

CI Acid Orange 137; Colour Index No. 19235. The disodium salt of 1-(4-Sulfophenyl)-3-ethylcarboxyl-4-(4-sulfonaphthylazo)-5-hydroxypyrazole.

Оранжевый B

$C_{22}H_{16}N_4Na_2O_9S_2 = 590.5.$

CAS — 15139-76-1.

Profile

Orange B is a colouring agent used in foods.

Pigment Rubine

Brilliant Carmine 6B; Carmine 6B; CI Pigment Red 57; Colour Index No. 15850; E180; FD & C Red No. 7; Lithol Rubine BK; Litholrubine BK; Litholrubintoner BKL; Litolrubina BK; Permanent Rubin L6B; Pigmento rubí; Rubinpigment. Calcium 3-hydroxy-4-(4-methyl-2-sulfonatophenylazo)-2-naphthalene carboxylate.

Рубиновый Литол BK

$C_{18}H_{12}CaN_2O_6S = 424.4.$

CAS — 5281-04-9.

Profile

Pigment rubine is used as a colouring agent for foodstuffs and cosmetics.

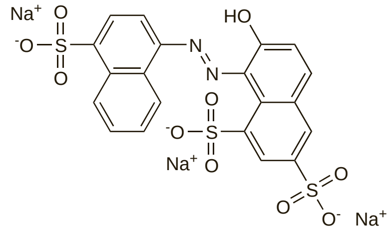
Ponceau 4R

Brilliant Ponceau 4RC; Brilliant Scarlet; CI Food Red 7; Coccine Nouvelle; Cochineal Red A; Colour Index No. 16255; E124; Punzó 4R; Rojo de cochinilla A; Rouge Cochenille A. Trisodium 7-hydroxy-8-(4-sulphonato-1-naphthylazo)naphthalene-1,3-disulphonate.

Понсо 4R; Пунцовый 4R

$C_{20}H_{11}N_2Na_3O_{10}S_3 = 604.5.$

CAS — 2611-82-7.



Profile

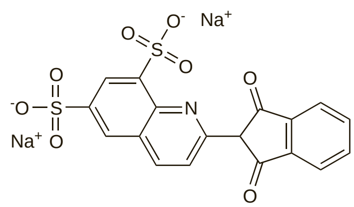
Ponceau 4R is used as a colouring agent in medicines, cosmetics, and foods. Sensitivity reactions have been reported.

Quinoline Yellow

Amarillo de quinoleína; Canary Yellow; CI Acid Yellow 3; CI Food Yellow 13; Colour Index No. 47005; E104; Jaune de Quinoléine; Kinolin Sarisi; Tartrazin. It consists essentially of sodium salts of a mixture of disulfonates (principally), monosulfonates, and trisulfonates of 2-(2-quinolyl)-1,3-indandione or a mixture containing about two-thirds of 2-(2-quinolyl)-1,3-indandione and one-third of 2-[2-(6-methyl-quinolyl)]1,3-indandione.

Жёлтый Хинолиновый

CAS — 8004-92-0 (unmethylated disulfonic acids).



(disulfonate)

NOTE. D & C yellow No. 10 has been used as a synonym for quinoline yellow, but describes a mixture consisting mainly of a monosulfonate.

Profile

Quinoline yellow is used as a colouring agent in medicines, cosmetics, and foodstuffs.

Hypersensitivity. A severe urticarial reaction[1] in a patient has been attributed to quinoline yellow.

1. Bell T. Colourants and drug reactions. *Lancet* 1991; **338:** 55–6.

Raspberry

Framboise; Frambuesa; Fructus Rubi Idaei; Himbeer.

Малина

CAS — 8027-46-1.

Profile

Raspberry, the fresh ripe fruit of *Rubus idaeus* (Rosaceae), is used as a colouring and flavouring agent in medicines and foodstuffs.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Fr.:*** IgeE.

Red Cherry

Cerasus; Cerise Rouge; Rojo cereza; Sour Cherry.

Вишня Кислая

Pharmacopoeias. *USNF* includes cherry juice.
Fr. includes, under the title Griottier, cherry stalks from either the red (sour) cherry, *Prunus cerasus*, or from the sweet cherry, *P. avium*.
USNF 26 (Cherry Juice). The liquid expressed from the fresh ripe fruit of *Prunus cerasus* (Rosaceae). It contains not less than 1.0% of malic acid. pH 3.0 to 4.0. Store in airtight containers. Protect from light.

Profile

Red cherry is used as a colouring and flavouring agent.

Inflammation. A small placebo-controlled crossover study[1] indicated that some symptoms of muscle damage induced by eccentric exercise (pain and strength loss) could be reduced by drinking cherry juice. It was suggested that anthocyanins and flavonoids present in tart cherry juice might have anti-inflammatory properties.

1. Connolly DAJ, *et al.* Efficacy of a tart cherry juice blend in preventing the symptoms of muscle damage. *Br J Sports Med* 2006; **40:** 679–83.

Preparations

USNF 26: Cherry Syrup.

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Arg.:*** Vitamina C-Complex; ***Fr.:*** Evacrine; ***Switz.:*** Drosana Resiston avec vitamine C.

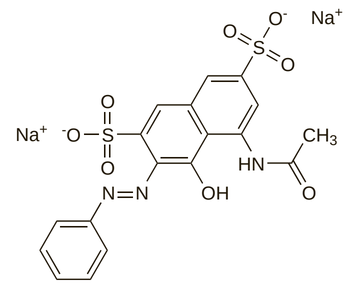
Red 2G

Acid Red 1; Azogeranina; Azogeranine; CI Food Red 10; Colour Index No. 18050; E128; Ext. D & C Red No. 11; Geranine 2G; Rojo 2G. Disodium 5-acetamido-4-hydroxy-3-phenylazonaphthalene-2,7-disulphonate.

Красный 2G

$C_{18}H_{13}N_3Na_2O_8S_2 = 509.4.$

CAS — 3734-67-6.



Profile

Red 2G may be used as a colouring agent in cosmetics. It has also been employed as a food colour but this use was suspended in the EU in 2007 on the basis that its main metabolite, aniline, has both genotoxic and carcinogenic effects in *rodents*.

Red-Poppy Petal

Aguonų birulių žiedai; Coquelicot; Coquelicot, pétales de; Corn Poppy Petal; Klatschrose; Kornvallmo, kronblad; Květ máku vlčího; Papaveris rhoeados flos; Pétalos de amapola; Rhoead. Pet.; Rhoeados Petalum; Unikonkukan terälehdet.

Мака Самосейки Лепестки

Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Red Poppy Petals). The dried, whole or fragmented petals of *Papaver rhoeas*.

Profile

Red-poppy petal has been used as a colouring agent. It is also included in several herbal preparations.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Fr.:*** Nocvalene†; ***Ital.:*** Altuss; Gastrotuss; ***Switz.:*** Baume†; Pectosan N†; Pommade au Baume; Tisane pectorale et antitussive.

Red-Rose Petal

Fleur de Rose; Flos Rosae; Pétalos de rosa; Red Rose Petals; Ros. Pet.; Rosae Gallicae Petala; Rosae Petalum; Rose Rouge; Rosenblüte.

Лепестки Розы

Pharmacopoeias. In *Fr.*

Profile

Red-rose petal, the petals of the red or Provins rose, *Rosa gallica* (Rosaceae), has been used as a colouring agent and for its mild astringent properties.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Arg.:*** Expectosan Hierbas y Miel; ***Fr.:*** Ophtalmine; ***Spain:*** Natusor Infenol†.

Saffron

Açafrão; Azafrán; CI Natural Yellow 6; Colour Index No. 75100; Croci stigma; Crocus; Estigmas de Azafrán; French Saffron; Keshar; Saffran; Safraan; Safran; Sahrami; Spanish Saffron.

Шафран

NOTE. Do not confuse with the meadow saffron (*Colchicum autumnale*), the source of colchicum (p.558) and colchicine (p.556), or Indian saffron, which is a name sometimes used for Turmeric (p.1473).

Pharmacopoeias. In *Chin.* and *Jpn.*
Eur. (see p.vii) includes Saffron for Homoeopathic Preparations.
Ph. Eur. 6.2 (Saffron for Homoeopathic Preparations). The dried stigmas of *Crocus sativus* usually joined by the base to a short style. It has a characteristic, aromatic odour. Protect from light.

Profile

Saffron consists of the dried stigmas and tops of the styles of *Crocus sativus* (Iridaceae), containing crocines, crocetins, and picrocrocine. Saffron is used to colour medicines, foods, and cosmetics. It is also used as a flavouring agent. Saffron has been included in preparations for teething pain. It is being investigated for the treatment of depression. There have been reports of poisoning with saffron, but in some cases these may have been due to meadow saffron, *Colchicum autumnale*.

Homoeopathy. Saffron has been used in homoeopathic medicines under the following names: Croci stigma; Crocus sativus; Crocus; Croc. s.

Preparations

Proprietary Preparations (details are given in Part 3)

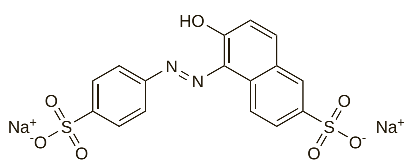
Multi-ingredient: ***Cz.:*** Dr Theiss Rheuma Creme†; Dr Theiss Schweden Krauter; Dr Theiss Schwedenbitter; ***Ger.:*** Infi-tract†; ***Rus.:*** Tentex (Тентекс); ***Spain:*** Dentol Topico; Dentomicin.

Sunset Yellow FCF

Amarillo anaranjado S; Amarillo ocaso FCF; CI Food Yellow 3; Colour Index No. 15985; Crelborange S; E110; FD & C Yellow No. 6; Günbatimi Sarisi FCF; Jaune Orangé S; Jaune Soleil; Orange Yellow S. Disodium 6-hydroxy-5-(4-sulphonatophenylazo)naphthalene-2-sulphonate.

Жёлтый Солнечный Закат

$C_{16}H_{10}N_2Na_2O_7S_2$ = 452.4.
CAS — 2783-94-0.



Profile

Sunset yellow FCF is used as a colouring agent in foods, medicines, and cosmetics. Sensitivity reactions have been reported.

Carcinogenicity. Although some evidence of carcinogenicity was found in early *animal* studies subsequent work failed to confirm these findings and in the UK sunset yellow FCF is considered suitable for use as a food colour.[1]

1. MAFF. Food advisory committee: final report on the review of the colouring matter in food regulations 1973. *FdAC/REP/4.* London. HMSO, 1987.

Hypersensitivity. Hypersensitivity reactions including severe abdominal cramps[1] and Quincke's oedema[2] have been recorded in individual patients receiving medication that was coloured with sunset yellow FCF.

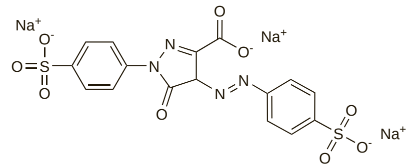
1. Gross PA, *et al.* Additive allergy: allergic gastroenteritis due to yellow dye #6. *Ann Intern Med* 1989; **111:** 87–8.
2. Lévesque H, *et al.* Reporting adverse drug reactions by proprietary name. *Lancet* 1991; **338:** 393.

Tartrazine

CI Food Yellow 4; Colour Index No. 19140; E102; FD & C Yellow No. 5; Jaune Tartrique; Tartracina; Tartrazin.; Tartrazina; Tartrazol Yellow. It consists mainly of trisodium 5-hydroxy-1-(4-sulphonatophenyl)-4-(4-sulphonatophenylazo)pyrazole-3-carboxylate.

Тартразин

$C_{16}H_9N_4Na_3O_9S_2$ = 534.4.
CAS — 1934-21-0.



Profile

Tartrazine is used as a colouring agent in foods, cosmetics, and medicines. Some patients may experience sensitivity reactions.

Adverse Effects. There have been numerous reports of reactions to tartrazine including angioedema, asthma, urticaria, and anaphylactic shock. Some of the reports have dealt with cross-sensitivity, especially with aspirin, although the connection with aspirin has been questioned.[1] A suggested incidence[2] of tartrazine sensitivity is 1 in 10 000. The mechanism of the reactions may not necessarily be immunological.[3]

In considering the reports of tartrazine sensitivity or intolerance the Food Advisory Committee in the UK[1] reported that similar evidence of intolerance might well be obtained for a variety of natural food ingredients if as many studies were conducted on them as on tartrazine. The Committee considered that tartrazine posed no more problems than other colours or food ingredients and recommended that the continued use of tartrazine in food was acceptable. However, use of tartrazine in medicines appears to be diminishing.

A systematic review[4] noted that there was no evidence that tartrazine makes asthma worse, nor did avoiding it make asthma any better.

Tartrazine has often been implicated in the aggravation of hyperactive behaviour in children; for a discussion, see Hyperactivity, p.1469.

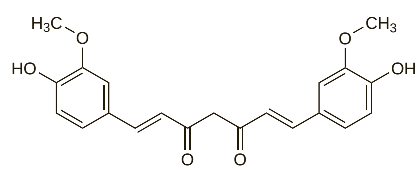
Turmeric

CI Natural Yellow 3; Cúrcuma; Indian Saffron.

Куркума; Турмерик
CAS — 458-37-7.



Pharmacopoeias. In *Chin.*

Profile

Turmeric, the dried rhizome of *Curcuma longa* (Zingiberaceae), is used principally as a constituent of curry powders and other condiments. Turmeric and its main ingredient curcumin (p.1471) are used as yellow colouring agents in foods. Turmeric has also been used as an ingredient of preparations indicated for biliary and gastrointestinal disorders and has been promoted as an anti-inflammatory. Turmeric is the source of turmeric oil. Turmeric is a commonly used ayurvedic medicine. Other species of *Curcuma* may be used similarly.

Vegetable Carbon

Bitkisel Kömür; Carbon Black; Carbón vegetal; E153; Vegetable Black.

Уголь Растительный

NOTE. The name Carbon Black has also been used as a synonym for Channel Black, a colouring agent not used in food; care should be taken to avoid confusion between the two compounds.

Profile

Vegetable carbon, which consists essentially of finely divided carbon, is produced by the carbonisation of vegetable material such as peat or wood. It is used as a colouring agent for medicines, foodstuffs, and cosmetics.

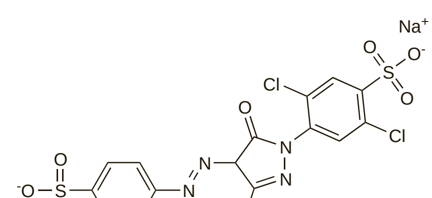
Preparations

Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Chile:*** Kordinol Compuesto†; ***Fr.:*** Stomargil.

Yellow 2G

107; Acid Light Yellow 2G; Acid Yellow 17; Amarillo 2G; CI Food Yellow 5; Colour Index No. 18965. Disodium 2,5-dichloro-4-[5-hydroxy-3-methyl-4-(4-sulphonatophenylazo)pyrazol-1-yl]benzenesulphonate.

Жёлтый 2G
$C_{16}H_{10}Cl_2N_4Na_2O_7S_2$ = 551.3.
CAS — 6359-98-4.



Profile

Yellow 2G is used as a colouring agent in cosmetics.

Contrast Media

Contrast media are widely used as adjuncts to diagnostic visualisation techniques such as radiography, magnetic resonance imaging, and ultrasound imaging. Although the techniques vary, they are all based on the fact that different tissues within the body have different physical properties, for example their ability to absorb radiation, or their density. These differences can be detected and used to produce images. Contrast media act in varying ways to accentuate the differences between tissues, and enhance the images obtained. There are different types of contrast medium, and choice depends upon the visualisation technique being used, as well as the properties of the individual media. The main groups described below are magnetic resonance contrast media, radiographic contrast media, and ultrasound contrast media.

Magnetic Resonance Contrast Media

Magnetic resonance imaging uses a combination of radiofrequency energy and magnetic fields to produce sectional images of the body. The technique is based on the property of hydrogen nuclei (protons) to absorb energy when aligned in a magnetic field; the energy is then released as the protons relax, generating a signal. Tissues differ in their proton content and factors affecting relaxation, and therefore produce different signals, which can be detected and analysed to produce an image.

Contrast media may be used to enhance magnetic resonance images. The media used are *paramagnetic* or *superparamagnetic* agents that develop magnetic properties when placed in a magnetic field. These properties affect the relaxation of adjacent protons during magnetic resonance imaging, and thus modify the signals produced. Paramagnetic compounds contain gadolinium or manganese and act by increasing relaxation and enhancing the signal. They are used as complexes or chelates to reduce their toxicity; gadopentetic acid is a typical gadolinium chelate, while mangafodipir is the only manganese chelate currently available. Superparamagnetic contrast media, such as ferucarbotran and ferumoxides, contain coated particles of iron compounds and act by interfering with the magnetic field to reduce the signal from proton relaxation.

Radiographic Contrast Media

Radiography (including X-ray imaging, computed tomography, and fluoroscopy) is based on the difference between tissues in the extent to which they absorb X-rays. This depends largely on the density of the tissue, and increasing the difference, or contrast, between specific tissues can enhance the images produced. In *positive contrast* imaging this is achieved by introducing a contrast medium into the area of interest to increase the density and enhance absorption of the X-rays. Alternatively, in *negative contrast* imaging, a gas (air, oxygen, or carbon dioxide) may be used to allow the X-rays to penetrate more easily. *Double contrast* uses both a gas and contrast medium together.

Radiographic contrast media are based on elements with high atomic numbers that absorb X-rays. The agents most commonly used are *iodinated organic compounds*, particularly tri-iodinated benzene compounds, and their degree of opacity or radiodensity is directly proportional to their iodine content. *Barium* is another element that absorbs X-rays, and barium sulfate has long been used in radiography. Other heavy atoms have been investigated but acute or chronic toxicity makes most of them unsuitable for use.

Iodinated contrast media may be classified as ionic or nonionic, and as monomeric or dimeric, and there are important differences between them that affect their use. The most important requirements for a contrast medium are that it absorbs X-rays efficiently, that it can be introduced into the area of the body to be visualised, and that it is safe. For iodinated contrast media, the radiodensity depends solely on the iodine concentration, whereas adverse effects are largely dependent on the osmolality of the solution (the number of particles present in a given weight of solution), with low-osmolality solutions being better tolerated. Distribution within the body depends on the pharmacokinetic and physical properties of the contrast medium.

Ionic monomeric media, such as the amidotrizoates, generally have a very high osmolality when given in concentrations suitable for radiographic visualisation, and therefore tend to be associated with a relatively high incidence of adverse effects. Osmolality may be reduced by using an *ionic dimeric* medium, such as adipiodone, which has twice the number of iodine atoms per molecule, or by using a *nonionic monomer*, such as iohexol, which does not dissociate into a cation and anion. *Nonionic dimeric* media, such as iodixanol, are also available and have the best ratio of radiodensity to osmolality; however, they also tend to be more viscous, and this may lead to problems with administration and distribution within the body.

Ultrasound Contrast Media

Ultrasound imaging uses the acoustic properties of different tissues to produce images. Reflection of sound waves (echo) occurs at the interface between tissues with different acoustic properties, particularly where this difference is large, and this can be detected and analysed to produce images. Contrast agents are generally used to enhance the echogenicity of blood and therefore to enable measurement of blood flow in different parts of the body.

Ultrasound contrast media increase echogenicity by providing an interface that reflects sound. Although usually referred to as ultrasound contrast media or *echocontrast* media, the increase in echogenicity may in fact reduce contrast between tissues, and *echoenhancers* may be a better term. Most ultrasound contrast media consist of microbubbles and provide a gas-liquid interface that reflects sound more effectively than blood alone, allowing blood flow to be more easily detected. The microbubbles may be air or another inert gas, such as perflutren or another perfluorocarbon, and may be either preformed or made at the time of injection. Agitated saline has been used as a simple ultrasound contrast medium, but is only suitable for cardiac imaging since the bubbles lack stability. Microbubbles of air formed during the dissolution of galactose are also used, and may be stabilised by addition of palmitic acid. Other stabilisers may be used, or the microbubbles may be encapsulated to increase the duration of their effect. Substances used for encapsulation include albumin (p.1052) and phospholipids; polycyanoacrylates have also been investigated.

Choice of Contrast Medium

Radiography, with and without the use of contrast, has been one of the most widely used diagnostic techniques and remains of great importance. However, concerns about the adverse effects of X-rays, and limitations of the images produced, have led to the increasing use of alternative methods such as ultrasound and magnetic resonance imaging. Choice of technique and use of contrast depends on the area to be visualised, the facilities available, and any patient characteristics affecting the likelihood of adverse effects, such as age and morbidity. Some imaging procedures and the factors affecting choice of technique and use of contrast, including adverse effects, are discussed below.

Uses of contrast media. For **urography** (visualisation of the kidneys and urinary tract) ultrasound is generally the most widely used technique, but radiography still has an important role. Contrast media that are excreted in the urine are used to enhance the images. Suitable media contain small, highly water-soluble molecules, with low protein-binding, that undergo rapid glomerular filtration and passage into the urinary tract. High plasma concentrations are needed to achieve adequate urinary concentrations for visualisation, so they are generally given intravenously. Most ionic iodinated media are suitable and the amidotrizoates have often been used, but lower-osmolality media are usually preferred since they have a lower incidence of adverse effects.

For **angiography** (visualisation of the circulatory system) radiography is still frequently used, particularly to produce dynamic images (fluoroscopy) during invasive procedures, although magnetic resonance angiography may be an alternative. Iodinated contrast media for angiography are similar to those used for urography; the main requirement is for a water-soluble molecule that will be rapidly distributed through the blood vessels. In addition, the solution should be of low viscosity to facilitate rapid injection and of high radiodensity to counteract the diluting effects of the blood. Low cardiotoxicity is particularly important for procedures that require a high concentration of contrast medium, such as angiocardiography or digital subtraction angiography, and low-osmolality media are now generally preferred for all angiographic procedures. Another widely used method for visualising the heart is echocardiography, which uses ultrasound imaging, and microbubble contrast media such as galactose or encapsulated gases (perfluorocarbons or sulfur hexafluoride) may be used to improve the images.

For **gastrointestinal imaging** endoscopy is often the preferred technique, but radiography also has a role. Positive, negative, and double contrast techniques are used. For positive contrast the contrast medium should not be absorbed but should form an even, homogeneous coat on the gastrointestinal mucosa, without interacting with gut secretions or producing misleading radiographic artefacts. The chief contrast medium for this purpose is barium sulfate, and much effort has been devoted to the production of suitable formulations to improve its coating properties and reduce the formation of bubbles, cracks, and other radiographic artefacts. Iodinated contrast media may be used as an alternative, but images tend to be inferior.

For **cholecystography** and **cholangiography** (visualisation of the gallbladder and biliary tract) ultrasound techniques have generally replaced radiography. Where radiography is used, choice of contrast medium depends on the intended procedure and the route. For intra-operative or endoscopic procedures, water-soluble contrast media may be used, but for non-invasive imaging the contrast medium used must be excreted in the bile. This requires a molecule with a free carboxy or other acidic group, since the biliary active transport mechanism is an anion transfer process; the molecule also needs to be large or highly protein-bound to prevent rapid excretion by the kidney. Suitable intravenous media include adipiodone and iotroxic acid. For oral use, absorption from the gastrointestinal tract is also required, and suitable media tend to be smaller molecules that are conjugated with glucuronic acid within the body before excretion in the bile, such as iopanoic acid. For visualisation of lesions within the liver itself, magnetic resonance imaging may be used; contrast media used to enhance the images include ferucarbotran and ferumoxides, as well as gadolinium or manganese chelates.

For **myelography** (visualisation of the structures of the spinal cord) and imaging of other parts of the CNS, magnetic resonance imaging is generally preferred, often with the use of gadolinium chelates such as gadopentetic acid as contrast media. Where radiography is used, the most important requirement for contrast media is low toxicity, and nonionic media are most common.

For **arthrography** (visualisation of the joint capsule) many radiographic contrast media are suitable provided they are well-diluted before use. Magnetic resonance imaging with gadolinium chelates may also have a role.

Bronchography (examination of the bronchial tree) has been performed with oily or aqueous media, such as iopydol or iopydone, instilled through a catheter or bronchoscope to coat the airways; however, other visualisation techniques are generally preferred.

For **hysterosalpingography** (visualisation of the uterus and fallopian tubes) ultrasound and endoscopic techniques are generally used, and microbubble contrast media such as galactose may be used to improve ultrasound images. If radiography is performed, water-soluble iodinated contrast media may be used.

For **lymphography** or **lymphangiography** (visualisation of the lymphatic system) a high radiodensity is required and the contrast medium must be retained within the lymphatic system for long enough to be visualised, requiring particulate, water-insoluble media, or very large molecules. Iodised oil has been most widely used, but adverse effects and limited distribution within the lymphatic system restrict its use.

Adverse effects of contrast media. Although contrast media are generally considered to be very safe, with most adverse effects being mild and transient, more severe and even life-threatening reactions are possible, and the risk of adverse effects may influence the choice of contrast medium or imaging technique in a particular patient.

Iodinated radiographic contrast media all have a similar range of adverse effects (see under Amidotrizoic Acid, p.1475) but the incidence and severity varies. Many of the adverse effects are related to the osmolality of the preparation, and the incidence tends to be lower with those that have low osmolality. Osmolality depends on the number of particles present in the solution; for a given iodine content, this is highest for the ionic monomers and lowest for nonionic dimers, and this is reflected in the incidence of adverse effects. Hypersensitivity reactions also tend to be less frequent with nonionic media (see under Amidotrizoic Acid, p.1476), although these reactions are not directly related to osmolality. However, low-osmolality media tend to be more expensive; while nonionics and dimers are preferred, ionic monomers may still have a role in patients at low risk of adverse effects. Ionic contrast media may also carry a lower risk of thromboembolism (see Effects on the Blood, p.1476).

Magnetic resonance contrast media tend to be safer than iodinated contrast media, although similar general effects may occur. Ionic and nonionic media are available, but this tends to have little influence on the incidence of adverse effects. All gadolinium chelates have similar adverse effects (see under Gadopentetic Acid, p.1479); there is a theoretical risk of gadolinium toxicity due to instability of the chelates and most preparations also contain free chelating agent to reduce this risk. The adverse effects of superparamagnetic iron compounds are described under ferumoxides (p.1478) and ferumoxsil (p.1478).

Ultrasound contrast media are generally safe; minor and transient adverse effects have been reported, but may be due to the procedure rather than to the contrast medium used.

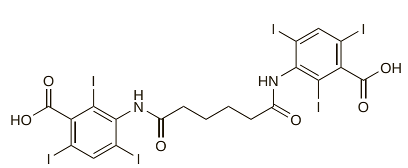
Adipiodone *(BAN, rINN)*

Adipiodon; Adipiodona; Adipiodoni; Adipiodonum; Iodipamide. 3,3′-Adipoyldiaminobis(2,4,6-tri-iodobenzoic acid).

Адипиодон

$C_{20}H_{14}I_6N_2O_6$ = 1139.8.
CAS — 606-17-7.
ATC — V08AC04.
ATC Vet — QV08AC04.



Description. Adipiodone contains about 66.8% of I.

Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Iodipamide). A white, practically odourless, crystalline powder. Very slightly soluble in water, in chloroform, and in ether; slightly soluble in alcohol. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Meglumine Adipiodone *(rINNM)*

Adipiodona de meglumina; Adipiodone Méglumine; Adipiodone Meglumine *(BANM)*; Dimeglumine Iodipamide; Iodipamide Meglumine; Meglumine Iodipamide; Meglumini Adipiodonum. The di(*N*-methylglucamine) salt of adipiodone.

Меглумина Адипиодон

$C_{20}H_{14}I_6N_2O_6,(C_7H_{17}NO_5)_2$ = 1530.2.
CAS — 3521-84-4.
ATC — V08AC04.
ATC Vet — QV08AC04.

Description. Meglumine adipiodone contains about 49.8% of I.

Pharmacopoeias. *US* includes only as an injection.

Incompatibility. Incompatibilities have been reported between meglumine adipiodone and some antihistamines.

Adverse Effects, Treatment, and Precautions

See under the amidotrizoates, p.1475. Rapid injection may increase the incidence of adverse effects.

Adipiodone may show some uricosuric activity.

Effects on the liver. Of 149 patients given the recommended dose of adipiodone, 13 developed elevated serum aspartate aminotransferase (SGOT) values; of 126 who received twice the dose, 23 developed elevated values.[1] Hepatotoxicity has also been reported[2-4] on isolated occasions in patients given meglumine adipiodone.

2. Stillman AE. Hepatotoxic reaction to iodipamide meglumine injection. *JAMA* 1974; **228:** 1420–1.
3. Sutherland LR, *et al.* Meglumine iodipamide (Cholografin) hepatotoxicity. *Ann Intern Med* 1977; **86:** 437–9.
4. Imoto S. Meglumine hepatotoxicity. *Ann Intern Med* 1978; **88:** 129.

Pharmacokinetics

Meglumine adipiodone is rapidly distributed in extracellular fluid after intravenous injection and is reported to be extensively bound to plasma proteins. It appears in the bile ducts within about 10 to 15 minutes after injection, with peak opacity at about 20 to 30 minutes, and reaches the gallbladder by about 1 hour, peak opacification occurring after about 2 hours. About 80 to 95% is excreted unchanged in the faeces; small amounts are excreted unchanged in urine. A terminal half-life of about 2 hours has been reported.

Uses and Administration

Adipiodone is an ionic dimeric iodinated radiographic contrast medium (see p.1474); it is taken up by the liver and excreted in bile, and is used in cholangiography and cholecystography.

Adipiodone is given intravenously as a solution containing 52% of the meglumine salt. The usual dose is about 10 g of meglumine adipiodone, given by slow intravenous injection over about 10 minutes.

A solution of meglumine adipiodone with meglumine diatrizoate is given by intra-uterine instillation for hysterosalpingography.

Preparations

BP 2008: Meglumine Iodipamide Injection;
USP 31: Iodipamide Meglumine Injection.

Proprietary Preparations (details are given in Part 3)
USA: Cholografin.

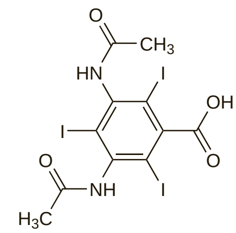
Multi-ingredient: ***USA:*** Sinografin.

Amidotrizoic Acid *(BAN, rINNM)*

Acide amidotrizoïque; Ácido amidotrizoico; Acidum amidotrizoicum; Acidum Diatrizoicum; Amidotritsoiinihappo; Amidotrizoesav; Amidotrizoinė rūgštis; Amidotrizoinsyra; Diatritsoiinihappo; Diatrizoic Acid *(USAN)*; Diatrizoinsyra; Kyselina amidotrizoová; NSC-262168. 3,5-Diacetamido-2,4,6-tri-iodobenzoic acid.

Амидотризоевая Кислота

$C_{11}H_9I_3N_2O_4,2H_2O$ = 649.9.
CAS — 117-96-4 (anhydrous amidotrizoic acid); 50978-11-5 (amidotrizoic acid dihydrate).
ATC — V08AA01.
ATC Vet — QV08AA01.



Description. Amidotrizoic acid contains about 62% of I calculated on the anhydrous substance.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Amidotrizoic Acid Dihydrate). A white or almost white, crystalline powder. Very slightly soluble in water and in alcohol; dissolves in dilute solutions of alkali hydroxides. Protect from light.

USP 31 (Diatrizoic Acid). It is anhydrous or contains two molecules of water of hydration. A white, odourless, powder. Very slightly soluble in water and in alcohol; soluble in dimethylformamide and in alkali hydroxide solutions.

Meglumine Amidotrizoate *(BANM, rINNM)*

Amidotrizoate de Méglumine; Amidotrizoato de meglumina; Diatrizoate Meglumine; Meglumine Diatrizoate; Meglumini Amidotrizoas; Methylglucamine Diatrizoate. *N*-Methylglucamine 3,5-diacetamido-2,4,6-tri-iodobenzoate.

Меглумина Амидотризоат

$C_{11}H_9I_3N_2O_4,C_7H_{17}NO_5$ = 809.1.
CAS — 131-49-7.
ATC — V08AA01.
ATC Vet — QV08AA01.

Description. Meglumine amidotrizoate contains about 47.1% of I.

Pharmacopoeias. In *US.*

USP 31 (Diatrizoate Meglumine). A white, odourless, powder. Freely soluble in water. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Sodium Amidotrizoate *(BANM, rINN)*

Amidotrizoate de Sodium; Amidotrizoato de sodio; Diatrizoate Sodium; Natrii amidotrizoas; Natrio amidotrizoatas; Natriumamidotritsoaatti; Natriumamidotrizoat; Nátrium-amidotrizoát; Natrium-amidotrizoát; NSC-61815; Sodium, amidotrizoate de; Sodium Diatrizoate; Sodu amidotrizoat. Sodium 3,5-diacetamido-2,4,6-tri-iodobenzoate.

Натрия Амидотризоат

$C_{11}H_8I_3N_2NaO_4$ = 635.9.
CAS — 737-31-5.
ATC — V08AA01.
ATC Vet — QV08AA01.

Description. Sodium amidotrizoate contains about 59.9% of I calculated on the anhydrous substance.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.,* and *US.*
Chin. includes the injection.

Ph. Eur. 6.2 (Sodium Amidotrizoate). A white or almost white powder. Freely soluble in water; slightly soluble in alcohol; practically insoluble in acetone. A 50% solution in water has a pH of 7.5 to 9.5. Protect from light.

USP 31 (Diatrizoate Sodium). A white, odourless, powder. Soluble in water; slightly soluble in alcohol; practically insoluble in acetone and in ether.

Incompatibility. Incompatibilities of sodium amidotrizoate with some antihistamines have been reported.

Adverse Effects and Treatment

Amidotrizoates and other iodinated contrast media may cause adverse effects due to direct toxicity, which tends to be dose-related and predictable, but use often leads to unpredictable or anaphylactoid reactions. Most reactions occur within 5 to 10 minutes and are mild and transient; however, severe, life-threatening reactions may also occur, and delayed reactions have been reported.

Direct toxic effects of iodinated contrast media are related to the osmolality of the solutions used and are most common with the amidotrizoates and other ionic monomeric compounds, which have a high osmolality. The route, the speed with which it is given, and the volume, concentration, and viscosity of the solution, also affect the incidence of adverse effects. For ionic media, the cation is also important: meglumine salts are generally better tolerated, but sodium salts have a lower viscosity and may produce fewer arrhythmias, and preparations containing a mixture of the salts are therefore often used. Anaphylactoid reactions are also more common with high-osmolality, ionic contrast media.

The most frequent direct adverse reaction to iodinated contrast media is flushing or a sensation of heat and caused by vasodilatation in response to the osmolality of the solution. Pain at the injection site is also common and extravasation may lead to tissue damage or thrombophlebitis.

General symptoms such as nausea, vomiting, headache, and dizziness may be related to patient anxiety or similar factors, or may be due to a mild anaphylactoid reaction. Urticaria, pruritus, pallor, sweating, a metallic taste, weakness, coughing, rhinitis, sneezing, lachrymation, and visual disturbances may also occur. Cardiovascular effects may also be due to direct toxicity, notably after intracoronary injection, or anaphylactoid response; they include hypotension, tachycardia, bradycardia, transient ECG abnormalities, and haemodynamic disturbances. More severe anaphylactoid reactions may lead to dyspnoea, bronchospasm, angioedema, severe urticaria, and eventually to profound hypotension, pulmonary oedema, respiratory arrest, ventricular fibrillation, circulatory failure, and cardiac arrest; fatalities have occurred.

CNS effects may result from direct toxicity, particularly after intrathecal use of ionic media or use in patients with a compromised blood-brain barrier, and can lead to severe neurotoxicity. Convulsions are more common in patients with epilepsy or brain tumours, but may also result from anaphylactoid reactions; paraesthesia, paralysis, and coma have also been reported.

Acute renal failure is an established adverse effect of contrast media, particularly in patients with predisposing factors such as dehydration (see Effects on the Kidneys, and Precautions, below). It appears to be related to the osmolality of the solution and is usually reversible, but deaths have occurred.

Iodinated contrast media also have direct effects on the blood, inhibiting blood coagulation and platelet aggregation. However, thromboembolism may also occur (see below). Disseminated intravascular coagulation and thrombocytopenia have also been reported.

Hyperthyroidism has been reported with use of iodinated contrast media, particularly in patients with goitre, and thyroid storm may be precipitated in patients with thyrotoxicosis. This is probably due to the small amounts of iodine present as a contaminant or released by any breakdown of the medium in the body. For the effects of iodine on the thyroid gland, see p.2169.

Mild diarrhoea may follow the oral or rectal use of amidotrizoates for gastrointestinal examinations. Aspiration of oral solutions has caused fatal pulmonary oedema.

Adverse effects are treated symptomatically; adequate resuscitative facilities should be available when radiographic procedures are undertaken, and patients should be kept under observation for a suitable period after the procedure.

Effects on the blood. Iodinated contrast media affect blood coagulation to differing degrees.[1,2] Amidotrizoates and other ionic contrast media have inhibitory effects on blood coagulation and platelet aggregation, whereas nonionic media lack these effects. In procedures such as angiography, which are associated with a risk of thromboembolism, there may therefore be an advantage in using ionic media. However, the better overall tolerability of nonionic media means that they are still generally preferred to ionic media for angiography, particularly in patients at high risk of non-thromboembolic adverse effects.

Other effects on the blood that have been reported with amidotrizoates and other iodinated contrast media include disseminated intravascular coagulation,[3,4] haemolysis,[5] thrombocytopenia,[6,7] and thrombotic microangiopathy.[8]

Effects on the kidneys. Contrast nephropathy or contrast-induced nephrotoxicity is a well-established adverse effect of iodinated contrast media.[1-9] Estimates of the incidence vary depending on the type and amount of contrast medium used, the definition of nephropathy, and the population of patients being studied, but is about 1 to 6% overall. In the majority of patients who develop contrast-medium-induced renal impairment the condition develops within about 24 hours of the procedure, is asymptomatic, and resolves completely within about 10 days. However, the condition may occasionally be severe, producing oliguria and renal failure that requires dialysis; fatalities have occurred.

The mechanism of nephrotoxicity is not certain, but is thought to involve both medullary hypoxia due to reduced renal blood flow, and direct toxicity. The osmolality of the contrast medium solution appears to be an important factor and most studies have shown that high-osmolality media increase the risk compared with low-osmolality media. There is also some evidence that use of media that are iso-osmolar with plasma may reduce the risk even further. The volume of contrast solution used is also important, and risk increases with higher volumes. The use of ionic or nonionic media appears to have less influence, except that nonionic media generally have a lower osmolality and may therefore be preferred.

The most important patient characteristic that increases the risk of nephrotoxicity is pre-existing renal impairment, especially in patients with diabetes mellitus. Other risk factors include conditions where there is reduced renal blood flow, such as heart failure and dehydration. Old age, repeated exposure (over a short period of time), multiple myeloma, and use with other nephrotoxic drugs, are also risk factors.

Various methods have been tried to prevent contrast medium-induced nephropathy.[1,3-12] All patients should be assessed for risk factors and those at high risk should be given a small volume of a low-osmolality or iso-osmolar nonionic medium if possible. Hydration before and after the procedure is of established benefit and is recommended in all patients, although the optimum route and fluid to use remains unclear. Oral hydration may be adequate in low risk patients, but most patients are given sodium chloride 0.45% or 0.9% intravenously. Sodium bicarbonate may be an alternative; a study[13] in patients with pre-existing stable renal impairment suggested that it was more effective than sodium chloride. However, a retrospective study[14] found an increased risk of nephropathy in patients given sodium bicarbonate compared with those who had no prophylaxis, and further studies are needed to confirm its role.

Antoxidants have been suggested as a way of reducing the direct toxicity of contrast media. Acetylcysteine is widely used,[15] but evidence of benefit is conflicting. Some studies have produced promising results, but others have been less positive and, although reviews and meta-analyses have shown benefit[16,17] or a trend towards benefit,[18-20] most have concluded[15,17-21] that the wide variation between the studies included means that the efficacy of acetylcysteine remains uncertain. Later randomised studies have also reported conflicting results.[22,23] An observational study[24] found that there was no difference in the incidence of contrast nephropathy before and after the introduction of acetylcysteine prophylaxis, while a follow-up study[25] found that acetylcysteine had no effect on overall outcomes over 9 months. However, some authors[4,7,15] recommend the use of acetylcysteine in particularly high-risk patients. Ascorbic acid has also been tried and showed benefit in one study,[26] and promising results have been reported with trimetazidine, an anti-anginal drug with antoxidant properties,[27] but further confirmation is needed.

Other approaches have generally produced disappointing results.[1,3-7,10] The use of diuretics may increase the risk of nephropathy and is not recommended. Vasodilators have been tried, including atrial natriuretic peptide, calcium-channel blockers, low-dose dopamine, and alprostadil, but benefit has not been established and they are not generally used. Although positive results have been reported[28] with fenoldopam, which has preferential effects on renal blood flow, a large randomised study[29] failed to confirm any benefit. Studies with theophylline have produced conflicting results, although a meta-analysis[30] concluded that it might be of benefit. Use of dialysis to remove contrast medium from the circulation has also been suggested; some benefit has also been found with haemofiltration started before the procedure,[31] but not with haemodialysis immediately after the procedure.[32]

Hypersensitivity. Anaphylactoid reactions to iodinated contrast media are more common with the ionic agents than the nonionic media of lower osmolality. Patients at increased risk are those with a history of asthma or allergy, drug hypersensitivity, adrenal suppression, heart disease, previous reaction to a contrast medium, and those receiving beta blockers or interleukin-2 therapy. In such patients, nonionic media are preferred. Stopping treatment with beta blockers should be considered in patients with other risk factors.

Pretreatment with corticosteroids may be considered for preventing anaphylactoid reactions in high-risk patients, and an antihistamine may be given. However, reactions may still occur and the value of premedication remains controversial.

Precautions

The risk of anaphylactoid reactions with amidotrizoates and other iodinated contrast media is increased in patients with asthma or a history of allergies and they should be used with great caution in such patients; they should not be used in patients with a previous reaction to contrast media or iodine. Test doses have been given but are not generally recommended since they do not predict hypersensitivity with certainty and may cause severe or fatal reactions. Pretreatment with corticosteroids may be considered in patients considered at high risk of reactions, but the value of this is uncertain (see Hypersensitivity, above). An antihistamine may be given with the corticosteroid.

Iodinated contrast media should be used with caution in patients with severe hepatic or renal impairment, diabetics with renal impairment, and others who may be at increased risk of renal failure. Dehydration should be avoided, and any fluid or electrolyte imbalance should be corrected before contrast media are given. Particular care is needed in patients with multiple myeloma since dehydration resulting from use of contrast media may cause precipitation of protein in the renal tubules, leading to anuria and fatal renal failure.

Caution is also necessary in patients with severe hypertension, advanced cardiac disease, phaeochromocytoma, sickle-cell disease, or hyperthyroidism or epilepsy, and in debilitated, severely ill, very old, or very young patients.

Amidotrizoates and other hypertonic contrast media are neurotoxic and should not be given intrathecally; patients with subarachnoid haemorrhage may be at risk with any intravascular use. Intravascular contrast media should also be used with caution in any patient with occlusive vascular disease. Iodinated contrast media should not be used for hysterosalpingography in the presence of infection or inflammation of the pelvic cavity, nor during menstruation or in pregnancy (although any abdominal radiography should be avoided during pregnancy because of the risks of radiation to the fetus).

Iodine-containing contrast media may interfere with thyroid function tests. There may also be interference with blood coagulation tests and certain urine tests.

Breast feeding. No adverse effects have been seen in breast-feeding infants whose mothers were receiving amidotrizoates and the American Academy of Pediatrics considers[1] that they are therefore usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 27/03/06)

Neonates. Although amidotrizoates may be used in the management of some forms of intestinal obstruction (see below), meglumine amidotrizoate was considered[1] a possible contributory factor in the deaths of 2 infants who developed bowel necrosis, perforation, and peritonitis after its use for meconium ileus.

1. Leonidas JC, *et al.* Possible adverse effects of methylglucamine diatrizoate compounds on the bowel of newborn infants with meconium ileus. *Radiology* 1976; **121:** 693–6.

Pharmacokinetics

Amidotrizoates are very poorly absorbed from the gastrointestinal tract. Amidotrizoates in the circulation are not significantly bound to plasma proteins. If renal function is not impaired, unchanged amidotrizoate is rapidly excreted by glomerular filtration; over 95% of an intravascular dose is reported to be excreted in urine within 24 hours, and about 1 to 2% of a dose may be excreted in faeces. Trace amounts may be detected in other body fluids including tears and saliva. Faecal excretion may increase to 10 to 50% in severe renal impairment. The half-life of amidotrizoates has been reported to be 30 to 60 minutes, which can increase to 20 to 140 hours in severe renal impairment. They are removed by haemodialysis and peritoneal dialysis.

The amidotrizoates cross the placenta and are distributed into breast milk.

Uses and Administration

The amidotrizoates are ionic monomeric iodinated radiographic contrast media (p.1474). Both the sodium and the meglumine salt have been widely used in diagnostic radiography; however, adverse effects may be reduced by using a mixture of both salts, and this is often preferred. Preparations are available containing a wide range of strengths. Mixtures containing sodium amidotrizoate 10% w/v with meglumine amidotrizoate 66% w/v, or sodium amidotrizoate 4% with meglumine amidotrizoate 26%, are commonly used. For use alone, preparations containing sodium amidotrizoate 25 to 50% w/v, or meglumine amidotrizoate 60% w/v, may be appropriate.

The amidotrizoates are used in an extensive range of procedures, although in many cases lower osmolality contrast media are now preferred. The dose and route depend on the procedure and the degree and extent of contrast required. They are given intravenously for urography, for venography, and in computed tomography; for urography, they have also been given by intramuscular or subcutaneous injection, but these routes are not generally recommended. They may be given intra-arterially for angiography, by intra-articular injection for arthrography, or by intra-osseous injection for imaging of the vasculature of the bones. For other procedures they may be instilled into body cavities, or injected into the gallbladder, biliary ducts, or spleen. Amidotrizoates have also been given orally or rectally for imaging of the gastrointestinal tract.

Solutions of amidotrizoates have also been given as an enema in the treatment of uncomplicated meconium ileus.

Calcium amidotrizoate and lysine amidotrizoate have also been used as contrast media.

Gastrointestinal obstruction. Amidotrizoates and other water-soluble contrast media have been given rectally as osmotic agents in the management of gastrointestinal obstruction due to meconium ileus;[1] however, adverse effects have been reported in neonates (see above). They have also been used as an alternative to barium sulfate enemas in the management of intussusception (see below). Amidotrizoates given orally have been used in the management of adhesive small bowel obstruction;[2] they allow identification of patients who require surgery and, although they have not been shown to relieve obstruction, they may reduce length of hospital stay in patients treated without surgery.

Barium Sulfate

Barii sulfas; Barii Sulphas; Bario sulfatas; Barium Sulfuricum; Barium Sulphate; Bariumsulfaatti; Bariumsulfat; Bárium-szulfát; Baru siarczan; Baryum (Sulfate de); Baryum, sulfate de; Síran barnatý; Sulfato de bario.

$BaSO_4$ = 233.4.
CAS — 7727-43-7.
ATC Vet — QV08BA02.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Barium Sulphate). A fine, white powder, free from gritty particles. Practically insoluble in water and in organic solvents; very slightly soluble in acids and in solutions of alkali hydroxides.

USP 31 (Barium Sulfate). A fine, white, odourless, bulky powder, free from grittiness. Practically insoluble in water, in organic solvents, and in solutions of acids and of alkalis. pH of a 10% w/w aqueous suspension is between 3.5 and 10.0.

Adverse Effects

Because barium sulfate is almost insoluble it lacks the severe toxicity characteristic of the barium ion; deaths have occurred in patients given the more soluble barium sulfide in error for the sulfate.

Constipation may occur after oral or rectal barium sulfate; impaction, obstruction, and appendicitis have occurred. Surgical removal of faecaliths has sometimes been necessary. Cramping or diarrhoea have also been reported. Venous intravasation has led to the formation of emboli; deaths have occurred. Perforation of the bowel has led to peritonitis, adhesions, granulomas, and a high mortality rate.

ECG abnormalities have occurred during the use of barium sulfate enemas.

Accidental aspiration into the lungs has led to pneumonitis or granuloma formation.

Hypersensitivity. A survey of hypersensitivity reactions to barium preparations found that although barium is inert many of the additives used in formulation have the potential to cause reactions.[1] Of 106 reactions reported or found in the literature, 61% involved the skin and only 8% the respiratory tract; unconsciousness was reported in 8% of cases. In view of the frequency of use of barium preparations, such adverse reactions must be very rare, but radiologists should be aware that they might be somewhat more common than was usually appreciated. A number of severe reactions associated with the use of barium enemas supplied with an inflatable latex cuff may have been due to leaching of components from the latex.[2]

1. Janower ML. Hypersensitivity reactions after barium studies of the upper and lower gastrointestinal tract. *Radiology* 1986; **161:** 139–40.
2. Nightingale SL. Severe adverse reactions to barium enema procedures. *JAMA* 1990; **264**: 2863.

Precautions

Barium sulfate should not be given to patients with intestinal obstruction and care is needed in those with conditions such as pyloric stenosis or lesions that may predispose to obstruction. Adequate hydration should be ensured after the procedure to prevent severe constipation.

It is contra-indicated in patients with gastrointestinal perforation, and should be avoided, particularly when given rectally, in those at risk of perforation, such as patients with acute ulcerative colitis or diverticulitis and after rectal or colonic biopsy, sigmoidoscopy, or radiotherapy.

Uses and Administration

Barium sulfate is used as a radiographic contrast medium (p.1474) for X-ray examination of the gastrointestinal tract involving single- or double-contrast techniques or computed tomography.

The dose of barium sulfate is dependent upon the type of examination and technique used. In the UK typical doses and concentrations used for examination are:

- oesophagus: up to 150 mL of a 50 to 200% w/v suspension given orally
- stomach and duodenum: up to 300 mL of a 30 to 200% w/v suspension given orally
- small intestine: 100 to 300 mL of a 30 to 150% w/v suspension given orally
- colon: 200 mL to 2 litres of a 20 to 130% w/v suspension given as an enema.

A suspension containing 1.6 to 2.2% may be used in gastrointestinal computed tomography.

In the USA, suspensions containing up to 230% w/v barium sulfate may be used; lower concentrations are available for use in computed tomography and usually contain about 1 to 2% w/v.

For double-contrast examination, gas can be introduced into the gastrointestinal tract by using suspensions of barium sulfate containing carbon dioxide; separate gas-producing preparations based on sodium bicarbonate are also available. Air given via a tube may be used as an alternative to carbon dioxide.

Intussusception. Contrast media enemas and ultrasound are both used in the diagnosis of intussusception, a condition in infants where part of the intestine prolapses into the lumen of an adjacent part causing an obstruction.[1,2] However, some consider ultrasound to be superior for diagnosis and reserve enemas for the therapeutic reduction of intussusception. Reduction is achieved as a result of the hydrostatic pressure of the enema pushing the intestine back into its natural position. Although there is extensive experience using barium enemas for reduction some centres prefer to use water-soluble contrast media so as to minimise the risk of chemical peritonitis if perforation of the bowel occurs. Other agents used instead of barium for reduction include air enemas or ultrasound guided saline enemas, both of which avoid or reduce radiographic exposure. Surgery is indicated when enema therapy fails or is considered unsuitable.

Ferristene *(BAN, USAN)*

Ferristeno.

$C_8H_{11}NO_3S,(Fe_2O_3)_{0.725}$.

CAS — 155773-56-1.

ATC — V08CB02.

ATC Vet — QV08CB02.

Description. Ferristene contains about 23.4% of Fe.

Profile

Ferristene consists of iron ferrite crystals carried on monosized spheres of cross-linked poly(ammonium styrenesulfonate). It has superparamagnetic properties and has been used orally as a magnetic resonance contrast medium (p.1474) for imaging of the abdomen.

Preparations

Proprietary Preparations (details are given in Part 3)
UK: Abdoscan†.

Ferucarbotran *(BAN, USAN)*

Ferrixan; Ferucarbotrano; SHU-555A; ZK-132281.

Profile

Ferucarbotran is a colloidal aqueous suspension of iron oxide (magnetite and maghemite) particles coated with carboxydextran. It has superparamagnetic properties and is used similarly to ferumoxides (below) as a magnetic resonance contrast medium (p.1474) for imaging of the liver; the particles are taken up by the reticuloendothelial system of the liver and spleen and provide contrast enhancement. It is given intravenously as a solution containing 28 mg/mL of iron. The usual dose is 0.9 mL for patients weighing less than 60 kg and 1.4 mL for patients weighing 60 kg and over.

◊ References.

Ferumoxides *(BAN, USAN)*

AMI-25; Ferumóxidos.

$(Fe_2O_3)_m(FeO)_n$.

CAS — 119683-68-0.

Adverse Effects and Precautions

The most common adverse effects with ferumoxides are pain, vasodilatation, and hypotension; paraesthesia may also occur. Hypersensitivity reactions have developed. Extravasation may lead to discoloration of the skin around the injection site. Ferumoxides should not be used in patients with known hypersensitivity to iron and should be used with caution in patients with iron overload disorders.

Uses and Administration

Ferumoxides consists of colloidal particles of magnetite (iron oxide). It has superparamagnetic properties and is used as a magnetic resonance contrast medium (p.1474) for imaging of the liver; the particles are taken up by the reticuloendothelial system of the liver and spleen and provide contrast enhancement. It is available as a suspension containing 11.2 mg/mL of iron, which should be diluted in 100 mL of glucose 5% before use and given intravenously over at least 30 minutes. The dose is expressed in terms of iron. In Europe, the usual dose is 0.84 mg/kg; in the USA, a dose of 0.56 mg/kg is used.

◊ Reference to the use of ferumoxides followed by a gadolinium-based contrast medium.[1]

Ferumoxsil *(BAN, USAN)*

AMI-121; Ferumoksiili; Ferumoxil; Férumoxsil; Ferumoxsilum.

ATC — V08CB01.

ATC Vet — QV08CB01.

Adverse Effects and Precautions

The most common adverse effects with ferumoxsil are diarrhoea, nausea, vomiting, and abdominal pain; oral paraesthesia has also been reported. Ferumoxsil should be used with caution in patients with iron overload disorders.

Uses and Administration

Ferumoxsil consists of a silicone polymer bonded to colloidal particles of magnetite (iron oxide). It has superparamagnetic properties and is used as a magnetic resonance contrast medium (p.1474) for imaging of the gastrointestinal tract; the particles remain in the stomach and intestine when given orally or rectally and provide contrast enhancement. It is given as a suspension containing 175 micrograms/mL of iron. The usual dose is 600 to 900 mL by mouth, or 300 to 600 mL rectally.

Preparations

USP 31: Ferumoxsil Oral Suspension.

Proprietary Preparations (details are given in Part 3)

Ferumoxtran-10 *(USAN)*

AMI-227; BMS-180549; Code 7227.

CAS — 189047-99-2.

Profile

Ferumoxtran-10 consists of colloidal particles of magnetite (iron oxide) coated with a low-molecular-weight dextran. It has superparamagnetic properties and is under investigation as a magnetic resonance contrast medium for imaging of the lymphatic system.

Gadobenic Acid *(BAN, rINN)*

Acide Gadobénique; Ácido gadobénico; Acidum Gadobenicum; B-19036; Gd-BOPTA. Dihydrogen [(±)-4-carboxy-5,8,11-tris(carboxymethyl)-1-phenyl-2-oxa-5,8,11-triazatridecan-13-oato(5−)]gadolinate(2−).

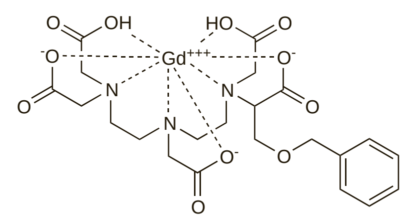
Гадобеновая Кислота

$C_{22}H_{28}GdN_3O_{11}$ = 667.7.

CAS — 113662-23-0.

ATC — V08CA08.

ATC Vet — QV08CA08.



Meglumine Gadobenate *(BANM, rINNM)*

B-19036/7; Gadobenaattidimeglumiini; Gadobenatdimeglumin; Gadobénate de Méglumine; Gadobenate Dimeglumine *(USAN)*; Gadobenato de meglumina; Gadobenatum Dimegluminum; Meglumini Gadobenas.

Меглумина Гадобенат

$C_{22}H_{28}GdN_3O_{11},2C_7H_{17}NO_5$ = 1058.1.

CAS — 127000-20-8.

ATC — V08CA08.

ATC Vet — QV08CA08.

Adverse Effects and Precautions

As for Gadopentetic Acid, p.1479.

◊ References.

1. Kirchin MA, *et al.* Safety assessment of gadobenate dimeglumine (MultiHance): extended clinical experience from phase I studies to post-marketing surveillance. *J Magn Reson Imaging* 2001; **14:** 281–94.
2. Shellock FG, *et al.* Safety of gadobenate dimeglumine (MultiHance): summary of findings from clinical studies and postmarketing surveillance. *Invest Radiol* 2006; **41:** 500–9.

Pharmacokinetics

Gadobenate is rapidly distributed into the extracellular space after intravenous injection. An elimination half-life of about 1.2 to 1.7 hours has been reported. It is not metabolised and about 78 to 94% of a dose is excreted in the urine within 24 hours; about 2 to 4% is excreted in the faeces.

Uses and Administration

Gadobenic acid is an ionic gadolinium chelate with actions and uses similar to those of gadopentetic acid (p.1480). It has paramagnetic properties and is used as a magnetic resonance contrast medium (p.1474). It distributes mainly into extracellular fluid, but does not cross the blood-brain barrier, and is used in imaging of the liver and CNS.

Gadobenic acid is given intravenously as the meglumine salt. It is available as a solution containing meglumine gadobenate 529 mg/mL (0.5 mmol/mL). Usual doses for imaging are:

- liver: 0.1 mL/kg (0.05 mmol/kg) intravenously
- brain or spine: 0.2 mL/kg (0.1 mmol/kg) intravenously.

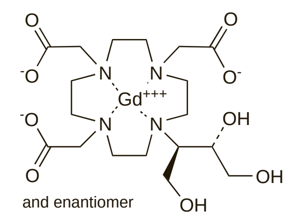
$C_{18}H_{31}GdN_4O_9$ = 604.7.

CAS — 138071-82-6.

ATC — V08CA09.

ATC Vet — QV08CA09.



and enantiomer

Adverse Effects and Precautions

As for Gadopentetic Acid, p.1479. Gadobutrol may prolong cardiac repolarisation and should not be used in patients with uncorrected hypokalaemia. Caution is required in patients with severe cardiovascular disease, and in those with congenital long QT syndrome or a history of drug-induced arrhythmias.

Pharmacokinetics

Gadobutrol is rapidly distributed into the extracellular space following intravenous injection. It is not significantly bound to plasma proteins. An elimination half-life of about 1.8 hours has been reported. It is not metabolised and more than 90% of a dose is excreted in the urine within 12 hours; less than 0.1% is excreted in the faeces.

Uses and Administration

Gadobutrol is a nonionic gadolinium chelate with actions and uses similar to those of gadopentetic acid (p.1480). It has paramagnetic properties and is used as a magnetic resonance contrast medium (p.1474). It distributes mainly into extracellular fluid, but does not cross the blood-brain barrier, and is used in imaging of the CNS, kidneys, and liver, and in magnetic resonance angiography.

Gadobutrol is available as a solution containing 605 mg/mL (1 mmol/mL). Usual doses are:

- cranial and spinal imaging: 0.1 mL/kg (0.1 mmol/kg) intravenously. A second dose of up to 0.2 mL/kg (0.2 mmol/kg) may be given within 30 minutes if required
- kidneys and liver: 0.1 mL/kg (0.1 mmol/kg) intravenously
- angiography: 0.1 to 0.3 mL/kg (0.1 to 0.3 mmol/kg) intravenously

A solution containing 302.5 mg/mL (0.5 mmol/mL) has also been used.

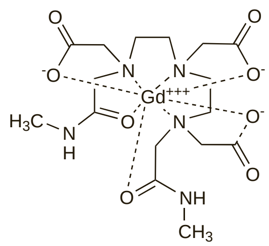
Gadodiamide *(BAN, USAN, rINN)*

Gadodiamid; Gadodiamida; Gadodiamidi; Gadodiamidum; Gd-DTPA-BMA; S-041. [*N,N*-Bis(2-{(carboxymethyl)[(methylcarbamoyl)methyl]amino}ethyl)glycinato(3−)]gadolinium; a complex of gadolinium with diethylenetriamine penta-acetic acid bismethylamide.

Гадодиамид

$C_{16}H_{26}GdN_5O_8$ = 573.7.
CAS — 131410-48-5 (anhydrous gadodiamide); 122795-43-1 (gadodiamide hydrate).
ATC — V08CA03.
ATC Vet — QV08CA03.



Pharmacopoeias. In *US.*

USP 31 (Gadodiamide). A white, odourless, powder. Freely soluble in water and in methyl alcohol; soluble in alcohol; slightly soluble in acetone and in chloroform. Store in airtight containers.

Adverse Effects and Precautions

As for Gadopentetic Acid, below.

Effects on the pancreas. Acute pancreatitis developed in a patient shortly after injection of gadodiamide for hepatic imaging.[1] Another patient[2] developed both acute pancreatitis and acute renal failure after use of gadodiamide for angiography.

1. Terzi C, Sökmen S. Acute pancreatitis induced by magnetic-resonance-imaging contrast agent. *Lancet* 1999; **354:** 1789–90. Correction. *ibid.* 2000; **355:** 660.
2. Schenker MP, *et al.* Gadolinium arteriography complicated by acute pancreatitis and acute renal failure. *J Vasc Interv Radiol* 2001; **12:** 393.

Interference with diagnostic tests. Gadodiamide may interfere with colorimetric methods for measuring serum calcium concentrations, resulting in falsely low measurements. Severe pseudohypocalcaemia has been reported[1-3] after the use of gadodiamide, particularly in patients with renal impairment.[2] There is also *in vitro* evidence that a similar interference may occur with gadoversetamide.[2]

1. Doorenbos CJ, *et al.* Severe pseudohypocalcemia after gadolinium-enhanced magnetic resonance angiography. *N Engl J Med* 2003; **349:** 817–18.
2. Prince MR, *et al.* Gadodiamide administration causes spurious hypocalcemia. *Radiology* 2003; **227** 639–46.
3. Williams SF, *et al.* Spurious hypocalcemia after gadodiamide administration. *Mayo Clin Proc* 2005; **80:** 1655–7.

Renal impairment. For the view that gadodiamide may carry a particular risk of the development of nephrogenic systemic sclerosis in patients with renal impairment, see p.1479.

Pharmacokinetics

Gadodiamide is rapidly distributed into extracellular fluid. About 96% of a dose is excreted unchanged in the urine within 24 hours. An elimination half-life of about 70 minutes has been reported. Gadodiamide is not bound to plasma proteins. It is removed by haemodialysis.

Uses and Administration

Gadodiamide is a nonionic gadolinium chelate with actions and uses similar to those of gadopentetic acid (p.1480). It has paramagnetic properties and is used as a magnetic resonance contrast medium (p.1474). It distributes mainly into extracellular fluid, but does not cross the blood-brain barrier, and is used in imaging of cranial and spinal structures, imaging of the whole body, angiography, and mammography.

Gadodiamide is available as a solution containing 287 mg/mL (0.5 mmol/mL). Usual doses are:

- cranial and spinal imaging: for adults and children, 0.2 mL/kg (0.1 mmol/kg). Adults may be given a second dose of 0.4 mL/kg (0.2 mmol/kg) within 20 minutes if required.
- whole body imaging: for adults and children, 0.2 mL/kg (0.1 mmol/kg)
- kidneys: 0.1 mL/kg (0.05 mmol/kg) may be adequate
- angiography: for adults, 0.2 mL/kg (0.1 mmol/kg)
- mammography: 0.2 to 0.4 mL/kg (0.1 to 0.2 mmol/kg).

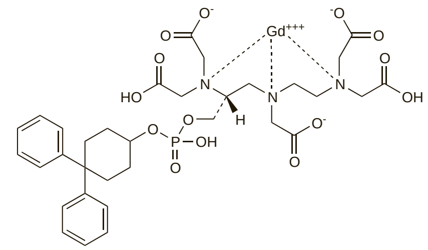
CAS — 201688-00-8 (gadofosveset); 193901-90-5 (gadofosveset trisodium).
ATC — V08CA11.
ATC Vet — QV08CA11.



(gadofosveset)

Profile

Gadofosveset is a gadolinium chelate used as a paramagnetic contrast medium (p.1474) in magnetic resonance angiography. It binds to plasma proteins, particularly albumin, and therefore acts as a blood pool agent, allowing visualisation of the vasculature.

Gadofosveset is given intravenously as the trisodium salt. It is available as a solution containing gadofosveset trisodium 244 mg/mL (0.25 mmol/mL). The usual dose is 0.12 mL/kg (0.03 mmol/kg) by intravenous injection.

ATC Vet — QV08CA01.

Pharmacopoeias. *Chin.* and *US* include only as an injection.

Adverse Effects

There may be headache, nausea, vomiting, and transient sensations of heat or cold or taste disturbances on injection of gadopentetate or other gadolinium chelates. Rarely, convulsions, hypotension, allergic or anaphylactoid reactions, and shock may occur. Paraesthesias, dizziness, and localised pain have also been reported. Transient elevations of serum iron and bilirubin values have been observed. Nephrogenic systemic fibrosis may occur rarely in patients with renal impairment (see under Precautions, below).

Precautions

Gadopentetate should not be used in patients with severe renal impairment (GFR less than 30 mL/minute per 1.73 m^2) or with acute renal impairment associated with hepato-renal syndrome or liver transplantation (see Renal Impairment, below). It should be given with care to patients with moderate renal impairment, epilepsy, hypotension, or a history of hypersensitivity, asthma, or other allergic respiratory disorders. Care should be taken to avoid extravasation. Gadopentetate may interfere with tests of serum iron or bilirubin concentrations.

Breast feeding. Studies[1-3] have shown that gadopentetate is distributed into breast milk in very small amounts; the total amount excreted in the milk within 24 hours was less than 0.04% of the intravenous dose in all cases. No adverse effects have been seen in breast-feeding infants whose mothers were receiving gadopentetic acid and the American Academy of Pediatrics considers[4] that it is therefore usually compatible with breast feeding.

Myasthenia gravis. Acute deterioration of myasthenia gravis has been reported[1] in a patient after imaging of the brain using gadopentetate.

1. Nordenbo AM, Somnier FE. Acute deterioration of myasthenia gravis after intravenous administration of gadolinium-DTPA. *Lancet* 1992; **340:** 1168.

Renal impairment. Nephrogenic systemic fibrosis (nephrogenic fibrosing dermopathy) is a rare condition that has been reported in patients with renal impairment. Use of gadolinium-containing contrast media appears to be a risk factor;[1-3] most cases have occurred with gadodiamide given in high doses for magnetic resonance angiography, but there have also been reports with other gadolinium-containing contrast media and with lower doses. It has been suggested that the mechanism involves release of free gadolinium ions into the tissues, and that the potential for this varies between the different gadolinium-based contrast media available, with gadodiamide and gadoversetamide more likely to do so.[4] The macrocyclic structure of gadoteridol and gadoterate was thought to be less prone to this effect, but further research is needed. The FDA[5] and the MHRA[6] advise that use of gadolinium-containing contrast media should be restricted in patients with severe renal impairment (GFR less than 30 mL/minute per 1.73 m^2). The MHRA contra-indicates the use of gadodiamide or gadopentetate in such patients (other gadolinium-containing contrast media are under review), whereas the FDA advises that all gadolinium-containing contrast media should be avoided unless the diagnostic information is essential and cannot be obtained another way. The FDA gives a similar warning for use in patients with acute renal failure associated with hepato-renal syndrome or around the time of liver transplantation. The value of haemodialysis to remove gadolinium-containing contrast media after use is unknown.

Pharmacokinetics

Gadopentetate is rapidly distributed into the extracellular space after intravenous injection. An elimination half-life of 1.6 hours has been reported. It is not metabolised and about 90% of a dose is excreted in the urine within 24 hours. It does not appear to bind to plasma proteins. A small amount is distributed into breast milk. Gadopentetate is removed by haemodialysis.

Uses and Administration

Gadopentetic acid is an ionic gadolinium chelate used as a contrast medium in magnetic resonance imaging (p.1474). Gadolinium has paramagnetic properties that affect the relaxivity of hydrogen ions, increasing the signal intensity and therefore enhancing the contrast between tissues. Chelation of gadolinium reduces its toxicity while retaining its paramagnetic properties; it also affects distribution within the body. Most gadolinium chelates distribute freely into extracellular fluid but do not cross the blood-brain barrier, and they are particularly useful for imaging the brain and associated structures.

Gadopentetic acid is given intravenously as meglumine gadopentetate for contrast enhancement in magnetic resonance imaging of cranial and spinal structures, and of the whole body, and may also be used for evaluation of renal function. It is given by intra-articular injection for arthrography, and has been used orally and rectally in imaging of the gastrointestinal tract.

For cranial, spinal, and whole body imaging, a solution containing meglumine gadopentetate 469.01 mg/mL (0.5 mmol/mL) is used. The usual dose in adults, children, and neonates is 0.2 mL/kg (0.1 mmol/kg) intravenously. For cranial and spinal imaging, a further dose of 0.2 mL/kg (0.1 mmol/kg) may be given within 30 minutes if necessary; in adults this second dose may be 0.4 mL/kg (0.2 mmol/kg). For whole body imaging in adults and children over 2 years, a dose of 0.4 mL/kg (0.2 mmol/kg) may be needed in some cases to produce adequate contrast and in special circumstances a dose of 0.6 mL/kg (0.3 mmol/kg) may be used in adults.

For arthrography a solution containing meglumine gadopentetate 1.876 mg/mL (0.002 mmol/mL) is given by intra-articular injection. The dose depends on the joint being imaged; the usual range is from 1 to 20 mL.

For imaging of the gastrointestinal tract a solution containing meglumine gadopentetate 9.38 mg/mL has been used, diluted further before use.

Preparations

USP 31: Gadopentetate Dimeglumine Injection.

Adverse Effects and Precautions

As for Gadopentetic Acid, p.1479.

Hypersensitivity. For reports of anaphylactoid reactions with gadoterate, see under Adverse Effects of Gadopentetic Acid, p.1479.

Pharmacokinetics

Gadoterate is distributed into the extracellular space after intravenous injection. It is not bound to plasma proteins. A plasma half-life of about 1.5 hours has been reported. It is not metabolised and about 90% of a dose is excreted in the urine within 24 hours.

Uses and Administration

Gadoteric acid is an ionic gadolinium chelate with actions and uses similar to those of gadopentetic acid (above). It has paramagnetic properties and is used as a magnetic resonance contrast medium (p.1474). It distributes mainly into extracellular fluid, but does not cross the blood-brain barrier, and is used in imaging of cranial and spinal structures and of the whole body, and in magnetic resonance angiography.

Gadoteric acid is given intravenously as the meglumine salt. It is available as a solution containing meglumine gadoterate 376.9 mg/mL (0.5 mmol/mL). The usual dose in adults and children is 0.2 mL/kg (0.1 mmol/kg) by intravenous injection. A second dose of up to 0.4 mL/kg (0.2 mmol/kg) may be given if necessary. For angiography, a dose of 0.1 to 0.2 mL/kg (0.05 to 0.1 mmol/kg) may be given, repeated if required.

As for Gadopentetic Acid, above.

◊ Reviews.

1. Runge VM, Parker JR. Worldwide clinical safety assessment of gadoteridol injection: an update. *Eur Radiol* 1997; **7** (suppl 5): 243–5.

Hypersensitivity. For a report of an anaphylactoid reaction with gadoteridol, see under Adverse Effects of Gadopentetic Acid, p.1479.

Pharmacokinetics

Gadoteridol is distributed into extracellular fluid after intravenous injection. About 94% of a dose is excreted unchanged in the urine within 24 hours. An elimination half-life of about 1.57 hours has been reported.

Uses and Administration

Gadoteridol is a nonionic gadolinium chelate with actions and uses similar to those of gadopentetic acid (p.1480). It has paramagnetic properties and is used as a magnetic resonance contrast medium (p.1474). It distributes mainly into extracellular fluid, but does not cross the blood-brain barrier, and is used in imaging of cranial and spinal structures and of the whole body.

Gadoteridol is available as a solution containing 279.3 mg/mL (0.5 mmol/mL). The usual adult dose is 0.2 mL/kg (0.1 mmol/kg) intravenously; for CNS imaging, an additional dose of up to 0.4 mL/kg (0.2 mmol/kg) may be given up to 30 minutes after the first if necessary. A single dose of 0.2 mL/kg (0.1 mmol/kg) is used in children from 6 months of age.

Preparations

USP 31: Gadoteridol Injection.

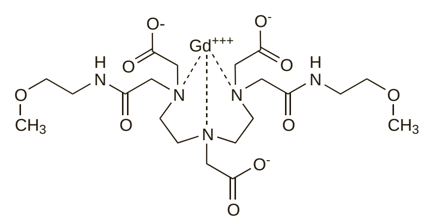
ATC Vet — QV08CA06.



Pharmacopoeias. In *US.*

USP 31 (Gadoversetamide). A white odourless powder. Freely soluble in water. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for Gadopentetic Acid, p.1479.

Interference with diagnostic tests. Like gadodiamide (see p.1479), gadoversetamide may interfere with colorimetric methods for measuring serum-calcium concentrations.

Gadoversetamide may also interfere with measurement of serum-copper, iron, and zinc concentrations.

Renal impairment. For the view that gadoversetamide may carry an increased risk of the development of nephrogenic systemic sclerosis in patients with renal impairment, see p.1479.

Pharmacokinetics

Gadoversetamide is distributed into the extracellular space after intravenous injection. It is not bound to plasma proteins. An elimination half-life of about 1.7 hours has been reported. It is not metabolised and about 95.5% of a dose is excreted in the urine within 24 hours. Gadoversetamide is removed by haemodialysis.

Uses and Administration

Gadoversetamide is a nonionic gadolinium chelate with actions and uses similar to those of gadopentetic acid (p.1480). It has paramagnetic properties and is used as a magnetic resonance contrast medium (p.1474). It distributes mainly into extracellular fluid, but does not cross the blood-brain barrier, and is used in imaging of cranial and spinal structures and of the whole body.

Gadoversetamide is available as a solution containing 330.9 mg/mL (0.5 mmol/mL). The usual dose is 0.2 mL/kg (0.1 mmol/kg) intravenously.

Preparations

USP 31: Gadoversetamide Injection.

Adverse Effects and Precautions

As for Gadopentetic Acid, p.1479.

Pharmacokinetics

Gadoxetate is distributed into the extracellular space after intravenous injection and is also taken up by the liver. It is less than 10% bound to plasma proteins. It is excreted in about equal amounts in the bile and in the urine. An elimination half-life of about 1 hour has been reported. Gadoxetate is removed by haemodialysis.

Uses and Administration

Gadoxetic acid is an ionic gadolinium chelate with actions similar to those of gadopentetic acid (p.1480). It has paramagnetic properties and is used as a magnetic resonance contrast medium (p.1474). It is taken up by the liver and excreted in bile and is used in imaging of the liver.

Gadoxetic acid is given intravenously as the sodium salt. It is available as a solution containing sodium gadoxetate 181.4 mg/mL (0.25 mmol/mL). The usual dose is 0.1 mL/kg (0.025 mmol/kg).

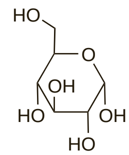
CAS — 59-23-4 (D-galactose); 3646-73-9 (α-D-galactose).
ATC — V04CE01; V08DA02 (microparticles of galactose).
ATC Vet — QV04CE01; QV08DA02 (microparticles of galactose).



Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*

Ph. Eur. 6.2 (Galactose). A white or almost white, crystalline or finely granulated powder. Freely soluble or soluble in water; very slightly soluble in alcohol.

USNF 26 (Galactose). A white, crystalline or finely granulated powder. Soluble in water; very slightly soluble in alcohol. Store in airtight containers.

Profile

Galactose is a naturally occurring monosaccharide used as an ultrasound contrast medium (p.1474); dissolution of galactose microparticles releases microbubbles of air that provide echo-enhancement. Galactose is used to enhance ultrasound imaging of the female genital tract. It is given transcervically as a microbubble-microparticle suspension prepared immediately before use by suspending 3 g of galactose microparticles in 13.5 mL of a solution containing 200 mg/mL galactose. The usual dose is 2 to 5 mL, with additional doses of 1 to 2 mL as required, to a maximum of 30 mL. Similar suspensions of galactose, with palmitic acid to stabilise the microbubbles, have been used in echocardiography.

The clearance of galactose given intravenously has been used as a measure of liver function. Galactose labelled with carbon-13 (p.2277) has also been used.

Precautions. Preparations that contain, or are metabolised to, galactose may interfere with the results from glucose tests (p.2314). Overestimation of glucose results may mask hypoglycaemia, resulting in the inappropriate use of insulin.[1,2]

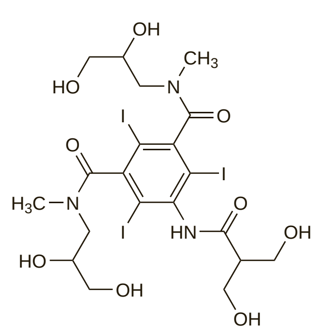
$C_{20}H_{28}I_3N_3O_9$ = 835.2.
CAS — 136949-58-1.
ATC — V08AB11.
ATC Vet — QV08AB11.



Profile

Iobitridol is a nonionic monomeric iodinated radiographic contrast medium (see p.1474). It may be given intravenously, intra-arterially, or by instillation into body cavities and is used in a wide range of procedures including angiography, arthrography, cholangiopancreatography, and hysterosalpingography. It is also used for contrast enhancement in computed tomography.

It is usually available as solutions containing 54.84 to 76.78% of iobitridol (equivalent to 250 to 350 mg/mL of iodine). The dose and strength used varies depending on the procedure and route.

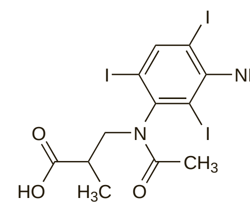
Iocetamic Acid *(BAN, USAN, pINN)*

Acide Iocétamique; Ácido iocetámico; Acidum Iocetamicum; DRC-1201; Jocetamsyra; Josetaamihappo; MP-620. *N*-Acetyl-*N*-(3-amino-2,4,6-tri-iodophenyl)-2-methyl-β-alanine; 2-[*N*-(3-Amino-2,4,6-tri-iodophenyl)acetamidomethyl]-propionic acid.

Йоцетамовая Кислота

$C_{12}H_{13}I_3N_2O_3$ = 614.0.
CAS — 16034-77-8.
ATC — V08AC07.
ATC Vet — QV08AC07.



Description. Iocetamic acid contains about 62% of I.

Profile

Iocetamic acid is an ionic monomeric iodinated radiographic contrast medium with similar properties to iopanoic acid (p.1484). It is absorbed from the gastrointestinal tract and excreted in bile and has been given orally for cholecystography.

Preparations

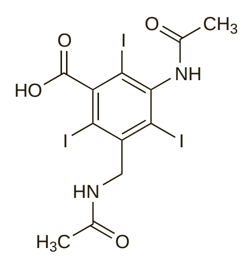
Proprietary Preparations (details are given in Part 3)
Neth.: Cholebrine†.

Iodamide *(BAN, USAN, rINN)*

Ametriodinic Acid; B-4130; Iodamida; Iodamidum; Jodamid; Jodiamidi; SH-926. α,5-Diacetamido-2,4,6-tri-iodo-*m*-toluic acid; 3-Acetamido-5-acetamidomethyl-2,4,6-tri-iodobenzoic acid.

Йодамид

$C_{12}H_{11}I_3N_2O_4$ = 627.9.
CAS — 440-58-4.
ATC — V08AA03.
ATC Vet — QV08AA03.



Description. Iodamide contains about 60.6% of I.

Pharmacopoeias. In *Jpn.*

Meglumine Iodamide *(BANM, rINNM)*

Iodamida de meglumina; Iodamide Meglumine *(USAN)*; Iodamide Méglumine; Meglumini Iodamidum. The *N*-methylglucamine salt of iodamide.

Меглумина Йодамид

$C_{12}H_{11}I_3N_2O_4,C_7H_{17}NO_5$ = 823.2.
CAS — 18656-21-8.
ATC — V08AA03.
ATC Vet — QV08AA03.

Description. Meglumine iodamide contains about 46.3% of I.

Sodium Iodamide *(BANM, rINNM)*

Iodamida sódica; Iodamide Sodique; Iodamide Sodium; Natrii Iodamidum.

Натрий Йодамид

$C_{12}H_{10}I_3N_2NaO_4$ = 649.9.
CAS — 10098-82-5.
ATC — V08AA03.
ATC Vet — QV08AA03.

Description. Sodium iodamide contains about 58.6% of I.

Profile

Iodamide is an ionic monomeric iodinated radiographic contrast medium (see p.1474). It is used in many procedures and may be given intravenously or by other routes, for example by instillation into the bladder or uterus; it has also been used for computed tomography.

It is usually given as a 24 to 65% solution of the meglumine salt, or as a mixture of the sodium and meglumine salts; solutions of the sodium salt have also been used. The dose varies according to the procedure and route.

Preparations

Proprietary Preparations (details are given in Part 3)

Iodised Oil

Aceite yodado; Ethiodized Oil.

CAS — 8001-40-9 (iodised oil); 8008-53-5 (ethiodized oil injection).
ATC — V08AD01.
ATC Vet — QV08AD01.

Description. Iodised oil is an iodine addition product of the ethyl esters of the fatty acids obtained from poppy-seed oil. It contains about 35 to 39% of combined iodine.

Incompatibility. Because of its solvent action on polystyrene, iodised oil injection should not be given in syringes made with polystyrene.

Adverse Effects and Precautions

The risk of hypersensitivity reactions or iodism is greater after the use of iodised oil than after water-soluble iodinated contrast media such as the amidotrizoates. Pulmonary oil embolism is reported to be relatively frequent after lymphography but is not usually severe; however, hypotension, tachycardia, and pulmonary oedema and infarction may occur rarely and deaths have been reported in patients with pulmonary disease. Chemical pneumonitis, oedema, granuloma formation, and goitre have occurred.

Great care must be taken to avoid vascular structures, because of the danger of oil embolism; it should therefore not be used in areas affected by haemorrhage or local trauma. Iodised oil should be used with care in patients with thyroid dysfunction or a history of allergic reactions. Use may interfere with thyroid-function tests for several months.

Hysterosalpingography. The use of oily contrast media such as iodised oil for hysterosalpingography has been associated with serious adverse effects, including tubal occlusion,[1] and cerebral and pulmonary oil embolism,[2,3] and water-soluble contrast media are usually preferred. However, diagnostic hysterosalpingography using iodised oil has been associated with an increase in fertility[4] and randomised trials[5,6] using iodised oil for treatment in patients with unexplained infertility have found a similar effect.

Pharmacokinetics

Iodised oil may persist in the body for several weeks or months. It is only slowly absorbed from most body sites, although absorption from the peritoneal cavity is stated to be relatively rapid. It is reported to be slowly metabolised to fatty acids and iodine.

Uses and Administration

Iodised oil is an iodinated radiographic contrast medium (p.1474) that is used mainly for lymphography. It has been used for hysterosalpingography but water-soluble agents are preferred. Although some preparations have been used in bronchography, the fluid injection of iodised oil is unsuitable for such use. Doses are dependent upon the procedure.

Because it is slowly metabolised to release iodine, iodised oil is used in the management of iodine deficiency (p.2170).

Infertility. For reference to the use of iodised oil in the management of infertility, see Hysterosalpingography under Adverse Effects and Precautions, above.

Malignant neoplasms. Intra-arterial injection of iodised oil has been used in both the diagnosis and management of malignant neoplasms of the liver (p.667). After injection into the hepatic artery, iodised oil is selectively retained by hepatic carcinomas and may have a role as an adjunct to computed tomography for both diagnosis and monitoring.[1-3] It has also been used in the management of hepatic carcinoma,[2,4] either to increase the retention of antineoplastics (chemoembolisation),[5] or to provide targeted delivery of radioactive iodine.[6]

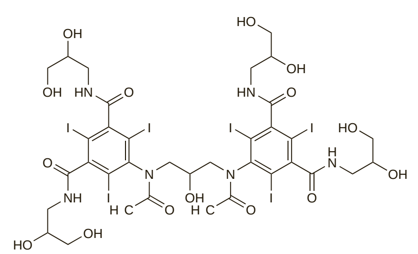
Iodixanol *(BAN, USAN, rINN)*

2-5410-3A; Iodixanolum; Jodiksanoli; Jodixanol. 5,5′-[(2-Hydroxytrimethylene)bis(acetylimino)]bis[*N*,*N*′-bis(2,3-dihydroxypropyl)-2,4,6-triiodoisophthalamide].

Йодиксанол

$C_{35}H_{44}I_6N_6O_{15}$ = 1550.2.
CAS — 92339-11-2.
ATC — V08AB09.
ATC Vet — QV08AB09.



Description. Iodixanol contains about 49.1% of I.

Pharmacopoeias. In *US.*

USP 31 (Iodixanol). A white to off-white, amorphous, odourless, hygroscopic powder. Freely soluble in water. Store at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects, Treatment, and Precautions

See under the amidotrizoates, p.1475. For adverse effects relating to the use of nonionic contrast media such as iodixanol for myelography, see under Iohexol (p.1483).

Pharmacokinetics

Iodixanol is rapidly distributed into extracellular fluid after intravenous injection. It is not bound to plasma proteins. It is not metabolised and about 97% of a dose is excreted in the urine within 24 hours. A terminal elimination half-life of about 2 hours has been reported. Iodixanol is removed by dialysis.

Uses and Administration

Iodixanol is a nonionic dimeric iodinated radiographic contrast medium (see p.1474); it is iso-osmolar with blood. It may be given intravenously, intra-arterially, intrathecally, orally, or by instillation into body cavities, and is used in procedures including angiography, arthrography, cholangiopancreatography, hysterosalpingography, myelography, and urography, as well as for imaging of the upper gastrointestinal tract and for contrast enhancement during computed tomography.

Iodixanol is usually available as a solution containing between 30.5 and 65.2% of iodixanol (equivalent to between 150 and 320 mg/mL of iodine). The dose and strength used vary according to the procedure and route.

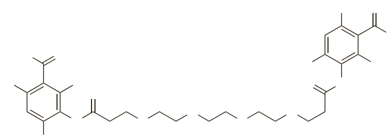
CAS — 31127-82-9.
ATC — V08AC01.
ATC Vet — QV08AC01.



Description. Iodoxamic acid contains about 59.1% of I.

Meglumine Iodoxamate *(BANM, rINNM)*

Dimeglumine Iodoxamate; Iodoxamate de Méglumine; Iodoxamate Meglumine *(USAN)*; Iodoxamato de meglumina; Meglumini Iodoxamas. The di(*N*-methylglucamine) salt of iodoxamic acid.

Меглумина Йодоксамат

$C_{26}H_{26}I_6N_2O_{10},(C_7H_{17}NO_5)_2$ = 1678.3.
CAS — 51764-33-1.
ATC — V08AC01.
ATC Vet — QV08AC01.

Description. Meglumine iodoxamate contains about 45.4% of I.

Profile

Iodoxamic acid is an ionic dimeric iodinated radiographic contrast medium (p.1474) that has been used intravenously as the meglumine salt for cholecystography and cholangiography.

Iofendylate *(BAN, rINN)*

Ethyl Iodophenylundecylate; Iodophendylate; Iofendilato; Iofendylatum; Iophendylate; Jofendylaatti; Jofendylat. A mixture of stereoisomers of ethyl 10-(4-iodophenyl)undecanoate.

Йофендилат

$C_{19}H_{29}IO_2$ = 416.3.
CAS — 99-79-6; 1320-11-2.
ATC — V08AD04.
ATC Vet — QV08AD04.

Description. Iofendylate contains about 30.5% of I.

Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Iophendylate). A colourless to pale yellow, viscous liquid, darkening on long exposure to air. Is odourless or has a faintly ethereal odour. Very slightly soluble in water; freely soluble in alcohol, in chloroform, in ether, and in benzene. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Profile

Iofendylate is an ionic monomeric iodinated radiographic contrast medium (p.1474). It was formerly used for myelography, but was associated with serious adverse effects, including allergy, arachnoiditis, and aseptic meningitis, and has now been superseded by nonionic media. Residues of iofendylate remaining years after myelography have been associated with adverse effects. Other former uses included ventriculography, and visualisation of the fetus in the amniotic sac.

Preparations

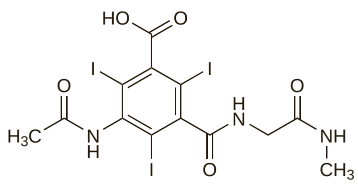
BP 2008: Iofendylate Injection;
USP 31: Iophendylate Injection.

Ioglicic Acid *(BAN, USAN, rINN)*

Acide Ioglicique; Ácido ioglícico; Acidum Ioglicicum; Joglicinsyra; Joglisiinihappo; SH-H-200-AB. 5-Acetamido-2,4,6-tri-iodo-*N*-(methylcarbamoylmethyl)isophthalamic acid.

Йоглициевая Кислота

$C_{13}H_{12}I_3N_3O_5$ = 671.0.
CAS — 49755-67-1.
ATC — V08AA06.
ATC Vet — QV08AA06.



Description. Ioglicic acid contains about 56.7% of I.

Meglumine Ioglicate *(BANM, rINNM)*

Ioglicate de Méglumine; Ioglicate Meglumine; Ioglicato de meglumina; Meglumini Ioglicas. The *N*-methylglucamine salt of ioglicic acid.

Меглумина Йоглициат

$C_{13}H_{12}I_3N_3O_5,C_7H_{17}NO_5$ = 866.2.
ATC — V08AA06.
ATC Vet — QV08AA06.

Description. Meglumine ioglicate contains about 44.0% of I.

Sodium Ioglicate *(BANM, rINNM)*

Ioglicate de Sodium; Ioglicate Sodium; Ioglicato sódico; Natrii Ioglicas.

Натрий Йоглициат

$C_{13}H_{11}I_3N_3NaO_5$ = 692.9.
ATC — V08AA06.
ATC Vet — QV08AA06.

Description. Sodium ioglicate contains about 54.9% of I.

Profile

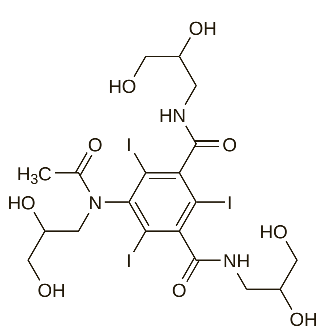
Ioglicic acid is an ionic monomeric iodinated radiographic contrast medium (p.1474) that has been used, as the meglumine and sodium salts, for diagnostic procedures.

Iohexol *(BAN, USAN, rINN)*

Iohexolum; Joheksoli; Joheksolis; Johexol; Win-39424. *N,N'*-Bis(2,3-dihydroxypropyl)-5-[*N*-(2,3-dihydroxypropyl)acetamido]-2,4,6-tri-iodoisophthalamide.

Йогексол

$C_{19}H_{26}I_3N_3O_9$ = 821.1.
CAS — 66108-95-0.
ATC — V08AB02.
ATC Vet — QV08AB02.



Description. Iohexol contains about 46.4% of I.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Iohexol). A white or greyish-white, hygroscopic powder. Very soluble in water; practically insoluble in dichloromethane; freely soluble in methyl alcohol. Store in airtight containers. Protect from light.

USP 31 (Iohexol). A white to off-white, hygroscopic, odourless powder. Very soluble in water and in methyl alcohol; practically insoluble or insoluble in chloroform and in ether. Store at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects, Treatment, and Precautions

Iohexol and other nonionic iodinated contrast media have similar adverse effects and precautions to ionic media but the effects tend to be less severe and the incidence is generally lower; see under the amidotrizoates, p.1475 for details.

Additional neurological adverse effects may occur when nonionic media such as iohexol are used for myelography. These include severe headache, backache, neck stiffness, dizziness, and leg or sciatic-type pain. Convulsions, aseptic meningitis, and mild and transitory perceptual aberrations, such as visual and speech disturbances, and confusion, may occur occasionally; rarely, more severe mental disturbances have occurred. Urinary retention has also been reported.

Breast feeding. Iohexol is distributed into breast milk in very small quantities[1] but no adverse effects have been seen in breast-feeding infants whose mothers were receiving iohexol and the American Academy of Pediatrics considers[2] that it is therefore usually compatible with breast feeding.

1. Nielsen ST, *et al.* Excretion of iohexol and metrizoate in human breast milk. *Acta Radiol* 1987; **28:** 523–6.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 27/03/06)

Effects on the nervous system. Encephalopathy developed in a 48-year-old man with sciatica within 9 hours of iohexol for lumbar myelography but had largely resolved 48 hours after the myelogram; complete resolution took 4 days.[1] However, recovery was slow in a patient who developed paraplegia and areflexia in the legs after a similar procedure. Five months later the patient still complained of paraesthesia in her legs and could not stand without support.[2]

1. Donaghy M, *et al.* Encephalopathy after iohexol myelography. *Lancet* 1985; **ii:** 887.
2. Noda K, *et al.* Prolonged paraplegia after iohexol myelography. *Lancet* 1991; **337**: 681.

Pharmacokinetics

After intravascular use, 90% or more of a dose of iohexol is eliminated unchanged in the urine within 24 hours. An elimination half-life of about 2 hours in patients with normal renal function has been reported. Protein binding in blood is reported to be very low.

Pregnancy. Contrast material was detected[1] in the intestines of twin neonates who were born 17 hours after iohexol was given to their mother for angiography, suggesting that transplacental transfer had taken place.

1. Moon AJ, *et al.* Transplacental passage of iohexol. *J Pediatr* 2000; **136:** 548–9.

Uses and Administration

Iohexol is a nonionic monomeric iodinated radiographic contrast medium (see p.1474). It may be given intravenously, intra-arterially, intrathecally, orally, rectally, or by instillation into body cavities and is used in diagnostic procedures including myelography, angiography, urography, arthrography, and visualisation of the gastrointestinal tract and body cavities. Iohexol is also used to produce contrast enhancement during computed tomography.

Iohexol is usually available as solutions containing 30.2 to 75.5% of iohexol (equivalent to 140 to 350 mg/mL of iodine) and the dose and strength used vary according to the procedure and the route.

Preparations

USP 31: Iohexol Injection.

Proprietary Preparations (details are given in Part 3)

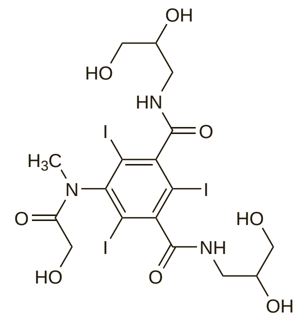
$C_{17}H_{22}I_3N_3O_8$ = 777.1.
CAS — 78649-41-9.
ATC — V08AB10.
ATC Vet — QV08AB10.



Description. Iomeprol contains about 49% of I.

Adverse Effects, Treatment, and Precautions

As for the amidotrizoates (p.1475). For adverse effects relating to the use of nonionic contrast media such as iomeprol for myelography, see under Iohexol (p.1483).

Pharmacokinetics

After intravascular use, iomeprol is rapidly eliminated unchanged in the urine, with a terminal elimination half-life of 1.9 hours. It is not significantly bound to plasma proteins.

Uses and Administration

Iomeprol is a nonionic monomeric iodinated radiographic contrast medium (see p.1474). It may be given intravenously, intra-arterially, intrathecally, or by instillation into body cavities, and is used in radiographic procedures including myelography, angiography, urography, and arthrography. It is also used to produce contrast enhancement during computed tomography.

Iomeprol is usually available as solutions containing 30.62 to 81.65% of iomeprol (equivalent to 150 to 400 mg/mL of iodine) and the dose and strength used vary according to the procedure and the route.

6. Klein KM, *et al.* Status epilepticus and seizures induced by iopamidol myelography. *Seizure* 2004; **13:** 196–9.

Pharmacokinetics

On intravascular use, iopamidol is rapidly eliminated, with up to 50% of the dose recovered unchanged in the urine within 2 hours; the elimination half-life is about 2 hours. It is not significantly bound to plasma proteins.

Uses and Administration

Iopamidol is a nonionic monomeric iodinated radiographic contrast medium (see p.1474). It may be given intravenously, intra-arterially, intrathecally, intra-articularly, orally, or rectally and is used in radiographic procedures including angiography, arthrography, myelography, urography, and imaging of the gastrointestinal tract. Iopamidol is also used for contrast enhancement during computed tomography.

Iopamidol is usually available as solutions containing 30.62 to 75.5% of iopamidol (equivalent to 150 to 370 mg/mL of iodine) and the dose and strength used vary according to the procedure and route.

Preparations

USP 31: Iopamidol Injection.

Proprietary Preparations (details are given in Part 3)

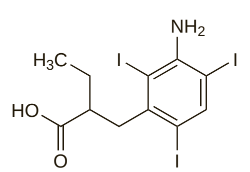
Iopanoic Acid *(BAN, rINN)*

Acide iopanoïque; Ácido iopanoico; Acidum iopanoicum; Iodopanoic Acid; Jopaanihappo; Jopano rūgštis; Jopánsav; Jopansyra; Kyselina jopanoová. 2-(3-Amino-2,4,6-tri-iodobenzyl)butyric acid.

Йопаноевая Кислота

$C_{11}H_{12}I_3NO_2$ = 570.9.
CAS — 96-83-3.
ATC — V08AC06.
ATC Vet — QV08AC06.



Description. Iopanoic acid contains about 66.7% of I.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Iopanoic Acid). A white or yellowish-white powder. Practically insoluble in water; soluble in dehydrated alcohol and in methyl alcohol; dissolves in dilute solutions of alkali hydroxides. Protect from light.

USP 31 (Iopanoic Acid). A cream-coloured powder, with a faint characteristic odour. Insoluble in water; soluble in alcohol, in chloroform, in ether, and in solutions of alkali hydroxides and carbonates. Store in airtight containers. Protect from light.

Adverse Effects

Gastrointestinal disturbances such as nausea, vomiting, abdominal cramp, and diarrhoea are reported to occur in up to 40% of patients but are usually mild and transient. Mild stinging or burning on micturition, and skin rashes and flushing have occurred occasionally. Acute renal failure, thrombocytopenia, and hypersensitivity reactions have been reported.

Iopanoic acid has potent uricosuric and anticholinesterase effects.

Precautions

Iopanoic acid is contra-indicated in severe hepatic or renal disease; doses higher than 3 g should not be given to patients with renal impairment. It should not be used in the presence of acute gastrointestinal disorders that may impair absorption. It should be used with caution in patients with a history of hypersensitivity to iodine or to other contrast media, severe hyperthyroidism, hyperuricaemia, or cholangitis. Because of its cholinergic action, premedication with atropine has been suggested in some countries for patients with coronary heart disease. Iodine-containing contrast media may interfere with thyroid-function tests and with some blood and urine tests.

Breast feeding. No adverse effects have been observed in breast-feeding infants whose mothers were receiving iopanoic acid and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 27/03/06)

Pharmacokinetics

Iopanoic acid is variably absorbed from the gastrointestinal tract and is strongly and extensively bound to plasma proteins. It is conjugated in the liver to the glucuronide and excreted largely in the bile and the remainder (about one-third of the dose) in the urine. It appears in the gallbladder about 4 hours after a dose is taken and maximum concentrations occur after about 17 hours. About 50% of a dose is excreted in 24 hours, but elevated protein-bound iodine concentrations may persist for several months.

Uses and Administration

Iopanoic acid is an ionic monomeric iodinated radiographic contrast medium (p.1474). It has been given orally for cholecystography and cholangiography in usual doses of 3 g, given with plenty of water, about 10 to 14 hours before X-ray examination.

Iopanoic acid has also been used in the management of hyperthyroidism (see below).

Hyperthyroidism. Iopanoic acid and other iodinated oral cholecystographic agents reduce conversion of thyroxine to tri-iodothyronine, as well as inhibiting release of thyroid hormones from the thyroid gland,[1] and they have been used in the management of hyperthyroidism (p.2165). Iopanoic acid has been used successfully for pre-operative preparation in severe hyperthyroidism,[2-4] and for control of hyperthyroidism before radio-iodine treatment.[5] It has a rapid effect but rebound hyperthyroidism may occur and it is not generally suitable for long-term use.[1]

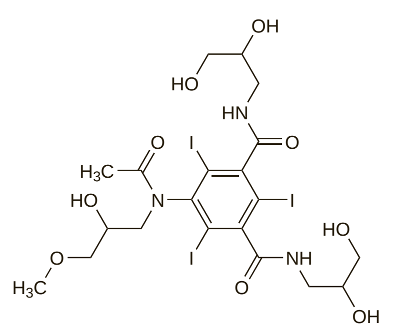
CAS — 89797-00-2.
ATC — V08AB08.
ATC Vet — QV08AB08.



Description. Iopentol contains about 45.6% of I.

Profile

Iopentol is a nonionic monomeric iodinated radiographic contrast medium (see p.1474). It may be given intravenously, intra-arterially, orally, or by instillation into body cavities, and is used in procedures including angiography, arthrography, endoscopic retrograde cholangiopancreatography, hysterosalpingography, urography, and visualisation of the gastrointestinal tract. It is also used for contrast enhancement in computed tomography.

Iopentol is usually available as solutions containing 32.9 to 76.8% of iopentol (equivalent to 150 to 350 mg/mL of iodine) and the dose and strength used vary according to the procedure and route.

ATC Vet — QV08AC08.

Description. Sodium iopodate contains about 61.4% of I.

Pharmacopoeias. In *US.*

USP 31 (Ipodate Sodium). A fine, white or off-white, odourless, crystalline powder. Soluble 1 in less than 1 of water, 1 in 2 of alcohol, 1 in 2 of dimethylacetamide, and 1 in 3.5 of dimethylformamide and of dimethyl sulfoxide; very slightly soluble in chloroform; freely soluble in methyl alcohol. Store in airtight containers.

Profile

Iopodic acid is an ionic monomeric iodinated radiographic contrast medium (see p.1474). It has similar properties to iopanoic acid (p.1484) and has been used orally as the sodium or calcium salt for cholecystography and cholangiography. It has also been tried in the management of hyperthyroidism.

Preparations

USP 31: Ipodate Sodium Capsules.

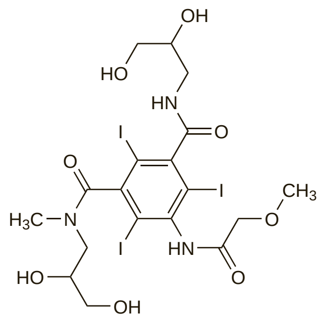
CAS — 73334-07-3.
ATC — V08AB05.
ATC Vet — QV08AB05.



Description. Iopromide contains about 48.1% of I.

Pharmacopoeias. In *US*.

USP 31 (Iopromide). A white to slightly yellow powder. Freely soluble in water and in dimethyl sulfoxide; practically insoluble in alcohol, in acetone, and in ether. Protect from light.

Adverse Effects, Treatment, and Precautions

See under the amidotrizoates, p.1475.

Pharmacokinetics

On intravascular use, iopromide is rapidly distributed in the extracellular fluid. It is not metabolised and is eliminated unchanged in the urine; about 2% of a dose is excreted in faeces. An elimination half-life of about 2 hours has been reported; about 60% of a dose is excreted in urine within 3 hours and about 92% within 24 hours. Iopromide is not significantly bound to plasma proteins.

Uses and Administration

Iopromide is a nonionic monomeric iodinated radiographic contrast medium (see p.1474). It may be given intravenously, intra-arterially, or by instillation into body cavities, and is used in procedures including angiography, arthrography, hysterosalpingography, urography, and assessment of dialysis shunt patency. It is also used for contrast enhancement during computed tomography.

Iopromide is usually available as solutions containing 31.2 to 76.9% of iopromide (equivalent to 150 to 370 mg/mL of iodine) and the dose and strength used vary according to the procedure and route.

Preparations

USP 31: Iopromide Injection.

Меглумина Йоталамат

$C_{11}H_9I_3N_2O_4,C_7H_{17}NO_5$ = 809.1.
CAS — 13087-53-1.
ATC — V08AA04.
ATC Vet — QV08AA04.

Description. Meglumine iotalamate contains about 47.1% of I.

Pharmacopoeias. *US* includes only as various injections.

Sodium Iotalamate *(BANM, rINNM)*

Iotalamate de Sodium; Iotalamato de sodico; Iotalamato de sodio; Iothalamate Sodium; Natrii Iotalamas; Sodium Iothalamate.

Натрий Йоталамат

$C_{11}H_8I_3N_2NaO_4$ = 635.9.
CAS — 17692-74-9; 1225-20-3.
ATC — V08AA04.
ATC Vet — QV08AA04.

Description. Sodium iotalamate contains about 59.9% of I.

Pharmacopoeias. *US* includes only as various injections.

Adverse Effects, Treatment, and Precautions

As for the amidotrizoates, p.1475.

Incidence of adverse effects. In 40 patients who underwent phlebography with 60% meglumine iotalamate minor adverse reactions were common despite the use of saline flushing and muscle contraction to clear the veins after examination.[1] The commonest effect was pain at the site of injection, or in the calf and foot; 15 patients of those who had pain in the calf or foot were found to have venous thrombosis. Major complications of phlebography appear to be rare but can cause serious morbidity; examination of 200 case notes and a retrospective study involving 3060 patients revealed 4 cases of necrosis in the skin of the foot and gangrene of the foot in 2.

1. Thomas ML, MacDonald LM. Complications of ascending phlebography of the leg. *BMJ* 1978; **ii:** 317–18.

Pharmacokinetics

On intravascular use the iotalamates are rapidly distributed; suitable concentrations for urography reach the urinary tract within 3 to 8 minutes of a bolus intravenous injection. Protein binding is reported to be low. The iotalamates are eliminated by the kidneys. In patients with normal renal function more than 90% of the dose injected is excreted in urine within 24 hours; an elimination half-life of about 90 minutes has been reported. Small amounts are reported to be excreted via the bile in the faeces. The iotalamates are removed by peritoneal dialysis and haemodialysis.

Uses and Administration

Iotalamic acid is an ionic monomeric iodinated radiographic contrast medium (p.1474) with actions similar to the amidotrizoates (p.1477). It may be given intravenously, intra-arterially, or by instillation into the bladder or uterus, and is used in procedures including angiography, arthrography, cholangiography, urography and hysterosalpingography. It is also used for contrast enhancement in computed tomography. Iotalamates have also been given orally or rectally for imaging of the gastrointestinal tract.

Iotalamic acid is usually available as solutions containing up to 66.8% of sodium iotalamate or up to 60% of meglumine iotalamate. The dose and strength used vary according to the procedure and route. A mixture of the two salts has been given to minimise adverse effects.

Preparations

USP 31: Iothalamate Meglumine and Iothalamate Sodium Injection; Iothalamate Meglumine Injection; Iothalamate Sodium Injection.

Proprietary Preparations (details are given in Part 3)

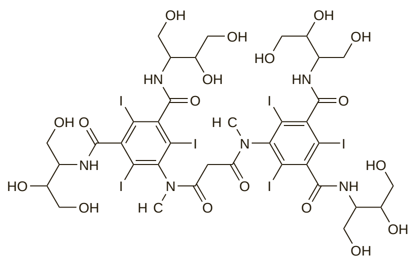
Йотролан

$C_{37}H_{48}I_6N_6O_{18}$ = 1626.2.
CAS — 79770-24-4.
ATC — V08AB06.
ATC Vet — QV08AB06.



Description. Iotrolan contains about 46.8% of I.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Iotrolan). A white or yellowish-white, hygroscopic powder. Very soluble in water; practically insoluble in alcohol; freely soluble in dimethyl sulfoxide. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for the amidotrizoates, p.1475. For the adverse effects relating to the use of nonionic contrast media such as iotrolan for myelography, see under Iohexol, p.1483.

Pharmacokinetics

Iotrolan is excreted unchanged in the urine. After intrathecal injection, about 80% is excreted in the urine within 24 hours.

Uses and Administration

Iotrolan is a nonionic dimeric iodinated radiographic contrast medium (p.1474). It is given intrathecally for myelography and for contrast enhancement in computed tomography, and by instillation into body ducts or cavities for procedures including lymphography, arthrography, hysterosalpingography, cholangiopancreatography, and for visualisation of the mammary ducts. It may also be given orally for imaging of the gastrointestinal tract.

Iotrolan is usually available as solutions containing 51.3% or 64.1% of iotrolan (equivalent to 240 or 300 mg/mL of iodine, respectively) and the dose and strength used vary according to the procedure and route.

Меглумина Йотроксат

$C_{22}H_{18}I_6N_2O_9,2C_7H_{17}NO_5$ = 1606.2.
CAS — 68890-05-1.
ATC — V08AC02.
ATC Vet — QV08AC02.

Description. Meglumine iotroxate contains about 47.4% of I.

Adverse Effects, Treatment, and Precautions

See under the amidotrizoates, p.1475.

Pharmacokinetics

After intravenous injection, iotroxic acid binds to plasma proteins and is taken up by the liver; plasma-protein binding is about 60 to 90%. It is excreted primarily unchanged in the bile; a small amount is metabolised and excreted in the urine.

Uses and Administration

Iotroxic acid is an ionic dimeric iodinated radiographic contrast medium (see p.1474); it is taken up by the liver and excreted in bile, and is used in cholecystography and cholangiography.

Iotroxic acid is given intravenously as a solution containing 10.5% of the meglumine salt. The usual dose is 10.5 g of meglumine iotroxate (equivalent to about 5 g of iodine), given by infusion over at least 15 minutes. Alternatively, a solution containing 22.8% of meglumine iotroxate may be used.

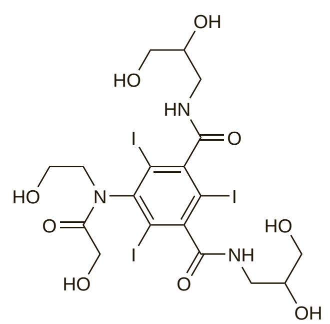
CAS — 87771-40-2.
ATC — V08AB07.
ATC Vet — QV08AB07.



Description. Ioversol contains about 47.2% of I.

Pharmacopoeias. In *US.*

USP 31 (Ioversol). Store at a temperature of 25°, excursions permitted between 15° and 30°.

Adverse Effects, Treatment, and Precautions

See under the amidotrizoates, p.1475.

Pharmacokinetics

When given intravascularly, ioversol is rapidly eliminated unchanged in the urine, with a half-life of about 1.5 hours; more than 95% of a dose is eliminated within 24 hours. Binding to plasma or serum proteins is very low.

Uses and Administration

Ioversol is a nonionic monomeric iodinated radiographic contrast medium (p.1474) that is given intra-arterially or intravenously for angiography and urography. It is also used for contrast enhancement during computed tomography. It is usually available as a solution containing 34 to 74% of ioversol (equivalent to 160 to 350 mg/mL of iodine). The dose and strength used vary according to the procedure and route.

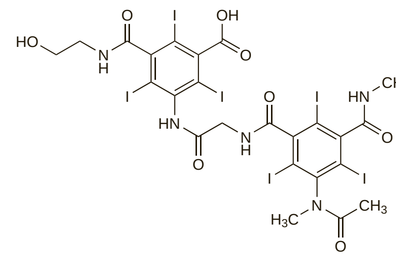
ATC Vet — QV08AB03.



Description. Ioxaglic acid contains about 60% of I.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Ioxaglic Acid). A white or almost white hygroscopic powder. Very slightly soluble in water and in dichloromethane; slightly soluble in alcohol. It dissolves in dilute solutions of alkali hydroxides. Store in airtight containers. Protect from light.

USP 31 (Ioxaglic Acid). Store at a temperature of 25°, excursions permitted between 15° and 30°.

Meglumine Ioxaglate *(BANM, rINNM)*

Ioxaglate de Méglumine; Ioxaglate Meglumine *(USAN)*; Ioxaglato de meglumina; Meglumini Ioxaglas; MP-302 (meglumine ioxaglate with sodium ioxaglate). The *N*-methylglucamine salt of ioxaglic acid.

Меглумина Йоксаглат

$C_{24}H_{21}I_6N_5O_8,C_7H_{17}NO_5$ = 1464.1.
CAS — 59018-13-2.
ATC — V08AB03.
ATC Vet — QV08AB03.

Description. Meglumine ioxaglate contains about 52% of I.

Sodium Ioxaglate *(BANM, rINNM)*

Ioxaglate de Sodium; Ioxaglate Sodium *(USAN)*; Ioxaglato sódico; MP-302 (sodium ioxaglate with meglumine ioxaglate); Natrii Ioxaglas; Natriumjoksaglaatti; Natriumjoxaglat.

Натрий Йоксаглат

$C_{24}H_{20}I_6N_5NaO_8$ = 1290.9.
CAS — 67992-58-9.
ATC — V08AB03.
ATC Vet — QV08AB03.

Description. Sodium ioxaglate contains about 59% of I.

Adverse Effects, Treatment, and Precautions

See under the amidotrizoates, p.1475.

Pharmacokinetics

On intravascular use, ioxaglates are rapidly distributed throughout the extracellular fluid. Protein binding is reported to be very low. They are mainly excreted unchanged in the urine, although biliary excretion may predominate in renal impairment. With normal renal function, about 90% of a dose is excreted in the urine within 24 hours; an elimination half-life of about 90 minutes has been reported. Ioxaglates cross the placenta and are distributed into breast milk. They are removed by haemodialysis and peritoneal dialysis.

Uses and Administration

Ioxaglic acid is an ionic dimeric iodinated radiographic contrast medium (p.1474). It is given intravenously, intra-arterially, intra-articularly, or by instillation into body ducts and cavities and is used in diagnostic procedures including angiography, arthrography, hysterosalpingography, and urography. It is also used for contrast enhancement during computed tomography.

Ioxaglic acid is usually available as solutions containing a mixture of the sodium and meglumine salts. Commonly used solutions contain 39.3% of meglumine ioxaglate and 19.6% of sodium ioxaglate (equivalent to 320 mg/mL of iodine) or 24.6% of meglumine ioxaglate and 12.3% of sodium ioxaglate (equivalent to 200 mg/mL of iodine). The dose and strength used depend upon the procedure and route.

Preparations

USP 31: Ioxaglate Meglumine and Ioxaglate Sodium Injection.

Proprietary Preparations (details are given in Part 3)

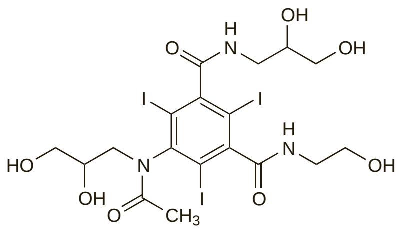
$C_{18}H_{24}I_3N_3O_8$ = 791.1.

CAS — 107793-72-6.

ATC — V08AB12.

ATC Vet — QV08AB12.



Description. Ioxilan contains about 48.1% of I.

Pharmacopoeias. In *US.*

USP 31 (Ioxilan). A white to off-white, practically odourless, powder. Soluble in water and in methyl alcohol. pH of a 10% solution in water is between 5.0 and 7.5. Store at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects, Treatment, and Precautions

See under the amidotrizoates, p.1475.

Pharmacokinetics

After intravascular use, ioxilan is rapidly eliminated unchanged in the urine; about 94% of a dose is excreted within 24 hours. Protein binding is reported to be very low. Ioxilan is dialysable.

Uses and Administration

Ioxilan is a nonionic monomeric iodinated radiographic contrast medium (see p.1474). It is given intra-arterially or intravenously for procedures including angiography and urography; it is also used for contrast enhancement during computed tomography.

Ioxilan is usually available as solutions containing 62.3 or 72.7% of ioxilan (equivalent to 300 or 350 mg/mL of iodine). The dose and strength used vary according to the procedure and route.

ATC Vet — QV08AA05.

Description. Meglumine ioxitalamate contains about 45.4% of I.

Sodium Ioxitalamate *(rINNM)*

Ioxitalamate de Sodium; Ioxitalamate Sodium; Ioxitalamato sódico; Natrii Ioxitalamas.

Натрий Йокситаламат

$C_{12}H_{10}I_3N_2NaO_5$ = 665.9.

CAS — 33954-26-6.

ATC — V08AA05.

ATC Vet — QV08AA05.

Description. Sodium ioxitalamate contains about 57.2% of I.

Profile

Ioxitalamic acid is an ionic monomeric iodinated radiographic contrast medium (p.1474) with actions similar to those of the amidotrizoates (p.1475). It is given intravenously or by instillation into body cavities for procedures including angiography, cholangiography, cystography, hysterosalpingography, and urography; it may be given orally or rectally for imaging of the gastrointestinal tract. It is also used for contrast enhancement in computed tomography.

Ioxitalamic acid is usually available as a solution containing 21% of the sodium salt (equivalent to 120 mg/mL of iodine), 55.1 to 66% of the meglumine salt (equivalent to 250 to 300 mg/mL of iodine), or as a mixture of both salts. The dose and strength used vary according to the procedure and route.

Monoethanolamine ioxitalamate has also been used.

Preparations

Proprietary Preparations (details are given in Part 3)

Mangafodipir Trisodium *(BANM, USAN, rINNM)*

Mangafodipir trisódico; Mangafodipir Trisodique; Mangafodipirum Trinatricum; MnDPDP (mangafodipir); S-095 (mangafodipir); Win-59010; Win-59010-2 (mangafodipir). Trisodium trihydrogen (*OC*-6-13)-{[*N*,*N'*-ethylenebis(*N*-{[3-hydroxy-5-(hydroxymethyl)-2-methyl-4-pyridyl]methyl}glycine) 5,5'-bis(phosphato)](8-)} manganate(6-); Trisodium trihydrogen (*OC*-6-13)-*N*,*N'*-ethane-1,2-diylbis{N-[2-methyl-3-oxido-κ*O*-5-(phosphonatooxymethyl)-4-pyridylmethyl]glycinato(*O*,*N*)}manganate(II).

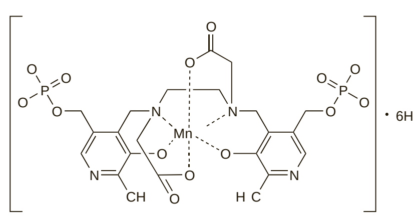
Тринатрий Мангафодипир

$C_{22}H_{27}MnN_4Na_3O_{14}P_2$ = 757.3.

CAS — 155319-91-8 (mangafodipir); 140678-14-4 (mangafodipir trisodium).

ATC — V08CA05.

ATC Vet — QV08CA05.



(mangafodipir)

Pharmacopoeias. In *US.*

USP 31 (Mangafodipir Trisodium). Pale yellow crystals or crystalline powder. Freely soluble in water; slightly soluble in alcohol and in acetone; slightly soluble in chloroform; sparingly soluble in methyl alcohol. pH of a 1% solution in water is between 5.5 and 7.0. Store at a temperature not exceeding 8°.

Adverse Effects and Precautions

The most common adverse effects of mangafodipir are injection site discomfort, feelings of warmth or flushing, headache, nausea, vomiting, abdominal pain, and taste disturbances. Hypersensitivity reactions, including anaphylactoid reactions, may occur. Transient increases in bilirubin and liver transaminase concentrations and decreases in plasma-zinc concentrations have been reported.

Mangafodipir should be used with caution in patients with hepatic or renal impairment and should be avoided if impairment is severe. It should not be given to patients with phaeochromocytoma.

◊ References.

1. Federle MP, *et al.* Safety and efficacy of mangafodipir trisodium (MnDPDP) injection for hepatic MRI in adults: results of the U.S. multicenter phase III clinical trials (safety). *J Magn Reson Imaging* 2000; **12:** 186–97.

Pharmacokinetics

After intravenous injection, mangafodipir is dephosphorylated and manganese is exchanged for zinc leading to the release of free manganese ions and the formation of 2 inactive metabolites. Manganese is rapidly taken up by the liver, pancreas, kidney and spleen; about 15 to 20% is excreted in the urine within 24 hours, with most of the remainder excreted in the faeces over about 4 days. The metabolites are almost entirely excreted in the urine within 24 hours.

Uses and Administration

Mangafodipir is a manganese chelate that is used as a magnetic resonance contrast medium (p.1474) for imaging of the liver and pancreas. Manganese has paramagnetic properties that increase the relaxivity of hydrogen ions, leading to signal enhancement. Free manganese is released from mangafodipir in the body and is taken up by normal liver and pancreatic tissue, increasing the degree of contrast.

Mangafodipir is given intravenously as the trisodium salt.

In the UK, a solution containing mangafodipir trisodium 7.57 mg/mL (10 micromol/mL) is used. Usual doses for imaging are:

- liver: 0.5 mL/kg (5 micromol/kg) given by intravenous infusion at a rate of 2 to 3 mL/minute
- pancreas: 0.5 mL/kg (5 micromol/kg) given by intravenous infusion at a rate of 4 to 6 mL/minute

In the USA, a more concentrated preparation is used, containing mangafodipir trisodium 37.9 mg/mL (50 micromol/mL). Usual doses are:

- liver: 0.1 mL/kg (5 micromol/kg), given by slow intravenous injection to a maximum dose of 15 mL

Preparations

USP 31: Mangafodipir Trisodium Injection.

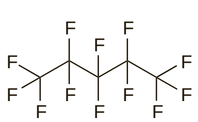
Dodecafluoropentanum; Dodekafluoropentaani; Dodekafluoropentan; Perflénapent; Perflenapentum. Dodecafluoropentane.

Перфленапент

C_5F_{12} = 288.0.
CAS — 678-26-2.
ATC — V08DA03.
ATC Vet — QV08DA03.



Profile

Perflenapent is a liquid perfluorocarbon that has been used as an ultrasound contrast medium (p.1474) for echocardiography. It has been given intravenously as an emulsion containing droplets of perflenapent; on warming to body temperature the droplets form microbubbles of perflenapent gas that provide echo-enhancement. A small amount of perflisopent (below) was also included in the formulation.

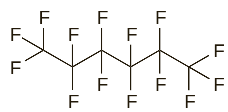
Perflexane *(USAN, rINN)*

Perflexano; Perflexanum. Tetradecafluorohexane.

Перфлексан

C_6F_{14} = 338.0.
CAS — 355-42-0.



Profile

Perflexane is a perfluorocarbon gas that has been used as an ultrasound contrast medium (p.1474) for echocardiography. Dry microspheres containing the gas are reconstituted immediately before use, leading to the formation of microbubbles of perflexane that provide echo-enhancement; lipids are included in the microspheres to stabilise the bubbles when they form.

Preparations

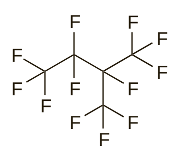
Proprietary Preparations (details are given in Part 3)
USA: Imagent.

Perflisopent *(USAN, rINN)*

Perflisopentum. Nonafluoro-2-(trifluoromethyl)butane.

Перфлизопент

C_5F_{12} = 288.0.
CAS — 594-91-2.



Profile

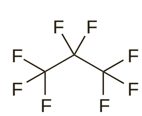
Perflisopent is a perfluorocarbon that has been used as an ultrasound contrast medium (p.1474) with perflenapent (above) for echocardiography.

Perflutren *(USAN, rINN)*

DMP-115; FS-069; MRX-115; Octafluoropropanum; Oktafluoropropaani; Oktafluoropropan; Perfluoropropane; Perflutrène; Perflutreno; Perflutrenum. Octafluoropropane.

Перфлутрен

C_3F_8 = 188.0.
CAS — 76-19-7.



Profile

Perflutren is a perfluorocarbon gas used as either albumin- or lipid-coated microspheres as an ultrasound contrast medium (p.1474) for echocardiography.

The albumin-coated microspheres are suspended in 1% albumin solution immediately before use and are given in a dose of 0.5 to 3 mL by intravenous injection, repeated if necessary up to a total dose of 8.7 mL.

The lipid-coated microsphere suspension is formed by agitating the gas with a lipid solution immediately before use and is given in a dose of 10 microlitre/kg by intravenous injection, repeated once after 30 minutes if required, or as intravenous injections of 100 to 400 microlitres repeated as required up to a maximum total dose of 1.6 mL. Alternatively, 1.3 mL of the suspension may be diluted in 50 mL of sodium chloride 0.9% and given by intravenous infusion at an initial rate of 4 mL/minute, adjusted as required, to a maximum rate of 10 mL/minute.

Serious cardiopulmonary reactions, including fatalities, have been reported with perflutren and it should be used with extreme caution in patients with pulmonary hypertension or unstable cardiopulmonary conditions. The safety of perflutren has not been established in patients with right-to-left cardiac shunts; it should also be used with extreme caution or avoided in such patients.

Perflutren has also been given by intra-ocular injection to provide tamponade in the management of retinal detachment.

Description. Propyliodone contains about 56.8% of I.

Pharmacopoeias. In *Int.* and *US.*

USP 31 (Propyliodone). A white or almost white, crystalline powder. Is odourless or has a faint odour. Practically insoluble in water; soluble in alcohol, in acetone, and in ether. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Profile

Propyliodone is an iodinated radiographic contrast medium (p.1474) that has been used for bronchography as either an aqueous or oily suspension.

Preparations

USP 31: Propyliodone Injectable Oil Suspension.

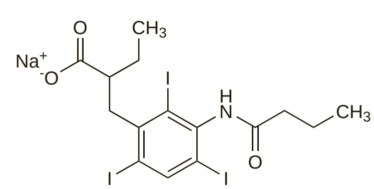
Proprietary Preparations (details are given in Part 3)
Israel: Dionosil†.

Sodium Tyropanoate *(BAN, rINN)*

Natrii Tyropanoas; NSC-107434; Tiropanoato de sodio; Tyropanoate de Sodium; Tyropanoate Sodium *(USAN)*; Win-8851-2. Sodium 2-(3-butyramido-2,4,6-tri-iodobenzyl)butyrate.

Натрия Тиропаноат

$C_{15}H_{17}I_3NNaO_3$ = 663.0.
CAS — 27293-82-9 (tyropanoic acid); 7246-21-1 (sodium tyropanoate).
ATC — V08AC09.
ATC Vet — QV08AC09.



Description. Sodium tyropanoate contains about 57.4% of I.

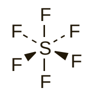
Profile

Sodium tyropanoate is an ionic monomeric iodinated radiographic contrast medium (p.1474) with actions similar to those of iopanoic acid (p.1484) and has been used for cholecystography and cholangiography.

Sulfur Hexafluoride *(USAN)*

BRI; Hexafluouro de azufre; Sulphur Fluoride; Sulphur Hexafluoride.

F_6S = 146.1.
CAS — 2551-62-4.
ATC — V08DA05.
ATC Vet — QV08DA05.



Profile

Sulfur hexafluoride is a gas with little biological activity that is used as an ultrasound contrast medium (p.1474) for imaging of the blood vessels and for echocardiography. Microbubbles of sulfur hexafluoride are formed on reconstitution of the preparation and provide echo-enhancement; phospholipids and surfactants are included to stabilise the microbubbles. It is given intravenously as a suspension containing 45 micrograms/mL, in a usual dose of 2 mL for echocardiography, or 2.4 mL for imaging blood vessels; the dose may be repeated once if necessary.

Sulfur hexafluoride has been associated with hypersensitivity reactions; patients should be monitored for at least 30 minutes after use, and resuscitation equipment should be available. Particular care is advised in patients with ischaemic heart disease, in whom serious and occasionally fatal cardiac events have occurred: sulfur hexafluoride is contra-indicated in patients with recent acute coronary syndrome or clinically unstable ischaemic heart disease. It should also not be given to patients with severe pulmonary hypertension, uncontrolled hypertension, acute respiratory distress syndrome, or right-to-left shunts. Care is advised in patients with lung disorders.

Sulfur hexafluoride has also been used as an adjunct in eye surgery for retinal detachment.

The adrenal cortex synthesises both corticosteroids, based on a 21-carbon nucleus, and some sex hormones, primarily androgens, based on a 19-carbon nucleus. The corticosteroids are traditionally divided into those with mainly glucocorticoid actions, of which cortisol (hydrocortisone) is the most important endogenous example, and those that are primarily mineralocorticoid, of which aldosterone is much the most important.

The endogenous glucocorticoids are under regulatory control from the hypothalamus and pituitary, via the releasing hormones corticorelin (p.1523) and corticotropin or ACTH (p.1523). In return the glucocorticoids act to inhibit production and release of these releasing hormones by a negative feedback mechanism. The system is known collectively as the hypothalamic-pituitary-adrenal (HPA) axis. Aldosterone secretion, by contrast, is under the control of the renin-angiotensin system.

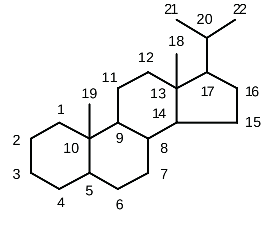
The main **mineralocorticoid** actions are on fluid and electrolyte balance. They enhance sodium reabsorption in the kidney and hence expand the extracellular fluid volume, and they enhance renal excretion of potassium and H^+.

The **glucocorticoid** actions are wide-ranging. They have potent anti-inflammatory and immunosuppressive effects, at least partly through inhibition of the release of various cytokines, and it is primarily these that are made use of clinically (see p.1495). They also have profound metabolic effects: blood glucose concentrations are maintained or increased by a decrease in peripheral glucose utilization and an increase in gluconeogenesis; glycogen deposition, protein breakdown, and lipolysis are increased, and effects on calcium uptake and excretion lead to a decrease in body calcium stores. Glucocorticoids facilitate the action of many other active endogenous substances, and affect the function of cardiovascular system, kidneys, skeletal muscle and CNS.

Many synthetic congeners and derivatives of the corticosteroids are available. The main corticosteroids used systemically are hydroxy compounds (alcohols). They are relatively insoluble in water and the sodium salt of the phosphate or succinate ester is generally used to provide water-soluble forms for injections or solutions. Such esters are readily hydrolysed in the body.

Various structure-activity relationships are understood for the corticosteroids and have been made use of in the development of new compounds. The presence of a hydroxyl group at position 11 seems to be essential for glucocorticoid activity, while a hydroxyl at position 21 is required for mineralocorticoid activity. Fluorination at position 9 enhances both mineralocorticoid and glucocorticoid activity. Substitution at carbon 16 (as in betamethasone, dexamethasone, or triamcinolone) virtually eliminates mineralocorticoid activity. Esterification of corticosteroids at the 17 or 21 positions with fatty acids generally increases the topical activity. The formation of cyclic acetonides at the 16 and 17 positions further increases topical anti-inflammatory activity, usually without increasing systemic glucocorticoid activity.

In the medical and pharmacological literature the names of unesterified corticosteroids have frequently been used indiscriminately for both the unesterified and esterified forms and it is not always apparent to which form reference is being made. The unesterified form is sometimes qualified by the phrase 'free alcohol'.



steroidal skeleton

Adverse Effects of Corticosteroids and their Treatment

The adverse effects of corticosteroids may result from unwanted mineralocorticoid or glucocorticoid actions, or from inhibition of the hypothalamic-pituitary-adrenal axis.

Mineralocorticoid adverse effects are manifest in the retention of sodium and water, with oedema and hypertension, and in the increased excretion of potassium with the possibility of hypokalaemic alkalosis. In susceptible patients, cardiac failure may be induced. Disturbances of electrolyte balance are common with the naturally occurring corticosteroids, such as cortisone and hydrocortisone, but are less frequent with many synthetic glucocorticoids, which have little or no mineralocorticoid activity.

Adverse **glucocorticoid** effects lead to mobilisation of calcium and phosphorus, with osteoporosis and spontaneous fractures; muscle wasting and nitrogen depletion; and hyperglycaemia with accentuation or precipitation of the diabetic state. The insulin requirements of diabetic patients are increased. Increased appetite is often reported.

Impaired tissue repair and immune function can lead to delayed wound healing, and increased susceptibility to infection. Increased susceptibility to all kinds of infection, including septicaemia, tuberculosis, fungal infections, and viral infections, has been reported in patients on corticosteroid therapy. Infections may also be masked by the anti-inflammatory, analgesic, and antipyretic effects of glucocorticoids. The increased severity of varicella and measles may lead to a fatal outcome in non-immune patients receiving systemic corticosteroid therapy.

Other adverse effects include menstrual irregularities, amenorrhoea, hyperhidrosis, skin thinning, ocular changes including development of glaucoma and cataract, mental and neurological disturbances, benign intracranial hypertension, acute pancreatitis, and avascular necrosis of bone. An increase in the coagulability of the blood may lead to thromboembolic complications. Peptic ulceration has been reported but reviews of the literature do not always agree that corticosteroids are responsible for an increased incidence.

The negative feedback effects of glucocorticoids on the hypothalamic-pituitary-adrenal (HPA) axis may lead to adrenal atrophy, in some cases after therapy for as little as 7 days. This produces secondary adrenocortical insufficiency, which may become manifest after overly rapid withdrawal of treatment or be precipitated by some stress such as infection or trauma. Patients vary considerably in the degree and duration of adrenal suppression after a given course of corticosteroid, but adrenal atrophy may persist for months or years, and withdrawal should be gradual in those who have been treated for any length of time (see also Withdrawal, below). High doses of corticosteroids given during pregnancy may cause fetal or neonatal adrenal suppression. Although the precise mechanism is uncertain, growth retardation may follow the use of even relatively small doses of corticosteroids in children.

Large doses of corticosteroids, or of corticotropin, may produce Cushingoid symptoms typical of hyperactivity of the adrenal cortex, with moon-face, sometimes with hirsutism, buffalo hump, flushing, increased bruising, ecchymoses, striae, and acne (see also Cushing's Syndrome, p.2344). Giving large intravenous doses of corticosteroids too rapidly may cause cardiovascular collapse.

Hypersensitivity reactions have occurred with corticosteroids, mainly when applied topically.

Adverse effects occur, in general, fairly equally with all systemic corticosteroid preparations and their incidence rises steeply if dosage increases much above physiological values, traditionally considered to be about 7.5 mg daily of prednisolone or its equivalent (see Uses and Administration, below, for equivalent doses of other corticosteroids). Short courses at high dosage for emergencies appear to cause fewer adverse effects than prolonged courses with lower doses.

Most topically applied (including inhaled) corticosteroids may, under certain circumstances, be absorbed in sufficient amounts to produce systemic effects. The topical application of corticosteroid preparations to the eyes has produced corneal ulcers, raised intra-ocular pressure, and reduced visual function. Application of corticosteroids to the skin has led to loss of skin collagen and subcutaneous atrophy; local hypopigmentation of deeply pigmented skins has been reported after both the intradermal injection and topical application of potent corticosteroids. Dryness, irritation, epistaxis, and rarely ulceration or perforation of the nasal septum have followed intranasal use; smell and taste disturbances may also occur. Hoarseness and candidiasis of the mouth or throat may occur in patients receiving inhaled corticosteroids.

Intrathecal dosage (including inadvertent intrathecal dosage after attempted epidural injection) has been associated with arachnoiditis.

Adverse effects should be treated symptomatically, with the corticosteroid dosage reduced or slowly withdrawn where possible.

Adrenal suppression. The inhibition of hypothalamic-pituitary-adrenocortical function associated with corticosteroid use may persist for a year or more after treatment is withdrawn and may cause acute adrenocortical insufficiency with circulatory collapse during stress. The degree of suppression depends on a number of factors, including length of treatment, time of day treatment is given, type of corticosteroid preparation used, route, dose used, and dosing interval. In general, suppression of secretion of adrenocorticotrophic hormone and atrophy of the adrenal gland become progressively more definite as doses of corticosteroid exceed physiological amounts (see Uses and Administration, below), and as the duration of therapy increases (significant suppression is likely in patients receiving more than 3 weeks of therapy). It is less when the corticosteroid is given as a single dose in the morning, and even less if this morning dose is given on alternate days or less frequently. In patients taking high enough doses of corticosteroids to suppress the adrenals the dose should be increased during any form of stress (for example, illness or surgery); similarly those treated with such doses within the last 2 or 3 months should be restarted on therapy. Where the interval since treatment is greater than 3 months, resumption of treatment depends on clinical assessment of signs of adrenocortical insufficiency.

To avoid precipitating acute adrenocortical insufficiency, withdrawal of corticosteroid treatment should be carried out gradually, differing regimens being used according to the disease being treated and the duration of therapy. Examples of withdrawal regimens that have been used are described under Withdrawal, below.

Adrenal suppression may occur after very short courses of high-dose therapy and since many patients undergoing such therapy will be under continuing stress when the drugs are stopped, gradual withdrawal of corticosteroids over 5 to 7 days is preferable.

It should also be remembered that corticosteroid-induced adrenal suppression has been associated not only with systemic therapy, but has followed topical application of corticosteroid preparations, particularly those containing potent corticosteroids. Some degree of adrenal suppression is also associated with the use of high dose inhalants and nasal preparations, and has followed the topical application of eye drops and eye ointments.

Effects on the bones and joints. Corticosteroid-induced **avascular necrosis** of bone is an uncommon but disabling complication of therapy.[1-3] The incidence may vary in patients with different disease states; alcoholics, and patients with connective tissue disease (especially SLE) may have increased susceptibility.[3,4] There may be a relationship with corticosteroid dose: even short courses of high-dose corticosteroids may be associated with its development.[1-3] Avascular necrosis has also been associated with topical application of corticosteroids.[5]

Corticosteroids may also produce **osteoporosis.** A review[6] of data obtained from studies published between 1970 and 1990 established that osteoporosis is a common consequence of long-term treatment with corticosteroids, occurring in about 50% of patients. Bone loss is more rapid during the early stages of therapy and is most rapid in areas of the skeleton containing the greatest proportion of trabecular bone such as the spine, hip, distal radius, pelvis, and ribs.

Reviews and guidelines[7-11] on the prevention and management of corticosteroid-induced osteoporosis suggest that the dose should be minimised, as oral doses above 7.5 mg of prednisolone or prednisone (or the equivalent) daily are associated with more significant bone loss and increased fracture risk.[12] Alternate-day therapy, although desirable for its reduced effect on the hypothalamic-pituitary-adrenal axis, does not reduce the risk of bone loss. It should be borne in mind that long-term use of inhaled corticosteroids may also reduce bone mineral density. Patients should maintain an adequate intake of calcium and vitamin D (prophylactic therapy with both has been advocated in all patients starting corticosteroids[13]), should take regular exercise, and avoid smoking and excessive alcohol intake. HRT has been advocated in postmenopausal women but recent re-evaluation of the risks and benefits of HRT may render this option unattractive. Bisphosphonates may be used in high-risk patients as they are effective at preventing and treating corticosteroid-induced bone loss[14] and may reduce fracture rates.[8-10] There is some evidence to suggest that calcitonin has a beneficial effect on bone mass, and it may be considered as an alternative when bisphosphonates cannot be used. Fluoride has been studied in corticosteroid-induced osteoporosis, but although it was found to increase bone density, there is concern about the resultant bone structure and a possible increase in fracture rates. There are reports of benefit from anabolic therapy, but evidence is limited. A thiazide diuretic may be helpful in controlling hypercalciuria in patients not receiving calcitriol.[8] Whether some corticosteroids have reduced effects on the bone is unclear.[9]

There is a risk of **tendinopathies** with the use of corticosteroids, especially of the Achilles and patellar tendons; ruptures have been reported.[15] Most reports have concerned oral or intra-articular use, but there have been occasional cases in patients receiving inhaled or topical corticosteroids.

Effects on carbohydrate and protein metabolism. Corticosteroids produce glucose intolerance[1-4] and protein catabolism.[5,6] Although mainly associated with systemic use, there is a report of deterioration in diabetic control associated with high-dose inhaled corticosteroid treatment.[7]

Effects on the cardiovascular system. Adverse effects of glucocorticoids include hypertension, hyperglycaemia, obesity, and dyslipidaemia,[1-3] which are independent risk factors for cardiovascular disease. However, glucocorticoids also have anti-inflammatory effects[1,2] which may exert an anti-atherosclerotic effect. Cohort studies[2,3] established that oral glucocorticoid use was associated with an increased risk for heart failure, and that high-dose therapy was associated with an increased risk for cardiovascular disease, including myocardial infarction.

3. Wei L, *et al.* Taking glucocorticoids by prescription is associated with subsequent cardiovascular disease. *Ann Intern Med* 2004; **141:** 764–70.

Effects on the cerebrovascular system. Despite being used in high doses to treat benign intracranial hypertension, corticosteroids may also occasionally cause this disorder. Children receiving long-term therapy are mainly affected, an increase in dosage often being responsible. Symptoms usually subside when dosage is reduced.[1]

1. Gibberd B. Drug-induced benign intracranial hypertension. *Prescribers' J* 1991; **31:** 118–21.

Effects on the eyes. During ophthalmic use of corticosteroids about one-third of patients will develop **raised intra-ocular pressure**, usually within a few weeks of treatment with potent corticosteroids, or within months with weaker ones.[1] The effects on children are variable, but they may be at risk of a greater and more rapid response to ophthalmic corticosteroids.[1] Raised intra-ocular pressure and glaucoma can also be caused by topical use of corticosteroids on the face, particularly with prolonged use.[2] There is evidence of an increased risk in patients receiving prolonged high-dose inhaled corticosteroids.[3] Increases in intra-ocular pressure appear to be less common with systemic corticosteroids,[4] but a study in elderly patients showed that the risk of raised intra-ocular pressure or open-angle glaucoma increased with the dose and duration of oral use.[5]

Topical application of corticosteroids in patients with bacterial, fungal, or viral **eye infection** can alleviate the symptoms but allow the infection to develop.[1,6] In ocular herpes simplex infection there is the risk of corneal ulceration and scarring that may lead to loss of vision.

Cataract formation is associated with systemic corticosteroid use. It has also been reported after ophthalmic[1,4] and topical[2,7] use. There is evidence that cataract formation may also be associated with prolonged use of high-dose inhaled corticosteroids.[8-10] The intranasal use of corticosteroids, however, does not appear to increase the risk.[11] It has been suggested that the lens in children might be more sensitive than in adults, but this may be due to the large doses of corticosteroids, relative to body size, given orally in these cases. Evidence of an increased risk in children from inhaled corticosteroids is limited, but is probably outweighed by the benefits of asthma control.[12]

Systemic corticosteroid use has also been associated with damage to the retinal pigment epithelial barrier, predisposing the patient to serous **retinal detachment**.[13]

Effects on the gastrointestinal tract. It has long been considered that treatment with corticosteroids might lead to peptic ulcers. Some years ago a review of the data then available suggested that since an ulcer developed in 1% of control patients not receiving corticosteroids, the 2% incidence for patients receiving corticosteroids did not warrant the prophylactic use of anti-ulcer drugs in all patients.[1] Others have found little evidence of an increased risk of peptic ulcer produced by corticosteroids alone although there is some increased risk when using them with NSAIDs.[2] A later cohort study[3] found a modest increase in risk of gastrointestinal bleeding with current use of corticosteroids, which increased when NSAIDs were also used. It has been suggested that it might be prudent to avoid such combination therapy whenever possible.[4]

Doubt has therefore been cast on the prophylactic value of anti-ulcer therapy given with corticosteroids.[1,5] If an ulcer does develop and there is good reason to continue treatment then corticosteroids may be continued along with some form of ulcer therapy.[1]

There have been several reports of corticosteroids being associated with gastrointestinal perforation.[6-9] There is a risk that the anti-inflammatory properties of corticosteroids may mask the signs of perforation and delay diagnosis with potentially fatal results.

Effects on growth. Corticosteroids impair normal growth in children when given systemically,[1-3] and although alternate-day therapy may reduce the effect on growth it does not abolish it. There has been some concern about possible effects of inhaled corticosteroids on growth.[1,4] Some studies have not found an effect of inhaled corticosteroids on growth if doses are modest, even when treatment is prolonged.[1,5,6] Others have found that inhaled corticosteroids, particularly in high doses, do have some effect on growth parameters,[5,7-10] but it is unclear whether this has long-term effects on the child's ultimate height, and the alternative in children requiring such high-dose therapy is likely to be an oral corticosteroid, with its consequent effects. Some studies,[11,12] in children with mild to moderate asthma, have suggested that a small reduction in growth velocity may occur in the first year of treatment, but that it then normalises and adult height is not adversely affected. Nonetheless, in the light of the increasing number of studies suggesting some effects of inhaled or intranasal corticosteroids on growth the FDA has required the inclusion of a warning in US labelling that such products may slow growth rates. For a suggestion that inhalation of a single dose of budesonide in the morning had less effect on growth than twice daily dosage, see Administration, p.1521.

Effects on immune response. Owing to their immunosuppressant effect, giving corticosteroids in doses greater than those required for physiological replacement therapy is associated with increased susceptibility to infection, aggravation of existing infection, and activation of latent infection. An additional problem is that the anti-inflammatory effect of corticosteroids may mask symptoms until the infection has progressed to an advanced stage; the altered response of the body may also permit the bizarre spread of infections, frequently in aberrant forms, such as disseminated parasitic infections. The risk is greater in patients receiving high doses, or associated therapy with other immunosuppressants such as cytotoxic drugs, and in those who are already debilitated. Children receiving high doses of corticosteroids are at special risk from childhood diseases, such as chickenpox, but vaccination with living organisms is contra-indicated since infection may be induced (killed vaccines or toxoids can be given but the response may be reduced).

This increased susceptibility to infection and masking of symptoms may also be caused by topical or local corticosteroid therapy. Thus, topical application to the skin has led to unusual changes such as atypical ringworm infection. Fungal infections (particularly candidiasis), generally restricted to the mouth and throat, are associated with corticosteroid inhalations. Severe damage to the eye has followed the ocular use of corticosteroids in herpetic infections, and a generalised spread of herpes infection may follow application to the mouth in the presence of herpes infection.

Conversely, the effect of corticosteroids on the symptoms and course of some infections may be life-saving (see Infections, under Uses and Administration, below). Before embarking on a long-term course of corticosteroid therapy general measures for the reduction of risk of infection include a diligent search for active or quiescent infection and, where appropriate, prevention or eradication of the infection before starting, or giving chemoprophylaxis during corticosteroid treatment.

Effects on lipid metabolism. Glucocorticoids have potent effects on lipid metabolism, facilitating the effects of growth hormone and endogenous stimulants of lipolysis. As a result they increase both high- and low-density lipoprotein cholesterol concentrations in the blood.

On prolonged use glucocorticoids also have a dramatic effect on body fat distribution, resulting in the characteristic Cushingoid appearance of moon face, and increased fat at the back of the neck and supraclavicular area.

Effects on mental state. Mental disturbances caused by corticosteroids include depression, mania, euphoria, and delirium.[1] Psychotic symptoms, insomnia, and hyperactivity have also been reported in children and adolescents treated with inhaled,[2,3] oral, and intravenous corticosteroids.[2] The risk of adverse effects appears to be dose-related, but there are reports of cases associated with very low dosages. Reversible impairment of memory has been associated with intravenous methylprednisolone.[4,5]

Effects on the neonate. Various adverse effects have been reported in premature neonates given corticosteroids, see under Dexamethasone, p.1526.

Effects on the nervous system. Paraesthesia, usually localised to the perineum, has been associated with intravenous use of dexamethasone sodium phosphate[1-4] and hydrocortisone sodium phosphate,[5] but not with hydrocortisone sodium succinate.[5] Descriptions of this reaction include itching, burning, tingling, and severe pain. It can begin within seconds of giving the injection, and clear within minutes of stopping. This reaction appears to be caused by the corticosteroid phosphate ester itself, and clears in the time it takes for the drug to be hydrolysed. It has been suggested that the reaction can be abolished or avoided by giving the drug as a dilute solution, over at least 5 to 15 minutes.[2-4]

Epidural lipomatosis (fat deposition around the spinal cord) is a rare complication of systemic corticosteroids.[6] It has been associated with both high daily doses (more than 30 mg prednisone daily) and lower doses given over several years. The onset of symptoms is usually gradual, ranging from 6 months to more than 20 years after beginning corticosteroid use. Spinal cord compression causes back pain radiating to the lower limbs, and severe neurological complications can develop. The lipomatosis may regress or disappear after the corticosteroid is withdrawn or the dose is lowered, but patients with myelopathy or rapidly progressive neurological deficit may need emergency surgery.

Effects on the pancreas. Acute pancreatitis has been associated with corticosteroid use,[1-3] although evidence supporting the association has been challenged on a number of grounds, both clinical and experimental.[2]

Effects on the skin. Topical corticosteroids are associated with a number of local adverse effects on the skin, principally due to their antiproliferative effects on keratinocytes and fibroblasts (leading to skin thinning and atrophy), and to possible interference with the skin flora (leading to increased risk of superinfection or opportunistic infection).[1] Skin thinning is more likely if corticosteroids are applied under occlusion (this is especially true of halogenated corticosteroids, which are more resistant to inactivation by enzymes in the epidermis). Striae, which occur usually in intertriginous areas such as axillae and groin where skin is thin, moist, and occluded, are the most readily appreciable manifestation of skin atrophy, and are irreversible, unlike more minor degrees of atrophy. Other local adverse effects include telangiectasias and purpura.[1] Acneform pustules at the site of application have occurred.

The balance between benefit and the likelihood of local or systemic adverse effects on topical application of corticosteroids will depend on the chemical structure of the drug (i.e. its lipophilicity and resistance to enzymic degradation), the formulation of the vehicle, the way in which it is applied, and the nature of the skin to be treated.[1]

Skin thinning, bruising, and purpura have also been reported in patients receiving inhaled corticosteroids.[2-4] There have been a few case reports of eczematous and erythematous lesions of the face and body, and urticaria, following inhalation or intranasal use.[5]

The adverse skin effects arising from systemic corticosteroids also include striae and skin thinning as well as acneform eruptions. Somewhat counter-intuitively a case-control study has suggested an increased risk of Stevens-Johnson syndrome or toxic epidermal necrolysis in patients receiving corticosteroids, particularly in the period shortly after beginning therapy.[6]

Effects on the voice. Dysphonia is associated with inhaled corticosteroids.[1] Although oropharyngeal candidiasis and dysphonia may occur at the same time, many patients with dysphonia do not have candidiasis, and the two conditions do not appear to be directly related. The cause of this dysphonia has not been fully explained, but clinical investigations have found changes including bowing of the vocal cords due to bilateral adductor myopathy, mucosal changes, and supraglottic hyperfunction.

1. Lavy JA, *et al.* Dysphonia associated with inhaled steroids. *J Voice* 2000; **14:** 581–8.

Hypersensitivity and anaphylaxis. There have been occasional reports of hypersensitivity reactions, and sometimes anaphylaxis, caused by corticosteroids.[1] Reactions have occurred with any route, although the topical route is mainly involved. It has been observed that the incidence of hypersensitivity is increasing[2] and it has been suggested that a lack of response in chronic eczema might be due to a reaction to the corticosteroid treatment.[2] Fluorinated corticosteroids may be less likely to induce a contact hypersensitivity reaction than non-fluorinated compounds.[3]

Withdrawal of Corticosteroids

The use of pharmacological doses of corticosteroids suppresses the endogenous secretion of corticotropin by the anterior pituitary, with the result that the adrenal cortex becomes atrophied. Sudden withdrawal or reduction in dosage, or an increase in corticosteroid requirements associated with the stress of infection or accidental or surgical trauma, may then precipitate acute adrenocortical insufficiency; deaths have followed the abrupt withdrawal of corticosteroids. Adrenocortical insufficiency has also occurred after the effective reduction in systemic corticosteroid concentrations produced by overly rapid transfer from oral to inhaled corticosteroid therapy. For the emergency treatment of acute adrenocortical insufficiency caused by abrupt withdrawal of corticosteroids, see Adrenocortical Insufficiency, p.1498.

In some instances, withdrawal symptoms may involve or resemble a clinical relapse of the disease for which the patient has been undergoing treatment. Other effects that may occur during withdrawal or change of corticosteroid therapy include fever, myalgia, arthralgia, weight loss, benign intracranial hypertension with headache and vomiting, and papilloedema caused by cerebral oedema. Latent rhinitis or eczema may be unmasked.

Duration of treatment and dosage are important factors in determining suppression of the pituitary-adrenal response to stress on cessation of corticosteroid treatment, and individual liability to suppression is also important.

After short courses at moderate doses it may be appropriate to withdraw corticosteroids without tapering the dose (see below). However, after high-dose or prolonged therapy, withdrawal should be gradual, the rate depending upon the individual patient's response, the dose, the disease being treated, and the duration of therapy. Recommendations for initial reduction, stated in terms of prednisolone, have varied from as little as steps of 1 mg monthly to 2.5 to 5 mg every 2 to 7 days. Provided the disease is unlikely to relapse the dose of systemic corticosteroid may be reduced rapidly to physiological values; dose reduction should then be slower to allow recovery of pituitary-adrenal function. Symptoms attributable to over-rapid withdrawal should be countered by resuming a higher dose and continuing the reduction at a slower rate. Giving corticotropin does not help to re-establish adrenal responsiveness.

This gradual withdrawal of corticosteroid therapy permits a return of adrenal function adequate for daily needs, but years may sometimes be required for the return of function necessary to meet the stress of infection, surgery, or trauma. On such occasions patients with a history of recent corticosteroid withdrawal should be protected by means of supplementary corticosteroid therapy as described under Precautions, below.

◊ The UK CSM recommends that moderate dosage with corticosteroids (up to 40 mg daily of prednisolone, or equivalent), for up to 3 weeks, may be stopped without tapering provided that the original disease is unlikely to relapse, although prophylactic cover may be required for any stress within a week of finishing the course.[1] However, it should be borne in mind that individuals vary widely in their response to corticosteroids and their ability to tolerate withdrawal. Gradual withdrawal should be considered, even after shorter courses, if higher doses are given, or in patients with other risk factors for adrenocortical insufficiency, including those who have had repeated courses of systemic corticosteroids, those who receive a course within one year of finishing long-term corticosteroid therapy, or those who regularly take doses in the evening, when their suppressive effect is greater. Withdrawal should not be abrupt in any patient who receives systemic corticosteroids for more than 3 weeks.[1]

How dose reduction is carried out depends largely on the likelihood of relapse of the original disease. If this is unlikely, the dose of systemic corticosteroid may be reduced rapidly to physiological values (traditionally considered to be 7.5 mg of prednisolone daily or equivalent). It should then be reduced more slowly to allow the hypothalamic-pituitary-adrenal axis to recover.[1] Where disease relapse is a possibility even the initial reduction may need to be more cautious. Long-term treatment may require withdrawal over many months (such as a reduction of 1 mg in the daily dose of prednisolone every 3 to 4 weeks).

In reviews of the inhibition of hypothalamic-pituitary-adrenocortical function associated with corticosteroid use, further regimens for corticosteroid withdrawal are described.[2-4] For example, patients who have been treated for weeks or months may have their daily dose of prednisolone reduced by 2.5 to 5 mg every 2 or 3 days, or, for those on longer-term treatment, the reduction may be more gradual at a rate of 2.5 mg every 1 to 3 weeks and possibly less. When the dose has reached 10 mg daily decrements may be made with 1-mg tablets. Another approach may be to convert daily therapy gradually into alternate-day therapy by progressively reducing the amount of corticosteroid received on every second day, and once alternate-day therapy is established the dose may be further reduced until, for example, a dose of 1 mg on alternate days for one week is attained.

Precautions for Corticosteroids

Systemic corticosteroids should be used with great caution in the presence of heart failure, recent myocardial infarction, or hypertension, in patients with diabetes mellitus, epilepsy (but see below for use in infantile seizures), glaucoma, hypothyroidism, hepatic failure, osteoporosis, peptic ulceration, psychoses or severe affective disorders, and renal impairment. Children may be at increased risk of some adverse effects; in addition, corticosteroids may cause growth retardation, and prolonged use is rarely justified. The elderly too may be at greater risk from adverse effects.

Corticosteroids are usually contra-indicated in the presence of acute infections uncontrolled by appropriate antimicrobial therapy. Similarly, patients already receiving corticosteroids are more susceptible to infection, the symptoms of which, moreover, may be masked until an advanced stage has been reached. Patients with active or doubtfully quiescent tuberculosis should not be given corticosteroids except, very rarely, as adjuncts to treatment with antitubercular drugs. Patients with quiescent tuberculosis should be observed closely and should receive chemoprophylaxis if corticosteroid therapy is prolonged.

The risks of chickenpox and probably of severe herpes zoster are increased in non-immune patients receiving therapeutic doses of systemic corticosteroids, and patients should avoid close personal contact with either infection. Passive immunisation is recommended for non-immune patients who do come into contact with chickenpox. Similar precautions apply to measles. Live vaccines should not be given to patients receiving high-dose systemic corticosteroid therapy nor for at least 3 months afterwards; killed vaccines or toxoids may be given although the response may be attenuated.

During prolonged courses of corticosteroid therapy, patients should be examined regularly. Sodium intake may need to be reduced and calcium and potassium supplements may be necessary. Monitoring of the fluid intake and output, and daily weight records may give early warning of fluid retention. Back pain may signify osteoporosis. Children are at special risk from raised intracranial pressure. Patients should carry cards (and preferably also wear bracelets) giving full details of their corticosteroid therapy; they and their relatives should be fully conversant with the implications of their therapy and the precautions to be taken.

Measures to compensate for the adrenals' inability to respond to stress (see Withdrawal, above) include increasing the dose to cover minor intercurrent illnesses or trauma such as surgery (with intramuscular doses to cover vomiting). For details of dosages used, see Uses and Administration, below.

Rapid intravenous injection of massive doses of corticosteroids may sometimes cause cardiovascular collapse and injections should therefore be given slowly or by infusion.

Many drugs have been reported to interfere with certain assay procedures for corticosteroids in body fluids and corticosteroids themselves may interfere with or alter the results of assays for some endogenous substances or drugs.

The risk of systemic absorption should always be considered when applying corticosteroids topically. They should not be applied with an occlusive dressing to large areas of the body. Long-term topical use is best avoided, especially in children. Also they should not be used for the treatment of ulcerative conditions, nor of rosacea, and should not be used indiscriminately for pruritus. Occasionally they may be used with the addition of a suitable antimicrobial substance in the treatment of infected skin but there is a risk of sensitivity reactions occurring.

Height should be monitored in children receiving prolonged therapy with inhaled or nasal corticosteroids. High doses of inhaled corticosteroids should preferably be inhaled using large-volume spacer devices to reduce oropharyngeal deposition and hence the incidence of candidiasis; rinsing the mouth with water after inhalation may also be helpful. In addition the use of spacer devices may reduce systemic absorption (see also Inhalation Therapy, under Uses and Administration, below). Paradoxical bronchospasm has occurred with inhaled corticosteroids and may require therapy to be stopped, although if mild it may be prevented by inhalation of a $beta_2$ adrenoceptor agonist, or by transfer from an aerosol to a dry powder formulation.

Caution is required when corticosteroids are used locally to treat eye disorders (see below).

Contraception. There are some isolated case reports of contraceptive failure in women using intra-uterine devices and receiving corticosteroid therapy.[1-3]

1. Zerner J, *et al.* Failure of an intrauterine device concurrent with administration of corticosteroids. *Fertil Steril* 1976; **27:** 1467–8.

3. Buhler M, Papiernik E. Successive pregnancies in women fitted with intrauterine devices who take anti-inflammatory drugs. *Lancet* 1983; **i:** 483.

Eye disorders. Topical corticosteroids have transformed the management of inflammatory disease of the anterior segment of the eye and it should be noted that while their proper use may be sight-saving their inappropriate use is potentially blinding.[1] The dangers include the conversion of a simple dendritic herpes simplex epithelial lesion into an extensive amoeboid ulcer with the likelihood of permanent corneal scarring and loss of vision and also the risk of potentiation of bacterial and fungal infections. Other dangers include the development of open-angle glaucoma and cataracts. Topical corticosteroids are used by ophthalmologists in herpes simplex keratitis but always under appropriate antiviral cover and their use requires considerable experience. They should never be given for an undiagnosed red eye and many consultant ophthalmic surgeons believe that general practitioners should never begin therapy without an ophthalmic opinion.

Further studies and discussions on the inappropriate use of corticosteroids to treat eye disorders are listed below.[2-10]

Intranasal administration. Local adverse effects from intranasal corticosteroids include irritation, epistaxis, and smell and taste disturbances (see also above). Ulceration, septal perforation, and hypersensitivity reactions have occurred.[1]

There have been cases of Cushing's syndrome associated with inappropriately prolonged use of corticosteroid nasal drops in children.[2,3] Such drops should not be prescribed on a repeat prescription basis; where treatment is contemplated for more than 6 weeks appropriate monitoring has been recommended. See also Adrenal Suppression, under Adverse Effects, above.

3. Perry RJ, *et al.* Cushing's syndrome, growth impairment, and occult adrenal suppression associated with intranasal steroids. *Arch Dis Child* 2002; **87:** 45–8.

Porphyria. Corticosteroids are generally considered to be safe in patients with porphyria although there is conflicting evidence of porphyrinogenicity. In a review[1] of drug-induced porphyrias it was noted that a report suggesting that corticosteroids may have a role in treating the acute attack together with many reports attesting to their safety, contrasted with their repeated incrimination as the offending agent in producing such episodes. It was considered that as corticosteroids may be life-saving, they should be used if really indicated.

1. Moore MR, Disler PB. Drug-induction of the acute porphyrias. *Adverse Drug React Acute Poisoning Rev* 1983; **2:** 149–89.

Pregnancy. Studies have shown that corticosteroid use in pregnant women did not have adverse effects on the fetus in terms of psychological development[1] or growth and general health factors.[2] However, in an isolated report[3] the topical use of triamcinolone in a pregnant woman for treatment of eczema was considered to have caused fetal growth retardation. In another study[4] of 11 women with placenta praevia given intramuscular betamethasone 12 mg repeated 24 hours later, there were 2 cases of constriction of the ductus arteriosus; neither case was severe.

Early studies in *animals* showed an increase in fetal cleft palate after maternal ingestion of high corticosteroid doses, and cortisone has been used widely as a tool for the investigation of mechanisms responsible for cleft lip and palate. With doses used in clinical practice, however, the risk appears to be low. In an analysis of several hundred cases reported in the literature[5] it was concluded that the incidence of cleft palate in exposed children was slightly higher than in a random sample, but that in the small selected group studied, this higher incidence might be fallacious. Although an increased incidence of malformations in the children of asthmatic mothers given prednisolone 2.5 to 30 mg daily during pregnancy was noted,[6] others[7] have suggested that the outcome might have been worse in untreated asthmatic mothers. Moreover, no significant increase in the risk of fetal or maternal complications was found in a study of asthmatic mothers given prednisolone 2.5 to 20 mg daily.[8] Subsequently, no evidence of a teratogenic effect for corticosteroids was noted in a comparison of the maternal drug histories of the mothers of 764 infants born with anomalies of the CNS and 764 controls,[9] and in another study[10] there were no striking differences in birth-weight and frequency of 'small for dates' infants born to mothers who received systemic corticosteroids during pregnancy for pemphigoid gestationis and those who did not.

Fears concerning the use of corticosteroids during late pregnancy relate to their direct adverse effects on the fetus. These involve the known adverse effects of corticosteroids, such as increased risk of infection and adrenal insufficiency. No such adverse effects were noted in the infants of 70 exposed pregnancies,[8] although there have been individual reports.[11,12] The potential dangers of maternal diabetogenic effects have been demonstrated in a study of metabolic changes induced in diabetic women by salbutamol (used in the prevention of premature labour) which could be exacerbated by use of dexamethasone (to promote maturation of the fetal lung) with consequent danger to the fetus.[13]

A review[14] by the UK CSM concluded that there was no convincing evidence that corticosteroids caused an increased incidence of congenital abnormality. Prolonged or repeated use during pregnancy did increase the risk of intra-uterine growth retardation but this did not seem to be a problem following short-term treatment. It was noted that the ability of different corticosteroids to cross the placenta varied very markedly.

Septic shock. Some manufacturers recommend that corticosteroids should not be given to patients with septic shock and references to the controversial use of high-dose corticosteroids are given under Septic Shock, in Uses and Administration, below.

Sickle-cell disease. Sickle-cell crisis was reported to have been precipitated by corticosteroids in 2 patients with sickle C disease.[1] The crises in these patients were considered to have started with ischaemic necrosis of the bone marrow leading to fat embolism, cerebral hypoxia, and coma.

For mention of the use of corticosteroids in sickle-cell crisis, see under Sickle-cell Disease, in Uses and Administration, below.

1. Huang JC, *et al.* Sickling crisis, fat embolism, and coma after steroids. *Lancet* 1994; **344:** 951–2.

Tooth erosion. The increased incidence of tooth erosion seen in patients with asthma might be related to the pH of inhaled powder (but not aerosol) formulations.[1] Beclometasone dipropionate and fluticasone had pHs of 4.76 as powder formulations, whereas the pHs of the aerosols were well above the pH of 5.5 at which tooth substance begins to dissolve. Budesonide was less acidic in its powder formulation (pH 6.47).

1. O'Sullivan EA, Curzon MEJ. Drug treatments for asthma may cause erosive tooth damage. *BMJ* 1998; **317:** 820.

Varicella. A number of cases of fatal or near fatal chickenpox have been reported in patients receiving corticosteroids.[1-3] Although mostly associated with systemic use, severe disseminated varicella and staphylococcal pericarditis have been reported in an infant following a single application of a potent topical corticosteroid cream.[4] Guidelines issued by the UK CSM state that all patients taking systemic corticosteroids for purposes other than replacement, and who have not had chickenpox, should be regarded as being at risk of severe chickenpox, irrespective of the dose or duration of treatment.[2,5] Passive immunisation with varicella-zoster immunoglobulin should be given to non-immune patients who are receiving corticosteroids, or who have received them within the last 3 months, if they are exposed to chickenpox. Passive immunisation should preferably be given within 3 days and not later than 10 days from exposure.[2] The CSM considered that there was no good evidence that topical, inhaled, or rectal corticosteroids were associated with an increased risk of severe chickenpox.

Interactions of Corticosteroids

Concurrent use of barbiturates, carbamazepine, phenytoin, primidone, or rifampicin may enhance the metabolism and reduce the effects of systemic corticosteroids. Conversely oral contraceptives or ritonavir may increase plasma concentrations of corticosteroids. Use of corticosteroids with potassium-depleting diuretics, such as thiazides or furosemide, may cause excessive potassium loss. There is also an increased risk of hypokalaemia with concurrent amphotericin B or bronchodilator therapy with xanthines or beta$_2$ agonists. There may be an increased incidence of gastrointestinal bleeding and ulceration when corticosteroids are given with NSAIDs. Response to anticoagulants may be altered by corticosteroids and requirements of antidiabetic drugs and antihypertensives may be increased. Corticosteroids may decrease serum concentrations of salicylates and may decrease the effect of anticholinesterases in myasthenia gravis.

Analgesics. For the effect of corticosteroids on *salicylates*, see Aspirin, Interactions, p.23.

Antibacterials. *Rifampicin* reduces the activity of corticosteroids[1-8] by accelerating their metabolism, and a similar effect would be expected with other rifamycins. There is limited evidence that the macrolide antibacterials *troleandomycin*,[9-11] and perhaps *erythromycin*,[12] may inhibit the metabolism of methylprednisolone, but not of prednisolone.[10] Dosage reduction should be made as necessary if troleandomycin and methylprednisolone are used together. There is no evidence of a clinically significant interaction between these macrolides and other corticosteroids.

For reference to corticosteroids lowering plasma concentrations of *isoniazid* and enhancing its renal clearance, see p.290.

Anticoagulants. For the various effects of corticosteroids on anticoagulants, see under Warfarin Sodium, p.1430.

Antiepileptics. Reduced efficacy of corticosteroids has been noted in asthmatic, arthritic, renal transplant, and other patients who also received *phenytoin* or *phenobarbital*,[1-3] and the clearance of corticosteroids has also been reported to be markedly increased by *carbamazepine*.[3] Induction of microsomal liver enzymes by the antiepileptic, resulting in enhanced metabolism of the corticosteroid is believed to be the underlying mechanism. Different corticosteroids appear to be affected to different degrees, but the disease state, doses, and other determinants such as diet, sex, and other drugs used may also be contributory factors. An increase in the dosage of the corticosteroids may be necessary in order to maintain the desired therapeutic response.[1]

Antifungals. *Ketoconazole*[1,2] and *itraconazole*[3,4] increase serum-methylprednisolone concentrations and enhance methylprednisolone's adrenal suppressive effects. A 50% reduction in intravenous methylprednisolone dose was suggested during ketoconazole therapy.[2] A similar effect was not evident with oral prednisone[4,5] although some workers[6] found that ketoconazole reduced the total clearance of prednisolone given intravenously and of prednisone given by mouth. Itraconazole can also reduce the clearance of dexamethasone; in a study[7] of 8 healthy subjects, the area under the concentration-time curve (AUC) for both intravenous and oral dexamethasone was increased about 3.5-fold, and the morning plasma-cortisol concentration was suppressed for at least 2 days longer. A study[8] of healthy subjects found that ketoconazole increased the AUC for oral budesonide more than sixfold when they were given together, but only about fourfold when the doses were given 12 hours apart. Systemic exposure to inhaled budesonide is increased by itraconazole, which probably reduces the metabolism of budesonide.[9] Adrenal suppression was found in 11 of 25 patients with cystic fibrosis who were treated with this combination; one patient developed Cushing's syndrome.[10] A similar interaction may have been the cause of significant adrenal suppression in a patient with cystic fibrosis who was treated with itraconazole and inhaled fluticasone propionate.[11]

Antineoplastics. For reference to single doses of prednisone inhibiting the activation of *cyclophosphamide* (but longer-term treatment increasing its activation), see Cyclophosphamide, p.703.

Antivirals. For a possible effect of corticosteroids on the metabolism of HIV-protease inhibitors, see p.883.

Ritonavir can greatly increase plasma concentrations of fluticasone, through inhibition of cytochrome P450 isoenzyme CYP3A4, leading to systemic corticosteroid effects including Cushing's syndrome and adrenal suppression.[1-3] There have been reports of osteoporosis, with fractures in one case, associated with Cushing's syndrome due to this interaction.[2] Similar interactions are expected with other HIV-protease inhibitors.

3. Johnson SR, *et al.* Cushing syndrome with secondary adrenal insufficiency from concomitant therapy with ritonavir and fluticasone. *J Pediatr* 2006; **148:** 386–8.

Calcium-channel blockers. Studies in healthy subjects have found that *diltiazem* reduces the clearance of methylprednisolone.[1,2]

1. Varis T, *et al.* Diltiazem and mibefradil increase the plasma concentrations and greatly enhance the adrenal-suppressant effect of oral methylprednisolone. *Clin Pharmacol Ther* 2000; **67:** 215–21.
2. Booker BM, *et al.* Pharmacokinetic and pharmacodynamic interactions between diltiazem and methylprednisolone in healthy volunteers. *Clin Pharmacol Ther* 2002; **72:** 370–82.

Gastrointestinal drugs. *Aprepitant* increased plasma concentrations of dexamethasone and methylprednisolone in a pharmacokinetic study.[1] Licensed product information for aprepitant recommends that the usual dose of oral dexamethasone be reduced by 50%, and the dose of methylprednisolone by about 25% when given intravenously, and by 50% when given orally. For the appropriate regimen when these drugs are given together for nausea and vomiting, see Administration under Aprepitant, p.1709.

1. McCrea JB, *et al.* Effects of the neurokinin receptor antagonist aprepitant on the pharmacokinetics of dexamethasone and methylprednisolone. *Clin Pharmacol Ther* 2003; **74:** 17–24.

Immunosuppressants. It has been suggested that mutual inhibition of metabolism occurs between *ciclosporin* and corticosteroids, and may increase the plasma concentrations of either drug.[1,2] A review[3] cited studies supporting this conclusion but also mentioned studies that showed that ciclosporin did not significantly decrease clearance of prednisolone[4] and that corticosteroids either did not change, or decreased, ciclosporin concentrations.[5,6] Some of these conflicting results may be due to differences in the methods used to measure ciclosporin concentrations.

6. Hricik DE, *et al.* Association of the absence of steroid therapy with increased cyclosporine blood levels in renal transplant recipients. *Transplantation* 1990; **49:** 221–3.

Leukotriene antagonists. Severe peripheral oedema occurred in a patient treated with *montelukast* and prednisone for asthma, but not when either drug was used alone.[1] Montelukast may have potentiated sodium and fluid retention caused by the corticosteroid.

1. Geller M. Marked peripheral edema associated with montelukast and prednisone. *Ann Intern Med* 2000; **132:** 924.

Lipid regulating drugs. Giving *colestipol* to a patient with hypopituitarism taking oral hydrocortisone maintenance therapy resulted in headaches, ataxia, and lethargy.[1] Mental status returned to normal within hours of an intravenous dose of hydrocortisone 100 mg, and colestipol was subsequently withdrawn uneventfully.

1. Nekl KE, Aron DC. Hydrocortisone-colestipol interaction. *Ann Pharmacother* 1993; **27:** 980–1.

Neuromuscular blockers. For reference to corticosteroids antagonising the effects of *competitive neuromuscular blockers*, see under Atracurium, p.1904.

Sex hormones. There have been reviews[1,2] discussing several reports of an enhanced effect of corticosteroids in women also receiving *oestrogens* or *oral contraceptives* and commenting that the dose of corticosteroids in some cases may need to be reduced. There is some evidence that budesonide may be less affected by use with oral contraceptives than prednisolone.[3]

1. Shenfield GM. Drug interactions with oral contraceptive preparations. *Med J Aust* 1986; **144:** 205–10.

3. Seidegård J, *et al.* Effect of an oral contraceptive on the plasma levels of budesonide and prednisolone and the influence on plasma cortisol. *Clin Pharmacol Ther* 2000; **67:** 373–81.

Smoking. There was a report of an appreciable and consistent increase in plasma corticosteroids after cigarette smoking.[1] However, a review concerning the clinical importance of smoking and drug interactions[2] concluded that in the majority of examples, including corticosteroids, there was little evidence of a recognisable hazard from the interaction.

2. D'Arcy PF. Tobacco smoking and drugs: a clinically important interaction? *Drug Intell Clin Pharm* 1984; **18:** 302–7.

Sympathomimetics. Studies in 21 asthmatic patients suggested that the plasma half-life of dexamethasone was decreased by *ephedrine*.[1] More importantly use of corticosteroids with *beta$_2$ agonists* may potentiate any hypokalaemic effects.[2]

1. Brooks SM, *et al.* The effects of ephedrine and theophylline on dexamethasone metabolism in bronchial asthma. *J Clin Pharmacol* 1977; **17:** 308–18.
2. Committee on Safety of Medicines. β agonists, xanthines and hypokalaemia. *Current Problems 28* 1990.

Thalidomide. In a double-blind crossover study of thalidomide in the treatment of severe chronic erythema nodosum leprosum,[1] the dose of prednisolone necessary to suppress symptoms was considerably reduced in 9 of 10 patients while they were receiving thalidomide; there has been a comment[2] that prednisolone should not be given with thalidomide.

For reference to a possible interaction between thalidomide and dexamethasone, see Effects on the Skin under Adverse Effects of Thalidomide, p.2397.

Xanthines. For the effect of corticosteroids on *aminophylline* and *theophylline*, see p.1144.

Pharmacokinetics of Corticosteroids

Corticosteroids are, in general, readily absorbed from the gastrointestinal tract. They are also absorbed when given locally. After topical use, particularly under an occlusive dressing or when the skin is broken, or use rectally as an enema, sufficient corticosteroid may be absorbed to give systemic effects; this is also a possibility with other local routes such as inhalation. Water-soluble forms of corticosteroids are given by intravenous injection for a rapid response; more prolonged effects are achieved using lipid-soluble forms of corticosteroids by intramuscular injection.

Corticosteroids are rapidly distributed to all body tissues. They cross the placenta to varying degrees and may be distributed in small amounts into breast milk.

Most corticosteroids in the circulation are extensively bound to plasma proteins, mainly to globulin and less so to albumin. The corticosteroid-binding globulin (transcortin) has high affinity but low binding capacity, while albumin has low affinity but large binding capacity. The synthetic corticosteroids are less extensively protein bound than hydrocortisone (cortisol). They also tend to have longer half-lives.

Corticosteroids are metabolised mainly in the liver but also in other tissues, and are excreted in the urine. The slower metabolism of the synthetic corticosteroids with their lower protein-binding affinity may account for their increased potency compared with the natural corticosteroids.

Uses and Administration of Corticosteroids

The corticosteroids are used in physiological doses for replacement therapy in adrenal insufficiency. Pharmacological doses are used when palliative anti-inflammatory or immunosuppressant effects are required. Before instituting therapy the benefits and risks of corticosteroids should be considered; where appropriate, local rather than systemic therapy should be used. The lowest effective dose should be used for the shortest possible time; high doses may be needed for life-threatening situations.

The effects of different corticosteroids vary qualitatively as well as quantitatively, and it may not be possible to substitute one for another in equal therapeutic amounts without provoking adverse effects. Thus, whereas cortisone and hydrocortisone have very appreciable mineralocorticoid (or sodium-retaining) properties relative to their glucocorticoid (or anti-inflammatory) properties, prednisolone and prednisone have considerably less, and others, such as betamethasone and dexamethasone, have none or virtually none. In contrast, the mineralocorticoid properties of fludrocortisone are so pronounced that its glucocorticoid effects are considered to have no clinical significance.

As a rough guide, the approximate **equivalent doses** of the main corticosteroids in terms of their glucocorticoid (or anti-inflammatory) properties alone, are:

- betamethasone 0.75 mg
- cortisone acetate 25 mg
- dexamethasone 0.75 mg
- hydrocortisone 20 mg
- methylprednisolone 4 mg
- prednisolone 5 mg
- prednisone 5 mg
- triamcinolone 4 mg

The mineralocorticoid properties of corticosteroids (see p.1490) are rarely used. Exceptions include the treatment of primary adrenocortical insufficiency, in which both mineralocorticoid and glucocorticoid replacement is necessary, usually in the form of fludrocortisone with hydrocortisone (for details, see p.1498). The mineralocorticoid properties of fludrocortisone are also used to maintain blood pressure in patients with orthostatic hypotension (see p.1530).

The anti-inflammatory and immunosuppressant glucocorticoid properties of corticosteroids (see p.1490) are used to suppress the clinical manifestations of disease in a wide range of disorders considered to have inflammatory or immunological components. For these purposes, the synthetic analogues with their considerably reduced mineralocorticoid properties linked with enhanced glucocorticoid properties, are preferred.

Despite the existence of very powerful synthetic glucocorticoids with virtually no mineralocorticoid activity, the hazards of inappropriately high glucocorticoid therapy are such that the less powerful prednisolone and prednisone are the glucocorticoids of choice for most conditions, since they allow for a greater margin of safety. There is little to choose between prednisolone and prednisone; prednisolone is usually recommended in the UK since it exists in a metabolically active form, whereas prednisone is inactive and must be converted into its active form by the liver; hence, particularly in some liver disorders, bioavailability of prednisone is less reliable (but see Hepatic Impairment under Precautions of Prednisolone, p.1541).

Because the therapeutic effects of corticosteroids seem to be of longer duration than the metabolic effects, intermittent treatment with corticosteroids has been used to allow the metabolic rhythm of the body to become re-established while maintaining the therapeutic effects. Regimens of intermittent therapy have usually consisted of short courses of treatment or of the use of single doses on alternate days. Such alternate-day therapy, however, is only appropriate for corticosteroids with a relatively short duration of action and small mineralocorticoid effect, such as prednisolone, and only in certain disease states. Corticosteroids are also given in single daily doses at times coinciding with maximum or minimum output of the adrenal cortex in order to obtain the desired effect on the adrenals (see Administration, below).

Doses of corticosteroids higher than those required for physiological replacement will eventually lead to some degree of adrenal suppression, the extent depending on the dose given, and the route, frequency, time, and duration of treatment. The adrenal glands are traditionally considered to have a daily output equivalent to about 20 mg of hydrocortisone (cortisol), but individual blood-cortisol concentrations may vary widely, and can increase up to tenfold or more during stress. Therefore, during periods of stress or trauma, such as during and after surgery and when suffering from infections, the corticosteroid dosage of patients must be increased. In patients on long-term corticosteroid therapy undergoing surgery this is usually provided by parenteral hydrocortisone; graduated regimens tailored to the severity of surgery (see p.1536) are now preferred to the former high-dose standard regimens tapered over 5 days, whose use has been questioned (see Surgery, under Administration, below).

Although the empirical use of a corticosteroid is appropriate in a life-threatening situation, generally it is advisable not to begin corticosteroid therapy until a definite diagnosis has been made, for otherwise symptoms may be masked to such an extent that a true diagnosis becomes extremely difficult to make and the disease may reach an advanced stage before detection.

Systemic therapy is indicated in a wide variety of conditions. Where possible the oral route is preferred but parenteral doses may be used if the disease is severe or an emergency arises. Intravenous therapy is generally used for intensive emergency treatment as the onset of action is relatively fast although intramuscular injections, often formulated as longer-acting depot preparations, may also be used to provide subsequent cover. Examples of conditions treated with systemic corticosteroids include:

- as an adjunct to adrenaline in life-threatening allergic reactions such as angioedema or anaphylaxis (see p.1205)
- some blood disorders, including auto-immune haemolytic anaemia (p.1043) and idiopathic thrombocytopenic purpura (p.1505)
- selected connective tissue and muscle disorders, such as Behçet's syndrome (p.1499), polymyalgia rheumatica (p.1510), polymyositis (p.1510), SLE (p.1513), and the vasculitic syndromes (p.1515)
- some inflammatory eye disorders, particularly those affecting the posterior chamber
- inflammatory gastrointestinal disorders, such as Crohn's disease and ulcerative colitis, although local administration by the rectal route may be preferred in some circumstances (see p.1697)
- infections accompanied by a severe inflammatory component provided that appropriate anti-infective drugs are also given and that the benefits of corticosteroid therapy outweigh the possible risk of disseminated infection; examples of conditions where corticosteroid may be considered include helminthic infections, the Jarisch-Herxheimer reaction, and tuberculous meningitis (p.1514)
- selected kidney disorders including lupus nephritis (see Systemic Lupus Erythematosus, p.1513) and various glomerular disorders (p.1504)
- selected liver disorders, including auto-immune chronic active hepatitis (p.1501)
- some neurological disorders such as infantile seizures and subacute demyelinating polyneuropathy; also in cerebral oedema (p.1501), including that associated with malignancy
- some respiratory disorders, such as asthma (see p.1108, although inhaled corticosteroids are preferred to oral therapy for prophylaxis), diffuse parenchymal lung disease (p.1502), pulmonary sarcoid (p.1512), and neonatal respiratory distress syndrome (p.1508)
- some cases of rheumatoid arthritis, where recent evidence suggests there may be value in early treatment of active disease (see p.1511)
- severe skin disorders such as pemphigus and pemphigoid (p.1582)

Glucocorticoids are also used with antineoplastics in regimens for the management of malignant disease. They are also given to reduce immune responses after organ transplantations, often with other immunosuppressants (see p.1810).

Corticosteroids are not now considered useful in patients with aspiration syndromes, stroke, or septic shock.

Intra-articular injection, in the absence of infection and with full aseptic precautions, may be used, for example, in the treatment of rheumatoid arthritis (p.11), osteoarthritis (p.11), and ankylosing spondylitis (see Spondyloarthropathies, p.13). Either hydrocortisone acetate or one of the esters of the synthetic corticosteroids is used. It should be noted that there have been several reports of joint damage after the intra-articular injection of corticosteroids into load-bearing joints.

Topical application often produces dramatic suppression of skin diseases in which inflammation is a prominent feature, such as eczema (p.1579), seborrhoeic dermatitis (p.1584), and some forms of psoriasis (p.1583). However, the disease may return or be exacerbated when corticosteroids are withdrawn and this appears to be a particular problem in some of the forms of psoriasis. Occasionally, corticosteroids may be used with the addition of a suitable antimicrobial, such as neomycin, in the treatment of infected skin. For comments on the topical application of preparations containing a corticosteroid and neomycin, see Adverse Effects of Neomycin, p.305.

Intralesional injection sometimes hastens the resolution of chronic skin lesions such as lichen planus (p.1580), alopecia areata (p.1577), and keloids.

Topical application to the eye in inflammatory and traumatic disorders has led to dramatic results, but the occurrence of herpetic and fungal infections of the cornea and other serious complications are considerable obstacles, and eye drops containing corticosteroids should be used under strict ophthalmic supervision with regular checks of intra-ocular pressure. Care is also required when corticosteroids are given by **subconjunctival injection** in inflammatory eye disorders.

Ear drops containing corticosteroids are used in the treatment of otitis externa (see p.182).

Inhalational therapy is widely used in the prophylaxis of asthma (see p.1108).

Nasal application is used in the prophylaxis and treatment of allergic and non-allergic rhinitis (see p.565) and nasal polyps (p.1508).

Rectal administration, by either suppository or enema, may be used for some corticosteroids, notably in the treatment of inflammatory bowel disease (p.1697).

Administration

Diurnal effect. The diurnal rhythm of the adrenal cortex leads to about 70% of the daily secretion being made between midnight and 9 am.[1] In the treatment of adrenal cortical hyperplasia a dose of hydrocortisone given at night will be nearly twice as suppressive as the same dose given during the day. However, in treating allergic or collagen disease when suppression of adrenal cortical activity is best avoided a dose of hydrocortisone at about 8 am is indicated. When reducing corticosteroid dosage after treatment, a single dose given at 8 am will be most beneficial and will not inhibit corticotropin secretion. Also, for similar reasons,[2] when used for replacement therapy corticosteroids are given in unequal doses during the day (two-thirds of the daily dose in the morning, and one-third at night).

2. Aronson JK. Chronopharmacology: reflections on time and a new text. *Lancet* 1990; **335:** 1515–16.

Epidural route. Reviews[1,2] of the epidural use of corticosteroids in sciatica concluded that reported clinical complications were uncommon but that their role is unclear. Another study[3] suggested that although epidural injection of methylprednisolone acetate produced short-term improvement in pain and sensory deficit, treatment resulted in no functional benefit and did not reduce the need for surgery.

It should be noted that inadvertent intrathecal injection of corticosteroids has resulted in severe neurological complications.

Inhalational therapy. Corticosteroids are given by inhalation, particularly in the maintenance therapy of asthma, in order to deliver the drug directly to the lungs, at smaller doses than are needed orally, and minimise systemic adverse effects. Different inhaled corticosteroids differ in their potency, though there is little evidence of a difference in efficacy at recommended doses.[1] Of those widely available by inhalation, flunisolide is less potent than beclometasone while budesonide is considered more potent, and fluticasone more potent still. (However, a general practice study in New Zealand has suggested that budesonide is less potent than beclometasone.[2]) The ability to use fewer inhalations with more potent drugs might enhance compliance.[1] For inhaled corticosteroids to be effective in the prophylaxis of asthma they must be taken regularly and patient compliance is important.

Efficient delivery to the bronchial tree is crucial and a number of different devices are available, including pressurised aerosol inhalers, breath-actuated aerosol inhalers, and dry powder inhalers. These devices appear to be equally effective for the delivery of corticosteroids.[3] However, many patients, especially children, find that inhalation is made much easier by fitting a spacer device to the inhaler.[4] Such a device is recommended when high doses are to be inhaled, to prevent oropharyngeal deposition and subsequent systemic absorption. However, the type of spacer used and the method of use may dramatically alter the amount of drug available for inhalation. The drug should be introduced into the spacer by single actuations, each followed by inhalation, with the delay between actuation of the inhaler and inhalation from the spacer kept to a minimum. In some spacers static electricity accumulates, and the build up of charge reduces drug delivery: this can be controlled by washing and drying the spacer in air once a month. Considerable differences in the dose delivered to the airways may also be seen between different types of nebuliser, and between nebulisers and spacer devices.[5]

Changes in formulation of the propellant, to remove chlorofluorocarbons, may also affect drug availability; it is reported to be increased, requiring dose reduction with some formulations.[6,7]

It should be borne in mind that apparent differences in the dose supplied from inhaler devices in different countries may in some cases be artefacts, due to variations in the way the dose is measured or expressed. In the UK, for example, the dose supplied from a metered-dose inhaler is generally quoted as the amount released into the mouthpiece from the valve. In the USA, however, doses may be stated in terms of the amount of drug emitted from the mouthpiece, which due to drug deposition will be slightly less than the amount released from the valve.

Intra-articular route. Intra-articular and periarticular injection of corticosteroids is an established treatment for a variety of joint and soft-tissue lesions.[1-3] Pain and inflammation associated with rheumatoid and juvenile idiopathic arthritis, crystal arthropathies such as gout, and osteoarthritis can be alleviated by injection of a suitable corticosteroid, and in some cases the benefits may be quite prolonged. The longer-acting esters methylprednisolone acetate, triamcinolone acetonide, and triamcinolone hexacetonide are generally preferred. In some cases these may be combined with a local anaesthetic and a short-acting soluble corticosteroid for more rapid relief and to reduce the risk of a post-injection flare.

The risks associated with this technique have been reviewed.[4] Accurate injection technique is essential, and vigorous skin cleansing and an aseptic technique are required to avoid the introduction of infection into the joint; pre-existing joint infection is a contra-indication to corticosteroid injection. Intra-articular injections may be repeated if necessary but it has been suggested that a single joint should not be injected more than 3 or 4 times a year.

Periarticular injection is also used in various soft tissue disorders such as bursitis, capsulitis (painful shoulder syndromes), epicondylitis, tenosynovitis, and carpal tunnel syndrome. Particular care is required to avoid injection directly into a tendon, as this may cause the tendon to rupture. A shorter-acting corticosteroid such as hydrocortisone acetate may be more suitable for extra-articular lesions.

Intranasal route. In the management of allergic rhinitis corticosteroids are given intranasally in order to deliver the drug directly to the affected area, to use lower doses than are needed orally, and reduce the risk of systemic adverse effects. They are usually given by metered dose pump spray. The extent of local effect versus systemic effect may be influenced by the drug's molecular weight, lipophilicity, metabolism in nasal tissue, and type of delivery device.[1] In practice, however, when intranasal corticosteroid sprays are used as recommended there is little evidence that they have a significant systemic effect, and their local adverse effects are similar.[2,3] For details of systemic effects associated with inappropriately prolonged use of corticosteroid nasal drops, see Intranasal Administration under Precautions, p.1494.

Surgery. In the light of what was known in 1994 about the adrenal stress response to surgery, a discussion on the appropriate glucocorticoid supplementation for patients receiving corticosteroids who undergo surgery concluded that some recommendations were excessive.[1] (At this time in the UK recommended regimens consisted of the equivalent of 100 mg of hydrocortisone, usually as the sodium succinate, intravenously or intramuscularly before surgery, repeated every 8 hours, with the dose being tapered over 5 days to 20 or 30 mg daily.) It was suggested that for minor surgery 25 mg of hydrocortisone or its equivalent pre-operatively was adequate; where surgical stress was likely to be moderate, 50 to 75 mg of hydrocortisone or its equivalent daily in divided doses for 1 to 2 days was suggested. For major surgical stress, a target of 100 to 150 mg of hydrocortisone or its equivalent should be given daily in divided doses for 2 to 3 days, although less might be given if the patient's pre-operative glucocorticoid dose was low. It was also considered that the practice of gradually reducing postoperative coverage over several days was not supported by evidence except in cases of high-dose glucocorticoid use for prolonged periods.

Another review[2] of this subject also concluded that for minor surgery, 25 mg of hydrocortisone, or the patient's usual dose of corticosteroid, given pre-operatively, was appropriate. However, the authors argued that for surgery causing greater stress, it was preferable to avoid the increases in plasma-cortisol associated with intermittent bolus doses. They suggested that for moderate surgery an intravenous dose of hydrocortisone 25 mg at induction should be followed by an infusion of 100 mg over 24 hours; for major surgery the infusion should be continued for 48 to 72 hours after surgery. The usual oral corticosteroid dose may be resumed once these infusions have been completed, providing the postoperative course is uncomplicated and gastrointestinal function has returned.

For currently recommended regimens see Uses and Administration of Hydrocortisone, p.1536.

Topical application. Guidelines[1,2] for the correct use of topical corticosteroids recommend that an appropriately potent preparation to bring the skin disorder under control should be used. Some recommend use of the lowest potency that will control the disorder, while others have advocated starting treatment with a more potent preparation, treatment may then be continued with a less potent preparation and with less frequent application, once control is obtained. The most potent topical corticosteroids are generally reserved for recalcitrant dermatoses. Once the skin has healed, treatment should be tailed off. Particular care is necessary in the use of topical corticosteroids in children, and the more potent preparations are contra-indicated in infants under 1 year of age, although potent preparations may be needed briefly in older children. It has been suggested that a 'steroid holiday' of at least 2 weeks be considered in children after each 2 or 3 weeks of daily topical therapy to allow thinned epidermis to restore itself and maintain its barrier function.[3]

Care is also necessary in applying corticosteroids to certain anatomical sites such as the face and flexures; some advocate using only hydrocortisone 0.5 or 1% on the face. Advice should be given that topical corticosteroids should be applied sparingly in thin layers, by smoothing gently into the skin preferably after a bath, and that no benefit is gained from more frequent than twice daily application or by vigorous rubbing.

In a study to determine the requirement of topical corticosteroids,[4] 16 adult patients with eczema were treated with a variety of topical preparations until substantial clearing had occurred (up to 10 days). Results indicated that the mean requirement of preparation, regardless of potency or vehicle, was 6.86 g/m^2. Using this value the calculated quantities of topical corticosteroid to the nearest 5 g required for twice daily application for one week for the whole body, arms and legs only, and trunk only respectively were as follows:

- 6 months of age, 35 g, 20 g, and 15 g
- 1 year, 45 g, 25 g, and 15 g
- 4 years, 60 g, 35 g, and 20 g
- 8 years, 90 g, 50 g, and 35 g
- 12 years, 120 g, 65 g, and 45 g
- 16 years, 155 g, 85 g, and 55 g
- adult (70-kg male), 170 g, 90 g, and 60 g

Calculated quantities for the same application schedule for an adult (70-kg male) for individual portions of the body were:

- face and neck, 10 g
- one arm, 15 g
- one leg, 30 g
- hands and feet, 10 g

Table 1, below, is a guide to the potency of topical corticosteroids. There may be some degree of overlap between these groups and, not surprisingly, there are minor varia-

Table 1. Guide to potencies of topical corticosteroids.

Very potent	Potent	Moderately potent	Mild
Clobetasol propionate 0.05%	Amcinonide 0.1%	Alclometasone dipropionate 0.05%	Fluocinolone acetonide 0.0025%
Diflucortolone valerate 0.3%	Beclometasone dipropionate 0.025%	Betamethasone valerate 0.025%	Hydrocortisone 0.5% and 1%
Fluocinolone acetonide 0.2%	Betamethasone benzoate 0.025%	Clobetasone butyrate 0.05%	Hydrocortisone acetate 1%
Halcinonide 0.1%	Betamethasone dipropionate 0.05%	Desoximetasone 0.05%	Methylprednisolone acetate 0.25%
Ulobetasol propionate 0.05%	Betamethasone valerate 0.1%	Fludroxycortide 0.0125%	
	Budesonide 0.025%	Flumetasone pivalate 0.02%	
	Desonide 0.05%	Fluocinolone acetonide 0.00625% and 0.01%	
	Desoximetasone 0.25%	Fluocortin butyl 0.75%	
	Diflorasone diacetate 0.05%	Fluocortolone preparations (caproate with pivalate, each 0.1% and caproate with either free alcohol or pivalate, each 0.25%)	
	Diflucortolone valerate 0.1%	Hydrocortisone aceponate 0.1%	
	Fluclorolone acetonide 0.025%	Hydrocortisone buteprate 0.1%	
	Fluocinolone acetonide 0.025%	Prednicarbate 0.25%	
	Fluocinonide 0.05%		
	Fluprednidene acetate 0.1%		
	Fluticasone propionate 0.005% and 0.05%		
	Hydrocortisone butyrate 0.1%		
	Methyprednisolone aceponate 0.1%		
	Mometasone furoate 0.1%		
	Triamcinolone acetonide 0.1%		

tions to this classification. For example, some authorities consider fluocinolone acetonide 0.2% to be potent rather than very potent and halcinonide 0.1% to be potent rather than very potent.

It has been suggested, however, that the advent of non-fluorinated double esters such as hydrocortisone and methylprednisolone aceponates, or prednicarbate, has resulted in corticosteroids whose topical anti-inflammatory potency is not as closely related to their potential atrophic effects on skin, and that a classification taking both into account would be desirable.[5,6]

Acute respiratory distress syndrome

Acute respiratory distress syndrome (ARDS) is characterised by areas of lung damage leading to decreased pulmonary compliance, pulmonary oedema associated with increased capillary and alveolar permeability, and refractory hypoxaemia. Diffuse pulmonary infiltrates are seen on radiography, and patients exhibit dyspnoea, tachypnoea, or both. Diagnosis is primarily clinical, and there has been some disagreement as to what should be included in the syndrome;[1] it is now seen as forming the most severe end of a spectrum of symptoms due to lung inflammation and increased permeability known as acute lung injury.[1-3] ARDS is sometimes considered to refer to 'adult respiratory distress syndrome' but it is not confined to adult patients.[1,2]

ARDS may be caused by a variety of pulmonary or systemic insults but is particularly frequent in patients with sepsis;[4] because of an association with failure of other organs it has been suggested that it represents the pulmonary component of multiple organ failure syndrome.[5] A wide variety of inflammatory mediators have been implicated in its pathogenesis but evidence suggests that recruitment of neutrophils by interleukins plays an important role.[1]
