Resistance has been reported in strains of many of the organisms normally sensitive to kanamycin, and at one time was widespread, but a decline in the use of kanamycin has meant that resistance has become somewhat less prevalent. Cross-resistance occurs between kanamycin and neomycin, framycetin, and paromomycin, and partial cross-resistance has been reported between kanamycin and streptomycin.

◊ References.

Pharmacokinetics

As for Gentamicin Sulfate, p.284.

Less than 1% of an oral dose is absorbed, although this may be significantly increased if the gastrointestinal mucosa is inflamed or ulcerated.

After intramuscular injection peak plasma concentrations of kanamycin of about 20 and 30 micrograms/mL are attained in about 1 hour following doses of 0.5 and 1 g respectively. A plasma half-life of about 3 hours has been reported. Absorption after intraperitoneal instillation is similar to that from intramuscular doses.

Kanamycin is rapidly excreted by glomerular filtration and most of a parenteral dose appears unchanged in the urine within 24 hours. It has been detected in cord blood and in breast milk.

Uses and Administration

Kanamycin is an aminoglycoside antibacterial with actions similar to those of gentamicin (p.284). It has been used in the treatment of susceptible Gram-negative and staphylococcal infections, including gonorrhoea (p.191) and neonatal gonococcal eye infections (p.180), although its use has declined in many centres because of the development of resistance. As with gentamicin it may be used with penicillins and with cephalosporins; the injections should be given at separate sites. Kanamycin has also been used as a second-line drug in tuberculosis (p.196), but other, safer drugs are usually preferred.

The sulfate or acid sulfate salts are often used: in the USA, preparations containing the bisulfate ($C_{18}H_{36}N_40_{11},2H_2SO_4$), but referred to as the sulfate, are available. Doses are expressed in terms of kanamycin base; 1.2 g of kanamycin sulfate, and 1.34 g of kanamycin acid sulfate, are each equivalent to about 1 g of kanamycin. It is usually given by intramuscular injection, and in acute infections adults may be given 15 mg/kg daily, to a maximum of 1.5 g daily, in 2 to 4 divided doses. The same doses may be given by intravenous infusion of a 0.25 to 0.5% solution over 30 to 60 minutes; in the UK, up to 30 mg/kg daily has been given in 2 or 3 divided doses by this route. Similar doses are used in children. Treatment of acute infections should preferably not continue for longer than 7 to 10 days or exceed a cumulative dose of 10 g kanamycin. A dose of 3 to 4 g weekly, given as 1 g on alternate days or as 1 g twice daily on 2 days each week, has been suggested in the UK for chronic bacterial infections, up to a maximum cumulative dose of 50 g, but prolonged use increases the risk of nephrotoxicity and is not generally recommended.

A single intramuscular dose of 2 g of kanamycin has been used in the treatment of penicillin-resistant gonorrhoea. In the treatment and prophylaxis of neonatal gonococcal infections in infants born to mothers with gonorrhoea, 25 mg/kg, up to a maximum of 75 mg, may be given as a single intramuscular dose.

Peak plasma concentrations greater than 30 micrograms/mL and trough concentrations greater than 10 micrograms/mL should be avoided. It is recommended that dosage should be adjusted in all patients according to plasma-kanamycin concentrations, and this is particularly important where factors such as age, renal impairment, or prolonged therapy may predispose to toxicity, or where there is a risk of subtherapeutic concentrations. For discussion of the methods of calculating aminoglycoside dosage requirements, see Administration and Dosage, under Gentamicin, p.284.

Kanamycin has been used orally similarly to neomycin (p.305), for the suppression of intestinal flora. For pre-operative use, 1 g may be given every hour for 4 hours, then 1 g every 6 hours for 36 to 72 hours. In the management of hepatic encephalopathy, 8 to 12 g daily in divided doses may be given.

Kanamycin has also been given in doses of 250 mg as a nebulised inhalation, 2 to 4 times daily. Solutions of kanamycin 0.25% have been used for the irrigation of body cavities.

Kanamycin tannate has also been used.

Preparations

USP 31: Kanamycin Injection; Kanamycin Sulfate Capsules.

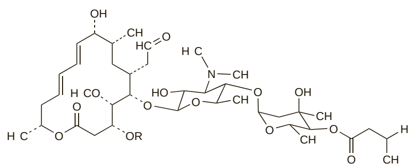
Kitasamycin *(BAN, USAN, rINN)*

Kitasamicina; Kitasamycine; Kitasamycinum; Leucomycin.

Китазамицин

CAS — 1392-21-8 (kitasamycin); 37280-56-1 (kitasamycin tartrate); 178234-32-7 (acetylkitasamycin).

ATC Vet — QJ01FA93.



Kitasamycin A : R = H
Kitasamycin A : R = COCH

Pharmacopoeias. In *Chin.* and *Jpn.*
Jpn also includes Acetylkitasamycin and Kitasamycin Tartrate.

Profile

Kitasamycin is a macrolide antibacterial produced by *Streptomyces kitasatoensis*, consisting mainly of kitasamycins A_4 and A_5. It has actions and uses similar to those of erythromycin (p.269) and has been given orally as the base or intravenously as the tartrate in the treatment of susceptible infections. Acetylkitasamycin has also been given orally.

Kitasamycin has been added to animal feeding stuffs as growth promotors for pigs.

Latamoxef Disodium *(BANM, rINNM)*

Latamoksefidinatrium; Latamoxef disódico; Latamoxef Disodique; Latamoxefdinatrium; Latamoxefum Dinatricum; LY-127935; Moxalactam Disodium *(USAN)*; 6059-S. (7*R*)-7-[2-Carboxy-2-(4-hydroxyphenyl)acetamido]-7-methoxy-3-(1-methyl-1*H*-tetrazol-5-ylthiomethyl)-1-oxa-3-cephem-4-carboxylic acid, disodium salt.

Динатрий Латамоксеф

$C_{20}H_{18}N_6Na_2O_9S$ = 564.4.

CAS — 64952-97-2 (latamoxef); 64953-12-4 (latamoxef disodium).

ATC — J01DD06.

ATC Vet — QJ01DD06.

Pharmacopoeias. In *Jpn.*

Profile

Latamoxef is an oxacephalosporin antibacterial that has been given intramuscularly or intravenously as the disodium salt in the treatment of susceptible infections. It differs from the cephalosporins in that the sulfur atom of the 7-aminocephalosporanic acid nucleus is replaced by oxygen. Like cefamandole (p.220) it has an *N*-methylthiotetrazole side-chain and may cause hypoprothrombinaemia. Serious bleeding episodes have been reported with latamoxef and prophylaxis with vitamin K and monitoring of bleeding time have been recommended during treatment. In addition to hypoprothrombinaemia, inhibition of platelet function and more rarely immune-mediated thrombocytopenia may be responsible for interference with haemostasis. As with the methylthiotetrazole-containing cephalosporins, a disulfiram-like reaction with alcohol may occur.

Latamoxef has antimicrobial activity similar to that of the third-generation cephalosporin cefotaxime (p.228), although it is generally less active against Gram-positive bacteria and more active against *Bacteroides fragilis*.

Breast feeding. The authors of a pharmacokinetic study[1] in 8 lactating women given latamoxef cautioned that there was a possibility of colonisation of the infant's bowel with Gram-positive bacteria and in consequence a risk of enterocolitis. They therefore advised against breast feeding during maternal use of the drug. However, no adverse effects have been seen in breast-fed infants whose mothers were receiving latamoxef, and the American Academy of Pediatrics considers[2] that it is therefore usually compatible with breast feeding.

Jpn: Shiomarin.

Levofloxacin *(BAN, USAN, rINN)*

DR-3355; HR-355; Levofloksasiini; Levofloksasin; Lévofloxacine; Levofloxacino; Levofloxacinum; *S*-(−)-Ofloxacin; RWJ-25213. (−)-(*S*)-9-Fluoro-2,3-dihydro-3-methyl-10-(4-methyl-1-piperazinyl)-7-oxo-7*H*-pyrido[1,2,3-*de*]-1,4-benzoxazine-6-carboxylic acid.

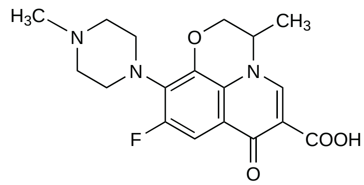
Левофлоксацин

$C_{18}H_{20}FN_3O_4$ = 361.4.

CAS — 100986-85-4 (levofloxacin); 138199-71-0 (levofloxacin hemihydrate).

ATC — J01MA12; S01AX19.

ATC Vet — QJ01MA12; QS01AX19.



Adverse Effects and Precautions

As for Ciprofloxacin, p.244.

Symptomatic hyperglycaemia and/or hypoglycaemia have been reported, usually in diabetics who are also taking hypoglycaemics or insulin. Such patients should have their blood-glucose concentrations closely monitored and if signs or symptoms of glucose disturbances develop, levofloxacin should be stopped.

Effects on glucose metabolism. See also under Gatifloxacin, p.281.

Interactions

As for Ciprofloxacin, p.246.

Use of levofloxacin with drugs that alter blood-glucose concentrations increases the risk of blood-glucose disturbances.

Levofloxacin does not appear to interact significantly with theophylline or ciclosporin.

Antimicrobial Action

As for Ciprofloxacin, p.246.

Levofloxacin is generally considered to be about twice as active as ofloxacin (p.310), the racemic substance. Levofloxacin has a broad spectrum of activity which includes Gram-positive bacteria.

◊ References.

1. Brown DFJ, *et al.*, eds. Levofloxacin: an extended spectrum 4-quinolone agent. *J Antimicrob Chemother* 1999; **43** (suppl C): 1–90.

Pharmacokinetics

Levofloxacin is rapidly and almost completely absorbed after oral doses with peak plasma concentrations occurring within 1 to 2 hours. It is widely distributed into body tissues including the bronchial mucosa and lungs, but penetration into CSF is relatively poor. Levofloxacin is about 30 to 40% bound to plasma proteins. Only small amounts are metabolised, to inactive metabolites. The elimination half-life of levofloxacin is 6 to 8 hours, although this may be prolonged in patients with renal impairment. Levofloxacin is excreted largely unchanged, primarily in the urine with less than 5% as metabolites. It is not removed by haemodialysis or peritoneal dialysis.

◊ References.

2. Piscitelli SC, *et al.* Pharmacokinetics and safety of high-dose and extended-interval regimens of levofloxacin in human immunodeficiency virus-infected patients. *Antimicrob Agents Chemother* 1999; **43:** 2323–7.

Uses and Administration

Levofloxacin is the *S*-(−)-isomer of the fluoroquinolone antibacterial ofloxacin (p.310). It is given orally, or by intravenous infusion as a 5 mg/mL solution over 30 to 90 minutes, to treat susceptible infections including tuberculosis (but see under Uses and Administration of Ciprofloxacin, p.248). Levofloxacin is given as the hemihydrate but doses are expressed in terms of the base; levofloxacin hemihydrate 256 mg is equivalent to about 250 mg of levofloxacin. Usual doses range from 250 to 500 mg once or twice daily for 7 to 14 days depending on the severity and nature of the infection. A dose of 250 mg once daily for 3 days may be given for uncomplicated urinary-tract infections. A 28-day course of treatment with a dose of 500 mg once daily should be given for chronic bacterial prostatitis. In the USA, doses of 750 mg once daily for 7 to 14 days may be used for complicated skin infections and for hospital-acquired pneumonia; a shorter course of 750 mg once daily for 5 days may be given for community-acquired pneumonia, acute bacterial sinusitis, complicated urinary-tract infections, and acute pyelonephritis. A 60-day course of treatment with a dose of 500 mg once daily is also licensed in the USA for treatment and postexposure prophylaxis of inhalation anthrax.

Doses should be reduced in patients with renal impairment (see below).

Levofloxacin is also used topically as the hemihydrate in eye drops. A solution containing the equivalent of 0.5% of levofloxacin is used for the treatment of bacterial conjunctivitis and 1.5% for corneal ulcers caused by susceptible strains of bacteria.

◊ Reviews.

1. Davis R, Bryson HM. Levofloxacin: a review of its antibacterial activity, pharmacokinetics and therapeutic efficacy. *Drugs* 1994; **4:** 677–700.
2. Martin SJ, *et al.* Levofloxacin and sparfloxacin: new quinolone antibiotics. *Ann Pharmacother* 1998; **32:** 320–36.
3. Martin SJ, *et al.* A risk-benefit assessment of levofloxacin in respiratory, skin and skin structure, and urinary tract infections. *Drugs* 2001; **24:** 199–222.
4. Croom KF, Goa KL. Levofloxacin: a review of its use in the treatment of bacterial infections in the United States. *Drugs* 2003; **63:** 2769–2802.
5. Anderson VR, Perry CM. Levofloxacin: a review of its use as a high-dose, short-course treatment for bacterial infection. *Drugs* 2008; **68:** 535–65.

Administration in children. Since fluoroquinolones can cause degenerative changes in weight-bearing joints of young *animals* they should only be used in children and adolescents where their use may be justified if the benefits outweigh the risks. Although levofloxacin is not licensed for use in this age group in either the UK or USA, a pharmacokinetic study[1] has suggested that the following doses would be needed:

- children 5 years of age and older, 10 mg/kg daily
- infants and children from 6 months to less than 5 years of age, 10 mg/kg every 12 hours

1. Chien S, *et al.* Levofloxacin pharmacokinetics in children. *J Clin Pharmacol* 2005; **45:** 153–60.

Administration in renal impairment. Although initial doses (see above) remain unchanged in patients with renal impairment, subsequent doses of levofloxacin should be adjusted according to creatinine clearance (CC).

In the UK, the following doses are recommended:

- CC 20 to 50 mL/minute: subsequent doses are halved
- CC 10 to 19 mL/minute: subsequent doses are reduced to one-quarter of the usual dose; a regimen of 250 mg daily should be reduced to 125 mg every 48 hours
- CC less than 10 mL/minute (including haemodialysis and continuous peritoneal dialysis patients): usual doses of 250 mg or 500 mg daily are reduced to 125 mg every 48 or 24 hours respectively; a regimen of 500 mg twice daily is reduced to 125 mg every 24 hours

In the USA, the following dose modifications are recommended:

After an initial dose of 750 mg daily,

- CC 20 to 49 mL/minute: subsequent doses are 750 mg every 48 hours
- CC up to 19 mL/minute (including haemodialysis and continuous peritoneal dialysis patients): subsequent doses are 500 mg every 48 hours

After an initial dose of 500 mg daily,

- CC 20 to 49 mL/minute: subsequent doses are 250 mg every 24 hours
- CC up to 19 mL/minute (including haemodialysis and continuous peritoneal dialysis patients): subsequent doses are 250 mg every 48 hours

After an initial dose of 250 mg daily,

- CC 10 to 19 mL/minute: subsequent doses are 250 mg every 48 hours

A pharmacokinetic study in 10 critically ill patients undergoing continuous renal replacement therapy with either venovenous haemofiltration or haemodiafiltration suggested that a dose of either levofloxacin 250 mg every 24 hours or 500 mg every 48 hours would be suitable in such situations.[1]

$C_{18}H_{34}N_2O_6S,HCl,H_2O = 461.0$.

CAS — 859-18-7 (anhydrous lincomycin hydrochloride); 7179-49-9 (lincomycin hydrochloride, monohydrate).

ATC — J01FF02.

ATC Vet — QJ01FF02.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Lincomycin Hydrochloride). An antimicrobial substance produced by *Streptomyces lincolnensis* var. *lincolnensis* or by any other means. A white or almost white crystalline powder. It contains not more than 5% of lincomycin B. Very soluble in water; slightly soluble in alcohol; very slightly soluble in acetone. A 10% solution in water has a pH of 3.5 to 5.5. Store at a temperature not exceeding 30° in airtight containers.

USP 31 (Lincomycin Hydrochloride). A white or practically white crystalline powder, odourless or with a faint odour. Freely soluble in water; very slightly soluble in acetone; soluble in dimethylformamide. pH of a 10% solution in water is between 3.0 and 5.5. Store in airtight containers.

Incompatibility. Solutions of lincomycin hydrochloride have an acid pH and incompatibility may be expected with alkaline preparations, or with drugs unstable at low pH.

Adverse Effects, Treatment, and Precautions

As for Clindamycin, p.251.

Hypersensitivity reactions such as skin rashes, urticaria, and angioedema may be less frequent with lincomycin than with clindamycin. Other adverse effects reported rarely with lincomycin include aplastic anaemia, pancytopenia, tinnitus, and vertigo.

Lincomycin should be used with caution in patients with hepatic or renal impairment; consideration should be given to decreasing the dosage frequency and serum concentrations should be monitored during high-dose therapy. Reduced doses may be necessary in those with severe renal impairment (see below).

Interactions

As for Clindamycin, p.251.

Absorption of lincomycin is reduced by adsorbent antidiarrhoeals and cyclamate sweeteners.

Antimicrobial Action

As for Clindamycin, p.252, but it is less potent. There is complete cross-resistance between clindamycin and lincomycin. Some cross-resistance with erythromycin, including a phenomenon known as dissociated cross-resistance or macrolide effect, has been reported.

Pharmacokinetics

About 20 to 30% of an oral dose of lincomycin is rapidly absorbed from the gastrointestinal tract; after a 500-mg dose, peak plasma concentrations of about 2 to 3 micrograms/mL are reached within 2 to 4 hours. Food markedly reduces the rate and extent of absorption. An intramuscular injection of 600 mg produces average peak plasma concentrations of between 11 and 12 micrograms/mL at 60 minutes and a 2-hour intravenous infusion of 600 mg produces an average of about 16 micrograms/mL.

The biological half-life of lincomycin is about 5 hours and may be prolonged in hepatic or renal impairment. Serum half-life may be doubled in patients with hepatic impairment and up to 3 times longer in those with severe renal impairment. Lincomycin is widely distributed in the tissues including bone and body fluids but diffusion into the CSF is poor, although it may be slightly better when the meninges are inflamed. It diffuses across the placenta and is distributed into breast milk.

Lincomycin is partially inactivated in the liver; unchanged drug and metabolites are excreted in the urine, bile, and faeces. Lincomycin is not effectively removed from the blood by haemodialysis or peritoneal dialysis.

Uses and Administration

Lincomycin is a lincosamide antibacterial with actions and uses similar to those of its chlorinated derivative, clindamycin (p.252). Clindamycin is usually preferred to lincomycin because of its greater activity and better absorption, although the usefulness of both drugs is limited by the risk of pseudomembranous colitis.

Lincomycin is given orally or parenterally as the hydrochloride but doses are expressed in terms of the base; 1.13 g of lincomycin hydrochloride is equivalent to about 1 g of lincomycin. The usual adult oral dose is 500 mg 3 or 4 times daily, taken at least 1 or 2 hours before or after food. It is given parenterally by intramuscular injection in a dose of 600 mg once or twice daily, or by slow intravenous infusion in a dose of 0.6 to 1 g two or three times daily. Higher intravenous doses have been given in very severe infections, up to a total daily dose of about 8 g. For intravenous use, lincomycin 1 g should be diluted in not less than 100 mL of diluent and infused over at least 1 hour.

For details of reduced doses in renal impairment, see below.

For details of doses in infants and children, see below.

Lincomycin hydrochloride may be given by subconjunctival injection in a dose equivalent to 75 mg of lincomycin.

Administration in children. The usual oral dose of lincomycin for infants and children aged 1 month and over is 30 to 60 mg/kg daily in divided doses. It is given parenterally to those over 1 month old in a dose of 10 to 20 mg/kg daily in divided doses by intramuscular injection or intravenous infusion.

For suggested doses in children with renal impairment see below.

Administration in renal impairment. Doses of lincomycin may need to be reduced in patients with severe renal impairment; a reduction down to 25 to 30% of the usual dose (see above) may be appropriate.

Adverse Effects and Precautions

The adverse effects most frequently reported in patients given linezolid include diarrhoea, nausea and vomiting, metallic taste, headache, insomnia, constipation, rashes, dizziness, fever, oral and vaginal candidiasis, and abnormal liver function tests. Lactic acidosis has been reported. Convulsions have also been reported in patients treated with linezolid. In some of these cases, a history of seizures or risk factors for seizures was reported. There have been rare reports of bullous skin eruptions including Stevens-Johnson syndrome. Peripheral and optic neuropathy, sometimes progressing to loss of vision, have occurred rarely, mainly in patients given linezolid for more than 28 days. Visual blurring has been reported in some patients given less than 28 days of treatment.

Reversible myelosuppression including anaemia, leucopenia, pancytopenia and, in particular, thrombocytopenia has been reported and blood counts should be monitored weekly in patients receiving linezolid. Patients particularly at risk are those who have received linezolid for more than 10 to 14 days, who are receiving other bone marrow suppressant drugs, or who have pre-existing myelosuppression or severe renal impairment.

Patients with mixed (Gram-negative and Gram-positive) infections are at a higher risk of mortality when linezolid is given as monotherapy (see Increased Mortality, below); linezolid must therefore be used with appropriate antibacterial cover for Gram-negative organisms in such patients.

Effects on the blood. Reversible myelosuppression with red cell hypoplasia occurred in 3 patients treated with linezolid.[1] Features of the myelosuppression were considered by some[1,2] to be similar to those associated with chloramphenicol, although this was disputed by the manufacturers.[3]

There have been reports of thrombocytopenia occurring at a higher incidence than that reported by the manufacturers; in one study,[4] 6 of 19 patients who had been treated with linezolid developed thrombocytopenia, while another[5] found that it occurred in 23 of 48 patients given the drug for more than 5 days.

During the initial 8 months of licensed use in the UK 12 reports of haematopoietic disorders (including thrombocytopenia, anaemia, leucopenia, and pancytopenia) were received by the UK CSM.[6]

Studies have shown that the risk of thrombocytopenia and anaemia is increased in patients on prolonged linezolid therapy with pre-existing myelosuppression[7,8] or severe renal impairment.[9]

Effects on the eyes. See under Effects on the Nervous System, below.

Effects on mitochondria. Linezolid appears to inhibit mitochondrial protein synthesis when given for prolonged courses. This decreases cellular energy production in tissues that are highly dependent on oxidative phosphorylation, such as the optic nerve, skeletal muscles, liver, and kidneys, leading to adverse effects such as lactic acidosis[1] or hyperlactataemia,[1,2] and optic[3] and/or peripheral neuropathy[1] (see also below). Encephalopathy, lactic acidosis, optic neuropathy, skeletal myopathy, and renal failure were reported[1] in a 63-year-old woman after a 4-month course of linezolid. The symptoms resolved when linezolid was stopped; however, the patient remained blind and disorientated. In contrast, bilateral mitochondrial optic neuropathy seen[3] in a 6-year-old boy after a 1-year course of oral linezolid resolved 3 months after linezolid treatment was stopped. In another study[2] reversible hyperlactataemia was reported in 5 patients given linezolid for 1 to 3 months. Mitochondrial activity and lactic acid levels returned to normal when linezolid therapy was stopped.

3. Javaheri M, *et al.* Linezolid-induced optic neuropathy: a mitochondrial disorder? *Br J Ophthalmol* 2007; **91:** 111–15. Correction. *ibid.*; 403.

Effects on the nervous system. The Australian Adverse Drug Reactions Advisory Committee[1] stated in February 2003 that it had received 4 reports of peripheral neuropathy in patients who had taken linezolid for 6 to 9 months; none of these cases had resolved at the time of the report. They suggested that the risk of peripheral neuropathy should be considered when treatment was extended beyond 28 days. There have been several published reports of peripheral and optic neuropathy associated with linezolid,[2-9] with some attributing these effects to the inhibition of mitochondrial protein synthesis by linezolid. For further discussion see Effects on Mitochondria, above. The regulatory authority in the UK has warned that patients should be advised to report any symptoms of visual impairment immediately, including changes in visual acuity or colour vision, blurred vision, or visual field defects.[10] Any linezolid-treated patient with new visual symptoms should be evaluated promptly and referred to an ophthalmologist if necessary; regular monitoring is advised in all patients who may require treatment for more than 28 days.

Increased mortality. In March 2007, the FDA[1] issued an alert advising that an open-label, randomised study comparing linezolid to vancomycin, oxacillin, or dicloxacillin in the treatment of seriously ill patients with intravascular catheter-related bloodstream infections, including catheter-site infections, had found that death rates were significantly higher in patients treated with linezolid (78 of 363) than in the comparator arm (58 of 363), particularly in those with Gram-negative or mixed infections. Mortality did not differ for patients with purely Gram-positive infections.

The FDA[1] and the UK manufacturer[2] therefore advised that linezolid should not be used in infections caused by Gram-negative bacteria and should only be used in mixed Gram-positive and Gram-negative infections when appropriate cover for Gram-negative organisms is given at the same time. Licensed product information now reflects these warnings.

Interactions

Linezolid is a reversible, nonselective MAOI and therefore has the potential to interact with adrenergic and serotonergic drugs. Enhanced pressor activity has been reported in patients receiving linezolid with phenylpropanolamine or pseudoephedrine and initial doses of dopamine or adrenaline should be reduced. There have also been cases of serotonin syndrome when linezolid was taken with serotonin reuptake inhibitors, and similar symptoms when it was taken with dextromethorphan. The interactions of conventional MAOIs, both with other drugs and with foods, are described under Phenelzine, p.417.

Antidepressants. Serotonin syndrome has been reported in patients taking linezolid with serotonergic antidepressants such as venlafaxine (see p.429) and SSRIs (though concomitant use may be possible, see p.396).

Opioid analgesics. For a report of an interaction between linezolid and *pethidine*, attributed to linezolid's inhibitory actions on monoamine oxidase, see p.114.

Antimicrobial Action

Linezolid is an oxazolidinone antibacterial with activity against a range of aerobic Gram-positive bacteria including vancomycin-resistant enterococci and meticillin-resistant *Staphylococcus aureus*. It is less active against Gram-negative bacteria, but has some *in-vitro* activity against *Haemophilus influenzae*, *Legionella* spp., *Moraxella catarrhalis* (*Branhamella catarrhalis*), *Neisseria gonorrhoeae*, and *Pasteurella* spp. It is not active against *Acinetobacter* spp., Enterobacteriaceae, or *Pseudomonas* spp.

Oxazolidinone antibacterials are bacteriostatic and act by inhibition of ribosomal protein synthesis. Cross-resistance between oxazolidinones and other classes of antibacterial is considered unlikely.

Resistant strains of enterococci and meticillin-resistant *Staph. aureus* have been reported.

Resistance. There have been reports of linezolid resistance in enterococci, involving both *Enterococcus faecium*[1-4] and *E. faecalis*.[2] There is also concern over the emergence of linezolid resistance in staphylococci, such as meticillin-resistant *Staphylococcus aureus*,[5,6] *Staph. auricularis*,[7] and *Staph. epidermidis*.[7,8] A survey[9] of reported resistance to linezolid in the USA found that it was still rare but was no longer limited to enterococci having also occurred in *Staph. epidermidis* and *Streptococcus oralis*.

Pharmacokinetics

Linezolid is rapidly and extensively absorbed after oral doses and maximum plasma concentrations are achieved after 1 to 2 hours. It is about 31% bound to plasma proteins. Linezolid is reported to be distributed into bone, fat, lungs, muscle, skin blister fluids, and into the CSF. It is metabolised mainly by oxidation to 2 main inactive metabolites, the hydroxyethyl glycine metabolite (PNU-142586) and the aminoethoxyacetic acid metabolite (PNU-142300); other minor inactive metabolites have also been identified. About 40% of a dose is excreted in the urine as PNU-142586, 30% as linezolid, and 10% as PNU-142300. Small amounts of metabolites are excreted in the faeces. The elimination half-life of linezolid is about 5 to 7 hours.

Children exhibit more rapid clearance of linezolid than adults; half-life is reported to range from about 2 to 4 hours, increasing with age.

Uses and Administration

Linezolid is an oxazolidinone antibacterial used for the treatment of Gram-positive infections of the skin and respiratory tract, including those due to vancomycin-resistant enterococci and meticillin-resistant *Staphylococcus aureus*.

It is given, orally or by intravenous infusion (over 30 to 120 minutes), in a usual adult dose of 600 mg every 12 hours for 10 to 14 days; treatment for up to 28 days may be necessary if there is vancomycin resistance. In uncomplicated skin and skin structure infections an oral dose of 400 mg every 12 hours for 10 to 14 days is usually sufficient.

For doses in neonates and children, see below.

Administration in children. UK licensed product information does not recommend the use of linezolid in children and adolescents below 18 years of age. However, the *BNFC* suggests the following doses of linezolid in the treatment of pneumonia or *complicated* skin and soft-tissue infections, given orally or by intravenous infusion over 30 to 120 minutes:

- neonates up to 7 days old: 10 mg/kg every 12 hours, increasing to every 8 hours if response is poor
- 7 days to 12 years of age: 10 mg/kg (to a maximum of 600 mg) every 8 hours
- 12 to 18 years: usual adult doses (see above).

Similar doses are licensed in the USA. US licensed product information also suggests that in the treatment of *uncomplicated skin* and *skin structure* infections, oral doses given every 12 hours are sufficient in those aged 5 to 11 years.

Administration in renal impairment. Linezolid should be used with caution in patients with renal impairment (creatinine clearance less than 30 mL/minute). Although no dosage adjustment is required, licensed product information states that peak plasma concentrations of linezolid's two major metabolites were about tenfold higher in such patients after several days of treatment. As about 30% of a dose is removed during 3 hours of haemodialysis it is recommended that linezolid should be given after dialysis.

Mycobacterial infections. A systematic review[1] noted that linezolid has been used with some success as an adjunct in the treatment of multidrug-resistant tuberculosis (p.196); it has also been tried in nontuberculous mycobacterial infections (p.181). However, serious adverse effects such as peripheral or optic neuropathy (in 11 of 24 patients), and anaemia (10 of 24) were observed. The review concluded that although there was limited evidence suggesting linezolid may be effective as second-line adjunct therapy for patients with mycobacterial infections, its usefulness is limited by the frequent potentially severe complications of prolonged linezolid use.

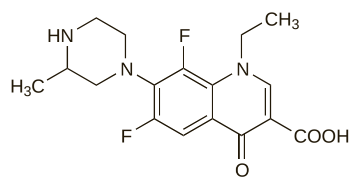
$C_{17}H_{19}F_2N_3O_3,HCl = 387.8.$

CAS — 98079-51-7 (lomefloxacin); 98079-52-8 (lomefloxacin hydrochloride).

ATC — J01MA07; S01AX17.

ATC Vet — QJ01MA07; QS01AX17.



(lomefloxacin)

Adverse Effects and Precautions

As for Ciprofloxacin, p.244.

A relatively high incidence of phototoxic reactions has been seen in patients taking lomefloxacin. Patients should be advised to avoid exposure to sunlight during, and for a few days after, lomefloxacin therapy, and to stop the drug immediately if phototoxicity occurs. Risk of phototoxicity may be reduced by taking lomefloxacin in the evening.

Effects on the skin. Lomefloxacin has been associated with a higher incidence of phototoxic reactions, particularly in patients over 60 years of age and/or with a history of fluoroquinolone treatment; the incidence was also high when used for 30 days or longer.[1] Experimental results[2] suggest that use of sunscreens to protect against lomefloxacin-induced phototoxicity may be feasible.

1. Arata J, *et al.* Photosensitivity reactions caused by lomefloxacin hydrochloride: a multicenter survey. *Antimicrob Agents Chemother* 1998; **42:** 3141–5.
2. Reinhardt P, *et al.* Broad-spectrum sunscreens prevent the secretion of proinflammatory cytokines in human keratinocytes exposed to ultraviolet A and phototoxic lomefloxacin. *Can J Physiol Pharmacol* 2006; **84:** 221–6.

Interactions

As for Ciprofloxacin, p.246.

Lomefloxacin does not appear to interact significantly with theophylline or caffeine.

Antimicrobial Action

As for Ciprofloxacin, p.246.

Most streptococci, including *Streptococcus pneumoniae*, are relatively resistant to lomefloxacin.

Pharmacokinetics

Lomefloxacin is rapidly and almost completely absorbed after oral doses with peak plasma concentrations of about 3 micrograms/mL occurring about 1.5 hours after a 400-mg dose. Lomefloxacin is about 10% bound to plasma proteins. It is widely distributed into body tissues including the lungs and prostate.

The elimination half-life of lomefloxacin is about 7 to 8 hours, and is prolonged in patients with renal impairment. Lomefloxacin is excreted in the urine, about 65% as unchanged drug, 9% as the glucuronide, and less than 0.5% as other metabolites. Small amounts (about 10%) are also eliminated unchanged in the faeces. Negligible amounts of lomefloxacin are removed by haemodialysis or peritoneal dialysis.

◊ References.

1. Freeman CD, *et al.* Lomefloxacin clinical pharmacokinetics. *Clin Pharmacokinet* 1993; **25:** 6–19.

Uses and Administration

Lomefloxacin is a fluoroquinolone antibacterial with actions and uses similar to those of ciprofloxacin (p.247).

It is given orally for the treatment of susceptible infections, including bronchitis due to *Haemophilus influenzae* or *Moraxella catarrhalis* (*Branhamella catarrhalis*), and urinary-tract infections. It is also used for surgical infection prophylaxis. Lomefloxacin is given as the hydrochloride but doses are expressed in terms of the base; lomefloxacin hydrochloride 441.5 mg is equivalent to about 400 mg of lomefloxacin. The usual dose is 400 mg once daily for 10 to 14 days. A dose of 400 mg once daily for 3 days is suitable in women with acute uncomplicated cystitis. Dosage in the evening may minimise the risk of phototoxic reactions.

For details of reduced doses in renal impairment, see below.

A single dose of 400 mg is used for surgical infection prophylaxis, given 1 to 6 hours before the procedure.

Lomefloxacin is also used topically as the hydrochloride in eye drops and ear drops containing the equivalent of 0.3% of lomefloxacin for the treatment of bacterial conjunctivitis and for the treatment of otitis externa and otitis media, respectively.

◊ General references.

2. Neu HC, ed. Lomefloxacin: development of a once-a-day quinolone. *Am J Med* 1992; **92** (suppl 4A): 1S–137S.

Administration in renal impairment. Dosage of lomefloxacin should be reduced in patients with renal impairment; the initial dose of 400 mg should be followed by maintenance doses of 200 mg daily in those with a creatinine clearance of 10 to 40 mL/minute per $1.73m^2$ and in those on haemodialysis.

Multi-ingredient: *Rus.:* Lomecomb (Ломекомб); Protiocomb (Протиокомб).

Loracarbef *(BAN, USAN, rINN)*

KT-3777; Loracarbefum; Lorakarbef; Lorakarbefi; LY-163892. (*6R,7S*)-3-Chloro-8-oxo-7-D-phenylglycylamino-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid monohydrate.

Лоракарбеф

$C_{16}H_{16}ClN_3O_4,H_2O = 367.8.$

CAS — 76470-66-1 (anhydrous loracarbef); 121961-22-6 (loracarbef monohydrate).

ATC — J01DC08.

ATC Vet — QJ01DC08.

Pharmacopoeias. In *US.*

USP 31 (Loracarbef). pH of a 10% suspension in water is between 3.0 and 5.5. Store in airtight containers.

Adverse Effects and Precautions

Adverse effects of loracarbef are generally similar to those of other beta lactams (see Benzylpenicillin, p.213, and Cefalotin, p.219). They include gastrointestinal disturbances, particularly diarrhoea, and hypersensitivity reactions such as skin rashes. In-

The symbol † denotes a preparation no longer actively marketed

creases in liver enzymes and abnormalities in haematological parameters have been reported.

Loracarbef should not be given to patients known to be hypersensitive to it or to other beta lactams because of the possibility of cross-sensitivity. It should be given with caution, with appropriate dosage reduction, in patients with renal impairment.

Effects on the kidneys. References.

1. Thieme RE, *et al.* Acute interstitial nephritis associated with loracarbef therapy. *J Pediatr* 1995; **127:** 997–1000.

Interactions

Probenecid decreases the renal excretion of loracarbef thereby increasing its plasma concentrations.

Antimicrobial Action

Loracarbef is bactericidal with antibacterial activity similar to that of cefaclor (p.217).

Pharmacokinetics

Loracarbef is well absorbed from the gastrointestinal tract with a bioavailability of 90%. Peak plasma concentrations after 200- and 400-mg doses as capsules are about 8 and 14 micrograms/mL respectively at 1.2 hours. Peak concentrations are achieved more rapidly after an oral suspension and a paediatric dose of 15 mg/kg produces a concentration of about 19 micrograms/mL within 40 to 60 minutes. Absorption is delayed by the presence of food. A plasma half-life of about 1 hour has been reported which is prolonged in renal impairment. About 25% is bound to plasma proteins.

Loracarbef is excreted largely unchanged in the urine, and therapeutic concentrations are maintained in the urine for up to 12 hours. Probenecid delays excretion. Loracarbef is removed by haemodialysis.

Uses and Administration

Loracarbef is an oral carbacephem antibiotic. The carbacephems are closely related to the cephalosporins, but replacement of the sulfur atom in the 7-aminocephalosporanic acid nucleus by a methylene group is said to enhance stability. It is used similarly to cefaclor in the treatment of susceptible infections of the respiratory and urinary tracts and of skin and soft tissue. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Loracarbef should be given 1 hour before food or on an empty stomach. Loracarbef is given as the monohydrate. Doses are expressed in terms of the equivalent amount of anhydrous loracarbef. The usual adult dose is 200 to 400 mg every 12 hours. In uncomplicated urinary-tract infections, a dose of 200 mg daily may be adequate. A dose for children is 7.5 mg/kg every 12 hours for uncomplicated infections or 15 mg/kg every 12 hours for acute otitis media or acute maxillary sinusitis.

For details of reduced doses of loracarbef in patients with renal impairment, see below.

◊ General references.

1. Moellering RC, Jacobs NF. Advances in outpatient antimicrobial therapy: loracarbef. *Am J Med* 1992; **92** (suppl 6A): 1S–103S.
2. Brogden RN, McTavish D. Loracarbef: a review of its antimicrobial activity, pharmacokinetic properties and therapeutic efficacy. *Drugs* 1993; **45:** 716–36.

Administration in renal impairment. Doses of loracarbef should be reduced in patients with renal impairment; patients with a creatinine clearance of 10 to 49 mL/minute may be given half the usual dose at the usual dosage interval or the full usual dose at twice the usual interval; patients with a creatinine clearance of less than 10 mL/minute may be treated with the usual dose given every 3 to 5 days. Patients on haemodialysis should receive another dose following dialysis.

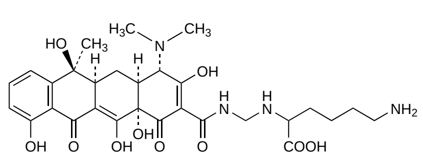
Lymecycline *(BAN, rINN)*

Limeciclina; Limesiklin; Lymécycline; Lymecyclinum; Lymecyklin; Lymecyklina; Lymesykliini; Tetracyclinemethylene lysine. (+)-*N*-(5-Amino-5-carboxypentylaminomethyl)-4-dimethylamino-1,4,4a,5,5a,6,11,12a-octahydro-3,6,10,12,12a-pentahydroxy-6-methyl-1,11-dioxonapthacene-2-carboxamide; N^2-{[(+)-5-Amino-5-carboxypentylamino]methyl}tetracycline.

Лимециклин

$C_{29}H_{38}N_4O_{10}$ = 602.6.
CAS — 992-21-2.
ATC — J01AA04.
ATC Vet — QJ01AA04.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Lymecycline). A reaction product of formaldehyde, lysine, and tetracycline. A yellow, hygroscopic powder. Very soluble in water; slightly soluble in alcohol; practically insoluble in dichloromethane. A 1% solution in water has a pH of 7.8 to 8.2. Store in airtight containers. Protect from light.

Profile

Lymecycline is a tetracycline derivative with general properties similar to those of tetracycline (p.347). Although its absorption is not significantly affected by moderate amounts of milk, it is still affected by divalent and trivalent cations such as aluminium, bismuth, calcium, iron, magnesium, and zinc.

Lymecycline is given orally and doses are expressed in terms of the equivalent amount of tetracycline base. Lymecycline 407 mg is equivalent to about 300 mg of tetracycline and to about 325 mg of tetracycline hydrochloride. The usual adult dose is the equivalent of 300 mg of tetracycline base twice daily. In severe infections total daily doses of up to the equivalent of 1.2 g may be given. In the treatment of acne, the equivalent of 300 mg is given daily for at least 8 weeks.

For details of use in children and adolescents, see below.

Administration in children. In children, the effects on teeth should be considered and tetracyclines only used when absolutely essential. In the UK, lymecycline is licensed for use in children aged 12 years and over; the usual adult dose (see above) may be given by mouth. However, in some countries, it is licensed for use in those over 8 years old.

Skin disorders. For reference to the use of lymecycline in the treatment of acne, see under Tetracycline, p.350.

Preparations

BP 2008: Lymecycline Capsules.

Proprietary Preparations (details are given in Part 3)

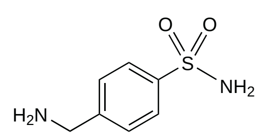
Mafenide *(BAN, USAN, rINN)*

Mafenid; Mafenida; Maféníde; Mafenidi; Mafenidum; NSC-34632. α-Aminotoluene-*p*-sulphonamide.

Мафенид

CAS — 138-39-6.
ATC — D06BA03.
ATC Vet — QD06BA03.



Mafenide Acetate *(BANM, rINNM)*

Acetato de mafenida; Maféníde, Acétate de; Mafenidi Acetas.

Мафенида Ацетат

$C_7H_{10}N_2O_2S,C_2H_4O_2$ = 246.3.
CAS — 13009-99-9.
ATC — D06BA03.
ATC Vet — QD06BA03.

Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Mafenide Acetate). A white to pale yellow crystalline powder. Freely soluble in water. pH of a 10% solution in water is between 6.4 and 6.8. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

Mafenide is absorbed to some extent after topical application and may produce systemic effects similar to those of other sulfonamides (see Sulfamethoxazole, p.340). Fatal haemolytic anaemia with disseminated intravascular coagulation, related to G6PD deficiency, has been reported.

Mafenide cream may cause pain or a burning sensation on application to the burnt area, with occasional bleeding or excoriation. The separation of the eschar may be delayed and fungal invasion of the wound has been reported. By its action in inhibiting carbonic anhydrase, mafenide may cause metabolic acidosis and hyperventilation; acid–base balance should therefore be monitored, particularly in patients with extensive burns, or with pulmonary or renal impairment. If persistent acidosis occurs, mafenide treatment should be temporarily suspended and fluid therapy continued.

Pharmacokinetics

Mafenide is absorbed from wounds into the circulation and is metabolised to *p*-carboxybenzenesulfonamide, which is excreted in the urine. The metabolite has no antibacterial action but retains the ability to inhibit carbonic anhydrase.

Uses and Administration

Mafenide is a sulfonamide that is not inactivated by *p*-aminobenzoic acid or by pus and serum. The acetate is used as a cream, containing the equivalent of mafenide 8.5%, in conjunction with debridement, for the prevention and treatment of infection, including *Pseudomonas aeruginosa*, in second- and third-degree burns (p.1578). A solution containing mafenide acetate 5% is also available for use under moist dressings in burns. Mafenide hydrochloride and mafenide propionate have also been used.

Preparations

USP 31: Mafenide Acetate Cream; Mafenide Acetate for Topical Solution.

Proprietary Preparations (details are given in Part 3)
USA: Sulfamylon.

Multi-ingredient: ***Indon.:*** FG Ointment; ***Spain:*** Pental Forte†.

Magainins

Magaininas.

Магаинины

Profile

The magainins are a group of antibacterial peptides derived from amphibians. A number of semisynthetic derivatives including pexiganan acetate (MSI-78), MSI-93, and MSI-94 have been investigated as topical anti-infectives.

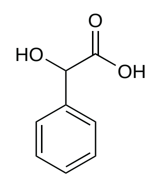
Mandelic Acid

Ácido fenilglicólico; Ácido mandélico racémico; Amygdalic Acid; Mandélico, ácido; Phenylglycolic Acid; Racemic Mandelic Acid. 2-Hydroxy-2-phenylacetic acid.

Миндальная Кислота

$C_8H_8O_3$ = 152.1.
CAS — 90-64-2; 17199-29-0 ((+)-mandelic acid); 611-71-2 ((−)-mandelic acid); 611-72-3 ((±)-mandelic acid).
ATC — B05CA06; J01XX06.
ATC Vet — QB05CA06; QJ01XX06.



Profile

Mandelic acid has bacteriostatic properties and is used as a 1% flushing solution for the maintenance of indwelling urinary catheters. Mandelic acid and acetyl mandelic acid are used topically in preparations for the treatment of acne. It was formerly given orally in the treatment of urinary-tract infections, usually as the ammonium or calcium salt.

Mandelic acid is a component of methenamine mandelate (p.298).

Preparations

Proprietary Preparations (details are given in Part 3)
Fr.: Rolip†.

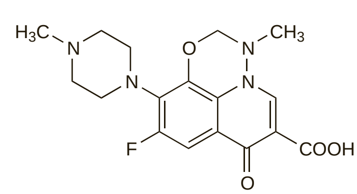
Multi-ingredient: ***Chile:*** Neostrata; ***Fr.:*** Sphingogel†; Zeniac LP Fort†; Zeniac LP†; Zeniac†; ***Ital.:*** Neoceuticals Clear Skin; Neoceuticals Spot Treatment; ***Port.:*** Mandelip†.

Marbofloxacin *(BAN, rINN)*

Marbofloksasiini; Marbofloxacine; Marbofloxacino; Marbofloxacinum. 9-Fluoro-2,3-dihydro-3-methyl-10-(4-methyl-1-piperazinyl)-7-oxo-7*H*-pyrido[3,2,1-*ij*][4,1,2]benzoxadiazine-6-carboxylic acid.

Марбофлоксацин

$C_{17}H_{19}FN_4O_4$ = 362.4.
CAS — 115550-35-1.
ATC Vet — QJ01MA93.



Pharmacopoeias. In *Eur.* (see p.vii) for veterinary use only.

Ph. Eur. 6.2 (Marbofloxacin for Veterinary Use). A light yellow, crystalline powder. Slightly soluble in water; very slightly soluble in alcohol; sparingly soluble or slightly soluble in dichloromethane. Protect from light.

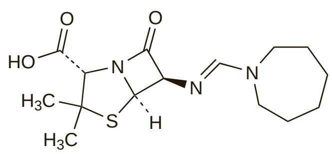
Profile
Marbofloxacin is a fluoroquinolone antibacterial used in veterinary medicine.

Mecillinam *(BAN, rINN)*

Amdinocillin *(USAN)*; FL-1060; Mecilinam; Mécillinam; Mecillinamum; Mesillinaami; Ro-10-9070. (6*R*)-6-(Perhydroazepin-1-ylmethyleneamino)penicillanic acid.

Мециллинам

$C_{15}H_{23}N_3O_3S = 325.4$.
CAS — 32887-01-7.
ATC — J01CA11.
ATC Vet — QJ01CA11.



Adverse Effects and Precautions
As for Benzylpenicillin, p.213.

Porphyria. Mecillinam has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions
As for Benzylpenicillin, p.214.

Antimicrobial Action
Mecillinam is a derivative of amidinopenicillanic acid. Unlike benzylpenicillin and related antibiotics, it is active against many Gram-negative bacteria, in particular Enterobacteriaceae including *Escherichia coli*, *Enterobacter*, *Klebsiella*, *Salmonella*, and *Shigella* spp. The susceptibility of *Proteus* spp. varies; *Serratia marcescens* is generally resistant. It is less active against *Neisseria* spp. and *Haemophilus influenzae*. *Pseudomonas aeruginosa* and *Bacteroides* spp. are considered to be resistant. It is much less active against Gram-positive bacteria; enterococci including *Enterococcus faecalis* are resistant.

Mecillinam interferes with the synthesis of the bacterial cell wall by binding with a different penicillin-binding protein from benzylpenicillin. This difference in mode of action may explain the synergism against many Gram-negative organisms that has been reported *in vitro* between mecillinam and various penicillins or cephalosporins.

Mecillinam is inactivated by beta-lactamases, but is more stable than ampicillin.

Pharmacokinetics
Mecillinam is poorly absorbed from the gastrointestinal tract. Peak plasma concentrations of about 6 and 12 micrograms/mL have been achieved half an hour after intramuscular doses of 200 and 400 mg, respectively. The usual plasma half-life of about 1 hour has been reported to be prolonged to 3 to 5 hours or more in severe renal impairment. Between 5 and 10% of mecillinam is bound to plasma proteins. Mecillinam is widely distributed into body tissues and fluids; little passes into the CSF unless the meninges are inflamed. It crosses the placenta into the fetal circulation; little appears to be distributed into breast milk.

Mecillinam is metabolised to only a limited extent. From 50 to 70% of a parenteral dose may be excreted in the urine within 6 hours by glomerular filtration and tubular secretion. Renal tubular secretion can be reduced by probenecid. Some mecillinam is excreted in bile where high concentrations are achieved.

Mecillinam is removed by haemodialysis.

Uses and Administration
Mecillinam is a semisynthetic penicillin with a substituted amidino group at the 6-position of the penicillanic acid nucleus. It is given by slow intravenous injection, by intravenous infusion, or intramuscularly, in the treatment of susceptible Gram-negative infections (see under Antimicrobial Action, above).

For urinary-tract infections a dose of 800 mg is given every 6 to 8 hours. A total dose of up to 60 mg/kg daily may be used in very severe infections.

Mecillinam has been used with other beta lactams to extend the spectrum of antimicrobial activity to Gram-positive organisms and because of reported synergism against Gram-negative bacteria *in vitro*.

The pivaloyloxymethyl ester of mecillinam, pivmecillinam, is used orally (see p.317).

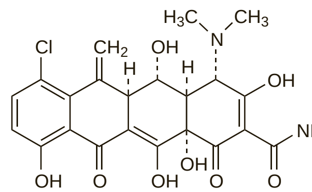
Preparations
Proprietary Preparations (details are given in Part 3)
Denm.: Selexid; ***Gr.:*** Selexid; ***Norw.:*** Selexid; ***Swed.:*** Selexid.

Meclocycline *(BAN, USAN, rINN)*

GS-2989; Meclociclina; Méclocycline; Meclocyclinum; Meklocyklin; Meklosykliini; NSC-78502. (4*S*,4a*R*,5*S*,5a*R*,6*S*,12a*S*)-7-Chloro-4-dimethylamino-1,4,4a,5,5a,6,11,12a-octahydro-3,5,10,12,12a-pentahydroxy-6-methylene-1,11-dioxonaphthacene-2-carboxamide; 7-Chloro-6-demethyl-6-deoxy-5β-hydroxy-6-methylenetetracycline.

Меклоциклин

$C_{22}H_{21}ClN_2O_8 = 476.9$.
CAS — 2013-58-3.
ATC — D10AF04.
ATC Vet — QD10AF04.



Meclocycline Sulfosalicylate *(USAN)*

Meclociclina, sulfosalicilato de; Meclocycline Sulphosalicylate. Meclocycline 5-sulphosalicylate.

$C_{22}H_{21}ClN_2O_8,C_7H_6O_6S = 695.0$.
CAS — 73816-42-9.
ATC — D10AF04.
ATC Vet — QD10AF04.

Pharmacopoeias. In *US.*

USP 31 (Meclocycline Sulfosalicylate). pH of a 1% solution in water is between 2.5 and 3.5. Store in airtight containers. Protect from light.

Profile
Meclocycline is a tetracycline antibacterial derived from oxytetracycline (p.312). It is applied topically as the sulfosalicylate for the treatment of acne vulgaris and superficial skin infections. Potency is expressed in terms of meclocycline. Preparations containing the equivalent of 1 or 2% are available. Meclocycline sulfosalicylate has also been given as a pessary in the treatment of vulvovaginal infections.

Preparations
USP 31: Meclocycline Sulfosalicylate Cream.

Proprietary Preparations (details are given in Part 3)
Ger.: Meclosorb; ***Ital.:*** Mecloderm; Mecloderm Antiacne; Mecloderm Ovuli; Mecloderm Polvere Aspersoria†; Meclutin Semplice†.

Multi-ingredient: *Ital.:* Anti-Acne; Mecloderm F; Meclutin†.

Meleumycin

Pharmacopoeias. In *Chin.*

Profile
Meleumycin, a macrolide antibacterial produced by the growth of *Streptomyces mycarofaciens*, consists of a mixture of midecamycin A_1 and kitasamycin A_6. It has actions and uses similar to those of erythromycin (p.269) and is given orally in the treatment of susceptible infections.

Meropenem *(BAN, USAN, rINN)*

ICI-194660; Meropeneemi; Méropénem; Meropenemum; SM-7338. (4*R*,5*S*,6*S*)-3-[(3*S*,5*S*)-5-Dimethylcarbamoylpyrrolidin-3-ylthio]-6-[(*R*)-1-hydroxyethyl]-4-methyl-7-oxo-1-azabicyclo[3.2.0]hept-2-ene-2-carboxylic acid trihydrate.

Меропенем

$C_{17}H_{25}N_3O_5S,3H_2O = 437.5$.
CAS — 96036-03-2 (meropenem); 119478-56-7 (meropenem trihydrate).
ATC — J01DH02.
ATC Vet — QJ01DH02.

Pharmacopoeias. In *Chin.*, *Jpn*, and *US.*

USP 31 (Meropenem). Colourless to white crystals. Sparingly soluble in water; very slightly soluble in alcohol; practically insoluble in acetone and in ether; soluble in dimethylformamide and in 5% monobasic potassium phosphate solution. pH of a 1% solution in water is between 4.0 and 6.0. Store in airtight containers.

Adverse Effects and Precautions
As for Imipenem, p.286.

Meropenem is more stable to renal dehydropeptidase I than imipenem and use with cilastatin, which inhibits this enzyme, is not required. Meropenem may have less potential to induce seizures than imipenem (see also below).

Effects on the nervous system. *Animal* studies have indicated that meropenem induces fewer seizures than imipenem-cilastatin and clinical data from the manufacturer have substantiated this.[1] Comparison of data[2] from 4872 patients with a variety of infections (including meningitis) treated with meropenem with that from 4752 patients who received other antibacterials, principally cephalosporin-based regimens or imipenem-cilastatin, showed that meropenem was not associated with any greater risk of seizures than the other antibacterials and was likely to have less neurotoxic potential than imipenem-cilastatin, making it a suitable drug to use in the treatment of meningitis.

1. Norrby SR, *et al.* Safety profile of meropenem: international clinical experience based on the first 3125 patients treated with meropenem. *J Antimicrob Chemother* 1995; **36** (suppl A): 207–23.
2. Norrby SR, Gildon KM. Safety profile of meropenem: a review of nearly 5,000 patients treated with meropenem. *Scand J Infect Dis* 1999; **31:** 3–10.

Interactions
Probenecid inhibits the renal excretion of meropenem thereby increasing its plasma concentrations and prolonging its elimination half-life.

Antiepileptics. For reports of decreased plasma-*valproate* concentrations (sometimes with loss of seizure control) attributed to meropenem, see p.510.

Antimicrobial Action
As for Imipenem, p.287.

Meropenem is slightly more active than imipenem against Enterobacteriaceae and slightly less active against Gram-positive organisms.

Pharmacokinetics
After intravenous injection of meropenem 0.5 and 1 g over 5 minutes, peak plasma concentrations of about 50 and 112 micrograms/mL respectively are attained. The same doses infused over 30 minutes produce peak plasma concentrations of 23 and 49 micrograms/mL, respectively.

Meropenem has a plasma elimination half-life of about 1 hour; this may be prolonged in patients with renal impairment and is also slightly prolonged in children. Meropenem is widely distributed into body tissues and fluids including the CSF and bile. It is about 2% bound to plasma proteins. It is more stable to renal dehydropeptidase I than imipenem and is mainly excreted in the urine by tubular secretion and glomerular filtration. About 70% of a dose is recovered unchanged in the urine over a 12-hour period and urinary concentrations above 10 micrograms/mL are maintained for up to 5 hours after a 500-mg dose. Meropenem is reported to have one metabolite (ICI-213689), which is inactive and is excreted in the urine.

Meropenem is removed by haemodialysis.

Uses and Administration

Meropenem is a carbapenem beta-lactam antibacterial with actions and uses similar to those of imipenem (p.287). It is more stable to renal dehydropeptidase I than imipenem and need not be given with an enzyme inhibitor such as cilastatin. It is used in the treatment of susceptible infections including intra-abdominal infections, gynaecological infections, meningitis, respiratory-tract infections (including in cystic fibrosis patients), septicaemia, skin and skin structure infections, urinary-tract infections, and infections in immunocompromised patients. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Meropenem is given intravenously as the trihydrate, but doses are expressed in terms of the amount of anhydrous meropenem; 1.14 g of meropenem trihydrate is equivalent to about 1 g of anhydrous meropenem. It is given by slow injection over 3 to 5 minutes or by infusion over 15 to 30 minutes in a usual adult dose of 0.5 to 1 g every 8 hours. A dose of 2 g every 8 hours is given for meningitis; doses of up to 2 g every 8 hours have also been used in cystic fibrosis. For details of reduced doses in renal impairment, see below.

For details of doses in infants and children, see below.

Administration in children. Use of meropenem is licensed in both the UK and the USA for infants and children over 3 months of age and weighing less than 50 kg. The usual dose is 10 to 20 mg/kg every 8 hours. A dose of 40 mg/kg is given every 8 hours for meningitis; doses of 25 to 40 mg/kg every 8 hours have been used in children aged 4 to 18 years with cystic fibrosis.

In addition, the *BNFC* suggests the following doses for those under 3 months of age:

- neonates under 7 days of age: 20 mg/kg every 12 hours (or 40 mg/kg every 12 hours in severe infections and in meningitis)
- neonates 7 to 28 days of age: 20 mg/kg every 8 hours (or 40 mg/kg every 8 hours in severe infections and in meningitis)
- infants 1 to 3 months of age: 10 mg/kg every 8 hours (or 20 mg/kg every 8 hours in severe infections; 40 mg/kg every 8 hours in meningitis)

Administration in renal impairment. Doses of meropenem should be reduced in patients with renal impairment. The following doses may be given to adults based on creatinine clearance (CC):

- CC 26 to 50 mL/minute: the usual dose given every 12 hours
- CC 10 to 25 mL/minute: one-half the usual dose every 12 hours
- CC less than 10 mL/minute: one-half the usual dose every 24 hours
- haemodialysis patients: the usual dose after the dialysis session

Preparations

USP 31: Meropenem for Injection.

Proprietary Preparations (details are given in Part 3)

Metampicillin Sodium *(rINNM)*

Metampicilina sódica; Métampicilline Sodique; Natrii Metampicillinum. Sodium (6*R*)-6-(D-2-methyleneamino-2-phenylacetamido)penicillanate.

Натрий Метампициллин

$C_{17}H_{18}N_3NaO_4S = 383.4.$
CAS — 6489-97-0 (metampicillin); 6489-61-8 (metampicillin sodium).
ATC — J01CA14.
ATC Vet — QJ01CA14.

Profile

Metampicillin has actions and uses similar to those of ampicillin (p.204).

After oral doses it is almost completely hydrolysed to ampicillin. When given parenterally, however, a proportion of the dose exists in the circulation as unchanged metampicillin which has some antibacterial activity of its own.

Preparations

Proprietary Preparations (details are given in Part 3)
Multi-ingredient: *Arg.:* Gentocelina†.

Methacycline *(BAN, USAN)*

Metacycline *(pINN)*; GS-2876; Metaciclina; Métacycline; Metacyclinum; Metacyklin; Metasykliini. (4*S*,4a*R*,5*S*,5a*R*,6*S*,12a*S*)-4-Dimethylamino-1,4,4a,5,5a,6,11,12a-octahydro-3,5,10,12,12a-pentahydroxy-6-methylene-1,11-dioxonaphthacene-2-carboxamide; 6-Demethyl-6-deoxy-5β-hydroxy-6-methylenetetracycline.

Метациклин

$C_{22}H_{22}N_2O_8 = 442.4.$
CAS — 914-00-1.

Methacycline Hydrochloride *(BANM)*

Metacycline Hydrochloride *(pINNM)*; Hidrocloruro de metaciclina; Métacycline, Chlorhydrate de; Metacyclini Chloridum; Metacyclini Hydrochloridum; Metacykliny chlorowodorek; Méthylènecycline Chlorhydrate; 6-Methyleneoxytetracycline Hydrochloride.

Метациклина Гидрохлорид

$C_{22}H_{22}N_2O_8,HCl = 478.9.$
CAS — 3963-95-9.
ATC — J01AA05.
ATC Vet — QJ01AA05.

Pharmacopoeias. In *Chin.*, *Pol.*, and *US.*

USP 31 (Methacycline Hydrochloride). A yellow to dark yellow crystalline powder. Soluble 1 in 100 of water, 1 in 300 of alcohol, and 1 in 25 of 0.1N sodium hydroxide; very slightly soluble in chloroform and in ether. pH of a solution in water containing the equivalent of methacycline 1% is between 2.0 and 3.0. Store in airtight containers. Protect from light.

Profile

Methacycline is a tetracycline derivative with uses similar to those of tetracycline (p.347). Like demeclocycline, it is excreted more slowly than tetracycline and effective blood concentrations are maintained for longer periods; the plasma elimination half-life is about 14 hours.

Methacycline hydrochloride is given orally in a usual adult dose of 600 mg daily in 2 divided doses, preferably 1 hour before or 2 hours after meals.

Preparations

USP 31: Methacycline Hydrochloride Capsules; Methacycline Hydrochloride Oral Suspension.

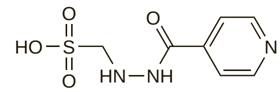
Proprietary Preparations (details are given in Part 3)
Fr.: Lysocline; Physiomycine; ***Ital.:*** Esarondil; Rotilen; Stafilon.

Methaniazide *(rINN)*

Isoniazid Mesylate; Isoniazid Methanesulfonate; Metaniazida; Méthaniazide; Methaniazidum. 2-Isonicotinoylhydrazinomethanesulphonic acid.

Метаниазид

$C_7H_9N_3O_4S = 231.2.$
CAS — 13447-95-5 (methaniazide); 6059-26-3 (methaniazide calcium); 3804-89-5 (methaniazide sodium).



Profile

Methaniazide is a derivative of isoniazid (p.288). It has been used orally and by injection as the calcium and sodium salts respectively in the treatment of tuberculosis.

Preparations

Proprietary Preparations (details are given in Part 3)
Austria: Neo-Tizide; ***India:*** Erbazide†.
Multi-ingredient: *India:* Strepto-Erbazide†.

Methenamine *(rINN)*

Aminoform; E239; Esametilentetrammina; Esammina; Formine; Heksamin; Hexamethylenamine; Hexamine; Metenamiini; Meténamin; Metenamin; Metenamina; Metenaminas; Metenammina; Methenamin; Méthénamine; Methenaminum; Urotropine. Hexamethylenetetramine; 1,3,5,7-Tetraazatricyclo[3.3.1.1^{3,7}]decane.

Methenamine Mandelate *(rINNM)*

Heksamin Mandelat; Hexamine Amygdalate; Hexamine Mandelate; Mandelato de metenamina; Metenamin Mandelat; Méthénamine, Mandelate de; Methenamini Mandelas. Hexamethylenetetramine mandelate.

Метенамина Манделат

$C_6H_{12}N_4,C_8H_8O_3 = 292.3.$
CAS — 587-23-5.
ATC — J01XX05.
ATC Vet — QJ01XX05.

Pharmacopoeias. In *US.*

USP 31 (Methenamine Mandelate). A white, practically odourless crystalline powder. Very soluble in water; soluble 1 in 10 of alcohol, 1 in 20 of chloroform, and 1 in 350 of ether. Its solutions have a pH of about 4.

Adverse Effects and Precautions

Methenamine and its salts are generally well tolerated but may cause gastrointestinal disturbances such as nausea, vomiting, and diarrhoea. Skin rashes, pruritus, and occasionally other hypersensitivity reactions, may occur.

Comparatively large amounts of formaldehyde may be formed during prolonged use or when large doses are given. This may produce irritation and inflammation of the urinary tract, especially the bladder, as well as painful and frequent micturition, haematuria, and proteinuria. The effect of the formaldehyde may be reduced by alkalinising drugs, such as sodium bicarbonate, or large quantities of water, but it is then less effective.

Methenamine and its salts are contra-indicated in patients with hepatic impairment because of the liberation of ammonia in the gastrointestinal tract. Although methenamine itself is not contra-indicated in renal impairment, its salts should be avoided in severe impairment because of the risk of mandelate or hippurate crystalluria. They should also be avoided in patients with severe dehydration, metabolic acidosis, or gout.

Interference with laboratory estimations for catecholamines, 17-hydroxycorticosteroids, and oestrogens in the urine has been reported.

Interactions

The use of drugs that alkalinise the urine, including some antacids, potassium citrate, and diuretics such as acetazolamide or the thiazides, should be avoided because the activation of methenamine to formaldehyde may be inhibited (but see above).

Use of methenamine with sulfonamides may increase the risk of crystalluria since methenamine requires low urinary pH for its effect, at which sulfonamides and their metabolites are poorly soluble; methenamine may also form poorly soluble compounds with some sulfonamides.

Antimicrobial Action

Methenamine owes its antibacterial properties to formaldehyde, a non-specific bactericide, which is slowly liberated by hydrolysis at acid pH. Most Gram-positive and Gram-negative organisms and fungi are susceptible. Hippuric and mandelic acids have some antibacterial activity *in vitro*, but their contribution to the antibacterial action of the salts *in vivo*, beyond assisting the maintenance of low urinary pH, is uncertain. Urea-splitting organisms such as *Proteus* and some *Pseudomonas* spp. tend to increase urinary pH and inhibit the release of formaldehyde, thereby decreasing the effectiveness of methenamine. Use with acetohydroxamic acid, a potent inhibitor of bacterial urease, has been suggested for urinary infections due to these organisms. True resistance to formaldehyde does not appear to be a problem in clinical use.

Pharmacokinetics

Methenamine is readily absorbed from the gastrointestinal tract and widely distributed in the body. Under acid conditions methenamine is slowly hydrolysed to formaldehyde and ammonia: about 10 to 30% of an oral dose may be converted in the stomach unless it is given as an enteric-coated preparation. Almost no hydrolysis of methenamine takes place at physiological pH, and it is therefore virtually inactive in the body. The half-life is reported to be about 4 hours. Methenamine is rapidly and almost completely eliminated in the urine, and provided this is acidic (preferably below pH 5.5) bactericidal concentrations of formaldehyde are achieved. Because of the time taken for hydrolysis, however, these are not achieved until the urine reaches the bladder, with peak concentrations occurring up to 2 hours after an oral dose. Absorption, and hence excretion, may be somewhat delayed in patients given enteric-coated formulations.

Methenamine crosses the placenta and small amounts may be distributed into breast milk.

The mandelate and hippurate moieties are also rapidly absorbed and are excreted in urine by tubular secretion as well as glomerular filtration.

Uses and Administration

Methenamine is used, usually as the hippurate or mandelate, in the prophylaxis and treatment of chronic or recurrent, uncomplicated, lower urinary-tract infections and asymptomatic bacteriuria. It has been considered suitable for long-term use because acquired resistance does not appear to develop.

Methenamine and its salts should not be used in upper urinary-tract infections because it is eliminated too rapidly to exert an effect, nor in acute urinary infections. It is only active in acidic urine, when formaldehyde is released, and although hippuric or mandelic acid helps to acidify the urine, ammonium chloride or ascorbic acid may be tried. If urea-splitting bacteria such as *Proteus* or some *Pseudomonas* spp. are present they may produce so much ammonia that the urine cannot be acidified (see also Antimicrobial Action, above).

The usual oral adult dose of methenamine or methenamine mandelate is 1 g given four times daily. Methenamine hippurate is given orally in a usual dose of 1 g twice daily; the dose may be increased to three times daily in catheterised patients.

For details of doses in children, see below.

Methenamine has been used topically in deodorant preparations, since in the presence of acid sweat it liberates formaldehyde. Methenamine calcium thiocyanate has been used in combination preparations for upper respiratory-tract disorders.

◊ Reviews.

2. Lee BB, *et al.* Methenamine hippurate for preventing urinary tract infections. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2007 (accessed 11/01/08).

Administration in children. In the USA, the usual recommended oral dose of methenamine mandelate in children up to 6 years old is about 18 mg/kg given four times daily; those aged 6 to 12 years may be given methenamine or methenamine mandelate 500 mg four times daily.

In the UK, methenamine hippurate may be given in a usual oral dose of 500 mg twice daily in children aged 6 to 12 years. Doses of up to 1 g twice daily have been given in the USA.

Meticillin Sodium *(rINNM)*

BRL-1241; Dimethoxyphenecillin Sodium; Dimethoxyphenyl Penicillin Sodium; Methicillin Sodium *(BANM, USAN)*; Meticilina sódica; Méticilline Sodique; Meticillinum Natricum; Natrii Meticillinum; SQ-16123; X-1497. Sodium (6*R*)-6-(2,6-dimethoxybenzamido)penicillanate monohydrate.

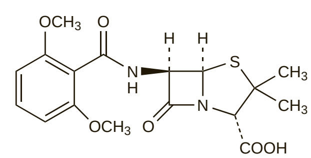
Натрий Метициллин

$C_{17}H_{19}N_2NaO_6S,H_2O = 420.4.$

CAS — 61-32-5 (meticillin); 132-92-3 (anhydrous meticillin sodium); 7246-14-2 (meticillin sodium monohydrate).

ATC — J01CF03.

ATC Vet — QJ01CF03.



(meticillin)

Incompatibility. Meticillin sodium has been reported to be incompatible with aminoglycosides and a number of other antimicrobials. It has also been reported to be incompatible with acidic and alkaline drugs.

Adverse Effects and Precautions

As for Benzylpenicillin, p.213.

Meticillin is the penicillin most commonly associated with acute interstitial nephritis.

Effects on the kidneys. References.

1. Sanjad SA, *et al.* Nephropathy, an underestimated complication of methicillin therapy. *J Pediatr* 1974; **84:** 873–7.
2. Galpin JE, *et al.* Acute interstitial nephritis due to methicillin. *Am J Med* 1978; **65:** 756–65.

Sodium content. Each g of meticillin sodium contains about 2.4 mmol of sodium.

Interactions

As for Benzylpenicillin, p.214.

Antimicrobial Action

Meticillin has a mode of action similar to that of benzylpenicillin (p.214) but it is resistant to staphylococcal penicillinase. There is evidence that meticillin is more stable to staphylococcal penicillinase than the other penicillinase-resistant penicillins.

Meticillin is active against both penicillinase-producing and non-penicillinase-producing staphylococci, and also against *Streptococcus pyogenes* (group A beta-haemolytic streptococci), *Str. pneumoniae*, and some viridans streptococci. Its activity against penicillin-sensitive staphylococci and streptococci is less than that of benzylpenicillin. It is virtually ineffective against *Enterococcus faecalis*.

Resistance of staphylococci to meticillin is due to the expression of an altered penicillin-binding protein and is not dependent on penicillinase production. There is cross-resistance with other penicillins, including the penicillinase-resistant penicillins cloxacillin, dicloxacillin, flucloxacillin, nafcillin, and oxacillin, and with the cephalosporins. Meticillin-resistant staphylococci are also frequently resistant to other antibacterials, including aminoglycosides, chloramphenicol, ciprofloxacin, clindamycin, erythromycin, and tetracycline. The incidence of such resistance has varied considerably. However, both endemic (restricted to one hospital) and epidemic (affecting more than one hospital) strains of meticillin-resistant *Staphylococcus aureus* (MRSA) are now recognised and infections are a problem in many hospitals.

There have been fewer studies on coagulase-negative staphylococci, but patterns of meticillin resistance in *Staph. epidermidis* are similar to those for MRSA and the frequency of resistance may be higher.

For further details on meticillin-resistant staphylococci and the management of infections, see under Staphylococcal Infections, p.195.

Resistance. References to meticillin-resistant staphylococci.

Pharmacokinetics

Meticillin is inactivated by gastric acid and must be given by injection. Peak plasma concentrations are attained within 0.5 to 1 hour of an intramuscular injection; concentrations of up to 18 micrograms/mL have been achieved after a dose of 1 g. A half-life of 0.5 to 1 hour has been reported, although this may be increased to 3 to 6 hours in renal impairment. About 40% of the meticillin in the circulation is bound to plasma proteins. It is widely distributed in body fluids and in tissues, but there is little diffusion into the CSF unless the meninges are inflamed. Meticillin also crosses the placenta and appears in breast milk. Relatively high concentrations are achieved in bile compared with plasma, although only small amounts are excreted in bile. The majority is rapidly excreted by tubular secretion and glomerular filtration; up to 80% of an injected dose has been detected unchanged in the urine.

Plasma concentrations are enhanced by probenecid. They may be reduced in patients with cystic fibrosis.

Uses and Administration

Meticillin is a penicillinase-resistant penicillin and has been used similarly to flucloxacillin (p.277) in the treatment of staphylococcal infections resistant to benzylpenicillin. It is not active orally and has been given by injection as the sodium salt.

Mezlocillin *(BAN, USAN, rINN)*

Metslosilliini; Mezlocilina; Mezlocilline; Mezlocillinum. 6-[*N*-(3-Methylsulfonyl-2-oxoimidazolidin-1-ylcarbonyl)-D-phenylglycylamino]penicillanic acid.

Мезлоциллин

$C_{21}H_{25}N_5O_8S_2 = 539.6.$

CAS — 51481-65-3.

ATC — J01CA10.

ATC Vet — QJ01CA10.

Mezlocillin Sodium *(BANM, rINNM)*

Bay-f-1353; Mezlocilina sódica; Mezlocilline Sodique; Natrii Mezlocillinum. Sodium (6*R*)-6-[D-2-(3-mesyl-2-oxoimidazolidine-1-carboxamido)-2-phenylacetamido]penicillanate monohydrate.

Натрий Мезлоциллин

$C_{21}H_{24}N_5NaO_8S_2,H_2O = 579.6.$

CAS — 42057-22-7 (anhydrous mezlocillin sodium); 80495-46-1 (mezlocillin sodium monohydrate).

ATC — J01CA10.

ATC Vet — QJ01CA10.

Pharmacopoeias. In *US.*

USP 31 (Mezlocillin Sodium). A white to pale yellow crystalline powder. Freely soluble in water. pH of a 10% solution in water is between 4.5 and 8.0. Store in airtight containers.

Incompatibility. Mezlocillin sodium has been reported to be incompatible with aminoglycosides, ciprofloxacin, metronidazole, and tetracyclines.

Adverse Effects and Precautions

As for Carbenicillin Sodium, p.216.

Prolongation of bleeding time has been less frequent and less severe with mezlocillin than with carbenicillin.

Sodium content. Each g of mezlocillin sodium contains about 1.7 mmol of sodium. As mezlocillin sodium has a lower sodium content than carbenicillin sodium, hypernatraemia and hypokalaemia are less likely to occur.

Interactions

As for Benzylpenicillin, p.214.

Cefotaxime. For the effect of mezlocillin on the clearance of cefotaxime, see p.228.

Antimicrobial Action

Mezlocillin has a similar antimicrobial action to piperacillin (p.315). Its activity against *Pseudomonas aeruginosa* is less than that of azlocillin or piperacillin.

Pharmacokinetics

Mezlocillin is not absorbed from the gastrointestinal tract to any significant extent. It is well absorbed after intramuscular injection, with peak plasma concentrations of 15 to 25 micrograms/mL 45 to 90 minutes after a single dose of 1 g. It is reported to have nonlinear dose-dependent pharmacokinetics. Between 16 and 42% of mezlocillin in the circulation is bound to plasma proteins. Mezlocillin is reported to have a plasma half-life of about 1 hour; this is slightly prolonged in neonates, and in patients with renal impairment half-lives of up to about 6 hours have been reported.

Mezlocillin is widely distributed in body tissues and fluids. It crosses the placenta into the fetal circulation and small amounts are distributed into breast milk. There is little diffusion into CSF except when the meninges are inflamed.

Mezlocillin is reported to be metabolised to a limited extent. About 55% of a dose is excreted unchanged in the urine by glomerular filtration and tubular secretion within 6 hours of a dose, hence achieving high urinary concentrations. High concentrations are also found in the bile; up to 30% of a dose has been reported to be excreted by this route.

Plasma concentrations are enhanced by probenecid.

Mezlocillin is removed by haemodialysis, and to some extent by peritoneal dialysis.

Uses and Administration

Mezlocillin is a ureidopenicillin with uses similar to those of piperacillin (p.316). It is commonly used with an aminoglycoside; however they should be given separately as they have been shown to be incompatible.

Administration and dosage. Mezlocillin is given by injection as the sodium salt. Doses are expressed in terms of the equivalent amount of mezlocillin; 1.07 g of mezlocillin sodium is equivalent to about 1 g of mezlocillin. Dosage may need to be reduced in renal impairment. It may be given by slow intravenous injection over 3 to 5 minutes, by intravenous infusion over 30 minutes, or by deep intramuscular injection. Single intramuscular doses should not exceed 2 g.

For the treatment of serious infections, 200 to 300 mg/kg daily in divided doses may be given intravenously. For life-threatening infections, up to 350 mg/kg daily may be used, but the total daily dose should not normally exceed 24 g. For uncomplicated urinary-tract infections, a dose of 1.5 to 2 g may be given intramuscularly or intravenously every 6 hours.

Uncomplicated gonorrhoea may be treated by a single intramuscular or intravenous dose of mezlocillin 1 to 2 g. Probenecid 1 g orally may be given at the same time or up to 30 minutes before the injection.

For the prophylaxis of infection during surgery, an intravenous pre-operative dose of mezlocillin 4 g, repeated at 6-hourly intervals for 2 further doses, may be given.

Preparations

USP 31: Mezlocillin for Injection.

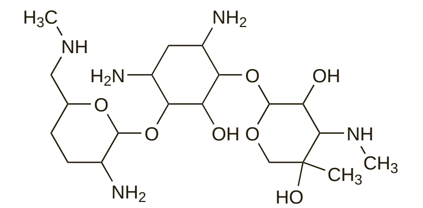
Micronomicin Sulfate *(pINNM)*

Gentamicin C_{2B} Sulphate; KW-1062 (micronomicin); 6′*N*-Methylgentamicin C_{1A} Sulphate; Micronomicin Sulphate; Micronomicine, Sulfate de; Micronomicini Sulfas; Sagamicin Sulphate; Sulfato de micronomicina. *O*-2-Amino-2,3,4,6-tetradeoxy-6-(methylamino)-α-D-*erythro*-hexopyranosyl-(1→4)-*O*-[3-deoxy-4-*C*-methyl-3-(methylamino)-β-L-arabinopyranosyl-(1→6)]-2-deoxy-D-streptamine hemipentasulphate.

Микрономицина Сульфат

$(C_{20}H_{41}N_5O_7)_2,5H_2SO_4$ = 1417.5.
CAS — 52093-21-7 (micronomicin).
ATC — S01AA22.
ATC Vet — QS01AA22.



(micronomicin)

Pharmacopoeias. In *Chin.* and *Jpn*.

Profile

Micronomicin is an aminoglycoside with general properties similar to those of gentamicin (p.282). It is given as the sulfate and doses are expressed in terms of micronomicin; 183 mg of micronomicin sulfate is equivalent to about 120 mg of micronomicin. It is given by intramuscular injection or by intravenous infusion over 30 minutes to 1 hour in doses of 120 to 240 mg daily in 2 or 3 divided doses. Dosage should be adjusted based on serum-micronomicin concentration monitoring. It is also used topically as eye drops or ointment in a concentration of 0.3% for infections of the eye.

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Luxomicina; ***Jpn:*** Sagamicin; ***Singapore:*** Sagamicin†.

Midecamycin *(rINN)*

Midecamicina; Midecamycin A_1; Midécamycine; Midecamycinum; Mydecamycin. 7-(Formylmethyl)-4,10-dihydroxy-5-methoxy-9,16-dimethyl-2-oxo-oxacyclohexadeca-11,13-dien-6-yl 3,6-dideoxy-4-*O*-(2,6-dideoxy-3-*C*-methyl-α-L-*ribo*-hexopyranosyl)-3-(dimethylamino)-β-D-glucopyranoside 4′,4″-dipropionate.

Pharmacopoeias. In *Jpn*.

Midecamycin Acetate *(rINNM)*

Acecamycin; Acetato de midecamicina; Midecamycin Diacetate; Midécamycine, Acétate de; Midecamycini Acetas; Miocamycin; Miokamycin; MOM; Ponsinomycin; 1532-RB. 9,3″-Diacetylmidecamycin; Leucomycin V 3^B, 9-diacetate $3,4^B$-dipropanoate.

Мидекамицина Ацетат

$C_{45}H_{71}NO_{17}$ = 898.0.
CAS — 55881-07-7.
ATC — J01FA11.
ATC Vet — QJ01FA11.

Pharmacopoeias. In *Jpn*.

Profile

Midecamycin is a macrolide antibacterial produced by the growth of *Streptomyces mycarofaciens* with actions and uses similar to those of erythromycin (p.269) but it is somewhat less active. It is given orally for the treatment of susceptible infections as the acetate in usual doses of 0.9 to 1.8 g daily in 2 or 3 divided doses. It has also been given as the base.

Preparations

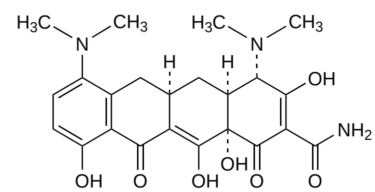
Proprietary Preparations (details are given in Part 3)
Arg.: Myoxam†; ***Belg.:*** Merced; ***Fr.:*** Mosil; ***Gr.:*** Miocacin; Miocamen; ***Hong Kong:*** Medemycin; ***Ital.:*** Macroral; Midecin; Miocamen; Miokacin; ***Jpn:*** Medemycin; Miocamycin; ***Mex.:*** Midecamin†; ***Port.:*** Miocacin; ***Rus.:*** Macropen (Макропен); ***Spain:*** Momicine; Myoxam; Normicina†; ***Thai.:*** Miotin.

Minocycline *(BAN, USAN, rINN)*

Minociclina; Minocyclinum; Minocyklin; Minosiklin; Minosykliini. (4*S*,4a*S*,5a*R*,12a*S*)4,7-Bis(dimethylamino)-1,4,4a,5,5a,6,11,12a-octahydro-3,10,12,12a-tetrahydroxy-1,11-dioxonaphthacene-2-carboxamide; 6-Demethyl-6-deoxy-7-dimethylaminotetracycline.

Миноциклин

$C_{23}H_{27}N_3O_7$ = 457.5.
CAS — 10118-90-8;.
ATC — A01AB23; J01AA08.
ATC Vet — QA01AB23; QJ01AA08.



Minocycline Hydrochloride *(BANM, rINNM)*

Hidrocloruro de minociclina; Minociklin-hidroklorid; Minociklino hidrochloridas; Minocycline, chlorhydrate de; Minocyclini hydrochloridum; Minocyklin-hydrochlorid; Minocyklinhydroklorid; Minocykliny chlorowodorek; Minosykliinihydrokloridi.

Миноциклина Гидрохлорид

$C_{23}H_{27}N_3O_7,HCl$ = 493.9.
CAS — 13614-98-7.
ATC — A01AB23; J01AA08.
ATC Vet — QA01AB23; QJ01AA08.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US*.

Ph. Eur. 6.2 (Minocycline Hydrochloride Dihydrate). A yellow, hygroscopic, crystalline powder. Sparingly soluble in water; slightly soluble in alcohol. It dissolves in solutions of alkali hydroxides and carbonates. A 1% solution in water has a pH of 3.5 to 4.5. Store in airtight containers. Protect from light.

USP 31 (Minocycline Hydrochloride). A yellow crystalline powder. Sparingly soluble in water; slightly soluble in alcohol; practically insoluble in chloroform and in ether; soluble in solutions of alkali hydroxides and carbonates. pH of a solution in water containing the equivalent of minocycline 1% is between 3.5 and 4.5. Store in airtight containers. Protect from light.

Incompatibility. Preparations of minocycline hydrochloride have an acid pH and incompatibility may reasonably be expected with alkaline preparations or with drugs unstable at low pH.

Adverse Effects and Precautions

As for Tetracycline, p.347.

Gastrointestinal disturbances with minocycline are reported to be less frequent than with the less well absorbed tetracyclines.

Oesophageal ulceration has occurred and may be a particular problem if capsules or tablets are taken with insufficient fluid or in a recumbent posture: minocycline should be taken with at least half a glass of water, in an upright position, and well before going to bed.

Vestibular adverse effects including dizziness or vertigo may occur with minocycline, particularly in women. Patients should be advised not to drive or operate machinery if affected. Tinnitus and decreased hearing have been reported rarely.

There have also been reports, some fatal, of a hypersensitivity syndrome (comprising eosinophilia, fever, rash, and varying additional symptoms), a lupus-like syndrome, and a serum-sickness-like syndrome (both comprising arthralgia, fever, and joint stiffness or swelling, amongst other symptoms).

Minocycline may also cause hyperpigmentation of the skin (see below).

Although minocycline, unlike many tetracyclines, does not appear to accumulate in patients with renal impairment, usual doses can lead to higher serum concentrations resulting in possible liver toxicity; reduced doses and monitoring of renal function may be necessary, particularly in those with severe impairment.

The *BNF* recommends that if treatment continues for longer than 6 months patients should be monitored every 3 months for hepatotoxicity, pigmentation, and SLE.

Incidence of adverse effects. Severe complications have been reported in patients given minocycline for acne, including serum-sickness-like disease,[1,2] lupus erythematosus,[3] and hepatitis.[3,4] The number of cases reported probably reflects the widespread use of this drug and the true incidence of such adverse effects is difficult to assess.[5] A study of 700 patients receiving minocycline for acne revealed adverse effects in 13.6%, mostly benign.[6] Gastrointestinal disturbances and vestibular disturbances were the most common, each occurring in about 2% of patients, and pigmentation in up to 4% of patients.

Another problem is that of assessing the efficacy of minocycline and the incidence of severe adverse effects relative to other antibacterials commonly used in acne such as tetracycline and erythromycin. A systematic review[7] suggested that the incidence of adverse effects might be greater with minocycline than with doxycycline. A retrospective analysis[8] of a UK population database found that minocycline was associated with an increased risk for drug-induced lupus erythematosus; no increased risk was reported for the other tetracyclines. Other systematic reviews[9,10] concluded that minocycline should not be used as a first-line oral tetracycline in patients with acne since there is no compelling evidence that it is more effective than some other tetracyclines or commonly used treatments; the risk of rare but serious adverse effects also makes it less suitable.[10]

Effects on intracranial pressure. Minocycline has been associated with benign intracranial hypertension; for further details, see under Tetracycline, p.348.

Effects on the liver. A systematic review[1] considered 65 published case reports of hepatitis or liver damage associated with the use of minocycline for acne, including 4 fatalities, and also data held by WHO concerning 493 reactions involving the liver in 393 patients in whom the indication for the use of minocycline was largely unspecified.

Of the 65 published cases, 38 occurred in females and 61 in patients under 40 years of age. These cases appeared to be of the following types:

- 16 cases appeared to be attributable to a hypersensitivity reaction, with a rapid onset usually within 1 month of starting treatment and sometimes associated with eosinophilia and exfoliative dermatitis
- 29 cases of hepatitis (of which 20 were in females) appeared to be of an auto-immune nature, occurring after 1 year or more of therapy and sometimes associated with lupus-like symptoms
- 20 cases could not be definitively classified into either group

The 393 patients described by the WHO data had 22 different types of hepatic reaction which could be broadly grouped into 4 categories:

- hepatic dysfunction (32% of patients)
- hepatitis (26%)
- abnormal liver function tests (24%)
- hyperbilirubinaemia or jaundice (14%)

There were, in addition, several other reactions, including hepatic damage or necrosis in 11 patients and fatty liver in 7. Gender distribution was almost even. Of the 393 patients, 14 also experienced lupus-like symptoms. The outcome of the hepatic reactions was reported in less than half of the patients, although it was apparent that there had been at least 3 fatalities.

Despite these findings, the reviewers concluded[1] that there was no clear information regarding the absolute or relative risks of hepatitis in patients given minocycline, and that it was inappropriate to comment as to whether monitoring would be worthwhile. A study of the comparative rates of hepatitis in people exposed to minocycline compared with those who were not was required.

1. Lawrenson RA, *et al.* Liver damage associated with minocycline use in acne: a systematic review of the published literature and pharmacovigilance data. *Drug Safety* 2000; **23:** 333–49.

Effects on the lungs. Hypersensitivity pneumonitis, characterised by pulmonary infiltrates and eosinophilia, has been reported[1-6] with minocycline. In most cases, the pneumonitis resolved after stopping minocycline but some required corticosteroid therapy; however, residual lung damage can occur. In one case[6] relapsing acute respiratory failure that required mechanical ventilation was reported.

Hyperpigmentation. Minocycline has been associated with pigmentation of the skin and other tissues.[1-3] Three patterns of skin pigmentation have been described:[1] blue-black macules occurring in areas of inflammation and scarring and possibly due to an iron chelate of minocycline within macrophages; blue-grey macules or hyperpigmentation affecting normal skin and which may be due to a breakdown product of minocycline; or a greyish-brown discoloration occurring particularly in sun-exposed areas of skin ('muddy skin syndrome'), apparently due to melanin deposition. In general, pigmentation results from long-term use of minocycline at cumulative doses greater than 100 g; however, skin or oral mucosal pigmentation may occur regardless of dose or duration of therapy.[2] Indeed, there have been reports[3] of skin pigmentation developing after short-term use ranging from 3 to 28 days. Pigmentation of the skin and oral mucosa usually appears to resolve slowly on stopping the drug although recovery may be incomplete; pigmentation is often permanent when other sites are involved.[2]

Interactions

As for Tetracycline, p.348.

Minocycline has a lower affinity for binding with calcium than tetracycline. Consequently its absorption is less likely to be affected by milk or food, although it is still affected by calcium-containing antacids and other divalent and trivalent cations such as aluminium, bismuth, iron, magnesium, and zinc.

Antimicrobial Action

Minocycline has a spectrum of activity and mode of action similar to that of tetracycline (p.348) but it is more active against many species including *Staphylococcus aureus*, streptococci, *Neisseria meningitidis*, various enterobacteria, *Acinetobacter*, *Bacteroides*, *Haemophilus*, *Nocardia*, and some mycobacteria, including *M. leprae*.

Partial cross-resistance exists between minocycline and other tetracyclines but some strains resistant to other drugs of the group remain sensitive to minocycline, perhaps because of better cell-wall penetration.

Pharmacokinetics

For the general pharmacokinetics of the tetracyclines, see Tetracycline, p.349.

Minocycline is readily absorbed from the gastrointestinal tract and absorption is not significantly affected by the presence of food or moderate amounts of milk. Oral doses of 200 mg followed by 100 mg every 12 hours are reported to produce plasma concentrations of about 2 to 4 micrograms/mL. It is more lipid-soluble than doxycycline and the other tetracyclines and is widely distributed in body tissues and fluids with high concentrations being achieved in the hepatobiliary tract, lungs, sinuses and tonsils, as well as in tears, saliva, and sputum. Penetration into the CSF is relatively poor, although a higher ratio of CSF to blood concentrations has been reported with minocycline than with doxycycline. It crosses the placenta and is distributed into breast milk. About 75% of minocycline in the circulation is bound to plasma proteins. It has a low renal clearance: only about 5 to 10% of a dose is excreted in the urine and up to about 34% is excreted in the faeces. However, in contrast to most tetracyclines it appears to undergo some metabolism in the liver, mainly to 9-hydroxyminocycline. Sources differ as to whether the normal plasma half-life of 11 to 26 hours is prolonged in patients with renal impairment, with a consequent risk of accumulation; hepatic impairment does not appear to lead to accumulation. Little minocycline is removed by haemodialysis and peritoneal dialysis.

◊ Reviews.

1. Saivin S, Houin G. Clinical pharmacokinetics of doxycycline and minocycline. *Clin Pharmacokinet* 1988; **15:** 355–66.

Uses and Administration

Minocycline is a tetracycline derivative with uses similar to those of tetracycline (p.349). It is also a component of multidrug regimens for the treatment of leprosy (p.176) and has been used in the prophylaxis of meningococcal infection to eliminate the carrier state, but the high incidence of vestibular disturbances means that it is not the drug of choice for the latter.

Minocycline is usually given orally as the hydrochloride; doses are expressed in terms of the base. Minocycline hydrochloride 108 mg is equivalent to about 100 mg of minocycline. Minocycline capsules and tablets should be taken with plenty of fluid, with the patient in an upright position, and well before going to bed.

In patients in whom oral therapy is not feasible, minocycline hydrochloride has been given by slow intravenous infusion in doses equivalent to those given orally. In some countries it has also been given by intramuscular injection.

The usual adult oral dose is 200 mg daily in divided doses, usually every 12 hours; an initial loading dose of 200 mg may be given.

An oral dose of 50 mg twice daily or 100 mg once daily is used for the treatment of acne; alternatively, a dose of about 1 mg/kg once daily is also given as a modified-release preparation to patients weighing 45 kg and over. In asymptomatic meningococcal carriers, 100 mg has been given orally twice daily for 5 days, usually followed by a course of rifampicin.

For multibacillary leprosy an oral dose of minocycline 100 mg daily with clofazimine and ofloxacin *or* 100 mg monthly with rifampicin and ofloxacin have been recommended by WHO as alternative multidrug therapy regimens. As an alternative regimen for patients with single-lesion paucibacillary leprosy WHO suggests a single dose of minocycline 100 mg with rifampicin and ofloxacin.

For details of doses in children and adolescents, see below.

For dosage recommendations in patients with renal impairment, see below.

In adults with periodontitis, a modified-release subgingival gel containing minocycline hydrochloride has been inserted into the periodontal pocket as an adjunct to scaling and root planing; each cartridge contains the equivalent of 1 mg of minocycline and the total used depends on the size, shape, and number of pockets being treated. Minocycline has also been applied as a 2% gel for periodontal infections.

Administration in children. In children, the effects on teeth should be considered and tetracyclines only used when absolutely essential. In the UK, minocycline is licensed for use in children aged 12 years and over; the usual adult dose (see above) may be given orally. However, in the USA, it may be given to those over 8 years old in usual oral doses of 4 mg/kg initially followed by 2 mg/kg every 12 hours.

Administration in renal impairment. US licensed product information states that pharmacokinetics in patients with renal impairment have not been fully characterised and therefore recommends that no more than 200 mg in any 24-hour period should be given to these patients.

Motor neurone disease. Minocycline is being investigated as a potential treatment for amyotrophic lateral sclerosis, a form of motor neurone disease (p.2380), on the basis of its neuroprotective properties.

Movement disorders. Minocycline is under investigation[1,2] for the management of Huntington's chorea (p.953).

Morinamida; Morinamidum; Morphazinamide. *N*-Morpholinomethylpyrazine-2-carboxamide.

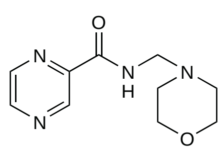
Моринамид

$C_{10}H_{14}N_4O_2$ = 222.2.

CAS — 952-54-5.

ATC — J04AK04.

ATC Vet — QJ04AK04.



Profile

Morinamide is an antimycobacterial that has been given orally as the hydrochloride in the treatment of tuberculosis.

Preparations

Proprietary Preparations (details are given in Part 3)

Turk.: Morfozid.

Moxifloxacin Hydrochloride *(BANM, USAN, rINNM)*

Bay-12-8039; Hidrocloruro de moxifloxacino; Moxifloxacine, chlorhydrate de; Moxifloxacini hydrochloridum. 1-Cyclopropyl-6-fluoro-1,4-dihydro-8-methoxy-7-[(4a*S*,7a*S*)-octahydro-6*H*-pyrrolo[3,4-*b*]pyridin-6-yl]-4-oxo-3-quinolinecarboxylic acid hydrochloride.

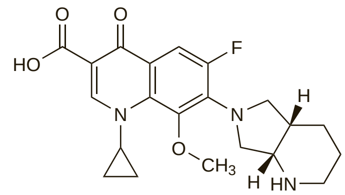
Моксифлоксацина Гидрохлорид

$C_{21}H_{24}FN_3O_4$,HCl = 437.9.

CAS — 151096-09-2 (moxifloxacin); 186826-86-8 (moxifloxacin hydrochloride).

ATC — J01MA14; S01AX22.

ATC Vet — QJ01MA14; QS01AX22.



(moxifloxacin)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Moxifloxacin Hydrochloride). Produced using a method validated to demonstrate the satisfactory enantiomeric purity of the final product. A light yellow or yellow powder or crystals, slightly hygroscopic. Sparingly soluble in water; slightly soluble in alcohol; practically insoluble in acetone. A 0.2% solution in water has a pH of 3.9 to 4.6. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for Ciprofloxacin, p.244.

◊ References.

1. Faich GA, *et al.* Clinical experience with moxifloxacin in patients with respiratory tract infections. *Ann Pharmacother* 2004; **38:** 749–54.
2. Ball P, *et al.* Safety profile of oral and intravenous moxifloxacin: cumulative data from clinical trials and postmarketing studies. *Clin Ther* 2004; **26:** 940–50.
3. Andriole VT, *et al.* Retrospective analysis of the safety profile of oral moxifloxacin in elderly patients enrolled in clinical trials. *Drug Safety* 2005; **28:** 443–52.

Interactions

As for Ciprofloxacin, p.246.

Moxifloxacin does not appear to interact significantly with theophylline or probenecid.

Antimicrobial Action

As for Ciprofloxacin, p.246.

Moxifloxacin is reported to have greater activity against Gram-positive bacteria, including pneumococci, than ciprofloxacin.

◊ References.

1. Stein GE, *et al.* Bactericidal activities of methoxyfluoroquinolones gatifloxacin and moxifloxacin against aerobic and anaerobic respiratory pathogens in serum. *Antimicrob Agents Chemother* 2003; **47:** 1308–12.
2. Pletz MWR, *et al.* Early bactericidal activity of moxifloxacin in treatment of pulmonary tuberculosis: a prospective, randomized study. *Antimicrob Agents Chemother* 2004; **48:** 780–2.

Pharmacokinetics

Moxifloxacin is readily absorbed from the gastrointestinal tract after oral doses with an absolute bioavailability of about 90%. It is widely distributed throughout the body tissues and is about 30 to 50% bound to plasma proteins. Moxifloxacin has an elimination half-life of about 12 hours, allowing once-daily dosing. It is metabolised mainly via sulfate and glucuronide conjugation, and is excreted in the urine and the faeces as unchanged drug and as metabolites, the sulfate conjugate primarily in the faeces and the glucuronide exclusively in the urine. Distribution into milk has been found in *animals*.

Uses and Administration

Moxifloxacin is a fluoroquinolone antibacterial with actions and uses similar to those of ciprofloxacin (p.247).

It is given orally, or by intravenous infusion over 60 minutes, for the treatment of susceptible infections including respiratory, skin and skin structure, and intra-abdominal infections. Moxifloxacin is given as the hydrochloride but doses are expressed in terms of the base; moxifloxacin hydrochloride 436.3 mg is equivalent to about 400 mg of moxifloxacin. The usual dose is 400 mg once daily.

Moxifloxacin is also used topically as the hydrochloride in eye drops containing the equivalent of 0.5% of moxifloxacin for the treatment of bacterial conjunctivitis.

Mupirocin *(BAN, USAN, rINN)*

BRL-4910A; Mupirocina; Mupirocinas; Mupirocine; Mupirocinum; Mupirosiini; Pseudomonic Acid. 9-[(2*E*)-4-[(2*S*,3*R*,4*R*,5*S*)-5-[(2*S*,3*S*,4*S*,5*S*)-2,3-Epoxy-5-hydroxy-4-methylhexyl]tetrahydro-3,4-dihydroxypyran-2-yl]-3-methylbut-2-enoyloxy]nonanoic acid; (2*S*-{2α(*E*),3β,4β,5α[2*R**,3*R**(1*R**,2*R**)]})-9-{[3-Methyl-1-oxo-4-(tetrahydro-3,4-dihydroxy-5-{[3-(2-hydroxy-1-methyl-propyl)oxiranyl]methyl}-2*H*-pyran-2-yl)-2-butenyl]oxy}nonanoic acid.

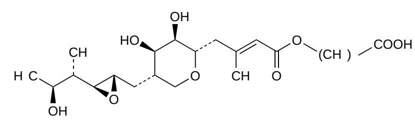
Мупироцин

$C_{26}H_{44}O_9$ = 500.6.

CAS — 12650-69-0.

ATC — D06AX09; R01AX06.

ATC Vet — QD06AX09; QR01AX06.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Mupirocin). A white or almost white powder. It shows polymorphism. Slightly soluble in water; freely soluble in dehydrated alcohol, in acetone, and in dichloromethane. The pH of a freshly prepared saturated solution in water is 3.5 to 4.0. Protect from light.

USP 31 (Mupirocin). A white to off-white crystalline solid. Very slightly soluble in water; freely soluble in dehydrated alcohol, in acetone, in chloroform, and in methyl alcohol; slightly soluble in ether. pH of a saturated solution in water is between 3.5 and 4.5. Store in airtight containers.

Mupirocin Calcium *(BANM, USAN, rINNM)*

BRL-4910F; Calcii Mupirocinum; Mupirocin vápenatá sůl dihydrát; Mupirocina cálcica; Mupirocine calcique; Mupirocinkalcium; Mupirocin-kalcium; Mupirocino kalcio druska; Mupirocinum calcicum; Mupirocinum Calcicum Dihydricum; Mupirosiinikalsium.

Кальций Мупироцин

$C_{52}H_{86}O_{18}Ca,2H_2O$ = 1075.3.

CAS — 104486-81-9 (anhydrous mupirocin calcium); 115074-43-6 (mupirocin calcium dihydrate).

ATC — D06AX09; R01AX06.

ATC Vet — QD06AX09; QR01AX06.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Mupirocin Calcium). A white or almost white powder. Very slightly soluble in water; sparingly soluble in dehydrated alcohol and in dichloromethane.

USP 31 (Mupirocin Calcium). Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°.

Adverse Effects and Precautions

Mupirocin is usually well tolerated but local reactions such as burning, stinging, and itching may occur after the application of mupirocin to the skin.

Some mupirocin products are formulated in a macrogol base: such formulations are not suitable for application to mucous membranes and should be used with caution in patients with extensive burns or wounds because of the possibility of macrogol toxicity. Care is also required in patients with renal impairment.

Antimicrobial Action

Mupirocin is an antibacterial that inhibits bacterial protein synthesis by binding to isoleucyl transfer RNA synthetase. It is mainly bacteriostatic at low concentrations, although it is usually bactericidal in the high concentrations achieved by topical application to the skin. At these concentrations it may have some activity against organisms reported to be relatively resistant to mupirocin *in vitro*.

It is mainly active against Gram-positive aerobes. Most strains of staphylococci (including meticillin-resistant and multiply-resistant *Staph. aureus*) and streptococci are susceptible *in vitro*, although the enterococci are relatively resistant. Mupirocin is also active against *Listeria monocytogenes* and *Erysipelothrix rhusiopathiae*. The Gram-negative organisms are generally insensitive, but *Haemophilus influenzae*, *Neisseria* spp. and a few others are sensitive. Anaerobic organisms, both Gram-positive and Gram-negative, are generally resistant, and activity against fungi is low. Mupirocin is more active *in vitro* at acid pH than in alkaline conditions.

Naturally resistant strains of *Staph. aureus* occur rarely but resistance, including high-level plasmid-mediated transferable resistance, has emerged, particularly during long-term use. There has been some concern that inappropriate prescribing of mupirocin has led to this steadily increasing resistance.

Activity against fungi. Activity of mupirocin 2% *in vitro* against *Candida albicans* was comparable to that of other commonly used topical antifungals. Although MICs were considerably in excess of those reported for susceptible bacteria, clinical responses in 10 patients suggested that adequate concentrations of mupirocin were achieved after topical application.[1]

Pharmacokinetics

Only very small amounts of topically applied mupirocin are absorbed into the systemic circulation where it is rapidly metabolised to monic acid which is excreted in the urine.

Uses and Administration

Mupirocin is an antibacterial produced by *Pseudomonas fluorescens*. It is applied topically as a 2% ointment in a macrogol base, or as a cream containing mupirocin calcium equivalent to 2% mupirocin, in the treatment of various bacterial skin infections. These preparations should be applied up to 3 times daily for up to 10 days; treatment should be re-evaluated if there is no response after 3 to 5 days. They are not suitable for application to mucous membranes, and therefore a nasal ointment containing mupirocin calcium equivalent to 2% mupirocin in a paraffin basis is used for eradication of the nasal carriage of *Staphylococcus aureus*, particularly epidemic meticillin-resistant strains. The nasal ointment should be applied into each nostril 2 or 3 times daily for a maximum of 7 days.

For further details of skin infections and staphylococcal infections and their treatment, see under Choice of Antibacterial, p.194.

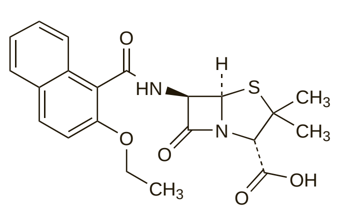
Nafcillin Sodium *(BANM, USAN, rINNM)*

Nafcilina sódica; Nafcilline Sodique; Nafcillinnatrium; Nafcillinum Natricum; Nafsilliininatrium; Natrii Nafcillinum; Wy-3277. Sodium (6*R*)-6-(2-ethoxy-1-naphthamido)penicillanate monohydrate.

Натрий Нафциллин

$C_{21}H_{21}N_2NaO_5S,H_2O$ = 454.5.
CAS — 147-52-4 (nafcillin); 985-16-0 (anhydrous nafcillin sodium); 7177-50-6 (nafcillin sodium monohydrate).



(nafcillin)

Pharmacopoeias. In *US.*

USP 31 (Nafcillin Sodium). A white to yellowish-white powder having not more than a slight characteristic odour. Freely soluble in water and in chloroform; soluble in alcohol. pH of a 3% solution in water is between 5.0 and 7.0. Store in airtight containers.

Incompatibility. Nafcillin sodium has been reported to be incompatible with aminoglycosides and a number of other antibacterials. It has also been reported to be incompatible with acidic and alkaline drugs.

Adverse Effects and Precautions

As for Benzylpenicillin, p.213.

Thrombophlebitis may occur when nafcillin is given by intravenous injection, and tissue damage has been reported on extravasation.

Effects on the kidneys. References.

Sodium content. Each g of nafcillin sodium contains about 2.2 mmol of sodium.

Interactions

As for Benzylpenicillin, p.214.

Ciclosporin. For the effect of nafcillin on ciclosporin, see p.1825.

Warfarin. For the effect of nafcillin on warfarin, see p.1428.

Antimicrobial Action

As for Flucloxacillin, p.277.

Pharmacokinetics

Nafcillin is incompletely and irregularly absorbed from the gastrointestinal tract, especially when given after food. After intramuscular injection it is absorbed more reliably, an injection of 0.5 to 1 g producing peak plasma concentrations of 5 to 8 micrograms/mL within about 0.5 to 1 hour. Up to 90% of nafcillin in the circulation is bound to plasma proteins. Nafcillin has been reported to have a plasma half-life of about 0.5 to 1.5 hours. The half-life is prolonged in neonates.

Nafcillin crosses the placenta into the fetal circulation and is distributed into breast milk. There is little diffusion into the CSF except when the meninges are inflamed. Nafcillin is distributed into pleural and synovial fluids and into bone.

Nafcillin differs from most other penicillins in that it is largely inactivated by hepatic metabolism. It is excreted via the bile although some reabsorption takes place in the small intestine. Only about 10% of a dose given orally before food, and about 30% of a dose given intramuscularly, is excreted in the urine.

Plasma concentrations are enhanced by probenecid.

Uses and Administration

Nafcillin is a penicillinase-resistant penicillin used similarly to flucloxacillin (p.277) in the treatment of infections due to staphylococci resistant to benzylpenicillin.

It is given by injection as the sodium salt. Doses are expressed in terms of the equivalent amount of nafcillin; 1.1 g of nafcillin sodium is equivalent to about 1 g of nafcillin. Nafcillin sodium may be given intravenously by slow injection over 5 to 10 minutes or by slow infusion over at least 30 to 60 minutes; usual adult doses are 0.5 to 1 g of nafcillin every 4 hours, although it is usually recommended that it be used for not more than 24 to 48 hours because of the risk of thrombophlebitis. It has also been given by intramuscular injection in a dose of 500 mg of nafcillin every 4 to 6 hours.

Nafcillin sodium has also been given orally but other penicillinase-resistant penicillins are preferred.

Preparations

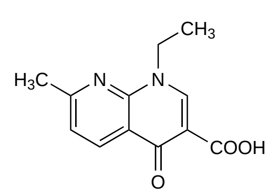
USP 31: Nafcillin for Injection; Nafcillin Injection; Nafcillin Sodium Capsules; Nafcillin Sodium for Oral Solution; Nafcillin Sodium Tablets.

Nalidixic Acid *(BAN, USAN, rINN)*

Acide nalidixique; Ácido nalidíxico; Acidum nalidixicum; Kwas nalidyksowy; Kyselina nalidixová; Nalidiksiinihappo; Nalidiksik Asit; Nalidikso rūgštis; Nalidixinic Acid; Nalidixinsyra; Nalidixsav; NSC-82174; Win-18320. 1-Ethyl-1,4-dihydro-7-methyl-4-oxo-1,8-naphthyridine-3-carboxylic acid.

Налидиксовая Кислота

$C_{12}H_{12}N_2O_3$ = 232.2.
CAS — 389-08-2.
ATC — J01MB02.
ATC Vet — QJ01MB02.



The symbol † denotes a preparation no longer actively marketed

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Nalidixic Acid). An almost white or pale yellow, crystalline powder. Practically insoluble in water; slightly soluble in alcohol and in acetone; soluble in dichloromethane. It dissolves in dilute solutions of alkali hydroxides. Store in airtight containers. Protect from light.

USP 31 (Nalidixic Acid). A white to very pale yellow, odourless crystalline powder. Very slightly soluble in water and in ether; soluble 1 in 910 of alcohol and 1 in 29 of chloroform; slightly soluble in acetone, in methyl alcohol, and in toluene; soluble in dichloromethane and in solutions of fixed alkali hydroxides and carbonates. Store in airtight containers.

Adverse Effects

The most frequent adverse reactions to nalidixic acid involve the gastrointestinal tract, skin, and CNS. Gastrointestinal effects have been reported in about 8% of patients and include nausea, vomiting, diarrhoea, and abdominal pain.

Adverse effects on the skin include photosensitivity reactions with erythema and bullous eruptions, allergic rashes, urticaria, and pruritus. Erythema multiforme and Stevens-Johnson syndrome have been reported rarely. Eosinophilia, fever, angioedema, and, rarely, anaphylactoid reactions have occurred.

Neurological effects include visual disturbances, headache, dizziness or vertigo, drowsiness, and sometimes confusion, depression, excitement, and hallucinations. Toxic psychoses or convulsions have occurred, especially after large doses; convulsions are most likely in patients with predisposing factors such as cerebral arteriosclerosis or epilepsy. There have been reports of intracranial hypertension, especially in infants and young children, and also of metabolic acidosis.

Peripheral neuropathies, muscular weakness, and myalgia are occasional adverse effects. Sixth cranial nerve palsy has been reported rarely.

Arthralgia has been reported (degenerative changes in weight-bearing joints of young *animals* are documented). Tendon damage has occasionally been associated with nalidixic acid and related compounds, the fluoroquinolones (see Effects on the Musculoskeletal System, under Ciprofloxacin, p.244).

Cholestatic jaundice, thrombocytopenia, and leucopenia have occurred rarely, as has haemolytic anaemia in patients who may or may not have G6PD deficiency. There have been isolated reports of fatal auto-immune haemolytic anaemia in elderly patients.

Precautions

Nalidixic acid is contra-indicated in patients with a history of convulsive disorders and in those with severe renal impairment. It should be given with care to patients with hepatic or moderate renal impairment, severe cerebral arteriosclerosis, or G6PD deficiency. Blood counts and renal and hepatic function should be monitored if treatment continues for more than 2 weeks.

It should be avoided in infants less than 3 months old. Since nalidixic acid and related antimicrobials have been shown to cause degenerative changes in weight-bearing joints of young *animals*, it has been suggested that these compounds should not generally be used in patients aged under 18 years, pregnant women, or during breast feeding (but see also below) unless the benefits outweigh the risks. Treatment should be stopped if symptoms of neuropathy or arthralgia occur. Tendon damage may occur rarely and treatment should be stopped if patients experience tendon pain, inflammation, or rupture.

Exposure to strong sunlight or sunlamps should be avoided during treatment with nalidixic acid.

Nalidixic acid may cause false-positive reactions in urine tests for glucose using copper reduction methods.

Breast feeding. The American Academy of Pediatrics[1] states that nalidixic acid is usually compatible with breast feeding, although haemolytic anaemia has been reported[2] in a breast-fed infant, with no evidence of G6PD deficiency, whose mother had received nalidixic acid.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 27/05/04)
2. Belton EM, Jones RV. Haemolytic anaemia due to nalidixic acid. *Lancet* 1965; **ii:** 691.

Porphyria. Nalidixic acid has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

The absorption of nalidixic acid is reduced by sucralfate, and divalent and trivalent cations such as aluminium, calcium, iron, magnesium, and zinc, and therefore use of nalidixic acid with antacids, iron preparations, or other preparations containing such cations, whether as active ingredients or excipients, may result in subtherapeutic serum concentrations of the antibacterial. It is recommended that such products should not be given within 2 hours before or after nalidixic acid.

The excretion of nalidixic acid is reduced and plasma concentrations increased by probenecid. Other antibacterials such as chloramphenicol, nitrofurantoin, and tetracycline have been shown to antagonise the action of nalidixic acid *in vitro* and should not be used together.

Fatal haemorrhagic enterocolitis has been associated with the use of nalidixic acid and high-dose intravenous melphalan in children; use with other alkylating antineoplastics is also contra-indicated. There is a possible risk of increased nephrotoxicity when nalidixic acid is given with ciclosporin.

Nalidixic acid is reported to enhance the effect of oral anticoagulants such as warfarin (see p.1428); this may be due in part to displacement of anticoagulant from its plasma binding sites. The dose of anticoagulant may need to be reduced.

The effect of some quinolone antibacterials on xanthines is discussed under Caffeine, p.1117, and Theophylline, p.1143.

Convulsions may be precipitated by the use of some quinolones with NSAIDs (see Analgesics, under Interactions of Ciprofloxacin, p.246), although this has not been reported with nalidixic acid.

Antimicrobial Action

Nalidixic acid is considered to act by interfering with the replication of bacterial DNA, probably by inhibiting DNA gyrase (topoisomerase) activity. It is active against Gram-negative bacteria including *Escherichia coli*, *Klebsiella* spp., *Proteus* spp., *Enterobacter* spp., *Salmonella* spp., and *Shigella* spp., and is usually bactericidal. *Pseudomonas aeruginosa*, Gram-positive bacteria, and anaerobes are not generally susceptible.

Bacterial resistance may develop rapidly, sometimes within a few days of commencing treatment, but it does not appear to be transferable or R-plasmid mediated (see also below). Cross-resistance occurs with oxolinic acid and cinoxacin.

The antibacterial activity of nalidixic acid is not significantly affected by differences in urinary pH. Antagonism between nalidixic acid and other antibacterials such as chloramphenicol, nitrofurantoin, and tetracycline has been shown *in vitro*.

Resistance. Bacterial plasmid-mediated resistance to quinolones had not been seen by the late 1980s.[1] A report[2] of such resistance to nalidixic acid in *Shigella dysenteriae* responsible for an epidemic of shigellosis in Bangladesh in 1987, was questioned at the time.[3] On reinspection of the data, chromosomal mutation rather than plasmid-mediated resistance was confirmed as the mechanism responsible so far for resistance to quinolones.[1] Subsequent data[4] in an isolate of *Klebsiella pneumoniae* has, however, suggested that plasma-mediated resistance to quinolones may be possible.

1. Courvalin P. Plasmid-mediated 4-quinolone resistance: a real or apparent absence? *Antimicrob Agents Chemother* 1990; **34:** 681–4.
2. Munshi MH, *et al.* Plasmid-mediated resistance to nalidixic acid in Shigella dysenteriae type 1. *Lancet* 1987; **ii:** 419–21.
3. Crumplin GC. Plasmid-mediated resistance to nalidixic acid and new 4-quinolones? *Lancet* 1987; **ii:** 854–5.
4. Martínez-Martínez L, *et al.* Quinolone resistance from a transferable plasmid. *Lancet* 1998; **351:** 797–9.

Pharmacokinetics

Nalidixic acid is rapidly and almost completely absorbed from the gastrointestinal tract, and peak plasma concentrations of 20 to 40 micrograms/mL have been reported 1 to 2 hours after a 1-g oral dose. Plasma half-lives of about 1 to 2.5 hours have been reported (but see below).

Nalidixic acid is partially metabolised to hydroxynalidixic acid, which has antibacterial activity similar to that of nalidixic acid and accounts for about 30% of active drug in the blood. About 93% of nalidixic acid and 63% of hydroxynalidixic acid are bound to plasma proteins. Both nalidixic acid and hydroxynalidixic acid are rapidly metabolised to inactive glucuronide and dicarboxylic acid derivatives; the major inactive metabolite 7-carboxynalidixic acid is usually only detected in urine.

Nalidixic acid and its metabolites are excreted rapidly in the urine, nearly all of a dose being eliminated within 24 hours. More than 80% of the drug excreted in the urine is as inactive metabolites, but peak urinary concentrations of active drug averaging about 150 to 200 micrograms/mL are achieved 3 to 4 hours after a single 1-g dose. Hydroxynalidixic acid accounts for about 80 to 85% of activity in the urine. Urinary excretion is reduced by probenecid. About 4% of a dose is excreted in the faeces.

Traces of nalidixic acid are distributed into breast milk and appear to cross the placenta.

◊ Although a plasma half-life of 1 to 2.5 hours is generally cited for nalidixic acid, values of 6 to 7 hours have been reported for active drug (nalidixic acid and hydroxynalidixic acid) after using more specific and sensitive assay techniques and longer sampling periods than previously.[1]

The elimination rate of nalidixic acid appears to be not markedly altered by renal impairment, but the elimination of hydroxynalidixic acid is significantly reduced. 7-Carboxynalidixic acid has appeared in the plasma of patients with renal impairment.[2] Plasma concentrations of active drug were higher and the half-life prolonged in elderly subjects.[3]

3. Barbeau G, Belanger P-M. Pharmacokinetics of nalidixic acid in old and young volunteers. *J Clin Pharmacol* 1982; **22:** 490–6.

Uses and Administration

Nalidixic acid is a 4-quinolone antibacterial used in the treatment of uncomplicated lower urinary-tract infections due to Gram-negative bacteria other than *Pseudomonas* spp. (p.199). It has also been used to treat shigellosis (bacillary dysentery) (p.173).

The usual dose is about 4 g daily in 4 divided oral doses for 7 to 14 days in acute infections, reducing thereafter to half this dose in chronic infections. Since bacterial resistance may develop rapidly it has been suggested that if treatment with nalidixic acid has not resulted in a negative urine culture within 48 hours another antimicrobial should be used.

For details of reduced doses in renal impairment, see below.

For details of doses in infants and children, see below.

Although the antibacterial activity of nalidixic acid does not appear to be influenced by urinary pH, the use of sodium bicarbonate or sodium citrate does increase the concentration of active drug in the urine. Commercial preparations containing nalidixic acid, sodium bicarbonate, and sodium citrate have been used in some countries.

It is also used with the analgesic phenazopyridine.

Administration in children. Although nalidixic acid is not generally recommended for use in patients under 18 years of age, it is licensed in both the UK and the USA for infants and children over 3 months of age. The usual oral dose is 55 to 60 mg/kg daily in 4 divided doses for at least 7 days, reducing thereafter to about 30 mg/kg daily in 4 divided doses for prolonged treatment (but see Precautions, above).

In addition, the *BNFC* suggests that a dose of 30 mg/kg daily in 2 divided doses may be given for prophylaxis of urinary-tract infections.

Administration in renal impairment. In the UK, some products of nalidixic acid have been licensed for use at half the usual dose in patients with a creatinine clearance below 20 mL/minute (the *BNFC* suggests a similar reduction in children with creatinine clearance 20 mL/minute per 1.73 m^2 or less). However, other licensed product information does not include this information and suggests that nalidixic acid should not be used in patients with severe renal impairment.

Preparations

BP 2008: Nalidixic Acid Oral Suspension; Nalidixic Acid Tablets;
USP 31: Nalidixic Acid Oral Suspension; Nalidixic Acid Tablets.

Neomycin B

Description. A mixture of 2 isomers, neomycin B ($C_{23}H_{46}N_6O_{13}$ = 614.6) and neomycin C ($C_{23}H_{46}N_6O_{13}$ = 614.6) with neomycin A (neamine, $C_{12}H_{26}N_4O_6$ = 322.4); neomycins B and C are glycoside esters of neamine and neobiosamines B and C. Framycetin (p.279) consists of neomycin B.

Neomycin Sulfate *(rINNM)*

Fradiomycin Sulfate; Neomicino sulfatas; Neomicin-szulfát; Neomisin Sülfat; Neomycin Sulphate *(BANM)*; Néomycine, sulfate de; Neomycini sulfas; Neomycinsulfat; Neomycin-sulfát; Neomycyny siarczan; Neomysiinisulfaatti; Sulfato de neomicina.

NOTE. NEO is a code approved by the BP 2008 for use on single unit doses of eye drops containing neomycin sulfate where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Neomycin Sulphate). A mixture of the sulfates of substances produced by the growth of certain selected strains of *Streptomyces fradiae*, the main component being the sulfate of neomycin B. The potency is not less than 680 units/mg, calculated with reference to the dried substance. A white or yellowish-white, hygroscopic powder. Very soluble in water; very slightly soluble in alcohol; practically insoluble in acetone. A 1% solution in water has a pH of 5.0 to 7.5. Store in airtight containers. Protect from light.

USP 31 (Neomycin Sulfate). The sulfate salt of a kind of neomycin, an antibacterial substance produced by the growth of *Streptomyces fradiae* (Streptomycetaceae), or a mixture of two or more such salts. It has a potency equivalent to not less than 600 micrograms of neomycin per mg, calculated on the dried basis. A white to slightly yellow powder, or cryodesiccated solid. It is odourless or practically so, and is hygroscopic. Soluble 1 in 1 of water; very slightly soluble in alcohol; insoluble in acetone, in chloroform, and in ether. pH of a solution in water containing the equivalent of neomycin 3.3% is between 5.0 and 7.5. Store in airtight containers. Protect from light.

Neomycin Undecenoate *(BANM)*

Neomycin Undecylenate *(USAN, rINNM)*; Néomycine, Undécylénate de; Neomycini Undecylenas; Undecilenato de neomicina. The 10-undecenoate salt of neomycin.

Неомицина Ундециленат

CAS — 1406-04-8.

ATC — A01AB08; A07AA01; B05CA09; D06AX04; J01GB05; R02AB01; S01AA03; S02AA07; S03AA01.

Adverse Effects and Treatment

As for Gentamicin Sulfate, p.282.

Neomycin has particularly potent nephrotoxic and ototoxic properties and so is generally no longer given parenterally. However, sufficient may be absorbed after use by other routes (e.g. orally, instillation into cavities or open wounds, or topical application to damaged skin), to produce irreversible partial or total deafness. The effect is dose-related and is enhanced by renal impairment. Nephrotoxic effects may also occur.

When given orally in large doses, neomycin causes nausea, vomiting, and diarrhoea. Prolonged oral use may cause a malabsorption syndrome with steatorrhoea and diarrhoea which can be very severe. Superinfection may occur, especially with prolonged treatment.

Neomycin has a neuromuscular-blocking action similar to, but stronger than, that of other aminoglycosides, and respiratory depression and arrest has followed the intraperitoneal instillation of neomycin. Fatalities have occurred.

Hypersensitivity reactions, such as rashes, pruritus, and sometimes drug fever or even anaphylaxis, during local treatment with neomycin and may be masked by the combined use of a corticosteroid. Cross-sensitivity with other aminoglycosides may occur.

Precautions

As for Gentamicin Sulfate, p.283. Parenteral use of neomycin, or its use for irrigation of wounds or serous cavities such as the peritoneum, is no longer recommended.

Neomycin is contra-indicated for intestinal disinfection when an obstruction is present, in patients with a known history of allergy to aminoglycosides, and in infants under 1 year. It should be used with great care in patients with renal or hepatic impairment, or with neuromuscular disorders, and in those with impaired hearing. The topical use of neomycin in patients with extensive skin damage or perforated tympanic membranes may result in deafness.

Prolonged local use should be avoided as it may lead to skin sensitisation and possible cross-sensitivity to other aminoglycosides.

Hypersensitivity and vaccination. Neomycin was thought to be responsible for a hypersensitivity reaction[1] in a child given measles, mumps, and rubella vaccine containing neomycin 25 micrograms. However, there is also a report of successful vaccination with measles, mumps, and rubella vaccine in a neomycin-sensitive child.[2] Although the vaccine may contain small amounts of neomycin or kanamycin, and sensitivity to either is considered a contra-indication to its use, it is only rarely necessary to withhold it once appropriate expert advice has been taken. There is little logic to intradermal testing since test solutions contain 4 to 40 times as much neomycin as the vaccine.[2]

2. Elliman D, Dhanraj B. Safe MMR vaccination despite neomycin allergy. *Lancet* 1991; **337:** 365.

Interactions

As for Gentamicin Sulfate, p.283. Absorption after oral or local use may be sufficient to produce interactions with other drugs given systemically.

Neomycin orally has been reported to impair the absorption of other drugs including phenoxymethylpenicillin, digoxin, and methotrexate; the efficacy of oral contraceptives might be reduced. The effects of acarbose may be enhanced by oral neomycin.

Antimicrobial Action

Neomycin has a mode of action and spectrum of activity similar to that of gentamicin (p.283) but it lacks activity against *Pseudomonas aeruginosa.* It is reported to be active against *Mycobacterium tuberculosis.*

Because of its extensive topical use, resistance has been reported to be relatively widespread, notably among staphylococci, and some *Salmonella*, *Shigella*, and *Escherichia coli* strains. Cross-resistance with kanamycin, framycetin, and paromomycin occurs.

Pharmacokinetics

Neomycin is poorly absorbed from the gastrointestinal tract, about 97% of an oral dose being excreted unchanged in the faeces. Doses of 3 g orally produce peak plasma concentrations of up to 4 micrograms/mL and absorption is similar after an enema. Absorption may be increased in conditions which damage or inflame the mucosa. Absorption has also been reported to occur from the peritoneum, respiratory tract, bladder, wounds, and inflamed skin.

Once neomycin is absorbed it is rapidly excreted by the kidneys in active form. It has been reported to have a half-life of 2 to 3 hours.

Uses and Administration

Neomycin is an aminoglycoside antibiotic used topically in the treatment of infections of the skin, ear, and eye due to susceptible staphylococci and other organisms. Most preparations contain the sulfate, but neomycin undecenoate is also used. Neomycin is often used with another antibacterial such as bacitracin, colistin, gramicidin, or polymyxin B. Such combinations have been used topically in the eye before ophthalmic surgery for infection prophylaxis and, with propamidine isetionate, in the treatment of acanthamoeba keratitis (p.822). A cream containing neomycin sulfate and chlorhexidine hydrochloride has been used for application to the nostrils in the treatment of staphylococcal nasal carriers (p.195) but, as with other topical antibacterial preparations, development of resistance may be a problem. Neomycin is often used with topical corticosteroids, but such preparations should be used with caution because of the risk that signs of resistant infection may be suppressed. Care must also be taken where there is skin trauma because of the risk of increased absorption and toxicity (see Adverse Effects, above). For details of bacterial skin infections and their treatment, see p.194.

Because neomycin sulfate is poorly absorbed from the gastrointestinal tract, it has been given orally for bowel preparation before abdominal surgery, often with erythromycin (p.195). Neomycin sulfate is also used with other antibacterials and antifungals in the selective decontamination of the digestive tract in patients in intensive care (p.175).

Neomycin is rarely used in the treatment of existing gastrointestinal infections. Although it has been used in the treatment of diarrhoea due to infection with enteropathogenic *Escherichia coli* (EPEC) (p.173), the use of neomycin in children with acute diarrhoea is generally not recommended.

Neomycin sulfate may be given orally to patients with incipient hepatic encephalopathy (p.1697) to reduce the flora of the gastrointestinal tract.

Neomycin has lipid regulating properties and has occasionally been given orally in the treatment of hyperlipidaemias (see below). It has also been used for the irrigation of wounds and body cavities but such use is no longer recommended because of the risk of toxicity.

Administration and dosage. For pre-operative use, 1 g of neomycin sulfate has been given hourly for 4 hours and then every 4 hours for 2 or 3 days before surgery; suggested doses in children, given every 4 hours, are 1 g in those aged over 12 years and 250 to 500 mg in those aged 6 to 12 years.

As an adjunct in the management of hepatic encephalopathy, 4 to 12 g may be given daily in divided doses, usually for 5 to 7 days; children may be given 50 to 100 mg/kg daily in divided doses. Prolonged use may cause malabsorption.

Topical preparations typically contain the equivalent of 0.35% neomycin base.

Neomycin hydrochloride has also been used.

Hyperlipidaemias. Neomycin has been given in doses of up to 2 g daily by mouth in the treatment of hypercholesterolaemia (p.1169). It is thought to reduce intestinal absorption of cholesterol through its action on microbial flora, resulting in greater catabolism of low-density lipoproteins in the body.[1] However, more effective and safer drugs are preferred.

Netilmicin Sulfate *(USAN, rINNM)*

N[1]-Ethylsissomicin; Netilmicin Sulphate *(BANM)*; Nétilmicine, sulfate de; Netilmicini sulfas; Netilmicino sulfatas; Netilmicinsulfat; Netilmicin-sulfát; Netilmicin-szulfát; Netilmisiinisulfaatti; Netilmisin sülfat; Netylmycyny siarczan; Sch-20569; Sulfato de netilmicina. 4-*O*-[(2*R*,3*R*)-*cis*-3-Amino-6-aminomethyl-3,4-dihydro-2*H*-pyran-2-yl]-2-deoxy-6-*O*-(3-deoxy-4-*C*-methyl-3-methylamino-β-L-arabinopyranosyl)-1-*N*-ethylstreptamine sulphate.

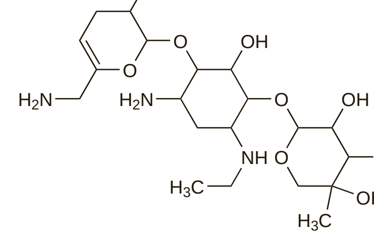
Нетилмицина Сульфат

$(C_{21}H_{41}N_5O_7)_2,5H_2SO_4 = 1441.6.$

CAS — 56391-56-1 (netilmicin); 56391-57-2 (netilmicin sulfate).

ATC — J01GB07; S01AA23.

ATC Vet — QJ01GB07; QS01AA23.



(netilmicin)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn*, and *US*.

Ph. Eur. 6.2 (Netilmicin Sulphate). A substance obtained by synthesis from sisomicin. The potency is not less than 650 units/mg, calculated with reference to the dried substance. A white or yellowish-white, very hygroscopic, powder. Very soluble in water; practically insoluble in alcohol and in acetone. A 4% solution in water has a pH of 3.5 to 5.5. Store in airtight containers. Protect from light.

USP 31 (Netilmicin Sulfate). The potency is equivalent to not less than 595 micrograms of netilmicin per milligram, calculated on the dried basis. A white to pale yellowish-white powder. Freely soluble in water; practically insoluble in dehydrated alcohol and in ether. pH of a solution in water containing the equivalent of netilmicin 4% is between 3.5 and 5.5. Store in airtight containers. Protect from moisture.

Incompatibility. For discussion of the incompatibility of aminoglycosides, including netilmicin, with beta lactams, see under Gentamicin Sulfate, p.282. Netilmicin is also reported to be incompatible with furosemide, heparin, and vitamin B complex.

Adverse Effects, Treatment, and Precautions

As for Gentamicin Sulfate, p.282. Some studies suggest that netilmicin is less nephrotoxic and ototoxic than gentamicin or tobramycin, although others have not found any significant differences in their toxicity.

It has been suggested that peak plasma concentrations of netilmicin should not exceed 12 micrograms/mL for prolonged therapy, and troughs should be below 2 micrograms/mL.

Effects on the cardiovascular system. Severe hypotension was associated with netilmicin in a patient undergoing artificial ventilation.[1] Hypotensive episodes were of short duration and coincided with netilmicin injection. They almost disappeared when sedation was stopped.

1. Rygnestad T. Severe hypotension associated with netilmicin treatment. *BMJ* 1997; **315:** 31.

Interactions

As for Gentamicin Sulfate, p.283.

Antimicrobial Action

As for Gentamicin Sulfate, p.283. It is active against a similar range of organisms although it is also reported to have some activity against *Nocardia*. It may be somewhat less effective against *Pseudomonas aeruginosa*. It is not degraded by all of the enzymes responsible for aminoglycoside resistance, and may be active against some strains resistant to gentamicin or tobramycin, but this is less marked than with amikacin: for example, gentamicin-resistant *Providencia*, *Pseudomonas*, and *Serratia* are usually also netilmicin-resistant. Between about 5 and 20% of Gram-negative isolates are reported to be resistant to netilmicin.

Pharmacokinetics

As for Gentamicin Sulfate, p.284.

After intramuscular injection of netilmicin, peak plasma concentrations are achieved within 0.5 to 1 hour, and concentrations of about 7 micrograms/mL have been reported following doses of 2 mg/kg; similar concentrations are obtained after intravenous infusion of the same dose over 1 hour. Peak concentrations after rapid intravenous injection may transiently be 2 or 3 times higher than those following infusion. Standard, once-daily doses may produce transient peak concentrations of 20 to 30 micrograms/mL. In multiple dosing studies, netilmicin in usual doses every 12 hours produced steady-state concentrations on the second day which were less than 20% higher than those seen after the first dose.

The half-life of netilmicin is usually 2.0 to 2.5 hours. About 80% of a dose is excreted in the urine within 24 hours.

Uses and Administration

Netilmicin is a semisynthetic aminoglycoside antibiotic with actions and uses similar to those of gentamicin (p.284). It may be used as an alternative to amikacin (p.201) in the treatment of infections caused by susceptible bacteria that are resistant to gentamicin and tobramycin. As with gentamicin, netilmicin may be used with penicillins and with cephalosporins; the injections should be given separately.

Netilmicin is given as the sulfate but doses are expressed in terms of the equivalent amount of base; 1.5 g of netilmicin sulfate is equivalent to about 1 g of netilmicin. It is usually given intramuscularly in doses of 4 to 6 mg/kg daily as a single dose; alternatively, it may be given in equally divided doses every 8 or 12 hours; for the control of life-threatening infections, up to 7.5 mg/kg may be given daily in divided doses every 8 hours for short periods. In the management of urinary-tract infections, a single daily dose of 150 mg for 5 days may be given; for complicated urinary-tract infections, 3 to 4 mg/kg daily in divided doses every 12 hours has been given. A single dose of 300 mg has been licensed for gonorrhoea (p.191).

The same doses may be given by slow intravenous injection over 3 to 5 minutes or infused intravenously over 0.5 to 2 hours in 50 to 200 mL of infusion fluid; proportionately less fluid should be given to children.

Treatment with netilmicin is usually given for 7 to 14 days. Peak plasma concentrations below 12 micrograms/mL and troughs below 2 micrograms/mL have been recommended for divided daily dose regimens.

Dosage recommendations in infants and children vary somewhat. One regimen is 7.5 to 9 mg/kg daily in infants and neonates older than 1 week, and 6 to 7.5 mg/kg daily in older children, both given in divided doses every 8 hours. Premature infants and neonates less than 1 week old may be given 6 mg/kg daily in divided doses every 12 hours. An alternative regimen is 4 to 6.5 mg/kg daily in neonates less than 6 weeks of age, in divided doses every 12 hours, and 5.5 to 8 mg/kg daily in divided doses every 8 or 12 hours in older infants and children.

Dosage should be adjusted in all patients according to plasma-netilmicin concentrations, and this is particularly important where factors such as age, renal impairment, or prolonged therapy may predispose to toxicity, or where there is a risk of subtherapeutic concentrations. For discussion of the methods of calculating aminoglycoside dosage requirements, see Administration and Dosage, under Gentamicin, p.284.

Preparations

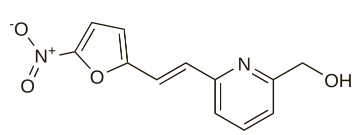
Nifurpirinol *(USAN, rINN)*

Furpirinol; Nifurpirinolum; P-7138.

Нифурпиринол

$C_{12}H_{10}N_2O_4$ = 246.2.

CAS — 13411-16-0.



Profile

Nifurpirinol is a nitrofuran antimicrobial used in veterinary medicine for the treatment of bacterial and fungal infections in ornamental fish.

Nifurtoinol *(rINN)*

Hydroxymethylnitrofurantoin; Nifurtoïnol; Nifurtoinolum. 3-Hydroxymethyl-1-(5-nitrofurfurylideneamino)hydantoin.

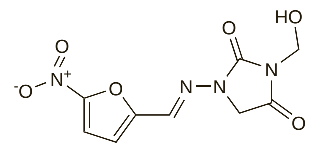
Нифуртоинол

$C_9H_8N_4O_6$ = 268.2.

CAS — 1088-92-2.

ATC — J01XE02.

ATC Vet — QJ01XE02.



Profile

Nifurtoinol is a nitrofuran antibacterial with properties similar to those of nitrofurantoin (below) and is used in the treatment of urinary-tract infections. It is given orally in doses of up to 300 mg daily in divided doses.

Preparations

Proprietary Preparations (details are given in Part 3)

Belg.: Urfadyn PL.

Nifurzide *(rINN)*

Nifurzida; Nifurzidum. 5-Nitro-2-thiophenecarboxylic acid [3-(5-nitro-2-furyl)allylidene]hydrazide.

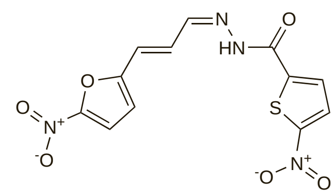
Нифурзид

$C_{12}H_8N_4O_6S$ = 336.3.

CAS — 39978-42-2.

ATC — A07AX04.

ATC Vet — QA07AX04.



Profile

Nifurzide is an antibacterial that is poorly absorbed from the gastrointestinal tract. It has been given orally in the treatment of diarrhoea.

Preparations

Proprietary Preparations (details are given in Part 3)

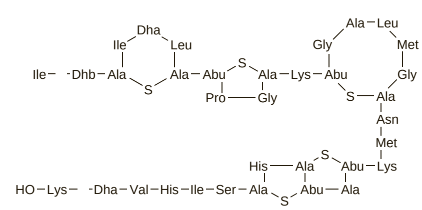
Fr.: Ricridene†.

Nisin

E234; Nisina.

Низин

CAS — 1414-45-5.



Abu = α-aminobutyric acid
Dha = dehydroalanine
Dhb = dehydrobutyrine

Profile

Nisin is a polypeptide antibacterial produced by *Lactococcus lactis* (*Streptococcus lactis*). It is used as a food preservative.

It has been investigated for the treatment of various infections, including those caused by *Helicobacter pylori* and *Clostridium difficile*.

Nitrofurantoin *(BAN, rINN)*

Furadoninum; Nitrofurantoiini; Nitrofurantoína; Nitrofurantoina; Nitrofurantoinas; Nitrofurantoïne; Nitrofurantoinum. 1-(5-Nitrofurfurylideneamino)hydantoin; 1-(5-Nitrofurfurylideneamino)imidazolidine-2,4-dione.

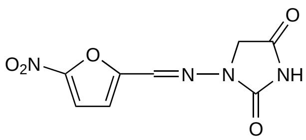
Нитрофурантоин

$C_8H_6N_4O_5$ = 238.2.

CAS — 67-20-9 (anhydrous nitrofurantoin); 17140-81-7 (nitrofurantoin monohydrate).

ATC — J01XE01.

ATC Vet — QJ01XE01.



Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).
Int. and *US* specify anhydrous or monohydrate.

Ph. Eur. 6.2 (Nitrofurantoin). A yellow, odourless or almost odourless, crystalline powder or crystals. Very slightly soluble in water and in alcohol; soluble in dimethylformamide. Store at a temperature not exceeding 25°. Protect from light.

USP 31 (Nitrofurantoin). It is anhydrous or contains one molecule of water of hydration. Lemon-yellow, odourless crystals or fine powder. Nitrofurantoin and its solutions are discoloured by alkalis and by exposure to light, and are decomposed on contact with metals other than stainless steel or aluminium. Very slightly soluble in water and in alcohol; soluble in dimethylformamide. Store in airtight containers. Protect from light.

Adverse Effects

The estimated incidence of adverse effects with nitrofurantoin has varied enormously, but may be around 10% overall; an incidence of serious reactions of about 0.001% for pulmonary, and 0.0007% for neurological reactions has been suggested. The most common adverse effects of nitrofurantoin involve the gastrointestinal tract. They are dose-related and generally include nausea, vomiting, and anorexia; abdominal pain and diarrhoea occur less frequently. It has been reported that adverse effects on the gastrointestinal tract are less common when nitrofurantoin is given in a macrocrystalline form or with food.

Neurological adverse effects include headache, drowsiness, vertigo, dizziness, nystagmus, and benign intracranial hypertension. Severe and sometimes irreversible peripheral neuropathy has developed, particularly in patients with renal impairment and in those given prolonged therapy.

Hypersensitivity reactions such as skin rashes, urticaria, pruritus, fever, sialadenitis, and angioedema may occur. Anaphylaxis, erythema multiforme, Stevens-Johnson syndrome, exfoliative dermatitis, pancreatitis, a lupus-like syndrome, myalgia, and arthralgia have also been reported. Patients with a history of asthma may experience acute asthmatic attacks.

Acute pulmonary sensitivity reactions characterised by sudden onset of fever, chills, eosinophilia, cough, chest pain, dyspnoea, pulmonary infiltration or consolidation, and pleural effusion may occur within hours to a few days of beginning therapy, but they usually resolve on stopping treatment.

Subacute or chronic pulmonary symptoms including interstitial pneumonitis and pulmonary fibrosis may develop more insidiously in patients on long-term therapy and the latter are not always reversible, particularly if therapy is continued after onset of symptoms.

Hepatotoxicity including cholestatic jaundice, hepatitis, and hepatic necrosis may develop rarely, particularly in women, and may represent a hypersensitivity reaction. Other adverse effects include megaloblastic anaemia, leucopenia, granulocytopenia or agranulocytosis, thrombocytopenia, aplastic anaemia, and haemolytic anaemia in persons with a genetic G6PD deficiency. Transient alopecia has been reported.

Nitrofurantoin may cause a brownish discoloration of the urine.

There is limited evidence from *animal* studies that nitrofurantoin may be carcinogenic, although this has not been shown conclusively in humans.

Precautions

Nitrofurantoin should not be given to patients with renal impairment since antibacterial concentrations in the urine may not be attained and toxic concentrations in the plasma can occur. Nitrofurantoin is also contra-indicated in patients known to be hypersensitive to nitrofurans, in those with G6PD deficiency, and in infants (in the UK it is contra-indicated below 3 months of age, though the USA permits use from 1 month old).

Nitrofurantoin should be used with care in the elderly, who may be at increased risk of toxicity, particularly acute pulmonary reactions. All patients undergoing prolonged therapy should be monitored for changes in pulmonary function, and the drug withdrawn at the first signs of pulmonary damage. Care is required in patients with pre-existing pulmonary, hepatic, neurological, or allergic disorders, and in those with conditions (such as anaemia, diabetes mellitus, electrolyte imbalance, debility, or vitamin B deficiency) which may predispose to peripheral neuropathy. Nitrofurantoin should be withdrawn if signs of peripheral neuropathy develop. Although hepatic reactions such as hepatitis, cholestatic jaundice, and hepatic necrosis rarely occur, fatalities have been reported. Patients should be monitored, and the drug stopped immediately if hepatitis occurs.

Nitrofurantoin may cause false positive reactions in urine tests for glucose using copper reduction methods.

Breast feeding. The American Academy of Pediatrics considers that, although nitrofurantoin is excreted into breast milk, it is usually compatible with breast feeding, but caution is necessary in breast-fed infants with G6PD deficiency.[1] The *BNFC* suggests that the amount ingested may be enough to produce haemolysis in G6PD-deficient infants; it recommends that nitrofurantoin should be avoided in mothers who are breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 11/01/08)

Porphyria. Nitrofurantoin has been associated with acute attacks of porphyria and is considered to be unsafe in porphyric patients.

Pregnancy. Licensed product information contraindicates the use of nitrofurantoin in pregnant patients at term (38 to 42 weeks' of gestation), or during labour and delivery, because of the possibility of producing haemolytic anaemia in the neonate.

Interactions

Nitrofurantoin and the quinolone antibacterials are antagonistic *in vitro* but the clinical significance is unknown. The antibacterial activity of nitrofurantoin may be decreased in the presence of carbonic anhydrase inhibitors and other drugs that alkalinise the urine.

Probenecid or sulfinpyrazone should not be given with nitrofurantoin as they may reduce its excretion. Magnesium trisilicate may reduce the absorption of nitrofurantoin but it is not clear whether this applies to other antacids.

Antiepileptics. For reference to the effect of nitrofurantoin on *phenytoin*, see p.498.

Antifungals. An elderly patient who had been taking nitrofurantoin daily for 5 years developed combined hepatic and pulmonary toxicity 2 months after also starting *fluconazole* therapy.[1] Although either drug may have caused the hepatic toxicity, possible pharmacokinetic changes induced by an interaction with fluconazole may have precipitated the nitrofurantoin-induced pulmonary toxicity.

1. Linnebur SA, Parnes BL. Pulmonary and hepatic toxicity due to nitrofurantoin and fluconazole treatment. *Ann Pharmacother* 2004; **38:** 612–16.

Hormonal contraceptives. For mention of a possible decrease in contraceptive efficacy when nitrofurantoin was used with oral contraceptives, see under Hormonal Contraceptives, p.2068.

Antimicrobial Action

Nitrofurantoin is bactericidal *in vitro* to most Gram-positive and Gram-negative urinary-tract pathogens. The mode of action is uncertain but appears to depend on the formation of reactive intermediates by reduction; this process occurs more efficiently in bacterial than in mammalian cells.

It is effective against the enterococci *in vitro*, as well as various other Gram-positive species including staphylococci, streptococci, and corynebacteria, although this is of little clinical significance. Most strains of *Escherichia coli* are particularly sensitive to nitrofurantoin but *Enterobacter* and *Klebsiella* spp. are less susceptible and some may be resistant. *Pseudomonas aeruginosa* is resistant as are most strains of *Proteus* spp.

Nitrofurantoin is most active in acid urine, and if the pH exceeds 8 most of the antibacterial activity is lost. Resistance rarely develops during nitrofurantoin treatment but may occur during prolonged treatment. Plasmid-encoded resistance has been reported in *E. coli*. Resistance may be due to the loss of nitrofuran reductases which generate the active intermediates.

Pharmacokinetics

Nitrofurantoin is readily absorbed from the gastrointestinal tract. The absorption rate is dependent on crystal size. The macrocrystalline form has slower dissolution and absorption rates, produces lower serum concentrations than the microcrystalline form, and takes longer to achieve peak concentrations in the urine. The presence of food in the gastrointestinal tract may increase the bioavailability of nitrofurantoin and prolong the duration of therapeutic urinary concentrations. Preparations of nitrofurantoin from different sources may not be bioequivalent, and care may be necessary if changing from one brand to another.

On absorption, concentrations in blood and body tissues are low because of rapid elimination, and antibacterial concentrations are not achieved. Nitrofurantoin crosses the placenta and the blood-brain barrier and traces have been detected in breast milk. There is some disagreement about the degree of protein binding, and although figures of up to about 60% are quoted by some sources, others suggest that the figure should be as much as 90%. The plasma half-life is reported to range from 0.3 to 1 hour.

Nitrofurantoin is metabolised in the liver and most body tissues while about 30 to 40% of a dose is excreted rapidly in the urine as unchanged nitrofurantoin. Some tubular reabsorption may occur in acid urine. Average doses give a concentration of 50 to 200 micrograms/mL in the urine in patients with normal renal function.

Uses and Administration

Nitrofurantoin is a nitrofuran antibacterial that is used in the treatment of uncomplicated lower urinary-tract infections (p.199), including prophylaxis or long-term suppressive therapy in recurrent infection.

It is given orally, in a usual dose of 50 to 100 mg four times daily, with food or milk. Treatment is usually continued for 7 days. A dual-release formulation, consisting of macrocrystalline nitrofurantoin and nitrofurantoin monohydrate, is available in some countries and is given in a dose of 100 mg twice daily. A usual long-term prophylactic dose is 50 to 100 mg at bedtime.

For details of doses in children, see below.

◊ Reviews.

1. Guay DR. An update on the role of nitrofurans in the management of urinary tract infections. *Drugs* 2001; **61:** 353–64.

Administration in children. In the UK, nitrofurantoin may be given to children aged 3 months to 12 years for the *treatment* of urinary-tract infection in a usual oral dose of 3 mg/kg daily given in 4 divided doses; 1 mg/kg may be given at night for long-term *prophylactic* therapy. However, a systematic review[1] concluded, on the basis of the rather low-grade evidence available, that the adverse effects of nitrofurantoin may outweigh its benefits and render it unacceptable for long-term therapy.

Higher oral doses of 5 to 7 mg/kg daily in 4 divided doses are recommended for the *treatment* of urinary-tract infection in the USA in children aged 1 month and above; for long-term *prophylactic* therapy 1 mg/kg daily given in one or two divided doses is considered adequate.

Older children may be given usual adult doses (see above).

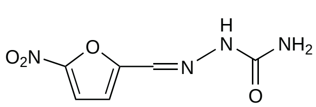
Nitrofurazone *(BAN)*

Nitrofural *(pINN)*; Furacilinum; Nitrofuraali; Nitrofurál; Nitrofuralis; Nitrofuralum; Nitrofuratsoni; Nitrofurazon; Nitrofurazonum. 5-Nitro-2-furaldehyde semicarbazone.

Нитрофурал

$C_6H_6N_4O_4$ = 198.1.
CAS — 59-87-0.
ATC — B05CA03; D08AF01; D09AA03; P01CC02; S01AX04; S02AA02.
ATC Vet — QB05CA03; QD08AF01; QD09AA03; QG01AX90; QP51AC02; QS01AX04; QS02AA02.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Nitrofural; Nitrofurazone BP 2008). A yellow or brownish-yellow, crystalline powder. Very slightly soluble in water; slightly soluble in alcohol. The filtrate from a 1% suspension in water has a pH of 5.0 to 7.0. Protect from light.

USP 31 (Nitrofurazone). A lemon-yellow, odourless crystalline powder. It darkens slowly on exposure to light. Soluble 1 in 4200 of water, 1 in 590 of alcohol, and 1 in 350 of propylene glycol; practically insoluble in chloroform and in ether; soluble in dimethylformamide; slightly soluble in polyethylene glycol mixtures. The filtrate from a 1% suspension in water has a pH of 5.0 to 7.5. Store in airtight containers at a temperature not exceeding 40°. Protect from light.

Sterilisation. Autoclaving gauze dressings impregnated with nitrofurazone, as recommended by the US manufacturer, resulted in a greater than 10% loss of the drug.[1] Since the spectroscopic assay used may not distinguish between nitrofurazone and some of its degradation products, the degree of degradation may have been greater than this.

1. Phillips C, Fisher E. Effect of autoclaving on stability of nitrofurazone soluble dressing. *Am J Health-Syst Pharm* 1996; **53:** 1169–71.

Adverse Effects

Sensitisation and generalised allergic skin reactions may be produced by topical nitrofurazone.

Nitrofurazone is a toxic drug when given orally and serious adverse effects include severe peripheral neuropathy; haemolysis may occur in patients with G6PD deficiency. Nitrofurazone in high oral doses is carcinogenic in *rats.*

Precautions

Nitrofurazone is contra-indicated in patients with known hypersensitivity. Preparations containing macrogols should be used with caution in patients with renal impairment since macrogols can be absorbed and their accumulation in such patients may result in symptoms of further impairment.

Oral nitrofurazone should be used with caution in patients with G6PD deficiency because of the risk of haemolysis.

Antimicrobial Action

Nitrofurazone is a nitrofuran derivative with a broad spectrum of antibacterial activity, but with little activity against *Pseudomonas* spp. It also has antitrypanosomal activity.

Uses and Administration

Nitrofurazone is a nitrofuran derivative that is used topically for wounds, burns, ulcers, and skin infections, and for the preparation of surfaces before skin grafting. It is usually applied in a concentration of 0.2% in a water-soluble or water-miscible basis. A solution of nitrofurazone is used for bladder irrigation.

Urinary catheters impregnated with nitrofurazone, to reduce bacterial colonisation and infection, are available in some countries.

Preparations

USP 31: Nitrofurazone Ointment; Nitrofurazone Topical Solution.

Proprietary Preparations (details are given in Part 3)

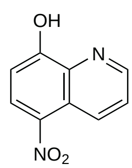
Nitroxoline *(BAN, pINN)*

Nitroxolina; Nitroxolinum. 5-Nitroquinolin-8-ol.

Нитроксолин

$C_9H_6N_2O_3$ = 190.2.
CAS — 4008-48-4.
ATC — J01XX07.
ATC Vet — QJ01XX07.



Profile

Nitroxoline has antibacterial and antifungal properties and is used in the treatment of urinary-tract infections in oral doses ranging from 80 to 250 mg three times daily before food. It has also been given with sulfamethizole.

Preparations

Proprietary Preparations (details are given in Part 3)
Fr.: Nibiol†; ***Ger.:*** Cysto-Saar; ***Rus.:*** 5-Nitrox (5-Нитрокс); 5-Nok (5-Нок); ***S.Afr.:*** Nicene N.

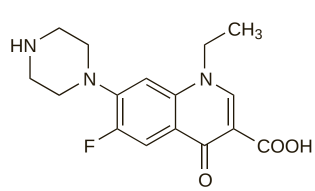
Multi-ingredient: ***Braz.:*** Minazol.

Norfloxacin *(BAN, USAN, rINN)*

AM-715; *N*-Desmethylpefloxacin; MK-366; Norfloksacinas; Norfloksacyna; Norfloksasiini; Norfloksasin; Norfloxacine; Norfloxacino; Norfloxacinum. 1-Ethyl-6-fluoro-1,4-dihydro-4-oxo-7-(piperazin-1-yl)quinoline-3-carboxylic acid.

Норфлоксацин

$C_{16}H_{18}FN_3O_3$ = 319.3.
CAS — 70458-96-7.
ATC — J01MA06; S01AX12.
ATC Vet — QJ01MA06; QS01AX12.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Norfloxacin). A white or pale yellow, hygroscopic, photosensitive, crystalline powder. Very slightly soluble in water; slightly soluble in alcohol and in acetone. Store in airtight containers. Protect from light.

USP 31 (Norfloxacin). A white to pale yellow crystalline powder. Slightly soluble in water, in alcohol, and in acetone; freely soluble in acetic acid; sparingly soluble in chloroform; practically insoluble in ether; very slightly soluble in ethyl acetate and in methyl alcohol. Store in airtight containers. Protect from light.

Norfloxacin Pivoxil *(BANM, rINNM)*

Norfloxacine, Pivoxil de; Norfloxacini Pivoxil; Norfloxacino pivoxilo. Pivaloyloxymethyl 1-ethyl-6-fluoro-1,4-dihydro-4-oxo-7-(piperazin-1-yl)quinoline-3-carboxylic acid.

Норфлоксацина Пивоксил

$C_{22}H_{28}FN_3O_5$ = 433.5.

Adverse Effects and Precautions

As for Ciprofloxacin, p.244.

Interactions

As for Ciprofloxacin, p.246.

Antimicrobial Action

As for Ciprofloxacin, p.246, although norfloxacin is less potent *in vitro.* Norfloxacin is not active against Chlamydiaceae, mycoplasmas, or mycobacteria.

Pharmacokinetics

About 30 to 40% of an oral dose of norfloxacin is absorbed. Peak plasma concentrations of about 1.5 micrograms/mL occur about 1 to 2 hours after a 400-mg oral dose; the presence of food can delay absorption. Norfloxacin is about 14% bound to plasma proteins. It is probably widely distributed, but information is limited. Norfloxacin penetrates well into tissues of the genito-urinary tract. It crosses the placenta. Relatively high concentrations are achieved in bile.

The plasma half-life is 3 to 4 hours and may be prolonged in renal impairment; a value of 6.5 hours or more has been reported when creatinine clearance is below 30 mL/minute per 1.73 m^2. About 30% of a dose is excreted unchanged in the urine within 24 hours, producing high urinary concentrations; norfloxacin is least soluble at a urinary pH of 7.5. Urinary excretion is by tubular secretion and glomerular filtration and is reduced by probenecid, although plasma concentrations of norfloxacin are not generally affected. Some metabolism occurs, possibly in the liver, and several metabolites have been identified in urine, some with antibacterial activity. About 30% of an oral dose is recovered from the faeces.

Uses and Administration

Norfloxacin is a fluoroquinolone antibacterial with properties similar to those of ciprofloxacin (p.243), but it is generally less potent *in vitro.*

Norfloxacin is used mainly in the treatment of urinary-tract infections (p.199) and for the treatment of gonorrhoea (p.191).

Norfloxacin is given orally at least 1 hour before, or 2 hours after, food or milk.

In urinary-tract infections the usual dose is 400 mg twice daily for 3 to 10 days. Treatment may need to be continued for up to 12 weeks in chronic relapsing urinary-tract infections; it may be possible to reduce the dose to 400 mg once daily if there is an adequate response within the first 4 weeks. A 28-day course of treatment with a dose of 400 mg twice daily should be given for acute or chronic bacterial prostatitis.

For details of reduced doses to be used in renal impairment, see below.

A single oral dose of 800 mg is given in the treatment of uncomplicated gonorrhoea.

Eye drops containing 0.3% of norfloxacin are used to treat eye infections.

The pivaloyloxymethyl salt of norfloxacin, norfloxacin pivoxil, is also used in some countries.

Administration in renal impairment. Doses of norfloxacin may need to be reduced in renal impairment; for urinary-tract infections, 400 mg once daily should be given to patients with a creatinine clearance of 30 mL/minute per 1.73 m^2 or less.

Preparations

BP 2008: Norfloxacin Eye Drops; Norfloxacin Tablets;
USP 31: Norfloxacin Ophthalmic Solution; Norfloxacin Tablets.

Proprietary Preparations (details are given in Part 3)

Norvancomycin Hydrochloride

N-Demethylvancomycin; 56-Demethylvancomycin. (S_a)-(3*S*,6*R*,7*R*,22*R*,23*S*,26*S*,36*R*,38a*R*)-44-{[2-*O*-(3-Amino-2,3,6-trideoxy-3-*C*-methyl-α-L-*lyxo*-hexopyranosyl)-β-D-glucopyranosyl]oxy}-3-(carbamoylmethyl)-10,19-dichloro-2,3,4,5,6,7,23,24,25,26,36,37,38,38a-tetradecahydro-7,22,28,30,32-pentahydroxy-6-[(2*R*)-4-methyl-2-(amino)valeramido]-2,5,24,38,39-pentaoxo-22*H*-8,11:18,21-dietheno-23,36-(iminomethano)-13,16:31,35-dimetheno-1*H*,16*H*-[1,6,9]oxadiazacyclohexadecino[4,5-*m*][10,2,16]-benzoxadiazacyclotetracosine-26-carboxylic acid, monohydrochloride.

$C_{65}H_{73}Cl_2N_9O_{24}$, HCl = 1471.7.
CAS — 91700-98-0 (norvancomycin).

Pharmacopoeias. In *Chin.*

Profile

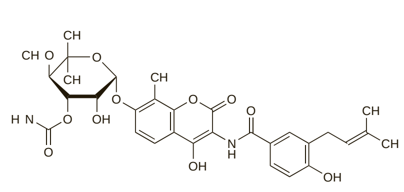
Norvancomycin is a glycopeptide antibacterial with properties similar to those of vancomycin (p.358).

Novobiocin *(BAN, rINN)*

Crystallinic Acid; Novobiocina; Novobiocine; Novobiocinum; Novobiosiini; Novobiosin; PA-93; Streptonivicin; U-6591. 4-Hydroxy-3-[4-hydroxy-3-(3-methylbut-2-enyl)benzamido]-8-methylcoumarin-7-yl 3-*O*-carbamoyl-5,5-di-*C*-methyl-α-L-lyxofuranoside.

Новобиоцин

$C_{31}H_{36}N_2O_{11}$ = 612.6.
CAS — 303-81-1.



Description. Novobiocin is an antimicrobial substance produced by the growth of *Streptomyces niveus* and *S. spheroides* or related organisms.

Novobiocin Calcium *(BANM, rINNM)*

Calcii Novobiocinum; Calcium Novobiocin; Novobiocina cálcica; Novobiocine Calcique; Novobiocinum Calcium.

Кальций Новобиоцин

$(C_{31}H_{35}N_2O_{11})_2Ca$ = 1263.3.
CAS — 4309-70-0.

Novobiocin Sodium *(BANM, rINNM)*

Natrii Novobiocinum; Novobiocina sódica; Novobiocine Sodique; Novobiocinum Natricum; Sodium Novobiocin.

Натрий Новобиоцин

$C_{31}H_{35}N_2NaO_{11}$ = 634.6.
CAS — 1476-53-5.

Pharmacopoeias. In *Fr.* and *US.*

USP 31 (Novobiocin Sodium). A white or yellowish-white, odourless, hygroscopic crystalline powder. Freely soluble in water, in alcohol, in methyl alcohol, in glycerol, and in propylene glycol; practically insoluble in acetone, in chloroform, and in ether; slightly soluble in butyl acetate. pH of a 2.5% solution in water is between 6.5 and 8.5. Store in airtight containers.

Profile

Novobiocin is an antibacterial which is structurally related to coumarin. It is active against Gram-positive bacteria such as *Staphylococcus aureus* (including meticillin-resistant strains) and other staphylococci; *Enterococcus faecalis* is usually resistant but *E. faecium* may be sensitive. Some Gram-negative organisms including *Haemophilus influenzae* and *Neisseria* spp. are also susceptible, as are some strains of *Proteus*, but most of the Enterobacteriaceae are resistant. Its action is primarily bacteriostatic, although it may be bactericidal against more sensitive species at high concentrations. It is an inhibitor of DNA gyrase and is effective in eliminating plasmids, but resistance to novobiocin develops readily *in vitro* and during therapy.

Although novobiocin has been used alone or with other drugs such as rifampicin or sodium fusidate in the treatment of infections due to staphylococci and other susceptible organisms, it has been largely superseded by other drugs because of the problems of resistance and toxicity.

Novobiocin is a potent sensitiser and hypersensitivity reactions are relatively common; they include rashes, fever, and pruritus, and more serious reactions such as Stevens-Johnson syndrome and pneumonitis. Jaundice and liver damage have occurred, although apparent jaundice may be due to a yellow metabolite of the drug rather than hyperbilirubinaemia. Other adverse effects include eosinophilia, leucopenia, thrombocytopenia, agranulocytosis, and haemolytic anaemia; gastrointestinal disturbances are common.

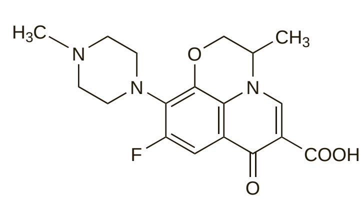
Porphyria. Novobiocin has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Ofloxacin *(BAN, USAN, rINN)*

DL-8280; Hoe-280; Ofloksacinas; Ofloksasiini; Ofloksasin; Ofloxacine; Ofloxacino; Ofloxacinum; RU-43280. (±)-9-Fluoro-2,3-dihydro-3-methyl-10-(4-methyl-1-piperazinyl)-7-oxo-7*H*-pyrido[1,2,3-de]-1,4-benzoxazine-6-carboxylic acid.

Офлоксацин

$C_{18}H_{20}FN_3O_4$ = 361.4.
CAS — 82419-36-1; 83380-47-6.
ATC — J01MA01; S01AX11.
ATC Vet — QJ01MA01; QS01AX11.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Ofloxacin). A pale yellow or bright yellow crystalline powder. Slightly soluble in water and in methyl alcohol; slightly soluble to soluble in dichloromethane; soluble in glacial acetic acid. Store in airtight containers. Protect from light.

USP 31 (Ofloxacin). Pale yellowish-white to light yellowish-white crystals or crystalline powder. Slightly soluble in water, in alcohol, and in methyl alcohol; sparingly soluble in chloroform. Store at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Ofloxacin Hydrochloride *(BANM, rINNM)*

Hidrocloruro de ofloxacino; Ofloxacine, Chlorhydrate d'; Ofloxacini Hydrochloridum.

Офлоксацина Гидрохлорид

$C_{18}H_{20}FN_3O_4$,HCl = 397.8.

Adverse Effects and Precautions

As for Ciprofloxacin, p.244.

Symptomatic hyperglycaemia and/or hypoglycaemia have been reported, usually in diabetics who are also taking hypoglycaemics or insulin. Such patients should have their blood-glucose concentrations closely monitored and if signs or symptoms of glucose disturbances develop, ofloxacin should be stopped.

A reduction in blood pressure may occur rarely after intravenous infusion. Similarly, sudden reductions in blood pressure may occur when intravenous ofloxacin is given with hypotensive drugs. Cardiovascular function should be monitored in such patients and in those also receiving barbiturate anaesthetics.

Certain medications may also increase these risks (see Interactions, below).

Breast feeding. The American Academy of Pediatrics has stated that no adverse effects have been seen in breast-fed infants whose mothers were receiving ofloxacin and that it is therefore usually compatible with breast feeding.[1] However, in a study[2] of 10 women given ofloxacin after termination of pregnancy, drug concentrations in breast milk were sufficiently high to recommend that the use of ofloxacin in lactating women should be avoided.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 27/05/04)
2. Giamarellou H, *et al.* Pharmacokinetics of three newer quinolones in pregnant and lactating women. *Am J Med* 1989; **87** (suppl 5A): 49S–51S.

Interactions

As for Ciprofloxacin, p.246.

Use with drugs that alter blood-glucose concentrations with ofloxacin increases the risk of blood-glucose disturbances.

Antimicrobial Action

As for Ciprofloxacin, p.246.

Ofloxacin is more active than ciprofloxacin against *Chlamydia trachomatis*. It is also active against *Mycobacterium leprae* as well as *M. tuberculosis* and some other *Mycobacterium* spp. Synergistic activity against *M. leprae* has been reported between ofloxacin and rifabutin.

The optically active *S*-(−)-isomer levofloxacin (p.292) has twice the activity of the racemate ofloxacin.

Resistance has been reported in some strains of *Neisseria gonorrhoeae*.

Pharmacokinetics

Ofloxacin is rapidly and well absorbed from the gastrointestinal tract. Oral bioavailability is almost 100% and a peak plasma concentration of about 3 to 5 micrograms/mL occurs 1 to 2 hours after an oral dose of 400 mg. Absorption may be delayed by the presence of food, but the extent of absorption is not substantially affected.

About 25% is bound to plasma proteins. Ofloxacin is widely distributed in body fluids, including the CSF, and tissue penetration is good. It crosses the placenta and is distributed into breast milk. It also appears in the bile.

The elimination of ofloxacin is biphasic; half-lives of about 4 to 5 and 20 to 25 hours have been reported for the 2 phases, respectively. In renal impairment values of 15 to 60 hours have been reported. There is limited metabolism to desmethyl and *N*-oxide metabolites; desmethylofloxacin has moderate antibacterial activity. Ofloxacin is eliminated mainly by the kidneys. Excretion is by tubular secretion and glomerular filtration and 65 to 80% of a dose is excreted unchanged in the urine over 24 to 48 hours, resulting in high urinary concentrations. Less than 5% is excreted in the urine as metabolites. From 4 to 8% of a dose may be excreted in the faeces.

Only small amounts of ofloxacin are removed by haemodialysis or peritoneal dialysis.

◊ References.

Uses and Administration

Ofloxacin is a fluoroquinolone antibacterial used similarly to ciprofloxacin (p.247). It is also used in *Chlamydia* or *Chlamydophila* infections including nongonococcal urethritis (p.166 and p.199) and in mycobacterial infections such as leprosy (p.176) and tuberculosis (see under Uses and Administration of Ciprofloxacin, p.248).

Ofloxacin is given orally as the base or by intravenous infusion as the hydrochloride. All doses are expressed in terms of the base; ofloxacin hydrochloride 220.2 mg is equivalent to about 200 mg of ofloxacin.

The usual oral or intravenous dose ranges from 200 mg daily to 400 mg twice daily depending on the severity and the nature of the infection. Oral doses of up to 400 mg may be given as a single dose, preferably in the morning. For intravenous use a 0.2% solution is infused over 30 minutes.

An oral dose of 200 mg twice daily for 3 days is suitable in women with acute uncomplicated cystitis. A 6-week course of treatment with an oral dose of 300 mg twice daily should be given for chronic bacterial prostatitis. Oral doses of 400 mg daily with clofazimine and minocycline *or* 400 mg monthly with rifampicin and minocycline have been recommended by WHO as alternative multidrug therapy regimens for multibacillary leprosy. As an alternative regimen for single-lesion paucibacillary leprosy WHO suggests a single dose of ofloxacin 400 mg with rifampicin and minocycline.

A single 400-mg dose of ofloxacin may be given by mouth for uncomplicated gonorrhoea.

Ofloxacin is used topically as 0.3% eye drops for the treatment of conjunctivitis and corneal ulcers caused by susceptible strains of bacteria. It is also used as 0.3% ear drops for the treatment of otitis externa and otitis media.

For details of reduced doses in hepatic or renal impairment, see below.

Administration in hepatic impairment. The clearance of ofloxacin is reduced in patients with severe hepatic impairment or cirrhosis and lower doses should be used; a maximum dose of 400 mg daily has been recommended.

Administration in renal impairment. Lower doses of ofloxacin may be necessary in patients with renal impairment. After the usual initial dose (see above), subsequent doses are adjusted according to creatinine clearance (CC):

- CC 20 to 50 mL/minute: doses halved to 100 to 200 mg daily or the usual dose is given every 24 hours
- CC less than 20 mL/minute: dose reduced to 100 mg every 24 hours
- patients on haemodialysis or peritoneal dialysis: 100 mg every 24 hours

BCG toxicity. For mention of the possible use of ofloxacin to reduce the incidence of toxicity after BCG intravesicular instillation, see p.2206.

Preparations

Oleandomycin Phosphate *(BANM, rINNM)*

Fosfato de oleandomicina; Oléandomycine, Phosphate d'; Oleandomycini Phosphas; PA-105 (oleandomycin). (2*R*,3*S*,4*R*,5*S*,6*S*,8*R*,10*R*,11*S*,12*R*,13*R*)-3-(2,6-Dideoxy-3-*O*-methyl-α-L-*arabino*-hexopyranosyloxy)-8,8-epoxymethano-11-hydroxy-2,4,6,10,12,13-hexamethyl-9-oxo-5-(3,4,6-trideoxy-3-dimethylamino-β-D-*xylo*-hexopyranosyloxy)tridecan-13-olide phosphate.

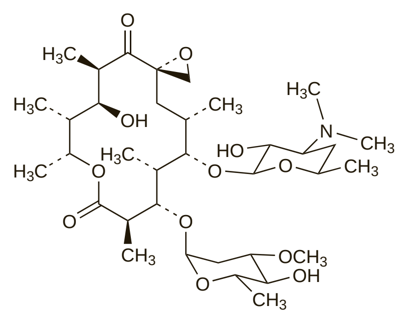
Олеандомицина Фосфат

$C_{35}H_{61}NO_{12},H_3PO_4$ = 785.9.

CAS — 3922-90-5 (oleandomycin); 7060-74-4 (oleandomycin phosphate).

ATC — J01FA05.

ATC Vet — QJ01FA05.



(oleandomycin)

Profile

Oleandomycin is a macrolide antibacterial produced by the growth of certain strains of *Streptomyces antibioticus* with actions and uses similar to those of erythromycin (p.269). It has antimicrobial activity weaker than that of erythromycin. It has been given orally or intravenously as the phosphate in the treatment of susceptible infections.

Troleandomycin (p.357) is the triacetyl ester.

Orbifloxacin *(rINN)*

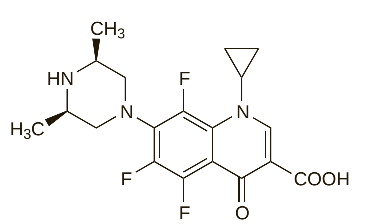
Orbifloksasiini; Orbifloxacine; Orbifloxacino; Orbifloxacinum. 1-Cyclopropyl-7-(*cis*-3,5-dimethyl-1-piperazinyl)-5,6,8-trifluoro-1,4-dihydro-4-oxo-3-quinolinecarboxylic acid.

Орбифлоксацин

$C_{19}H_{20}F_3N_3O_3$ = 395.4.

CAS — 113617-63-3.

ATC Vet — QJ01MA95.



Profile

Orbifloxacin is a fluoroquinolone antibacterial used in veterinary medicine for the treatment of susceptible infections in dogs.

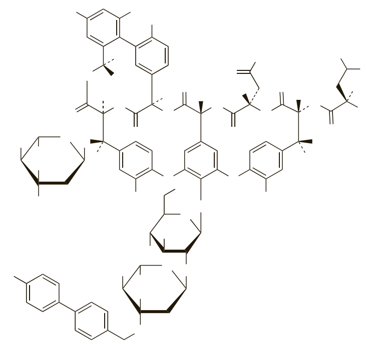
Oritavancin *(rINN)*

LY-333328; Oritavancina; Oritavancine; Oritavancinum. (4″*R*)-22-*O*-(3-Amino-2,3,6-trideoxy-3-*C*-methyl-α-L-*arabino*-hexopyranosyl)-$N^{3''}$-[*p*-(*p*-chlorophenyl)benzyl]vancomycin.

Оритаванцин

$C_{86}H_{97}Cl_3N_{10}O_{26}$ = 1793.1.

CAS — 171099-57-3 (oritavancin); 192564-14-0 (oritavancin phosphate).



NOTE. Oritavancin phosphate is *USAN*.

Profile

Oritavancin is a glycopeptide antibacterial under investigation for the treatment of complicated infections of the skin and soft tissues due to Gram-positive bacteria.

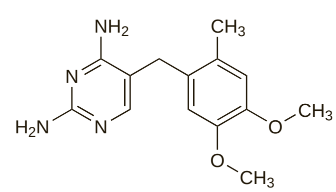
Ormetoprim *(USAN, rINN)*

NSC-95072; Ormetoprima; Ormétoprime; Ormetoprimum; Ro-5-9754. 5-(4,5-Dimethoxy-2-methylphenyl)methyl-2,4-pyrimidinediamine.

Орметоприм

$C_{14}H_{18}N_4O_2$ = 274.3.

CAS — 6981-18-6.



Profile

Ormetoprim is a diaminopyrimidine antibacterial used with sulfadimethoxine in veterinary medicine.

Oxacillin Sodium *(BANM, USAN, rINNM)*

(5-Methyl-3-phenyl-4-isoxazolyl)penicillin Sodium; Natrii Oxacillinum; Oksacylina sodowa jednowodna; Oksasilliininatriummonohydraatti; Oxacilin sodná sůl monohydrát; Oxacilina sódica; Oxacilline Sodique; Oxacilline sodique monohydratée; Oxacillinnatriummonohydrat; Oxacillinum natricum monohydricum; Oxacillinum Natrium; P-12; SQ-16423. Sodium (6*R*)-6-(5-methyl-3-phenylisoxazole-4-carboxamido)penicillanate monohydrate.

Натрий Оксациллин

$C_{19}H_{18}N_3NaO_5S,H_2O$ = 441.4.

CAS — 66-79-5 (oxacillin); 1173-88-2 (anhydrous oxacillin sodium); 7240-38-2 (oxacillin sodium monohydrate).

ATC — J01CF04.

ATC Vet — QJ01CF04.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Oxacillin Sodium Monohydrate). A white or almost white powder. Freely soluble in water; practically insoluble in dichloromethane; soluble in methyl alcohol. A 3.0% solution in water has a pH of 4.5 to 7.5.

USP 31 (Oxacillin Sodium). A fine white crystalline powder, odourless or having a slight odour. Freely soluble in water, in dimethyl sulfoxide, and in methyl alcohol; slightly soluble in dehydrated alcohol, in chloroform, in methyl acetate, and in pyridine; insoluble in ether, in ethyl acetate, in ethylene chloride, and in benzene. pH of a 3% solution in water is between 4.5 and 7.5. Store in airtight containers at a mean temperature not exceeding 25°.

Incompatibility. Oxacillin sodium has been reported to be incompatible with aminoglycosides and tetracyclines.

Adverse Effects and Precautions

As for Flucloxacillin, p.277.

Effects on the liver. References.

3. Maraqa NF, *et al.* Higher occurrence of hepatotoxicity and rash in patients treated with oxacillin, compared with those treated with nafcillin and other commonly used antimicrobials. *Clin Infect Dis* 2002; **34:** 50–4.

Sodium content. Each g of oxacillin sodium contains about 2.3 mmol of sodium.

Interactions

As for Benzylpenicillin, p.214.

Antimicrobial Action

As for Flucloxacillin, p.277.

Resistance. The isolation of pneumococci resistant to oxacillin but sensitive to benzylpenicillin has been reported.[1,2] The resistance was due to acquisition of a low-affinity penicillin-binding protein and conferred cross-resistance to meticillin and cloxacillin, and, to a lesser degree, to cefotaxime.

1. Johnson AP, *et al.* Oxacillin-resistant pneumococci sensitive to penicillin. *Lancet* 1993; **341:** 1222.
2. Dowson CG, *et al.* Genetics of oxacillin resistance in clinical isolates of Streptococcus pneumoniae that are oxacillin resistant and penicillin susceptible. *Antimicrob Agents Chemother* 1994; **38:** 49–53.

Pharmacokinetics

Oxacillin is incompletely absorbed from the gastrointestinal tract. Absorption is reduced by the presence of food in the stomach and is less than with cloxacillin. Peak plasma concentrations of 3 to 6 micrograms/mL have been achieved 1 hour after an oral dose of 500 mg given to fasting subjects. After intramuscular injection of 500 mg, peak plasma concentrations of up to 15 micrograms/mL have been achieved by 30 minutes. Doubling the dose can double the plasma concentration. About 93% of the oxacillin in the circulation is bound to plasma proteins. Oxacillin has been reported to have a plasma half-life of about 0.5 hours. The half-life is prolonged in neonates.

The distribution of oxacillin into body tissues and fluids is similar to that of cloxacillin (p.256).

Oxacillin undergoes some metabolism, and the unchanged drug and metabolites are excreted in the urine by glomerular filtration and renal tubular secretion.

About 20 to 30% of an oral dose, and more than 40% of an intramuscular dose, is rapidly excreted in the urine. Oxacillin is also excreted in the bile.

Plasma concentrations are enhanced by probenecid.

Uses and Administration

Oxacillin is an isoxazolyl penicillin used similarly to flucloxacillin (p.277) in the treatment of infections due to staphylococci resistant to benzylpenicillin.

Oxacillin is given orally or by injection as the sodium salt. Doses are expressed in terms of the equivalent amount of oxacillin; 1.1 g of oxacillin sodium is equivalent to about 1 g of oxacillin. Oral doses should preferably be given at least 1 hour before, or 2 hours after, meals. The usual adult oral dose is 1 g of oxacillin twice daily. Oxacillin may be given by intramuscular injection, by slow intravenous injection over about 10 minutes, or by intravenous infusion. Usual parenteral doses for adults are 250 to 500 mg every 4 to 6 hours; doses may be increased to 1 g every 4 to 6 hours for severe infections.

The usual oral dose for children is 500 mg twice daily. The parenteral dose for children weighing less than 40 kg is 50 mg/kg daily in 4 to 6 divided doses; the dose may be increased to 100 mg/kg daily for severe infections.

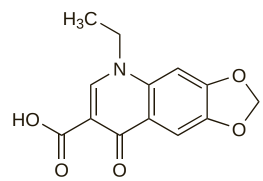
Оксолиновая Кислота

$C_{13}H_{11}NO_5$ = 261.2.
CAS — 14698-29-4.
ATC — J01MB05.
ATC Vet — QJ01MB05.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Oxolinic Acid). An almost white or pale yellow crystalline powder. Practically insoluble in water and in alcohol; very slightly soluble in dichloromethane; dissolves in dilute solutions of alkali hydroxides. Protect from light.

Profile

Oxolinic acid is a 4-quinolone antibacterial with properties similar to those of nalidixic acid (p.303), although adverse effects on the CNS may be more frequent. It has been given orally in the treatment of urinary-tract infections.

Preparations

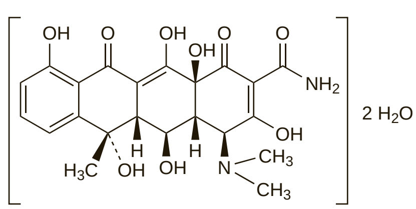
Proprietary Preparations (details are given in Part 3)
Braz.: Urilin†; ***Cz.:*** Desurol†; ***Port.:*** Cistopax†; ***Spain:*** Oxoinex†.

Oxytetracycline *(BAN, rINN)*

Glomycin; Hydroxytetracycline; Oksitetraciklinas; Oksitetrasiklin; Oksitetrasykliini; Oksytetracyklina; Oxitetraciclina; Oxitetraciklin; Oxitetracyklin; Oxytétracycline; Oxytetracyclinum; Oxytetracyklin; Riomitsin; Terrafungine. 4S,4aR,5S,5aR,6S,12aS-4-Dimethylamino-1,4,4a,5,5a,6,11,12a-octahydro-3,5,6,10,12,12a-hexahydroxy-6-methylene-1,11-dioxonaphthacene-2-carboxamide; 5β-Hydroxytetracycline.

Окситетрациклин

$C_{22}H_{24}N_2O_9$ = 460.4.
CAS — 79-57-2 (anhydrous oxytetracycline); 6153-64-6 (oxytetracycline dihydrate).
ATC — D06AA03; G01AA07; J01AA06; S01AA04.
ATC Vet — QD06AA03; QG01AA07; QG51AA01; QJ01AA06; QJ51AA06; QS01AA04.



(oxytetracycline dihydrate)

Pharmacopoeias. In *Eur.* (see p.vii) and *Int.*, which specify the dihydrate ($C_{22}H_{24}N_2O_9$,$2H_2O$ = 496.5); *US* allows the anhydrous substance or the dihydrate.

Ph. Eur. 6.2 (Oxytetracycline Dihydrate). A substance produced by the growth of certain strains of *Streptomyces rimosus* or obtained by any other means. A yellow, crystalline powder. Very slightly soluble in water; dissolves in dilute acid and alkaline solutions. A 1% suspension in water has a pH of 4.5 to 7.5. Store in airtight containers. Protect from light.

USP 31 (Oxytetracycline). A pale yellow to tan, odourless crystalline powder, that darkens on exposure to strong sunlight. Soluble 1 in 4150 of water, 1 in 66 of dehydrated alcohol, and 1 in 6250 of ether; sparingly soluble in alcohol; practically insoluble in chloroform; freely soluble in 3N hydrochloric acid and in alkaline solutions. pH of a 1% suspension in water is between 4.5 and 7.0. It loses potency in solutions of pH below 2 and is rapidly destroyed by alkali hydroxide solutions. Store in airtight containers. Protect from light.

Oxytetracycline Calcium *(BANM, rINNM)*

Calcii Oxytetracyclinum; Oxitetraciclina cálcica; Oxytétracycline Calcique.

Кальций Окситетрациклин

$C_{44}H_{46}CaN_4O_{18}$ = 958.9.
CAS — 15251-48-6 (xCa).
ATC — D06AA03; G01AA07; J01AA06; S01AA04.
ATC Vet — QD06AA03; QG01AA07; QJ01AA06; QS01AA04.

Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Oxytetracycline Calcium). A pale yellow to greenish-fawn, crystalline powder. Practically insoluble in water; soluble in dilute acids; dissolves slowly in dilute ammonia solution. A 2.5% suspension in water has a pH of 6.0 to 7.5. Store at a temperature of 2° to 8°. Protect from light.

USP 31 (Oxytetracycline Calcium). A yellow to light brown crystalline powder. Insoluble in water; soluble 1 in more than 1000 of alcohol, of chloroform, and of ether, and 1 in 15 of 0.1N sodium hydroxide. pH of a 2.5% suspension in water is between 6.0 and 8.0. Store in airtight containers at a temperature between 8° and 15°. Protect from light.

Oxytetracycline Hydrochloride *(BANM, rINNM)*

Hidrocloruro de oxitetraciclina; Oksitetraciklino hidrochloridas; Oksitetrasiklin Hidroklorür; Oksitetrasykliinihydrokloridi; Oksytetracykliny chlorowodorek; Oxitetraciklin-hidroklorid; Oxitetracyklinhydroklorid; Oxytétracycline, chlorhydrate d'; Oxytetracyclini hydrochloridum; Oxytetracyklin-hydrochlorid.

Окситетрациклина Гидрохлорид

$C_{22}H_{24}N_2O_9$,HCl = 496.9.
CAS — 2058-46-0.
ATC — D06AA03; G01AA07; J01AA06; S01AA04.
ATC Vet — QD06AA03; QG01AA07; QJ01AA06; QS01AA04.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Oxytetracycline Hydrochloride). A yellow, hygroscopic, crystalline powder. Freely soluble in water; sparingly soluble in alcohol. Solutions in water become turbid on standing owing to the precipitation of oxytetracycline. A 1% solution in water has a pH of 2.3 to 2.9. Store in airtight containers. Protect from light.

USP 31 (Oxytetracycline Hydrochloride). A yellow, odourless, hygroscopic, crystalline powder. It decomposes at temperatures exceeding 180°, and exposure to strong sunlight or temperatures exceeding 90° in moist air causes it to darken. Its potency is diminished in solutions having a pH below 2, and it is rapidly destroyed by alkali hydroxide solutions. Freely soluble in water, but crystals of oxytetracycline separate as a result of partial hydrolysis of the hydrochloride; sparingly soluble in alcohol and in methyl alcohol, and even less soluble in dehydrated alcohol; insoluble in chloroform and in ether. pH of a 1% solution in water is between 2.0 and 3.0. Store in airtight containers. Protect from light.

Incompatibility. Oxytetracycline injections have an acid pH and incompatibility may reasonably be expected with alkaline preparations, or with drugs unstable at low pH. Tetracyclines can chelate metal cations to produce insoluble complexes, and incompatibility has been reported with solutions containing metallic salts.

Reports of incompatibility are not always consistent, and other factors, such as the strength and composition of the vehicles used, may play a role.

Adverse Effects and Precautions

As for Tetracycline, p.347.

Oxytetracycline may produce less tooth discoloration than some other tetracyclines but gastrointestinal symptoms tend to be more severe.

Porphyria. For the suggestion that oxytetracycline might be porphyrinogenic, see under Tetracycline, p.348.

Interactions

As for Tetracycline, p.348.

Antimicrobial Action

As for Tetracycline, p.348.

Oxytetracycline is somewhat less active against many organisms.

Pharmacokinetics

For the general pharmacokinetics of the tetracyclines, see Tetracycline, p.349.

An oral dose of 500 mg every 6 hours is reported to produce steady-state plasma concentrations of 3 to 4 micrograms/mL. Plasma protein binding is reported to be about 20 to 40% and the half-life to be about 9 hours.

Uses and Administration

Oxytetracycline is a tetracycline derivative with actions and uses similar to those of tetracycline (p.349).

Oxytetracycline dihydrate or hydrochloride are usually used in tablets, capsules, and injections, and the calcium salt in aqueous oral suspensions; all three are also used in topical preparations. Doses have been expressed as anhydrous oxytetracycline, the dihydrate, or the hydrochloride but in practice this appears to make little difference. Oxytetracycline dihydrate and oxytetracycline hydrochloride 269.8 mg, and oxytetracycline calcium 260.3 mg, are each equivalent to about 250 mg of oxytetracycline.

Oxytetracycline is usually given orally in adult doses of 250 to 500 mg four times daily, usually 1 hour before or 2 hours after food. Higher doses, up to 4 g daily, have occasionally been given to adults with severe infection, but increase the risk of adverse effects.

Doses of oxytetracycline 250 to 500 mg daily have been used in acne, although the *BNF* advocates a dose of 1 g daily.

Oxytetracycline is sometimes given intramuscularly, in doses of 250 mg once daily or 300 mg daily in 2 or 3 divided doses, but this route may be painful and produces lower blood concentrations than recommended oral doses. As intramuscular injections are painful, lidocaine is usually included in the solution. Oxytetracycline has also been given intravenously.

For details of doses in children and adolescents, see below.

Oxytetracycline and its salts have been applied topically, often with other agents, as a variety of eye and ear drops, ointments, creams, and sprays.

Administration in children. In children, the effects on teeth should be considered and tetracyclines only used when absolutely essential. In the UK, oxytetracycline is licensed for use in children aged 12 years and over; the usual adult dose (see above) may be given orally. However, in the USA, it may be given to those over 8 years old in usual oral doses of 25 to 50 mg/kg daily in 4 divided doses or by intramuscular injection in usual doses of 15 to 25 mg/kg (to a maximum of 250 mg) daily in 2 or 3 divided doses.

Skin disorders. For reference to the use of oxytetracycline in the treatment of various skin disorders, see under Tetracycline, p.350.

Preparations

BP 2008: Oxytetracycline Capsules; Oxytetracycline Tablets;
USP 31: Oxytetracycline and Nystatin Capsules; Oxytetracycline and Nystatin for Oral Suspension; Oxytetracycline Calcium Oral Suspension; Oxytetracycline for Injection; Oxytetracycline Hydrochloride and Hydrocortisone Acetate Ophthalmic Suspension; Oxytetracycline Hydrochloride and Hydrocortisone Ointment; Oxytetracycline Hydrochloride and Polymyxin B Sulfate Ointment; Oxytetracycline Hydrochloride and Polymyxin B Sulfate Ophthalmic Ointment; Oxytetracycline Hydrochloride and Polymyxin B Sulfate Topical Powder; Oxytetracycline Hydrochloride and Polymyxin B Sulfate Vaginal Tablets; Oxytetracycline Hydrochloride Capsules; Oxytetracycline Injection; Oxytetracycline Tablets.

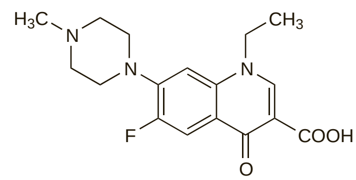
Пефлоксацина Мезилат

$C_{17}H_{20}FN_3O_3,CH_4O_3S,2H_2O$ = 465.5.

CAS — 70458-92-3 (pefloxacin); 70458-95-6 (pefloxacin mesilate).

ATC — J01MA03.

ATC Vet — QJ01MA03.



(pefloxacin)

Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Pefloxacin Mesilate Dihydrate). A fine, white or almost white powder. Freely soluble in water; slightly soluble in alcohol; very slightly soluble in dichloromethane. A 1% solution in water has a pH of 3.5 to 4.5. Store in airtight containers. Protect from light.

Profile

Pefloxacin is a fluoroquinolone antibacterial with actions and uses similar to those of ciprofloxacin (p.243). It also has bactericidal activity against *Mycobacterium leprae* and has been tried in the treatment of leprosy (p.176).

Pefloxacin has a longer plasma half-life than ciprofloxacin (about 8 to 13 hours) and is also extensively metabolised, the principal metabolite being *N*-desmethylpefloxacin (norfloxacin, p.309).

Pefloxacin is given orally or by intravenous infusion as the mesilate in the treatment of susceptible infections. Doses are expressed in terms of the base; pefloxacin mesilate 558.5 mg is equivalent to about 400 mg of pefloxacin. The usual dose is 400 mg twice daily. A single oral dose of 800 mg may be used in the treatment of gonococcal urethritis in men and acute uncomplicated cystitis in women.

Fluoroquinolones have caused adverse effects on the musculoskeletal system (see under Adverse Effects of Ciprofloxacin, p.244) and in the case of pefloxacin this has led to restrictions in some countries.

Adverse effects. References to adverse effects with pefloxacin.

Phenoxymethylpenicillin Potassium *(BANM, rINNM)*

Fenoksimetil Penisilin Potasyum; Fenoksimetilpenicilino kalio druska; Fenoksimetyylipenisilliinikalium; Fenoksymetylopenicylina potasowa; Fenoximetilpenicilina potásica; Fenoximetilpenicilina Potássica; Fenoximetilpenicillin-kálium; Fenoximetylpenicillin kalium; Fenoxymethylpenicilin draselná sůl; Kalii Phenoxymethylpenicillinum; Penicillin V Potassium *(USAN)*; Phénoxyméthylpénicilline potassique; Phenoxymethylpenicillinum kalicum.

Калия Феноксиметилпенициллин

$C_{16}H_{17}KN_2O_5S = 388.5.$

CAS — 132-98-9.

ATC — J01CE02.

ATC Vet — QJ01CE02.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., US*, and *Viet.*
Ph. Eur. 6.2 (Phenoxymethylpenicillin Potassium). A white or almost white, crystalline powder. Freely soluble in water; practically insoluble in alcohol. A 0.5% solution in water has a pH of 5.5 to 7.5.
USP 31 (Penicillin V Potassium). A white, odourless crystalline powder. Very soluble in water; soluble 1 in 150 of alcohol; insoluble in acetone. pH of a 3% solution in water is between 4.0 and 7.5. Store in airtight containers.

Units

The first International Standard Preparation (1957) of phenoxymethylpenicillin contained 1695 units/mg but was withdrawn in 1968. Despite this, doses of phenoxymethylpenicillin are still expressed in units in some countries.

Phenoxymethylpenicillin 250 mg is equivalent to about 400 000 units.

Adverse Effects and Precautions

As for Benzylpenicillin, p.213.

Phenoxymethylpenicillin is usually well tolerated but may occasionally cause transient nausea and diarrhoea.

Potassium content. Each g of phenoxymethylpenicillin potassium contains about 2.6 mmol of potassium.

Interactions

As for Benzylpenicillin, p.214.

Antibacterials. Reduced absorption was reported when phenoxymethylpenicillin was given after an oral course of *neomycin*.[1]

1. Cheng SH, White A. Effect of orally administered neomycin on the absorption of penicillin V. *N Engl J Med* 1962; **267:** 1296–7.

Beta blockers. Fatal anaphylactic reactions to phenoxymethylpenicillin in 2 patients on *nadolol* and *propranolol* respectively, might have been potentiated by the beta blocker.[1]

1. Berkelman RL, *et al.* Beta-adrenergic antagonists and fatal anaphylactic reactions to oral penicillin. *Ann Intern Med* 1986; **104:** 134.

Antimicrobial Action

Phenoxymethylpenicillin has a range of antimicrobial activity similar to that of benzylpenicillin (p.214) and a similar mode of action. It may be less active against some susceptible organisms, particularly Gram-negative bacteria.

The mechanisms and patterns of resistance to phenoxymethylpenicillin are similar to those of benzylpenicillin.

Pharmacokinetics

Phenoxymethylpenicillin is more resistant to inactivation by gastric acid and is more completely absorbed than benzylpenicillin from the gastrointestinal tract. Absorption is usually rapid, although variable, with about 60% of an oral dose being absorbed. The calcium and potassium salts are better absorbed than the free acid. Peak plasma concentrations of 3 to 5 micrograms/mL have been observed 30 to 60 minutes after a dose of 500 mg. The effect of food on absorption appears to be slight. The plasma half-life of phenoxymethylpenicillin is about 30 to 60 minutes and may be increased to about 4 hours in severe renal impairment. About 80% is reported to be protein bound. The distribution and elimination of phenoxymethylpenicillin is similar to that of benzylpenicillin (p.214). It is metabolised in the liver to a greater extent than benzylpenicillin; several metabolites have been identified including penicilloic acid. The unchanged drug and metabolites are excreted rapidly in the urine. Only small amounts are excreted in the bile.

Uses and Administration

Phenoxymethylpenicillin is used similarly to benzylpenicillin (p.215) in the treatment or prophylaxis of infections caused by susceptible organisms, especially streptococci. It is used only for the treatment of mild to moderate infections, and not for chronic, severe, or deep-seated infections since absorption can be unpredictable. Patients treated initially with parenteral benzylpenicillin may continue treatment with oral phenoxymethylpenicillin once a satisfactory clinical response has been obtained. Specific indications for phenoxymethylpenicillin include anthrax (mild uncomplicated infections), Lyme disease (early stage in pregnant women or young children), pharyngitis or tonsillitis, rheumatic fever (primary and secondary prophylaxis), streptococcal skin infections, and spleen disorders (pneumococcal infection prophylaxis). For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Administration and dosage. Phenoxymethylpenicillin is given orally, usually as the potassium or calcium salt, preferably at least 30 minutes before, or 2 hours after, food. Benzathine phenoxymethylpenicillin (p.212) is also used.

Doses are expressed in terms of the equivalent amount of phenoxymethylpenicillin; 1.1 g of phenoxymethylpenicillin calcium and 1.1 g of phenoxymethylpenicillin potassium are each equivalent to about 1 g of phenoxymethylpenicillin.

Usual adult doses have been 250 to 500 mg every 6 hours, but the *BNF* recommends up to 1 g every 6 hours in severe infections. Children may be given the following doses every 6 hours: up to 1 year, 62.5 mg; 1 to 5 years, 125 mg; and 6 to 12 years, 250 mg. The *BNFC* recommends that doses be increased to ensure at least 12.5 mg/kg every 6 hours in severe infection. Dosage may need to be modified in severe renal impairment.

To prevent recurrences of rheumatic fever, WHO and the *BNF* recommend 250 mg twice daily.

Preparations

BP 2008: Phenoxymethylpenicillin Oral Solution; Phenoxymethylpenicillin Tablets;
USP 31: Penicillin V for Oral Suspension; Penicillin V Potassium for Oral Solution; Penicillin V Potassium Tablets; Penicillin V Tablets.

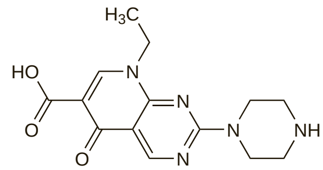
Пипемидовая Кислота

$C_{14}H_{17}N_5O_3$ = 303.3.

CAS — 51940-44-4 (anhydrous pipemidic acid); 72571-82-5 (pipemidic acid trihydrate).

ATC — J01MB04.

ATC Vet — QJ01MB04.



(anhydrous pipemidic acid)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *Jpn* (all as the trihydrate).

Ph. Eur. 6.2 (Pipemidic Acid Trihydrate). A pale yellow or yellow crystalline powder. Very slightly soluble in water. It dissolves in dilute solutions of acids and of alkali hydroxides. Protect from light.

Profile

Pipemidic acid is a 4-quinolone antibacterial with properties similar to those of nalidixic acid (p.303), but is more active *in vitro* against some bacteria, including *Pseudomonas aeruginosa*. It is used (as the trihydrate) in the treatment of urinary-tract infections in oral doses equivalent to 400 mg of the anhydrous substance twice daily.

Interactions. For the effect of pipemidic acid on the clearance of xanthines, see under Caffeine, p.1117, and Theophylline, p.1143.

Porphyria. Pipemidic acid is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

$C_{23}H_{27}N_5O_7S,H_2O$ = 535.6.

CAS — 61477-96-1 (anhydrous piperacillin); 66258-76-2 (piperacillin monohydrate).

ATC — J01CA12.

ATC Vet — QJ01CA12.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Piperacillin). A white or almost white powder. Slightly soluble in water and in ethyl acetate; freely soluble in methyl alcohol.

USP 31 (Piperacillin). A white to off-white crystalline powder. Very slightly soluble in water; slightly soluble in ethyl acetate; sparingly soluble in isopropyl alcohol; very soluble in methyl alcohol.

Piperacillin Sodium *(BANM, USAN, rINNM)*

CL-227193; Natrii Piperacillinum; Piperacilin sodná sůl; Piperacilina sódica; Piperacilino natrio druska; Pipéracilline sodique; Piperacillin-nátrium; Piperacillinnatrium natricum; Piperacillinum; Piperacillinum natricum; Piperacylina sodowa; Piperasilin Sodyum; Piperasilliininatrium; T-1220.

Натрий Пиперациллин

$C_{23}H_{26}N_5NaO_7S$ = 539.5.

CAS — 59703-84-3.

ATC — J01CA12.

ATC Vet — QJ01CA12.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Piperacillin Sodium). A white or almost white, hygroscopic powder. Freely soluble in water and in methyl alcohol; practically insoluble in ethyl acetate. A 10% solution in water has a pH of 5.0 to 7.0. Store in airtight containers.

USP 31 (Piperacillin Sodium). A white to off-white solid. Freely soluble in water and in alcohol. pH of a 40% solution in water is between 5.5 and 7.5. Store in airtight containers.

Incompatibility. Piperacillin sodium has been reported to be incompatible with aminoglycosides and sodium bicarbonate.

Stability. References.

1. Zhang Y, Trissel LA. Stability of piperacillin and ticarcillin in AutoDose Infusion System bags. *Ann Pharmacother* 2001; **35:** 1360–3.

Adverse Effects and Precautions

As for Carbenicillin Sodium, p.216.

Prolongation of bleeding time has been less frequent and less severe with piperacillin than with carbenicillin.

Effects on the blood. References.

1. Scheetz MH, *et al.* Systematic review of piperacillin-induced neutropenia. *Drug Safety* 2007; **30:** 295–306.

Hypersensitivity. In the mid 1980s there were reports of a relatively high incidence of adverse reactions to piperacillin, especially fever, in patients with cystic fibrosis.[1-3] However, the manufacturers[4] considered such patients to be particularly prone to allergy and cited reactions with other semisynthetic penicillins including carbenicillin and azlocillin.

Similar apparent hypersensitivity reactions have been reported in patients taking high doses of piperacillin and other ureidopenicillins, over long periods for other indications,[5] and with other penicillins in patients with cystic fibrosis,[6] although piperacillin does appear to be most frequently implicated.[6]

2. Strandvik B. Adverse reactions to piperacillin in patients with cystic fibrosis. *Lancet* 1984; **i:** 1362.
3. Stead RJ, *et al.* Adverse reactions to piperacillin in adults with cystic fibrosis. *Thorax* 1985; **40:** 184–6.
4. Brock PG, Roach M. Adverse reactions to piperacillin in cystic fibrosis. *Lancet* 1984; **i:** 1070–1.
5. Lang R, *et al.* Adverse reactions to prolonged treatment with high doses of carbenicillin and ureidopenicillins. *Rev Infect Dis* 1991; **13:** 68–72.
6. Pleasants RA, *et al.* Allergic reactions to parenteral beta-lactam antibiotics in patients with cystic fibrosis. *Chest* 1994; **106:** 1124–8.

Sodium content. Each g of piperacillin sodium contains about 1.85 mmol of sodium. As piperacillin sodium has a lower sodium content than carbenicillin sodium, hypernatraemia and hypokalaemia are less likely to occur.

Interactions

As for Benzylpenicillin, p.214.

Neuromuscular blockers. Piperacillin and other ureidopenicillins are reported to prolong the action of competitive muscle relaxants such as *vecuronium* (see Atracurium, p.1903).

Antimicrobial Action

Piperacillin has a similar antimicrobial action to carbenicillin (p.216) and ticarcillin (p.352), but is active against a wider range of Gram-negative organisms, including *Klebsiella pneumoniae*. It is also generally more active *in vitro*, especially against *Pseudomonas aeruginosa* and the Enterobacteriaceae, against Gram-positive *Enterococcus faecalis*, and possibly against *Bacteroides fragilis*. There is, however, an inoculum effect, i.e. minimum inhibitory concentrations of piperacillin increase with the size of the inoculum.

Combinations of piperacillin and aminoglycosides have been shown to be synergistic *in vitro* against *Ps. aeruginosa* and Enterobacteriaceae. The effect of using piperacillin with other beta lactams has been less predictable. The activity of piperacillin against some organisms, resistant because of the production of beta-lactamases, may be restored by tazobactam, a beta-lactamase inhibitor. Such organisms include beta-lactamase-producing strains of staphylococci, *Escherichia coli*, *Haemophilus influenzae*, and *Bacteroides* spp.; the activity of piperacillin against *Ps. aeruginosa* is not enhanced by tazobactam.

Resistance has developed in *Ps. aeruginosa* during treatment with piperacillin, especially when used alone. There may be some cross-resistance with other antipseudomonal penicillins.

Pharmacokinetics

Piperacillin is not absorbed from the gastrointestinal tract. It is well absorbed after intramuscular use, with peak plasma concentrations of 30 to 40 micrograms/mL 30 to 50 minutes after a dose of 2 g. The pharmacokinetics of piperacillin are reported to be nonlinear and dose-dependent. The plasma half-life is about 1 hour, but is prolonged in neonates. In patients with severe renal impairment there may be a threefold increase in half-life; in those with end-stage renal failure half-lives of 4 to 6 hours have been reported, and in those with both renal and hepatic impairment much longer half-lives may result. About 20% of piperacillin in the circulation is bound to plasma proteins.

Piperacillin is widely distributed in body tissues and fluids. It crosses the placenta into the fetal circulation and small amounts are distributed into breast milk. There is little diffusion into the CSF except when the meninges are inflamed.

About 60 to 80% of a dose is excreted unchanged in the urine by glomerular filtration and tubular secretion within 24 hours, achieving high concentrations. High concentrations are also found in the bile and up to 20% of a dose may be excreted by this route.

Plasma concentrations are enhanced by probenecid.

Piperacillin is removed by haemodialysis.

Piperacillin with tazobactam. The pharmacokinetics of piperacillin do not appear to be altered by tazobactam, but piperacillin reduces the renal clearance of tazobactam.

Uses and Administration

Piperacillin is a ureidopenicillin that is used similarly to ticarcillin (p.353) for the treatment of infections caused by *Pseudomonas aeruginosa*, and also infections due to other susceptible bacteria. It has been used particularly in immunocompromised patients (neutropenic patients) and for biliary-tract infections (cholangitis). Other indications have included uncomplicated gonorrhoea due to penicillin-sensitive gonococci, and urinary-tract infections. It has also been used for surgical infection prophylaxis. For details of these infections and their treatment, see under Choice of Antibacterial, p.162. For the treatment of serious infections piperacillin is commonly used with an aminoglycoside, but they should be given separately because of possible incompatibility.

Administration and dosage. Piperacillin is given by injection as the sodium salt. Doses are expressed in terms of the equivalent amount of piperacillin; 1.04 g of piperacillin sodium is equivalent to about 1 g of piperacillin. Doses should generally be reduced in moderate to severe renal impairment.

Piperacillin may be given by slow intravenous injection over 3 to 5 minutes, by intravenous infusion over 20 to 30 minutes, or by deep intramuscular injection. Single doses of more than 2 g for adults or 500 mg for children should not be given by the intramuscular route.

For the treatment of serious or complicated infections, adults may be given piperacillin 200 to 300 mg/kg daily in divided doses intravenously; the usual dose is 3 to 4 g every 4 or 6 hours. In life-threatening infections, particularly those caused by *Pseudomonas* or *Klebsiella* spp., it should be given in a dose of not less than 16 g daily. The usual maximum daily dose is 24 g, although this has been exceeded.

For mild or uncomplicated infections, 100 to 125 mg/kg daily may be given to adults; usual doses are 2 g every 6 or 8 hours, or 4 g every 12 hours, intravenously, or 2 g every 8 or 12 hours intramuscularly.

Uncomplicated gonorrhoea may be treated by a single intramuscular dose of 2 g. Probenecid 1 g may be given orally 30 minutes before the injection.

For the prophylaxis of infection during surgery, 2 g just before the procedure, or when the umbilical cord is clamped in caesarean section, followed by at least 2 doses of 2 g at intervals of 4 or 6 hours within 24 hours of the procedure, may be given.

The intravenous route is preferred for infants and children. Those aged 1 month to 12 years may be given 100 to 300 mg/kg daily in 3 or 4 divided doses. Neonates less than 7 days old or weighing less than 2 kg may be given 150 mg/kg daily in 3 divided doses. Those more than 7 days old and weighing more than 2 kg may be given 300 mg/kg daily in 3 or 4 divided doses.

Piperacillin with tazobactam. Piperacillin has also been used with tazobactam (p.344), a beta-lactamase inhibitor, to widen its antibacterial spectrum to organisms usually resistant because of the production of beta-lactamases. The combination is given intravenously in a ratio of piperacillin (as the sodium salt) 8 parts to 1 part of tazobactam (as the sodium salt). Doses, calculated on piperacillin content, are similar to those of piperacillin alone.

CAS — 26309-95-5.

ATC — J01CA02.

ATC Vet — QJ01CA02.

Adverse Effects and Precautions

As for Ampicillin, p.204. Pivampicillin is reported to cause a lower incidence of diarrhoea than ampicillin. Upper gastrointestinal discomfort may be more frequent when pivampicillin is taken on an empty stomach.

Pivaloyloxymethyl esters such as pivampicillin have been associated with the induction of carnitine deficiency (see below).

Carnitine deficiency. Carnitine deficiency (see p.1933) has been reported after the use of pivampicillin and pivmecillinam.[1] It is thought that the pivalic acid liberated on hydrolysis of these pivaloyloxymethyl esters *in vivo* is excreted as pivaloyl-carnitine with a consequent depletion in plasma and muscle concentrations of carnitine.[2] Low plasma-carnitine concentrations persisted in a patient after stopping pivampicillin, despite 6 weeks of replacement therapy with oral carnitine 1g daily. She had originally presented with skeletal myopathy when given pivampicillin for 3 months. A more intensive carnitine replacement regimen might be necessary in such patients.[3]

1. Holme E, *et al.* Carnitine deficiency induced by pivampicillin and pivmecillinam therapy. *Lancet* 1989; **ii:** 469–73.
2. Anonymous. Carnitine deficiency. *Lancet* 1990; **335:** 631–3.
3. Rose SJ, *et al.* Carnitine deficiency associated with long-term pivampicillin treatment: the effect of a replacement therapy regime. *Postgrad Med J* 1992; **68:** 932–4.

Porphyria. Pivampicillin has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for Benzylpenicillin, p.214.

There is a theoretical possibility that carnitine deficiency may be increased in patients receiving pivampicillin and valproate.

Antimicrobial Action

Pivampicillin has the antimicrobial activity of ampicillin to which it is hydrolysed *in vivo* (p.204).

Pharmacokinetics

Pivampicillin is acid-stable and is readily absorbed from the gastrointestinal tract. On absorption it is rapidly and almost completely hydrolysed to ampicillin, pivalic acid, and formaldehyde. Plasma-ampicillin concentrations 1 hour after a dose are 2 to 3 times those attained after an equivalent dose of ampicillin. The absorption of pivampicillin is generally not significantly affected by food. About 70% of a dose is excreted in the urine as ampicillin within 6 hours.

Uses and Administration

Pivampicillin is the pivaloyloxymethyl ester of ampicillin (p.205) and has similar uses; 1.3 g of pivampicillin and 1.43 g of pivampicillin hydrochloride are each equivalent to about 1 g of ampicillin.

Pivampicillin is given orally to adults and children over 10 years of age in doses of 500 mg twice daily with food, which may be doubled in severe infections. In children aged 3 months to 1 year a dose of 20 to 30 mg/kg twice daily may be used. Children older than 1 year may be given 12.5 to 17.5 mg/kg twice daily, up to 500 mg twice daily.

In areas where gonococci remain sensitive a single dose of 1.5 g is given for gonorrhoea, with probenecid 1 g.

Pivampicillin hydrochloride has been used in some countries.

Pivampicillin has also been given with pivmecillinam (below).

Preparations

Proprietary Preparations (details are given in Part 3)

Hidrocloruro de pivmecilinam; Pivmecillinam-hydrochlorid; Pivmecilinamo hidrochloridas; Pivmécillinam, Chlorhydrate de; Pivmecillinám-hidroklorid; Pivmecillinamhydroklorid; Pivmecillinami hydrochloridum; Pivmesillinaamihydrokloridi.

Пивмециллинама Гидрохлорид

$C_{21}H_{33}N_3O_5S,HCl = 476.0.$

CAS — 32887-03-9.

ATC — J01CA08.

ATC Vet — QJ01CA08.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*

Ph. Eur. 6.2 (Pivmecillinam Hydrochloride). A white or almost white crystalline powder. Freely soluble in water, in dehydrated alcohol, and in methyl alcohol; slightly soluble in acetone. A 10% solution in water has a pH of 2.8 to 3.8. Store at a temperature of 2° to 8°. Protect from light.

Adverse Effects and Precautions

As for Benzylpenicillin, p.213.

Pivaloyloxymethyl esters such as pivmecillinam have been associated with the induction of carnitine deficiency (see Pivampicillin, above).

Administration. Oesophageal injury has been associated rarely with pivmecillinam tablets.[1,2] Patients are advised to take them during a meal, while sitting or standing, and with at least half a glass of water.[3]

1. Committee on Safety of Medicines. Pivmecillinam and oesophageal injury. *Current Problems 19* 1987. Available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2024426&RevisionSelectionMethod=LatestReleased (accessed 22/07/08)
2. Mortimer Ö, Wiholm B-E. Oesophageal injury associated with pivmecillinam tablets. *Eur J Clin Pharmacol* 1989; **37:** 605–7.
3. Anonymous. CSM warning on pivmecillinam. *Pharm J* 1987; **238:** 443.

Porphyria. Pivmecillinam has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for Benzylpenicillin, p.214.

Antimicrobial Action

Pivmecillinam has the antimicrobial activity of mecillinam (p.297) to which it is hydrolysed *in vivo*.

Pharmacokinetics

Pivmecillinam is well absorbed from the gastrointestinal tract and is rapidly hydrolysed to the active drug mecillinam (p.297), pivalic acid, and formaldehyde. The presence of food in the stomach does not appear to have a significant effect on absorption. Peak plasma concentrations of mecillinam of 5 micrograms/mL have been achieved 1 to 2 hours after a 400-mg dose of pivmecillinam.

About 45% of a dose may be excreted in the urine as mecillinam, mainly within the first 6 hours.

◊ References.

1. Heikkilä A, *et al.* The pharmacokinetics of mecillinam and pivmecillinam in pregnant and non-pregnant women. *Br J Clin Pharmacol* 1992; **33**; 629–33.

Uses and Administration

Pivmecillinam is the pivaloyloxymethyl ester of mecillinam (p.297), to which it is hydrolysed after oral dosage. It is used in the treatment of urinary-tract infections (p.199).

Doses of pivmecillinam have often been expressed in a confusing manner since no differentiation has been made between the hydrochloride, used in tablets, and the base, used in suspensions for oral use. Pivmecillinam 1.35 g and pivmecillinam hydrochloride 1.46 g are each equivalent to about 1 g of mecillinam.

Pivmecillinam should preferably be taken with food (see also Administration, under Adverse Effects and Precautions, above).

In acute uncomplicated cystitis, the initial adult dose is 400 mg orally followed by 200 mg three times daily for 8 doses. In chronic or recurrent bacteriuria, 400 mg may be given 3 or 4 times daily. The dose for children (weighing less than 40 kg) with urinary-tract infections is 20 to 40 mg/kg daily in 3 or 4 divided doses.

Pivmecillinam has been given with other beta lactams, particularly pivampicillin (p.316), to extend the spectrum of antimicrobial activity to Gram-positive organisms and because of reported synergism against Gram-negative bacteria *in vitro*.

For parenteral use, mecillinam is given.

Polymyxin	R	R'	X	Mol. Formula
B1	CH	CH	-Leu	C H N O
B2	H	CH	-Leu	C H N O
B3	CH	H	-Leu	C H N O
B1-I	CH	CH	-Ile	C H N O

(polymyxin B)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US*.

Ph. Eur. 6.2 (Polymyxin B Sulphate). A mixture of the sulfates of polypeptides produced by the growth of certain strains of *Bacillus polymyxa* or obtained by any other means. A white or almost white, hygroscopic powder. Soluble in water; slightly soluble in alcohol. A 2% solution in water has a pH of 5.0 to 7.0. Store in airtight containers. Protect from light.

USP 31 (Polymyxin B Sulfate). The sulfate salt of a kind of polymyxin, a substance produced by the growth of *Bacillus polymyxa* (Bacillaceae), or a mixture of two or more such salts. A white to buff-coloured, powder, odourless or has a faint odour. It has a potency of not less than 6000 Polymyxin B units/mg, calculated on the dried substance. Freely soluble in water; slightly soluble in alcohol. pH of a 0.5% solution in water is between 5.0 and 7.5. Store in airtight containers. Protect from light.

Incompatibility. Incompatibility has been reported with many other drugs including antibacterials. Polymyxin B sulfate is rapidly inactivated by strong acids and alkalis.

Units

The second International Standard Preparation (1969) of polymyxin B sulfate contains 8403 units/mg.

NOTE. The available forms of polymyxin B sulfate are generally less pure than the International Standard Preparation. Doses have sometimes been stated in terms of pure polymyxin base; 100 mg of pure polymyxin B is considered to be equivalent to 1 million units (1 mega unit).

Adverse Effects, Treatment, and Precautions

When given parenterally, the major adverse effects of the polymyxins are dose-related neurotoxicity and nephrotoxicity. Hypersensitivity reactions are rare, although rashes and fever have been reported, and polymyxins cause histamine release, which may lead to bronchoconstriction and other anaphylactoid symptoms. Polymyxins should be avoided in patients with a history of hypersensitivity to any of the group.

Neurotoxic reactions can occur in up to 7% of patients with normal renal function and include peripheral effects such as circumoral and 'stocking-glove' pattern paraesthesias, visual disturbances, and dizziness, ataxia, confusion, drowsiness, and other CNS effects. The polymyxins are potent neuromuscular blockers, and respiratory paralysis and apnoea may result, especially in overdosage and in patients with renal impairment or pre-existing disorders of neuromuscular transmission such as myasthenia gravis, in whom particular care is needed; certain medications may also increase the risk (see Interactions, below). Neostigmine or calcium salts are usually of little value in reversing neuromuscular blockade and artificial ventilation may be required if it develops.

Nephrotoxicity may occur in up to 20% of patients after parenteral use and may be marked by nitrogen retention, haematuria, proteinuria, and tubular necrosis. Electrolyte disturbances are common. Baseline renal function levels should be established before starting parenteral polymyxin B therapy and renal function and blood concentrations of polymyxins should be monitored frequently during therapy. Patients with pre-existing renal impairment and nitrogen retention are at particular risk and require dosage reduction. Signs of decreasing urine output and increasing nitrogen retention are an indication for stopping the drug in all patients. Although polymyxin B is said to be more nephrotoxic than colistin on a weight-for-weight basis, their effects on the kidney seem to be similar at therapeutically equivalent doses.

Polymyxin B is irritant; pain after intramuscular injection may be severe and thrombophlebitis can occur after intravenous injection. Meningeal irritation, manifest as fever, headache, stiff neck, and increased cell count and protein levels in the CSF, may follow intrathecal doses.

Ear drops containing polymyxins should not be used in patients with perforated ear drums, due to the increased risk of ototoxicity. Topical application to large areas of skin should be avoided because of the risk of systemic absorption resulting in neurotoxicity and nephrotoxicity, particularly in children, the elderly, and patients with renal impairment.

Interactions

Polymyxins may enhance the action of neuromuscular blockers (p.1903) possibly resulting in respiratory depression and apnoea, and concurrent use should be avoided. Additive neurotoxicity and/or nephrotoxicity may occur if polymyxins are given with other potentially neurotoxic and/or nephrotoxic drugs including aminoglycosides and cefaloridine; concurrent use should also be avoided.

Antimicrobial Action

Polymyxin B and the other polymyxin antibacterials act primarily by binding to membrane phospholipids and disrupting the bacterial cytoplasmic membrane. Polymyxin B has a bactericidal action on most Gram-negative bacilli except *Proteus* spp. It is particularly effective against *Pseudomonas aeruginosa*. Of the other Gram-negative organisms, *Acinetobacter* spp., *Escherichia coli*, *Enterobacter* and *Klebsiella* spp., *Haemophilus influenzae, Bordetella pertussis, Salmonella,* and *Shigella* spp. are sensitive. Classical *Vibrio cholerae* 01 is sensitive but the El Tor and O139 biotypes are resistant. *Serratia*, *Burkholderia*, and *Providencia* spp., and *Bacteroides fragilis* are usually resistant. It is not active against *Neisseria* spp., obligate anaerobes, and Gram-positive bacteria. Some fungi such as *Coccidioides immitis* are susceptible but most are resistant.

Antimicrobial synergy has been reported with other drugs, including chloramphenicol, tetracyclines, and the sulfonamides and trimethoprim.

The action of polymyxin B is reduced by divalent cations such as calcium and magnesium, and so activity *in vivo* is less marked than *in vitro*.

Acquired resistance to polymyxin B is uncommon, although adaptive resistance may develop in enterobacteria exposed to sublethal concentrations. There is complete cross-resistance between polymyxin B and colistin.

Pharmacokinetics

Polymyxin B sulfate is not absorbed from the gastrointestinal tract, except in infants who may absorb up to 10% of a dose. It is not absorbed through mucous membranes, or intact or denuded skin.

Peak plasma concentrations after intramuscular injection usually occur within 2 hours, but are variable and polymyxin B sulfate is partially inactivated by serum. It is widely distributed and extensively bound to cell membranes in the tissues; it does not appear to be highly bound to serum proteins. Accumulation may occur after repeated doses. There is no diffusion into the CSF and it does not cross the placenta. Polymyxin B is reported to have a serum half-life of about 6 hours but this is prolonged in renal impairment; values of 2 to 3 days have been reported in patients with a creatinine clearance of less than 10 mL/minute.

Polymyxin B sulfate is excreted mainly by the kidneys by glomerular filtration, about 60% of a dose being recovered unchanged in the urine, but there is a time lag of 12 to 24 hours before polymyxin B is recovered in the urine.

Polymyxin B is not removed to an appreciable extent by peritoneal dialysis or haemodialysis.

Uses and Administration

Polymyxin B sulfate is used topically, often with other drugs, in the treatment of skin, ear, and eye infections due to susceptible organisms. Eye drops containing polymyxin B with neomycin and gramicidin have been used for the prophylaxis of infection in patients undergoing ocular surgery and, with propamidine isetionate, for the treatment of acanthamoeba keratitis (p.822). Polymyxin B has been given orally with other drugs in regimens for selective digestive-tract decontamination (SDD) in patients at high risk of endogenous infections (see under Intensive Care, p.175). Polymyxin B has also been used parenterally for the treatment of infections due to susceptible Gram-negative bacteria, especially *Pseudomonas aeruginosa,* but other drugs are generally preferred. Polymyxin B has been given intrathecally in meningeal infection, and by subconjunctival injection for eye infections.

For topical application polymyxin B is usually available as a 0.1% solution or ointment (10 000 units per mL or per g respectively) combined with other drugs. Intravenous doses range from 15 000 to 25 000 units/kg daily, by infusion and may be given every 12 hours. The intramuscular route has also been used despite the severe pain which may be associated with it; doses range from 25 000 to 30 000 units/kg daily, and may be given every 4 or 6 hours.

Doses should be reduced in patients with renal impairment (see below).

Intrathecal doses of 50 000 units may be given once daily for 3 to 4 days, then on alternate days for at least 2 weeks after the CSF cultures become negative.

For details of doses in children, including infants, see below.

For subconjunctival injection, doses of up to 100 000 units daily may be used for infections of the cornea and conjunctiva.

Administration in children. Up to 40 000 units/kg daily of polymyxin sulfate may be given to infants with normal renal function by intravenous infusion or by intramuscular injection, although the latter is not recommended routinely because of severe pain at injection sites. Doses as high as 45 000 units/kg daily have been tried in premature and full-term neonates. For suggested doses in children with renal impairment see below.

In children under 2 years of age, intrathecal doses of 20 000 units once daily for 3 to 4 days or 25 000 units on alternate days may be given, followed by the latter dose for at least 2 weeks after the CSF cultures become negative.

Older children may be given the usual adult dose (see above).

Administration in renal impairment. Parenteral doses of polymyxin sulfate should be reduced in adults and children with renal impairment; a maximum intravenous dose of 15 000 units/kg daily has been suggested.

Pristinamycin *(BAN, rINN)*

Pristinamicina; Pristinamycine; Pristinamycinum; RP-7293.

Пристинамицин

CAS — 270076-60-3.
ATC — J01FG01.
ATC Vet — QJ01FG01.

Profile

Pristinamycin is a streptogramin antibacterial produced by the growth of *Streptomyces pristina spiralis*, with actions and uses similar to those of virginiamycin (p.361). It is given orally in the treatment of susceptible infections, particularly staphylococcal infections, in a dose of 2 to 4 g daily in divided doses.

◊ Pristinamycin is a naturally occurring mixture of two synergistic components, pristinamycin I which is a macrolide, and pristinamycin II which is a depsipeptide.[1] It has been available for many years as an oral antistaphylococcal drug, and also acts against streptococci. It is effective against strains showing resistance to erythromycin; resistance to pristinamycin is rare,[2,3] although resistance in staphylococci has been reported in the past.[4,5] It is effective against meticillin-resistant *Staphylococcus aureus* (MRSA)[6,7] but its usefulness in severe infection is limited by its poor solubility, which prevents development of an intravenous formulation. Oral pristinamycin has been shown to be as effective as standard therapy with intravenous then oral penicillin in the treatment of erysipelas.[8]

Mixtures of water-soluble derivatives of pristinamycins I and II, such as quinupristin/dalfopristin (p.322), are in clinical use or under investigation.

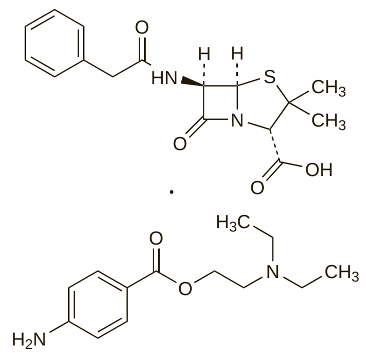
CAS — 54-35-3 (anhydrous procaine benzylpenicillin); 6130-64-9 (procaine benzylpenicillin monohydrate).
ATC — J01CE09.
ATC Vet — QJ01CE09; QJ51CE09.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Benzylpenicillin, Procaine). A white or almost white, crystalline powder. Slightly soluble in water; sparingly soluble in alcohol. A 0.33% solution in water has a pH of 5.0 to 7.5. Store in airtight containers.

USP 31 (Penicillin G Procaine). White crystals or white, very fine, microcrystalline powder, odourless or practically odourless. Slightly soluble in water; soluble in alcohol and in chloroform. It is rapidly inactivated by acids, by alkali hydroxides, and by oxidising agents. pH of a saturated solution in water is between 5.0 and 7.5.

Adverse Effects and Precautions

As for Benzylpenicillin, p.213.

Procaine benzylpenicillin should not be given to patients known to be hypersensitive to either of its components. Procaine benzylpenicillin should not be injected intravascularly since ischaemic reactions may occur.

Severe, usually transient, reactions with symptoms of severe anxiety and agitation, confusion, psychotic reactions including visual and auditory hallucinations, seizures, tachycardia and hypertension, cyanosis, and a sensation of impending death have occasionally been reported with procaine benzylpenicillin and may be due to accidental intravascular injection. Since similar reactions have also occurred with other depot penicillin preparations that do not contain procaine, its presence is unlikely to be the major cause of such reactions, but may be a contributory factor, especially after injection of high doses. These reactions have been termed non-allergic, pseudoallergic, pseudoanaphylactic, or Hoigné's syndrome; the term 'embolic-toxic reaction' has also been proposed.

Interactions

As for Benzylpenicillin, p.214.

Pharmacokinetics

When procaine benzylpenicillin is given by intramuscular injection, it forms a depot from which it is slowly released and hydrolysed to benzylpenicillin. Peak plasma concentrations are produced in 1 to 4 hours, and effective concentrations of benzylpenicillin are usually maintained for 12 to 24 hours. However, plasma concentrations are lower than those after an equivalent dose of benzylpenicillin potassium or sodium.

Distribution into the CSF is reported to be poor.

Uses and Administration

Procaine benzylpenicillin has the same antimicrobial action as benzylpenicillin (p.214) to which it is hydrolysed gradually following deep intramuscular injection. This results in a prolonged effect, but because of the relatively low blood concentrations produced, its use should be restricted to infections caused by micro-organisms that are highly sensitive to penicillin. Procaine benzylpenicillin should not be used as the sole treatment for severe acute infections, or when bacteraemia is present.

Procaine benzylpenicillin is used mainly in the treatment of syphilis; other indications have included pneumonia (in children in developing countries), and Whipple's disease. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Administration and dosage. Doses of procaine benzylpenicillin may sometimes be expressed in terms of equivalent units of benzylpenicillin. Procaine benzylpenicillin 600 mg is equivalent to about 360 mg of benzylpenicillin (600 000 units). Procaine benzylpenicillin is given by deep intramuscular injection in usual doses of 0.6 to 1.2 g daily.

Patients with syphilis are given procaine benzylpenicillin 1.2 g daily for 10 to 14 days; infants up to 2 years of age with congenital syphilis may be given 50 mg/kg daily. Treatment may be continued for 3 weeks in patients with late syphilis.

Procaine benzylpenicillin is also used in combined preparations with other penicillins, including benzylpenicillin and benzathine benzylpenicillin.

Preparations

USP 31: Penicillin G Benzathine and Penicillin G Procaine Injectable Suspension; Penicillin G Procaine for Injectable Suspension; Penicillin G Procaine Injectable Suspension.

Proprietary Preparations (details are given in Part 3)

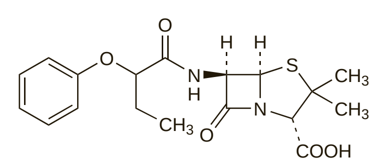
Propicillin Potassium *(BANM, pINNM)*

Kalii Propicillinum; Potassium α-Phenoxypropylpenicillin; Propicilina potásica; Propicilline Potassique; Propicillinum Kalicum. A mixture of the D(+)- and L(−)-isomers of potassium (6*R*)-6-(2-phenoxybutyramido)penicillanate.

Калия Пропициллин

$C_{18}H_{21}KN_2O_5S$ = 416.5.
CAS — 551-27-9 (propicillin); 1245-44-9 (propicillin potassium).
ATC — J01CE03.
ATC Vet — QJ01CE03.



(propicillin)

The symbol † denotes a preparation no longer actively marketed

Profile

Propicillin is a phenoxypenicillin with actions and uses similar to those of phenoxymethylpenicillin (p.314). Propicillin potassium is given orally for the treatment of susceptible mild to moderate infections in a usual dose of 700 mg three times daily.

Preparations

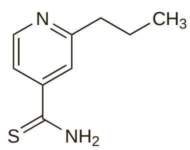
Proprietary Preparations (details are given in Part 3)
Ger.: Baycillin.

Protionamide *(BAN, rINN)*

Prothionamide; Protionamid; Protionamida; Protionamidi; Protionamidum; RP-9778; TH-1321. 2-Propylpyridine-4-carbothioamide.

Протионамид

$C_9H_{12}N_2S$ = 180.3.
CAS — 14222-60-7.
ATC — J04AD01.
ATC Vet — QJ04AD01.



Pharmacopoeias. In *Chin.*, *Int.*, and *Jpn.*

Adverse Effects, Precautions, and Antimicrobial Action

As for Ethionamide, p.275.

Pharmacokinetics

Protionamide is readily absorbed from the gastrointestinal tract and produces peak plasma concentrations about 2 hours after an oral dose. It is widely distributed throughout body tissues and fluids, including the CSF. Protionamide is metabolised to the active sulfoxide and other inactive metabolites and less than 1% of a dose appears in the urine as unchanged drug.

Uses and Administration

Protionamide is a thioamide derivative considered to be interchangeable with ethionamide (p.276) and is used as a second-line drug in the treatment of multidrug-resistant tuberculosis (p.196). It has also been used, as a substitute for clofazimine, in regimens for the treatment of leprosy (p.176) but less toxic alternatives are now preferred. Complete cross-resistance occurs between the two drugs. Protionamide has been given orally in doses similar to those used for ethionamide. It has also been given as rectal suppositories; protionamide hydrochloride has been given intravenously. Like ethionamide, it has generally been replaced by less toxic antimycobacterials.

Preparations

Proprietary Preparations (details are given in Part 3)
Ger.: ektebin; Peteha; ***Hong Kong:*** Peteha; ***India:*** Prothicid; ***Turk.:*** Promid; Tionamid.

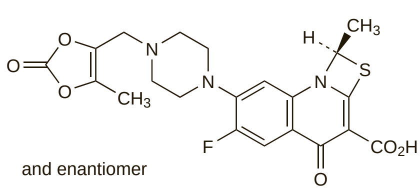
Multi-ingredient: ***Austria:*** Isoprodian; ***Ger.:*** Isoprodian†; Peteha†; ***Rus.:*** Protiocomb (Протиокомб).

Prulifloxacin *(rINN)*

NM-441; Prulifloxacine; Prulifloxacino; Prulifloxacinum. (±)-7-{4-[(*Z*)-2,3-Dihydroxy-2-butenyl]-1-piperazinyl}-6-fluoro-1-methyl-4-oxo-1*H*,4*H*-[1,3]thiazeto[3,2-*a*]quinoline-3-carboxylic acid cyclic carbonate.

Прулифлоксацин

$C_{21}H_{20}FN_3O_6S$ = 461.5.
CAS — 123447-62-1.
ATC — J01MA17.
ATC Vet — QJ01MA17.



and enantiomer

Profile

Prulifloxacin is the prodrug of ulifloxacin, a fluoroquinolone antibacterial. It is given for the treatment of susceptible infections in a usual oral dose of 600 mg daily.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Pyrazinamide). A white or almost white, crystalline powder. Sparingly soluble in water, slightly soluble in alcohol and in dichloromethane.

USP 31 (Pyrazinamide). A white to practically white, odourless or practically odourless, crystalline powder. Soluble 1 in 67 of water, 1 in 175 of dehydrated alcohol, 1 in 135 of chloroform, 1 in 1000 of ether, and 1 in 72 of methyl alcohol; slightly soluble in alcohol.

Adverse Effects and Treatment

Hepatotoxicity is the most serious adverse effect of pyrazinamide therapy and its frequency appears to be dose related. However, in currently recommended doses, when given with isoniazid and rifampicin, the incidence of hepatitis has been reported to be less than 3%. Patients may have a transient increase in liver enzyme values; more seriously hepatomegaly, splenomegaly, and jaundice may develop and on rare occasions death has occurred.

Hyperuricaemia commonly occurs and may lead to attacks of gout.

Other adverse effects are anorexia, nausea, vomiting, aggravation of peptic ulcer, arthralgia, malaise, fever, sideroblastic anaemia, thrombocytopenia, and dysuria. Photosensitivity, pellagra, and skin rashes have been reported on rare occasions.

Effects on the cardiovascular system. Acute hypertension was associated with pyrazinamide in a previously normotensive woman.[1]

1. Goldberg J, *et al.* Acute hypertension as an adverse effect of pyrazinamide *JAMA* 1997; **277:** 1356.

Effects on the liver. The risk of hepatitis with antituberculous regimens containing pyrazinamide may be lower than suggested by early studies, in which large doses were used, often for long periods. The incidence of hepatitis in studies[1] of short-course regimens containing pyrazinamide has ranged from 0.2% in Africa, to 0.6% in Hong Kong, to 2.8% in Singapore. These and later studies[2-4] have shown that hepatotoxicity is not increased when pyrazinamide is added to the initial phase of short-term chemotherapy containing rifampicin and isoniazid. Nevertheless, a report[5] of 4 cases of fulminant hepatic failure in patients given triple therapy with the potentially hepatotoxic drugs rifampicin, isoniazid, and pyrazinamide (1 patient also received ethambutol) highlighted the importance of strict liver function monitoring and this was reinforced by others. The Joint Tuberculosis Committee of the British Thoracic Society has produced recommendations[6] for initial measurement of liver function in all patients and regular monitoring in patients with pre-existing liver disease, as well as the response to deteriorating liver function; prompt re-introduction of appropriate antituberculosis therapy is recommended once normal liver function is restored. Similar guidelines have been produced for the USA.[7,8] For further information on hepatotoxicity caused by antituberculous drugs see Effects on the Liver, under Isoniazid, p.288.

The incidence of severe hepatotoxicity was found to be lower in patients receiving isoniazid, rifampicin, and pyrazinamide for initial treatment of active disease, than in those receiving rifampicin and pyrazinamide for 2 months for latent tuberculosis infection. For further information on hepatotoxicity caused by rifampicin and pyrazinamide see Effects on the Liver, under Rifampicin, p.326.

Effects on the nervous system. Convulsions that developed in a 2-year-old child receiving antituberculous therapy appeared to be due to pyrazinamide, given in a dose of 250 mg daily.[1]

1. Herlevsen P, *et al.* Convulsions after treatment with pyrazinamide. *Tubercle* 1987; **68:** 145–6.

Hyperuricaemia. Hyperuricaemia during therapy with pyrazinamide may be due to inhibition of uric acid excretion by pyrazinoic acid, the main metabolite of pyrazinamide.[1]

In a large multicentre study,[2] the incidence of elevated serum concentrations of uric acid for patients receiving rifampicin, isoniazid, and pyrazinamide was 52.2% at 8 weeks while the incidence for patients receiving rifampicin and isoniazid was 5.4%. Arthralgia was reported in 6 of 617 patients receiving rifampicin, isoniazid, and pyrazinamide, but in none of 445 patients receiving rifampicin and isoniazid.

Slight increases in plasma concentrations of uric acid occurred in 9 of 43 children after one month's treatment with rifampicin, isoniazid, ethambutol, and pyrazinamide. Arthralgias and gout did not occur. Uric acid concentrations were normal on completion of treatment with pyrazinamide.[3] Some studies[4] have suggested a relationship between elevated serum uric acid levels and arthralgia, but this has not been confirmed.[5]

Pellagra. Pellagra, probably due to pyrazinamide, developed in a 26-year-old woman receiving antituberculous therapy.[1] Symptoms regressed, despite continued therapy, on giving nicotinamide.

1. Jørgensen J. Pellagra probably due to pyrazinamide: development during combined chemotherapy of tuberculosis. *Int J Dermatol* 1983; **22:** 44–5.

Precautions

Pyrazinamide should be used with caution in patients with liver disorders and is contra-indicated in established chronic or severe liver disease. In patients with liver disorders, liver function should be assessed before and regularly during treatment. The British Thoracic Society has recommended that pyrazinamide treatment should be suspended if serum aminotransferase concentrations are elevated to 5 times the normal upper limit or if the bilirubin concentration rises. They allow cautious sequential re-introduction of antimycobacterial drugs once liver function has returned to normal: first isoniazid, then rifampicin, and then pyrazinamide. WHO recommends that pyrazinamide not be reintroduced if the hepatitis produced a clinical jaundice.

Pyrazinamide should not be given to patients with acute gout or hyperuricaemia and should be used with caution in patients with a history of gout. Caution should also be observed in patients with renal impairment. Increased difficulty has been reported in controlling diabetes mellitus when diabetics are given pyrazinamide.

Porphyria. Pyrazinamide has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. Although detailed teratogenicity data are not available, WHO,[1] the IUATLD,[2] the British Thoracic Society,[3] and the CDC[4] do not contra-indicate pyrazinamide in pregnant patients.

Interactions

Antigout drugs. The complex interactions occurring when pyrazinamide and *probenecid* are given to patients with gout have been studied.[1] Urinary excretion of urate depends on the relative size and timing of doses of the two drugs. Probenecid is known to block the excretion of pyrazinamide. A pharmacokinetic study[2] in 6 healthy subjects found that *allopurinol*, a xanthine oxidase inhibitor, increases concentrations of pyrazinoic acid (the main metabolite of pyrazinamide) thereby worsening pyrazinamide-induced hyperuricaemia. Allopurinol would therefore also appear to be unsuitable for treating pyrazinamide-induced hyperuricaemia.

1. Yü TF, *et al.* The effect of the interaction of pyrazinamide and probenecid on urinary uric acid excretion in man. *Am J Med* 1977; **63:** 723–8.
2. Lacroix C, *et al.* Interaction between allopurinol and pyrazinamide. *Eur Respir J* 1988; **1:** 807–11.

Zidovudine. Low or undetectable concentrations of pyrazinamide occurred in 4 patients also taking zidovudine.[1] In the same study, 6 of 7 patients with HIV infection taking pyrazinamide without zidovudine had normal serum pyrazinamide concentrations.

1. Peloquin CA, *et al.* Low antituberculosis drug concentrations in patients with AIDS. *Ann Pharmacother* 1996; **30:** 919–25.

Antimicrobial Action

Pyrazinamide has a bactericidal effect on *Mycobacterium tuberculosis* but appears to have no activity against other mycobacteria or micro-organisms *in vitro*. It is almost completely inactive at a neutral pH, but is effective against persisting tubercle bacilli within the acidic intracellular environment of the macrophages. The initial inflammatory response to chemotherapy increases the number of organisms in the acidic environment. As inflammation subsides and pH increases, the sterilising activity of pyrazinamide decreases. This pH-dependent activity explains the clinical effectiveness of pyrazinamide as part of the initial 8-week phase in short-course treatment regimens.

Resistance to pyrazinamide rapidly develops when it is used alone.

Action. Although the antimicrobial activity of pyrazinamide has been recognised since the 1950s, the mode of action is still unclear. One proposal is that pyrazinoic acid is the active moiety. Pyrazinamidase produced by the tubercle bacilli is known to convert pyrazinamide to pyrazinoic acid. A further proposal[1] is that the pyrazinoic acid formed within the macrophage would be trapped, thereby lowering intracellular pH to levels toxic to tubercle bacilli.

1. Salfinger M, *et al.* Pyrazinamide and pyrazinoic acid activity against tubercle bacilli in cultured human macrophages and in the BACTEC system. *J Infect Dis* 1990; **162:** 201–7.

Activity with other antimicrobials. Pyrazinamide exhibited synergistic activity against *Mycobacterium tuberculosis* with clarithromycin.[1]

1. Mor N, Esfandiari A. Synergistic activities of clarithromycin and pyrazinamide against Mycobacterium tuberculosis in human macrophages. *Antimicrob Agents Chemother* 1997; **41:** 2035–6.

Pharmacokinetics

Pyrazinamide is readily absorbed from the gastrointestinal tract. Peak serum concentrations occur about 2 hours after an oral dose and have been reported to be about 33 micrograms/mL after 1.5 g, and 59 micrograms/mL after 3 g. Pyrazinamide is widely distributed in body fluids and tissues and diffuses into the CSF. The half-life has been reported to be about 9 to 10 hours. It is metabolised primarily in the liver by hydrolysis to the major active metabolite pyrazinoic acid, which is subsequently hydroxylated to the major excretory product 5-hydroxypyrazinoic acid. It is excreted via the kidneys mainly by glomerular filtration. About 70% of a dose appears in the urine within 24 hours mainly as metabolites and about 4% as unchanged drug. Pyrazinamide is removed by dialysis. Pyrazinamide is distributed into breast milk.

◊ A short distribution phase and an elimination phase of 9.6 hours in healthy subjects after a single oral dose of pyrazinamide 27 mg/kg has been reported;[1] the half-life for the major metabolite pyrazinoic acid was 11.8 hours.

In the major metabolic pathway, pyrazinamide was deaminated to pyrazinoic acid which was hydroxylated to hydroxypyrazinoic acid; in the minor pathway, pyrazinamide was hydroxylated to hydroxypyrazinamide which was then deaminated to hydroxypyrazinoic acid. The limiting step was deamination; oxidation by xanthine oxidase occurred very quickly.

1. Lacroix C, *et al.* Pharmacokinetics of pyrazinamide and its metabolites in healthy subjects. *Eur J Clin Pharmacol* 1989; **36:** 395–400.

Bioavailability. The oral bioavailability of rifampicin and isoniazid, but not of pyrazinamide, was decreased by food in a study.[1] However, another report[2] showed slightly reduced peak serum concentrations when pyrazinamide was given with a high-fat meal, and the authors suggested that pyrazinamide should preferably be given on an empty stomach.

1. Zent C, Smith P. Study of the effect of concomitant food on the bioavailability of rifampicin, isoniazid and pyrazinamide. *Tubercle Lung Dis* 1995; **76:** 109–13.
2. Peloquin CA, *et al.* Pharmacokinetics of pyrazinamide under fasting conditions, with food, and with antacids. *Pharmacotherapy* 1998; **18:** 1205–11.

Breast feeding. The peak concentration of pyrazinamide in breast milk of a 29-year-old woman was 1.5 micrograms/mL 3 hours after a 1-g dose.[1] The peak plasma concentration was 42 micrograms/mL after 2 hours.

1. Holdiness MR. Antituberculosis drugs and breast-feeding. *Arch Intern Med* 1984; **144:** 1888.

Distribution. Pyrazinamide was given to 28 patients with suspected tuberculous meningitis in doses of 34 to 41 mg/kg. The mean concentration of pyrazinamide in the CSF after 2 hours was 38.6 micrograms/mL and represented about 75% of that in serum; concentrations at 5 and 8 hours were 44.5 and 31.0 micrograms/mL respectively and were about 10% higher than those in serum.[1] The use of corticosteroids appeared to have no influence on penetration of pyrazinamide into the CSF of patients with tuberculous meningitis.[2]

1. Ellard GA, *et al.* Penetration of pyrazinamide into the cerebrospinal fluid in tuberculous meningitis. *BMJ* 1987; **294:** 284–5.
2. Woo J, *et al.* Cerebrospinal fluid and serum levels of pyrazinamide and rifampicin in patients with tuberculous meningitis. *Curr Ther Res* 1987; **42:** 235–42.

Hepatic impairment. A study[1] of the pharmacokinetics of pyrazinamide was carried out in 10 patients with cirrhosis of the liver. After a dose of 19.3 mg/kg, the elimination phase was about 15 hours for pyrazinamide and 24 hours for the major metabolite pyrazinoic acid.

1. Lacroix C, *et al.* Pharmacokinetics of pyrazinamide and its metabolites in patients with hepatic cirrhotic insufficiency. *Arzneimittelforschung* 1990; **40:** 76–9.

HIV-infected patients. Malabsorption of pyrazinamide and other antituberculous drugs may occur in patients with HIV infection and tuberculosis, and may contribute to acquired drug resistance and reduced efficacy of tuberculosis treatment. For further information on the absorption of antituberculous drugs in HIV-infected patients see Pharmacokinetics, under Rifampicin, p.328.

Uses and Administration

Pyrazinamide is used as part of multidrug regimens for the treatment of tuberculosis (p.196), primarily in the initial 8-week phase of short-course treatment. Pyrazinamide is usually given daily or 2 or 3 times weekly. In the UK, usual recommended oral doses for adults under 50 kg are 1.5 g daily, or 2 g three times weekly, or 3 g twice weekly. The usual dose for those 50 kg or greater is 2 g daily, or 2.5 g three times weekly, or 3.5 g twice weekly. The recommended doses in the USA are 20 to 25 mg/kg daily (maximum 2 g) or 1.5 to 3 g three times weekly or 2 to 4 g twice weekly. WHO recommends 25 mg/kg daily or 35 mg/kg three times weekly.

For details of doses in infants, children, and adolescents, see below.

Pyrazinamide has also been used in the chemoprophylaxis of tuberculosis (see below).

Fixed-dose combination products have been developed in order to improve patient compliance and avoid monotherapy; thereby decreasing the risk of acquired drug resistance. Combination products containing pyrazinamide with isoniazid, isoniazid and rifampicin, or isoniazid, rifampicin, and ethambutol are available in some countries.

Administration in children. For the treatment of tuberculosis in infants, children, and adolescents the American Academy of Pediatrics suggests a dose of pyrazinamide of 20 to 40 mg/kg daily or 50 mg/kg (to a maximum of 2 g) twice weekly by mouth, for the initial treatment phase. For children 1 month and older the *BNFC* suggests a dose of 35 mg/kg (to a maximum of 1.5 g in those under 50 kg and 2 g in those over 50 kg) once daily or 50 mg/kg (to a maximum of 2 g in those under 50 kg and 2.5 g in those over 50 kg) three times a week. WHO recommends 25 mg/kg once daily or 35 mg/kg three times a week.

Administration in hepatic impairment. See Precautions, above.

Administration in renal impairment. Pyrazinamide is mainly metabolised in the liver, but its metabolites are excreted in the urine, therefore the CDC[1] suggests that the dose may need to be reduced in patients with renal impairment. The Joint Tuberculosis Committee of the British Thoracic Society[2] and WHO[3] consider that standard dosage may be used in such patients. Dialysis affects the clearance of pyrazinamide and CDC recommends reducing the dose to 25 to 35 mg/kg three times a week after dialysis.

In a study[4] of 6 patients on haemodialysis, the average amount of pyrazinamide and its metabolites removed during a dialysis session was 926 mg after an oral dose of 1700 mg. It was recommended that the usual pyrazinamide dose be given to patients on dialysis as the risk of accumulation was negligible, and that the dose on dialysis days be given after the procedure.

Tuberculosis chemoprophylaxis. In the USA, the American Thoracic Society and the CDC recommended a dose of pyrazinamide 15 to 20 mg/kg daily (maximum 2 g daily) with rifampicin 600 mg daily as an alternative to isoniazid monotherapy for the treatment of latent tuberculosis infection.[1] (In those unable to take rifampicin, it was substituted with rifabutin 300 mg daily.) However, owing to reports of serious and fatal liver damage (see Effects on the Liver, under Adverse Effects, above) the CDC and the American Thoracic Society now recommend that the combination of pyrazinamide with rifampicin should not be offered to persons with latent tuberculosis.[2].

(quinupristin)

Adverse Effects and Treatment

The adverse effects most frequently reported in patients receiving quinupristin/dalfopristin include nausea and vomiting, diarrhoea, skin rash, pruritus, headache, and pain. Myalgia and arthralgia have occurred and may be severe; symptoms may be improved by decreasing the dose frequency. Eosinophilia, anaemia, leucopenia, and neutropenia are also common. Individual cases of severe thrombocytopenia and pancytopenia have been reported. Pseudomembranous colitis has also been reported.

Hyperbilirubinaemia and raised liver enzyme values may occur.

Pain and inflammation at the injection site is common, and thrombophlebitis has occurred.

Quinupristin/dalfopristin is not removed by peritoneal dialysis, and removal by haemodialysis is considered unlikely.

Effects on the musculoskeletal system. References.

3. Raad I, *et al.* Relationship between myalgias/arthralgias occurring in patients receiving quinupristin/dalfopristin and biliary dysfunction. *J Antimicrob Chemother* 2004; **53:** 1105–8.
4. Gupte G, *et al.* Quinupristin-dalfopristin use in children is associated with arthralgias and myalgias. *Pediatr Infect Dis J* 2006; **25:** 281.

Precautions

Quinupristin/dalfopristin should be used with caution in patients with hepatic impairment and avoided in severe impairment, as elevated plasma concentrations of quinupristin and dalfopristin and their metabolites have been found in patients with hepatic dysfunction, and elevated concentrations of quinupristin metabolites have occurred in patients with hyperbilirubinaemia. The combination is contra-indicated in patients who have plasma-bilirubin concentrations greater than 3 times the normal upper limit.

Prolongation of the QT interval has been seen in *animals* given quinupristin/dalfopristin; therefore caution is advised in patients at risk of cardiac arrhythmias.

Interactions

Quinupristin/dalfopristin inhibits the cytochrome P450 isoenzyme CYP3A4 and it may therefore inhibit the metabolism of a number of drugs. In particular, there is a theoretical possibility of serious ventricular arrhythmias when given with drugs that prolong the QT interval, such as astemizole, cisapride, and terfenadine. Quinupristin/dalfopristin has been shown to increase plasma concentrations of ciclosporin, midazolam, nifedipine, and tacrolimus. The use of ergot alkaloids with quinupristin/dalfopristin should be avoided.

Antimicrobial Action

Quinupristin/dalfopristin is a streptogramin antibacterial. Quinupristin and dalfopristin each have bacteriostatic activity and in combination usually act synergistically to produce bactericidal activity. The streptogramins act on the ribosome to block protein synthesis.

Quinupristin/dalfopristin is active against a range of Gram-positive bacteria including meticillin- and multidrug-resistant strains of *Staphylococcus aureus* and *S. epidermidis*, vancomycin-resistant *Enterococcus faecium* (but not *E. faecalis*), and penicillin- and macrolide-resistant *Streptococcus pneumoniae*. It is also active against the anaerobe *Clostridium perfringens*, and Gram-negative bacteria *Legionella pneumophila*, *Moraxella catarrhalis* (*Branhamella catarrhalis*), *Mycoplasma pneumoniae*, and *Neisseria meningitidis*.

Pharmacokinetics

After parenteral doses, quinupristin and dalfopristin are rapidly metabolised. At steady state, the half-life of quinupristin and its metabolites is about 3 hours and that of dalfopristin and its metabolites about 1 hour. Elimination half-lives of unchanged quinupristin and dalfopristin are 0.9 and 0.75 hours, respectively. Protein binding ranges from 55 to 78% for quinupristin and 11 to 26% for dalfopristin. The main route of excretion is biliary, with 75 to 77% of a dose detectable in the faeces. Urinary excretion accounts for 15% of the quinupristin and 19% of the dalfopristin dose. Negligible amounts are removed by peritoneal dialysis and probably also by haemodialysis.

Distribution into milk has been found in studies in *rats*.

◊ References.

1. Bearden DT. Clinical pharmacokinetics of quinupristin/dalfopristin. *Clin Pharmacokinet* 2004; **43:** 239–52.

Uses and Administration

Quinupristin/dalfopristin is a streptogramin antibacterial related to pristinamycin. Quinupristin and dalfopristin are semisynthetic derivatives of pristinamycin I and pristinamycin IIA respectively, and are used in the ratio 3:7. Quinupristin/dalfopristin is active against a range of Gram-positive and some Gram-negative organisms, but it is reserved for the treatment of serious infections with multidrug-resistant Gram-positive bacteria, specifically MRSA and vancomycin-resistant *Enterococcus faecium*.

Quinupristin/dalfopristin is given as the mesilate salts by intravenous infusion, in glucose 5% over 60 minutes, in a dose of 7.5 mg/kg (equivalent to quinupristin 2.25 mg/kg and dalfopristin 5.25 mg/kg) every 8 or 12 hours for at least 7 days. To minimise venous irritation, the vein should be flushed with glucose 5% after each infusion; alternatively, the infusion may be given through a central venous catheter. The injection should not be diluted with saline solutions since it is incompatible with sodium chloride.

Doses may need to be reduced in patients with hepatic impairment (see below).

Administration in hepatic impairment. Licensed product information states that in clinical studies of quinupristin/dalfopristin the incidence of adverse effects in patients with chronic liver impairment or cirrhosis was similar to that in patients with normal liver function. However, pharmacokinetic studies have shown that systemic exposure to quinupristin/dalfopristin and their metabolites may be increased in those with hepatic impairment. In some countries it has therefore been recommended that quinupristin/dalfopristin should be avoided in patients with severe hepatic impairment, and that for those with moderate impairment a dose reduction to 5 mg/kg (equivalent to quinupristin 1.5 mg/kg and dalfopristin 3.5 mg/kg) should be considered if 7.5 mg/kg is not tolerated.

Ramoplanin *(USAN, rINN)*

A-16686; MDL-62198; Ramoplanina; Ramoplanine; Ramoplaninum.

Рамопланин

CAS — 76168-82-6.

Profile

Ramoplanin is a glycopeptide antibiotic with a spectrum of activity *in vitro* similar to that of vancomycin (p.359) but considerably more potent. It is also active against *Bacteroides* spp. It is under investigation, notably for the treatment of *Clostridium difficile*-associated diarrhoea. It has also been investigated for use in the prevention of systemic infection in patients colonised with vancomycin-resistant enterococci.

◊ Reviews.

Retapamulin *(USAN, rINN)*

Retapamulina; Rétapamuline; Retapamulinum; SB-275833. (3a*S*,4*R*,5*S*,6*S*,8*R*,9*R*,9a*R*,10*R*)-6-Ethenyl-5-hydroxy-4,6,9,10-tetramethyl-1-oxodecahydro-3a,9-propanocyclopenta[8]annulen-8-yl{[(1*R*,3s,5*S*)-8-methyl-8-azabicyclo[3.2.1]octan-3-yl]sulfanyl}acetate.

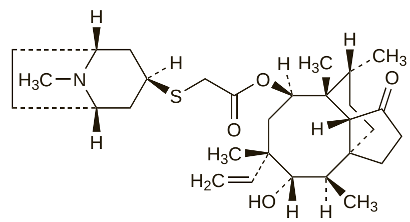
Ретапамулин

$C_{30}H_{47}NO_4S$ = 517.8.

CAS — 224452-66-8.

ATC — D06AX13.

ATC Vet — QD06AX13.



Adverse Effects and Precautions

Retapamulin is usually well tolerated; the most common reported adverse effect is application site irritation. Other local reactions such as erythema, pain, and pruritus occur rarely. Retapamulin ointment contains butylated hydroxytoluene (p.1633), which may cause local adverse effects such as contact dermatitis, or irritation to the eyes and mucous membranes. It should not be applied to abscesses.

Retapamulin has proved ineffective in infections caused by meticillin-resistant *Staphylococcus aureus*, and should not be used in their treatment.

Antimicrobial Action

Retapamulin is an antibacterial that selectively inhibits bacterial protein synthesis by binding to the 50S subunit of the ribosome. It is mainly bacteriostatic against meticillin-susceptible *Staphylococcus aureus*, and streptococci such as *Strep. pyogenes*. Although *in vitro* activity has been shown against meticillin-resistant *Staph. aureus* the *in vivo* efficacy of retapamulin was found to be inadequate in clinical studies.

◊ References.

3. Rittenhouse S, *et al.* Selection of retapamulin, a novel pleuromutilin for topical use. *Antimicrob Agents Chemother* 2006; **50:** 3882–5.
4. Champney WS, Rodgers WK. Retapamulin inhibition of translation and 50S ribosomal subunit formation in Staphylococcus aureus cells. *Antimicrob Agents Chemother* 2007; **51:** 3385–7.

Pharmacokinetics

Only very small amounts of topically applied retapamulin are absorbed into the systemic circulation. It is about 94% bound to plasma proteins and is shown to be metabolised by mono-oxygenation and N-demethylation *in vitro*.

Uses and Administration

Retapamulin is a pleuromutilin antibacterial isolated from the fungus *Clitopilus passeckerianus*. It is applied topically as a 1% ointment in the treatment of impetigo and other bacterial skin infections due to meticillin-susceptible *Staphylococcus aureus* and *Streptococcus pyogenes*. The preparation should be applied twice daily for 5 days; treatment should be re-evaluated if there is no response within about 3 days. It is not suitable for application to mucous membranes.

For further details of skin infections and staphylococcal infections and their treatment, see p.194.

USP 31 (Rifabutin). An amorphous red-violet powder. Very slightly soluble in water; sparingly soluble in alcohol; soluble in chloroform and in methyl alcohol. Store at a temperature not exceeding 40°. Protect from light.

Stability. Study of the stability of two extemporaneous oral liquid preparations of rifabutin.[1]

1. Haslam JL, *et al.* Stability of rifabutin in two extemporaneously compounded oral liquids. *Am J Health-Syst Pharm* 1999; **56:** 333–6.

Adverse Effects and Precautions

As for Rifampicin, p.325.

Rifabutin is usually well tolerated. The most common adverse effects include rash, gastrointestinal disturbances, and neutropenia. It produces a syndrome of polyarthralgia-arthritis at doses greater than 1 g daily. Uveitis has been reported, especially in patients also receiving clarithromycin or other macrolides and possibly also with fluconazole. Asymptomatic corneal opacities have been reported after long-term use.

Rifabutin should be used with caution in patients with severe hepatic or renal impairment.

◊ An orange-tan skin pigmentation has been reported to occur in most patients receiving rifabutin.[1] Urine may be discoloured.[2] A flu-like syndrome has been reported in 2 of 12 patients given 300 mg daily for Crohn's disease,[3] in 1 of 16 HIV-infected patients on continuous rifabutin,[1] and in 8 of 15 HIV-infected patients receiving increasing doses of rifabutin.[2]

Other reported adverse effects include hepatitis,[1] leucopenia[2] (including neutropenia[4]), epigastric pain,[3] rash,[3] erythema,[2] and ageusia.[5]

Rash, fever, and vomiting occurred in 1 of 2 children receiving 6.5 mg/kg daily.[6]

Effects on the eyes. Uveitis may occur a few weeks or months after starting rifabutin, and generally necessitates withdrawal of the drug and treatment with topical or systemic corticosteroids and cycloplegics.[1] In 1994, the UK CSM was aware of 48 reports of uveitis in patients taking rifabutin.[2] Most patients were also receiving clarithromycin for treatment of AIDS-related *Mycobacterium avium* complex (MAC) infection and many were also receiving fluconazole (see Interactions, below). A dosage reduction to 300 mg rifabutin daily is now recommended in patients also receiving macrolides or triazole antifungals[2,3] and is reported to produce a satisfactory response in MAC infections.[4] Panuveitis and retinal vasculitis has been reported[5] in 4 patients with active tuberculosis given rifabutin, and was thought to be a result of activation of the immune system by *Mycobacterium tuberculosis* and the very low weight of the patients.

Rifabutin-associated uveitis in children is less commonly reported probably because they may not notice or complain about visual changes, therefore monitoring of their vision while on treatment is advised.[6]

Effects on the joints. A polyarthralgia-arthritis syndrome was reported in an initial dose finding study[1] in 9 of 10 patients receiving rifabutin, as monotherapy, at doses greater than 1 g. The syndrome did not occur in patients receiving less than 1 g daily and disappeared on drug withdrawal. Two patients with polyarthralgia-arthritis symptoms developed uveitis (see also under Effects on the Eyes, above) and aphthous stomatitis at doses of about 1.8 g daily. However, a later study[2] and case reports[3] have reported polyarthralgia-arthritis syndrome when rifabutin was given at doses of 300 to 600 mg daily as part of a multidrug regimen, including a macrolide (azithromycin or clarithromycin), for the treatment of *Mycobacterium avium* complex infection. Concentrations of rifabutin were increased as a result of inhibition of cytochrome P450 isoenzymes by the macrolide and some have suggested a maximum dose of rifabutin of 300 mg daily when used with a macrolide.[2] Higher doses of 450 to 600 mg daily may be considered for patients of large body mass or those who have failed to respond to initial treatment with a lower dose.

Interactions

As for Rifampicin, p.327.

Rifabutin accelerates the metabolism of many drugs by inducing microsomal liver enzymes (in particular the cytochrome P450 isoenzyme CYP3A4). It is a less potent inducer of cytochrome P450 isoenzymes than rifampicin, but similar interactions should nevertheless be anticipated. Use with other drugs that induce or inhibit these isoenzymes may result in changes in plasma concentrations of rifabutin, and possibly adverse effects.

Plasma concentrations of rifabutin are increased by clarithromycin (and possibly other macrolides) or fluconazole, resulting in increased rifabutin toxicity, in particular uveitis, (see Effects on the Eyes, above), neutropenia, and polyarthralgia-arthritis syndrome (see Effects on the Joints, above).

Some other interactions affecting the activity of rifabutin are discussed below.

Antiretroviral drugs. Rifabutin may be used as a substitute for rifampicin in the treatment of tuberculosis.[1,2] It has little effect on the serum concentrations of unboosted *HIV-protease inhibitors* (except saquinavir) and ritonavir-boosted HIV-protease inhibitors. However, HIV-protease inhibitors, particularly if boosted with ritonavir, significantly increase serum concentrations and toxicity of rifabutin. The dose of rifabutin is therefore usually substantially decreased when given with HIV-protease inhibitors (see Tuberculosis and HIV infection under Uses, below). Rifabutin should not be given with unboosted saquinavir; but saquinavir may be given with rifabutin if boosted with ritonavir.[2] Increases in the dose of indinavir are also required.[2]

Serum concentrations of rifabutin may be increased or decreased in those taking *NNRTIs*. However, rifabutin may usually be given to patients taking etravirine or nevirapine without the need for any dose modifications. Rifabutin is, however, not recommended in patients taking delavirdine or in those taking etravirine with ritonavir-boosted darunavir or ritonavir-boosted saquinavir. In patients taking efavirenz, the dose of rifabutin should be increased by at least 50% (see Tuberculosis and HIV infection under Uses, below).

No clinically significant interactions are expected with the integrase inhibitor *raltegravir* or the CCR-5 receptor antagonist *maraviroc*.[2] For further information on drug interactions with HIV-protease inhibitors see Table 1, p.917, and with NNRTIs see Table 2, p.944 in Antivirals.

Although rifabutin is reported to reduce the plasma concentrations of *zidovudine*, studies have shown that the effect is not marked (see p.915), and licensed product information for rifabutin suggests that the reduction may not be clinically relevant.

2. CDC. Managing Drug Interactions in the Treatment of HIV-Related Tuberculosis (issued December 2007). Available at: http://www.cdc.gov/tb/TB_HIV_Drugs/PDF/tbhiv.pdf (accessed 28/07/08)

Azole antifungals. Rifabutin concentrations are increased by triazole antifungals and patients are at increased risk of rifabutin toxicity, specifically uveitis (see under Effects on the Eyes, above). Rifabutin also markedly reduces the plasma concentrations of *itraconazole*, *posaconazole*, and *voriconazole*, but does not affect the metabolism of *fluconazole*.

The area under the concentration-time curve (AUC) for rifabutin and its active 25-deacetyl metabolite were increased by 82% and 216% respectively when fluconazole was given to 12 HIV-infected patients.[1] Another study[2] in 10 patients with HIV infection, found that fluconazole increased the AUC of rifabutin by 76% and by 152% when the patients were also given clarithromycin. Raised plasma-rifabutin concentrations were reported in a patient who developed uveitis while also receiving itraconazole.[3] The mechanism of the interaction remains uncertain but could involve microsomal cytochrome P450 isoenzyme CYP3A4 (see Metabolism under Pharmacokinetics, below).

3. Lefort A, *et al.* Uveitis associated with rifabutin prophylaxis and itraconazole therapy. *Ann Intern Med* 1996; **125:** 939–40.

Macrolides. As discussed under Effects on the Eyes, above, most patients developing uveitis during rifabutin treatment are also receiving *clarithromycin* and it may also be implicated in the polyarthralgia-arthritis syndrome (see Effects on the Joints, above). In a study[1] of the treatment of *Mycobacterium avium* complex infection in AIDS patients, uveitis or pseudojaundice or both were noted in those receiving rifabutin, ethambutol, and clarithromycin, but not in those receiving rifabutin, ethambutol, ciprofloxacin, and clofazimine. A retrospective study[2] after an outbreak of uveitis in a similar patient population also found clarithromycin to be a risk factor, with a trend towards greater risk at higher rifabutin doses, although patient numbers were small. In 26 patients taking rifabutin with either clarithromycin or *azithromycin*,[3] the incidence and severity of adverse effects in general was similar, although the 2 patients who developed uveitis were both receiving clarithromycin.

Pharmacokinetic studies have found increased rifabutin concentrations when clarithromycin is also used. A study in healthy subjects[4] was terminated prematurely because of the high incidence of adverse effects, including neutropenia, fevers, and myalgia, particularly in subjects receiving rifabutin with azithromycin or clarithromycin. Mean serum concentrations of rifabutin and its 25-*O*-deacetyl metabolite in subjects also receiving clarithromycin were more than 4 times and 37 times those in subjects receiving rifabutin alone. Plasma concentrations were unaffected by azithromycin. Similar effects on rifabutin concentrations were found in HIV-infected subjects receiving clarithromycin[5] and reductions in clarithromycin concentrations were also noted. A study[6] to determine the tolerance and pharmacokinetic interactions of rifabutin and azithromycin in subjects with or without HIV infection found no significant drug interaction; however, the combination was poorly tolerated, mainly because of a high incidence of gastrointestinal symptoms and neutropenia.

Antimicrobial Action

Rifabutin possesses a spectrum of antibacterial activity similar to that of rifampicin (p.327). However, most investigations have concentrated on its action against mycobacteria. Cross-resistance with rifampicin is common.

Antimycobacterial action. Rifabutin possesses activity against most species of mycobacteria. It may be more active *in vivo* than *in vitro* studies suggest, as a result of its favourable pharmacokinetic profile and prolonged postantibiotic effect.[1]

Rifabutin has been reported to be active in *animal* assays against *Mycobacterium leprae*,[2] including a rifampicin-resistant strain.[3] Synergistic activity against *M. leprae* has been reported[4] *in vitro* for rifabutin with sparfloxacin.

Resistance. Rifampicin-resistant strains of *Mycobacterium tuberculosis* have been identified in 2 patients receiving rifabutin alone as prophylaxis against *M. avium* complex.[1,2] It is therefore important to exclude *M. tuberculosis* infection before beginning rifabutin prophylaxis.

Rifampicin-resistant *M. kansasii* has also been reported in a patient receiving rifabutin.[3]

Acquired resistance has been reported in HIV-infected persons receiving highly intermittent regimens (once- or twice-weekly) of rifabutin for the treatment of active tuberculosis,[4,5] and the CDC has advised that such patients receive daily treatment during the intensive phase of therapy and daily or 3 times-weekly treatment during the continuation phase.

Pharmacokinetics

Rifabutin is readily but incompletely absorbed from the gastrointestinal tract and peak plasma concentrations of about 0.25 to 0.6 micrograms/mL have been reported 2 to 4 hours after an oral dose of 300 mg; doubling the dose increases the peak plasma concentration. Food may delay absorption but does not affect the extent of absorption. Rifabutin is about 70% bound to plasma proteins. Rifabutin is lipophilic and therefore is widely distributed in body tissues and fluids.

Rifabutin is rapidly metabolised in the liver by the cytochrome P450 isoenzyme CYP3A4 mainly to active 25-O-deacetyl and 31-hydroxy metabolites. Rifabutin induces its own metabolism resulting in a lower area under the curve after 4 weeks of continuous treatment than after the first few doses.

About 53% of a dose is found in the urine, mainly as metabolites and about 30% of a dose is excreted in the faeces. The mean half-life for rifabutin is reported to be about 40 hours, with a range of 16 to 69 hours.

HIV-infected patients. Malabsorption of rifabutin and other antituberculous drugs may occur in patients with HIV infection and tuberculosis, and may contribute to acquired drug resistance and reduced efficacy of tuberculosis treatment. For further information on the absorption of antituberculous drugs in HIV-infected patients see Pharmacokinetics, under Rifampicin, p.328.

The pharmacokinetics of rifabutin were studied in HIV-infected patients with normal renal and hepatic function.[1] A two-compartment open pharmacokinetic model was proposed. Rifabutin was rapidly but incompletely absorbed from the gastrointestinal tract and bioavailability was poor, being 20% on day 1 of the study and 12% on day 28. Mean peak plasma concentrations occurred 2 to 3 hours after oral doses and were about 350, 500, and 900 nanograms/mL after doses of 300, 600, and 900 mg respectively. The peak and trough concentrations after 600 mg twice daily were about 900 and 200 nanograms/mL respectively. Rifabutin was about 70% bound to plasma proteins. The area under the curve showed a decrease on repeated dosage which might be explained by the induction of drug-metabolising liver enzymes. A large volume of distribution of 8 to 9 litres/kg, indicative of extensive tissue distribution, and a mean terminal half-life of 32 to 38 hours were reported.

This study[1] also showed that the peak plasma concentration of the major metabolite, 25-deacetylrifabutin, was 10% of the parent compound. Only 4% of unchanged rifabutin was excreted in the urine after oral use and between 6 to 14% after intravenous use. Total urinary excretion of rifabutin and metabolite 72 hours after intravenous use was 44%; total faecal excretion was between 30 and 49%.

Peak and trough concentrations at steady state were reported as 900 and 200 nanograms/mL respectively in a patient with tuberculosis given rifabutin 450 mg daily.[2] While these figures were the same as those previously reported with 600 mg twice daily,[1] the earlier study showed that there was considerable interpatient variability.

CSF concentrations in 5 patients with AIDS on rifabutin 450 mg daily ranged from 36 to 70% of serum concentrations.[3]

2. Gillespie SH, *et al.* The serum rifabutin concentrations in a patient successfully treated for multi-resistant mycobacterium tuberculosis infection. *J Antimicrob Chemother* 1990; **25:** 490–1. Correction. *ibid.* 1991; **27:** 877.
3. Siegal FP, *et al.* Dose-limiting toxicity of rifabutin in AIDS-related complex: syndrome of arthralgia/arthritis. *AIDS* 1990; **4:** 433–41.

Metabolism. Five metabolites of rifabutin were identified in an *in-vitro* study[1] using human hepatic and enterocyte microsomes. Cytochrome P450 isoenzyme CYP3A4 was involved in the formation of all metabolites except 25-*O*-deacetylrifabutin. Deacetylation of rifabutin was apparently mediated by microsomal cholinesterase,[1] although another study[2] showed that further metabolism of 25-*O*-deacetylrifabutin is dependent on CYP3A4. The results[1] also suggested that metabolism by intestinal CYP3A4 contributes significantly to presystemic metabolism of rifabutin (and consequently its low bioavailability) and to drug interactions with azole antifungals and with macrolides (see above).

1. Iatsimirskaia E, *et al.* Metabolism of rifabutin in human enterocyte and liver microsomes: kinetic parameters, identification of enzyme systems, and drug interactions with macrolides and antifungal agents. *Clin Pharmacol Ther* 1997; **61:** 554–62.
2. Trapnell CB, *et al.* Metabolism of rifabutin and its 25-desacetyl metabolite, LM565, by human liver microsomes and recombinant human cytochrome P-450 3A4: relevance to clinical interaction with fluconazole. *Antimicrob Agents Chemother* 1997; **41:** 924–6.

Uses and Administration

Rifabutin is a rifamycin antibacterial used as an alternative to the macrolides for the prophylaxis of *Mycobacterium avium* complex (MAC) infection in immunocompromised patients. It is also used for the treatment of other nontuberculous mycobacterial infections (including those due to MAC) (p.181) and tuberculosis (p.196). When used for treatment rifabutin, like rifampicin, should be used with other antibacterials to prevent the emergence of resistant organisms.

Rifabutin is given as a single oral daily dose. The dose for the prophylaxis of MAC infection is 300 mg daily. For the treatment of nontuberculous mycobacterial infections the dose is 450 to 600 mg daily in a multidrug regimen for up to 6 months after negative cultures are obtained. For pulmonary tuberculosis the usual dose is 300 mg daily for at least 6 months as part of a multidrug regimen; it can also be given intermittently (usually 3 times each week) as an alternative to daily use.

For details of doses in infants, children, and adolescents, see below.

Doses should be reduced to 300 mg daily in patients also receiving macrolides or azole antifungals (see under Adverse Effects, Effects on the Eyes, above). Dosage alterations may also be necessary in patients receiving HIV-protease inhibitors (see under Tuberculosis, below) and in those with severe renal impairment (see below).

◊ Reviews.

1. Brogden RN, Fitton A. Rifabutin: a review of its antimicrobial activity, pharmacokinetic properties and therapeutic efficacy. *Drugs* 1994; **47:** 983–1009.

Administration in children. For the prophylaxis of MAC in HIV-infected infants and children with low CD4+ counts, the American Academy of Pediatrics (AAP) suggests an oral dose of rifabutin 5 mg/kg daily in those older than 6 years; the *BNFC* suggest the same dose may be given from 1 year of age and those 12 years of age and older may be given the usual adult dose.

For the treatment of nontuberculous mycobacterial disease in children aged 1 month to 12 years the *BNFC* suggests a dose of 5 mg/kg once daily for at least 6 months as part of a multidrug regimen; those 12 years of age and older may be given the usual adult dose.

For the treatment of tuberculosis in those 12 years of age and older the *BNFC* suggests a dose of 150 to 450 mg once daily for at least 6 months as part of a multidrug regimen.

Administration in renal impairment. Dosage of rifabutin should be reduced by 50% in patients with severe renal impairment (creatinine clearance less than 30 mL/minute).

Cryptosporidiosis. Rifabutin may have a potential prophylactic effect against cryptosporidiosis (p.823).

Mycobacterium avium complex infections. Alterations in rifabutin dosage may be necessary in patients receiving antiretrovirals for the management of HIV infection; further details are given under Tuberculosis, below.

Peptic ulcer disease. For mention of the use of rifabutin in eradication regimens for *Helicobacter pylori* see p.1702.

References.

Toxoplasmosis. A beneficial response to rifabutin used with pyrimethamine was reported in a patient with AIDS-related *Toxoplasma gondii* encephalitis.[1] The patient was allergic to sulfonamides and clindamycin, which are commonly used (see p.826).

1. Schürmann D, *et al.* Rifabutin appears to be a promising agent for combination treatment of AIDS-related toxoplasma encephalitis. *J Infect* 1998; **36:** 352–3.

Tuberculosis and HIV infection. Rifabutin may be used in place of rifampicin in short-course therapy for tuberculosis in patients given antiretroviral drugs for HIV infection and may be preferred for patients unable to take efavirenz.[1,2] However, dose modifications are often necessary; additionally, some combinations, notably rifabutin with delavirdine, or saquinavir alone, should not be used, although rifabutin may be given with saquinavir if ritonavir is also given.

- In patients taking ritonavir-boosted HIV-protease inhibitors the dose of rifabutin should be substantially reduced from 300 mg daily or intermittently to 150 mg every other day or three times each week
- In patients taking unboosted atazanavir the dose of rifabutin should be substantially reduced from 300 mg daily or intermittently to 150 mg every other day or three times each week
- In those taking unboosted amprenavir, fosamprenavir, indinavir, or nelfinavir the daily dose of rifabutin should be decreased from 300 mg to 150 mg, and the dose for intermittent therapy should be 300 mg three times weekly. The dose of indinavir may need to be increased
- In patients taking efavirenz, the dose of rifabutin should be increased from 300 mg daily or intermittently to 450 to 600 mg daily or three times each week
- In patients taking nevirapine or etravirine, the usual dose of rifabutin is given (300 mg daily or 300 mg three times each week); rifabutin should not be used in patients taking etravirine plus ritonavir-boosted darunavir or saquinavir

Rifampicin *(BAN, rINN)*

Ba-41166/E; L-5103; NSC-113926; Rifaldazine; Rifampicina; Rifampicinas; Rifampicine; Rifampicinum; Rifampin *(USAN)*; Rifampisiini; Rifampisin; Rifamycin AMP; Ryfampicyna. 3-(4-Methylpiperazin-1-yliminomethyl)rifamycin SV; (12*Z*,14*E*,24*E*)-(2*S*,16*S*,17*S*,18*R*,19*R*,20*R*,21*S*,22*R*,23*S*)-1,2-Dihydro-5,6,9,17,19-pentahydroxy-23-methoxy-2,4,12,16,18,20,22-heptamethyl-8-(4-methylpiperazin-1-yliminomethyl)-1,11-dioxo-2,7-(epoxypentadeca-[1,11,13]trienimino)naphtho[2,1-*b*]furan-21-yl acetate.

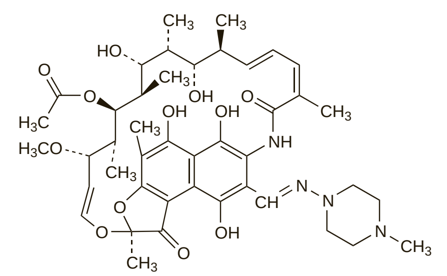
Рифампицин

$C_{43}H_{58}N_4O_{12}$ = 822.9.

CAS — 13292-46-1.

ATC — J04AB02.

ATC Vet — QJ04AB02; QJ54AB02.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Rifampicin). A reddish-brown or brownish-red, crystalline powder. Slightly soluble in water, in alcohol, and in acetone; soluble in methyl alcohol. A 1% suspension has a pH of 4.5 to 6.5. Store at a temperature not exceeding 25° in an atmosphere of nitrogen in airtight containers. Protect from light.

USP 31 (Rifampin). A red-brown crystalline powder. Very slightly soluble in water; freely soluble in chloroform; soluble in ethyl acetate and in methyl alcohol. A 1% suspension in water has a pH of 4.5 to 6.5. Store at a temperature not exceeding 40° in airtight containers. Protect from light.

Adverse Effects

Rifampicin is usually well tolerated. Adverse effects are more common during intermittent therapy or after restarting interrupted treatment.

Some patients may experience a cutaneous syndrome that presents 2 to 3 hours after a daily or intermittent dose as facial flushing and itching, with or without a rash, or rarely eye irritation and visual disturbances. A flu-like syndrome characterised by episodes of fever, chills, headache, dizziness, bone pain, shortness of breath, and malaise has been associated with intermittent use. It usually occurs after 3 to 6 months of intermittent treatment and has a higher incidence with doses of 25 mg/kg or more given once weekly than with currently recommended regimens. Anaphylaxis or shock has occurred rarely.

Gastrointestinal adverse effects include nausea, vomiting, anorexia, diarrhoea, and epigastric distress. Taking doses on an empty stomach is recommended for maximal absorption, but dosage after a meal will minimise gastrointestinal intolerance. Pseudomembranous colitis has been reported. Rifampicin produces transient abnormalities in liver function and hepatitis. Fatalities due to hepatotoxicity have been reported occasionally (see Effects on the Liver, below).

Rifampicin can cause thrombocytopenia and purpura, usually when given as an intermittent regimen, and if this occurs further use of rifampicin is contra-indicated. Other haematological adverse effects include eosinophilia, leucopenia, and haemolytic anaemia.

Alterations in kidney function and renal failure have occurred, particularly during intermittent therapy. Menstrual disturbances have been reported.

Nervous system adverse effects include headache, drowsiness, ataxia, dizziness, and numbness.

Oedema, myopathy, and muscular weakness have been reported.

Thrombophlebitis has occurred after prolonged intravenous infusion. Extravasation during intravenous infusion may cause local irritation and inflammation.

Rifampicin causes a harmless orange-red discoloration of the urine, faeces, sweat, saliva, sputum, tears, and other body fluids. Soft contact lenses may become permanently stained.

Effects on the blood. Thrombocytopenia may occur in patients taking rifampicin, most commonly as intermittent therapy, and probably has an immunological basis. The platelet count may fall within 3 hours of a dose and return to normal within 36 hours, if additional doses are not given.[1] There may also be a risk of thrombocytopenia when re-introducing rifampicin to patients who have interrupted their treatment.[2] Thrombocytopenia has also been reported in a patient taking rifampicin for the first time for meningococcal prophylaxis.[3] Thrombotic thrombocytopenic purpura has been reported in a patient after two weeks of treatment with oral rifampicin and intravenous vancomycin for a meticillin-resistant *Staphylococcus aureus* infection.[4] Fatalities have occurred when rifampicin was not withdrawn once thrombocytopenic purpura had developed or when treatment with rifampicin was resumed in patients who had experienced purpura.[1] However, there is a report of the successful re-introduction of rifampicin in a patient who developed thrombocytopenia without rifampicin-dependent antibodies.[5]

Bleeding from the oral cavity not associated with thrombocytopenia has been reported in a patient taking rifampicin.[6] Leucopenia,[7,8] haemolysis or haemolytic anaemia,[9] and red cell aplasia[10] have occurred. Disseminated intravascular coagulation has been reported in a patient receiving intermittent rifampicin therapy.[11] The incidence of deep-vein thrombosis increased in one group of hospitalised tuberculosis patients when rifampicin was introduced as standard therapy,[12] but data from others have not supported a causal relationship.[13]

Effects on the gastrointestinal tract. In addition to symptoms of gastrointestinal intolerance, there have been reports of gastrointestinal bleeding and erosive gastritis,[1] ulcerative colitis,[2] and eosinophilic colitis[3] in patients receiving rifampicin.

1. Zargar SA, *et al.* Rifampicin-induced upper gastrointestinal bleeding. *Postgrad Med J* 1990; **66:** 310–11.

Effects on the liver. Transient abnormalities in liver function are common during the early stages of antituberculous therapy with rifampicin and other first-line antituberculous drugs, but sometimes the hepatotoxicity may be more serious and require a change of treatment. Drug-induced hepatitis usually occurs within the first few weeks of treatment and it may not be possible to identify which drug or drugs are responsible. Rifampicin is thought to have a lower potential for hepatotoxicity than isoniazid or pyrazinamide.[1]

Risk factors for hepatotoxicity include alcoholism, old age, female gender, malnutrition, HIV infection, and chronic hepatitis B and C infections.[1]

The Joint Tuberculosis Committee of the British Thoracic Society has published recommendations[2] for initial measurement of liver function in all patients and regular monitoring in patients with pre-existing liver disease. Details are given concerning the response to deteriorating liver function and guidelines included for prompt re-introduction of appropriate antituberculosis therapy once normal liver function is restored. Similar guidelines have been produced for the USA.[3,4]

The incidence of severe hepatotoxicity was found to be lower in patients receiving isoniazid, rifampicin, and pyrazinamide for initial treatment of active disease, than in those receiving rifampicin and pyrazinamide for 2 months for latent tuberculosis infection. Management of latent tuberculosis with the rifampicin plus pyrazinamide regimen was also associated with a higher incidence of severe hepatotoxicity than was isoniazid monotherapy for 6 months.[5] Severe and sometimes fatal hepatotoxicity has been associated with the combined regimen of rifampicin and pyrazinamide for the treatment of latent tuberculosis in a predominantly HIV-negative study population.[5-9] In the USA, the CDC and the American Thoracic Society[10] now recommend that the combination of rifampicin with pyrazinamide should not generally be offered to persons with latent tuberculosis. However, an evaluation of studies[11] for the prevention of tuberculosis, involving HIV-infected patients, reported very little evidence of hepatotoxicity among patients taking rifampicin plus pyrazinamide and among those taking isoniazid.

For further information on hepatotoxicity caused by antituberculous drugs see Effects on the Liver, under Isoniazid, p.288.

Hepatitis and liver dysfunction have also been reported in patients taking rifampicin, in the absence of other hepatotoxic drugs, for the treatment of pruritus associated with primary biliary cirrhosis.[12]

Effects on the skin. Skin reactions to rifampicin are usually mild, irrespective of it being given daily or intermittently.[1] However, there have been a few isolated reports of severe reactions such as toxic epidermal necrolysis,[2] exfoliative dermatitis,[3] fixed drug eruptions,[4,5] and acute generalised exanthematous pustulosis.[6] Contact dermatitis has been seen after handling rifampicin powder.[7]

Lupus. Symptoms including malaise, arthralgia, arthritis, and oedema of the extremities, occurring in 4 patients taking rifampicin and 3 taking rifabutin, were considered to be due to drug-induced lupus syndrome.[1] Cutaneous lupus erythematosus was reported in a patient receiving rifampicin with clarithromycin and ethambutol.[2] All patients had positive anti-nuclear antibody titres.[1,2]

Overdosage. Cases of skin pigmentation induced by rifampicin overdose have been reviewed.[1] Reddish-orange discoloration of the skin appeared within a few hours of taking the drug; urine, mucous membranes, and sclera were also discoloured. Periorbital or facial oedema, pruritus, and gastrointestinal intolerance occurred in most patients. Treatment was supportive and clinical symptoms resolved in most patients over 3 to 4 days, although fatalities occurred with doses over 14 g.

Precautions

Liver function should be checked before treatment with rifampicin and special care should be taken in alcoholic patients or those with pre-existing liver disease who require regular monitoring during therapy. UK licensed product information states that use is contra-indicated in patients with jaundice. A self-limiting hyperbilirubinaemia may occur in the first 2 or 3 weeks of treatment. Alkaline phosphatase values may be raised moderately due to rifampicin's enzyme-inducing capacity. Isolated results showing hyperbilirubinaemia in the first few weeks and/or moderately elevated transaminase values are not indications to withdraw rifampicin. However, dose adjustment is necessary when there is other evidence of hepatic impairment and treatment should be suspended when there is evidence of more serious liver toxicity.

Blood counts should be monitored during prolonged treatment and in patients with hepatic disorders. Should thrombocytopenia or purpura occur then rifampicin should be withdrawn permanently. UK product information also recommends such withdrawal in patients who develop haemolytic anaemia or renal failure.

Use of rifampicin after interruption of treatment has been associated with increased risk of serious adverse effects.

Patients should be advised that rifampicin may colour faeces, saliva, sputum, sweat, tears, urine, and other body-fluids orange-red. Soft contact lenses may become permanently stained.

Rifampicin should not be given by the intramuscular or subcutaneous route. When given by intravenous infusion care should be taken to avoid extravasation.

Adrenocortical insufficiency. Adrenal insufficiency has been associated with tuberculosis and induction of microsomal enzymes by rifampicin may accelerate the metabolism of cortisol and precipitate an acute adrenal crisis in such patients.[1] Induction of microsomal enzymes may be enough to compromise even patients with mildly impaired cortisol production. Critical hypotension has also developed in non-Addisonian patients within a week to 10 days of starting rifampicin therapy. However, it has not been necessary to suspend the use of rifampicin if patients are treated with corticosteroids.[2] The effectiveness of corticosteroid therapy can be reduced by rifampicin.

2. Boss G. Rifampicin and adrenal crisis. *BMJ* 1983; **287:** 62.

Breast feeding. Rifampicin is excreted into breast milk. No adverse effects have been seen in breast-fed infants whose mothers were taking rifampicin, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 05/10/07)

Porphyria. Rifampicin has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. Treatment guidelines produced by WHO,[1] by an expert group in the UK,[2] and by the CDC in the USA[3] have recommended treatment of pregnant patients with the same rifampicin-containing multidrug regimens as would be used in non-pregnant patients. While use of rifampicin in pregnant patients is generally considered to be safe, the drug does cross into the fetus[4] and malformations and bleeding tendencies have been reported.[5] A literature review[5] revealed 386 normal term infants and 29 elective terminations out of 446 pregnancies in patients who took rifampicin with other antimycobacterial drugs. A variety of malformations were reported; there were 14 abnormal infants or fetuses, 2 premature births, 9 still-births and 7 spontaneous abortions. It was considered that rifampicin did not increase the overall risk of congenital malformations.

Rifampicin treatment can increase the metabolism of vitamin K, resulting in clotting disorders associated with vitamin K deficiency. Bleeding disorders in 2 mothers shortly after delivery, and scalp haemorrhage, anaemia, and shock in one of the infants have been reported.[6] The authors recommended blood coagulation monitoring and giving prophylactic vitamin K to mothers and neonates when the mother has received rifampicin during pregnancy.

Interactions

Rifampicin accelerates the metabolism of many drugs by inducing microsomal liver enzymes (in particular the cytochrome P450 isoenzyme CYP3A) or drug transporter proteins (such as p-glycoprotein). Drugs so affected may require an increase in dosage to maintain effectiveness and patients should be monitored closely when starting or stopping concurrent rifampicin treatment. Women taking oral contraceptives should use additional precautions or change to a non-hormonal form of contraception (see Rifamycins, p.2068).

The absorption of rifampicin may be reduced by antacids, but this interaction can be overcome by giving rifampicin 1 hour before any antacids. Similarly, rifampicin and preparations containing bentonite (for example some aminosalicylic acid preparations) should be given 8 hours apart. Isoniazid and halothane may increase the potential for hepatotoxicity when given with rifampicin. Atovaquone may increase the concentration of rifampicin, while rifampicin decreases the concentration of atovaquone. Some other interactions affecting the activity of rifampicin are discussed below.

Antiretroviral drugs. Rifamycins can induce the metabolism of *zidovudine*, the NNRTIs delavirdine, efavirenz, and nevirapine, and *HIV-protease inhibitors*, resulting in potentially subtherapeutic plasma concentrations. In addition HIV-protease inhibitors inhibit the metabolism of rifamycins resulting in elevated plasma-rifamycin concentrations and an increased incidence of adverse effects.[1,2]

Guidelines in the UK[3] and the USA[2] recommend that rifampicin should not be used with the *NNRTIs* delavirdine, and etravirine but opinion varies on whether it should be used with nevirapine. Licensed product information for nevirapine contraindicates the use of rifampicin and nevirapine. Rifampicin decreases the serum concentration of efavirenz and it is recommended that the dose of efavirenz be increased in patients weighing more than 60 kg; no dose modification is needed for rifampicin.

It is also recommended that rifampicin should not be used with unboosted or low-dose ritonavir-boosted *HIV-protease inhibitor* regimens. For reference to suitable antiretroviral regimens for use in patients requiring rifampicin-containing treatment for tuberculosis, see p.196.

Rifampicin significantly decreases the serum concentration of the CCR-5 receptor antagonist, *maraviroc*, and it is recommended that the dose of maraviroc be increased; no dose modification is needed for rifampicin. No clinically significant interactions are expected with the integrase inhibitor *raltegravir*,[2] or the HIV fusion inhibitor *enfuvirtide*.[4] For further information on drug interactions with HIV-protease inhibitors see Table 1, p.917 and with NNRTIs see Table 2, p.944. See also p.324 for comment on the interaction of antiretrovirals with rifabutin.

Clofazimine. Use of clofazimine in leprosy patients receiving rifampicin with or without dapsone may decrease the rate of absorption of rifampicin and increase the time to peak plasma concentration.[1] In patients receiving clofazimine, rifampicin, and dapsone, the area under the curve for rifampicin was reduced.[1] However, a multiple dose study[2] showed that the pharmacokinetics of rifampicin were similar after 7 days of treatment with rifampicin and dapsone or rifampicin, dapsone, and clofazimine.

1. Mehta J, *et al.* Effect of clofazimine and dapsone on rifampicin (Lositril) pharmacokinetics in multibacillary and paucibacillary leprosy cases. *Lepr Rev* 1986; **57** (suppl 3): 67–76.
2. Venkatesan K, *et al.* The effect of clofazimine on the pharmacokinetics of rifampicin and dapsone in leprosy. *J Antimicrob Chemother* 1986; **18:** 715–18.

Co-trimoxazole. In 15 patients receiving therapy including rifampicin for tuberculosis, a course of co-trimoxazole resulted in increases in maximum plasma concentrations and in the area under the concentration-time curve for rifampicin.[1] No adverse effects were observed and the clinical implications of this observation remain unclear. In another study,[2] significant reductions in the area under the plasma concentration-time curves for trimethoprim and sulfamethoxazole were observed after therapy including rifampicin was given to 10 HIV-infected patients on co-trimoxazole prophylaxis. Again, the clinical significance of this interaction is unclear.

2. Ribera E, *et al.* Rifampin reduces concentrations of trimethoprim and sulfamethoxazole in serum in human immunodeficiency virus-infected patients. *Antimicrob Agents Chemother* 2001; **45:** 3238–41.

Isoniazid. There is little significant pharmacokinetic interaction between rifampicin and isoniazid.[1] Although lower blood concentrations of rifampicin have been reported with isoniazid, the effect is not considered clinically significant.[2] Since both drugs are hepatotoxic, there could be an increased incidence of hepatic damage, although the benefits of using this combination are considered to outweigh any potential risks.

1. Acocella G, *et al.* Kinetics of rifampicin and isoniazid administered alone and in combination to normal subjects and patients with liver disease. *Gut* 1972; **13:** 47–53.
2. Mouton RP, *et al.* Blood levels of rifampicin, desacetylrifampicin and isoniazid during combined therapy. *J Antimicrob Chemother* 1979; **5:** 447–54.

Ketoconazole. Giving rifampicin, ketoconazole, and isoniazid together has produced low serum concentrations of each drug resulting in failure of antifungal treatment.[1] Rifampicin serum concentrations are reduced when rifampicin is given with ketoconazole;[2] separation of the doses by 30 minutes[3] to 12 hours[2] may result in similar rifampicin concentrations to those attained when rifampicin is given alone, although serum concentrations of ketoconazole remain depressed regardless of the timing of doses.

Probenecid. Although a study[1] showed that probenecid could increase serum-rifampicin concentrations, another[2] subsequently found that the effect was uncommon and inconsistent and concluded that probenecid had no place as an adjunct to routine rifampicin therapy.

Antimicrobial Action

Rifampicin is bactericidal against a wide range of micro-organisms and interferes with their synthesis of nucleic acids by inhibiting DNA-dependent RNA polymerase. It has the ability to kill intracellular organisms. It is active against mycobacteria, including *Mycobacterium tuberculosis*, *M. avium*, and *M. leprae* and, having high sterilising activity against these organisms, it possesses the ability to eliminate semi-dormant or persisting organisms. Rifampicin is also active against Gram-positive bacteria, especially staphylococci, but less active against Gram-negative organisms. The most sensitive Gram-negative bacteria include *Neisseria meningitidis*, *N. gonorrhoeae*, *Haemophilus influenzae*, and *Legionella* spp. Rifampicin also has activity against *Chlamydia trachomatis* and some anaerobic bacteria. At high concentrations it is active against some viruses.

Strains of *M. tuberculosis*, *M. leprae*, and other susceptible bacteria (such as *N. meningitidis*) have shown resistance, both initially and during treatment. Acquired resistance to rifampicin develops rapidly if it is used alone in the treatment of clinical infection, and resistance is thought to be due to a single-step mutation of the DNA-dependent RNA polymerase. Thus in tuberculosis and leprosy treatment regimens, rifampicin is used with other antimycobacterials to delay or prevent the development of rifampicin resistance. Resistance does not appear to be a problem when rifampicin is used alone in the management of latent tuberculosis, probably because the bacillary load is low. Cross-resistance has been shown between rifampicin and other rifamycins. Strains of *M. tuberculosis* resistant to both rifampicin and isoniazid (termed multidrug-resistant tuberculosis) are increasingly being reported; some strains are also resistant to second-line antimycobacterials (termed extensively drug-resistant tuberculosis).

Pharmacokinetics

Rifampicin is readily absorbed from the gastrointestinal tract and peak plasma concentrations varying from 4 to 32 micrograms/mL (average 7 micrograms/mL) have been reported after a dose of 600 mg. Food may reduce and delay absorption. Rifampicin is about 80% bound to plasma proteins. It is widely distributed in body tissues and fluids and diffusion into the CSF is increased when the meninges are inflamed. Rifampicin is distributed into breast milk and crosses the placenta (see Breast Feeding and Pregnancy, under Precautions, above). Half-lives for rifampicin have been reported to range initially from 2 to 5 hours, the longest elimination times occurring after the largest doses. However, as rifampicin induces its own metabolism, elimination time may decrease by up to 40% during the first 2 weeks, resulting in half-lives of about 2 to 3 hours. The half-life is prolonged in patients with severe hepatic impairment.

Rifampicin is rapidly metabolised in the liver mainly to active 25-*O*-deacetylrifampicin and excreted in the bile. Deacetylation diminishes intestinal reabsorption and increases faecal excretion, although significant enterohepatic circulation still takes place. About 60% of a dose eventually appears in the faeces. The amount excreted in the urine increases with increasing doses and up to 30% of a dose may be excreted in the urine, about half of it being unchanged drug. The metabolite formylrifampicin is also excreted in the urine. In patients with renal impairment the half-life of rifampicin is not prolonged at doses of 600 mg or less.

Distribution. Rifampicin is widely distributed in most body tissues and fluids after oral or intravenous use.[1] Rifampicin is also able to penetrate into polymorphonuclear leucocytes to kill intracellular pathogens.[2] Rifampicin does not appear to diffuse well through the uninflamed meninges[3] but therapeutic concentrations have been attained in the CSF after daily doses of 600 and 900 mg when the meninges are inflamed;[4] concentrations in the CSF are about 10 to 20% of simultaneous serum concentrations, and approximately represent the fraction unbound to plasma proteins. Corticosteroids do not appear to influence the penetration of rifampicin into the CSF of patients with tuberculous meningitis.[5]

HIV-infected patients. Malabsorption of rifampicin and other antituberculous drugs has been reported in some patients with HIV infection and tuberculosis,[1-6] and may contribute to acquired drug resistance and reduced efficacy of tuberculosis treatment. It is not clear whether this is related to the HIV infection itself or associated diarrhoea. A pilot study[2] in 26 HIV-positive patients undergoing multidrug antituberculosis treatment found that serum concentrations of isoniazid were generally regarded as adequate; serum concentrations of rifampicin and ethambutol were low. A study[3] in patients with HIV infection but not co-infected with tuberculosis reported reduced absorption for rifampicin and pyrazinamide compared to healthy subjects; isoniazid was generally well absorbed. A pharmacokinetic study[4] reported malabsorption of all first-line antituberculous drugs in patients who had advanced HIV infection with diarrhoea and cryptosporidial infection. A further pharmacokinetic study,[5] in a similar subject population, found a significant degree of malabsorption of rifampicin and isoniazid in HIV-infected patients with or without diarrhoea. Low serum concentrations of rifabutin were reported in HIV-infected patients co-infected with tuberculosis treated with an intermittent (twice-weekly) tuberculosis regimen.[6] However, others found that HIV infection either did not affect[7,8] or uncommonly affected[9] the pharmacokinetics of antituberculous drugs.

Some authorities[10,11] consider that HIV-infected patients (including children) with tuberculosis have a similar response to short-course multidrug therapy as HIV-negative tuberculosis patients, and that most can be treated with the standard 6-month regimen. US[11,12] and UK[13]guidelines recommend that highly intermittent (once or twice weekly) tuberculosis regimens should not be used for co-infected patients with CD4+ cell counts less than 100 cells/microlitre.

Intravenous administration. Mean peak plasma concentrations of 10 micrograms/mL have been reported after rifampicin 600 mg by intravenous infusion over 3 hours. Peak plasma concentrations declined with repeated doses but to a less marked extent than occurs with oral use.[1] Mean peak plasma concentrations of 27 micrograms/mL have been reported in children after doses of 11.5 mg/kg infused over 30 minutes. Mean concentrations of 1.9 micrograms/mL were reported 8 hours after the dose.[2]

2. Koup JR, *et al.* Pharmacokinetics of rifampin in children I. Multiple dose intravenous infusion. *Ther Drug Monit* 1986; **8:** 11–16.

Oral administration. Gastrointestinal absorption of rifampicin is considered good. However, analysis of serum-rifampicin concentrations in children indicated that only 50 ± 22% of a freshly prepared oral suspension was absorbed.[1] Varying oral bioavailability from capsule formulations has also been reported and could result in ineffective therapy[2] or higher than needed serum concentrations.[3]

The oral bioavailability of rifampicin and isoniazid, but not of pyrazinamide, was decreased by food in a study.[4] Another report[5] also showed reduced peak serum concentrations when rifampicin was given with a high-fat meal, and it was suggested that rifampicin should preferably be given on an empty stomach.

Uses and Administration

Rifampicin belongs to the rifamycin group of antimycobacterials (p.159) and is used in the treatment of various infections due to mycobacteria and other susceptible organisms (see Antimicrobial Action, above). It is usually given with other antibacterials to prevent the emergence of resistant organisms.

Rifampicin is used, mainly with isoniazid and pyrazinamide, as a component of multidrug regimens for the treatment of tuberculosis, and with dapsone and clofazimine in the treatment of leprosy. For the treatment of nontuberculous mycobacterial infections it is usually used with clarithromycin and ethambutol as part of a multidrug regimen.

Other uses include the treatment of brucellosis, Legionnaires' disease, mycetoma, penicillin-resistant pneumococcal meningitis, Q-fever, and various staphylococcal infections, including endocarditis. Rifampicin is used for the prophylaxis of epiglottitis and meningitis due to *Haemophilus influenzae* and for meningococcal meningitis. It is also used for the eradication of pharyngeal streptococcal carriage in pharyngitis, to reduce staphylococcal carriage, and to eliminate the carrier states for meningococcal and *H. influenzae* meningitis. It may be used as part of a multidrug regimen for the treatment of inhalation and gastrointestinal anthrax. For discussions of all these infections and their treatment, see under Choice of Antibacterial, p.162.

The usual oral adult dose of rifampicin is 8 to 12 mg/kg (to a maximum of 600 mg) daily, preferably on an empty stomach, or the same dose by intravenous infusion as the base or the sodium salt; higher doses are sometimes used (see below).

Rifampicin is given in the initial and continuation phases of short-course **tuberculosis** regimens (p.196) with other antimycobacterials. Rifampicin is given orally on an empty stomach in adult doses of 10 mg/kg (maximum 600 mg) daily or two or three times weekly. (WHO does not recommend twice-weekly regimens as there is an increased risk of treatment failure if one of the doses are missed.) Alternatively, doses may be expressed as follows: with daily use, adults weighing less than 50 kg receive 450 mg and those over 50 kg receive 600 mg; with intermittent use, adults receive 600 to 900 mg three times weekly. The maximum recommended dose is considered to be 900 mg because a greater incidence of adverse effects is associated with doses above 900 mg.

For the treatment of latent tuberculosis oral rifampicin 10 mg/kg (to a maximum dose of 600 mg) may be given once daily with isoniazid for 3 months. If the contact is infected with isoniazid-resistant tuberculosis then rifampicin monotherapy may be given daily for 4 to 6 months.

In **leprosy** regimens (p.176), rifampicin is usually given with dapsone for paucibacillary leprosy, and with dapsone and clofazimine for multibacillary leprosy. WHO recommends that rifampicin is given once monthly in a usual oral adult dose of 600 mg. Single-dose treatment with rifampicin, ofloxacin, and minocycline may be an alternative in patients with single-lesion paucibacillary leprosy.

In the treatment of **brucellosis**, **Legionnaires' disease**, and serious **staphylococcal infections** a dose of 600 to 1200 mg daily, orally or by intravenous infusion, in divided doses has been recommended in combination with other antibacterials.

For **prophylaxis** against meningococcal meningitis and the treatment of meningococcal carriers, rifampicin is usually given in an oral dose of 600 mg twice daily for 2 days. For prophylaxis against meningitis due to *Haemophilus influenzae*, an oral dose of 20 mg/kg once daily (to a maximum dose of 600 mg daily) for 4 days is given to adults.

For details of doses in infants, children, and adolescents, see below.

Fixed-dose combination products for antimycobacterial therapy have been developed in order to improve patient compliance and avoid monotherapy, thereby decreasing the risk of acquired drug resistance. Combination products containing rifampicin with isoniazid, isoniazid and pyrazinamide, isoniazid and ethambutol, and isoniazid, ethambutol, and pyrazinamide are available in some countries.

Doses of rifampicin should be reduced in patients with hepatic impairment (see below).

Administration in children. For the treatment of **tuberculosis** in infants, children, and adolescents the American Academy of Pediatrics (AAP) suggests a dose of rifampicin of 10 to 20 mg/kg (to a maximum of 600 mg) daily or twice weekly by mouth, for both the initial and continuation phases. For children 1 month and older the *BNFC* suggests a dose of 10 mg/kg once daily or 15 mg/kg (to a maximum of 900 mg) three times a week by mouth; while WHO recommends 8 to 12 mg/kg (to a maximum of 600 mg) once daily or two or three times a week.

For the treatment of *latent* tuberculosis the *BNFC* suggests that children 1 month and older are given rifampicin 10 mg/kg (to a maximum of 600 mg) once daily by mouth with isoniazid for 3 months. If the contact is infected with isoniazid-resistant tuberculosis then rifampicin monotherapy should be given daily for 6 months. The AAP, however, suggest rifampicin 10 to 20 mg/kg daily by mouth for 6 months.

In the treatment of tuberculosis and latent tuberculosis the *BNFC* suggests a maximum dose of rifampicin of 450 mg daily for children weighing less than 50 kg.

In **leprosy** regimens rifampicin is usually given with dapsone for the treatment of paucibacillary leprosy, and with dapsone and clofazimine for the treatment of multibacillary leprosy. WHO recommends that rifampicin is given once monthly in a dose of 450 mg by mouth to children 10 years of age and older.

In the treatment of **brucellosis, Legionnaires' disease**, and serious **staphylococcal infections** doses recommended by the *BNFC* are 5 to 10 mg/kg twice daily in neonates and infants up to 12 months of age, and 10 mg/kg in those older than one year of age. Doses are given by mouth or intravenous infusion and in combination with other antibacterials.

For prophylaxis against meningococcal **meningitis** the AAP recommends infants less then 1 month old are given 5 mg/kg, while infants and children aged 1 month or more are given 10 mg/kg (to a maximum of 600 mg), both twice daily by mouth for 2 days. The *BNFC* recommends doses of 5 mg/kg for neonates and infants up to 12 months of age and 10 mg/kg for children between 1 and 12 years of age, each twice daily by mouth for 2 days.

For prophylaxis against meningitis due to *Haemophilus influenzae* the AAP recommends infants less then 1 month old are given 10 mg/kg once daily by mouth for 4 days, while the *BNFC* suggests that this dose should be given to infants aged 1 to 3 months. For older infants and children both the AAP and the *BNFC* recommend a dose of 20 mg/kg (to a maximum of 600 mg) once daily by mouth for 4 days.

Administration in hepatic impairment. Reduced doses of rifampicin are recommended for patients with hepatic impairment and a maximum of 8 mg/kg daily has been suggested. See also Precautions, above.

Ehrlichiosis. Beneficial responses to rifampicin have been reported[1] in 2 pregnant women with human granulocytic anaplasmosis (see Ehrlichiosis, p.168), in whom the usual treatment with a tetracycline was contra-indicated.

1. Buitrago MI, *et al.* Human granulocytic ehrlichiosis during pregnancy treated successfully with rifampin. *Clin Infect Dis* 1998; **27:** 213–15.

Meningitis prophylaxis. *HAEMOPHILUS INFLUENZAE MENINGITIS PROPHYLAXIS.* Meningeal infection with *Haemophilus influenzae* type b (Hib) in children is associated with substantial morbidity, but the incidence has decreased since the introduction of immunisation with *H. influenzae* type b vaccine. Although a worldwide problem, the disease (p.178) and its prophylaxis has been studied mainly in the USA, where it was shown that children under 4 years of age formed the highest risk group for primary infection while children under 2 years of age formed the highest risk group for secondary infection.[1] The goal of prophylaxis in close contacts is to eliminate carriage of the organism to prevent spread to young children. Risk of infection to young children with recent household contact to the primary case of infection with *H. influenzae* type b is increased 600- to 800-fold,[1,2] but only increased 20-fold[3] from day-care or school contact. The risk may be higher when more than 1 index patient is identified.

Rifampicin in doses of 20 mg/kg once daily for 4 days (maximum dose 600 mg) has been shown to eradicate Hib nasopharyngeal carriage in at least 95% of contacts of the primary case.[4] There is some evidence from a study involving 68 families of patients with Hib infection that rifampicin 20 mg/kg daily for 2 days may be as effective as a 4-day course in eradicating Hib pharyngeal colonisation.[5] Rifampicin prophylaxis appears to be successful in preventing infection in household contacts, but benefit in school settings where there has been a single index case has not been established.[3]

Recommendations have been made for rifampicin prophylaxis.[6,7] The American Academy of Pediatrics (AAP) recommends[6] that all household contacts be given rifampicin prophylaxis where there is at least 1 contact person who is younger than 4 years of age who is not or incompletely immunised against Hib, where there is an unimmunised child younger than 12 months of age, or where there is an immunocompromised child (regardless of vaccine status), in the household. Similar recommendations have been made in the UK.[7] The AAP[6] also recommends rifampicin prophylaxis when 2 or more cases of Hib disease have occurred within 60 days in a day-care or school. In the UK,[7] prophylaxis has been recommended for all room contacts when 2 or more cases of disease have occurred within 120 days. Rifampicin prophylaxis is not recommended for pregnant women.[6]

For recommended *doses* see Uses and Administration and Administration in Children, above.

Rifampicin should also be given to the primary case since treatment of the infection does not eradicate nasopharyngeal carriage.[2,6]

MENINGOCOCCAL MENINGITIS PROPHYLAXIS. *Neisseria meningitidis* is an important cause of bacterial meningitis (p.178); all age groups are at risk during epidemics but children are usually at highest risk during endemic outbreaks. Vaccines are available for meningococci groups A, C, Y, and W135 but not usually for group B, therefore antimicrobial prophylaxis remains important in preventing the spread of the disease. The aim of prophylaxis is to eliminate nasopharyngeal carriage of the organism. Sulfadiazine and minocycline are no longer used because of resistance and adverse effects. The current antibacterial of choice is rifampicin which should be given for 2 days (for doses see Uses and Administration and Administration in Children, above). Alternatives include a single oral dose of ciprofloxacin, ofloxacin, or azithromycin, or a single intramuscular dose of ceftriaxone.[1,2] Antibacterial prophylaxis should be given as soon as possible to close contacts (ideally within 24 hours of diagnosis of the index case). It is also recommended for child care or nursery school contacts in the USA,[2] but is not usually advised for this group in the UK after a single case.[1] The index patient should also receive rifampicin for 2 days before hospital discharge since treatment with penicillin does not eliminate nasopharyngeal carriage.

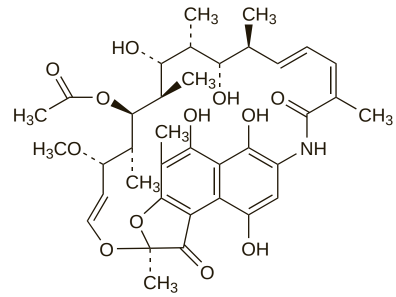
Sodium (12*Z*,14*E*,24*E*)-(2*S*,16*S*,17*S*,18*R*,19*R*,20*R*,21*S*,22*R*,23*S*)-21-acetoxy-1,2-dihydro-6,9,17,19-tetrahydroxy-23-methoxy-2,4,12,16,18,20,22-heptamethyl-1,11-dioxo-2,7-(epoxypentadeca-1,11,13-trienimino)-naphtho-[2,1-*b*]furan-5-olate.

Натрий Рифамицин

$C_{37}H_{46}NNaO_{12}$ = 719.8.
CAS — 6998-60-3 (rifamycin); 14897-39-3 (rifamycin sodium); 15105-92-7 (rifamycin sodium).
ATC — J04AB03; S01AA16; S02AA12.
ATC Vet — QJ04AB03; QS01AA16; QS02AA12.



(rifamycin SV)

Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Rifamycin Sodium). The monosodium salt of rifamycin SV, a substance obtained by chemical transformation of rifamycin B which is produced during growth of certain strains of *Amycolatopsis mediterranei*. Rifamycin SV may also be obtained directly from certain mutants of *A. mediterranei*. The potency is not less than 900 units/mg calculated with reference to the anhydrous substance. A red, fine or slightly granular powder. Soluble in water; freely soluble in dehydrated alcohol. A 5% solution in water has a pH of 6.5 to 8.0. Store in airtight containers at a temperature of 2° to 8°. Protect from light.

Adverse Effects and Precautions

Some gastrointestinal adverse effects have occurred after injections of rifamycin. High doses may produce alterations in liver function. Hypersensitivity reactions including rashes, pruritus, and anaphylaxis have occurred rarely, but prolonged use increases the risk of sensitisation. A reddish coloration of the urine and other body fluids has been reported. Rifamycin should be used with care in patients with hepatic dysfunction.

Antimicrobial Action

Rifamycin has similar antimicrobial actions to those of rifampicin (p.327).

Pharmacokinetics

Rifamycin is not effectively absorbed from the gastrointestinal tract. Plasma concentrations of 2 micrograms/mL have been achieved 2 hours after a dose of 250 mg by intramuscular injection; concentrations of about 11 micrograms/mL have been achieved 2 hours after an intravenous dose of 500 mg. Rifamycin is about 80% bound to plasma proteins and has a plasma half-life of about 1 hour.

Rifamycin is excreted mainly in the bile and only small amounts appear in the urine.

Uses and Administration

Rifamycin is a rifamycin antibacterial that has been used in the treatment of infections caused by susceptible organisms including Gram-positive organisms such as staphylococci. It has been given as the sodium salt by intramuscular injection and by slow intravenous infusion and is also given by local instillation and topical application.

Preparations

Proprietary Preparations (details are given in Part 3)
Arg.: Plusderm ATB†; Rifocina; ***Austria:*** Rifocin; ***Belg.:*** Rifocine; ***Braz.:*** Rifan; Rifocina; ***Fr.:*** Otofa; ***Ital.:*** Rifocin; ***Mex.:*** Rifocyna; ***Port.:*** Rifocina; ***Rus.:*** Otofa (Отофа); ***Switz.:*** Otofa; ***Turk.:*** Rif; Rifocin; ***Venez.:*** Rifocina.

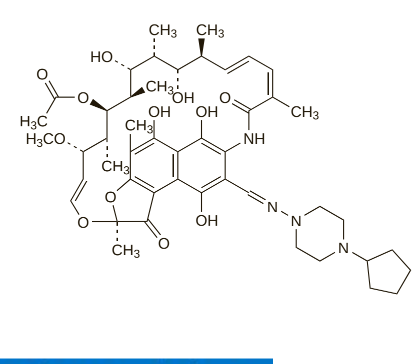
Rifapentine *(BAN, USAN, rINN)*

DL-473; DL-473-IT; L-11473; MDL-473; Rifapentina; Rifapentinum. 3-[*N*-(4-Cyclopentyl-1-piperazinyl)formimidoyl]rifamycin.

Рифапентин

$C_{47}H_{64}N_4O_{12}$ = 877.0.
CAS — 61379-65-5.
ATC — J04AB05.
ATC Vet — QJ04AB05.



The symbol † denotes a preparation no longer actively marketed

Adverse Effects
As for Rifampicin, p.325.

A higher incidence of hyperuricaemia has been reported with rifapentine than with rifampicin.

Precautions
As for Rifampicin, p.326.

Rifapentine is only licensed for use in once- or twice-weekly regimens, and should not be given to patients with HIV infection because of potential interactions with HIV-protease inhibitors; an increased risk of developing resistance to rifamycins with highly intermittent (once- or twice-weekly) dosing regimens may occur in these patients.

Rifapentine is teratogenic in *animals*.

Interactions
As for Rifampicin, p.327.

Enzyme induction studies have suggested that rifapentine is a more potent inducer of cytochrome P450 isoenzymes than rifabutin, but less potent then rifampicin. It should not be used with HIV-protease inhibitors because of the risk of developing resistance, see Precautions, above.

Antimicrobial Action
As for Rifampicin, p.327.

Cross-resistance is common between rifapentine and rifampicin in *Mycobacterium tuberculosis*.

Antimycobacterial action. References.

1. Mor N, *et al*. Comparison of activities of rifapentine and rifampin against Mycobacterium tuberculosis residing in human macrophages. *Antimicrob Agents Chemother* 1995; **39:** 2073–7.
2. Vernon A, *et al*. Acquired rifamycin monoresistance in patients with HIV-related tuberculosis treated with once-weekly rifapentine and isoniazid. *Lancet* 1999; **353:** 1843–7.

Pharmacokinetics
Rifapentine is absorbed after oral doses. Absorption is enhanced by about 50% when rifapentine is taken with food. Peak plasma concentrations are achieved 5 to 6 hours after a single dose of 600 mg and steady-state concentrations are achieved by day 10 during daily use. A half-life of about 13 hours has been reported. Rifapentine undergoes nonoxidative metabolism and does not induce its own metabolism. Rifapentine and its active metabolite 25-deacetylrifapentine are 98% and 93% bound to plasma proteins, respectively.

Rifapentine and 25-deacetylrifapentine are excreted mainly in the faeces with a small amount appearing in the urine.

5. Langdon G, *et al*. Population pharmacokinetics of rifapentine and its primary desacetyl metabolite in South African tuberculosis patients. *Antimicrob Agents Chemother* 2005; **49:** 4429–36.

Uses and Administration
Rifapentine is a rifamycin antibacterial (see Rifampicin, p.325) that is used, with other antimycobacterials, for the treatment of tuberculosis (p.196).

For drug-susceptible organisms rifapentine is given orally in a dose of 600 mg twice weekly during the initial intensive phase of short-course tuberculosis regimens, then once weekly during the continuation phase.

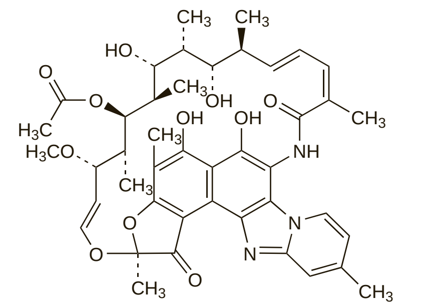
Rifaximin *(USAN, rINN)*

L-105; Rifaxidin; Rifaximina; Rifaximine; Rifaximinum. (2*S*,16*Z*,18*E*,20*S*,21*S*,22*R*,23*R*,24*R*,25*S*,26*S*,27*S*,28*E*)-5,6,21,23,25-Pentahydroxy-27-methoxy-2,4,11,16,20,22,24,26-octamethyl-2,7-(epoxypentadeca[1,11,13]trienimino)benzofuro[4,5-e]pyrido[1,2-*a*]benzimidazole-1,15(2*H*)-dione 25-acetate.

Рифаксимин

$C_{43}H_{51}N_3O_{11}$ = 785.9.
CAS — 80621-81-4.
ATC — A07AA11; D06AX11.
ATC Vet — QA07AA11; QD06AX11; QG51AA06; QJ51XX01.



NOTE. The code L-105 has also been applied to the cephalosporin cefuzonam.

Profile
Rifaximin is a rifamycin antibacterial with antimicrobial actions similar to those of rifampicin *in-vitro* (p.327), but which is poorly absorbed from the gastrointestinal tract, having a bioavailability of about only 0.4%. Therefore, it does not have the usual adverse effects or interactions of rifampicin. Hypersensitivity reactions, including exfoliative dermatitis and angioneurotic oedema have been reported. Rifaximin should not be given to patients with travellers' diarrhoea complicated by fever or blood in the stool.

It has been licensed in the USA and some other countries for the treatment of travellers' diarrhoea caused by noninvasive strains of *Escherichia coli*. It has also been tried for other gastrointestinal disorders, including infectious diarrhoea in nontravellers, inflammatory bowel disease, abdominal distension, bloating, and flatulence, small bowel bacterial overgrowth, diverticulitis, Crohn's disease, for surgical infection prophylaxis, and hepatic encephalopathy (p.1697).

For the treatment of travellers' diarrhoea in those 12 years of age and older, the recommended oral dose is 200 mg three times daily for 3 days. Doses given for other indications range from 600 to 1200 mg daily, in 2 to 4 divided doses.

Rifaximin has also been used topically as a 5% ointment.

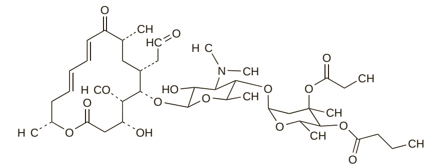
[(4*R*,5*S*,6*S*,7*R*,9*R*,10*R*,11*E*,13*E*,16*R*)-7-(Formylmethyl)-4,10-dihydroxy-5-methoxy-9,16-dimethyl-2-oxooxacyclohexadeca-11,13-dien-6-yl]-3,6-dideoxy-4-*O*-(2,6-dideoxy-3-*C*-methyl-α-L-*ribo*-hexopyranosyl)-3-(dimethylamino)-β-D-glucopyranoside 4″-butyrate 3″-propionate.

Рокитамицин

$C_{42}H_{69}NO_{15}$ = 828.0.
CAS — 74014-51-0.
ATC — J01FA12.
ATC Vet — QJ01FA12.



Pharmacopoeias. In *Jpn.*

Profile
Rokitamycin is a macrolide antibacterial with actions and uses similar to those of erythromycin (p.269). It has been given orally in usual doses of 400 mg twice daily in the treatment of susceptible infections.

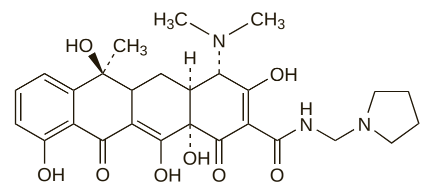
Preparations
Proprietary Preparations (details are given in Part 3)
Ital.: Paidocin; Rokital.

Rolitetracycline *(BAN, USAN, rINN)*

PMT; Pyrrolidinomethyltetracycline; Rolitetraciclina; Rolitétracycline; Rolitetracyclinum; Rolitetracyklin; Rolitetrasykliini; SQ-15659. N^2-(Pyrrolidin-1-ylmethyl)tetracycline.

Ролитетрациклин

$C_{27}H_{33}N_3O_8$ = 527.6.
CAS — 751-97-3.
ATC — J01AA09.
ATC Vet — QJ01AA09.



Profile
Rolitetracycline is a tetracycline derivative with general properties similar to those of tetracycline (p.347). It is included in some topical eye preparations used for the treatment of susceptible infections. It has also been given by injection, when it has been associated with shivering and, more rarely, rigor, due to a Jarisch-Herxheimer reaction. Injection has also been followed by a peculiar taste sensation, often similar to ether.

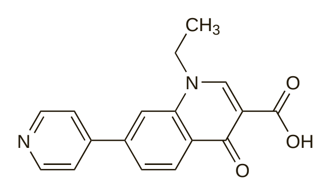
Preparations
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Arg.:*** Eubetal Biotic†; ***Ital.:*** Colbiocin; Eubetal Antibiotico; Vitecaf; ***Rus.:*** Colbiocin (Колбиоцин).

Rosoxacin *(BAN, USAN, rINN)*

Acrosoxacin; Rosoksasiini; Rosoxacine; Rosoxacino; Rosoxacinum; Win-35213. 1-Ethyl-1,4-dihydro-4-oxo-7-(4-pyridyl)quinoline-3-carboxylic acid.

Розоксацин

$C_{17}H_{14}N_2O_3$ = 294.3.
CAS — 40034-42-2.
ATC — J01MB01.
ATC Vet — QJ01MB01.



Adverse Effects and Precautions
As for Nalidixic Acid, p.304.

Dizziness, drowsiness, and visual disturbances occur relatively frequently, and patients should be advised not to drive or operate machinery if affected.

Uses and Administration
Rosoxacin is a 4-quinolone antibacterial with actions similar to those of nalidixic acid (p.304). It is active against *Neisseria gonorrhoeae* and has been given as single-dose oral treatment for gonorrhoea. It has also been used in the treatment of urinary-tract infections.

Preparations

Proprietary Preparations (details are given in Part 3)
Braz.: Eradacil; ***Mex.:*** Eradacil; ***Port.:*** Eradacil†.

Roxithromycin *(USAN, rINN)*

Roksitromicinas; Roksitromisin; Roksitromysiini; Roxithromycine; Roxithromycinum; Roxitromicin; Roxitromicina; Roxitromycin; RU-965; RU-28965. Erythromycin 9-{*O*-[(2-methoxyethoxy)-methyl]oxime}.

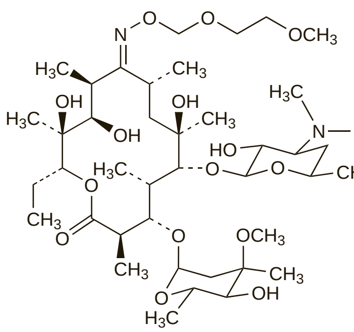
Рокситромицин

$C_{41}H_{76}N_2O_{15}$ = 837.0.

CAS — 80214-83-1.

ATC — J01FA06.

ATC Vet — QJ01FA06.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *Jpn.*

Ph. Eur. 6.2 (Roxithromycin). A white or almost white, crystalline powder. It exhibits polymorphism. Very slightly soluble in water; freely soluble in alcohol, in acetone, and in dichloromethane; slightly soluble in dilute hydrochloric acid. Store in airtight containers.

Adverse Effects and Precautions

As for Erythromycin, p.270.

Gastrointestinal disturbances are the most frequent adverse effect, but are less frequent than with erythromycin.

The dose of roxithromycin may need to be reduced in patients with hepatic or renal impairment.

Effects on the kidneys. Acute interstitial nephritis has been reported[1] in a patient given roxithromycin; renal function improved over several days after the drug was stopped.

1. Akcay A, *et al.* Acute renal failure and hepatotoxicity associated with roxithromycin. *Ann Pharmacother* 2004; **38:** 721–2.

Effects on the lungs. Acute eosinophilic pneumonia was attributed in a patient to the use of roxithromycin.[1] The condition resolved after treatment with methylprednisolone.

1. Pérez-Castrillón JL, *et al.* Roxithromycin-induced eosinophilic pneumonia. *Ann Pharmacother* 2002; **36:** 1808–9.

Effects on the pancreas. Acute pancreatitis, with duodenal inflammation, pain, pancreatic enlargement, and raised serum-amylase developed in a patient within 24 hours of substituting roxithromycin for erythromycin ethyl succinate.[1] Symptoms resolved rapidly once roxithromycin was stopped.

1. Souweine B, *et al.* Acute pancreatitis associated with roxithromycin therapy. *DICP Ann Pharmacother* 1991; **25:** 1137.

Eosinophilia. For a report of an eosinophilic syndrome in a patient after treatment with azithromycin or roxithromycin, see Azithromycin, p.207. See also under Effects on the Lungs, above.

Interactions

For a discussion of drug interactions of macrolide antibacterials, see Erythromycin, p.271.

Roxithromycin has a much lower affinity for cytochrome P450 isoenzymes than erythromycin and therefore has fewer interactions. It does not appear to interact with antacids, carbamazepine, oral contraceptives, prednisolone, or ranitidine.

Antimicrobial Action

As for Erythromycin, p.271. It is reported to be as active or slightly less active than erythromycin.

Pharmacokinetics

Roxithromycin is absorbed after oral doses with a bioavailability of about 50%. Peak plasma concentrations of about 6 to 8 micrograms/mL occur around 2 hours after a single dose of 150 mg. The mean peak plasma concentration at steady state after a dose of 150 mg twice daily is 9.3 micrograms/mL. Absorption is reduced when taken after a meal. It is widely distributed into tissues and body fluids; high concentrations are taken up into white blood cells. Small amounts of roxithromycin are distributed into breast milk. It is about 96% bound to plasma proteins (mainly α_1-acid glycoprotein) at trough concentrations, but binding is saturable, and only about 87% is bound at usual peak concentrations. Small amounts of roxithromycin are metabolised in the liver, and the majority of a dose is excreted in the faeces as unchanged drug and metabolites; about 7 to 10% is excreted in urine, and up to 15% via the lungs. The elimination half-life is reported to range from about 8 to 13 hours, but may be more prolonged in patients with hepatic or renal impairment and in children. It has been reported that roxithromycin is not substantially removed by peritoneal dialysis.

◊ References.

1. Puri SK, Lassman HB. Roxithromycin: a pharmacokinetic review of a macrolide. *J Antimicrob Chemother* 1987; **20** (suppl B): 89–100.

Uses and Administration

Roxithromycin is a macrolide antibacterial with actions and uses similar to those of erythromycin (p.272). It is given orally to adults in a usual dose of 150 mg twice daily or sometimes 300 mg once daily, at least 15 minutes before meals, for 5 to 10 days in the treatment of susceptible infections.

Dosage may need to be modified in patients with hepatic or renal impairment (see below).

For doses in infants and children, see below.

Administration in children. In children weighing from 6 up to 40 kg a dose of 5 to 8 mg/kg daily of roxithromycin may be used.

Administration in hepatic impairment. The licensed product information for roxithromycin notes that safety in hepatic impairment has not been established and advises halving the usual daily dose (see above) if used.

Administration in renal impairment. The licensed product information for roxithromycin notes that safety in renal impairment has not been established and dosage adjustment details are not specified.

A pharmacokinetic study[1] in 20 subjects (10 with normal renal function and 10 with severely impaired function) suggested that doubling the dosage interval of roxithromycin would be suitable in those with a creatinine clearance of less than 15 mL/minute.

1. Halstenson CE, *et al.* Disposition of roxithromycin in patients with normal and severely impaired renal function. *Antimicrob Agents Chemother* 1990; **34:** 385–9.

Hyperplasia. Gingival hyperplasia is a well recognised adverse effect of ciclosporin treatment; a small study[1] indicated that roxithromycin could reduce overgrowth, possibly by an effect on transforming growth factor-β. For the use of another macrolide, azithromycin, for this indication see Hyperplasia, p.1824.

$(C_{19}H_{37}N_5O_7)_2,5H_2SO_4$ = 1385.4.

CAS — 32385-11-8 (sisomicin); 53179-09-2 (sisomicin sulfate).

ATC — J01GB08.

ATC Vet — QJ01GB08.

Pharmacopoeias. In *Chin.*, *Jpn*, and *US.*

USP 31 (Sisomicin Sulfate). It loses not more than 15% of its weight on drying. 1 mg of sisomicin sulfate has a potency equivalent to not less than 580 micrograms of sisomicin calculated on the dried basis. A 4% solution in water of sisomicin has a pH of 3.5 to 5.5. Store in airtight containers.

Profile

Sisomicin, an antibiotic produced by *Micromonospora inyoensis* and closely related to gentamicin C_{1A}, is an aminoglycoside with general properties similar to those of gentamicin (p.282). It is given as the sulfate but doses are expressed in terms of the base; 1.5 g of sisomicin sulfate is equivalent to about 1 g of sisomicin. The usual dose for adults is 3 mg/kg daily given intramuscularly in 2 or 3 divided doses. It may be given by intravenous infusion if necessary.

Preparations

USP 31: Sisomicin Sulfate Injection.

Proprietary Preparations (details are given in Part 3)
India: Sisoptin; ***Ital.:*** Mensiso†.

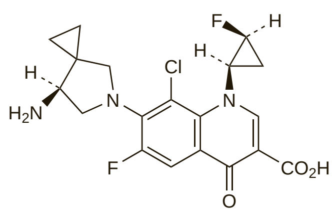
Sitafloxacin *(USAN, rINN)*

DU-6859 (anhydrous sitafloxacin); DU-6859a (sitafloxacin sesquihydrate); Sitafloxacine; Sitafloxacino; Sitafloxacinum. (−)-7-[(7*S*)-7-Amino-5-azaspiro[2.4]hept-5-yl]-8-chloro-6-fluoro-1-[(1*R*,2*S*)-2-fluorocyclopropyl]-1,4-dihydro-4-oxo-3-quinolinecarboxylic acid.

Ситафлоксацин

$C_{19}H_{18}ClF_2N_3O_3$ = 409.8.

CAS — 127254-12-0 (anhydrous sitafloxacin); 163253-37-0 (sitafloxacin monohydrate); 163253-35-8 (sitafloxacin sesquihydrate).



NOTE. Sitafloxacin exists in several hydration states; the name sitafloxacin has been used to refer to both the anhydrous substance and the sesquihydrate ($C_{19}H_{18}ClF_2N_3O_3,1\frac{1}{2}H_2O$ = 436.8); the latter is known in Japan as sitafloxacin hydrate.

Profile

Sitafloxacin is a fluoroquinolone that is given orally in the treatment of susceptible infections.

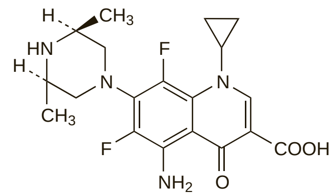
ATC Vet — QJ01MA09.



Pharmacopoeias. In *Chin.*

Adverse Effects and Precautions

As for Ciprofloxacin, p.244.

Concern over phototoxicity associated with sparfloxacin has led to restriction of its use in some countries; patients should be advised to avoid exposure to sunlight during, and for a few days after, sparfloxacin therapy, and to stop the drug immediately if phototoxicity occurs.

Photosensitivity. In a survey[1] of the reporting rate for phototoxicity associated with sparfloxacin in France, the manufacturer or the French Pharmacovigilance System received 371 reports of severe phototoxic reactions during the first 9 months after marketing of the drug; this approximated to between 4 and 25 times the rate reported for other fluoroquinolones.

1. Pierfitte C, *et al.* The link between sunshine and phototoxicity of sparfloxacin. *Br J Clin Pharmacol* 2000; **49:** 609–12.

Interactions

As for Ciprofloxacin, p.246.

Sparfloxacin does not appear to interact with theophylline or caffeine, nor with warfarin or cimetidine. Probenecid does not alter the pharmacokinetics of sparfloxacin.

Antimicrobial Action

As for Ciprofloxacin, p.246.

Sparfloxacin is reported to be more active *in vitro* than ciprofloxacin against mycobacteria and against Gram-positive bacteria, including *Streptococcus pneumoniae* and other streptococci and staphylococci.

Pharmacokinetics

Sparfloxacin is well absorbed from the gastrointestinal tract with a bioavailability of about 90%. Peak plasma concentrations occur 3 to 6 hours after a dose. Sparfloxacin is widely distributed into body tissues and fluids, including respiratory tissues, but is only about 45% bound to plasma proteins. It is metabolised in the liver by glucuronidation and has an elimination half-life of about 20 hours. It is excreted in equal amounts in the faeces and urine as unchanged drug and as the glucuronide metabolite.

Uses and Administration

Sparfloxacin is a fluoroquinolone antibacterial with actions and uses similar to those of ciprofloxacin (p.247). It is given orally for the treatment of susceptible infections in a usual dose of 100 to 300 mg in 1 or 2 divided doses daily. It has also been tried in tuberculosis (see under Uses and Administration of Ciprofloxacin, p.248).

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Spectinomycin Dihydrochloride Pentahydrate). A substance produced by *Streptomyces spectabilis* or by any other means. A white or almost white, slightly hygroscopic, powder. Freely soluble in water; very slightly soluble in alcohol. A 10% solution in water has a pH of 3.8 to 5.6. Store in airtight containers.

USP 31 (Spectinomycin Hydrochloride). A white to pale buff crystalline powder. 1 mg of monograph substance has a potency equivalent to not less than 603 micrograms of spectinomycin. Freely soluble in water; practically insoluble in alcohol, in chloroform, and in ether. A 1% solution in water has a pH of 3.8 to 5.6. Store in airtight containers.

Adverse Effects and Precautions

Nausea, dizziness, fever and chills, insomnia, and urticaria have occasionally occurred with single doses of spectinomycin. Anaphylaxis has occurred rarely. Mild to moderate pain has been reported after intramuscular injections. Alterations in kidney and liver function and a decrease in haemoglobin and haematocrit have occasionally been seen with repeated doses. Although a reduction in urine output has been seen after single and multiple doses, spectinomycin has not been noted to produce functional changes indicative of nephrotoxicity.

Spectinomycin is ineffective in the treatment of syphilis and patients being treated for gonorrhoea should be observed for evidence of syphilis.

Interactions

Lithium. For the effect of spectinomycin on lithium, see Antimicrobials, under Interactions of Lithium, p.404.

Antimicrobial Action

Spectinomycin is an aminocyclitol antibacterial that acts by binding to the 30S subunit of the bacterial ribosome and inhibiting protein synthesis. Its activity is generally modest, particularly against Gram-positive organisms. Anaerobic organisms are mostly resistant. Various Gram-negative organisms are sensitive, including many enterobacteria and also *Haemophilus ducreyi*, and it is particularly effective against *Neisseria gonorrhoeae*. Although generally bacteriostatic, spectinomycin is bactericidal against susceptible gonococci at concentrations not much above the MIC.

Resistance may develop by chromosomal mutation or may be plasmid-mediated in some organisms; resistant gonococci have been reported clinically, notably in the Far East, but in most parts of the world resistant neisserial strains have been uncommon to date.

Pharmacokinetics

Spectinomycin is poorly absorbed orally but is rapidly absorbed after the intramuscular injection of the hydrochloride. A 2-g dose produces peak plasma concentrations of about 100 micrograms/mL at 1 hour while a 4-g dose produces peak concentrations of about 160 micrograms/mL at 2 hours. Therapeutic plasma concentrations are maintained for up to 8 hours. Distribution into saliva is poor (which limits its value in pharyngeal gonorrhoea). It is poorly bound to plasma proteins. Spectinomycin is excreted in an active form in the urine and up to 100% of a dose has been recovered within 48 hours. A half-life of about 1 to 3 hours has been reported; it is prolonged in patients with renal impairment. Spectinomycin is partially removed by dialysis.

Uses and Administration

Spectinomycin is used as an alternative to cephalosporins or fluoroquinolones in the treatment of gonorrhoea (p.191) although poor distribution into saliva limits its usefulness in pharyngeal infections. It has also been used in the treatment of chancroid (p.191).

Spectinomycin is given as the hydrochloride but doses are expressed in terms of the base. Spectinomycin hydrochloride 1.5 g is equivalent to about 1 g of spectinomycin. In the treatment of gonorrhoea it is given by deep intramuscular injection as a single dose equivalent to 2 g of spectinomycin, although a dose of 4 g may sometimes be required, divided between two injection sites. Multiple-dose courses have been used for the treatment of disseminated infections.

Spectinomycin is not effective against syphilis or chlamydial infections and additional therapy for these infections may also be needed.

For details of doses in children, see below.

Administration in children. Parenteral spectinomycin is not recommended in neonates because of the presence of benzyl alcohol, a preservative that has been associated with fatalities in neonates due to the 'gasping syndrome' (see p.1632).

For prophylaxis in neonates born to mothers with gonorrhoea WHO recommends a single intramuscular dose of spectinomycin 25 mg/kg (maximum 75 mg) as an alternative to ceftriaxone. The CDC recommends spectinomycin as an alternative to cephalosporins in the treatment of uncomplicated gonorrhoea (p.191) in children beyond the newborn period and weighing under 45 kg; a single intramuscular dose equivalent to 40 mg/kg of spectinomycin may be given.

Preparations

Spiramycin I R = H
Spiramycin II R = $COCH_3$
Spiramycin III R = $COCH_2CH_3$

Pharmacopoeias. In *Eur.* (see p.vii). Also in *BP (Vet)*. *Jpn* includes Acetylspiramycin.

Ph. Eur. 6.2 (Spiramycin). A macrolide antibiotic produced by the growth of certain strains of *Streptomyces ambofaciens* or obtained by any other means. The potency is not less than 4100 units/mg, calculated with reference to the dried substance. A white or slightly yellowish, slightly hygroscopic powder. Slightly soluble in water; freely soluble in alcohol, in acetone, and in methyl alcohol. A 0.5% solution in methyl alcohol and water has a pH of 8.5 to 10.5. Store in airtight containers.

Adverse Effects and Precautions

As for Erythromycin, p.270.

The most frequent adverse effects are gastrointestinal disturbances. Transient paraesthesia has been reported during parenteral use.

Interactions

For a discussion of drug interactions of macrolide antibacterials, see Erythromycin, p.271.

Cytochrome P450 isoenzymes. Spiramycin is reported to have little or no effect on hepatic cytochrome P450 isoenzymes and may therefore produce fewer interactions than erythromycin with other drugs metabolised by this enzyme system (see Mechanism, under Interactions of Erythromycin, p.271). The lack of interactions between spiramycin and theophylline and ciclosporin would appear to support this. Nevertheless, a report of torsade de pointes in a patient with a congenital long QT syndrome during treatment with spiramycin and *mequitazine*[1] suggests that caution is still needed.

Reduced plasma concentrations of *levodopa* have been reported when given with spiramycin (see p.807).

1. Verdun F, *et al*. Torsades de pointes sous traitement par spiramycine et méquitazine: à propos d'un cas. *Arch Mal Coeur Vaiss* 1997; **90:** 103–6.

Antimicrobial Action

As for Erythromycin, p.271, although it is somewhat less active *in vitro* against many species. It is active against *Toxoplasma gondii*.

Pharmacokinetics

Spiramycin is incompletely absorbed from the gastrointestinal tract and absorption is reduced by food. It is widely distributed into tissues, although it does not cross the blood-brain barrier. Spiramycin crosses the placenta and is distributed into breast milk. Plasma protein binding ranges from 10 to 25%. An oral dose of 6 million units produces peak blood concentrations of 3.3 micrograms/mL after 1.5 to 3 hours; the half-life is about 5 to 8 hours. High tissue concentrations are achieved and persist long after the plasma concentration has fallen to low levels.

Spiramycin is metabolised in the liver to active metabolites; substantial amounts are excreted in the bile and about 10% in the urine.

Uses and Administration

Spiramycin is a macrolide antibacterial that is used similarly to erythromycin (p.272) in the treatment of susceptible bacterial infections. It has also been used in the protozoal infections cryptosporidiosis (p.823) and toxoplasmosis (p.826).

Spiramycin is given orally as the base or intravenously as the adipate; it has also been given rectally as the adipate. The usual oral adult dose is 6 to 9 million units daily, in 2 or 3 divided doses. Doses of up to 15 million units have been given daily in divided doses for severe infections. A dose of 1.5 million units of spiramycin may be given by slow intravenous infusion every 8 hours; in severe infection the dose may be doubled.

Spiramycin is available in combination preparations with metronidazole in some countries.

Acetylspiramycin is also used.

CAS — 3810-74-0.

ATC — A07AA04; J01GA01.

ATC Vet — QA07AA04; QJ01GA01.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Streptomycin Sulphate). A white or almost white, hygroscopic powder. The potency is not less than 720 units/mg, calculated with reference to the dried substance. Very soluble in water; practically insoluble in dehydrated alcohol. A 25% solution in water has a pH of 4.5 to 7.0. Store in airtight containers.

USP 31 (Streptomycin Sulfate). A white or practically white, hygroscopic powder; odourless or with not more than a faint odour. It has a potency equivalent to not less than 650 micrograms and not more than 850 micrograms of streptomycin per mg. Freely soluble in water; very slightly soluble in alcohol; practically insoluble in chloroform. A solution in water containing the equivalent of streptomycin 20% has a pH of 4.5 to 7.0. Store in airtight containers.

Incompatibility. Streptomycin sulfate is incompatible with acids and alkalis.

Adverse Effects, Treatment, and Precautions

As for Gentamicin Sulfate, p.282. Like gentamicin the ototoxic effects of streptomycin are mainly vestibular rather than auditory. Ototoxicity has been seen in infants whose mothers had been given streptomycin during pregnancy. However, streptomycin is reported to be somewhat less nephrotoxic than the other aminoglycosides.

Paraesthesia in and around the mouth is not uncommon after intramuscular injection of streptomycin, and other neurological symptoms, including peripheral neuropathies, optic neuritis, and scotoma have occasionally occurred. Intrathecal use has resulted in symptoms of meningeal inflammation including radiculitis, arachnoiditis, nerve root pain, and paraplegia, and some recommend that it be avoided. The risk of neurotoxic reactions is greater in patients with renal impairment or pre-renal azotaemia.

Hypersensitivity skin reactions are reported in about 5% of patients, and eosinophilia may occur. There have been reports of Stevens-Johnson syndrome, toxic epidermal necrolysis, severe exfoliative dermatitis, and anaphylaxis. Sensitisation is common among those who handle streptomycin occupationally. Topical and inhalational use of streptomycin should be avoided. If necessary, hypersensitivity can usually be overcome by desensitisation. Aplastic anaemia and agranulocytosis have been reported rarely.

Although sources differ, it is usually suggested that peak plasma concentrations should be between 15 and 40 micrograms/mL, and trough concentrations below 3 to 5 micrograms/mL; in the UK the *BNF* recommends that trough concentrations in excess of 1 microgram/mL should be avoided in those over 50 years of age or those with renal impairment. A total cumulative dose in excess of 100 g may be associated with a higher incidence of adverse effects and should only be exceeded in exceptional circumstances.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving streptomycin, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/05/04)

Handling. Streptomycin may cause severe dermatitis in sensitised persons, and pharmacists, nurses, and others who handle the drug frequently should wear masks and rubber gloves.

Interactions

As for Gentamicin Sulfate, p.283.

Antimicrobial Action

Streptomycin has a mode of action and antimicrobial spectrum similar to that of gentamicin (p.283), although most strains of *Pseudomonas aeruginosa* are resistant. It is effective against *Yersinia pestis, Francisella tularensis,* and *Brucella* spp. Streptomycin has particular activity against *Mycobacterium tuberculosis*.

Resistance to streptomycin has often been reported and may develop in strains which are initially sensitive within a few days or weeks of beginning therapy. The widespread emergence of resistance has largely halted its use in infections due to the common Gram-negative aerobes. Primary resistance in *M. tuberculosis* is relatively uncommon in the UK and USA but may be seen in a third or more of cases in the Far East.

Both low-level and high-level resistance have been reported; the latter is thought to be due to mutation of the ribosomal binding site of the antibiotic and cannot be overcome by the synergistic use of another drug such as a beta lactam, whereas strains with moderate resistance due to decreased uptake or permeability of streptomycin may respond to combined use.

Organisms resistant to framycetin, kanamycin, neomycin, and paromomycin usually show cross-resistance to streptomycin, although streptomycin-resistant strains sometimes respond to one of these drugs.

◊ References.

2. Ho YII, *et al.* In-vitro activities of aminoglycoside-aminocyclitols against mycobacteria. *J Antimicrob Chemother* 1997; **40:** 27–32.

Pharmacokinetics

As for Gentamicin Sulfate, p.284. After intramuscular injection of streptomycin, maximum concentration in the blood is reached in 0.5 to 2 hours but the time taken and the concentration attained, which may be as high as about 50 micrograms/mL after a dose of 1 g, vary considerably. The half-life of streptomycin is about 2.5 hours. About one-third of streptomycin in the circulation is bound to plasma proteins. It is rapidly excreted by glomerular filtration and the concentration of streptomycin in the urine is often very high, with about 30 to 90% of a dose usually being excreted within 24 hours. It is distributed into breast milk.

Uses and Administration

Streptomycin is an aminoglycoside antibacterial mainly used as a first-line drug, with other antimycobacterials, in the treatment of tuberculosis. It is given during the initial phase of treatment unless the risk of drug resistance is small. Streptomycin has been used, with a penicillin, as an alternative to gentamicin in the treatment of bacterial endocarditis. Streptomycin is effective in the treatment of plague, tularaemia, and, with a tetracycline, in brucellosis. It has also been used, with other drugs, in various other infections including mycetoma and Whipple's disease. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Streptomycin is mostly used as the sulfate but doses are expressed in terms of the base; 1.25 g of streptomycin sulfate is equivalent to about 1 g of streptomycin. It is given by intramuscular injection.

In the treatment of tuberculosis, streptomycin is given during the initial phase of short-course regimens in usual adult doses of 15 mg/kg daily, up to a maximum of 1 g daily. The maximum daily dose should be reduced to 500 to 750 mg in adults aged over 40 years, and in those weighing less than 50 kg. Dosage should also be reduced in those with renal impairment, in whom plasma-drug concentration should be monitored. Streptomycin may also be given as part of an intermittent regimen 2 or 3 times weekly. It has been given by the intrathecal route, together with intramuscular dosage, for tuberculous meningitis, but this is no longer recommended.

Children and infants aged 1 month to 18 years with tuberculosis may be given streptomycin 20 to 40 mg/kg daily (to a maximum of 1 g daily).

In the treatment of non-tuberculous infections, streptomycin has been given in usual adult doses of 1 to 2 g daily in divided doses, depending on the susceptibility and severity of infection; children may be given 20 to 40 mg/kg daily (maximum 1 g daily), usually in 2 to 4 divided doses.

In all patients dosage should preferably be adjusted according to plasma-streptomycin concentrations, and particularly where factors such as age, renal impairment, or prolonged therapy may predispose to toxicity. The course of treatment (other than in tuberculosis) should usually be limited to 7 to 14 days, and peak plasma concentrations should be between 15 and 40 micrograms/mL and trough concentrations below 3 to 5 micrograms/mL or below 1 microgram/mL in renal impairment or in those over 50 years of age. For discussion of the methods used to calculate aminoglycoside dosage requirements, see under Gentamicin Sulfate, p.284.

Streptomycin has also been used as the hydrochloride, the pantothenate, and as a complex with calcium chloride.

Administration and dosage. A report of the successful use of streptomycin 7 to 15 mg/kg as an intravenous infusion over 30 to 60 minutes in 4 patients with tuberculosis. Despite the view that streptomycin should be given intramuscularly because of the greater risk of toxicity with the intravenous route, this study was considered to indicate that intravenous use was feasible in selected patients unable to tolerate the intramuscular route.[1]

Ménière's disease. Streptomycin and gentamicin have been used for medical ablation in advanced Ménière's disease (p.564). Systemic treatment has generally been limited by the development of chronic ataxia and oscillopsia (oscillating vision). However, streptomycin sulfate 1 g twice daily by intramuscular injection on 5 days each week for 2 weeks, repeated as necessary to a total dose of up to 60 g,[1,2] or 1 g twice daily for 5 days, followed if necessary by a further 3 days of treatment in the second week,[3] has produced improvements in vestibular symptoms without hearing loss in patients with Ménière's disease. Local (intratympanic) injections have also been tried,[4] but gentamicin is considered to be less toxic and is now generally preferred.

Sulbactam Sodium *(BANM, USAN, rINNM)*

CP-45899-2; Natrii Sulbactamum; Sulbactam sódico; Sulbactam sodique; Sulbactamum natricum; Sulbaktaaminatrium; Sulbaktam sodná sůl; Sulbaktam sodowy; Sulbaktamnatrium.

Натрий Сульбактам

$C_8H_{10}NNaO_5S = 255.2.$
CAS — 69388-84-7.
ATC — J01CG01.
ATC Vet — QJ01CG01.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US*.

Ph. Eur. 6.2 (Sulbactam Sodium). A white or almost white, hygroscopic, crystalline powder. Freely soluble in water; very slightly soluble in alcohol; sparingly soluble in ethyl acetate. It is freely soluble in diluted acids. A 5.0% solution in water has a pH of 4.5 to 7.2; if the substance is sterile: 5.2 to 7.2. Store in airtight containers.

USP 31 (Sulbactam Sodium). A white to off-white crystalline powder. It contains not less than 886 micrograms and not more than 941 microgram of sulbactam per mg, calculated on the anhydrous basis. Freely soluble in water and in dilute acid; sparingly soluble in acetone, in chloroform, and in ethyl acetate. Store in airtight containers.

Pivsulbactam *(BAN)*

CP-47904; Sulbactam Pivoxil *(USAN)*. Pivaloyloxymethyl penicillanate 1,1-dioxide.

Пивсульбактам

$C_{14}H_{21}NO_7S = 347.4.$
CAS — 69388-79-0.

Profile

Sulbactam is a penicillanic acid sulfone with beta-lactamase inhibitory properties. It is active against Neisseriaceae and *Acinetobacter baumanii*, but generally has only weak antibacterial activity against other organisms. It is an irreversible inhibitor of many plasmid-mediated and some chromosomal beta-lactamases and has a similar spectrum of beta-lactamase inhibition to clavulanic acid (p.250), although it is regarded as less potent. Sulbactam can therefore enhance the activity of penicillins and cephalosporins against many resistant strains of bacteria.

It is given with ampicillin (p.204) in the treatment of infections where beta-lactamase production is suspected. Sulbactam is poorly absorbed from the gastrointestinal tract and is given by injection as the sodium salt. The pharmacokinetics of parenteral sulbactam and ampicillin are similar. For oral use the mutual prodrug sultamicillin (p.344) is available in some countries. Sulbactam is also given orally as the pivoxil derivative, pivsulbactam, with amoxicillin. Sulbactam has also been given with cefoperazone.

Indon.: Kedacillin; ***Jpn:*** Lilacillin†; ***Mex.:*** Kedacillin; ***Philipp.:*** Kedacillin.

Sulfabenzamide *(BAN, USAN, rINN)*

Sulfabensamid; Sulfabentsamidi; Sulfabenzamida; Sulfabenzamidum. *N*-Sulphanilylbenzamide.

Сульфабензамид

$C_{13}H_{12}N_2O_3S = 276.3.$
CAS — 127-71-9.

Pharmacopoeias. In *US.*

USP 31 (Sulfabenzamide). A fine, white, practically odourless powder. Insoluble in water and in ether; soluble in alcohol, in acetone, and in sodium hydroxide 4% solution. Protect from light.

Profile

Sulfabenzamide is a sulfonamide with properties similar to those of sulfamethoxazole (p.340). It is reported to exert an optimal bacteriostatic action at pH 4.6. It is used with sulfacetamide and sulfathiazole in pessaries or a vaginal cream for the treatment of bacterial vaginosis, although its value has been questioned. The vaginal cream has also been used for the prevention of bacterial infection after cervical and vaginal surgery.

Preparations

USP 31: Triple Sulfa Vaginal Cream; Triple Sulfa Vaginal Tablets.

Proprietary Preparations (details are given in Part 3)

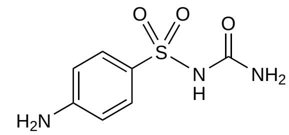
Multi-ingredient: ***Belg.:*** Sultrin†; ***Braz.:*** Vagi-Sulfa; ***Gr.:*** Sultrin; ***Irl.:*** Sultrin†; ***Philipp.:*** Sultrin; ***Port.:*** Sultrin†; ***S.Afr.:*** Sultrin; ***UK:*** Sultrin†; ***USA:*** Sultrin.

Sulfacarbamide *(BAN, rINN)*

Sulfacarbamida; Sulfacarbamidum; Sulfakarbamid; Sulfanilcarbamide; Sulfaurea; Sulphacarbamide; Sulphanilylurea; Sulphaurea; Urosulphanum. Sulphanilylurea monohydrate.

Сульфакарбамид

$C_7H_9N_3O_3S,H_2O = 233.2.$
CAS — 547-44-4 (anhydrous sulfacarbamide); 6101-35-5 (sulfacarbamide monohydrate).



Pharmacopoeias. In *Pol.*

Profile

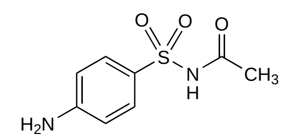
Sulfacarbamide is a sulfonamide with properties similar to those of sulfamethoxazole (p.340). It has been used in the treatment of urinary-tract infections, sometimes with other drugs.

Sulfacetamide *(BAN, rINN)*

Acetosulfaminum; Sulfacetamid; Sulfacetamida; Sulfacétamide; Sulfacetamidum; Sulfatsetamidi; Sulphacetamide. *N*-Sulphanilyacetamide.

Сульфацетамид

$C_8H_{10}N_2O_3S = 214.2.$
CAS — 144-80-9.
ATC — S01AB04.
ATC Vet — QS01AB04.



Pharmacopoeias. In *Int.* and *US.*

USP 31 (Sulfacetamide). A white, odourless, crystalline powder. Slightly soluble in water and in ether; soluble in alcohol; very slightly soluble in chloroform; freely soluble in dilute mineral acids and in solutions of potassium and sodium hydroxides; practically insoluble in benzene. Solutions in water are acid to litmus and sensitive to light; they are unstable when acidic or strongly alkaline. Protect from light.

Sulfacetamide Sodium *(BANM, rINNM)*

Natrii Sulfacetamidum; Soluble Sulphacetamide; Sulfacetamid sodná sůl monohydrát; Sulfacetamid sodowy; Sulfacetamida sódica; Sulfacétamide sodique; Sulfacetamidnatrium; Sulfacetamido natrio druska; Sulfacetamidum natricum; Sulfacetamidum Natricum Monohydricum; Sulfacylum; Sülfasetamid Sodyum; Sulfasetamidinatrium; Sulphacetamide Sodium; Sulphacetamidum Sodium; Szulfacetamid-nátrium.

Натрий Сульфацетамид

$C_8H_9N_2NaO_3S,H_2O = 254.2.$
CAS — 127-56-0 (anhydrous sulfacetamide sodium); 6209-17-2 (sulfacetamide sodium monohydrate).
ATC — S01AB04.
ATC Vet — QS01AB04.

NOTE. SULF is a code approved by the BP 2008 for use on single unit doses of eye drops containing sulfacetamide sodium where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *US*, and *Viet.*

Ph. Eur. 6.2 (Sulfacetamide Sodium). A white or yellowish-white, crystalline powder. Freely soluble in water; slightly soluble in dehydrated alcohol. A 5% solution in water has a pH of 8.0 to 9.5. Protect from light.

USP 31 (Sulfacetamide Sodium). A white odourless crystalline powder. Soluble 1 in 2.5 of water; sparingly soluble in alcohol; practically insoluble in chloroform and in ether. A 5% solution in water has a pH of 8.0 to 9.5. Store in airtight containers. Protect from light.

Stability. When solutions of sulfacetamide sodium are heated, hydrolysis occurs forming sulfanilamide which may be deposited as crystals, especially from concentrated solutions and under cold storage conditions.

Adverse Effects, Treatment, and Precautions

As for Sulfamethoxazole, p.340.

Local application of sulfacetamide sodium to the eye may cause burning or stinging but this is rarely severe enough to require stopping treatment.

The symbol † denotes a preparation no longer actively marketed

Antimicrobial Action

As for Sulfamethoxazole, p.341.

Pharmacokinetics

When sulfacetamide sodium is applied to the eye it penetrates into ocular tissues and fluids; sulfacetamide may be absorbed into the blood when the conjunctiva is inflamed.

Uses and Administration

Sulfacetamide is a sulfonamide antibacterial that is used with sulfabenzamide and sulfathiazole in preparations for vaginal use, and is applied, as the sodium salt, in infections or injuries of the eyes, although it is rarely of much value. Eye drops containing sulfacetamide sodium 10% to 30% and eye ointments containing 10% have been used. The sodium salt is also applied topically in the treatment of skin infections.

Preparations

USP 31: Neomycin Sulfate, Sulfacetamide Sodium, and Prednisolone Acetate Ophthalmic Ointment; Sulfacetamide Sodium and Prednisolone Acetate Ophthalmic Ointment; Sulfacetamide Sodium and Prednisolone Acetate Ophthalmic Suspension; Sulfacetamide Sodium Ophthalmic Ointment; Sulfacetamide Sodium Ophthalmic Solution; Sulfacetamide Sodium Topical Suspension; Triple Sulfa Vaginal Cream; Triple Sulfa Vaginal Tablets.

Proprietary Preparations (details are given in Part 3)

Profile

Sulfaclozine is a sulfonamide antibacterial that has been used in veterinary medicine.

Sulfadiazine *(BAN, rINN)*

Sulfadiazina; Solfapirimidina; Sulfadiatsiini; Sülfadiazin; Sulfadiazin; Sulfadiazina; Sulfadiazinas; Sulfadiazinum; Sulphadiazine; Szulfadiazin. N^1-(Pyrimidin-2-yl)sulphanilamide.

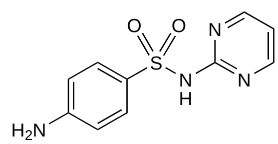
Сульфадиазин

$C_{10}H_{10}N_4O_2S$ = 250.3.

CAS — 68-35-9.

ATC — J01EC02.

ATC Vet — QJ01EQ10.



NOTE. Compounded preparations of sulfadiazine may be represented by the following names:

- Co-tetroxazine (*BAN*)—sulfadiazine 5 parts and tetroxoprim 2 parts (see p.257)
- Co-trimazine (*BAN*)—sulfadiazine 5 parts and trimethoprim 1 part (see p.258).

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *US,* and *Viet.*

Ph. Eur. 6.2 (Sulfadiazine). White, yellowish-white, or pinkish-white, crystalline powder or crystals. Practically insoluble in water; very slightly soluble in alcohol; slightly soluble in acetone. It dissolves in solutions of alkali hydroxides and in dilute mineral acids. Protect from light.

USP 31 (Sulfadiazine). White or slightly yellow, odourless or nearly odourless, powder, slowly darkening on exposure to light. Soluble 1 in 13 000 of water; sparingly soluble in alcohol and in acetone; freely soluble in dilute mineral acids and in solutions of potassium and sodium hydroxides, and ammonia. Protect from light.

Sulfadiazine Sodium *(BANM, rINN)*

Sodium Sulfadiazine; Soluble Sulphadiazine; Sulfadiazina de sodio; Sulfadiazina sódica; Sulfadiazine sodique; Sulfadiazinum Natricum; Sulphadiazine Sodium.

Сульфадиазин Натрий

$C_{10}H_9N_4NaO_2S$ = 272.3.

CAS — 547-32-0.

ATC — J01EC02.

Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Sulfadiazine Sodium). A white powder. Soluble 1 in 2 of water; slightly soluble in alcohol. On prolonged exposure to humid air it absorbs carbon dioxide with the liberation of sulfadiazine and becomes incompletely soluble in water. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Incompatibility. Solutions of sulfadiazine sodium are alkaline, and incompatibility may reasonably be expected with acidic drugs or with preparations unstable at high pH. In the UK, licensed product information states that sulfadiazine sodium injection is incompatible with fructose, iron salts, and salts of heavy metals.

Adverse Effects, Treatment, and Precautions

As for Sulfamethoxazole, p.340.

Because of the low solubilities of sulfadiazine and its acetyl derivative in urine, crystalluria is more likely after use of sulfadiazine than after sulfamethoxazole.

Sulfadiazine sodium solution is strongly alkaline and it should therefore be given intravenously in a strength not exceeding 5%, over at least 10 minutes. For the same reason, intramuscular injections are painful and sulfadiazine sodium should not be given by intrathecal or subcutaneous injection.

Carnitine deficiency. Hyperammonaemia and carnitine deficiency developed in an immunocompromised patient given sulfadiazine and pyrimethamine for the treatment of toxoplasmosis.[1]

1. Sekas G, Harbhajan SP. Hyperammonemia and carnitine deficiency in a patient receiving sulfadiazine and pyrimethamine. *Am J Med* 1993; **95:** 112–13.

Effects on the eyes. Numerous white stone-like concretions of sulfadiazine occurred in the conjunctiva of a woman who had used sulfadiazine eye drops for about 1 year.[1]

1. Boettner EA, *et al.* Conjunctival concretions of sulfadiazine. *Arch Ophthalmol* 1974; **92:** 446–8.

Effects on the kidneys. Reports of crystalluria and renal failure associated with the use of sulfadiazine in immunocompromised patients,[1-8] including the suggestion that AIDS patients may be particularly prone to sulfadiazine-induced renal toxicity.[3] Renal failure and leucopenia in a patient treated with sulfadiazine silver for pyoderma gangrenosum were thought to be due to systemic absorption of the silver component.[9]

9. Chaby G, *et al.* Insuffisance rénale aiguë après application topique de sulfadiazine argentique. *Ann Dermatol Venereol* 2005; **132:** 891–3.

Effects on the salivary glands. Enlargement of the salivary glands (sialadenitis) has been reported[1] in a patient who received a preparation containing sulfadiazine; complete recovery followed within 3 days of stopping therapy. Rechallenge confirmed that sulfadiazine was the causative agent.

1. Añíbarro B, Fontela JL. Sulfadiazine-induced sialadenitis. *Ann Pharmacother* 1997; **31:** 59–60.

Interactions

As for Sulfamethoxazole, p.341.

Antimicrobial Action

As for Sulfamethoxazole, p.341.

Pharmacokinetics

Sulfadiazine is readily absorbed from the gastrointestinal tract, peak blood concentrations being reached 3 to 6 hours after a single dose; 20 to 55% has been reported to be bound to plasma proteins. It penetrates into the CSF within 4 hours of an oral dose to produce therapeutic concentrations which may be more than half those in the blood. Up to 40% of sulfadiazine in the blood is present as the acetyl derivative. The half-life of sulfadiazine is about 10 hours; it is prolonged in renal impairment.

About 50% of a single dose of sulfadiazine given by mouth is excreted in the urine in 24 hours; 15 to 40% is excreted as the acetyl derivative.

◊ The urinary excretion of sulfadiazine and the acetyl derivative is dependent on pH. About 30% is excreted unchanged in both fast and slow acetylators when the urine is acidic whereas about 75% is excreted unchanged by slow acetylators when the urine is alkaline. The half-life of sulfadiazine ranges from 7 to 12 hours and that of its metabolite from 8 to 12 hours.[1]

1. Vree TB, *et al*. Determination of the acetylator phenotype and pharmacokinetics of some sulphonamides in man. *Clin Pharmacokinet* 1980; **5:** 274–94.

Uses and Administration

Sulfadiazine is a short-acting sulfonamide that has been used similarly to sulfamethoxazole (p.341) in the treatment of infections due to susceptible organisms. It has been used in the treatment of nocardiosis and lymphogranuloma venereum, and has been given for the prophylaxis of rheumatic fever in penicillin-allergic patients. For details of these infections and their treatment, see Choice of Antibacterial, p.162. Sulfadiazine is also given with pyrimethamine for the treatment and prevention of relapse of toxoplasmosis (p.826) and has been tried in disseminated *Acanthamoeba* infection (p.822).

In the treatment of susceptible infections, sulfadiazine may be given orally in usual initial doses of 2 to 4 g, followed by up to 6 g daily in divided doses. A dose in children is 75 mg/kg initially, then 150 mg/kg daily in divided doses to a maximum of 6 g daily. Sulfadiazine is used in infants less than 2 months of age for congenital toxoplasmosis; an oral dose of 50 mg/kg twice daily for 12 months has been suggested by the *BNFC* for use in neonates.

Immunocompromised patients who have toxoplasmosis should be given a dose of 4 to 6 g daily in 4 divided doses for at least 6 weeks, followed by a suppressive dose of 2 to 4 g daily, which should continue indefinitely. Pyrimethamine should always be given as well.

For the prophylaxis of rheumatic fever, patients weighing less than about 30 kg are given 500 mg once daily, while those over 30 kg may receive 1 g once daily.

Sulfadiazine is also given intravenously as the sodium salt. Sulfadiazine sodium 1.09 g is equivalent to about 1 g of sulfadiazine. The usual dose is the equivalent of sulfadiazine 2 to 3 g initially, then 1 g four times daily for 2 days; subsequent treatment is given orally. Children and infants over 2 months of age may be given the equivalent of 50 mg/kg initially, followed by 25 mg/kg four times daily.

Intravenous doses of sulfadiazine sodium are given by infusion or by slow intravenous injection of a solution containing up to 5% sulfadiazine. It may be diluted with sodium chloride 0.9%. Sulfadiazine sodium has been given by deep intramuscular injection, but great care must be taken to prevent damage to subcutaneous tissues; the intravenous route is preferred.

Sulfadiazine has been used with trimethoprim as co-trimazine (p.258). Sulfadiazine has also been used with other sulfonamides, particularly sulfamerazine and sulfadimidine, to reduce the problems of low solubility in urine.

Preparations

BP 2008: Sulfadiazine Injection;
USP 31: Sulfadiazine Sodium Injection; Sulfadiazine Tablets; Trisulfapyrimidines Oral Suspension; Trisulfapyrimidines Tablets.

Proprietary Preparations (details are given in Part 3)

Arg.: Sulfatral; ***Braz.:*** Neo Sulfazina†; Suladrin; Sulfadiazinac†; ***Fr.:*** Adiazine†; ***Gr.:*** Adiazine; ***Mex.:*** Bioarginol-C; Sularyn; ***Port.:*** Labdiazina.

Сульфадиазин Серебра

$C_{10}H_9AgN_4O_2S$ = 357.1.

CAS — 22199-08-2.

ATC — D06BA01.

ATC Vet — QD06BA01.

Pharmacopoeias. In *Chin.*, *Int.*, *Jpn*, and *US*.

USP 31 (Silver Sulfadiazine). A white to creamy-white, odourless or almost odourless crystalline powder. It becomes yellow on exposure to light. Practically insoluble in alcohol, in chloroform, and in ether; slightly soluble in acetone; freely soluble in 30% ammonia solution. It decomposes in moderately strong mineral acids. Protect from light.

Adverse Effects, Treatment, and Precautions

Sulfadiazine silver may be absorbed after topical application and produce systemic effects similar to those of other sulfonamides (see Sulfamethoxazole, p.340).

Local pain or irritation are uncommon; the separation of the eschar may be delayed and fungal invasion of the wound may occur.

Transient leucopenia does not usually require withdrawal of sulfadiazine silver, but blood counts should be monitored to ensure they return to normal within a few days. Systemic absorption of silver, resulting in argyria, can occur when sulfadiazine silver is applied to large area wounds or over prolonged periods.

Argyria. A report of argyria, with discoloration of the skin and sensorimotor neuropathy, caused by excessive application of sulfadiazine silver 1% cream to extensive leg ulcers.[1]

1. Payne CMER, *et al.* Argyria from excessive use of topical silver sulphadiazine. *Lancet* 1992; **340**: 126.

Effects on the kidneys. For mention of renal failure and leucopenia associated with the use of sulfadiazine silver see under Sulfadiazine, above.

Interactions

As for Sulfamethoxazole, p.341.

Sulfadiazine silver is not antagonised by *p*-aminobenzoic acid or related compounds. The silver content of sulfadiazine silver may inactivate enzymatic debriding agents.

Antimicrobial Action

Sulfadiazine silver has broad antimicrobial activity against Gram-positive and Gram-negative bacteria including *Pseudomonas aeruginosa*, and some yeasts and fungi. Sulfadiazine silver has a bactericidal action; in contrast to sulfadiazine, the silver salt acts primarily on the cell membrane and cell wall and its action is not antagonised by *p*-aminobenzoic acid. Resistance to sulfadiazine silver has been reported and may develop during therapy.

Pharmacokinetics

Sulfadiazine silver slowly releases sulfadiazine when in contact with wound exudates. Up to about 10% of the sulfadiazine may be absorbed; concentrations in blood of 10 to 20 micrograms/mL have been reported, although higher concentrations may be achieved when extensive areas of the body are treated. Some silver may also be absorbed.

Uses and Administration

Sulfadiazine silver is a sulfonamide that is used, in conjunction with debridement, as a 1% cream for the prevention and treatment of infection in severe burns (p.1578).

Sulfadiazine silver has also been used in other skin conditions, such as leg ulcers (p.1585), where infection may prevent healing and for the prophylaxis of infection in skin grafting. It has also been applied to the eyes in the treatment of superficial *Aspergillus* infections.

Catheters impregnated with sulfadiazine silver have been used to reduce catheter colonisation and related bloodstream infection (p.1624).

Preparations

USP 31: Silver Sulfadiazine Cream.

Proprietary Preparations (details are given in Part 3)

$C_{12}H_{13}N_4NaO_2S$ = 300.3.

CAS — 1981-58-4.

ATC — J01EB03.

Pharmacopoeias. In *Int.*

Profile

Sulfadimidine is a short-acting sulfonamide with properties similar to those of sulfamethoxazole (p.340).

It is well absorbed from the gastrointestinal tract and is about 80 to 90% bound to plasma proteins. Reported half-lives have ranged from 1.5 to 4 hours in fast and 5.5 to 8.8 hours in slow acetylators. Because of the relatively high solubility of the drug and its acetyl metabolite, crystalluria may be less likely than with sulfamethoxazole.

In the treatment of susceptible infections, sulfadimidine has been given orally in an initial dose of 2 g, followed by 0.5 to 1.0 g every 6 to 8 hours. It has also been given parenterally as the sodium salt.

Sulfadimidine has also been used with other sulfonamides, particularly sulfamerazine and sulfadiazine. It is also used in veterinary medicine, sometimes with baquiloprim or trimethoprim.

Because its pharmacokinetics differ in fast and slow acetylators, sulfadimidine has been used to determine acetylator status.

Preparations

USP 31: Trisulfapyrimidines Oral Suspension; Trisulfapyrimidines Tablets.

Proprietary Preparations (details are given in Part 3)
Hung.: Septosyl.

Multi-ingredient: ***Hung.:*** Potesept†; ***Indon.:*** Trisulfa; ***Thai.:*** Sulfatril.

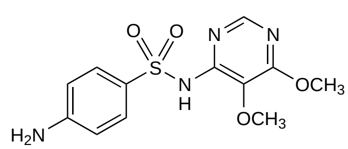
Сульфадоксин

$C_{12}H_{14}N_4O_4S$ = 310.3.

CAS — 2447-57-6.

ATC Vet — QJ01EQ13.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *US*, and *Viet.*

Ph. Eur. 6.2 (Sulfadoxine). White or yellowish-white crystalline powder or crystals. Very slightly soluble in water; slightly soluble in alcohol and in methyl alcohol. It dissolves in solutions of alkali hydroxides and in dilute mineral acids. Protect from light.

USP 31 (Sulfadoxine). Protect from light.

Adverse Effects, Treatment, and Precautions

As for Sulfamethoxazole, p.340. For reference to the adverse effects of a combination of sulfadoxine and pyrimethamine, see Pyrimethamine, p.610.

If adverse effects occur, sulfadoxine has the disadvantage that several days are required for elimination from the body.

Interactions

As for Sulfamethoxazole, p.341.

Antimicrobial Action

As for Sulfamethoxazole, p.341. Synergy exists between sulfadoxine and pyrimethamine, which act against folate metabolism at different points of the metabolic cycle.

Resistance to the combination of sulfadoxine and pyrimethamine in plasmodia, first noted in Thailand in the late 1970s, has become widespread in many malarious areas of the world. For further details of resistance to antimalarial drugs, see p.594.

Pharmacokinetics

Sulfadoxine is readily absorbed from the gastrointestinal tract. High concentrations in the blood are reached in about 4 hours; the half-life in the blood is about 4 to 9 days. About 90 to 95% is reported to be bound to plasma proteins.

Sulfadoxine is widely distributed to body tissues and fluids; it passes into the fetal circulation and has been detected in low concentrations in breast milk. Sulfadoxine is excreted very slowly in urine, primarily unchanged.

Uses and Administration

Sulfadoxine is a long-acting sulfonamide that has been used in the treatment of various infections but is now rarely used alone.

It is given as a fixed-dose combination of 20 parts sulfadoxine with 1 part pyrimethamine (*Fansidar*, *Roche*) in the treatment of falciparum malaria resistant to other therapies (p.594), usually after a course of quinine. Although the combination has been used in the prophylaxis of malaria, the risk of toxicity is now generally considered to outweigh its value.

In the treatment of malaria, the usual oral dose is 1.5 g of sulfadoxine with 75 mg of pyrimethamine as a single dose; this should not be repeated for at least 7 days. Oral doses for children are: 5 to 10 kg bodyweight, 250 mg sulfadoxine with 12.5 mg pyrimethamine; 11 to 20 kg, 500 mg sulfadoxine with 25 mg pyrimethamine; 21 to 30 kg, 750 mg sulfadoxine with 37.5 mg pyrimethamine; 31 to 45 kg, 1 g sulfadoxine with 50 mg pyrimethamine.

Sulfadoxine with pyrimethamine has also been given intramuscularly.

Sulfadoxine with pyrimethamine has also been tried in the treatment of actinomycetomas (see Mycetoma p.180), and for prophylaxis of pneumocystis pneumonia in immunocompromised patients (see p.521 for the more usual prophylactic regimens).

A mixture of 5 parts of sulfadoxine with 1 part trimethoprim is used in veterinary medicine.

Preparations

USP 31: Sulfadoxine and Pyrimethamine Tablets.

Proprietary Preparations (details are given in Part 3)
Malaysia: Fansidar.

Sulfafurazole *(BAN, pINN)*

Sulfafuratsoli; Sulfafurazol; Sulfafurazolas; Sulfafurazolum; Sulfisoxazole; Sülfizoksazol; Sulphafuraz; Sulphafurazole; Szulfafurazol. N^1-(3,4-Dimethylisoxazol-5-yl)sulphanilamide.

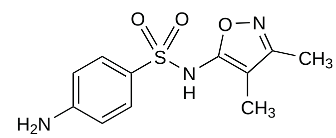
Сульфафуразол

$C_{11}H_{13}N_3O_3S$ = 267.3.

CAS — 127-69-5.

ATC — J01EB05; S01AB02.

ATC Vet — QJ01EQ05; QS01AB02.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US*.

Ph. Eur. 6.2 (Sulfafurazole). White or yellowish-white, crystalline powder or crystals. Practically insoluble in water; sparingly soluble in alcohol; slightly soluble in dichloromethane. It dissolves in solutions of alkali hydroxides and in dilute mineral acids. Protect from light.

USP 31 (Sulfisoxazole). A white to slightly yellowish, odourless crystalline powder. Soluble 1 in 7700 of water and 1 in 10 of boiling alcohol; soluble in 3N hydrochloric acid. Store in airtight containers. Protect from light.

Acetyl Sulfafurazole

Acetilsulfafurazol; Acetyl Sulphafurazole; Sulfisoxazole Acetyl. N^1-Acetyl Sulphafurazole; *N*-(3,4-Dimethylisoxazol-5-yl)-*N*-sulphanilylacetamide.

$C_{13}H_{15}N_3O_4S$ = 309.3.

CAS — 80-74-0.

ATC — J01EB05; S01AB02.

ATC Vet — QS01AB02.

NOTE. Acetyl sulfafurazole is to be distinguished from the N^4-acetyl derivative formed from sulfafurazole by conjugation in the body.

Compounded preparations of acetyl sulfafurazole may be represented by the following name:

- Co-erynsulfisox (*PEN*)—acetyl sulfafurazole and erythromycin ethyl succinate.

Pharmacopoeias. In *US*.

USP 31 (Sulfisoxazole Acetyl). A white or slightly yellow crystalline powder. Practically insoluble in water; soluble 1 in 176 of alcohol, 1 in 35 of chloroform, 1 in 1064 of ether, and 1 in 203 of methyl alcohol. Store in airtight containers. Protect from light.

Sulfafurazole Diolamine *(pINNM)*

NU-445; Sulfafurazol diolamina; Sulfafurazol, Diolamine de; Sulfafurazoli Diolaminum; Sülfisoksazol Dietanolamin; Sulfisoxazole Diolamine *(USAN)*; Sulphafurazole Diethanolamine; Sulphafurazole Diolamine. The 2,2′-iminobisethanol salt of sulphafurazole.

Сульфафуразола Диоламин

$C_{11}H_{13}N_3O_3S,C_4H_{11}NO_2$ = 372.4.

CAS — 4299-60-9.

ATC — J01EB05; S01AB02.

ATC Vet — QS01AB02.

Adverse Effects, Treatment, and Precautions

As for Sulfamethoxazole, p.340.

Sulfafurazole and its acetyl derivative are relatively soluble in urine and the risk of crystalluria is generally slight, but nevertheless adequate fluid intake is recommended.

Breast feeding. A study[1] in 6 women who received sulfafurazole concluded that the amount of drug secreted into breast milk poses no risk to the healthy infant beyond the immediate newborn period, but potential risk in breast-fed infants with jaundice or G6PD deficiency, or who are ill, stressed, or premature, was more difficult to evaluate. Based on this evidence, the American Academy of Pediatrics[2] has stated that sulfafurazole is usually compatible with breast feeding, but caution is required in the infants mentioned above.

1. Kauffman RE, *et al.* Sulfisoxazole secretion into human milk. *J Pediatr* 1980; **97:** 839–41.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/05/04)

Interactions

As for Sulfamethoxazole, p.341.

Sulfafurazole has been reported to increase the anaesthetic effect of thiopental.

Eye preparations of sulfafurazole diolamine should not be applied with preparations of silver salts.

Antimicrobial Action

As for Sulfamethoxazole, p.341.

Pharmacokinetics

Sulfafurazole is readily absorbed from the gastrointestinal tract with peak plasma concentrations occurring 1 to 4 hours after an oral dose. Acetyl sulfafurazole (the N^1-acetyl derivative) is broken down to sulfafurazole in the gastrointestinal tract before absorption, resulting in delayed and somewhat lower peak concentrations. After absorption about 85 to 90% is bound to plasma proteins. Sulfafurazole readily diffuses into extracellular fluid, but very little diffuses into cells. Concentrations in the CSF are about one-third of those in the blood. It crosses the placenta into the fetal circulation and is distributed into breast milk. About 30% of sulfafurazole in the blood and in the urine is in the form of the N^4-acetyl derivative.

Sulfafurazole is excreted rapidly in the urine, up to 97% of a single dose being eliminated in 48 hours. The half-life is reported to range from about 5 to 8 hours. Both sulfafurazole and its N^4-acetyl derivative are more soluble than many other sulfonamides in urine.

Uses and Administration

Sulfafurazole is a short-acting sulfonamide that is used similarly to sulfamethoxazole (p.341), notably in the treatment of urinary-tract infections, pneumonia due to *Chlamydophila pneumoniae* (*Chlamydia pneumoniae*), nocardiosis, and trachoma. It is also used, usually with erythromycin, in the treatment of otitis media. For details of these infections and their treatment see Choice of Antibacterial, p.162.

Sulfafurazole is usually given orally. In the treatment of susceptible infections, it has been given in an initial dose of 2 to 4 g, followed by 4 to 8 g daily in divided doses every 4 to 6 hours. For children and infants over 2 months of age, the dose has been 75 mg/kg initially, followed by 150 mg/kg daily in divided doses to a maximum of 6 g daily. Dosage modification may be necessary in patients with renal impairment. Acetyl sulfafurazole is tasteless and is used in liquid oral preparations of the drug; doses are expressed in terms of sulfafurazole. 1.16 g of acetyl sulfafurazole is equivalent to about 1 g of sulfafurazole.

Sulfafurazole diolamine has been used, as an ophthalmic ointment or solution containing the equivalent of 4% of sulfafurazole, in the topical treatment of susceptible eye infections. Sulfafurazole diolamine 1.39 g is equivalent to about 1 g of sulfafurazole.

Sulfafurazole diolamine has also been given parenterally.

Preparations

Pharmacopoeias. In *Eur.* (see p.vii).
Viet. includes the monohydrate.
Ph. Eur. 6.2 (Sulfaguanidine). A white or almost white, fine crystalline powder. Very slightly soluble in water and in alcohol; slightly soluble in acetone; practically insoluble in dichloromethane. It dissolves in dilute solutions of mineral acids. Protect from light.

Profile

Sulfaguanidine is a sulfonamide with properties similar to those of sulfamethoxazole (p.340). It is absorbed to a limited extent from the gastrointestinal tract and may therefore be more likely to cause systemic effects than less well absorbed drugs such as phthalylsulfathiazole and succinylsulfathiazole. It is used, usually with other drugs, in the treatment of gastrointestinal infections, and has also been applied locally to the skin and throat.

Preparations

Proprietary Preparations (details are given in Part 3)
Fr.: Enteropathyl.

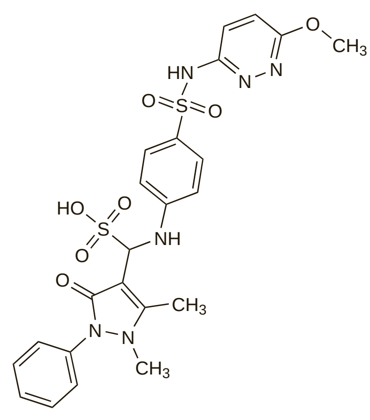
Multi-ingredient: ***Braz.:*** Sanadiar†; ***Chile:*** Carbon Sulfaguanidina; ***Mex.:*** Neopecsul; ***Thai.:*** Biodan†.

Sulfamazone Sodium *(rINNM)*

Natrii Sulfamazonum; Sulfamazona sódica; Sulfamazone Sodique; Sulfenazone; Sulphenazone. Sodium α-{*p*-[(6-methoxy-3-pyridazinyl)sulfamoyl]anilino}-2,3-dimethyl-5-oxo-1-phenyl-3-pyrazoline-4-methanesulphonate.

Натрий Сульфамазон

$C_{23}H_{24}N_6O_7S_2Na = 583.6.$
CAS — 65761-24-2 (sulfamazone); 13061-27-3 (sulfamazone sodium).
ATC — J01ED09.



(sulfamazone)

Profile

Sulfamazone is an antibacterial with antipyretic activity that has been given as the sodium salt, orally or rectally, in infections of the upper respiratory tract.

Preparations

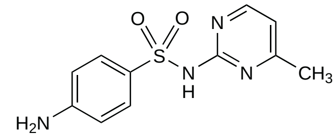
Proprietary Preparations (details are given in Part 3)
Ital.: Marespin†.

Sulfamerazine *(BAN, rINN)*

RP-2632; Solfamerazina; Sulfamerasinum; Sulfameratsiini; Sulfamerazin; Sulfamerazina; Sulfamerazinas; Sulfamérazine; Sulfamerazinum; Sulfamethyldiazine; Sulfamethylpyrimidine; Sulphamerazine; Szulfamerazin. N^1-(4-Methylpyrimidin-2-yl)sulphanilamide.

Сульфамеразин

$C_{11}H_{12}N_4O_2S = 264.3.$
CAS — 127-79-7.
ATC — D06BA06; J01ED07.
ATC Vet — QD06BA06.



Pharmacopoeias. In *Eur.* (see p.vii). Also in *BP(Vet)*.
Ph. Eur. 6.2 (Sulfamerazine). White, yellowish-white, or pinkish-white, crystalline powder or crystals. Very slightly soluble in water and in dichloromethane; slightly soluble in alcohol; sparingly soluble in acetone. It dissolves in solutions of alkali hydroxides and in dilute mineral acids. Protect from light.

Sulfamerazine Sodium *(BANM, rINN)*

Soluble Sulphamerazine; Sulfamerazina de sodio; Sulfamerazina sódica; Sulfamérazine sodique; Sulfamerazinum Natricum; Sulphamerazine Sodium.

Сульфамеразин Натрий

$C_{11}H_{11}N_4NaO_2S = 286.3.$
CAS — 127-58-2.
ATC — D06BA06; J01ED07.
ATC Vet — QD06BA06.

Profile

Sulfamerazine is a short-acting sulfonamide with properties similar to those of sulfamethoxazole (p.340). It has usually been given with other sulfonamides, or with trimethoprim.

Preparations

USP 31: Trisulfapyrimidines Oral Suspension; Trisulfapyrimidines Tablets.

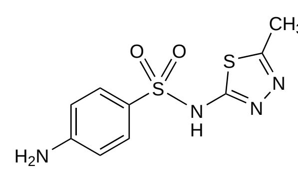
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Ger.:*** Berlocombin†; ***Indon.:*** Trisulfa; ***Thai.:*** Sulfatril.

Sulfamethizole *(BAN, rINN)*

Sulfaméthizol; Sulfamethizol; Sulfamethizolum; Sulfametitsoli; Sulfametizol; Sulfametizolas; Sulphamethizole; Szulfametizol. N^1-(5-Methyl-1,3,4-thiadiazol-2-yl)sulphanilamide.

Сульфаметизол

$C_9H_{10}N_4O_2S_2 = 270.3.$
CAS — 144-82-1.
ATC — B05CA04; D06BA04; J01EB02; S01AB01.
ATC Vet — QB05CA04; QD06BA04; QJ01EQ02; QS01AB01.



Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*
Ph. Eur. 6.2 (Sulfamethizole). White or yellowish-white crystalline powder or crystals. Very slightly soluble in water; sparingly soluble in alcohol; soluble in acetone. It dissolves in dilute solutions of alkali hydroxides and in dilute mineral acids. Protect from light.
USP 31 (Sulfamethizole). Practically odourless, white crystals or powder. Soluble 1 in 2000 of water, 1 in 38 of alcohol, 1 in 13 of acetone, and 1 in 1900 of chloroform and of ether; freely soluble in solutions of ammonium, potassium, and sodium hydroxides; soluble in dilute mineral acids; practically insoluble in benzene. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Sulfamethoxazole, p.340.

Sulfamethizole and its acetyl derivative are relatively soluble in urine, and the risk of crystalluria is quite low, but an adequate fluid intake should generally be maintained.

Interactions
As for Sulfamethoxazole, p.341.

Antimicrobial Action
As for Sulfamethoxazole, p.341.

Pharmacokinetics
Sulfamethizole is readily absorbed from the gastrointestinal tract; about 90% has been reported to be bound to plasma proteins. Its half-life has been reported to range from about 1.5 to 3 hours. It is only slightly acetylated in the body and is rapidly excreted, about 60% of a dose being eliminated in the urine in 5 hours and around 90% within 10 hours. Sulfamethizole and its acetyl derivative are readily soluble in urine over a wide pH range. Only low concentrations are achieved in blood and tissues because of its rapid excretion.

Uses and Administration
Sulfamethizole is a short-acting sulfonamide that is given orally in the treatment of infections of the urinary tract, sometimes with other antibacterials; it is unsuitable for the treatment of systemic infection since only relatively low concentrations of drug are achieved in the blood and tissues.

It is given in adult doses of 1.5 to 4 g daily in 3 or 4 divided doses. A usual dose for children is 30 to 45 mg/kg daily in 4 divided doses.

Sulfamethizole monoethanolamine has also been used.

Preparations
USP 31: Sulfamethizole Oral Suspension; Sulfamethizole Tablets.

Proprietary Preparations (details are given in Part 3)
Denm.: Lucosil; ***Fr.:*** Rufol; ***Norw.:*** Lucosil†; ***Thai.:*** Luco-Oph†.

Multi-ingredient: ***Spain:*** Micturol Sedante; ***USA:*** Urobiotic-250; ***Venez.:*** Bacteval.

Sulfamethoxazole *(BAN, USAN, rINN)*

Ro-4-2130; Sulfamethoxazol; Sulfaméthoxazole; Sulfamethoxazolum; Sulfametoksatsoli; Sulfametoksazol; Sulfametoksazolas; Sulfametoxazol; Sulfisomezole; Sulphamethoxazole; Szulfametoxazol. N^1-(5-Methylisoxazol-3-yl)sulphanilamide.

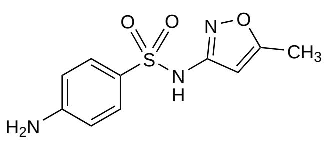
Сульфаметоксазол

$C_{10}H_{11}N_3O_3S$ = 253.3.

CAS — 723-46-6.

ATC — J01EC01.

ATC Vet — QJ01EQ11.



NOTE. Compounded preparations of sulfamethoxazole may be represented by the following names:

- Co-trimoxazole (*BAN*)—sulfamethoxazole 5 parts and trimethoprim 1 part (see p.258)
- Co-trimoxazole (*PEN*)—sulfamethoxazole and trimethoprim.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Sulfamethoxazole). A white or almost white, crystalline powder. Practically insoluble in water; sparingly soluble in alcohol; freely soluble in acetone. It dissolves in dilute solutions of sodium hydroxide and in dilute acids. Protect from light.

USP 31 (Sulfamethoxazole). A white to off-white, practically odourless, crystalline powder. Soluble 1 in 3400 of water, 1 in 50 of alcohol, and 1 in 1000 of chloroform and of ether; slowly and usually incompletely soluble 1 in 2 of carbon disulfide; freely soluble in acetone and in dilute solutions of sodium hydroxide. Protect from light.

Adverse Effects and Treatment
Nausea, vomiting, anorexia, and diarrhoea are relatively common after use of sulfamethoxazole and other sulfonamides.

Hypersensitivity reactions to sulfonamides have proved a problem. Fever is relatively common, and reactions involving the skin may include rashes, pruritus, photosensitivity reactions, exfoliative dermatitis, and erythema nodosum. Severe, potentially fatal, skin reactions including toxic epidermal necrolysis and the Stevens-Johnson syndrome have occurred in patients treated with sulfonamides. Dermatitis may also occur from contact of sulfonamides with the skin. SLE, particularly exacerbation of pre-existing disease, has also been reported.

Nephrotoxic reactions including interstitial nephritis and tubular necrosis, which may result in renal failure, have been attributed to hypersensitivity to sulfamethoxazole. Lumbar pain, haematuria, oliguria, and anuria may also occur due to crystallisation in the urine of sulfamethoxazole or its less soluble acetylated metabolite. The risk of crystalluria can be reduced by giving fluids to maintain a high urine output. If necessary, alkalinisation of the urine with sodium bicarbonate may increase solubility and aid the elimination of sulfonamides.

Blood disorders have occasionally occurred during treatment with the sulfonamides including sulfamethoxazole, and include agranulocytosis, aplastic anaemia, thrombocytopenia, leucopenia, hypoprothrombinaemia, and eosinophilia. Many of these effects on the blood may result from hypersensitivity reactions. Sulfonamides may rarely cause cyanosis due to methaemoglobinaemia. Acute haemolytic anaemia is a rare complication which may be associated with G6PD deficiency.

Other adverse effects that may be manifestations of a generalised hypersensitivity reaction to sulfonamides include a syndrome resembling serum sickness, hepatic necrosis, hepatomegaly and jaundice, myocarditis, pulmonary eosinophilia and fibrosing alveolitis, and vasculitis including polyarteritis nodosa. Anaphylaxis has been reported only very rarely.

Other adverse reactions reported after sulfamethoxazole or other sulfonamides include hypoglycaemia, hypothyroidism, neurological reactions including aseptic meningitis, ataxia, benign intracranial hypertension, convulsions, dizziness, drowsiness, fatigue, headache, insomnia, mental depression, peripheral or optic neuropathies, psychoses, tinnitus, vertigo, and pancreatitis.

Sulfonamides may displace serum-bound bilirubin, resulting in kernicterus in premature neonates.

As with other antimicrobials, sulfamethoxazole may cause alterations of the bacterial flora in the gastrointestinal tract. There is, therefore, the possibility, although it appears to be small, that pseudomembranous colitis may occur.

Slow acetylators of sulfamethoxazole may be at greater risk of adverse reactions than fast acetylators.

For further information on the adverse effects of sulfamethoxazole when used with trimethoprim, see Co-trimoxazole, p.258.

Precautions
In patients given sulfamethoxazole, adequate fluid intake is necessary to reduce the risk of crystalluria; the daily urine output should be 1200 mL or more. Compounds that render the urine acidic may increase the risk of crystalluria; the risk may be reduced with alkaline urine.

Treatment with sulfonamides should be stopped immediately a rash appears because of the danger of severe allergic reactions such as the Stevens-Johnson syndrome.

Sulfamethoxazole should be given with care to patients with renal or hepatic impairment and is contra-indicated in patients with severe impairment or with blood disorders. Dosage reduction may be necessary in renal impairment. Complete blood counts and urinalyses with microscopic examination should be carried out particularly during prolonged therapy. Sulfamethoxazole should not be given to patients with a history of hypersensitivity to sulfonamides as cross-sensitivity may occur between drugs of this group. Care is generally advisable in patients with a history of allergy or asthma. Caution is also needed in the elderly, who may be more likely to have other risk factors for reactions. Some consider sulfamethoxazole to be contra-indicated in lupus erythematosus as it may exacerbate the condition. Patients with glucose 6-phosphate dehydrogenase deficiency may be at risk of haemolytic reactions.

Sulfamethoxazole and other sulfonamides are not usually given to infants within 1 to 2 months of birth because of the risk of producing kernicterus; for the same reason, they are generally contra-indicated in women prior to delivery (see below).

Patients with AIDS may be particularly prone to adverse reactions, especially when sulfamethoxazole is given with trimethoprim as co-trimoxazole.

Sulfonamides have been reported to interfere with some diagnostic tests, including those for urea, creatinine, and urinary glucose and urobilinogen.

Breast feeding. Sulfonamides are excreted into breast milk in low concentrations and, although they are generally contra-indicated in the USA in breast-feeding women because of the risk of kernicterus, they are usually thought to pose a negligible risk to healthy neonates. However, sulfonamides should be used with caution in breast-feeding mothers of ill, stressed, or premature infants and of infants with jaundice, hyperbilirubinaemia or G6PD deficiency.

The American Academy of Pediatrics considers sulfamethoxazole, when given with trimethoprim, to be compatible with breast feeding.[1]

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/05/04)

Immunocompromised patients. Sulfamethoxazole is mainly conjugated in the liver to the N^4-acetyl derivative, but is also oxidised, to a limited extent, to the hydroxylamine metabolite.[1-5] Although this metabolite was originally implicated[6] in the development of adverse reactions to sulfonamides, recent work[7] has cast some doubt on this hypothesis. The metabolite appears to be produced through cytochrome P450 oxidative metabolism, and it has been suggested that slow acetylators of sulfamethoxazole exhibit increased oxidation compared with other metabolic routes.[1] AIDS patients also exhibit increased oxidation, since they may be depleted of substrates such as acetylcoenzyme A or glutathione necessary for acetylation or detoxification, and this may explain their susceptibility to sulfamethoxazole toxicity.[2,3]

There have been attempts to inhibit the formation of the hydroxylamine metabolite by competitive inhibition of cytochrome P450 enzymes, notably with fluconazole and ketoconazole.[4,5] Encouraging results have been obtained with fluconazole in healthy subjects, but the potential for clinical benefit in AIDS patients requires further study.[5]

However, one successful method of overcoming adverse effects in AIDS patients has been **desensitisation**. Desensitisation by use of initial doses of 4 mg of sulfamethoxazole or 5 mg of sulfadiazine every 6 hours, doubled at 24-hour intervals until the desired dose was reached, was uneventful in 9 of 13 patients with AIDS requiring sulfonamide treatment for opportunistic infections.[8] The remaining 4 had cutaneous reactions with fever, but in 2 of these the reactions were successfully managed with an antihistamine. Although there is a risk of anaphylaxis, patients with AIDS can be successfully treated with sulfonamides after desensitisation.

Porphyria. Sulfonamides have been associated with acute attacks of porphyria and are considered unsafe in porphyric patients.

Pregnancy. Some sulfonamides have been shown to cause fetal abnormalities including cleft palate in *animals*, but fears of teratogenic effects in humans do not appear to be substantiated. Sulfonamides are probably safe in the first trimester of pregnancy, although throughout pregnancy they should be used only in the absence of a suitable alternative drug.[1] Sulfonamides may displace serum-bound bilirubin and they should be avoided close to delivery because of the risk of kernicterus in the neonate. The risk of drug-induced bilirubin displacement has been reviewed.[2] The initial evidence suggesting a kernicterus-promoting effect of drugs in neonates was reported for sulfafurazole, and this drug now serves as a standard displacing agent against which other drugs are evaluated. Although all sulfonamides are highly protein bound, each has a different capacity to displace bilirubin. Sulfadiazine and sulfanilamide have been found to be the least displacing of the sulfonamides and the effects of sulfadiazine on bilirubin may not be clinically significant; an increased incidence of hyperbilirubinaemia and kernicterus has not been shown after use for prophylaxis of rheumatic fever during pregnancy. Sulfasalazine should theoretically cause significant bilirubin displacement, but studies suggest that the drug may be given to patients with Crohn's disease who are pregnant or breast feeding. Metabolites of sulfonamides have also been evaluated for kernicterus-promoting effects; glucuronide metabolites are expected to compete for binding sites less effectively than the parent compound, whereas acetylated metabolites of some sulfonamides appear to be more potent bilirubin displacers.

Interactions

The action of sulfonamides may be antagonised by *p*-aminobenzoic acid and its derivatives, particularly potassium aminobenzoate and the procaine group of local anaesthetics.

Sulfamethoxazole and other sulfonamides may potentiate the effects of some drugs, such as oral anticoagulants (p.1428), methotrexate (p.748), and phenytoin (p.498); this may be due to displacement of the drug from plasma protein binding sites or to inhibition of metabolism. However, the clinical significance of these interactions appears to depend on the particular sulfonamide involved. The possibility of interactions with other highly protein-bound drugs, such as NSAIDs, should be considered.

High doses of sulfonamides have been reported to have a hypoglycaemic effect; the antidiabetic effect of the sulfonylurea compounds may be enhanced by sulfonamides (p.462). Some sulfonamides have been associated with a decrease in plasma-ciclosporin concentrations when used together (p.1826). Isolated reports have described possible failures of hormonal contraceptives resulting in pregnancy in patients given sulfonamides (p.2068).

The use of compounds which render the urine acidic may increase the risk of crystalluria.

Antimicrobial Action

Sulfamethoxazole and other sulfonamides have a similar structure to *p*-aminobenzoic acid and interfere with the synthesis of nucleic acids in sensitive micro-organisms by blocking the conversion of *p*-aminobenzoic acid to the coenzyme dihydrofolic acid, a reduced form of folic acid; in man, dihydrofolic acid is obtained from dietary folic acid so sulfonamides do not affect human cells. Their action is primarily bacteriostatic, although they may be bactericidal where concentrations of thymine are low in the surrounding medium. The sulfonamides have a broad spectrum of action, but the development of widespread resistance (see below) has greatly reduced their usefulness, and susceptibility often varies widely even among nominally sensitive pathogens.

Gram-positive cocci, particularly the Group A streptococci and some strains of *Streptococcus pneumoniae*, are usually sensitive and staphylococci also demonstrate sensitivity but to a lesser extent. Enterococci and many of the clostridia are more or less resistant, although strains of *Clostridium perfringens* are moderately susceptible. Among other Gram-positive organisms that have been reported to be sensitive are *Bacillus anthracis* and many strains of Nocardia, especially *N. asteroides*.

The Gram-negative cocci *Neisseria meningitidis* and *N. gonorrhoeae* were formerly extremely susceptible to sulfonamides, but many strains are now resistant. Susceptibility is often seen in *Haemophilus influenzae* although resistance in *H. ducreyi* is increasingly common. Susceptibility varies widely among the Enterobacteriaceae: strains of *Escherichia coli*, *Klebsiella*, *Proteus*, *Salmonella*, and *Serratia* are sometimes sensitive, but few strains of *Shigella* are now susceptible. *Vibrio cholerae* may be sensitive.

Other organisms that have been reported to be sensitive include *Actinomyces* spp., *Brucella*, *Klebsiella granulomatis*, *Legionella*, and *Yersinia pestis*. Chlamydiaceae are sensitive, but not mycoplasmas, rickettsias, or spirochaetes, nor in general the mycobacteria. *Pseudomonas aeruginosa* is resistant, although sulfonamides may be effective against *Burkholderia pseudomallei* (*Pseudomonas pseudomallei*).

Sulfonamides have some activity against the protozoa *Plasmodium falciparum* and *Toxoplasma gondii*. They are also active against *Pneumocystis jirovecii*, but are ineffective against most fungi.

Sulfamethoxazole and other sulfonamides demonstrate synergy with the dihydrofolate reductase inhibitors pyrimethamine and trimethoprim which inhibit a later stage in folic acid synthesis. For reports of the antimicrobial activity of sulfamethoxazole with trimethoprim, see Co-trimoxazole, p.259.

The *in-vitro* antimicrobial activity of sulfamethoxazole is very dependent on both the culture medium and size of inoculum used.

Resistance. Acquired resistance to sulfonamides is common and widespread among formerly susceptible organisms, particularly *Neisseria* spp., *Shigella* and some other enterobacteria, staphylococci, and streptococci.

There appear to be several mechanisms of resistance including alteration of dihydropteroate synthetase, the enzyme inhibited by sulfonamides, to a less sensitive form, or an alteration in folate biosynthesis to an alternative pathway; increased production of *p*-aminobenzoic acid; or decreased uptake or enhanced metabolism of sulfonamides.

Resistance may result from chromosomal alteration, or may be plasmid-mediated and transferable, as in many resistant strains of enterobacteria. High-level resistance is usually permanent and irreversible. There is complete cross-resistance between the different sulfonamides.

Pharmacokinetics

Sulfamethoxazole is readily absorbed from the gastrointestinal tract and peak plasma concentrations are reached after about 2 hours. Following a single 2-g oral dose, blood concentrations of up to 100 micrograms/mL are achieved. About 70% is bound to plasma proteins. The plasma half-life is about 6 to 12 hours; it is prolonged in patients with severe renal impairment.

Sulfamethoxazole, like most sulfonamides, diffuses freely throughout the body tissues and may be detected in the urine, saliva, sweat, and bile, in the cerebrospinal, peritoneal, ocular, and synovial fluids, and in pleural and other effusions. It crosses the placenta into the fetal circulation and low concentrations have been detected in breast milk.

Sulfamethoxazole undergoes conjugation mainly in the liver, chiefly to the inactive N^4-acetyl derivative; this metabolite represents about 15% of the total amount of sulfamethoxazole in the blood. Metabolism is increased in patients with renal impairment and decreased in those with hepatic impairment. Elimination in the urine is dependent on pH. About 80 to 100% of a dose is excreted in the urine, of which about 60% is in the form of the acetyl derivative, with the remainder as unchanged drug and glucuronide.

Sulfamethoxazole is also oxidised to the hydroxylamine, a metabolite that has been implicated in adverse reactions to sulfonamides (see also Immunocompromised Patients, under Precautions, above), although some doubt has been cast upon this hypothesis.

Uses and Administration

The use of sulfamethoxazole and other sulfonamides has been limited by the increasing incidence of resistant organisms. Their main use has been in the treatment of acute, uncomplicated urinary-tract infections, particularly those caused by *Escherichia coli*. They have also been used in nocardiosis, and in some other bacterial infections such as otitis media, *Chlamydia* and *Chlamydophila* infections, and prophylaxis of meningococcal meningitis, but have largely been replaced by other drugs: even where pathogens retain some sensitivity to sulfonamides, a combination such as co-trimoxazole (sulfamethoxazole with trimethoprim) has often been preferred. The usual treatment of these infections is discussed under Choice of Antibacterial, p.162. Sulfonamides are also used, often with pyrimethamine or trimethoprim, in the treatment of protozoal infections, particularly malaria (p.594) and toxoplasmosis (p.826). They are also used similarly in pneumocystis pneumonia (p.521).

Sulfamethoxazole is an intermediate-acting sulfonamide that has been given orally in a usual dose of 2 g initially, followed by 1 g twice daily. In severe infections 1 g three times daily has been given.

Children have been given a dose of 50 to 60 mg/kg initially, followed by 25 to 30 mg/kg twice daily, up to a maximum daily dose of 75 mg/kg.

Reduction of dosage may be required in patients with renal impairment.

For the uses and dosage of sulfamethoxazole with trimethoprim, see Co-trimoxazole, p.259.

Sulfamethoxazole lysine has also been used.

Administration. US licensed product information for a former product of sulfamethoxazole recommended that blood concentrations be measured in patients receiving sulfonamides for serious infections. The following concentrations of free sulfonamide in the blood were considered to be therapeutically effective:

- for most infections, 50 to 150 micrograms/mL
- for serious infections, 120 to 150 micrograms/mL

Concentrations of 200 micrograms/mL should not be exceeded since the incidence of adverse reactions might be increased.

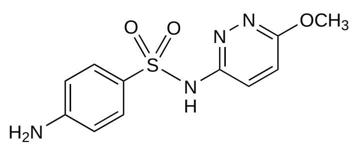
Sulfamethoxypyridazine *(BAN, rINN)*

Solfametossipiridazina; Sulfamethoxypyridazin; Sulfaméthoxypyridazine; Sulfamethoxypyridazinum; Sulfamethoxypyridazinum ad usum veterinarium; Sulfametoksipyridatsiini; Sulfametoxipiridazina; Sulfametoxipyridazin; Sulphamethoxypyridazine; Szulfametoxipiridazin. N^1-(6-Methoxypyridazin-3-yl)sulphanilamide.

Сульфаметоксипиридазин

$C_{11}H_{12}N_4O_3S$ = 280.3.
CAS — 80-35-3.
ATC — J01ED05.
ATC Vet — QJ01EQ15.



Pharmacopoeias. In *Int.* and *Viet.* In *Eur.* (see p.vii) for veterinary use only.

Ph. Eur. 6.2 (Sulfamethoxypyridazine for Veterinary Use; Sulfametoxypyridazine BP(Vet) 2008). A white or slightly yellowish crystalline powder which colours slowly on exposure to light. Practically insoluble in water; slightly soluble in alcohol; sparingly soluble in acetone; very slightly soluble in dichloromethane; dissolves in dilute mineral acids and solutions of alkali hydroxides. Protect from light.

Profile

Sulfamethoxypyridazine is a long-acting sulfonamide with properties similar to those of sulfamethoxazole (p.340) and has been used for the treatment of susceptible infections. It is rapidly absorbed from the gastrointestinal tract and excreted slowly in urine, partly as the N^4-acetyl metabolite; it remains detectable for up to 7 days after a dose. It has also been used with trimethoprim similarly to co-trimoxazole.

Acetyl sulfamethoxypyridazine, which is hydrolysed in the gastrointestinal tract forming sulfamethoxypyridazine, and sulfamethoxypyridazine sodium have also been used.

Skin disorders. Reference to the use of sulfamethoxypyridazine in the treatment of pemphigoid.[1] Sulfamethoxypyridazine has also been used in the treatment of dermatitis herpetiformis.[2]

1. Thornhill M, *et al.* An open clinical trial of sulphamethoxypyridazine in the treatment of mucous membrane pemphigoid. *Br J Dermatol* 2000; **143:** 117–26.
2. Fry L. Dermatitis herpetiformis. *Baillieres Clin Gastroenterol* 1995; **9:** 371–93.

Preparations

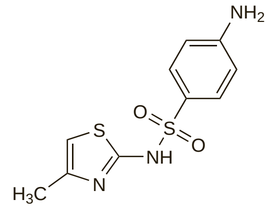
Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Braz.:*** Urofen†; Uropac.

Sulfamethylthiazole

Methylsulfathiazole; Sulfametiltiazol. 4-Amino-*N*-(4-methyl-2-thiazolyl)benzenesulfonamide.

$C_{10}H_{11}N_3O_2S_2$ = 269.3.
CAS — 515-59-3.



Profile

Sulfamethylthiazole is a sulfonamide with properties similar to those of sulfamethoxazole (p.340). It is applied topically with tetracycline in the treatment of eye infections.

Preparations

Proprietary Preparations (details are given in Part 3)

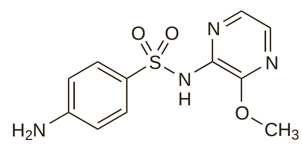
Multi-ingredient: ***Ital.:*** Pensulvit.

Sulfametopyrazine *(BAN)*

Sulfalene *(USAN, pINN)*; AS-18908; NSC-110433; Solfametopirazina; Sulfametossipirazina; Sulfaleeni; Sulfalen; Sulfalène; Sulfaleno; Sulfalenum; Sulfamethoxypyrazine; Sulfapirazinmetossina; Sulfapyrazin Methoxyne; Sulphalene. N^1-(3-Methoxypyrazin-2-yl)sulphanilamide.

Сульфален

$C_{11}H_{12}N_4O_3S$ = 280.3.
CAS — 152-47-6.
ATC — J01ED02.



Pharmacopoeias. In *It.*

Adverse Effects, Treatment, and Precautions

As for Sulfamethoxazole, p.340.

If adverse effects occur, sulfametopyrazine has the disadvantage that several days are required for its elimination from the body.

Interactions

As for Sulfamethoxazole, p.341.

Antimicrobial Action

As for Sulfamethoxazole, p.341.

Pharmacokinetics

Sulfametopyrazine is readily absorbed from the gastrointestinal tract; 60 to 80% is bound to plasma proteins. Only about 5% of a dose is metabolised to the acetyl derivative. It is slowly excreted in the urine. The biological half-life has been reported to be about 60 to 65 hours.

Uses and Administration

Sulfametopyrazine is a long-acting sulfonamide that has been used orally in the treatment of respiratory- and urinary-tract infections due to sensitive organisms.

Sulfametopyrazine is given with pyrimethamine (p.611) in the treatment of malaria.

It has also been given in the ratio 4 parts of sulfametopyrazine to 5 parts of trimethoprim as a combination with uses similar to those of co-trimoxazole (p.259).

Preparations

Proprietary Preparations (details are given in Part 3)

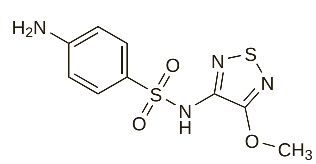
Sulfametrole *(BAN, rINN)*

Sulfametrol; Sulfamétrole; Sulfametrolum. N^1-(4-Methoxy-1,2,5-thiadiazol-3-yl)sulphanilamide.

Сульфаметрол

$C_9H_{10}N_4O_3S_2$ = 286.3.
CAS — 32909-92-5.



Profile

Sulfametrole is a sulfonamide with properties similar to those of sulfamethoxazole (p.340). It is given in the ratio of 5 parts of sulfametrole to 1 part of trimethoprim as a combination with uses similar to those of co-trimoxazole (p.259). Usual oral doses are 960 mg (800 mg of sulfametrole and 160 mg of trimethoprim) twice daily. It has also been given as the sodium salt by intravenous infusion.

Preparations

Proprietary Preparations (details are given in Part 3)

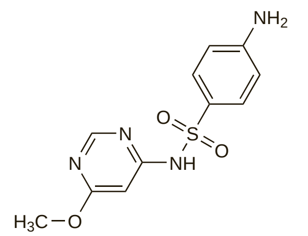
CAS — 1220-83-3 (anhydrous sulfamonomethoxine).



(anhydrous sulfamonomethoxine)

Pharmacopoeias. In *Jpn.*

Profile

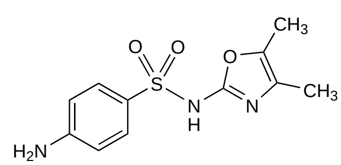
Sulfamonomethoxine is a sulfonamide antibacterial with properties similar to those of sulfamethoxazole (p.340). It is used in veterinary medicine.

Sulfamoxole *(BAN, USAN, rINN)*

Sulfamoksoli; Sulfamoxol; Sulfamoxolum; Sulphadimethyloxazole; Sulphamoxole. N^1-(4,5-Dimethyloxazol-2-yl)sulphanilamide.

Сульфамоксол

$C_{11}H_{13}N_3O_3S$ = 267.3.
CAS — 729-99-7.
ATC — J01EC03.



NOTE. Compounded preparations of sulfamoxole may be represented by the following name:

- Co-trifamole (*BAN*)—sulfamoxole 5 parts and trimethoprim 1 part (see p.257).

Pharmacopoeias. In *Fr.*

Profile

Sulfamoxole is a sulfonamide antibacterial with properties similar to those of sulfamethoxazole (p.340). It has been used with trimethoprim as co-trifamole (p.257).

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***S.Afr.:*** Supristol†.

Sulfanilamide *(rINN)*

Solfammide; Streptocidum; Sulfaminum; Sulfaniiliamidi; Sulfanilamid; Sulfanilamida; Sulfanilamidas; Sulfanilamidum; Sulphanilamide; Szulfanilamid. 4-Aminobenzenesulphonamide; *p*-Sulphamidoaniline.

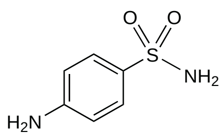
Сульфаниламид

$C_6H_8N_2O_2S$ = 172.2.

CAS — 63-74-1.

ATC — D06BA05; J01EB06.

ATC Vet — QD06BA05; QJ01EQ06.



Pharmacopoeias. In *Eur.* (see p.vii). Also in *BP(Vet).*

Ph. Eur. 6.2 (Sulfanilamide). White or yellowish-white crystals or fine powder. Slightly soluble in water; sparingly soluble in alcohol; freely soluble in acetone; practically insoluble in dichloromethane; dissolves in solutions of alkali hydroxides and in dilute mineral acids. Protect from light.

Profile

Sulfanilamide is a short-acting sulfonamide with properties similar to those of sulfamethoxazole (p.340). Its antibacterial activity is less than that of sulfamethoxazole. It has been used topically, including vaginally, for the treatment of susceptible infections, often with other drugs. The sodium, sodium mesilate, and camsilate salts have also been used.

Preparations

Proprietary Preparations (details are given in Part 3)

Canad.: AVC†; ***Spain:*** Azol.

Multi-ingredient: ***Arg.:*** Clinal; Iodotiazol†; ***Belg.:*** Polyseptol; Sulfa-Sedemol; ***Braz.:*** Gargotan†; Otovix†; ***Port.:*** Otocalma†; ***S.Afr.:*** Achromide; Daromide; Ung Vernleigh; ***Spain:*** Buco Regis; Cilinafosal; Cilinafosal Dihidroestreptomicina; Cilinafosal Hidrocortisona; Kanafosal; Kanafosal Predni; Nasopomada; Odontocromil c Sulfamida†; Oto Difusor†; Pental Forte†; Polvos Wilfe†; Pomada Heridas†; Pomada Wilfe; Vitavox Pastillas†; ***USA:*** Alasulf; Deltavac; DIT1-2; ***Venez.:*** Otanol†.

Sulfapyridine *(BAN, rINN)*

Sulfapiridina; Sulfapyridiini; Sulfapyridin; Sulfapyridinum; Sulphapyridine. N^1-(2-Pyridyl)sulphanilamide.

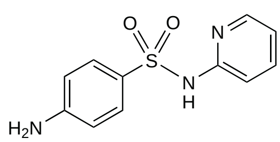
Сульфапиридин

$C_{11}H_{11}N_3O_2S$ = 249.3.

CAS — 144-83-2.

ATC — J01EB04.

ATC Vet — QJ01EQ04.



Pharmacopoeias. In *Fr.* and *US.*

USP 31 (Sulfapyridine). White or faintly yellowish-white, odourless or practically odourless, crystals, granules, or powder. It slowly darkens on exposure to light. Soluble 1 in 3500 of water, 1 in 440 of alcohol, 1 in 65 of acetone; freely soluble in dilute mineral acids and in solutions of potassium and sodium hydroxides. Protect from light.

Profile

Sulfapyridine is a short- or intermediate-acting sulfonamide, with properties similar to those of sulfamethoxazole (p.340). It is slowly and incompletely absorbed from the gastrointestinal tract and excreted in urine; sulfapyridine and its acetyl metabolite are poorly soluble in urine and the risk of crystalluria is relatively high. Adverse effects are common, and gastrointestinal disturbances may preclude continued therapy. Because of its toxicity, sulfapyridine is now little used except occasionally for dermatitis herpetiformis and related skin disorders when alternative treatment cannot be used; oral doses of up to 1 g four times daily have been given initially, reduced to the minimum effective maintenance dose once improvement occurs.

Breast feeding. The American Academy of Pediatrics[1] states that, although sulfapyridine is usually compatible with breast feeding, caution is required in breast-fed infants with jaundice or G6PD deficiency, or who are ill, stressed, or premature, whose mothers have received the drug.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/05/04)

Pemphigoid. Benefit has been seen with sulfapyridine in ocular cicatricial pemphigoid.[1]

1. Elder MJ, *et al.* Sulphapyridine—a new agent for the treatment of ocular cicatricial pemphigoid. *Br J Ophthalmol* 1996; **80:** 549–52.

Preparations

USP 31: Sulfapyridine Tablets.

Sulfaquinoxaline *(BAN, rINN)*

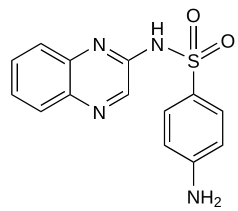
Sulfabenspyrazin; Sulfabentspyratsiini; Sulfabenzpyrazine; Sulfabenzpyrazinium; Sulfabenzpyrazinum; Sulfaquinoxalina; Sulfaquinoxalinum; Sulphaquinoxalina; Sulphaquinoxaline. N^1-(Quinoxalin-2-yl)sulphanilamide.

Сульфахиноксалин

$C_{14}H_{12}N_4O_2S$ = 300.3.

CAS — 59-40-5 (sulfaquinoxaline); 967-80-6 (sulfaquinoxaline sodium).

ATC Vet — QJ01EQ16; QP51AG03.



Pharmacopoeias. In *Fr.* Also in *BP(Vet)* and in *US* for veterinary use only.

Fr. also includes Sulfaquinoxaline Sodium, $C_{14}H_{11}N_4NaO_2S$ = 322.3.

BP(Vet) 2008 (Sulfaquinoxaline). A yellow powder. Practically insoluble in water and in ether; very slightly soluble in alcohol. It dissolves in aqueous solutions of alkalis. Protect from light.

USP 31 (Sulfaquinoxaline). Protect from light.

Profile

Sulfaquinoxaline is a sulfonamide antibacterial used in veterinary medicine, sometimes with trimethoprim.

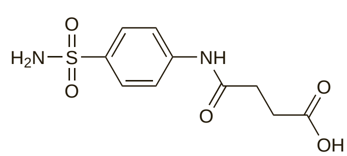
Sulfasuccinamide *(rINN)*

Sulfasuccinamida; Sulfasuccinamidum. 4′-Sulphamoylsuccinanilic acid.

Сульфасукцинамид

$C_{10}H_{12}N_2O_5S$ = 272.3.

CAS — 3563-14-2.



Profile

Sulfasuccinamide is a sulfonamide antibacterial with properties similar to those of sulfamethoxazole (p.340). It has been applied topically in the treatment of local infections of the ear, nose, and throat. It has also been given as the sodium salt.

Sulfathiazole *(BAN, rINN)*

M&B-760; Norsulfazole; RP-2090; Solfatiazolo; Sulfanilamidothiazolum; Sulfathiazol; Sulfathiazolum; Sulfatiatsoli; Sulfatiazol; Sulfatiazolas; Sulfonazolum; Sulphathiazole; Szulfatiazol. N^1-(1,3-Thiazol-2-yl)sulphanilamide.

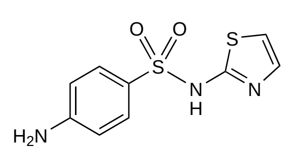
Сульфатиазол

$C_9H_9N_3O_2S_2$ = 255.3.

CAS — 72-14-0.

ATC — D06BA02; J01EB07.

ATC Vet — QD06BA02; QJ01EQ07.



Pharmacopoeias. In *Eur.* (see p.vii), *US,* and *Viet.*

Ph. Eur. 6.2 (Sulfathiazole). A white or slightly yellowish, crystalline powder. Practically insoluble in water; slightly soluble in alcohol; practically insoluble in dichloromethane. It dissolves in dilute solutions of alkali hydroxides and in dilute mineral acids. Protect from light.

USP 31 (Sulfathiazole). A white or faintly yellowish-white, practically odourless, fine powder. Very slightly soluble in water; slightly soluble in alcohol; soluble in acetone, in dilute mineral acids, in solutions of alkali hydroxides, and in 6N ammonium hydroxide. Protect from light.

Sulfathiazole Sodium *(BANM, rINNM)*

Natrii Sulfathiazolum; Soluble Sulphathiazole; Sulfathiazol Sodique; Sulfathiazolum Natricum; Sulfatiazol sódico; Sulphathiazole Sodium.

Натрий Сульфатиазол

$C_9H_8N_3NaO_2S_2,5H_2O$ = 367.4.

CAS — 144-74-1 (anhydrous sulfathiazole sodium); 6791-71-5 (sulfathiazole sodium pentahydrate).

ATC — D06BA02; J01EB07.

ATC Vet — QD06BA02.

Pharmacopoeias. In *BP(Vet)* ($1\frac{1}{2}H_2O$ or $5H_2O$).

BP(Vet) 2008 (Sulfathiazole Sodium). A white or yellowish-white crystalline powder or granules. Freely soluble in water; soluble in alcohol. A solution in water containing the equivalent of 1% of the anhydrous substance has a pH of 9.0 to 10.0. Protect from light.

Profile

Sulfathiazole is a short-acting sulfonamide with properties similar to those of sulfamethoxazole (p.340). It is now rarely used systemically due to its toxicity.

Sulfathiazole is used with other sulfonamides, usually sulfabenzamide and sulfacetamide, in preparations for the topical treatment of vaginal infections and is also used with other drugs in the treatment of skin infections.

Sulfathiazole sodium has been applied topically with other drugs in the treatment of eye infections.

Preparations

USP 31: Triple Sulfa Vaginal Cream; Triple Sulfa Vaginal Tablets.

Ph. Eur. 6.2 (Sultamicillin Tosilate Dihydrate; Sultamicillini Tosilas Dihydricus). A white or almost white, crystalline powder. Practically insoluble in water; sparingly soluble in alcohol. Store in airtight containers.

Profile

Sultamicillin is a prodrug of ampicillin (p.204) and of the beta-lactamase inhibitor sulbactam (p.335); it consists of the two compounds linked as a double ester. During absorption from the gastrointestinal tract it is hydrolysed, releasing equimolar quantities of ampicillin and sulbactam.

Sultamicillin is given orally as tablets containing sultamicillin tosilate or as oral suspension containing sultamicillin. It is used in the treatment of infections where beta-lactamase-producing organisms might occur, including uncomplicated gonorrhoea, otitis media, and respiratory-tract and urinary-tract infections. The usual dose is 375 to 750 mg of sultamicillin (equivalent to 147 to 294 mg of sulbactam and 220 to 440 mg of ampicillin) twice daily. A single dose of sultamicillin 2.25 g with probenecid 1 g may be used for uncomplicated gonorrhoea.

When parenteral therapy is necessary a combined preparation of ampicillin with sulbactam is given.

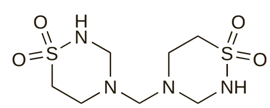
Taurolidine *(BAN, rINN)*

Taurolidina; Taurolidinum. 4,4′-Methylenebis(perhydro-1,2,4-thiadiazine 1,1-dioxide).

Тауролидин

$C_7H_{16}N_4O_4S_2$ = 284.4.
CAS — 19388-87-5.
ATC — B05CA05.
ATC Vet — QB05CA05.



Profile

Taurolidine is a broad-spectrum antibacterial. It is hydrolysed in aqueous solution to its monomeric form taurultam and other metabolites, with the release of what was originally thought to be formaldehyde but is now considered to be activated methylene glycol or methylol groups, from which it is believed to derive its activity. Its antibacterial activity *in vitro* is modest but is reported to be enhanced in the presence of serum or urine; it is active against pathogens including *Staphylococcus aureus*, *Escherichia coli*, and *Pseudomonas aeruginosa*. Taurolidine is also reported to inactivate bacterial endotoxin.

Taurolidine is used in peritonitis; a solution containing 0.5% is used for irrigation and another containing 2% is available for instillation. It has been given experimentally as an intravenous infusion in the treatment of severe sepsis or endotoxic shock and in pancreatitis.

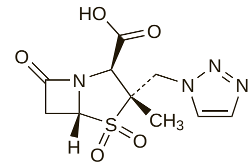
Sodium (2*S*,3*S*,5*R*)-3-methyl-7-oxo-3-(1*H*-1,2,3-triazol-1-ylmethyl)-4-thia-1-azabicyclo[3.2.0]-heptane-2-carboxylate 4,4-dioxide.

Натрий Тазобактам

$C_{10}H_{11}N_4NaO_5S$ = 322.3.
CAS — 89786-04-9 (tazobactam); 89785-84-2 (tazobactam sodium).
ATC — J01CG02.
ATC Vet — QJ01CG02.



(tazobactam)

Profile

Tazobactam is a penicillanic acid sulfone derivative with beta-lactamase inhibitory properties similar to those of sulbactam (p.335) although it is regarded as more potent. It has the potential to enhance the activity of beta-lactam antibacterials against beta-lactamase-producing bacteria.

Tazobactam sodium is given intravenously with piperacillin sodium (p.315) for the treatment of bacterial infections. The pharmacokinetics of tazobactam and piperacillin are similar.

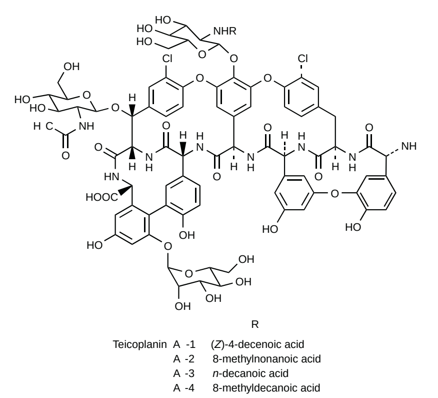
Teicoplanin *(BAN, USAN, rINN)*

A-8327; DL-507-IT; L-12507; MDL-507; Teichomycin A_2; Teicoplanina; Téicoplanine; Teicoplaninum; Teikoplaniini; Teikoplanin.

Тейкопланин

CAS — 61036-62-2 (teichomycin); 61036-64-4 (teichomycin A_2).
ATC — J01XA02.
ATC Vet — QJ01XA02.



Description. A glycopeptide antibiotic obtained from cultures of *Actinoplanes teichomyceticus* or the same substance obtained by any other means.

Pharmacopoeias. In *Jpn.*

Adverse Effects and Precautions

Fever, skin rash and pruritus, and occasional bronchospasm and anaphylaxis have been reported with teicoplanin, but, in comparison with vancomycin (p.359), it appears to be better tolerated when given by rapid intravenous injection and, although erythema and flushing of the upper body have occurred, the 'red-man syndrome' has been reported less often. In addition, unlike vancomycin, teicoplanin does not appear to cause tissue necrosis and can be given by intramuscular injection. Other hypersensitivity reactions have included rigors, angioedema, and, rarely, severe skin reactions including exfoliative dermatitis, erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis.

Other reported reactions include gastrointestinal disturbances, dizziness, headache, thrombocytopenia (especially at high doses), leucopenia, neutropenia, eosinophilia, disturbances in liver enzyme values, and pain, erythema, and thrombophlebitis or abscess at the injection site. Rare cases of agranulocytosis have occurred. Renal impairment and ototoxicity have been reported but both appear to be less frequent than with vancomycin.

Renal and auditory function should be monitored during prolonged therapy in patients with pre-existing renal impairment, and in those receiving other ototoxic or nephrotoxic drugs, although opinions conflict as to whether increased risk of nephrotoxicity exists with combined therapy with drugs such as the aminoglycosides. In general, periodic blood counts and liver- and renal-function tests are advised during treatment.

No relationship has yet been established between plasma concentration and toxicity, and plasma-concentration monitoring is not generally considered necessary. Dosage adjustment is required in renal impairment.

Hypersensitivity. Although there have been occasional reports of cross-sensitivity to teicoplanin in patients hypersensitive to vancomycin,[1-4] the majority of reports suggest that cross-sensitivity is very rare and teicoplanin can usually be used in patients intolerant of vancomycin.[5-7]

7. Wood G, Whitby M. Teicoplanin in patients who are allergic to vancomycin. *Med J Aust* 1989; **150:** 668.

Red-man syndrome. Although teicoplanin is believed[1,2] to be less likely than vancomycin to induce the red-man syndrome, symptoms consistent with the syndrome have nevertheless been reported after intravenous use.[3]

3. Dubettier S, *et al.* Red man syndrome with teicoplanin. *Rev Infect Dis* 1991; **13:** 770.

Antimicrobial Action

As for Vancomycin Hydrochloride, p.359, although in general teicoplanin is more active against susceptible strains. In particular, it may be more active *in vitro* against enterococci and some anaerobic organisms, including strains of *Clostridium*. However, some coagulase-negative staphylococci are less sensitive to teicoplanin than to vancomycin.

Acquired resistance to teicoplanin has developed in staphylococci during treatment with teicoplanin. Cross-resistance with vancomycin has occurred in staphylococci and enterococci.

Pharmacokinetics

Teicoplanin is poorly absorbed from the gastrointestinal tract. After a 400-mg intravenous dose, peak plasma concentrations 1 hour later are reported to be in the range 20 to 50 micrograms/mL. It is well absorbed on intramuscular injection with a bioavailability of about 90%; after a dose of 3 mg/kg intramuscularly, peak plasma concentrations of 5 to 7 micrograms/mL have been reported after 2 to 4 hours.

The pharmacokinetics of teicoplanin are triphasic, with a biphasic distribution and a prolonged elimination. Penetration into the CSF is poor. It is taken up into white blood cells, and about 90 to 95% of teicoplanin in plasma is protein bound. It is excreted almost entirely by glomerular filtration in the urine, as unchanged drug. The terminal half-life is prolonged, but reported half-lives have ranged from about 30 to 190 hours or longer, depending on the sampling time; an effective clinical half-life of about 60 hours has been suggested for use in calculating dosage regimens. Half-life is increased progressively with increasing degrees of renal impairment. Teicoplanin is not removed by haemodialysis.

Teicoplanin is a mixture of several components, the pharmacokinetics of which have been shown to vary slightly, depending on their lipophilicity.

◊ Reviews.

1. Wilson APR. Clinical pharmacokinetics of teicoplanin. *Clin Pharmacokinet* 2000; **39:** 167–83.

Uses and Administration

Teicoplanin is a glycopeptide antibiotic that may be used as an alternative to vancomycin (p.360) in the treatment of serious Gram-positive infections where other drugs cannot be used, including the treatment and prophylaxis of infective endocarditis, peritonitis associated with continuous ambulatory peritoneal dialysis, and suspected infection in neutropenic or otherwise immunocompromised patients. Teicoplanin, given orally, has been suggested as a possible alternative to vancomycin or metronidazole in antibiotic-associated colitis. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Teicoplanin is given intravenously, as a bolus dose or by infusion over 30 minutes, or by intramuscular injection. The usual mean dose is 6 mg/kg intravenously or intramuscularly initially, followed by 3 mg/kg intravenously or intramuscularly on each subsequent day of treatment (in practice this equates to a usual dose of 400 mg initially followed by 200 mg daily, except in patients weighing more than 85 kg in whom it is adapted accordingly). In more severe infections, 6 mg/kg may be given every 12 hours for the first 3 doses, followed by 6 mg/kg daily.

For the prophylaxis of endocarditis in high-risk patients undergoing dental or other procedures who are unable to receive penicillin, teicoplanin may be given in a single dose of 400 mg by intravenous injection, with gentamicin, before the procedure. A similar dose of teicoplanin is given for prophylaxis in orthopaedic surgery at induction of anaesthesia.

In children, a loading dose of 10 mg/kg every 12 hours for 3 doses is followed by 6 to 10 mg/kg daily, depending on the severity of infection. In neonates, a loading dose of 16 mg/kg on the first day is followed by maintenance doses of 8 mg/kg daily, given by intravenous infusion. Although no relationship between plasma concentrations and toxicity has been established, the *BNF* suggests that the former may sometimes be used as a guide to optimise treatment: trough concentrations should be above 10 micrograms/mL (15 to 20 micrograms/mL in patients with endocarditis) but less than 60 micrograms/mL.

Dosage should be adjusted in patients with impaired renal function (see Administration in Renal Impairment, below).

◊ Reviews.

Administration in renal impairment. Doses of teicoplanin should be adjusted in patients with renal impairment, though reduction is not required until the fourth day of treatment. Teicoplanin should be given in usual doses for the first 3 days of therapy, thereafter the dose is adjusted according to creatinine clearance (CC):

- CC 40 to 60 mL/minute: half initial dose given daily or initial dose given every 2 days
- CC less than 40 mL/minute: one-third initial dose given daily or initial dose given every 3 days

Telithromycin *(BAN, USAN, rINN)*

HMR-3647; RU-66647; Télithromycine; Telithromycinum; Telitromicina; Telitromisin. (3a*S*,4*R*,7*R*,9*R*,10*R*,11*R*,13*R*,15*R*,15a*R*)-4-Ethyloctahydro-11-methoxy-3a,7,9,11,13,15-hexamethyl-1-{4-[4-(3-pyridyl)imidazol-1-yl]butyl}-10-{[3,4,6-trideoxy-3-(dimethylamino)-β-D-*xylo*-hexopyranosyl]oxy}-2*H*-oxacyclotetradecino[4,3-*d*][1,3]oxazole-2,6,8,14(1*H*,7*H*,9*H*)-tetrone.

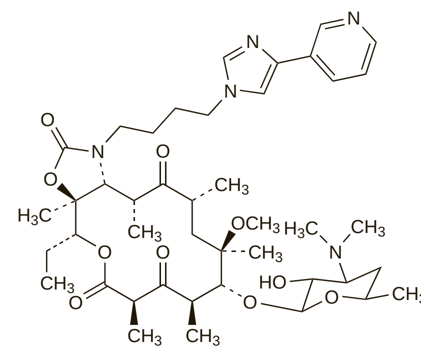
Телитромицин

$C_{43}H_{65}N_5O_{10}$ = 812.0.

CAS — 173838-31-8; 191114-48-4.

ATC — J01FA15.

ATC Vet — QJ01FA15.



Adverse Effects

Diarrhoea and other gastrointestinal disturbances such as nausea, vomiting, abdominal pain, and flatulence are among the most common adverse reactions after use of telithromycin. Severe, but usually reversible, hepatic dysfunction, including elevation of liver enzymes and hepatitis, with or without jaundice has been reported; however, there have been cases of fatal hepatotoxicity including fulminant hepatitis, hepatic necrosis, and hepatic failure. Effects on the CNS may include dizziness, headache, vertigo, and, occasionally, insomnia or drowsiness. Taste, and very rarely smell, disturbances may occur. Other less commonly reported adverse effects include paraesthesia, eosinophilia, skin rashes, and cardiovascular effects such as arrhythmias, hypotension, and bradycardia. Visual disturbances, particularly affecting accommodation, have occurred. Syncope, usually associated with the vagal syndrome, has been noted. Very rarely reported adverse effects include angioedema and anaphylaxis. There have been isolated cases of erythema multiforme, pseudomembranous colitis, and muscle cramps. Life-threatening acute respiratory failure has been reported in patients with myasthenia gravis (see also Precautions, below).

Effects on the eyes. Visual disturbances, namely blurred vision, difficulty with focusing, and diplopia have been associated with telithromycin. These have been reported to be more common in females under the age of 40 years and to occur in 1.1% of patients compared with 0.28% in those receiving a comparable antibacterial.[1] Licensed product information reports that symptoms are fully reversible, mostly mild to moderate in severity, and typically occur within a few hours of the first or second dose, lasting for several hours and recurring upon subsequent dosing. They have not been associated with any ocular abnormality.

1. Lonks JR, Goldmann DA. Telithromycin: a ketolide antibiotic for treatment of respiratory tract infections. *Clin Infect Dis* 2005; **40:** 1657–64.

Effects on the kidneys. Acute interstitial nephritis has been reported[1] in an 18-year-old man who received telithromycin for 5 days. Complete recovery of renal function occurred 2 weeks after starting symptomatic treatment with methylprednisolone.

1. Tintillier M, *et al.* Telithromycin-induced acute interstitial nephritis: a first case report. *Am J Kidney Dis* 2004; **44:** e25–e27.

Effects on the liver. Hepatotoxicity is an established adverse effect of telithromycin and may be severe. Of 3 case reports of serious liver toxicity in patients with no pre-existing hepatic impairment, after receiving telithromycin at the usual dose,[1] one patient spontaneously recovered, one required a liver transplant, and one died.

1. Clay KD, *et al.* Brief communication: severe hepatotoxicity of telithromycin: three case reports and literature review. *Ann Intern Med* 2006; **144:** 415–20.

Effects on the skin. A 26-year-old woman with a history of rash to penicillin and sulfonamides developed toxic epidermal necrolysis after 13 doses of oral telithromycin for treatment of sinusitis; she was discharged 4 weeks after admission to hospital but had scars on her face and body and had lost her eyelashes.[1]

1. Health Canada. Telithromycin (Ketek): suspected association with toxic epidermal necrolysis. *Can Adverse React News* 2007; **17** (2): 2. Available at: http://www.hc-sc.gc.ca/dhp-mps/alt_formats/hpfb-dgpsa/pdf/medeff/carn-bcei_v17n2-eng.pdf (accessed 18/06/08)

Precautions

Telithromycin should not be given to patients with known hypersensitivity to it or to the macrolides; similarly, a history of hepatitis and/or jaundice associated with telithromycin or macrolides is a contra-indication.

Telithromycin is contra-indicated in patients with myasthenia gravis because it may exacerbate symptoms of the disease; exacerbations usually occur within 1 to 3 hours of the first dose. Fatalities have been reported.

Patients with a congenital or family history of QT interval prolongation should not receive telithromycin; it should be used with care in those with coronary heart disease, cardiac arrhythmias, and in those with hypokalaemia or hypomagnesaemia, due to its potential to prolong the QT interval. Certain medications may also increase the risk of cardiac arrhythmias and prolong the QT interval (see Interactions, below).

Patients should be informed about signs and symptoms of hepatitis. Should any of these develop during treatment with telithromycin, they should stop taking the drug and consult their doctor. It should be used with caution in patients with hepatic impairment; however, this is based on limited data in such patients. Reduced doses may be necessary in those with severe renal impairment (see below).

Since telithromycin can produce visual disturbances or loss of consciousness caution is advised when driving, operating machinery, or undertaking similar hazardous activities.

Breast feeding. Telithromycin has been shown to be excreted in the milk of lactating *animals* at concentrations about 5 times greater than those in maternal plasma, although corresponding data for humans is not available.

Pregnancy. Reproductive toxicity, but not teratogenicity, has been seen in *animals*; the potential risk for humans is unknown.

Interactions

Telithromycin is an inhibitor of the cytochrome P450 isoenzymes CYP3A4 and CYP2D6. Although there have been few clinical reports, drug interactions with telithromycin may be expected to be similar to those seen with erythromycin (see p.271). In particular, caution is required when telithromycin is given with drugs that may prolong the QT interval. Use of telithromycin with cisapride, ergot alkaloid derivatives, pimozide, astemizole, or terfenadine is usually contra-indicated. Caution is usually necessary with benzodiazepines such as alprazolam, midazolam, and triazolam, and with metoprolol. Telithromycin should not be given with drugs that induce the cytochrome P450 isoenzyme CYP3A4, such as rifampicin, phenytoin, carbamazepine, or St John's wort. Telithromycin increases plasma concentrations of some statins and hence the risk of myopathy; it should not be given with atorvastatin, lovastatin, or simvastatin.

Antimicrobial Action

Telithromycin is a ketolide antibacterial with a bactericidal action and is highly active against certain Gram-positive bacteria, including multidrug-resistant strains of *Streptococcus pneumoniae*. Some strains of *Streptococcus pyogenes* and of *Staphylococcus aureus* are also sensitive.

Telithromycin also shows good activity against the Gram-negative organisms *Haemophilus influenzae* and *Moraxella catarrhalis* (*Branhamella catarrhalis*). Activity against *Mycoplasma pneumoniae* and *Chlamydophila pneumoniae* (*Chlamydia pneumoniae*) is comparable with macrolides, and it shows greater activity than erythromycin and roxithromycin against *Legionella* spp. *Mycobacterium* spp. are reported to be moderately susceptible.

Enterobacteriaceae, *Pseudomonas* spp., and *Acinetobacter* spp. are not susceptible.

Pharmacokinetics

Telithromycin is rapidly absorbed after an oral dose, with a bioavailability of 57%. Peak plasma concentrations of about 2 micrograms/mL are reached around 1 to 3 hours after a dose of 800 mg. Food does not affect the absorption of telithromycin.

Telithromycin is widely distributed in body fluids and tissues, including those of the respiratory tract, and plasma protein binding is 60 to 70%. Concentrations in target tissues are reported to be higher than plasma concentrations, suggesting the drug may remain active when the plasma concentration has fallen below the MIC.

About two-thirds of a dose is metabolised in the liver to inactive metabolites and the remaining third is eliminated unchanged in the urine and faeces. Metabolism is mediated both by cytochrome P450 isoenzymes (mainly CYP3A4) and non-cytochrome P450 enzymes. The pharmacokinetics of telithromycin are triphasic with a biphasic elimination phase; the elimination half-life is 2 to 3 hours and the terminal half-life about 10 hours.

Distribution into milk has been found in studies in *animals*.

Uses and Administration

Telithromycin is a ketolide antibacterial used for the treatment of susceptible respiratory-tract infections in adults including mild to moderate community-acquired pneumonia. In some countries it is also licensed for use in the treatment of acute sinusitis and acute bacterial exacerbations of chronic bronchitis when resistance to beta-lactam and/or macrolide antibacterials is known or suspected; and as an alternative to beta-lactam antibacterials for tonsillitis or pharyngitis caused by Group A *beta streptococci* in patients over 12 years of age. It is given orally in a usual dose of 800 mg once daily.

Doses may need to be reduced in patients with renal impairment (see below).

Administration in renal impairment. Doses of telithromycin should be reduced in severe renal impairment (creatinine clearance of less than 30 mL/minute):

- UK licensed product information states that alternating daily doses of 800 mg and 400 mg, starting with 800 mg may be given whether or not hepatic function is also impaired
- US licensed product information recommends a dose of 600 mg once daily if there is no hepatic impairment but a dose of 400 mg once daily if there is co-existing impairment

Doses should be given after dialysis sessions to patients on haemodialysis.

Respiratory disorders. As well as their established antibacterial effect, it has been suggested that macrolides also have immunomodulatory effects that could be useful in the management of respiratory diseases (see also Respiratory Disorders, under Uses of Erythromycin, p.273). Ketolides also appear to have such effects: a 10-day course of oral telithromycin 800 mg daily, started with standard treatment for acute asthma (p.1108) in adults, was reported to improve asthma symptoms regardless of infection with *Chlamydophila pneumoniae* (*Chlamydia pneumoniae*) or *Mycoplasma pneumoniae*.[1] The mechanism of this effect is unclear, however, and further studies are needed.

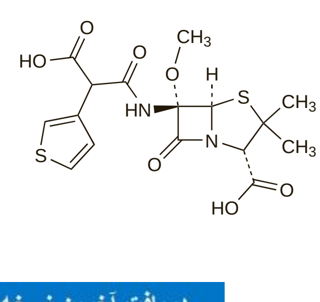
Temocillin *(BAN, USAN, rINN)*

Temocilina; Témocilline; Temocillinum. (6*S*)-6-[2-carboxy-2-(3-thienyl)acetamido]-6-methoxypenicillanic acid.

Темоциллин

$C_{16}H_{18}N_2O_7S_2$ = 414.5.
CAS — 66148-78-5.
ATC — J01CA17.
ATC Vet — QJ01CA17.



Temocillin Sodium *(BANM, rINNM)*

BRL-17421; Natrii Temocillinum; Temocilina sódica; Temocillin Disodium; Témocilline Sodique. The disodium salt of (6*S*)-6-[2-carboxy-2-(3-thienyl)acetamido]-6-methoxypenicillanic acid.

Натрий Темоциллин

$C_{16}H_{16}N_2Na_2O_7S_2$ = 458.4.
CAS — 61545-06-0.
ATC — J01CA17.
ATC Vet — QJ01CA17.

Profile

Temocillin is a semisynthetic penicillin that is highly resistant to a wide range of beta-lactamases and is used for the treatment of infections caused by beta-lactamase-producing strains of Gram-negative aerobic bacteria, including those resistant to third-generation cephalosporins.

It is given as the sodium salt and doses are expressed in terms of the base; 1.11 g of temocillin sodium is equivalent to about 1 g of temocillin. It is given by intravenous or intramuscular injection or by intravenous infusion in usual doses of 1 g every 12 hours. A dose of 12.5 mg/kg every 12 hours may be used in children. Intravenous doses may be doubled in severe infections.

In patients with renal impairment the interval between doses may need to be increased.

Preparations

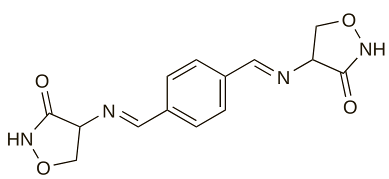
Proprietary Preparations (details are given in Part 3)
Belg.: Negaban; ***Ital.:*** ISF 09338†; ***UK:*** Negaban.

Terizidone *(rINN)*

B-2360; Terizidona; Térizidone; Terizidonum. 4,4′-[*p*-Phenylenebis(methyleneamino)]bis(isoxazolidin-3-one).

Теризидон

$C_{14}H_{14}N_4O_4$ = 302.3.
CAS — 25683-71-0.
ATC — J04AK03.
ATC Vet — QJ04AK03.



Profile

Terizidone has been used in the treatment of infections of the urinary tract and of pulmonary and extrapulmonary tuberculosis.

Preparations

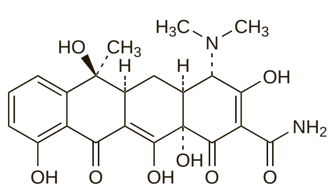
Proprietary Preparations (details are given in Part 3)
Austria: Terivalidin; ***Braz.:*** Terizidex; ***S.Afr.:*** Terivalidin.

Tetracycline *(BAN, rINN)*

Tetraciclina; Tetraciklin; Tetraciklinas; Tétracycline; Tetracyclinum; Tetracyklin; Tetracyklina; Tetrasykliini. A variably hydrated form of (4*S*,4a*S*,5a*S*,6*S*,12a*S*)-4-Dimethylamino-1,4,4a,5,5a,6,11,12a-octahydro-3,6,10,12,12a-pentahydroxy-6-methyl-1,11-dioxonaphthacene-2-carboxamide.

Тетрациклин

$C_{22}H_{24}N_2O_8$ = 444.4.
CAS — 60-54-8 (anhydrous tetracycline); 6416-04-2 (tetracycline trihydrate).
ATC — A01AB13; D06AA04; J01AA07; S01AA09; S02AA08; S03AA02.
ATC Vet — QA01AB13; QD06AA04; QG01AA90; QG51AA02; QJ01AA07; QJ51AA07; QS01AA09; QS02AA08; QS03AA02.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Tetracycline). A yellow crystalline powder. Very slightly soluble in water; soluble in alcohol and in methyl alcohol; sparingly soluble in acetone. It dissolves in dilute acid and alkaline solutions. A 1% suspension in water has a pH of 3.5 to 6.0. Protect from light.

USP 31 (Tetracycline). A yellow, odourless, crystalline powder. It darkens in strong sunlight. Soluble 1 in 2500 of water and 1 in 50 of alcohol; practically insoluble in chloroform and in ether; soluble in methyl alcohol; freely soluble in dilute acids and in alkali hydroxide solutions. It loses not more than 13% of its weight on drying. A 1% suspension in water has a pH of 3.0 to 7.0. The potency of tetracycline is reduced in solutions having a pH below 2 and it is rapidly destroyed in solutions of alkali hydroxides. Store in airtight containers. Protect from light.

Tetracycline Hydrochloride *(BANM, rINNM)*

Hidrocloruro de tetraciclina; Tetraciklinhidroklorid; Tetraciklino hidrochloridas; Tétracycline, chlorhydrate de; Tetracyclini hydrochloridum; Tetracyklin hydrochlorid; Tetracyklinhydroklorid; Tetracykliny chlorowodorek; Tetrasiklin Hidroklorür; Tetrasykliinihydrokloridi.

Тетрациклина Гидрохлорид

$C_{22}H_{24}N_2O_8,HCl$ = 480.9.
CAS — 64-75-5.
ATC — A01AB13; D06AA04; J01AA07; S01AA09; S02AA08; S03AA02.
ATC Vet — QA01AB13; QD06AA04; QJ01AA07; QS01AA09; QS02AA08; QS03AA02.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

US also includes Epitetracycline Hydrochloride.

Ph. Eur. 6.2 (Tetracycline Hydrochloride). A yellow crystalline powder. Soluble in water; slightly soluble in alcohol; practically insoluble in acetone. It dissolves in solutions of alkali hydroxides and carbonates. Solutions in water become turbid on standing, owing to the precipitation of tetracycline. A 1% solution in water has a pH of 1.8 to 2.8. Protect from light.

USP 31 (Tetracycline Hydrochloride). A yellow, odourless, hygroscopic, crystalline, powder. Tetracycline hydrochloride darkens in moist air when exposed to strong sunlight. Soluble 1 in 10 of water and 1 in 100 of alcohol; practically insoluble in chloroform and in ether; soluble in solutions of alkali hydroxides and carbonates, although it is rapidly destroyed by alkali hydroxide solutions. A 1% solution in water has a pH of 1.8 to 2.8. The potency of tetracycline hydrochloride is reduced in solutions having a pH below 2. Store in airtight containers. Protect from light.

Tetracycline Phosphate Complex *(BAN)*

Tetraciclina, complejo con fosfato.

CAS — 1336-20-5.
ATC — A01AB13; D06AA04; J01AA07; S01AA09; S02AA08; S03AA02.
ATC Vet — QA01AB13; QD06AA04; QJ01AA07; QS01AA09; QS02AA08; QS03AA02.

Description. A complex of sodium metaphosphate and tetracycline.

Incompatibility. Tetracycline injections have an acid pH and incompatibility may reasonably be expected with alkaline preparations, or with drugs unstable at low pH. Tetracyclines can chelate metal cations to produce insoluble complexes, and incompatibility has been reported with solutions containing metallic salts. Reports of incompatibility are not always consistent, and other factors, such as the strength and composition of the vehicles used, may play a role.

Stability. Tetracycline undergoes reversible epimerisation in *solution* to the less active 4-epitetracycline;[1,2] the degree of epimerisation is dependent on pH, and is greatest at a pH of about 3, with conversion of some 55% to the epimer at equilibrium.[1] The rate at which epimerisation occurs is affected by a variety of factors including temperature and the presence of phosphate or citrate ions.[1] Intravenous solutions of tetracycline hydrochloride with a pH between 3 and 5 have been reported to be stable for 6 hours, but to lose about 8 to 12% of their potency in 24 hours at room temperature.[3] Although epimerisation has been observed to be the dominant degradation reaction at pH 2.5 to 5, outside this pH range other reactions become important, with the pH-dependent formation of anhydrotetracycline at very low pH, and oxidation to isotetracycline at alkaline pH.[4]

In contrast to the case in solution, *suspensions* of tetracycline hydrochloride with a pH between 4 and 7 are stable for at least 3 months.[2] This is because epimerisation, which continues until an equilibrium is achieved between tetracycline and its epimer, depends only on the portion in solution, and the solubility of tetracycline at this pH range is low.

The stability of *solid* dosage forms and powder at various temperatures and humidities has also been studied; tetracycline hydrochloride was fairly stable when stored at 37° and 66% humidity for 2 months, with about a 10% loss of potency, but the phosphate was rather less stable, with potency losses of 25 to 40% and the formation of potentially toxic degradation products.[5] Comparison with other tetracyclines indicated that tetracycline was less stable than demeclocycline and more stable than rolitetracycline.[5] However, although this study, and an accelerated stability study carried out by WHO[6] indicate that there is a risk of deterioration of solid dose tetracycline, in practice a study of its stability during shipment to the tropics found that deterioration was not a problem.[7]

Adverse Effects

The adverse effects of tetracycline are common to all tetracyclines. Gastrointestinal effects including nausea, vomiting, and diarrhoea are common especially with high doses and most are attributed to irritation of the mucosa. Oesophageal ulceration has been reported with doxycycline, minocycline, and tetracycline, particularly after ingestion of capsules or tablets with insufficient water at bedtime. Other effects that have been reported include glossitis, stomatitis, and dysphagia.

Oral candidiasis, vulvovaginitis, and pruritus ani occur, mainly due to overgrowth with *Candida albicans*, and there may be overgrowth of resistant coliform organisms, such as *Pseudomonas* spp. and *Proteus* spp., causing diarrhoea. More seriously, enterocolitis due to superinfection with resistant staphylococci and pseudomembranous colitis due to *Clostridium difficile* have occasionally been reported. It has been suggested that disturbances in the intestinal flora are more common with tetracycline than with better absorbed derivatives such as doxycycline.

Renal dysfunction has been reported with tetracyclines, particularly exacerbation of dysfunction in those with pre-existing renal impairment. Usual therapeutic doses given to patients with renal impairment increase the severity of uraemia with increased excretion of nitrogen and loss of sodium, accompanied by acidosis and hyperphosphataemia, and may lead to excessive systemic accumulation of the tetracycline and possible liver toxicity. These effects are related to the dose and the severity of renal impairment and are probably due to the anti-anabolic effects of the tetracycline. Acute renal failure and interstitial nephritis have occurred rarely.

Increases in liver enzyme values have been reported with tetracyclines. In some cases severe and sometimes fatal hepatotoxicity, associated with fatty changes in the liver and pancreatitis, has occurred in pregnant women and in patients with renal impairment or those given high doses. However, hepatotoxicity has also occurred in patients without these predisposing factors but is rarely reported with doxycycline.

Tetracyclines are deposited both in deciduous teeth (milk teeth; primary teeth) and in permanent teeth during their formation, causing permanent discoloration and enamel hypoplasia. The darkening effect of tetracyclines on permanent teeth appears to be related to the total dose given. Doxycycline binds less with calcium compared with other tetracyclines and these changes may occur less frequently. Tetracyclines are also deposited in calcifying areas in bone and the nails and interfere with bone growth when given in therapeutic doses to young infants or pregnant women.

Nail discoloration and onycholysis may occur. Abnormal pigmentation of the skin, conjunctiva, oral mucosa, tongue, and internal organs such as the thyroid has occurred rarely. Permanent discoloration of the cornea has been reported in infants born to mothers given tetracycline in high doses during pregnancy.

Intracranial hypertension with headache, dizziness, tinnitus, visual disturbances, and papilloedema has been reported. The use of tetracyclines in infants has been associated with a bulging fontanelle. If raised intracranial pressure occurs tetracycline treatment should be stopped. Transient myopia in patients taking tetracyclines may be due to changes in refractive power of the lens. Other adverse effects that have occasionally been reported with tetracyclines include increased muscle weakness in patients with myasthenia gravis and exacerbation of SLE.

Hypersensitivity to the tetracyclines is much less common than to the beta lactams, but hypersensitivity reactions, including rashes, fixed drug eruptions, exfoliative dermatitis, toxic epidermal necrolysis, drug fever, pericarditis, angioedema, urticaria, and asthma have been reported; anaphylaxis has occurred very rarely. Photosensitivity, which has been reported with most tetracyclines, occurs most frequently with demeclocycline and other long-acting derivatives, less with chlortetracycline, and very rarely with oxytetracycline and tetracycline; it appears to be phototoxic rather than photoallergic in nature. Paraesthesia may be an early sign of impending phototoxicity.

Local pain and irritation can occur when tetracyclines are given parenterally and thrombophlebitis may follow intravenous injections. A Jarisch-Herxheimer reaction occurs commonly in patients with relapsing fever treated with tetracyclines.

Although rare, agranulocytosis, aplastic anaemia, haemolytic anaemia, eosinophilia, neutropenia, and thrombocytopenia have been reported. Tetracyclines may produce hypoprothrombinaemia. They have also been associated with reductions in serum-vitamin B concentrations, including a case of folate deficiency and concomitant megaloblastic anaemia.

The use of tetracyclines that are out-of-date or which have deteriorated has been associated with the development of a reversible Fanconi-type syndrome characterised by polyuria and polydipsia with nausea, glycosuria, aminoaciduria, hyperphosphaturia, hypokalaemia, and hyperuricaemia with acidosis and proteinuria; these effects have been attributed to the presence of degradation products, in particular anhydroepitetracycline.

Effects on intracranial pressure. Benign intracranial hypertension (pseudotumor cerebri) has been described in patients given tetracyclines.[1] Tetracycline is most commonly implicated, usually in patients being treated for acne; it has also been associated with doxycycline[2,3] and minocycline.[4,5] Presenting symptoms, such as headaches, tinnitus, visual loss, diplopia, nausea, and vomiting, usually develop from within 2 weeks to 1 year or more of starting a tetracycline. Most cases resolved when the drug was stopped although some required symptomatic treatment with diuretics (including acetazolamide), corticosteroids, and/or lumbar puncture. Nevertheless, permanent visual loss has been reported.

Precautions

The tetracyclines are contra-indicated in patients hypersensitive to any of this group of antibacterials, since cross-sensitivity may occur.

Tetracyclines should not be used during pregnancy because of the risk of hepatotoxicity in the mother as well as the effects on the developing fetus. They should also be avoided during breast feeding and in children up to the age of 8, or according to the *BNF*, 12, years. Use in pregnancy, potentially during breast feeding, or in childhood, may result in impaired bone growth and permanent discoloration of the child's teeth.

In general the tetracyclines, with the exception of doxycycline, should be used with caution in those with renal impairment and, if they must be given, doses should be reduced. However, the *BNF* advises avoiding tetracyclines, except doxycycline and minocycline, even in mild impairment. Care should also be taken if tetracyclines are given to patients with hepatic impairment and high doses should be avoided.

Patients who may be exposed to direct sunlight should be warned of the risk of photosensitivity. Care is advisable in patients with myasthenia gravis, who may be at risk of neuromuscular blockade. Tetracyclines should be avoided in those with SLE.

Serum monitoring of tetracyclines may be helpful in patients with risk factors given prolonged therapy: it has been suggested that serum concentrations of tetracycline should not exceed 15 micrograms/mL. To avoid the risk of oesophageal ulceration oral tetracyclines (notably doxycycline, see p.267) should be taken with plenty of fluid while sitting or standing, and well before going to bed.

Tetracycline may interfere with some diagnostic tests including determination of urinary catecholamines or glucose.

Breast feeding. The American Academy of Pediatrics[1] states that, after use of tetracycline by breast-feeding mothers, there is negligible absorption by the infant and that tetracycline is therefore usually compatible with breast feeding. However, licensed product information states that adverse effects including permanent tooth discoloration and enamel hypoplasia may occur in breast-fed infants and that breast feeding is contra-indicated during treatment with tetracyclines.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/05/04)

Porphyria. Tetracyclines are considered to be probably safe in patients with porphyria, although there is conflicting experimental evidence of porphyrinogenicity. Doxycycline has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients, and results from *animals* or *in-vitro* systems suggest that oxytetracycline might be porphyrinogenic.

Interactions

The absorption of the tetracyclines is reduced by divalent and trivalent cations such as aluminium, bismuth, calcium, iron, magnesium, and zinc, and therefore use of tetracyclines with antacids, iron preparations, some foods such as milk and dairy products, or other preparations containing such cations, whether as active ingredients or excipients, may result in subtherapeutic serum concentrations of the antibacterial. Sodium bicarbonate, colestipol, colestyramine, and kaolin-pectin are also reported to reduce tetracycline absorption, but potential reductions due to cimetidine or sucralfate are probably of little clinical significance. These interactions can be minimised by giving such products at least 1 to 3 hours apart from tetracyclines. Strontium ranelate should not be given with tetracyclines because of possible complex formation.

The nephrotoxic effects of tetracyclines may be exacerbated by diuretics, methoxyflurane, or other potentially nephrotoxic drugs. Potentially hepatotoxic drugs should be used with caution in patients receiving tetracyclines. An increased incidence of benign intracranial hypertension has been reported when retinoids and tetracyclines are given together; such use should be avoided. Tetracyclines have been reported to produce increased concentrations of lithium, digoxin, halofantrine, and theophylline (although these interactions are not strongly established); the effects of oral anticoagulants have also been increased in a few patients. There have been occasional reports of tetracyclines increasing the toxic effects of ergot alkaloids and methotrexate. Tetracyclines may decrease plasma-atovaquone concentrations. Ocular inflammation has occurred after the use of ocular preparations preserved with thiomersal in some patients receiving tetracyclines. Tetracyclines may decrease the effectiveness of oral contraceptives.

Because of possible antagonism of the action of the penicillins by the mainly bacteriostatic tetracyclines it has been recommended that the two types of drug should not be used together, especially when a rapid bactericidal action is necessary.

Antimicrobial Action

The tetracyclines are mainly bacteriostatic, with a broad spectrum of antimicrobial activity including Chlamydiaceae, *Mycoplasma* spp., *Rickettsia* spp., spirochaetes, many aerobic and anaerobic Gram-positive and Gram-negative pathogenic bacteria, and some protozoa.

Mechanism of action. Tetracyclines are taken up into sensitive bacterial cells by an active transport process. Once within the cell they bind reversibly to the 30S subunit of the ribosome, preventing the binding of aminoacyl transfer RNA and inhibiting protein synthesis, and hence cell growth. Although tetracyclines also inhibit protein synthesis in mammalian cells they are not actively taken up, permitting selective activity against the infecting organism.

Spectrum of activity. The following pathogenic organisms are usually sensitive to tetracyclines:

Gram-positive cocci including some strains of *Staphylococcus aureus* and coagulase-negative staphylococci, and streptococci including *Str. pneumoniae*, *Str. pyogenes* (group A), and some viridans streptococci. Enterococci are essentially resistant.

Other sensitive Gram-positive bacteria including strains of *Actinomyces israelii*, *Bacillus anthracis*, *Erysipelothrix rhusiopathiae*, *Listeria monocytogenes*, and among the anaerobes some *Clostridium* spp. *Nocardia* spp. are generally much less susceptible although some are sensitive to minocycline. *Propionibacterium acnes* is susceptible although the action of the tetracyclines in acne is complex and benefit may be seen even at subinhibitory concentrations.

Gram-negative cocci including *Neisseria meningitidis* (meningococci) and *N. gonorrhoeae* (gonococci), although some strains are resistant, and *Moraxella catarrhalis* (*Branhamella catarrhalis*). *Acinetobacter* spp. may be resistant to tetracycline, but most strains are susceptible to doxycycline and minocycline.

Other sensitive Gram-negative aerobes including *Bordetella pertussis*, *Brucella* spp., *Klebsiella granulomatis*, *Campylobacter* spp., *Eikenella corrodens*, *Francisella tularensis*, *Haemophilus influenzae* and some strains of *H. ducreyi*, *Legionella* spp., *Pasteurella multocida*, *Streptobacillus moniliformis*, and various members of the Vibrionaceae including *Aeromonas hydrophila*, *Plesiomonas shigelloides*, *Vibrio cholerae* and *V. parahaemolyticus*. Although many of the Enterobacteriaceae, including *Salmonella*, *Shigella*, and *Yersinia* spp., are susceptible, resistant strains are common; *Proteus* and *Providencia* spp. are not susceptible. *Pseudomonas aeruginosa* is not susceptible either, although some other species formerly classified as *Pseudomonas* respond, including *Burkholderia mallei*, *B. pseudomallei*, and *Stenotrophomonas maltophilia* (*Xanthomonas maltophilia*).

Among the Gram-negative anaerobes *Bacteroides fragilis* may sometimes be susceptible, although wild strains are often resistant, and *Fusobacterium* may also be sensitive.

Other organisms usually sensitive to tetracyclines include *Helicobacter pylori*, Chlamydiaceae, *Rickettsia* and *Coxiella* spp., many spirochaetes including *Borrelia burgdorferi*, *Leptospira* spp., and *Treponema pallidum*, atypical mycobacteria such as *Mycobacterium marinum*, and mycoplasmas including *Mycoplasma pneumoniae* and *Ureaplasma urealyticum*. In addition the tetracyclines are active against some protozoa including *Plasmodium falciparum* and *Entamoeba histolytica*.

Fungi, yeasts, and viruses are generally resistant.

Resistance. Resistance to the tetracyclines is usually plasmid-mediated and transferable. It is often inducible, and appears to be associated with the ability to prevent accumulation of the antibacterial within the bacterial cell, both by decreasing active transport of the drug into the cell and by increasing tetracycline efflux.

Unsurprisingly, given the widespread use of the tetracyclines (including as components of animal feeds, although this is now banned in some countries), resistant strains of the majority of sensitive species have now been reported. Resistance has increased particularly among Enterobacteriaceae such as *Escherichia coli*, *Enterobacter*, *Salmonella*, and *Shigella* spp., especially in hospital isolates, and multiple resistance is common. Staphylococci are commonly resistant, although doxycycline or minocycline are occasionally effective against tetracycline-resistant strains. Resistance is now also common among group A streptococci, and even more so among group B streptococci; there is also resistance among pneumococci, which often show multiple drug resistance. Emergence of high-level tetracycline-resistant strains of *Neisseria gonorrhoeae* is common in some areas. Frequent resistance is also seen in clostridia, and in *Bacteroides fragilis* (among more than 60% of isolates in some countries), while increasing resistance amongst *Haemophilus ducreyi* has limited the value of tetracyclines in chancroid.

Pharmacokinetics

Most tetracyclines are incompletely absorbed from the gastrointestinal tract, about 60 to 80% of a dose of the drug usually being available. The degree of absorption is reduced by the presence of divalent and trivalent metal ions and also certain drugs, with which tetracyclines form stable insoluble complexes, and to a variable degree by milk or food (see Interactions above). However, the more lipophilic derivatives doxycycline and minocycline are almost completely absorbed (more than 90%), and they are little affected by food. Formulation with phosphate may enhance the absorption of tetracycline.

Tetracycline 500 mg orally every 6 hours generally produces steady-state plasma concentrations of 4 to 5 micrograms/mL, whereas with doxycycline a dose of 200 mg is sufficient to produce peak concentrations of about 3 micrograms/mL. Peak plasma concentrations occur about 1 to 3 hours after oral use. Higher concentrations can be achieved after intravenous use; concentrations may be higher in women than in men.

In the circulation, tetracyclines are bound to plasma proteins to varying degrees, but reported values differ considerably, ranging from about 20 to 40% for oxytetracycline, 20 to 65% for tetracycline, about 45% for chlortetracycline, 35 to 90% for demeclocycline, 75% for minocycline, and about 80 to 95% for methacycline and for doxycycline.

The tetracyclines are widely distributed throughout the body tissues and fluids. Concentrations in CSF are relatively low, but may be raised if the meninges are inflamed, and small amounts appear in saliva and in the fluids of the eye; higher concentrations are achieved with more lipid-soluble derivatives such as minocycline and doxycycline. Tetracyclines appear in breast milk, where concentrations may be 60% or more of those in the maternal plasma. They diffuse across the placenta and appear in the fetal circulation in concentrations of about 25 to 75% of those in the maternal blood. Tetracyclines are retained at sites of new bone formation and recent calcification and in developing teeth.

The tetracyclines have been classified in terms of their duration of action in the body, although the divisions appear to overlap somewhat. Of the 'short-acting' analogues, chlortetracycline has a reported half-life of about 6 hours, oxytetracycline 9 hours, and tetracycline 8 hours, although reported values for the latter two range from about 6 to 12 hours. The 'intermediate-acting' tetracyclines, demeclocycline and methacycline, have reported half-lives of about 12 and 14 hours respectively, although various sources cite values of 7 to 17 hours, and the 'long-acting' minocycline and doxycycline have half-lives of about 16 and 18 hours, with reported values anywhere between 11 to 26 and 12 to 24 hours respectively.

The tetracyclines are excreted in the urine and in the faeces. Renal clearance is by glomerular filtration. Up to 60% of an intravenous dose of tetracycline, and up to 55% of an oral dose, is eliminated unchanged in the urine; tetracycline concentrations in the urine of up to 300 micrograms/mL may be reached 2 hours after a usual dose is taken and be maintained for up to 12 hours. Usually about 40 to 70% of a dose is excreted in the urine, but for chlortetracycline, doxycycline, and minocycline, rather less is eliminated by this route since chlortetracycline and minocycline undergo metabolism, and doxycycline is excreted mainly in the faeces. Urinary excretion is increased if urine is alkalinised.

The tetracyclines are excreted in the bile, where concentrations 5 to 25 times those in plasma can occur. Since there is some enterohepatic reabsorption complete elimination is slow. Considerable quantities occur in the faeces after oral doses and lesser amounts after injection.

Tetracyclines are slowly removed by haemodialysis, except for doxycycline which is not removed; they are not removed by peritoneal dialysis.

Uses and Administration

The tetracyclines are bacteriostatic antibacterials with a wide spectrum of activity and have been used in the treatment of a large number of infections caused by susceptible organisms. With the emergence of bacterial resistance and the development of other antibacterials their use has become more restricted, but they remain drugs of choice in rickettsial infections (including Q fever, spotted fevers, and typhus), ehrlichiosis, trench fever, chlamydial infections (including psittacosis, lymphogranuloma venereum, trachoma, non-gonococcal urethritis, and conjunctivitis), and also pharyngitis, sinusitis, or pneumonia due to *Chlamydophila pneumoniae* (*Chlamydia pneumoniae*), and mycoplasmal infections (especially pneumonia caused by *Mycoplasma pneumoniae*). They are widely used as part of regimens for pelvic inflammatory disease. A tetracycline is often used with fluid and electrolyte replacement in the treatment of cholera, and is usually the treatment of choice in relapsing fever and in the early stages of Lyme disease. Tetracyclines may be of benefit in the treatment of melioidosis. They may be used for mouth infections, especially in destructive forms of periodontal disease. Tetracyclines are used, often with streptomycin or rifampicin, in the treatment of brucellosis, and may be given with streptomycin in plague, and as an alternative to streptomycin or gentamicin in the treatment of tularaemia.

Tetracyclines are used as an alternative to other drugs in the treatment of actinomycosis, infected animal bites, anthrax, chronic bronchitis, gas gangrene, gastroenteritis (due to *Campylobacter* or *Yersinia enterocolitica*), granuloma inguinale, leptospirosis, and syphilis. Opinions differ as to their value in listeriosis. There are now relatively few areas where tetracycline-resistant gonococci are uncommon, which limits the value of tetracyclines in gonorrhoea, but they are often given with antigonorrhoeal therapy to treat concomitant chlamydial infections, and they retain some value in the prophylaxis of neonatal gonococcal conjunctivitis by topical application.

For details of all these infections and their treatment, see under Choice of Antibacterial, p.162.

Tetracyclines are also used in the oral treatment of acne and rosacea (see Skin Disorders, below).

Tetracyclines have antiprotozoal actions and tetracycline or doxycycline may be given with quinine in the management of falciparum malaria resistant to chloroquine (below). Tetracyclines are the usual treatment for balantidiasis (p.823) and they have been used with an amoebicide in the treatment of severe amoebic dysentery and in *Dientamoeba fragilis* infections (see Amoebiasis, p.822).

Tetracycline has been used in the management of malabsorption syndromes such as tropical sprue.

Tetracycline has been instilled as a sclerosant solution for pleurodesis and in the management of malignant effusions (p.659).

Administration and dosage. In the treatment of systemic infections the tetracyclines are usually given orally. They should be taken with plenty of fluid while sitting or standing, and well before going to bed, to avoid the risk of oesophageal ulceration. In severe acute infections they have been given by slow intravenous infusion or, rarely, by intramuscular injection; parenteral therapy should be substituted by oral dosage as soon as practicable.

Doses of tetracycline base and tetracycline hydrochloride are expressed in terms of tetracycline hydrochloride. Tetracycline (anhydrous) 231 mg is equivalent to about 250 mg of tetracycline hydrochloride. The usual adult oral dosage of tetracycline hydrochloride is 250 or 500 mg every 6 hours, preferably 1 hour before or 2 hours after meals. Higher doses, up to 4 g daily, have occasionally been given to adults with severe infection, but increase the risk of adverse effects. It is also sometimes given orally with other tetracycline derivatives.

Tetracycline hydrochloride has been given by slow intravenous infusion or by intramuscular injection in severe infections. As intramuscular injections were painful, procaine hydrochloride was usually included in the solution.

For details of doses in children and adolescents, see below.

Care is required if tetracyclines are given to the elderly. They should be avoided if possible in renal impairment (with the exception of doxycycline and minocycline) and doses reduced if they must be used. For dosage recommendations in patients with hepatic impairment, see below.

Other routes. Although topical application carries the risk of sensitisation and may contribute to the development of resistance, tetracycline hydrochloride has been used as a 3% ointment; a 0.2% solution has been used in acne but systemic treatment appears to produce better results. A 1% eye ointment or eye drops have been used in the treatment of ocular infections due to susceptible organisms. For the treatment of pleural effusions, 500 mg of tetracycline hydrochloride has been dissolved in 30 to 50 mL of sodium chloride 0.9% and instilled into the pleural space. For periodontal disease, fibres that release tetracycline have been inserted into the periodontal pocket.

Administration in children. In children, the effects on teeth should be considered and tetracyclines only used when absolutely essential. In the UK, tetracycline is licensed for use in children aged 12 years and over; the usual adult dose (see above), to a maximum of 2 g daily, may be given orally. However, in the USA, it may be given to those over 8 years old in usual doses of 25 to 50 mg/kg daily by mouth in 4 divided doses.

Administration in hepatic impairment. Some licensed product information has stated that the dosage of tetracycline should not exceed 1 g daily in patients with known liver disease.

Diabetic complications. The *BNF* notes that diabetic diarrhoea in patients with autonomic neuropathy can often be managed with 2 or 3 doses of oral tetracycline 250 mg.

Malaria. Tetracyclines have been used with quinine to treat falciparum malaria (p.594).[1] They are active against both blood and tissue forms of the parasite, and high cure rates have been obtained with such combinations. The action of tetracyclines is relatively slow and they should never be used alone to treat malaria.

A usual oral regimen is a 3 to 7 day course of quinine given with 7 days of the tetracycline. The total daily dose of tetracycline should be divided, and that usually recommended is 250 mg four times daily, although 500 mg twice daily may be more practical in the field. If the patient is too ill for oral medication quinine should be given parenterally until oral therapy can be begun; tetracycline should not be used parenterally. Although tetracycline therapy is normally contra-indicated in pregnant women and children, it may have to be given if the risk of withholding the drug is judged to outweigh the risk to developing teeth and bones.

The dose of doxycycline given orally with quinine is 200 mg daily for at least 7 days.

Tetracyclines are not considered suitable for extended prophylactic use, although doxycycline 100 mg daily has been used for short-term prophylaxis in areas of high risk where other drugs are likely to be ineffective.

Mouth ulceration. Tetracyclines may be used as mouthwashes in recurrent aphthous stomatitis (p.1700) and reportedly reduce ulcer pain and duration,[1] but their potential for adverse effects if swallowed must be borne in mind, and their acidity can damage tooth enamel if poorly formulated. Topical application of a tetracycline has been tried for oral ulceration associated with Behçet's syndrome (p.1499).

1. Henricsson V, Axéll T. Treatment of recurrent aphthous ulcers with Aureomycin mouth rinse or Zendium dentifrice. *Acta Odontol Scand* 1985; **43:** 47–52.

Musculoskeletal and joint disorders. Tetracyclines, usually minocycline, are among the wide range of drugs tried in rheumatoid arthritis (p.11). Studies[1,2] indicate that minocycline can produce modest beneficial effects in patients with advanced disease, but the clinical significance of these improvements has been questioned.[3] Greater symptomatic improvements have been obtained with minocycline when it is used in patients with early rheumatoid arthritis;[4,5] continued treatment with minocycline may also reduce the need for disease-modifying antirheumatic drugs (DMARDs).[6] A systematic review,[7] which included these and some other studies, reported that the use of tetracyclines (doxycycline, minocycline, or tetracycline) for 3 months or longer was associated with a reduction in disease activity but not in joint damage when compared with placebo or a DMARD (hydroxychloroquine or methotrexate); the authors also noted that patients with early onset disease responded better to tetracyclines. There has been speculation over the role of infection as a cause of rheumatoid arthritis.[3,8] A later study[9] in patients with early seropositive disease found that initial therapy with methotrexate plus doxycycline was superior to methotrexate alone. It was also noted that therapeutic responses to doxycycline 100 mg twice daily and 20 mg twice daily were similar, suggesting that its anti-inflammatory effects were more important; however, further studies are needed.

Although there has been little convincing clinical evidence that any treatment can slow the progression of osteoarthritis (p.11), a placebo-controlled study involving 431 women with unilateral osteoarthritis of the knee found that treatment with doxycycline 100 mg twice daily over 30 months was associated with a reduction in the rate of joint space narrowing.[10] It had no effect on the contralateral knee, and did not reduce pain scores, although these were low at baseline.

The role of antibacterials is also uncertain in reactive arthritis (see Bone and Joint Infections, p.164), although long-term treatment with a tetracycline in addition to an NSAID has been reported to shorten the duration of reactive arthritis resulting from *Chlamydia trachomatis* infection.[11] However, another small study[12] found that treatment with a 4-month course of doxycycline 100 mg twice daily was not superior to a 10-day course.

Peptic ulcer disease. Tetracycline has been used as part of triple therapy to eradicate *Helicobacter pylori* in patients with peptic ulcer disease (p.1702). The usual dose of tetracycline in these regimens has been 500 mg four times daily for 2 weeks.

Periodontal disease. For the use of doxycycline in subantimicrobial doses as an adjunct in the treatment of periodontal disease, see Administration, Subantimicrobial Doses, p.268.

Skin disorders. *ACNE.* Tetracyclines may be used topically or orally in the treatment of acne (p.1577). In acne, antibacterials appear to act by suppressing the growth of *Propionibacterium acnes*, but also by suppressing inflammation. Topical tetracycline is used for mild inflammatory acne and as an adjunct to systemic treatment in more severe forms. Tetracyclines, given orally, are the drugs of choice for moderate acne and may be considered, in high doses, for severe acne. Licensed doses in the UK are:

- doxycycline 50 mg daily (the *BNF* advocates 100 mg daily)
- lymecycline equivalent to 300 mg of tetracycline daily
- minocycline 100 mg daily
- oxytetracycline 250 to 500 mg daily (the *BNF* advocates 1 g daily)
- tetracycline 1 g daily

Treatment should be changed to another antibacterial if there has been no improvement in the first 3 months. Maximum improvement is said to occur after 3 to 6 months, but treatment may need to continue for 2 or more years.

Minocycline has been reported to have superior antibacterial activity against *P. acnes* and a reduced incidence of resistance compared with tetracycline;[1] it has also been reported to be more effective than erythromycin against oxytetracycline-resistant acne.[2] However, a later randomised study[3] found minocycline to be comparable in efficacy to oxytetracycline, topical erythromycin with benzoyl peroxide, and topical benzoyl peroxide alone in the treatment of mild to moderate acne; in another randomised study[4] lymecycline also showed comparable efficacy and safety. Moreover, minocycline can cause skin pigmentation and may be associated rarely with immunologically-mediated reactions.[5] Although the usual dose of minocycline is 100 mg daily in one or two divided doses some patients may need up to 200 mg daily.[6]

PEMPHIGUS AND PEMPHIGOID. Corticosteroids are generally given to control the blistering in pemphigus and pemphigoid (p.1582), although there have been reports[1-8] suggesting that a tetracycline (often minocycline) may be of value in controlling the lesions associated with various types of pemphigus and pemphigoid.

ROSACEA. Tetracyclines are commonly used in the treatment of rosacea (p.1583). Long-term treatment is usually necessary.

Tetracycline and doxycycline have also been shown to improve ocular manifestations of rosacea.[1] However, a review[2] of the literature concluded that the treatment effect and optimal dose and duration of these 2 drugs have yet to be established; oxytetracycline was found to be of moderate benefit.

For the use of doxycycline in subantimicrobial doses in patients with rosacea, see p.268.

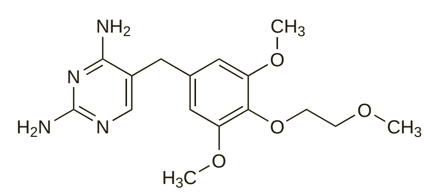
Tetroxoprim *(BAN, USAN, rINN)*

Tetroxoprima; Tétroxoprime; Tetroxoprimum. 5-[3,5-Dimethoxy-4-(2-methoxyethoxy)benzyl]pyrimidine-2,4-diyldiamine.

Тетроксоприм

$C_{16}H_{22}N_4O_4$ = 334.4.

CAS — 53808-87-0.



NOTE. Compounded preparations of tetroxoprim may be represented by the following name:

- Co-tetroxazine (*BAN*)—tetroxoprim 2 parts and sulfadiazine 5 parts (see p.257).

Profile

Tetroxoprim is a dihydrofolate reductase inhibitor similar to, but less active than, trimethoprim (p.355). It has been used, with sulfadiazine, as co-tetroxazine (p.257).

Tetroxoprim embonate has been used similarly.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: *Ger.:* Sterinor†; ***Venez.:*** Esterinor†.

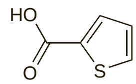
Thenoic Acid

Tenoic Acid; Tenoico, ácido; 2-Thiophenic Acid. Thiophene-2-carboxylic acid.

Тиофенкарбоновая Кислота

$C_5H_4O_2S$ = 128.1.

CAS — 527-72-0.



Profile

Thenoic acid has been given orally, rectally, or intranasally as the sodium salt, and orally as the lithium salt, in the treatment of respiratory-tract infections. The monoethanolamine salt has been used sublingually as a mucolytic.

Preparations

Proprietary Preparations (details are given in Part 3)
Fr.: Rhinotrophyl; Soufrane.

Multi-ingredient: ***Fr.:*** Glossithiase; Trophires; Trophires Compose; ***Spain:*** Trophires†.

Thiamphenicol *(BAN, USAN, rINN)*

CB-8053; Dextrosulphenidol; Thiamfenicol; Thiamfenikol; Thiamphénicol; Thiamphenicolum; Thiophenicol; Tiamfenicolo; Tiamfenikol; Tiamfenikoli; Tiamfenikolis; Tianfenicol; Win-5063-2; Win-5063 (racephenicol). (αR,βR)-2,2-Dichloro-N-(β-hydroxy-α-hydroxymethyl-4-methylsulphonylphenethyl)acetamide.

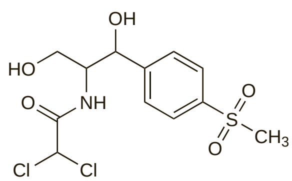
Тиамфеникол

$C_{12}H_{15}Cl_2NO_5S$ = 356.2.

CAS — 15318-45-3 (thiamphenicol); 847-25-6 (racephenicol).

ATC — J01BA02.

ATC Vet — QJ01BA02; QJ51BA02.



NOTE. Racephenicol, the racemic form of thiamphenicol, is *USAN*.

Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Thiamphenicol). A fine, white or yellowish-white, crystalline powder or crystals. Slightly soluble in water and in ethyl acetate; sparingly soluble in dehydrated alcohol and in acetone; freely soluble in acetonitrile and in dimethylformamide; very soluble in dimethylacetamide; soluble in methyl alcohol. Protect from light and moisture.

Thiamphenicol Glycinate Hydrochloride

Thiamphenicol Aminoacetate Hydrochloride; Tiamfenicolo Glicinato Cloridrato; Tianfenicol, hidrocloruro del glicinato de.

$C_{14}H_{18}Cl_2N_2O_6S,HCl$ = 449.7.

CAS — 2393-92-2 (thiamphenicol glycinate); 2611-61-2 (thiamphenicol glycinate hydrochloride).

ATC — J01BA02.

ATC Vet — QJ01BA02.

Pharmacopoeias. In *It.*

Adverse Effects and Precautions

As for Chloramphenicol, p.240.

Thiamphenicol is probably more liable to cause dose-dependent reversible depression of the bone marrow than chloramphenicol but it is not usually associated with aplastic anaemia. Thiamphenicol also appears to be less likely to cause the 'grey syndrome' in neonates.

Doses of thiamphenicol should be reduced in patients with renal impairment. It is probably not necessary to reduce doses in patients with hepatic impairment.

Interactions

As for Chloramphenicol, p.240.

Although thiamphenicol is not metabolised in the liver and might not be expected to be affected by drugs which induce hepatic enzymes, it is reported to inhibit hepatic microsomal enzymes and may affect the metabolism of other drugs.

Antimicrobial Action

Thiamphenicol has a broad spectrum of activity resembling that of chloramphenicol (p.241). Although in general it is less active than chloramphenicol it is reported to be equally effective, and more actively bactericidal, against *Haemophilus* and *Neisseria* spp.

Cross-resistance occurs between thiamphenicol and chloramphenicol. However, some strains resistant to chloramphenicol may be susceptible to thiamphenicol.

Pharmacokinetics

Thiamphenicol is absorbed from the gastrointestinal tract after oral doses and peak serum concentrations of 3 to 6 micrograms/mL have been achieved about 2 hours after a 500-mg dose.

Thiamphenicol diffuses into the CSF, across the placenta, into breast milk, and penetrates well into the lungs. About 10% is bound to plasma proteins. The half-life of thiamphenicol is around 2 to 3 hours but unlike chloramphenicol the half-life is increased in patients with renal impairment. It is excreted in the urine, about 70% of a dose being excreted in 24 hours as unchanged drug. It undergoes little or no conjugation with glucuronic acid in the liver. A small amount is excreted in the bile and the faeces.

Uses and Administration

Thiamphenicol has been used similarly to chloramphenicol (p.241) in the treatment of susceptible infections, including sexually transmitted diseases. The usual adult oral dose is 1.5 g daily in divided doses; up to 3 g daily has been given initially in severe infections. A daily dose of 30 to 100 mg/kg may be used in children. Equivalent doses, expressed in terms of thiamphenicol base, may be given by intramuscular or intravenous injection as the more water soluble glycinate hydrochloride; 1.26 g of thiamphenicol glycinate hydrochloride is equivalent to about 1 g of thiamphenicol. Doses should be reduced in patients with renal impairment (see below).

For the treatment of gonorrhoea, oral doses of thiamphenicol have ranged from 2.5 g daily for 1 or 2 days through to 2.5 g on the first day followed by 2 g daily on each of 4 subsequent days. The single daily dose may be most appropriate for male patients with uncomplicated gonorrhoea.

Thiamphenicol glycinate hydrochloride may also be given by inhalation, or by endobronchial or intracavitary instillation.

Thiamphenicol has also been used as thiamphenicol glycinate acetylcysteinate, thiamphenicol sodium glycinate isophthalolate, and thiamphenicol palmitate.

Administration in renal impairment. Doses of thiamphenicol should be reduced in patients with renal impairment according to creatinine clearance (CC):

- CC 30 to 60 mL/minute: 500 mg twice daily
- CC 10 to 30 mL/minute: 500 mg once daily

Preparations

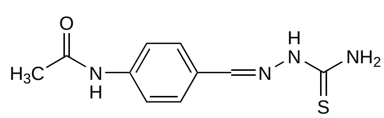
Thioacetazone *(BAN, rINN)*

Amithiozone; Amitiozon; TBI/698; Tebezonum; Thiacetazone; Thioacétazone; Thioacetazonum; Tiasetazon; Tioacetazona. 4-Acetamidobenzaldehyde thiosemicarbazone.

Тиоацетазон

$C_{10}H_{12}N_4OS$ = 236.3.

CAS — 104-06-3.



Pharmacopoeias. In *Int.*

Adverse Effects

Gastrointestinal disturbances, hypersensitivity reactions including skin rashes, conjunctivitis, and vertigo are the adverse effects most frequently reported with thioacetazone although the incidence appears to vary between countries. Toxic epidermal necrolysis, exfoliative dermatitis (which has sometimes been fatal), and the Stevens-Johnson syndrome have been reported; the incidence of severe skin reactions is especially high in patients with HIV infection (see below). Thioacetazone may cause bone-marrow depression with leucopenia, agranulocytosis, and thrombocytopenia. Acute haemolytic anaemia may occur and a large percentage of patients will have some minor degree of anaemia. Hepatotoxicity with jaundice may also develop and acute hepatic failure has been reported. Cerebral oedema has been reported. Dose-related ototoxicity may occur rarely.

Incidence of adverse effects. In a 10-year series of 1212 patients with tuberculosis who were treated with a regimen of streptomycin, isoniazid, and thioacetazone, 171 (14%) had adverse reactions associated with thioacetazone. The most common adverse effects were giddiness (10%), occurring mainly when used with streptomycin, and skin rashes (3%) including exfoliation and the Stevens-Johnson syndrome.[1]

1. Pearson CA. Thiacetazone toxicity in the treatment of tuberculosis patients in Nigeria. *J Trop Med Hyg* 1978; **81:** 238–42.

Effects on the nervous system. Acute peripheral neuropathy which occurred in a 50-year-old man on 2 separate occasions within 15 minutes of a dose of thioacetazone may have been due to an allergic reaction.[1]

1. Gupta PK, *et al.* Acute severe peripheral neuropathy due to thiacetazone. *Indian J Tuberc* 1984; **31:** 126–7.

Effects on the skin. A high incidence of severe and sometimes fatal cutaneous hypersensitivity reactions to thioacetazone has been reported in patients with HIV infection being treated for tuberculosis.[1,2] WHO advised that thioacetazone should be avoided in such patients.[3] Unfortunately, thioacetazone has been one of the mainstays of tuberculosis treatment in the developing world because of its relatively low cost.[4] Some have supported a change to rifampicin-based regimens in, for example, parts of Africa with a high incidence of HIV infection.[5] Others have found a lower frequency of fatalities from adverse cutaneous reactions to thioacetazone than reported previously and have suggested that improved management might allow retention of thioacetazone in tuberculosis programmes.[6] This was rejected by other workers who considered that better and more cost-effective regimens were available than those containing thioacetazone.[7] A pragmatic approach may be to adopt a strategy depending upon the prevailing incidence of HIV infection in the population.[8] Thus, where the incidence of HIV infection is high, ethambutol should be substituted for thioacetazone; where the incidence is moderate, routine HIV testing could be used to identify patients at risk; and where the incidence is low, education of patients on the risks of skin reaction would be adequate.

Cost-effectiveness and total costs of three alternative strategies for the prevention and management of severe skin reactions attributable to thiacetazone in the treatment of human immunodeficiency virus positive patients with tuberculosis in Kenya. *Tubercle Lung Dis* 1996; **77:** 30–6.

Hypertrichosis. Hypertrichosis occurred in 2 children receiving thioacetazone.[1]

1. Nair LV, Sugathan P. Thiacetazone induced hypertrichosis. *Indian J Dermatol Venereol* 1982; **48:** 161–3.

Precautions

The efficacy and toxicity of a regimen of treatment which includes thioacetazone should be determined in a community before it is used widely since there appear to be geographical differences.

Thioacetazone should not be given to patients with hepatic impairment. It has also been suggested that, because thioacetazone has a low therapeutic index and is excreted mainly in the urine, it should not be given to patients with renal impairment. Treatment should be stopped if rash or other signs of hypersensitivity occur. It should probably be avoided in HIV-positive patients because they are at increased risk of severe adverse effects (see Effects on the Skin, above).

Interactions

Thioacetazone may enhance the ototoxicity of streptomycin.

Antimicrobial Action

Thioacetazone is bacteriostatic. It is effective against most strains of *Mycobacterium tuberculosis*, although sensitivity varies in different parts of the world.

Thioacetazone is also bacteriostatic against *M. leprae.* Resistance to thioacetazone develops when used alone. Cross-resistance can develop between thioacetazone and ethionamide or protionamide.

Pharmacokinetics

Thioacetazone is absorbed from the gastrointestinal tract and peak plasma concentrations of 1 to 2 micrograms/mL have been obtained about 4 to 5 hours after a 150-mg dose. About 20% of a dose is excreted unchanged in the urine. A half-life of about 12 hours has been reported.

Uses and Administration

Thioacetazone has been used with other antimycobacterials as a first-line drug in the treatment of tuberculosis (p.196). Thioacetazone-containing regimens are less effective than the short-course regimens recommended by WHO but are used in long-term regimens with isoniazid in some developing countries to reduce drug costs. However, thioacetazone is now used as a second-line drug for multidrug-resistant tuberculosis and is not generally recommended for use in HIV-positive patients because of the risk of severe adverse reactions (but see Effects on the Skin, above).

Thioacetazone has been used in the treatment of leprosy (p.176), but WHO now considers that such use is no longer justified.

In the treatment of tuberculosis, thioacetazone has been given orally in doses of 150 mg daily or 2.5 mg/kg daily. Daily use is recommended as the drug is less effective when given intermittently.

Preparations

Proprietary Preparations (details are given in Part 3)
Turk.: Citazon.

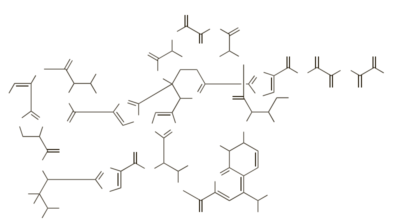
Multi-ingredient: ***India:*** Isokin-T Forte.

Thiostrepton

Thiostreptonum; Tiostreptón; Tiostrepton; Tiostreptoni.

Тиострептон

$C_{72}H_{85}N_{19}O_{18}S_5$ = 1664.9.
CAS — 1393-48-2.



Pharmacopoeias. In *US* for veterinary use only.
USP 31 (Thiostrepton). An antibacterial substance produced by the growth of strains of *Streptomyces azureus*. It has a potency of not less than 900 units/mg, calculated on the dried basis. A white to off-white crystalline solid. Practically insoluble in water, in the lower alcohols, in nonpolar organic solvents, and in dilute aqueous acids or alkalis; soluble in glacial acetic acid, in chloroform, in dimethylformamide, in dimethyl sulfoxide, in dioxan, and in pyridine. Store in airtight containers.

Profile

Thiostrepton is an antibacterial produced by strains of *Streptomyces azureus*. It is included in topical antibacterial preparations for veterinary use.

Tiamulin Fumarate *(BANM, USAN, rINNM)*

Fumarato de tiamulina; 81723-hfu; SQ-14055 (tiamulin); SQ-22947 (tiamulin fumarate); Tiamuliinivetyfumaraatti; Tiamuline, Fumarate de; Tiamuline, hydrogénofumarate de; Tiamulin-fumarát; Tiamulini Fumaras; Tiamulini hydrogenofumaras; Tiamulinvätefumarat. 11-Hydroxy-6,7,10,12-tetramethyl-1-oxo-10-vinylperhydro-3a,7-pentanoinden-8-yl (2-diethylaminoethylthio)acetate hydrogen fumarate.

Тиамулина Фумарат

$C_{28}H_{47}NO_4S,C_4H_4O_4$ = 609.8.

Adverse Effects and Precautions

As for Carbenicillin Sodium, p.216.

Cholestatic jaundice and hepatitis have been reported when ticarcillin was used with clavulanic acid; the clavulanic acid component has been implicated.

Ticarcillin should be given with caution to patients with renal impairment.

Breast feeding. Although ticarcillin is distributed into breast milk in small amounts,[1] no adverse effects have been seen in breast-fed infants and the American Academy of Pediatrics considers that it is usually compatible with breast feeding.[2]

1. von Kobyletzki D, *et al.* Ticarcillin serum and tissue concentrations in gynecology and obstetrics. *Infection* 1983; **11:** 144–9.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/05/04)

Effects on the bladder. The Australian Adverse Drug Reactions Advisory Committee had received 15 reports of haemorrhagic cystitis associated with ticarcillin or ticarcillin-clavulanic acid between 1980 and June 2002, mainly in paediatric cystic fibrosis patients.[1] Almost all patients recovered quickly after the withdrawal of ticarcillin.

1. Adverse Drug Reactions Advisory Committee (ADRAC). Haemorrhagic cystitis with ticarcillin in cystic fibrosis patients. *Aust Adverse Drug React Bull* 2002; **21:** 6–7. Also available at: http://www.tga.gov.au/adr/aadrb/aadr0206.pdf (accessed 29/07/08)

Effects on the liver. Cholestatic jaundice and hepatitis have been associated with combined preparations of a penicillin and clavulanic acid (see Amoxicillin, p.202) and 2 cases had been reported to the UK CSM with ticarcillin and clavulanic acid.[1] It appeared that the clavulanic acid was probably responsible.

1. Committee on Safety of Medicines/Medicines Control Agency. Cholestatic jaundice with co-amoxiclav. *Current Problems* 1993; **19:** 2. Available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2024454&RevisionSelectionMethod=LatestReleased (accessed 22/07/08)

Sodium content. Each g of ticarcillin sodium contains about 4.7 mmol of sodium.

Interactions

As for Benzylpenicillin, p.214.

Antimicrobial Action

Ticarcillin is bactericidal and has a mode of action and range of activity similar to that of carbenicillin (p.216), but is reported to be 2 to 4 times more active against *Pseudomonas aeruginosa*.

Combinations of ticarcillin and aminoglycosides have been shown to be synergistic *in vitro* against *Ps. aeruginosa* and Enterobacteriaceae.

The activity of ticarcillin against organisms usually resistant because of the production of certain beta-lactamases is enhanced by clavulanic acid, a beta-lactamase inhibitor. Such organisms have included staphylococci, many Enterobacteriaceae, *Haemophilus influenzae*, and *Bacteroides* spp.; the activity of ticarcillin against *Ps. aeruginosa* is not enhanced by clavulanic acid. Resistance to ticarcillin with clavulanic acid has been reported.

There is cross-resistance between carbenicillin and ticarcillin.

Pharmacokinetics

Ticarcillin is not absorbed from the gastrointestinal tract. After intramuscular injection of 1 g peak plasma concentrations in the range of 22 to 35 micrograms/mL are achieved after 0.5 to 1 hour. About 50% of ticarcillin in the circulation is bound to plasma proteins. A plasma half-life of 70 minutes has been reported. A shorter half-life in patients with cystic fibrosis (about 50 minutes in one study) has been attributed to increased renal and non-renal elimination. The half-life is prolonged in neonates and also in patients with renal impairment, especially if hepatic function is also impaired. A half-life of about 15 hours has been reported in severe renal impairment.

Distribution of ticarcillin in the body is similar to that of carbenicillin. Relatively high concentrations have been reported in bile, but ticarcillin is excreted principally by glomerular filtration and tubular secretion. Concentrations of 2 to 4 mg/mL are achieved in the urine after the intramuscular injection of 1 or 2 g. Ticarcillin is metabolised to a limited extent. Up to 90% of a dose is excreted unchanged in the urine, mostly within 6 hours after a dose. Plasma concentrations are enhanced by probenecid.

Ticarcillin is removed by haemodialysis and, to some extent, by peritoneal dialysis.

Ticarcillin crosses the placenta and small amounts are distributed into breast milk.

Ticarcillin with clavulanic acid. The pharmacokinetics of ticarcillin and clavulanic acid are broadly similar and neither appears to affect the other to any great extent.

Uses and Administration

Ticarcillin is a carboxypenicillin used in the treatment of severe Gram-negative infections, especially those due to *Pseudomonas aeruginosa*. Pseudomonal infections where ticarcillin is used include those in cystic fibrosis (respiratory-tract infections), immunocompromised patients (neutropenia), peritonitis, and septicaemia. Other infections that may be due to *Ps. aeruginosa* include bone and joint infections, meningitis, otitis media (chronic), skin infections (burns, ecthyma gangrenosum, ulceration), and urinary-tract infections. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Administration and dosage. Ticarcillin is given by injection as the sodium salt. Doses are expressed in terms of the equivalent amount of ticarcillin; 1.1 g of ticarcillin sodium is equivalent to about 1 g of ticarcillin. Doses may need to be reduced in renal impairment (see below).

Ticarcillin is given to adults and children in a dose of 200 to 300 mg/kg daily by intravenous infusion in divided doses every 4 or 6 hours.

In adults the use of probenecid 500 mg four times daily by mouth may produce higher and more prolonged plasma concentrations of ticarcillin, but caution is advised in patients with renal impairment.

In the treatment of complicated urinary-tract infections, adults and children may be given a dose of ticarcillin 150 to 200 mg/kg daily by intravenous infusion in divided doses every 4 or 6 hours. In uncomplicated urinary-tract infections, the usual adult dose is ticarcillin 1 g every 6 hours intramuscularly or by slow intravenous injection. Children with uncomplicated urinary-tract infections may be given 50 to 100 mg/kg daily in divided doses every 6 or 8 hours. Not more than 2 g of ticarcillin should be injected intramuscularly into one site.

In patients with cystic fibrosis, ticarcillin has been given by nebuliser in the management of respiratory-tract infections.

Ticarcillin is often used with an aminoglycoside but the injections must be given separately because of possible incompatibility.

Ticarcillin with clavulanic acid. Ticarcillin may be used with clavulanic acid (p.250), a beta-lactamase inhibitor, to widen its antibacterial spectrum to organisms usually resistant because of the production of beta-lactamases. This combination is given by intravenous infusion in a ratio of 15 or 30 parts of ticarcillin (as the sodium salt) to 1 part of clavulanic acid (as the potassium salt). Doses are according to the content of ticarcillin, and usual adult doses range from 9 to 18 g daily in 3 to 6 divided doses.

Administration in renal impairment. Doses of ticarcillin may need to be reduced in patients with renal impairment. After an initial intravenous loading dose of 3 g, the intravenous maintenance dosage should be adjusted according to the patient's creatinine clearance (CC):

- CC 30 to 60 mL/minute: 2 g every 4 hours
- CC 10 to 30 mL/minute: 2 g every 8 hours
- CC less than 10 mL/minute: 2 g every 12 hours (or 1 g intramuscularly every 6 hours)
- CC less than 10 mL/minute in presence of *hepatic impairment*: 2 g intravenously every 24 hours or 1 g intramuscularly every 12 hours
- peritoneal dialysis patients: 3 g every 12 hours
- haemodialysis patients: 2 g every 12 hours plus an additional dose of 3 g after each dialysis session

Preparations

USP 31: Ticarcillin and Clavulanic Acid for Injection; Ticarcillin and Clavulanic Acid Injection; Ticarcillin for Injection.

Proprietary Preparations (details are given in Part 3)
Fr.: Ticarpen; ***Neth.:*** Ticarpen; ***Spain:*** Ticarpen; ***USA:*** Ticar.

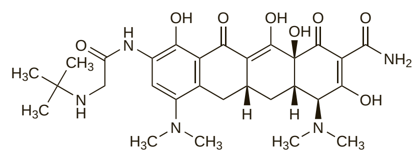
Tigecycline *(USAN, rINN)*

GAR-936; TBG-MINO; Tigeciclina; Tigécycline; Tigecyclinum; WAY-GAR-936. (4*S*,4a*S*,5a*R*,12a*S*)-9-[2-(*tert*-Butylamino)acetamido]-4,7-bis(dimethylamino)-1,4,4a,5,5a,6,11,12a-octahydro-3,10,12,12a-tetrahydroxy-1,11-dioxo-2-naphthacenecarboxamide.

Тигециклин

$C_{29}H_{39}N_5O_8$ = 585.6.
CAS — 220620-09-7.
ATC — J01AA12.
ATC Vet — QJ01AA12.



Stability and compatibility. Formulations of tigecycline without excipients should be used immediately after reconstitution; however, a pH-adjusted formulation with lactose monohydrate is available in the USA, and may be stored at room temperature for up to 24 hours after reconstitution (up to 6 hours in the vial and the remaining time in the infusion bag), or up to 45 hours at 2 to 8° after reconstitution and transfer to an infusion bag.

The latter formulation is compatible when given via a Y-site with amikacin, gentamicin, haloperidol, morphine, noradrenaline, piperacillin with tazobactam, propofol, and tobramycin; it is incompatible with diazepam. Both formulations are stated to be compatible with dobutamine, dopamine hydrochloride, lidocaine hydrochloride, potassium chloride, ranitidine hydrochloride, and theophylline, but are incompatible with amphotericin B. The excipient-free formulation should also not be given with chlorpromazine, methylprednisolone, or voriconazole.

Adverse Effects

Tigecycline is a glycylcycline antibacterial with structural similarity to the tetracyclines and adverse effects similar to those of tetracyclines may potentially occur (see p.347). The most common adverse effects associated with tigecycline have been nausea, vomiting, and diarrhoea. Other common adverse effects include abscess, abdominal pain, anorexia, dyspepsia, dizziness, headache, phlebitis, pruritus, and rash. Infection-related serious adverse events, including sepsis or septic shock have been reported; however, a causal relationship could not be established. Raised liver enzymes, bilirubinaemia, increased serum amylase, and increased blood urea nitrogen have also been reported. Local reactions have been reported at the infusion site and thrombocythaemia, anaemia, and leucocytosis may occur. Acute pancreatitis has been reported, usually after at least one week of treatment; symptoms generally resolve on stopping tigecycline. Potentially life-threatening anaphylaxis or anaphylactoid reactions have also been reported.

Precautions

Due to the potential for similar adverse effects, precautions applicable to the tetracyclines (see p.348) should be taken with tigecycline. In particular, tigecycline should not be given in pregnancy as it has caused fetal harm in *animal* studies. Distribution into milk has also been found in *animal* studies. It should also not be given during tooth development (up to 8 years of age) as it may cause permanent tooth discoloration. Caution should be exercised when using tigecycline as monotherapy in patients with complicated intra-abdominal infections secondary to intestinal perforation. Patients taking anticoagulants should be closely monitored as tigecycline may prolong both the prothrombin time and the activated partial thromboplastin time. Dosage of tigecycline should be adjusted in patients with severe hepatic impairment (see below).

Antimicrobial Action

Tigecycline is generally bacteriostatic and acts by binding to the 30S subunit of the ribosome and preventing the binding of aminoacyl transfer RNA, similarly to tetracyclines (see p.348). It has activity against a broad range of Gram-positive and Gram-negative bacteria, including tetracycline-resistant organisms, and some anaerobic organisms. Tigecycline has demonstrated activity both *in vitro* and in clinical infection with both meticillin-susceptible and meticillin-resistant *Staphylococcus aureus*, vancomycin-susceptible *Enterococcus faecalis*, and some streptococci. Gram-negative organisms that have proven susceptible include *Citrobacter freundii*, *Enterobacter cloacae*, *Escherichia coli*, and some *Klebsiella* spp. Tigecycline also has activity against some anaerobic bacteria including *Bacteroides fragilis* and some other *Bacteroides* spp., *Clostridium perfringens*, and *Peptostreptococcus micros*.

Pharmacokinetics

After intravenous doses tigecycline is widely distributed into the tissues. Binding to plasma proteins has been reported to be 71 to 89% *in vitro*. Tigecycline is not thought to be extensively metabolised, although some trace metabolites have been identified including a glucuronide, an *N*-acetyl metabolite, and a tigecycline epimer. Tigecycline is primarily eliminated (about 60%) via biliary excretion of unchanged drug and some metabolites with a reported half-life of about 42 hours after multiple doses. About 22% is excreted unchanged in the urine.

Uses and Administration

Tigecycline is a glycylcycline antibacterial used in adults for the intravenous treatment of complicated skin and skin structure infections or complicated intra-abdominal infections caused by susceptible organisms. It may also be given empirically. Tigecycline is given by intravenous infusion over 30 to 60 minutes in an initial loading dose of 100 mg followed by 50 mg every 12 hours. For details of reduced dosage to be given in severe hepatic impairment, see below.

10. Mullangi PK, Pankey GA. Tigecycline in critical care. *Crit Care Clin* 2008; **24:** 365–75.

Administration in hepatic impairment. Dosage of tigecycline should be adjusted in patients with severe hepatic impairment (Child-Pugh category C); the initial intravenous loading dose should be 100 mg with reduced maintenance doses of 25 mg every 12 hours.

CAS — 137330-13-3.

Profile

Tilmicosin is a macrolide antibacterial used as the base or the phosphate in veterinary medicine.

Adverse effects. Accidental self-injection of tilmicosin by a farm worker, resulting in asthenia and temporary pulmonary, gastrointestinal, and neuromuscular toxicity has been reported.[1] A review[2] of human exposures to tilmicosin injection reported between March 1992 and March 2005 suggested that the overall risk of serious adverse effects was about 2 cases per million doses. Serious cardiovascular adverse effects, including bradycardia, hypertension, hypotension, tachycardia, and tachypnoea, occurred in 156 of 3168 reported cases and, of these, fatalities occurred in 13.

CAS — 49842-07-1 ($C_{18}H_{37}N_5O_9,xH_2SO_4$); 79645-27-5 ($(C_{18}H_{37}N_5O_9)_2,5H_2SO_4$).
ATC — J01GB01; S01AA12.
ATC Vet — QJ01GB01; QS01AA12.

Pharmacopoeias. In *Pol.* and *US.*

USP 31 (Tobramycin Sulfate). It has a potency of not less than 634 micrograms and not more than 739 micrograms of tobramycin per mg. A 4% solution in water has a pH of 6.0 to 8.0. Store in airtight containers.

Incompatibility. For discussion of the incompatibility of aminoglycosides, including tobramycin, with beta lactams, see under Gentamicin Sulfate, p.282. Tobramycin is also reported to be incompatible with various other drugs and, as injections have an acid pH, incompatibility with alkaline preparations or with drugs unstable at acid pH may reasonably be expected.

Adverse Effects, Treatment, and Precautions

As for Gentamicin Sulfate, p.282. Some studies suggest that tobramycin is slightly less nephrotoxic than gentamicin, but others have not found any significant difference in their effects on the kidneys.

Peak plasma-tobramycin concentrations greater than 12 micrograms/mL (the *BNF* suggests 10 micrograms/mL) and trough concentrations greater than 2 micrograms/mL should be avoided.

When tobramycin is given by inhalation with other inhaled drugs, they should be given first before the dose of tobramycin. After the first inhaled dose of tobramycin, patients should be monitored for bronchospasm and if it occurs, the test should be repeated using a bronchodilator. Peak flow should be measured before nebulisation and again after it. Caution should be exercised in the presence of severe haemoptysis. Renal function should be monitored before treatment and every six months during use.

Effects on the ear. Reversible vestibular toxicity (ataxia, dizziness, and oscillopsia) occurred in a patient on haemodialysis after about 3 weeks' treatment with inhaled tobramycin for bronchiectasis due to colonisation with *Pseudomonas aeruginosa*.[1]

1. Edson RS, *et al.* Vestibular toxicity due to inhaled tobramycin in a patient with renal insufficiency. *Mayo Clin Proc* 2004; **79:** 1185–91.

Effects on the kidney. Irreversible acute renal failure requiring haemodialysis occurred in a high-risk patient with chronic renal failure after being treated for 4 weeks with inhaled tobramycin for *Pseudomonas aeruginosa* pneumonia.[1]

1. Cannella CA, Wilkinson ST. Acute renal failure associated with inhaled tobramycin. *Am J Health-Syst Pharm* 2006; **63:** 1858–61.

Effects on the liver. A case of possible tobramycin-induced hepatotoxicity was reported in a 20-year-old patient receiving antibacterial treatment for *Pseudomonas aeruginosa* bacteraemia and osteomyelitis. Liver enzyme values started to increase when empirical treatment was changed to intravenous tobramycin and ceftazidime, and markedly increased when the regimen was changed, increasing the dose of tobramycin and replacing ceftazidime with piperacillin/tazobactam and then later aztreonam. Enzyme values began to decrease after all treatment was stopped on day 12.[1]

1. Nisly SA, *et al.* Tobramycin-induced hepatotoxicity. *Ann Pharmacother* 2007; **41:** 2061–5.

Interactions

As for Gentamicin Sulfate, p.283.

Antimicrobial Action

As for Gentamicin Sulfate, p.283. Tobramycin is reported to be somewhat more active *in vitro* than gentamicin against *Pseudomonas aeruginosa* and less active against *Serratia*, staphylococci, and enterococci; however these differences do not necessarily translate into differences in clinical effectiveness.

Cross-resistance between tobramycin and gentamicin is generally seen, but about 10% of strains resistant to gentamicin are susceptible to tobramycin.

4. Shawar RM, *et al.* Activities of tobramycin and six other antibiotics against Pseudomonas aeruginosa isolates from patients with cystic fibrosis. *Antimicrob Agents Chemother* 1999; **43:** 2877–80.

Pharmacokinetics

As for Gentamicin Sulfate, p.284.

After intramuscular use of tobramycin, peak plasma concentrations are achieved within 30 to 90 minutes and concentrations of about 4 micrograms/mL have been reported following doses of 1 mg/kg. Usual doses by slow intravenous injection may result in plasma concentrations which briefly exceed 12 micrograms/mL. A plasma half-life of 2 to 3 hours has been reported. Sufficient tobramycin may be absorbed after inhalation to produce systemic adverse effects (see above).

Inhalation. References.

Uses and Administration

Tobramycin is an aminoglycoside antibiotic with actions and uses similar to those of gentamicin (p.284). It is used, usually as the sulfate, particularly in the treatment of pseudomonal infections.

As with gentamicin, tobramycin may be used with penicillins or cephalosporins; the injections should be given separately.

Doses of tobramycin sulfate are expressed in terms of tobramycin base; 1.5 g of tobramycin sulfate is equivalent to about 1 g of tobramycin. Doses are similar to those of gentamicin, with the usual adult dose ranging from 3 to 5 mg/kg daily in 3 or 4 divided doses. In patients with cystic fibrosis, doses of 8 to 10 mg/kg daily in divided doses may be necessary to achieve therapeutic plasma concentrations.

The usual dose for children is 6 to 7.5 mg/kg daily in 3 or 4 divided doses. Premature and full-term neonates may be given 2 mg/kg every 12 hours.

For mild to moderate urinary-tract infections in adults, a dose of 2 to 3 mg/kg once daily may be effective. As with some other aminoglycosides, once-daily dosage has been used successfully in selected patients for the treatment of other infections without increasing toxicity but local guidelines should be consulted for dosage and serum concentrations (see also Once-daily Dosage, under Gentamicin, p.285).

Tobramycin sulfate is given by intramuscular injection, or by intravenous infusion over 20 to 60 minutes in 50 to 100 mL of sodium chloride 0.9% or glucose 5% injection; proportionately less fluid should be given to children. It has also been given slowly by direct intravenous injection.

Treatment should generally be limited to 7 to 10 days, and peak plasma concentrations greater than 12 micrograms/mL (the *BNF* suggests 10 micrograms/mL) or trough concentrations greater than 2 micrograms/mL should be avoided. In all patients, dosage should be adjusted according to plasma-tobramycin concentrations and particularly where factors such as age, renal impairment, or prolonged therapy may predispose to toxicity (see Uses and Administration of Gentamicin Sulfate, p.284).

Tobramycin may be used as a 0.3% eye ointment or eye drops in the treatment of eye infections. It is also given by inhalation in patients with cystic fibrosis to control *Pseudomonas aeruginosa* infections in a dose of 300 mg every 12 hours for 28 days using a suitable nebuliser. Treatment is then stopped for 28 days before being resumed for another treatment period. This cycle may be repeated indefinitely.

CAS — 115964-29-9; 144742-63-2.

Profile

Tosufloxacin is a fluoroquinolone antibacterial with properties similar to those of ciprofloxacin (p.243). It is given orally as the tosilate in the treatment of susceptible infections in usual doses of 300 to 450 mg daily in 2 or 3 divided doses.

For blepharitis, conjunctivitis, corneal ulcers, and other eye infections caused by susceptible strains of bacteria, eye drops containing 0.3% of tosufloxacin tosilate are used.

NOTE. Compounded preparations of trimethoprim may be represented by the following names:

- Co-trifamole (*BAN*)—trimethoprim 1 part and sulfamoxole 5 parts (see p.257)
- Co-trimazine (*BAN*)—trimethoprim 1 part and sulfadiazine 5 parts (see p.258)
- Co-trimoxazole (*BAN*)—trimethoprim 1 part and sulfamethoxazole 5 parts (see p.258)
- Co-trimoxazole (*PEN*)—trimethoprim and sulfamethoxazole.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *US*, and *Viet.*

Ph. Eur. 6.2 (Trimethoprim). A white or yellowish-white powder. Very slightly soluble in water; slightly soluble in alcohol.

USP 31 (Trimethoprim). White to cream-coloured, odourless crystals or crystalline powder. Very slightly soluble in water; slightly soluble in alcohol and in acetone; soluble in benzyl alcohol; practically insoluble in carbon tetrachloride and in ether; sparingly soluble in chloroform and in methyl alcohol. Store in airtight containers. Protect from light.

Trimethoprim Sulfate *(USAN, rINNM)*

BW-72U; Sulfato de trimetoprima; Trimethoprim Sulphate *(BANM)*; Triméthoprime, Sulfate de; Trimethoprimi Sulfas; Trimetoprim Sülfat.

Триметоприма Сульфат

$(C_{14}H_{18}N_4O_3)_2.H_2SO_4$ = 678.7.
CAS — 56585-33-2.

Pharmacopoeias. In *Viet.* and *US.*

USP 31 (Trimethoprim Sulfate). A white to off-white crystalline powder. Soluble in water, in alcohol, in dilute mineral acids, and in fixed alkalis. pH of a 0.05% solution in water is between 7.5 and 8.5. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Incompatibility. UK licensed product information states that trimethoprim injections (containing the lactate) should not be mixed with solutions of sulfonamides because of incompatibility. Although a former such preparation stated that it should not be diluted in chloride-containing infusion solutions, because of the risk of precipitating trimethoprim hydrochloride, others are stated to be compatible with sodium chloride 0.9% and some other chloride-containing solutions including Ringer's solution. Injections are considered compatible with glucose 5% and with sodium lactate.

Adverse Effects and Treatment

Trimethoprim is reasonably well tolerated in general, and the most frequent adverse effects at usual doses are pruritus and skin rash (in about 3 to 7% of patients) and mild gastrointestinal disturbances including nausea, vomiting, and glossitis.

Rarely, more severe effects have been reported. Sulfonamide-like skin reactions including exfoliative dermatitis, erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis have occurred. Disturbances of liver enzyme values and cholestatic jaundice have been associated with trimethoprim. Rises in serum creatinine and blood-urea nitrogen have been reported although it is unclear whether this represents genuine renal dysfunction or inhibition of tubular secretion of creatinine. Photosensitivity has been reported. Fever is not uncommon but occasionally hypersensitivity reactions may be severe and anaphylaxis and angioedema have been reported. Cases of aseptic meningitis have also occurred.

Trimethoprim may cause a depression of haematopoiesis due to interference of the drug in the metabolism of folic acid, particularly when given over a prolonged period or in high doses. This may manifest as megaloblastic anaemia, or as thrombocytopenia and leucopenia; methaemoglobinaemia has also been seen. Calcium folinate 5 to 15 mg daily by mouth may be given to counter this effect. Trimethoprim is teratogenic in *animals*.

For further information on the adverse effects of trimethoprim when used with sulfamethoxazole, see Co-trimoxazole, p.258.

Effects on the eyes. There have been isolated reports of bilateral anterior uveitis associated with trimethoprim. In 2 such patients,[1,2] the reaction recurred upon rechallenge with trimethoprim. A third patient developed uveitis after co-trimoxazole, and subsequently uveitis with retinal haemorrhage following trimethoprim alone.[3]

1. Gilroy N, *et al.* Trimethoprim-induced aseptic meningitis and uveitis. *Lancet* 1997; **350:** 112.
2. Arola O, *et al.* Arthritis, uveitis, and Stevens-Johnson syndrome induced by trimethoprim. *Lancet* 1998; **351:** 1102.
3. Kristinsson JK, *et al.* Bilateral anterior uveitis and retinal haemorrhages after administration of trimethoprim. *Acta Ophthalmol Scand* 1997; **75:** 314–15.

Hyperkalaemia. Trimethoprim has been reported to induce hyperkalaemia,[1] particularly in HIV-infected patients being treated for pneumocystis pneumonia or in the elderly. The hyperkalaemia may be due to amiloride-like potassium-sparing properties of trimethoprim, and may be potentiated by ACE inhibitors.

1. Perazella MA. Trimethoprim-induced hyperkalaemia: clinical data, mechanism, prevention and management. *Drug Safety* 2000; **22:** 227–36.

Precautions

Trimethoprim should not be given to patients with a history of hypersensitivity to the drug, and it should be stopped if a skin rash appears. Care is necessary in giving trimethoprim to patients with renal impairment to avoid accumulation and toxicity: it should not be given in severe renal impairment unless blood concentrations can be monitored. It should be used with caution in patients with severe hepatic damage as changes may occur in the absorption and metabolism of trimethoprim.

It is suggested that regular haematological examination should be made during prolonged courses of treatment although the *BNF* considers evidence of their practical value to be unsatisfactory; patients or their carers should be told how to recognise signs of blood toxicity and should be advised to seek immediate medical attention if symptoms such as fever, sore throat, rash, mouth ulcers, purpura, bruising or bleeding develop. Trimethoprim should not usually be given to patients with serious haematological disorders and particularly not in megaloblastic anaemia secondary to folate depletion. Care should be taken in patients with actual, or possible, folate deficiency and use of folinic acid should be considered. Trimethoprim should be avoided during pregnancy. Elderly patients may be more susceptible to adverse effects and a lower dosage may be advisable.

Trimethoprim may interfere with some diagnostic tests, including serum-methotrexate assay where dihydrofolate reductase is used and the Jaffé reaction for creatinine.

For further information on precautions for trimethoprim given with sulfamethoxazole, see Co-trimoxazole, p.258.

Breast feeding. Trimethoprim appears in breast milk and the US licensed product information has stated that care is required when it is used in breast-feeding mothers.

The American Academy of Pediatrics considers trimethoprim, when given with sulfamethoxazole, to be compatible with breast feeding.[1]

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/05/04)

Fragile X syndrome. A warning that trimethoprim and other folate antagonists should be avoided in children with the fragile X chromosome which is associated with mental retardation and is folate sensitive.[1]

1. Hecht F, Glover TW. Antibiotics containing trimethoprim and the fragile X chromosome. *N Engl J Med* 1983; **308:** 285–6.

Porphyria. Trimethoprim has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

Trimethoprim may increase serum concentrations and potentiate the effect of a number of drugs, including phenytoin, digoxin, procainamide, rosiglitazone, and repaglinide. The effect may be due to competitive inhibition of renal excretion, decreased metabolism, or both. It has been suggested that trimethoprim may potentiate the effects of warfarin. Trimethoprim has been reported to reduce the renal excretion and increase blood concentrations of zidovudine, zalcitabine, and lamivudine. Trimethoprim and dapsone increase each other's serum concentrations, whereas rifampicin may decrease trimethoprim concentrations.

An increased risk of nephrotoxicity has been reported with the use of trimethoprim or co-trimoxazole and ciclosporin. Intravenous use of trimethoprim and sulfonamides may reduce ciclosporin concentrations in blood. Hyponatraemia has been reported in patients given trimethoprim with diuretics. An increased risk of thrombocytopenia has been seen in elderly patients given co-trimoxazole with diuretics, although it is unclear which component of the antibacterial is responsible.

Use of trimethoprim with other depressants of bone marrow function may increase the likelihood of myelosuppression, and there may be a particular risk of megaloblastic anaemia if it is given with other folate inhibitors, such as pyrimethamine or methotrexate.

Severe hyperkalaemia has been noted in patients given trimethoprim (or co-trimoxazole) together with an ACE inhibitor.

Antimicrobial Action

Trimethoprim is a dihydrofolate reductase inhibitor. It inhibits the conversion of bacterial dihydrofolic acid to tetrahydrofolic acid which is necessary for the synthesis of certain amino acids, purines, thymidine, and ultimately DNA. It acts in the same metabolic pathway as the sulfonamides. It exerts its selective action because of a far greater affinity for the bacterial than the mammalian enzyme. Trimethoprim may be bacteriostatic or bactericidal depending on growth conditions; pus, for example, may inhibit the action of trimethoprim because of the presence of thymine and thymidine.

Spectrum of activity. Trimethoprim is active against many Gram-negative and Gram-positive aerobes, as well as some protozoa. The following species are usually susceptible (but see also Resistance, below).

Many Gram-positive cocci are sensitive, including *Staphylococcus aureus*, streptococci including *Streptococcus pyogenes*, *Str. pneumoniae*, and the viridans streptococci, and to a variable extent enterococci, although their sensitivity is reduced in the presence of folate.

Other sensitive Gram-positive organisms include strains of *Listeria*, *Corynebacterium diphtheriae*, and the Gram-positive bacilli.

Among the Gram-negative organisms, most of the Enterobacteriaceae are susceptible, or moderately so, including *Citrobacter*, *Enterobacter*, *Escherichia coli*, *Hafnia*, *Klebsiella*, *Proteus mirabilis*, *Providencia*, *Salmonella*, some *Serratia*, *Shigella*, and *Yersinia*. *Legionella* and *Vibrio* are also sensitive, and so are *Haemophilus influenzae* and *H. ducreyi*.

Anaerobic species are usually resistant, and so, to varying degrees are *Brucella*, *Neisseria*, and *Nocardia*. *Mycobacterium tuberculosis* is resistant although *M. marinum* may not be. *Pseudomonas aeruginosa* is resistant, and so are the Chlamydiaceae, Mycoplasma spp., and Rickettsia spp., as well as the spirochaetes.

Trimethoprim has some activity against *Pneumocystis jirovecii* and against some protozoa such as *Naegleria*, *Plasmodium*, and *Toxoplasma*.

Activity with other antimicrobials. Because their modes of action are complementary, affecting different stages in folate metabolism, a potent synergistic effect exists between trimethoprim and sulfonamides against many organisms *in vitro*.

Fixed-dose combinations of trimethoprim with various sulfonamides are available, of which co-trimoxazole (trimethoprim with sulfamethoxazole in a 1:5 mixture) is the most widely used. For further details on the antimicrobial action of co-trimoxazole, see p.259.

Synergy has also been reported with rifampicin, and with the polymyxins.

Resistance. Resistance to trimethoprim may be due to several mechanisms. Clinical resistance is often due to plasmid-mediated dihydrofolate reductases that are resistant to trimethoprim: such genes may become incorporated into the chromosome via transposons. Resistance may also be due to overproduction of dihydrofolate reductase, changes in cell permeability, or bacterial mutants which are intrinsically resistant to trimethoprim because they depend on exogenous thymine and thymidine for growth. Despite fears of a rapid increase in resistance if trimethoprim was used alone there is little evidence that this has been any worse than in areas where it has been used in combination with sulfonamides. Nonetheless, trimethoprim resistance has been reported in many species, and very high frequencies of resistance have been seen in some developing countries, particularly among the Enterobacteriaceae.

Pharmacokinetics

Trimethoprim is rapidly and almost completely absorbed from the gastrointestinal tract and peak concentrations in the circulation occur about 1 to 4 hours after an oral dose; peak plasma concentrations of about 1 microgram/mL have been reported after a single dose of 100 mg. About 45% is bound to plasma proteins. Trimethoprim is widely distributed to various tissues and fluids including kidneys, liver, lung and bronchial secretions, saliva, aqueous humour, prostatic tissue and fluid, and vaginal secretions; concentrations in many of these tissues are reported to be higher than serum concentrations but concentrations in the CSF are about one-quarter to one-half of those in serum. Trimethoprim readily crosses the placenta and it appears in breast milk. The half-life is about 8 to 10 hours in adults and somewhat less in children, but is prolonged in severe renal impairment and in neonates, whose renal function is immature.

Trimethoprim is excreted primarily by the kidneys through glomerular filtration and tubular secretion. About 10 to 20% of trimethoprim is metabolised in the liver and small amounts are excreted in the faeces via the bile, but most, about 40 to 60% of a dose, is excreted in urine, predominantly as unchanged drug, within 24 hours. Trimethoprim is removed from the blood by haemodialysis to some extent.

Uses and Administration

Trimethoprim is a diaminopyrimidine antibacterial that is used for the treatment of infections due to sensitive organisms, including gastro-enteritis and respiratory-tract infections, and in particular for the treatment and prophylaxis of urinary-tract infections. For details of these infections and their treatment, see Choice of Antibacterial, p.162.

Trimethoprim is also used with sulfonamides. The most common combination is co-trimoxazole (trimethoprim with sulfamethoxazole) (p.258). Other combinations are co-trimazine (with sulfadiazine) and co-trifamole (with sulfamoxole); trimethoprim has also been used with sulfamerazine, sulfametopyrazine, sulfametrole, and sulfamethoxypyridazine, and, in veterinary practice, with sulfadoxine, sulfaquinoxaline, sulfatroxazole, sulfadimethoxine, sulfadimidine, or sulfafurazole.

Trimethoprim with sulfamethoxazole (co-trimoxazole) or with dapsone is used in the management of pneumocystis pneumonia (p.521).

The usual adult oral dose of trimethoprim in acute infection is 100 or 200 mg twice daily; doses of 200 or 300 mg daily as a single dose are also used. For the dosage of trimethoprim when given with sulfamethoxazole, see under Co-trimoxazole, p.259. Up to 20 mg/kg daily may be given in combination with dapsone for the treatment of pneumocystis pneumonia.

Children may be given 6 to 8 mg/kg daily of trimethoprim in 2 divided doses: regimens for children are, 6 to 12 years, 100 mg twice daily; 6 months to 5 years, 50 mg twice daily; 6 weeks to 5 months, 25 mg twice daily.

For long-term prophylaxis the usual dose is 100 mg at night for adults; children aged 6 to 12 years may be given 50 mg at night and those aged 6 months to 5 years, 25 mg at night. Alternatively, children may be given a dose of 1 to 2 mg/kg at night.

Trimethoprim is also given intravenously by injection or infusion as the lactate although doses are in terms of the base. The usual dose is 200 mg every 12 hours in adults; children may be given 8 mg/kg daily in 2 or 3 divided doses. Initial doses may be higher or given more frequently in severely ill patients.

Care should be taken in patients with moderate to severe renal impairment and doses generally should be reduced (see below).

Trimethoprim with polymyxin B has been used topically in the treatment and prophylaxis of eye infections. Trimethoprim sulfate and trimethoprim hydrochloride are also used.

Administration. *SINGLE-DOSE THERAPY.* Although there are obvious advantages to a single-dose regimen, one study[1] found that there was about a 1 in 4 risk of recurrence of urinary-tract infection within 10 days in 50 children given, according to age, a single dose of 75 to 450 mg of trimethoprim. The problems with a single-dose regimen were confirmed by others[2] in a study involving 344 evaluated cases of cystitis in 306 women. Only 122 of 173 cases treated with trimethoprim 320 mg as a single dose were evaluated as cured after 5 weeks, compared with 149 of 171 given 160 mg twice daily for 1 week (71 versus 87%). Again, these results suggest that about 1 patient in 4 would have to be re-treated.

1. Nolan T, *et al.* Single dose trimethoprim for urinary tract infection. *Arch Dis Child* 1989; **64:** 581–6.
2. Österberg E, *et al.* Efficacy of single-dose versus seven-day trimethoprim treatment of cystitis in women: a randomized double-blind study. *J Infect Dis* 1990; **161:** 942–7.

Administration in renal impairment. Doses of trimethoprim should generally be reduced in patients with moderate to severe renal impairment according to creatinine clearance (CC):

- CC 15 to 27 mL/minute: normal dose for 3 days reduced to one-half thereafter
- CC below 15 mL/minute: half the normal dose from the start of treatment

Plasma concentrations should be monitored in patients with severe renal impairment.

Troleandomycin *(BAN, USAN, rINN)*

NSC-108166; Triacetyloleandomycin; Troleandomicina; Troleandomisin; Troléandomycine; Troleandomycinum; Troleandomysiini. The triacetyl ester of oleandomycin .

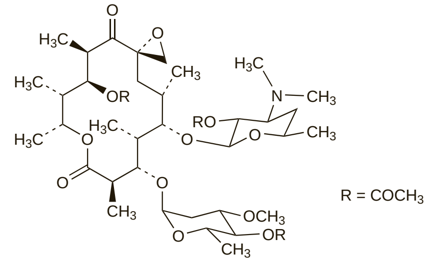
Тролеандомицин

$C_{41}H_{67}NO_{15}$ = 814.0.

CAS — 2751-09-9.

ATC — J01FA08.

ATC Vet — QJ01FA08.



Pharmacopoeias. In *Fr.* and *US.*

USP 31 (Troleandomycin). A white, odourless, crystalline powder. It contains the equivalent of not less than 750 micrograms of oleandomycin per mg. Slightly soluble in water and in ether; freely soluble in alcohol; soluble in chloroform. A 10% solution in alcohol and water (1:1) has a pH of 7.0 to 8.5. Store in airtight containers.

Profile

Troleandomycin is a prodrug of the macrolide antibacterial oleandomycin that has actions similar to those of erythromycin (p.269). It has been given orally in the treatment of susceptible infections although more effective antibacterials are generally preferred.

Preparations

USP 31: Troleandomycin Capsules.

Proprietary Preparations (details are given in Part 3)
Ital.: Triocetin†; ***Turk.:*** Tekmisin; ***USA:*** TAO†.

Trospectomycin Sulfate *(USAN, rINNM)*

Sulfato de trospectomicina; Trospectomycin Sulphate *(BANM)*; Trospectomycine, Sulfate de; Trospectomycini Sulfas; U-63366 (trospectomycin); U-63366F. (2*R*,4a*R*,5a*R*,6*S*,7*S*,8*R*,9*S*,9a*R*,10a*S*)-2-Butyl-4a,7,9-trihydroxy-6,8-bis(methylamino)perhydropyrano[2,3-*b*][1,4]benzodioxin-4-one sulphate pentahydrate.

Тросопектомицина Сульфат

$C_{17}H_{30}N_2O_7,H_2SO_4,5H_2O$ = 562.6.

CAS — 88669-04-9 (trospectomycin); 88851-61-0 (trospectomycin sulfate).

Profile

Trospectomycin is a water-soluble derivative of spectinomycin (p.332) but is more active against Gram-positive organisms, *Haemophilus influenzae*, and *Chlamydia trachomatis* as well as *Neisseria*. It has been investigated in various infections and given as the sulfate intravenously or intramuscularly. Reported adverse effects include perioral paraesthesia, pain at the injection site, nausea, and dizziness.

Trovafloxacin Mesilate *(rINNM)*

CP-99219-27; CP-99219 (trovafloxacin); Mesilato de trovafloxacino; Trovafloxacin Mesylate *(USAN)*; Trovafloxacine, Mésilate de; Trovafloxacini Mesilas. 7-[(1*R*,5*S*,6*S*)-6-Amino-3-azabicyclo[3.1.0]hex-3-yl]-1-(2,4-difluorophenyl)-6-fluoro-1,4-dihydro-4-oxo-1,8-naphthyridine-3-carboxylic acid monomethanesulphonate.

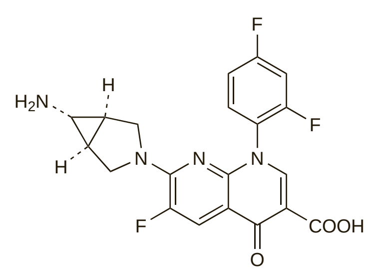
Тровафлоксацина Мезилат

$C_{20}H_{15}F_3N_4O_3,CH_4O_3S$ = 512.5.

CAS — 147059-72-1 (trovafloxacin); 147059-75-4 (trovafloxacin mesilate).

ATC — J01MA13.

ATC Vet — QJ01MA13.



(trovafloxacin)

Adverse Effects and Precautions

As for Ciprofloxacin, p.244.

Dizziness was the most common adverse effect reported with trovafloxacin.

Trovafloxacin preparations have been withdrawn worldwide after reports of unpredictable severe hepatic adverse effects, including some fatalities. Symptomatic pancreatitis was also reported.

Antimicrobial Action

As for Ciprofloxacin, p.246. It is more active against pneumococci.

Pharmacokinetics

Trovafloxacin is readily absorbed from the gastrointestinal tract after an oral dose, peak plasma concentrations occurring after about 1 to 2 hours. After intravenous use, alatrofloxacin is rapidly converted to trovafloxacin. Oral bioavailability is 88%. Trovafloxacin is widely distributed into body tissues and is about 76% bound to plasma proteins. It appears in breast milk.

The serum half-life of trovafloxacin ranges from about 9 to 12 hours. Trovafloxacin is metabolised by conjugation, 13% of a dose appearing in the urine as the glucuronide and 9% in the faeces as the *N*-acetyl metabolite; other metabolites appear in both the urine and faeces in minor amounts, but about 50% of an oral dose is excreted unchanged, mainly in the faeces but also in the urine.

Uses and Administration

Trovafloxacin is a fluoroquinolone antibacterial with actions and uses similar to those of ciprofloxacin (p.247). It was given orally as the mesilate for the treatment of susceptible infections. The prodrug alatrofloxacin (p.200) was used as the mesilate for intravenous infusion.

Trovafloxacin and alatrofloxacin preparations have been withdrawn worldwide after reports of unpredictable severe hepatic adverse effects, including some fatalities.

Preparations

Proprietary Preparations (details are given in Part 3)
Canad.: Trovan†; ***Gr.:*** Trovan†; ***Mex.:*** Trovan†; ***USA:*** Trovan†.

Tulathromycin *(USAN, rINN)*

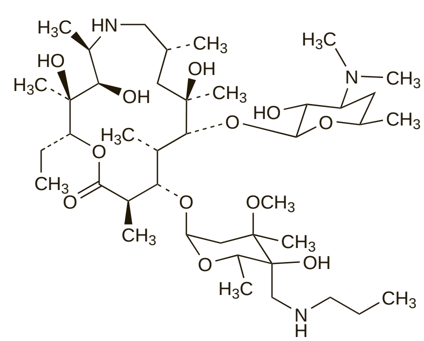
CP-472295 (component A); CP-547272 (component B); Tulathromycine; Tulathromycinum; Tulatromicina.

Тулатромицин

$C_{41}H_{79}N_3O_{12}$ = 806.1.

CAS — 217500-96-4 (component A); 280755-12-6 (component B).

ATC Vet — QJ01FA94.



(tulathromycin A)

Profile

Tulathromycin is a macrolide antibacterial used in veterinary medicine for the treatment of susceptible infections in cattle and pigs.

Tylosin *(BAN, rINN)*

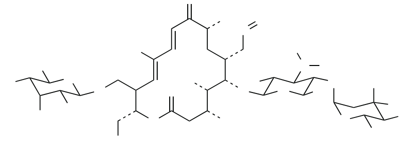
Tilosina; Tilozin; Tylosiini; Tylosine; Tylosinum; Tylozyna.

Тилозин

$C_{46}H_{77}NO_{17}$ = 916.1.

CAS — 1401-69-0.

ATC Vet — QJ01FA90; QJ51FA90.



(tylosin A)

The symbol † denotes a preparation no longer actively marketed

Pharmacopoeias. In *Eur.* (see p.vii) and *US*, both for veterinary use.

Ph. Eur. 6.2 (Tylosin for Veterinary Use; Tylosin BP 2008; Tylosin BP(Vet) 2008). A mixture of macrolide antibiotics produced by a strain of *Streptomyces fradiae* or by any other means. The main component of the mixture is tylosin A, but tylosin B (desmycosin), tylosin C (macrocin), and tylosin D (relomycin) may also be present. An almost white or slightly yellow powder. Slightly soluble in water; freely soluble in dehydrated alcohol and in dichloromethane. It dissolves in dilute solutions of mineral acids. A 2.5% suspension in water has a pH of 8.5 to 10.5. Protect from light.

USP 31 (Tylosin). A macrolide antibiotic substance or mixture of such substances produced by the growth of *Streptomyces fradiae* or by any other means. A white to buff-coloured powder. Slightly soluble in water; soluble in alcohol, in amyl acetate, in chloroform, and in dilute mineral acids; freely soluble in methyl alcohol. It loses not more than 5% of its weight on drying. Protect from light, moisture, and temperatures exceeding 40°.

Tylosin Tartrate *(BANM, rINNM)*

Tartrato de tilosina; Tilozin-tartarát; Tylosiinitartraatti; Tylosin tartarát; Tylosine, tartrate de; Tylosini tartras; Tylosintartrat; Tylozyny winian.

Тилозина Тартрат

$(C_{46}H_{77}NO_{17})_2,C_4H_6O_6$ = 1982.3.

CAS — 1405-54-5.

Pharmacopoeias. In *Eur.* (see p.vii) and *US* for veterinary use.

Ph. Eur. 6.2 (Tylosin Tartrate for Veterinary Use; Tylosin Tartrate BP 2008; Tylosin Tartrate BP(Vet) 2008). An almost white or slightly yellow hygroscopic powder. Freely soluble in water and in dichloromethane; slightly soluble in dehydrated alcohol. It dissolves in dilute solutions of mineral acids. A 2.5% solution in water has a pH of 5.0 to 7.2. Store in airtight containers. Protect from light.

USP 31 (Tylosin Tartrate). A tartrate of a mixture of macrolide antibiotic substances, or the mixture of such substances, produced by the growth of *Streptomyces fradiae*, or by any other means. Its potency is not less than 800 micrograms of tylosin per mg, calculated on the dried basis.

An almost white or slightly yellow, hygroscopic powder. Freely soluble in water and in dichloromethane; slightly soluble in alcohol. It dissolves in dilute solutions of mineral acids. pH of a 2.5% solution in water is between 5.0 and 7.2. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Profile

Tylosin is a macrolide antibacterial with actions similar to those of erythromycin (p.269). Tylosin and its phosphate and tartrate salts are used in veterinary medicine in the prophylaxis and treatment of infections caused by susceptible organisms.

Tylosin and tylosin phosphate have been added to animal feeding stuffs as growth promotors for pigs.

Tylvalosin Tartrate *(USAN, rINNM)*

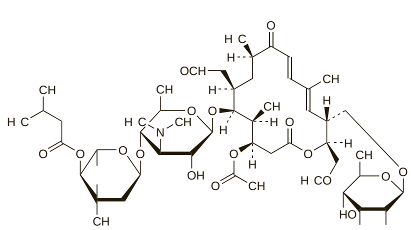
Acetyl Isovaleryl Tylosin Tartrate; Acetylisovaleryltylosin Tartrate; Tartrato de tilvalosina; Tylvalosine, Tartrate de; Tylvalosini Tartras. (4*R*,5*S*,6*S*,7*R*,9*R*,11*E*,13*E*,15*R*,16*R*)-15-{[(6-Deoxy-2,3-di-*O*-methyl-β-*D*-allopyranosyl)oxy]methyl}-6-({3,6-dideoxy-4-*O*-[2,6-dideoxy-3-*C*-methyl-4-*O*-(3-methylbutanoyl)-α-L-*ribo*-hexopyranosyl]-3-(dimethylamino)-β-D-glucopyranosyl}oxy)-16-ethyl-5,9,13-trimethyl-2,10-dioxo-7-(2-oxoethyl)oxacyclohexadeca-11,13-dien-4-yl acetate (2*R*,3*R*)-2,3-dihydroxybutanedioate.

Тильвалозина Тартрат

$C_{53}H_{87}NO_{19},xC_4H_6O_6$.

CAS — 63409-12-1 (tylvalosin); 63428-13-7 (tylvalosin tartrate).

ATC Vet — QJ01FA92.



(tylvalosin)

Profile

Tylvalosin is a derivative of tylosin (p.357) and is used similarly as the tartrate in veterinary medicine.

Tyrothricin *(BAN, rINN)*

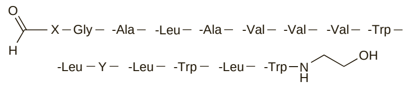
Tirotricina; Tirotricinas; Tirotrisin; Tyrothricine; Tyrothricinum; Tyrotricin; Tyrotrisiini.

Тиротрицин

CAS — 1404-88-2.

ATC — D06AX08; R02AB02; S01AA05.

ATC Vet — QD06AX08; QR02AB02; QS01AA05.



Gramicidin	Mol. Formula	X	Y
A1	C H N O	-Val	-Trp
A2	C H N O	-Ile	-Trp
C1	C H N O	-Val	-Tyr
C2	C H N O	-Ile	-Tyr

Tyrocidin	Mol. Formula	X	Y	Z
A	C H N O	-Phe	-Phe	-Tyr
B	C H N O	-Trp	-Phe	-Tyr
C	C H N O	-Trp	-Trp	-Tyr
D	C H N O	-Trp	-Trp	-Trp
E	C H N O	-Phe	-Phe	-Phe

Pharmacopoeias. In *Eur.* (see p.vii) and *US*.

Ph. Eur. 6.2 (Tyrothricin). A mixture of antimicrobial linear and cyclic polypeptides, isolated from the fermentation broth of *Bacillus brevis*. It consists mainly of gramicidins and tyrocidins; other related compounds may be present in smaller amounts. The potency is 180 to 280 international units/mg, calculated with reference to the dried substance. A white or almost white powder. Practically insoluble in water; soluble in alcohol and in methyl alcohol. Store in airtight containers. Protect from light.

USP 31 (Tyrothricin). An antibacterial substance produced by the growth of *Bacillus brevis*. It is a mixture consisting chiefly of gramicidin and tyrocidine, the latter being usually present as the hydrochloride. Store in airtight containers.

Adverse Effects and Precautions

Tyrothricin is too toxic to be used systemically; effects that have been reported include hepatic and renal toxicity as well as Stevens-Johnson syndrome. It damages the sensory epithelium of the nose and instances of prolonged loss of smell have occurred after its use as a nasal spray or instillation. Tyrothricin should not be instilled into the nasal cavities or into closed body cavities.

Uses and Administration

Tyrothricin is unsuitable for systemic use. It is active *in vitro* against many Gram-positive bacteria and has been used either alone or with other antibacterials in the local treatment of infections mainly of the skin and mouth.

Valnemulin *(BAN, rINN)*

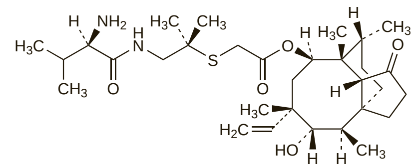
Valnemuliini; Valnemulina; Valnémuline; Valnemulinum. ({2-[(*R*)-2-Amino-3-methylbutyramido]-1,1-dimethylethyl}thio)acetic acid 8-ester with (3a*S*,4*R*,5*S*,6*S*,8*R*,9*R*,9a*R*,10*R*)-octahydro-5,8-dihydroxy-4,6,9,10-tetramethyl-6-vinyl-3a,9-propano-3a*H*-cyclopentacycloocten-1(4*H*)-one.

Вальнемулин

$C_{31}H_{52}N_2O_5S$ = 564.8.

CAS — 101312-92-9 (valnemulin); 133868-46-9 (valnemulin hydrochloride).

ATC Vet — QJ01XQ02.



Pharmacopoeias. *Eur.* (see p.vii) includes the hydrochloride for veterinary use.

Profile

Valnemulin is an antibacterial used as the hydrochloride in veterinary medicine.

Vancomycin *(BAN, rINN)*

Vancomicina; Vancomycine; Vancomycinum; Vankomycin; Vankomysiini. (S_a)-(3*S*,6*R*,7*R*,22*R*,23*S*,26*S*,36*R*,38a*R*)-44-{[2-*O*-(3-Amino-2,3,6-trideoxy-3-*C*-methyl-α-L-*lyxo*-hexopyranosyl)-β-D-glucopyranosyl]oxy}-3-(carbamoylmethyl)-10,19-dichloro-2,3,4,5,6,7,23,24,25,26,36,37,38,38a-tetradecahydro-7,22,28,30,32-pentahydroxy-6-[(2*R*)-4-methyl-2-(methylamino)valeramido]-2,5,24,38,39-pentaoxo-22*H*-8,11:18,21-dietheno-23,36-(iminomethano)-13,16:31,35-dimetheno-1*H*,16*H*-[1,6,9]oxadiazacyclohexadecino[4,5-*m*][10,2,16]-benzoxadiazacyclotetracosine-26-carboxylic acid.

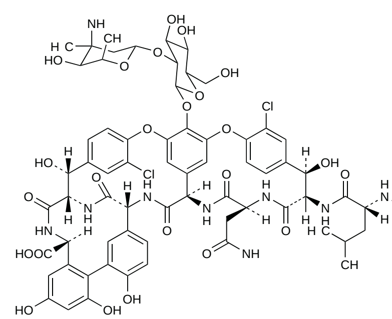
Ванкомицин

$C_{66}H_{75}Cl_2N_9O_{24}$ = 1449.3.

CAS — 1404-90-6.

ATC — A07AA09; J01XA01.

ATC Vet — QA07AA09; QJ01XA01.



Description. A glycopeptide antimicrobial substance or mixture of glycopeptides produced by the growth of certain strains of *Amycolatopsis orientalis* (*Nocardia orientalis*, *Streptomyces orientalis*), or by any other means.

Pharmacopoeias. In *US*.

USP 31 (Vancomycin). Store in airtight containers.

Vancomycin Hydrochloride *(BANM, rINNM)*

Hidrocloruro de vancomicina; Vancomycine, chlorhydrate de; Vancomycin-hydrochlorid; Vancomycini hydrochloridum; Vankomicinhidroklorid; Vankomicino hidrochloridas; Vankomisin Hidroklorür; Vankomycinhydroklorid; Vankomysiinihydrokloridi; Wankomycyny chlorowodorek.

Ванкомицина Гидрохлорид

$C_{66}H_{75}Cl_2N_9O_{24},HCl$ = 1485.7.

CAS — 1404-93-9.

ATC — A07AA09; J01XA01.

ATC Vet — QA07AA09; QJ01XA01.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US*.

Ph. Eur. 6.2 (Vancomycin Hydrochloride). A mixture of related glycopeptides, consisting principally of vancomycin B, a substance produced by certain strains of *Amycolatopsis orientalis* or obtained by any other means. A white or almost white, hygroscopic powder. Freely soluble in water; slightly soluble in alcohol. A 5% solution in water has a pH of 2.5 to 4.5. Store in airtight containers. Protect from light.

USP 31 (Vancomycin Hydrochloride). A substance or mixture of substances produced by the growth of *Streptomyces orientalis*. A tan to brown, odourless, free-flowing powder. Freely soluble in water; insoluble in chloroform and in ether. A 5% solution in water has a pH of 2.5 to 4.5. Store in airtight containers.

Incompatibility. Solutions of vancomycin hydrochloride have an acid pH and incompatibility may reasonably be expected with alkaline preparations, or with drugs unstable at low pH. Reports of incompatibility are not always consistent, and other factors such as the strength of solution, and composition of the vehicles used, may play a part.

Stability. Although licensed product information recommends storage at 2° to 8°, solutions of vancomycin hydrochloride in various diluents (sodium chloride 0.9%, glucose 5%, and peritoneal dialysis solution) have been found to be stable for at least 14 days at room temperature.[1-3]

The stability of vancomycin in ophthalmic solution has also been studied.[4]

1. Das Gupta V, *et al.* Stability of vancomycin hydrochloride in 5% dextrose and 0.9% sodium chloride injections. *Am J Hosp Pharm* 1986; **43:** 1729–31.
2. Walker SE, Birkhans B. Stability of intravenous vancomycin. *Can J Hosp Pharm* 1988; **41:** 233–8.
3. Mauhinuey WM, *et al.* Stability of vancomycin hydrochloride in peritoneal dialysis solution. *Am J Hosp Pharm* 1992; **49:** 137–9.
4. Fuhrman LC, Stroman RT. Stability of vancomycin in an extemporaneously compounded ophthalmic solution. *Am J Health-Syst Pharm* 1998; **55:** 1386–8.

Adverse Effects

The intravenous use of vancomycin may be associated with the so-called 'red-neck' or 'red-man' syndrome, characterised by erythema, flushing, or rash over the face and upper torso, and sometimes by hypotension and shock-like symptoms. The effect appears to be due in part to the release of histamine and is usually related to rapid infusion.

Hypersensitivity reactions may occur in about 5% of patients and include rashes, fever, chills, and rarely, anaphylactoid reactions, exfoliative dermatitis, Stevens-Johnson syndrome, toxic epidermal necrolysis, and vasculitis. Many reactions have become less frequent with the availability of more highly purified preparations. Reversible neutropenia, eosinophilia, and rarely thrombocytopenia and agranulocytosis have been reported; neutropenia is stated to be more common in patients who have received a total dose of 25 g or more. Nephrotoxicity, including rare cases of interstitial nephritis, may occur, particularly at high doses or in patients with predisposing factors, but has declined in frequency with greater awareness of the problem and appropriate monitoring of plasma concentrations and renal function.

Ototoxicity is also associated with vancomycin, and is more likely in patients with high plasma concentrations, or with renal impairment or pre-existing hearing loss.. It may progress after drug withdrawal, and may be irreversible. Hearing loss may be preceded by tinnitus, which must be regarded as a sign to stop treatment.

Vancomycin is irritant; intravenous use may be associated with thrombophlebitis, although this can be minimised by the slow infusion of dilute solutions, and by using different infusion sites. Extravasation may cause tissue necrosis.

Because of its poor absorption, relatively few adverse effects have been reported after the oral use of vancomycin, although mild gastrointestinal disturbances have occurred.

Effects on the ears. Reviews[1,2] of ototoxicity associated with vancomycin therapy have indicated that the actual number of cases is quite small, and close examination suggests that in most cases where hearing loss occurred patients had also received an aminoglycoside. The degree, and the reversibility, of ototoxicity associated with vancomycin alone is uncertain.

2. Brummett RE, Fox KE. Vancomycin- and erythromycin-induced hearing loss in humans. *Antimicrob Agents Chemother* 1989; **33:** 791–6.

Effects on the gastrointestinal tract. A 25-year-old woman developed *Clostridium difficile* colitis after a course of vancomycin and metronidazole, both orally, for pelvic inflammatory disease.[1] The condition resolved after treatment with vancomycin given alone.

1. Bingley PJ, Harding GM. Clostridium difficile colitis following treatment with metronidazole and vancomycin. *Postgrad Med J* 1987; **63:** 993–4.

Effects on the heart. A report[1] of cardiac arrest associated with an inadvertent rapid intravenous dose of vancomycin 150 mg in a neonate.

1. Boussemart T, *et al.* Cardiac arrest associated with vancomycin in a neonate. *Arch Dis Child* 1995; **73:** F123.

Effects on the kidneys. In a study,[1] nephrotoxicity was seen in 14 of 101 patients assigned to vancomycin 1 g before and after vascular surgery for infection prophylaxis compared with 2 of 99 assigned to saline placebo, suggesting that even short regimens of vancomycin can affect renal function. In another study involving 224 patients, nephrotoxicity was seen in 8 of 168 given vancomycin alone, 14 of 63 given vancomycin with an aminoglycoside, and 11 of 103 given an aminoglycoside without vancomycin.[2] This latter study found that use with aminoglycosides, trough serum concentrations of vancomycin greater than 10 micrograms/mL, and prolonged vancomycin therapy (for more than 21 days) were associated with an increased risk of nephrotoxicity. In both studies nephrotoxicity was defined in terms of increased serum creatinine.

2. Rybak MJ, *et al.* Nephrotoxicity of vancomycin, alone and with an aminoglycoside. *J Antimicrob Chemother* 1990; **25:** 679–87.

Effects on the liver. A 57-year-old man with multiple medical conditions developed raised liver enzyme values, on 5 different occasions, while being treated with oral vancomycin for episodes of *Clostridium difficile*-associated enterocolitis; liver enzymes returned to normal values each time the vancomycin was stopped.[1]

1. Cadle RM, *et al.* Vancomycin-induced elevation of liver enzyme levels. *Ann Pharmacother* 2006; **40:** 1186–9.

Effects on the nervous system. Reports of encephalopathy[1] (associated with high CSF concentrations after oral doses) and peripheral neuropathy[2] associated with vancomycin.

2. Leibowitz G, *et al.* Mononeuritis multiplex associated with prolonged vancomycin treatment. *BMJ* 1990; **300:** 1344.

Effects on the skin. Rashes, erythema, or pruritus are the most common skin reactions associated with vancomycin but there have also been reports of linear IgA dermatosis,[1-4] Stevens-Johnson-like reaction,[5] bullous eruption,[6] local skin necrosis,[7] and exfoliative dermatitis.[6] In an analysis, risk factors for adverse cutaneous reactions were suggested to be age under 40 years and duration of therapy greater than 7 days.[6]

Red-man syndrome. References[1-3] to the 'red-man syndrome', and evidence that pretreatment with an antihistamine can provide significant protection against it.[4,5] Similar reactions appear to be much less of a problem with teicoplanin and substitution of teicoplanin for vancomycin may be a viable alternative in patients at risk.[2,3,6] Skin tests are reported[7] to be of little value in predicting the severity of 'red-man syndrome'.

Precautions

Vancomycin should not be given to patients who have experienced a hypersensitivity reaction to it. It should not be given intramuscularly, and care should be taken when it is given intravenously to avoid extravasation, because of the risk of tissue necrosis. The adverse effects of infusion may be minimised by dilution of each 500 mg of vancomycin in at least 100 mL of fluid, and by infusion of doses over not less than 60 minutes.

Because the risk of ototoxicity and nephrotoxicity is thought to be increased at high plasma concentrations it may be desirable to adjust dosage requirements according to plasma-vancomycin concentrations. It has been suggested that dosage should be adjusted to avoid peak plasma concentrations above 30 to 40 micrograms/mL and trough concentrations exceeding 10 micrograms/mL, although uncertainty about the optimum methods and sampling times for monitoring, as well as some uncertainty about the degree of risk, means that there is less general agreement than for the aminoglycosides. It is generally agreed, however, that vancomycin should be avoided in patients with a history of impaired hearing and that particular care is necessary in patients with renal impairment, in neonates (especially if premature), and in the elderly, all of whom may be at increased risk of toxicity. Renal function and blood counts should be monitored regularly in all patients, and monitoring of auditory function is advisable, especially in high-risk patients. Vancomycin should be stopped in patients who develop tinnitus.

Since vancomycin is poorly absorbed, toxicity is much less of a problem after oral use than with the intravenous route, but care is required in patients with inflammatory gastrointestinal disorders, including antibiotic-associated colitis, in whom absorption may be enhanced.

Interactions

Other ototoxic or nephrotoxic drugs, such as aminoglycosides, polymyxins, cisplatin, and loop diuretics, markedly increase the risk of toxicity and should be given with vancomycin only with great caution.

Some of the adverse effects of vancomycin may be enhanced by the use of general anaesthetics; it has been suggested that, where patients require both, vancomycin infusions should be completed before the induction of anaesthesia.

Vancomycin may increase neuromuscular blockade produced by drugs such as suxamethonium or vecuronium.

Antimicrobial Action

Vancomycin is a glycopeptide antibiotic with a primarily bactericidal action against a variety of Gram-positive bacteria.

Mechanism of action. Vancomycin exerts its action by inhibiting the formation of the peptidoglycan polymers of the bacterial cell wall. Unlike penicillins, which act primarily to prevent the cross-linking of peptidoglycans which gives the cell wall its strength, vancomycin prevents the transfer and addition of the muramylpentapeptide building blocks that make up the peptidoglycan molecule itself. Vancomycin may also exert some effects by damaging the cytoplasmic membrane of the protoplast, and by inhibiting bacterial RNA synthesis.

Spectrum of activity. Staphylococci, notably *Staph. aureus* and *Staph. epidermidis* (including meticillin-resistant strains), *Streptococcus pneumoniae*, *Str. pyogenes*, and some strains of Group B streptococci are reported to be susceptible to vancomycin. The viridans streptococci, and enterococci such as *Enterococcus faecalis*, are often 'tolerant', i.e. inhibition, but no bactericidal effect, can be achieved at usual plasma concentrations (but see Activity with other Antimicrobials and Resistance, below).

Clostridium difficile is usually highly susceptible as are most other clostridia. *Actinomyces* spp., *Bacillus anthracis*, *Corynebacterium* spp., some lactobacilli, and

Listeria are usually susceptible. Virtually all Gram-negative organisms, as well as mycobacteria and fungi, are intrinsically resistant.

Activity with other antimicrobials. Vancomycin exhibits synergy with the aminoglycosides against enterococci; such combinations are usually bactericidal, even against vancomycin-tolerant strains. The synergistic effect is reported to be greater with gentamicin than with streptomycin. Combinations with an aminoglycoside are also reported to show synergy against *Staph. aureus*; however, variable results, including antimicrobial antagonism, or lack of synergy, have been reported against strains of *Staph. aureus* when vancomycin was combined with rifampicin. Synergy has been reported with the third-generation cephalosporins against *Staph. aureus* and enterococci.

Resistance to vancomycin in normally susceptible organisms has until recently remained relatively uncommon, although high-level intrinsic resistance has been seen in some species of *Lactobacillus, Leuconostoc,* and *Erysipelothrix*. However, there are an increasing number of reports of high-level acquired resistance amongst enterococci, apparently plasmid-mediated and transferable to other Gram-positive organisms, notably *Staph. aureus,* which are causing considerable concern. Organisms exhibiting high-level vancomycin resistance demonstrate cross-resistance to teicoplanin. Low-level resistance has also been reported in enterococci, but these organisms remain sensitive to teicoplanin, and this form of resistance does not appear to be transferable. Low-level vancomycin resistance has also been seen rarely among some staphylococcal strains: in contrast to the enterococci, these are often cross-resistant to teicoplanin. The mechanism of acquired resistance is uncertain, although it appears to be associated with the development of novel cell-membrane proteins.

Pharmacokinetics

Vancomycin is only poorly absorbed from the gastrointestinal tract, although absorption may be somewhat greater when the gastrointestinal tract is inflamed. Infusion of a 1-g dose intravenously over 60 minutes has reportedly been associated with plasma concentrations of up to about 60 micrograms/mL immediately after completion of the infusion, and about 25 micrograms/mL 2 hours later, falling to under 10 micrograms/mL after 11 hours. However, there may be considerable interindividual variation in the pharmacokinetics of vancomycin: a range of half-lives between 3 and 13 hours has been reported, with an average of about 6 hours, in patients with normal renal function. Half-life may be prolonged in patients with renal impairment, to 7 days or more in anephric patients. About 55% is bound to plasma proteins, although large variations have been reported.

Vancomycin diffuses into extracellular fluid, including pleural, pericardial, ascitic, and synovial fluid. Small amounts are found in bile. However, there is little diffusion into the CSF and even when the meninges are inflamed effective concentrations may not be achieved. Vancomycin crosses the peritoneal cavity; about 60% of an intraperitoneal dose is reported to be absorbed in 6 hours. It is reported to cross the placenta. It is also distributed into breast milk.

Little or no metabolism of vancomycin is thought to take place. It is excreted unchanged by the kidneys, mostly by glomerular filtration. Some 80 to 90% of the dose is excreted in urine within 24 hours. There appears to be a small amount of non-renal clearance, although the mechanism for this has not been determined.

The pharmacokinetics of vancomycin may be altered by conditions which affect renal clearance: clearance of vancomycin has been reported to be enhanced in burn patients, whereas in those with renal impairment, or reduced renal function (such as neonates or the elderly), clearance is reduced and plasma-concentrations and half-lives increased. Dosage adjustment is often necessary in patients with reduced or impaired renal function; ideally, this should be based on plasma-concentration monitoring. Although clearance is also altered in hepatic impairment, it has been suggested that dosage adjustment is not necessary in the absence of other factors.

Plasma concentrations of vancomycin are reported to be little affected by conventional haemodialysis, although the use of high-flux membranes may significantly reduce vancomycin concentrations. Peritoneal dialysis, although it may decrease concentrations, is also thought not to do so by significant amounts, but haemoperfusion or haemofiltration effectively removes vancomycin from the blood.

Uses and Administration

Vancomycin is a glycopeptide antibiotic that is used in the treatment of serious staphylococcal or other Gram-positive infections when other drugs such as the penicillins cannot be used because of resistance or patient intolerance. It is used particularly in the treatment of meticillin-resistant staphylococcal infections (p.195), in conditions such as brain abscess, staphylococcal meningitis, peritonitis associated with continuous ambulatory peritoneal dialysis, and septicaemia. It is used alone, or with another drug such as an aminoglycoside, in the treatment and prophylaxis of endocarditis, for the prophylaxis of surgical infection, and in intensive care and the management of immunocompromised patients. It may be used as part of a multi-drug regimen for the treatment of inhalation and gastrointestinal anthrax. For details of all these infections and their treatment, see under Choice of Antibacterial, p.162. It is also used (by mouth) in the treatment of antibiotic-associated colitis (p.171).

Vancomycin may be used with other antibacterials to extend the spectrum of efficacy or increase effectiveness, notably with gentamicin or other aminoglycosides, or with rifampicin (but see Antimicrobial Action, above).

Administration and dosage. Vancomycin is given as the hydrochloride but doses are expressed in terms of the base. 1.03 g of vancomycin hydrochloride is equivalent to about 1 g of vancomycin. It is given intravenously, preferably by intermittent infusion, although continuous infusion has been used. For intermittent infusion, a concentrated solution containing the equivalent of 500 mg of vancomycin in 10 mL of water is prepared and then added to glucose 5% or sodium chloride 0.9% to produce a diluted solution containing not more than 5 mg/mL; this diluted solution is then infused over at least 60 minutes for a 500-mg dose or 100 minutes for a 1-g dose. Final concentrations of up to 10 mg/mL may be used for patients requiring fluid restriction, although there is an increased risk of adverse events. For continuous intravenous infusion when intermittent infusion is not feasible, the equivalent of 1 to 2 g is added to a sufficiently large volume of glucose or sodium chloride to permit the daily dose to be given over a period of 24 hours.

The usual adult dose is the equivalent of 500 mg of vancomycin every 6 hours or 1 g every 12 hours. Response is generally seen within 48 to 72 hours in sensitive infections. In patients with staphylococcal endocarditis, treatment for at least 3 weeks has been recommended.

For the prophylaxis of endocarditis in high-risk patients undergoing dental or other procedures who are unable to receive penicillin, vancomycin may be given before the procedure in a single dose of 1 g by intravenous infusion over at least 100 minutes followed by intravenous gentamicin.

Doses in infants and children. UK licensed product information states that children and infants over 1 month of age may be given 10 mg/kg every 6 hours. Neonates and infants up to 1 month old may be given an initial dose of 15 mg/kg; this is followed by 10 mg/kg every 12 hours in the first week of life or by 10 mg/kg every 8 hours in those aged 1 week to 1 month. The *BNFC* recommends the following doses:

- neonates less than 29 weeks postmenstrual age, 15 mg/kg every 24 hours;
- 29 to 35 weeks postmenstrual age, 15 mg/kg every 12 hours
- over 35 weeks postmenstrual age, 15 mg/kg every 8 hours
- infants and children 1 month of age and over, 15 mg/kg every 8 hours (to a maximum daily dose of 2 g)

Dose adjustment and monitoring. It has been recommended that dosage should be adjusted if necessary according to plasma-vancomycin concentrations, and this is particularly important where factors such as age or renal impairment (see also below) may predispose to toxicity, or where there is a risk of subtherapeutic concentrations. There has been some dispute about the relationship between plasma concentrations and toxicity, and this, complicated by differences in the sampling time after the end of infusion and by differences in the regimens and assay method used, has meant that suggested peak and trough concentrations have varied considerably. However, in order to avoid toxic concentrations immediately after the end of infusion the consensus appears to be that concentrations of not more than 30 to 40 micrograms/mL should be aimed for 1 to 2 hours after completion of infusion. It is usually recommended that trough concentrations (measured just before the next dose) should be below 10 micrograms/mL. The *BNF* suggests a trough concentration of 10 to 15 micrograms/mL, or 15 to 20 micrograms/mL to treat less sensitive strains of meticillin-resistant *Staph. aureus*.

Other routes. Vancomycin hydrochloride is given by mouth in the treatment of staphylococcal enterocolitis and antibiotic-associated colitis, including pseudomembranous colitis associated with the overgrowth of *Clostridium difficile*. It is given in a dose of 0.5 to 2 g daily in 3 or 4 divided doses for 7 to 10 days; the lowest dose of 500 mg daily is often considered adequate. A suggested dose for children in licensed product information is 40 mg/kg daily in 3 or 4 divided doses; the *BNFC* suggests a dose of 5 mg/kg 4 times daily for infants and children from 1 month of age up to 5 years of age, 62.5 mg 4 times daily for children aged 5 to 12 years, and 125 mg 4 times daily for children over 12 years of age.

In meningitis or other CNS infections, vancomycin has sometimes been given by the intrathecal or intraventricular route in order to ensure adequate CSF concentrations of antibiotic. Vancomycin has also been applied topically to the eye or given by subconjunctival or intravitreal injection; it has also been given by inhalation.

Administration in renal impairment. Various methods, including predictive nomograms based on creatinine clearance and pharmacokinetic methods such as those using Bayesian statistics, have been suggested for calculating vancomycin dosage requirements in patients with reduced renal function. One suggested approach has been a loading dose of 15 mg/kg followed by a daily dose in mg equivalent to about 15 times the glomerular filtration rate in mL/minute; or in anuric patients a dose of 1 g every 7 to 10 days. However, individualised dosage based on plasma concentrations is generally to be preferred.

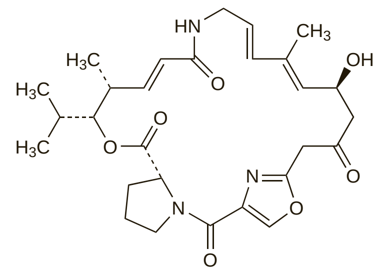
Virginiamycin *(BAN, USAN, rINN)*

Antibiotic 899; SKF-7988; Virgimycin; Virginiamicina; Virginiamycine; Virginiamycinum.

Виргиниамицин

CAS — 11006-76-1; 21411-53-0 (virginiamycin M_1); 23152-29-6 (virginiamycin S_1).
ATC — D06AX10.
ATC Vet — QD06AX10; QJ01FG90.



(virginiamycin M_1)

Profile

Virginiamycin is a streptogramin antibacterial mixture consisting principally of 2 antimicrobial substances, virginiamycin M_1, and virginiamycin S_1, produced by the growth of *Streptomyces virginiae*. It has been used for the treatment of infections due to sensitive organisms, particularly Gram-positive cocci. It has been given orally and applied locally. It may cause gastrointestinal disturbances including diarrhoea and vomiting. A few instances of hypersensitivity have been observed.

Virginiamycin has been used in animal feeding stuffs as a growth promotor.

Preparations

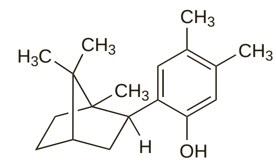
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: *Belg.:* Spitalen†.

Xibornol *(BAN, rINN)*

CP3H; 1HP; 1BX; Xibornolum. 6-(Isoborn-2-yl)-3,4-xylenol; 6-[(1*R*,2*S*,4*S*)-Born-2-yl]-3,4-xylenol.

Ксиборнол

$C_{18}H_{26}O = 258.4.$
CAS — 38237-68-2; 13741-18-9.
ATC — J01XX02.
ATC Vet — QJ01XX02.



Profile

Xibornol is an antibacterial that is reported to have a bacteriostatic action on Gram-positive organisms such as staphylococci and streptococci, as well as activity against *Haemophilus influenzae*. It has been given orally, as an oral spray, and rectally.

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Bornilene.

Antidementia Drugs

This chapter includes some drugs used or promoted in the management of dementia, including centrally acting anticholinesterases such as donepezil, galantamine, rivastigmine, and tacrine, the *N*-methyl-D-aspartate receptor antagonist memantine, and drugs considered to have nootropic properties, such as piracetam.

Many other drugs have been tried in various forms of dementia (see below) and are discussed elsewhere in *Martindale*.

Dementia

Dementia is a syndrome in which impairment of cortical or subcortical function leads to deterioration of cognitive processes or intellectual abilities including memory, judgement, language, communication, and abstract thinking. Unlike delirium there is no gross clouding of consciousness. There may be changes in personality and behaviour disturbances. Dementia is usually progressive, though not always irreversible, and loss of social and other skills often leads to complete dependence on others.

Although dementia is more prevalent in the elderly it is not an inevitable consequence of ageing. Dementia can result from many conditions[1-4] including:

- *neurodegenerative diseases*: Alzheimer's disease, Pick's disease, Huntington's chorea, Parkinson's disease, Lewy-body disease, multiple sclerosis, progressive supranuclear palsy
- *vascular diseases*: multiple cerebral infarcts, occlusion of carotid artery, cranial arteritis
- *trauma*: subdural haematoma
- *neoplasms*
- *CNS infections*: encephalitis, syphilis, toxoplasmosis, AIDS, Creutzfeldt-Jakob disease
- *endocrine/metabolic disorders*: hypothyroidism, uraemia, hepatic failure, cardiac failure, respiratory failure, hypoxia, hyponatraemia
- *toxic insults*: alcohol, solvents, heavy metals, drug therapy
- *hydrocephalus*
- *nutritional deficiency*: vitamin B_{12}, folic acid, thiamine
- *depression*
- *sleep disorders*: obstructive sleep apnoea, narcolepsy

Alzheimer's disease is the most common cause of dementia and accounts for over half of all patients;[1,2,4-6] about one-third of dementia cases are due to vascular disease.

Treatment of dementia can be broadly divided into control of disturbed behaviour (p.954) and attempts to improve or preserve cognitive function (see below). Although many drugs have been tried in the management of cognitive impairment most have produced little or no benefit.

Alzheimer's disease is a progressive degenerative condition affecting mainly patients over 60 years of age. The rare early-onset form of Alzheimer's disease (familial Alzheimer's disease) is sometimes referred to as pre-senile dementia. Death usually occurs within 10 years of onset.[1] Apart from age other risk factors include Down's syndrome and a family history of Alzheimer's disease.[1,2,4,7] Presence of the ε4 allele of apolipoprotein E is another risk factor; it correlates with prevalence and age of onset in some forms of Alzheimer's disease but use for routine clinical or predictive testing is not recommended.[4,5,8] Elevated levels of plasma homocysteine have been linked with the development of dementia and Alzheimer's disease.[9] Cardiovascular risk factors such as diabetes, hypercholesterolaemia, hypertension, and obesity have also been associated with an increased risk.[4,6] Dialysis dementia, an irreversible condition which has occurred in dialysis patients, has been associated with excess aluminium in the dialysing fluid but the role of aluminium in Alzheimer's disease, if any, is unclear.[5]

Deficiencies in numerous neurotransmitters have been found in patients with Alzheimer's disease but reduced choline acetyltransferase activity leading to reduced synthesis of acetylcholine remains the most consistent defect correlating with the severity of the condition.[10-17] Attempts to increase acetylcholine concentrations in the brain have included use of *acetylcholine precursors*, *cholinesterase inhibitors*, *enhancers of acetylcholine release*, and *cholinergic agonists*. However, none replace lost cholinergic neurones and therefore none affect overall progression of the disease.

Treatments using *precursors of acetylcholine* such as lecithin or choline alone are not generally considered to produce useful improvements,[15-17] although it has been suggested that choline alfoscerate may be of some benefit.

Donepezil, galantamine, rivastigmine, and tacrine are the main *cholinesterase inhibitors*.[6-8,16-23] All have produced modest improvement in cognition and global clinical impression in patients with mild to moderately severe disease. However, there is a lack of long-term studies and little evidence of their effectiveness in advanced disease although donepezil is licensed for the treatment of severe dementia in many countries. Tacrine is often poorly tolerated and may cause serious hepatotoxicity; for these reasons it is rarely used now. Donepezil, galantamine, and rivastigmine may be more acceptable to patients. A systematic review found no evidence of any difference between these 3 drugs with regard to efficacy although there appeared to be fewer adverse effects associated with donepezil compared with rivastigmine.[24] In the UK, NICE[25] recommends that the use of donepezil, galantamine, and rivastigmine is limited to patients with moderate dementia and given under the following conditions:

- treatment should only be started under specialist supervision
- patients who continue on the drug should be reviewed every 6 months
- treatment should only be continued if there was evidence of benefit

In a somewhat controversial decision, NICE considered that these 3 drugs could no longer be recommended in the treatment of mild dementia because their cost-effectiveness was questionable; however, it was recommended that those currently taking one of these drugs for mild dementia should continue on therapy until it was considered appropriate to stop. Other cholinesterase inhibitors that have been tried in Alzheimer's disease include metrifonate and physostigmine.

Fampridine, which *enhances acetylcholine release from nerve terminals* has also been tried in Alzheimer's disease but there is little evidence of clinical benefit.

Limited improvement has been reported with some *cholinergic agonists* but pilocarpine may exacerbate the dementia. Muscarinic M_1 agonists such as cevimeline and xanomeline have been investigated[17,26] on the basis that muscarinic M_1 receptors appear to be preserved throughout the course of Alzheimer's disease. However, these drugs have not been successful in improving symptoms of the disease. An alternative line of investigation is the *stimulation of nicotinic receptors* using nicotine.[17]

A hypothesis that free radicals may initiate and maintain mechanisms responsible for neurodegeneration in Alzheimer's disease has prompted the investigation of drugs such as vitamin E (e.g. α-tocopherol), ginkgo biloba, idebenone, and selegiline for *antoxidant* therapy but their value remains to be confirmed.[10,15,20,27-29] Although some US guidelines[17] suggested consideration of vitamin E supplementation in an attempt to slow progression of the disease, more recent ones[3] no longer recommend it for the treatment of cognitive symptoms because of limited evidence of efficacy as well as safety concerns. Selegiline has produced mixed results in a large number of controlled studies and US guidelines[3] note that few clinicians actually use the drug in clinical practice. A systematic review[30] has found no convincing evidence that ginkgo biloba is effective in the treatment of dementia or cognitive impairment.

Neurotropic or nootropic drugs such as piracetam are considered to enhance memory and cognition. They have been tried in preventing cognitive deficits associated with Alzheimer's disease and other dementias but there is little convincing evidence of clinical usefulness.[10,13,17]

The *N-methyl-D-aspartate (NMDA) receptor antagonist* memantine has shown some benefit in various dementias[6,7,19,29,31] and is used in the treatment of moderately severe to severe Alzheimer's disease;[21] it is thought to act through modulation of the effects of the neurotransmitter glutamate. However, in the UK, NICE[25] has not recommended memantine in the treatment of patients with moderately severe to severe disease because of insufficient evidence of clinical effectiveness.

Many drugs with *vasodilator activity* were originally tried in dementia when it was believed that the condition was due to 'cerebrovascular insufficiency' (p.1165), but overall there is little convincing evidence of benefit.[32] Ergot derivatives such as codergocrine mesilate and nicergoline have been the most commonly used; however, any effectiveness is now attributed to their action as metabolic enhancers or nootropic drugs and their place in therapy has still to be established.[27]

The *calcium-channel blocker* nimodipine has been of benefit in dementia of various aetiologies but its role in therapy remains unclear.[27,31]

Observations have suggested that *oestrogens* may reduce the risk and delay the onset of Alzheimer's disease in postmenopausal women receiving HRT.[7,8,13,17] However, a large controlled study found that combined HRT increased the risk of substantial decline in global cognitive function, did not prevent the development of mild cognitive impairment, and doubled the risk of dementia. A beneficial effect of oestrogens on cognitive function in postmenopausal women who already have mild or moderate Alzheimer's disease has not been demonstrated in controlled studies (see p.2076).

Some retrospective studies also indicate an inverse association between the use of *anti-inflammatory drugs* such as NSAIDs and the risk of developing Alzheimer's disease.[10,12,17,19] However, there is currently insufficient evidence to support the use of NSAIDs in the treatment of Alzheimer's disease.[6,7,19,33]

The possibility of an association between *statin* therapy and a reduced risk of developing dementia has also been mooted.[34] Evidence has been conflicting and further study is ongoing.[6]

A vaccine for Alzheimer's disease is being investigated.[4,6,19] Methylthioninium chloride, which is thought to dissolve and prevent the aggregation of tau protein filaments in the brain, is also under investigation.

A less marked degree of impaired memory, without dementia, is seen in some patients. Many, but not all, patients with such **mild cognitive impairment** (MCI) go on to develop Alzheimer's disease, and there has been considerable interest in treating them, in the hope of retarding progression to the more severe condition.[35,36] However, appropriate strategies for management are unclear: although treatment with cholinesterase inhibitors, antoxidants, and other drugs used for Alzheimer's disease has been investigated, there has been some concern about a possibly increased risk of death in patients with MCI treated with galantamine (see Effects on the Cardiovascular and Cerebrovascular Systems, p.366). In the UK, NICE[37] does not recommend the use of cholinesterase inhibitors in patients with MCI.

Vascular dementia[31,38-41] is a syndrome produced by ischaemic, hypoxic, or haemorrhagic brain lesions. Vessel occlusion is the most common cause of vascular dementia and produces a variety of cognitive deficits depending on the site of ischaemia. Among the major forms of dementia recognised are those due to multiple infarcts, single strategic infarcts, and subcortical white matter ischaemia (Binswanger's disease). Vascular dementia has a more acute onset than dementia due to Alzheimer's disease and in contrast to the continuous progression of Alzheimer's disease often has a stepwise progression. Risk factors for vascular dementia parallel those for stroke (p.1185) and similar methods for prevention and treatment may be of use but there is a lack of evidence from adequately controlled trials. Cholinergic deficits are well documented in patients with vascular dementia; cholinesterase inhibitors such as *donepezil* and *galantamine* have been found to be well tolerated and effective in these patients. Positive results have also been seen with the NMDA receptor antagonist *memantine*.[31,41] However, in the UK, NICE[37] does not recommend the use of cholinesterase inhibitors or memantine for cognitive decline in vascular dementia.

Lewy-body dementia[32,42-44] is distinguished from other types of dementia by a state of fluctuating cognitive impairment and confusion; hallucinations, paranoid delusions, a tendency to fall for no apparent reason, and transient clouding or loss of consciousness are also characteristic symptoms. In addition, mild extrapyramidal symptoms may be present and there is increased susceptibility to the extrapyramidal adverse effects of antipsychotics (see the Elderly, under Precautions of Chlorpromazine on p.973). Severe cholinergic deficits in patients with Lewy-body dementia have prompted treatment with cholinesterase inhibitors. *Donepezil* and *rivastigmine* have been shown to be well tolerated and effective, but further studies are needed to establish their role.

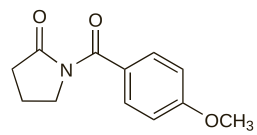
Aniracetam *(USAN, rINN)* ⊗

Aniracétam; Aniracetamum; Ro-13-5057. 1-(4-Methoxybenzoyl)-2-pyrrolidinone.

Анирацетам

$C_{12}H_{13}NO_3$ = 219.2.
CAS — 72432-10-1.
ATC — N06BX11.
ATC Vet — QN06BX11.



Profile

Aniracetam is a nootropic drug that has been tried in senile dementia (p.362). It is given orally in usual doses of 1.5 g daily.

◊ References.

Preparations

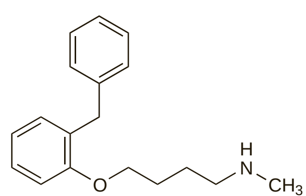
Proprietary Preparations (details are given in Part 3)
Arg.: Aniran; Conectol†; Pergamid; ***Gr.:*** Memodrin; Referan; ***Ital.:*** Ampamet; Draganon†.

Bifemelane *(rINN)*

Bifémélane; Bifemelano; Bifemelanum; MCI-2016 (bifemelane hydrochloride). *N*-Methyl-4-[(α-phenyl-*o*-tolyl)oxy]butylamine.

Бифемелан

$C_{18}H_{23}NO$ = 269.4.
CAS — 90293-01-9 (bifemelane); 62232-46-6 (bifemelane hydrochloride).
ATC — N06AX08.
ATC Vet — QN06AX08.



Profile

Bifemelane is a nootropic that has been given orally in a usual dose of 150 mg of the hydrochloride daily in divided doses for the treatment of cerebrovascular disorders including some forms of dementia (p.362).

Preparations

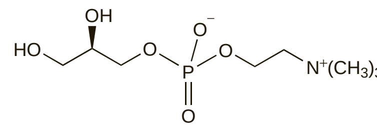
Proprietary Preparations (details are given in Part 3)
Arg.: Alemelano†; Cordinal; Neurocine; Neurolea†.

Choline Alfoscerate *(rINN)*

Alfoscerato de colina; Choline, Alfoscérate de; Choline Alphoscerate; Choline Glycerophosphate; Cholini Alfosceras; L-α-Glycerylphosphorylcholine. Choline hydroxide, (*R*)-2,3-dihydroxypropyl hydrogen phosphate, inner salt.

Холина Альфосцерат

$C_8H_{20}NO_6P$ = 257.2.
CAS — 28319-77-9.
ATC — N07AX02.
ATC Vet — QN07AX02.



Profile

Choline alfoscerate is a precursor of acetylcholine and has been tried in the treatment of Alzheimer's disease and other dementias (below). The usual oral dose is 0.8 to 1.2 g daily in divided doses; doses of 1 g daily have been given by intramuscular or slow intravenous injection.

Dementia. Treatment with precursors of acetylcholine is not generally thought to be of benefit in dementia (p.362). However, in an analysis[1] of 8 controlled clinical studies the use of choline alfoscerate in patients with dementia of the Alzheimer's type, vascular dementia, or acute cerebrovascular disease was claimed to be of some benefit. Results of a further 3 uncontrolled studies in the same review suggested that it might favour functional recovery in patients with cerebral stroke.

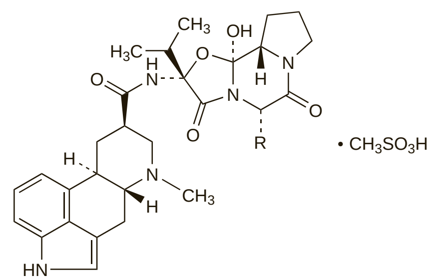
CAS — 11032-41-0 (codergocrine); 8067-24-1 (codergocrine mesilate).
ATC — C04AE01.
ATC Vet — QC04AE01.



Dihydroergocornine	R = $CH(CH_3)_2$
Dihydroergocristine	R = $CH_2C_6H_5$
Dihydro-α-ergocryptine	R = $CH_2CH(CH_3)_2$
Dihydro-β-ergocryptine	R = $CH(CH_3)CH_2CH_3$

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Codergocrine Mesilate). A mixture of dihydroergocornine mesilate ($C_{31}H_{41}N_5O_5,CH_4O_3S$ = 659.8), dihydroergocristine mesilate, α-dihydroergocryptine mesilate, and β-dihydroergocryptine mesilate (epicriptine mesilate). It contains 30 to 35% of dihydroergocornine, 30 to 35% of dihydroergocristine, 20 to 25% of α-dihydroergocryptine, and 10 to 13% of β-dihydroergocryptine. A white or yellowish powder. Sparingly soluble in water; sparingly soluble to soluble in alcohol; slightly soluble in dichloromethane. A 0.5% solution in water has a pH of 4.2 to 5.2. Protect from light.

USP 31 (Ergoloid Mesylates). A mixture of the methanesulfonate salts of the three hydrogenated alkaloids, dihydroergocristine, dihydroergocornine, and dihydroergocryptine, in an approximate weight ratio of 1:1:1. Dihydroergocryptine mesylate exists as a mixture of alpha- and beta-isomers. The ratio of alpha- to beta-isomers is not less than 1.5:1.0 and not more than 2.5:1.0. A white to off-white, microcrystalline or amorphous, practically odourless powder. Slightly soluble in water; soluble in alcohol and in methyl alcohol; sparingly soluble in acetone. A 0.5% solution in water has a pH of 4.2 to 5.2. Store in airtight containers. Protect from light.

Adverse Effects

Adverse effects occasionally reported with codergocrine mesilate include abdominal cramps, nausea, vomiting, headache, blurred vision, skin rashes, nasal congestion, flushing of the skin, dizziness, bradycardia, and orthostatic hypotension.

Local irritation has occurred after sublingual use.

Effects on the cardiovascular system. Of 8 patients given codergocrine mesilate 1.5 mg three times daily for the treatment of dementia, 3 developed severe sinus bradycardia associated with general deterioration in their condition, necessitating withdrawal of the treatment.[1] However, no sinus bradycardia had been seen in 40 elderly patients in whom the dose was built up to 1.5 mg three times daily over 3 weeks.[2]

1. Cayley ACD, *et al.* Sinus bradycardia following treatment with Hydergine for cerebrovascular insufficiency. *BMJ* 1975; **4:** 384–5.
2. Cohen C. Sinus bradycardia following treatment with Hydergine. *BMJ* 1975; **4:** 581.

Precautions

Codergocrine mesilate should be used with caution in patients with severe bradycardia.

Pharmacokinetics

Codergocrine is rapidly absorbed from the gastrointestinal tract; peak plasma concentrations are reached in about 1 to 2 hours after an oral dose. Oral bioavailability is low; this has been attributed to incomplete absorption from the gastrointestinal tract and extensive first-pass metabolism. It is 81% bound to plasma proteins. Elimination is biphasic with a short half-life of 1.5 to 2.5 hours (α phase) and a longer half-life of 13 to 15 hours (β phase). Codergocrine is mainly excreted with bile in the faeces, although small amounts are eliminated in the urine as metabolites and unchanged drug.

Uses and Administration

Unlike the natural ergot alkaloids, codergocrine mesilate has only limited vasoconstrictor effects.

A mixture of hydrogenated ergot alkaloids, codergocrine mesilate is used as an adjunct in the symptomatic treatment of mild to moderate dementia in the elderly (see also below). It is given in oral doses of 3 or 4.5 mg daily, preferably before meals. Higher doses have also been used. It is also given sublingually in similar doses. It has been given intramuscularly, subcutaneously, or by intravenous infusion.

In some countries, codergocrine mesilate has been used in the treatment of hypertension, migraine, and in peripheral vascular disease.

Codergocrine esilate has been used similarly to the mesilate.

Dementia. Codergocrine has been used for many years in dementia (p.362) but its value is not established.[1-3] Originally its effects were thought to be mediated through peripheral and cerebral vasodilatation but it is now classified as a metabolic enhancer.

ATC — N04BC03.

ATC Vet — QN04BC03.

Profile

Dihydroergocryptine mesilate is a component of codergocrine mesilate (p.363) and has similar actions. It has been given orally in doses of up to 20 mg daily for migraine, and in maintenance doses of up to 60 to 120 mg daily for parkinsonism. It has also been used for age-related dementia and to inhibit lactation. In some countries it has been given with caffeine for cerebrovascular and peripheral vascular disorders.

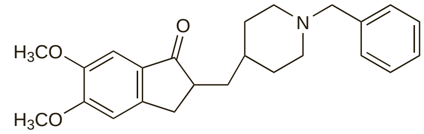
ATC — N06DA02.

ATC Vet — QN06DA02.



(donepezil)

Adverse Effects and Treatment

Adverse effects of acetylcholinesterase inhibitors such as donepezil notably include nausea, vomiting, anorexia, diarrhoea, fatigue, and dizziness. Other common adverse effects include abdominal pain, dyspepsia, rash, pruritus, headache, somnolence, muscle cramps, insomnia, sweating, tremor, and syncope; upper-respiratory-tract and urinary-tract infections have been noted. Rare cases of angina, sino-atrial and AV blocks, bradycardia, peptic ulcers, gastrointestinal haemorrhage, extrapyramidal symptoms, and seizures have been observed. Psychiatric disturbances, including depression, hallucinations, agitation, aggressive behaviour, and confusion have also been reported. There is a potential for bladder outflow obstruction. Minor increases in serum-creatine kinase have also occurred with donepezil.

Hepatotoxicity has occurred with tacrine, and has limited its use (see Tacrine, Precautions, p.370); individual cases of increased liver transaminases have been noted with other acetylcholinesterase inhibitors.

The use of acetylcholinesterase inhibitors has been associated with weight loss and consequently some licensed product information has recommended that a patient's weight is monitored during treatment. Female patients have been found to be more susceptible to nausea, vomiting, anorexia, and weight loss.

Overdosage with cholinesterase inhibitors may result in 'cholinergic crisis', the details of which are described under Adverse Effects of Neostigmine, p.631.

◊ Reviews of the safety profile of donepezil.

1. Committee on Safety of Medicines/Medicines Control Agency. Donepezil (Aricept). *Current Problems* 1999; **25:** 7. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2023235&RevisionSelectionMethod=LatestReleased (accessed 13/08/07)
2. Jackson S, *et al.* The safety and tolerability of donepezil in patients with Alzheimer's disease. *Br J Clin Pharmacol* 2004; **58** (suppl 1): 1–8.

Effects on the cardiovascular system. The Australian Adverse Drug Reactions Advisory Committee noted in October 2004 that it had received 32 reports of cardiac arrhythmias associated with donepezil (14 of bradycardia, 1 bundle branch block, 5 AV blocks, 10 cases of syncope, and 2 unspecified), as well as 7 cases of myocardial infarction or cardiac arrest.[1] There had been 7 reports of similar cardiovascular effects with rivastigmine and 6 with galantamine; the larger number with donepezil was almost certainly due to wider usage of this drug. Most patients recovered when the drug was stopped or the dose reduced, though many were hospitalised and in 4 cases a pacemaker was required.

One study in vascular dementia reported an increased death rate with donepezil (see Dementia, below) but no increase in vascular events.

1. Adverse Drug Reactions Advisory Committee (ADRAC). Cholinesterase inhibitors and cardiac arrhythmias. *Aust Adverse Drug React Bull* 2004; **23:** 19–20. Also available at: http://www.tga.gov.au/adr/aadrb/aadr0410.htm (accessed 13/02/06)

Effects on the nervous system. Restless legs, mumbling, and stuttering developed in an elderly patient after increasing the dose of donepezil to 10 mg daily.[1] Symptoms resolved when donepezil was withdrawn and recurred on rechallenge.

1. Amouyal-Barkate K, *et al.* Abnormal movements with donepezil in Alzheimer disease. *Ann Pharmacother* 2000; **34:** 1347.

Effects on the urinary tract. Urinary incontinence is a recognised adverse effect of the older anticholinesterases such as neostigmine; not unexpectedly there have also been cases associated with donepezil.[1]

1. Hashimoto M, *et al.* Urinary incontinence: an unrecognised adverse effect with donepezil. *Lancet* 2000; **356:** 568.

Precautions

Donepezil and other acetylcholinesterase inhibitors should be used with caution, if at all, in patients with gastrointestinal or urinary-tract obstruction; their use is not recommended in patients recovering from bladder or gastrointestinal surgery. Care is also required in patients with a history of asthma, obstructive pulmonary disease, Parkinson's disease, or seizures, and in those, with, or at risk of developing, peptic ulcer disease. Patients with cardiovascular conduction disorders such as sick-sinus syndrome may be susceptible to the vagotonic effects of acetylcholinesterase inhibitors.

Dizziness, somnolence, fatigue, and muscle cramps may occur especially when starting treatment with or increasing the dose of acetylcholinesterase inhibitors; the performance of skilled tasks such as driving may be affected.

Interactions

As for Neostigmine, p.632. Hepatic metabolism of donepezil via the cytochrome P450 system has been demonstrated; plasma concentrations of donepezil may be raised by drugs that inhibit the isoenzyme CYP3A4 such as ketoconazole, itraconazole, and erythromycin, and by those that inhibit the isoenzyme CYP2D6 such as fluoxetine and quinidine. Conversely, plasma-donepezil concentrations may be reduced by enzyme inducers such as rifampicin, phenytoin, carbamazepine, and alcohol.

Antimuscarinics. Although antimuscarinics are expected to antagonise the effects of anticholinesterases, such combinations are sometimes used in patients with dementia who are distressed by symptoms of urge incontinence.[1] There have been, however, a few cases[2] of agitation, anxiety, confusion, aggression, and delusion precipitated by *tolterodine* in patients who had been stable on donepezil or rivastigmine. The interaction appeared to cause a state of cholinergic neurogenic hypersensitivity, similar to sudden withdrawal of the anticholinesterase.

1. Siegler EL, Reidenberg M. Treatment of urinary incontinence with anticholinergics in patients taking cholinesterase inhibitors for dementia. *Clin Pharmacol Ther* 2004; **75:** 484–8.
2. Edwards KR, O'Connor JT. Risk of delirium with concomitant use of tolterodine and acetylcholinesterase inhibitors. *J Am Geriatr Soc* 2002; **50:** 1165–6.

Pharmacokinetics

Donepezil hydrochloride is well absorbed from the gastrointestinal tract, maximum plasma concentrations being achieved within 3 to 4 hours after ingestion. It is about 95% bound to plasma proteins, mainly albumin. Donepezil undergoes partial metabolism via the cytochrome P450 isoenzyme CYP3A4, and to a lesser extent by CYP2D6, to 4 major metabolites. About 11% of a dose is present in plasma as 6-*O*-desmethyldonepezil, which has similar activity to the parent compound. Over 10 days, about 57% of a dose is recovered from the urine as unchanged drug and metabolites, and about 15% from the faeces; 28% remains unrecovered suggesting accumulation. The elimination half-life is about 70 hours. Steady-state concentrations are achieved within 3 weeks of the start of therapy.

Uses and Administration

Donepezil hydrochloride, a piperidine derivative, is a reversible and selective inhibitor of acetylcholinesterase with actions similar to those of neostigmine (p.632). It is highly selective for the CNS and is used for the symptomatic treatment of dementia in Alzheimer's disease (below). In the UK, the licensed use of donepezil is limited to those patients with mild to moderately severe dementia; however, in the USA it is also licensed for use in those with severe symptoms.

Regardless of severity, donepezil hydrochloride is given in an initial oral dose of 5 mg once daily increased if necessary after 4 to 6 weeks to a maximum of 10 mg once daily; the dose should be taken just before bedtime. Clinical benefit should be reassessed on a regular basis.

In some countries, donepezil is also licensed for use in patients with vascular dementia (below); doses are similar to those used for the treatment of dementia in Alzheimer's disease.

Dementia. Donepezil hydrochloride is used in the symptomatic treatment of dementia in *Alzheimer's disease* (see Dementia, p.362). In individual studies, it appears to produce modest benefits in some patients with mild to moderately severe dementia.[1-4] These findings are also supported by a systematic review[5] which concluded that, for treatment periods of up to 1 year, donepezil produces modest improvements in cognitive function and global clinical state. Benefit has also been reported in patients with more severe dementia.[5-8] Although there are no comparative studies of donepezil and tacrine it has been suggested[9-11] that donepezil may prove preferable as it appears to be better tolerated and hepatotoxicity has not been reported to be a problem (but see Adverse Effects, above).

In the UK, NICE has recommended that treatment with donepezil should be limited to patients with moderate dementia and given under the following conditions:[12]

- treatment should only be started under specialist supervision
- patients who continue on the drug should be reviewed every 6 months
- treatment should only be continued if there was evidence of benefit

In a somewhat controversial decision, NICE considered that donepezil could no longer be recommended in the treatment of mild dementia because its cost-effectiveness was questionable; however, it was recommended that those currently taking donepezil for mild dementia should continue on therapy until it was considered appropriate to stop.

Donepezil has also been tried in patients with *mild cognitive impairment*.[13,14] Findings from a double-blind study[14] have suggested that although donepezil therapy was associated with a lower rate of progression to Alzheimer's disease during the first year of treatment when compared with placebo, the rate of progression after 3 years of therapy was not lower than that of the placebo group. The authors of a systematic review[15] of these 2 studies found no evidence to support the use of donepezil in patients with mild cognitive impairment. Any benefits were considered to be minor, short-lived, and associated with significant adverse effects.

Donepezil may be effective in the treatment of *vascular dementia*. Results from a randomised, controlled study[16] have shown an improvement in cognition and global function in patients with probable or possible vascular dementia. A systematic review also concluded that donepezil improved mild to moderate vascular cognitive impairment in the short term (treatment for 6 months).[17] The manufacturer has reported[18] that out of a total of 3 studies of donepezil in vascular dementia, one (Study 319) showed an apparently increased mortality compared with placebo: 1.7% and 0%, respectively. In a combined analysis of the other 2 studies, the mortality rate was 1.7% in the donepezil group and 2% in the placebo group. Combined analysis of all 3 studies showed no statistically significant difference in the mortality rates between the donepezil (1.7%) and placebo (1.1%) groups; the risk of vascular events such as stroke and myocardial infarction was also similar for each group. The unexpectedly low mortality rate with placebo in Study 319 was unusual given the age and pathology of the subjects. An increased risk of death has been reported with *galantamine* when used in patients who did not have Alzheimer's disease (see Effects on the Cardiovascular and Cerebrovascular Systems, p.366).

Parkinsonism. Although acetylcholinesterase inhibitors such as donepezil hydrochloride may theoretically worsen parkinsonism symptoms, particularly tremor, it has been tried for use in the treatment of drug-induced psychosis in patients with Parkinson's disease (see Disturbed Behaviour, p.954).

Preparations

Proprietary Preparations (details are given in Part 3)

Galantamine Hydrobromide

(BANM, USAN, rINNM)

Galantamine, bromhydrate de; Galantamini hydrobromidum; Galanthamine Hydrobromide; Galanthamini Hydrobromidum; Hidrobromuro de galantamina. (4a*S*,6*R*,8a*S*)-4a,5,9,10,11,12-Hexahydro-3-methoxy-11-methyl-6*H*-benzofuro[3a,3,2-*ef*][2]benzazepin-6-ol hydrobromide.

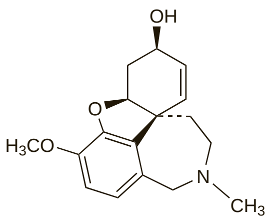
Галантамина Гидробромид

$C_{17}H_{21}NO_3,HBr$ = 368.3.

CAS — 357-70-0 (galantamine); 1953-04-4 (galantamine hydrobromide).

ATC — N06DA04.

ATC Vet — QN06DA04.



(galantamine)

Description. The hydrobromide of galantamine, an alkaloid which has been obtained from the Caucasian snowdrop (Voronov's snowdrop), *Galanthus woronowii* (Amaryllidaceae), and related species.

Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Galantamine Hydrobromide). A white to almost white powder. Sparingly soluble in water; very slightly soluble in alcohol; soluble in 0.1N sodium hydroxide; insoluble in propyl alcohol.

Adverse Effects, Treatment, and Precautions

As for Donepezil, p.364. Hypertension has also been reported with galantamine.

For details regarding dose adjustments in moderate hepatic or renal impairment, see under Uses and Administration, below. There are no data on the use of galantamine in patients with severe hepatic or renal impairment and consequently in the licensed product information it is contra-indicated in such patients; it should also not be given to patients with both significant hepatic and renal impairment.

Effects on the cardiovascular and cerebrovascular systems. Results from 2 studies of the use of galantamine in mild cognitive impairment (an unlicensed indication) have suggested that there may be an increased risk of death in patients given galantamine compared with those on placebo: out of a total of about 2000 patients, 13 died in the galantamine groups with only 1 death reported in the placebo groups.[1,2] About half of the deaths were caused by cardiovascular or cerebrovascular events.

For a suggestion of possibly increased mortality with *donepezil* in patients with vascular dementia, see Dementia, p.365.

Interactions

As for Neostigmine, p.632. Galantamine is partially metabolised by the cytochrome P450 isoenzymes CYP2D6 and CYP3A4. Consequently its bioavailability may be increased by drugs that inhibit CYP2D6, such as quinidine, fluoxetine, fluvoxamine, and paroxetine, and by those that inhibit CYP3A4, such as ketoconazole and ritonavir. Dose reduction of galantamine may be required when given with such drugs.

Pharmacokinetics

Galantamine is well absorbed from the gastrointestinal tract. Peak plasma concentrations are reached in about 1 hour after ingestion from conventional formulations; with modified-release formulations, peak concentrations occur about 4 to 5 hours after a dose and are somewhat lower. The absolute oral bioavailability of galantamine is about 90%. The presence of food delays the rate of absorption although the extent of absorption is not affected. Protein binding is about 18%. Galantamine is partially metabolised by the cytochrome P450 isoenzymes CYP2D6 and CYP3A4; a number of active metabolites are formed. The elimination half-life is about 7 to 8 hours. After 7 days, the majority of a single oral dose is recovered in the urine with up to about 6% detected in the faeces; about 20 to 30% of the dose is excreted in the urine as unchanged galantamine. Clearance is reported to be 20% lower in females than in males and 25% lower in poor metabolisers than in extensive metabolisers.

Uses and Administration

Galantamine hydrobromide is a reversible inhibitor of acetylcholinesterase activity, with actions similar to those of neostigmine (p.632). It also has an intrinsic action on nicotinic receptors. It is used in the symptomatic treatment of mild to moderately severe dementia in Alzheimer's disease (below).

Galantamine is given as the hydrobromide although doses are expressed in terms of the base; 5.1 mg of galantamine hydrobromide is equivalent to about 4 mg of galantamine. An initial oral dose of 4 mg is given twice daily with food for 4 weeks, then increased to 8 mg twice daily. This dose should be maintained for at least 4 weeks; thereafter, the dose may be further increased to 12 mg twice daily according to response and tolerance. A modified-release preparation is also available for once-daily use. The clinical benefit of galantamine should be reassessed, preferably within the first 3 months, and thereafter on a regular basis. Reductions in dose may be necessary in patients with hepatic or renal impairment (see below) or in those also taking certain cytochrome P450 isoenzyme inhibitors (see Interactions, above).

Galantamine hydrobromide has also been used in various neuromuscular disorders, and to curtail the muscle relaxation produced by competitive neuromuscular blockers.

Administration in hepatic impairment. No dose adjustment is necessary in mild hepatic impairment. Patients with moderate impairment should begin with an oral dose of 4 mg once daily (or 8 mg every other day if using a modified-release preparation), preferably taken in the morning, for at least one week; thereafter the dose may be increased to 4 mg twice daily (or its once-daily equivalent if using a modified-release preparation) for at least 4 weeks, with subsequent increases up to a maximum of 8 mg twice daily (or its once-daily equivalent if using a modified-release preparation). Galantamine is contra-indicated in severe impairment (Child-Pugh Category C) due to lack of data.

Administration in renal impairment. UK licensed product information states that no dose adjustment is necessary in mild or moderate renal impairment. However, US licensed product information recommends that the dose should not exceed 16 mg daily in patients with moderate impairment.

Galantamine is contra-indicated in severe impairment (creatinine clearance less than 9 mL/minute) due to lack of data.

Dementia. Reviews[1-3] suggest that galantamine is of benefit in patients with mild to moderate symptoms of *Alzheimer's disease* (see Dementia, p.362); evidence in more severely impaired subjects is lacking. In the UK, NICE has recommended that the use of galantamine should be limited to patients with moderate dementia and given under the following conditions:[4]

- treatment should only be started under specialist supervision
- patients who continue on the drug should be reviewed every 6 months
- treatment should only be continued if there was evidence of benefit

In a somewhat controversial decision, NICE considered that galantamine could no longer be recommended in the treatment of mild dementia because its cost-effectiveness was questionable; however, it was recommended that those currently taking galantamine for mild dementia should continue on therapy until it was considered appropriate to stop.

Galantamine may also be effective in the treatment of *vascular dementia*. Results from a randomised, controlled study[5] have shown a trend towards improved cognition in patients with probable vascular dementia, although patients numbers were too small for this to be significant. A more recent multicentre study[6] in patients with probable vascular dementia found cognitive improvement with galantamine to be greater than with placebo; however, improvement in daily activities with galantamine was similar to that seen with placebo.

A systematic review[3] concluded that galantamine could not be recommended for treatment in patients with *mild cognitive impairment* because of limited clinical benefit and an unexplained association with an excess death rate (see also Effects on the Cardiovascular and Cerebrovascular Systems, above).

Idebenone *(rINN)*

CV-2619; Idebenona; Idébénone; Idebenonum. 2-(10-Hydroxydecyl)-5,6-dimethoxy-3-methyl-*p*-benzoquinone.

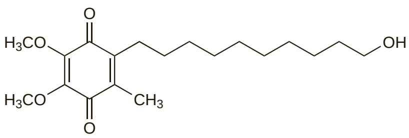
Идебенон

$C_{19}H_{30}O_5$ = 338.4.

CAS — 58186-27-9.

ATC — N06BX13.

ATC Vet — QN06BX13.



Profile

Idebenone has been used in the treatment of mental impairment associated with cerebrovascular disorders. A dose of 90 mg daily has been given orally in 2 divided doses after food. Idebenone has also been tried in Alzheimer's disease. It has also been investigated for the management of various clinical manifestations of Friedreich's ataxia and is used orally in a dose of 5 mg/kg daily in 3 divided doses for cardiomyopathy in this disease.

Idebenone is also available as a 1% cream for the cosmetic treatment of wrinkles.

Dementia. Idebenone was found to be safe and effective in patients with mild to moderate Alzheimer's disease (p.362) when followed for up to 2 years.[1,2] In a further study,[3] its safety and efficacy were comparable to tacrine. However, another study[4] found no clinically significant slowing of cognitive decline in patients with Alzheimer's disease treated with idebenone.

1. Weyer G, *et al.* Efficacy and safety of idebenone in the long-term treatment of Alzheimer's disease: a double-blind, placebo controlled multicentre study. *Hum Psychopharmacol Clin Exp* 1996; **11:** 53–65.

Memantine Hydrochloride

(BANM, USAN, rINNM)

1-Amino-3,5-dimethyladamantane Hydrochloride; D-145 (memantine); 3,5-Dimethyl-1-adamantanamine hydrochloride; DMAA (memantine); Hidrocloruro de memantina; Memantin Hidroklorür; Mémantine, Chlorhydrate de; Memantini Hydrochloridum. 3,5-Dimethyltricyclo[3.3.1.1.^{3,7}]decan-l-amine hydrochloride.

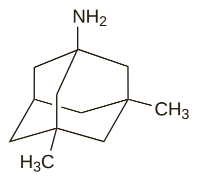
Мемантина Гидрохлорид

$C_{12}H_{21}N,HCl$ = 215.8.

CAS — 19982-08-2 (memantine); 41100-52-1 (memantine hydrochloride).

ATC — N06DX01.

ATC Vet — QN06DX01.



(memantine)

Adverse Effects and Precautions

Common adverse effects with memantine include constipation, dizziness, headache, hypertension, and somnolence. Less common reactions such as anxiety, hallucinations, confusion, fatigue, abnormal gait, hypertonia, vomiting, fungal infections, cystitis, thromboembolism, and increased libido have also occurred. Isolated cases of psychotic reactions and pancreatitis have been reported.

Dosage adjustment may be required in renal impairment, but recommendations vary, (see below).

Only limited clinical data are available for patients with recent myocardial infarction, uncompensated congestive heart failure, and uncontrolled hypertension and use of memantine in these patients should be closely monitored. Seizures have occurred rarely and caution is recommended in patients at risk of convulsions. Conditions that increase urinary pH, such as drastic changes in diet, renal tubular acidosis, or severe infections of the urinary tract, may decrease elimination of memantine resulting in increased plasma levels; patient monitoring is recommended in such cases.

Interactions

Use of other *N*-methyl-D-aspartate antagonists such as amantadine, ketamine, or dextromethorphan with memantine may increase both the incidence and severity of adverse effects and should be avoided. The effects of dopaminergics and antimuscarinics may also be enhanced whereas memantine may reduce the actions of barbiturates and antipsychotics.

Memantine may alter the effects of the antispasmodics baclofen and dantrolene. The clearance of memantine is reduced under alkaline urine conditions and drugs such as carbonic anhydrase inhibitors and sodium bicarbonate should be used with caution.

Pharmacokinetics

Memantine is well absorbed after oral doses. Peak plasma concentrations are achieved in about 3 to 8 hours. Plasma protein binding is about 45%. Memantine undergoes partial hepatic metabolism; the main metabolites include *N*-3,5-dimethyl-gludantan and 1-nitroso-3,5-dimethyl-adamantane. The majority of a dose is excreted unchanged via the kidney; some active renal tubular secretion and reabsorption occurs. The terminal half-life ranges from 60 to 100 hours although under alkaline conditions the rate of elimination is reduced.

◊ References.

2. Kornhuber J, *et al.* Memantine pharmacotherapy: a naturalistic study using a population pharmacokinetic approach. *Clin Pharmacokinet* 2007; **46:** 599–612. Correction. *ibid.*; 712.

Uses and Administration

Memantine is a derivative of amantadine (p.792) and is likewise an antagonist of *N*-methyl-D-aspartate receptors. It is given in the treatment of moderate to severe Alzheimer's disease (see Dementia, below). Memantine has also been given in the treatment of parkinsonism and central spasticity, and in other disorders such as brain injury or comatose states. It is given orally as the hydrochloride.

In the treatment of **Alzheimer's disease**, the initial dose of memantine hydrochloride is 5 mg daily in the morning for the first week; this should be increased in weekly increments of 5 mg to a maximum dose of 20 mg daily. Doses of 10 mg daily and over should be taken in 2 divided doses. Dosage adjustment may be required in patients with renal impairment (see below). Clinical benefit should be reassessed on a regular basis.

Memantine hydrochloride has also been given by slow intravenous injection.

Memantine is under investigation in the treatment of glaucoma and peripheral neuropathy.

Administration in renal impairment. UK licensed product information advises that no dose adjustment is needed when memantine hydrochloride is given for Alzheimer's disease in patients with mild renal impairment (creatinine clearance [CC] 50 to 80 mL/minute). However, in those with moderate impairment (CC 30 to 49 mL/minute) a dose of 10 mg daily may be used (after starting at 5 mg daily) and if well tolerated after at least 7 days, it may be increased to 20 mg daily as described above (see above). In those with severe impairment (CC 5 to 29 mL/minute) the maximum daily dose is 10 mg. In the USA, licensed product information states that no dose reduction is required in those with mild or moderate impairment; a target dose of 10 mg daily is recommended in patients with severe impairment (CC 5 to 29 mL/minute).

Dementia. A systematic review[1] of the use of memantine in dementia (p.362) concluded that it did have a small beneficial effect on cognitive and functional decline at 6 months in patients with moderate to severe Alzheimer's disease; the effects were not clinically discernible in those with mild to moderate vascular dementia but were discernible in those with mild to moderate Alzheimer's disease. In the UK, NICE[2] has not recommended memantine in the treatment of patients with moderately severe to severe disease because of insufficient evidence of clinical effectiveness. A general review, including a safety profile, of memantine in Alzheimer's disease has also been published.[3]

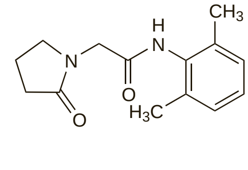
Nefiracetam *(rINN)*

DM-9384; DZL-221; Néfiracétam; Nefiracetamum. 2-Oxo-1-pyrrolidineaceto-2',6'-xylidide.

Нефирацетам

$C_{14}H_{18}N_2O_2$ = 246.3.

CAS — 77191-36-7.



Profile

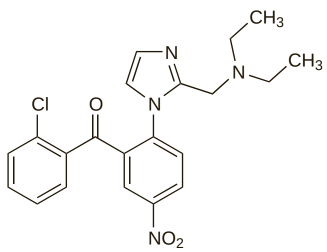
Nefiracetam acts on the CNS and has been described as a nootropic. It has been investigated in some cerebrovascular disorders and for the treatment of Alzheimer's disease.

Nizofenone *(rINN)*

Nizofenona; Nizofénone; Nizofenonum; Y-9179. 2′-Chloro-2-[2-[(diethylamino)methyl]imidazol-1-yl]-5-nitrobenzophenone.

Низофенон

$C_{21}H_{21}ClN_4O_3$ = 412.9.
CAS — 54533-85-6.
ATC — N06BX10.
ATC Vet — QN06BX10.



Profile

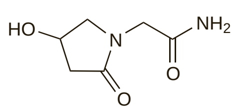
Nizofenone has been investigated as a nootropic and cerebral vasodilator. It has been used parenterally as the fumarate.

Oxiracetam *(BAN, rINN)*

CGP-21690E; CT-848; ISF-2522; Oksirasetaami; Oxiracétam; Oxiracetamum; Oxracetam. 4-Hydroxy-2-oxo-1-pyrrolidineacetamide.

Оксирацетам

$C_6H_{10}N_2O_3$ = 158.2.
CAS — 62613-82-5.
ATC — N06BX07.
ATC Vet — QN06BX07.



Profile

Oxiracetam has been used as a nootropic in organic brain syndromes and senile dementia.

Dementia. Clinical benefit has been reported in patients with dementia (p.362) given oxiracetam,[1] but in the USA it was withdrawn from phase II clinical studies in patients with Alzheimer's disease due to lack of efficacy.[2]

1. Maina G, *et al.* Oxiracetam in the treatment of primary degenerative and multi-infarct dementia: a double-blind, placebo-controlled study. *Neuropsychobiology* 1990; **21**: 141–5.

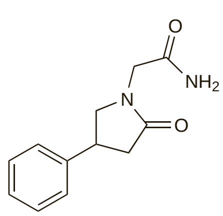
4-Phenylpiracetam ⊗

BRN-5030440; Carphedon; Karfedon. 2-Oxo-4-phenyl-1-pyrrolidineacetamide.

$C_{12}H_{14}N_2O_2$ = 218.3.
CAS — 77472-70-9.



Profile

4-Phenylpiracetam is a nootropic and has been used in the management of various cerebrovascular disorders. It has also been abused in sport.

Preparations

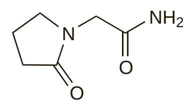
Proprietary Preparations (details are given in Part 3)
Rus.: Phenotropil (Фенотропил).

Piracetam *(BAN, USAN, rINN)*

CI-871; Piracétam; Piracetamas; Piracetamum; Pirasetaami; Pirasetam; Pyrrolidone Acetamide; UCB-6215. 2-(2-Oxopyrrolidin-1-yl)acetamide.

Пирацетам

$C_6H_{10}N_2O_2$ = 142.2.
CAS — 7491-74-9.
ATC — N06BX03.
ATC Vet — QN06BX03.



Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).
Ph. Eur. 6.2 (Piracetam). A white or almost white powder. It exhibits polymorphism. Freely soluble in water; soluble in alcohol. Protect from light.

Adverse Effects and Precautions

Piracetam is reported to produce insomnia or somnolence, weight gain, hyperkinesia, nervousness, and depression. Other reported adverse effects include gastrointestinal disorders such as abdominal pain, diarrhoea, nausea and vomiting, hypersensitivity reactions, ataxia, vertigo, confusion, hallucinations, angioedema, and rashes. Piracetam should not be given to patients with hepatic impairment or severe renal impairment; dosage reduction is recommended for those with mild to moderate renal impairment. Therapy with piracetam should not be withdrawn abruptly in myoclonic patients due to the risk of inducing seizures. When used to treat cortical myoclonus, piracetam is contra-indicated in patients with cerebral haemorrhage, and should be used with caution after major surgery and in those with haemostatic disorders or severe haemorrhage.

Interactions

Anticoagulants. For reference to the effect of piracetam on *warfarin* therapy, see p.1431.

Pharmacokinetics

Piracetam is rapidly and extensively absorbed from the gastrointestinal tract; peak plasma concentrations are reached within 1.5 hours after oral doses. The plasma half-life is reported to be 5 hours and it crosses the blood-brain barrier. Piracetam is excreted almost completely in the urine. It crosses the placenta and is distributed into breast milk.

Uses and Administration

Piracetam acts on the CNS and has been described as a nootropic; it is said to protect the cerebral cortex against hypoxia. It is also reported to inhibit platelet aggregation and reduce blood viscosity at high doses. Piracetam is used as an adjunct in the treatment of myoclonus of cortical origin, and has also been used in dementia (see also below). Other disorders or states in which it has been tried (on the basis of a supposed 'cerebrocortical insufficiency' responsive to piracetam) include alcoholism, vertigo, cerebrovascular accidents, dyslexia, behavioural disorders in children, and after trauma or surgery.

In cortical myoclonus, piracetam is given in oral doses of 7.2 g daily increasing by 4.8 g daily every 3 or 4 days up to a maximum of 20 g daily. It is given in 2 or 3 divided doses. Once the optimal dose of piracetam has been established, attempts should be made to reduce the dose of other drugs. For dosage in renal impairment see below.

Piracetam has been given for various other disorders in a usual oral dose of up to 2.4 g daily in 2 or 3 divided doses; higher doses of up to 4.8 g daily have been used in severe cases. In severe disorders it has also been given by intramuscular or intravenous injection.

◊ General references.

Administration in renal impairment. Dosage should be reduced in patients with mild to moderate renal impairment according to creatinine clearance (CC):

- CC between 50 and 79 mL/minute: two-thirds of the usual dose, given in 2 or 3 divided doses
- CC between 30 and 49 mL/minute: one-third of the usual dose, given in 2 divided doses
- CC between 20 and 29 mL/minute: one-sixth of the usual dose, given as a single dose
- CC less than 20 mL/minute: contra-indicated

Dementia. Although piracetam is used in some countries in the management of cognitive impairment and dementia (p.362), a systematic review[1] concluded that the evidence from the published literature did not support this use.

1. Flicker L, Grimley Evans J. Piracetam for dementia or cognitive impairment. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2004 (accessed 14/02/06).

Myoclonus. A review[1] of 62 case reports, 3 open studies, and 2 double-blind studies concluded that piracetam is beneficial in the treatment of disabling myoclonus (p.470), either as adjunctive treatment or as monotherapy. Similar conclusions were made in another review[2] in which experience of 12 patients with progressive myoclonus epilepsy, 8 of whom benefited from piracetam in doses of up to 45 g daily without significant adverse effects, was described.

Stroke. Piracetam did not influence the outcome if given within 12 hours of the onset of acute ischaemic stroke in a multicentre, randomised, double-blind study,[1] although post hoc analyses suggested that it might confer benefit when given within 7 hours of onset, particularly in patients with stroke of moderate to severe degree. Further analyses of the same data concluded that piracetam did not produce significant adverse effects when given in high doses to patients with acute stroke,[2] and significantly more patients had recovered from aphasia on piracetam than placebo.[3] The results of two further randomised, double-blind, placebo-controlled studies supporting the role of piracetam as an adjunct to intensive speech therapy in improving aphasia following stroke were also reported.[3] In contrast, a systematic review including the first study considered that the trend towards an increased risk of early death in patients allocated to piracetam was of concern, and concluded that the data did not support routine use of piracetam in acute ischaemic stroke.[4]

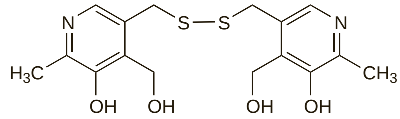
ATC — N06BX02.
ATC Vet — QN06BX02.



(pyritinol)

Pharmacopoeias. In *Chin.* and *Pol.*

Profile

Pyritinol hydrochloride has been described as a nootropic that promotes the uptake of glucose by the brain. It has been used in the treatment of various cerebrovascular and mental function disorders. It has been given in a usual oral dose of 600 mg daily in 3 divided doses. Pyritinol hydrochloride has also been given as an alternative to penicillamine in rheumatoid arthritis. It is also an ingredient of various preparations promoted as tonics.

$C_{14}H_{22}N_2O_2.C_4H_6O_6$ = 400.4.
CAS — 129101-54-8.
ATC — N06DA03.
ATC Vet — QN06DA03.

Adverse Effects, Treatment, and Precautions

As for Donepezil, p.364.

Effects on the gastrointestinal tract. A 67-year-old woman experienced severe vomiting after rivastigmine, in an oral dose of 4.5 mg, was mistakenly reintroduced without the recommended titration phase;[1] the vomiting was so severe that the patient also suffered a rupture of the oesophagus that needed corrective surgery. The authors' commented that careful dose titration of rivastigmine is necessary even when restarting treatment.

1. Babic T, *et al.* Spontaneous rupture of oesophagus (Boerhaave's syndrome) related to rivastigmine. *Age Ageing* 2000; **29:** 370–1.

Interactions

As for Neostigmine, p.632. See also Antimuscarinics, under Donepezil, p.365, for mention of an interaction between rivastigmine and tolterodine.

Pharmacokinetics

Rivastigmine is readily absorbed from the gastrointestinal tract and peak plasma concentrations are reached in about 1 hour after oral doses. Food delays absorption by about 1.5 hours and reduces maximum plasma concentrations. Absorption from transdermal patches is slow and peak plasma concentrations are reached in 10 to 16 hours after applying the first patch; with subsequent patches, peak concentrations are reached in about 8 hours. Exposure to rivastigmine is highest when the patch is applied to the upper back, chest, or upper arm, and about 20 to 30% lower when applied to the abdomen or thigh. Rivastigmine is about 40% bound to plasma proteins and readily crosses the blood-brain barrier; it is widely distributed throughout the body. Rivastigmine is rapidly and extensively metabolised, primarily by cholinesterase-mediated hydrolysis to the weakly active decarbamylated metabolite. The plasma half-life is about 1 hour after oral doses and about 3 hours after patch removal. After oral use, more than 90% of a dose is excreted in the urine within 24 hours; no unchanged rivastigmine is detected in the urine. Less than 1% of a dose appears in the faeces.

Uses and Administration

Rivastigmine is a carbamate type reversible acetylcholinesterase inhibitor; it also inhibits butyrylcholinesterase. Rivastigmine is selective for the CNS and is used for the symptomatic treatment of mild to moderately severe dementia in Alzheimer's disease (below) and idiopathic Parkinson's disease (below). It is given orally as the hydrogen tartrate or in transdermal patches as the base. For both routes doses are expressed in terms of the base; 2.4 mg of rivastigmine hydrogen tartrate is equivalent to about 1.5 mg of rivastigmine.

An initial oral dose is 1.5 mg given twice daily with food. Thereafter, the dose may be increased according to response and tolerance by increments of 1.5 mg twice daily at intervals of at least 2 weeks to a maximum dose of 6 mg twice daily. In the USA, licensed product information recommends dose increments at intervals of at least 4 weeks when treating dementia associated with Parkinson's disease.

Transdermal patches delivering 4.6 or 9.5 mg of rivastigmine over 24 hours are also available for once-daily application. In the USA, rivastigmine patches may be used for the treatment of dementia in Alzheimer's disease or Parkinson's disease; however, in the UK, use is restricted to dementia in Alzheimer's disease. An initial transdermal dose is 4.6 mg daily; after at least 4 weeks and if well tolerated, the dose should be increased to 9.5 mg daily. Patients already taking oral rivastigmine may be changed to the patches as follows:

- those taking 6 mg daily or less of oral rivastigmine may be switched to patches delivering 4.6 mg over 24 hours
- those taking more than 6 mg daily orally may be switched to patches delivering 9.5 mg over 24 hours

The first patch should be applied on the day following the last oral dose. The patch should be applied to intact skin on the upper or lower back, or on the upper arm or chest; it should not be applied to the abdomen or thigh due to decreased bioavailability. Re-application to the same site should be avoided for 14 days.

If treatment with oral or transdermal rivastigmine is interrupted for more than a few days, it should be restarted at the low initial dose, and then increased as described above. Clinical benefit should be reassessed on a regular basis; treatment should be stopped if there is no improvement after 3 months.

Dementia. Studies[1-4] and a systematic review[5] indicate that rivastigmine may be of benefit in the management of patients with mild to moderate dementia in *Alzheimer's disease* (see Dementia, p.362). In the UK, NICE has recommended that its use should be limited to patients with moderate dementia and given under the following conditions:[6]

- treatment should only be started under specialist supervision
- patients who continue on the drug should be reviewed every 6 months
- treatment should only be continued if there was evidence of benefit

In a somewhat controversial decision, NICE considered that rivastigmine could no longer be recommended in the treatment of mild dementia because its cost-effectiveness was questionable; however, it was recommended that those currently taking rivastigmine for mild dementia should continue on therapy until it was considered appropriate to stop.

Rivastigmine given in titrated doses of up to 6 mg twice daily was also found to be well tolerated, and to produce some improvement in behavioural and psychiatric symptoms, in a group of patients with *Lewy-body dementia*.[7] However, a systematic review[8] that included this study noted that rivastigmine did not have significant benefit in cognitive function compared with placebo; the authors considered that the evidence for its use in such patients was weak and that further trials were needed.

Rivastigmine has also been tried in the treatment of *vascular dementia*. A systematic review[9] concluded that although there is some evidence of benefit in these patients, available data are inadequate and further trials were warranted before rivastigmine could be recommended.

For the use of rivastigmine in the treatment of dementia in Parkinson's disease, see below.

Parkinsonism. Although acetylcholinesterase inhibitors such as rivastigmine may theoretically worsen parkinsonian symptoms, particularly tremor, it has been tried for use in the treatment of drug-induced psychosis in patients with Parkinson's disease (see Disturbed Behaviour, p.954). In 2 large studies,[1,2] rivastigmine was found to produce some improvement in symptoms of dementia associated with Parkinson's disease when compared with placebo.

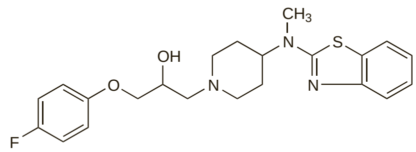
Sabeluzole *(BAN, USAN, rINN)*

R-58735; Sabeluzol; Sabéluzole; Sabeluzolum. (±)-4-(2-Benzothiazolylmethylamino)-α-[(4-fluorophenoxy)methyl]-1-piperidineethanol.

Сабелузол

$C_{22}H_{26}FN_3O_2S = 415.5.$

CAS — 104153-38-0; 104383-17-7;.



Profile

Sabeluzole is a benzothiazole derivative with anticonvulsant and antihypoxic properties. It has been investigated in the treatment of Alzheimer's disease and of sleep apnoea.

Tacrine Hydrochloride

(BANM, USAN, rINNM)

CI-970; Hidrocloruro de tacrina; Tacrine, chlorhydrate de; Tacrini hydrochloridum; Tetrahydroaminoacridine Hydrochloride; THA. 1,2,3,4-Tetrahydroacridin-9-ylamine hydrochloride.

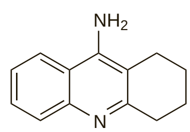
Такрина Гидрохлорид

$C_{13}H_{14}N_2,HCl = 234.7.$

CAS — 321-64-2 (tacrine); 1684-40-8 (tacrine hydrochloride).

ATC — N06DA01.

ATC Vet — QN06DA01.



(tacrine)

Pharmacopoeias. In *US* as the monohydrate.

USP 31 (Tacrine Hydrochloride). The monohydrate occurs as a white powder. Freely soluble in water, in alcohol, in dimethyl sulfoxide, in methyl alcohol, in propylene glycol, and in 0.1N hydrochloric acid; sparingly soluble in linoleic acid and in macrogol 400.

Adverse Effects and Treatment

As for Donepezil, p.364. Hepatotoxicity is common, and may be severe.

Effects on the CNS. Tonic or tonic-clonic seizures were reported in 6 of 78 patients given tacrine for mild or moderate dementia of the Alzheimer's type.[1]

1. Lebert F, *et al.* Convulsive effects of tacrine *Lancet* 1996; **347:** 1339–40.

Effects on the liver. Examination of data from 2446 patients who were at least 50 years old and received tacrine for Alzheimer's disease suggested that raised serum-alanine aminotransferase (ALT) concentrations are likely to occur in about 50% of patients.[1] Most cases developed within the first 12 weeks of therapy,[1] but an asymptomatic increase in ALT concentrations has been reported in a patient after more than 80 weeks of therapy.[2] The increase is usually asymptomatic and mild, and resolves upon dosage reduction or stopping treatment. However, a small percentage of patients may develop unpredictable life-threatening hepatotoxicity although frequent monitoring of ALT concentrations during the first 12 weeks of therapy can identify susceptible individuals. No significant correlation has been found between plasma-tacrine concentrations and hepatotoxicity.[3]

For guidelines on the monitoring of ALT concentrations during tacrine therapy, see Precautions, below.

1. Watkins PB, *et al.* Hepatotoxic effects of tacrine administration in patients with Alzheimer's disease. *JAMA* 1994; **271:** 992–8.
2. Terrell PS, *et al.* Late-onset alanine aminotransferase increase with tacrine. *Ann Pharmacother* 1996; **30:** 301.
3. Ford JM, *et al.* Serum concentrations of tacrine hydrochloride predict its adverse effects in Alzheimer's disease. *Clin Pharmacol Ther* 1993; **53:** 691–5.

Precautions

As for Donepezil, p.365. Tacrine should be used with care in patients with impaired liver function or who have a history of such impairment.

Serum-alanine aminotransferase (ALT) concentrations should be monitored in patients receiving continuous treatment with tacrine. Monitoring should be carried out every other week from at least week 4 to week 16 of therapy, and then every 3 months thereafter. Weekly monitoring is recommended in patients with ALT concentrations that are greater than twice the upper limit of the normal range.

If signs of liver involvement worsen, the dose should be reduced or the drug withdrawn. If a three- to five-fold increase of ALT concentrations occurs, a reduction in the dose by 40 mg daily is recommended. For greater increases in ALT, tacrine should be withdrawn. Treatment with tacrine may be restarted once signs of liver dysfunction return to normal; more frequent monitoring of liver enzyme values will be required. Withdrawal is also imperative in patients who develop jaundice, confirmed by elevated total bilirubin levels; such patients should not be treated again with tacrine.

Abruptly stopping tacrine therapy, or a large reduction in the dose, may be associated with behavioural disturbances and a decline in cognitive function.

Interactions

As for Neostigmine, p.632. Since tacrine is metabolised in the liver by the cytochrome P450 enzyme system (principally CYP1A2), drugs that either inhibit or induce the same isoenzymes may raise or lower plasma concentrations of tacrine, respectively. Tacrine may competitively inhibit the metabolism of other drugs that are also metabolised by the cytochrome P450 isoenzyme CYP1A2.

Antidepressants. *Fluvoxamine*, an inhibitor of the cytochrome P450 isoenzyme CYP1A2, has increased plasma concentrations and reduced oral clearance of tacrine.[1]

1. Becquemont L, *et al.* Influence of the CYP1A2 inhibitor fluvoxamine on tacrine pharmacokinetics in humans. *Clin Pharmacol Ther* 1997; **61:** 619–27.

Antiparkinsonian drugs. Tacrine has been reported to exacerbate symptoms of parkinsonism and may therefore appear to reduce the effectiveness of *levodopa* therapy, see Antidementia drugs, p.807.

H_2-antagonists. *Cimetidine*, a non-specific inhibitor of the cytochrome P450 enzyme system, has been shown to inhibit the metabolism of tacrine resulting in reduced oral clearance and an increase in plasma concentrations.[1,2]

1. de Vries TM. Effect of cimetidine and low-dose quinidine on tacrine pharmacokinetics in humans. *Pharm Res* 1993; **10:** S337.
2. Forgue ST, *et al.* Inhibition of tacrine oral clearance by cimetidine. *Clin Pharmacol Ther* 1996; **59:** 444–9.

HRT. HRT with estradiol and levonorgestrel significantly increased tacrine plasma concentrations in all but one person in a study involving 10 healthy female subjects.[1] Metabolism of tacrine via the cytochrome P450 isoenzyme CYP1A2 was said to have been inhibited by the HRT.

1. Laine K, *et al.* Plasma tacrine concentrations are significantly increased by concomitant hormone replacement therapy. *Clin Pharmacol Ther* 1999; **66:** 602–8.

Tobacco smoking. Cigarette smoking can markedly reduce plasma-tacrine concentrations.[1]

1. Welty D, *et al.* The effect of smoking on the pharmacokinetics and metabolism of Cognex in healthy volunteers. *Pharm Res* 1993; **10:** S334.

Xanthines. For the effect of tacrine on the metabolism of *theophylline*, see p.1145.

Pharmacokinetics

Tacrine is rapidly absorbed from the gastrointestinal tract but large interindividual variations in oral bioavailability have been reported; peak plasma concentrations are achieved within 1 to 2 hours. Food reduces the absorption of tacrine by about 30 to 40%. It is about 55% bound to plasma proteins. Tacrine is subject to an extensive first-pass effect in the liver, and is metabolised by the cytochrome P450 system (principally CYP1A2) to several metabolites, the main one of which is the 1-hydroxy metabolite velnacrine. The elimination half-life is about 2 to 4 hours; little unchanged drug is excreted in the urine.

◊ In 3 studies in a total of 21 patients peak plasma concentrations of tacrine hydrochloride were achieved 0.5 to 3 hours after oral doses of 25 or 50 mg and oral bioavailability ranged from less than 5% to up to 36%.[1-3] Mean elimination half-lives were 1.37 and 1.59 hours after the 25 mg dose and 2.14 and 3.2 hours after the 50 mg dose. Tacrine's elimination appears to be mainly by metabolism in the liver and less than 3% of a dose was recovered unchanged in the urine of one patient.[1] Plasma concentrations of tacrine's main metabolite 1-hydroxy-9-aminotetrahydroacridine (velnacrine) rapidly exceed those of the parent compound and elimination half-lives of 43 and 81 minutes were found for this metabolite in 2 patients studied.[2] Tacrine's pharmacokinetics have been reviewed.[4]

Uses and Administration

Tacrine hydrochloride is a centrally acting reversible inhibitor of acetylcholinesterase activity used in the treatment of mild to moderately severe dementia in Alzheimer's disease (below).

The initial oral dose of tacrine hydrochloride, expressed in terms of the base, is 10 mg four times a day for a minimum of 4 weeks. Dosage should not be increased during this period because the potential exists for a delay in onset of increased liver enzyme concentrations. Serum-alanine aminotransferase concentrations should be monitored regularly (see Precautions, above) and, if there is no significant increase, the daily dose may be increased by 40 mg at four-week intervals according to response and tolerance, to a maximum of 160 mg daily in four divided doses. Tacrine should be taken on an empty stomach to improve absorption, although it can be taken with food if gastrointestinal adverse effects are a problem.

Tacrine has been used intravenously to antagonise competitive neuromuscular blockers and as a postoperative respiratory stimulant.

Dementia. Tacrine is used in the symptomatic management of Alzheimer's disease (see Dementia, p.362). It may delay cognitive decline in some patients with mild or moderate Alzheimer's disease but many cannot tolerate the dosage required and have to stop treatment because of gastrointestinal effects or signs of hepatotoxicity. There have been numerous studies of the use of tacrine in Alzheimer's disease and a meta-analysis[1] found tacrine to have a small beneficial effect on both cognition and global clinical impression, although it was considered that the clinical relevance of these findings was unclear and that there were no data from long-term controlled studies. Some have considered[2-6] that a cautious trial of tacrine may be warranted in patients with mild to moderately severe Alzheimer's disease (although alternative drugs are now available) and various guidelines on its use have been issued.[5,6] The metabolite velnacrine has also been tried but does not appear to be effective, and is also associated with hepatotoxicity.[7]

Antidepressants

Bipolar disorder, p.372
Depression, p.373
Mania, p.375

This chapter describes drugs used principally in the treatment of affective disorders. Affective disorders are disorders of mood that may manifest as ***depression*** or ***mania*** or, in some cases, as ***mixed affective states*** in which depressive and manic or hypomanic episodes may coexist or rapidly alternate.

- The core features of ***depressive disorders*** are low mood, anhedonia (the loss of interest in former pleasures or activities), pessimism, and lethargy. They were formerly classified either as ***endogenous***, in which the symptoms were independent of external factors and considered to be a consequence of factors within the patient, or ***reactive***, in which depressive symptoms were a result of external stressors (i.e. exogenous). It is now recognised that depressive disorders are composed of both endogenous and reactive factors. Similarly, the classification of ***neurotic depression*** is no longer considered useful because it encompasses several different syndromes.

  Depressive episodes generally last for at least 2 weeks and are classified according to severity as mild, moderate, severe, or severe with psychosis. ***Recurrent brief depression*** is defined as depressive episodes of a few days' duration that recur regularly. Depression is often accompanied by characteristic ***somatic*** symptoms, including anorexia, weight loss, insomnia, early morning waking, and psychomotor retardation. Symptoms associated with ***atypical depression*** include overeating and oversleeping. Some classifications distinguish between major depressive episodes and minor (and hence ***major*** or ***minor depression***) based on the number and type of symptoms.
- The main symptoms of ***mania*** are overactivity, mood changes ranging from elation to irritability, expansive ideas, and inflated self-importance. Manic episodes are classified according to severity in a similar manner to depressive disorders: namely, mild, moderate, severe, or severe with psychosis. ***Hypomania*** is differentiated from mania in terms of a reduction in intensity of symptoms and social incapacity.
- Alternating episodes of mania or hypomania and depression are termed ***bipolar disorder (bipolar affective disorder)***. (To differentiate between alternating episodes of depression and mania or depression and hypomania, some classification systems use the terms ***bipolar I disorder*** and ***bipolar II disorder***, respectively.) Since it is very rare for repeated episodes of mania to occur without alternating episodes of depression, it is accepted practice to include mania without depression within the bipolar category. The term ***unipolar disorder*** (***unipolar depression***) is reserved for depressive disorders without mania.
- States of persistent but mild disturbances of mood exist in which the symptoms are not severe enough to meet the criteria for classification as a major depressive or hypomanic disorder, but may nevertheless cause considerable suffering to the patient. ***Dysthymia*** is the term used to describe a chronic milder depressive state whereas ***cyclothymia*** has some similarity to bipolar disorder, the instability characterised by long periods of hypomania and mild depression.
- The term ***seasonal affective disorder*** has been applied to depressive disorders repeatedly occurring seasonally, but not related to seasonal stressful life events; the depressive symptoms usually occur during the autumn and winter months. There have also been reports of patients developing seasonal bipolar disorder with hypomania or mania occurring in the summer months.
- Anxiety is often associated with depressive disorders at all levels of severity and it may be difficult to distinguish between the two conditions, especially in the milder forms. ***Mixed anxiety and depressive disorder*** defines a state in which anxiety and depressive symptoms coexist but neither component is severe enough to merit classification as an anxiety disorder or a depressive disorder.

Classification of antidepressants. Antidepressants are classified into different groups either structurally or depending on which central neurotransmitters they act upon. The older tricyclic (e.g. amitriptyline) and related cyclic antidepressants and the monoamine oxidase inhibitors (MAOIs) (e.g. phenelzine) have now been joined by the selective serotonin reuptake inhibitors (SSRIs) (e.g. fluoxetine), the reversible inhibitors of monoamine oxidase type A (RIMAs) (e.g. moclobemide), and more recently by the serotonin and noradrenaline reuptake inhibitors (SNRIs) (e.g. venlafaxine). Other antidepressants that do not fit exactly into these groups include bupropion, the herbal preparation St John's wort, mirtazapine, reboxetine, and trazodone.

Lithium salts provide a source of lithium ions that compete with sodium ions at various sites in the body and thus have an action and adverse effects distinct and separate from those of other antidepressants.

Bipolar disorder

Bipolar disorder (manic depression) is a mixed affective disorder in which the patient has alternating episodes of hypomania or mania and depression. Although isolated episodes of mania may occur, they are more usually part of bipolar disorder; for the purposes of classification, mania without depression is therefore included in the bipolar category. Manic episodes usually start suddenly and last on average for about 4 months. The depressive phase may last longer with an average duration of 6 months. The course of the illness is unpredictable; most patients will suffer a relapse after an initial manic episode, and of these, probably 10 to 20% will experience more than 3 episodes a year with partial or full remission in between, or switch to the alternative phase (rapid cycling). The diagnosis of bipolar disorder can be difficult, particularly if patients are only seen during the depressive phase. The morbidity of the disorder is often substantial especially during the depressive phase. Suicide is a significant risk and up to one-third of patients may attempt to take their own life.

The treatment of bipolar disorder is generally divided into the following phases:

- acute manic or mixed episode
- acute depressive episode
- maintenance and long-term treatment

Guidelines have been issued in the UK[1-4] and USA[5] to facilitate treatment choice in the management of bipolar disorder; international guidelines and expert consensus statements are also available.[6-9] The choice of drug therapy should be guided by severity, the type of episode (including associated symptoms), and patient preference.[5]

In patients with severe **manic** or mixed episodes, initial treatment with an antipsychotic or the mood stabiliser valproate should be considered because of their rapid onset of action; for less severe cases lithium, another mood stabiliser, may also be appropriate.[2,3,6,8] The choice between lithium or valproate as first-line treatment has been a matter of debate: although there is more reliable evidence for the use of lithium, its narrow therapeutic index and monitoring requirements[10-12] (see under Pharmacokinetics of Lithium, p.405) have led to the increased use of valproate in some countries.[10] Lithium must also be given in high doses in acute mania and its antimanic actions may be delayed by at least a week.[11,13] Nonetheless, lithium is still widely used[11] and some guidelines[6,8] prefer it to other mood stabilisers in patients with euphoric mania. However, valproate may be a better first-choice drug in rapid cycling bipolar disorder, for which it is particularly effective, and in mixed or dysphoric states.[3,5,6,8,9] Carbamazepine and its derivative oxcarbazepine are sometimes used as alternatives to lithium or valproate although their efficacy is not as well established and they are considered a second-line choice by most guidelines.[2,5,6,8] Treatment with carbamazepine is also complicated by its numerous drug interactions.[10,12,13]

Patients with mania and co-existing psychotic features usually require treatment with an antipsychotic to produce a rapid tranquillising effect.[5,8] Traditionally, classical antipsychotics such as the phenothiazine chlorpromazine and the butyrophenone haloperidol have been used although most guidelines now recommend the atypical antipsychotics, particularly olanzapine, quetiapine, and risperidone, because of their more favourable adverse effect profile.[2,3,5,6,8] Nevertheless, classical antipsychotics still appear to be widely used in the treatment of mania although high-dose therapy should be avoided because of the risk of extrapyramidal effects.[8] If sedation is required the short-term use of a benzodiazepine such as clonazepam or lorazepam should be considered instead of high-dose antipsychotics;[2,3,5] however, such treatments should be stopped as soon as symptoms subside in order to reduce the risk of dependence.[12]

The initial treatment should be continued at an optimal dose for at least 1 week before making any change to the regimen if the patient is unresponsive; if there is a partial response it may be appropriate to wait at least another week before considering the treatment ineffective. Options for patients who are inadequately controlled on optimised first-line treatment include a trial of lithium or valproate with an antipsychotic.[2,3,5,6,8] (Combination therapy has also been recommended as first-line treatment in patients with particularly severe symptoms.[2,5]) Another option is to try an alternative mood stabiliser or antipsychotic.[6] Clozapine may be considered in more refractory cases[2,5] and ECT is effective in patients who are severely ill or resistant to treatment.[2,3,5,8]

The treatment of the acute **depressive phase** of bipolar disorder depends on the severity of the depression and whether any psychotic symptoms are still present. Less severe cases may be adequately controlled by lithium, which has a modest antidepressant action.[2,7] Alternatively, treatment with lamotrigine or an antidepressant may be considered although most guidelines[2,3,6,7] recommend that antidepressants should be given with a mood stabiliser such as lithium or valproate to reduce the risk of antidepressant-induced switching (see below).

The selection of an antidepressant for bipolar depression generally involves the same considerations as those for unipolar depression (see below) although the risk of switching to mania should also be taken into account. Antidepressants have also been implicated in the induction of rapid cycling;[5,12] they should be tapered and stopped if either switching or rapid cycling occurs.[2,3,6] The SSRIs and possibly bupropion are usually first-choice antidepressants as they have a low risk of switching when compared with other antidepressants.[2,5-7,14] Tricyclic antidepressants should only be used in resistant cases as the risk of switching to mania is higher than with other antidepressant groups.[2,3] Data for the newer antidepressants such as nefazodone and venlafaxine are limited; it has been suggested that the risk of switching with venlafaxine is increased.[6,7] MAOIs may be less likely to induce mania than other antidepressants, but troublesome adverse effects and safety issues have limited their use.

As with the manic phase, treatment should be tried at an optimal dose and for an adequate time before it is considered ineffective.[6] If there is no response, second-line options include adding an antidepressant or lamotrigine in those patients on monotherapy with a mood stabiliser such as lithium, or in those patients already on an antidepressant, an alternative antidepressant may be tried or a second mood stabiliser added.[5-7] Additional treatment with an antipsychotic may be necessary if psychotic symptoms are also present.[2,5,7] However, some atypical antipsychotics have also been shown to be of benefit in non-psychotic bipolar depression when given with an antidepressant[6] and one such combination preparation (olanzapine with fluoxetine) is available in some countries. In the USA, the atypical antipsychotic quetiapine is licensed for use as monotherapy in bipolar depression. ECT is a valuable alternative and should be considered for resistant or severe bipolar depression.[2,3,5,7]

Once the acute phase has been brought under control, drug therapy should be continued until the patient is thought unlikely to suffer a relapse; this might entail **maintaining treatment** for several months.[2,5,15] When full remission has been achieved treatment should be gradually stopped over several weeks unless long-term treatment is planned (see below). Antipsychotics and antidepressants are usually stopped unless residual symptoms persist.

Some guidelines[2,5] recommend that **long-term** treatment should be started after a single episode of mania although others generally wait until a patient has had at least 2 manic episodes.[6] Lithium is often the drug of choice for the long-term treatment of bipolar disorder.[2,3,5] It reduces the risk of relapse, particularly mania,[2] although its prophylactic effects on depression are less obvious.[16] Long-term lithium treatment has also been associated with an anti-suicide effect.[2,15] Other treatment options include valproate, lamotrigine (particularly if bipolar depression is a burden), olanzapine, and possibly carbamazepine or oxcarbazepine.[2,3,5,6,9] Combination therapy may be necessary in those who fail on monotherapy; ECT and clozapine have also been tried in treatment-resistant patients.[2,9] However, it is usual practice for patients to continue with their acute treatment, given at the same doses, if effective.[2,5,6]

There is no consensus on the appropriate duration of long-term treatment and in some patients with severe disorders it may be necessary to continue treatment indefinitely.

Depression

Clinical depression (unipolar depression) is a disturbance of mood that is distinguishable from the usual mood fluctuations of everyday life. A depressed mood is usually the major symptom, which may be accompanied by other mental or somatic symptoms representing several depressive syndromes (see p.372). Suicide is a significant risk and up to half of all patients with depression may attempt suicide during their lifetime. Risk factors for developing depression include female gender and a positive family history.

The aetiology of depression is unknown but it may represent an interaction between psychological and biochemical mechanisms rather than any single factor. The symptoms appear to be mediated through alterations in levels of some central neurotransmitters, although it is not certain that this represents a cause of the disorder. However, it is at this level that the antidepressant drugs currently in clinical use exert their action.

Guidelines have been issued nationally in, for example, the UK[1,2] and the USA,[3-5] and internationally,[6,7] which provide evidence-based recommendations for the treatment of depression. The decision to start treatment should be based on the severity of the condition and the risks to the patient.

- Patients with *mild depression* may improve while being monitored without any additional help; in others simple interventions such as problem-solving, counselling, or exercise may be effective.[2] The evidence for the efficacy of antidepressants in mild depression is lacking and initial treatment with antidepressants is not recommended;[1,2,4] however, patients with persistent mild depression or those with a history of depression may benefit from antidepressant treatment.[1,2]
- Patients with *moderate* depression should be treated with an antidepressant;[2] in addition, psychological treatments (particularly cognitive behavioural therapy) are also effective.[2]
- A combination of antidepressants and psychological treatments should be considered in patients with *severe* depression.[2] ECT may also be of value, particularly when a rapid improvement of symptoms is essential (e.g. in patients at high risk of suicide) or in patients with depressive psychosis or psychomotor retardation.[8,9]
- For patients with *psychotic depression*, an antipsychotic may be required in addition to any antidepressant treatment;[2,4] ECT should also be considered.[4]
- Light therapy appears to be effective in patients with *seasonal affective disorder*.[10,11] Exposure to bright artificial light may take place at any time of the day, and the therapy should continue until the natural seasonal remission of the disorder; antidepressant drugs may also be used.

Choice of antidepressant. In more recent years many newer drugs have been licensed and added to the original treatments for depression. The role of these drugs relative to the older drugs is established for some of the newer drug groups, particularly the SSRIs, and evidence suggests that efficacy is comparable. In addition, many new drugs have been promoted on the basis of superior tolerability and this is also supported by clinical studies (see below for further details). The improved choice of treatment options offered by the newer antidepressants has meant that therapy is increasingly tailored to individual patient requirements.

- Tricyclic antidepressants have long been preferred over MAOIs because of the problem of drug interactions and the need for strict dietary precautions with the latter group. Tricyclics with sedative properties may be more suitable for agitated and anxious patients, whereas those with less sedative properties may be preferred for withdrawn and apathetic patients. Unfortunately, the traditional tricyclics such as amitriptyline have antimuscarinic and cardiotoxic adverse effects that can limit their use. Their cardiotoxicity also means that they are associated with a high risk of fatality in patients taking overdoses (see toxicity in overdosage, below).
- Continuing development produced lofepramine and drugs related to the tricyclic group such as mianserin that are less cardiotoxic than the earlier tricyclics.
- The subsequent introduction of SSRIs such as fluoxetine provided a group of drugs with still fewer antimuscarinic and cardiotoxic adverse effects. However, the SSRIs themselves have characteristic adverse effects; gastrointestinal symptoms such as nausea and vomiting may be a problem, and sleep disturbances and anxiety may be exacerbated at the start of treatment. Moreover, those in current clinical use interact to varying degrees with cytochrome P450 isoenzymes, which carries a potential for interaction with a wide range of compounds.
- More recently serotonin and noradrenaline reuptake inhibitors (SNRIs) such as duloxetine and venlafaxine have been developed, as well as reversible inhibitors of monoamine oxidase type A (RIMAs) such as moclobemide. RIMAs offer a safer alternative to the MAOIs and fewer dietary restrictions are necessary. Nefazodone, mirtazapine, and reboxetine, which have slightly different biochemical profiles from the major groups, are also more recent introductions. Bupropion, another unrelated antidepressant, is also available in some countries. With the exception of nefazodone, which causes hepatotoxicity and venlafaxine, which is cardiotoxic, most of these newer drugs seem to be associated with fewer severe adverse effects; their efficacy is also comparable to that of the tricyclics and SSRIs.[12-14]
- Other drugs used in the treatment of depression include flupentixol, the antidepressant dose of which is lower than that used for the treatment of psychoses. Ademetionine, the active derivative of methionine, has been tried in depressive disorders, and extracts of the plant St John's wort are widely used in some countries for depression. Transdermal patches containing selegiline, an irreversible inhibitor of monoamine oxidase type B, are available in the USA for the treatment of depression. Lithium may be used for the prophylaxis of recurrent unipolar depression as an alternative to standard antidepressants, although it is more commonly used in the management of bipolar disorder (see above); its role in unipolar depression is more usually to augment the effect of standard antidepressants in treatment-resistant disease.

An area of particular concern with regard to initial choice of an antidepressant is the most appropriate drug for patients considered to be a high suicide risk.[15] It is important to remember that suicide is an inherent risk in depression; it is generally accepted that with all antidepressant therapies the risk of suicide may increase in the early stages of recovery (for further details, see Effects on Mental State, under Fluoxetine, p.392). Varying relative risks of **toxicity in overdosage** for different groups of antidepressant have been assessed:[16-19]

- older tricyclics and the tetracyclic maprotiline[20] appear to be more toxic in overdosage than the tetracyclic mianserin[21] and the SSRIs[18,22]
- MAOIs have an intermediate risk[22,23]
- within the tricyclic group, desipramine[16,17,22] has been reported to be associated more frequently with fatal overdosage although some[24] assign this status to dosulepin. The *BNF* considers amitriptyline and dosulepin to be particularly dangerous in overdosage; lofepramine[19,22,25] may be one of the safer tricyclics
- toxicity of the SNRI venlafaxine in overdose appears to be greater than other new serotonergic antidepressants and comparable to some of the less toxic tricyclics[22]

Although such analyses cannot determine to what extent the data reflect prescribing patterns and patient selection as opposed to drug toxicity[16,17,25] it is widely accepted that the older tricyclics are more toxic in overdosage, and that the SSRIs[26,27] and the newer tricyclic and related cyclic antidepressants are safer.[27] In practice, it is often difficult to identify patients at high risk for suicide, and it has therefore been suggested that a routine strategy should be to begin antidepressant therapy in all patients with drugs that have low toxicity in overdose.[15,27] However, whichever antidepressant is chosen, all patients should be closely monitored during early therapy until significant improvement in depression has been observed and limited quantities of antidepressants should be prescribed at any one time.

Current guidelines recommend that choice of antidepressant should be based on superior tolerability, safety in overdose, and efficacy at prescribed doses.[1-4,6] Meta-analyses[28-31] comparing the efficacy of SSRIs and tricyclics in general find no difference in efficacy although there is the suggestion of a greater efficacy for some tricyclics when given to inpatients. However, drop-out rates due to adverse effects have generally been higher in patients receiving tricyclics than in those taking SSRIs. Based on these findings, most guidelines recommend that an SSRI[1,2,4,6] should be used as first-line treatment. In addition some consider that lofepramine, nortriptyline, or newer antidepressants such as mirtazapine or reboxetine are suitable alternatives.[1,4,6] Bupropion, which is marketed as an antidepressant in the USA, is considered to be a first-line choice in US guidelines.[4] Older tricyclics may, however, be more appropriate in severely ill, hospitalised patients or in other situations where maximising efficacy is important.[1] The use of an MAOI may be considered in patients with atypical depression[4,6] although, in practice, SSRIs are often tried initially because of their more favourable adverse effects profile.[4]

The sedative properties of some of the antidepressants may adversely affect the performance of potentially hazardous tasks such as driving and the operation of machinery. One of the less sedative antidepressants should be used where appropriate, although care is needed with all psychotropic drugs, especially at the start of treatment.

Regardless of antidepressant choice, certain principles of management apply when **starting antidepressant therapy**.

- A low initial dose will minimise adverse effects; this is then increased until an adequate response is observed.[4] When this is done with the newer antidepressants, including the SSRIs, the dose can generally be increased after a few days; for the tricyclics the increase should be more gradual.[32] Gradual introduction of treatment is of particular importance in the elderly who may be more susceptible to adverse effects.
- Although some adverse effects of antidepressant drugs appear soon after treatment is started, there is a delay of about 2 weeks before any therapeutic benefit is observed, and at least 6 weeks before maximum improvement in depressive symptoms occurs.[33] Claims of a fast onset of action have been made for several antidepressants, but in a review[34] of data relating to onset of action with currently available antidepressants, none have been shown conclusively to work faster than any other. This delay in benefit may relate to a combination of pharmacokinetic and neurochemical factors.
- Patients should not be considered resistant to the chosen drug until they have been maintained at an adequate dose for at least 4 weeks[1,2] (the *BNF* and NICE[2] have recommended 6 weeks in the elderly). Patients with a partial response should continue for a further 2 weeks (6 weeks in the elderly[2]) before being considered resistant.[1,2] Treatment failure is often due to subtherapeutic doses,[1,2] particularly with the older tricyclics whose adverse effects limit maximum tolerable doses in many patients.[35] Where lack of compliance leads to subtherapeutic doses therapeutic drug monitoring may be of value.[6]

In those who show little or no response to an adequate trial of the first-choice antidepressant the following options exist:

- switching to an alternative antidepressant
- adding another drug (augmentation), particularly if there has been a partial response
- introducing psychological treatments such as cognitive behavioural therapy

Guidelines generally consider it preferable to try an alternative single antidepressant before giving combinations of drugs (augmentation).[1-4,6] It has been suggested that for practical purposes a patient should not be considered to have treatment-resistant depression until 2 or more consecutive antidepressants at adequate doses have been tried without response.[2]

If **switching antidepressants** the choice is between a drug from the same pharmacological group or one from a different group.[1-4,6] In the UK, venlafaxine is usually reserved for patients with treatment-resistant depression because of its adverse cardiovascular effects and toxicity in overdose.[2] MAOIs can also be tried in patients who are refractory to or intolerant of treatment with other antidepressants.[1,2,4]

When changing a patient from one type of antidepressant to another an appropriate drug-free interval may be needed. An MAOI (including a RIMA and selegiline) should not be started until at least one week after stopping a tricyclic antidepressant, an SSRI, or any related antidepressant; in the case of bupropion, mirtazapine, and the SSRI sertraline the drug-free interval is extended to 2 weeks, and for fluoxetine, to 5 weeks because of their longer half-lives. For the tricyclics clomipramine and imipramine a drug-free interval of 3 weeks should be allowed. Conversely, 2 weeks should elapse between stopping MAOI (including selegiline) therapy and starting patients on a tricyclic antidepressant (3 weeks in the case of clomipramine or imipramine), an SSRI, or any related antidepressant. No treatment-free period is necessary between stopping a reversible inhibitor of monoamine oxidase type A (RIMA) and starting an SSRI or another antidepressant.

Drugs that have been used in **augmentation strategies** for resistant depression include lithium,[1,2,4,6] thyroid hormones (liothyronine),[1,4,6,36] and central stimulants[4,36] such as methylphenidate. Pindolol has also been studied as an augmentation agent with several SSRIs and other serotonergic antidepressants.[6,36] Another method is to combine different classes of antidepressants. Although this has been used successfully in the treatment of drug-resistant depression,[2,4,6,36] it may result in enhanced adverse reactions or interactions and the *BNF* considers it hardly ever justified; it should only ever be done under expert supervision. For further details of the interactions between different antidepressants, see under Interactions of Phenelzine, p.418.

If the response to treatment is good, the patient should continue with the same treatment for at least 4 to 6 months,[1-4] and perhaps 12 months in the elderly;[6] symptoms are likely to recur if treatment is stopped too soon.[37-39] In general, the dose should not be reduced for this **continuation phase**.[1-4,7] Continuing therapy beyond this phase[1,2,4,7,40] is a matter of clinical judgement and should take into account the number of prior episodes, any residual symptoms, and the severity of the episode. **Maintenance therapy** should be considered for recurrent depressive disorders,[1,2,4,7,37,39,41] and may be necessary for several years, if not indefinitely, in some cases. Again, full therapeutic doses are recommended for prophylaxis rather than reduced doses.[1,2,4,7,38,41]

Suddenly **stopping antidepressant therapy** after regular use for 8 weeks or more may precipitate withdrawal symptoms.[42-44] Common symptoms seen after antidepressant withdrawal include headache, anorexia, nausea, insomnia, and anxiety; the SSRIs have also been associated with episodes of dizziness and paraesthesia which are rarely seen with the tricyclics.[45] Withdrawal reactions may be more severe with the MAOIs especially tranylcypromine.[45] To minimise symptoms, most guidelines[1,4] and authorities such as the *BNF* recommend reducing the dose over a period of about 4 weeks, although considerably longer periods (6 months) may be required when withdrawing maintenance therapy.

Depressive disorders may arise in **childhood and adolescence**, the prevalence increasing with age.[6] Concerns about a possible increased risk of suicide with antidepressant treatment, have led to considerable uncertainty about appropriate management in young patients.[46-50] In the UK, guidelines state that the mainstay of treatment for this patient group should be psychological therapy;[46] treatment with antidepressants should only be offered alongside psychological therapy. For children and adolescents with mild depression, as for adults, a period of watchful waiting may be appropriate before starting any treatment. If symptoms have not resolved after several weeks, patients should be started on an appropriate course of psychological therapy such as group cognitive behavioural therapy or guided self-help which should be continued for 2 to 3 months. Antidepressants should not be used for the initial treatment of mild depression. Children or adolescents with moderate to severe depression (or those with mild depression unresponsive to the above measures) should be given more specific psychological treatment such as individual cognitive behavioural therapy, interpersonal therapy, or short-term family therapy. Combined treatment with an antidepressant (which, as in adults, appears more effective than either alone[51]) should only be considered if there is a lack of response to psychotherapy alone.[46] The SSRI fluoxetine is considered the first-choice antidepressant in children aged 12 and over because of proven efficacy and low toxicity in overdose;[6,46] although the evidence for its efficacy in younger children has been questioned,[46] a review by the EMEA concluded that studies showed a positive effect and allowed its use throughout the EU in children from 8 years of age.[52] The other SSRIs should not be used in children (but see below) because of a lack of demonstrated efficacy and/or an increased risk of a harmful outcome (see Effects on Mental State under Fluoxetine, p.392 for further details). Similar recommendations have been made for the SNRI venlafaxine (see p.428). Patients who remain unresponsive to combined treatment should be initially tried on an alternative psychological therapy.[46] A change in antidepressant may also be warranted and guidelines issued in the UK have suggested that citalopram and sertraline may be appropriate, provided certain criteria have been met.[46] (Paroxetine and venlafaxine should not be used.[46]) Lithium has also been tried[6] and ECT may be considered for older children with severe, unresponsive depression.[6,46] Tricyclics may have a modest effect in the treatment of depression in adolescents; however, they are not effective in the treatment of younger children.[53] In practice they have often been reserved for refractory cases in adolescents[54] although evidence to support this role is lacking[53] and recent UK guidelines[46] do not recommend their use. There have also been reports of death due to cardiotoxicity in children taking tricyclic antidepressants, in particular desipramine and imipramine.

Following the concerns raised about the possible increased risk of suicide in children and adolescents treated with antidepressants, the FDA undertook a meta-analysis of 372 studies in adults. From 295 studies in psychiatric patients, the overall risk of suicide was not increased, but there was a trend toward increased risk with younger age. Although the effect was not statistically significant, the FDA considered the trend sufficiently convincing to warn that, like children and adolescents, **young adults** (aged 18 to 24 years) treated with antidepressants of any type may be at increased risk of suicidal thinking and behaviour.[55] In the UK, an Expert Working Group of the CSM found no clear evidence that use of SSRIs in young adults increased the risk of self-harm or suicidal thoughts;[56] however, it was noted that such patients have a higher background risk of suicidal behaviour than older adults and consequently should be closely monitored during treatment.

Depression in the **elderly** is not uncommon and may affect up to 4% of this population.[57] Suicide is also more frequent in the elderly than in the general population and depressive symptoms are present in about 80% of patients aged over 74 years who commit suicide.[57] Depression in the elderly is often undertreated and prognosis is poor; treatment is also often complicated by co-existing medical conditions.[4,6,57,58] SSRIs are often the first choice of treatment in the elderly because of their favourable adverse effect profile and low toxicity in overdose.[4,6,57,58] They may be especially appropriate in patients with an existing cardiovascular disease or in those taking other medications that may lower the blood pressure. Tricyclics such as amitriptyline and imipramine are probably best avoided in the elderly as their cardiotoxic, antimuscarinic, and sedative effects may be particularly troublesome. However, the tricyclics desipramine and nortriptyline are considered by some[4,6,57] to be an alternative first-choice as they are less cardiotoxic and have fewer antimuscarinic and sedative actions compared with amitriptyline or imipramine. Other newer antidepressants may also be useful in specific situations; bupropion, which has the advantage of a relative lack of cardiotoxicity and drug interactions, may be an appropriate option.[4] Lower initial doses of antidepressant drugs are often recommended in the elderly to minimise adverse effects but individual differences in metabolism and excretion may mean that some patients are undertreated. The elderly tend to respond more slowly to antidepressants than younger patients[6] and additional psychosocial or psychotherapeutic management is often warranted.[4,57] The treatment of resistant depression in elderly patients should follow the same principles as in younger patients.[6,57] ECT is also safe and effective in the elderly, and should be considered in those at high risk for suicide or who are refractory to or intolerant of antidepressant drugs.[6,57] Depression late in life may require long-term antidepressant treatment beyond the recovery phase, even after first episodes of depression and should be a continuation of the treatment that was successful in the initial acute phase (see above).

Treatment of women with depressive disorders during and after **pregnancy** raises concerns about the risk of teratogenicity, fetal growth retardation, or perinatal problems (see also individual drug monographs); the ratio of risk to the child versus the benefit to the mother must therefore be considered very carefully.[4,6,59] It should also be remembered that untreated depression during pregnancy has been associated with poor neonatal outcomes such as low birthweight.[4] In some cases starting treatment with an antidepressant will be appropriate although psychotherapy and ECT should also be considered as alternatives.[6] Treatment should not be stopped as a matter of routine in early pregnancy in women who become pregnant while taking an antidepressant.[59] Maternal mood disorders in the immediate postpartum period are related to hormonal changes, particularly falling progesterone levels; the symptoms are mild and resolve spontaneously after several days, therefore no treatment is required.[4,6] Of greater concern are major depressive episodes that occur beyond this initial phase, which are clinically identical to depressive disorders in general and call for the same principles of management[59] (although there are few studies to support this[60]). These depressive episodes have been found to be related to the presence of immediate postpartum mood disorders, although no hormonal basis to this association has been identified.[59] Nevertheless, there has been interest in the use of oestrogen as a treatment.

As with use of any medication in **breast-feeding** mothers, the risks to the infant from drugs distributed into breast milk must be considered. The American Academy of Pediatrics[61] considers that all antidepressants are drugs whose effect on nursing infants could be of concern.

Symptoms of **anxiety and depression** often coexist, and although it may be difficult to distinguish which is the predominant disorder, especially in milder forms, patients usually require an antidepressant. Anxiolytics and antipsychotics can be useful adjuncts in agitated depression, but a sedative antidepressant might be preferable. Combination preparations of antidepressants with antipsychotics or anxiolytics should not be used because the dosage of the individual components should be adjusted separately. Also, anxiolytics should only be prescribed on a short-term basis whereas antidepressants are given for longer periods.

The efficacy of antidepressants in **chronic fatigue syndrome** in clinical studies have been equivocal although it has been suggested that antidepressant therapy should be tried in patients with co-existing depression.[62] Cognitive therapy may also be useful.

Mania

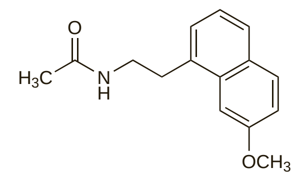
Although isolated episodes of mania (see p.372) may occur, mania is usually followed by depression when it is considered to be part of bipolar disorder. It is accepted practice to include mania without depression within the bipolar category. The treatment and prophylaxis of acute mania are therefore described under Bipolar Disorder, above.

Agomelatine *(rINN)*

Agomelatina; Agomélatine; Agomelatinum; S-20098. *N*-[2-(7-Methoxy-1-naphthyl)ethyl]acetamide.

Агомелатин

$C_{15}H_{17}NO_2$ = 243.3.
CAS — 138112-76-2.
ATC — N06AX22.
ATC Vet — QN06AX22.



Profile

Agomelatine is an agonist at melatonergic MT_1 and MT_2 receptors and an antagonist at $5\text{-}HT_{2C}$ receptors. It has antidepressant actions and is used orally in the treatment of depression (p.373) in doses of 25 to 50 mg given daily at bedtime.

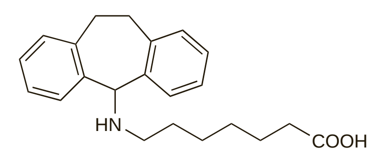
Amineptine, Chlorhydrate d'; Amineptini Hydrochloridum; Hidrocloruro de amineptina; S-1694. 7-[(10,11-Dihydro-5*H*-dibenzo[*a,d*]cyclohepten-5-yl)amino]heptanoic acid hydrochloride.

Аминептина Гидрохлорид

$C_{22}H_{27}NO_2,HCl$ = 373.9.
CAS — 57574-09-1 (amineptine); 30272-08-3 (amineptine hydrochloride).
ATC — N06AA19.
ATC Vet — QN06AA19.



(amineptine)

Profile

Amineptine hydrochloride is a tricyclic antidepressant (see Amitriptyline, below). It has been given orally in the treatment of depression.

Hepatic adverse effects seem to be more common than with most other tricyclic antidepressants (see Effects on the Liver, p.377). Also amineptine has been subject to abuse and withdrawal has been both prolonged and difficult; for these reasons, it is no longer marketed in many countries.

Adverse effects. In 5 patients very severe acne-type lesions were associated with the chronic self-increased use of high doses of amineptine (200 to 1000 mg daily).[1] Unusual lactam metabolites were detected in all patients and in 2 these metabolites were still present, along with the lesions, 3 months after therapy had been withdrawn. In another case, a 48-year-old woman developed acne-like eruptions after long-term treatment with amineptine at a dose of 400 mg daily.[2] There was no clinical improvement 6 months after amineptine withdrawal.

1. Vexiau P, *et al.* Severe acne-like lesions caused by amineptine overdose. *Lancet* 1988; **i:** 585.
2. De Gálvez Aranda MV, *et al.* Acneiform eruption caused by amineptine: a case report and review of the literature. *J Eur Acad Dermatol Venereol* 2001; **15:** 337–9.

Porphyria. Amineptine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Preparations

Proprietary Preparations (details are given in Part 3)
Braz.: Survector†; ***Port.:*** Directim†; Survector†.

Amitriptyline *(BAN, rINN)*

Amitriptilina; Amitriptyliini; Amitriptylin; Amitriptylinum. 3-(10,11-Dihydro-5*H*-dibenzo[*a,d*]cyclohepten-5-ylidene)propyldimethylamine; 10,11-Dihydro-*N,N*-dimethyl-5*H*-dibenzo[*a,d*]cycloheptene-$\Delta^{5,}$ -propylamine.

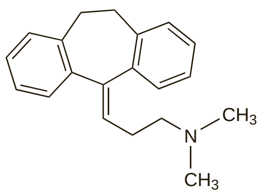
Амитриптилин

$C_{20}H_{23}N$ = 277.4.

CAS — 50-48-6.

ATC — N06AA09.

ATC Vet — QN06AA09.



Amitriptyline Embonate *(BANM, rINNM)*

Amitriptyline, Embonate d'; Amitriptylini Embonas; Embonato de amitriptilina.

Амитриптилина Эмбонат

$(C_{20}H_{23}N)_2,C_{23}H_{16}O_6$ = 943.2.

CAS — 17086-03-2.

Pharmacopoeias. In *Br.*

BP 2008 (Amitriptyline Embonate). A pale yellow to brownish-yellow, odourless or almost odourless powder. Practically insoluble in water; slightly soluble in alcohol; freely soluble in chloroform. Protect from light.

Amitriptyline Hydrochloride *(BANM, rINNM)*

Amitriptilin Hidroklorür; Amitriptilin-hidroklorid; Amitriptilino hidrochloridas; Amitriptyliinihydrokloridi; Amitriptyline, chlorhydrate d'; Amitriptylin-hydrochlorid; Amitriptylinhydroklorid; Amitriptylini hydrochloridum; Amitryptyliny chlorowodorek; Hidrocloruro de amitriptilina.

Амитриптилина Гидрохлорид

$C_{20}H_{23}N,HCl$ = 313.9.

CAS — 549-18-8.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Amitriptyline Hydrochloride). A white or almost white powder or colourless crystals. Freely soluble in water, in alcohol, and in dichloromethane. Protect from light.

USP 31 (Amitriptyline Hydrochloride). A white or practically white, odourless or practically odourless, crystalline powder or small crystals. Freely soluble in water, in alcohol, in chloroform, and in methyl alcohol; insoluble in ether. pH of a 1% solution in water is between 5.0 and 6.0.

Stability. Decomposition occurred when solutions of amitriptyline hydrochloride in water or phosphate buffers were autoclaved at 115° to 116° for 30 minutes in the presence of excess oxygen.[1]

The decomposition of amitriptyline as the hydrochloride in buffered aqueous solution stored at 80° in the dark was accelerated by metal ions.[2] Disodium edetate 0.1% significantly reduced the decomposition rate of these amitriptyline solutions but propyl gallate and hydroquinone were less effective. Sodium metabisulfite produced an initial lowering of amitriptyline concentration and subsequently an acceleration of decomposition. The rate of decomposition was also much greater in amber glass ampoules than in clear glass ones (the metal ion content of amber glass is higher than that of clear glass). However, there were considerable variations between different batches of amber glass and, since amitriptyline is photolabile, its solutions are likely to be stored in amber containers.

Solutions of amitriptyline hydrochloride in water are stable for at least 8 weeks at room temperature if protected from light either by storage in a cupboard or in amber containers.[3] Decomposition to ketone and, to a lesser extent, other unidentified products was found to occur on exposure to light.

Adverse Effects

Many adverse effects of amitriptyline and similar tricyclic antidepressants are caused by their antimuscarinic actions. Antimuscarinic effects are relatively common and occur before an antidepressant effect is obtained. They include dry mouth, constipation occasionally leading to paralytic ileus, urinary retention, blurred vision and disturbances in accommodation, increased intra-ocular pressure, and hyperthermia. Tolerance is often achieved if treatment is continued and adverse effects may be less troublesome if treatment is begun with small doses and then increased gradually, although this may delay the clinical response.

Drowsiness may also be common, although a few tricyclic antidepressants possess little or no sedative potential and may produce nervousness and insomnia. Other neurological adverse effects include headache, peripheral neuropathy, tremor, ataxia, epileptiform seizures, tinnitus, and occasional extrapyramidal symptoms including speech difficulties (dysarthria). Confusion, hallucinations, or delirium may occur, particularly in the elderly, and mania or hypomania, and behavioural disturbances (particularly in children) have been reported.

Gastrointestinal complaints include sour or metallic taste, stomatitis, and gastric irritation with nausea and vomiting.

Effects on the cardiovascular system are discussed in more detail below. Orthostatic hypotension and tachycardia can occur in patients without a history of cardiovascular disease, and may be particularly troublesome in the elderly.

Hypersensitivity reactions, such as urticaria and angioedema, and photosensitisation have been reported and, rarely, cholestatic jaundice and blood disorders, including eosinophilia, bone-marrow depression, thrombocytopenia, leucopenia, and agranulocytosis.

Endocrine effects include testicular enlargement, gynaecomastia and breast enlargement, and galactorrhoea. Sexual dysfunction may also occur. Changes in blood sugar concentrations may also occur, and, very occasionally, hyponatraemia associated with inappropriate secretion of antidiuretic hormone.

Other adverse effects that have been reported are increased appetite with weight gain (or occasionally anorexia with weight loss). Sweating may be a problem.

Symptoms of **overdosage** may include excitement and restlessness with marked antimuscarinic effects, including dryness of the mouth, hot dry skin, dilated pupils, tachycardia, urinary retention, and intestinal stasis. Severe symptoms include unconsciousness, convulsions and myoclonus, hyperreflexia, hypothermia, hypotension, metabolic acidosis, and respiratory and cardiac depression, with life-threatening cardiac arrhythmias that may recur some days after apparent recovery. Delirium, with confusion, agitation and hallucinations, is common during recovery.

Antimuscarinic and antihistaminic properties. Studies *in vitro*[1] showed antidepressant affinities for human muscarinic acetylcholine receptors and therefore the likelihood of antimuscarinic effects to be, in descending order:

- amitriptyline
- protriptyline
- clomipramine
- trimipramine
- doxepin
- imipramine
- nortriptyline
- desipramine
- amoxapine
- maprotiline
- trazodone

The effect of affinities for other receptor sites was less certain, although those antidepressants with high affinity for histamine H_1 receptors might be expected to be more sedating. Affinities for *murine* histamine H_1 receptors in descending order were:

- doxepin
- trimipramine
- amitriptyline
- maprotiline
- amoxapine
- nortriptyline
- imipramine
- clomipramine
- protriptyline
- trazodone
- desipramine

Effects on the blood. After a case report of agranulocytosis linked with imipramine, review of the literature suggested that agranulocytosis associated with tricyclic antidepressant use was a rare idiosyncratic condition, resulting from a direct toxic effect rather than an allergic mechanism, and particularly affected the elderly from 4 to 8 weeks after beginning treatment.[1]

Between 1963 and 1993 the UK CSM received 912 reports of drug-induced agranulocytosis of which 38 were due to tricyclic antidepressants (12 fatal) and 1499 cases of neutropenia of which 46 were due to tricyclics (none fatal).[2] In a report[3] on a patient who developed aplastic anaemia associated with use of remoxipride and dosulepin it was noted that up to May 1993 the CSM had also received 11 reports of aplastic anaemia secondary to use of dosulepin.

Neutropenia reported[4] in a patient after separate exposure to imipramine and nortriptyline, indicated that there might be cross-intolerance between the tricyclic antidepressants and if neutropenia developed with one member of the group the use of others on future occasions should be avoided.

Effects on the cardiovascular system. The cardiotoxic potential of tricyclic antidepressants after **overdosage** is widely acknowledged; symptoms include arrhythmias, conduction defects, and hypotension. This factor was, in part, responsible for the development of antidepressants with different chemical structures and pharmacological properties that are less cardiotoxic. It also led to some concern over whether tricyclic antidepressants had adverse effects on the heart or cardiovascular system when used in usual therapeutic doses.

Since the introduction of the tricyclic antidepressants, reports, often anecdotal, have been published of adverse cardiovascular effects at **therapeutic doses** and have included malignant hypertension with amitriptyline,[1] and cardiomyopathy in a patient who had received amitriptyline and imipramine.[2] QT prolongation, which in some cases progressed to torsade de pointes, has also been associated with the use of some tricyclics.[3,4] Sudden cardiac death in patients with pre-existing cardiac disease has been linked with amitriptyline[5-7] or imipramine,[6] although the Boston Collaborative Drug Surveillance Program failed to substantiate these findings.[8] In a more recent analysis, it has been suggested that the risk of sudden cardiac death may increase with high doses of tricyclic antidepressants.[9] Using patient medication records, it was found that the rate of sudden cardiac death in patients taking less than 100 mg of amitriptyline or its equivalent, [presumably as a daily dose although this is not specified], did not differ from that among non-users of antidepressants even in those with cardiovascular disease or other conditions considered to increase the risk of sudden death; however, the risk was significantly increased in those patients on doses of 100 mg or greater when compared to non-users, regardless of any predisposing conditions.

There have also been reports of sudden death in children given desipramine[10-12] or imipramine;[12-14] in at least some of these cases plasma concentrations were not elevated and the children had no cardiac abnormality. Again, however, evaluation of much of the evidence for the association suggests it is weak;[15] nonetheless, the American Heart Association recommends baseline ECG monitoring in children who are to be treated with tricyclic antidepressants, and a repeat ECG when steady-state dosage is achieved.[16]

Re-evaluations and reviews of this topic[17,18] concluded that the only significant or serious cardiovascular adverse effects, seen in *patients with no history* of cardiovascular disease given therapeutic doses of tricyclic antidepressants, are orthostatic hypotension and tachycardia, and that these effects may be particularly troublesome in elderly patients. However, a later study[19] also considered that prolongation of the QT interval might occur with therapeutic doses of tricyclics in non-risk patients.

In *patients with overt heart disease* it was considered[17] that increased risk was likely in those with intraventricular conduction abnormalities; in patients with a history of myocardial infarction or angina, but free of conduction defects, the use of tricyclics appeared to be primarily limited by how often they developed orthostatic hypotension and to what degree. In a re-evaluation of the risks and benefits of tricyclics in patients with ischaemic heart disease no consensus was reached.[20] In practice the authors used SSRIs or bupropion as first-choice therapy in patients with ischaemic heart disease who were mildly or moderately depressed; tricyclics were reserved for unresponsive patients and were also used as first-choice therapy for patients with more severe depression despite cardiac risks. More recently an increased risk of myocardial infarction has been found in patients taking tricyclic antidepressants (but not SSRIs) with treatment for heart disease.[21] Results of a later case-control study[22] examining the risk of ischaemic heart disease for different types of antidepressants and individual antidepressants support these findings. After adjustment for confounders and use of other antidepressants the risk of ischaemic heart disease was significantly raised in patients who had ever taken tricyclics but not in those who had received other antidepressants. When the risk was calculated for the tricyclics amitriptyline, dosulepin, and lofepramine, and confounders had been adjusted for, an increased risk of ischaemic heart disease remained only for dosulepin with evidence of a dose-response relationship.

EFFECTS ON THE PERIPHERAL CIRCULATION. Painful vasospastic episodes, characterised by cold and blue hands and feet, occurred in a woman each time she received imipramine 150 mg daily and also with amitriptyline, but only when the dose was increased to 200 mg daily.[1] This suggested that the ability of tricyclic antidepressants to induce vasospasm was not limited to imipramine and that the effect might be partly dose-dependent. Additionally, acrocyanosis of the hands and feet has been reported in a child receiving imipramine for nocturnal enuresis.[2]

2. Anderson RP, Morris BAP. Acrocyanosis due to imipramine. *Arch Dis Child* 1988; **63:** 204–5.

Effects on the endocrine system. The *syndrome of inappropriate antidiuretic hormone secretion with hyponatraemia* has been reported in patients receiving tricyclics and other antidepressants. The UK CSM, commenting on reports it had received of hyponatraemia associated with antidepressants (fluoxetine, paroxetine, lofepramine, clomipramine, and imipramine), considered that it was likely to occur with any antidepressant and usually involved elderly patients.[1] Case reports of hyponatraemia in 24 patients treated with tricyclics and 20 patients treated with other antidepressants have been summarised.[2]

In a review covering the effects of drugs on *prolactin secretion*[3] it was stated that antidepressants could affect prolactin secretion by disturbing the balance of catecholaminergic inhibition and serotonergic stimulation of prolactin release, although any change is less than with antipsychotic therapy. Clomipramine and nortriptyline had been reported to stimulate prolactin release whereas amitriptyline, desipramine, and imipramine had been reported to be without effect. Such stimulation may account for symptoms of galactorrhoea or amenorrhoea reported with some tricyclics.

Effects on the gastrointestinal tract. Rare cases of ileus and pseudo-obstruction have apparently resulted from the antimuscarinic effects of tricyclic antidepressants.[1-4] An early report[1] from the UK CSM noted no evidence that any tricyclic was especially liable to cause ileus.

1. CSM. Tricyclic antidepressants and ileus. *Current Problems 3* 1978. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2024410&RevisionSelectionMethod=LatestReleased (accessed 04/08/08)

Effects on the kidneys and urine. Haematuria has been seen in a patient receiving amitriptyline and carbamazepine;[1] carbamazepine had previously been taken alone for a long period without producing this effect.

Amitriptyline may have produced a blue-green colour in urine,[2] although it was considered to be a rare phenomenon.

2. Beeley L. *BMJ* 1986; **293:** 750.

Effects on the liver. In a report of 91 cases of hepatitis due to antidepressant therapy, 63 occurred in patients receiving the tricyclic antidepressant amineptine, sometimes with other psychotropic drugs; in about 50% of these amineptine cases, benzodiazepines had also been taken and it was postulated that the benzodiazepines may have increased the oxidation of amineptine to a toxic metabolite.[1] Most patients presented with abdominal pain and mixed liver damage with predominant cholestasis. One died after myocardial infarction, but all the others recovered. The mean amineptine dosage was 200 mg daily. In comparison, only a few cases were attributed to other tricyclic antidepressants—amitriptyline (4), clomipramine (3), and dibenzepin (1). Cross-hepatotoxicity between amineptine and clomipramine has also been reported in a patient.[2]

Hepatotoxicity has also been noted with lofepramine. The UK CSM had by the end of 1987 received 57 reports of abnormal liver function tests associated with lofepramine.[3] They included hepatic failure (1), jaundice (9), and hepatitis (5). All reactions occurred within the first 8 weeks of treatment and all were reversible on stopping the drug.

Effects on the mouth. The inhibition of salivation caused by tricyclic antidepressants (in this case clomipramine) has been implicated in dental caries formation.[1]

1. deVries MW, Peeters F. Dental caries with longterm use of antidepressants. *Lancet* 1995; **346:** 1640.

Effects on the nervous system. Effects on the nervous system attributed to tricyclic antidepressants include drowsiness (especially with those with antihistaminic activity), peripheral neuropathy, tremor, ataxia, confusion, and delirium. Of particular concern is a reduction in the seizure threshold (see Epileptogenic Effect, below). Extrapyramidal effects and neuroleptic malignant syndrome (see below) may also occasionally occur.

Effects on sexual function. Loss of libido and impotence are common in depression, often making the role of drugs in producing sexual dysfunction difficult to assess.[1]

Sedation due to tricyclic antidepressants may lead to loss of libido and many of the tricyclics have been reported to cause impotence.[1,2] Amitriptyline, clomipramine, desipramine, doxepin, nortriptyline, and trimipramine have been stated to delay or inhibit ejaculation, and amoxapine, imipramine, and protriptyline, also to cause painful ejaculation. However, some tricyclics have been used for their effect on ejaculation in the management of premature ejaculation (see Clomipramine, p.387).

In women, anorgasmia or delayed orgasm has been reported with amitriptyline, amoxapine, clomipramine, and imipramine,[1-3] although spontaneous orgasm associated with yawning has been reported with clomipramine.[4]

Effects on the skin. Hypersensitivity reactions to tricyclic antidepressants are said to be uncommon.[1] Urticaria and angioedema have occurred, the urticaria occasionally clearing without drug withdrawal. Pruritus is also uncommon, but may be associated with transient erythema. Photosensitivity reactions are far less common than with phenothiazines; protriptyline has been the tricyclic most frequently implicated.[2,3] Rarely, exfoliative dermatitis has developed, and purpura, pigmentation, and lichen planus have been noted in isolated reports. In some cases pigmentation changes may be permanent.[4] Toxic epidermal necrolysis has been reported in a patient 2 weeks after starting therapy with amoxapine.[5] Hypersensitivity reactions to tricyclic antidepressants usually occur between 14 and 60 days after the start of treatment.[6]

Amitriptyline and fluoxetine have been implicated in the development of atypical cutaneous lymphoid hyperplasia in 8 patients, 7 of whom either had an underlying immunosuppressant systemic disease or were also receiving immunomodulatory drugs.[7] The lesions improved or resolved on stopping the antidepressant, although in some patients other factors may have contributed to lesional resolution.

Epileptogenic effect. Seizures have been reported after therapeutic doses of tricyclic antidepressants as well as after overdosage, although the mechanism by which the seizures are induced is unclear.[1] Seizures usually appear within a few days of starting the drug or changing to a higher dose but in patients with no history of epilepsy or no predisposing medical condition the frequency seems[1] to be very low with an incidence of about 1 in 1000. An incidence of 0.4 per 1000 was reported[2] based on 16 cases out of an estimated group of 42 000 patients receiving tricyclics and who had no predisposing factors, but in another review[3] a reasonable estimate of the incidence was considered to be 3 to 6 per 1000. However, it is widely agreed that tricyclics should be used very cautiously in patients with epilepsy or those with a low convulsive threshold.

In a retrospective analysis of 1313 cases[4] of overdosage involving cyclic antidepressants, seizures occurred more commonly with the tricyclics amoxapine (24.5%) and desipramine (17.9%), and the tetracyclic maprotiline (12.2%). In another analysis of 302 consecutive cases of tricyclic overdosage a higher rate of seizures was seen with dosulepin in overdosage (13%) than other tricyclics.[5]

Extrapyramidal effects. Extrapyramidal effects such as orofacial and choreoathetoid movements, and dyskinesias have been attributed to treatment with tricyclic antidepressants. Dysarthria has also been reported[1] and was said to be not uncommon in those taking higher doses of tricyclic antidepressants, but unusual at lower doses.[2]

Some patients with panic disorder may be sensitive to imipramine, developing symptoms of insomnia, jitteriness, and irritability.[3] Symptoms have also been seen in patients with panic disorder treated with low doses of desipramine although the symptoms usually subsided when the dose of the tricyclic was gradually increased. It has been suggested[4] that these symptoms may be related to akathisia and are more likely to occur with those tricyclics that have a more potent effect on inhibition of noradrenaline reuptake.

Reviews of adverse effects of drugs on the nervous system have also listed acute torsion dystonias and tremors[5] as being caused or exacerbated by tricyclic antidepressants.

Hypersensitivity. A hypersensitivity syndrome developed in a 24-year-old woman 3 weeks after starting amitriptyline 50 mg daily for the treatment of depression;[1] symptoms included generalised erythroderma with mild scaling, sinus tachycardia, haematological abnormalities such as eosinophilia, and raised liver enzyme values. The patient recovered after drug withdrawal and treatment with intravenous prednisolone.

Hyponatraemia. See Effects on the Endocrine System, above.

Neuroleptic malignant syndrome. Of 16 cases of neuroleptic malignant syndrome reported to the UK CSM by July 1986, 3 cases occurred in patients receiving a tricyclic antidepressant; amitriptyline with perphenazine had been taken by one patient and dosulepin or clomipramine alone by 2 other patients. The clomipramine case was fatal.[1] Other reports have been associated with amoxapine,[2] clomipramine alone,[3] clomipramine with triazolam,[4] and nortriptyline.[5]

Overdosage. In a 1993 report[1] tricyclic antidepressants were associated with a higher risk of fatality after suicide attempts by drug overdose compared with the non-tricyclics available at the time. Some reports[2] have considered desipramine to be associated more frequently than other tricyclic antidepressants with fatal overdosage, although others[3] assign this status to dosulepin. The *BNF* considers amitriptyline and dosulepin to be particularly dangerous in overdosage.

Later reviews continue to cite tricyclic antidepressants as one of the most commonly ingested substances in fatal cases of self-poisoning.[3,4]

Treatment of Adverse Effects

The basis of the management of tricyclic antidepressant poisoning is intensive supportive care and symptomatic therapy.

Since tricyclic antidepressants slow gastrointestinal transit time, absorption may be delayed in overdosage. Activated charcoal may be given by mouth or nasogastric tube if more than 4 mg/kg of a tricyclic antidepressant has been ingested and the patient presents within 1 hour; a second dose may be considered after 2 hours in patients with central features of toxicity. Gastric lavage is rarely used but may be considered in life-threatening overdoses. Multiple doses of charcoal may be appropriate in patients who have ingested modified-release preparations.

The patient should be monitored for cardiac arrhythmias. UK authorities consider that although cardiac arrhythmias are of concern they are best treated by correction of hypoxia and acidosis with intravenous sodium bicarbonate; the use of antiarrhythmic drugs is best avoided. Intravenous sodium bicarbonate should also be given to treat arrhythmias or significant ECG abnormalities even in the absence of acidosis.

Convulsions can be managed by giving diazepam or lorazepam intravenously. Phenytoin should be avoided because it may increase the risk of arrhythmias. Diazepam by mouth is usually adequate to sedate delirious patients, although large doses may be needed.

Peritoneal dialysis, haemodialysis, and measures to increase urine production are not of value in tricyclic antidepressant poisoning, and charcoal haemoperfusion is of doubtful benefit.

Precautions

The antimuscarinic effects of tricyclic antidepressants warrant care in patients with urinary retention, prostatic hyperplasia, or chronic constipation; caution has also been advised in untreated angle-closure glaucoma and in phaeochromocytoma.

The epileptogenic potential of tricyclic antidepressants requires care in patients with a history of epilepsy. In addition, because of their potential cardiotoxicity, tricyclics should be used with caution in patients with cardiovascular disease and avoided in those with heart block, cardiac arrhythmias, or in the immediate recovery period after myocardial infarction. Caution has also been recommended in patients with hyperthyroidism as tricyclics may increase the risk of developing cardiac arrhythmias.

Blood-sugar concentrations may be altered in diabetic patients.

Because tricyclic antidepressants are metabolised and inactivated in the liver they should be used with caution in patients with hepatic impairment and avoided in severe liver disease.

Patients should be closely monitored during early antidepressant therapy until significant improvement in depression is observed because suicide is an inherent risk in depressed patients. For further details, see under Depression, p.373. Suicidal thoughts and behaviour may also develop during early treatment with antidepressants for other disorders; the same precautions observed when treating patients with depression should therefore be followed when treating patients with other disorders.

If tricyclic antidepressants are used for the depressive component of bipolar disorder, mania may be precipitated; similarly, psychotic symptoms may be aggravated if tricyclics are used for a depressive component of schizophrenia.

Drowsiness often occurs, particularly at the start of therapy, and patients, if affected, should not drive or operate machinery.

Tricyclic antidepressants may inhibit salivation and regular dental check-ups are recommended for patients on long-term therapy, particularly when taking those with marked antimuscarinic actions.

Elderly patients can be particularly sensitive to the adverse effects of tricyclic antidepressants and a reduced dose, especially initially, should be used.

Tricyclic antidepressants are not recommended for depression in children. If they are used for nocturnal enuresis in children they should be limited to short courses with a full physical examination before subsequent courses.

Tricyclic antidepressants should be withdrawn gradually to reduce the risk of withdrawal symptoms (see below).

Licensed drug information recommends that, where possible, tricyclic antidepressants should be stopped several days before elective surgery, and that they should be used with caution in patients requiring ECT; however, see also under Anaesthesia, below.

Anaesthesia. Patients receiving tricyclic antidepressants are at an increased risk of developing hypotension or cardiac arrhythmias during anaesthesia. Tricyclics may also dangerously potentiate the cardiovascular effects of vasopressor drugs such as sympathomimetics that may be required during anaesthesia. Although some licensed drug information recommends stopping tricyclics several days before elective surgery where possible, the *BNF* advises that this is unnecessary as long as the anaesthetist is informed.

Commenting on the anaesthetic considerations relevant to ECT,[1] it was considered that therapy with tricyclic antidepressants should not be a contra-indication to anaesthesia for ECT. A major consideration, though, was said to be the interaction of tricyclics with barbiturates resulting in increased sleep time and duration of anaesthesia. This meant that lower doses of barbiturate anaesthetics should be used.

Antidepressants with significant serotonergic effects such as the tricyclic clomipramine may increase the risk of bleeding during surgery; for further details see under Precautions in Fluoxetine, p.396.

1. Gaines GY, Rees DI. Electroconvulsive therapy and anesthetic considerations. *Anesth Analg* 1986; **65:** 1345–56.

Breast feeding. In general, only small amounts of tricyclic antidepressants are distributed into breast milk. Nevertheless, the American Academy of Pediatrics[1] considers that all antidepressants, including tricyclics, are drugs whose effect on nursing infants is unknown but may be of concern. In addition, most manufacturers advise that tricyclics should be avoided by the mother during breast feeding.

Case reports indicate that amitriptyline and its metabolite (nortriptyline),[2,3] clomipramine,[4] desipramine and its metabolite (2-hydroxydesipramine),[5] dosulepin and its primary metabolites (nordothiepin, dothiepin-*S*-oxide, and nordothiepin-*S*-oxide),[6] doxepin and its metabolite (*N*-desmethyldoxepin),[7-9] imipramine and its metabolite (desipramine),[10] and maprotiline[11] are all present in breast milk in concentrations similar to those in maternal blood; amoxapine and its metabolite (8-hydroxyamoxapine)[12] have also been detected in breast milk but in concentrations lower than in maternal blood. In all but two of the above cases the infants were breast fed without experiencing adverse effects and tricyclics were undetectable in the infant's blood or present only in minute amounts. In one of the affected infants,[8] adverse effects included sedation and shallow respiration. The infant's mother had received doxepin and, although doxepin was almost undetectable in the infant's serum, the desmethyl metabolite appeared to have accumulated. In the other infant, drowsiness, poor suckling, and difficulty in swallowing were noted.[9] In this case the levels of both doxepin and its desmethyl metabolite were below the lower level of quantification; however, it was considered that the infant may have been at a greater risk for adverse effects because he had also developed hyperbilirubinaemia. There were no data for the effects of amoxapine on breast-fed infants because the case reported[12] involved samples of milk taken from a woman who had galactorrhoea as an adverse effect of tricyclic use. No adverse effects were seen during a 27-month follow-up of 14 breast-fed infants whose mothers had received imipramine 100 to 225 mg daily for 4 to 24 weeks.[13]

Cardiovascular disease. For comments on the potential cardiotoxicity of tricyclic antidepressants and precautions to be observed in patients with pre-existing cardiovascular disorders, see under Effects on the Cardiovascular System in Adverse Effects, above.

Contact lenses. Based on reports involving amitriptyline[1] and maprotiline[2] it has been considered that the antimuscarinic action of tricyclic antidepressants may decrease tear flow enough to cause corneal drying and staining of contact lenses.[3]

1. Litovitz GL. Amitriptyline and contact lenses. *J Clin Psychiatry* 1984; **45:** 188.

3. Anonymous. Drugs interfering with contact lenses. *Aust J Hosp Pharm* 1987; **17:** 55–6.

Diabetes mellitus. The fact that tricyclic antidepressants may cause alterations in blood-glucose concentrations has led to the recommendation that these drugs should be used with caution in diabetic patients. Amitriptyline has also been reported[1] to cause hypoglycaemic unawareness; a patient did not experience the usual adrenergic symptoms that preceded or accompanied her hypoglycaemic episodes.

1. Sherman KE, Bornemann M. Amitriptyline and asymptomatic hypoglycemia. *Ann Intern Med* 1988; **109:** 683–4.

Driving. While affective disorders probably adversely affect driving skill,[1,2] treatment with antidepressant drugs may also be hazardous,[1] although patients may be safer drivers with medication than without.[2] Impairment of performance is largely related to sedative and antimuscarinic effects both of which are more pronounced at the start of treatment; sedative tricyclics, such as amitriptyline and doxepin, are likely to cause greater psychomotor impairment than less sedative tricyclics such as imipramine and nortriptyline.[1] However, an epidemiological study[3] was unable to confirm any increased risk of road-traffic accidents in those drivers receiving tricyclic antidepressants or SSRIs. In healthy subjects fluoxetine (an SSRI) and dosulepin appeared to have a similar but apparently small potential for impairing psychomotor and driving performance.[4]

In the UK, the Driver and Vehicle Licensing Authority (DVLA) considers that drugs such as the older tricyclic antidepressants may have pronounced antimuscarinic and antihistaminic effects which may impair driving.[5] In addition, all drugs acting on the CNS can impair alertness, concentration, and driving performance, particularly at the start of treatment or when the dose is increased; driving must cease if patients are adversely affected. Patients with severe depressive illnesses complicated by significant memory or concentration problems, agitation, behavioural disturbances, or suicidal thoughts should cease driving pending the outcome of medical enquiry.

ECT. For comments concerning the precautions to be observed in patients receiving ECT, see under Anaesthesia, above.

Epilepsy. For comments on the epileptogenic effect of tricyclic antidepressants and the need for caution in patients with a history of epilepsy or other risk factors for development of seizures, see under Epileptogenic Effect in Adverse Effects, above.

Food. A high-fibre diet reduced or abolished the effectiveness of tricyclic antidepressant therapy in 3 patients;[1] the tricyclics involved were doxepin in two patients and desipramine in one.

1. Stewart DE. High-fiber diet and serum tricyclic antidepressant levels. *J Clin Psychopharmacol* 1992; **12:** 438–40.

Gastro-oesophageal reflux disease. The antimuscarinic action of tricyclic antidepressants may cause relaxation of the lower oesophageal sphincter and could aggravate nocturnal symptoms of gastro-oesophageal reflux if given in the late evening.[1]

1. Atkinson M. Use and misuse of drugs in the treatment of gastro-oesophageal reflux. *Prescribers' J* 1982; **22:** 129–36.

Glaucoma. It has been considered by the manufacturers that tricyclic antidepressants, because of their antimuscarinic actions, should be used with caution in patients with angle-closure glaucoma or raised intra-ocular pressure. There have been few reports of glaucoma associated with tricyclics, although acute angle-closure glaucoma was reported in 4 patients with narrow angles while taking imipramine in usual doses,[1] and in another patient taking clomipramine.[2] In the latter case, the presenting sign was amaurosis fugax, caused by the combination of raised intra-ocular pressure and an abnormally large drop in blood pressure on standing.

1. Ritch R, *et al.* Oral imipramine and acute angle closure glaucoma. *Arch Ophthalmol* 1994; **112:** 67–8.
2. Schlingemann RO, *et al.* Amaurosis fugax on standing and angle-closure glaucoma with clomipramine. *Lancet* 1996; **347:** 465.

Phaeochromocytoma. Use of imipramine[1,2] or desipramine[3] has caused adverse effects such as seizures and cardiovascular abnormalities (tachycardia and hypertension or hypotension) in patients with previously undiagnosed phaeochromocytoma. It has been suggested[3] that imipramine and its metabolite, desipramine, may be particularly effective in unmasking phaeochromocytoma and that this may be a reflection of their relative potency in inhibiting the noradrenaline reuptake mechanism.

1. Kaufmann JS. Pheochromocytoma and tricyclic antidepressants. *JAMA* 1974; **229:** 1282.

3. Achong MR, Keane PM. Pheochromocytoma unmasked by desipramine therapy. *Ann Intern Med* 1981; **94:** 358–9.

Porphyria. Amitriptyline has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. Management of depression during pregnancy can be difficult, and one report[1] on experience in 8 pregnant women being treated with a tricyclic antidepressant suggested that the dose might need to be increased during the second half of pregnancy to achieve a response. There are obvious concerns about such treatment (see also Depression, p.373). However, although there have been isolated reports[2] attributing *congenital malformations* to the use of tricyclic antidepressants during pregnancy, large-scale studies and case-control data[3,4] have failed to substantiate any association.

The effects of tricyclics on *fetal neurodevelopment* were studied[5] in 80 pregnant women by later assessing global IQ of the children; no differences were seen in those exposed to tricyclics *in utero* in the first trimester compared with those exposed to fluoxetine or no adverse developmental influences. A subsequent study indicated that exposure to tricyclic antidepressants or fluoxetine throughout gestation did not appear to adversely affect cognition.[6]

Fetal tachyarrhythmia detected at 37 weeks of gestation was attributed to maternal use of dosulepin during pregnancy. When this was stopped, no abnormalities in fetal heart rate were found and an uneventful labour led to a healthy infant being delivered. However, the authors expressed concern that fetal tachycardias might result in *in-utero* cardiac failure and considered that tricyclic antidepressants should be used during pregnancy only if there were compelling reasons.[7]

Withdrawal syndromes manifesting as hypothermia and jitteriness,[8] convulsions,[9,10] or myoclonus[11] have been reported in neonates whose mothers took clomipramine during pregnancy. Management has been with phenobarbital or clomipramine. Licensed product information advises that if it is justifiable to do so, clomipramine should be withdrawn at least 7 weeks before the calculated date of delivery.

Surgery. For comments regarding the precautions to be observed in patients undergoing surgery, see under Anaesthesia, above.

Withdrawal. Suddenly stopping antidepressant therapy after regular use for 8 weeks or more may precipitate withdrawal symptoms. The symptoms associated with withdrawal of tricyclic antidepressants appear to form four distinct syndromes:[1]

- gastrointestinal disturbances and generalised somatic symptoms such as malaise, chills, headache, and increased perspiration, which may also be accompanied by anxiety and agitation
- sleep disturbances characterised by insomnia followed by excessive and vivid dreams
- parkinsonism or akathisia
- hypomania or mania

Tricyclic withdrawal has also resulted in cardiac arrhythmias in some patients. Withdrawal symptoms seem to be more common and more severe in children.[2]

Many of the symptoms associated with stopping tricyclics may be produced by cholinergic rebound[1] and can be minimised by a gradual reduction in dosage. The *BNF* recommends that any antidepressant, including a tricyclic, that has been given regularly for 8 weeks or more should be stopped gradually over a period of at least 4 weeks, or as much as 6 months in patients who have been receiving long-term maintenance therapy. If withdrawal symptoms do occur, they can be managed by restarting at a dose sufficient to eliminate them, and then stopping gradually.[1,2] On the occasions that it may be necessary to stop a tricyclic abruptly, the withdrawal symptoms can be treated with a centrally active antimuscarinic such as atropine or benzatropine,[1] or alternatively, if withdrawal symptoms are just gastrointestinal, an antimuscarinic that does not cross the blood-brain barrier such as propantheline.[1] Awareness of the possibility of withdrawal syndromes helps to avoid misinterpreting new symptoms after withdrawal as evidence of relapse.

Tricyclic antidepressants have been included in some classifications as drugs of dependence because of their potential to produce withdrawal syndromes, but a review[3] of several substance abuse studies challenged this on finding no evidence of abuse or dependence of the barbiturate type developing with the tricyclics.

For reports of withdrawal symptoms in neonates born to mothers who took tricyclic antidepressants during pregnancy, and their management, see under Pregnancy, above.

Interactions

Interactions involving tricyclic antidepressants often result from additive toxicity or from altered metabolism of one drug by the other. Drugs that inhibit or induce the cytochrome P450 isoenzyme CYP2D6 may affect tricyclic metabolism and produce marked alterations in plasma concentrations.

Adverse effects may be enhanced by antimuscarinic drugs or CNS depressants, including alcohol. Barbiturates and other enzyme inducers such as rifampicin and some antiepileptics can increase the metabolism of tricyclic antidepressants and may lower plasma concentrations and reduce antidepressant response. Cimetidine, methylphenidate, antipsychotics, and calcium-channel blockers can reduce the metabolism of the tricyclics, leading to the possibility of increased plasma concentrations and accompanying toxicity.

Patients taking thyroid preparations may show an accelerated response to tricyclic antidepressants and occasionally liothyronine has been used to produce this effect in patients with refractory depression. However, the use of tricyclics with thyroid hormones may precipitate cardiac arrhythmias.

The antihypertensive effects of debrisoquine, guanethidine, and clonidine may be reduced by tricyclic antidepressants. The pressor effects of sympathomimetics, especially those of the direct-acting drugs adrenaline and noradrenaline, can be enhanced by tricyclic antidepressants; however, there is no clinical evidence of dangerous interactions between adrenaline-containing local anaesthetics and tricyclic antidepressants. Great care should, however, be taken to avoid inadvertent intravenous injection of the local anaesthetic preparation.

Drugs that prolong the QT interval, including antiarrhythmics such as amiodarone or quinidine, the antihistamines astemizole and terfenadine, some antipsychotics (notably pimozide, sertindole, and thioridazine), cisapride, halofantrine, and sotalol, may increase the likelihood of ventricular arrhythmias when taken with tricyclic antidepressants. This may be exacerbated where the interacting drug (such as quinidine or some antipsychotics) also reduces tricyclic metabolism.

Although different antidepressants have been used together under expert supervision in refractory cases of depression, severe adverse reactions including the serotonin syndrome (see p.416) may occur. For this reason an appropriate drug-free interval should elapse between stopping some types of antidepressant and starting another. Tricyclic antidepressants should not generally be given to patients receiving MAOIs or for at least 2 weeks (3 weeks if starting clomipramine or imipramine) after their withdrawal. No treatment-free period is necessary after stopping a reversible inhibitor of monoamine oxidase type A (RIMA) and starting a tricyclic. At least 1 to 2 weeks (3 weeks in the case of clomipramine or imipramine) should elapse between withdrawing a tricyclic antidepressant and starting any drug liable to provoke a serious reaction (e.g. phenelzine).

Further details concerning some of the above interactions, and others, are given below.

Alcohol. For reference to the effect of alcohol on amitriptyline, see under CNS depressants, below.

Analgesics. Doubling of plasma-doxepin concentrations with associated lethargy has been reported in a patient after the addition of *dextropropoxyphene* to the tricyclic.[1] This was consistent with previous studies indicating that dextropropoxyphene can impair the hepatic metabolism of other drugs.

For general reference to the effect of tricyclic antidepressants, notably amitriptyline and clomipramine, on *opioid analgesics*, see under Morphine, p.88.

1. Abernethy DR, *et al.* Impairment of hepatic drug oxidation by propoxyphene. *Ann Intern Med* 1982; **97:** 223–4.

Antiarrhythmics. Antiarrhythmics that prolong the QT interval may increase the likelihood of ventricular arrhythmias when given with tricyclic antidepressants. This includes various class I antiarrhythmics such as *disopyramide*, *flecainide*, *procainamide*, *propafenone*, and *quinidine*, and the class III antiarrhythmic *amiodarone*.

Raised serum-desipramine concentrations and signs of toxicity were noted[1] in a patient taking desipramine after starting treatment with digoxin and propafenone for paroxysmal atrial fibrillation. It was considered that propafenone probably reduced the metabolism and clearance of desipramine.

1. Katz MR. Raised serum levels of desipramine with the antiarrhythmic propafenone. *J Clin Psychiatry* 1991; **52:** 432–3.

Anticoagulants. For the effect of tricyclic antidepressants on anticoagulants, see under Warfarin, p.1428.

Antidepressants. Combination therapy with differing classes of antidepressants has been used successfully in the treatment of drug-resistant depression. It should be emphasised, however, that such combinations may result in interactions or enhanced adverse reactions, and should be used only under expert supervision. This practice is considered unsuitable or controversial by some authorities. For further details of the interactions between different antidepressants when used together, see Phenelzine, p.418. For details of the serotonin syndrome that can arise when two serotonergic drugs with different mechanisms of action are given, see under Adverse Effects of Phenelzine, p.416.

Antidiabetics. For the effect of tricyclic antidepressants on *sulfonylureas* and *insulin*, see Interactions, p.461 and p.449, respectively.

Antiepileptics. Antidepressants may antagonise the activity of antiepileptics by lowering the convulsive threshold.

A review[1] of drug interactions with *phenytoin* noted that although there had been reports of interactions between antiepileptics and tricyclic or related antidepressants, most involved enzyme-inducing antiepileptics other than phenytoin or phenytoin with other drugs. In the only report where phenytoin could be identified as the sole antiepileptic used, 2 patients required high doses of desipramine to achieve an antidepressant effect and to maintain plasma-desipramine concentrations in the range usually associated with therapeutic efficacy.

Carbamazepine has been reported to induce the metabolism of a number of tricyclic antidepressants (amitriptyline, desipramine, doxepin, imipramine, and nortriptyline) and to reduce their plasma concentrations. The clinical importance of the interaction is unclear. Use of nortriptyline with carbamazepine in a patient led to a decrease in serum-nortriptyline concentration requiring an increase in nortriptyline dose.[2] In another patient a prolonged QT interval was noted after use of desipramine with carbamazepine;[3] the authors hypothesised that the accelerated metabolism of desipramine had resulted in high levels of a cardiotoxic metabolite.

Valproate has been reported to increase plasma concentrations of amitriptyline,[4] clomipramine,[5] and nortriptyline.[4,6]

For the effect of the cyclic antidepressants desipramine and viloxazine on carbamazepine, see p.474. For the effects of tricyclic antidepressants on phenytoin, see p.498.

Antifungals. Increased serum concentrations of nortriptyline[1] or amitriptyline[2,3] have occurred in patients also taking *fluconazole*. In some patients the use of amitriptyline with fluconazole has led to syncope[3] or torsade de pointes.[4] Raised serum concentrations of nortriptyline and associated symptoms of intoxication have been reported in 2 patients during treatment with *terbinafine*;[5,6] the interaction was confirmed on rechallenge. In another case, dizziness, dry mouth, and muscle twitching were reported in a patient on long-term imipramine treatment after starting terbinafine;[7] serum imipramine concentrations were found to be elevated and symptoms subsided after the dose of imipramine was reduced. A study in healthy subjects also indicated that terbinafine similarly inhibited the metabolism of desipramine.[8]

Antihypertensives. In general, the hypotensive effect of antihypertensives is enhanced by tricyclic antidepressants, but there may be antagonism of the effect of *adrenergic neurone blockers* and of *clonidine*.

Antimigraine drugs. For the effects when some tricyclics are used with *dihydroergotamine*, see p.621.

Antineoplastics. For the effects when tricyclic antidepressants are used with *altretamine*, see p.678.

Antiprotozoals. Toxic psychosis developed in a patient on amitriptyline after starting *furazolidone*, an antiprotozoal with monoamine oxidase inhibiting activity.[1]

1. Aderhold RM, Muniz CE. Acute psychosis with amitriptyline and furazolidone. *JAMA* 1970; **213:** 2080.

Antipsychotics. For a discussion of interactions between antipsychotics and tricyclic antidepressants, see *Chlorpromazine* (p.974). For details of a possible interaction between clomipramine and *clozapine*, see p.984.

Antivirals. HIV-protease inhibitors may increase the plasma concentrations of tricyclic antidepressants whose metabolism is mediated through common cytochrome P450 isoenzymes. *Ritonavir* has produced moderate increases in the plasma concentrations of desipramine and a lower initial dose of desipramine may be appropriate. Licensed product information for ritonavir has warned that a similar increase may occur for other tricyclics; monitoring of therapeutic and adverse effects is recommended when tricyclics are used with ritonavir.

Anxiolytics. For a suggestion that *benzodiazepines* may increase the oxidation of amineptine to a toxic metabolite, see under Effects on the Liver in Adverse Effects, above. For a possible interaction of desipramine and other antidepressants with *zolpidem* see p.1038.

Barbiturates. Antidepressants may antagonise the antiepileptic activity of some barbiturates by lowering the convulsive threshold.

Barbiturates can increase the metabolism of tricyclic antidepressants and thereby produce lower plasma concentrations.

For details of the interaction of tricyclic antidepressants with barbiturate anaesthetics, see under Anaesthesia in Precautions, above.

Beta blockers. Raised imipramine plasma concentrations were noted in two 9-year-old children also given *propranolol*;[1] in both cases, no significant adverse effects were reported. *Labetalol* has also increased the bioavailability of imipramine in healthy subjects and inhibited its metabolism.[2]

The risk of ventricular arrhythmias may be increased when tricyclic antidepressants are taken with *sotalol*.

1. Gillette DW, Tannery LP. Beta blocker inhibits tricyclic metabolism. *J Am Acad Child Adolesc Psychiatry* 1994; **33:** 223–4.
2. Hermann DJ, *et al.* Comparison of verapamil, diltiazem, and labetalol on the bioavailability and metabolism of imipramine. *J Clin Pharmacol* 1992; **32:** 176–83.

Calcium-channel blockers. *Diltiazem* and *verapamil* each increased the bioavailability of imipramine in healthy subjects; second-degree heart block developed in 2 subjects.[1] Diltiazem also increased the bioavailability of nortriptyline in one patient,[2] probably by reducing the first-pass metabolism of nortriptyline. Increased serum concentrations of trimipramine have been reported when taken with diltiazem,[3] although there was no evidence of toxicity.

1. Hermann DJ, *et al.* Comparison of verapamil, diltiazem, and labetalol on the bioavailability and metabolism of imipramine. *J Clin Pharmacol* 1992; **32:** 176–83.
2. Krähenbühl S, *et al.* Pharmacokinetic interaction between diltiazem and nortriptyline. *Eur J Clin Pharmacol* 1996; **49:** 417–19.
3. Cotter PA, *et al.* Asymptomatic tricyclic toxicity associated with diltiazem. *Ir J Psychol Med* 1996; **13:** 168–9.

CNS depressants. Drugs with depressant actions on the CNS may be expected to enhance the drowsiness and related effects produced by the sedating type of tricyclic antidepressants. Such an interaction may occur between *alcohol* and tricyclic antidepressants and a study has shown that alcohol decreases the hepatic first-pass extraction of amitriptyline resulting in increased free plasma-amitriptyline concentrations, especially during the period of drug absorption.[1]

The problems that may be encountered with *barbiturate anaesthetics* are discussed under Anaesthesia in Precautions, above.

1. Dorian P, *et al.* Amitriptyline and ethanol: pharmacokinetic and pharmacodynamic interaction. *Eur J Clin Pharmacol* 1983; **25:** 325–31.

Disulfiram. Acute organic brain syndrome has been reported in 2 patients receiving disulfiram after the addition of amitriptyline to their treatment.[1] It was suspected that the syndrome was potentiated by the combined action of the drugs and the synergistic elevation in dopamine concentration.

For a report of the enhancement of the disulfiram-alcohol reaction by amitriptyline, see p.2297.

1. Maany I, *et al.* Possible toxic interaction between disulfiram and amitriptyline. *Arch Gen Psychiatry* 1982; **39:** 743–4.

Dopaminergics. Serious adverse effects have been reported[1] when *selegiline*, an irreversible selective inhibitor of monoamine oxidase type B, was used with tricyclic antidepressants. In some instances effects resembled the potentially fatal serotonin syndromes reported when tricyclics are given with non-selective MAOIs (see under Phenelzine, p.416).

Some manufacturers of selegiline advise that tricyclic antidepressants should not generally be given at the same time, or for at least 2 weeks after it has been discontinued. Similarly, at least one week should elapse between withdrawing a tricyclic antidepressant and starting selegiline.

For reference to the effect of tricyclic antidepressants on *levodopa*, see p.807.

1. Anonymous. Selegiline and antidepressants: risk of serious interactions. *WHO Drug Inf* 1995; **9:** 160–1.

General anaesthetics. For the effect of amitriptyline on *enflurane*, see p.1783. For the effects of using tricyclic antidepressants with *barbiturates* see under Anaesthesia in Precautions, above.

Histamine H_2-antagonists. *Cimetidine* is a known inhibitor of hepatic metabolism of drugs and symptoms of tricyclic toxicity have been reported in patients receiving cimetidine with desipramine,[1] doxepin,[2] and imipramine;[1] there has been a report of psychosis developing in a patient given imipramine and cimetidine.[3] Elevated tricyclic concentrations during combined therapy or reductions in tricyclic concentrations after withdrawal of cimetidine have been reported for imipramine[4] and nortriptyline.[5] Studies in healthy subjects have also indicated increased bioavailability and/or impaired hepatic metabolism of amitriptyline,[6] doxepin,[7,8] and imipramine[9] during cimetidine therapy. Adjustment of tricyclic antidepressant dosage may therefore be required if cimetidine therapy is begun or stopped.

Ranitidine has been reported not to alter the pharmacokinetics of amitriptyline,[10] doxepin,[8] or imipramine.[9]

9. Wells BG, *et al.* The effect of ranitidine and cimetidine on imipramine disposition. *Eur J Clin Pharmacol* 1986; **31:** 285–90.
10. Curry SH, *et al.* Lack of interaction of ranitidine with amitriptyline. *Eur J Clin Pharmacol* 1987; **32:** 317–20.

Muscle relaxants. There has been an isolated report[1] of a patient taking *baclofen* for spasticity who experienced leg weakness and was unable to stand after starting treatment with nortriptyline. Symptoms improved on stopping nortriptyline but recurred when imipramine was given.

1. Silverglat MJ. Baclofen and tricyclic antidepressants: possible interaction. *JAMA* 1981; **246:** 1659.

Sex hormones. There have been anecdotal reports of interactions between tricyclic antidepressants and *oestrogens*[1-3] resulting in a lack of antidepressant response and/or tricyclic toxicity; the significance of these interactions is not, however, established.

1. Prange AJ, *et al.* Estrogen may well affect response to antidepressant. *JAMA* 1972; **219:** 143–4.
2. Khurana RC. Estrogen-imipramine interaction. *JAMA* 1972; **222:** 702–3.
3. Somani SM, Khurana RC. Mechanism of estrogen-imipramine interaction. *JAMA* 1973; **223:** 560.

Smoking. Tobacco smoke has been reported to reduce the plasma levels of tricyclic antidepressants.[1-3] The clinical significance is not, however, fully established as the plasma concentration of unbound drug may not be affected.[3] The mechanism is probably by stimulation of hepatic drug metabolism by components present in cigarette smoke.

1. Perel JM, *et al.* Pharmacodynamics of imipramine in depressed patients. *Psychopharmacol Bull* 1975; **11:** 16–18.
2. John VA, *et al.* Effects of age, cigarette smoking and the oral contraceptive on the pharmacokinetics of clomipramine and its desmethyl metabolite during chronic dosing. *J Int Med Res* 1980; **8** (suppl 3): 88–95.
3. Perry PJ, *et al.* Effects of smoking on nortriptyline plasma concentrations in depressed patients. *Ther Drug Monit* 1986; **8:** 279–84.

Sympathomimetics. The pressor effects of sympathomimetics can be enhanced by tricyclic antidepressants.

For precautions to be observed in patients on tricyclic therapy who may require sympathomimetics during anaesthesia, see under Anaesthesia in Precautions, above.

Thyroid hormones. An increase in receptor sensitivity to catecholamines produced by thyroid hormones has been proposed as the reason for an increase in response to tricyclic antidepressants given with *liothyronine*.[1,2]

1. Banki CM. Cerebrospinal fluid amine metabolites after combined amitriptyline-triiodothyronine treatment of depressed women. *Eur J Clin Pharmacol* 1977; **11:** 311–15.
2. Goodwin FK, *et al.* Potentiation of antidepressant effects by -triiodothyronine in tricyclic nonresponders. *Am J Psychiatry* 1982; **139:** 34–8.

Pharmacokinetics

Amitriptyline is readily absorbed from the gastrointestinal tract, peak plasma concentrations occurring within about 6 hours after oral doses.

Amitriptyline undergoes extensive first-pass metabolism and is demethylated in the liver by the cytochrome P450 isoenzymes CYP3A4, CYP2C9, and CYP2D6 to its primary active metabolite, nortriptyline. Other paths of metabolism of amitriptyline include hydroxylation (possibly to active metabolites) by CYP2D6 and *N*-oxidation; nortriptyline follows similar paths. Amitriptyline is excreted in the urine, mainly in the form of its metabolites, either free or in conjugated form.

Amitriptyline and nortriptyline are widely distributed throughout the body and are extensively bound to plasma and tissue protein. Amitriptyline has been estimated to have an elimination half-life ranging from about 9 to 25 hours, which may be considerably extended in overdosage. Plasma concentrations of amitriptyline and nortriptyline vary very widely between individuals and no simple correlation with therapeutic response has been established.

Amitriptyline and nortriptyline cross the placenta and are distributed into breast milk (see Breast Feeding under Precautions, above).

Uses and Administration

Tricyclic antidepressants such as amitriptyline were developed from phenothiazine compounds related to chlorpromazine and, as the name suggests, possess a 3-ring molecular structure. They inhibit the neuronal reuptake of noradrenaline in the CNS; some, in addition, inhibit the reuptake of serotonin (5-HT). Prevention of the reuptake of these monoamine neurotransmitters, which potentiates their action in the brain, appears to be associated with antidepressant activity. Tricyclic antidepressants also possess affinity for muscarinic and histamine H_1 receptors to varying degrees, see under Adverse Effects, above. Amitriptyline is one of the more sedating tricyclics. Antidepressants with one, two, or four rings have also been developed, and these share only some of the properties of the tricyclics.

While the sedative action and other adverse effects of amitriptyline and other tricyclics are soon apparent, it may be several weeks before any antidepressant effect is seen. After a response has been obtained, maintenance therapy should be continued at the optimum dose for at least 4 to 6 months (12 months in the elderly) to avoid relapse on stopping therapy. Patients with a history of recurrent depression should continue to receive maintenance treatment for at least 5 years and possibly indefinitely. It is important to use doses that are sufficiently high for effective treatment, but not so high as to cause toxic effects.

Amitriptyline, a dibenzocycloheptadiene, is usually given orally as the hydrochloride and doses are expressed in terms of this salt. Amitriptyline hydrochloride is also given by intramuscular or slow intravenous injection; doses may be expressed in terms of the base or the hydrochloride. Amitriptyline hydrochloride 75 mg is equivalent to about 66.3 mg of the base. Amitriptyline has also been given orally as the embonate and as the oxide (amitriptylinoxide).

In the treatment of **depression**, amitriptyline hydrochloride is given initially in a daily dose of 50 to 75 mg orally in divided doses (or as a single dose at night). Thereafter, the dose may be gradually increased, if necessary, to 150 mg daily, the additional doses being given in the late afternoon or evening. Doses of up to 200 mg daily and, occasionally, up to 300 mg daily have been used in severely depressed patients in hospital.

Adolescent and elderly patients often have reduced tolerance to tricyclic antidepressants and UK licensed drug information states that initial doses of amitriptyline hydrochloride as low as 25 mg daily may be used in these groups, given either in divided doses or as a single dose, preferably at bedtime. The *BNF* suggests a minimum initial dose of 30 mg daily. In the UK, the use of amitriptyline in children under 16 years for the treatment of depression is not recommended.

In the initial stages of treatment, if dosage by mouth is impracticable or inadvisable, amitriptyline hydrochloride may be given by intramuscular injection, but the oral route should be substituted as soon as possible. Doses are similar to those usually given orally. The intravenous route has also been used.

Amitriptyline is also used for the treatment of **nocturnal enuresis** in children in whom organic pathology has been excluded. However, drug therapy for nocturnal enuresis should be reserved for when other methods have failed and should preferably only be given to cover periods away from home; tricyclic antidepressants are not recommended in children under 6 years of age (the *BNF* recommends that they should not be given until 7 years of age). Oral doses of amitriptyline hydrochloride that may be used are:

- 10 to 20 mg for children aged 6 to 10 years
- 25 to 50 mg for children 11 years and over

The dose should be given 30 minutes before bedtime and treatment, including a period of gradual withdrawal, should not continue for longer than 3 months. A full physical examination is recommended before a further course.

Tricyclic antidepressants, including amitriptyline, may be helpful in some **anxiety disorders** such as panic disorder, and in the management of **neuropathic pain** (see below).

Amitriptyline should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Anxiety disorders. For the use of tricyclic antidepressants in anxiety disorders, see under Clomipramine, p.387.

Bulimia nervosa. A combination of counselling, support, psychotherapy, and antidepressants is the usual treatment for bulimia nervosa. Antidepressants can help to reduce the frequency of overeating and some other symptoms of bulimia but relapse tends to occur when stopped. Many antidepressants have been tried, but the tricyclic desipramine and the SSRI fluoxetine have been the most commonly used and are considered to be well tolerated.

Ciguatera poisoning. Amitriptyline has relieved some of the neurological symptoms associated with ciguatera poisoning (see Mannitol, p.1331).

Cocaine dependence. For the use of tricyclic antidepressants in cocaine dependence, see under Desipramine, p.387.

Depression. As discussed on p.373, there is very little difference in efficacy between the different groups of antidepressant drugs, and choice is often made on the basis of adverse effect profile. Although less well tolerated than the newer antidepressants, tricyclic antidepressants may still be chosen because of wide experience with their use and familiarity with their pharmacological actions. The more sedating tricyclics such as amitriptyline, clomipramine, dosulepin, doxepin, and trimipramine may be of value in depression with associated agitation or anxiety. The less sedating tricyclics such as amoxapine, desipramine, imipramine, lofepramine, nortriptyline, and protriptyline may be of value for withdrawn or apathetic depressed patients.

Combination therapy with differing classes of antidepressants, including the tricyclics, has been used in the treatment of refractory or drug-resistant depression. However, such therapy may result in enhanced adverse reactions or interactions and requires expert supervision; it is considered unsuitable or controversial by some. For further details, see Antidepressants under Interactions of Phenelzine, p.418.

Headache. Tricyclic antidepressants can be effective in the management of some types of headache and, although they are especially useful when the headache is accompanied by depression, their beneficial effects appear to be independent of their antidepressant action. They are used for the prophylaxis of migraine (p.616) when drugs such as propranolol have proved ineffective. Amitriptyline is the tricyclic usually used but others have been tried. It has also been investigated in children. The *BNF* suggests an adult dosage for amitriptyline in the prophylaxis of migraine of 10 mg at night, increased to a maintenance dose of 50 to 75 mg at night; the need for continuing prophylaxis should be reviewed at intervals of about 6 months. Tricyclics are also used prophylactically in the control of chronic tension-type headache (p.617) although benefit is rarely complete. Improvement is generally seen with low doses, but full antidepressant doses are necessary in the presence of underlying depression.

7. Holroyd KA, *et al.* Management of chronic tension-type headache with tricyclic antidepressant medication, stress management therapy, and their combination: a randomized controlled trial. *JAMA* 2001; **285:** 2208–15.

Hiccup. Amitriptyline is one of many drugs for which there are anecdotal reports[1] of success in the treatment of intractable hiccup (p.976).

1. Stalnikowicz R, *et al.* Amitriptyline for intractable hiccups. *N Engl J Med* 1986; **315:** 64–5.

Hyperactivity. When drug therapy is required for attention deficit hyperactivity disorder (p.2148), initial treatment is usually with a central stimulant. Tricyclic antidepressants such as imipramine or desipramine are reserved for patients who fail to respond to or who are intolerant of stimulants. They may also be of use for selected patients with certain co-existing disorders.

Interstitial cystitis. Tricyclic antidepressants have been found to be of benefit in the treatment of interstitial cystitis (p.2179). In a placebo-controlled trial in 48 patients with interstitial cystitis, amitriptyline treatment (in doses ranging from 25 to 100 mg daily) significantly reduced the symptom score and improved pain and urgency when compared to placebo;[1] however, in some patients the antimuscarinic adverse effects of amitriptyline were troublesome. Amitriptyline or imipramine have also been given at night, together with methenamine hippurate during the day, in the treatment of interstitial cystitis.[2]

1. van Ophoven A, *et al.* A prospective, randomized, placebo controlled, double-blind study of amitriptyline for the treatment of interstitial cystitis. *J Urol (Baltimore)* 2004; **172:** 533–6.
2. Cardozo L. Postmenopausal cystitis. *BMJ* 1996; **313:** 129.

Irritable bowel syndrome. A tricyclic antidepressant may be tried in irritable bowel syndrome (p.1699), particularly where diarrhoea and abdominal pain are presenting symptoms.

Micturition disorders. Tricyclic antidepressants are among the drugs used as an alternative or adjunct to nonpharmacological methods for the treatment of **nocturnal enuresis** in children (p.2180) in whom organic pathology has been excluded. However, because of their potentially fatal toxicity in overdosage, there has been concern over the safety of using tricyclics in households with children. Most experience in nocturnal enuresis has been with imipramine, but other tricyclics such as amitriptyline, nortriptyline, and clomipramine have also been used. Their mechanism of action in nocturnal enuresis is unclear. It may be the result of their antimuscarinic and antispasmodic actions as well as their effect on sleep patterns and possible stimulation of antidiuretic hormone secretion. Imipramine appears to be most effective in older children, but many patients develop tolerance and increasingly higher doses are required.

Tricyclic antidepressants are also sometimes used in the management of **urinary incontinence** (p.2180).

References.

1. Glazener CMA, *et al.* Tricyclic and related drugs for nocturnal enuresis in children. Available in The Cochrane Database of Systematic Reviews; Issue 3. Chichester: John Wiley; 2003 (accessed 24/11/05).

Narcoleptic syndrome. Tricyclic antidepressants are the primary treatment for cataplexy and sleep paralysis associated with narcolepsy (p.2148). Imipramine has been widely used for these symptoms although some consider clomipramine more effective. The onset of action is quicker than when used for depression and doses required appear to be lower (typically 10 to 75 mg of imipramine daily) although tolerance may develop. Doses should be titrated to provide maximal protection for the time of day when symptoms usually occur.

Pain. Tricyclic antidepressants, usually amitriptyline, are useful in alleviating some types of pain when given in subantidepressant doses. An initial oral dose of amitriptyline hydrochloride 10 to 25 mg at night increased gradually if necessary to about 75 mg daily has been suggested by the *BNF* for the management of neuropathic pain in adults. Similar doses of amitriptyline hydrochloride are also suggested by the *BNFC* for the treatment of neuropathic pain in palliative care in children aged 12 years and over; in addition, younger children aged 2 years and above may receive an initial dose of 200 to 500 micrograms/kg (to a maximum of 25 mg) once daily at night, increased if necessary to a maximum of 1 mg/kg twice daily. See also Choice of Analgesic on p.2. Chronic neuropathic pain as seen in cancer (p.5), central post-stroke pain (p.6), diabetic neuropathy (p.6), phantom limb pain (p.9), and postherpetic neuralgia (p.9) responds to therapy with tricyclics. Tricyclics are also often of benefit in the treatment of idiopathic orofacial pain (p.8), and may be of value for patients with complex regional pain syndrome (p.6). Pain and sleep quality may be improved by tricyclics in patients with fibromyalgia (see Soft-tissue Rheumatism, p.13), a condition that responds poorly to analgesics and anti-inflammatory drugs. Patients with migraine or chronic tension-type headache may also benefit from tricyclics (see Headache, above). There is little evidence for an analgesic effect of tricyclics in acute or arthritic pain.

Premenstrual syndrome. For reference to the tricyclic antidepressant, clomipramine, in premenstrual syndrome, see p.387.

Schizophrenia. Antidepressants such as the tricyclics are considered worth trying as an adjunct in the treatment of patients with schizophrenia (p.955) who develop depression during the recovery phase after an acute episode of psychosis. There is, however, no clear evidence that they are effective during acute psychotic episodes or for depression during periods of remission in patients with chronic schizophrenia.[1]

1. Anonymous. The drug treatment of patients with schizophrenia. *Drug Ther Bull* 1995; **33:** 81–6.

Sexual dysfunction. Impotence or ejaculatory problems have been reported as adverse effects of tricyclic antidepressants (see Effects on Sexual Function in Adverse Effects, above). Such properties have been studied as a potential form of treatment for men with premature ejaculation (see Clomipramine, p.387).

Skin disorders. See under Doxepin, p.389, for use of tricyclic antidepressants in skin disorders.

Smoking cessation. Tricyclic antidepressants are among the drugs that have been tried with varying degrees of success as alternatives to nicotine replacement therapy (NRT) to alleviate the withdrawal syndrome associated with smoking cessation (p.2354). Nortriptyline is recommended by some as a second-line treatment in those patients who cannot tolerate or relapse after NRT.

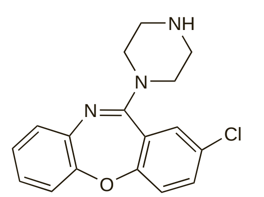
Amoxapine *(BAN, USAN, rINN)*

Amoksapiini; Amoksapin; Amoxapin; Amoxapina; Amoxapinum; CL-67772. 2-Chloro-11-(piperazin-1-yl)dibenz[*b,f*][1,4]oxazepine.

Амоксапин

$C_{17}H_{16}ClN_3O$ = 313.8.
CAS — 14028-44-5.
ATC — N06AA17.
ATC Vet — QN06AA17.



Pharmacopoeias. In *Jpn* and *US.*

USP 31 (Amoxapine). A white to yellowish crystalline powder. Practically insoluble in water; slightly soluble in acetone; freely soluble in chloroform; sparingly soluble in methyl alcohol and in toluene; soluble in tetrahydrofuran. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for tricyclic antidepressants in general (see Amitriptyline, p.376).

Rare cases of tardive dyskinesias and the neuroleptic malignant syndrome have been reported with amoxapine.

Antidopaminergic effects. Amoxapine is a derivative of the antipsychotic loxapine (p.1005) and possesses some antipsychotic activity. It also has dopamine-receptor blocking properties as do its hydroxylated metabolites. Adverse effects that are symptoms of such blockade have been reported and reviewed[1,2] and include akinesia, akathisia, withdrawal dyskinesia, reversible tardive dyskinesia, persistent dyskinesia, elevated serum concentration of prolactin, and galactorrhoea. Chorea[3] and oculogyric crisis[4] have also been reported.

1. Tao GK, *et al.* Amoxapine-induced tardive dyskinesia. *Drug Intell Clin Pharm* 1985; **19:** 548–9.
2. Devarajan S. Safety of amoxapine. *Lancet* 1989; **ii:** 1455.
3. Patterson JF. Amoxapine-induced chorea. *South Med J* 1983; **76:** 1077.
4. Hunt-Fugate AK, *et al.* Adverse reactions due to dopamine blockade by amoxapine. *Pharmacotherapy* 1984; **4:** 35–9.

Antimuscarinic effects. Amoxapine therapy has been reported to produce adverse effects associated with antimuscarinic activity (such as constipation, blurred vision, and dry mouth), but such reports did not reflect *in-vitro* findings that amoxapine had considerably less affinity for muscarinic binding sites than amitriptyline;[1] this was supported by results in healthy subjects. The adverse effects described as antimuscarinic could possibly be explained by amoxapine affecting noradrenergic mechanisms.

1. Bourne M, *et al.* A comparison of the effects of single doses of amoxapine and amitriptyline on autonomic functions in healthy volunteers. *Eur J Clin Pharmacol* 1993; **44:** 57–62.

Breast feeding. For comments on the use of tricyclic antidepressants in breast feeding patients, see under Precautions for Amitriptyline, p.378.

Effects on the endocrine system. Reversible nonketotic hyperglycaemia developed in a 49-year-old woman with no history of diabetes mellitus within 5 days of oral therapy with amoxapine 50 mg three times daily.[1] She had previously had nonketotic hyperglycaemic coma after loxapine 150 mg daily. 7-Hydroxyamoxapine, a metabolite common to both amoxapine and loxapine, was implicated.

See also Antidopaminergic Effects, above, for mention of galactorrhoea and hyperprolactinaemia.

1. Tollefson G, Lesar T. Nonketotic hyperglycemia associated with loxapine and amoxapine: case report. *J Clin Psychiatry* 1983; **44:** 347–8.

Overdosage. In overdosage, amoxapine is reported to cause acute renal failure with rhabdomyolysis,[1,2] coma, and seizures.[3-5] Although there has been some debate as to whether the incidence of seizures and death is higher with overdosage of amoxapine than with other tricyclic antidepressants, some[6] consider that evidence does seem to favour increased neurological consequences.

It has been reported that amoxapine is not cardiotoxic in overdosage[3] but later evidence would suggest that there is cardiotoxic potential.[6,7]

Interactions

For interactions associated with tricyclic antidepressants, see Amitriptyline, p.379.

Pharmacokinetics

Amoxapine is readily absorbed from the gastrointestinal tract. It bears a close chemical relationship to loxapine (p.1005) and is similarly metabolised by hydroxylation. It is excreted in the urine, mainly as its metabolites in conjugated form as glucuronides.

Amoxapine has been reported to have a plasma half-life of 8 hours and its major metabolite, 8-hydroxyamoxapine, has been reported to have a biological half-life of 30 hours; 7-hydroxyamoxapine has been identified as another metabolite. Both metabolites are pharmacologically active. Amoxapine is about 90% bound to plasma proteins.

Amoxapine and its metabolite 8-hydroxyamoxapine are distributed into breast milk.

Uses and Administration

Amoxapine, the *N*-desmethyl derivative of loxapine (p.1005), is a dibenzoxazepine tricyclic antidepressant with actions and uses similar to those of amitriptyline (p.381). Amoxapine is one of the less sedating tricyclics and its antimuscarinic effects are mild; it also inhibits the reuptake of dopamine.

In the treatment of depression (p.373) amoxapine is given in oral doses of 50 mg two or three times daily initially, gradually increased up to 100 mg three times daily as necessary. In the USA, higher doses of up to 600 mg daily may also be given, if required, in severely depressed patients in hospital. A suggested dose for the elderly is 25 mg two or three times daily initially, increased after 5 to 7 days to up to 150 mg daily as necessary; in the USA further increases to a maximum of 300 mg daily are permitted, if required.

Once-daily dosage regimens, usually given at night, are suitable for amoxapine up to 300 mg daily; divided-dosage regimens are recommended for doses above 300 mg daily.

It has been claimed that, in the treatment of depression, amoxapine has a more rapid onset of action than amitriptyline or imipramine with a clinical effect possibly appearing 4 to 7 days after starting therapy, although this has been disputed.

Amoxapine should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Amoxapine has also been investigated for its potential as an antipsychotic.

Proprietary Preparations (details are given in Part 3)
Denm.: Demolox†; ***Fr.:*** Defanyl; ***India:*** Demolox; ***Indon.:*** Asendin; ***UK:*** Asendis†; ***USA:*** Asendin†.

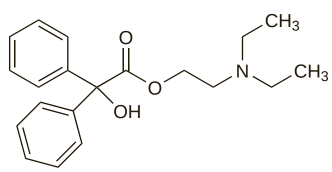
Benactyzine Hydrochloride *(BANM, rINNM)*

Amizylum; Bénactyzine, Chlorhydrate de; Benactyzini Hydrochloridum; Hidrocloruro de benacticina. 2-Diethylaminoethyl benzilate hydrochloride.

Бенактизина Гидрохлорид

$C_{20}H_{25}NO_3$,HCl = 363.9.

CAS — 302-40-9 (benactyzine); 57-37-4 (benactyzine hydrochloride).



(benactyzine)

Profile

Benactyzine has antidepressant and antimuscarinic activity. It has been used as the hydrochloride in the management of depression and associated anxiety. It is also used as a pharmacological tool. Methylbenactyzium bromide (p.1747), the methobromide of benactyzine, has been used for its antimuscarinic activity in the treatment of gastrointestinal spasm and nocturnal enuresis.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Arg.:*** Dimaval.

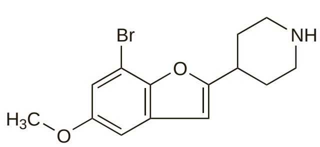
Brofaromine *(rINN)*

Brofaromina; Brofarominum; CGP-11305A (brofaromine hydrochloride). 4-(7-Bromo-5-methoxy-2-benzofuranyl)piperidine.

Брофаромин

$C_{14}H_{16}BrNO_2$ = 310.2.

CAS — 63638-91-5.



Profile

Brofaromine is a reversible inhibitor of monoamine oxidase type A (RIMA) (see Moclobemide, p.411). It has been studied in the treatment of depression and in anxiety disorders including social anxiety disorder.

Bupropion Hydrochloride

(BANM, USAN, rINNM)

Amfebutamone Hydrochloride; Bupropione, Chlorhydrate de; Bupropionhydroklorid; Bupropioni Hydrochloridum; Bupropionihydrokloridi; BW-323; Hidrocloruro de bupropión. (±)-2-(*tert*-Butylamino)-3′-chloropropiophenone hydrochloride.

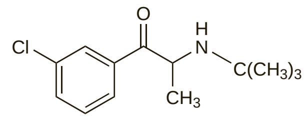
Бупропиона Гидрохлорид

$C_{13}H_{18}ClNO$,HCl = 276.2.

CAS — 34911-55-2 (bupropion); 31677-93-7 (bupropion hydrochloride).

ATC — N07BA02.

ATC Vet — QN07BA02.



(bupropion)

Pharmacopoeias. In *US.*

USP 31 (Bupropion Hydrochloride). A white powder. Soluble in water, in alcohol, and in 0.1N hydrochloric acid. Protect from light.

Adverse Effects and Treatment

Agitation, anxiety, and insomnia often occur during the initial stages of bupropion therapy. Other relatively common adverse effects reported with bupropion include fever, dry mouth, headache or migraine, dizziness, urinary frequency, nausea and vomiting, constipation, tremor, sweating, and skin rashes. Hypersensitivity reactions, ranging from pruritus and urticaria to, less commonly, angioedema, dyspnoea, and anaphylactoid reactions, have occurred, as have symptoms suggestive of serum sickness. There have been rare reports of Stevens-Johnson syndrome and erythema multiforme. Tachycardia, chest pain, and hypertension (sometimes severe), or occasionally vasodilatation, orthostatic hypotension, palpitations, and syncope have been reported. Psychotic episodes, confusion, nightmares, impaired memory, dysgeusia, anorexia with weight loss, paraesthesia, tinnitus, and visual disturbances have also been reported.

Hyponatraemia, possibly due to inappropriate secretion of antidiuretic hormone, has been associated with the use of antidepressants, particularly in the elderly.

Seizures, which appear to be partially dose-related, may occur with bupropion and have been particularly notable in patients with anorexia nervosa or bulimia nervosa; the risk is also increased in patients with a history of seizure disorders or other predisposing factor. The manufacturers state that the overall incidence of seizure in patients receiving bupropion at recommended doses is about 0.1 to 0.4%.

Symptoms of overdosage include hallucinations, nausea and vomiting, tachycardia, loss of consciousness, and death (following massive overdose); seizures have occurred in about one-third of all bupropion overdose cases. Activated charcoal should be considered in adult patients who have taken more than 450 mg and in all children, if they present within 1 hour of ingestion; gastric lavage may also be used to decrease absorption. Treatment is supportive. Benzodiazepines may be tried for seizures. Diuresis, dialysis, and haemoperfusion are unlikely to be of benefit.

Incidence of adverse effects. Up to 24 July 2002 (the first 25 months of marketing), the UK CSM had received 7630 reports of suspected adverse reactions associated with the use of bupropion.[1] Of these reports, 60 were associated with a fatal outcome although in most cases underlying conditions could have been responsible. Cardiovascular and cerebrovascular disorders such as myocardial infarction and stroke were reported as the cause of death in 70% of cases. The CSM also commented that adverse reactions were mainly recognised ones and listed in the licensed product information.

In January 2005 the German pharmacovigilance network reviewed[2] 273 reports of adverse effects associated with bupropion, received between June 2000 and September 2004. The most frequent adverse effects were: psychiatric disorders (79.3%), including suicide attempts (17.6%), and tachycardia (11.15%), seizures (8.8%), and dyspnoea (8.8%). There were also 4 cases of pancreatitis and one of raised pancreatic enzyme activity three times greater than normal.

Effects on the cardiovascular system. Up to the end of December 2001 the national pharmacovigilance centre in the Netherlands had received 591 adverse reaction reports associated with the use of bupropion for smoking cessation since its marketing 2 years earlier;[1] of these, 45 concerned cardiac complaints such as palpitations (21), arrhythmias (7), myocardial infarction (3), anginal pain (2), and cardiac arrest (1). Twenty-two reports also mentioned chest pain or tightness, although these were considered to be of noncardiac origin. In another report a 43-year-old male suffered an acute myocardial infarction 2 weeks after starting bupropion for smoking cessation;[2] he had experienced central chest and arm pain 3 days before the infarction. The authors of the report said that up to 30 April 2001 the UK CSM had received 238 reports of chest pain and 134 reports of chest tightness associated with bupropion use.

2. Patterson RN, Herity NA. Acute myocardial infarction following bupropion (Zyban). *QJM* 2002; **95:** 58–9.

Effects on the cerebrovascular system. A 67-year-old male had paraesthesia, dizziness, tinnitus, confusion, and gait impairment after taking bupropion for smoking cessation.[1] Although a transient ischaemic attack was suspected symptoms resolved on stopping bupropion and recurred on rechallenge.

1. Humma LM, Swims MP. Bupropion mimics a transient ischemic attack. *Ann Pharmacother* 1999; **33:** 305–7.

Effects on the pancreas. See under Incidence of Adverse Effects, above.

Effects on the skin. *Erythema multiforme* developed in a 31-year-old woman several weeks after starting modified-release bupropion for depression.[1] Symptoms resolved on drug withdrawal. In another report, 3 patients with controlled *psoriasis* had an exacerbation of their psoriatic symptoms after starting bupropion for smoking cessation.[2] All 3 patients required hospitalisation to control their symptoms. There have also been several reports of patients developing *generalised acute urticaria*;[3,4] systemic symptoms resembling serum sickness were also reported in 1 case[4] (see also Hypersensitivity, below).

4. Loo WJ, *et al.* Bupropion and generalized acute urticaria: a further case. *Br J Dermatol* 2003; **149:** 660.

Extrapyramidal effects. A 44-year-old man had acute head and neck dystonia while taking buspirone and modified-release bupropion.[1] No recurrence was noted on rechallenge with buspirone although symptoms did develop on rechallenge with bupropion when the dose was increased from 150 mg once daily to 150 mg twice daily. In another case, a 42-year-old woman had gross involuntary movements of her torso, arms, and legs (diagnosed as ballism) 8 days after starting bupropion for smoking cessation;[2] the dose had been increased from 150 mg once daily to 150 mg twice daily on the fourth day. She recovered when bupropion was stopped and treatment with haloperidol and oxazepam was given.

2. de Graaf L, *et al.* Ballism associated with bupropion use. *Ann Pharmacother* 2003; **37:** 302–3.

Hypersensitivity. Eosinophilia has been reported[1] in a patient 12 days after bupropion was added to her existing treatment regimen of glibenclamide and tolmetin. The eosinophil count returned to normal after all medication was stopped. Bupropion appeared to be the causative drug.

Serum sickness or symptoms suggestive of serum sickness has also been associated with bupropion use.[2-5] In one case,[5] although the initial presentation resembled serum sickness, the patient went on to develop multisystem complications that included hepatitis, cholestasis, and myocarditis.

Overdosage. Unlike the tricyclic antidepressants, bupropion appears to lack any significant cardiovascular or antimuscarinic adverse effects when taken in overdose. In an early review[1] of 58 overdose cases involving immediate-release bupropion alone, the most common symptoms were sinus tachycardia, lethargy, tremor, and seizures; other effects included confusion, lightheadedness, hallucinations, paraesthesias, and vomiting. Most patients had minor effects or none at all. Similar symptoms have also been noted in reviews of overdose cases involving modified-release bupropion.[2,3] UK licensed prescribing information for bupropion also lists ECG changes such as conduction disturbances, arrhythmias, and tachycardia although a literature review[4] concluded that cardiotoxicity appeared to be rare with bupropion overdosage. Although rare, there have been fatalities after overdose; in some cases other drugs may have been involved.[3,5,6]

More recent case reports and reviews with modified-release preparations have highlighted that seizures are a particular feature of bupropion overdose.[2,3,7,8]

Precautions

Bupropion may induce seizures and consequently its use is contra-indicated in patients with epilepsy. It is also contra-indicated in patients with a history of anorexia nervosa or bulimia nervosa, as a higher incidence of seizures has been noted in such patients treated with bupropion, and in those undergoing abrupt withdrawal from alcohol or benzodiazepines. It should be used with extreme caution, if at all, in patients with a history of seizure disorders or other predisposing factors such as severe hepatic cirrhosis or a CNS tumour. The use of bupropion in patients with other risk factors for seizures (for example, alcohol abuse, a history of head trauma, diabetes, and drugs known to lower the seizure threshold) should only be undertaken when there are compelling clinical reasons.

Bupropion should be used with caution in patients with bipolar disorder or psychoses because of the risk of precipitating mania; use for smoking cessation in such patients may be contra-indicated. It should also be used cautiously in patients with a recent history of myocardial infarction or unstable heart disease, and in hepatic or renal impairment.

When bupropion is used for depression, patients should be closely monitored during early therapy until significant improvement is observed because suicide is an inherent risk in depressed patients. For further details, see under Depression, p.373. Suicidal thoughts and behaviour may also develop during early treatment with antidepressants for other disorders; the same precautions observed when treating patients with depression should therefore be observed when treating patients with other disorders.

As with other CNS-active drugs, the ability to perform tasks requiring motor or cognitive skills or judgement may be impaired by bupropion, and patients, if affected, should not drive or operate machinery.

Breast feeding. The American Academy of Pediatrics considers[1] that the effect of bupropion on nursing infants is unknown but may be of concern.

There has been a report of accumulation of bupropion in human breast milk in concentrations higher than those in maternal plasma.[2] However, neither bupropion nor its metabolites were detected in the plasma of the infant who was breast fed twice daily by the affected mother, and no adverse effects were noted in the infant. Similar findings have been noted in a more recent study in 2 breast-fed infants whose mothers took bupropion for postpartum depression.[3] However, in another report, a 6-month-old infant had a seizure after being fed breast milk that had been expressed and stored 2 days earlier, after the infant's mother had taken a single dose of bupropion.[4] Before the seizure, the mother had taken 2 doses of bupropion and breast fed the infant several times with no adverse effects.

Children. Bupropion has not been studied for the treatment of depression in adolescents and children; consequently its use in patients under 18 years of age, regardless of indication, is not recommended. In addition, other antidepressants have been shown to increase the risk of suicidal thoughts and behaviour in these patients (see Effects on Mental State, under Fluoxetine, p.392).

Pregnancy. The safety of bupropion in pregnancy has not been established. In a study of 136 women who took bupropion for either depression or smoking cessation in at least the first trimester of pregnancy, there were 105 live births, 20 spontaneous abortions, 10 therapeutic abortions, 1 still-birth, and 1 neonatal death; no major congenital malformations were reported.[1] Compared to a control group not exposed to teratogens, the rate of spontaneous abortions was significantly higher in the bupropion group when both indications were considered; however, there was no difference in the rate when women taking bupropion for depression were compared to this control group and another control group of women taking other antidepressants.

Complications at birth requiring prolonged hospitalisation, breathing support, and tube feeding have been reported with some of the newer antidepressants such as bupropion.[2] Other reported symptoms have included seizures, muscle rigidity, jitteriness, and prolonged crying. It is not known whether such symptoms represent a direct toxicity of bupropion or a possible withdrawal syndrome.

Interactions

Bupropion should not be given with or within 14 days of stopping an MAOI; however, no treatment-free period is necessary after stopping a reversible inhibitor of monoamine oxidase type A (RIMA) and starting bupropion.

The use of alcohol with bupropion should be minimised or avoided completely because it may alter the seizure threshold. Similarly, extreme caution is needed if other drugs that lower the seizure threshold, such as other antidepressants, antimalarials, antipsychotics, sedating antihistamines, quinolones, tramadol, theophylline, or systemic corticosteroids are used with bupropion. In the UK, where it is licensed as a modified-release product for smoking cessation, a maximum dose of 150 mg daily is recommended if patients are also taking such drugs.

Use of nicotine transdermal patches with bupropion has been associated with hypertension, and patients using both should therefore have their blood pressure monitored.

Caution has been advised in patients receiving either amantadine or levodopa with bupropion because of reports of a higher incidence of adverse effects in patients receiving these combinations.

Animal studies have indicated that bupropion may induce drug-metabolising enzymes and pharmacokinetic interactions with other drugs are therefore a possibility. Bupropion is itself metabolised by hepatic enzyme systems and drugs known to affect such systems may interact with bupropion. For example carbamazepine, phenobarbital, or phenytoin may induce the metabolism of bupropion while other drugs such as cimetidine or valproate may inhibit its metabolism. *In-vitro* studies have shown that bupropion is metabolised by the cytochrome P450 isoenzyme CYP2B6. Consequently interactions may occur between bupropion and drugs that affect this isoenzyme, for example orphenadrine, cyclophosphamide, and ifosfamide.

In-vitro studies have also shown that bupropion is also an inhibitor of the isoenzyme CYP2D6; caution should be exercised when it is given with drugs metabolised by this isoenzyme and they should be started at the lower end of their dose range. Such drugs include some antidepressants, antipsychotics, beta blockers, and type Ic antiarrhythmics.

Antiepileptics. Plasma-bupropion concentrations became undetectable in 2 patients who were also receiving *carbamazepine*; plasma concentrations of hydroxybupropion, an active metabolite of bupropion, were high.[1]

1. Popli AP, *et al.* Bupropion and anticonvulsant drug interactions. *Ann Clin Psychiatry* 1995; **7:** 99–101.

Antivirals. There is some evidence from study *in vitro* that the antivirals *efavirenz, nelfinavir,* and *ritonavir* can inhibit the cytochrome P450 isoenzyme CYP2B6,[1] and licensed product information for ritonavir mentions the possibility of an interaction with bupropion. However, evidence of clinically significant interaction is lacking: a small case series of 10 patients who took bupropion with low-dose ritonavir (100 mg twice daily), or efavirenz or nelfinavir, did not note any episodes of seizures.[2] A study[3] in 7 healthy male subjects also found that 2 days of low-dose ritonavir (200 mg twice daily) had little impact on the pharmacokinetics of a single bupropion dose.

In contrast, the UK licensed product information for bupropion describes a study in healthy subjects in which 20 days of full-dose ritonavir (600 mg twice daily) reduced the area under the concentration-time curve (AUC) and maximum plasma concentration of bupropion, possibly by inducing its metabolism. Plasma concentrations of bupropion's active metabolites were also reduced. In another study[4] in healthy subjects, the plasma concentrations and AUC of bupropion and its active metabolite hydroxybupropion, from a single dose of bupropion, were reduced by about 50% after 14 days of a *lopinavir/ritonavir* combination (400 mg/100 mg twice daily). This effect was attributed to induction of CYP2B6 and UDP-glucuronosyltransferase by the HIV-protease inhibitor combination. In discussing the contrasting results that have been reported, the authors suggested that the higher ritonavir concentrations achieved *in-vitro* had an inhibitory effect, compared with the inducing effect of lower steady-state concentrations achieved *in-vivo*.

Histamine H_2-antagonists. A randomised controlled study in 24 subjects found that *cimetidine* had no effect on the pharmacokinetics of modified-release bupropion or its active metabolite, hydroxybupropion.[1]

1. Kustra R, *et al.* Lack of effect of cimetidine on the pharmacokinetics of sustained-release bupropion. *J Clin Pharmacol* 1999: **39:** 1184–8.

Pharmacokinetics

Bupropion is well absorbed from the gastrointestinal tract but may undergo extensive first-pass metabolism. Several metabolites of bupropion are pharmacologically active and have longer half-lives, and achieve higher plasma concentrations, than the parent compound. Hydroxybupropion is the major metabolite, produced by the metabolism of bupropion by the cytochrome P450 isoenzyme CYP2B6; in *animal* studies hydroxybupropion was one-half as potent as bupropion. Threohydrobupropion and erythrohydrobupropion are produced by reduction and are about one-fifth the potency of the parent compound. Bupropion is 80% or more bound to plasma proteins. The terminal plasma half-life of immediate-release bupropion is about 14 hours; the terminal plasma half-life of modified-release bupropion is about 20 hours. The metabolites of bupropion are excreted primarily in the urine; less than 1% of the parent drug is excreted unchanged. Bupropion and its metabolites cross the placenta and are distributed into breast milk.

Uses and Administration

Bupropion is a chlorpropiophenone antidepressant chemically unrelated to other classes of antidepressants but similar in structure to the central stimulant diethylpropion (p.2154). It is a weak blocker of neuronal reuptake of serotonin and noradrenaline compared with tricyclic antidepressants; it also inhibits the neuronal reuptake of dopamine. The antidepressant effect may not be evident until after 4 weeks of therapy. Bupropion is also used as an aid to smoking cessation.

Bupropion is given orally as the hydrochloride. To minimise agitation, anxiety, and insomnia often experienced at the start of therapy, and to reduce the risk of seizures, doses should be increased gradually; the total daily dose should be given in equally divided doses and the maximum recommended single and total daily doses should not be exceeded. Insomnia at the start of therapy may be minimised by avoiding bedtime doses. Patients with hepatic or renal impairment should be given reduced doses and monitored for toxic effects (see below).

In the treatment of **depression** bupropion hydrochloride is given in initial doses of 100 mg twice daily increased, if necessary, after at least 3 days to 100 mg three times daily. In severe cases, if no improvement has been observed after several weeks of therapy, the dose may be increased further to a maximum of 150 mg three times daily. Bupropion hydrochloride is also available as a modified-release preparation given in an initial dose of 150 mg once daily in the morning increased, if necessary, after at least 3 days to 150 mg twice daily; in severe cases, the dose of the modified-release preparation may be increased further after several weeks to 200 mg twice daily. A modified-release preparation that is given once daily is also available; the maximum daily dose for this preparation is 450 mg as a single dose in the morning. A modified-release preparation is also licensed for the prevention of depression in patients with seasonal affective disorder; the maximum dose for this disorder is 300 mg once daily.

Bupropion hydrochloride is given as a modified-release preparation as an aid to **smoking cessation** in an initial dose of 150 mg once daily for 6 days, increasing to 150 mg twice daily on day 7. In the USA, the dose may be increased after 3 days. In the UK, the maximum recommended dose in the elderly, or in patients with predisposing risk factors for seizure (see Precautions, above), is 150 mg daily. Treatment should be started about 1 to 2 weeks before the patient attempts to stop smoking, to allow steady-state blood levels of bupropion to be reached, and normally continues for 7 to 12 weeks; if there is no significant progress towards smoking abstinence by the seventh week, then therapy should be stopped. Use with nicotine transdermal patches may be warranted in some patients, although there is a risk of hypertension with such therapy (see Interactions, above).

Administration in hepatic impairment. When used as an aid to *smoking cessation* in patients with mild to moderate hepatic impairment, bupropion should be given at a reduced frequency; UK licensed product information suggests an oral dose of 150 mg once daily. The use of bupropion in patients with severe hepatic cirrhosis is contra-indicated in the UK although doses of 150 mg every other day are permitted in the USA.

In the treatment of *depression*, a reduction in the frequency and/or the dose of bupropion should be considered in patients with mild to moderate impairment. In patients with severe hepatic cirrhosis the dose varies according to the preparation given; for modified-release bupropion the suggested maximum oral dose is 100 mg once daily or 150 mg every other day while the maximum dose of immediate-release bupropion is 75 mg once daily.

Administration in renal impairment. When used as an aid to *smoking cessation* in patients with renal impairment, bupropion should be given at a reduced frequency; UK licensed product information suggests an oral dose of 150 mg once daily.

In the treatment of *depression*, a reduction in the frequency and/or the dose of bupropion should be considered.

Depression. As discussed on p.373, there is very little difference in efficacy between the different groups of antidepressant drugs, and choice is often made on the basis of adverse effect profile. Bupropion has a different biochemical profile from both the tricyclics and the SSRIs; however, like the SSRIs, it may be safer in overdosage than the older tricyclics.

Hyperactivity. When drug therapy is indicated for attention deficit hyperactivity disorder (p.2148) initial treatment is usually with a central stimulant. Antidepressants may be used for patients who fail to respond to, or who are intolerant of, central stimulants. Data from open and controlled studies involving small numbers of patients suggest that bupropion is effective in adults and children.[1,2]

2. Wilens TE, *et al.* A controlled clinical trial of bupropion for attention deficit hyperactivity disorder in adults. *Am J Psychiatry* 2001; **158:** 282–8.

Smoking cessation. Bupropion is effective in the management of smoking cessation (p.2354) and may be used as a first-line alternative to nicotine replacement therapy (NRT); its action is said to be independent of its antidepressant activity. Bupropion with NRT has also been used successfully although there is an increased risk of hypertension with this combination (see Interactions, above).

Preparations

USP 31: Bupropion Hydrochloride Extended-Release Tablets; Bupropion Hydrochloride Tablets.

Proprietary Preparations (details are given in Part 3)
Arg.: Odranal; Wellbutrin; ***Austral.:*** Clorpax; Prexaton; Zyban; ***Austria:*** Quomem; Zyban; ***Belg.:*** Zyban; ***Braz.:*** Bup; Wellbutrin; Zetron; Zyban; ***Canad.:*** Wellbutrin; Zyban; ***Chile:*** Buxon; Dosier†; Mondrian†; Wellbutrin; ***Cz.:*** Elontril; Wellbutrin; Zyban; ***Denm.:*** Zyban; ***Fin.:*** Zyban; ***Fr.:*** Zyban; ***Ger.:*** Zyban; ***Gr.:*** Zyban; ***Hong Kong:*** Wellbutrin; Zyban; ***Hung.:*** Wellbutrin; Zyban†; ***India:*** Nicotex; Zyban; ***Irl.:*** Zyban; ***Israel:*** Zyban; ***Ital.:*** Quomem†; Zyban; ***Malaysia:*** Zyban; ***Mex.:*** Butrew; Wellbutrin; ***Neth.:*** Quomem; Zyban; Zyntabac; ***Norw.:*** Zyban; ***NZ:*** Zyban; ***Pol.:*** Zyban; ***Port.:*** Elontril; Wellbutrin; Zyban; Zyntabac; ***S.Afr.:*** Wellbutrin; Zyban; ***Singapore:*** Wellbutrin; Zyban; ***Spain:*** Quomem; Zyntabac; ***Swed.:*** Zyban; ***Switz.:*** Zyban; ***Thai.:*** Quomem; ***Turk.:*** Zyban; ***UK:*** Zyban; ***USA:*** Budeprion; Wellbutrin; Zyban; ***Venez.:*** Wellbutrin; Zyban†.

Citalopram *(BAN, rINN)*

Citalopramum; Lu-10-171; Sitalopraami. 1-(3-Dimethylaminopropyl)-1-(4-fluorophenyl)-1,3-dihydroisobenzofuran-5-carbonitrile.

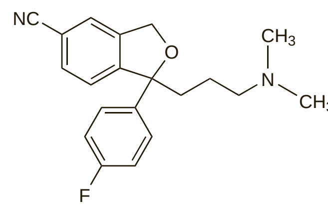
Циталопрам

$C_{20}H_{21}FN_2O$ = 324.4.

CAS — 59729-33-8.

ATC — N06AB04.

ATC Vet — QN06AB04.



Citalopram Hydrobromide *(BANM, USAN, rINNM)*

Citalopram, bromhydrate de; Citaloprami hydrobromidum; Hidrobromuro de citalopram; Lu-10-171B; Nitalapram Hydrobromide; Sitalopram Hidrobromür.

Циталопрама Гидробромид

$C_{20}H_{21}FN_2O,HBr$ = 405.3.

CAS — 59729-32-7.

Pharmacopoeias. In *US.*

USP 31 (Citalopram Hydrobromide). A white to almost white, crystalline powder. Freely soluble in water, in alcohol, and in chloroform. A 0.5% solution in water has a pH of 5.5 to 6.5.

Citalopram Hydrochloride *(BANM, rINNM)*

Citalopram, chlorhydrate de; Citaloprami hydrochloridum; Hidrocloruro de citalopram.

Циталопрама Гидрохлорид

$C_{20}H_{21}FN_2O,HCl$ = 360.9.

Adverse Effects, Treatment, and Precautions

As for SSRIs in general (see Fluoxetine, p.391) although increased appetite and weight gain have also been reported with citalopram. Citalopram may be more cardiotoxic in overdosage than other SSRIs; for further details, see p.394.

Breast feeding. For comments on the use of SSRIs in breast feeding patients, see under Precautions for Fluoxetine, p.394.

Children. SSRIs are associated with an increased risk of potentially suicidal behaviour when used for the treatment of depression in children and adolescents under 18 years old; for further details, see under Effects on Mental State in Fluoxetine, p.392.

Interactions

For interactions associated with SSRIs, see Fluoxetine, p.396.

Pharmacokinetics

Citalopram is readily absorbed from the gastrointestinal tract and maximum plasma concentrations are reached 2 to 4 hours after oral doses. Citalopram is widely distributed throughout the body; protein binding is less than 80%. Citalopram is metabolised by demethylation, deamination, and oxidation to active and inactive metabolites. The demethylation of citalopram to one of its active metabolites, demethylcitalopram, involves the cytochrome P450 isoenzymes CYP3A4 and CYP2C19; the metabolism of citalopram is also partly dependent on CYP2D6. Didemethylcitalopram has also been identified as a metabolite of citalopram. The elimination half-life of citalopram is reported to be about 36 hours. It is excreted mainly via the liver (85%) with the remainder via the kidneys. About 12% of the daily dose is excreted in the urine as unchanged drug. Citalopram is distributed into breast milk in very low concentrations (see Breast Feeding under Precautions in Fluoxetine, p.394).

Uses and Administration

Citalopram, a phthalane derivative, is an SSRI with actions and uses similar to those of fluoxetine (p.397). Citalopram is given orally as the hydrobromide or hydrochloride, usually as a single daily dose. Doses are expressed in terms of citalopram; citalopram hydrobromide 25.0 mg and citalopram hydrochloride 22.3 mg are each equivalent to about 20.0 mg of citalopram.

In the treatment of **depression**, the initial dose (given as tablets or a liquid) is the equivalent of 20 mg daily by mouth. After at least one week, the dose may be increased to 40 mg daily; a dose of 60 mg daily may be necessary in some patients. In the UK citalopram is also given as the hydrochloride in the form of concentrated oral drops containing the equivalent of 40 mg/mL of citalopram. The bioavailability of the drops is about 25% greater than that of the tablets and consequently daily doses appear to be lower: a 20-mg tablet dose is equivalent to a 16-mg (8 drops) dose of the concentrate. In some countries, citalopram hydrochloride has also been given by intravenous infusion in doses of 20 to 40 mg when the oral route is impracticable.

In the treatment of **panic disorder** with or without agoraphobia, the initial oral dose is 10 mg (or the equivalent as the concentrate) daily increasing to 20 mg daily after one week. The dose may be increased thereafter as required up to a maximum of 60 mg daily. In some countries citalopram is also used in the treatment of **obsessive-compulsive disorder** in doses similar to those used in depression (see above).

A dose of 20 mg daily, up to a maximum of 40 mg (or their equivalents as the concentrate), should be used in elderly patients. For dosage in hepatic and renal impairment see below.

Citalopram should be withdrawn gradually to reduce the risk of withdrawal symptoms.

The *S*-enantiomer of citalopram, escitalopram (p.391) is given for the treatment of depression and some anxiety disorders.

◊ Reviews.

1. Milne RJ, Goa KL. Citalopram: a review of its pharmacodynamic and pharmacokinetic properties, and therapeutic potential in depressive illness. *Drugs* 1991; **41**: 450–77.

Administration in hepatic or renal impairment. Licensed drug information suggests that dosage of citalopram should be restricted to the lower end of the dose range in patients with hepatic impairment. A usual oral dose for depression in this group would be 20 mg daily although the dose may be increased up to 40 mg daily, if necessary.

There is no need for dose adjustment in mild to moderate renal impairment although information is lacking on appropriate dosage in severe impairment.

Anxiety disorders. Citalopram has been given in anxiety disorders (p.952) including panic disorder (p.952), obsessive-compulsive disorder (p.952), post-traumatic stress disorder (p.953), and social anxiety disorder (see under Phobic Disorders, p.953).

Depression. As discussed on p.373, there is very little difference in efficacy between the different groups of antidepressant drugs. SSRIs such as citalopram are widely used as an alternative to the older tricyclics as they have fewer adverse effects and are safer in overdosage.

Pathological crying or laughing. Inappropriate or uncontrolled crying or laughing can occur in patients with lesions in certain areas of the brain. Attempts at treatment have mostly been with antidepressant drugs, including SSRIs. Favourable results with citalopram have been reported in a double-blind placebo-controlled study[1] and in case reports.[2,3]

3. Kaschka WP, *et al.* Treatment of pathological crying with citalopram. *Pharmacopsychiatry* 2001; **34:** 254–8.

Schizophrenia. The treatment of schizophrenia consists mainly of a combination of social therapy and antipsychotic drugs (see p.955). Like other antidepressants, citalopram has been examined for its potential value as an adjuvant in schizophrenia.[1-4] In a preliminary placebo-controlled study[1] in 15 patients with chronic schizophrenia who exhibited signs of impulsive aggression, adding citalopram to existing antipsychotic therapy significantly reduced the frequency, but not the average severity, of aggressive incidents. In a subsequent study involving 90 patients, citalopram appeared to improve subjective well-being but had no clear effect on psychopathological symptoms.[2]

Clomipramine Hydrochloride

(BANM, USAN, rINNM)

Chlorimipramine Hydrochloride; Clomipramine, chlorhydrate de; Clomipramini hydrochloridum; G-34586; Hidrocloruro de clomipramina; Klomipramiinihydrokloridi; Klomipramin Hidroklorür; Klomipramin hydrochlorid; Klomipramin-hidroklorid; Klomipraminhydroklorid; Klomipramino hidrochloridas; Monochlorimipramine Hydrochloride. 3-(3-Chloro-10,11-dihydro-5*H*-dibenz[*b,f*]azepin-5-yl)propyldimethylamine hydrochloride.

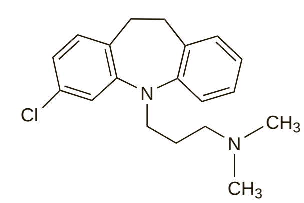
Кломипрамина Гидрохлорид

$C_{19}H_{23}ClN_2,HCl = 351.3.$

CAS — 303-49-1 (clomipramine); 17321-77-6 (clomipramine hydrochloride).

ATC — N06AA04.

ATC Vet — QN06AA04.



(clomipramine)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Clomipramine Hydrochloride). A white or slightly yellow, slightly hygroscopic, crystalline powder. Freely soluble in water and in dichloromethane; soluble in alcohol. A 10% solution in water has a pH of 3.5 to 5.0. Protect from light.

USP 31 (Clomipramine Hydrochloride). A white to faintly yellow crystalline powder. Very soluble in water. pH of a 10% solution in water is between 3.5 and 5.0.

Adverse Effects, Treatment, and Precautions

As for tricyclic antidepressants in general (see Amitriptyline, p.376).

Breast feeding. For comments on the use of tricyclic antidepressants in breast feeding patients, see under Precautions for Amitriptyline, p.378.

Porphyria. Clomipramine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems, although there is conflicting evidence of porphyrinogenicity.

Interactions

For interactions associated with tricyclic antidepressants, see Amitriptyline, p.379.

MAOIs. The combination of clomipramine and *tranylcypromine* is considered particularly hazardous.

The serotonin syndrome (p.416) has occurred in patients receiving clomipramine and *moclobemide* (see under Interactions of Antidepressants in Phenelzine, p.418).

Pharmacokinetics

Clomipramine is readily absorbed from the gastrointestinal tract, and extensively demethylated during first-pass metabolism in the liver to its primary active metabolite, desmethylclomipramine.

Clomipramine and desmethylclomipramine are widely distributed throughout the body and are extensively bound to plasma and tissue protein. Clomipramine has been estimated to have a plasma elimination half-life of about 21 hours, which may be considerably extended in overdosage; that of desmethylclomipramine is longer (about 36 hours).

Paths of metabolism of both clomipramine and desmethylclomipramine include hydroxylation and *N*-oxidation. About two-thirds of a single dose of clomipramine is excreted in the urine, mainly in the form of its metabolites, either free or in conjugated form; the remainder of the dose is excreted in the faeces. Clomipramine crosses the placenta and is distributed into breast milk.

Uses and Administration

Clomipramine is a dibenzazepine tricyclic antidepressant with actions and uses similar to those of amitriptyline (p.381). It has antimuscarinic properties and is also a potent serotonin reuptake inhibitor. Clomipramine is one of the more sedating tricyclics. It is used as the hydrochloride.

In the treatment of **depression** in adults, clomipramine hydrochloride is given in oral doses of 10 mg daily initially, increasing gradually to 30 to 150 mg daily if required; up to 250 mg daily or higher may be given in severe cases. A suggested initial dose for the elderly is 10 mg daily increasing gradually over 10 days to 30 to 75 mg daily if required. Clomipramine may be given in divided doses throughout the day, but since it has a prolonged half-life, once-daily dosage regimens are also suitable, usually given at night.

In the treatment of **obsessive-compulsive disorder** and **phobias**, clomipramine hydrochloride may be given in an initial oral dose of 25 mg daily (or 10 mg daily for elderly patients or those sensitive to tricyclics) increased gradually over two weeks to 100 to 150 mg daily. In some countries, maximum doses of 250 mg daily have been used. Similar doses have also been used in the management of **panic disorder**. In some countries clomipramine hydrochloride is also used for the treatment of obsessive-compulsive disorder in children and adolescents aged 10 years and over (see below for doses).

In some countries clomipramine may be given for depression or obsessive-compulsive disorder by the intramuscular or intravenous routes if giving it orally is impracticable or inadvisable. The initial dose of clomipramine hydrochloride by intramuscular injection is 25 to 50 mg daily, increasing to a maximum of 100 to 150 mg daily; oral dosage should be substituted as soon as possible. Clomipramine hydrochloride may also be given by intravenous infusion in doses of 50 to 75 mg daily diluted in 250 to 500 mL of sodium chloride 0.9% or glucose 5% and infused over 1.5 to 3 hours. When a satisfactory response to parenteral doses has been obtained oral therapy should be substituted, initially giving double the parenteral dose by mouth and subsequently adjusting if necessary. Patients must be carefully supervised during intravenous infusion of clomipramine hydrochloride and the blood pressure carefully monitored owing to the risk of hypotension.

In the adjunctive treatment of **cataplexy associated with narcolepsy**, clomipramine hydrochloride is given in an initial oral dose of 10 mg daily and gradually increased until a satisfactory response occurs, usually within the range of 10 to 75 mg daily.

Clomipramine should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Administration in children. In the UK, the use of clomipramine in children under 18 years is not recommended in the treatment of depressive states, phobias, or cataplexy associated with narcolepsy. However, in some countries clomipramine hydrochloride is used for the treatment of *obsessive-compulsive disorder* in children and adolescents aged 10 years and over. Initial oral doses are 25 mg daily, increased gradually during the first 2 weeks to a maximum daily dose of 3 mg/kg or 100 mg, whichever is smaller, and given in divided doses. Further increases are permitted, over several weeks to a maximum daily dose of 3 mg/kg or 200 mg, whichever is smaller. Once titration has been achieved the dose may be given as a single dose at bedtime.

Clomipramine hydrochloride is also licensed for oral use in the management of *nocturnal enuresis* in some countries (for a discussion of tricyclic use in nocturnal enuresis see Micturition Disorders under Amitriptyline, p.381). The age ranges and licensed doses vary somewhat from country to country, however. For example, in *France*, use is licensed in children over 6 years of age, at a daily dose of 10 to 30 mg, or 0.5 to 1 mg/kg, whereas in *Austria* and *Switzerland* the licensed dose is: 6 to 8 years, 20 to 30 mg; 9 to 12 years, 25 to 50 mg; over 12 years, 25 to 75 mg.

Anxiety disorders. Tricyclic antidepressants that inhibit serotonin reuptake, such as clomipramine and imipramine, have been given in the management of anxiety disorders (p.952) including obsessive-compulsive disorder (p.952), panic disorder (p.952), post-traumatic stress disorder (p.953), and trichotillomania.

6. Sasson Y, *et al.* A double-blind crossover comparison of clomipramine and desipramine in the treatment of panic disorder. *Eur Neuropsychopharmacol* 1999; **9:** 191–6.

Autism. Clomipramine reduced adventitious movements when tried in 5 boys with autistic disorder.[1] However, in a small study in 7 children no improvement in symptoms was noted and adverse effects were common and serious.[2] In another study,[3] although clomipramine was found to be as effective as haloperidol in the treatment of some autistic symptoms, patients on clomipramine were significantly less likely to complete the trial for reasons that included the onset of adverse effects.

3. Remington G, *et al.* Clomipramine versus haloperidol in the treatment of autistic disorder: a double-blind, placebo-controlled, crossover study. *J Clin Psychopharmacol* 2001; **21:** 440–4.

Micturition disorders. In some countries, clomipramine is used in children for the treatment of nocturnal enuresis; for further details, see Administration in Children, above.

Pain. Antidepressants, usually amitriptyline or another tricyclic, are useful in alleviating some types of pain (see Choice of Analgesic, p.2). In a number of countries, clomipramine hydrochloride is licensed for the treatment of chronic pain; oral doses range from 10 to 150 mg daily. Parenteral doses are licensed in some countries.

Premenstrual syndrome. Clomipramine reduced premenstrual irritability and depressed mood when given during the luteal phase;[1] doses of clomipramine ranged from 25 to 75 mg daily. It was postulated that the efficacy of clomipramine in relieving premenstrual symptoms is related to its serotonin reuptake inhibitor activity. For the overall management of premenstrual syndrome, see p.2099.

1. Sundblad C, *et al.* Clomipramine administered during the luteal phase reduces the symptoms of premenstrual syndrome: a placebo-controlled trial. *Neuropsychopharmacology* 1993; **9:** 133–45.

Sexual dysfunction. Clomipramine has been used for its inhibitory effect on ejaculation in the management of premature ejaculation[1-5] (p.2181). In some men with very short latencies (less than 1 minute) continuous therapy with a low daily dose of clomipramine, typically 20 or 30 mg, may be more effective than taking 25 mg as required.[5] Any benefits may relate to its effect as a serotonin reuptake inhibitor; other antidepressants with serotonin reuptake inhibiting actions, such as fluoxetine and sertraline, have also been tried in this condition.[4]

2. Althof SE, *et al.* A double-blind crossover trial of clomipramine for rapid ejaculation in 15 couples. *J Clin Psychiatry* 1995; **56:** 402–7.
3. Haensel SM, *et al.* Clomipramine and sexual function in men with premature ejaculation and controls. *J Urol (Baltimore)* 1996; **156:** 1310–15.
4. Kim SC, Seo KK. Efficacy and safety of fluoxetine, sertraline and clomipramine in patients with premature ejaculation: a double-blind, placebo controlled study. *J Urol (Baltimore)* 1998; **159:** 425–7.
5. Rowland DL, *et al.* Effective daily treatment with clomipramine in men with premature ejaculation when 25 mg (as required) is ineffective. *BJU Int* 2001; **87:** 357–60.

Stuttering. Clomipramine was of modest success in a controlled study[1] of 17 patients with developmental stuttering (p.1001). It was suggested that its efficacy may be related to its serotonin reuptake inhibitor activity.

1. Gordon CT, *et al.* A double-blind comparison of clomipramine and desipramine in the treatment of developmental stuttering. *J Clin Psychiatry* 1995; **56:** 238–42.

Desipramine Hydrochloride *(BANM, USAN, rINNM)*

Desipramiinihydrokloridi; Désipramine, chlorhydrate de; Desipramin-hydrochlorid; Desipraminhydroklorid; Desipramini hydrochloridum; Desmethylimipramine Hydrochloride; Dezipramin-hidroklorid; Dezipramino hidrochloridas; Dezypraminy chlorowodorek; DMI; EX-4355; G-35020; Hidrocloruro de desipramina; JB-8181; NSC-114901; RMI-9384A. 3-(10,11-Dihydro-5*H*-dibenz[*b,f*]azepin-5-yl)propyl(methyl)amine hydrochloride.

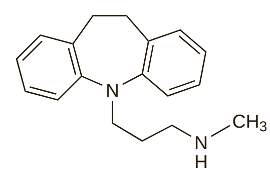
Дезипрамина Гидрохлорид

$C_{18}H_{22}N_2,HCl = 302.8.$

CAS — 50-47-5 (desipramine); 58-28-6 (desipramine hydrochloride).

ATC — N06AA01.

ATC Vet — QN06AA01.



(desipramine)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Desipramine Hydrochloride). A white or almost white crystalline powder. Soluble in water and in alcohol. Protect from light.

USP 31 (Desipramine Hydrochloride). A white to off-white crystalline powder. Soluble 1 in 12 of water, 1 in 14 of alcohol, and 1 in 3.5 of chloroform; insoluble in ether; freely soluble in methyl alcohol. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for tricyclic antidepressants in general (see Amitriptyline, p.376).

Breast feeding. For comments on the use of tricyclic antidepressants in breast feeding patients, see under Precautions for Amitriptyline, p.378.

Interactions

For interactions associated with tricyclic antidepressants, see Amitriptyline, p.379.

Pharmacokinetics

Desipramine is the principal active metabolite of imipramine (p.400).

Uses and Administration

Desipramine, the principal active metabolite of imipramine (p.400), is a dibenzazepine tricyclic antidepressant with actions and uses similar to those of amitriptyline (p.381). It is one of the less sedating tricyclics and its antimuscarinic effects are mild. Desipramine is used as the hydrochloride.

In the treatment of depression, desipramine hydrochloride is given orally in daily doses of 100 to 200 mg; higher doses of up to 300 mg daily may be required in severely depressed patients in hospital. Lower doses should be used in adolescents and the elderly and are usually 25 to 100 mg daily; up to 150 mg daily may be required for severe depression. Initial doses should be low and gradually increased according to tolerance and clinical response. Therapy may initially be given as a single daily dose or in divided doses; maintenance therapy may be given as a single daily dose usually at night.

Desipramine should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Cocaine dependence. Since dopamine depletion may be the cause of the depression often associated with cocaine craving and with relapse, drugs such as desipramine that interact with dopaminergic systems have been tried in managing cocaine

The symbol † denotes a preparation no longer actively marketed

withdrawal symptoms (p.1860). However, a systematic review[1] was unable to find evidence to support the use of antidepressants in the treatment of cocaine dependence although the efficacy of desipramine was suggested in some individual studies.

1. Lima MS, *et al.* Antidepressants for cocaine dependence. Available in The Cochrane Database of Systematic Reviews; Issue 2. Chichester: John Wiley; 2003 (accessed 24/11/05).

Hyperactivity. When drug therapy is required for attention deficit hyperactivity disorder (see p.2148) tricyclic antidepressants such as imipramine or desipramine[1-4] are usually reserved for patients who fail to respond to, or who are intolerant of, stimulants. They may also be of use for selected patients with co-existing disorders such as Tourette's syndrome, anxiety, and enuresis.

1. Rapport MD, *et al.* Methylphenidate and desipramine in hospitalized children: I. separate and combined effects on cognitive function. *J Am Acad Child Adolesc Psychiatry* 1993; **32:** 333–42.
2. Pataki CS, *et al.* Side effects of methylphenidate and desipramine alone and in combination in children. *J Am Acad Child Adolesc Psychiatry* 1993; **32:** 1065–72.
3. Singer HS, *et al.* The treatment of attention-deficit hyperactivity disorder in Tourette's syndrome: a double-blind placebo-controlled study with clonidine and desipramine. *Pediatrics* 1995; **95:** 74–81.

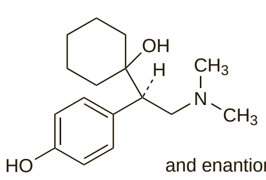
CAS — 93413-62-8 (desvenlafaxine); 386750-22-7 (desvenlafaxine succinate).

ATC — N06AX23.

ATC Vet — QN06AX23.



and enantiomer

(desvenlafaxine)

Profile

Desvenlafaxine, the major active metabolite of venlafaxine, is a serotonin and noradrenaline reuptake inhibitor (SNRI) (see Venlafaxine, p.427). It is given orally as the succinate but doses are expressed in terms of the base; desvenlafaxine succinate 75.8 mg is equivalent to about 50 mg of desvenlafaxine. The succinate is given in the treatment of depression (p.373) as a modified-release preparation providing a dose equivalent to desvenlafaxine 50 mg once daily. Higher doses of up to 400 mg daily have been studied, but provide no additional benefit and are associated with more frequent adverse effects. The dose may need to be reduced in patients with renal impairment (see below).

Desvenlafaxine should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Desvenlafaxine is under investigation in the management of menopausal vasomotor symptoms, neuropathic pain, and fibromyalgia.

3. Liebowitz MR, *et al.* A randomized, double-blind, placebo-controlled trial of desvenlafaxine succinate in adult outpatients with major depressive disorder. *J Clin Psychiatry* 2007; **68:** 1663–72.

Administration in renal impairment. The usual desvenlafaxine oral dose of 50 mg daily may be given to patients with mild to moderate renal impairment. In severe impairment (creatinine clearance less than 30 mL/minute) a dose of 50 mg may be given on alternate days. Supplemental doses should not be given after dialysis.

Proprietary Preparations (details are given in Part 3)
USA: Pristiq.

Dibenzepin Hydrochloride *(BANM, USAN, rINNM)*

Dibenzépine, Chlorhydrate de; Dibenzepini Hydrochloridum; HF-1927; Hidrocloruro de dibenzepina. 10-(2-Dimethylaminoethyl)-5,10-dihydro-5-methyl-dibenzo[*b*,*e*][1,4]diazepin-11-one hydrochloride.

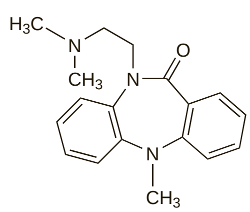
Дибензепина Гидрохлорид

$C_{18}H_{21}N_3O,HCl = 331.8.$

CAS — 4498-32-2 (dibenzepin); 315-80-0 (dibenzepin hydrochloride).

ATC — N06AA08.

ATC Vet — QN06AA08.



(dibenzepin)

Profile

Dibenzepin hydrochloride is a tricyclic antidepressant (see Amitriptyline, p.376).

In the treatment of depression dibenzepin hydrochloride is given in oral doses of 480 mg daily; higher doses of up to 720 mg daily may be required in some patients with severe depression. Elderly patients should be given reduced doses of 240 mg daily initially, increased to a maximum of 480 mg daily if required.

Dibenzepin hydrochloride has also been given by intravenous infusion.

In some countries it has also been used for nocturnal enuresis.

Dibenzepin should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Dosulepin Hydrochloride *(BANM, rINNM)*

Dosulepiinihydrokloridi; Dosulépine, chlorhydrate de; Dosulepin-hydrochlorid; Dosulepinhydroklorid; Dosulepini hydrochloridum; Dosulepino hidrochloridas; Doszulepin-hidroklorid; Dothiepin Hydrochloride *(USAN)*; Hidrocloruro de dosulepina. 3-(Dibenzo[*b*,*e*]thiepin-11-ylidene)propyldimethylamine hydrochloride.

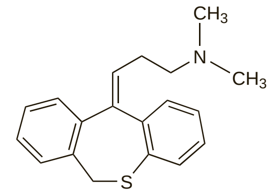
Досулепина Гидрохлорид

$C_{19}H_{21}NS,HCl = 331.9.$

CAS — 113-53-1 (dosulepin); 897-15-4 (dosulepin hydrochloride).

ATC — N06AA16.

ATC Vet — QN06AA16.



(dosulepin)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Dosulepin Hydrochloride). A white or faintly yellow crystalline powder. It consists chiefly of the *E*-isomer. Freely soluble in water, in alcohol, and in dichloromethane. A 10% solution in water has a pH of 4.2 to 5.2. Protect from light.

Adverse Effects, Treatment, and Precautions

As for tricyclic antidepressants in general (see Amitriptyline, p.376).

Breast feeding. For comments on the use of tricyclic antidepressants in breast feeding patients, see under Precautions for Amitriptyline, p.378.

Effects on the cardiovascular system. For reference to an increased risk of ischaemic heart disease in patients treated with dosulepin, see under Amitriptyline, p.376.

Overdosage. After an overdose of 1 g of dosulepin, the ECG of a 41-year-old man showed cardiac abnormalities mimicking an acute myocardial infarction.[1] However, as cardiac enzymes did not confirm an ischaemic event, the abnormalities were thought to be due to either the quinidine-like effect of dosulepin or changes in potassium membrane permeability.

1. Steeds RP, Muthusamy R. Abnormal ventricular conduction following dothiepin overdose simulating acute myocardial infarction. *Heart* 2000; **83:** 289.

Porphyria. Dosulepin hydrochloride is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Interactions

For interactions associated with tricyclic antidepressants, see Amitriptyline, p.379.

Pharmacokinetics

Dosulepin hydrochloride is readily absorbed from the gastrointestinal tract, and extensively demethylated by first-pass metabolism in the liver to its primary active metabolite, desmethyldothiepin (also termed northiaden). Paths of metabolism also include *S*-oxidation.

Dosulepin is excreted in the urine, mainly in the form of its metabolites; small amounts are also excreted in the faeces. Elimination half-lives of about 14 to 24 and 23 to 46 hours have been reported for dosulepin and its metabolites, respectively.

Dosulepin is distributed into breast milk (see Breast Feeding under Precautions in Amitriptyline, p.378).

◊ References.

3. Ilett KF, *et al.* The excretion of dothiepin and its primary metabolites in breast milk. *Br J Clin Pharmacol* 1992; **33:** 635–9.

Uses and Administration

Dosulepin hydrochloride is a tricyclic antidepressant with actions and uses similar to those of amitriptyline (p.381). It is one of the more sedating tricyclics. In the UK, the MHRA suggests that the use of dosulepin for depression should be limited, because of the small margin of safety between the maximum therapeutic dose and potentially fatal overdose. It advises that treatment should only be started by a specialist-care prescriber, and that the quantity issued per prescription should be limited. In patients with increased risk factors for suicide at the start of treatment, during dose adjustment, and until improvement occurs, the MHRA suggests a maximum supply equivalent to 2 weeks of treatment with 75 mg daily.

In the treatment of depression, dosulepin hydrochloride is given in oral doses of 25 mg three times daily initially, gradually increased to 50 mg three times daily if necessary; alternatively a single dose at night may be given. Higher doses of up to 225 mg daily have been given to severely depressed patients in hospital. The recommended initial dose for the elderly is 50 to 75 mg daily.

Dosulepin should be withdrawn gradually to reduce the risk of withdrawal symptoms.

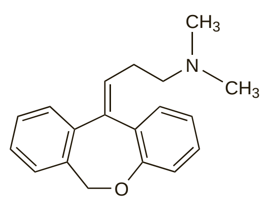
CAS — 1668-19-5 (doxepin); 1229-29-4 (doxepin hydrochloride); 4698-39-9 (doxepin hydrochloride, E-isomer); 25127-31-5 (doxepin hydrochloride, Z-isomer).

ATC — N06AA12.

ATC Vet — QN06AA12.



(doxepin)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Doxepin Hydrochloride). A white or almost white crystalline powder. Freely soluble in water, in alcohol, and in dichloromethane. Protect from light.

USP 31 (Doxepin Hydrochloride). It consists of a mixture of *Z*- and *E*-isomers.

Adverse Effects, Treatment, and Precautions

As for tricyclic antidepressants in general (see Amitriptyline, p.376). Drowsiness and other systemic effects can also occur after topical application. In addition, local effects, most commonly burning and stinging, have been reported.

Breast feeding. For comments on the use of tricyclic antidepressants in breast feeding patients, see under Precautions for Amitriptyline, p.378.

Effects on the skin. Up to January 2002 the FDA was aware of 26 cases of allergic contact dermatitis associated with the use of doxepin 5% cream;[1] manifestations included eczema, urticaria, purpura, and papulovesicular lesions. Of the 20 cases where details were known, 13 occurred after use for more than the recommended 8 days. Patch testing was positive in the 21 cases where it was performed, supporting an allergic reaction rather than an exacerbation of the original condition.

1. Bonnel RA, *et al.* Allergic contact dermatitis from topical doxepin: Food and Drug Administration's postmarketing surveillance experience. *J Am Acad Dermatol* 2003; **48:** 294–6.

Overdosage. An infant became difficult to arouse after the application of doxepin cream 5% to about 50% of her body-surface; an entire 30-g tube of the cream was used in only 2 applications.[1] The cream is not recommended for use in children.

1. Zell-Kanter M, *et al.* Doxepin toxicity in a child following topical application. *Ann Pharmacother* 2000; **34:** 328–9.

Interactions

For interactions associated with tricyclic antidepressants, see Amitriptyline, p.379.

Pharmacokinetics

Doxepin is readily absorbed from the gastrointestinal tract after oral doses, and is extensively demethylated by first-pass metabolism in the liver, to its primary active metabolite, desmethyldoxepin. Doxepin is also absorbed through the skin after topical application.

Paths of metabolism of both doxepin and desmethyldoxepin include hydroxylation and *N*-oxidation. Doxepin is excreted in the urine, mainly in the form of its metabolites, either free or in conjugated form.

Doxepin and desmethyldoxepin are widely distributed throughout the body; the plasma protein binding of doxepin is about 76%. Doxepin has been estimated to have a plasma elimination half-life ranging from 8 to 24 hours, which may be considerably extended in overdosage; that of desmethyldoxepin is longer.

Doxepin crosses the blood-brain barrier and the placenta. It is distributed into breast milk (see Breast Feeding under Precautions in Amitriptyline, p.378).

◊ References.

Uses and Administration

Doxepin is a dibenzoxepine tricyclic antidepressant with actions and uses similar to those of amitriptyline (p.381). It has moderate antimuscarinic and marked sedative properties and has serotonin reuptake inhibitor activity.

In the treatment of depression doxepin is given orally as the hydrochloride although doses are expressed in terms of the base; doxepin hydrochloride 84.8 mg is equivalent to about 75 mg of doxepin. The initial dose is 75 mg daily, gradually adjusted according to response. Doses of up to 300 mg daily may be required in severely depressed patients; mildly affected patients may respond to as little as 25 to 50 mg daily. Daily doses up to 100 mg may be given in divided doses or as a single dose at bedtime. If the total daily dose exceeds 100 mg, it should be given in 3 divided doses, although the largest portion, up to a maximum of 100 mg, may be given at bedtime. In the USA, the maximum single dose is 150 mg. A suggested starting dose in the elderly is 10 to 50 mg daily.

Doxepin hydrochloride has also been given by intramuscular or intravenous injection.

Doxepin should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Doxepin has histamine H_1- and H_2-antagonist activity and is used topically in a cream containing 5% of the hydrochloride for the short-term (up to 8 days) relief of moderate pruritus associated with various types of dermatitis (see below).

Headache. Tricyclic antidepressants can be effective in the management of some types of headache—see p.381.

Skin disorders. Tricyclic antidepressants have a wide range of pharmacological activity and some drugs in this group have notable antihistaminic actions. Doxepin in particular has very potent antihistaminic activity. It has been shown to be an effective oral alternative to conventional antihistamines in the treatment of chronic urticaria,[1-3] and to be an effective oral treatment for idiopathic cold urticaria.[4,5] In the case of cold urticaria doxepin may act by inhibiting release of a platelet-activating factor-like lipid.[5]

For an overview of the possible treatments for the various urticarias, including mention of the use of doxepin, see p.1584.

Like standard antihistamines (p.565) doxepin has also been used topically for the relief of pruritus (see also p.1582) associated with various types of allergic and inflammatory skin disorders[6,7] although some authorities remain to be convinced of its efficacy.[8,9] Topical application of doxepin can also produce contact dermatitis (see Effects on the Skin, above) and drowsiness and other systemic effects.

Duloxetine Hydrochloride

(BANM, USAN, rINNM)

Duloxétine, Chlorhydrate de; Duloxetini Hydrochloridum; Hidrocloruro de duloxetina; LY-248686 (duloxetine). (+)-(*S*)-*N*-Methyl-γ-(1-naphthyloxy)-2-thiophenepropylamine hydrochloride.

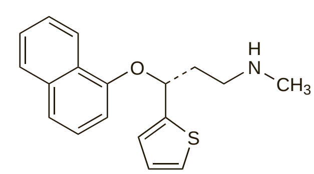
Дулоксетина Гидрохлорид

$C_{18}H_{19}NOS,HCl = 333.9.$

CAS — 116539-59-4 (duloxetine); 136434-34-9 (duloxetine hydrochloride).

ATC — N06AX21.

ATC Vet — QN06AX21.



(duloxetine)

Adverse Effects and Treatment

Adverse effects reported most frequently with duloxetine include nausea, headache, insomnia, fatigue, somnolence, dry mouth, dizziness, and constipation. Other common adverse effects include anorexia, diarrhoea, dyspepsia, vomiting, anxiety, visual disturbances, tremor, weight gain or loss, sexual dysfunction, nervousness, lethargy, yawning, hot flushes, increased sweating, and pruritus. Dose-related increases in blood pressure have also been observed in some patients. Reports of reversible increases in liver enzymes, tachycardia, ecchymosis, urinary hesitation, skin rashes, and photosensitivity reactions are less common, and hepatitis, cholestatic jaundice, convulsions and activation of mania or hypomania have occurred rarely. Cases of orthostatic hypotension and syncope, serotonin syndrome, and akathisia have also been reported. Suicidal ideation may occur in some patients.

Hyponatraemia, possibly due to inappropriate secretion of antidiuretic hormone, has been associated with the use of antidepressants, particularly in the elderly.

In the treatment of overdosage oral activated charcoal should be considered if more than 7.5 mg/kg of duloxetine has been ingested and the patient presents within 1 hour of ingestion; this should be followed by symptomatic and supportive therapy. Dialysis, haemoperfusion, exchange perfusion, and measures to increase urine production are considered unlikely to be of benefit.

Precautions

Duloxetine should not be used in patients with hepatic or severe renal impairment and is contra-indicated in patients with uncontrolled narrow-angle glaucoma or hypertension. Patients with raised intra-ocular pressure or at risk of angle-closure glaucoma should be monitored closely. Blood pressure should also be monitored because of the risk of hypertension. Increases in fasting blood glucose and in total cholesterol have been reported in diabetic patients. It should be used with caution in patients with a history of seizures, of bleeding disorders, or of hypomania or mania.

Patients should be closely monitored during early antidepressant therapy until significant improvement in depression is observed because suicide is an inherent risk in depressed patients. For further details, see under Depression, p.373. Suicidal thoughts and behaviour may also develop during early treatment with antidepressants for other disorders; the same precautions observed when treating patients with depression should therefore be observed when treating patients with other disorders.

As with other antidepressants, duloxetine may impair performance of skilled tasks and, if affected, patients should not drive or operate machinery.

Symptoms reported when duloxetine therapy was stopped abruptly include headache, nausea, vomiting, dizziness, insomnia, anxiety, and paraesthesia. It is therefore recommended that duloxetine should be withdrawn gradually over at least 2 weeks after more than one week of therapy and the patient monitored to minimise the risk of withdrawal reactions.

Children. Duloxetine has not been studied for the treatment of depression in adolescents and children; consequently its use in patients under 18 years of age is not generally recommended. In addition, other antidepressants have been shown to increase the risk of suicidal thoughts and behaviour in such patients (see Effects on the Mental State, under Fluoxetine, p.392).

Interactions

Duloxetine should not be used with MAOIs and at least 14 days should elapse between stopping an MAOI and starting treatment with duloxetine. At least 5 days should elapse between stopping duloxetine and starting any drug liable to provoke a serious reaction (e.g. phenelzine). The use of duloxetine with other antidepressants including the SSRIs, other serotonin and noradrenaline reuptake inhibitors, and the reversible inhibitors of monoamine oxidase is not recommended. For further details, see Antidepressants under Interactions of Phenelzine, p.418.

Caution is advised when using duloxetine with other centrally acting drugs including alcohol and those with sedative properties.

Duloxetine is metabolised by the cytochrome P450 isoenzymes CYP1A2 and CYP2D6. It should not be given with potent inhibitors of CYP1A2 such as fluvoxamine, ciprofloxacin, and enoxacin as such combinations are likely to result in increased duloxetine concentrations. Similarly, caution is recommended when duloxetine is given with potent CYP2D6 inhibitors such as paroxetine. Duloxetine itself is also a moderate inhibitor of CYP2D6 and, consequently, licensed drug information recommends that it should be used cautiously with drugs that have a narrow therapeutic index and are extensively metabolised by this isoenzyme. In particular, use with thioridazine is contra-indicated because of the risk of serious ventricular arrhythmias and sudden death associated with raised thioridazine concentrations.

Duloxetine is highly protein bound and adverse effects may occur if given with other highly protein-bound drugs.

Antimigraine drugs. There have been rare reports of serotonin syndrome associated with the use of serotonin and noradrenaline reuptake inhibitors (SNRIs) with serotonin ($5\text{-}HT_1$) agonists such as *sumatriptan* (see p.626).

Pharmacokinetics

Duloxetine is well absorbed from the gastrointestinal tract with peak plasma concentrations occurring about 6 hours after an oral dose. Food delays the time to reach peak concentrations to 10 hours. Protein binding is about 96%, primarily to albumin and $alpha_1$-acid glycoprotein. Duloxetine is extensively metabolised by the cytochrome P450 isoenzymes CYP1A2 and CYP2D6; two major, but inactive, metabolites are formed, 4-hydroxy duloxetine glucuronide and 5-hydroxy, 6-methoxy duloxetine sulfate. These and other metabolites are principally excreted in the urine; about 20% is excreted in the faeces. Less than 1% of a dose is excreted in the urine as unchanged duloxetine. The elimination half-life of duloxetine is 8 to 17 hours with an average of about 12 hours. Duloxetine is distributed into breast milk.

Uses and Administration

Duloxetine hydrochloride is a serotonin and noradrenaline reuptake inhibitor (SNRI) (see Venlafaxine, p.427). It is given orally as the hydrochloride although doses are expressed in terms of the base; duloxetine hydrochloride 22.5 mg is equivalent to about 20 mg of duloxetine.

Duloxetine is used in the treatment of **depression** in usual initial doses of 20 or 30 mg twice daily, or 60 mg once daily. A lower starting dose of 30 mg once daily for the first week may be suitable for some patients, to allow them to adjust to the effects of duloxetine before increasing the dose. A dose of 60 mg once daily may be used for maintenance therapy.

Duloxetine is also used in the treatment of **generalised anxiety disorder**, in a usual dose of 60 mg once daily. A lower starting dose of 30 mg daily for the first week may be considered in some patients, before increasing to 60 mg daily.

In the treatment of diabetic **peripheral neuropathic pain** the usual dose is 60 mg once daily. Some patients who respond insufficiently to this dose may benefit from up to 120 mg daily in divided doses. Response to therapy should be evaluated after 2 months and every 3 months thereafter.

Duloxetine is also used in the treatment of moderate to severe **stress urinary incontinence** in women. Usual initial doses are 40 mg twice daily; however, some patients may benefit from an initial dose of 20 mg twice daily for 2 weeks before increasing to 40 mg twice daily.

For dosage in hepatic or renal impairment, see below.

Duloxetine should be withdrawn gradually to reduce the risk of withdrawal symptoms (see Precautions, above).

Administration in hepatic or renal impairment. Duloxetine should not be used in patients with hepatic impairment. UK licensed product information for duloxetine states that no dosage adjustment is necessary in mild to moderate renal impairment (creatinine clearance 30 mL/minute or above). However, US information suggests that a lower starting dose and gradual dose increase may be warranted for patients, such as diabetics, with renal impairment. Both UK and US information recommend that duloxetine should not be used in more severe renal impairment (creatinine clearance less than 30 mL/minute).

Anxiety disorders. Duloxetine is used in the treatment of generalised anxiety disorder (see under Phobic Disorders, p.953).

Depression. As discussed on p.373, there is very little difference in efficacy between the different groups of antidepressant drugs, and choice is often made on the basis of adverse effect profile. SSRIs are widely used as an alternative to the older tricyclics as they have fewer adverse effects and are safer in overdosage. Similar properties may also favour the use of serotonin and noradrenaline reuptake inhibitors such as duloxetine.

Micturition disorders. Duloxetine is used[1-3] to increase urethral tone in the treatment of women with moderate to severe stress urinary incontinence (p.2180). A systematic review[3] concluded that duloxetine treatment reduced the frequency of incontinence episodes and significantly improved the patient's quality of life; however, it was unclear if these benefits were sustained. In addition, the review showed that adverse effects, particularly nausea, were common with duloxetine and led some patients to stop treatment.

Pain. Duloxetine is used[1] in the treatment of diabetic peripheral neuropathic pain (p.6). It has also been tried[2] with some success in fibromyalgia (see Soft-tissue Rheumatism, p.13), a condition that responds poorly to analgesics and anti-inflammatory drugs.

Escitalopram Oxalate

(BANM, USAN, rINNM)

S-Citalopram Oxalate; Escitalopram, Oxalate d'; Escitaloprami Oxalas; Lu-26-054/0; Oxalato de escitalopram. (+)-(*S*)-1-[3-(dimethylamino)propyl]-1-(*p*-fluorophenyl)-5-phthalancarbonitrile oxalate.

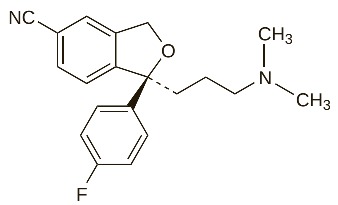
Эсциталопрама Оксалат

$C_{20}H_{21}FN_2O,C_2H_2O_4$ = 414.4.

CAS — 128196-01-0 (escitalopram); 219861-08-2 (escitalopram oxalate).

ATC — N06AB10.

ATC Vet — QN06AB10.



(escitalopram)

Adverse Effects and Precautions

As for Citalopram, p.385.

Children. SSRIs are associated with an increased risk of potentially suicidal behaviour when used for the treatment of depression in children and adolescents under 18 years old; for further details, see under Effects on Mental State in Fluoxetine, p.392.

Pharmacokinetics

Escitalopram has similar pharmacokinetics to those of racemic citalopram (p.385).

◊ References.

1. Søgaard B, *et al.* The pharmacokinetics of escitalopram after oral and intravenous administration of single and multiple doses to healthy subjects. *J Clin Pharmacol* 2005; **45:** 1400–6.
2. Rao N. The clinical pharmacokinetics of escitalopram. *Clin Pharmacokinet* 2007; **46:** 281–90.

Uses and Administration

Escitalopram, the *S*-enantiomer of citalopram (p.385), is an SSRI with actions and uses similar to those of fluoxetine (p.391). It is given orally as the oxalate although doses are expressed in terms of the base; escitalopram oxalate 12.8 mg is equivalent to about 10 mg of escitalopram.

In the treatment of **depression**, the usual dose is 10 mg once daily increased, after at least a week, to a maximum of 20 mg once daily if necessary.

Escitalopram is also used in the treatment of **panic disorder** with or without agoraphobia. Initial doses are 5 mg once daily, increased after a week to 10 mg once daily; further increases up to a maximum of 20 mg daily may be necessary in some patients.

Doses of escitalopram used in the treatment of **generalised anxiety disorder**, **social anxiety disorder**, and **obsessive-compulsive disorder** are similar to those used in depression.

Initial treatment with half the usual recommended dose and a lower maximum dose should be considered in elderly patients. Patients with hepatic impairment or those who are poor metabolisers with respect to the cytochrome P450 isoenzyme CYP2C19 may also require lower doses (see below).

Escitalopram should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Administration in hepatic impairment. Increases of 51% and 69% in the area under the concentration-time curve occurred in a single-dose study of escitalopram in patients with mild and moderate hepatic impairment (Child-Pugh score 5 or 6, and 7 to 9, respectively).[1] This study also reported that activity of the cytochrome P450 isoenzyme CYP2C19 was a better predictor of escitalopram clearance than the Child-Pugh classification.

UK licensed product information for escitalopram suggests that patients with mild to moderate hepatic impairment or those who are poor metabolisers with respect to the cytochrome P450 isoenzyme CYP2C19 should receive an initial oral dose of 5 mg daily, increased to 10 mg daily after 2 weeks depending on response; more careful dose titration is advised in those with severe impairment. US licensed product information recommends 10 mg daily as a suitable dose for most patients with hepatic impairment.

1. Areberg J, *et al.* The pharmacokinetics of escitalopram in patients with hepatic impairment. *AAPS J* 2006; **8:** E14–E19.

Anxiety disorders. Escitalopram has been given in anxiety disorders (p.952) including panic disorder (p.952), obsessive-compulsive disorder (p.952), and social anxiety disorder (see under Phobic Disorders, p.953).

Depression. As discussed on p.373, there is very little difference in efficacy between the different groups of antidepressant drugs. SSRIs such as escitalopram are widely used as an alternative to the older tricyclics as they have fewer adverse effects and are safer in overdosage.

Fluoxetine Hydrochloride

(BANM, USAN, rINNM)

Fluoksetiinihydrokloridi; Fluoksetin Hidroklorür; Fluoksetino hidrochloridas; Fluoksetyny chlorowodorek; Fluoxétine, chlorhydrate de; Fluoxetin-hidroklorid; Fluoxetin-hydrochlorid; Fluoxetinhydroklorid; Fluoxetini hydrochloridum; Hidrocloruro de fluoxetina; Lilly-103472; LY-110140. (±)-*N*-Methyl-3-phenyl-3-(α,α,α-trifluoro-*p*-tolyloxy)propylamine hydrochloride.

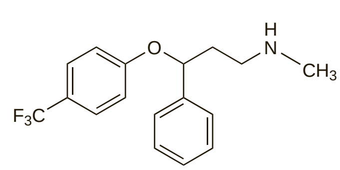
Флуоксетина Гидрохлорид

$C_{17}H_{18}F_3NO,HCl$ = 345.8.

CAS — 54910-89-3 (fluoxetine); 59333-67-4 (fluoxetine hydrochloride).

ATC — N06AB03.

ATC Vet — QN06AB03.



(fluoxetine)

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of fluoxetine:

Distas; Green and whites; Greens; Limes; Pros; Zacs.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Fluoxetine Hydrochloride). A white or almost white crystalline powder. Sparingly soluble in water and in dichloromethane; freely soluble in methyl alcohol. A 1% solution in water has a pH of 4.5 to 6.5.

USP 31 (Fluoxetine Hydrochloride). A white to off-white crystalline powder. Sparingly soluble in water and in dichloromethane; freely soluble in alcohol and in methyl alcohol; practically insoluble in ether. Store in airtight containers.

Adverse Effects

SSRIs such as fluoxetine are less sedating than tricyclic antidepressants and have fewer antimuscarinic and cardiotoxic effects. Adverse effects reported with SSRIs include dry mouth and gastrointestinal disturbances such as nausea, vomiting, dyspepsia, constipation, and diarrhoea. Anorexia and weight loss may also occur. Neurological adverse effects have included either anxiety, restlessness, nervousness, and insomnia, or drowsiness and fatigue; headache, tremor, dizziness, seizures, hallucinations, confusion, agitation, extrapyramidal effects, depersonalisation, mania, panic attacks, sexual dysfunction, and symptoms suggestive of a serotonin syndrome (p.416) have also occurred. The concern that SSRIs may be associated with increased suicidal ideation is discussed under Effects on Mental State, below.

Excessive sweating, pruritus, skin rashes, alopecia, photosensitivity, and urticaria have also been reported. Angioedema and anaphylactoid reactions have occurred. In some patients who have developed rashes while taking fluoxetine, systemic hypersensitivity reactions involving the lungs, kidneys, or liver, and possibly related to vasculitis, have developed; it has therefore been advised that fluoxetine therapy should be stopped in any patient who develops a skin rash.

Hyponatraemia, possibly due to inappropriate secretion of antidiuretic hormone, has been associated with the use of antidepressants, particularly in the elderly. Hyperprolactinaemia and galactorrhoea have occurred, as have changes in blood sugar, in patients receiving SSRIs.

Arthralgia and myalgia have been reported and there have also been cases of orthostatic hypotension, yawning, urinary retention, and abnormal vision including blurred vision and mydriasis. Abnormal liver function tests have been reported rarely. SSRIs have occasionally been associated with bleeding disorders such as ecchymosis and purpura and other effects on the blood.

In overdosage nausea, vomiting, and excitation of the CNS are considered to be prominent features; death has been reported.

Incidence of adverse effects. In June 1992 the UK CSM had received 1236 reports of adverse effects with fluvoxamine (from about 280 000 prescriptions) compared with 2422 for fluoxetine (from about 480 000 prescriptions).[1] The overall patterns of adverse effects were similar but dermatological reactions were more likely with fluoxetine and gastrointestinal reactions with fluvoxamine. Reports of attempted suicide increased after adverse publicity about SSRIs in 1990, and the number of reports per million prescriptions were similar for the 2 drugs (25 for fluoxetine and 20 for fluvoxamine); at that time such figures were not considered disconcerting given that features of depression, including attempted suicide, can worsen after the introduction of any antidepressant (see also Effects on Mental State, below). A later review[2] by the CSM of the 5 SSRIs available in the UK (citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline) found that the SSRIs were broadly similar with respect to their safety profile. A list of adverse reactions common to all SSRIs was provided.

A review[3] of 1861 adverse reactions to citalopram, fluoxetine, fluvoxamine, paroxetine, or sertraline reported to the Swedish Adverse Drug Reactions Advisory Committee found that the most commonly reported reactions were neurological (22.4% of all reports), psychiatric (19.5%), and gastrointestinal (18.0%). Compared with other SSRIs, gastrointestinal symptoms were more common with fluvoxamine, psychiatric symptoms with sertraline, and dermatological symptoms with fluoxetine.

A more recent meta-analysis[4] has compared the adverse effect profile of fluoxetine with other antidepressants including the tricyclics and other SSRIs. The overall risk of any adverse effect with fluoxetine was less than that for the tricyclic antidepressants; however, there was no difference in risk when fluoxetine was compared with other SSRIs. When considering individual adverse reactions, fluoxetine was more likely to cause activating effects such as insomnia, agitation, tremor, and anxiety, and gastrointestinal disturbances such as nausea, vomiting, diarrhoea, weight loss, and anorexia than other antidepressants. In contrast, the tricyclics were associated with a greater risk of sedation, antimuscarinic effects (such as dry mouth, dizziness, and blurred vision), constipation, and weight gain, than fluoxetine.

Effects on the blood. Abnormalities in platelet aggregation were associated with fluoxetine given to a severely underweight patient.[1] Platelet activity returned to normal when fluoxetine was stopped. Fluoxetine was also suspected of being the cause of bruising in a patient whose blood clotting parameters were within normal limits.[2] Purpura and bruising have been reported to be the commonest adverse blood effects associated with fluoxetine, paroxetine, or sertraline although cases of thrombocytopenia have been recorded for all three antidepressants.[3] The suggested mechanism was inhibition of uptake of serotonin into platelets, thereby disrupting platelet aggregation; caution was recommended when treating patients with a history of bleeding disorders with SSRIs. However, a subsequent cohort study based on prescription-event monitoring provided only weak evidence of a link between the use of SSRIs and the development of bleeding disorders.[4] A similar study[5] found no evidence of a major increased risk of intracranial haemorrhage with the use of SSRIs, although smaller increases in risk could not be ruled out.

For mention of a possibly increased risk of gastrointestinal bleeding, see Effects on the Gastrointestinal Tract, below.

Effects on the cardiovascular system. SSRIs are not associated with the same degree of cardiotoxicity as the tricyclic antidepressants (see p.376), although orthostatic hypotension has been reported in some patients. A decrease in heart rate with ECG changes has been noted with fluvoxamine. However, a study[1] on long-term fluvoxamine treatment in 311 patients followed for 1 year revealed no significant effect on ECG findings compared with patients given placebo.

Concern over the use of sertraline in patients with coronary heart disease was raised after a report[2] of a 53-year-old man with a history of coronary heart disease who experienced attacks of sudden precordial chest pain on starting treatment with sertraline. The pain responded to glyceryl trinitrate. The manufacturers[3] pointed out that there had been no ECG changes confirming an ischaemic origin of the disorder in this patient and that in studies sertraline had had no demonstrable clinical effects on intraventricular conduction or ECG intervals. Furthermore, no significant changes in cardiovascular indices had been recorded in patients who had taken overdoses of up to 6 g of sertraline. It was suggested that this might have been an effect on the gastrointestinal tract possibly at the oesophageal level.

Effects on the cerebrovascular system. There have been rare reports of cerebral ischaemic events associated with the use of SSRIs. In one case[1] a 57-year-old man receiving long-term treatment for atrial fibrillation and hypercholesterolaemia presented with a facial droop and slurred speech 3 days after starting paroxetine 20 mg twice daily. Symptoms resolved after anticoagulant therapy and stopping paroxetine but recurred when paroxetine was reintroduced at a dose of 10 mg twice daily. Paroxetine was stopped and no further episodes had occurred within 4 months at follow-up.

For a report that there is no major increased risk of intracranial haemorrhage associated with the SSRIs, see Effects on the Blood, above.

1. Manos GH, Wechsler SM. Transient ischemic attack reported with paroxetine use. *Ann Pharmacother* 2004; **38:** 617–20.

Effects on the endocrine system. The *syndrome of inappropriate antidiuretic hormone secretion (SIADH)* with *hyponatraemia* has been reported in patients receiving antidepressants. The UK CSM, commenting on reports it had received of hyponatraemia associated with antidepressants (fluoxetine, paroxetine, lofepramine, clomipramine, and imipramine), considered that it was likely to occur with any antidepressant, and usually involved elderly patients.[1] However, the results of a later study[2] have suggested that cases are more likely to occur with serotonergic antidepressants such as the SSRIs, clomipramine, and venlafaxine. Case reports of hyponatraemia in 16 patients treated with SSRIs have been summarised.[3] A further review[4] of reports on 15 patients with hyponatraemia with SIADH induced by fluoxetine (12 cases), fluvoxamine (2 cases), and paroxetine (1 case) showed that the risk was greatest during the early treatment phase. This is borne out by single-case reports[5-12] of hyponatraemia with SIADH in elderly patients receiving either citalopram, paroxetine, or sertraline. A retrospective study[13] of hyponatraemia associated with either fluoxetine or paroxetine use also showed the early onset of the condition and identified low bodyweight as being another risk factor for developing hyponatraemia. Not unexpectedly, replacing one SSRI with another has resulted in a recurrence of hyponatraemia; however, in one report,[14] the symptoms of hyponatraemia did not recur until about 16 months after switching SSRIs.

SSRI-associated *hyperprolactinaemia* has been reported.[15] Lactation and raised prolactin levels occurred in a teenager 3 days after fluoxetine was added to her existing therapy which included pimozide. Stopping fluoxetine had no effect on lactation, which only ceased after withdrawing pimozide. In another report,[16] hyperprolactinaemia and galactorrhoea in an elderly woman receiving fluoxetine resolved on stopping the drug.

Gynaecomastia, unrelated to prolactin concentrations, was associated with the start of fluoxetine therapy in a 49-year-old man. Symptoms subsided 10 months after withdrawing fluoxetine.[17]

Although SSRIs may be favoured for the management of depression in patients with diabetes, there is some evidence that sertraline and fluoxetine can induce *hypoglycaemia*.[18,19] Licensed product information for other SSRIs also warns of similar risks with these products.

Effects on the eyes. Symptoms of glaucoma that developed in a patient receiving fluoxetine subsided within 2 days of drug withdrawal.[1] Similar symptoms have been reported with citalopram,[2] fluvoxamine,[3] paroxetine,[2,4] and sertraline.[2] In some cases, the SSRI may have aggravated pre-existing glaucoma.[2,3] Intra-ocular pressure after doses of fluoxetine was recorded in 20 patients in a placebo-controlled crossover double-blind study.[5] Significant increases were found in all patients 2 hours after receiving fluoxetine by mouth; some patients still had raised intraocular pressure after 8 hours. A review of case reports documenting SSRI-associated changes in intra-ocular pressure concluded that such changes were difficult to predict;[6] however, it was recommended that those with risk factors for glaucoma, such as elderly patients with a family history, should be considered for ophthalmic consultations before starting an SSRI and regularly throughout treatment.

Anisocoria (uneven pupillary dilatation) has been reported[7] in a patient taking paroxetine and in another taking sertraline. It was noted that the UK CSM had received 21 reports of mydriasis associated with paroxetine but it appeared that noticeably asymmetrical mydriasis as seen in these 2 patients had not previously been reported.

Effects on the gastrointestinal tract. A case-control study[1] suggested that treatment with SSRIs produced a moderately increased risk of upper gastrointestinal bleeding (adjusted relative risk 3.0). The risk was greatly increased if SSRIs were given with NSAIDs (relative risk 15.6). Treatment with SSRIs did not appear to increase the risk of ulcer perforation. The absolute risk of bleeding was estimated at one case per 8000 prescriptions, a risk similar to that of low-dose ibuprofen. A more recent cohort study[2] found a similar increase in risk. However, others have questioned whether such an association exists.[3]

A retrospective cohort study[4] in *elderly* patients found that there was an increasing risk of upper gastrointestinal bleeding as the extent of inhibition of serotonin reuptake by the antidepressant used increased. The effect was considered to be clinically important for patients with a high risk of such bleeding, namely the very elderly and those with a history of previous upper gastrointestinal bleeding.

Some[5] consider that gastroprotection is unlikely to be justified in those given SSRIs alone and furthermore there are no studies to suggest that gastroprotective drugs reduce the risk of SSRI-associated haemorrhage. However, it has been recommended[5] that such protection should be considered when SSRIs and NSAIDs are used together because of the increased risk.

Effects on the hair. A report[1] on 2 patients who had hair loss associated with the use of fluoxetine noted 4 other published cases and stated that, up to the end of 1991, the US manufacturers had received 498 reports of fluoxetine-associated alopecia.

1. Ogilvie AD. Hair loss during fluoxetine treatment. *Lancet* 1993; **342:** 1423.

Effects on the liver. Acute hepatitis occurred in 2 patients after several months of fluoxetine treatment;[1] it was noted that 5 other cases of acute hepatitis with fluoxetine had been reported.

Abnormal liver function tests were seen in a patient after a suicide attempt with sertraline and cefalexin.[2] The patient was then started on venlafaxine but, again abnormal liver function tests were noted. When these abnormal values had decreased, sertraline was restarted at therapeutic doses, with a subsequent increase in liver function tests. Values returned to normal once all medications were stopped. Auto-immune hepatitis has been reported after therapeutic doses of sertraline;[3] rechallenge in this case was also positive.

Hepatotoxicity has also been rarely associated with citalopram[4] and with paroxetine use.[5]

Effects on mental state. As early as 1990 there was concern that the SSRIs increased the risk of *suicidal ideation* after the publication of a case series of such events with fluoxetine.[1] Meta-analyses[2,3] performed around that time (criticism of statistical power notwithstanding[4]) did not confirm an increased risk and this was supported by the results of prescription-event monitoring.[5] Nevertheless, reports of suicidal ideation as well as suicide and self-harm have continued to be published for the SSRIs and the issue remains controversial. A subsequent meta-analysis[6] of 702 randomised controlled studies found an increased risk for attempted suicide in those taking SSRIs when compared with placebo but not when compared with tricyclic antidepressants.

Risk analysis of suicidal behaviour with any antidepressant is confounded by the rarity of suicide even in patients with depression, and by the possibility that such behaviour is a manifestation of the underlying depression. Furthermore, the more favourable safety profile of the SSRIs, particularly in overdosage (see Depression, p.373), when compared to the older MAOIs and tricyclic antidepressants may have resulted in the SSRIs being prescribed to those patients at greater risk of suicidal behaviour.

In 2003, the UK CSM established an Expert Working Group to address increasing public concerns regarding the safety of the SSRIs. The serotonergic antidepressants venlafaxine and mirtazapine were also included and the conclusions given below also apply to these drugs. In its final report[7] issued in December 2004, the Working Group concluded that the risk of suicide may increase in the early stages of treatment for depression in **adults** and consequently careful and frequent monitoring is important, particularly if a patient has worsening of symptoms or new symptoms after starting therapy. However, the Working Group noted that increases in the prescribing of SSRIs have not been associated with an increase in suicide rates, although they acknowledged that the interpretation of these findings was difficult. They could not rule out that there might be a modest increase in the risk of suicidal ideation and self-harm with the SSRIs when compared with placebo. However, there was insufficient evidence from clinical trials to determine any differences between the SSRIs as a group, or between the SSRIs and other antidepressants regarding the risk of suicidal behaviour; evidence from the General Practice Research database has suggested that there is no increased risk of such behaviour with the SSRIs when compared with the tricyclic antidepressants. The Working Group also concluded that the evidence for a relationship between suicidal behaviour and a change in dose was not robust; however, patients should be monitored for any new symptoms or worsening of disease around the time of any dose change.

The Expert Working Group of the CSM has also commented[7] on the use of SSRIs in **young adults**. They concluded that although there was no clear evidence of an increased risk of self-harm or suicidal thoughts in young adults of 18 years or over, such patients have a higher background risk of suicidal behaviour than older adults and consequently those treated with SSRIs should be closely monitored. Furthermore, the results of a meta-analysis undertaken by the FDA found that although the overall risk of suicide was not increased in adult patients receiving antidepressants, there was a non-significant trend toward increased risk with younger age. The FDA considered the trend sufficiently convincing to warn that, like children and adolescents, young adults aged between 18 and 24 years treated with antidepressants of any type may be at increased risk of suicidal thinking and behaviour.[8]

In 2003 the CSM recommended (on the basis of their Expert Working Group's finding) that paroxetine should not be used to treat depressive illness in **children under 18 years old**. Data from studies received by CSM in May 2003 failed to show that paroxetine was effective in depressive illness in this age group and indicated that the risk of harmful outcome, including self-harm and potentially suicidal behaviour, was 1.5 to 3.2 times greater in those who received paroxetine when compared with placebo.[9] Following a further review,[10] the CSM extended their recommendation to include the SSRIs citalopram, escitalopram, and sertraline; subsequent analysis had also associated these antidepressants with an unfavourable risk to benefit ratio in the treatment of depression in children under 18. The CSM also included fluvoxamine in their recommendation as its risk to benefit ratio was unassessable. Fluoxetine was not included and the CSM acknowledged that clinical trials had shown a favourable risk to benefit ratio for fluoxetine in the treatment of depression in young patients. The European Medicines Agency (EMEA) has also recommended that serotonergic antidepressants, including the SSRIs, should not be used in children and adolescents except within their approved indications,[11] but considered[12] that studies with fluoxetine in children and adolescents have shown a positive effect that outweighs any potential risks, and recommended that it should be licensed for use where needed, as an adjunct to psychological therapies in children from 8 years of age.

The FDA have not issued advice contra-indicating the use of these antidepressants in those under 18 years old in the USA, although they have stressed that all patients, including adolescents and children, should be closely monitored for worsening depression or suicidal behaviour, especially at the beginning of treatment.[13] They also comment that, apart from fluoxetine, the SSRIs are not licensed in the USA for the treatment of depression in young patients.

The use of SSRIs has been associated with the development of *akathisia*, *restlessness*, and *psychomotor agitation* such as an inability to sit or stand still, particularly in the first few weeks of treatment.[14] In some patients these symptoms have precipitated suicidal behaviour. However, the Expert Working Group of the CSM considered that it was not possible to draw any conclusions on the link between the development of these symptoms and the risk of suicidal behaviour, as such data were not included in the majority of cases.[7]

There have been suggested links between the use of fluoxetine and *irritability, hostility, and aggression*.[15] However, one review[16] noted that an unpublished analysis had indicated that patients taking fluoxetine for a variety of disorders were not more likely to be aggressive than those taking placebo. Prescription-event monitoring has also found no evidence to suggest that fluoxetine increases the frequency of aggression.[5]

Initiation of antidepressant therapy with paroxetine or sertraline has been associated with either worsening or a new onset of *flashback syndrome* in 2 patients with a history of lysergide abuse.[17]

There have been isolated reports of *memory loss* associated with the use of SSRIs.[18]

Effects on sexual function. Sexual dysfunction is often noted in patients with depression and may be due to their antidepressant medication or to the disease itself. Complaints include a decrease in or loss of libido, delayed ejaculation, erectile difficulty, or anorgasmia in men;[1] loss of libido, delayed orgasm, or anorgasmia have been reported in women.[1,2] Early identification is important since drug-induced sexual dysfunction is a common cause of non-compliance; in addition, it may adversely affect the quality of life of patients and hamper their recovery.[3,4]

It has been considered that sexual dysfunction occurs in up to 1.9% of patients taking fluoxetine, with impotence or ejaculatory problems occurring in less than 1% of patients.[5] However, these figures, which were based on information supplied by the US manufacturer, have been disputed[6,7] and the incidence of sexual dysfunction may be higher than the manufacturer's data suggest. Earlier studies and anecdotal reports quoted rates of 7.8 to 75% for sexual dysfunction with fluoxetine but it appears that only small numbers of men were studied.[8] A later review[9] also estimated the incidence of SSRI-induced sexual dysfunction at between 10 and 75%.

The incidence of sexual dysfunction may differ between types of antidepressants. A large, observational study[3] found the rate of sexual dysfunction to be higher with the SSRIs (citalopram, fluoxetine, paroxetine, and sertraline) and the SNRI venlafaxine than with bupropion or nefazodone. However, no significant difference in rate was found among the SSRIs as a group. The study also identified other risk factors for developing sexual dysfunction which included increasing age, the use of high doses, and use with other medications. Gender, race, and length of treatment were not associated with an increased risk.

Suggested[1,4,10] strategies for managing SSRI-induced sexual dysfunction include reducing the dosage of the SSRI or altering the timing of doses, or changing to another antidepressant. In some cases tolerance may develop, particularly if the dysfunction occurred early in treatment. One small study[11] has indicated that spontaneous improvement may occur even up to 6 months after the start of therapy.[11] Evidence of efficacy for drug treatments is mainly anecdotal. Cyproheptadine seems to have been tried most often, but the SSRI may become less effective (see Antihistamines, under Interactions, below) and patients should be monitored for worsening symptoms of depression.

The effects of the SSRIs on sexual function have been studied as a potential form of treatment for men with premature ejaculation (see Sexual Dysfunction in Uses, below).

Effects on the skin. *Toxic epidermal necrolysis* developed in a 16-year-old girl 8 days after beginning fluvoxamine therapy.[1] Other drugs, which included metoclopramide, clorazepate, and clomipramine were discounted as possible causes.

Amitriptyline and fluoxetine have been implicated in the development of *atypical cutaneous lymphoid hyperplasia* in 8 patients, 7 of whom either had an underlying immunosuppressant systemic disease or were also receiving immunomodulatory drugs.[2] The lesions improved or resolved on stopping the antidepressant, although in some patients other factors may have contributed to the improvement.

Bullous pemphigoid induced by fluoxetine has been reported in a 75-year-old woman.[3] Spontaneous resolution followed within 3 weeks of stopping the drug.

Paroxetine treatment has been associated with the development of *cutaneous vasculitis*, which involved several fingers, in a 20-year-old woman;[4] rechallenge was positive. On both occasions the patient recovered when paroxetine was withdrawn.

A severe *bullous reaction with full-thickness skin necrosis* has been reported in a 48-year-old woman after 6 months of treatment with sertraline.[5] The lesions required extensive skin grafts and recovery was prolonged, with drug-induced scleroderma developing in the affected area.

Epileptogenic effect. Generalised seizures have been reported in 2 patients with no history of seizures after starting fluoxetine therapy.[1,2] Although convulsions have been noted in patients taking fluvoxamine (see Incidence of Adverse Effects, p.399), a small clinical study involving 35 depressed epileptic patients[3] found no change in the number of seizures or in their nature when fluvoxamine was given in doses of up to 200 mg daily.

Extrapyramidal effects. Extrapyramidal effects, such as tics[1] and akathisia,[2,3] have been reported with fluoxetine. By 1993, the

UK CSM had received 39 reports of extrapyramidal reactions with paroxetine including 15 of dystonia of the face and mouth.[4] Although extrapyramidal effects might occur with other SSRIs, orofacial dystonias appeared to be more common with paroxetine. However, evidence from monitoring prescriptions within the UK showed that the overall incidence of extrapyramidal effects was the same for paroxetine as for other SSRIs.[5] Orofacial dystonias (teeth clenching) or dyskinesias (teeth grinding), resulting in severe damage to teeth and gums in many cases, have been reported[6] in 6 patients receiving fluoxetine, fluvoxamine, paroxetine, or sertraline. The authors concluded that these adverse effects were not specific for any particular SSRI. Analysis of spontaneous adverse reaction reports received by the national pharmacovigilance centre in The Netherlands found that there had been 41 reports of extrapyramidal effects associated with the SSRIs over a period of nearly 15 years;[7] parkinsonism and dystonia were the most frequently reported effects. Over the same time period, 14 reports had been received in total for other antidepressants. The authors commented that the results might be biased by the selective reporting of adverse reactions to the SSRIs.

Dyskinesia associated with withdrawal of citalopram and risperidone has been reported in a patient.[8]

The onset of akathisia may be linked to suicidal ideation; for further details, see Effects on Mental State, above.

Hypersensitivity. Hypersensitivity reactions to SSRIs are well documented. Interestingly, despite structural dissimilarities, there have been a few reports of cross-sensitivity between SSRIs. A young man who had previously developed a maculopapular rash while taking paroxetine suffered a similar reaction after starting sertraline;[1] both episodes resolved after the SSRI was withdrawn.

Hyponatraemia. See Effects on the Endocrine System, above.

Overdosage. SSRIs are generally regarded as being less toxic in overdosage than tricyclic antidepressants or MAOIs. A review[1] of SSRI overdosage, covering the period 1985 to 1997, noted that there had been remarkably few fatal overdoses when taken alone. Moderate overdoses (up to about 30 times the usual daily dose) were generally associated with minor symptoms at most; only at very high doses (more than 75 times the usual daily dose) did more serious effects such as seizures, ECG abnormalities, and decreased consciousness tend to occur. Toxicity was greatly increased, however, when overdoses of SSRIs were taken with alcohol or other drugs. There was no evidence of a difference in the various SSRIs with respect to safety in overdosage. The results of a more recent cohort study[2] have also confirmed the relative safety of the SSRIs in overdosage. However, the study also found that citalopram was potentially more cardiotoxic than other SSRIs in overdose, causing significant prolongation of the QT interval (see below). In addition, serotonin syndrome was noted as being a common feature of SSRI overdosage although in most cases symptoms were not severe or life-threatening.

- Fatal overdose was reported with *citalopram* in 6 patients,[3] although the suggested cause of death as cardiac dysfunction rather than seizures was disputed.[4] Nonetheless, cases[2,5] of cardiac abnormalities (including prolongation of the QT interval) associated with citalopram overdose have continued to be reported, and routine ECG monitoring may be necessary in the management of overdosage. Some authors consider that a metabolite, didemethylcitalopram, rather than citalopram itself, may be responsible for the cardiotoxicity seen with citalopram overdose.[5] At therapeutic doses, concentrations of didemethylcitalopram are much lower than those of citalopram and, in general, significant cardiotoxicity is not seen; however, in overdosage the amount of didemethylcitalopram may be sufficient to induce cardiac conduction abnormalities.
- A report involving 87 cases in which *fluoxetine* was taken in overdosage without other drugs found that the main symptoms were tachycardia, drowsiness, tremor, and nausea and vomiting.[6] These were considered relatively minor, and were of short duration, and supportive care was considered to be the only intervention necessary.
- Of 41 cases of self-poisoning with *fluvoxamine*, only one patient died and even here fluvoxamine was not implicated.[7] Prolonged cerebral depression occurred in a patient after fluvoxamine overdose,[7] but this may have been due to an interaction with temazepam which the patient also took in overdose.
- One hour after taking 2 g of *sertraline* in a suicide attempt a 42-year-old woman was flushed, angry, emotionally labile, and easily distracted but not psychotic.[8] Apart from watery bowel movements recovery was mainly uneventful after treatment with gastric lavage, oral activated charcoal with sorbitol, and intravenous hydration. In another case,[9] symptoms resembling serotonin syndrome developed in a 51-year-old woman after an overdose attempt with sertraline; it was believed that the patient may have taken as much as 8 g of sertraline. She recovered with supportive treatment. Abnormal liver function tests have also been noted after a suicide attempt with sertraline (see Effects on the Liver, above).

For a discussion of choice of antidepressant with respect to toxicity in overdosage, see under Depression, p.373.

Treatment of Adverse Effects

Treatment of overdosage with an SSRI involves appropriate symptomatic and supportive therapy. Activated charcoal may be given by mouth if the amount ingested was large (see below) and treatment is within an hour of ingestion. Dialysis, haemoperfusion, exchange transfusion, and measures to increase urine production are considered unlikely to be of benefit.

Activated charcoal. The UK Poisons Information Service considers the benefit of gastric decontamination in the management of overdosage with SSRIs to be uncertain. However, it is suggested that oral activated charcoal may be considered if this is given within 1 hour of ingestion and the quantity of SSRI exceeds the following amount:

- citalopram: 5 mg/kg (adult); 5 mg/kg (child)
- escitalopram: 2.5 mg/kg (adult); 2.5 mg/kg (child)
- fluoxetine: 500 mg (adult); 5 mg/kg (child)
- fluvoxamine: 1 g (adult); 100 mg (child)
- paroxetine: 600 mg (adult); 5 mg/kg (child)
- sertraline: 1 g (adult); 10 mg/kg (child)

Precautions

Because of their epileptogenic effect SSRIs should be used with caution in patients with epilepsy or a history of such disorders (and should be avoided if the epilepsy is poorly controlled). Treatment should be stopped if seizures develop or when there is an increase in seizure frequency. Care is advised in patients receiving ECT as prolonged seizures have occurred rarely. SSRIs should also be used with caution in patients with cardiac disease or a history of bleeding disorders. Although SSRIs are preferred to tricyclics for the treatment of depression in patients with diabetes, they may alter glycaemic control and therefore caution is also warranted in diabetic subjects. SSRIs should be used with caution in patients with angle-closure glaucoma.

Fluoxetine should be stopped in patients who develop a rash since systemic effects, possibly related to vasculitis, have occurred in such patients. Fluoxetine undergoes hepatic metabolism and should be used with caution and in reduced doses in patients with impaired hepatic function.

Patients should be closely monitored during early therapy until significant improvement in depression is observed because suicide is an inherent risk in depressed patients. For further details, see under Depression, p.373. For a discussion of the concern that SSRIs may increase suicidal ideation, and concerns about their use for depression in children and adolescents, see Effects on Mental State in Adverse Effects, above. Suicidal thoughts and behaviour may also develop during early treatment with antidepressants for other disorders; the same precautions observed when treating patients with depression should therefore be observed when treating patients with other disorders. If SSRIs are given for the depressive component of bipolar disorder, mania may be precipitated. Symptoms may also worsen during the initial treatment of panic disorder with SSRIs.

SSRIs may impair performance of skilled tasks and, if affected, patients should not drive or operate machinery.

Some licensed product information recommends reduced or less frequent dosage of SSRIs for elderly patients.

SSRIs should generally be withdrawn gradually to reduce the risk of withdrawal symptoms although this may be unnecessary for fluoxetine because of its long half-life.

Abuse. There have been occasional reports of individuals abusing fluoxetine.[1,2]

Blood disorders. For a reference recommending cautious use of SSRIs in patients with a history of bleeding disorders, see Effects on the Blood in Adverse Effects, above.

Breast feeding. The American Academy of Pediatrics[1] considers that all antidepressants, including SSRIs (fluoxetine, fluvoxamine, paroxetine, and sertraline) are drugs whose effect on nursing infants is unknown but may be of concern. In addition, most licensed drug information advises that SSRIs should be avoided by the mother during breast feeding.

- *Citalopram* and its metabolites have been detected in breast milk; however, in one study, the plasma concentrations in exposed infants were either very low or undetectable and no adverse effects were reported.[2] In another study, 3 out of 31 breast-fed infants whose mothers were taking citalopram had adverse effects, specifically one case each of colic, decreased feeding, and irritability.[3] However, there was no significant increase in the risk of adverse events in this group of infants when compared with either infants of depressed mothers not taking citalopram, or infants of healthy controls.
- Symptoms of colic were reported[4] in a 6-week-old infant whose mother was taking *fluoxetine* 20 mg daily. The concentrations of fluoxetine and its active metabolite norfluoxetine were 69 nanograms/mL and 90 nanograms/mL respectively in breast milk, and 340 nanograms/mL and 208 nanograms/mL respectively in the infant's plasma. The infant's symptoms resolved when he was formula fed. Postnatal weight gain has been reduced in infants exposed to fluoxetine during breast feeding, although in all cases the reduction was less than 2 standard deviations below the norm.[5] In another report,[6] several seizure-like episodes occurred in a breast-fed infant whose mother was taking fluoxetine in addition to carbamazepine and buspirone; however, plasma drug concentrations in the infant were significant only for fluoxetine and norfluoxetine. In a study[7] of 10 women taking fluoxetine while breast feeding 11 infants, breast milk concentrations of fluoxetine ranged from 17.4 to 293 nanograms/mL and of norfluoxetine from 23.4 to 379.1 nanograms/mL. No adverse effects were noted in the infants. Similar levels have occurred in other breast-fed infants without any apparent drug-induced adverse effects.[8-10] Fluoxetine and norfluoxetine were detected in the milk of 14 nursing women.[11] Blood samples were taken from 9 of the infants in the study, and of these, fluoxetine was detected in the plasma of 5 and norfluoxetine in 7. Although it was felt that many infants would tolerate the mean combined dose of fluoxetine and norfluoxetine transmitted via breast milk in this study, there was considerable interpatient variability in estimated infant dose and caution should be exercised; neonates in particular exhibited higher concentrations of norfluoxetine than older infants. Moreover, since both fluoxetine and norfluoxetine have long half-lives, neonates already exposed *in utero* may have an additional risk of adverse effects during breast feeding.
- The excretion of *fluvoxamine* into breast milk was studied[12] in a woman who had been receiving fluvoxamine maleate 100 mg twice daily for 2 weeks. The concentration of fluvoxamine base 4.75 hours after a dose was 310 nanograms/mL in maternal plasma and 90 nanograms/mL in breast milk. It was estimated that an infant would ingest only 0.5% of the daily maternal intake. It was considered that these data supported the notion that the use of fluvoxamine by nursing mothers posed little risk to the infant. A subsequent study[13] found no detectable drug levels in the plasma of breast-fed infants

exposed to fluvoxamine; the authors suggested that fluvoxamine was a reasonable choice for nursing mothers requiring treatment for depression.

- Although *paroxetine* was detected in measurable concentrations in the breast milk of a group of 10 nursing mothers receiving paroxetine no adverse effects were reported in any of their breast-fed infants.[14] Paroxetine could not be detected in the plasma of 7 of the 8 infants from whom samples were obtained and in the other infant, concentrations were not quantifiable. Another study involving 7 women suggested that the dose of paroxetine to suckling infants would be 0.7 to 2.9% of the weight-adjusted maternal dose.[15] A later study[13] also found no detectable drug levels in the plasma of breast-fed infants exposed to paroxetine; the authors suggested that paroxetine was a reasonable choice for nursing mothers requiring treatment for depression. In a prospective cohort study, weight gain at 6 and 12 months of age in infants whose mothers took paroxetine during breast feeding was not adversely affected when compared with the infants of mothers who either did not breast feed or breast fed without taking any drugs during lactation;[16] in addition, there was no difference in reaching the usual developmental milestones between the infants of the 3 groups.
- Plasma concentrations of *sertraline* were undetectable in a breast-fed infant despite the presence of concentrations in the mother's breast milk ranging from 8.8 to 43 nanograms/mL over a 24-hour period.[17] However, the authors pointed out that metabolite levels were not measured and that sertraline may have been present in the infant at a concentration below the level of sensitivity of the assay. Other studies[13,18-21] have detected desmethylsertraline in breast milk, which was also detected in the plasma of some of the infants in a number of the studies[13,18,20,21] but not all.[19] The authors of at least one study[13] suggested that sertraline was a reasonable choice for nursing mothers requiring treatment for depression. In addition, some authors recommend expressing and discarding breast milk 8 to 9 hours after a maternal dose, when levels of desmethylsertraline and sertraline are maximal, in order to significantly reduce infant exposure to sertraline.[21]

Children. SSRIs are associated with an increased risk of potentially suicidal behaviour when used for the treatment of depression in children and adolescents under 18 years old; for further details, see under Effects on Mental State, above.

Diabetes mellitus. A patient with type 1 diabetes mellitus experienced a loss of hypoglycaemic awareness following the start of treatment with fluoxetine.[1] Awareness returned on tapered withdrawal of fluoxetine. Changes in blood sugar concentrations may occur in patients with diabetes treated for depression with SSRIs (see also Effects on the Endocrine System, above); however, these may represent an improvement in glycaemic control.[2]

Driving. While affective disorders probably adversely affect driving skill,[1,2] treatment with antidepressants can also be hazardous,[1] although patients may be safer drivers with medication than without.[2] Impairment of performance is largely related to sedative and antimuscarinic effects. These are more pronounced with older antidepressants such as the tricyclic antidepressants than with the SSRIs, but a comparative study[3] of fluoxetine (an SSRI) and dosulepin (a tricyclic) in healthy subjects showed a similar but apparently small potential for impairing psychomotor and driving performance. A later epidemiological study[4] was unable to confirm any increased risk of road-traffic accidents in those drivers receiving tricyclic antidepressants or SSRIs.

In the UK, the Driver and Vehicle Licensing Authority[5] considers that drugs such as SSRIs may have fewer adverse effects on drivers than antidepressants with pronounced antimuscarinic or antihistaminic adverse effects, such as tricyclic antidepressants. However, all drugs acting on the CNS can impair alertness, concentration, and driving performance, particularly at the start of treatment or when the dose is increased; driving must cease if patients are adversely affected. Patients with severe depressive illnesses complicated by significant memory or concentration problems, agitation, behavioural disturbances, or suicidal thoughts should also cease driving pending the outcome of medical enquiry.

Gastrointestinal disorders. For the opinion that the SSRIs may produce a clinically important increase in the risk of upper gastrointestinal bleeding in patients with a high risk of such bleeding, see under Effects on the Gastrointestinal Tract, above.

Glaucoma. For reference to SSRIs precipitating or exacerbating symptoms of glaucoma, see Effects on the Eyes, above.

Mania. Hypomania or mania have been reported with the SSRIs; consequently, UK licensed drug information recommends that SSRIs should be withdrawn in any patient entering a manic phase.

Fluvoxamine was associated with manic behaviour in 8 patients who were being treated for major depression;[1] 3 also had obsessive-compulsive disorder. Daily doses of fluvoxamine ranged from 75 to 300 mg and duration of therapy to development of manic behaviour from 2 to 6 weeks. The authors were unable to determine whether fluvoxamine had induced mania or unmasked latent bipolar disorder in these patients. However, they recommended that fluvoxamine-treated patients should be monitored for manic behaviour.

Symptoms of manic behaviour also developed in a 7-year-old girl after taking *sertraline* for about 2 weeks for the treatment of major depression.[2] She recovered within a few weeks of stopping sertraline.

Pregnancy. In an early prospective study[1] comparing 128 pregnant women exposed to a mean daily dose of about 26 mg of fluoxetine during their first trimester with control groups receiving tricyclic antidepressants or non-teratogens, the incidence of **neonatal malformations** was similar in all groups and did not exceed that in the general population. However, there was a tendency to a higher incidence of **miscarriages** in the groups receiving fluoxetine or tricyclics. A more recent prospective study[2] comparing 228 pregnant women taking fluoxetine with a control group taking non-teratogens also failed to find a significant increased incidence in major fetal abnormalities in the fluoxetine group; it also did not reveal an increased risk of miscarriage. There was an increase in the incidence of minor fetal abnormalities in infants exposed to fluoxetine during the first trimester. Also, infants exposed to fluoxetine during the third trimester experienced more perinatal complications such as prematurity, low full-term birth-weight and length, and poor neonatal adaptation compared with infants exposed only during the first and second trimesters. However, the design of this study was criticised[3] because of several methodological problems such as unmatched controls and a higher maternal age in the fluoxetine group, which may partly explain the excess of poor perinatal outcomes.

The manufacturer evaluated the outcome of 796 pregnancies in which the mother received fluoxetine during the first trimester and considered that it was unlikely that fluoxetine increased the risk of miscarriage or fetal malformation.[4] A prospective controlled study[5] on pregnancy outcome in women exposed to fluvoxamine, paroxetine, or sertraline also found that, when used in recommended doses, there appeared to be no increase in the risk of major congenital malformations, miscarriages, or still-births when compared with women exposed to non-teratogens. Nonetheless, the results from a more recent meta-analysis which included some of the above studies have suggested that maternal exposure to antidepressant treatment (specifically SSRIs, tricyclics, nefazodone, trazodone, or venlafaxine) may significantly increase the risk of miscarriage in comparison to women not exposed to antidepressants.[6] However, the authors acknowledged that the underlying depression itself might be a contributing factor to the increased risk.

There is some evidence that paroxetine may be more teratogenic than other antidepressants. The manufacturer *GlaxoSmithKline* has reported[7] that overall the data from a retrospective US epidemiological study and a study using the Swedish national birth registry have indicated that there was a twofold increase in cardiovascular malformations, particularly ventricular septal defects, in infants born to mothers who had taken paroxetine during pregnancy compared with the general population. However, whereas the US study also showed an overall risk of major congenital malformations (inclusive of the cardiovascular defects), the Swedish study found no such increase.

Maternal use of SSRIs has been associated with **neonatal complications**. CNS toxicity and an increased heart rate were reported in a neonate whose mother had received 20 mg of fluoxetine daily throughout most of her pregnancy.[8] The neonate's symptoms resolved 96 hours after delivery. In another neonate whose mother took up to 30 mg daily of fluoxetine throughout the third trimester cardiac arrhythmias were noted.[9] In a matched-control study[10] the rate of complications after delivery in 55 infants exposed to paroxetine during the third trimester was higher than in a control group who had been exposed to paroxetine or non-teratogenic agents during the first or second timesters. Complications that occurred in the infants exposed in the third trimester included respiratory distress (9), hypoglycaemia (2), bradycardia (1), jaundice (1), and suckling problems (1). More recently, another matched-control study[11] has suggested that exposure to SSRIs (in this case fluoxetine, paroxetine, and sertraline) after the 20th week of gestation may increase the risk of persistent pulmonary hypertension of the newborn (PPHN). Of 377 infants with a confirmed diagnosis of PPHN, the mothers of 14 (3.7%) had taken an SSRI after the 20th week of gestation, compared with only 6 out of 836 infants (0.7%) in the matched-control group. Although these figures represent about a sixfold increase in the risk of PPHN in infants exposed to SSRIs *in utero*, the absolute risk remains relatively low (about 6 to 12 per 1000 women).

A number of reports[2,12-16] have described symptoms such as jitteriness, irritability, sleep disturbances, and altered muscle tone in neonates who had been exposed to SSRIs *in utero*, especially during the third trimester; in the majority of cases the symptoms are mild and self-limiting. Although withdrawal symptoms have been reported with most SSRIs, they have been more commonly reported in those neonates exposed to paroxetine.[17] More recently, some authors have used the term neonatal behavioural syndrome to refer to such symptoms.[15] It is unclear whether the symptoms represent a withdrawal syndrome or direct serotonin toxicity;[14,16,18] however, it has been suggested by some that *in-utero* exposure to SSRIs with a short half-life such as paroxetine may lead to a neonatal withdrawal syndrome whereas exposure to an SSRI with a long half-life, particularly fluoxetine, may manifest as neonatal serotonin toxicity.[15] There have been case reports of intraventricular haemorrhage in neonates whose mothers took SSRIs during late pregnancy but there is currently not enough data to determine whether the frequency of such bleeds in infants exposed to SSRIs is higher than normal.[16]

The effects of fluoxetine on fetal **neurodevelopment** were studied[19] in 55 pregnant women by later assessing global IQ of the children; no differences were seen in those exposed to fluoxetine *in utero* during the first trimester compared with those exposed to tricyclic antidepressants or adverse developmental influences. A subsequent study indicated that exposure to fluoxetine or tricyclic antidepressants throughout gestation did not appear to affect cognition adversely.[20] In another follow-up study, subtle differences in motor development and control, in particular tremulousness and inappropriate fine motor movements, were noted in the infants and children of depressed mothers who had taken SSRIs during pregnancy when compared with the infants of depressed mothers who had not taken any medication.[21] However, in other measures of mental development there were no observed differences between the two groups.

Surgery. In patients undergoing orthopaedic surgery, the risk of perioperative blood loss was significantly increased in those taking serotonergic antidepressants (specifically clomipramine, fluoxetine, fluvoxamine, paroxetine, sertraline, and venlafaxine) when compared with those on non-serotonergic antidepressants.[1] In addition, there was a significant increase in the need for blood transfusion during surgery in those on serotonergic antidepressants compared with those not receiving antidepressant medication.

1. Movig KLL, *et al.* Relationship of serotonergic antidepressants and need for blood transfusion in orthopedic surgical patients. *Arch Intern Med* 2003; **163:** 2354–8.

Withdrawal. Withdrawal reactions have been reported for all SSRIs and the related antidepressants mirtazapine and venlafaxine on dosage reduction or stopping treatment, although the frequency of such reactions may vary.[1-5] Paroxetine and venlafaxine have been associated with withdrawal reactions more often than other serotonergic antidepressants; in the case of paroxetine this may be due, in part, to its short half-life. Fluvoxamine also has a short half-life and has been shown in some studies to have a high risk of withdrawal reactions. The apparent lower risk of withdrawal reactions with fluoxetine may be due to its long half-life. Other factors that increase the risk of withdrawal reactions include abrupt withdrawal, the use of high doses, and prolonged therapy.[5]

In general, withdrawal reactions tend to occur within 3 days of stopping an SSRI or related antidepressant,[1,4,5] although a delay of up to 2 weeks may be noted with fluoxetine.[5] Common symptoms include dizziness, numbness and tingling, gastrointestinal disturbances (particularly nausea and vomiting), headache, sweating, anxiety, and sleep disorders. In some cases withdrawal symptoms may be severe and disabling. There has also been a report[6] of 2 patients without a history of major psychiatric disorder who developed severe behavioural symptoms when paroxetine was withdrawn. Withdrawal was abrupt in one patient and more gradual, over a 12-day period, in the other. Symptoms were mainly hypomanic over the first few days, followed by a period of escalated ego-dystonic aggression, behavioural dyscontrol, and suicidal ideation.

Antidepressant dose tapering appears to reduce the frequency and severity of withdrawal reactions.[5] The *BNF* recommends that any antidepressant, including an SSRI, that has been taken regularly for 8 weeks or more should be stopped gradually over a period of about 4 weeks, or as much as 6 months in patients who have been receiving long-term maintenance therapy.

The withdrawal syndrome of the SSRIs is not considered to be a consequence of dependence.[4,5]

See also Extrapyramidal Effects under Adverse Effects, above. For debate about whether a withdrawal syndrome exists in neonates whose mothers have received SSRIs see Pregnancy, above.

Interactions

SSRIs interact with other drugs mainly as a result of their inhibitory activity on hepatic cytochrome P450 isoenzymes. Individual SSRIs do not all exhibit the same degree of inhibition nor do they react with the same isoenzymes. The drugs inhibited by specific SSRIs depends on the isoenzyme affected.

As SSRIs have occasionally been associated with bleeding disorders and other effects on the blood, caution is advised when they are given with drugs known to affect platelet function.

Although different antidepressants have been used together under expert supervision in refractory cases of depression, severe adverse reactions including the *serotonin syndrome* (see p.416) may occur. Sequential prescribing of different types of antidepressant may also produce adverse reactions, and an appropriate drug-free interval should elapse between stopping one type of antidepressant and starting another. SSRIs should not generally be given to patients receiving MAOIs or for at least 2 weeks after their use. No treatment-free period is necessary after stopping a reversible inhibitor of monoamine oxidase type A (RIMA) and starting an SSRI. At least one week should elapse between withdrawing an SSRI and starting any drug liable to provoke a serious reaction (e.g. phenelzine); in the case of the SSRI sertraline the drug-free interval is extended to 2 weeks, and for fluoxetine 5 weeks, because of their longer half-lives. (For fluoxetine, the interval may need to be further extended if therapy has been prolonged or if high doses have been given.) Adverse effects such as the serotonin syndrome may also occur when the SSRIs are given with other drugs known to act on the same neurotransmitter, a consequence of synergistic interaction.

Further details concerning some of these interactions, and others, are given below.

Antibacterials. Rapid development of delirium was reported[1] in a patient when *clarithromycin* was added to his existing regimen of fluoxetine and nitrazepam. It was suggested that his delirium was a result of increased plasma-fluoxetine concentrations produced by the inhibition of cytochrome P450 enzymes by clarithromycin. Serotonin syndrome developed in a patient given *erythromycin* in addition to sertraline;[2] this was attributed to inhibition of CYP3A4 by the antibacterial, resulting in accumulation of the SSRI. There have also been reports of serotonin syndrome when *linezolid* was given with fluoxetine,[3] sertraline,[4] paroxetine,[5] and citalopram[6]; in the latter case the patient developed complications including metabolic acidosis and ultimately fatal cardiac arrest.[6] Reviews of serotonin syndrome associated with the use of linezolid suggest that SSRIs are the interacting drug most often implicated.[7,8] However, it has been suggested that if warranted, linezolid may be given to patients receiving SSRIs provided the patient is carefully monitored for signs and symptoms of serotonin syndrome.[8]

Anticoagulants. SSRIs may increase the anticoagulant activity of some anticoagulants including *acenocoumarol* and *warfarin* (see p.1428).

Antidepressants. Combination therapy with differing classes of antidepressants has been used successfully in the treatment of drug-resistant depression. It should be emphasised, however, that such combinations may result in enhanced adverse reactions or interactions, and should be used only under expert supervision. This practice is considered unsuitable or controversial by some authorities. For further details of the interactions between different antidepressants when given together, see Phenelzine, p.418. For details of the serotonin syndrome that can arise when two serotonergic drugs with different mechanisms of action are given, see under Adverse Effects of Phenelzine, p.416.

Antiepileptics. Antidepressants may antagonise the activity of antiepileptics by lowering the convulsive threshold.

There has been a report of the serotonin syndrome (see p.416) developing in a patient 14 days after fluoxetine had been added to *carbamazepine* therapy.[1]

Phenobarbital has been reported to reduce serum concentrations of paroxetine.[2] Steady-state serum concentrations of paroxetine were found to be lower in patients taking *phenytoin* than in those taking carbamazepine or valproate.[3]

Low serum concentrations of citalopram have been reported in 2 patients also taking carbamazepine.[4] Serum concentrations increased when carbamazepine was changed to oxcarbazepine.

Some SSRIs have been reported to increase plasma concentrations of carbamazepine (see p.474) and phenytoin (see p.498). For conflicting reports of the effect of fluoxetine on serum-*valproate* concentrations, see p.511.

4. Leinonen E, *et al.* Substituting carbamazepine with oxcarbazepine increases citalopram levels. A report on two cases. *Pharmacopsychiatry* 1996; **29:** 156–8.

Antihistamines. *Cyproheptadine* given to male and female patients as treatment for sexual dysfunction induced by fluoxetine or paroxetine has produced re-emergence of previously controlled depressive symptoms[1,2] or bulimia nervosa[3] in some patients.

Citalopram, fluoxetine, and fluvoxamine may increase plasma concentrations of *astemizole* or *terfenadine* by inhibition of their hepatic cytochrome P450 metabolism, increasing the risk of ventricular arrhythmias; use together should be avoided.

2. Christensen RC. Adverse interaction of paroxetine and cyproheptadine. *J Clin Psychiatry* 1995; **56:** 433–4.
3. Goldbloom DS, Kennedy SH. Adverse interaction of fluoxetine and cyproheptadine in two patients with bulimia nervosa. *J Clin Psychiatry* 1991; **52:** 261–2.

Antimalarials. For mention of the effect of the SSRI fluvoxamine on the metabolism of *proguanil*, see p.609.

Antimigraine drugs. There have been rare reports of serotonin syndrome associated with the use of SSRIs with serotonin ($5\text{-}HT_1$) agonists such as *sumatriptan* (see p.626). Fluvoxamine may inhibit the metabolism of *frovatriptan* and *zolmitriptan* (see p.622 and p.628, respectively). For the effects when some SSRIs are used with *dihydroergotamine*, see p.621.

Antimuscarinics. For the effect of SSRIs on *benzatropine*, see p.797. For the effect of paroxetine on *procyclidine*, see p.815.

Antineoplastics. Paroxetine may inhibit the metabolism of *tamoxifen*; for further details, see p.774.

Antipsychotics. For reports of adverse effects in patients treated with SSRIs and antipsychotics, see under *Chlorpromazine*, p.974. Interactions between SSRIs and atypical antipsychotics are also mentioned under *clozapine*, p.984, *olanzapine*, p.1013, *risperidone*, p.1025, *sertindole*, p.1028, and *zotepine*, p.1040.

Antivirals. Plasma concentrations of fluoxetine and other SSRIs are possibly increased by HIV-protease inhibitors, such as *ritonavir*, which may inhibit metabolism of the SSRI. Unexpectedly, however, total exposure to paroxetine was approximately halved by a *ritonavir-boosted fosamprenavir* combination in a study in healthy subjects.[1] Although the free fraction of paroxetine in plasma was increased, suggesting that it had been displaced from protein binding, the maximum concentration of free paroxetine was reduced.

The serotonin syndrome has been described[2] in a few patients given regimens that included fluoxetine and antiretroviral-dose ritonavir. The reaction also occurred in another patient given fluoxetine and *efavirenz*.

1. van der Lee MJ, *et al.* Interaction study of the combined use of paroxetine and fosamprenavir-ritonavir in healthy subjects. *Antimicrob Agents Chemother* 2007; **51:** 4098–4104.
2. DeSilva KE, *et al.* Serotonin syndrome in HIV-infected individuals receiving antiretroviral therapy and fluoxetine. *AIDS* 2001; **15:** 1281–5.

Anxiolytics. Fluoxetine and fluvoxamine increase plasma concentrations of some *benzodiazepines* (see under Diazepam, p.990). There is a report of hyponatraemia and serotonin syndrome developing in a patient who received high doses of citalopram and *buspirone*.[1]

1. Spigset O, Adielsson G. Combined serotonin syndrome and hyponatraemia caused by a citalopram-buspirone interaction. *Int Clin Psychopharmacol* 1997; **12:** 61–3.

Beta blockers. For the effect of fluoxetine and fluvoxamine on beta blockers, see p.1228.

Ciclosporin. For the effect of fluoxetine and fluvoxamine on ciclosporin, see p.1826.

Cough suppressants. For the effects when using fluoxetine or paroxetine with *dextromethorphan*, see p.1556.

Dopaminergics. *Selegiline* is an irreversible selective inhibitor of monoamine oxidase type B. Serious adverse effects have been reported when selegiline and SSRIs have been used together (see p.817). In some instances, these reactions resemble the potentially fatal serotonin syndromes reported when SSRIs are given with non-selective MAOIs (see p.416).

SSRIs should not generally be given to patients receiving selegiline, or for at least 2 weeks after it has been stopped. Similarly, at least one week should elapse between withdrawing an SSRI and starting selegiline; this interval should be increased to 2 weeks for sertraline, and to 5 weeks for fluoxetine because of their longer half-lives.

Gastrointestinal drugs. Acute dystonia has been noted in a patient given fluvoxamine and *metoclopramide*.[1] Similar reports have been published for other SSRIs (fluoxetine[2] or sertraline[3]) and metoclopramide. Involuntary twitching, tremor, and stiffness of the jaw and tongue occurred on both occasions after the use of intravenous metoclopramide in a patient also taking sertraline.[4] The authors considered the adverse effects to be features of the serotonin syndrome.

For the effect of fluvoxamine on *alosetron*, and a recommendation that the combination be avoided, see p.1706.

For the effect of fluvoxamine on proton pump inhibitors, including *omeprazole*, see p.1755.

Hypnotics. For reference to visual hallucinations in patients receiving an SSRI concomitantly with *zolpidem*, see p.1038.

Levothyroxine. For mention of a decreased effect of levothyroxine in patients given sertraline concomitantly, see p.2172.

Local anaesthetics. For the effect of fluvoxamine on *ropivacaine*, see p.1871.

Muscle relaxants. For a report of QT prolongation in a patient taking fluoxetine and *cyclobenzaprine*, see p.1895.

For the effect of fluvoxamine on *tizanidine*, see p.1898.

NSAIDs. For reference to an increased risk of upper gastrointestinal bleeding in patients taking SSRIs and NSAIDs together, see under Effects on the Gastrointestinal Tract, above.

Opioid analgesics. A possible case of serotonin syndrome (p.416) has been reported with *tramadol* and sertraline,[1] and another when sertraline was given with high doses of *oxycodone*.[2] There have also been occasional reports of the syndrome in patients given tramadol with citalopram,[3] fluoxetine,[4] or paroxetine.[5,6] Other reports of serotonin syndrome were associated with use of oxycodone and fluvoxamine,[7] *pethidine* and fluoxetine,[8] and citalopram with *fentanyl*[9] or pethidine.[10] For reference to SSRIs enhancing the effects and toxicity of *methadone*, see p.84.

Stimulants. For the effect of paroxetine on the metabolism of *atomoxetine*, see p.2151.

Theophylline. For the effect of fluvoxamine on theophylline, see p.1143.

Pharmacokinetics

Fluoxetine is readily absorbed from the gastrointestinal tract with peak plasma concentrations appearing about 6 to 8 hours after oral doses. Systemic bioavailability does not appear to be affected by food. Fluoxetine is extensively metabolised, by demethylation, in the liver to its primary active metabolite norfluoxetine. Excretion is mainly via the urine. Protein binding is reported to be about 95%.

Fluoxetine used clinically is a racemic mixture consisting of *R*- and *S*-enantiomers in equal amounts. Both enantiomers are active according to *animal* studies, but *S*-fluoxetine is eliminated more slowly. Metabolism is believed to be mediated by cytochrome P450 isoenzyme CYP2D6 (but see below), and leads to *R*- and *S*-enantiomers of norfluoxetine, with the *S*-enantiomer being considered as active as the parent drug; the *R*-enantiomer is considered to be much less active. This metabolism is subject to genetic polymorphism. While the small proportion of the population known as slow metabolisers do show a different spectrum of parent drug and metabolite, the overall activity does not appear to be altered.

Fluoxetine is widely distributed throughout the body.

Fluoxetine has a relatively long elimination half-life of about 1 to 3 days after acute use and 4 to 6 days after long-term use; that of its metabolite, norfluoxetine, is even longer, being about 4 to 16 days. These long half-lives have clinical implications. Steady-state plasma concentrations will only be attained after several weeks. Additionally, fluoxetine and its metabolites may persist for a considerable time after treatment, and this has led to precautions concerning the subsequent use of other serotonergic drugs (see Interactions, above).

Fluoxetine and norfluoxetine are distributed into breast milk (see Breast Feeding under Precautions, above).

Metabolism. Although fluoxetine is stated by the manufacturers to be metabolised by the cytochrome P450 isoenzyme CYP2D6, which is supported by studies[1] indicating that its disposition is altered in poor metabolisers of debrisoquine (a substrate for this enzyme), others have suggested that CYP2C19, and perhaps CYP2C9, play an important role.[2]

Uses and Administration

Prevention of the reuptake of monoamine transmitters such as serotonin, which potentiates their action in the brain, appears to be associated with antidepressant activity. SSRIs such as fluoxetine preferentially inhibit the reuptake of serotonin compared with noradrenaline, and have limited direct action at other neurotransmitter sites, including muscarinic receptors. They therefore cause fewer antimuscarinic or sedative adverse effects than the tricyclic antidepressants and are less cardiotoxic. Citalopram is the most selective of the SSRIs currently available, whereas paroxetine is the most potent.

SSRIs provide an alternative to the tricyclics for the treatment of depression. As with the tricyclics, it may be several weeks before an antidepressant effect is seen. Once depression has then resolved, maintenance therapy should be continued for at least 4 to 6 months (12 months in the elderly) to avoid relapse on stopping therapy. Patients with a history of recurrent depression should continue to receive maintenance treatment for at least 5 years and possibly indefinitely.

Some SSRIs are also used as part of the management of generalised anxiety disorder, obsessive-compulsive disorder, panic disorders with or without agoraphobia, social phobia, and post-traumatic stress disorder, and as part of the management of bulimia nervosa. Fluoxetine is also used in the treatment of premenstrual dysphoric disorder.

Fluoxetine, a phenylpropylamine derivative, is given orally as the hydrochloride; doses are expressed in terms of the base. Fluoxetine hydrochloride 22.4 mg is equivalent to about 20 mg of fluoxetine.

In the treatment of **depression** the usual initial dose of fluoxetine is 20 mg once daily; US product information recommends giving this dose in the morning. If no clinical response is seen after several weeks, the daily dose may be gradually increased, up to a maximum of 80 mg daily (60 mg in the elderly). Doses above 20 mg daily may be given in 2 divided doses, for example in the morning and at noon, or as a once daily dose. A once-weekly, modified-release preparation equivalent to 90 mg of fluoxetine is available in the USA for use in patients whose depressive symptoms have stabilised, and who require long-term treatment; it is recommended that weekly dosing is started 7 days after the last daily dose of fluoxetine.

Fluoxetine is also used for the treatment of depression in children aged 8 years and over. Initial doses of 10 mg should be increased to 20 mg daily after 1 week (except in low-weight children when such increases should not be made for several weeks, and then only if the clinical response is insufficient). Because of concerns about the use of SSRIs in children (see Effects on Mental State, above) its use is licensed in the European Union only as an adjunct to psychological therapy in children and adolescents with moderate to severe depression who have not responded to psychological therapy alone.

Fluoxetine is used in recommended doses of 60 mg once daily in the management of **bulimia nervosa**.

In the management of **obsessive-compulsive disorder** the initial dose of fluoxetine is 20 mg once daily increased after several weeks if there is no response to up to 60 mg daily. Up to 80 mg daily has been used, sometimes divided into 2 doses. Fluoxetine is also licensed in the USA for use in children aged 7 years and over for obsessive-compulsive disorder. The starting dose is 10 mg daily; in low-weight children this is increased after several weeks to 20 to 30 mg daily, if required. Adolescents and heavier children may be increased to 20 mg daily after 2 weeks; further increases to 60 mg daily may be made after several weeks, as necessary.

Fluoxetine may be used in the treatment of **panic disorder** in initial doses of 10 mg once daily. After a week the dose should be increased to 20 mg daily; further increases to 60 mg daily may be considered after several weeks if no improvement is seen.

A dose of 20 mg daily is used in the treatment of **premenstrual dysphoric disorder**. Intermittent dosing is also permitted: for each new cycle, fluoxetine should be started 14 days before the onset of menstruation and continued until the first full day of menstruation. Treatment may be continued for 6 months; benefit should then be reassessed before continuing further.

A lower or less frequent dosage is recommended in elderly patients. For dosage in hepatic or renal impairment see below.

It should be noted that because fluoxetine and norfluoxetine have prolonged half-lives several weeks of therapy are required before steady-state concentrations are attained; similarly after dosage adjustments a time lag will occur before steady-state concentrations are again achieved. Although SSRIs should generally be withdrawn gradually to reduce the risk of withdrawal symptoms, the long half-life may reduce the need for dose tapering with fluoxetine.

Administration in hepatic or renal impairment. Fluoxetine is subject to hepatic metabolism, and, therefore, lower doses, such as alternate-day dosing, have been recommended in patients with significant hepatic impairment.

It is also excreted by the kidneys and licensed information for some UK products recommends a similar dose reduction in patients with mild to moderate renal impairment and that fluoxetine should be avoided in those with severe impairment. However, other UK and US product information states that plasma concentrations of fluoxetine or its metabolite norfluoxetine in patients with severe impairment requiring dialysis did not differ from those in controls with normal renal function when given fluoxetine 20 mg daily for 2 months.

Anorexia nervosa. Counselling and psychotherapy form the major part of treatment of anorexia nervosa and there is little or no role for specific drug therapy. Antidepressants may be indicated when there is co-existing depression or obsessive-compulsive disorder but malnourished anorexic patients may be more susceptible to adverse effects and less responsive than other patients with depression. Fluoxetine has been tried with some success particularly when used to prevent relapse once weight gain has been achieved.

Anxiety disorders. SSRIs have been given in a variety of anxiety disorders but their role in these disorders is most well established in the treatment of *obsessive-compulsive disorder* (p.952). Efficacy in obsessive-compulsive disorder appears to have been best demonstrated for fluvoxamine and fluoxetine but other SSRIs are also effective and patients unresponsive to one SSRI may respond to another. SSRIs are also of use in the treatment of *generalised anxiety disorder* (p.952), *panic disorder* (p.952), and *post-traumatic stress disorder* (p.953). SSRIs are considered to be the first choice for the treatment of *social anxiety disorder* (see under Phobic Disorders, p.953). Fluoxetine is one of the SSRIs that has been tried in the treatment of *trichotillomania.*

Bipolar disorder. Treatment of the depressive phase of bipolar disorder (p.372) with antidepressants needs caution since these drugs may precipitate mania or hypomania. SSRIs such as fluoxetine have nonetheless been used in bipolar disorder with some success. In some countries, fluoxetine is also available as a fixed-dose combination with the atypical antipsychotic olanzapine for use in the depressive phase of bipolar disorder.

Bulimia nervosa. A combination of counselling, support, psychotherapy, and antidepressants is the usual treatment for bulimia nervosa. Fluoxetine and the tricyclic desipramine have been suggested as the antidepressants of choice because they have been used extensively and are considered to be well tolerated. Other SSRIs that have been tried include sertraline, fluvoxamine, and paroxetine. Antidepressants in general do not appear to alter the patient's disturbed self-image, although disturbed attitudes might improve during short-term therapy with fluoxetine.

Depression. As discussed on p.373, there is very little difference in efficacy between the different groups of antidepressant drugs, and choice is often made on the basis of adverse effect profile. SSRIs such as fluoxetine are widely used as an alternative to the older tricyclics as they have fewer adverse effects and are safer in overdosage.

Combination therapy with differing classes of antidepressants, including the SSRIs, has been used in the treatment of drug-resistant depression. However, such therapy may result in enhanced adverse reactions or interactions and is considered unsuitable or controversial by some workers. For further details see Antidepressants, under Interactions of Phenelzine, p.418.

Disturbed behaviour. SSRIs appear to have been of some benefit in controlling symptoms such as impulsiveness and aggression[1-3] when tried in various disorders for the management of disturbed behaviour (see p.954). There have been several case reports of fluoxetine being used with some success in the control of fantasies associated with various paraphilias.[4]

Headache. The results of several studies have suggested that SSRIs may be of benefit in the treatment of chronic tension-type headache (p.617); however, results in the prophylaxis of migraine (p.616) have been conflicting.

Hot flushes. HRT with oestrogens is usually the mainstay of acute treatment for symptoms such as hot flushes associated with the menopause (see p.2077); however, HRT has potentially tumour-stimulating effects and may be unsuitable in some patients, particularly those with a history of breast cancer (see Malignant Neoplasms, under Precautions of HRT, p.2075). Preliminary studies have shown that some SSRIs (fluoxetine, paroxetine, and sertraline) have a modest effect on alleviating hot flushes and may be an alternative to HRT in peri- and postmenopausal women and in women with a history of breast cancer.[1-4] However, there is some concern that the SSRI paroxetine may interact with tamoxifen treatment in patients with breast cancer (see Antidepressants under Interactions in Tamoxifen, p.774 for details).

In addition, paroxetine has been tried in the treatment of hot flushes in men receiving anti-androgen therapy for prostate cancer.[5]

The serotonergic antidepressant venlafaxine has also been tried with some success in men and women with hot flushes in whom other treatments were unsuitable.[6]

Hyperactivity. When drug therapy is indicated for attention deficit hyperactivity disorder (ADHD—p.2148) initial treatment is usually with a central stimulant. SSRIs such as fluoxetine have produced beneficial effects as an adjunct to central stimulants in small numbers of patients with comorbid disorders such as depression or obsessive-compulsive disorder;[1-3] although there is insufficient evidence to assess their efficacy in ADHD alone.

1. Gammon GD, Brown TE. Fluoxetine and methylphenidate in combination for treatment of attention deficit disorder and comorbid depressive disorder. *J Child Adolesc Psychopharmacol* 1993; **3:** 1–10.

Hypochondriasis. SSRIs may be of benefit in patients with hypochondriasis.[1] Fluoxetine in an initial dose of 20 mg daily gradually increased up to 80 mg daily produced some beneficial results in 10 of 14 patients with hypochondriasis (p.954) who completed 12 weeks of treatment.[2] Fluvoxamine[3] and paroxetine[4] have also been tried.

4. Oosterbaan DB, *et al.* An open study of paroxetine in hypochondriasis. *Prog Neuropsychopharmacol Biol Psychiatry* 2001; **25:** 1023–33.

Hypotension. SSRIs have been used in patients with neurally mediated hypotension refractory to standard treatment (see p.1174), although evidence of benefit is mainly anecdotal. However, a small study[1] found that paroxetine reduced the incidence of both tilt-induced and spontaneous syncope.

See also Orthostatic Hypotension, below.

1. Di Girolamo E, *et al.* Effects of paroxetine hydrochloride, a selective serotonin reuptake inhibitor, on refractory vasovagal syncope: a randomized, double-blind, placebo-controlled study. *J Am Coll Cardiol* 1999; **33:** 1227–30.

Obesity. Fluoxetine has been tried with some success as part of the management of obesity (p.2149). Fluoxetine's mechanism of action in obesity is unknown. Serotonin is believed to be involved in the regulation of satiety[1] but fluoxetine has also been shown to increase resting energy expenditure and raise basal body temperature.[2] A common dose for fluoxetine in the management of obesity has been 60 mg daily; it appears that fluoxetine has a dose-related effect on weight loss.[3] Reviews[1,4,5] agree that fluoxetine can aid weight reduction in the short term but after 16 to 20 weeks some patients have started to regain weight and its long-term efficacy remains to be established. Troublesome adverse effects can occur.[1] Some patients treated with fluoxetine for depression have experienced an increase of appetite and some have gained weight. There has been a report[6] of a patient who lost weight during treatment with fluoxetine for depression despite an increased appetite and food intake.

6. Fichtner CG, Braun BG. Hyperphagia and weight loss during fluoxetine treatment. *Ann Pharmacother* 1994; **28:** 1350–2.

Orthostatic hypotension. Although orthostatic hypotension has been reported in some patients taking SSRIs, there has been a report[1] that fluoxetine 20 mg daily for 6 to 8 weeks produced beneficial effects in 4 of 5 patients with chronic symptomatic orthostatic hypotension (p.1530) refractory to other treatment. Modest benefits have also been seen in patients with orthostatic hypotension associated with parkinsonism.[2]

Parkinsonism. It has been suggested that fluoxetine might be of use in the management of selected patients with Parkinson's disease (p.791) who have levodopa-induced dyskinesias unresponsive to other measures.[1] However, although fluoxetine has been reported to have produced beneficial results in such patients[2] there has also been a report of increased disability in patients with Parkinson's disease given fluoxetine.[3] Extrapyramidal effects have also been reported in other patients taking fluoxetine (see under Adverse Effects, above). Fluoxetine has been tried in parkinsonism-related orthostatic hypotension (above).

2. Durif F, *et al.* Levodopa-induced dyskinesias are improved by fluoxetine. *Neurology* 1995; **45:** 1855–8.
3. Steur ENHJ. Increase of Parkinson disability after fluoxetine medication. *Neurology* 1993; **43:** 211–3.

Pathological crying or laughing. Inappropriate or uncontrolled crying or laughing can occur in patients with lesions in certain areas of the brain. Attempts at treatment have mostly been with antidepressant drugs, including SSRIs. Beneficial effects have been claimed for fluoxetine in a number of uncontrolled studies and reports.[1-4]

Peripheral vascular disease. Anecdotal reports[1,2] and a small pilot study[3] of fluoxetine (in a daily dose of 20 to 60 mg) suggest it may produce favourable therapeutic responses in patients with Raynaud's syndrome (see Vasospastic Arterial Disorders, p.1188).

3. Coleiro B, *et al.* Treatment of Raynaud's phenomenon with the selective serotonin reuptake inhibitor fluoxetine. *Rheumatology (Oxford)* 2001; **40:** 1038–43.

Premenstrual syndrome. Fluoxetine is used to control both the psychological and somatic symptoms of women with premenstrual dysphoric syndrome, a severe form of premenstrual syndrome (p.2099). Other SSRIs also appear to be useful, although evidence is so far more limited.

Sexual dysfunction. Impotence or ejaculatory problems have been reported as adverse effects of SSRIs (see Effects on Sexual Function in Adverse Effects, above). Such properties of the SSRIs have been studied as a potential form of treatment for men with premature ejaculation[1-3] (p.2181). The relative effects of the SSRIs on delaying ejaculation have also been studied.[4] Paroxetine was found to cause the strongest delay, followed by fluoxetine and then sertraline; fluvoxamine caused a slight delay although the effect was not significantly different from that seen with placebo. (Citalopram was unavailable at the time of the study; later studies of its effect have been conflicting[3].)

Fluvoxamine Maleate *(BANM, USAN, rINNM)*

DU-23000; Fluvoksamiinimaleaatti; Fluvoksamin Maleat; Fluvoxamine, maléate de; Fluvoxamini maleas; Fluvoxaminmaleat; Maleato de fluvoxamina. (*E*)-5-Methoxy-4′-trifluoromethylvalerophenone *O*-2-aminoethyloxime maleate.

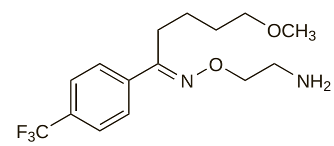
Флувоксамина Малеат

$C_{15}H_{21}F_3N_2O_2,C_4H_4O_4 = 434.4.$

CAS — 54739-18-3 (fluvoxamine); 61718-82-9 (fluvoxamine maleate).

ATC — N06AB08.

ATC Vet — QN06AB08.



(fluvoxamine)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Fluvoxamine Maleate). A white or almost white, crystalline powder. Sparingly soluble in water; freely soluble in alcohol and in methyl alcohol.

USP 31 (Fluvoxamine Maleate). A white to off-white, crystalline powder. Sparingly soluble in water; freely soluble in alcohol and in chloroform; practically insoluble in solvent ether. Protect from light.

Adverse Effects, Treatment, and Precautions

As for SSRIs in general (see Fluoxetine, p.391).

Bradycardia with ECG changes has been noted with fluvoxamine (but see also Effects on the Cardiovascular System in Adverse Effects of Fluoxetine, p.392).

It is recommended that fluvoxamine should be withdrawn in patients who have increased serum liver enzyme concentrations.

Fluvoxamine may need to be given with caution to patients with hepatic or renal impairment, and to the elderly (see under Uses and Administration, below).

Incidence of adverse effects. The UK CSM has reported[1] that between 25 September 1986 and 23 March 1988 it had received 961 reports of adverse reactions, including 5 deaths, associated with the use of fluvoxamine. The most frequently reported reactions were nausea (183) and vomiting (101). Other reactions included dizziness, somnolence, agitation, headache, tremor, and, during the first few days, worsening of anxiety. There were 13 reports of convulsions. Reports of appetite stimulation and antimuscarinic reactions were unusual. The effects sometimes resolved with time or dose reduction.

The safety profile of fluvoxamine has been reviewed.[2] For a comparison of the adverse reaction profiles of other SSRIs including fluoxetine with that of fluvoxamine, see Incidence of Adverse Effects, under Adverse Effects of Fluoxetine, p.391.

1. CSM. Fluvoxamine (Faverin): adverse reaction profile. *Current Problems 22* 1988. Also available at: http:// www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2024429&RevisionSelectionMethod=LatestReleased (accessed 04/08/08)
2. Wagner W, *et al.* Fluvoxamine: a review of its safety profile in world-wide studies. *Int Clin Psychopharmacol* 1994; **9:** 223–7.

Breast feeding. For comments on the use of SSRIs in breast feeding patients, see under Precautions for Fluoxetine, p.394.

Children. SSRIs are associated with an increased risk of potentially suicidal behaviour when used for the treatment of depression in children and adolescents under 18 years old; for further details, see under Effects on Mental State in Fluoxetine, p.392.

Interactions

For interactions associated with SSRIs, see Fluoxetine, p.396.

Fluvoxamine can greatly increase plasma concentrations of theophylline (see p.1143), and they should not be given together, or, if this is unavoidable, the dose of theophylline should be halved and plasma-theophylline concentrations monitored more closely.

◊ References.

1. Wagner W, Vause EW. Fluvoxamine: a review of global drug-drug interaction data. *Clin Pharmacokinet* 1995; **29** (suppl 1): 26–32.

Pharmacokinetics

Fluvoxamine is readily absorbed from the gastrointestinal tract with peak plasma concentrations occurring 3 to 8 hours after a dose. Systemic bioavailability does not appear to be affected by food. It is extensively metabolised in the liver by oxidative demethylation and deamination, to inactive metabolites. Excretion is mainly in the urine; about 2% of a dose is excreted as unchanged drug. Fluvoxamine is widely distributed throughout the body and protein binding is reported to be about 80%; it has a plasma-elimination half-life of about 15 hours. Fluvoxamine is distributed into breast milk (see Breast Feeding under Precautions in Fluoxetine, p.394).

Uses and Administration

Fluvoxamine, an aralkylketone derivative, is an SSRI with actions and uses similar to those of fluoxetine (p.397). It is used as the maleate and doses are expressed in terms of this salt.

In the treatment of **depression** fluvoxamine maleate is given in an initial oral dose of 50 or 100 mg once daily, preferably in the evening; in some patients the dose may need to be gradually increased to a maximum of 300 mg daily. It is recommended that daily dosages exceeding 150 mg should be given in 2 or 3 divided doses.

Fluvoxamine maleate is also used in the management of **obsessive-compulsive disorder**. In the UK, doses are similar to those used in the treatment of depression. The recommended starting dose in the USA is 50 mg once daily; this dose may be increased by increments of 50 mg every 4 to 7 days to a maximum of 300 mg daily. Doses above 100 mg daily should be given in 2 divided doses. In both countries the drug may also be used in children aged 8 years and over with obsessive-compulsive disorder. The recommended starting dose is 25 mg once daily, which may be increased in increments of 25 mg every 4 to 7 days to a maximum daily dose of 200 mg (in the USA adolescents over 11 years may be given a maximum dose of 300 mg daily). Daily doses of more than 50 mg should be given as 2 divided doses. It is recommended that if no improvement occurs within 10 weeks, treatment with fluvoxamine should be re-assessed.

In the USA, a modified-release preparation of fluvoxamine maleate is available for the treatment of obsessive-compulsive disorder and **social anxiety disorder** in adults; the initial dose is 100 mg once daily increased, as necessary, to a maximum of 300 mg once daily.

US licensed product information recommends that dosage modification be considered in elderly patients, in whom clearance may be decreased. For dosage in renal and hepatic impairment, see below.

Fluvoxamine should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Administration in hepatic or renal impairment. UK licensed drug information recommends that patients with hepatic or renal impairment should begin therapy with a low dose of fluvoxamine maleate and be carefully monitored; US product information only recommends that dosage modification be considered in hepatic impairment, since it considers evidence of accumulation in renal impairment to be lacking.

Anxiety disorders. Fluvoxamine has been given in a variety of anxiety disorders including obsessive-compulsive disorder (p.952), panic disorder (p.952), and social anxiety disorder (see under Phobic Disorders, p.953).

Имипрамина Гидрохлорид

$C_{19}H_{24}N_2,HCl$ = 316.9.

CAS — 113-52-0.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn*, and *US.*

Ph. Eur. 6.2 (Imipramine Hydrochloride). A white or slightly yellow crystalline powder. Freely soluble in water and in alcohol. A 10% solution in water has a pH of 3.6 to 5.0. Protect from light.

USP 31 (Imipramine Hydrochloride). A white to off-white, odourless or practically odourless, crystalline powder. Freely soluble in water and in alcohol; soluble in acetone; insoluble in ether and in benzene. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for tricyclic antidepressants in general (see Amitriptyline, p.376).

Breast feeding. For comments on the use of tricyclic antidepressants in breast feeding patients, see under Precautions for Amitriptyline, p.378.

Porphyria. Imipramine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

For interactions associated with tricyclic antidepressants, see Amitriptyline, p.379.

Pharmacokinetics

Imipramine is readily absorbed from the gastrointestinal tract, and extensively demethylated by first-pass metabolism in the liver, to its primary active metabolite, desipramine.

Paths of metabolism of both imipramine and desipramine include hydroxylation and *N*-oxidation. Imipramine is excreted in the urine, mainly in the form of its metabolites, either free or in conjugated form; small amounts are excreted in the faeces via the bile.

Imipramine and desipramine are widely distributed throughout the body and are extensively bound to plasma and tissue protein. Imipramine has been estimated to have an elimination half-life ranging from 9 to 28 hours, which may be considerably extended in overdosage. Plasma concentrations of imipramine and desipramine vary very widely between individuals but some correlation with therapeutic response has been established.

Imipramine and desipramine cross the blood-brain barrier and placenta and are distributed into breast milk (see Breast Feeding under Precautions in Amitriptyline, p.378).

◊ References.

1. Sallee FR, Pollock BG. Clinical pharmacokinetics of imipramine and desipramine. *Clin Pharmacokinet* 1990; **18:** 346–64.

Uses and Administration

Imipramine is a dibenzazepine tricyclic antidepressant with actions and uses similar to those of amitriptyline (p.381). Imipramine is one of the less sedating tricyclics and has moderate antimuscarinic activity. Imipramine is usually given orally as the hydrochloride or embonate, with doses expressed in terms of the hydrochloride. Imipramine embonate 149.8 mg and imipramine base 88.5 mg are both equivalent to about 100 mg of imipramine hydrochloride.

In the treatment of **depression**, the usual daily dose of imipramine hydrochloride is up to 75 mg in divided doses initially, gradually increased to 150 to 200 mg daily as necessary; higher doses of up to 300 mg daily may be required in severely depressed patients in hospital. A suggested initial dose for the elderly in the UK is 10 mg daily, gradually increasing to 30 to 50 mg daily. In the USA, daily doses of 25 to 50 mg are recommended for initial therapy in the elderly and adolescents, increasing to a maximum of 100 mg daily as required. Since imipramine has a prolonged half-life, once-daily dosage regimens may also be suitable, usually given at night.

Imipramine, as the hydrochloride, has also been given by intramuscular injection in the treatment of depression.

Imipramine is also used for the treatment of **nocturnal enuresis** in children in whom organic pathology has been excluded. However, drug therapy for nocturnal enuresis should be reserved for those in whom other methods have failed and should preferably only be given to cover periods away from home; tricyclic antidepressants are not recommended in children under 6 years of age (the *BNF* recommends that they should not be given until 7 years of age). Suggested doses of imipramine hydrochloride are:

- 25 mg for children aged 6 to 7 years (20 to 25 kg)
- 25 to 50 mg for children aged 8 to 11 years (25 to 35 kg)
- 50 to 75 mg for children over 11 years (35 to 54 kg)

The dose should be taken just before bedtime and treatment, including a period of gradual withdrawal, should not continue for longer than 3 months. A full physical examination is recommended before a further course.

Imipramine oxide hydrochloride (imipraminoxide hydrochloride) has also been used as an antidepressant and for nocturnal enuresis.

Imipramine should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Anxiety disorders. See under Clomipramine, p.387. In some countries, imipramine hydrochloride is licensed for the treatment of panic disorder in an initial oral dose of 10 mg daily; this dose may be increased as necessary to between 75 to 150 mg daily although doses of 200 mg daily may be needed in some patients.

Some references to the use of imipramine in anxiety disorders are given below.

Hyperactivity. Although not licensed in the UK for use in children with attention deficit hyperactivity disorder, the *BNFC* has suggested that imipramine hydrochloride may be given to those aged 6 years and over in an oral dose of 10 to 30 mg twice daily.

See also under Desipramine, p.388.

Pain. Antidepressants, usually amitriptyline or another tricyclic, are useful in alleviating some types of pain (see Choice of Analgesic, p.2). In some countries, imipramine hydrochloride is also available for the treatment of chronic pain; the usual recommended oral dose is 25 to 75 mg daily, although doses of up to 300 mg daily may be necessary.

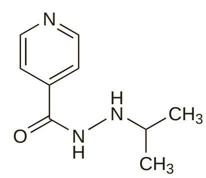
Iproniazid Phosphate *(BANM, rINNM)*

Fosfato de iproniazida; Iproniazide, Phosphate d'; Iproniazidi Phosphas. 2′-Isopropylisonicotinohydrazide phosphate.

Ипрониазида Фосфат

$C_9H_{13}N_3O,H_3PO_4$ = 277.2.
CAS — 54-92-2 (iproniazid); 305-33-9 (iproniazid phosphate).
ATC — N06AF05.
ATC Vet — QN06AF05.



(iproniazid)

Profile

Iproniazid, a hydrazine derivative, is an irreversible inhibitor of both monoamine oxidase types A and B with actions and uses similar to those of phenelzine (p.419). It has been given orally in the treatment of depression.

Iproniazid is the isopropyl derivative of isoniazid (see p.288) and was developed for use in tuberculosis, but owing to its toxicity is no longer used for this purpose.

Effects on the liver. Of 91 cases of hepatitis due to antidepressant therapy, cytolytic reactions occurred in 11 treated with iproniazid.[1] Five patients died, 3 of them after involuntary rechallenge. High levels of antimitochondrial antibody were found in 5 patients.

1. Lefebure B, *et al.* Hépatites aux antidépresseurs. *Therapie* 1984; **39:** 509–16.

Porphyria. Iproniazid has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Preparations

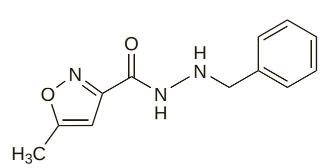
Proprietary Preparations (details are given in Part 3)
Fr.: Marsilid†.

Isocarboxazid *(BAN, rINN)*

Isocarboxazida; Isocarboxazide; Isocarboxazidum; Isokarboksatsidi; Isokarboxazid; Ro-50831. 2′-Benzyl-5-methylisoxazole-3-carbohydrazide.

Изокарбоксазид

$C_{12}H_{13}N_3O_2$ = 231.3.
CAS — 59-63-2.
ATC — N06AF01.
ATC Vet — QN06AF01.



Pharmacopoeias. In *Chin.*

Adverse Effects, Treatment, and Precautions

As for MAOIs in general (see Phenelzine, p.415).

Interactions

For interactions associated with MAOIs, see Phenelzine, p.417.

Pharmacokinetics

Isocarboxazid is readily absorbed from the gastrointestinal tract reaching peak plasma concentrations 3 to 5 hours after ingestion. It is metabolised by the liver, and is excreted in the urine mainly in the form of metabolites.

Uses and Administration

Isocarboxazid, a hydrazine derivative, is an irreversible inhibitor of both monoamine oxidase types A and B with actions and uses similar to those of phenelzine (p.419).

Isocarboxazid is used in the treatment of depression but because of the risks associated with irreversible non-selective MAOIs (see p.373) usually other antidepressants are preferred. It is given in an initial oral dose of 30 mg daily in single or divided doses. If no improvement occurs after 4 weeks, doses of up to 60 mg daily can be tried for up to 4 to 6 weeks. Once a response has been obtained the dosage may be gradually reduced to a maintenance dose of 10 to 20 mg daily, although doses of up to 40 mg daily may be needed in some patients. Half the normal maintenance dose may be adequate in the elderly.

Isocarboxazid should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Preparations

Proprietary Preparations (details are given in Part 3)
Chile: Marplan†; ***Denm.:*** Marplan; ***USA:*** Marplan.

Lithium Carbonate *(USAN)*

CP-15467-61; Dilithium Carbonate; Ličio karbonatas; Lithii carbonas; Lithium Carb.; Lithium, carbonate de; Litio, carbonato de; Litiumkarbonaatti; Litiumkarbonat; Lítium-karbonát; Litu węglan; Litu weglan; Lityum Karbonat; NSC-16895; Uhličitan lithný. Carbonic acid, dilithium salt.

Li_2CO_3 = 73.89.
CAS — 554-13-2.
ATC — N05AN01.
ATC Vet — QN05AN01.

NOTE. Commercially available lithium materials have atomic weights ranging from 6.939 to 6.996. The molecular weight of lithium carbonate of 73.89 given above has been calculated using the lowest atomic weight; using the highest figure would give a molecular weight of 74.00. This difference does not affect the figure of 27 mmol of lithium being provided by 1 g of lithium carbonate and is unlikely to contribute noticeably to any variations in serum concentration. Nor should it affect the outcome of assays of serum-lithium concentrations given the limits of error of the assay methods.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Lithium Carbonate). A white or almost white powder. Slightly soluble in water; practically insoluble in alcohol.

USP 31 (Lithium Carbonate). A white odourless granular powder. Sparingly soluble in water, very slightly soluble in alcohol; dissolves, with effervescence, in dilute mineral acids.

Lithium Citrate

Citronan lithný tetrahydrát; Ličio citratas; Lithii citras; Lithii Citras Tetrahydricus; Lithium, citrate de; Litio, citrato de; Litiumcitrat; Lítium-citrát; Litiumsitraatti; Lityum Sitrat.

$C_6H_5Li_3O_7,4H_2O$ = 282.0.
CAS — 919-16-4 (anhydrous lithium citrate); 6080-58-6 (lithium citrate tetrahydrate).

NOTE. Commercially available lithium materials have atomic weights ranging from 6.939 to 6.996. The molecular weight of lithium citrate of 282.0 given above has been calculated using the lowest atomic weight; using the highest figure would give a molecular weight of 282.1. This difference does not affect the figure of 10.6 mmol of lithium being provided by 1 g of lithium citrate and is unlikely to contribute noticeably to any variations in serum concentration. Nor should it affect the outcome of assays of serum-lithium concentrations given the limits of error of the assay methods.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*
US also includes lithium hydroxide.

Ph. Eur. 6.2 (Lithium Citrate). A white or almost white fine crystalline powder. Freely soluble in water; slightly soluble in alcohol.

USP 31 (Lithium Citrate). A white odourless deliquescent powder or granules. Freely soluble in water; slightly soluble in alcohol. pH of a 5% solution in water is between 7.0 and 10.0. Store in airtight containers.

Adverse Effects

Many of the adverse effects of lithium are dose-related and the margin between the therapeutic and toxic dose is narrow.

Initial adverse effects of lithium therapy include nausea, diarrhoea, vertigo, muscle weakness, and a dazed feeling; these effects often abate with continued therapy. Fine hand tremors, polyuria, and polydipsia may, however, persist. Other adverse effects that may occur at therapeutic serum-lithium concentrations include weight gain and oedema (which should not be treated with diuretics). Hypercalcaemia, hypermagnesaemia, and hyperparathyroidism have been reported. Skin disorders such as acne, psoriasis, and rashes may be exacerbated by lithium therapy. Leucocytosis is a relatively common adverse effect. Long-term adverse effects include hypothyroidism and/or goitre, rarely hyperthyroidism, and mild cognitive and memory impairment. Histological and functional changes in the kidney have been noted after long-term use of therapeutic concentrations of lithium (but see under Effects on the Kidneys, below).

Toxic effects may be expected at serum-lithium concentrations of about 1.5 mmol/litre, although they can appear at lower concentrations. They call for immediate withdrawal of treatment and should always be considered very seriously.

Signs of lithium toxicity include increasing diarrhoea, vomiting, anorexia, muscle weakness, lethargy, giddiness with ataxia, lack of coordination, tinnitus, blurred vision, coarse tremor of the extremities and lower jaw, muscle hyperirritability, choreoathetoid movements, dysarthria, and drowsiness. Symptoms of severe overdosage at serum-lithium concentrations above 2 mmol/litre include hyperreflexia and hyperextension of limbs, syncope, toxic psychosis, seizures, polyuria, renal failure, electrolyte imbalance, dehydration, circulatory failure, coma, and occasionally death.

The hazards of lithium in pregnant patients are discussed under Pregnancy in Precautions, below.

Effects on the blood. A patient developed thrombocytopenia after restarting lithium therapy after a gap of some weeks.[1] Stopping lithium led to an improvement in platelet count, but the count fell when lithium therapy was tried again. Leucocytosis is a recognised effect of lithium which this patient also experienced. Although concerns about leukaemia induction have not been verified, the author noted earlier reports of aplastic and megaloblastic anaemia and a case of fatal haemolytic anaemia reported to the UK CSM.

1. Collings S. Thrombocytopenia associated with lithium carbonate. *BMJ* 1992; **305:** 159.

Effects on the cardiovascular system. Reports of adverse effects on the heart associated with lithium have included bradycardia due to sinus node dysfunction,[1] which has persisted after stopping lithium,[2] premature ventricular contractions,[3] atrioventricular block,[4] and T-wave depression.[5] For the adverse cardiac effects associated with lithium intoxication, see under Overdosage, below.

Effects on the endocrine system. There is a small, but definite, risk that patients taking lithium in therapeutic doses will develop *goitre*, clinical or subclinical *hypothyroidism*, or, rarely, both.[1-3] Published prevalence figures have varied widely although most studies have found an increased risk of hypothyroidism in patients treated with lithium when compared to the general population.[2] Prevalence also appears to be higher in women taking lithium than in men;[2] in addition, the increased risk in women may be greatest during the first 2 years of lithium therapy. Other risk factors identified include a family history of thyroid disorders.[3] However, a long-term, follow-up study[4,5] suggested that the incidence of thyroid abnormalities was no greater in lithium-treated patients than in the general population.

Early goitre and lithium-induced hypothyroidism are both reversible if lithium is withdrawn; if continued treatment with lithium is desirable the patient should be treated with levothyroxine.

There have been rare reports of *hyperthyroidism* in lithium-treated patients[6] and the association may only be one of coincidence, although it is important to realise that hyperthyroidism can precipitate mania and can also be mistaken for an attack of mania.

Increases in serum concentrations of calcium and parathyroid hormone have been described in patients receiving lithium therapy. Although generally considered to be slight, some patients have experienced *parathyroid hyperplasia*.[7,8]

Cases of *diabetes mellitus* developing in patients treated with lithium have been reported but may not be attributable to lithium.[9]

Effects on the eyes. Decrease in accommodation has been reported in up to 10% of patients taking lithium; younger patients are most affected.[1] Blurred vision can also occur, most commonly early in therapy, but this may improve with time. Lithium can affect extra-ocular muscles and produce diplopia. A reduction in dosage or withdrawal of therapy may be required. It reduces lachrymal secretions and is excreted in tears in increased concentrations. In rare cases this may result in ocular irritation but this usually causes few problems when artificial tears are used. Photophobia, which occurs rarely with lithium therapy, may also be associated with the excretion of lithium in tears. Lithium can reduce dark adaptation due to a direct neural effect but whether this can progress further to cause irreversible macular or retinal degeneration is not proven. There are some rare but poorly documented reports of deposits in the cornea or conjunctiva. It was considered unlikely that lithium increased the risk of developing senile cataracts.

Lithium can cause nystagmus, many forms of which are reversible on reducing the dose or withdrawal of the drug. However, downbeat nystagmus is a serious adverse effect and is often irreversible. Irreversible oscillopsia can occur rarely secondary to nystagmus. Oculogyric crisis has been associated with lithium therapy and may be exacerbated by haloperidol.

Some ocular effects may be secondary to the effects of lithium on other systems. Exophthalmos and other thyroid-related eye disorders may occur rarely as a secondary effect of lithium on the thyroid. Lithium can also cause pseudotumor cerebri with papilloedema (benign intracranial hypertension). Most cases have occurred a few years after starting therapy but there has been a report of this condition after only 7 months of treatment. Ptosis has been reported, mainly associated with unmasking of myasthenia gravis.

1. Fraunfelder FT, *et al.* The effects of lithium on the human visual system. *J Toxicol Cutan Ocul Toxicol* 1992; **11:** 97–169.

Effects on the kidneys. Polyuria with associated polydipsia, due to drug-induced nephrogenic diabetes insipidus, is the most common result of the effects of lithium on the kidney; an early review[1] stated that the incidence ranged from 4 to 50%. In some patients, irreversible kidney damage, associated with renal histological changes that included tubular atrophy, focal interstitial nephropathy and focal fibrosis, and impairment of glomerular filtration rate, was reported. However, although patients on long-term maintenance lithium therapy did appear to be susceptible to the development of progressive impairment of urinary concentrating ability it was most noticeable in patients with a history of acute lithium toxicity. The risk of renal damage and impaired glomerular filtration rate was thought to be extremely small in patients on stable maintenance lithium therapy with no history of acute lithium intoxication.[1]

A similar review considered that, although it was necessarily an oversimplified view, many, and perhaps all, of the renal adverse effects of lithium were induced by excessive dosage.[2] Others have also defended lithium with respect to its renal toxicity and stated that long-term therapy, if properly controlled, does not necessarily lead to chronic or irreversible renal damage.[3-5]

Effects on the musculoskeletal system. The effects of lithium on skeletal muscle are represented mainly by varying degrees of weakness and tremor (for further details see under Effects on the Nervous and Neuromuscular Systems, below). Aggravation of myasthenia gravis has been reported. Acute or subacute painful proximal myopathy causing myalgia, cramps, myokymia, or weakness has also been described. An association with myocarditis has been proposed[1] but it is unclear whether this is causal.

1. Coulter DM, *et al.* Antipsychotic drugs and heart muscle disorder in international pharmacovigilance: data mining study. *BMJ* 2001; **322:** 1207–9.

Effects on the nervous and neuromuscular systems. Neurotoxicity has long been recognised as a potential adverse effect of lithium. Minor effects of lithium on the nervous system can be minimised by reduction of lithium dose during maintenance therapy but severe effects warrant immediate and complete withdrawal of the drug.[1] Minor effects have been considered to include impaired concentration, comprehension, and short-term memory, restlessness and anxiety, depression, fine rapid tremors, and easy fatigue. Serious or severe effects might include declining cognition and mental status, gait disturbances, movement disorders such as choreoathetosis, myoclonus, and parkinsonism, seizures, cerebellar signs, pseudotumor cerebri (although this was rare), neuroleptic malignant syndrome, myopathy, axonal neuropathy, a myasthenic syndrome, and exacerbation of underlying neuromuscular disease. The cognitive effects of lithium such as mental slowing may be subtle.[2]

There are 2 types of lithium-induced tremor.[3] The first is a coarse tremor occurring with impending and actual lithium toxicity and appears to have both cerebellar and parkinsonian components. It is often associated with incoordination, facial spasms, twitching of muscles and limbs, hyperactive reflexes, and more general systemic signs of toxicity. With this type of tremor it was mandatory to stop or decrease the dose of lithium. The second type, which is more common, is a fine tremor, usually occurring within normal therapeutic concentrations, either transiently within a few days of starting treatment or later as a long-standing adverse effect. With this type of fine tremor there was evidence to show that a slight decrease in dose may be beneficial.

In addition to the effects mentioned above, impairment of taste perception (mainly involving butter and celery)[4] and speech disturbances with few other signs of toxicity[5-8] have been reported.

Neurotoxicity persisting for at least 2 months after stopping lithium therapy (SILENT; syndrome of irreversible lithium-effectuated neurotoxicity) has been described.[9] Common presentations included cerebellar dysfunction, extrapyramidal symptoms, brainstem dysfunction, and dementia with varying degrees of organic mental syndromes.

For further details of the effects of lithium on the nervous system, see under Effects on the Eyes above, Effects on the Musculoskeletal System, above, and under Epileptogenic Effect, below.

Effects on respiration. Lithium is not generally recognised as a respiratory depressant but an episode of reversible respiratory failure about 3 weeks after the start of lithium therapy has been described in a patient with stable chronic airways obstruction.[1] Recovery of consciousness and resolution of hypercapnia occurred within 24 to 36 hours of stopping lithium.

1. Weiner M, *et al.* Effect of lithium on the responses to added respiratory resistances. *N Engl J Med* 1983; **308:** 319–22.

Effects on sexual function and fertility. Lithium does not seem to interfere with sexual function in most patients, but there have been isolated reports of impotence and loss of libido attributed to lithium therapy.[1]

Studies *in vitro* have demonstrated that lithium can inhibit sperm motility in concentrations comparable with those reported to be achieved in semen,[2] but concentrations found in cervico-vaginal mucus were considered unlikely to affect motility.[3]

1. Beeley L. Drug-induced sexual dysfunction and infertility. *Adverse Drug React Acute Poisoning Rev* 1984; **3:** 23–42.

3. Salas IG, *et al.* Lithium carbonate concentration in cervico-vaginal mucus and serum after repeated oral dose administration. *Br J Clin Pharmacol* 1989; **28:** 751P.

Effects on the skin and hair. Patients taking lithium may develop skin disorders, though these are not necessarily serious or severe.[1-3] Male patients may be more susceptible to such effects than female, although early results suggested the reverse.[3] Onset can vary from 2 or 3 weeks to 7 or more years, but many reactions start to appear once optimal serum-lithium concentrations have been attained. Effects reported include psoriasis which may be severe and require lithium withdrawal. Seborrhoeic dermatitis and follicular keratosis also occur and can improve spontaneously or after stopping lithium. Acneform eruptions are found in areas not usually affected by acne vulgaris; in general the face is less affected or not affected at all.

Hair loss, not always severe, is more frequent than cutaneous effects. About 6% of patients may be affected and all forms of alopecias have been found. The onset occurs several weeks or months after the start of lithium therapy. The hair usually regrows despite continuing therapy but in some cases regrowth only occurs after withdrawal of lithium. In a review[4] of the effects on the ocular system, loss of eyebrows and eyelashes was noted as a rare event. Hair loss due to lithium-induced hypothyroidism can be corrected by thyroid replacement therapy.

For references to the association of lithium with lupus, see under Lupus, below.

4. Fraunfelder FT, *et al.* The effects of lithium on the human visual system. *J Toxicol Cutan Ocul Toxicol* 1992; **11:** 97–169.

Epileptogenic effect. Seizures during lithium therapy usually indicate toxicity or impending toxicity. There have, however, been a few isolated reports describing seizures in patients with serum-lithium concentrations within the normally accepted therapeutic range.[1,2]

1. Demers R, *et al.* Convulsion during lithium therapy. *Lancet* 1970; **ii:** 315–16.
2. Massey EW, Folger WN. Seizures activated by therapeutic levels of lithium carbonate. *South Med J* 1984; **77:** 1173–5.

Lupus. Studies have found that antinuclear antibodies were more common in patients taking lithium carbonate than in controls.[1,2] The absence of anti-DNA antibodies indicated that they did not have true SLE but it was considered that patients ingesting lithium might be at risk. Dermatological manifestations of lupus with the presence of antinuclear antibodies have been reported in a patient taking lithium.[3]

1. Johnstone EC, Whaley K. Antinuclear antibodies in psychiatric illness: their relationship to diagnosis and drug treatment. *BMJ* 1975; **2:** 724–5.
2. Presley AP, *et al.* Antinuclear antibodies in patients on lithium carbonate. *BMJ* 1976; **2:** 280–1.
3. Shukla VR, Borison RL. Lithium and lupuslike syndrome. *JAMA* 1982; **248:** 921–2.

Overdosage. Nausea, vomiting, and diarrhoea are common early features of lithium toxicity, and are followed by coarse tremor, increased muscle tone, cogwheel rigidity, fasciculation, and myoclonus.[1] Coma and convulsions may occur in serious cases and cardiac effects (first-degree heart block and QRS and QT prolongation) have been described rarely. A patient may appear to be aware with open eyes but have an expressionless face and be unable to move or speak (coma vigil). Acute renal failure and nephrogenic diabetes insipidus may develop.

In **acute overdosage**[2] vomiting often occurs within an hour of ingestion due to the high concentration of lithium in the stomach, but significant amounts of lithium can still reach the systemic circulation. The typical clinical symptoms often appear after a latency period and gastrointestinal symptoms can re-appear at a later time. The symptoms of overdosage are reported to be mainly related to the gastrointestinal and nervous systems and include abdominal pain, anorexia, nausea, and vomiting, occasionally mild diarrhoea, giddiness, tremor, ataxia, slurring speech, myoclonus, twitching, asthenia, and depression; renal symptoms have also been noted by some investigators. Efficient detoxification procedures (see Treatment of Adverse Effects, below) should be instituted as rapidly as possible.

Symptoms associated with **chronic intoxication** can be more severe and neurotoxicity may be a particular feature.[3,4] One reviewer considered that the majority of lithium intoxications reported had occurred in patients with renal impairment or in patients who had been given too high a dose.[2] The patient usually experiences a prodromal period of days to a few weeks with minor 'nervous' symptoms which are signs of a manifest slight intoxication. At an unpredictable point renal function starts to deteriorate and within hours or at the most within a few days, the patient will become severely intoxicated. By this point lithium should have been stopped and efficient detoxification measures (see Treatment of Adverse Effects, below) begun if the patient is to make a complete recovery. Other risk factors[3-5] for developing chronic intoxication include use with certain medications (see Interactions, below), older age, and the presence of other conditions such as neurogenic diabetes insipidus and thyroid dysfunction (see also Precautions, below).

In a series of 28 patients with lithium self-poisoning or therapeutic intoxication many of the features and symptoms mentioned above were noted.[6] Other workers[7,8] have also reported cases which illustrate the differences between acute and chronic toxicity encountered clinically.

Serum concentrations of lithium should be measured routinely throughout treatment to ensure that values do not rise to levels associated with toxicity. However, some patients may have concentrations considered to be toxic without showing any symptoms and others may develop signs of toxicity at therapeutic serum concentrations.[9]

Other symptoms that have been noted in case reports of lithium intoxication in individual patients include photophobia,[10] acute polyarthritis involving several large joints,[11] severe hypertension,[12] deep venous thrombophlebitis,[13] reduction of central temperature,[14] and severe leucopenia.[15]

Treatment of Adverse Effects

In recent acute overdosage with lithium, consideration should be given to emptying the stomach if ingestion has occurred within 1 hour of presentation. However gastric lavage may be of limited value after overdosage with modified-release preparations, which do not disintegrate in the stomach and may be too large to pass through a lavage tube. Activated charcoal is of no value. Whole-bowel irrigation has been suggested although there do not appear to be clinical studies to confirm efficacy.

Further measures may involve procedures to enhance the renal clearance of lithium or its active removal. Adequate hydration should be ensured and any electrolyte imbalance corrected, but forced diuresis or diuretics are contra-indicated. Appropriate supportive care may include measures to control hypotension and convulsions. Maintenance of fluid and electrolyte balance is particularly important because of the risk of hypernatraemia. The ECG should be monitored in symptomatic patients.

In severe poisoning, haemodialysis is the treatment of choice (particularly if there is renal impairment). Although effective in reducing serum-lithium concentrations, substantial rebound increases can be expected when dialysis is stopped, and prolonged or repeated treatments may be required. Peritoneal dialysis is less effective and only appropriate if haemodialysis facilities are not available. Haemofiltration has been tried to good effect.

Serum lithium concentrations should be monitored regularly throughout treatment. Once the serum and dialysis fluid are free of lithium, it has been recommended that serum-lithium concentrations should be monitored for at least another week so that allowance can be made for delayed diffusion from body tissues.

As a result of the narrow margin between therapeutic and toxic serum concentrations, lithium poisoning may also develop during the course of therapy. In some instances temporary withdrawal of lithium therapy and giving generous amounts of sodium and fluid may be all that is required while adverse effects abate. In any serious or severe case of intoxication active measures such as dialysis and supportive measures outlined above may need to be instituted.

Precautions

The margin between the therapeutic and the toxic concentration of lithium is narrow so therapy usually requires specialist advice, and serum concentrations should be monitored regularly under controlled conditions. Patients receiving lithium therapy should be taught to recognise the symptoms of early toxicity (see Adverse Effects, above) and, should these occur, to stop therapy and request medical aid at once. They should be warned not to compensate for an omitted dose by subsequently taking a double dose. Additionally, patients should not be switched between different formulations or preparations of lithium without therapeutic monitoring, as bioavailability may be different.

Lithium should be avoided in patients with cardiac disease or renal impairment; cardiac and renal function should be monitored regularly during treatment. It should also be avoided in Addison's disease or other conditions with a sodium imbalance and in severely debilitated or dehydrated patients.

Patients receiving lithium should be examined periodically for abnormal thyroid function, since goitre and hypothyroidism may develop. Lithium should be avoided in untreated hypothyroidism. Lithium should be used with caution in patients with myasthenia gravis because exacerbation of this disorder has been reported (see Effects on the Musculoskeletal System in Adverse Effects, above).

Lithium should be used with special care in the elderly since this group may be particularly susceptible to toxicity owing to reduced renal function.

Impaired driving performance or machine operating skills may occur in patients receiving lithium (see Driving, below).

It may be necessary to temporarily reduce or stop lithium therapy in patients suffering from vomiting, diarrhoea, intercurrent infection, excessive sweating, or any other condition that causes excessive sodium loss and hence increased serum-lithium concentrations. Conversely, increased sodium levels are likely to reduce serum-lithium concentrations. Patients taking lithium should therefore maintain an adequate fluid intake and should avoid increasing or decreasing sodium intake through dietary changes or ingestion of sodium-containing medicaments. Significant changes in caffeine intake may affect serum-lithium concentrations (see Xanthines under Interactions, below).

Lithium therapy should, where possible, be withdrawn slowly over a period of weeks to allay any concerns about relapse (see Withdrawal, below).

The risks of using lithium in pregnant patients are described under Pregnancy, below. If lithium is used during pregnancy then dose adjustments will be required to compensate for the altered renal handling.

Lithium should be temporarily stopped 24 hours before major surgery to safeguard the patient from accumulation (see under Anaesthesia, below).

Anaesthesia. The *BNF* states that lithium should be stopped 24 hours before major surgery, but the normal dose can be continued for minor surgery if fluids and electrolytes are carefully monitored. Lithium may accumulate because of reduced renal clearance associated with anaesthesia;[1] treatment should be resumed as soon as possible after surgery, when kidney function and fluid-electrolyte balance have become normal. Patients are often not allowed fluids or foods by mouth the night before surgery but patients with lithium-induced polyuria should be given fluids parenterally during the night before the operation, if they vomit copiously, or if they are unconscious for several hours.

There is no clinical evidence of interaction between lithium and anaesthetics, although lithium may prolong the action of neuromuscular blockers.[1]

1. Schou M, Hippus H. Guidelines for patients receiving lithium treatment who require major surgery. *Br J Anaesth* 1987; **59:** 809–10.

Breast feeding. Lithium is distributed into breast milk. Early reports suggested that serum concentrations in breast-fed infants were about one-third to one-half of those measured in mothers.[1] However, advice regarding the decision to breast feed remains equivocal. The American Academy of Pediatrics[2] considers that lithium should be given with caution to breast-feeding women but does not contra-indicate such use, and this is supported by some authors.[3,4] Conversely, most manufacturers in the UK and other authors[5,6] suggest that mothers receiving lithium should bottle feed their infants. It has been recommended[5] that if a mother did want to breast feed this should be done at times to avoid peak blood concentrations of lithium and the infant carefully monitored. Medication should be withheld or breast feeding stopped if the infant developed an infection or dehydration as they would be more susceptible to the adverse effects of lithium.

Cystic fibrosis. Reduced renal excretion of lithium was demonstrated in 8 patients with cystic fibrosis compared with healthy subjects.[1] The authors recommended caution when prescribing standard doses of lithium to patients with cystic fibrosis until more definitive data were available.

1. Brager NPD, *et al.* Reduced renal fractional excretion of lithium in cystic fibrosis. *Br J Clin Pharmacol* 1996; **41:** 157–9.

Driving. In the UK, the Driver and Vehicle Licensing Authority considers that patients with severe depressive illnesses complicated by significant memory or concentration problems, agitation, behavioural disturbances, or suicidal thoughts should cease driving pending the outcome of medical enquiry.[1] Mania or hypomania is particularly dangerous and driving should cease during the acute illness. After an isolated episode, re-licensing can be reconsidered provided the patient has remained well and stable for at least 3 months, is compliant with treatment, and has regained insight; in addition, the patient should be free from any adverse effects of medication that would impair driving. If there have been 4 or more episodes of mood swing within the previous 12 months, at least 6 months of stability will be required before re-licensing can be considered.

Treatment with antidepressant drugs, including lithium, may also be hazardous,[2] although patients may be safer drivers with medication than without.[3] Lithium has been reported[2] to adversely affect the choice reaction time (a test to assess the time taken to respond correctly to some signals but not others) to a level considered dangerous for driving. Another study has found that elderly patients taking lithium may be at an increased risk of being involved in an injurious motor vehicle accident while driving when compared to a cohort of elderly, non-lithium users.[4]

Pregnancy. The decision whether to continue lithium treatment during pregnancy is difficult and should involve careful consideration of the risk-benefit ratio which in some cases may favour treatment. Early case reports of mothers taking lithium during pregnancy pointed to an increased risk of congenital abnormalities with the baby's heart being mainly affected.[1] Support for this increased risk also came from a study[2] of the records of 59 children born to women who had taken lithium during pregnancy. However, another study[3] which prospectively followed 138 pregnant women being treated with lithium did not identify any difference in pregnancy outcome between them and a control group. The authors considered that lithium was not a major teratogen and felt that women with major affective disorders could continue lithium treatment during pregnancy provided that adequate fetal screening tests were carried out. A subsequent review[4] considered that the teratogenic risk was lower than previously thought, but that it would still be wise for women who wished to become pregnant to stop lithium if at all possible, at least during the period of embryogenesis. If lithium is stopped, withdrawal should be slow to prevent a relapse (see below).

There is limited evidence that lithium treatment during pregnancy may increase the risk of fetal macrosomia, premature delivery, and perinatal mortality.[1,5] Polyhydramnios (an excess of amniotic fluid) in the last trimester of pregnancy has been reported and has been attributed to fetal lithium toxicity (polyuria and diabetes insipidus).[6,7]

Monitoring of serum-lithium concentrations is particularly important during pregnancy. The renal clearance of lithium by the mother is not constant during pregnancy; in the second half of the pregnancy clearance rises gradually by 30 to 50% but falls abruptly and significantly after delivery to pre-pregnancy values.[1,8] The increased doses of lithium that may be given during pregnancy to compensate for this increased clearance may result in lithium toxicity.[8] It is generally considered[1,9,10] advisable to stop lithium during the last few days of pregnancy to reduce the risk of maternal lithium toxicity due to accumulation of lithium but it should be started again a few days later after delivery at reduced dosage because of the increased postpartum risk of manic and depressive relapse.[1,10]

Reducing the dosage during the last few days of pregnancy also helps to reduce lithium concentrations in the neonate and avoid associated adverse effects.[1,9] Adverse effects that have been reported in neonates exposed *in utero* to lithium include cyanosis, lethargy, flaccidity, hypotonia, poor gag and sucking reflexes, feeding problems, bradycardia, tachycardia, goitre, hypothyroidism, nephrogenic diabetes, and jaundice;[9-12] withdrawal symptoms have also been observed.

Surgery. For comments regarding the precautions to be observed in patients undergoing surgery, see under Anaesthesia, above.

Withdrawal. Symptoms such as anxiety, tremor, fatigue, nausea, sweating, headache, sleep disturbances, diarrhoea, or blurred vision have developed within days of sudden cessation of treatment with lithium.[1] These symptoms may simply be a recurrence of the mood disorder. Uncontrolled studies of withdrawal symptoms have raised the possibility of a lithium-withdrawal state although controlled studies have been convincingly negative. It is, however, wise to reduce lithium dosage gradually rather than stop high-dosage treatment abruptly.

A frequent worry associated with stopping lithium therapy is that of relapse. Most evidence has supported the view that any relapses occurring in the first weeks after lithium withdrawal are simply part of a pattern of recurrence of bipolar disorder in general and are not indicative of a higher rate of recurrence. Some,[2] however, have found the proportion of patients relapsing on sudden withdrawal of lithium therapy to be 50%, a figure they consider to be too high to be accounted for by the natural history of the disease process. They and others[3] advise that this risk should be considered when prescribing lithium for bipolar disorder. In patients who previously had been stable on lithium for at least 18 months, the risk of early recurrence of bipolar disorder was higher when therapy was withdrawn rapidly in less than 2 weeks than when it was withdrawn gradually over 2 to 4 weeks.[4]

Interactions

Some diuretics may reduce lithium excretion and result in toxicity (see below for further details). Thiazide diuretics may also show a paradoxical antidiuretic effect. Consequently, diuretics should be avoided or used with caution in those receiving lithium; if used together, a reduction in the lithium dose may be appropriate. Other drugs affecting electrolyte balance may also alter lithium excretion and should be avoided if possible or used with care.

Further interactions reported with lithium are discussed below.

ACE inhibitors. Giving lithium with ACE inhibitors has been reported[1-5] to increase serum-lithium concentrations, resulting in some cases in lithium toxicity. ACE inhibitors such as *captopril*,[2] *enalapril*,[1,3,5] and *lisinopril*[4,5] have been implicated, although in a study[6] of enalapril and lithium in healthy subjects, the lithium levels remained unchanged. The mechanism is unclear but it has been suggested[7] that suppression of the renin-angiotensin-aldosterone system by ACE inhibitors may be responsible. Lithium excretion by the kidney is dependent on both glomerular filtration and sodium concentration in the proximal tubule, both of which are reduced by ACE inhibitors. It has also been suggested[5] that inhibition of angiotensin II production may lead to reduced fluid intake through lack of activation of the thirst stimulus and this would enhance the tendency to volume depletion caused by natriuresis. Patients considered[7] to be at risk from this reaction would include those whose renal function is largely dependent on the effect of angiotensin II, those with congestive heart failure, and those with volume depletion.

Analgesics. See NSAIDs and Opioid Analgesics, below.

Angiotensin II receptor antagonists. There have been case reports of lithium intoxication occurring in patients after the addition of *candesartan*,[1] *losartan*,[2] or *valsartan*[3] to their therapy. The mechanism may be similar to that for ACE inhibitors (above).

1. Zwanzger P, *et al.*. Lithium intoxication after administration of AT blockers. *J Clin Psychiatry* 2001; **62:** 208–9.

3. Leung M, Remick RA. Potential drug interaction between lithium and valsartan. *J Clin Psychopharmacol* 2000; **20:** 392–3.

Antidepressants. Lithium has been used to augment the effect of other antidepressants in refractory depression. However, there have been reports of adverse reactions with some of these combinations. For further details, see Antidepressants under Interactions of Phenelzine, p.418.

Antiepileptics. Severe CNS toxicity despite 'normal' serum-lithium concentrations has been described in a patient also taking *phenytoin* and *phenobarbital*.[1] Symptoms indicative of lithium toxicity have also been reported in a patient taking lithium with phenytoin alone;[2] again concentrations were not abnormal.

For reports of neurotoxicity in patients receiving *carbamazepine* and lithium, see p.474. Carbamazepine-induced renal failure has also resulted in toxic serum-lithium concentrations.[3]

2. MacCallum WAG. Interaction of lithium and phenytoin. *BMJ* 1980; **280:** 610–11.
3. Mayan H, *et al.* Lithium intoxication due to carbamazepine-induced renal failure. *Ann Pharmacother* 2001; **35:** 560–2.

Antimicrobials. Lithium toxicity has been reported on isolated occasions in patients receiving *doxycycline*,[1] *metronidazole*,[2] *spectinomycin*,[3] and *tetracycline*.[4]

However, it has been noted that lithium and tetracycline have been used together without serious problems in many patients and that additionally tetracycline has been used to treat the acneform skin eruptions induced by lithium.[5] It has also been found[5] that in healthy subjects lithium concentrations were decreased, rather than increased, after the addition of tetracycline but this was probably of no clinical significance.

5. Fankhauser MP, *et al.* Evaluation of lithium-tetracycline interaction. *Clin Pharm* 1988; **7:** 314–17.

Antimigraine drugs. For comment on the suggestion that there may be a risk of increased CNS toxicity when *sumatriptan* and lithium are given together, see p.626.

Antineoplastics. Transient decreases in serum-lithium concentration occurred in a patient given *cisplatin*.[1] The relative contributions of cisplatin itself, or the fluid loading procedure involving intravenous fluids and mannitol, or their combined effects were unclear. The interaction, however, had no apparent clinical significance in this patient although a risk of undertreatment with lithium may occur in other patients.

1. Pietruszka LJ, *et al.* Evaluation of cisplatin-lithium interaction. *Drug Intell Clin Pharm* 1985; **19:** 31–2.

Antipsychotics and anxiolytics. In the control of acute mania lithium is often too slow in onset to be used alone and therefore additional therapy with an antipsychotic may be necessary. It should be noted, however, that such combinations should be used with care as interactions and adverse reactions have occurred.

The renal excretion of lithium is increased by *chlorpromazine* treatment,[1] which means that subsequent withdrawal of chlorpromazine can result in an abrupt rise in serum-lithium concentrations.[2] The serum concentration of chlorpromazine can also be reduced by lithium,[3] and chlorpromazine toxicity may be precipitated by the abrupt withdrawal of lithium in patients previously stabilised on both drugs. Ventricular fibrillation has been described after withdrawal of lithium in a patient also taking chlorpromazine;[4] it was suggested that the chlorpromazine dose should be reduced if lithium is to be stopped.

There have been isolated reports of neurotoxicity or brain damage, characterised by delirium, seizures, encephalopathy, or an increased incidence of extrapyramidal symptoms in patients receiving lithium with *flupentixol decanoate*,[5] *fluphenazine decanoate*,[6] or high-dose *haloperidol*,[7-9] although two earlier retrospective studies of patients taking lithium with antipsychotics had failed to detect such adverse reactions.[10,11] Neurological reactions have also been reported in patients receiving lithium with *thioridazine*,[12,13] *sulpiride*,[14] *clozapine*,[15] and *risperidone*.[16] Although a causal relationship between these events and use of lithium with antipsychotics has not been fully established, patients should be monitored for signs of neurotoxicity if receiving such combinations.

A 1987 review considered that the neurotoxicity induced by lithium and antipsychotics was a rare entity.[17] Whether the combination produced any greater risk than either drug alone, and whether the neurotoxicity was a distinct diagnostic entity or simply represented atypical cases of lithium toxicity or the neuroleptic malignant syndrome, was debatable. The interaction between lithium and haloperidol might represent a form of neuroleptic malignant syndrome and that between lithium and the phenothiazines, especially thioridazine, a form of lithium toxicity. It was concluded that the risk from combination therapy was very small but that the clinician should, nevertheless, be aware of it.

Although lithium has been reported to interact with *diazepam* resulting in hypothermic episodes,[18] this may be an idiosyncratic response rather than a true drug interaction;[17] in general it was considered safe to use lithium with benzodiazepines.

Benzodiazepines. See Antipsychotics and Anxiolytics, above.

Calcium-channel blockers. Neurotoxicity has been reported in a patient receiving lithium after the addition of *verapamil*.[1] Serum-lithium concentrations were still inside the accepted therapeutic range and it was considered that the similar actions of lithium and verapamil on neurosecretory processes may have been responsible. Verapamil has also been reported to decrease serum-lithium concentrations.[2] Neurotoxicity has also been reported in a patient receiving lithium and *diltiazem*[3] as well as other drugs. Psychosis, possibly induced by the use of diltiazem and lithium together, has been reported in another patient.[4]

2. Weinrauch LA, *et al.* Decreased serum lithium during verapamil therapy. *Am Heart J* 1984; **108:** 1378–80.
3. Valdiserri EV. A possible interaction between lithium and diltiazem: case report. *J Clin Psychiatry* 1985; **46:** 540–1.
4. Binder EF, *et al.* Diltiazem-induced psychosis and a possible diltiazem-lithium interaction. *Arch Intern Med* 1991; **151:** 373–4.

Central stimulants. A woman who had been stabilised on lithium treatment for 15 months developed lithium toxicity within a few days of being given *mazindol*.[1]

There is a risk of CNS toxicity due to synergistic serotonergic actions when lithium is given with *sibutramine*.

1. Hendy MS, *et al.* Mazindol-induced lithium toxicity. *BMJ* 1980; **280:** 684–5.

Diuretics. *Thiazide diuretics* produce sodium depletion by inhibiting distal tubular sodium reabsorption. The consequent increase in proximal tubular reabsorption frequently results in an increase in serum-lithium concentrations.[1] Patients who are stabilised on lithium therapy and begin taking thiazide diuretics are at significant risk of developing lithium toxicity. Toxic lithium concentrations may be seen within 3 to 5 days of starting a diuretic. *Loop diuretics* (*furosemide*, *bumetanide*, and *etacrynic acid*) seem less likely to cause lithium retention, although caution is warranted, especially in patients whose dietary sodium is restricted.[1] *Amiloride*, and probably other potassium-sparing diuretics, have no effect on lithium excretion, but *acetazolamide* increases lithium excretion. However, the diuretic action of acetazolamide is short-lived and the interaction may therefore be transient.[1]

It has therefore been suggested that if diuretic therapy is necessary in patients stabilised on lithium, the lithium dose should be reduced by 25 to 50%,[1,2] lithium concentrations measured twice weekly until re-stabilisation occurs, and that perhaps loop diuretics such as bumetanide or furosemide would be preferable.

The topic of lithium-diuretic interaction and precautions to be observed has also been discussed.[3]

3. Grau E. Diuretics. In: Johnson FN, ed. *Depression & mania: modern lithium therapy.* Oxford: IRL Press, 1987: 180–3.

Gastrointestinal drugs. Giving *sodium bicarbonate* with lithium has led to reduced blood-lithium concentrations, attributed to increased renal excretion of the lithium cation in response to the extra load of bicarbonate anion to be excreted.[1] *Antacids* containing combinations of *aluminium and magnesium hydroxides* and *simeticone* had no effect on the dissolution and solubility of lithium carbonate *in vitro*[2] nor on its bioavailability *in vivo*.[3]

There has been a case report describing a possible interaction between lithium and *ispaghula* where low serum concentrations of lithium may have been due to ispaghula inhibiting intestinal absorption of lithium.[4]

There is an increased risk of extrapyramidal effects and the possibility of neurotoxicity when drugs such as *metoclopramide* are given to patients receiving lithium.

Use of *cisapride* with lithium may increase the risk of ventricular arrhythmias.

Ion-exchange resins. The cation-exchange resin *sodium polystyrene sulfonate* may decrease the absorption of lithium salts.

Methyldopa. Lithium toxicity induced by methyldopa has been described on a number of occasions.[1-3] Symptoms of toxicity may occur even though serum-lithium concentrations remain within the therapeutic range.

3. Osanloo E, Deglin JH. Interaction of lithium and methyldopa. *Ann Intern Med* 1980; **92:** 433–4.

Muscle relaxants. For reports of hypothermic episodes occurring with lithium and *diazepam*, see under Antipsychotics and Anxiolytics, above.

Severe aggravation of hyperkinetic symptoms occurred in 2 patients with Huntington's chorea when *baclofen* was added to their treatment with lithium and haloperidol.[1]

1. Andén N-E, *et al.* Baclofen and lithium in Huntington's chorea. *Lancet* 1973; **ii:** 93.

Neuromuscular blockers. For reports of prolongation of neuromuscular blockade by lithium see under Atracurium, p.1904. For further comments relating to surgery and anaesthesia, see under Anaesthesia in Precautions, above.

NSAIDs. Decreased clearance and increased serum concentrations of lithium, resulting in toxicity on some occasions, have been reported after use of lithium with *celecoxib*,[1] *diclofenac*,[2] *ibuprofen*,[3,4] *indometacin*,[5,6] *ketorolac*,[7,8] *mefenamic acid*,[9,10] *naproxen*,[11] *piroxicam*,[12,13] *rofecoxib*,[14-16] and *tiaprofenic acid*;[17] secondary sources have also implicated *azapropazone, ketoprofen*,[18] *parecoxib*, and *phenylbutazone*.[18] However, serum-lithium concentration is not increased by *sulindac*.[11,19,20] Although serum-lithium concentrations were increased in a patient receiving *aspirin*[21] this has not been substantiated in others and an interaction is considered unlikely;[6,22] it has also been pointed out that control of sodium balance is necessary in such studies[22] and in the report purporting to demonstrate an interaction the diet had not been controlled.

It has been stated that for mild occasional aches, pains, and fever paracetamol was the preferred analgesic in patients receiving lithium, although occasional doses of aspirin were acceptable.[18] Sulindac appeared to be the safest NSAID for long-term use. Diclofenac, ibuprofen, indometacin, ketoprofen, naproxen, phenylbutazone, and piroxicam should be avoided where possible but if it was necessary to use one of these drugs the maintenance dose of lithium should be reduced. It was also considered that perhaps other NSAIDs, for which no information was available at that time, should be regarded as having the potential to cause a rise in serum-lithium concentrations.

Opioid analgesics. There is a risk of CNS toxicity due to synergistic serotonergic actions when lithium is given with *tramadol*.

Parasympathomimetics. For the effect of lithium on parasympathomimetics, see Interactions of Neostigmine, p.632.

Xanthines. It has been reported[1] that *theophylline* enhances the renal clearance of lithium, thus tending to reduce serum-lithium concentrations. Lithium blood concentrations increased by 24% when *caffeine* was eliminated from the diet of 11 patients taking lithium.[2] No toxicity was observed but these patients had been maintained on low baseline lithium concentrations; toxicity might occur in patients maintained at higher concentrations.

2. Mester R, *et al.* Caffeine withdrawal increases lithium blood levels. *Biol Psychiatry* 1995; **37:** 348–50.

Pharmacokinetics

Lithium is readily and completely absorbed from the gastrointestinal tract when taken as one of its salts. Absorption can be affected by the formulation of the preparation taken. Peak serum concentrations are obtained between 0.5 and 3 hours after ingestion from conventional tablets, capsules, or liquids; with modified-release formulations peak concentrations are delayed and may occur between 2 and 12 hours after a dose. Lithium is distributed throughout the body and distribution is complete within about 6 to 10 hours; higher concentrations occur in the bones, the thyroid gland, and portions of the brain, than in the serum.

Lithium is excreted mainly in the urine; only a small amount can be detected in the faeces, saliva, and sweat. It is not bound to plasma proteins. It crosses the placenta and is distributed into breast milk. The elimination half-life in patients with normal renal function is about 12 to 24 hours, but increases with decreasing renal function; half-lives of up to 36 hours have been reported for elderly patients and 40 to 50 hours for patients with renal impairment. Steady-state concentrations may not, therefore, be attained until 4 to 7 days after starting treatment.

There is wide intersubject variation in the serum concentrations obtained after a given dose, and also in those required for therapeutic effect. Concentrations also vary considerably according to factors such as the dosage regimen (whether given in single or divided daily doses), renal function, the dietary regimen of the patient, the patient's state of health, the time at which the blood sample is taken, and other medication, such as sodium salts or diuretics, as well as by formulation and bioavailability. Moreover, there is only a narrow margin between the therapeutic and the toxic serum concentration of lithium. Therefore, not only is individual titration of lithium dosage essential to ensure constant appropriate concentrations for the patient, but the conditions under which the blood samples are taken for monitoring must be carefully controlled. In practice, a blood sample drawn 12 hours after the last dose of lithium following a consistent dosing schedule for 4 to 7 days is used for measurement of serum-lithium concentrations. Under these conditions the distribution of the last dose of lithium is complete, and steady-state concentrations will have been attained. The usual maintenance therapeutic serum concentrations of lithium are 0.4 to 1 mmol/litre; toxic effects may be expected at concentrations exceeding 1.5 mmol/litre. For further details regarding monitoring of serum concentrations of lithium, see under Uses and Administration, below. Estimation of lithium concentrations in other body fluids such as saliva has been investigated as a less invasive method of monitoring. However, results have been equivocal and these methods have not replaced serum monitoring in general practice.

Uses and Administration

Lithium, given as one of its salts, provides a source of lithium ions, which compete with sodium ions at various sites in the body. It thus has an action and adverse effects distinct and separate from those of other antidepressants. Its mode of action is not understood, but it is effective in the management of **mania**, **bipolar disorder**, and **recurrent unipolar depression**. Since the margin between therapeutic and toxic serum concentrations is narrow the decision to give lithium is usually based on specialist advice; lithium should not be prescribed unless facilities for monitoring serum concentrations are available.

Treatment with lithium needs to be monitored by measurement of serum concentrations, which must be adjusted for each patient to give a clinical response without evidence of toxicity. There is evidence that patients are most likely to respond to concentrations of 0.8 mmol/litre or above, but individual patients may respond to concentrations as low as 0.4 mmol/litre, and it is impossible to identify these patients beforehand. Because toxic effects are associated with concentrations above 1.5 mmol/litre, and may occur with concentrations as low as 1 mmol/litre in susceptible patients such as the elderly, it is therefore recommended that doses are adjusted to provide a serum-lithium concentration of 0.4 to 1 mmol/litre (at the lower end of this range for maintenance therapy and elderly patients). Patients must be taught to recognise the symptoms of early lithium intoxication (see Adverse Effects, above) in order to omit further doses of lithium and seek medical care should it be impending.

The dose of lithium given depends on the preparation chosen since different preparations of lithium salts vary widely in bioavailability. This can be illustrated by the recommended doses for some UK preparations:

- *Camcolit* tablets (*Norgine, UK*) containing lithium carbonate; for treatment, initially 1 to 1.5 g daily; for prophylaxis, initially 300 to 400 mg daily
- *Li-Liquid* syrup (*Rosemont, UK*) containing lithium citrate; for treatment and prophylaxis, initially 1.018 to 3.054 g daily in two divided doses (elderly or patients less than 50 kg, 509 mg twice daily)
- *Liskonum* tablets (*GlaxoSmithKline, UK*) containing lithium carbonate; for treatment, initially 450 to 675 mg twice daily (elderly, 225 mg twice daily); for prophylaxis, initially 450 mg twice daily (elderly, 225 mg twice daily)
- *Priadel* tablets (*Sanofi-Aventis, UK*) containing lithium carbonate; for treatment and prophylaxis, initially 400 mg to 1.2 g daily as a single dose or in two divided doses (elderly or patients less than 50 kg, 200 to 400 mg daily)
- *Priadel* syrup (*Sanofi-Aventis, UK*) containing lithium citrate; for treatment and prophylaxis, initially 1.04 to 3.12 g daily in two divided doses (elderly or patients less than 50 kg, 520 mg to 1.04 g daily)

Doses of lithium are initially divided throughout the day; however, when serum-lithium concentrations are stabilised once-daily dosage may be preferred.

The initial dose given is adjusted after 4 to 7 days according to the results of serum-lithium estimations obtained under controlled conditions (samples being taken 12 hours after the preceding dose). Serum-lithium concentrations are then checked once a week until the dosage has remained constant for 4 weeks. The frequency of estimations can then be reduced to about once every 3 months. Should the patient's circumstances change such that the lithium pharmacokinetics or requirements might be affected, close control of serum concentrations should be reinstated until the concentrations stabilise once more. Such circumstances could involve a change of lithium preparation, an intercurrent illness (including a urinary-tract infection), a manic or depressive phase, a change in dietary regimen or body temperature, pregnancy, or use of other drugs (in particular, sodium-containing preparations and diuretics). For further details see Precautions and Interactions, above. Long-term use of lithium has been associated with thyroid disorders and mild cognitive and memory impairment. Therefore, long-term treatment should only be undertaken if it is definitely indicated. Patients need to be regularly assessed and treatment should only continue after 3 to 5 years if the benefit persists.

Lithium is also used for the management of **aggressive or self-mutilating behaviour**. The doses are similar to those used in the prophylaxis of recurrent affective disorders described above.

Lithium is not licensed in the UK for use in children; however, the *BNFC* suggests that it may be considered, on the advice of a specialist, in the management of mania, bipolar disorder, recurrent depression, and aggressive or self-mutilating behaviour in those aged 12 years and over. Suggested doses are similar to those given above.

Lithium therapy should, where possible, be withdrawn slowly over a period of weeks to allay any concerns about relapse. For further details, see Withdrawal under Precautions, above.

Other lithium salts have been used in the treatment of psychiatric disorders and these include the acetate, gluconate, glutamate, and sulfate.

Homoeopathy. Lithium carbonate has been used in homoeopathic medicines under the following names: Lithium carbonicum; Lith. carb.

Lithium citrate has been used in homoeopathic medicines under the following names: Lithium citricum.

Anxiety disorders. Lithium has been tried as augmentation therapy in the treatment of obsessive-compulsive disorder (p.952).

Bipolar disorder. Lithium's main role in the management of bipolar disorder is for prophylaxis (see p.372). It is sometimes used in the control of the acute manic stage, but, because of its slow onset of action, usually with an antipsychotic.

Disturbed behaviour. For mention of lithium in the management of children with disturbed behaviour see p.954.

Headache. Lithium is one of a number of drugs tried in cluster headache (p.616) to prevent headache attacks during cluster periods when ergotamine is ineffective or has had to be withdrawn. In a double-blind study[1] lithium and verapamil were found to be of similar efficacy for cluster headache prophylaxis although verapamil appeared to produce fewer adverse effects. However, in a later placebo-controlled trial[2] lithium was found to be no more effective than the placebo and the trial was stopped early.

2. Steiner TJ, *et al.* Double-blind placebo-controlled trial of lithium in episodic cluster headache. *Cephalalgia* 1997; **17:** 673–5.

Hyperthyroidism. Lithium has been tried in hyperthyroidism (p.2165), though its practical value is a matter of debate and, rarely, it may even cause hyperthyroidism (see Effects on the Endocrine System in Adverse Effects, above). Pretreatment with lithium has also been reported to prolong the exposure of the thyroid to radioactive iodine in patients with Graves' thyrotoxicosis.[1]

1. Bogazzi F, *et al.* Treatment with lithium prevents serum thyroid hormone increase after thionamide withdrawal and radioiodine therapy in patients with Graves' disease. *J Clin Endocrinol Metab* 2002; **87:** 4490–5.

Schizophrenia. The addition of lithium to antipsychotic treatment has been tried in patients with schizophrenia (p.955) or schizoaffective disorders who fail to respond to an antipsychotic alone. The results of a meta-analysis have suggested that lithium augmentation is of some benefit, particularly in those with schizoaffective disorders, although the evidence is inconsistent.[1] However, significantly more patients with lithium augmentation left the studies early, suggesting adverse effects may be problematic and the danger of an interaction between the drugs should also be borne in mind (see under Interactions, above).

Lofepramine Hydrochloride *(BANM, USAN, rINNM)*

Hidrocloruro de lofepramina; Leo-640; Lofépramine, Chlorhydrate de; Lofepramini Hydrochloridum; Lopramine Hydrochloride; WHR-2908A. 5-{3-[*N*-(Chlorophenacyl)-*N*-methylamino]propyl}-10,11-5*H*-dihydrodibenz[*b,f*]azepine hydrochloride.

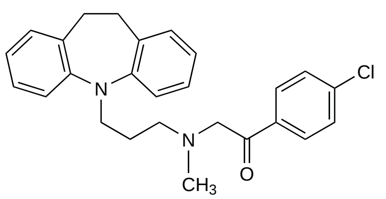
Лофепрамина Гидрохлорид

$C_{26}H_{27}ClN_2O,HCl = 455.4.$

CAS — 23047-25-8 (lofepramine); 26786-32-3 (lofepramine hydrochloride).

ATC — N06AA07.

ATC Vet — QN06AA07.



(lofepramine)

Pharmacopoeias. In *Br.*

BP 2008 (Lofepramine Hydrochloride). A fine, yellowish-white to green-yellow powder with a faint characteristic odour. It exhibits polymorphism. Very slightly soluble in alcohol and in methyl alcohol; slightly soluble in acetone. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for tricyclic antidepressants in general (see Amitriptyline, p.376) although it has a lower incidence of antimuscarinic adverse effects. Lofepramine should be avoided in patients with severe hepatic or severe renal impairment.

Effects on the liver. See under Amitriptyline, p.377.

Overdosage. Lofepramine may be less toxic in overdosage than earlier tricyclics.[1] An analysis of data from the Office of National Statistics in England and Wales has also shown that the risk of death after an overdose with lofepramine was not significantly different from that associated with the SSRIs which, as a group, are considered to be safer in overdose than the tricyclics.[2]

1. Reid F, Henry JA. Lofepramine overdosage. *Pharmacopsychiatry* 1990; **23:** 23–27.
2. Mason J, *et al*. Fatal toxicity associated with antidepressant use in primary care. *Br J Gen Pract* 2000; **50:** 366–70.

Interactions

For interactions associated with tricyclic antidepressants, see Amitriptyline, p.379.

Pharmacokinetics

Lofepramine is readily absorbed from the gastrointestinal tract; peak plasma concentrations occur within 1 hour of oral doses. Since lofepramine slows gastrointestinal transit time absorption can, however, be delayed, particularly in overdosage. It is extensively demethylated by first-pass metabolism in the liver to its active, primary metabolite, desipramine (p.387). Paths of metabolism also include *N*-oxidation and hydroxylation. The plasma half-life is about 5 hours. Lofepramine is mainly excreted in the urine, chiefly in the form of its metabolites. Up to 99% of lofepramine is bound to plasma proteins. Lofepramine is distributed into breast milk.

Uses and Administration

Lofepramine is a dibenzazepine tricyclic antidepressant with actions and uses similar to those of amitriptyline (p.381). One of its metabolites is desipramine (p.387). Lofepramine is one of the less sedating tricyclics.

In the treatment of depression (p.373) lofepramine is given orally as the hydrochloride although doses are expressed in terms of the base. Lofepramine hydrochloride 76.1 mg is equivalent to about 70 mg of lofepramine. The usual dose is the equivalent of 70 mg two or three times daily.

Lofepramine should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Administration in the elderly. UK licensed drug information suggests that some elderly patients may respond to lower than usual doses of lofepramine, but in a study[1] involving 46 elderly patients with various grades of depression lofepramine 70 mg once daily was no more effective than placebo at the end of 28 days of treatment.

CAS — 10347-81-6.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Maprotiline Hydrochloride). A white or almost white crystalline powder. It shows polymorphism. Slightly soluble in water; soluble in alcohol; very slightly soluble in acetone; sparingly soluble in dichloromethane; freely soluble in methyl alcohol.

USP 31 (Maprotiline Hydrochloride). A fine white to off-white, practically odourless, crystalline powder. Slightly soluble in water; freely soluble in chloroform and in methyl alcohol; practically insoluble in isooctane. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

Adverse effects with maprotiline, a tetracyclic antidepressant, are broadly similar to those with tricyclic antidepressants (see Amitriptyline, p.376) but antimuscarinic effects are less frequent.

Skin rashes seem more common with maprotiline than with tricyclic antidepressants. Seizures have occurred in patients with no prior history of such disorders as well as in those with a history of epilepsy and the risk is increased if high doses of maprotiline are given. It should not be used in patients with epilepsy or a lowered seizure threshold.

Incidence of adverse effects. By March 1985 the UK CSM[1] had received reports of the following adverse reactions associated with maprotiline from a cumulative total of 2.5 million prescriptions: convulsions (124), hepatic reactions (4), and haematological reactions (8). There had also been 454 reports of skin rashes.

1. CSM. Dangers of newer antidepressants. *Current Problems 15* 1985. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2024422&RevisionSelectionMethod=LatestReleased (accessed 05/08/08)

Effects on the skin. In addition to many recorded instances of skin rashes with maprotiline (see Incidence of Adverse Effects, above) cutaneous vasculitis, which resolved on stopping therapy, has also been seen.[1]

1. Oakley AMM, Hodge L. Cutaneous vasculitis from maprotiline. *Aust N Z J Med* 1985; **15:** 256–7.

Epileptogenic effect. In a retrospective review of 186 psychiatric patients with no history of seizures, 5 of 32 patients taking maprotiline developed generalised tonic-clonic seizures, compared with 1 of 45 receiving a tricyclic antidepressant.[1] There were no seizures in the remaining patients who received other medications, or no drug treatment. Two of the 5 patients having seizures with maprotiline were taking doses of 75 to 150 mg daily, 2 were taking daily doses of 200 to 300 mg, and one patient had partial complex seizures with a daily dose of 150 mg and generalised tonic-clonic seizures after increasing the daily dose to 300 mg.

1. Jabbari B, *et al*. Incidence of seizures with tricyclic and tetracyclic antidepressants. *Arch Neurol* 1985; **42:** 480–1.

Overdosage. Apart from seizures being more common with maprotiline, features of overdosage are similar to those experienced with tricyclic antidepressant poisonings (see Adverse Effects of Amitriptyline, p.376).

For a discussion of choice of antidepressant with respect to toxicity in overdosage, see under Depression, p.373.

Porphyria. Maprotiline hydrochloride is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Interactions

Interactions associated with maprotiline are similar to those associated with tricyclic antidepressants (see Amitriptyline, p.379).

Pharmacokinetics

Maprotiline is slowly but completely absorbed from the gastrointestinal tract. Peak plasma concentrations are reached within 8 hours of an oral dose. It is widely distributed throughout the body and plasma protein binding is about 88 to 89%.

Maprotiline is extensively demethylated in the liver to its principal active metabolite, desmethylmaprotiline; paths of metabolism of both maprotiline and desmethylmaprotiline include *N*-oxidation, aliphatic and aromatic hydroxylation, and the formation of aromatic methoxy derivatives. In addition to desmethylmaprotiline, maprotiline-*N*-oxide is also reported to be pharmacologically active. The average elimination half-life of maprotiline is reported to be about 43 hours and that of its active metabolite even longer (range 60 to 90 hours). Maprotiline is excreted in the urine, mainly in the form of its metabolites, either in free or in conjugated form; appreciable amounts are also excreted in the faeces.

Maprotiline is distributed into breast milk (see Breast Feeding under Precautions of Amitriptyline, p.378).

Uses and Administration

Maprotiline is a tetracyclic antidepressant with actions and uses similar to those of tricyclic antidepressants (see Amitriptyline, p.381). It is one of the more sedating antidepressants but antimuscarinic effects are less marked. Like the tricyclics, maprotiline is an inhibitor of the reuptake of noradrenaline; it also has weak affinity for central adrenergic (α_1) receptors.

Maprotiline is usually given orally as the hydrochloride but it has also been given by injection as the mesilate and in oral drops as the resinate.

In the treatment of depression (p.373) maprotiline hydrochloride is given in oral doses of 25 to 75 mg daily in divided doses, gradually increased to 150 mg daily if necessary; up to 225 mg daily may be required in severely depressed patients in hospital. The dosage should be adjusted after 2 weeks according to response. Because of the prolonged half-life of maprotiline the total daily dose may also be given as a single dose. A suggested initial dose for elderly patients is 25 mg daily gradually increased according to response to 50 to 75 mg daily.

Maprotiline should be withdrawn gradually to reduce the risk of withdrawal symptoms.

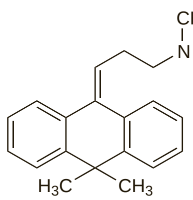
ATC — N06AA14.

ATC Vet — QN06AA14.



(melitracen)

Profile

Melitracen is a tricyclic antidepressant (see Amitriptyline, p.376).

In the treatment of depression (p.373) melitracen is given orally as the hydrochloride although doses are expressed in terms of the base; melitracen hydrochloride 28.1 mg is equivalent to about 25 mg of melitracen. The recommended initial dose is the equivalent of 25 mg two or three times daily gradually increased to a total of 225 mg daily if necessary. Elderly patients should generally be given reduced doses of 25 or 30 mg daily initially. Melitracen may also be given in lower doses with flupentixol (p.997) in the management of depression with anxiety. A combination of melitracen 10 mg and flupentixol 500 micrograms is given orally in the morning and at midday. In severe cases the morning dose may be doubled. The total daily dose should not exceed melitracen 40 mg and flupentixol 2 mg. Elderly patients may be given melitracen 10 mg with flupentixol 500 micrograms in the morning; in severe cases this dose may be given in the morning and at midday.

Melitracen should be withdrawn gradually to reduce the risk of withdrawal symptoms.

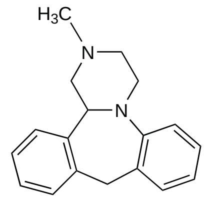
ATC — N06AX03.

ATC Vet — QN06AX03.



(mianserin)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Mianserin Hydrochloride). A white or almost white crystalline powder or crystals. Sparingly soluble in water; slightly soluble in alcohol; soluble in dichloromethane. A 1% solution in water has a pH of 4.0 to 5.5. Protect from light.

Adverse Effects

Antimuscarinic and cardiac adverse effects are fewer and milder with mianserin, a tetracyclic antidepressant, than with tricyclic antidepressants but effects are otherwise broadly similar (see Amitriptyline, p.376); mianserin may be associated with a lower risk of cardiotoxicity in overdosage.

The most common adverse effect associated with mianserin is drowsiness. Mianserin also causes bone-marrow depression usually presenting as leucopenia, granulocytopenia, or agranulocytosis; aplastic anaemia has been reported. These adverse haematological reactions generally occur during the first few weeks of therapy and especially in the elderly.

Other adverse effects reported include disturbances of liver function and jaundice, breast disorders (gynaecomastia, nipple tenderness, and non-puerperal lactation), and polyarthropathy.

Effects on the blood. Between 1976 and the end of 1988 the UK CSM had received 239 reports of adverse haematological reactions associated with mianserin use.[1] The reports included 68 of agranulocytosis and 84 of granulocytopenia or leucopenia where mianserin was considered to be the probable or possible cause; there had been 17 fatalities. Allowing for the pattern of prescribing there was a greater number of reports of white blood cell disorders in patients over 65 years of age but there was no sex difference. The data also indicated that the adverse reactions were most likely to develop during the first 3 months of therapy. By the end of 1992 the number of reports of mianserin-induced agranulocytosis or neutropenia received by the CSM[2] had risen to 79 and 105, respectively.

A case of fatal aplastic anaemia associated with mianserin use has also been reported.[3]

Proposed mechanisms of mianserin haematotoxicity have included a direct toxicity[4] and an immunologically-mediated mechanism.[5] There is evidence from studies *in vitro* of a significant correlation between the desmethyl metabolite and cytotoxicity. Mianserin is given as a racemic preparation and the formation of metabolites was greater with the *R*(−)-enantiomer than with the *S*(+)-enantiomer.[6]

Effects on the cardiovascular system. Although mianserin is considered to be less cardiotoxic than the tricyclic antidepressants adverse effects have been noted in individual patients. Two elderly patients developed signs of disturbed cardiac function (cardiac failure, atrial and ventricular fibrillation, bradycardia, and frequent ventricular ectopic beats) which resolved after the drug was stopped.[1] One of the patients also developed hypokalaemia which was possibly caused by mianserin. It was suggested that persons most likely to experience problems were the elderly with a history of cardiovascular disorders. Further reports of mianserin-induced cardiac effects include recurrent ventricular fibrillation in a 61-year-old man after an overdose of mianserin[2] and bradycardia in a 50-year-old woman after a therapeutic dose.[3]

2. Haefeli WE, *et al.* Recurrent ventricular fibrillation in mianserin intoxication. *BMJ* 1991; **302:** 415–16.
3. Carcone B, *et al.* Symptomatic bradycardia caused by mianserin at therapeutic doses. *Hum Exp Toxicol* 1991; **10:** 383–4.

Effects on the liver. By March 1985 the UK CSM had received 57 reports of hepatic reactions associated with mianserin use from a total of 5 million prescriptions. Reactions had included jaundice and other abnormalities of liver function, but no fatalities had been reported.[1]

Case reports have also been published concerning jaundice;[2-5] liver function returned to normal after stopping mianserin or lowering the dose.

1. CSM. Dangers of newer antidepressants. *Current Problems 15* 1985. http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2024422&RevisionSelectionMethod=LatestReleased (accessed 14/08/08)

5. Otani K, *et al.* Hepatic injury caused by mianserin. *BMJ* 1989; **299:** 519.

Effects on the musculoskeletal system. A patient developed an acute polyarthritis affecting the hands and feet 6 days after starting therapy with mianserin;[1] at that time the UK CSM had received 19 reports of arthritis and arthralgia associated with mianserin. For the suggestion that effects at serotonin receptors may be involved in such adverse effects see under Mirtazapine, p.410.

1. Hughes A, Coote J. Arthropathy associated with treatment with mianserin. *BMJ* 1986; **292:** 1050.

Effects on the skin. Reports of adverse dermatological reactions in individual patients related to mianserin therapy have included toxic epidermal necrolysis[1] and erythema multiforme.[2,3]

1. Randell P. Tolvon and toxic epidermal necrolysis. *Med J Aust* 1979; **2:** 653.

3. Cox NH. Erythema multiforme due to mianserin—a case against generic prescribing. *Br J Clin Pract* 1985; **39:** 293–4.

Effects on the tongue. Glossitis associated with mianserin therapy was reported in 2 patients.[1] Additionally, glossitis accompanied by severe facial oedema has been noted in another patient.[2] In all cases symptoms resolved after withdrawal of mianserin.

1. de la Fuente JR, Berlanga C. Glossitis associated with mianserin. *Lancet* 1984; **i:** 233.
2. Leibovitch G, *et al.* Severe facial oedema and glossitis associated with mianserin. *Lancet* 1989; **ii:** 871–2.

Epileptogenic effect. By March 1985 the UK CSM had received 64 reports of convulsions associated with mianserin use from a total of 5 million prescriptions.[1] In a previous review[2] concerning 40 of these cases it was considered that a causal connection could be established only in a minority. It was suggested that mianserin is no more epileptogenic than tricyclic antidepressants, an opinion that was also shared by other reviewers.[3]

1. CSM. Dangers of newer antidepressants. *Current Problems 15* 1985. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2024422&RevisionSelectionMethod=LatestReleased (accessed 05/08/08)

3. Richens A, *et al.* Antidepressant drugs, convulsions and epilepsy. *Br J Clin Pharmacol* 1983; **15:** 295S–298S.

Overdosage. Experience with 100 consecutive cases of intoxication with mianserin[1] revealed that when it was the only drug ingested symptoms were mild and neither deep coma nor convulsions occurred. More serious symptoms and 2 fatalities were seen in patients who had taken multiple drug overdoses. The results suggested that after an acute overdose mianserin is less toxic than the tricyclic antidepressants. This conclusion was also supported by a large follow-up study[2] comparing the outcome of suicide attempts among patients who had taken mianserin in overdose with those who had taken amitriptyline.

1. Chand S, *et al.* One hundred cases of acute intoxication with mianserin hydrochloride. *Pharmakopsychiatrie* 1981; **14:** 15–17.
2. Inman WHW. Blood disorders and suicide in patients taking mianserin or amitriptyline. *Lancet* 1988; **ii:** 90–2.

Precautions

As for tricyclic antidepressants in general (see Amitriptyline, p.378). Although mianserin is less cardiotoxic than the tricyclic antidepressants, it still should be used with caution in patients with cardiovascular disorders, such as heart block, or after recent myocardial infarction. Similarly, patients with angle-closure glaucoma or prostatic hyperplasia should be monitored even though antimuscarinic effects are rare. Mianserin should be used with caution in patients with diabetes mellitus, epilepsy, and hepatic or renal impairment; it should be avoided in severe hepatic disease.

Patients should be carefully monitored during early antidepressant therapy until significant improvement in depression is observed because suicide is an inherent risk in depressed patients. For further details, see under Depression, p.373. Suicidal thoughts and behaviour may also develop during early treatment with antidepressants for other disorders; the same precautions observed when treating patients with depression should therefore be observed when treating patients with other disorders.

A full blood count is recommended every 4 weeks during the first 3 months of treatment with mianserin, because of the risk of bone-marrow depression. Similarly, if a patient receiving mianserin develops fever, sore throat, stomatitis, or other signs of infection, treatment should be stopped and a full blood count obtained. The elderly are considered to be at special risk of blood disorders from mianserin. For further details see Effects on the Blood under Adverse Effects, above.

UK licensed drug information recommends that mianserin should not be given during breast feeding, but the *BNF* considers the amount distributed into breast milk too small to be harmful.

Porphyria. Mianserin hydrochloride is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals.*

Interactions

It is recommended that mianserin should not be given to patients receiving MAOIs or for at least 14 days afterwards. At least one week should elapse between withdrawing mianserin and starting any drug liable to provoke a serious reaction (e.g. phenelzine). Unlike the tricyclics (p.379), mianserin does not diminish the effects of the antihypertensives guanethidine, hydralazine, propranolol, or clonidine. However, it is still recommended that blood pressure be monitored when mianserin is prescribed with antihypertensive therapy. Plasma-phenytoin concentrations should be monitored carefully in patients also treated with mianserin; phenytoin has also been reported to reduce concentrations of mianserin (see below). There may be potentiation of effects when mianserin is given with CNS depressants such as alcohol, anxiolytics, or antipsychotics.

Antiepileptics. Reduced plasma concentrations and half-lives of mianserin and desmethylmianserin were seen in 6 patients also receiving antiepileptic therapy consisting of *phenytoin* with either *carbamazepine* or *phenobarbital.*[1] Carbamazepine alone may also reduce the plasma concentration of mianserin.[2,3]

Mianserin may antagonise the action of antiepileptics by lowering the convulsive threshold.

1. Nawishy S, *et al.* Kinetic interaction of mianserin in epileptic patients on anticonvulsant drugs. *Br J Clin Pharmacol* 1982; **13:** 612P–13P.
2. Leinonen E, *et al.* Effects of carbamazepine on serum antidepressant concentrations in psychiatric patients. *J Clin Psychopharmacol* 1991; **11:** 313–18.
3. Eap CB, *et al.* Effects of carbamazepine coadministration on plasma concentrations of the enantiomers of mianserin and of its metabolites. *Ther Drug Monit* 1999; **21:** 166–70.

Pharmacokinetics

Mianserin is readily absorbed from the gastrointestinal tract, but its bioavailability is reduced by extensive first-pass metabolism in the liver.

Paths of metabolism of mianserin include aromatic hydroxylation, *N*-oxidation, and *N*-demethylation. Desmethylmianserin and 8-hydroxymianserin are pharmacologically active.

Mianserin is excreted in the urine, almost entirely as its metabolites, either free or in conjugated form; some is also found in the faeces.

Mianserin is widely distributed throughout the body and is extensively bound to plasma proteins. It has been found to have a biphasic plasma half-life with the duration of the terminal phase ranging from about 6 to 40 hours. Mianserin crosses the blood-brain barrier and the placenta. It is distributed into breast milk.

Uses and Administration

Mianserin is a tetracyclic antidepressant. It does not appear to have significant antimuscarinic properties, but has a marked sedative action. Unlike the tricyclic antidepressants (see Amitriptyline, p.381), mianserin does not prevent the peripheral reuptake of noradrenaline; it blocks presynaptic adrenergic (α_2) receptors and increases the turnover of brain noradrenaline. Mianserin is also an antagonist of postsynaptic serotonin receptors in some parts of the brain.

In the treatment of depression (p.373) mianserin hydrochloride is given in initial oral doses of 30 to 40 mg daily increased gradually thereafter as necessary. The effective daily dosage is usually between 30 and 90 mg. The daily dosage may be divided throughout the day or given as a single dose at night. Divided daily dosages of up to 200 mg have been given. The recommended initial daily dose in the elderly is not more than 30 mg, which may be slowly increased if necessary.

Mianserin should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Preparations

BP 2008: Mianserin Tablets.

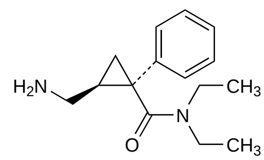
CAS — 92623-85-3 (milnacipran); 101152-94-7 (milnacipran hydrochloride); 175131-61-0 (milnacipran hydrochloride).

ATC — N06AX17.

ATC Vet — QN06AX17.



(milnacipran)

Profile

Milnacipran hydrochloride is a serotonin and noradrenaline reuptake inhibitor (SNRI) (see Venlafaxine, p.427) used for the treatment of depression (p.373). It is given in usual oral doses of 50 mg twice daily. Milnacipran is also being investigated in the treatment of fibromyalgia.

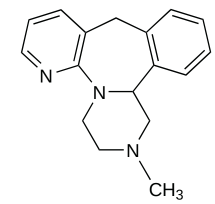
ATC — N06AX11.

ATC Vet — QN06AX11.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Mirtazapine). A white or almost white powder, slightly hygroscopic to hygroscopic. It exhibits polymorphism. Practically insoluble in water; freely soluble in anhydrous alcohol. Store in airtight containers.

USP 31 (Mirtazapine). It is anhydrous or contains one-half molecule of water of hydration. A white to creamy white, crystalline powder. Practically insoluble in water; soluble in solvent ether; sparingly soluble in *n*-hexane; freely soluble in methyl alcohol and in toluene. Store in airtight containers.

Adverse Effects

Adverse effects commonly reported with mirtazapine are an increase in appetite and weight, and oedema; drowsiness or sedation generally occur during the first few weeks of treatment. Dizziness, headache, and increases in liver enzyme levels have been reported less commonly; jaundice may occur. Other rarely reported adverse effects include orthostatic hypotension, skin rashes, nightmares, agitation, mania, hallucinations, paraesthesia, convulsions, tremor, myoclonus, psychomotor restlessness including akathisia, restless legs syndrome, arthralgia, myalgia, and reversible agranulocytosis, leucopenia, and granulocytopenia.

Hyponatraemia, possibly due to inappropriate secretion of antidiuretic hormone, has been associated with the use of antidepressants, particularly in the elderly.

Incidence of adverse effects. The Australian Adverse Drug Reactions Advisory Committee has reported[1] that, up to October 2003, it had received 253 reports of adverse reactions associated with the use of mirtazapine. The most frequently reported reactions were oedema (33), anxiety or agitation (24), myalgia or arthralgia (24), sedation (23), and skin reactions (20). Other reactions included hyperkinesis, diarrhoea, and nausea and vomiting. There were 16 cases of convulsions, all in patients without a history of epilepsy. Blood dyscrasias were also reported and included 8 cases of neutropenia, 6 of thrombocytopenia, and 1 each of lymphopenia and pancytopenia; in the majority of cases onset was within 2 months of starting mirtazapine.

A prescription-event monitoring study conducted in England identified 13 554 patients who had been prescribed mirtazapine during the first 2 years of marketing in the UK;[2] within this cohort, 807 adverse drug reactions were reported in 573 patients. The most common adverse reactions included drowsiness or sedation (116), malaise (71), dizziness (57), nausea and vomiting (33), weight gain (31), and headache or migraine (21). Facial oedema (5), allergy (3), bone marrow toxicity (2), and myelodysplasia (1) were the more serious suspected adverse reactions.

Effects on the endocrine system. An elderly woman developed *hyponatraemia* within 4 days of starting mirtazapine at a dose of 15 mg at night.[1] Apart from her age, other risk factors for hyponatraemia included diuretic use and a previous episode while taking venlafaxine.

1. Roxanas MG. Mirtazapine-induced hyponatraemia. *Med J Aust* 2003; **179:** 453–4.

Effects on mental state. An Expert Working Group was convened in May 2003 by the UK CSM to consider the ongoing safety concerns of the SSRIs particularly the risk of suicidal behaviour in children; the safety of mirtazapine (another serotonergic antidepressant) was also considered. In its final report[1] in December 2004, the group concluded that data from trials received by the CSM had failed to show that mirtazapine was effective in the treatment of depression in **adolescents and children** under 18 years old, although the risk of suicidal behaviour was not increased. Consequently, it was considered that the balance of risks and benefits of mirtazapine for the treatment of depression in this group was unfavourable. Similar recommendations have also been issued in the EU.[2]

The risk of suicide and suicide-related events with serotonergic antidepressant treatment in **adults**, including young adults, are discussed under Fluoxetine, p.392.

Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON019472&RevisionSelectionMethod=LatestReleased (accessed 14/08/08)
2. European Medicines Agency. European Medicines Agency finalises review of antidepressants in children and adolescents (issued 25th April, 2005). Available at: http://www.emea.europa.eu/pdfs/human/press/pr/12891805en.pdf (accessed 14/08/08)

Effects on the musculoskeletal system. The Netherlands Pharmacovigilance Centre Lareb received 8 reports of arthralgia associated with the use of mirtazapine between May 1995 and October 2004; the effect usually developed within a short time of starting treatment and resolved once the drug was withdrawn.[1] The authors noted that of 4578 reported reactions to mirtazapine held in the WHO database up to March 2004, 110 concerned the development of arthralgia. Similar reactions have occurred with mianserin and nefazodone, and it was suggested that effects at serotonin 5-HT_1 or 5-HT_2 receptors might be involved.

1. Passier A, van Puijenbroek E. Mirtazapine-induced arthralgia. *Br J Clin Pharmacol* 2005; **60:** 570–2.

Extrapyramidal effects. Akathisia that developed in 2 patients given mirtazapine 30 mg at night[1] resolved in one after being treated with clonazepam and in the other patient after reducing the dose of mirtazapine to 15 mg at night.

1. Girishchandra BG, *et al.* Mirtazapine-induced akathisia. *Med J Aust* 2002; **176:** 242.

Serotonin syndrome. The serotonin syndrome (p.416) is most commonly due to the additive adverse effects of two or more drugs that enhance serotonin activity at central receptors; rarely, a single serotonergic drug has caused the syndrome. One such case[1] occurred in an elderly patient given mirtazapine 15 mg daily; he was also taking salbutamol, ipratropium, and nimodipine, although none of these are known to have serotonergic effects.

1. Hernández JL, *et al.* Severe serotonin syndrome induced by mirtazapine monotherapy. *Ann Pharmacother* 2002; **36:** 641–3.

Precautions

Mirtazapine should be used with caution in patients with epilepsy or a history of seizures, and it should be avoided completely if these disorders are unstable. Care is also required in hepatic or renal impairment, and cardiac disorders such as conduction disturbances, angina pectoris, and recent myocardial infarction; caution is further advised in patients with hypotension, diabetes mellitus, psychoses, and in those with a history of bipolar disorder. Treatment should be stopped if jaundice develops. Although mirtazapine has only weak antimuscarinic activity, it should nevertheless be used with care in patients with micturition disturbances, angle-closure glaucoma, and raised intra-ocular pressure.

Because of the risk of bone-marrow depression, patients should be advised to report any of the following symptoms during treatment: fever, sore throat, stomatitis, or other signs of infection; treatment should be stopped and a blood count performed.

Drowsiness is often experienced at the start of therapy and patients, if affected, should not drive or operate machinery.

Patients should be closely monitored during early therapy until significant improvement in depression is observed because suicide is an inherent risk in depressed patients. For further details, see under Depression, p.373. Suicidal thoughts and behaviour may also develop during early treatment with antidepressants for other disorders; the same precautions observed when treating patients with depression should therefore be observed when treating patients with other disorders.

Mirtazapine should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Breast feeding. Mirtazapine has been detected in breast milk;[1] however, the plasma concentration in a breast-fed infant was very low (0.2 nanograms/mL) and no adverse events were detected.

1. Aichhorn W, *et al.* Mirtazapine and breast-feeding. *Am J Psychiatry* 2004; **161:** 2325.

Children. The use of mirtazapine in adolescents and children with depression is not recommended; for further details, see Effects on Mental State, above.

Pregnancy. A small case series followed the pregnancies of 9 women exposed to mirtazapine during the first trimester;[1] in the majority of cases the women were also exposed to other drugs. Within the group there were 7 healthy deliveries, 1 induced abortion, and 1 spontaneous abortion. In another report healthy male twins were delivered by a mother who was given mirtazapine at 2 periods during her pregnancy for the successful treatment of hyperemesis gravidarum.[2] A follow-up examination of the twins at 6 months was normal.

Health Canada has reported that some newborn infants of mothers who took newer antidepressants such as mirtazapine mainly during the third trimester of pregnancy have experienced complications at birth requiring prolonged hospitalisation, breathing support, and tube feeding.[3] Reported symptoms included seizures, muscle rigidity, jitteriness, and constant crying. It was considered that these symptoms represented either direct toxicity of mirtazapine or a possible withdrawal syndrome.

2. Rohde A, *et al.* Mirtazapine (Remergil) for treatment resistant hyperemesis gravidarum: rescue of a twin pregnancy. *Arch Gynecol Obstet* 2003; **268:** 219–21.
3. Health Canada. Health Canada advises of potential adverse effects of SSRIs and other anti-depressants on newborns (issued 9th August 2004). Available at: http://www.hc-sc.gc.ca/ahc-asc/media/advisories-avis/_2004/2004_44-eng.php (accessed 14/08/08)

Interactions

Mirtazapine should not be used with or within 2 weeks of stopping an MAOI; at least one week should elapse between stopping mirtazapine and starting any drug liable to provoke a serious reaction (e.g. phenelzine). Use of mirtazapine with alcohol or benzodiazepines may potentiate sedative effects.

The cytochrome P450 isoenzyme CYP3A4 is involved in the metabolism of mirtazapine and caution is advised when mirtazapine is given with potent inhibitors of this isoenzyme such as HIV-protease inhibitors, azole antifungals including ketoconazole, erythromycin, and nefazodone; raised plasma levels of mirtazapine have been noted after use with ketoconazole. Conversely, carbamazepine and other inducers of CYP3A4 increased the clearance of mirtazapine and the dose of mirtazapine may need to be increased when given with these drugs.

Cimetidine, which inhibits a range of cytochrome P450 isoenzymes, has more than doubled the bioavailability of mirtazapine; the dose of mirtazapine may need to be reduced if given with cimetidine.

Pharmacokinetics

Mirtazapine is well absorbed from the gastrointestinal tract with peak plasma levels occurring after about 2 hours. Plasma protein binding is about 85%. Mirtazapine is extensively metabolised in the liver and the major biotransformation pathways are demethylation and oxidation followed by glucuronide conjugation; cytochrome P450 isoenzymes involved are CYP2D6, CYP1A2, and CYP3A4. The *N*-desmethyl metabolite is pharmacologically active. Elimination is via urine (75%) and faeces (15%). The mean plasma elimination half-life is 20 to 40 hours. Data from *animal* studies indicate that mirtazapine crosses the placenta. Mirtazapine is distributed into breast milk.

Uses and Administration

Mirtazapine, a piperazinoazepine, is an analogue of mianserin (p.408); it is a noradrenergic and specific serotonergic antidepressant. It enhances the release of noradrenaline and, indirectly, serotonin through blockade of central presynaptic adrenergic (α_2) receptors. The effects of released serotonin are mediated via 5-HT_1 receptors as mirtazapine blocks both 5-HT_2 and 5-HT_3 receptors. Mirtazapine is given as a racemic mixture: the *S*(+)-enantiomer blocks α_2 and 5-HT_2 receptors whereas the *R*(−)-enantiomer blocks 5-HT_3 receptors. Mirtazapine is also a potent antagonist at histamine (H_1) receptors which gives it sedative properties; it has very little antimuscarinic activity.

In the treatment of depression (p.373), mirtazapine is given in an initial oral daily dose of 15 mg, which may be increased gradually according to response. Changes in dose should be made at intervals of at least 1 to 2 weeks because of the long half-life. The usual effective daily dose lies within the range of 15 to 45 mg. Daily doses may be given as a single dose, preferably at bedtime, or in 2 equally divided doses. Mirtazapine may also be given by intravenous infusion.

Mirtazapine should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Anxiety disorders. Mirtazapine has been tried with some success in the treatment of anxiety disorders (p.952) including obsessive-compulsive disorder (p.952), panic disorder (p.952), and post-traumatic stress disorder (p.953).

Depression. As discussed on p.373, there is very little difference in efficacy between the different groups of antidepressant drugs, and choice is often made on the basis of adverse effect profile. Mirtazapine is a central presynaptic adrenergic (α_2) receptor antagonist and has a slightly different biochemical profile from both the tricyclics and the SSRIs; however, like the SSRIs, mirtazapine appears to have fewer unpleasant adverse effects in comparison with the older tricyclics.

Moclobemide *(BAN, USAN, rINN)*

Moclobemida; Moclobémide; Moclobemidum; Moklobemid; Moklobemidi; Ro-11-1163; Ro-11-1163/000. 4-Chloro-*N*-(2-morpholinoethyl)benzamide.

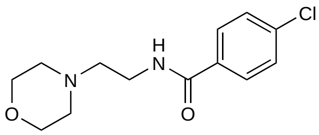
Моклобемид

$C_{13}H_{17}ClN_2O_2$ = 268.7.

CAS — 71320-77-9.

ATC — N06AG02.

ATC Vet — QN06AG02.



Pharmacopoeias. In *Chin.* and *Swiss.*

Adverse Effects

Adverse effects reported to occur with moclobemide include sleep disturbances, dizziness, agitation, feelings of anxiety, restlessness, irritability, and headache. Gastrointestinal disturbances include dry mouth, diarrhoea, constipation, and nausea and vomiting. Paraesthesia, visual disturbances, and oedema have also been reported, and skin reactions include rash, pruritus, urticaria, and flushing. Confusional states have been observed that disappear rapidly on stopping the drug. Raised liver enzymes and galactorrhoea have been reported rarely.

Hyponatraemia, possibly due to inappropriate secretion of antidiuretic hormone, has been associated with the use of antidepressants, particularly in the elderly.

Effects on the cardiovascular system. Hypertension has been reported[1,2] rarely in patients taking moclobemide, some of whom were also taking other drugs although moclobemide was suspected to be the cause. Blood pressure usually returned to normal after stopping moclobemide.

1. Coulter DM, Pillans PI. Hypertension with moclobemide. *Lancet* 1995; **346:** 1032.
2. Boyd IW. Hypertension with moclobemide. *Lancet* 1995; **346:** 1498.

Effects on the endocrine system. A prescription-event monitoring study found that galactorrhoea is significantly associated with the use of moclobemide.[1]

1. Dunn NR, *et al.* Galactorrhoea with moclobemide. *Lancet* 1998; **351:** 802.

Effects on the liver. An 85-year-old woman developed intrahepatic cholestasis after taking moclobemide for about 1 week;[1] she had previously been taking fluoxetine and was switched to moclobemide without a washout period. She died 12 days after the onset of jaundice despite prompt moclobemide withdrawal.

1. Timmings P, Lamont D. Intrahepatic cholestasis associated with moclobemide leading to death. *Lancet* 1996; **347:** 762–3.

Overdosage. Several case series[1-3] have suggested that moclobemide is relatively safe when taken alone in overdose; symptoms such as gastrointestinal irritation, agitation, aggression, behavioural disturbances, and tachycardia have been noted. However, fatalities have been reported, particularly when taken with other serotonergic drugs.[3,4]

1. Hetzel W. Safety of moclobemide taken in overdose for attempted suicide. *Psychopharmacology (Berl)* 1992; **106:** S127–S129.
2. Myrenfors PG, *et al.* Moclobemide overdose. *J Intern Med* 1993; **233:** 113–15.
3. Isbister GK, *et al.* Moclobemide poisoning: toxicokinetics and occurrence of serotonin toxicity. *Br J Clin Pharmacol* 2003; **56:** 441–50.
4. Giroud C, *et al.* Death following acute poisoning by moclobemide. *Forensic Sci Int* 2004; **140:** 101–7.

Precautions

Moclobemide is contra-indicated in patients with acute confusional states and in those with phaeochromocytoma. It should be avoided in excited or agitated patients, unless used with a sedative. Manic episodes may be provoked in patients with bipolar disorder. Care is also required in patients with thyrotoxicosis as moclobemide may theoretically precipitate a hypertensive reaction. Reduced doses should be used in patients with severe hepatic impairment.

Patients should be closely monitored during early antidepressant therapy until significant improvement in depression is observed because suicide is an inherent risk in depressed patients. For further details, see under Depression, p.373. Suicidal thoughts and behaviour may also develop during early treatment with antidepressants for other disorders; the same precautions observed when treating patients with depression should therefore be observed when treating patients with other disorders.

Although impairment of mental alertness is generally not expected with moclobemide, caution should be exercised with respect to driving or operating machinery until individual reactions have been assessed.

Antidepressants, particularly MAOIs, should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Breast feeding. In a study[1] of the distribution of moclobemide into the breast milk of 6 mothers given a single 300-mg dose of moclobemide, a mean of 0.057% of the dose appeared in breast milk as moclobemide and 0.031% as Ro-12-8095, its major metabolite, within 24 hours of a dose. It was considered that this small amount of moclobemide was unlikely to be hazardous to breast-fed infants. UK licensed drug information advises caution and consideration of the benefits of moclobemide therapy to the mother against possible risks to the infant.

1. Pons G, *et al.* Moclobemide excretion in human breast milk. *Br J Clin Pharmacol* 1990; **29:** 27–31.

Children. Moclobemide has not been adequately studied for the treatment of depression in children and its use is not recommended in UK licensed product information. In addition, other antidepressants have been shown to increase the risk of suicidal thoughts and behaviour in these patients (see Effects on Mental State, under Fluoxetine, p.392).

Pregnancy. UK licensed drug information recommends that moclobemide should only be used during pregnancy if the benefits to the mother outweigh any possible risks to the fetus.

A patient who took at least 300 mg daily of moclobemide throughout her pregnancy delivered a healthy, full-term infant after an uncomplicated pregnancy.[1] The infant was monitored from birth, and psychomotor and somatic development for the first 14 months was found to be normal.

1. Rybakowski JK. Moclobemide in pregnancy. *Pharmacopsychiatry* 2001; **34:** 82–3.

Withdrawal. Withdrawal symptoms may occur if an antidepressant such as moclobemide is suddenly stopped after regular use for 8 weeks or more; the *BNF* recommends that the dose should be tapered gradually over a period of about 4 weeks, or as much as 6 months in patients who have been receiving long-term maintenance therapy.

Despite reducing the dose of moclobemide over 3 days, symptoms such as muscle cramps, shivering, headache, nausea, and hot flushes developed in a 47-year-old woman on the day that moclobemide was completely stopped.[1] The patient had been taking moclobemide for about 15 months.

1. Curtin F, *et al.* Moclobemide discontinuation syndrome predominantly presenting with influenza-like symptoms. *J Psychopharmacol* 2002; **16:** 271–2.

Interactions

The dietary restrictions that need to be followed with selective reversible inhibitors of monoamine oxidase type A such as moclobemide are less stringent than those for non-selective inhibitors of monoamine oxidase types A and B (see under Interactions of Phenelzine, p.417). However, UK licensed drug information recommends that since some patients may be especially sensitive to tyramine, consumption of large amounts of tyramine-rich food should be avoided.

Medicines containing *sympathomimetics, dextromethorphan*, or *anorectics* should not be taken with moclobemide. Moclobemide should not be given with *other antidepressants* although, owing to its short duration of action, a treatment-free period is generally considered unnecessary after its cessation. For further details, see Antidepressants under Interactions of Phenelzine, p.418. Therapy with moclobemide should not be started until at least a week after cessation of a tricyclic or related antidepressant or an SSRI or related antidepressant (2 weeks in the case of paroxetine and sertraline; at least 5 weeks in the case of fluoxetine) or for at least a week after stopping treatment with non-selective MAOIs. CNS excitation or depression may occur if moclobemide is taken with *opioid analgesics*, and there is also a risk of CNS toxicity if taken with *serotonin (5-HT$_1$) agonists*. The metabolism of moclobemide is inhibited by *cimetidine*, leading to increased plasma concentrations and a need for reduced dosage (see below).

Antimigraine drugs. For the effects of moclobemide on *serotonin (5-HT$_1$) agonists*, see under Sumatriptan, p.626.

Cimetidine. Cimetidine 1 g daily for 2 weeks increased the mean maximum plasma concentration of moclobemide in 8 healthy subjects from 575 nanograms/mL to 787 nanograms/mL; several other parameters associated with moclobemide absorption and disposition were also affected.[1] It was suggested that a reduction in the dosage of moclobemide might be required. UK licensed drug information for moclobemide recommends reducing its dose by half in patients also receiving cimetidine.

1. Schoerlin M-P, *et al.* Cimetidine alters the disposition kinetics of the monoamine oxidase-A inhibitor moclobemide. *Clin Pharmacol Ther* 1991; **49:** 32–8.

Dopaminergics. Adverse effects including nausea, vomiting, and dizziness were noted in healthy subjects given moclobemide and *levodopa with benserazide*;[1] however, no significant hypertensive reactions were seen.

Caution is also required when *selegiline* and moclobemide are given together.[1] Dietary restrictions with this combination (see under Phenelzine, p.417) are recommended by one manufacturer of selegiline, whereas another advises that this combination should be avoided (as does the manufacturer of moclobemide).

See also under Selegiline, p.817.

1. Dingemanse J. An update of recent moclobemide interaction data. *Int Clin Psychopharmacol* 1993; **7:** 167–80.

Omeprazole. Omeprazole, which is an inhibitor of cytochrome P450 isoenzyme CYP2C19, increased plasma concentrations and elimination half-life of moclobemide in extensive metabolisers of the drug towards values seen in poor metabolisers.[1] It had little effect on pharmacokinetic parameters in poor metabolisers. The clinical effects were uncertain but extra care might be warranted if the 2 drugs are given together.

1. Yu K-S, *et al.* Effect of omeprazole on the pharmacokinetics of moclobemide according to the genetic polymorphism of CYP2C19. *Clin Pharmacol Ther* 2001; **69:** 266–73.

Opioid analgesics. Symptoms suggestive of a mild serotonin syndrome (p.416) developed in a 73-year-old woman taking moclobemide, nortriptyline, and lithium after she was given *pethidine* intravenously.[1] Licensed drug information recommends that moclobemide should not be given with pethidine.

1. Gillman PK. Possible serotonin syndrome with moclobemide and pethidine. *Med J Aust* 1995; **162:** 554.

Pharmacokinetics

Moclobemide is readily absorbed from the gastrointestinal tract with peak plasma concentrations occurring within about 1 hour of ingestion. Absorption is virtually complete but first-pass metabolism reduces bioavailability of the drug. Moclobemide is widely distributed throughout the body and is 50% bound to plasma proteins. It undergoes extensive metabolism in the liver, in part by the cytochrome P450 isoenzymes CYP2C19 and CYP2D6. Metabolites of moclobemide and a small amount of unchanged drug are excreted in the urine. Moclobemide has a plasma elimination half-life of 2 to 4 hours. Moclobemide is distributed into breast milk.

Uses and Administration

Moclobemide, a benzamide derivative, is a reversible inhibitor of monoamine oxidase type A (RIMA) (see under Phenelzine, p.419) used for the treatment of depression and of social anxiety disorder.

In the treatment of **depression** the usual initial oral dose of moclobemide is 300 mg daily in divided doses. This may be increased up to 600 mg daily according to response. In some patients, a maintenance dose of 150 mg daily may be sufficient.

In the treatment of **social anxiety disorder**, the initial daily dose of moclobemide is 300 mg increased after 3 days to 600 mg given in 2 divided doses. Treatment should be continued for 8 to 12 weeks to assess efficacy; patients should be periodically re-evaluated thereafter to determine the need for further treatment.

Moclobemide should be taken after food.

Reduced doses should be given in hepatic impairment (see below) and in patients also taking cimetidine (see above).

Antidepressants, particularly MAOIs, should be withdrawn gradually to reduce the risk of withdrawal symptoms.

◊ Reviews.

1. Bonnet U. Moclobemide: therapeutic use and clinical studies. *CNS Drug Rev* 2003; **9:** 97–140.

Administration in hepatic impairment. UK licensed drug information states that doses of moclobemide in patients with severe hepatic impairment may need to be reduced to half or one-third of the recommended dose (see above).

Anxiety disorders. The use of MAOIs in general in the management of anxiety disorders is discussed under Phenelzine on p.420. For a discussion of the overall treatment of anxiety disorders, see p.952.

5. Stein DJ, *et al.* Moclobemide is effective and well tolerated in the long-term pharmacotherapy of social anxiety disorder with or without comorbid anxiety disorder. *Int Clin Psychopharmacol* 2002; **17:** 161–70.

Depression. As discussed on p.373 there is very little difference in efficacy between the different groups of antidepressant drugs, and choice is often made on the basis of adverse effects. The traditional MAOIs such as phenelzine are rarely used as first-choice antidepressants because of the dangers of dietary and drug interactions. Reversible inhibitors of monoamine oxidase type A (RIMAs) such as moclobemide offer a safer alternative to the irreversible non-selective MAOIs and fewer dietary restrictions are necessary.

Nefazodone Hydrochloride *(BANM, USAN, rINNM)*

BMY-13754; Hidrocloruro de nefazodona; MJ-13754-1; Néfazodone, Chlorhydrate de; Nefazodoni Hydrochloridum. 2-{3-[4-(3-Chlorophenyl)piperazin-1-yl]propyl}-5-ethyl-2,4-dihydro-4-(2-phenoxyethyl)-1,2,4-triazol-3-one monohydrochloride.

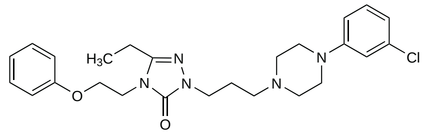
Нефазодона Гидрохлорид

$C_{25}H_{32}ClN_5O_2,HCl = 506.5.$

CAS — 83366-66-9 (nefazodone); 82752-99-6 (nefazodone hydrochloride).

ATC — N06AX06.

ATC Vet — QN06AX06.



(nefazodone)

Pharmacopoeias. In *US.*

USP 31 (Nefazodone Hydrochloride). A non-hygroscopic white powder. Slightly soluble in water and in macrogols; freely soluble in chloroform; soluble in propylene glycol. Store in airtight containers at a temperature between 15° and 30°.

Adverse Effects and Treatment

The most common adverse effects seen with nefazodone are weakness, dry mouth, nausea, constipation, somnolence, dizziness, insomnia, and lightheadedness. Other effects which have occurred less frequently include chills, fever, orthostatic hypotension, incoordination, vasodilatation, arthralgia, paraesthesia, confusion, memory impairment, abnormal dreams, ataxia, and amblyopia and other visual disturbances. Syncope, priapism, and seizures have occurred rarely and there have been reports of sinus bradycardia. Hepatotoxicity has occurred (see below).

Hyponatraemia, possibly due to inappropriate secretion of antidiuretic hormone, has been associated with the use of antidepressants, particularly in the elderly.

In overdosage, the symptoms that have been reported most frequently include hypotension, dizziness, nausea, vomiting, and drowsiness. The value of gastric decontamination in the treatment of overdosage is uncertain. Activated charcoal should be considered if more than 1.5 g (in an adult) or 20 mg/kg (in a child) has been taken and treatment is within 1 hour of ingestion. US licensed product information recommends gastric lavage, although this technique is seldom practicable and should not be attempted unless the airway is protected. Supportive therapy should be given as necessary. Dialysis, haemoperfusion, exchange perfusion, and measures to increase urine production are considered unlikely to be of benefit.

◊ Reviews.

1. Robinson DS, *et al.* The safety profile of nefazodone. *J Clin Psychiatry* 1996; **57** (suppl 2): 31–8.

Effects on the liver. Subfulminant hepatic failure developed in 3 women given nefazodone for depression.[1] Two patients required liver transplantation although this was unsuccessful in one case and the patient died. Hepatitis, positive on rechallenge, has also been reported with nefazodone.[2]

The original US manufacturer (*Bristol-Myers Squibb*) of nefazodone have stated that rare events of raised liver enzymes, hepatitis, hepatic failure and necrosis have been reported since marketing but no causal relationship has been established. In the USA, a reported rate of about 1 case of hepatic failure resulting in death or transplantation per 250 000 to 300 000 patient years of nefazodone treatment has been estimated by the manufacturer; this rate is about 3 to 4 times greater than the background rate of hepatic failure.[3] Onset times for such cases ranged from 2 weeks to 6 months. The Canadian manufacturers have indicated[4] that as of June 2001 there had been 109 reports of serious hepatic adverse events associated with nefazodone from postmarketing surveillance worldwide. These included 23 cases of hepatic failure, of which 16 led to transplantation and/or death. Most cases occurred within 4 months of beginning treatment although a few were after continuous use for up to 2 years. After a review[5] of the data available to December 2002, it was decided to withdraw nefazodone from the Canadian market in November 2003. Subsequently, one manufacturer (*Bristol-Myers Squibb*) withdrew nefazodone worldwide.

Overdosage. A 27-year-old woman developed no serious toxicity after taking 3 g of nefazodone in a suicide attempt.[1] Somnolence was the most severe effect noted. In another case, a 31-year-old woman attempted suicide with 16.8 g of nefazodone and an unknown quantity of verapamil.[2] The patient was lethargic, and developed significant bradycardia and hypotension; she recovered after supportive therapy. The authors reported that among the 7 cases of overdose occurring during clinical trials, there were no fatalities or permanent sequelae.

In a review of 1338 cases of nefazodone-only overdoses reported to the American Association of Poison Control Centres over a 2-year period, it was found that the majority of cases were either asymptomatic or mild in nature with symptoms such as nausea, vomiting, dizziness, and drowsiness.[3] More severe symptoms were noted in only 2 patients. In one case, an 11-year-old boy with a history of seizures suffered several seizures after starting nefazodone at a dose of 100 mg twice daily; the other case involved a 47-year-old man who developed premature ventricular contractions, bradycardia, agitation, and hypotension after an intentional overdose of an unknown quantity. No deaths were recorded in any of the cases where the outcome was known.

2. Catalano G, *et al.* Nefazodone overdose: a case report *Clin Neuropharmacol* 1999; **22:** 63–5.
3. Benson BE, *et al.* Toxicities and outcomes associated with nefazodone poisoning: an analysis of 1,338 exposures. *Am J Emerg Med* 2000; **18:** 587–92.

Precautions

Treatment with nefazodone should not generally be started in patients with active hepatic disease or elevated baseline serum transaminases. Patients who develop signs or symptoms of hepatic impairment such as jaundice, anorexia, abdominal pain, elevated transaminase levels, or malaise during treatment should be evaluated for hepatic damage and the drug withdrawn if necessary. Nefazodone is contra-indicated in patients previously withdrawn from the drug because of hepatotoxicity.

Nefazodone should be used with caution in patients with epilepsy, or a history of hypomania or mania. It should also be used with caution in cardiovascular or cerebrovascular disease that could be exacerbated by hypotension (for example recent history of myocardial infarction, unstable heart disease, angina, or ischaemic stroke), and in any condition such as dehydration or hypovolaemia that may predispose patients to hypotension.

Since nefazodone is structurally related to trazodone which is known to have caused priapism (see Effects on Sexual Function, p.425), US licensed product information recommends that any patient developing inappropriate or prolonged penile erections should stop nefazodone immediately.

Patients should be closely monitored during early antidepressant therapy until significant improvement in depression is observed because suicide is an inherent risk in depressed patients. For further details, see under Depression, p.373. Suicidal thoughts and behaviour may also develop during early treatment with antidepressants for other disorders; the same precautions observed when treating patients with depression should therefore be observed when treating patients with other disorders.

Nefazodone may impair performance of skilled tasks and, if affected, patients should not drive or operate machinery.

Antidepressants should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Breast feeding. A study[1] in 2 nursing mothers receiving nefazodone for postpartum depression indicated that nefazodone, but not its major active metabolites, was distributed into breast milk in variable amounts; the quantity present did not seem to be dose-related. The calculated exposure of the two women's offspring was 2.2% and 0.4% of the maternal dose respectively. Another report suggested that even such low exposures might result in clinically significant effects:[2] drowsiness, inability to maintain normal body temperature, and poor feeding were reported in the breast-fed infant of a woman receiving nefazodone. After breast feeding was stopped the symptoms resolved, suggesting an association between the two despite a calculated exposure in the infant of only 0.45% of the maternal dose.

1. Dodd S, *et al.* Nefazodone in the breast milk of nursing mothers: a report of two patients. *J Clin Psychopharmacol* 2000; **20:** 717–18.
2. Yapp P, *et al.* Drowsiness and poor feeding in a breast-fed infant: association with nefazodone and its metabolites. *Ann Pharmacother* 2000; **34:** 1269–72.

Children. US licensed product information considers that the safety and efficacy of nefazodone have not been established for the treatment of depression in adolescents and children. In addition, other antidepressants have been shown to increase the risk of suicidal thoughts and behaviour in these patients (see Effects on Mental State, under Fluoxetine, p.392).

Pregnancy. Licensed drug information states that nefazodone should only be used during pregnancy if the benefits to the mother outweigh the risks to the fetus.

In a multicentre study of 147 women who took either nefazodone or trazodone in at least the first trimester of pregnancy there were 121 live births, 20 spontaneous abortions, 6 therapeutic abortions, and 2 reports of major malformations (Hirschsprung disease and neural tube defect);[1] no still-births were recorded. There were no significant differences in pregnancy outcome in the nefazodone/trazodone group when compared to the 2 control groups (women with depression taking non-teratogenic antidepressants and women taking non-teratogenic drugs). The rate of spontaneous abortions was non-significantly higher in both the antidepressant groups than in the other control group. It was suggested that the rate of major malformations in all 3 groups was not greater than the baseline rate of 1 to 3%.

1. Einarson A, *et al.* A multicentre prospective controlled study to determine the safety of trazodone and nefazodone use during pregnancy. *Can J Psychiatry* 2003; **48:** 106–10.

Interactions

Nefazodone should not be given to patients receiving MAOIs or for at least 14 days after they are stopped; it has also been recommended that any drug liable to provoke a serious reaction (e.g. phenelzine) should not be given within one week of stopping nefazodone therapy. For further details on the combined use of antidepressants, see Antidepressants under Interactions of Phenelzine, p.418.

Orthostatic hypotension can be a problem with nefazodone, and therefore caution is required for any patient also on antihypertensive therapy.

Nefazodone is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 responsible for the metabolism of some benzodiazepines, and consequently it may produce clinically important increases in their plasma concentrations. Use with astemizole, cisapride, pimozide, and terfenadine (which are metabolised by the same isoenzyme) is best avoided because the potential also exists for increased plasma concentrations of these drugs, with the risk of inducing ventricular arrhythmias. Other substrates for this isoenzyme may also interact with nefazodone: atorvastatin, lovastatin, and simvastatin should be used with caution with nefazodone since there have been rare reports of rhabdomyolysis with such combinations. Increased serum concentrations of ciclosporin or tacrolimus, both substrates for CYP3A4, have been reported in patients also receiving nefazodone. Monitoring of serum ciclosporin or tacrolimus levels is recommended when either of these two drugs is given with nefazodone.

Plasma concentrations of digoxin are increased by nefazodone, and because of digoxin's narrow therapeutic index, plasma concentrations of digoxin should be monitored if use with nefazodone is necessary.

Caution should be exercised when haloperidol is given with nefazodone as the clearance of haloperidol may be reduced. Plasma concentrations of carbamazepine are also increased when used with nefazodone. More importantly, carbamazepine may reduce nefazodone plasma concentrations to subtherapeutic levels and therefore use together is not recommended. Giving buspirone with nefazodone significantly increases the serum concentrations of buspirone; the manufacturers of nefazodone recommend that the initial dose of buspirone is reduced if these drugs are given together.

The potential for interaction between nefazodone and general anaesthetics exists and the manufacturer recommends that nefazodone should be stopped before elective surgery for as long as clinically feasible.

Benzodiazepines. For further details of interactions between nefazodone and benzodiazepines, see Diazepam, p.990.

Pharmacokinetics

Nefazodone is readily absorbed from the gastrointestinal tract and peak plasma concentrations have been obtained within about 2 hours after oral doses. Absorption is delayed and reduced by food but this is not considered to be clinically significant. Nefazodone undergoes extensive first-pass metabolism and is more than 99% bound to plasma proteins; it is widely distributed. It is extensively metabolised by *N*-dealkylation and hydroxylation in the liver to several metabolites, two of which, hydroxynefazodone and *m*-chlorophenylpiperazine, are known to be pharmacologically active. Excretion is mainly as metabolites via the urine (about 55%) and the faeces (20 to 30%). The plasma elimination half-life is 2 to 4 hours. Pharmacokinetic parameters are reported to be non-linear with increasing doses. Nefazodone is distributed in small amounts into breast milk (see Breast Feeding, above).

◊ Reviews.

1. Greene DS, Barbhaiya RH. Clinical pharmacokinetics of nefazodone. *Clin Pharmacokinet* 1997; **33:** 260–75.

Uses and Administration

Nefazodone is a phenylpiperazine antidepressant structurally related to trazodone (see p.424). It blocks the reuptake of serotonin at presynaptic neurones and is an antagonist at postsynaptic 5-HT_2 receptors. Unlike trazodone, nefazodone inhibits the reuptake of noradrenaline. It blocks α_1-adrenoceptors but has no apparent effect on dopamine receptors. Nefazodone does not appear to have very significant antimuscarinic properties compared with tricyclic antidepressants.

Nefazodone hydrochloride has been given for the treatment of depression. One manufacturer (*Bristol-Myers Squibb*) has withdrawn nefazodone worldwide (see also Effects on the Liver, above); however, nefazodone remains available in the USA, and possibly some other countries, as a generic preparation. The usual initial oral dose is 100 mg twice daily increased if necessary, in increments of 100 to 200 mg at intervals of at least a week, to a maximum of 300 mg twice daily. Doses are restricted in elderly patients: a recommended initial dose is 50 mg twice daily.

Antidepressants should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Nefazodone has been tried in anxiety disorders, but other drugs may now be preferred.

Nortriptyline Hydrochloride

(BANM, USAN, rINNM)

38489; Hidrocloruro de nortriptilina; Nortriptilin-hidroklorid; Nortriptilino hidrochloridas; Nortriptyliinihydrokloridi; Nortriptyline, chlorhydrate de; Nortriptylin-hydrochlorid; Nortriptylinhydroklorid; Nortriptylini hydrochloridum; Nortryptyliny chlorowodorek. 3-(10,11-Dihydro-5*H*-dibenzo[*a,d*]cyclohepten-5-ylidene) propyl(methyl)amine hydrochloride.

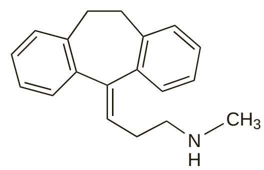
Нортриптилина Гидрохлорид

$C_{19}H_{21}N,HCl = 299.8.$

CAS — 72-69-5 (nortriptyline); 894-71-3 (nortriptyline hydrochloride).

ATC — N06AA10.

ATC Vet — QN06AA10.



(nortriptyline)

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Nortriptyline Hydrochloride). A white or almost white powder. Sparingly soluble in water; soluble in alcohol and in dichloromethane. Protect from light.

USP 31 (Nortriptyline Hydrochloride). A white to off-white powder having a slight characteristic odour. Soluble 1 in 90 of water, 1 in 30 of alcohol, 1 in 20 of chloroform, and 1 in 10 of methyl alcohol; practically insoluble in ether, in benzene, and in most other organic solvents. pH of a 1% solution in water is about 5. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for tricyclic antidepressants in general (see Amitriptyline, p.376).

Breast feeding. For comments on the use of tricyclic antidepressants in breast feeding patients, see under Precautions for Amitriptyline, p.378.

Effects on ventilation. Severe hyperventilation developed in a 61-year-old man with end-stage renal disease after receiving nortriptyline 125 mg daily;[1] mechanical ventilation was necessary to correct severe respiratory alkalosis.

1. Sunderrajan S, *et al.* Nortriptyline-induced severe hyperventilation. *Arch Intern Med* 1985; **145:** 746–7.

Porphyria. Nortriptyline is considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity.

Interactions

For interactions associated with tricyclic antidepressants, see Amitriptyline, p.379.

Pharmacokinetics

Nortriptyline is the principal active metabolite of amitriptyline (p.381). Nortriptyline has been reported to have a longer plasma half-life than amitriptyline. Nortriptyline is subject to extensive first-pass metabolism in the liver to 10-hydroxynortriptyline, which is active.

Metabolism. Individuals with a poor debrisoquine hydroxylation phenotype may be at greater risk of confusional states when taking nortriptyline.[1] This was thought to be because the polymorphic hydroxylation of debrisoquine and nortriptyline are mediated by similar enzymatic mechanisms [the cytochrome P450 isoenzyme CYP2D6], with poor oxidisers having higher plasma nortriptyline concentrations.[2,3] A nonlinear (dose-dependent) relationship between dose and plasma-nortriptyline concentrations has been observed during therapeutic drug monitoring[4] in subjects who were considered to be extensive metabolisers of debrisoquine; nonlinearity did not appear to occur in poor metabolisers. There was no significant correlation between hydroxylation phenotype and amitriptyline concentrations, suggesting that demethylation and hydroxylation of tricyclic antidepressants are mediated by different cytochrome P450 isoenzymes.[5]

The pharmacokinetics and pharmacological actions of 10-hydroxynortriptyline, the major active metabolite of nortriptyline, have been reviewed.[3]

5. Bertilsson L, *et al.* Metabolism of various drugs in subjects with different debrisoquine and sparteine oxidation phenotypes. *Br J Clin Pharmacol* 1982; **14:** 602P.

Therapeutic plasma concentrations. Nortriptyline appears to have an optimum antidepressant effect at plasma concentrations between 50 and 150 nanograms/mL. Outside this range, there is a poor clinical response. Plasma concentration measurements are unequivocally useful in problem patients who do not respond to usual oral doses or in high-risk patients for whom, because of age or medical illness, it is especially important to use the lowest possible effective dose of the drug.[1]

It has been suggested[2] that within this window of total nortriptyline concentrations there is a probability of an antidepressant response of 68% or more with free concentrations of 7 to 10 nanograms/mL.

For reference to dose-dependent kinetics of nortriptyline observed in individuals with an extensive debrisoquine hydroxylation phenotype, see under Metabolism, above.

Uses and Administration

Nortriptyline is a dibenzocycloheptadiene tricyclic antidepressant with actions and uses similar to those of amitriptyline (p.381). It is the principal active metabolite of amitriptyline. Nortriptyline is one of the less sedating tricyclics and its antimuscarinic effects are mild.

Nortriptyline is given orally as the hydrochloride although doses are expressed in terms of the base; nortriptyline hydrochloride 113.8 mg is equivalent to about 100 mg of nortriptyline. In the treatment of **depression** a low starting dose is given gradually increasing to the equivalent of 75 to 100 mg daily in 3 or 4 divided doses. Up to a maximum of 150 mg daily may be required in patients with severe depression. Licensed drug information recommends that plasma concentrations of nortriptyline should be monitored when doses above 100 mg daily are given; however, the *BNF* considers that the evidence of any practical value is uncertain. Adolescents and the elderly may be given 30 to 50 mg daily in divided doses. Since nortriptyline has a prolonged half-life, once-daily dosage regimens are also suitable, usually given at night.

Nortriptyline is also used for the treatment of **nocturnal enuresis** in children in whom organic pathology has been excluded. However, drug therapy for nocturnal enuresis should be reserved for those in whom other methods have failed and should preferably only be given to cover periods away from home; tricyclic antidepressants are not recommended in children under 6 years of age (the *BNF* recommends that they should not be given until 7 years of age). Suggested doses are:

- 10 mg for children aged 6 to 7 years (20 to 25 kg)
- 10 to 20 mg for children aged 8 to 11 years (25 to 35 kg)
- 25 to 35 mg for children aged over 11 years (35 to 54 kg)

The dose should be given 30 minutes before bedtime and treatment, including a period of gradual withdrawal, should not continue for longer than 3 months. A full physical examination is recommended before a further course.

Nortriptyline should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Pain. Antidepressants, usually amitriptyline or another tricyclic, are useful in alleviating some types of pain (see Choice of Analgesic, p.2). Nortriptyline has also been tried and may produce fewer adverse effects than amitriptyline. An initial oral dose of 10 to 25 mg at night has been suggested by the *BNF* for the management of **neuropathic pain**.

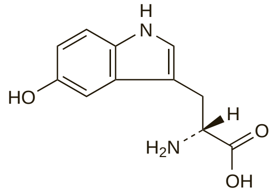
CAS — 4350-09-8 (oxitriptan); 56-69-9 (DL-5-hydroxytryptophan).
ATC — N06AX01.
ATC Vet — QN06AX01.



Profile

Oxitriptan is the L form of 5-hydroxytryptophan, a precursor of serotonin. Like tryptophan (p.427) it is used in the treatment of depression; it is given in oral doses of up to 600 mg daily.

Oxitriptan is also used in doses of up to 1 g daily in myoclonic disorders, especially posthypoxic myoclonus (p.470). It has also been used in neurological conditions including migraine, pain syndromes, and sleep disorders, and as an adjunct in epilepsy and parkinsonism.

DL-Oxitriptan has also been used as an antidepressant.

ATC — N06AB05.
ATC Vet — QN06AB05.

Adverse Effects, Treatment, and Precautions

As for SSRIs in general (see Fluoxetine, p.391).

Extrapyramidal reactions (including orofacial dystonias) and withdrawal symptoms associated with paroxetine have been reported to the UK CSM more commonly than with other SSRIs. For further details, see Extrapyramidal Effects under Adverse Effects of Fluoxetine, p.393 and Withdrawal under Precautions, p.396.

Breast feeding. For comments on the use of SSRIs in breast feeding patients, see under Precautions for Fluoxetine, p.394.

Children. SSRIs are associated with an increased risk of potentially suicidal behaviour when used for the treatment of depression in children and adolescents under 18 years old; for further details, see under Effects on Mental State in Fluoxetine, p.392.

Pregnancy. For discussion of the risks of SSRIs during pregnancy, and whether paroxetine is associated with a greater teratogenic risk than other SSRIs, see under Fluoxetine, p.395.

Interactions

For interactions associated with SSRIs, see Fluoxetine, p.396.

Pharmacokinetics

Paroxetine is readily absorbed from the gastrointestinal tract with peak plasma concentrations occurring within about 5 hours of ingestion. It undergoes extensive first-pass metabolism in the liver. The main metabolic pathway is oxidation followed by methylation and formation of glucuronide and sulfate conjugates. The cytochrome P450 isoenzyme CYP2D6 is partly responsible for the metabolism of paroxetine. Paroxetine is widely distributed throughout body tissues and is about 95% bound to plasma proteins. The elimination half-life of paroxetine is reported to be about 21 hours. Excretion is via the urine (about 64%) and the faeces (about 36%), mainly as metabolites in both cases. Paroxetine is distributed into breast milk (see Breast Feeding under Precautions in Fluoxetine, p.394).

Uses and Administration

Paroxetine, a phenylpiperidine derivative, is an SSRI with actions and uses similar to those of fluoxetine (p.397). It is given orally usually as paroxetine hydrochloride, as a single dose in the morning; it is also given as the mesilate. Doses are expressed in terms of the base; paroxetine hydrochloride 22.8 mg or paroxetine mesilate 25.8 mg are each equivalent to about 20 mg of paroxetine. The doses given below refer to preparations containing paroxetine hydrochloride; similar doses are also used when paroxetine is given as the mesilate.

In the treatment of **depression**, the usual dose of paroxetine is 20 mg daily, increased gradually, if necessary, in weekly increments of 10 mg to a maximum of 50 mg daily (but see Administration, below).

In the treatment of **generalised anxiety disorder**, the initial dose is 20 mg daily; further increases in increments of 10 mg at intervals of at least one week to a maximum of 50 mg have been given (but see Administration, below).

The initial dose in **obsessive-compulsive disorder** is 20 mg daily increased weekly in 10-mg increments to a usual maintenance dose of 40 mg daily; some patients may require up to 60 mg daily (but see Administration, below).

In the treatment of **panic disorder** with or without agoraphobia, the initial dose is 10 mg daily increased weekly in 10-mg increments according to response; the usual recommended maintenance dose is 40 mg daily, although some patients may benefit from 60 mg daily (but see Administration, below).

The recommended starting dose for the treatment of **post-traumatic stress disorder** is 20 mg daily. If necessary this may be increased in increments of 10 mg at intervals of at least one week to a maximum of 50 mg daily (but see Administration, below).

The initial dose for the treatment of **social anxiety disorder** is 20 mg daily increased after several weeks, if necessary, by increments of 10 mg to a maximum of 50 or 60 mg daily (but see Administration, below).

A suggested maximum daily dose in elderly or debilitated patients is 40 mg; US licensed product information also recommends a starting dose of 10 mg daily in such patients. Reduced doses should be given to patients with hepatic or renal impairment, see below.

A modified-release preparation (as the hydrochloride) is also available in the USA for the treatment of depression, panic disorder, and social anxiety disorder; the maximum doses with this preparation may be slightly greater than those recommended with the immediate-release preparation. The modified-release preparation may also be used in the treatment of **premenstrual dysphoric disorder**. The initial dose is 12.5 mg once daily, usually in the morning, which may be increased to 25 mg once daily, if necessary, after an interval of at least one week. Treatment may be given throughout the menstrual cycle or limited to the luteal phase.

Paroxetine should be withdrawn gradually to reduce the risk of withdrawal symptoms. For further details, see Withdrawal under Precautions of Fluoxetine, p.396.

◊ Reviews.

1. Wagstaff AJ, *et al.* Paroxetine: an update of its use in psychiatric disorders in adults. *Drugs* 2002; **62:** 655–703. Correction. *ibid.*; 1461.

Administration. Although paroxetine is licensed in the UK at higher doses the UK CSM considers that there is a lack of evidence from clinical trials of additional efficacy with paroxetine when given above the following daily doses:

- depression, generalised anxiety disorder, social anxiety disorder, post-traumatic stress disorder: 20 mg
- obsessive-compulsive disorder, panic disorder: 40 mg

1. CSM/MCA Paroxetine prescribing advice. *Current Problems* 2004; **30:** 3. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON007448&RevisionSelectionMethod= LatestReleased (accessed 14/08/08)

Administration in hepatic or renal impairment. In the USA the recommended initial oral dose of paroxetine in patients with severe renal or hepatic impairment is the equivalent of 10 mg daily, increased to a maximum of 40 mg daily as necessary. UK licensed drug information recommends that doses in such patients are limited to the lower end of the range.

Anxiety disorders. Paroxetine is used in anxiety disorders including generalised anxiety disorder (p.952), obsessive-compulsive disorder (p.952), panic disorder (p.952), post-traumatic stress disorder (p.953), and social anxiety disorder (see under Phobic Disorders, p.953). It has also been tried for adult night terrors (see under Sleep-associated Movement Disorders, p.958).

16. Rickels K, *et al.* Remission of generalized anxiety disorder: a review of the paroxetine clinical trials database. *J Clin Psychiatry* 2006; **67:** 41–7.

Depression. As discussed on p.373, there is very little difference in efficacy between the different groups of antidepressant drugs, and choice is often made on the basis of adverse effect profile. SSRIs such as paroxetine are widely used as an alternative to the older tricyclics as they have fewer adverse effects and are safer in overdosage.

Phenelzine Sulfate *(pINNM)*

Phénelzine, Sulfate de; Phenelzine Sulphate *(BANM)*; Phenelzini Sulfas; Sulfato de fenelzina. Phenethylhydrazine hydrogen sulphate.

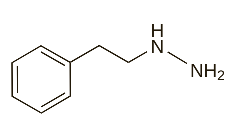
Фенельзина Сульфат

$C_8H_{12}N_2,H_2SO_4 = 234.3.$

CAS — 51-71-8 (phenelzine); 156-51-4 (phenelzine sulfate).

ATC — N06AF03.

ATC Vet — QN06AF03.



(phenelzine)

Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Phenelzine Sulphate). A white powder or pearly platelets with a pungent odour. Freely soluble in water; practically insoluble in alcohol, in chloroform, and in ether. Protect from light.

USP 31 (Phenelzine Sulfate). A white to yellowish-white powder having a characteristic odour. Freely soluble in water; practically insoluble in alcohol, in chloroform, and in ether. pH of a 1% solution in water is between 1.4 and 1.9. Store in airtight containers. Protect from heat and light.

Adverse Effects

Adverse effects commonly associated with phenelzine and other MAOIs include orthostatic hypotension and attacks of dizziness. Other common adverse effects include headache, dry mouth, constipation and other gastrointestinal disturbances (including nausea and vomiting), and oedema. Drowsiness, weakness, and fatigue are reported frequently although CNS stimulation may also occur and symptoms include agitation, nervousness, euphoria, restlessness, insomnia, and convulsions. Psychotic episodes, with hypomania or mania, confusion, hallucinations, or toxic delirium, may be induced in susceptible persons.

Sweating and muscle tremors, twitching, or hyperreflexia may occur, which in overdosage may present as extreme hyperpyrexia and neuromuscular irritability. Other reported reactions include blurred vision, nystagmus, urinary retention or difficulty in micturition, arrhythmias, skin rashes, leucopenia, sexual disturbances, and weight gain with inappropriate appetite. Jaundice has been reported with hydrazine MAOIs and, on rare occasions, fatal progressive hepatocellular necrosis. Peripheral neuropathies associated with the hydrazine derivatives may be caused by pyridoxine deficiency. Hyponatraemia, possibly due to inappropriate secretion of antidiuretic hormone, has been associated with the use of antidepressants, particularly in the elderly.

Symptoms of **overdosage** may be minor at first and progress over the ensuing 24 to 48 hours. After mild overdosage and symptomatic and supportive therapy, recovery may occur in 3 to 4 days, but after massive overdosage symptoms may persist for up to 2 weeks. CNS depression and drowsiness have been observed with overdosage, but CNS stimulation is more common, with irritability, hyperactivity, agitation, hallucinations, or convulsions. Respiratory depression and coma may ultimately occur. Cardiovascular effects include hypertension, sometimes with severe headache, although hypotension is more frequently observed; cardiac arrhythmias and peripheral collapse can also develop. Profuse sweating, hyperpyrexia, and neuromuscular excitation with hyperreflexia are also prominent features of overdosage.

MAOIs have been the most commonly implicated drugs in the serotonin syndrome (see below). A severe hypertensive crisis, sometimes fatal, may occur if an MAOI is taken with some other drugs or certain foods (see Interactions, below). These reactions are characterised by severe headache and a rapid and sometimes prolonged rise in blood pressure followed by intracranial haemorrhage or acute cardiac failure.

For the adverse effects of reversible inhibitors of monoamine oxidase type A (RIMAs), see Moclobemide, p.411.

Incidence of adverse effects. A suspicion that the reported adverse effects of MAOIs were both exaggerated and overemphasised prompted a comparative study in patients receiving phenelzine or imipramine.[1] The report noted that the dosages of phenelzine used were at the upper end of the usual therapeutic range (mean 77 mg daily) while those of imipramine were in the middle of the usual therapeutic range (mean 139 mg daily). A very similar profile of adverse effects in the two groups was observed. With the exception of significantly increased incidence of drowsiness in the phenelzine-treated group, the 2 groups did not differ in the frequency of autonomic, CNS, cardiovascular, or psychological adverse effects. However, a significantly greater number of phenelzine-treated patients had to stop their treatment because of the severity of the adverse effects. Nonetheless it was considered that phenelzine was reasonably well-tolerated when compared with imipramine.

Others have also studied the adverse effect profile of phenelzine and made comparisons with tranylcypromine and imipramine.[2,3] A retrospective review involving 198 patients concluded that although phenelzine was more likely than the other two drugs to induce adverse effects, drug withdrawal because of adverse effects was less likely to occur. This was probably because phenelzine showed clear-cut clinical efficacy resulting in prescribers being reluctant to stop therapy.

Effects on the cardiovascular system. MAOIs are generally considered to be relatively free of adverse cardiovascular effects. The hypertensive reaction that may follow interactions of MAOIs with foods or other drugs is well known (see Interactions, below) but orthostatic hypotension may also occur when these drugs are used on their own.

In a study[1] involving 14 patients it was found that phenelzine produced both a significant decrease in systolic blood pressure while lying down, and significant orthostatic hypotension; in 2 patients these effects on blood pressure meant treatment had to be altered. Differences between the effects of phenelzine and those reported for the tricyclic antidepressants were noted. Tricyclics were not known to affect lying systolic blood pressure and although both tricyclics and phenelzine could cause orthostatic hypotension, with the tricyclics it typically reaches a maximum within the first week of treatment whereas with phenelzine the maximum effect was noted after 4 weeks. Additionally, the study provided some indication that the blood pressure effects of phenelzine may attenuate with time, a phenomenon that is not known to occur with the tricyclics.

1. Kronig MH, *et al.* Blood pressure effects of phenelzine. *J Clin Psychopharmacol* 1983; **3:** 307–10.

Effects on the endocrine system. MAOIs may induce *hyperprolactinaemia*[1] and this has led to galactorrhoea in women.[2] Occasionally, MAOIs may cause *dilutional hyponatraemia* due to a reduction in the renal excretion of free water mediated by both enhanced vasopressin release and increased antidiuretic action on the renal tubule.[3] The UK CSM, commenting on reports[4] it had received of hyponatraemia with antidepressants (fluoxetine, paroxetine, lofepramine, clomipramine, and imipramine), considered that it was likely to occur with any antidepressant and usually involved elderly patients.

Effects on the liver. Published case reports of hepatotoxic reactions to MAOIs have included jaundice in 4 patients[1] and hepatic failure progressing to encephalopathy in 2 patients;[2] this latter reaction was attributed to a hypersensitivity reaction.

Of 91 cases of hepatitis associated with antidepressants reported to French pharmacovigilance centres from 1977 to 1983, an MAOI (iproniazid) was implicated in 11. These 11 cases were associated with cytolytic reactions and 5 patients died.[3]

Two cases of fulminant hepatic failure have been reported[4] after use of phenelzine for 4 months; all other causes of acute liver damage were ruled out. Both patients recovered after emergency liver transplantation.

4. Gómez-Gil E, *et al.* Phenelzine-induced fulminant hepatic failure. *Ann Intern Med* 1996; **124:** 692–3.

Effects on the nervous system. MAOIs produce a variety of effects on the nervous system. Drowsiness is frequently reported but symptoms of CNS stimulation, including agitation, nervousness, and euphoria may also occur; psychotic episodes may be induced in susceptible individuals. Further adverse neurological reactions are described under Epileptogenic Effect and Extrapyramidal Effects, below.

Peripheral neuropathies, sometimes associated with a documented pyridoxine deficiency, have been reported in patients receiving phenelzine.[1,2] In most of the patients the neuropathies developed 6 weeks to 4 months after starting phenelzine,[2] although in one case symptoms did not occur for 11 years.[1] The symptoms also generally disappeared when pyridoxine was given with continued phenelzine therapy.[2] The possibility that the dietary restrictions imposed on persons taking phenelzine might have contributed to a low pyridoxine intake was considered unlikely. The most probable mechanism for the induced pyridoxine deficiency was combination of the hydrazine moiety with the pyridoxal form of the vitamin to form an inactive compound.

Many drugs can inhibit transmission at the myoneural junction under experimental conditions and it has been said that phenelzine may cause postoperative respiratory depression, possibly through a combined action with neuromuscular blockers.[3] For further details, see Anaesthesia under Precautions, below.

Effects on sexual function. MAOIs such as phenelzine and tranylcypromine have been implicated in producing both impotence and failure of ejaculation.[1,2] Priapism has been reported with phenelzine.[3] There have also been several reports of female anorgasmia attributed to MAOIs, an effect which appears to be dose-related.[4] Loss of libido and impotence are common symptoms of depression, often making the role of drugs in producing sexual dysfunction difficult to assess.

Epileptogenic effect. Licensed product information indicates that convulsions represent one of the less common adverse effects of MAOIs; they may be a feature of overdosage.

A typical grand-mal seizure with tonic-clonic convulsions has been reported in a patient with no history of epilepsy or predisposing factors shortly after the start of phenelzine therapy.[1] The point was made that phenelzine-induced seizures had rarely been observed.

1. Bhugra DK, Kaye N. Phenelzine induced grand mal seizure. *Br J Clin Pract* 1986; **40:** 173–4.

Extrapyramidal effects. A parkinsonian syndrome developed in a patient about 5 weeks after the start of therapy with phenelzine. Symptoms gradually resolved over 10 days after the withdrawal of phenelzine. The mechanisms by which phenelzine could have induced these effects were discussed.[1]

Hyponatraemia. See Effects on the Endocrine System, above.

Lupus. A reversible lupus-like reaction has been reported in a patient who had been taking phenelzine sulfate for 8 months.[1]

1. Swartz C. Lupus-like reaction to phenelzine. *JAMA* 1978; **239:** 2693.

Overdosage. MAOIs in overdose rarely produce severe hypertension; the blood pressure may be high or low, or may alternate between the two. More commonly the patient gradually develops widespread muscle spasms, trismus, and opisthotonus with widely dilated pupils and a hot and sweating skin. About 16 to 24 hours after ingestion potentially fatal hyperthermia may develop; temperatures of 42.1 to 43.8° have been recorded immediately before death. Disseminated intravascular coagulation, rhabdomyolysis, and acute tubular necrosis can also occur.[1]

1. Henry JA. Specific problems of drug intoxication. *Br J Anaesth* 1986; **58:** 223–33.

Serotonin syndrome. The serotonin syndrome is a drug-induced excess in serotonergic activity at central receptors.[1-10] It is characterised by the development of *at least three* of the following clinical features after a recent change in a treatment regimen involving serotonergic drugs:[1]

- agitation
- ataxia
- diaphoresis
- diarrhoea
- fever
- hyperreflexia
- myoclonus
- shivering
- changes in mental status

Strict application of these criteria may not identify early, mild, or subacute cases of serotonin syndrome and a simpler diagnostic approach focusing on neuromuscular features has also been suggested.[10] The syndrome should be distinguished from the hypertensive crises produced by the interaction between MAOIs and tyramine (see Interactions of MAOIs with Foods, below), and from the neuroleptic malignant syndrome (see p.972).[3,8-10]

The onset of the syndrome is often within minutes of altering the regimen,[10] although some cases have occurred as much as several weeks later.[2] The occurrence and severity of the syndrome do not appear to be dose-related,[2] but to depend on the extent and duration of the rise in intrasynaptic serotonin.[5]

The serotonin syndrome is relatively uncommon and symptoms are usually mild. However, severe complications, including disseminated intravascular coagulation, severe hyperthermia, respiratory failure, and seizures have been reported; there have also been fatalities.

The serotonin syndrome may follow exposure to a single serotonergic drug or, more commonly, a combination of such drugs.[2,8-10] In the past, **MAOIs** have been the most commonly implicated drugs in this syndrome, particularly when taken with other antidepressants such as the tricyclics, SSRIs, serotonin and noradrenaline reuptake inhibitors (SNRIs) including venlafaxine, trazodone, lithium, and tryptophan. (The use of combination therapy with serotonergic antidepressant drugs is discussed under Interactions of MAOIs with other Drugs, below.) MAOIs combined with the opioids dextromethorphan and pethidine have also produced the serotonin syndrome. The interaction can occur with both irreversible and reversible MAOIs, and with those selective for monoamine oxidase type A such as moclobemide as well as with non-selective MAOIs.[11] The selective inhibitor of monoamine oxidase type B, selegiline, may also pose problems at high doses as its selectivity starts to diminish.

As usage of the **SSRIs** has increased, so too has the number of reports of adverse reactions when these drugs have been combined with other serotonergic drugs, including the herbal preparation St John's wort.

Other drugs that may potentially cause serotonin syndrome in certain circumstances include antiemetics such as ondansetron, buspirone, carbamazepine, dihydroergotamine, methylenedioxyamfetamine, sibutramine, selective serotonin (5-HT_1) agonists such as sumatriptan, and tramadol.[5,8-10]

Serotonergic potentiation may also occur if one serotonergic drug is used after another without allowing a sufficient **drug-free interval** after stopping the first. This is a particular problem when the first drug is an irreversible MAOI or a drug with a long half-life such as the SSRI fluoxetine.

Most cases of serotonin syndrome resolve within 24 hours after withdrawal of the offending drugs and giving supportive **therapy**,[1-4,8-10] including appropriate management of fever and hyperthermia (p.10). Benzodiazepines may be of value to control agitation, myoclonus, and seizures. The non-specific serotonin antagonist cyproheptadine may be useful in more severe cases although its efficacy has not been established;[8,10] methysergide has also been used with some success.[2,3,6] Other drugs that have been tried include propranolol, chlorpromazine, and dantrolene[2,3,6,8-10] although adverse effects may limit their usefulness.

Treatment of Adverse Effects

In cases of overdosage with MAOIs the benefit of gastric decontamination is uncertain; however, in patients who present within 1 hour activated charcoal may be given by mouth, or, in potentially life-threatening cases, the stomach may be emptied by lavage. Management then largely involves intensive symptomatic and supportive therapy with particular attention being given to CNS effects, raised body temperature (which may develop into malignant hyperthermia), and cardiovascular effects. Delayed effects may develop some time after the overdose even in patients who are initially asymptomatic, and therefore prolonged monitoring is warranted. Other drugs taken with an overdose of MAOIs may complicate the features and result in the need for an even longer period of monitoring. Special care should be observed with any drug therapy used in the management of MAOI overdosage in view of the many known interactions which occur with this class of drugs.

Muscle spasm, agitation, and convulsions should be treated with diazepam. Severe neuromuscular irritability may call for the use of a competitive neuromuscular blocker such as pancuronium and intubation with assisted ventilation. Hyperthermia may be a particular problem; if simple antipyretics such as paracetamol and external cooling measures fail a competitive neuromuscular blocker has often been advocated; dantrolene has also been suggested.

Hypotension, which is a fairly common feature, should be managed by intravenous fluid therapy and volume expansion; vasopressors should be avoided. Conversely, a hypertensive crisis may occasionally occur after an overdose with MAOIs and can be managed with phentolamine given by slow intravenous injection. A short-acting beta blocker such as esmolol or metoprolol has also been advocated for persistent tachycardia and hypertension.

Precautions

Phenelzine and other MAOIs should not be given to patients with liver disease or a history of abnormal liver function tests, or, because of their effects on blood pressure, to patients with congestive heart failure, cerebrovascular disease, or phaeochromocytoma. (Blood pressure should be monitored in all patients.) MAOIs should be avoided or only used with great caution in patients with blood disorders or cardiovascular disease, and in elderly or agitated patients who may be particularly susceptible to their adverse effects. They should be given with caution to epileptic patients. Caution has also been advised in diabetic patients because of conflicting evidence whether glucose metabolism is altered or requirements for hypoglycaemics changed. MAOIs should be used with caution in patients with hyperthyroidism because of increased sensitivity to pressor amines.

Patients should be closely monitored during early antidepressant therapy until significant improvement in depression is observed because suicide is an inherent risk in depressed patients. For further details, see under Depression, p.373. Suicidal thoughts and behaviour may also develop during early treatment with antidepressants for other disorders; the same precautions observed when treating patients with depression should therefore be observed when treating patients with other disorders.

Mania may be precipitated if MAOIs are used for the depressive component of bipolar disorder, and they are not usually indicated; similarly psychotic symptoms may be aggravated if they are used for a depressive component of schizophrenia.

MAOIs have a prolonged action so patients should not take any of the foods or drugs known to cause reactions (see Interactions, below) for at least 14 days after stopping treatment. A similar drug-free period has been advised before any patient undergoes surgery since it may involve the use of drugs that can interact with MAOIs, although not all agree that this is necessary; caution has been advised in patients requiring MAOIs with ECT; for further details see under Anaesthesia, below. Patients should carry cards giving details of their MAOI therapy; they and their relatives should be fully conversant with the implications of food and drug interactions and the precautions to be taken.

Patients liable to take charge of vehicles or other machinery should be warned that MAOIs may modify behaviour and state of alertness. Patients affected by drowsiness should not drive or operate machinery.

MAOIs should be withdrawn gradually to reduce the risk of withdrawal symptoms (see below).

For the precautions to be observed with reversible inhibitors of monoamine oxidase A (RIMAs), see Moclobemide, p.411.

Anaesthesia. The considerations given to patients receiving tricyclic antidepressants before receiving anaesthesia for ECT or surgery (see Amitriptyline, p.378) are also generally applicable to patients being treated with MAOIs; licensed drug information for phenelzine also warns that transient respiratory and cardiovascular depression following ECT have been reported. The interactions of other drugs with MAOIs may be more numerous or more severe than those with tricyclics and the interaction with pethidine should not be forgotten.

A review[1] of the potential problems of anaesthesia in patients receiving MAOIs considered that stopping MAOIs about 2 weeks before anaesthesia was unreasonable, as there was a wide range of safe and suitable anaesthetics available, although the dangers of sympathetic overactivity must always be remembered. This view, that it is safe to continue MAOIs throughout the period of anaesthesia, ECT, and surgery, is also held by others[2-4] although some disagree.[5]

Regardless of any decision, the anaesthetist should be informed of all drugs that the patient is or has been taking; this is particularly important when emergency surgery is required in a patient receiving MAOI therapy.

- It has been stated[1] that the interaction between MAOIs and *opioid analgesics* has two distinct forms: an excitatory form [serotonin syndrome—see above]; and a depressive form consisting of respiratory depression, hypotension, and coma as a result of the inhibition of hepatic microsomal enzymes by the MAOI leading to accumulation of free opioid analgesic. *Pethidine* use during anaesthesia has elicited the excitatory response, which has frequently been severe and often fatal. For this reason, pethidine should never be given to patients receiving MAOIs. *Morphine* does not block neuronal serotonin uptake but its narcotic effects may be potentiated in the presence of MAOIs and a single case report of the depressive type of reaction has been described. Thus, morphine is the opioid analgesic of choice but must be given in reduced dosage and the dosage carefully titrated against clinical response. *Papaveretum* would appear to have no advantage over morphine. Although interactions of MAOIs with *pentazocine* have occurred in *animals*, it is not clear if this occurs in man. *Methadone* has been used in a patient without mishap and there is also anecdotal evidence to support the safety of *fentanyl*. A case report[6] described the successful use of *alfentanil* (with propofol and atracurium) mentioning that this was the first report of such use in patients receiving MAOIs. A further case report[7] has also described the safe use of alfentanil (with propofol and suxamethonium) for anaesthesia during ECT in 2 patients taking phenelzine. *Remifentanil* has also been used safely as part of an anaesthetic regimen (with sevoflurane, vecuronium, and isoflurane) in a patient also taking phenelzine.[8] In another case[9] a patient underwent successful anaesthesia with *sufentanil* (with thiopental, lidocaine, and vecuronium) while continuing to take an MAOI (tranylcypromine) as well as a tricyclic antidepressant (imipramine) and lorazepam.
- With regard to induction agents,[1] the use of *ketamine* in patients receiving MAOIs should be avoided on theoretical grounds, although no interactions have been reported. Potentiation of *barbiturates* may be expected.
- With neuromuscular blockers, phenelzine has been shown to decrease plasma cholinesterase concentrations and there have been case reports of a prolonged effect with *suxamethonium*; additionally this prolongation of the effect of suxamethonium may lead to apnoea and modification of the convulsion during ECT. However, a small case series of 4 patients taking tranylcypromine while undergoing ECT treatment (with suxamethonium as the neuromuscular blocker) found no difference in seizure length when compared to previous ECT courses when the patients were not taking an MAOI.[4] There may be a theoretical hazard with *pancuronium* since it releases stored adrenaline (although its use has been advocated in the treatment of symptoms of overdosage with MAOIs, see above), but *alcuronium*, *atracurium*, or *vecuronium* would all appear to be suitable alternatives.[1]
- *Enflurane*, *halothane*, *isoflurane*, and *nitrous oxide* are all safe in the presence of MAOIs, although there is a theoretical possibility of an increased risk of hepatic damage with halothane.
- *Indirect-acting sympathomimetics* pose the risk of a serious and possibly lethal hypertensive interaction but *direct-acting sympathomimetics*, such as *adrenaline*, *isoprenaline*, and *noradrenaline*, are reliable vasopressors in the presence of MAOIs although great care should be taken with their use because of enhanced receptor sensitivity.

Children. Phenelzine is not recommended for the treatment of depression in children and adolescents less than 16 years of age. In addition, other antidepressants have been shown to increase the risk of suicidal thoughts and behaviour in such patients (see Effects on Mental State, under Fluoxetine, p.392).

Driving. While affective disorders probably impair driving skill,[1,2] treatment with antidepressant drugs may also be hazardous,[1] although patients may be safer drivers with medication than without.[2] Impairment of performance is largely related to sedative properties and some MAOIs can adversely affect psychomotor performance.[1,2]

In the UK, the Driver and Vehicle Licensing Authority (DVLA) considers that all drugs acting on the CNS can impair alertness, concentration, and driving performance, particularly at the start of treatment or when the dose is increased;[3] driving must cease if patients are adversely affected. Patients with severe depressive illnesses complicated by significant memory or concentration problems, agitation, behavioural disturbances or suicidal thoughts should cease driving pending the outcome of medical enquiry.

ECT. For comments concerning the precautions to be observed in patients receiving ECT, see under Anaesthesia, above.

Porphyria. Phenelzine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Surgery. For comments regarding the precautions to be observed in patients undergoing surgery, see under Anaesthesia, above.

Withdrawal. Suddenly stopping antidepressant therapy after regular use for 8 weeks or more can precipitate withdrawal symptoms which may be very severe.

Symptoms associated with withdrawal of MAOIs[1,2] include gastrointestinal disturbances and generalised somatic symptoms such as nausea and vomiting, anorexia, chills, headache, and giddiness; sleep disturbances characterised by insomnia, severe nightmares, and somnolence; and a range of CNS symptoms including panic, anxiety, restlessness, agitation, cognitive impairment, mood swings, depression and suicidal ideation, hypomania, delusions, and hallucinations. Some of the above may be controlled by restarting the MAOI in low doses, but the best management is considered to be prevention by gradually stopping the drug.[2] The *BNF* recommends reducing the dose over a period of 4 weeks, or as much as 6 months in patients who have been receiving long-term maintenance therapy.

The pathophysiology of the MAOI withdrawal syndrome is not fully known, although it has been hypothesised that some of the symptoms represent adrenergic hyperactivity[1] produced by the release of excessive amounts of dopamine and noradrenaline.[2]

With the exception of tranylcypromine, the withdrawal syndrome of MAOIs is not a consequence of drug dependence.[1] Tranylcypromine has been reported to produce dependence and tolerance in patients receiving high doses irrespective of whether or not they had a history of substance abuse. Tranylcypromine is similar in structure to amfetamine, which may be responsible for its addictive properties.[1]

Interactions of MAOIs with Foods

A major disadvantage of MAOIs such as phenelzine is that by inhibiting monoamine oxidase they cause an accumulation of amine neurotransmitters. This means that the pressor effects of *tyramine*, which occurs in a number of common foods and is also metabolised by monoamine oxidase, can be dangerously enhanced. Reactions to foods rich in pressor amines such as tyramine can therefore occur in patients being treated with MAOIs, producing hypertensive crises. Cheese, especially aged or matured cheeses, meat or yeast extracts, pickled herrings, sauerkraut, dry sausage, smoked foods, and broad bean pods have caused such reactions. Patients should be warned not to eat any of these foods while being treated with an MAOI and for at least 14 days after its discontinuation. Some foods will only cause a reaction if large amounts are eaten, and foods may vary in tyramine content depending upon methods of manufacture and storage. Any protein-containing food such as meat, fish, or game subject to hydrolysis, fermentation, pickling, smoking, or spoilage could contain tyramine derived from tyrosine as a result of these processes or of deterioration. Patients taking MAOIs should therefore be advised to eat protein-containing foods only if fresh.

Alcoholic beverages, including wines, beers, and drinks that are de-alcoholised or are low in alcohol, contain variable amounts of tyramine and are best avoided.

The above dietary restrictions that need to be observed with MAOIs may be less stringent for reversible inhibitors of monoamine oxidase type A (RIMAs) such as moclobemide (see p.411), although licensed drug information recommends that since some patients may be especially sensitive to tyramine, consumption of large amounts of tyramine-rich food should be avoided.

◊ MAOIs can, when taken with certain foodstuffs, cause a potentially fatal hypertensive reaction. This effect is accepted and well documented and has led to the publication of many lists of prohibited foods and drinks. Some workers consider that the dangers of the interaction may have been slightly overemphasised or exaggerated and that the published lists may have been overinclusive;[1-3] this may have led to reduced compliance in a number of patients.

A review and discussion[1] of the MAOI interaction with tyramine made the following observations and recommendations:

- the hyperadrenergic state resulting from this interaction consisted of three syndromes although significant overlap between them existed: paroxysmal headache of great severity; cardiovascular symptoms with paroxysmal hypertension; and intracerebral haemorrhage and death
- the most common offending drug reported had been tranylcypromine at doses of 20 to 50 mg daily although a few reports had involved phenelzine
- only 4 foodstuffs clearly warranted total prohibition: aged cheese, pickled herring or fish, concentrated yeast extracts, and broad bean pods
- the ingestion of cheese was said to have been associated with 80% of all case reports and with virtually all fatalities. It was agreed that aged cheese should not be permitted, although cottage and cream cheese required no restriction. There was less agreement concerning dairy products such as yogurt and sour cream and it was suggested that limited amounts were permissible
- pickled herring or smoked fish were to be avoided because of several well-documented cases of hypertensive crisis as well as detection of high levels of tyramine. Any meat may become dangerous unless consumed while fresh as tyramine is formed from bacterial protein degradation
- concentrated yeast extracts have a significant tyramine content and yeast vitamin supplements may also constitute a hazard; baker's yeast was considered to be safe
- broad bean pods contain dopamine although the beans themselves were stated to have little pressor activity and carried no prohibition
- other foods which had been reported to have caused a hypertensive reaction but for which these authors considered that there was insufficient evidence to warrant dietary restriction were chocolate and caffeine-containing beverages, soy sauce, fresh fish, wild game, and fruits although caution was necessary with avocados and bananas.

Other reviews of foods[2,4,5] give broadly similar recommendations.

The consumption of alcoholic beverages, and in particular Chianti wine, has frequently been advised against. However, sources have differed on whether particular types of drink (white wine, red wine, spirits, or beer) are safe or not. A study[6] demonstrated no significant differences in mean free tyramine concentration between white wine, red wine, Chianti, and beer although within each category of wine there could be up to a fiftyfold variation even if from the same grape stock. Mention has also been made[7,8] that alcohol-free or low-alcohol beers are likely to contain similar amounts of tyramine to alcoholic beers. The consumption of alcoholic drinks with MAOIs still appears to be controversial with some advocating total abstinence while others permit a modest intake.

Interactions of MAOIs with other Drugs

MAOIs inhibit the metabolism of some *amine drugs* (notably indirect-acting sympathomimetics), which can lead to dangerous enhancement of their pressor effects. MAOIs also inhibit other drug-metabolising enzymes and are therefore responsible for a large number of *other drug interactions*. Moreover, they have an additive effect with serotonergic drugs which may result in the *serotonin syndrome* (see under Adverse Effects, above). As in the case of foods, the danger of an interaction persists for at least 14 days after treatment with an MAOI has been stopped.

Severe hypertensive reactions due to enhancement of pressor activity have followed the use of sympathomimetics such as *amfetamines*, *dopamine*, *ephedrine*, *levodopa*, *phenylephrine*, *phenylpropanolamine*, and *pseudoephedrine*. Reactions may also follow the use of anorectics and stimulants with sympathomimetic activity such as *fenfluramine*, *methylphenidate*, *pemoline*, and *phentermine*. There have been case reports of fatalities in patients who took cough preparations containing *dextromethorphan*. There is no clinical evidence of dangerous interactions between *local anaesthetic preparations containing adrenaline* and MAOIs although they could occur if the preparation was accidentally given into a vein. Significant rises in blood pressure have been reported after the use of *buspirone* with MAOIs.

Inhibition of drug-metabolising enzymes by MAOIs may enhance the effects of *barbiturates* and possibly other *hypnotics*, *hypoglycaemics*, and possibly *antimuscarinics*. *Alcohol* metabolism may be altered and its effects enhanced; see also under Interactions of MAOIs with Foods, above. Licensed drug information suggests that the effects of various classes of *antihypertensives* may be enhanced by MAOIs, including *ACE inhibitors*, *beta blockers*, *calcium-channel blockers* and *thiazides*, with the potential for hypotension, although published evidence for most of these seems to be scanty. Some antihypertensives with direct actions on the sympathetic nervous system, such as *guanethidine*, *indoramin*, *methyldopa*, and, historically, *reserpine*, are suggested to be contra-indicated or used with great caution; both hypotensive and hypertensive reactions have been suggested.

Giving *pethidine* and possibly other *opioid analgesics* to patients taking an MAOI has also been associated with very severe and sometimes fatal reactions. When it is considered essential to use an opioid analgesic a test dose of morphine should be given. It has been suggested that the test dose should be one-tenth to one-fifth of the normal dose and if this produces no untoward reaction, the dose of morphine can be gradually and carefully increased over a period of 2 to 3 hours. The use of opioid analgesics and other drugs used during general anaesthesia in patients continuing to take MAOIs is discussed in Anaesthesia under Precautions, above.

Clozapine may enhance the CNS effects of MAOIs.

Although different antidepressants have been used together under expert supervision in refractory cases of depression, severe adverse reactions may occur. MAOIs should not generally be given to patients receiving *tricyclic antidepressants*, *SSRIs*, *serotonin and noradrenaline reuptake inhibitors (SNRIs)*, *bupropion*, *mirtazapine*, *nefazodone*, *reboxetine*, or *trazodone*. An appropriate drug-free interval should elapse between stopping one type of antidepressant and starting another. An MAOI should not be started until at least 1 or 2 weeks after stopping a tricyclic antidepressant. For the tricyclic antidepressants clomipramine and imipramine a drug-free interval of 3 weeks should be allowed. For an SSRI, an SNRI, reboxetine, nefazodone, trazodone, or any related antidepressant the drug-free interval should be at least one week; in the case of bupropion, mirtazapine, and the SSRI sertraline, the interval is extended to 2 weeks, and for fluoxetine, at least 5 weeks because of their longer half-lives. Conversely, 2 weeks should elapse between stopping MAOI therapy and starting patients on a tricyclic antidepressant (3 weeks in the case of clomipramine or imipramine), an SSRI, an SNRI, bupropion, mirtazapine, reboxetine, or any related antidepressant. For further warnings on the combined use of antidepressants, see below. Interactions can also occur between MAOIs themselves.

For details of the less severe interactions associated with reversible inhibitors of monoamine oxidase A (RIMAs), see Interactions of Moclobemide, p.411.

Antidepressants. Combination therapy with differing classes of antidepressants may result in interactions or enhanced adverse reactions such as the serotonin syndrome (see under Adverse Effects, above), and is therefore considered unsuitable or controversial by some authorities. Despite these drawbacks certain combinations of drugs have been found to be beneficial in the treatment of drug-resistant depression, although others are considered unsuitable; absence of information documenting unsuitability or hazard does not necessarily imply that the two drugs may be used safely together but may merely reflect an untried combination. Because combination therapy poses increased risks it should be used only under expert supervision.

- MAOIs have been used fairly frequently under expert supervision with tricyclics in refractory depression and it has been stated[1] that the risk of serious problems in combining *tricyclic antidepressant and MAOI* antidepressant therapy is almost exclusively limited to sequential prescribing, in particular the addition of a tricyclic to established treatment with an MAOI. The recommended procedure was said to be to allow a drug-free interval of at least one week and then to start both drugs together at a low dosage. The dosage of both drugs is then gradually increased to around half that normally prescribed for the drugs when given on their own. The dietary restrictions for MAOIs alone apply equally to the combined antidepressant regimen.

  Amitriptyline and trimipramine were considered to be the tricyclics least likely to produce adverse effects with MAOIs, while phenelzine and isocarboxazid were the safest MAOIs. In contrast, clomipramine (a tricyclic with serotonin reuptake inhibiting activity) and imipramine are unsuitable for such use.[2,3] The combination of clomipramine with tranylcypromine is particularly dangerous. Symptoms suggestive of the serotonin syndrome occurred in an elderly patient due to an interaction between clomipramine and moclobemide, a reversible inhibitor of monoamine oxidase type A (RIMA).[4] Two fatalities due to serotonin syndrome have been reported after overdosage with clomipramine and moclobemide.[5] The syndrome has also developed when a patient was switched from clomipramine to moclobemide with no suitable drug-free interval.[6] A 39-year-old woman developed the serotonin syndrome while taking imipramine with moclobemide, although it was suggested that an excessive dose of the tricyclic may have been ingested accidentally.[7]
- The UK CSM has warned[8] that enhanced serotonergic effects may result from using *SSRIs with MAOIs* or other antidepressants. Although such an enhancement may be beneficial in some instances it can produce a life-threatening serotonin syndrome. Such reactions were later reported in patients taking sertraline with MAOIs.[9-11] Three fatalities due to serotonin syndrome have been reported after overdosage with citalopram and moclobemide.[5] A case of serotonin syndrome has been reported after switching from fluoxetine to moclobemide with no suitable drug-free interval.[6] Some authors[12] have reported good efficacy and tolerability with combinations of moclobemide and SSRIs. However, others[13] reported a high rate of adverse events although, as significant improvement in depressive symptoms was observed in some patients, it was suggested that giving moclobemide with SSRIs deserved consideration as an option for the treatment of refractory depression.
- Combination therapy with a *tricyclic antidepressant and an SSRI* has sometimes been used to treat resistant depression. Fluvoxamine[14] and fluoxetine[15] have been reported to increase plasma concentrations of the tricyclic, although to varying degrees. Fluoxetine has been reported to produce three- to fourfold increases in plasma concentrations of desipramine and imipramine. Fluvoxamine has a minimal effect on desipramine plasma levels but produces a three- to fourfold increase in concentrations of imipramine.[16] Plasma-desipramine concentrations are elevated threefold by paroxetine but increases of only 30% are produced by sertraline.[16] However, an inadequate interval of one day between stopping desipramine and starting paroxetine resulted in a case of serotonin syndrome.[6] Serotonin syndrome has also been reported[17] in a patient who received paroxetine and imipramine and in another given sertraline and amitriptyline.[18] A threefold increase in concentrations of trimipramine resulting in sedation and orthostatic hypotension has been reported[19] in 2 patients also given paroxetine. Additionally, norfluoxetine, the active metabolite of fluoxetine, has a long half-life and is responsible for the continuing interaction with tricyclics for

several days or weeks after fluoxetine has been withdrawn. Citalopram was reported to have no effect on plasma-tricyclic concentrations in a patient although antidepressant effects were augmented.[20]

- *Lithium* and *tryptophan* have been used to augment the effect of other antidepressants in refractory depression. Phenelzine has been used successfully with lithium and tryptophan[21] in patients with treatment-resistant chronic depression although such a regimen has probably been used less since the reports of the eosinophilia-myalgia syndrome associated with tryptophan (see p.427). There have, however, been several case reports of reactions similar to the serotonin syndrome in patients receiving MAOIs with tryptophan.[22,23]

  Although lithium is often added to tricyclic antidepressant therapy in patients with refractory depression, epileptic seizures have been reported in a patient receiving amitriptyline when lithium was added.[24] Serotonin syndrome has been reported[25] in a patient given clomipramine and lithium. Severe neurotoxicity has been reported[26,27] in some patients receiving lithium and tricyclic or tetracyclic antidepressants; adverse effects included tremor, memory impairment, disorganised thinking, and auditory hallucinations. One manufacturer of lithium preparations also reports symptoms of nephrogenic diabetes in patients receiving these combinations.

  By 1989 the CSM had received 19 reports of adverse reactions in patients treated with fluvoxamine and lithium; 5 reports concerned convulsions and 1 hyperthermia.[8] Tremor has been reported when lithium was given with paroxetine,[28] and in general the risk of CNS toxicity is increased when lithium is given with fluoxetine, fluvoxamine, paroxetine, or sertraline. There has been a report[29] of a fatality when fluoxetine was replaced by tranylcypromine and tryptophan with no drug-free period; the patient was also receiving other drugs concurrently.
- Use of the serotonin and noradrenaline reuptake inhibitor (SNRI) *venlafaxine with tricyclic antidepressants* has been associated with increased antimuscarinic adverse effects.[30,31] Seizures have also been reported with venlafaxine and trimipramine[32] and serotonin syndrome developed in a patient given amitriptyline, venlafaxine, and pethidine.[33] Similar antimuscarinic adverse effects have occurred in patients given *venlafaxine and the SSRI* fluoxetine;[31] serotonin syndrome has been reported in a patient who received venlafaxine and paroxetine.[6] The use of *venlafaxine with MAOIs* is contra-indicated by the manufacturers of venlafaxine because of the risk of life-threatening adverse reactions. Serious adverse reactions have been reported when venlafaxine was combined with isocarboxazid,[34] moclobemide,[6] phenelzine,[35] or tranylcypromine.[36]
- *Trazodone* is chemically unrelated to other antidepressants but does have serotonergic actions. Serotonin syndrome has been reported when trazodone was combined with the SSRI *paroxetine*.[37]
- Serotonin syndrome has been reported[38] in a patient who took *nefazodone* with *fluoxetine*. There has been a similar report[39] in a patient who received *paroxetine* 2 days after finishing gradual withdrawal from over 6 months of treatment with nefazodone.
- Symptoms resembling serotonin syndrome have occurred in a patient taking the noradrenergic and specific serotonergic antidepressant, *mirtazapine* with *fluvoxamine*;[40] another report[41] suggests that the plasma concentrations of mirtazapine may be increased as much as fourfold by fluvoxamine.
- Raised *nortriptyline* levels were noted in a patient also taking *bupropion*; the effect recurred on rechallenge.[42]
- In a report[43] of an interaction between *St John's wort* and *paroxetine*, a 50-year-old woman was found incoherent, groggy, and slow-moving after self-administering a single dose of paroxetine while taking St John's wort; recovery was uneventful. Use of St John's wort with the SSRIs may potentiate their serotonergic effects and increase the incidence of adverse reactions. The CSM has advised that patients should stop taking St John's wort if treatment with an SSRI is necessary.[44] Symptoms of serotonin syndrome have also been reported when St John's wort and *nefazodone* were taken.[45]

Antiepileptics. Antidepressants may antagonise the activity of antiepileptics by lowering the convulsive threshold.

Licensed UK drug product information states that *carbamazepine* should be avoided with or within 2 weeks of a MAOI because of structural similarities with the tricyclic antidepressants; however, published evidence of adverse interactions is lacking. There is also a theoretical possibility of a similar interaction with *oxcarbazepine*.

Antimigraine drugs. For the effect of MAOIs on *serotonin (5-HT_1) agonists*, see under Sumatriptan, p.626.

Antineoplastics. For the effect when MAOIs are used with *altretamine*, see p.678.

Dopaminergics. For the effect of MAOIs with *amantadine*, see p.793, with *levodopa*, see p.807, and with *selegiline*, see p.817.

General anaesthetics. The problems that may occur when patients receiving MAOIs are also given general anaesthetics are discussed under Anaesthesia in Precautions, above.

Ginseng. There have been 2 reports[1,2] of adverse effects, including headaches, insomnia, tremulousness, and irritability when ginseng was taken with phenelzine.

2. Jones BD, Runikis AM. Interaction of ginseng with phenelzine. *J Clin Psychopharmacol* 1987; **7:** 201–2.

Insulin. For the effect of MAOIs on insulin, see p.449.

Neuromuscular blockers. For the effects of MAOIs on *suxamethonium*, see p.1912. Problems that may be encountered with MAOIs and neuromuscular blockers used during anaesthesia are discussed under Anaesthesia in Precautions, above.

Opioid analgesics. The problems that may occur with MAOIs and opioid analgesics used during anaesthesia are discussed under Anaesthesia in Precautions, above.

Respiratory stimulants. For the effect of MAOIs on *doxapram*, see p.2155.

Pharmacokinetics

Phenelzine is readily absorbed from the gastrointestinal tract reaching peak plasma concentrations 2 to 4 hours after ingestion. It is metabolised in the liver and is excreted in the urine almost entirely in the form of metabolites.

Uses and Administration

Monoamine oxidase inhibitors (MAOIs) inhibit the action of monoamine oxidase, the enzyme responsible for the metabolism of several biogenic amines. Monoamine oxidase exists in two forms, type A and type B. Monoamine oxidase type A preferentially deaminates adrenaline, noradrenaline, and serotonin whereas monoamine oxidase type B preferentially metabolises benzylamine and phenylethylamine; dopamine and tyramine are de-aminated by both forms of the enzyme.

- The traditional MAOIs such as phenelzine, iproniazid, isocarboxazid, and tranylcypromine are inhibitors of both types; apart from tranylcypromine, which produces a less prolonged inhibition of the enzyme than phenelzine, all are hydrazine derivatives and bind irreversibly.
- Selective inhibitors include selegiline (p.817), an irreversible inhibitor of monoamine oxidase type B used in the treatment of Parkinson's disease and depression. Clorgiline, an irreversible selective type A inhibitor, was investigated for use as an antidepressant.
- Reversible inhibitors of monoamine oxidase type A (RIMAs) include brofaromine and moclobemide.

Antidepressant activity appears to reside mainly with inhibition of monoamine oxidase type A although the mode of action of these drugs in depression is not fully understood. Selective inhibitors are claimed to have fewer or less severe adverse effects than non-selective inhibitors. As tyramine is de-aminated by both monoamine oxidase types A and B, inhibiting only one of the enzymes allows for continued, albeit reduced, de-amination. Thus the dietary precautions that need to be observed with non-selective inhibitors are less stringent with the selective inhibitors.

Phenelzine and other antidepressant MAOIs are used in the treatment of atypical depression, particularly where phobic features or associated anxiety are present, or in patients who have not responded to other antidepressants. However, the risks associated with irreversible non-selective MAOIs usually mean that other antidepressants are preferred. Up to a month may elapse before an antidepressant response is obtained with MAOIs. After a response has been obtained maintenance therapy may need to be continued for at least 4 to 6 months (12 months in the elderly) to avoid relapse on stopping therapy. Patients with a history of recurrent depression should continue to receive maintenance treatment for at least 5 years and possibly indefinitely. Care should be taken in elderly patients because of an increased susceptibility to adverse effects. Moreover, therapy with the non-selective inhibitors is particularly unsuitable for patients considered unable to adhere to the strict dietary requirements necessary for safe usage. (For contra-indication in children, see under Precautions, above).

Phenelzine is given orally as the sulfate although doses are expressed in terms of the base. Phenelzine sulfate 25.8 mg is equivalent to about 15 mg of phenelzine. The usual initial dose is equivalent to phenelzine 15 mg three times daily; if no response has been obtained after 2 weeks the dosage may be increased to 15 mg four times daily; severely depressed patients in hospital may be given up to 30 mg three times daily. Once a response has been obtained the dosage may be gradually reduced for maintenance therapy; some patients may continue to respond to 15 mg on alternate days.

Phenelzine should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Anxiety disorders. MAOIs have been used in the treatment of anxiety disorders. MAOIs appear to be effective in *panic disorder* (p.952). They also appear to be effective in *social anxiety disorder* (see under Phobic Disorders, p.953) and can improve anticipatory anxiety and functional disability. The main treatment for *post-traumatic stress disorder* (p.953) is psychotherapy but MAOIs are one of the alternatives that can help to reduce traumatic recollections and nightmares, and to repress flashbacks.

Depression. As discussed on p.373 there is very little difference in efficacy between the different groups of antidepressant drugs, and choice is often made on the basis of adverse effects. MAOIs are rarely used as first-choice antidepressants because of the dangers of dietary and drug interactions. Even in depressed patients with atypical, hypochondriacal, hysterical, or phobic features, for which MAOIs are particularly effective, it is often recommended that another antidepressant type should be tried first. Reversible inhibitors of monoamine oxidase type A (RIMAs) offer an alternative to the MAOIs and less strict dietary restrictions are necessary. They may be effective in a wide range of depressive disorders, although their relative efficacy in atypical depression remains to be established.

Combination therapy with differing classes of antidepressants, including the MAOIs, has been used in the treatment of drug-resistant depression. However, such therapy may result in enhanced adverse reactions or interactions and is considered unsuitable or controversial by some. For further details, see Antidepressants under Interactions, above.

Hyperactivity. When drug therapy is required for attention deficit hyperactivity disorder (p.2148), initial treatment is usually with a central stimulant. MAOIs have been used successfully but problems with dietary restriction and potential drug interactions have limited their use.

Migraine. A number of drugs have been used for the prophylaxis of migraine (p.616), although propranolol is generally preferred. Antidepressants such as the tricyclics can be useful alternatives when these drugs are ineffective or unsuitable. MAOIs are best reserved for severe cases refractory to other forms of prophylactic treatment.

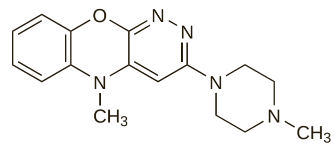
Pipofezine Hydrochloride *(rINNM)*

Hidrocloruro de pipofezina; Pipofézine, Chlorhydrate de; Pipofezine Dihydrochloride; Pipofezini Hydrochloridum. 5-Methyl-3-(4-methyl-1-piperazinyl)-5*H*-pyridazino[3,4-*b*][1,4]benzoxazine dihydrochloride.

Пипофезина Гидрохлорид

$C_{16}H_{19}N_5O,2HCl = 370.3.$

CAS — 24886-52-0 (pipofezine); 24853-80-3 (pipofezine hydrochloride).



(pipofezine)

Profile

Pipofezine is a tricyclic antidepressant (see Amitriptyline, p.376).

In the treatment of depression (p.373) pipofezine is usually given orally as the hydrochloride although doses are expressed in terms of the base; pipofezine hydrochloride 31.1 mg is equivalent to about 25 mg of pipofezine. An initial dose is 25 mg given four times daily, increased to an optimum total daily dose of 150 to 200 mg; if necessary up to a maximum of 500 mg may be given daily in divided doses. For maintenance a modified-release preparation providing pipofezine 150 mg may be given once or twice daily.

Pipofezine should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Preparations

Proprietary Preparations (details are given in Part 3)
Rus.: Azaphen (Азафен).

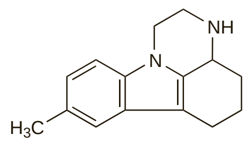
Pirlindole *(rINN)*

Pirlindol; Pirlindolum. 2,3,3a,4,5,6-Hexahydro-8-methyl-1*H*-pyrazino[3,2,1-*jk*]carbazole.

Пирлиндол

$C_{15}H_{18}N_2 = 226.3.$

CAS — 60762-57-4.



Profile

Pirlindole has been given by mouth in the treatment of depression.

Port.: Implementor; ***Rus.:*** Pyrazidol (Пиразидол).

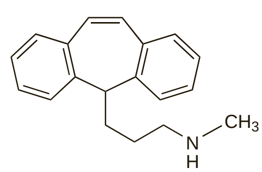
Protriptyline Hydrochloride *(BANM, USAN, rINNM)*

Hidrocloruro de protriptilina; MK-240; Protriptyline, chlorhydrate de; Protriptylini hydrochloridum. 3-(5*H*-Dibenzo[*a,d*]cyclohept-5-enyl)propyl(methyl)amine hydrochloride.

Протриптилина Гидрохлорид

$C_{19}H_{21}N,HCl = 299.8.$

CAS — 438-60-8 (protriptyline); 1225-55-4 (protriptyline hydrochloride).
ATC — N06AA11.
ATC Vet — QN06AA11.



(protriptyline)

Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Protriptyline Hydrochloride). A white to yellowish-white, odourless or almost odourless, powder. Freely soluble in water, in alcohol, and in chloroform; practically insoluble in ether. A 1% solution in water has a pH of 5.0 to 6.5.

USP 31 (Protriptyline Hydrochloride). A white to yellowish powder. Is odourless or has not more than a slight odour. Soluble 1 in 2 of water, 1 in 3.5 of alcohol, and 1 in 2.5 of chloroform; practically insoluble in ether. pH of a 1% solution in water is between 5.0 and 6.5.

Adverse Effects, Treatment, and Precautions

As for tricyclic antidepressants in general (see Amitriptyline, p.376).

Since protriptyline may have some stimulant properties anxiety and agitation can occur more frequently; cardiovascular effects such as tachycardia and orthostatic hypotension may also be more frequent than with other tricyclics. Photosensitivity rashes have been noted more often with protriptyline than with other tricyclic antidepressants and patients taking it should avoid direct sunlight.

Interactions

For interactions associated with tricyclic antidepressants, see Amitriptyline, p.379.

Pharmacokinetics

Protriptyline is well but slowly absorbed after oral doses: licensed drug information states that peak plasma concentrations are achieved only after 8 to 12 hours.

Paths of metabolism of protriptyline include *N*-oxidation and hydroxylation. Protriptyline is excreted in the urine, mainly in the form of its metabolites, either free or in conjugated form.

Protriptyline is widely distributed throughout the body and extensively bound to plasma and tissue protein. Protriptyline has been estimated to have a very prolonged elimination half-life ranging from 55 to 198 hours, which may be further prolonged in overdosage.

Uses and Administration

Protriptyline is a dibenzocycloheptatriene tricyclic antidepressant with actions and uses similar to those of amitriptyline (p.381). It is considerably less sedative than other tricyclics and may have a stimulant effect, thus making it particularly suitable for apathetic and withdrawn patients; its antimuscarinic effects are moderate.

In the treatment of depression, protriptyline hydrochloride is given in oral doses of 5 to 10 mg three or four times daily. It has been suggested that, because of its potential stimulant activity, any dosage increases should be added to the morning dose first and if insomnia occurs the last dose should be given no later than mid-afternoon. Higher doses of up to 60 mg daily may be required in severely depressed patients. A suitable initial dose for adolescents and the elderly is 5 mg three times daily; close monitoring of the cardiovascular system has been recommended if the dose exceeds a total of 20 mg daily in elderly subjects.

Protriptyline should be withdrawn gradually to reduce the risk of withdrawal symptoms.

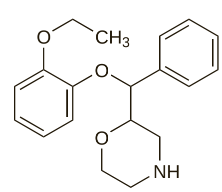
ATC — N06AX18.
ATC Vet — QN06AX18.



(reboxetine)

Adverse Effects

Adverse effects most commonly seen with reboxetine include insomnia, dry mouth, constipation, and increased sweating. Disturbance of visual accommodation, loss of appetite, vertigo, tachycardia, palpitations, vasodilatation, orthostatic hypotension, urinary hesitancy or retention (mainly in men), and erectile dysfunction including ejaculatory delay are also reported as being common adverse reactions. There have been reports of allergic dermatitis, convulsions, aggressive behaviour, cold extremities, and nausea and vomiting. Reduced plasma-potassium concentrations have been seen in elderly patients after prolonged use.

Hyponatraemia, possibly as a result of inappropriate secretion of antidiuretic hormone, has been associated with the use of antidepressants, particularly in the elderly.

Effects on the CNS. Episodes of sleepwalking (somnambulism) were seen in an 18-year-old woman several weeks after starting reboxetine (at an initial dose of 2 mg daily gradually increased to 8 mg daily).[1] The patient had a history of childhood somnambulism that had resolved spontaneously; these particular episodes ceased after the dose of reboxetine was reduced to 4 mg daily.

1. Künzel HE, *et al.* Sleepwalking associated with reboxetine in a young female patient with major depression: a case report. *Pharmacopsychiatry* 2004; **37:** 307–8.

Effects on the endocrine system. Hyponatraemia thought to be associated with reboxetine therapy and to be due to the syndrome of inappropriate antidiuretic hormone secretion, has been reported in an elderly patient.[1]

1. Ranieri P, *et al.* Reboxetine and hyponatremia. *N Engl J Med* 2000; **342:** 215–16.

Effects on sexual function. The Australian Adverse Drug Reactions Advisory Committee has received 130 reports of adverse reactions associated with reboxetine use;[1] of these, 22 described male sexual dysfunction including ejaculation disorder (7), erectile dysfunction (4), and testicular pain or swelling (10). In addition there were 2 reports of increased libido in women.

1. Adverse Drug Reactions Advisory Committee (ADRAC). Genitourinary symptoms with reboxetine. *Aust Adverse Drug React Bull* 2005; **24:** 10. Also available at: http://www.tga.gov.au/adr/aadrb/aadr0506.pdf (accessed 24/11/05)

Effects on the urinary system. The Australian Adverse Drug Reactions Advisory Committee has received 26 reports of urinary symptoms such as hesitancy, reduced urine flow, and retention in patients taking reboxetine.[1] Although the majority of cases occurred in male patients, 6 reports mentioned such symptoms in women.

1. Adverse Drug Reactions Advisory Committee (ADRAC). Genitourinary symptoms with reboxetine. *Aust Adverse Drug React Bull* 2005; **24:** 10. Also available at: http://www.tga.gov.au/adr/aadrb/aadr0506.pdf (accessed 24/11/05)

Treatment of Adverse Effects

Symptomatic and supportive therapy should be given as required; activated charcoal may be given to adults who have ingested more than 40 mg of reboxetine, and to children, if they present within 1 hour of ingestion. Heart rhythm should be monitored if changes in blood pressure occur.

Genito-urinary disorders. Tamsulosin has been used successfully in the treatment of urinary hesitancy and painful ejaculation associated with reboxetine (see p.2197).

Precautions

Reboxetine should be used with caution in patients with renal or hepatic impairment. It should also be used under close supervision in patients with bipolar disorder, urinary retention, benign prostatic hyperplasia, glaucoma, or a history of epilepsy or cardiac disorders.

Patients should be closely monitored during early therapy until significant improvement in depression is observed because suicide is an inherent risk in depressed patients. For further details, see under Depression, p.373. Suicidal thoughts and behaviour may also develop during early treatment with antidepressants for other disorders; the same precautions observed when treating patients with depression should therefore be observed when treating patients with other disorders.

Ability to perform tasks requiring motor or cognitive skills or judgement may be impaired by reboxetine and patients, if affected, should not drive or operate machinery.

Children. Reboxetine has not been studied for the treatment of depression in children and consequently its use in such patients is not recommended by UK licensed product information. In addition, other antidepressants have been shown to increase the risk of suicidal thoughts and behaviour in children and adolescents (see Effects on Mental State, under Fluoxetine, p.392).

The elderly. Reboxetine is not recommended by UK licensed product information for use in elderly patients, because of a lack of experience in this patient group. However, reboxetine 2 mg twice daily by mouth was well tolerated in a study in 16 elderly patients (mean age 77.5 years) with post-stroke depression.[1]

1. Rampello L, *et al.* An evaluation of efficacy and safety of reboxetine in elderly patients affected by "retarded" post-stroke depression: a random, placebo-controlled study. *Arch Gerontol Geriatr* 2005; **40:** 275–85.

Interactions

Reboxetine should not be taken with, or within 2 weeks of stopping, an MAOI; at least one week should elapse after stopping reboxetine therapy before starting any drug liable to provoke a serious reaction (e.g. phenelzine). Caution should be exercised when reboxetine is given with other drugs that lower blood pressure because orthostatic hypotension has occurred with reboxetine. However, the use of reboxetine with ergot derivatives may cause an increase in blood pressure. The possibility of hypokalaemia if reboxetine is given with potassium-depleting diuretics should also be considered.

Reboxetine is primarily metabolised by the cytochrome P450 isoenzyme CYP3A4 and potent inhibitors of this isoenzyme may limit the elimination of reboxetine. Consequently, reboxetine should not be given with drugs known to inhibit CYP3A4 such as azole antifungals (e.g. ketoconazole), macrolide antibacterials (e.g. erythromycin) or fluvoxamine. Reboxetine in high concentrations has also been shown *in vitro* to inhibit CYP3A4 and CYP2D6; however studies *in vivo* have suggested that interactions with drugs metabolised by these isoenzymes are unlikely.

Antifungals. Plasma levels of reboxetine were significantly increased when given with *ketoconazole*.[1] The interaction was said to have involved the inhibition of the cytochrome P450 isoenzyme CYP3A4 by ketoconazole.

1. Herman BD, *et al.* Ketoconazole inhibits the clearance of the enantiomers of the antidepressant reboxetine in humans. *Clin Pharmacol Ther* 1999; **66:** 374–9.

Pharmacokinetics

Reboxetine is well absorbed from the gastrointestinal tract with peak plasma levels occurring after about 2 hours. Plasma protein binding is about 97% (92% in elderly subjects). *In-vitro* studies indicate that reboxetine is metabolised by the cytochrome P450 isoenzyme CYP3A4; the main metabolic pathways identified are dealkylation, hydroxylation, and oxidation followed by glucuronide or sulfate conjugation. Elimination is mainly via urine (78%) with 10% excreted as unchanged drug. The plasma elimination half-life is 13 hours. Data from *animal* studies indicate that reboxetine crosses the placenta and is distributed into breast milk.

4. Poggesi I, *et al.* Pharmacokinetics of reboxetine in elderly patients with depressive disorders. *Int J Clin Pharmacol Ther* 2000; **38:** 254–9.

Uses and Administration

Reboxetine is a selective and potent inhibitor of the reuptake of noradrenaline; it also has a weak effect on serotonin reuptake. Reboxetine has no significant affinity for muscarinic receptors. It is given orally as the mesilate for the treatment of depression with doses expressed as the base. Reboxetine mesilate 5.2 mg is equivalent to about 4 mg of reboxetine. The dose of reboxetine is 4 mg twice daily, which may be increased after 3 to 4 weeks, if necessary, to 10 mg daily; the maximum daily dose should not exceed 12 mg. Reduced doses should be given in hepatic or renal impairment, see below. Reboxetine is not recommended for use in elderly patients (see under Precautions, above).

Antidepressants should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Administration in hepatic or renal impairment. Lower initial oral doses equivalent to 2 mg of reboxetine twice daily are recommended by UK licensed product information in hepatic or renal impairment; doses may be increased thereafter according to tolerance.

Anxiety disorders. Reboxetine has been tried with some benefit in panic disorder (p.952) although it may be less effective than the SSRIs.

3. Bertani A, *et al.* Comparison of the treatment with paroxetine and reboxetine in panic disorder: a randomized, single-blind study. *Pharmacopsychiatry* 2004; **37:** 206–10.

Depression. As discussed on p.373, there is very little difference in efficacy between the different groups of antidepressant drugs, and choice is often made on the basis of adverse effect profile. Reboxetine, a selective inhibitor of noradrenaline reuptake, has a slightly different biochemical profile from both the tricyclics and the SSRIs; however, like the SSRIs, reboxetine appears to have fewer unpleasant adverse effects and to be safer in overdosage in comparison with the older tricyclics.

Sertraline Hydrochloride

(BANM, USAN, rINNM)

CP-51974-01; CP-51974-1; Hidrocloruro de sertralina; Sertraline, chlorhydrate de; Sertralini hydrochloridum. (1*S*,4*S*)-4-(3,4-Dichlorophenyl)-1,2,3,4-tetrahydro-1-naphthyl(methyl)amine hydrochloride.

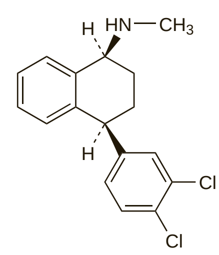
Сертралина Гидрохлорид

$C_{17}H_{17}Cl_2N,HCl = 342.7.$

CAS — 79617-96-2 (sertraline); 79559-97-0 (sertraline hydrochloride).

ATC — N06AB06.

ATC Vet — QN06AB06.



(sertraline)

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of sertraline:
Z's; Zloft; Zoomers.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Sertraline Hydrochloride). A white or almost white, crystalline powder. It exhibits polymorphism. Slightly soluble in water; freely soluble in anhydrous alcohol; slightly soluble in acetone and in isopropyl alcohol. Protect from light.

Adverse Effects, Treatment, and Precautions

As for SSRIs in general (see Fluoxetine, p.391). Menstrual irregularities and, rarely, erythema multiforme and pancreatitis have also been reported.

Sertraline should be used with caution in patients with hepatic or renal impairment; reduced doses should be considered in patients with hepatic impairment.

Breast feeding. For comments on the use of SSRIs in breast feeding patients, see under Precautions for Fluoxetine, p.394.

Children. SSRIs are associated with an increased risk of potentially suicidal behaviour when used for the treatment of depression in children and adolescents under 18 years old; for further details, see under Effects on Mental State in Fluoxetine, p.392.

Interactions

For interactions associated with SSRIs, see Fluoxetine, p.396.

Pharmacokinetics

Sertraline is slowly absorbed from the gastrointestinal tract with peak plasma concentrations occurring about 4.5 to 8.4 hours after ingestion. It undergoes extensive first-pass metabolism in the liver. The main pathway is demethylation to inactive *N*-desmethylsertraline, a process that appears to involve multiple cytochrome P450 isoenzymes; further metabolism and glucuronide conjugation occurs. Sertraline is widely distributed throughout body tissues and is about 98% bound to plasma proteins. The plasma elimination half-life of sertraline is reported to be about 26 hours; steady-state concentrations are achieved after about one week with regular oral doses. Sertraline is excreted in about equal amounts in the urine and faeces, mainly as metabolites. Sertraline is distributed into breast milk (see Breast Feeding under Precautions in Fluoxetine, p.394).

Uses and Administration

Sertraline, a naphthaleneamine derivative, is an SSRI with actions and uses similar to those of fluoxetine (p.397). It is given orally as sertraline hydrochloride as a single dose in the morning or evening. Doses are expressed in terms of the base; sertraline hydrochloride 56 mg is equivalent to about 50 mg of sertraline.

In the treatment of **depression**, the usual initial dose of sertraline is 50 mg daily increased, if necessary, in increments of 50 mg at intervals of at least a week to a maximum of 200 mg daily.

The usual initial dose of sertraline in **obsessive-compulsive disorder** is 50 mg daily. In the treatment of **panic disorder** with or without agoraphobia, **social anxiety disorder**, and **post-traumatic stress disorder**, the usual initial dose is 25 mg daily increased after one week to 50 mg daily. Thereafter, doses in all these disorders may be increased, if necessary, in increments of 50 mg at intervals of at least a week to a maximum of 200 mg daily.

Sertraline is also given for the treatment of obsessive-compulsive disorder in *children and adolescents* aged 6 years and over. In children aged 6 to 12 years the usual initial dose is 25 mg once daily; adolescents may be started on 50 mg once daily. Increases in doses, if necessary, are similar to those in adults; however, the lower body-weights of children should be considered in order to avoid excessive doses.

In the treatment of **premenstrual dysphoric disorder**, sertraline is given in an initial dose of 50 mg daily either throughout the menstrual cycle or during the luteal phase only, as appropriate. Doses may be increased by 50 mg each menstrual cycle up to a maximum of 150 mg daily for continuous dosing or 100 mg daily when dosing during the luteal phase only. Those patients who require 100 mg daily during luteal phase-only dosing should initially be given 50 mg daily for the first 3 days of each luteal phase dosing period.

Once the optimal therapeutic response is obtained dosage should be reduced to the lowest effective level for maintenance.

Reduced doses are recommended in patients with hepatic impairment, see below.

Sertraline should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Administration in hepatic impairment. The clearance of sertraline was reduced in patients with liver cirrhosis, in a single-dose pharmacokinetic study.[1] US licensed product information states that in a small group of patients with chronic mild impairment (Child-Pugh scores of 5 to 8), given 50 mg daily for 21 days, exposure to sertraline was about 3 times that found in subjects with normal hepatic function. It also states that the effects of sertraline have not been studied in moderate and severe impairment. If sertraline is to be used in patients with hepatic impairment, it suggests that the drug should be used with caution and given at a lower dose or less frequently. UK product information considers sertraline to be contra-indicated in significant hepatic impairment, because of insufficient clinical experience.

1. Démolis J-L, *et al.* Influence of liver cirrhosis on sertraline pharmacokinetics. *Br J Clin Pharmacol* 1996; **42:** 394–7.

Anxiety disorders. Sertraline has been given in a variety of anxiety disorders (p.952) including obsessive-compulsive disorder (p.952), panic disorder (p.952), social anxiety disorder (see under Phobic Disorders, p.953), and post-traumatic stress disorder (p.953).

Depression. As discussed on p.373, there is very little difference in efficacy between the different groups of antidepressant drugs, and choice is often made on the basis of adverse effect profile. SSRIs such as sertraline are widely used as an alternative to the older tricyclics as they have fewer adverse effects and are safer in overdosage.

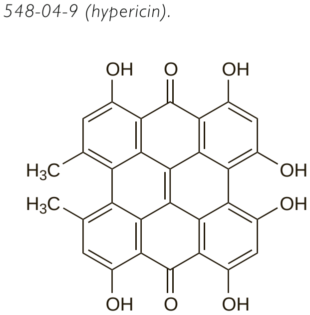
St John's Wort

Hipérico; Hiperikum; Hyperici herba; Hypericum; Johannesört; Johanniskraut; Jonažolių žolė; Mäkikuisma; Millepertuis; Orbáncfű; Třezalková nať; Ziele dziurawca.

CAS — 548-04-9 (hypericin).



(hypericin)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Eur. also includes a form for homoeopathic preparations.

Swiss also includes monographs for hypericum (fresh flowering tops) and hypericum oil.

Ph. Eur. 6.2 (St. John's Wort). The whole or cut, dried flowering tops of *Hypericum perforatum* gathered during flowering. It contains not less than 0.08% of total hypericins, expressed as hypericin ($C_{30}H_{16}O_8$ = 504.4) calculated with reference to the dried drug. Protect from light.

Ph. Eur. 6.2 (Hypericum for Homoeopathic Preparations; Hypericum Perforatum ad Praeparationes Homoeopathicas). The whole, fresh plant of *Hypericum perforatum*, at the beginning of the flowering period. Protect from light.

USP 31 (St. John's Wort). The dried flowering tops or aerial parts of *Hypericum perforatum* (Hypericaceae), gathered shortly before or during flowering. It contains not less than 0.04% of the combined total of hypericin ($C_{30}H_{16}O_8$ = 504.4) and pseudohypericin ($C_{30}H_{16}O_9$ = 520.4) and not less than 0.6% of hyperforin ($C_{35}H_{52}O_4$ = 536.8). Store in airtight containers. Protect from light.

Adverse Effects and Precautions

Adverse effects reported with St John's wort have included gastrointestinal symptoms, dizziness, headache, confusion, urinary frequency, allergic reactions, and fatigue. Photosensitivity has also been reported; hypericin and pseudohypericin are the constituents of St John's wort thought to be responsible for this reaction.

Effects on the nervous system. Subacute polyneuropathy after sun exposure developed in a woman who had taken St John's wort for mild depression; she improved after drug withdrawal.[1] Seizures and confusion occurred in a 16-year-old girl after an overdose of St John's wort.[2] She had taken large daily doses for 2 weeks and an overdose just before presentation.

2. Karalapillai DC, Bellomo R. Convulsions associated with an overdose of St John's wort. *Med J Aust* 2007; **186:** 213–14.

Effects on the skin. In addition to photosensitivity reactions associated with St John's wort use,[1] there has been a report of severe erythroderma in a patient who supplemented his regular antidepressant medication (dosulepin) with St John's wort.[2] The reaction was seen on both light-exposed and non-exposed areas, and was thought to be due to the St John's wort although there remained a possibility that it was due to an interaction between the 2 drugs.

2. Holme SA, Roberts DL. Erythroderma associated with St John's wort. *Br J Dermatol* 2000; **143:** 1127–8.

Mania. There have been a number of cases of mania or hypomania associated with the use of St John's wort.[1-3]

1. Neirenberg AA, *et al.* Mania associated with St John's wort. *Biol Psychiatry* 1999; **46:** 1707–8.
2. Fahmi M, *et al.* A case of mania induced by hypericum. *World J Biol Psychiatry* 2002; **3:** 58–9.
3. Stevinson C, Ernst E. Can St John's wort trigger psychoses? *Int J Clin Pharmacol Ther* 2004; **42:** 473–80.

Withdrawal. A 58-year-old woman developed symptoms such as nausea, anorexia, dizziness, dry mouth, thirst, chills, and fatigue the day after stopping St John's wort;[1] she had taken the drug for 32 days. The symptoms, which the authors considered suggestive of a withdrawal syndrome, resolved within 8 days.

1. Dean AJ, *et al.* Suspected withdrawal syndrome after cessation of St John's wort. *Ann Pharmacother* 2003; **37:** 150.

Interactions

St John's wort has been shown to induce several drug metabolising enzymes including some cytochrome P450 isoenzymes (in particular CYP3A4) and the transport protein P-glycoprotein. Clinically important interactions resulting in decreased plasma concentrations of the interacting drug have been reported with ciclosporin, digoxin, HIV-protease inhibitors, NNRTIs, oral contraceptives, tacrolimus, theophylline, and warfarin. There is also a possibility of an interaction between St John's wort and antiepileptics. In addition, stopping St John's wort may result in increased, and possibly toxic, concentrations of the interacting drug.

In many countries, including the UK and USA, preparations of St John's wort are not required to be licensed as medicines, and the amount of active ingredient may vary widely between preparations. Changing preparations may therefore alter the degree of enzyme induction.

Use of St John's wort with drugs known to act on serotonergic neurotransmitters may result in synergistic interactions and an increased risk of adverse effects may also occur. Examples include the SSRIs and nefazodone (see Antidepressants, p.418) and the selective serotonin (5-HT_1) agonists (see under Sumatriptan, p.626) used to treat migraine.

Verapamil. For details of a possible interaction between St John's wort and verapamil, see p.1423.

Xanthines. For details of a possible interaction between St John's wort and *theophylline*, see p.1143.

Uses and Administration

Herbal preparations containing St John's wort are used, frequently for self-medication, in the treatment of depression. Such preparations are also promoted for the treatment of other nervous disorders such as insomnia and anxiety, particularly if associated with the menopause. St John's wort oil has also been used as an astringent. Hypericin, a major constituent of St John's wort, has been investigated as an antiviral in the treatment of HIV infection and AIDS (but see Antiviral Action, below).

The amount of active constituents can vary between different preparations and doses depend on the preparation being used.

Homoeopathy. St John's wort has been used in homoeopathic medicines under the following names: Hypericum; Hypericum perforatum; Hypericum perforatum ex herba; Hypericum, herba; Hyper.

Depression. St John's wort extracts are widely used in some countries for the treatment of depression (p.373).

Two systematic reviews[1,2] of randomised controlled studies found St John's wort extracts to be more effective than placebo in the treatment of mild to moderate depressive disorders. However, the results of the more recent review[2] also suggested that St John's wort extracts were only of minor benefit in patients with major depression and probably of no benefit in those with a prolonged history of the condition; in addition, there was no evidence of effectiveness in severe depression. The authors of this review commented that recent placebo-controlled studies tended to show less favourable results for St John's wort than older studies. It was considered that the heterogeneous findings were due partly to overestimation of effects in some smaller, older studies, and partly to the variable efficacy of St John's wort extracts in different patient populations; non-publication of negative studies was not thought to have played a major role.

The efficacy of St John's wort compared with standard antidepressants has also been reviewed and found to be comparable.[2] However, this finding should be interpreted with caution, not least because doses of the standard antidepressants used were at the lower end of the range in some studies.

The mechanism of action of St John's wort extracts in the treatment of depression remains unclear. Extracts contain at least 10 active principles. Hypericin, one of the major constituents of St John's wort, was first thought responsible for the antidepressant effect since it had an inhibitory action on monoamine oxidase *in vitro*. However it was later shown that this action was, at best, weak and it is now generally believed that monoamine oxidase inhibition is not responsible for the antidepressant effect of St John's wort. More recent studies have suggested that hyperforin may be one of the major constituents responsible for the antidepressant effect.[3] Although the evidence is mainly from *in vitro* studies, hyperforin inhibits the reuptake of several major neurotransmitters including serotonin, dopamine, and noradrenaline.[4]

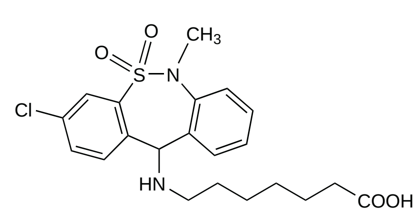
CAS — 66981-73-5 (tianeptine).

ATC — N06AX14.

ATC Vet — QN06AX14.



(tianeptine)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Tianeptine Sodium). A white or yellowish, very hygroscopic, powder. Freely soluble in water, in dichloromethane, and in methyl alcohol. Store in airtight containers.

Profile

Tianeptine sodium is an antidepressant reported to act by increasing (rather than inhibiting) the presynaptic reuptake of serotonin. It is given in oral doses of 12.5 mg three times daily in the treatment of depression (p.373). Doses should be reduced to a total of 25 mg daily in elderly patients; for details of dosage in those with renal impairment, see below.

Isolated cases of hepatitis have been reported during treatment with tianeptine.

Abuse. Reports of misuse of tianeptine.[1,2]

1. Leterme L, *et al.* Usage détourné de tianeptine: à propos de cinq cas de surconsommation. *Ann Med Interne (Paris)* 2003; **154:** 2S58–2S63.
2. Kisa C, *et al.* Is it possible to be dependent to tianeptine, an antidepressant? A case report. *Prog Neuropsychopharmacol Biol Psychiatry* 2007; **31:** 776–8.

Administration in renal impairment. Licensed product information recommends that oral doses of tianeptine sodium should not exceed a total of 25 mg daily in patients with renal impairment.

Asthma. Tianeptine has been reported to improve symptoms in patients with asthma.[1] It was thought that reduction of raised levels of free serotonin found in such patients contributed to the beneficial effect of tianeptine.

1. Lechin F, *et al.* The serotonin uptake-enhancing drug tianeptine suppresses asthmatic symptoms in children: a double-blind, crossover, placebo-controlled study. *J Clin Pharmacol* 1998; **38:** 918–25.

Tranylcypromine Sulfate *(rINNM)*

SKF-385; Sulfato de tranilcipromina; Transamine Sulphate; Tranylcypromine, Sulfate de; Tranylcypromine Sulphate *(BANM)*; Tranylcypromini Sulfas. (±)-*trans*-2-Phenylcyclopropylamine sulphate.

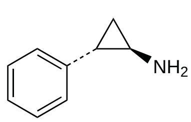
Транилципромина Сульфат

$(C_9H_{11}N)_2,H_2SO_4 = 364.5.$

CAS — 155-09-9 (tranylcypromine); 13492-01-8 (tranylcypromine sulfate).

ATC — N06AF04.

ATC Vet — QN06AF04.



(tranylcypromine)

Pharmacopoeias. In *Br.*

BP 2008 (Tranylcypromine Sulphate). A white or almost white crystalline powder; odourless or with a faint odour of cinnamaldehyde. Soluble in water; very slightly soluble in alcohol and in ether; insoluble in chloroform.

Adverse Effects, Treatment, and Precautions

As for MAOIs in general (see Phenelzine, p.415).

Tranylcypromine has a stimulant action and insomnia is a common adverse effect if it is taken in the evening.

Hypertensive reactions are more likely to occur with tranylcypromine than with other MAOIs, but severe liver damage occurs less frequently.

Dependence. Dependence on tranylcypromine with tolerance has been reported in patients receiving high doses with or without a history of previous substance abuse. For further details, see Withdrawal under Precautions in Phenelzine, p.417.

Effects on the cardiovascular system. Although orthostatic hypotension is more common, hypertension can occur with MAOIs. A hypertensive crisis has been described in 2 patients after only one dose of tranylcypromine.[1,2] In the first case it was thought possible that an autointeraction may have occurred between tranylcypromine and amfetamine to which it is partly metabolised. In the second case the provocation of hypertension led to the finding of a previously undiagnosed phaeochromocytoma and it was suggested this may have been a possibility in previous reports of hypertension induced by MAOIs.

1. Gunn J, *et al.* Hypertensive crisis and broad complex bradycardia after a single dose of monoamine oxidase inhibitor. *BMJ* 1989; **298:** 964.
2. Cook RF, Katritsis D. Hypertensive crisis precipitated by a monoamine oxidase inhibitor in a patient with phaeochromocytoma. *BMJ* 1990; **300:** 614.

Porphyria. Tranylcypromine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Interactions

For interactions associated with MAOIs, see Phenelzine, p.417.

The use of clomipramine with tranylcypromine is particularly hazardous.

Pharmacokinetics

Tranylcypromine is readily absorbed from the gastrointestinal tract with peak plasma concentrations occurring about 1 to 3 hours after ingestion. It is excreted in the urine mainly in the form of metabolites. Tranylcypromine has a reported plasma elimination half-life of about 2.5 hours.

◊ In 9 depressed patients, tranylcypromine absorption was rapid after oral dosing.[1] Absorption was biphasic in 7. Elimination was also rapid, with an elimination half-life of 1.54 to 3.15 hours. From 2 to 7 hours after dosing, standing systolic and diastolic blood pressures were lowered, and standing pulse was raised. The onset of the effect on standing systolic blood pressure correlated with the time of peak plasma tranylcypromine concentration. Maximum orthostatic drop of blood pressure and rise in pulse rate occurred 2 hours after dosing. Mean plasma-tranylcypromine concentrations correlated with mean orthostatic drop of systolic blood pressure and rise of pulse rate. Patients experiencing clinically significant hypotensive reactions to tranylcypromine may benefit from changes in their dose regimen aimed at minimising peak concentrations.

Uses and Administration

Tranylcypromine, a cyclopropylamine derivative, is an MAOI with actions and uses similar to those of phenelzine (p.419). It produces a less prolonged inhibition of the enzymes than phenelzine.

Tranylcypromine is used in the treatment of depression, but as discussed on p.373 the risks associated with traditional non-selective MAOIs such as tranylcypromine usually mean that other antidepressants are preferred. It is given orally as the sulfate although doses are expressed in terms of the base. Tranylcypromine sulfate 13.7 mg is equivalent to about 10 mg of tranylcypromine.

The usual initial dose is equivalent to tranylcypromine 10 mg in the morning and 10 mg in the afternoon; if the response is inadequate after a week, the afternoon dose may be increased to 20 mg or alternatively, 10 mg may be given additionally at midday. A dosage of 30 mg daily should only be exceeded with caution, although in the USA a maximum dose of 60 mg daily is allowed. Once a satisfactory response has been obtained the dosage may be gradually reduced for maintenance; some patients may continue to respond to 10 mg daily.

Tranylcypromine should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Preparations

BP 2008: Tranylcypromine Tablets.

Trazodone Hydrochloride

(BANM, USAN, rINNM)

AF-1161; Hidrocloruro de trazodona; Trazodon Hidroklorür; Trazodone, Chlorhydrate de; Trazodoni Hydrochloridum. 2-[3-(4-*m*-Chlorophenylpiperazin-1-yl)propyl]-1,2,4-triazolo[4,3-*a*]pyridin-3(2*H*)-one hydrochloride.

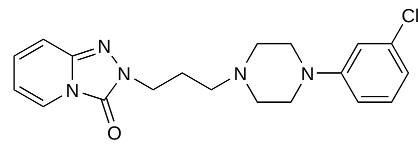
Тразодона Гидрохлорид

$C_{19}H_{22}ClN_5O,HCl = 408.3.$

CAS — 19794-93-5 (trazodone); 25332-39-2 (trazodone hydrochloride).

ATC — N06AX05.

ATC Vet — QN06AX05.



(trazodone)

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of trazodone hydrochloride:

Sleepeasy.

Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Trazodone Hydrochloride). A white or almost white crystalline powder. Soluble in water; sparingly soluble in alcohol; practically insoluble in ether. A 1% solution in water has a pH of 3.9 to 4.5. Store in airtight containers. Protect from light.

USP 31 (Trazodone Hydrochloride). A white to off-white crystalline powder. Sparingly soluble in water and in chloroform. Store in airtight containers. Protect from light.

Adverse Effects and Treatment

Trazodone has sedative properties although drowsiness usually disappears on continuing treatment. Other adverse effects occasionally reported include dizziness, headache, nausea and vomiting, weakness, weight loss, tremor, dry mouth, bradycardia or tachycardia, orthostatic hypotension, oedema, constipation, diarrhoea, blurred vision, restlessness, confusional states, insomnia, and skin rash. Although some of these effects are typical of antimuscarinic activity it is reported that trazodone has little antimuscarinic activity compared with tricyclic antidepressants. *Animal* studies have also indicated that trazodone is less cardiotoxic than the tricyclics. Priapism has been reported on a number of occasions.

Agranulocytosis, thrombocytopenia, and anaemia have been reported rarely. Adverse effects on hepatic function, including jaundice and hepatocellular damage, which may be severe, have also been reported rarely. There have been occasional reports of serotonin syndrome. Neuroleptic malignant syndrome has occurred rarely.

Hyponatraemia possibly due to inappropriate secretion of antidiuretic hormone has been associated with the use of antidepressants, particularly in the elderly.

Symptoms of overdosage include drowsiness, dizziness, vomiting, priapism, respiratory arrest, seizures, and ECG changes. The value of gastric decontamination after overdosage is uncertain. However, activated charcoal may be considered in adults who have taken more than 1 g (children more than 150 mg) and present within 1 hour; gastric lavage may also be considered in adults in life-threatening overdoses. Thereafter, symptomatic and supportive therapy should be given as appropriate.

Effects on the cardiovascular system. Although trazodone is considered to cause fewer adverse cardiovascular reactions than the tricyclic antidepressants, they have, nevertheless, been reported in individual patients. In therapeutic doses it has been associated with heart block in a patient with pre-existing cardiovascular disease,[1] as well as in a patient with no ECG abnormalities.[2] Similarly, ventricular arrhythmias have been associated with therapeutic doses of trazodone both in patients with a history of cardiac problems,[3,4] and with no history of cardiac abnormalities.[5] Atrial fibrillation has been reported in a patient with ischaemic heart disease.[6]

6. White WB, Wong SHY. Rapid atrial fibrillation associated with trazodone hydrochloride. *Arch Gen Psychiatry* 1985; **42:** 424.

Effects on the eyes. A patient receiving clomipramine and trazodone orally noted excessive blinking whenever the dose of trazodone exceeded or equalled that of clomipramine.[1] When trazodone, but not clomipramine, was withdrawn, blinking became normal within 3 weeks.

1. Cooper MA, Dening TR. Excessive blinking associated with combined antidepressants. *BMJ* 1986; **293:** 1243.

Effects on the liver. A mixed hepatocellular-cholestatic liver enzyme pattern has been reported in a patient after about 3 weeks of treatment with trazodone in doses of up to 500 mg daily.[1] The enzyme abnormalities returned to normal 4 weeks after trazodone was stopped but it was suggested that liver enzyme values should be monitored during the first 4 weeks of therapy. A similar case apparently presenting as obstructive jaundice and hepatocellular inflammation, in which the patient had only been receiving 50 mg daily for 2 weeks, has also been described.[2] It was believed that the patient suffered an idiosyncratic drug reaction to trazodone. Further reports of trazodone-induced liver injury include an elderly patient who developed chronic active hepatitis after receiving trazodone 150 mg daily for about 8 months.[3] A case of fatal hepatic necrosis reported in another elderly patient was considered to be due to treatment with trazodone and antipsychotics.[4] The authors of the report[4] noted that up to August 1991 the UK CSM had received 14 reports of adverse effects on the liver associated with trazodone including one episode of fatal hepatic necrosis. In one of 2 later reports of trazodone-induced hepatotoxicity,[5] a female patient with rheumatoid arthritis developed jaundice 18 months after trazodone was added to her existing medications. All drugs were stopped and the patient improved; however, an inadvertent rechallenge with trazodone (without any other medication) led to a recurrence of her symptoms which again resolved following trazodone withdrawal. The second case[6] involved a HIV-positive male who was started on methadone, clonidine, and trazodone as part of a detoxification programme; 4 days later acute hepatitis and cholestasis was noted and trazodone and clonidine were withdrawn with subsequent resolution of symptoms. The authors considered that trazodone was probably the causative agent.

Effects on mental state. There have been reports of mania,[1,2] and psychosis with hallucinations[3,4] associated with the use of trazodone in depressed patients; delirium[5] in patients with bulimia nervosa and possible psychosis or hypomania[6] in a patient receiving trazodone-tryptophan treatment for aggression have also been reported.

Effects on sexual function. Trazodone is notable for the number of reports of priapism associated with its use.[1,2] In most cases, priapism occurred during treatment with standard doses after 1 to 3 weeks of therapy. Several patients required surgery and recovery was not always complete.[1] A review[3] of priapism induced by psychotropic drugs proposed that the effect was related to blockade of alpha-adrenoceptors in the absence of sufficient antimuscarinic activity, criteria fulfilled by the pharmacological profile of trazodone.

Inhibition of ejaculation,[4] and an increase in libido in women[5] and men[6] have also been reported with trazodone therapy. There have also been reports of trazodone-associated priapism of the clitoris.[7,8]

2. Lefkowitz D, *et al.* Seizures and trazodone therapy. *Arch Gen Psychiatry* 1985; **42:** 523.

Overdosage. Reviews have indicated that the incidence of serious toxicity from trazodone overdose alone was low compared with tricyclic antidepressant overdose.[1-4]

In a review covering 149 overdose cases,[1] only 10 deaths had been reported and in only 1 case was trazodone the sole agent reported to be ingested; in this case autopsy revealed an acute myocardial infarction after the patient was stable. The remaining 9 patients also had histories of ingestion of unknown quantities of alcohol, benzodiazepines, or other sedative-hypnotics that may have contributed to their demise. In the surviving 139 patients, 2 cases of respiratory arrest, 2 cases of right bundle branch block, and one case each of priapism, seizure, atrioventricular block, and T-wave inversion were reported. The remaining patients had minor CNS-depressant effects.

In a second review[2] of 88 cases of overdose, no fatalities occurred in the 39 cases where trazodone alone was ingested. However 9 deaths occurred in the remaining 49 cases where trazodone was ingested with other drugs or alcohol.

For a discussion of choice of antidepressant with respect to toxicity in overdosage, see under Depression, p.373.

Precautions

Trazodone should be used with caution in patients with cardiovascular disorders, such as ischaemic heart disease, and its use is not recommended in the immediate recovery phase after myocardial infarction. Similarly, it should be used with caution in patients with epilepsy and severe hepatic or renal impairment. Trazodone should be stopped immediately if patients develop signs of hepatic dysfunction or blood dyscrasias. Patients developing inappropriate or prolonged penile erections should also stop trazodone immediately.

Patients should be closely monitored during early antidepressant therapy until significant improvement in depression is observed because suicide is an inherent risk in depressed patients. For further details, see under Depression, p.373. Suicidal thoughts and behaviour may also develop during early treatment with antidepressants for other disorders; the same precautions observed when treating patients with depression should therefore be observed when treating patients with other disorders.

Drowsiness often occurs at the start of trazodone therapy and patients, if affected, should not drive or operate machinery.

As with other antidepressants, trazodone therapy should be withdrawn gradually.

Breast feeding. The American Academy of Pediatrics[1] considers that, although the effect of trazodone on breast-fed infants is unknown, its use by mothers during breast feeding may be of concern since antidepressant drugs do appear in breast milk and thus could conceivably alter CNS function in the infant both in the short and long term.

A study of 6 women each given a single 50-mg dose of trazodone concluded that the exposure of infants to trazodone via breast milk was very small.[2] However, trazodone has been reported to form an active metabolite and it was not known to what extent this metabolite distributed into breast milk.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 24/11/05)
2. Verbeeck RK, *et al.* Excretion of trazodone in breast milk. *Br J Clin Pharmacol* 1986; **22:** 367–70.

Porphyria. Trazodone hydrochloride is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Pregnancy. UK licensed drug information states that trazodone should be avoided during pregnancy; that for the USA indicates that trazodone should only be used if the benefits to the mother outweigh the risks to the fetus.

For details of outcome in a multicentre study on the use of trazodone during pregnancy, see under Nefazodone, p.412.

Interactions

Trazodone should not be given to patients receiving MAOIs or for at least 14 days afterwards. It has also been recommended that any drug liable to provoke a serious reaction (e.g. phenelzine) should not be given within one week of stopping trazodone therapy. For further details of combination antidepressant therapy, see Antidepressants under Interactions of Phenelzine, p.418.

It is considered unlikely that trazodone will alter the effects of antihypertensives such as guanethidine; some interaction may, however, occur with clonidine. The dose of other antihypertensives may need to be reduced if used with trazodone.

The sedative effects of trazodone may be enhanced by alcohol or other CNS depressants. The potential for interaction between trazodone and general anaesthetics or muscle relaxants exists and some licensed product information recommends that trazodone should be stopped before elective surgery for as long as clinically feasible.

Trazodone may increase plasma concentrations of digoxin or phenytoin and some product information recommends monitoring their serum concentrations if used with trazodone.

Trazodone is metabolised by the cytochrome P450 isoenzyme CYP3A4 and inhibitors of this isoenzyme may limit the elimination of trazodone. Consequently, trazodone may need to be given in reduced doses with drugs known to be potent inhibitors of CYP3A4 such as the azole antifungals itraconazole and ketoconazole, and the HIV-protease inhibitors. CYP3A4 inducers such as carbamazepine may reduce the plasma concentrations of trazodone.

Anticoagulants. For the effect of trazodone on *warfarin*, see p.1428.

Antiepileptics. Antidepressants may antagonise the activity of antiepileptics by lowering the convulsive threshold.

Trazodone may increase plasma concentrations of *carbamazepine* (see p.474) and *phenytoin* (see p.498). Some licensed product information recommends monitoring concentrations of phenytoin if used with trazodone.

Antivirals. In a small study in 10 subjects, the use of low-dose *ritonavir* (200 mg twice daily for 2 days) with trazodone (50 mg once daily) more than halved the clearance of trazodone resulting in significant increases in its peak plasma concentrations.[1] Adverse reactions were noted in 3 subjects and included dizziness, nausea, hypotension, and syncope.

1. Greenblatt DJ, *et al.* Short-term exposure to low-dose ritonavir impairs clearance and enhances adverse effects of trazodone. *J Clin Pharmacol* 2003; **43:** 414–22.

Ginkgo biloba. Coma, reversible by flumazenil, developed in an 80-year-old woman with Alzheimer's disease 3 days after starting to take a preparation of ginkgo biloba with trazodone.[1]

1. Galluzzi S, *et al.* Coma in a patient with Alzheimer's disease taking low dose trazodone and gingko biloba. *J Neurol Neurosurg Psychiatry* 2000; **68:** 679–80.

Pharmacokinetics

Trazodone is readily absorbed from the gastrointestinal tract although absorption is affected by food. When trazodone is taken shortly after a meal there may be an increase in the amount absorbed, a decrease in the maximum concentration, and a lengthening in the time to maximum concentration compared with the fasting state; peak plasma concentrations occur about one hour after a dose when taken on an empty stomach and after about 2 hours when taken with food. Protein binding is reported to be about 89 to 95%.

Trazodone is extensively metabolised in the liver and paths of metabolism include *N*-oxidation and hydroxylation. It is metabolised to its active metabolite *m*-chlorophenylpiperazine via the cytochrome P450 isoenzyme CYP3A4. Trazodone is excreted mainly in the urine almost entirely in the form of its metabolites, either in free or in conjugated form: some is excreted in the faeces via biliary elimination. The elimination of trazodone from the plasma is biphasic, with a terminal elimination half-life of 5 to 9 hours.

Small amounts of trazodone are distributed into breast milk.

Uses and Administration

Trazodone is a triazolopyridine antidepressant chemically unrelated to other classes of antidepressants. It blocks the reuptake of serotonin at presynaptic neurones and has an action at 5-HT_1 receptors. Trazodone is also an antagonist at 5-$HT_{2A/2C}$ receptors. Unlike the tricyclic antidepressants, trazodone does not inhibit the peripheral reuptake of noradrenaline, although it may indirectly facilitate neuronal release. Trazodone blocks central α_1-adrenoceptors and appears to have no effect on the central reuptake of dopamine. It does not appear to have very significant antimuscarinic properties, but has a marked sedative action.

For the treatment of **depression** trazodone hydrochloride is given in oral doses of 150 mg daily initially; total daily dosage may be increased by 50 mg every 3 or 4 days up to 300 to 400 mg daily if necessary. The daily dosage may be divided throughout the day after food or be given as a single dose at night. Divided daily dosages of up to 600 mg may be given in severe depression in hospitalised patients. A suggested initial dose in elderly and other susceptible patients is 100 mg daily, and total daily doses above 300 mg are unlikely to be needed in these patients.

In the treatment of **anxiety** (p.952), trazodone hydrochloride is given in an initial oral dose of 75 mg daily increasing to 300 mg daily if necessary.

As with other antidepressants, trazodone should be withdrawn gradually.

Depression. As discussed on p.373, there is very little difference in efficacy between the different groups of antidepressant drugs, and choice is often made on the basis of adverse effect profile. Trazodone has a different biochemical profile from both the tricyclics and the SSRIs.

Disturbed behaviour. Trazodone has produced beneficial results[1-3] when tried in various disorders for the control of symptoms such as agitation, aggression, and disruptive behaviour (see p.954). Some[4] also consider that, in the management of dementia, trazodone might be worth trying in nonpsychotic patients with disturbed behaviour, especially those with mild symptoms or those intolerant of or unresponsive to antipsychotics. However, the evidence for such use is poor; a systematic review on the use of trazodone in the treatment of behavioural and psychological symptoms of dementia found that the evidence from randomised, placebo-controlled studies was insufficient for any recommendations to be made.[5] The risk of adverse effects such as sedation and orthostatic hypotension, which may be particularly problematic in the elderly, should also be considered.[4]

Sexual dysfunction. Priapism can occur as an adverse effect of trazodone (see Effects on Sexual Function in Adverse Effects, above) and this has led to trials of oral trazodone for the treatment of erectile dysfunction (p.2179). Positive responses have been reported, both with yohimbine[1] and alone.[2] However, there appear to have been few controlled studies and a systematic review[3] considered some of these to be either small, brief, or methodologically weak. Meta-analysis[3] of data from 6 studies did not find trazodone to be superior to placebo but subgroup analysis possibly suggested a better outcome in patients with psychogenic erectile dysfunction and in those given doses of 150 to 200 mg daily.

3. Fink HA, *et al*. Trazodone for erectile dysfunction: a systematic review and meta-analysis. *BJU Int* 2003; **92:** 441–6.

Substance dependence. The antidepressant, anxiolytic, and sedative properties of trazodone have been reported to have been useful when tried in patients having withdrawal syndromes from a variety of substances including alcohol (p.1626),[1] cocaine (p.1860),[2] and benzodiazepines (p.987).[3-5]

Trimipramine *(BAN, USAN, rINN)*

IL-6001; 7162-RP; Trimeprimine; Trimipramiini; Trimipramin; Trimipramina; Trimipraminum. Dimethyl{3-(10,11-dihydro-5*H*-dibenz[*b*,*f*]azepin-5-yl-2-methyl)propyl}amine.

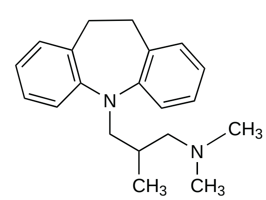
Тримипрамин

$C_{20}H_{26}N_2$ = 294.4.

CAS — 739-71-9.

ATC — N06AA06.

ATC Vet — QN06AA06.



Trimipramine Maleate *(BANM, USAN, rINNM)*

Maleato de trimipramina; Trimipramiinimaleaatti; Trimipramin maleinát; Trimipramine Hydrogen Maleate; Trimipramine, maléate de; Trimipramini maleas; Trimipraminmaleat; Trimipramin-maleát; Trimipramino maleatas.

Тримипрамина Малеат

$C_{20}H_{26}N_2,C_4H_4O_4$ = 410.5.

CAS — 521-78-8.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Trimipramine Maleate). A white or almost white crystalline powder. Slightly soluble in water and in alcohol. Protect from light.

USP 31 (Trimipramine Maleate). A white to almost white crystalline powder. Slightly soluble in water and in alcohol. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for tricyclic antidepressants in general (see Amitriptyline, p.376).

Porphyria. Trimipramine is considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity.

Interactions

For interactions associated with tricyclic antidepressants, see Amitriptyline, p.379.

Pharmacokinetics

Trimipramine is readily absorbed after oral doses, peak plasma concentrations being obtained in 2 hours. It is metabolised in the liver to its major metabolite desmethyltrimipramine, which is active. Trimipramine is excreted in the urine mainly in the form of its metabolites. It is about 95% bound to plasma proteins. The plasma elimination half-life is reported to be about 23 hours.

◊ References.

2. Musa MN. Nonlinear kinetics of trimipramine in depressed patients. *J Clin Pharmacol* 1989; **29:** 746–7.

Uses and Administration

Trimipramine is a dibenzazepine tricyclic antidepressant with actions and uses similar to those of amitriptyline (p.381). It has marked antimuscarinic and sedative properties.

Trimipramine is given orally as the maleate although doses are expressed in terms of the base. Trimipramine maleate 34.9 mg is equivalent to about 25 mg of trimipramine. In the treatment of depression, the usual initial dose is the equivalent of trimipramine 50 to 75 mg daily, gradually increased as necessary to 150 to 300 mg daily. The recommended initial dose for the elderly in the UK is 30 to 75 mg daily, gradually increased as necessary. In the USA, the elderly and adolescents may be given 50 mg daily initially followed by gradual increments as necessary up to a maximum of 100 mg daily. Trimipramine may be given in divided doses during the day, but since it has a prolonged half-life, once-daily dosage regimens are also suitable and usually given at night.

Trimipramine has also been given orally as the hydrochloride and the mesilate; the mesilate has also been given intramuscularly.

Trimipramine should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Preparations

BP 2008: Trimipramine Tablets.

Proprietary Preparations (details are given in Part 3)

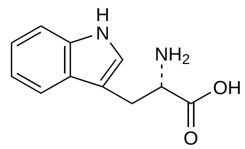
Tryptophan *(USAN, rINN)*

Triptofán; Triptofanas; Triptófano; Tryptofaani; Tryptofan; L-Tryptophan; Tryptophane; Tryptophanum; W. L-2-Amino-3-(indol-3-yl)propionic acid.

Триптофан

$C_{11}H_{12}N_2O_2$ = 204.2.
CAS — 73-22-3.
ATC — N06AX02.
ATC Vet — QN06AX02.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn*, and *US*.

Ph. Eur. 6.2 (Tryptophan). A white or almost white crystalline or amorphous powder. Sparingly soluble in water; slightly soluble in alcohol; dissolves in dilute mineral acids and in dilute solutions of alkali hydroxides. Protect from light.

USP 31 (Tryptophan). White to slightly yellowish-white crystals or crystalline powder. Soluble in hot alcohol and in dilute hydrochloric acid. pH of a 1% solution in water is between 5.5 and 7.0.

Adverse Effects

Tryptophan-containing products have been associated with the eosinophilia-myalgia syndrome; for further details, see below.

Other adverse effects that have been reported include nausea, headache, lightheadedness, and drowsiness.

An increased incidence of bladder tumours has been reported in *mice* given L-tryptophan orally as well as in cholesterol pellets embedded in the bladder lumen. However, there was no increase in tumour incidence when only high-dose, oral tryptophan was given.

Eosinophilia-myalgia syndrome. In late 1989 the first notification linking the eosinophilia-myalgia syndrome with the use of tryptophan-containing products was made in the USA.[1] There followed a number of similar published case reports from the USA, Europe, and Japan. Reviews of tryptophan-associated eosinophilia-myalgia syndrome have noted that by early 1990 over 1500 cases were known in the USA.[2,3]

In early 1990 the CDC in the USA summarised the features and known reports concerning the syndrome.[4] As the name implies the characteristic features are an intense eosinophilia together with disabling fatigue and muscle pain, although multisystem organ involvement and inflammatory disorders affecting the joints, skin, connective tissue, lungs, heart, and liver have also been recorded. Symptoms have generally developed over several weeks and the syndrome has occurred in patients who had been receiving tryptophan for many years previously with no untoward effect. In most patients slow and gradual improvement in the degree of eosinophilia and other clinical manifestations has followed the withdrawal of tryptophan, but in some patients the disease has progressed despite withdrawal and there have been fatalities.[5-7] The inflammatory condition has necessitated the use of corticosteroids in some patients.

The eosinophilia-myalgia syndrome has been reported in patients taking both tryptophan-containing prescription products for depression and non-prescription dietary supplements for a number of disorders including insomnia, the premenstrual syndrome, and stress; it does not appear to have occurred in patients receiving amino-acid preparations containing tryptophan as part of total parenteral nutrition regimens. The recognition of this syndrome led to the withdrawal of tryptophan-containing products or severe restrictions being imposed upon their use in many countries during 1990.

Various theories were proposed as to the reason for the association of tryptophan with this syndrome. Confusion existed because the reports implicated a very wide range of products from different manufacturers. However, later evidence appeared to have confirmed that contaminated tryptophan had originated from a single manufacturer in Japan.[8-10] Bulk tryptophan was imported from Japan for manufacture into finished pharmaceutical dosage forms and it was noted in one of these reports[9] that a single product was often found to contain two or more lots of powdered tryptophan that were blended together during the production of tablets or capsules. Many trace contaminants have been found in batches of tryptophan associated with the syndrome.[11] One contaminant has been identified as 1,1′-ethylidenebis(tryptophan).[12] Its inclusion in bulk tryptophan powder appeared to coincide with alterations in the manufacturing conditions that involved a change in the strain of *Bacillus amyloliquefaciens* used in the fermentation process and a reduction in the amount of charcoal used for purification.[9] Other investigations indicated the presence of bacitracin-like peptides in batches of the contaminated tryptophan.[13] However, further work[14] has provided only weak support for an association between the syndrome and any one particular contaminant and the causative agent remains to be confirmed. Nonetheless, since the syndrome only appeared to be associated with tryptophan from one manufacturer, tryptophan preparations were reintroduced in the UK in 1994 for restricted use under carefully monitored conditions.[15] In January 2005, the UK requirement for patient registration and monitoring was removed.

Precautions

Tryptophan has been associated with eosinophilia-myalgia syndrome (see above); caution is advised in patients receiving the drug who develop some, but not all, of the symptoms of this syndrome. It should not be used in those with a history of eosinophilia-myalgia syndrome associated with tryptophan treatment.

Patients taking tryptophan may experience drowsiness and, if affected, they should not drive or operate machinery. For further details of the effects of antidepressant therapy on driving see under Amitriptyline, p.379.

Abnormal metabolism of tryptophan may occur in patients with pyridoxine deficiency and tryptophan is thus sometimes given with pyridoxine supplements.

Interactions

Although tryptophan has been given to patients receiving MAOIs in the belief that clinical efficacy may be improved, it should be noted that the adverse effects may also be potentiated. For further details, see Antidepressants under Interactions of Phenelzine, p.418.

Use of tryptophan with drugs that inhibit the reuptake of serotonin may exacerbate the adverse effects of the latter and precipitate the serotonin syndrome (p.416).

There have been occasional reports of sexual disinhibition in patients taking tryptophan with phenothiazines or benzodiazepines.

For a report of tryptophan reducing blood concentrations of levodopa, see Nutritional Agents under Interactions of Levodopa, p.808.

Pharmacokinetics

Tryptophan is readily absorbed from the gastrointestinal tract. Tryptophan is extensively bound to plasma albumin. It is metabolised in the liver by tryptophan pyrrolase and tryptophan hydroxylase. Metabolites include hydroxytryptophan, which is then converted to serotonin, and kynurenine derivatives. Some tryptophan is converted to nicotinic acid and nicotinamide. Pyridoxine and ascorbic acid are cofactors in the decarboxylation and hydroxylation, respectively, of tryptophan; pyridoxine apparently prevents the accumulation of the kynurenine metabolites.

◊ References.

1. Green AR, *et al.* The pharmacokinetics of -tryptophan following its intravenous and oral administration. *Br J Clin Pharmacol* 1985; **20:** 317–21.

Uses and Administration

Tryptophan is an amino acid that is an essential constituent of the diet. Tryptophan and DL-tryptophan have been used as dietary supplements.

Tryptophan is a precursor of serotonin. Because CNS depletion of serotonin is considered to be involved in depression, tryptophan has been used in its treatment. Although it has been given alone, evidence of effectiveness is scant and tryptophan has generally been used as adjunctive therapy in depression. It has sometimes been given with pyridoxine and ascorbic acid, which are involved in its metabolism to serotonin (see Pharmacokinetics, above).

In many countries preparations containing tryptophan have either been withdrawn from the market or their availability severely restricted or limited because of its association with the eosinophilia-myalgia syndrome. In the UK, tryptophan is restricted to use as an adjunct to other antidepressant medication or in patients who have failed to respond to an adequate trial of standard antidepressant drug treatment. Therapy should be started by hospital specialists; thereafter tryptophan may be prescribed in the community.

In the treatment of depression the usual oral dose of tryptophan is 1 g given three times daily, but some patients may require up to 6 g daily in divided doses. Lower doses may be required in the elderly especially those with renal or hepatic impairment.

Depression. Evidence of benefit for tryptophan when given alone for depression (p.373) is lacking, though there is some suggestion of a weak antidepressant effect.[1] It has therefore mainly been used with other antidepressants in the belief that it would potentiate their effects. Although beneficial effects have been reported in some patients given tryptophan with SSRIs, tricyclic antidepressants, or MAOIs, either alone or with lithium, evidence of efficacy is mainly limited to case reports and small controlled studies.[2-4]

After the publication of reports linking the use of tryptophan with the eosinophilia-myalgia syndrome (see under Adverse Effects, above) preparations containing tryptophan for depression were withdrawn from the market or their use restricted. For details of UK restrictions see Uses and Administration, above.

4. Levitan RD, *et al.* Preliminary randomized double-blind placebo-controlled trial of tryptophan combined with fluoxetine to treat major depressive disorder: antidepressant and hypnotic effects. *J Psychiatry Neurosci* 2000; **25:** 337–46.

Dietary supplementation. The use of tryptophan as a dietary supplement has been reviewed.[1] However, because of its association with the eosinophilia-myalgia syndrome (see under Adverse Effects, above), the addition of tryptophan to food intended for human consumption is prohibited in some countries.

1. Li Wan Po A, Maguire T. Tryptophan: useful dietary supplement or a health hazard? *Pharm J* 1990; **244:** 484–5.

Insomnia. Tryptophan, sometimes in the form of dietary supplements, has enjoyed some popularity for the treatment of insomnia (p.957). However, in comparison with other hypnotics such as the benzodiazepines, the effects of tryptophan have been difficult to substantiate, and enthusiasm for tryptophan has waned considerably amongst sleep researchers.[1] It should also be noted that since the publication of reports linking the use of tryptophan with the eosinophilia-myalgia syndrome (see under Adverse Effects, above) preparations indicated for insomnia have been withdrawn from the market in many countries.

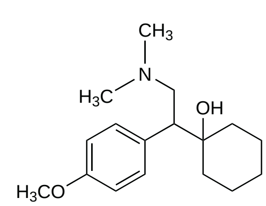
Venlafaxine Hydrochloride

(BANM, USAN, rINNM)

Hidrocloruro de venlafaxina; Venlafaxine, chlorhydrate de; Venlafaxin-hydrochlorid; Venlafaxini hydrochloridum; Venlafaxinum hydrochloridum; Wenlafaksyny chlorowodorek; Wy-45030. (*RS*)-1-(2-Dimethylamino-1-*p*-methoxyphenylethyl)cyclohexanol hydrochloride.

Венлафаксина Гидрохлорид

$C_{17}H_{27}NO_2$,HCl = 313.9.
CAS — 93413-69-5 (venlafaxine); 99300-78-4 (venlafaxine hydrochloride).
ATC — N06AX16.
ATC Vet — QN06AX16.



(venlafaxine)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Venlafaxine Hydrochloride). A white or almost white powder. It exhibits polymorphism. Freely soluble in water and in methyl alcohol; soluble in dehydrated alcohol; slightly soluble or practically insoluble in acetone.

Adverse Effects and Treatment

Adverse effects that have been reported most frequently with venlafaxine include nausea, headache, insomnia, somnolence, dry mouth, dizziness, constipation, sexual dysfunction, asthenia, sweating, and nervousness. Other common adverse effects have included anorexia, diarrhoea, dyspepsia, abdominal pain, anxiety, urinary frequency, visual disturbances, mydriasis, vasodilatation, vomiting, tremor, paraesthesia, hypertonia, chills or fever, palpitations, weight gain or loss, increased serum-cholesterol, agitation, abnormal dreams, confusion, arthralgia, myalgia, tinnitus, pruritus, dyspnoea, yawning, and skin rashes. Dose-related increases in blood pressure have also been observed in some patients.

Less common effects have included reversible increases in liver enzymes, orthostatic hypotension, syncope, arrhythmias, tachycardia, mucous membrane bleeding, ecchymosis, hallucinations, bruxism, muscle spasm, myoclonus, alopecia, altered taste, urinary retention, menorrhagia, angioedema, and photosensitivity reactions.

Convulsions, galactorrhoea, haemorrhage including gastrointestinal bleeding, anaphylaxis, hepatitis, erythema multiforme, Stevens-Johnson syndrome, ataxia, dysarthria, extrapyramidal disorders including psychomotor restlessness and akathisia, and activation of mania or hypomania have been reported rarely. Other rare adverse effects include blood dyscrasias such as agranulocytosis, aplastic anaemia, neutropenia, pancytopenia, and thrombocytopenia, prolongation of the QT interval and torsade de pointes, ventricular tachycardia or fibrillation, rhabdomyolysis, delirium, pancreatitis, and pulmonary eosinophilia.

Aggressive behaviour has developed with venlafaxine treatment particularly at the start and when stopping therapy. Suicidal ideation has been reported, particularly in children (see under Effects on Mental State, below).

Hyponatraemia possibly due to inappropriate secretion of antidiuretic hormone has been associated with the use of antidepressants, particularly in the elderly.

In overdosage, symptoms such as sweating, dizziness, somnolence, ECG changes, cardiac arrhythmias, and seizures may be noted. Treatment of overdosage includes consideration of the use of activated charcoal if more than 12.5 mg/kg has been ingested and the patient presents within 1 hour; this should be followed by symptomatic and supportive therapy. Dialysis, haemoperfusion, exchange perfusion, and measures to increase urine production are considered unlikely to be of benefit.

Effects on the endocrine system. The syndrome of inappropriate antidiuretic hormone secretion (SIADH) with hyponatraemia may be more likely to occur with serotonergic antidepressants such as venlafaxine than with other antidepressants; for further details, see under Fluoxetine p.392.

Effects on the eyes. Acute angle-closure glaucoma developed in a 45-year-old woman 3 days after starting venlafaxine;[1] she recovered after iridotomy. In another case, a 35-year-old man presented with bilateral acute angle-closure glaucoma 10 days after starting venlafaxine.[2] The patient had also experienced visual disturbances while on mirtazapine and sertraline.

2. de Guzman MHP, *et al.* Bilateral acute angle closure caused by supraciliary effusions associated with venlafaxine intake. *Med J Aust* 2005; **182:** 121–2.

Effects on the hair. Hair loss has been described in 3 women given venlafaxine. The effect was noticed by the patients within a few weeks[1] to 5 months[2] after starting treatment. One patient who noticed hair loss within 1 week of starting venlafaxine had experienced the same problem during previous fluoxetine treatment.[3] In all 3 cases, hair loss abated soon after stopping venlafaxine. In 2 cases hair regrowth was reported within a few weeks,[2,3] but the third report was unclear as to whether regrowth occurred.[1]

3. O'Bryan EC, Albanese RP. A case report of fluoxetine- and venlafaxine-induced hair loss. *Prim Care Companion J Clin Psychiatry* 2004; **6:** 181.

Effects on the liver. Acute hepatitis developed in a 44-year-old woman about 6 months after starting venlafaxine;[1] she recovered once venlafaxine was withdrawn. In another report,[2] acute hepatitis developed in a 78-year-old man about a month after venlafaxine was added to therapy. Again, symptoms resolved when the drug was stopped. Hepatitis was noted in a 60-year-old woman about a month after starting low-dose venlafaxine (75 mg daily); symptoms resolved when the drug was stopped and recurred on rechallenge.[3] Hepatitis has also been attributed to low-dose venlafaxine (37.5 mg daily) in a patient with chronic hepatitis B; other causes of hepatitis and relapse of viral hepatitis were excluded.[4]

For a report of hepatotoxicity in patients taking venlafaxine subsequent to an attempted overdose with sertraline, see p.392.

Effects on mental state. An expert working group was convened in May 2003 by the UK CSM to consider the ongoing safety concerns of the SSRIs and, in particular, the risk of suicidal behaviour in children; the safety of venlafaxine (another serotonergic antidepressant) was also considered. An interim report issued in September 2003 concluded that data from trials received by the CSM failed to show that venlafaxine was effective in the treatment of depressive illness in **children under 18 years old** and indicated that the risk of harmful outcome including self-harm and suicidal ideation was increased in those receiving venlafaxine when compared with placebo.[1] The CSM recommended that venlafaxine should not be used to treat depressive illness in children under 18 years old. Similar warnings have also been issued in Canada,[2] the EU,[3] and the USA. (The final report[4] of the CSM's expert working group was published in December 2004.)

The risk of suicide and suicide-related events with antidepressant treatment in **adults** including young adults is discussed under Fluoxetine, p.392.

Effects on the skin. Stevens-Johnson syndrome developed in a patient 12 days after beginning treatment with venlafaxine for recurrent depression.[1] She had also been taking several other drugs for at least 6 months. Symptoms resolved on withdrawal of all medication and treatment with an intravenous corticosteroid.

1. Weiss NT, *et al.* A possible case of venlafaxine-induced Stevens-Johnson syndrome. *J Clin Psychiatry* 2004; **65:** 1431–3.

Overdosage. Rare serious events including seizures and ECG changes[1-3] have occurred after venlafaxine overdoses; in some cases, death has ensued.[4,5] Symptoms suggestive of serotonin toxicity may also develop.[6,7]

Venlafaxine may not be as safe in overdose as some other serotonergic antidepressants. A review[8] of UK data recording the number of deaths due to acute poisoning by a single drug, with or without alcohol, found the number of fatalities per million prescriptions (the fatal toxicity index) was higher for venlafaxine than for other serotonergic antidepressants, and was similar to that for some of the less toxic tricyclic antidepressants.

Serotonin syndrome. The serotonin syndrome (p.416) is most often due to the additive adverse effects of two or more drugs that enhance serotonin activity at central receptors; rarely, a single serotonergic drug may cause the syndrome. One such case[1] was reported to have occurred in a 29-year-old woman who developed symptoms suggestive of serotonin syndrome 3 days after starting low-dose venlafaxine. However, this patient had been switched to venlafaxine the day after stopping imipramine treatment; it is usually recommended that at least 3 weeks should elapse after stopping imipramine before starting another drug with serotonergic properties.

1. Pan J-J, Shen WW. Serotonin syndrome induced by low-dose venlafaxine. *Ann Pharmacother* 2003; **37:** 209–11.

Precautions

Venlafaxine should not be used in patients with an identified very high risk of a serious ventricular arrhythmia or uncontrolled hypertension. Caution is advised in those with a recent history of myocardial infarction or whose condition might be exacerbated by an increase in heart rate. Due to the risk of dose-related increases in blood pressure, blood pressure measurement should be performed regularly during therapy. Measurement of serum-cholesterol levels should also be considered with long-term treatment.

Venlafaxine should be used with caution in patients with moderate to severe hepatic or renal impairment and dosage adjustment may be necessary. It should also be used with caution in patients with a history of epilepsy and avoided in those with unstable disease; it should be stopped in any patient developing a seizure or if there is an increase in seizure frequency. Caution is also advised in patients with a history of bleeding disorders or of hypomania or mania. Patients with raised intra-ocular pressure or at risk of angle-closure glaucoma should be monitored closely. Patients who develop a rash, urticaria, or related allergic reaction with venlafaxine should be advised to contact their doctor.

Patients should be closely monitored during early antidepressant therapy until a significant improvement in depression is observed because suicide is an inherent risk in depressed patients. For further details, see under Depression, p.373. Suicidal thoughts and behaviour may also develop during early treatment with antidepressants for other disorders; the same precautions observed when treating patients with depression should therefore be observed when treating patients with other disorders.

As with other antidepressants, venlafaxine may impair performance of skilled tasks and, if affected, patients should not drive or operate machinery. Patients, especially the elderly, should be warned of the risk of dizziness or unsteadiness due to orthostatic hypotension.

Symptoms reported on abrupt withdrawal or dose reduction of venlafaxine include fatigue, somnolence, headache, nausea, vomiting, anorexia, palpitations, dizziness, dry mouth, diarrhoea, insomnia, agitation, anxiety, nervousness, confusion, hypomania, paraesthesia, sweating, and vertigo. It is therefore recommended that venlafaxine should be withdrawn gradually over at least one week after more than one week's therapy; patients receiving high-dose venlafaxine for longer than 6 weeks should be tapered over at least 2 weeks. All patients should also be monitored to minimise the risk of withdrawal reactions.

Abuse. A patient had an amfetamine-like "high" after taking crushed modified-release tablets of venlafaxine in doses of up to 3600 mg daily.[1] He continued to ingest increasing amounts of venlafaxine until a 4050-mg dose produced chest pain. On evaluation he had a raised pulse and blood pressure but these returned to normal within a few days.

1. Sattar SP, *et al.* A case of venlafaxine abuse. *N Engl J Med* 2003; **348:** 764–5.

Breast feeding. Licensed product information recommends that venlafaxine should not be used in women who are breast feeding.

Venlafaxine and its metabolite *O*-desmethylvenlafaxine were both detected in breast milk in significant quantities in 3 women;[1] there were also measurable concentrations of desmethylvenlafaxine in the infants' plasma. In another study[2] by the same group the mean milk-to-plasma ratio in 6 breast-feeding women was calculated to be 2.5 for venlafaxine and 2.74 for *O*-desmethylvenlafaxine. Detectable plasma concentrations of venlafaxine were found only in 1 of 7 breast-fed infants while 4 had detectable *O*-desmethylvenlafaxine levels; no adverse effects were reported in the infants. Nonetheless, the authors recommended caution when giving venlafaxine to breast-feeding women particularly for those feeding premature or very young neonates. The distribution of venlafaxine into breast milk and the presence of *O*-desmethylvenlafaxine in the serum of a further 5 breast-fed infants has also been reported.[3,4] There were no detectable adverse effects in the infants, and the authors of 1 report[4] suggested that women being treated for postpartum depression should not be generally discouraged from breast feeding. It has been suggested that venlafaxine in breast milk might alleviate a withdrawal syndrome in the neonate (see Pregnancy, below).

Children. Venlafaxine is associated with an increased risk of potentially suicidal behaviour when used for the treatment of depression in children and adolescents under 18 years old; for further details, see under Effects on Mental State, above.

US licensed product information also refers to studies that suggest that venlafaxine may adversely affect weight and height changes in children. In particular, the difference between the observed and the expected growth rate was larger for those children under 12 years of age than for older children.

Pregnancy. Licensed product information recommends that venlafaxine should not be used during pregnancy unless clearly necessary.

In a study of 150 women who took venlafaxine in the first trimester of pregnancy there were 125 live births, 18 spontaneous abortions, 7 therapeutic abortions, and 2 reports of major malformations (hypospadias and neural tube defect with club foot).[1] Although the rate of spontaneous abortions was non-significantly higher in the venlafaxine group than in historical controls, the rate of major malformations was not greater than the baseline rate of 1 to 3%.

A neonatal withdrawal syndrome developed in the infant of a mother who had taken venlafaxine throughout her pregnancy;[2] symptoms included restlessness, hypertonia, irritability, and poor feeding. The infant recovered within 8 days. Seizures have been described in 2 neonates whose mothers were taking venlafaxine.[3] Lip smacking and extensor limb posturing began at 30 minutes of age in 1 case, and multifocal myoclonic seizures occurred at 24 hours of age in the other; both recovered and were well at 1 year of age. Serum-venlafaxine concentrations had not been measured and the authors were unsure whether the adverse effects in the neonates were due to withdrawal or toxicity. In a retrospective study[4] of women who had taken SSRIs or venlafaxine during the third trimester (9 had taken venlafaxine), there were reports of adverse effects on the CNS and respiratory tract in the neonates, such as abnormal movements, tonus abnormalities, irritability, insomnia, indrawing, apnoea/bradycardia, and tachypnoea. The signs usually appeared on the first day of life and lasted for about 3 days in full-term neonates and about 5 days in those born prematurely.

Venlafaxine and its metabolite *O*-desmethylvenlafaxine are distributed into breast milk (see Breast Feeding, above), and it has been suggested that breast feeding might have helped to alleviate symptoms of a withdrawal syndrome in a neonate whose mother took venlafaxine throughout her pregnancy.[5]

Renal impairment. The mean terminal disposition half-life of venlafaxine was prolonged from a mean of 3.8 hours in 18 healthy subjects to 5.8 hours in 12 patients with mild to moderate renal impairment (creatinine clearance 10 to 70 mL/minute) and 10.6 hours in patients requiring haemodialysis;[1] corresponding values for *O*-desmethylvenlafaxine, the active major metabolite of venlafaxine, were 11.8, 16.8, and 28.5 hours, respectively. Because of the large intersubject variability, the change in disposition for venlafaxine and its active metabolite was evident only in patients with a creatinine clearance of less than 30 mL/minute; drug clearance in these patients was reduced by about 55% and half-life more than doubled. It was calculated that for these patients half the usual daily dose could be given once daily.

Similar recommendations are made in licensed drug information, see under Uses and Administration, below.

1. Troy SM, *et al.* The effect of renal disease on the disposition of venlafaxine. *Clin Pharmacol Ther* 1994; **56:** 14–21.

Surgery. Serotonergic antidepressants such as venlafaxine may be associated with an increased risk of blood loss during surgery; for further details, see under Fluoxetine, p.396.

Withdrawal. Withdrawal reactions may be more common with venlafaxine than with some other serotonergic antidepressants; for further details, see under Fluoxetine, p.396. Withdrawal reactions may also be seen in neonates after maternal venlafaxine use, see under Pregnancy above.

Some cases[1,2] of withdrawal reactions to venlafaxine have been reported.

2. Johnson H, *et al.* Withdrawal reaction associated with venlafaxine. *BMJ* 1998; **317:** 787.

Interactions

Although different antidepressants have been used together under expert supervision in refractory cases of depression, severe adverse reactions including the *serotonin syndrome* (see p.416) may occur. Sequential prescribing of different types of antidepressant may also produce adverse reactions, and an appropriate drug-free interval should elapse between stopping one type of antidepressant and starting another. Venlafaxine should not be used with MAOIs and at least 14 days should elapse between stopping an MAOI and starting treatment with venlafaxine. At least 7 days should elapse between stopping venlafaxine and starting any drug liable to provoke a serious reaction (e.g. phenelzine). For further details, see Antidepressants under Interactions of Phenelzine, p.418. Adverse effects such as the serotonin syndrome may also occur when venlafaxine is given with other drugs known to act on the same neurotransmitter, a consequence of synergistic interaction.

Venlafaxine has occasionally been associated with bleeding disorders and other effects on the blood; caution is advised when giving venlafaxine with other drugs known to affect platelet function.

Although cimetidine inhibits the first-pass hepatic metabolism of venlafaxine, it has no effect on the active metabolite *O*-desmethylvenlafaxine, which is present in the plasma in much greater concentrations. Licensed product information therefore considers that when cimetidine and venlafaxine are used together, clinical monitoring may only be necessary in elderly patients and in those with hepatic impairment or pre-existing hypertension.

◊ Conversion of venlafaxine to its equally active metabolite *O*-desmethylvenlafaxine is mediated by the cytochrome P450 isoenzyme CYP2D6. Therefore the potential exists for drugs that inhibit or act as a substrate for this enzyme to affect plasma concentrations of venlafaxine and its active metabolite. However, the US product information indicates that, as the total amount of active compounds is unaffected, no dosage adjustment is usually necessary for venlafaxine. Venlafaxine is also metabolised by CYP3A4 to the less active metabolite *N*-desmethylvenlafaxine. This is a relatively minor pathway and the potential for clinically significant interactions between venlafaxine and CYP3A4 inhibitors is considered to be small. However, potent inhibitors of CYP3A4 or drugs that inhibit both CYP2D6 and CYP3A4 could significantly increase venlafaxine concentrations in patients who are poor CYP2D6 metabolisers; such combinations should therefore be used with caution.

Venlafaxine itself is considered to be a relatively weak inhibitor of CYP2D6.

Antiarrhythmics. Psychosis with raised serum concentrations of venlafaxine and its metabolite *O*-desmethylvenlafaxine developed when *propafenone* therapy was started in a 67-year-old woman. There was improvement when venlafaxine was stopped and restarted at a reduced dose; 50 mg daily was sufficient to maintain therapeutic serum concentrations.[1]

1. Pfeffer F, Grube M. An organic psychosis due to a venlafaxine-propafenone interaction. *Int J Psychiatry Med* 2001; **31:** 427–32.

Antibacterials. Tingling in the tip of the tongue, intense paraesthesia in the fingers, severe abdominal cramps, profuse diarrhoea, cold sweats, and uncontrolled shivering and tremor occurred when *co-amoxiclav* was started in a man taking venlafaxine.[1] The reaction lasted for about 6 hours. It occurred again 2 months later after a single dose of co-amoxiclav. The patient reported that he had taken co-amoxiclav in the past without any reaction at a time when he was not taking venlafaxine. The mechanism for an interaction between venlafaxine and co-amoxiclav causing this serotonin syndrome is unknown. The author also suggested that many patients must have taken this combination without adverse effect, and found no other reports.

Serotonin syndrome has been reported in an elderly patient taking venlafaxine, after 20 days of antibacterial treatment including *linezolid*.[2] In another report, serotonin syndrome developed 8 days after starting treatment with intravenous linezolid in a patient taking venlafaxine.[3]

1. Connor H. Serotonin syndrome after single doses of co-amoxiclav during treatment with venlafaxine. *J R Soc Med* 2003; **96:** 233–4.
2. Jones SL, *et al.* Serotonin syndrome due to co-administration of linezolid and venlafaxine. *J Antimicrob Chemother* 2004; **54:** 289–90.
3. Bergeron L, *et al.* Serotonin toxicity associated with concomitant use of linezolid. *Ann Pharmacother* 2005; **39:** 956–61.

Antimigraine drugs. There have been rare reports of serotonin syndrome associated with the use of serotonin and noradrenaline reuptake inhibitors (SNRIs) with serotonin ($5\text{-}HT_1$) agonists such as *sumatriptan* (see p.626).

Antipsychotics. For mention of neuroleptic malignant syndrome developing in patients who received venlafaxine with antipsychotics see under Interactions in Chlorpromazine, p.974.

Gastrointestinal drugs. Signs suggestive of the serotonin syndrome that occurred after intravenous *metoclopramide* were attributed to an interaction with venlafaxine.[1] The 32-year-old woman experienced confusion, agitation, generalised shaking, myoclonus, facial twitching, diaphoresis, horizontal nystagmus, and dilated pupils, that resolved within 2 days after stopping both drugs and treatment with diazepam.

1. Fisher AA, Davis MW. Serotonin syndrome caused by selective serotonin reuptake-inhibitors–metoclopramide interaction. *Ann Pharmacother* 2002; **36:** 67–71.

Selegiline. Although it is generally recommended that venlafaxine should not be started for at least 14 days after stopping an MAOI, there is a report[1] of serotonin syndrome developing when a patient began venlafaxine treatment 15 days after stopping selegiline, an MAO type B inhibitor.

1. Gitlin MJ. Venlafaxine, monoamine oxidase inhibitors, and the serotonin syndrome. *J Clin Psychopharmacol* 1997; **17:** 66–7.

Pharmacokinetics

Venlafaxine is readily absorbed from the gastrointestinal tract. After oral doses it undergoes extensive first-pass metabolism in the liver mainly to the active metabolite *O*-desmethylvenlafaxine; formation of *O*-desmethylvenlafaxine is mediated by the cytochrome P450 isoenzyme CYP2D6. The isoenzyme CYP3A4 is also involved in the metabolism of venlafaxine. Other metabolites include *N*-desmethylvenlafaxine and *N,O*-didesmethylvenlafaxine. Peak plasma concentrations of venlafaxine and *O*-desmethylvenlafaxine appear about 2 and 4 hours after a dose, respectively. Venlafaxine is 27% and *O*-desmethylvenlafaxine 30% bound to plasma proteins. The mean elimination half-life of venlafaxine and *O*-desmethylvenlafaxine is about 5 and 11 hours, respectively. Venlafaxine is excreted mainly in the urine, mainly in the form of its metabolites, either free or in conjugated form; about 2% is excreted in the faeces. Venlafaxine and *O*-desmethylvenlafaxine have been detected in amniotic fluid and umbilical cord blood, and are distributed into breast milk.

Uses and Administration

Venlafaxine, a phenylethylamine derivative, is a serotonin and noradrenaline reuptake inhibitor (SNRI); it also weakly inhibits dopamine reuptake. It is reported to have little affinity for muscarinic, histaminergic, or α_1-adrenergic receptors *in vitro*. Venlafaxine is given orally as the hydrochloride although doses are expressed in terms of the base; venlafaxine hydrochloride 28.3 mg is equivalent to about 25 mg of venlafaxine.

Venlafaxine is used in the treatment of **depression**. The initial daily dose is equivalent to venlafaxine 75 mg in two or three divided doses with food. In the USA, it is suggested that some patients may be best started on 37.5 mg daily for the first 4 to 7 days before increasing the dose to 75 mg daily. The dose may be increased, if necessary, after several weeks to 150 mg daily. Further increases, to a maximum daily dose of 375 mg, may be made in increments of up to 75 mg at intervals of at least 2 to 4 days. Such doses may be required in severely depressed or hospitalised patients and should be gradually reduced to the minimum effective dose. Modified-release preparations are available for once-daily dosing.

Venlafaxine is also used, as a modified-release preparation, in the treatment of **generalised anxiety disorder**. The recommended initial dose is 75 mg once daily. In the USA it is suggested that some patients may be best begun with 37.5 mg daily for 4 to 7 days initially; dosage may subsequently be adjusted in increments of up to 75 mg, at intervals of at least 4 days, to a maximum of 225 mg daily. Venlafaxine should be withdrawn gradually if there is no response after 8 weeks.

In the USA, modified-release venlafaxine is licensed for the treatment of **social anxiety disorder** in doses similar to those used for generalised anxiety disorder. It is also licensed in the USA for **panic disorder** with or without agoraphobia in doses of 37.5 mg once daily for the first 7 days, then increasing to 75 mg daily. Subsequent increases in increments of up to 75 mg may be made at intervals of at least 7 days, to a maximum dose of 225 mg daily.

Reduced doses may need to be given in hepatic or renal impairment, see below.

Venlafaxine should be withdrawn gradually to reduce the risk of withdrawal symptoms (see Precautions, above).

Administration in hepatic impairment. UK licensed product information considers that patients with mild hepatic impairment do not require a change in dose of venlafaxine. For those with moderate impairment, the dose should be reduced by half and given once daily. There are insufficient data to make any recommendations for patients with severe impairment.

Administration in renal impairment. The UK licensed product information states that, based on glomerular filtration rate (GFR), patients with mild renal impairment (GFR above 30 mL/minute) do not require a change in dose of venlafaxine. For those with moderate impairment (GFR 10 to 30 mL/minute), the dose should be reduced by 50% and once-daily dosage may be appropriate. There are insufficient data to make any recommendations for patients with severe impairment (GFR less than 10 mL/minute).

In the USA, it is recommended that patients with a GFR of 10 to 70 mL/minute reduce the dose of immediate-release venlafaxine by 25% and of modified-release venlafaxine by 25 to 50%; regardless of preparation, in those undergoing haemodialysis, the dose should be reduced by 50% and withheld until the dialysis is completed.

Anxiety disorders. Venlafaxine is used in the treatment of generalised anxiety disorder and social anxiety disorder (see under Phobic Disorders, p.953); it may also be of use in a variety of other types of anxiety disorders (p.952) including the treatment of obsessive-compulsive disorder (p.952), panic disorder (p.952), and post-traumatic stress disorder (p.953).

Depression. As discussed on p.373, there is very little difference in efficacy between the different groups of antidepressant drugs, and choice is often made on the basis of adverse effect profile. In December 2004 the UK CSM recommended that, because of the risk of adverse cardiovascular effects and toxicity in overdosage (see above), venlafaxine treatment should be begun and maintained under specialist supervision only. After an assessment of further safety evidence, these restrictions were revised in May 2006 and specialist supervision was considered only necessary when starting venlafaxine treatment in severely depressed or hospitalised patients who require doses of 300 mg daily or above. However, it was also advised that venlafaxine should be considered a second-line treatment, after the SSRIs.

The *O*-desmethyl metabolite of venlafaxine, desvenlafaxine (p.388), is also used in depression.

Hot flushes. For the reference to the use of venlafaxine in the treatment of hot flushes, see under Fluoxetine, p.398.

Hyperactivity. When drug therapy is indicated for attention deficit hyperactivity disorder (p.2148) initial treatment is usually with a central stimulant. Antidepressants may be used for patients who fail to respond to, or who are intolerant of, central stimulants; in open studies venlafaxine has been reported to be effective in both adults[1-3] and children[4,5] although in one study[4] some patients experienced a worsening of symptoms.

1. Hedges D, *et al.* An open trial of venlafaxine in adult patients with attention deficit hyperactivity disorder. *Psychopharmacol Bull* 1995; **31:** 779–83.

Migraine. Retrospective analysis[1] in patients with tension-type headache (p.617) or migraine (p.616) indicated that venlafaxine, as a modified-release preparation, had potential for headache prophylaxis. A more recent randomised placebo-controlled study[2] also supports the use of modified-release venlafaxine in the prophylaxis of migraine.

Viloxazine Hydrochloride *(BANM, USAN, rINNM)*

Hidrocloruro de viloxazina; ICI-58834; Viloxazine, Chlorhydrate de; Viloxazini Hydrochloridum. 2-(2-Ethoxyphenoxymethyl)morpholine hydrochloride.

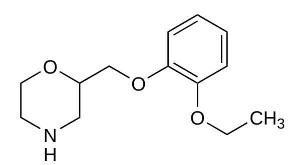
Вилоксазина Гидрохлорид

$C_{13}H_{19}NO_3,HCl = 273.8.$

CAS — 46817-91-8 (viloxazine); 35604-67-2 (viloxazine hydrochloride).

ATC — N06AX09.

ATC Vet — QN06AX09.



(viloxazine)

Profile

Viloxazine is a bicyclic antidepressant. Like the tricyclic antidepressants (see Amitriptyline, p.376), viloxazine is an inhibitor of the reuptake of noradrenaline; it may also enhance the release of serotonin from neuronal stores. However, it does not have marked antimuscarinic, cardiotoxic, or sedative properties.

Viloxazine is given for the treatment of depression (p.373) as the hydrochloride although doses are expressed in terms of viloxazine; viloxazine hydrochloride 57.7 mg is equivalent to about 50 mg of viloxazine. The usual oral dose is equivalent to viloxazine 200 to 300 mg daily in 2 or 3 divided doses. This may be increased, if necessary, to 600 mg daily as tolerated. The initial dose for the elderly or patients with hepatic or renal impairment is 100 mg daily cautiously increased if necessary. A modified-release preparation is also available for once daily use. Viloxazine hydrochloride has also been given by intravenous infusion.

Viloxazine should be withdrawn gradually to reduce the risk of withdrawal symptoms.

Porphyria. Viloxazine hydrochloride is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Antidiabetics

This chapter describes diabetes mellitus and its management with antidiabetics. The oral drugs included in this chapter are classified in Table 1, below. Insulin, which is given parenterally, is discussed on p.443 and classified in Table 2, p.444. The adjunct pramlintide given subcutaneously, is described on p.457, and the incretin mimetic, exenatide, on p.439.

Table 1. Classification of oral antidiabetics.

Aldose Reductase Inhibitors	*Sulfonylureas*
Epalrestat	Acetohexamide
Alpha-glucosidase Inhibitors	Carbutamide
Acarbose	Chlorpropamide
Miglitol	Glibenclamide
Voglibose	Glibornuride
	Gliclazide
Biguanides	Glimepiride
Buformin	Glipizide
Metformin	Gliquidone
Phenformin	Glisentide
Dipeptidylpeptidase-4 inhibitors	Glisolamide
Sitagliptin	Glisoxepide
Vildagliptin	Glycyclamide
Meglitinides	Tolazamide
Nateglinide	Tolbutamide
Repaglinide	*Thiazolidinediones*
Miscellaneous	Pioglitazone
Glybuzole	Rosiglitazone
Guar Gum	Troglitazone

Diabetes mellitus

Diabetes mellitus is a group of disorders of carbohydrate metabolism in which the action of insulin is diminished or absent through altered secretion, decreased insulin activity, or a combination of both factors. It is characterised by hyperglycaemia. As the disease progresses tissue or vascular damage ensues leading to severe complications such as retinopathy, nephropathy, neuropathy, cardiovascular disease, and foot ulceration.

Diabetes mellitus may be categorised into several types but the two major types are type 1 (insulin-dependent diabetes mellitus; IDDM) and type 2 (non-insulin-dependent diabetes mellitus; NIDDM). The term juvenile-onset diabetes has sometimes been used for type 1 and maturity-onset diabetes for type 2. Malnutrition-related diabetes is no longer considered a separate entity (see Effects of Cassava, under Adverse Effects of Starch, p.1968).

Type 1 diabetes mellitus is present in patients who have little or no endogenous insulin secretory capacity and who therefore require exogenous insulin therapy for survival. This form of the disease has an auto-immune basis in most cases, and usually develops before adulthood. The associated hypoinsulinaemia and hyperglucagonaemia put such patients at risk of ketosis and ketoacidosis.

In **type 2 diabetes mellitus** the disease typically develops in later life. Insulin secretion may appear normal or even excessive (and type 2 patients are thus less prone to ketosis) but it is insufficient to compensate for insulin resistance (p.449). Obesity is present in the majority of type 2 patients; non-obese patients tend to have low insulin secretory capacity (although not as low as in type 1 diabetes) rather than appreciable insulin resistance. It is closely associated with cardiovascular disease, and the 2 may arise from a common antecedent described as the metabolic syndrome.

Diagnosis of diabetes mellitus. Diagnosis is based upon blood-glucose concentrations exceeding set values under specified conditions.[1-4] Diagnostic values for measurements in venous whole blood are greater than or equal to 6.1 mmol/litre for the fasting state and 10.0 mmol/litre after a glucose load. The corresponding values for capillary whole blood are 6.1 and 11.1 mmol/litre, and for venous plasma 7.0 and 11.1 mmol/litre.[1] If there are accompanying symptoms of increased thirst and urine volume, recurrent infections and weight loss, then a plasma-glucose concentration in excess of 11.1 mmol/litre in a single random sample is considered diagnostic. If symptoms are absent, a fasting plasma-glucose of 7.0 mmol/litre or more, repeated on a subsequent day, can be used to confirm the diagnosis. Alternatively, diagnosis can be confirmed with the **oral glucose tolerance test** (OGTT). This test consists of an overnight fast followed by measurement of the fasting blood-glucose concentration, then the administration of a 75-g oral glucose load (in children 1.75 g/kg up to a maximum of 75 g), and further measurement of the blood-glucose concentration two hours later. There has been some confusion at an international level as to whether the glucose load should be 75 g of the anhydrous form or the monohydrate. Sources at WHO have therefore suggested that the form should be standardised as 75 g of anhydrous glucose (anhydrous dextrose), which would be equivalent to 82.5 g of the monohydrate (Glucose BP; dextrose monohydrate). The threshold for the diagnosis of diabetes was lowered in the late 1990s from an earlier fasting plasma glucose concentration of 7.8 mmol/litre,[5] to reflect an increased risk of microvascular disease in patients with concentrations of 7.0 mmol/litre or more. Patients with abnormal blood sugar who do not reach the defined threshold for overt diabetes may be considered to have impaired fasting glucose or impaired glucose tolerance.[6]

Measurement of glycosylated haemoglobin (HbA_{1c}) is not recommended for routine diagnosis.[6] Similarly, other indicators, such as measurement of autoantibodies (to insulin or islet cells, for example) are not routinely used for diagnosis.

Once the presence of diabetes has been confirmed the distinction between type 1 and type 2 is made on clinical grounds.

Management of diabetes mellitus.

- *DIETARY MODIFICATION.* Dietary control is important in both type 1 and type 2 diabetes.[6-10] The goals of dietary modification are to maintain glucose concentrations in the normal range or as close to normal as possible, and a lipid and lipoprotein profile and blood pressure that reduce the risk of macrovascular disease (see Diabetic Complications, below). Correction of obesity is desirable in all patients, and weight loss in patients with type 2 diabetes can decrease insulin resistance, improve glycaemic and lipid measures, and reduce blood pressure. Anorectic drugs are not appropriate in these patients,[11] although orlistat, a gastric and pancreatic lipase inhibitor, can be used as an adjunctive treatment to reduce weight and improve blood glucose control in overweight patients with type 2 diabetes.[12-14] A high fibre intake may also lower blood-glucose concentrations and additional fibre is sometimes taken in the form of guar gum (see p.443). The influence of diet on diabetes is such that all diabetic patients need to be aware of the composition of foods and to be able to make adjustments to their diet, especially to counteract treatment-induced hypoglycaemia. However, neither protein restriction nor very low calorie diets are recommended.
- *EXERCISE.* All diabetic patients should be encouraged to exercise, according to their age and physical capability.[5,6,8,10] Exercise improves carbohydrate metabolism, insulin sensitivity,[15,16] and cardiovascular function.[17] It is also a useful component of any weight reduction programme although diet may be more effective in promoting weight loss and metabolic control.[11]
- *ORAL ANTIDIABETICS.* If patients with type 2 diabetes have not achieved suitable control after about 3 months of dietary modification and increased physical activity, then oral antidiabetics (oral hypoglycaemics) may be tried. The two major classes are the *sulfonylureas* and the *biguanides.* Sulfonylureas act mainly by increasing endogenous insulin secretion, while biguanides act chiefly by decreasing hepatic gluconeogenesis and increasing peripheral utilisation of glucose. Both types function only in the presence of some endogenous insulin production. More recently developed classes of oral antidiabetics include the *alpha-glucosidase inhibitors,* the *meglitinides,* and the *thiazolidinediones* (see Table 1, above). Alpha-glucosidase inhibitors act by delaying the absorption of glucose from the gastrointestinal tract; meglitinides increase endogenous insulin secretion; and thiazolidinediones appear to increase insulin sensitivity.

  Most patients with type 2 diabetes are overweight, and are preferably treated with the biguanide metformin rather than with a sulfonylurea (which can cause weight gain). Results from the UK Prospective Diabetes Study (UKPDS) have suggested that the use of metformin to provide intensive blood-glucose control in overweight diabetic patients substantially reduced the risk of diabetes-related end-points such as myocardial infarction, stroke, amputation, renal failure, blindness, and death.[18] Metformin is as effective as the sulfonylureas in terms of blood-glucose control and is less likely to cause hypoglycaemia,[18] but has a rare tendency to cause lactic acidosis in patients with renal impairment, in whom it should not be used.

  Oral treatment of type 2 diabetes in patients who are not overweight may be begun with a sulfonylurea. Chlorpropamide and glibenclamide have long half-lives and hence an increased tendency to cause hypoglycaemia, although a large study[19] reported that hypoglycaemic episodes were less frequent with chlorpropamide than glibenclamide. These 2 drugs are best avoided in the elderly; a sulfonylurea with a short half-life, such as gliclazide or tolbutamide, should be used instead.

  There is evidence that the use of low-dose sulfonylurea therapy in patients with diagnosed type 2 diabetes but near-normoglycaemia due to early remission (the so-called honeymoon period) can delay the onset of hyperglycaemia.[20]

  Drug treatment may also involve an alpha-glucosidase inhibitor such as acarbose or miglitol.[21] These have a small but significant effect in lowering blood glucose and do not cause hypoglycaemia when used alone, but they can cause intolerable gastrointestinal effects. Meglitinides such as repaglinide and nateglinide are a new chemical class of antidiabetics which act similarly to sulfonylureas; repaglinide has a rapid onset and short duration of action and is given with meals. The thiazolidinediones, such as pioglitazone or rosiglitazone, appear to increase insulin sensitivity and have been the subject of much interest for type 2 diabetes and insulin resistance.

  Should treatment with one of the oral antidiabetics fail then a different type or in some instances combinations of different types may produce improvement. Alarming evidence[18] of an increased risk of death in UKPDS patients given intensive therapy with metformin plus a sulfonylurea was not borne out by further analysis, and this combination is widely used. In patients in whom such combinations fail or are contra-indicated, pioglitazone or rosiglitazone may be combined with metformin or a sulfonylurea as an alternative to progressing to insulin. Triple therapy, combining a sulfonylurea, metformin, and either rosiglitazone[22] or pioglitazone[23] has also been shown to be effective. Biguanides may also be added to meglitinide therapy. Alpha-glucosidase inhibitors may improve diabetes control when used as an adjunct to sulfonylureas or biguanides. Guar gum may also be used as an adjunct to any of the oral hypoglycaemics to enhance the improvement in blood-glucose control.

  Patients with type 2 diabetes who cannot be controlled adequately by oral therapy and diet need insulin either in addition to or in place of oral therapy. Type 2 diabetes is a progressive disease, and about 30% of those on sulfonylureas will be transferred to insulin treatment within 4 years, a change which now tends to be made earlier owing to increasingly strict criteria for glycaemic control (tight control of blood glucose has now been shown to decrease the risk of complications, see Diabetic Complications, below). However, as insulin therapy is associated with more hypoglycaemic episodes and a greater tendency to weight gain it remains reasonable to begin with oral therapy in type 2 diabetes before proceeding to insulin.[24] Combination of a single insulin injection at bedtime (morning injection is less effective) with oral hypoglycaemics (either a sulfonylurea, metformin, or both) is as effective as insulin alone, and if metformin is used, is associated with less weight gain.[25] In general, as the disease progresses, the majority of patients need multiple therapies to achieve glycaemic control.[26] Biguanides and alpha-glucosidase inhibitors may also be combined with insulin. There is increasing interest in the use of metformin and other oral hypoglycaemics as potential adjuncts to insulin therapy in patients with type 1 diabetes.[27]

Insulin is also substituted for oral treatment to provide cover during periods of severe stress, as in severe infection, trauma, or major surgery. Type 2 patients who become pregnant should also be switched from oral therapy to insulin (see Pregnancy, below).

- ***INSULIN THERAPY.*** While insulin may not be a necessary part of the treatment of type 2 diabetes, it is essential in the treatment of patients with type 1, since they have little or no endogenous insulin secretory capacity.[8,28]

  The aim of insulin therapy is to achieve the best possible control of blood-glucose concentrations without the risk of the hypoglycaemia that can occur if too fine a degree of control is attempted. Tight control of blood-glucose concentrations can reduce the long-term complications of diabetes such as retinopathy, nephropathy, and neuropathy (see Diabetic Complications, below) but in some patients (such as the elderly, or those who lack motivation) it may be better merely to alleviate symptoms rather than attempt tight control. Exercise and dietary discipline are necessary to maintain normal sensitivity to insulin.

  Insulin may be of beef or pork origin, or it may be human insulin produced by gene technology or by modification of porcine insulin. Human and porcine insulin are less immunogenic than bovine insulin and where possible most newly diagnosed type 1 patients are now given human insulin. Modified insulin analogues such as insulin lispro, insulin aspart, insulin detemir, and insulin glargine are now available.

  Insulin is available in preparations offering a short, intermediate, or long action. It may be given intramuscularly but the subcutaneous route is usually preferred. Soluble insulin can also be given intravenously. More recently, products delivering insulin for absorption through the buccal mucosa or lungs have been developed. Details of insulin routes are given on p.450. Insulin dosage schedules make use of the varying durations of action, for example by incorporating a short-acting and intermediate-acting insulin into a daily schedule. Most patients with type 1 diabetes require two or three injections of insulin daily, or with intensive regimens even more. A once-daily regimen can be used if the patient is simply to be kept asymptomatic; this may also be successful in patients with type 2 diabetes not satisfactorily controlled by oral antidiabetics.

- ***IMMUNOSUPPRESSION.*** Many patients with type 1 diabetes have a temporary improvement in pancreatic beta-cell function soon after initial treatment with insulin. This produces a period of partial remission known as the honeymoon period, during which a small dose of insulin (0.5 units/kg or less daily) is sufficient to maintain good control. Attempts to prolong the honeymoon period have included tight control immediately following diagnosis and also, given the probable auto-immune nature of the condition, use of an immunosuppressant.[8] However, results have been at best ambiguous.

- ***PANCREATIC TRANSPLANTATION.*** Transplantation of the whole pancreas in patients with type 1 diabetes poorly controlled by insulin therapy has led to insulin independence, and has usually been carried out with kidney transplantation (see also Pancreatic Transplantation, p.1816).[29] Transplantation of pancreatic islet cells has been investigated as an alternative. Since the introduction of the so-called 'Edmonton Protocol' and related regimens for immunosuppression, and improvements in techniques for harvesting and preparing islet cells, more experienced centres are now reporting some success in achieving insulin independence,[29,30] and development of new immunosuppressive regimens continues.[31,32] However, at present successful patients exchange life-long insulin therapy for life-long immunosuppression. The induction of tolerance, less toxic immunosuppression, and enhanced islet engraftment remain the focus of investigation.[30] Results in *animals* have suggested that a reasonable degree of glycaemic control may be achievable long term without immunosuppression, using a vascularised 'artificial pancreas' containing allogeneic or even xenogeneic islet cells.[33] The use of stem cells as potential sources of islet cells is also under investigation.[34]

- ***OTHER DRUG TREATMENTS.*** Other drugs have been tried for diabetes mellitus, particularly when conventional therapy has proved unsuccessful. Addition of the amylin analogue *pramlintide* to insulin therapy has improved glycaemic control in patients with type 1 and type 2 diabetes.[35,36] Other approaches under investigation include inhibition of fatty acid oxidation or the use of β_3-adrenoceptor agonists (selective agonists of β-receptors thought to be associated with lipolysis and thermogenesis) to stimulate energy expenditure.[37]

  Mecasermin (insulin-like growth factor I; IGF-I) has been shown to improve metabolic control in patients with type 1 diabetes and insulin resistance (and in some type 2 patients).[38,39] The incretin hormone *glucagon-like peptide 1* (GLP-1; insulinotropin) plays a role in glucose homoeostasis, and when given therapeutically improves glycaemic control in type 2 patients.[40,41] Incretin mimics such as *exenatide* (synthetic exendin-4) and *liraglutide*,[42-44] and inhibitors of the incretin-degrading enzyme dipeptidylpeptidase-4 (such as *sitagliptin* and *vildagliptin*),[43,44] are also under investigation or have been licensed for use in type 2 diabetes. Improvements in insulin sensitivity have also been seen in insulin-resistant type 2 patients treated with a haemodialysate of calf blood,[45] while in other studies improved insulin sensitivity was seen after treatment with the *vanadium* salt, vanadyl sulfate.[46,47] Adjunctive *chromium* supplementation may reduce serum-glucose in type 2 diabetes, but high doses may be required and long-term safety and efficacy have not been established.[48]

- ***PROPHYLAXIS.*** Because overt diabetes is the culmination of a prolonged process, methods to delay or prevent its development are being investigated, either by modifying risk factors in populations or groups, or by targeting individuals thought to be at high risk. Strategies under consideration for the prevention of type 1 diabetes include avoidance of cows' milk proteins (thought to be a possible environmental trigger) during infancy;[49] giving free radical scavengers such as nicotinamide;[50] prophylactic insulin[51-53] (or possibly oral antidiabetics) to allow 'beta cell rest'; encouraging the development of antigen tolerance, for example by taking oral antigens such as insulin, glutamic acid decarboxylase, or heat shock protein[52,54,55] (a similar approach using subcutaneous antigen has apparently extended the honeymoon period in *animal* studies[56]); or by immunosuppression (see above) or immunomodulation with agents such as BCG vaccine,[57] although some have found the latter ineffective.[58] Preventive strategies for insulin resistance and type 2 diabetes have tended to focus on weight loss, dietary modification, and exercise. However, prophylactic drug therapy may be possible. A systematic review concluded that there was good evidence for a reduced incidence of diabetes in patients treated with metformin, acarbose, orlistat, and troglitazone, although the attrition rates were high with the latter 2 drugs; evidence of benefit from statins, oestrogen, and various antihypertensive drugs (including ACE inhibitors) was more equivocal. It was considered likely that some of the benefits were indirect, due to drug-induced weight loss, and in no case was the benefit definitive enough that the drug could be recommended for diabetes prevention.[59] Studies are ongoing with drugs including ramipril, telmisartan, valsartan, nateglinide, rosiglitazone, and insulin glargine.[59-61] Guidelines[62] for the prevention of type 2 diabetes recommend that individuals with pre-diabetes (impaired fasting glucose or impaired glucose tolerance) should be counselled on weight loss and exercise, and that drug therapy should not be routinely used until more information becomes available. Screening for diabetes has been encouraged, particularly for those patients with risk factors.[63]

Monitoring of therapy. Monitoring of therapy is an integral part of the management of the diabetic patient.[64] Detection of urinary glucose has generally been superseded by the monitoring of blood glucose (see Glucose Tests, p.2314). For adequate diabetic control, the aim is to reduce fasting blood-glucose concentrations to within the range 3.3 to 5.6 mmol/litre of venous whole blood, and postprandial concentrations to below 10 mmol/litre.[5] Many patients monitor their blood-glucose concentrations regularly at home and this is essential for intensified insulin regimens when tight control is required. Although the value of self-monitoring of blood-glucose concentrations in type 2 patients is less clear, the results of a large cohort study[65] suggest that such monitoring can improve glycaemic control in these patients. Detection of urinary ketones is useful in diabetics prone to ketosis; this is usually done in clinics. Diabetic clinics also measure the degree of haemoglobin glycosylation (HbA_1 or HbA_{1c}) as an indicator of longer term blood-glucose control and hence the risk of complications (see Diabetic Complications, below). UK guidelines[9] recommend that a general target of 6.5 to 7.5% should be set for HbA_{1c} in individuals with type 2 diabetes. In the USA,[6] a target of HbA_{1c} below 7.0% has been recommended for diabetes patients in general. The advanced glycation end-product (AGE) of haemoglobin has also been found to be a useful indicator of long-term blood glucose control.[66] Measurement of glycated serum proteins, particularly albumin, is also used to give an indication of glucose control, but for a shorter period than haemoglobin. Other techniques that have been developed for monitoring blood-glucose concentrations include continuous monitoring by a subcutaneous system, and a minimally invasive device that uses reverse iontophoresis through the skin.

Pregnancy. Adverse pregnancy outcomes, including spontaneous abortion and congenital malformation, are more common in diabetic than in nondiabetic women. Improved management of the pregnant diabetic patient, particularly in early pregnancy, lessens the incidence of such events,[67,68] but an increased risk still exists.[69] Diabetic women are advised to plan their pregnancies so that glycaemic control can be improved before conception.[70] Some may need to avoid pregnancy (most commonly because of renal disease),[71] but management has improved sufficiently for this to be rare.[68]

Insulin is the preferred treatment in pregnancy,[72] even in women with type 2 diabetes; patients taking oral antidiabetics should therefore be switched to insulin. However, there is increasing evidence to suggest that metformin might be used safely during pregnancy, and NICE[73] has suggested that it may be used either as an adjunct or alternative to insulin if the likely benefits from improved glycaemic control outweigh the potential for harm. Insulin regimens are similar to those in nonpregnant patients, the dose being adjusted according to regular blood-glucose measurements. Insulin requirements may decrease during the first trimester but they increase during the latter two, reaching about twice pre-pregnancy requirements at term; they then fall once labour has begun and fall again after delivery.[72]

Pregnant diabetic patients are at risk of nocturnal hypoglycaemia owing to continued fetal glucose consumption while the mother is in a relatively fasting state. They are also prone to diabetic ketoacidosis which must be treated with great urgency because of the high risk of fetal loss.

Gestational diabetes mellitus is defined as glucose intolerance with onset or first recognition during pregnancy.[74-76] Many women with gestational diabetes can be managed by diet alone or, if necessary, also with insulin. Some suggest giving prophylactic insulin even to women who could be managed by diet alone, in view of the metabolic effects of insulin.[77] Insulin analogues such as insulin lispro and insulin aspart have been investigated.[76] Dietary management of gestational diabetes can improve maternal and fetal outcomes, and insulin therapy reduces fetal macrosomia and perinatal morbidity.[75] NICE[73] also considers that metformin or glibenclamide may be considered as an adjunct or alternative to insulin. There has been much debate about the benefits of screening for gestational diabetes, and both universal[74] and selective screening based on risk factors[75] have been promoted.

Surgery. Insulin-dependent diabetics who require surgery may be managed with a continuous intravenous insulin infusion.[78] Insulin is given as normal the night before operation, and switched to either a variable rate infusion via a syringe pump, with a 5 or 10% glucose drip (with potassium chloride, provided the patient is not hyperkalaemic), or to a combined insulin-glucose infusion, on the day of operation. (Many anaesthetists prefer insulin and a sodium chloride infusion if blood glucose is already high.[79]) Subsequent conversion back to subcutaneous insulin should be undertaken before breakfast, giving the first subcutaneous dose 30 minutes before stopping continuous infusion. Non-insulin-dependent patients should have any oral treatment omitted on the day of operation, and may be given insulin by a similar regimen if control is poor or deteriorates as can happen with major surgery.

Diabetic complications

Much of the increased mortality and morbidity seen in diabetic patients is the result of complications that develop with increasing duration of disease, particularly when glycaemic control is poor. Such complications may originate from increased glycation of proteins and other biological macromolecules in the hyperglycaemic environment, pathological activation of protein kinase C, or from increased accumulation of sorbitol and other polyols via the aldose reductase pathway,[1] but other factors play an important role in determining susceptibility. At the *macrovascular* level, diabetics are prone to hypertension and ischaemic heart disease, and heart disease is a major cause of death; control of blood pressure is now seen as being as important as glycaemic control in patients with type 2 diabetes. *Microvascular* tissue damage is an important factor in the development of diabetic nephropathy and retinopathy; it may also contribute to the other major complication, diabetic neuropathy. Collagen abnormalities are also seen. Diabetics with poor glycaemic control also have an increased liability to severe bacterial or fungal infection. Sometimes several factors may interact; thus neuropathy, infection, and impaired blood flow due to macro- or microvascular disease may all play a role in the development of diabetic foot disease, a complication which can ultimately lead to amputation.

Prevention of diabetic complications. Much attention has been focused on whether strict or tight glycaemic control can modify the development or progression of diabetic complications. In general, the longer-term studies have provided more encouraging results than initial results indicated, and meta-analysis of such studies[2] has suggested that intensive regimens may prevent microvascular complications.

The Diabetes Control and Complications Trial (DCCT)[3] confirmed this view in type 1 diabetes. It compared in selected patients the effects of conventional insulin therapy with those of continuous subcutaneous insulin infusion or multiple-injection regimens, on the development and progression of complications. The intensive treatment was aimed at keeping preprandial blood-glucose concentrations between 3.9 and 6.7 mmol/litre, postprandial concentrations at less than 10 mmol/litre, a weekly 3 a.m. measurement at greater than 3.6 mmol/litre, and the monthly glycosylated haemoglobin measurement at less than 6.05%. Intensive insulin therapy reduced the development and progression of retinopathy; it also reduced the occurrence of microalbuminuria, albuminuria, and clinical neuropathy. The major disadvantage of intensive insulin therapy was a threefold greater risk of hypoglycaemia; weight gain was also significantly greater.

While it is accepted that some patients will benefit from intensive insulin regimens, this approach requires caution in patients at risk of hypoglycaemia. Also such intensive treatment may not always be necessary, for example in patients known to maintain good control by conventional dosage schedules, or where improvement can be obtained by setting achievable targets and improving patient education.[4] However, intensive therapy can help sustain endogenous insulin secretion in type 1 diabetes, which is associated with improved metabolic control;[5] this would favour starting intensive insulin therapy at an early stage. After the DCCT finished the patients returned to their own health care providers for diabetes care, but were followed in a cohort study for a further 11 years.[6] Although more than 90% of all patients went on to use intensive therapy, and glycosylated haemoglobin values became very similar for both groups during this time, there were fewer cardiovascular events and less microalbuminuria and albuminuria in the group that had received intensive treatment during the original DCCT, showing that the beneficial effects of intensive therapy were maintained long term.

The reports of the UK Prospective Diabetes Study (UKPDS) have provided similar evidence in patients with type 2 diabetes. This study has examined the benefits of intensive therapy, using a variety of drugs with diet and exercise. Intensive therapy, which aimed at producing fasting plasma-glucose concentrations of below 6 mmol/litre, substantially decreased the risk of microvascular complications (particularly retinopathy). There was no difference in benefit between intensive therapy with sulfonylureas and with insulin.[7] Metformin also produced benefit in the overweight patients who received it.[8] The UKPDS did not provide unequivocal evidence of a reduction in macrovascular disease with improved glycaemic control, although there was some suggestion of a reduction in risk of myocardial infarction (in line with a small earlier Japanese study[9]). However, it did show that vigorous control of blood pressure, using captopril or atenolol as the first-line drugs, reduced the risk of both macrovascular and microvascular complications,[10,11] suggesting that this should have a high priority in the treatment of type 2 diabetes. A subsequent study has confirmed the importance of a multifactorial approach in reducing cardiovascular events.[12] It has been suggested that thiazolidinediones may have beneficial effects in addition to their hypoglycaemic effect, and a study[13] in patients with type 2 diabetes and extensive macrovascular disease found that pioglitazone improved cardiovascular outcome and reduced the need to add insulin. There has, however, been some concern about possible adverse cardiovascular effects of rosiglitazone (see p.459).

Diabetic eye disease. Diabetic patients are prone to potentially blinding eye disease, usually in the form of cataract or diabetic retinopathy. Cataract generally requires surgical extraction, particular care being taken to avoid infection. Diabetic retinopathy may take a 'background', nonproliferative form, or become a more serious proliferative retinopathy associated with neovascularisation, vitreous haemorrhage and retinal detachment. Macular oedema, characterised by retinal thickening from leaky blood vessels, can develop at any stage.[14,15]

Aggressive glycaemic and blood pressure control are the main methods of prevention.[15,16] However, once proliferative retinopathy has developed, glycaemic control is not adequate to prevent worsening.[17] Moreover, transient early worsening may occur in patients transferred to more intensive glycaemic regimens.[18]

Once severe nonproliferative or proliferative retinopathy has developed, photocoagulation using an argon laser or a xenon arc is effective in limiting progression, while vitrectomy may be helpful for vitreous haemorrhage and retinal detachment.[19]

Numerous drugs have been tried for the prevention or retardation of diabetic eye disease, mostly with indifferent results.[15,16] Aldose reductase inhibitors such as sorbinil, aspirin, statins, oxygen (and conversely, the antoxidant vitamin E), ACE inhibitors, angiotensin II receptor antagonists such as losartan, interferon alfa-2a, and the matrix metalloproteinase inhibitor prinomastat, have all produced either minor benefit or no benefit at all, while the non-specific kinase inhibitor PKC-412 has produced some benefit but accompanied by significant adverse effects.[16] Other drugs for which benefit has been claimed include ticlopidine,[20] epoetin,[21] and danaparoid sodium.[22] Ongoing studies include those with the somatostatin analogue octreotide, the specific protein kinase C inhibitor ruboxistaurin mesilate, and the growth factor antagonist pegaptanib.[16] Intravitreal injection of the corticosteroid triamcinolone acetonide may be useful for diabetic macular oedema.[23]

Diabetic nephropathy. Nephropathic changes associated with microvascular disease develop in up to 30% of patients with type 1 diabetes and up to 40% of those with type 2 disease; diabetic nephropathy, of which the first clinical sign is albuminuria, is one of the major causes of end-stage renal disease (see Chronic Renal Failure, p.1672).

Results from the DCCT indicate that strict glycaemic control reduces the incidence of microalbuminuria in type 1 diabetes,[3] (with long-term renal benefits[24]) and a smaller reduction was seen in the UKPDS in patients with type 2 diabetes.[7] However, while good control may prevent development of the initial lesion, it is not clear whether it can prevent progression in patients who are already microalbuminuric. Some studies, including the DCCT, have suggested that this is the case;[3,9] others have failed to confirm it.[25]

Dietary protein restriction (see Renal Failure, p.1923), which appears from a number of small studies to have a beneficial, although small, effect on disease progression,[26,27] has been recommended in patients with overt nephropathy.[28]

The most important approach to slowing the progression of diabetic nephropathy is aggressive antihypertensive control.[10,28-30] Although most patients will require combination therapy, first-line use of ACE inhibitors has been particularly recommended,[28,30] as they have been suggested to reduce proteinuria to a greater extent than other antihypertensives. However, results from the UKPDS showed no difference between the effects of an ACE inhibitor and a beta blocker in reducing microalbuminuria in type 2 diabetics with hypertension,[11] and a systematic review[31] found limited evidence to support a specific renoprotective action in diabetics, independent of their effect on blood pressure. Another systematic review[32] found ACE inhibitors to be effective for the primary prevention of developing microalbuminuria. The authors noted that although data were limited this effect appeared independent of baseline blood pressure, renal function, and type of diabetes. Beneficial effects have also been reported when ACE inhibitors are given to patients with microalbuminuria but without hypertension,[33-35] and it has been recommended that such patients receive ACE inhibitors, initially in small doses, to slow the progression of renal disease.[36] Some consider that small decreases in blood pressure associated with such therapy may be responsible for the benefit.[11] ACE inhibition also had a modest renal protective effect in normotensive diabetics with normal urinary albumin excretion,[37] and such use requires further study.

Angiotensin II receptor antagonists have also been shown to reduce the progression of renal disease in type 2 patients with both microalbuminuria and macroalbuminuria, and US recommendations consider them an equal first choice with ACE inhibitors;[28] UK guidelines suggest they may be used in those unable to tolerate ACE inhibitors.[30] Although a systematic review failed to find evidence that the two classes were equivalent in their effects on survival,[38] their effects on progression of nephropathy appear equivalent.[38,39]

The aldose reductase inhibitors have been investigated for their effects on nephropathy, but results have been, at best, ambiguous; a study in microalbuminuric patients given tolrestat (now withdrawn worldwide) did show a decrease in urinary albumin excretion but there was also a decrease in the (initially raised) glomerular filtration rate.[40] Pimagedine, which inhibits the formation of glycosylated end products, is also under investigation.

Diabetic neuropathy. Peripheral neuropathies are common complications of diabetes mellitus. The intensity and extent of neurological abnormalities are proportional to the degree and duration of hyperglycaemia. Neuropathic symptoms include symmetrical sensory loss, particularly in the feet and lower limbs; features of autonomic neuropathy such as gastroparesis, orthostatic hypotension, erectile dysfunction, and gustatory sweating; pain and cranial nerve palsy associated with mononeuropathies; and acute, painful, sensory neuropathy.[41,42]

Results from the DCCT indicated that strict glycaemic control could substantially reduce the occurrence of clinical neuropathy in patients with type 1 diabetes,[3,43] a result which was not duplicated in the UKPDS in patients with type 2 diabetes.[7]

Although some studies have suggested that aldose reductase inhibitors such as epalrestat[44] can reduce the severity of diabetic neuropathy, larger scale analysis has apparently failed to show any benefit. However, studies with some newer members of the class such as fidarestat are still ongoing.[42] Interesting preliminary results have suggested that ACE inhibitors may also have benefits in diabetic neuropathy.[45] An analysis[46] of 4 studies using the antoxidant thioctic acid found variable results, but an overall benefit, in symptomatic diabetic polyneuropathy. Results from another study[47] have suggested some improvement in cardiac autonomic neuropathy. Inhibition of protein kinase C with ruboxistaurin is also under investigation.[42]

Other management of diabetic neuropathy is essentially symptomatic.[41,42] The pain, which can be severe, may be managed with tricyclic antidepressants; duloxetine, mexiletine, antiepileptics including carbamazepine, and topical capsaicin or lidocaine may also be tried, as discussed on p.6.

Diabetic gastroparesis may respond to prokinetic drugs such as metoclopramide, cisapride, domperidone, or erythromycin,[41,42,48] but their effects can be variable and long-term use may be limited by adverse effects. Endoscopic or surgical interventions may be needed when symptoms cannot be controlled. Diarrhoea may respond to tetracycline (see below), while orthostatic hypotension should be managed conventionally (see under Fludrocortisone, p.1530) although care may be required in the use of elastic stockings in patients with impaired blood flow to the feet. For the management of erectile dysfunction, see p.2179.

Diarrhoea. Diabetic patients may develop intermittent bouts of watery diarrhoea, sometimes alternating with constipation; autonomic neuropathy and abnormalities of digestion and bowel flora may play a role.[49] Clonidine has been suggested for severe cases,[41] and octreotide has been tried,[50,51] but conventional management with antidiarrhoeal drugs (p.1694) is otherwise used; a broad spectrum antibacterial (especially tetracycline) may also be effective. The mechanism of action of tetracycline in diabetic diarrhoea is uncertain, but it has been suggested that one or two doses of tetracycline should be the first line of treatment.[52]

Foot disease. Peripheral arterial disease, neuropathy, collagen changes, and increased susceptibility to infection may contribute to the foot lesions to which diabetics are prone. Ulceration and tissue necrosis at pressure-points may be followed by infection, gangrene, and sepsis. Management involves drainage and debridement of dead and infected tissue, and the use of antibacterials if necessary:[53] broad spectrum cover should be given intravenously if there is severe infection, and adapted once the results of bacteriological culture are available.[54] Local antiseptic therapy may be helpful, especially for infections with *Pseudomonas* or *Proteus* spp. Neuropathic skin ulcers of the lower extremities have responded to a platelet-derived growth factor, becaplermin.[55] Granulocyte colony-stimulating factors have been used as adjunctive therapy with antibacterials in severe foot infections.[56] Strict control of blood glucose is important and insulin should be given as required. Effective pain relief and bed rest may be needed, and surgical reconstruction to improve blood supply may be helpful in some cases. Ultimately, some patients require amputation of all or part of the foot. Preventive care, with regular visits to a chiropodist, is therefore particularly important.

Heart disease. Cardiovascular disease (heart failure, ischaemic heart disease, and stroke) is a major cause of morbidity and death in patients with diabetes, who are at greatly increased risk of such disorders, often have a worse prognosis when they occur, and who may be undertreated for cardiovascular complications.[57-59] Conventional risk factors such as obesity, hypertension, and hyperlipidaemias tend to be common in diabetic patients, but other factors, including hyperglycaemia itself (and particularly postprandial hyperglycaemia[60]), may play a role.

Management of cardiovascular disease in diabetic patients should be essentially the same as in other patients; there have been concerns about the use of individual drug classes—beta blockers, aspirin (which may need to be given in higher than usual doses[61]), and calcium-channel blockers[62]—but in general the benefits of intensive treatment are seen to outweigh the risks.[57-59] Treatment should also include strict glycaemic control: it has been shown that insulin-glucose infusion after myocardial infarction, followed by subcutaneous insulin for at least 3 months, improves long-term survival in patients with both type 1 and type 2 diabetes.[63]

Primary prevention of cardiovascular disease with lipid-lowering drugs (see also Hyperlipidaemias, below) is an increasingly important part of management in high-risk patients.[64,65] It has proved hard to demonstrate that good glycaemic control also plays a role in reducing cardiovascular risk (see Prevention of Complications, above); however, there is evidence from a study in patients with impaired glucose tolerance but not diabetes that decreasing postprandial hyperglycaemia with acarbose reduced the risk of hypertension and cardiovascular events such as myocardial infarction.[66]

Diabetics may also develop a form of restrictive cardiomyopathy in the absence of ischaemic heart disease. Again, the condition is managed similarly to cardiomyopathy in non-diabetic patients (see p.1163).

Cardiac autonomic neuropathy has been reported to be improved by thioctic acid (see Diabetic Neuropathy, above).

Hyperlipidaemias. Insulin plays an important role in lipid metabolism and deficient insulin action means that diabetics are prone to hypertriglyceridaemia and have a blood-lipid profile associated with an increased risk of atherosclerosis, and hence of macrovascular complications (see also Cardiovascular Risk Reduction, p.1164 and Hyperlipidaemias, p.1169). The American Diabetes Association recommends that LDL cholesterol concentrations should be below 2.6 mmol/litre, HDL cholesterol concentrations more than 1.15 mmol/litre, and triglyceride concentrations less than 1.7 mmol/litre.[67]

Where drug therapy is needed, statins, in at least moderate doses, are the lipid-lowering drugs of choice for both secondary and primary prevention of cardiovascular events in type 2 diabetes; studies have shown benefit with atorvastatin, fluvastatin, lovastatin, pravastatin, and simvastatin, and there is no clear evidence to favour one statin over another in these patients.[68] Fibrates such as gemfibrozil may be an alternative,[67] particularly for secondary prevention in patients with low levels of both LDL and HDL cholesterol.[68] Nicotinic acid has been used to raise HDL cholesterol concentrations,[69] but high doses can have an adverse effect on glycaemic control.[67]

Hypertension. Hypertension is twice as common in the diabetic as in the non-diabetic population, and is associated with both macrovascular complications and microvascular disease (especially diabetic nephropathy). Management of hypertension in diabetics follows the same principles as in the general population, but it should be treated aggressively with a view to retarding development of complications,[10,30,70,71] and the threshold for drug treatment and the treatment goal are lower than in non-diabetic patients (see Hypertension, p.1171). All of the main groups of antihypertensive drugs may be used although an ACE inhibitor,[72,73] such as ramipril,[74] an angiotensin II receptor antagonist,[73] or a beta blocker may be effective in reducing complications.[10,11] Low-dose diuretic therapy has also been shown to be beneficial.[75] Results with calcium-channel blockers have been variable, and there has even been a suggestion that they may increase cardiovascular adverse effects (see Diabetes Mellitus under Precautions of Nifedipine, p.1352). However, a review of randomised studies concluded that they were safe and effective in this population, although possibly less so than other antihypertensive drugs.[62] In the UK, guidelines recommend that long-acting calcium-channel blockers may be used as second-line treatment or as part of combination therapy.[30]

Diabetic emergencies

Hypoglycaemia. The most frequent complication of insulin therapy is hypoglycaemia and patients taking insulin need to be educated about its cause, symptoms, and treatment. Most patients can recognise the early warning signs of hypoglycaemia and by taking sugar immediately can prevent more serious symptoms developing. Comatose patients need to be given intravenous glucose or, if this is not practicable, subcutaneous, intramuscular, or intravenous glucagon (although glucose is still required if there is no response within 10 minutes). Hypoglycaemia can also develop in patients taking oral antidiabetics, notably the sulfonylureas.

Some patients report loss of the warning signs of hypoglycaemia after transferring from animal to human insulin and these patients, if appropriate, may need to be transferred back to animal insulin. However, the most significant factor in loss of hypoglycaemic warning signs may be exposure to hypoglycaemia itself; a study found that total avoidance of hypoglycaemic episodes for 3 weeks while maintaining glycaemic control restored awareness.[1] Loss of hypoglycaemic awareness, which appears to be due to an adaptive conservation of glucose uptake in the brain,[2] is liable to be a particular problem in patients receiving intensive therapy. There is limited data to suggest that caffeine can improve awareness of hypoglycaemia.[3,4]

For further details on the treatment of insulin-induced hypoglycaemia, see p.447.

Diabetic ketoacidosis is caused by an absolute or relative lack of insulin and commonly occurs after noncompliance or failure to adjust insulin dosage in the presence of factors such as infection that increase insulin requirements (see Precautions for Insulin, p.447). Failure of an insulin pump can be a cause.[5] Also pregnant diabetic women are more prone to development of diabetic ketoacidosis.

Diabetic ketoacidosis is characterised by hyperglycaemia, hyperketonaemia, and acidaemia, with subsequent dehydration and electrolyte abnormalities. Onset may be rapid, or insidious over many days. Initial presenting symptoms such as thirst, polyuria, fatigue, and weight loss are those of any newly presenting type 1 diabetic; they then progress to nausea, vomiting, abdominal pain, and impaired consciousness or coma, and, if untreated, death.[5,6]

Diabetic ketoacidosis is a medical emergency and should be treated immediately with fluid replacement and insulin.[5-8] Fluid requirements depend on the needs of the individual; overvigorous fluid replacement without severe dehydration carries the risk of precipitating cerebral oedema.[6-8]

Soluble insulin should also be given immediately. Large doses were formerly thought necessary, but lower dose regimens accompanied by adequate hydration have since been shown to be preferable.[5] Insulin resistance in diabetic ketoacidosis is generally exacerbated by hyperosmolarity and other confounding factors, and insulin therapy is therefore most effective when preceded or accompanied by adequate fluid and electrolyte replacement.[5] In the UK, the *BNF* considers that insulin should preferably be given by intravenous infusion, with the intramuscular route used if facilities for intravenous infusion are not available. However, in the USA some consider that an intravenous bolus followed by subcutaneous injection may be appropriate in certain patients.[5] Intramuscular or subcutaneous injection are not appropriate in patients with hypovolaemic shock, due to poor tissue perfusion.[5] Where the response to insulin is inadequate the intravenous route is generally required[5] and the rate of infusion may be doubled on an hourly basis until an appropriate response is seen. A case report has suggested that mecasermin may be useful if there is insulin resistance.[9]

When the blood-glucose concentration has fallen to about 12.5 mmol/litre the dose of insulin may be reduced by about half and glucose given intravenously,[5] usually in a strength of 5% with saline although in rare cases a glucose strength of 10% may be necessary.[5] The use of glucose enables insulin to be continued in order to clear ketone bodies without inducing hypoglycaemia. Once glucose concentrations have been controlled and acidosis has completely cleared, subcutaneous injections of insulin can begin;[6] but intravenous insulin should not be stopped until subcutaneous dosage has begun.

Total body stores of potassium are depleted in patients with diabetic ketoacidosis. Insulin deficiency appears to be the main initiating factor for hyperkalaemia in diabetic ketoacidosis.[10] Although patients may present with raised, normal, or decreased serum-potassium concentrations, the concentrations will start to fall with the correction of acidosis. Potassium is added to the infusion fluid after initial fluid expansion and once insulin therapy has begun.[5] In hyperkalaemic patients, potassium is given once serum concentrations have fallen to within normal limits.[5,6] In the rare patient presenting with hypokalaemia potassium replacement should be begun before insulin therapy and the latter withheld until potassium concentrations have risen to normal values.[5]

Intravenous bicarbonate is now generally reserved for patients with severe acidaemia; a common practice[5,6] is to give isotonic bicarbonate to those with a pH of less than 7.0 with the aim of raising the pH to 7.1.

Phosphate concentrations are affected in a similar manner to potassium concentrations in the ketoacidotic state, but there is less agreement on the need for routine doses of phosphate. Phosphate concentrations should be monitored and phosphate given if clinically significant hypophosphataemia occurs.[5,6]

The precipitating cause of diabetic ketoacidosis should also be identified and managed appropriately.

Hyperosmolar hyperglycaemic state or hyperosmolar hyperglycaemic nonketotic coma (HONK) occurs mainly in elderly patients with type 2 diabetes and though much less common than diabetic ketoacidosis it carries a higher mortality. Patients may present in coma with severe hyperglycaemia but with minimal ketosis; dehydration and renal impairment are common.[5] Treatment is similar to that of diabetic ketoacidosis (see above), although potassium requirements are lower and large amounts of fluid and less insulin may be required; some suggest the use of hypotonic fluid if necessary.[11] There is an increased likelihood of thrombotic events, so prophylactic anticoagulation should be considered.

Acarbose *(BAN, USAN, rINN)*

Acarbosa; Acarbosum; Akarboosi; Akarbos; Akarbosa; Akarboz; Akarbozė; Bay-g-5421. *O*-{4-Amino-4,6-dideoxy-*N*-[(1*S*,4*R*,5*S*,6*S*)-4,5,6-trihydroxy-3-hydroxymethylcyclohex-2-enyl]-α-D-glucopyranosyl}-(1→4)-*O*-α-D-glucopyranosyl-(1→4)-D-glucopyranose.

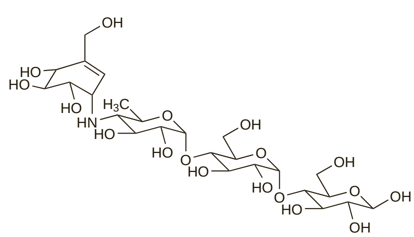
Акарбоза

$C_{25}H_{43}NO_{18}$ = 645.6.

CAS — 56180-94-0.

ATC — A10BF01.

ATC Vet — QA10BF01.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Acarbose). A white or yellowish, amorphous, hygroscopic powder. Very soluble in water; practically insoluble in dichloromethane; soluble in methyl alcohol. A 5% solution in water has a pH of 5.5 to 7.5. Store in airtight containers.

USP 31 (Acarbose). Produced by certain strains of *Actinoplanes utahensis*. Store in airtight containers.

Adverse Effects

Acarbose often causes gastrointestinal disturbances, particularly flatulence due to bacterial action on nonabsorbed carbohydrate in the colon. Abdominal distension, diarrhoea, and pain may occur. Ileus has been rarely reported. A decrease in dosage and improved dietary habits may reduce these adverse effects. Hepatotoxicity may occur and may necessitate a reduction in dosage or withdrawal of the drug. Skin reactions have occurred rarely. Very rarely oedema has been reported.

Incidence of adverse effects. The manufacturers reported that adverse effects of acarbose were rarer in a postmarketing surveillance study than in previous clinical trials;[1] this was held to represent better tailoring of individual doses to patient tolerability.

1. Spengler M, Cagatay M. The use of acarbose in the primary-care setting: evaluation of efficacy and tolerability of acarbose by postmarketing surveillance study. *Clin Invest Med* 1995; **18:** 325–31.

Effects on the liver. Hepatocellular liver damage, with jaundice and elevated serum aminotransferases, have been reported in patients receiving acarbose.[1-3] Symptoms resolved on stopping the drug.

1. Andrade RJ, *et al.* Hepatic injury caused by acarbose. *Ann Intern Med* 1996; **124:** 931.
2. Carrascosa M, *et al.* Acarbose-induced acute severe hepatotoxicity. *Lancet* 1997; **349:** 698–9.
3. Fujimoto Y, *et al.* Acarbose-induced hepatic injury. *Lancet* 1998; **351:** 340.

Effects on the skin. Generalised erythema multiforme and eosinophilia occurred in a male diabetic patient 13 days after starting acarbose.[1] The hypersensitivity reaction was confirmed by rechallenge.

1. Kono T, *et al.* Acarbose-induced generalised erythema multiforme. *Lancet* 1999; **354:** 396–7.

Precautions

Acarbose is contra-indicated in inflammatory bowel disease, particularly where there is associated ulceration, and in gastrointestinal obstruction or patients predisposed to it. It should be avoided in patients with chronic intestinal diseases that significantly affect digestion or absorption, and in conditions which may deteriorate as a result of increased gas formation, such as hernia.

Acarbose is also contra-indicated in patients with hepatic impairment and liver enzyme values should be monitored, particularly at high doses.

If hypoglycaemia should develop in a patient receiving acarbose it needs to be treated with glucose, since the action of acarbose inhibits the hydrolysis of disaccharides.

Breast feeding. In the absence of evidence, licensed product information recommends that acarbose should be avoided during breast feeding.

Interactions

Acarbose may enhance the effects of other antidiabetics, including insulin, and a reduction in their dosage may be needed. Use with gastrointestinal adsorbents and digestive enzyme preparations can diminish the effects of acarbose and should be avoided. Neomycin and colestyramine may enhance the effects of acarbose and a reduction in its dosage may be required. Acarbose may inhibit the absorption of digoxin (see Antidiabetics, under Interactions of Digoxin, p.1261).

Pharmacokinetics

After ingestion of acarbose, the majority of active unchanged drug remains in the lumen of the gastrointestinal tract to exert its pharmacological activity and is metabolised by intestinal enzymes and by the microbial flora. Ultimately about 35% of a dose is absorbed in the form of metabolites. Acarbose is excreted in the urine and faeces.

Uses and Administration

Acarbose is an inhibitor of alpha glucosidases, especially sucrase. This slows the digestion and absorption of carbohydrates in the small intestine and hence reduces the increase in blood-glucose concentrations after a carbohydrate load. It is given in the treatment of type 2 diabetes mellitus (p.431) either alone or with a sulfonylurea, biguanide, or insulin. Acarbose treatment may be started with a low oral dose of 25 or 50 mg daily to minimise gastrointestinal disturbance. It is then gradually increased to a usual dose of 25 or 50 mg three times daily, immediately before food. Doses up to 100 to 200 mg three times daily may be given if necessary. Some benefit has also been found when acarbose is used to supplement insulin therapy in type 1 diabetes mellitus.

Acarbose has also been studied for the treatment of reactive hypoglycaemia, the dumping syndrome, and certain types of hyperlipoproteinaemia.

Acetohexamide *(BAN, USAN, rINN)*

Acetohexamid; Acetohexamida; Acétohexamide; Acetohexamidum; Asetoheksamidi; Compound 33006. 1-(4-Acetylbenzenesulphonyl)-3-cyclohexylurea.

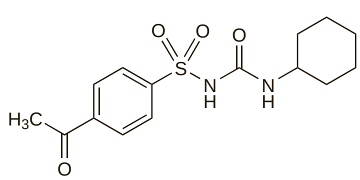
Ацетогексамид

$C_{15}H_{20}N_2O_4S$ = 324.4.

CAS — 968-81-0.

ATC — A10BB31.

ATC Vet — QA10BB31.



Pharmacopoeias. In *Jpn* and *US.*

USP 31 (Acetohexamide). A white, practically odourless, crystalline powder. Practically insoluble in water and in ether; soluble 1 in 230 of alcohol and 1 in 210 of chloroform; soluble in pyridine and in dilute solutions of alkali hydroxides.

Profile

Acetohexamide is a sulfonylurea antidiabetic (p.460). Its duration of action is 12 hours or more. It has been given orally in the treatment of type 2 diabetes mellitus (p.431) in a usual initial dose of 250 mg daily before breakfast. The daily dose may then be increased by 250 to 500 mg at intervals of 5 to 7 days, to a maintenance dose of up to 1.5 g daily; increasing the dose above 1.5 g does not usually lead to further benefit. Doses in excess of 1 g daily may be taken in 2 divided doses, before the morning and evening meals.

Preparations

USP 31: Acetohexamide Tablets.

Proprietary Preparations (details are given in Part 3)

USA: Dymelor†.

Biguanide Antidiabetics

Antidiabéticos biguanídicos.

Adverse Effects

Gastrointestinal adverse effects including anorexia, nausea, vomiting, and diarrhoea may occur with biguanides; patients may experience taste disturbance and there may be weight loss. Absorption of various substances including vitamin B_{12} may be impaired. Skin reactions have been reported rarely.

Hypoglycaemia is rare with a biguanide given alone, although it may occur if other contributing factors or drugs are present.

Lactic acidosis, sometimes fatal, has occurred with biguanides, primarily with phenformin. When it has occurred with metformin most cases have been in patients whose condition contra-indicated the use of the drug, particularly those with renal impairment.

Phenformin has been implicated in the controversial reports of excessive cardiovascular mortality associated with oral hypoglycaemic therapy (see under Sulfonylureas, Effects on the Cardiovascular System, p.461).

◊ Reviews.

2. Howlett HCS, Bailey CJ. A risk-benefit assessment of metformin in type 2 diabetes mellitus. *Drug Safety* 1999; **20:** 489–503.

Effects on the blood. Megaloblastic anaemia has occurred with biguanide therapy (see Malabsorption, under Effects on the Gastrointestinal Tract, below). A few cases of metformin-induced haemolysis resulting in hyperbilirubinaemia and jaundice have also been described.[1,2]

1. Lin K-D, *et al.* Metformin-induced hemolysis with jaundice. *N Engl J Med* 1998; **339:** 1860–1.
2. Meir A, *et al.* Metformin-induced hemolytic anemia in a patient with glucose-6-phosphate dehydrogenase deficiency. *Diabetes Care* 2003; **26:** 956–7.

Effects on the gastrointestinal tract. *DIARRHOEA.* In a retrospective survey,[1] 30 of 265 diabetic patients reported diarrhoea or alternating diarrhoea and constipation, comprising: 11 of 54 taking metformin; 9 of 45 taking metformin with a sulfonylurea; 3 of 53 taking a sulfonylurea only; 5 of 78 on insulin therapy; 2 of 35 on diet alone. Among 150 nondiabetic controls 12 reported diarrhoea. Chronic diarrhoea described as watery, often explosive, and frequently causing faecal incontinence, has been reported as an adverse effect of late onset in patients receiving metformin. Some patients had been on stable metformin therapy for several years before the onset of diarrhoea. Symptoms ceased upon withdrawal of metformin, and recurred in cases of rechallenge.[2,3]

MALABSORPTION. Megaloblastic anaemia due to vitamin B_{12} malabsorption in a 58-year-old woman was associated with long-term treatment with metformin.[1]

In a survey of diabetic patients receiving biguanide therapy,[2] malabsorption of vitamin B_{12} was observed in 14 of 46 diabetics taking metformin or phenformin; metformin was more commonly to blame. Withdrawal of the drug resulted in normal absorption in only 7 of the 14. In a series of 10 patients[3] with vitamin B_{12} deficiency associated with metformin, vitamin B_{12} concentrations and blood count abnormalities were reported to have been corrected within 3 months of starting treatment with intramuscular or oral cyanocobalamin; 2 patients were transferred to treatment with other antidiabetic agents.

3. Andrès E, *et al.* Metformin-associated vitamin B deficiency. *Arch Intern Med* 2002; **162:** 2251–2.

Effects on the liver. Severe cholestatic hepatitis attributed to metformin has been reported.[1]

1. Babich MM, *et al*. Metformin-induced acute hepatitis. *Am J Med* 1998; **104:** 490–2.

Effects on the pancreas. Acute pancreatitis is more commonly associated with phenformin.[1,2] However, there have also been a few cases of pancreatitis associated with metformin, in which renal failure may have precipitated metformin toxicity.[3,4]

1. Wilde H. Pancreatitis and phenformin. *Ann Intern Med* 1972; **77:** 324.
2. Chase HS, Mogan GR. Phenformin-associated pancreatitis. *Ann Intern Med* 1977; **87:** 314–15.

4. Fimognari FL, *et al.* Metformin-induced pancreatitis: a possible adverse drug effect during acute renal failure. *Diabetes Care* 2006; **29:** 1183.

Hypersensitivity. Vasculitis and pneumonitis in a 59-year-old woman was associated with use of metformin.[1] Symptoms improved on withdrawal of metformin, but reappeared on its reintroduction. Cutaneous vasculitis in a 33-year-old woman also resolved on withdrawal of metformin and recurred with its reintroduction.[2]

2. Salem CB, *et al.* Rare case of metformin-induced leukocytoclastic vasculitis. *Ann Pharmacother* 2006; **40:** 1685–7.

Hypoglycaemia. UK licensed product information for metformin states that hypoglycaemia does not occur with metformin alone, even in overdosage, although it may occur if given with alcohol or other hypoglycaemics. Interim results from the UK Prospective Diabetes Study,[1] however, indicate that metformin therapy was associated with fewer hypoglycaemic episodes than sulfonylurea or insulin treatment, but more than with diet alone. One or more hypoglycaemic episodes were reported in 6% of the patients receiving the biguanide in this study, although only 1 patient had a severe episode.

1. United Kingdom Prospective Diabetes Study Group. United Kingdom prospective diabetes study (UKPDS) 13: relative efficacy of randomly allocated diet, sulphonylurea, insulin, or metformin in patients with newly diagnosed non-insulin dependent diabetes followed for 3 years. *BMJ* 1995; **310:** 83–8.

Lactic acidosis. There is a small but definite risk of lactic acidosis associated with use of biguanide antidiabetics. Most early reports involved phenformin, which was consequently removed from the market in many countries although cases of phenformin-associated lactic acidosis still occur.[1-3] There has therefore been concern about the risks of lactic acidosis with metformin, which is still in wide use. However, lactic acidosis with metformin appears to be much less common: a review suggested that the incidence was of the order of 3 cases per 100 000 patient years, which was 20 times less frequent than with phenformin.[4] This concurs with the findings of the FDA after the introduction of metformin to the US market: in the year after the marketing of metformin in the USA, the FDA had received reports of metformin-associated lactic acidosis in 66 patients,[5] the diagnosis being confirmed in 47. This represented a rate of about 5 cases per 100 000. Most patients who do develop lactic acidosis with metformin have one or more precipitating risk factors such as renal impairment, congestive heart failure, or other conditions predisposing to hypoxaemia or acute renal failure, including septicaemia, acute hepatic decompensation, alcohol abuse, acute myocardial infarction, and shock.[4] A systematic review,[6] which considered results comprising nearly 48 000 patient years of treatment with metformin, concluded that provided metformin was prescribed taking into account the proper contra-indications, there was no evidence of an increased risk of lactic acidosis. Nonetheless, there have been a few reports of lactic acidosis developing in metformin-treated patients without apparent risk factors.[4]

Treatment of Adverse Effects

Acute poisoning with biguanides may lead to the development of lactic acidosis (see Metabolic Acidosis, p.1667) and calls for intensive supportive therapy. Glucose or glucagon may be required for hypoglycaemia, the general management of which is outlined in Insulin, p.447.

Precautions

Biguanides are inappropriate for patients with diabetic coma and ketoacidosis, or for those with severe infection, trauma, or other severe conditions where the biguanide is unlikely to control the hyperglycaemia; insulin should be used in such situations. Biguanides should not be given to patients with even mild renal impairment, as it may predispose patients to lactic acidosis, and renal function should be monitored throughout therapy. Dehydration may contribute to renal impairment. Conditions associated with hypoxia, such as

The symbol † denotes a preparation no longer actively marketed

acute heart failure, recent myocardial infarction, or shock, may increase the risk of lactic acidosis. Other conditions that may also predispose to lactic acidosis in a patient taking a biguanide include excessive alcohol intake and hepatic impairment. Biguanides should be temporarily stopped for examinations using contrast media (see under Interactions, below).

Insulin is preferred for the treatment of diabetes in pregnancy.

Owing to the possibility of decreased vitamin B_{12} absorption, annual monitoring of vitamin B_{12} concentrations is advisable during long-term treatment.

Driving. In the UK, patients with diabetes mellitus treated with insulin or oral hypoglycaemics are required to notify their condition to the Driver and Vehicle Licensing Agency, who then assess their fitness to drive. Patients treated with oral hypoglycaemics are generally allowed to retain standard driving licences; those treated with insulin receive restricted licences which must be renewed (with appropriate checks) every 1 to 3 years. Patients should be warned of the dangers of hypoglycaemic attacks while driving, and should be counselled in appropriate management of the situation (stopping driving as soon as it is safe to do so, taking carbohydrate immediately, and quitting the driving seat and removing the ignition key from the car) should such an event occur. Patients who have lost hypoglycaemic awareness, or have frequent hypoglycaemic episodes, should not drive. In addition, eyesight must be adequate (field of vision of at least 120°) for a licence to be valid. Patients treated with diet or oral hypoglycaemics are normally allowed to hold vocational driving licences for heavy goods vehicles or passenger carrying vehicles; those treated with insulin may not drive such vehicles, and are restricted in driving some other vehicles such as small lorries and minibuses.

Interactions

Use of a biguanide with other drugs that lower blood-glucose concentrations increases the risk of hypoglycaemia, while drugs that increase blood glucose may reduce the effect of biguanide therapy.

In general fewer drug interactions have been reported with biguanides than with sulfonylureas. Alcohol may increase the risk of lactic acidosis as well as of hypoglycaemia. Care should be taken if biguanides are given with drugs that may impair renal function.

Anticoagulants. For the effect of metformin on *phenprocoumon* activity, see Antidiabetics, p.1428.

Antivirals. Fatal lactic acidosis has been reported[1] in a patient given metformin with *didanosine*, *stavudine*, and *tenofovir*.

1. Worth L, *et al.* A cautionary tale: fatal lactic acidosis complicating nucleoside analogue and metformin therapy. *Clin Infect Dis* 2003; **37:** 315–16.

Cimetidine. Cimetidine increased plasma-metformin concentrations in 7 healthy subjects.[1] The renal clearance of metformin was reduced; competition for proximal tubular secretion was considered responsible. A reduction in metformin dosage may be required in patients taking metformin and cimetidine, in order to reduce the risk of lactic acidosis.

1. Somogyi A, *et al.* Reduction of metformin renal tubular secretion by cimetidine in man. *Br J Clin Pharmacol* 1987; **23:** 545–51.

Contrast media. Biguanides should be temporarily stopped for examinations using iodinated contrast media and withheld after the examination until normal renal function is confirmed, because of the risk of contrast media-induced renal impairment leading to biguanide toxicity and associated lactic acidosis. Licensed product information for some contrast media preparations warns that biguanides should be temporarily stopped 48 hours before the examination, and withheld for at least 48 hours after and until normal renal function is confirmed.

A number of guidelines on the use of iodinated contrast media give advice for the management of patients taking metformin. Some suggest that, in general, metformin can be stopped at the time of the examination.[1,2] Others are more detailed, suggesting that if serum-creatinine is normal metformin may be stopped at the time of the examination, but that if it is raised metformin should be stopped 48 hours before giving the contrast medium.[3,4] They all agree that metformin should be withheld for 48 hours after the examination and until normal renal function is confirmed, although one suggests that no special precaution is needed for patients with normal serum-creatinine who are to be given a low volume of iodinated contrast medium (up to 100 mL).[3]

Ketotifen. Platelet counts in 10 diabetic patients receiving biguanides fell (markedly in 3 patients) when they were also given ketotifen.[1] Counts returned to normal a few days after the end of ketotifen therapy. However, the investigators did not consider the effect clinically significant.

1. Doleček R. Ketotifen in the treatment of diabetics with various allergic conditions. *Pharmatherapeutica* 1981; **2:** 568–74.

Sulfonylureas. For reference to an apparent increase in mortality with an intensive regimen of metformin plus a sulfonylurea, see p.462.

Uses and Administration

The biguanide antidiabetics are a class of oral antidiabetic drugs used in the treatment of type 2 diabetes mellitus (p.431). They are given to supplement treatment by diet modification when such modification has not proved effective on its own. In addition, because biguanides are not associated with weight gain they are preferred in obese patients. Although sulfonylureas (p.460) may be preferred in non-obese patients, a biguanide is often added or given instead to patients who are not responding to a sulfonylurea.

The mode of action of biguanides is not clear. They do not stimulate insulin release but require that some insulin be present in order to exert their antidiabetic effect. Possible mechanisms of action include delay in the absorption of glucose from the gastrointestinal tract, an increase in insulin sensitivity and glucose uptake into cells, and inhibition of hepatic gluconeogenesis. Biguanides do not usually lower blood-glucose concentrations in non-diabetic subjects.

Hyperlipidaemias. The effect of biguanides on lipid metabolism is unclear, although some studies have shown a beneficial effect on serum-lipid profiles in both obese and lean patients with type 2 diabetes, hypertension, and/or hyperlipidaemia.[1] Reductions in concentrations of total cholesterol, low-density and very low-density-lipoprotein cholesterol have been reported, as well as modest increases in high-density-lipoprotein cholesterol. Some studies have also reported a reduction in serum-triglyceride levels. Such effects may be beneficial in the long-term treatment of type 2 diabetes mellitus with concomitant lipid disorders.

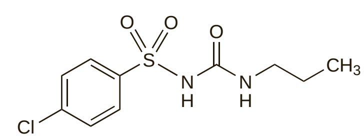
Хлорпропамид

$C_{10}H_{13}ClN_2O_3S$ = 276.7.
CAS — 94-20-2.
ATC — A10BB02.
ATC Vet — QA10BB02.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Chlorpropamide). A white or almost white, crystalline powder. It exhibits polymorphism. Practically insoluble in water; soluble in alcohol; freely soluble in acetone and in dichloromethane; dissolves in dilute solutions of alkali hydroxides. Protect from light.

USP 31 (Chlorpropamide). A white crystalline powder having a slight odour. Practically insoluble in water; soluble in alcohol; sparingly soluble in chloroform.

Adverse Effects and Treatment

As for sulfonylureas in general, p.460.

Chlorpropamide may be more likely than other sulfonylureas to induce a syndrome of inappropriate secretion of antidiuretic hormone characterised by water retention, hyponatraemia, and CNS effects. Patients receiving chlorpropamide may develop facial flushing after drinking alcohol.

Precautions

As for sulfonylureas in general, p.461.

Chlorpropamide should be avoided in the elderly and in renal or hepatic impairment because its long half-life increases the risk of hypoglycaemia. The antidiuretic effect of chlorpropamide may cause problems in patients with conditions associated with fluid retention.

Fasting. For the view that although some sulfonylurea antidiabetics may be able to be used with caution in fasting Muslim patients during Ramadan, chlorpropamide is contra-indicated, see under Precautions of Insulin, p.448.

Porphyria. Chlorpropamide has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Thyroid disorders. Some manufacturers recommend that chlorpropamide should not be used in patients with impaired thyroid function, but see under Sulfonylureas, p.461.

Interactions

As for sulfonylureas in general, p.461.

Chlorpropamide may produce profound facial flushing associated with alcohol ingestion.

Pharmacokinetics

Chlorpropamide is readily absorbed from the gastrointestinal tract and is extensively bound to plasma proteins. The half-life is about 35 hours. About 80% of a dose is metabolised in the liver; metabolites and unchanged drug are excreted in the urine. Chlorpropamide crosses the placenta and has been detected in breast milk.

Uses and Administration

Chlorpropamide is a sulfonylurea antidiabetic (p.460). It has a duration of action of at least 24 hours, and is given orally in the treatment of type 2 **diabetes mellitus** (p.431) in an initial daily dose of 250 mg as a single dose with breakfast. After 5 to 7 days the dose may be adjusted, in steps of 50 to 125 mg at intervals of 3 to 5 days, to achieve an optimum maintenance dose which is usually in the range 100 to 500 mg daily. Increasing the dose above 500 mg daily is unlikely to produce further benefit, and doses above 750 mg daily should be avoided. Although a reduced dose range has been proposed for the elderly, use of chlorpropamide is inadvisable in this group.

Chlorpropamide, though not the other sulfonylureas, is also sometimes used in cranial **diabetes insipidus** (p.2179). It has been reported to act by sensitising the renal tubules to antidiuretic hormone. The dose has to be carefully adjusted to minimise the risk of hypoglycaemia. An initial dose of 100 mg daily, adjusted if necessary to a maximum of 350 mg daily has been recommended, although doses of up to 500 mg daily have been used.

Diabetes mellitus. Patients with type 2 diabetes whose blood glucose is adequately controlled at first by sulfonylureas often eventually have treatment failure and loss of diabetic control. Results from the UK Prospective Diabetes Study[1] have suggested that the 6-year failure rate was higher in patients treated with glibenclamide (48%) than in those given chlorpropamide (40%). This difference was equivalent to delaying the requirement for additional therapy for a year in chlorpropamide-treated patients.

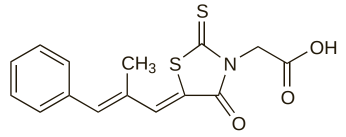
Epalrestat *(rINN)*

Épalrestat; Epalrestatum; ONO-2235. 5-[(*Z*,*E*)-β-Methylcinnamylidene]-4-oxo-2-thioxo-3-thiazolidineacetic acid.

Эпалрестат

$C_{15}H_{13}NO_3S_2$ = 319.4.
CAS — 82159-09-9.



Profile

Epalrestat inhibits the enzyme aldose reductase which catalyses the conversion of glucose to sorbitol. It has been suggested that accumulation of sorbitol in certain cells, occurring only in conditions of hyperglycaemia and resulting in a hyperosmotic effect, may be involved in the pathogenesis of some diabetic complications. Aldose reductase inhibitors have no influence on blood-glucose concentrations. Epalrestat is given orally for the treatment of diabetic complications including neuropathy (p.433), in a usual dose of 50 mg three times daily before meals.

Ser–Lys–Gln–Met–Glu–Glu–Glu–Ala–Val–Arg– (20)
Leu–Phe–Ile–Glu–Trp–Leu–Lys–Asn–Gly–Gly– (30)
Pro–Ser–Ser–Gly–Ala–Pro–Pro–Pro–Ser–NH_2 (39)

Adverse Effects and Precautions

Hypoglycaemia can occur in patients given exenatide, particularly when given with a sulfonylurea (see also Interactions, below). Exenatide commonly causes mild to moderate nausea, which is dose-dependent and tends to decrease with continued therapy in most patients. Other adverse effects include vomiting, diarrhoea, nervousness, dizziness, headache, and dyspepsia. Less frequent reports include asthenia, decreased appetite, gastro-oesophageal reflux, and hyperhidrosis. Rashes and hypersensitivity reactions have occurred rarely. Acute pancreatitis has been reported, and in such cases exenatide should be stopped permanently.

Exenatide should not be used in type 1 diabetes mellitus or for the treatment of diabetic ketoacidosis. Use is not recommended in patients with severe renal impairment, in whom clearance is reduced and adverse gastrointestinal effects have been reported.

Effects on the pancreas. A 69-year-old man developed pancreatitis within a few days of starting exenatide therapy. Serum-lipase concentrations returned to normal and abdominal pain resolved rapidly when exenatide was stopped.[1] The FDA has also reviewed 30 reports of acute pancreatitis in patients treated with exenatide.[2] In 27 cases there was at least one other risk factor for acute pancreatitis such as gallstones, severe hypertriglyceridaemia, and alcohol use. Improvement after stopping exenatide was confirmed in 22 reports, and in 3 cases of rechallenge there was a return of symptoms of acute pancreatitis. The FDA subsequently reported[3] in August 2008 that they had received reports of 6 cases of haemorrhagic or necrotising pancreatitis associated with exenatide; all patients required hospitalisation and 2 died. It was recommended that exenatide therapy should be stopped if signs or symptoms of pancreatitis develop and should not be restarted if pancreatitis is confirmed. Other antidiabetic drugs should be considered for those with a history of pancreatitis.

2. FDA. Information for healthcare professionals: exenatide (marketed as Byetta) (issued October 2007). Available at: http://www.fda.gov/cder/drug/InfoSheets/HCP/exenatideHCP.htm (accessed 17/10/07)
3. FDA. Information for healthcare professionals: exenatide (marketed as Byetta) (issued August 2008). Available at: http://www.fda.gov/cder/drug/InfoSheets/HCP/exenatide2008HCP.htm (accessed 20/08/08)

Interactions

A reduction in the sulfonylurea dose may be required when exenatide is added to therapy, because of an increased risk of hypoglycaemia with this combination. No increase in hypoglycaemia occurs when exenatide is used with metformin or a thiazolidinedione. The extent and rate of absorption of oral drugs may be reduced by exenatide. Where such an interaction would be undesirable, the oral medication should be given at least 1 hour before exenatide. If the oral medication is to be taken with food, where possible, it should be with a meal or snack when exenatide is not used.

Pharmacokinetics

After subcutaneous injection, peak plasma concentrations of exenatide are reached in about 2 hours. It is eliminated through the kidneys by glomerular filtration followed by proteolytic degradation, with a terminal half-life of about 2.4 hours. Clearance is reduced in patients receiving dialysis for end-stage renal disease.

2. Linnebjerg H, *et al.* Effect of renal impairment on the pharmacokinetics of exenatide. *Br J Clin Pharmacol* 2007; **64:** 317–27.

Uses and Administration

Exenatide is a synthetic form of exendin-4, a 39-amino acid peptide isolated from the venom of the Gila monster lizard (*Heloderma suspectum*, Helodermatidae). The drug is an incretin mimic that acts as an agonist at the glucagon-like peptide 1 receptor to enhance insulin secretion in the presence of raised glucose concentrations; it also suppresses inappropriate glucagon secretion and slows gastric emptying. Exenatide is used as adjunctive therapy in type 2 diabetes mellitus (p.431) in patients who do not have adequate glycaemic control with metformin, a sulfonylurea, a thiazolidinedione, or dual therapy with metformin plus a sulfonylurea or thiazolidinedione. It is given by subcutaneous injection in an initial dose of 5 micrograms twice daily within 60 minutes before the morning and evening meals. The dose of exenatide may be increased after 1 month to 10 micrograms twice daily if required.

Glibenclamide *(BAN, rINN)*

Glibenclamida; Glibenclamidum; Glibenklamid; Glibenklamidas; Glibenklamidi; Glybenclamide; Glybenzcyclamide; Glyburide *(USAN)*; HB-419; U-26452. 1-{4-[2-(5-Chloro-2-methoxybenzamido)ethyl]benzenesulphonyl}-3-cyclohexylurea.

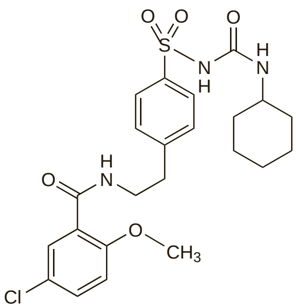
Глибенкламид

$C_{23}H_{28}ClN_3O_5S = 494.0$.

CAS — 10238-21-8.

ATC — A10BB01.

ATC Vet — QA10BB01.



NOTE. The name glibornuride has frequently but erroneously been applied to glibenclamide.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Glibenclamide). A white or almost white, crystalline powder. Practically insoluble in water; slightly soluble in alcohol and in methyl alcohol; sparingly soluble in dichloromethane.

USP 31 (Glyburide). Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for sulfonylureas in general, p.460.

◊ For a suggestion that the failure rate in type 2 diabetics treated with glibenclamide may be higher than that for those treated with chlorpropamide, see Diabetes Mellitus under Uses and Administration of Chlorpropamide, p.439.

Effects on the blood. References.

Hypoglycaemia. Severe hypoglycaemia may occur in any patient given any sulfonylurea (see p.461); glibenclamide which has a relatively prolonged duration of action, may cause severe hypoglycaemia more often than shorter-acting sulfonylureas.

In a 1983 review[1] of 57 instances of hypoglycaemia associated with glibenclamide the median age of patients affected was 70 years; only one was less than 60 years old. Median daily dosage was 10 mg. Coma or disturbed consciousness was seen in 46 patients. Ten of these remained comatose despite alleviation of their hypoglycaemia and died up to 20 days after presentation. The authors noted that, including their series of 57 cases, there had been published reports on 101 cases of severe hypoglycaemia with glibenclamide, 14 with a fatal outcome.

There has been a report[2] of hypoglycaemic coma associated with the inhalation of glibenclamide by a worker at a pharmaceutical plant.

2. Albert F, *et al.* Hypoglycaemia by inhalation. *Lancet* 1993; **342:** 47–8.

Porphyria. Glibenclamide has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for sulfonylureas in general, p.461.

Pharmacokinetics

Glibenclamide is readily absorbed from the gastrointestinal tract, peak plasma concentrations usually occurring within 2 to 4 hours, and is extensively bound to plasma proteins. Absorption may be slower in hyperglycaemic patients and may differ according to the particle size of the preparation used. It is metabolised, almost completely, in the liver, the principal metabolite being only very weakly active. About 50% of a dose is excreted in the urine and 50% via the bile into the faeces.

Uses and Administration

Glibenclamide is a sulfonylurea antidiabetic (p.460). It is given orally in the treatment of type 2 diabetes mellitus (p.431) and has a duration of action of up to 24 hours.

The usual initial dose of conventional formulations in type 2 diabetes mellitus is 2.5 to 5 mg daily with breakfast, adjusted every 7 days in steps of 2.5 or 5 mg daily up to 15 mg daily. Although increasing the dose above 15 mg is unlikely to produce further benefit, doses of up to 20 mg daily have been given. Doses greater than 10 mg daily may be given in 2 divided doses. Because of the relatively long duration of action of glibenclamide, it is best avoided in the elderly.

In some countries micronised preparations of glibenclamide are available, in which the drug is formulated with a smaller particle size, and which have enhanced bioavailability. The usual initial dose of one such preparation (*Glynase PresTab; Pharmacia Upjohn, USA*) is 1.5 to 3 mg daily, adjusted every 7 days in steps of 1.5 mg, up to a usual maximum of 12 mg daily. Doses greater than 6 mg daily may be given in 2 divided doses.

Action. Proceedings of a symposium on the mechanism of action of glibenclamide.[1]

1. Gavin JR, ed. Glyburide: new insights into its effects on the beta cell and beyond. *Am J Med* 1990; **89** (suppl 2A): 1–53S.

EFFECTS ON THE HEART. A reduced incidence of ventricular fibrillation has been reported in diabetics treated with glibenclamide who develop myocardial infarction, compared with those receiving other treatments or with nondiabetic patients with myocardial infarction.[1] However, some evidence has also suggested that sulfonylureas may impair the adaptive responses of the heart to ischaemia—see p.461.

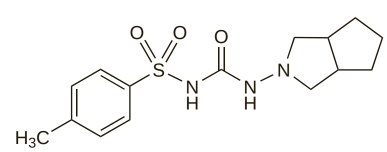
ATC Vet — QA10BB09.



Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Gliclazide). A white or almost white powder. Practically insoluble in water; slightly soluble in alcohol; sparingly soluble in acetone; freely soluble in dichloromethane.

Adverse Effects, Treatment, and Precautions

As for sulfonylureas in general, p.460.

The *BNF* suggests that gliclazide may be suitable for use in patients with renal impairment, but that careful monitoring of blood-glucose concentration is essential. UK licensed product information recommends that it should not be used in patients with severe renal impairment.

Interactions

As for sulfonylureas in general, p.461.

Pharmacokinetics

Gliclazide is readily absorbed from the gastrointestinal tract. It is extensively bound to plasma proteins. The half-life is about 10 to 12 hours. Gliclazide is extensively metabolised in the liver to metabolites that have no significant hypoglycaemic activity. Metabolites and a small amount of unchanged drug are excreted in the urine.

◊ References.

1. Kobayashi K, *et al*. Pharmacokinetics of gliclazide in healthy and diabetic subjects. *J Pharm Sci* 1984; **73:** 1684–7.

Uses and Administration

Gliclazide is a sulfonylurea antidiabetic (p.460). It is given orally in the treatment of type 2 diabetes mellitus (p.431) and has a duration of action of 12 to 24 hours. Because its effects are less prolonged than those of chlorpropamide or glibenclamide it may be more suitable for elderly patients, who are prone to hypoglycaemia with longer-acting sulfonylureas. The usual initial dose is 40 to 80 mg daily, gradually increased, if necessary, up to 320 mg daily. Doses of more than 160 mg daily are given in 2 divided doses. A modified-release tablet is also available: the usual initial dose is 30 mg once daily, increased if necessary up to a maximum of 120 mg daily.

Glimepiride *(BAN, USAN, rINN)*

Glimepirid; Glimepirida; Glimépiride; Glimepiridi; Glimepiridum; Glimepiryd; Hoe-490. 1-({*p*-[2-(3-Ethyl-4-methyl-2-oxo-3-pyrroline-1-carboxamido)ethyl]phenyl}sulfonyl)-3-(*trans*-4-methylcyclohexyl)urea.

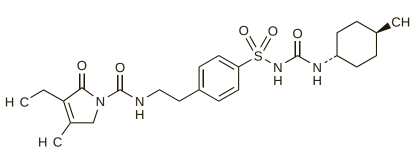
Глимепирид

$C_{24}H_{34}N_4O_5S$ = 490.6.

CAS — 93479-97-1.

ATC — A10BB12.

ATC Vet — QA10BB12.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Glimepiride). A white to almost white powder. It exhibits polymorphism. Practically insoluble in water; slightly soluble in dichloromethane; soluble in dimethylformamide; very slightly soluble in methyl alcohol.

USP 31 (Glimepiride). A white to almost white powder. Practically insoluble in water; sparingly soluble in dichloromethane; soluble in dimethylformamide; slightly soluble in methyl alcohol. It dissolves in dilute alkali hydroxides and in dilute acids. Store at a temperature not exceeding 25°.

Adverse Effects, Treatment, and Precautions

As for sulfonylureas in general, p.460. In some countries hepatic and haematological monitoring is recommended in patients receiving glimepiride; in the UK the *BNF* considers the practical value of such monitoring unproven.

Fasting. Glimepiride, given in unchanged doses but with the time of the single daily dose switched from morning to just before breaking fast after sunset, was used in Muslim patients during Ramadan without causing an increased incidence of hypoglycaemic episodes.[1]

For further advice on the management of diabetes mellitus in fasting Muslim patients during Ramadan see under Precautions of Insulin, p.448.

1. The Glimepiride in Ramadan (GLIRA) Study Group. The efficacy and safety of glimepiride in the management of type 2 diabetes in Muslim patients during Ramadan. *Diabetes Care* 2005; **28:** 421–2.

Interactions

As for sulfonylureas in general, p.461.

Pharmacokinetics

Glimepiride is completely absorbed from the gastrointestinal tract. Peak plasma concentrations occur in 2 to 3 hours, and it is highly protein bound. The drug is extensively metabolised to two main metabolites, a hydroxy derivative and a carboxy derivative. The half-life after multiple doses is about 9 hours. About 60% of a dose is eliminated in the urine and 40% in the faeces.

Uses and Administration

Glimepiride is a sulfonylurea antidiabetic (p.460). It is given orally for the treatment of type 2 diabetes mellitus (p.431). Initial doses of 1 to 2 mg daily may be increased if necessary to 4 mg daily for maintenance. The maximum recommended dose is 6 mg in the UK and 8 mg in the USA.

Glipizide *(BAN, USAN, pINN)*

CP-28720; Glipitsidi; Glipizid; Glipizida; Glipizidas; Glipizidum; Glipizyd; Glydiazinamide; K-4024. 1-Cyclohexyl-3-{4-[2-(5-methylpyrazine-2-carboxamido)ethyl]benzenesulphonyl}urea.

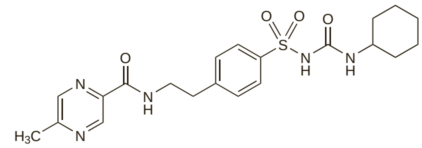
Глипизид

$C_{21}H_{27}N_5O_4S$ = 445.5.

CAS — 29094-61-9.

ATC — A10BB07.

ATC Vet — QA10BB07.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Glipizide). A white or almost white crystalline powder. Practically insoluble in water and in alcohol; very slightly soluble in acetone and in dichloromethane. It dissolves in dilute solutions of alkali hydroxides.

USP 31 (Glipizide). Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for sulfonylureas in general, p.460.

Porphyria. Glipizide has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for sulfonylureas in general, p.461.

Antacids. *Magnesium hydroxide* and *sodium bicarbonate* have been reported to increase the rate of absorption, although not the total amount absorbed, of a dose of glipizide in healthy subjects.[1,2] No such effect was seen with *aluminium hydroxide*.[2]

1. Kivisto KT, Neuvonen PJ. Enhancement of absorption and effect of glipizide by magnesium hydroxide. *Clin Pharmacol Ther* 1991; **49:** 39–43.
2. Kivisto KT, Neuvonen PJ. Differential effects of sodium bicarbonate and aluminium hydroxide on the absorption and activity of glipizide. *Eur J Clin Pharmacol* 1991; **40:** 383–6.

Pharmacokinetics

Glipizide is readily absorbed from the gastrointestinal tract with peak plasma concentrations occurring 1 to 3 hours after a single dose. It is extensively bound to plasma proteins and has a half-life of about 2 to 4 hours. It is metabolised mainly in the liver and excreted chiefly in the urine, largely as inactive metabolites.

Uses and Administration

Glipizide is a sulfonylurea antidiabetic (p.460). It is given orally in the treatment of type 2 diabetes mellitus (p.431) and has a duration of action of up to 24 hours. The usual initial dose is 2.5 to 5 mg daily given as a single dose about 30 minutes before breakfast. Dosage may be adjusted at intervals of several days by amounts of 2.5 to 5 mg daily, to a maximum of 20 mg daily. Doses up to 40 mg daily have been used, but see below. Doses larger than 15 mg daily are given in two divided doses before meals. Modified-release formulations of glipizide are available in some countries; one such preparation (*Glucotrol XL; Pfizer, USA*) is given in doses of 5 to 10 mg daily as a single dose with breakfast.

Administration. Although glipizide may be given in doses up to a maximum of 40 mg daily, evidence for the benefits of high doses is scanty. A small study in patients with type 2 diabetes mellitus found that not only did increases in glipizide doses to more than 10 mg daily produce little or no benefit, but that the higher doses were associated with reduced rises in plasma-insulin concentrations and a lesser reduction in plasma-glucose concentrations.[1] There is, however, some evidence that glycaemic control and insulin sensitivity can be improved by the use of a modified-release rather than a conventional formulation of glipizide.[2,3]

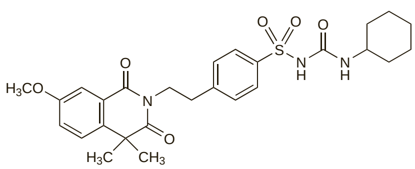
Гликвидон

$C_{27}H_{33}N_3O_6S$ = 527.6.
CAS — 33342-05-1.
ATC — A10BB08.
ATC Vet — QA10BB08.



Pharmacopoeias. In *Br.* and *Chin.*
BP 2008 (Gliquidone). A white or almost white powder. Practically insoluble in water; slightly soluble in alcohol and in methyl alcohol; soluble in acetone; freely soluble in dimethylformamide.

Adverse Effects, Treatment, and Precautions
As for sulfonylureas in general, p.460.

Interactions
As for sulfonylureas in general, p.461.

Pharmacokinetics
Gliquidone is readily absorbed from the gastrointestinal tract. It is extensively bound to plasma proteins and has a half-life of about 1.5 hours. It is extensively metabolised in the liver, the metabolites having no significant hypoglycaemic effect, and is eliminated chiefly in the faeces via the bile; only about 5% of a dose is excreted in the urine.

Uses and Administration
Gliquidone is a sulfonylurea antidiabetic (p.460). It has been given orally in the treatment of type 2 diabetes mellitus (p.431) in a usual initial dosage of 15 mg daily given as a single dose up to 30 minutes before breakfast. Dosage may be adjusted by increments of 15 mg to a usual dose of 45 to 60 mg daily in 2 or 3 unequally divided doses, the largest dose being taken in the morning with breakfast. Single doses above 60 mg and daily doses above 180 mg are not recommended.

Preparations

BP 2008: Gliquidone Tablets.
