2. Albonico M, *et al.* A randomized controlled trial comparing mebendazole and albendazole against Ascaris, Trichuris and hookworm infections. *Trans R Soc Trop Med Hyg* 1994; **88:** 585–9.
3. Sacko M, *et al.* Comparison of the efficacy of mebendazole, albendazole and pyrantel in treatment of human hookworm infections in the southern region of Mali, West Africa. *Trans R Soc Trop Med Hyg* 1999; **93:** 195–203.
4. Idris MA, *et al.* Effective control of hookworm infection in school children from Dhofar, Sultanate of Oman: a four-year experience with albendazole mass chemotherapy. *Acta Trop* 2001; **80:** 139–43.

Loiasis. Albendazole has been investigated[1,2] to reduce microfilariasis in patients infected with *Loa loa* (see Loiasis, p.137) with modest success.

1. Klion AD, *et al.* Albendazole in human loiasis: results of a double-blind, placebo-controlled trial. *J Infect Dis* 1993; **168:** 202–6.
2. Tabi TE, *et al.* Human loiasis in a Cameroonian village: a double-blind, placebo-controlled, crossover clinical trial of a three-day albendazole regimen. *Am J Trop Med Hyg* 2004; **71:** 211–15.

Lymphatic filariasis. Albendazole is used in the management of lymphatic filariasis (p.137). In endemic areas mass treatment of the entire population (excluding neonates, pregnant women, and debilitated individuals) can reduce the intensity of transmission and the incidence of disease. The Global Programme to eliminate Lymphatic Filariasis launched by WHO, with other international agencies, advocates a single dose of albendazole 400 mg with either a single dose of ivermectin 150 to 200 micrograms/kg (if there is co-endemic loiasis or onchocerciasis) or with a single dose of diethylcarbamazine 6 mg/kg (if there is no co-endemic loiasis or onchocerciasis); these doses are given once each year for at least 5 years.

Microsporidiosis. Albendazole has been tried[1-6] in the treatment of the protozoal infection microsporidiosis (p.826) in patients with AIDS. Albendazole has also been used empirically in the treatment of HIV-associated infections and complications (p.857).

1. Blanshard C, *et al.* Treatment of intestinal microsporidiosis with albendazole in patients with AIDS. *AIDS* 1992; **6:** 311–13.

6. Tremoulet AH, *et al.* Albendazole therapy for Microsporidium diarrhea in immunocompetent Costa Rican children. *Pediatr Infect Dis J* 2004; **23:** 915–18.

Strongyloidiasis. Albendazole is generally preferred to tiabendazole or mebendazole in the treatment of strongyloidiasis (p.138) although ivermectin is now generally considered to be the drug of choice. Both drugs have been used together in disseminated disease.

6. Singthong S, *et al.* Randomized comparative trial of two high-dose albendazole regimens for uncomplicated human strongyloidiasis. *Southeast Asian J Trop Med Public Health* 2006; **37** (suppl 3): 32–4.

Toxocariasis. Albendazole is one of the drugs that might be used for the treatment of toxocariasis (p.139) and in a small study[1] it produced improvement similar to that achieved with tiabendazole but with fewer problems.

1. Stürchler D, *et al.* Thiabendazole vs albendazole in treatment of toxocariasis: a clinical trial. *Ann Trop Med Parasitol* 1989; **83:** 473–8.

Trichinosis. Albendazole may be effective in the treatment of trichinosis (p.139). A retrospective study in 44 patients with trichinosis comparing albendazole treatment with tiabendazole found that, while the two drugs were of comparable efficacy, albendazole was the better tolerated.[1] Albendazole has been used to treat a patient infected with *Trichinella pseudospiralis*, an organism related to *T. spiralis*, the usual cause of trichinosis.[2]

Trichostrongyliasis. Albendazole in a single dose of 400 mg has been suggested[1] as an alternative to pyrantel embonate or mebendazole in the treatment of trichostrongyliasis (p.139).

1. Abramowicz M, ed. *Drugs for parasitic infections*. 1st ed. New Rochelle NY: The Medical Letter, 2007.

Trichuriasis. Albendazole is used in the treatment of trichuriasis (p.139). It is normally given in a single dose and is often used in mixed intestinal nematode infections.[1] However, it has been reported[1-3] that in children with mixed intestinal worm infections single doses of albendazole are ineffective in eliminating *Trichuris trichiura* and multiple doses are required to produce worthwhile reductions in egg production. Treatment for 3 days has been used[4] (but for a suggestion that such regimens may be associated with impaired growth in less heavily infected children, see Effects on Growth under Adverse Effects, above). Combined use of albendazole with ivermectin may prove useful.[5]

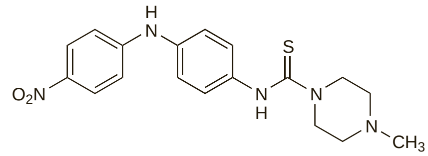
Amocarzine *(rINN)*

Amocarzina; Amocarzinum; CGP-6140. 4-Methyl-4′-(*p*-nitroanilino)thio-1-piperazinecarboxanilide.

Амокарзин

$C_{18}H_{21}N_5O_2S = 371.5.$

CAS — 36590-19-9.



NOTE. Amocarzine has sometimes been referred to as thiocarbamazine.

Profile

Amocarzine is an antifilarial anthelmintic that is active against the adult worms of *Onchocerca volvulus.* It has been studied for the oral treatment of onchocerciasis (p.137).

◊ References.

Trivalent Antimony Compounds

Compuestos de antimonio trivalente.

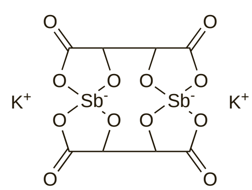
Antimony Potassium Tartrate

Antim. Pot. Tart.; Antimónico potásico, tartrato; Antymonu potasu winian; Brechweinstein; Kalii Stibyli Tartras; Potassium Antimonyltartrate; Stibii et Kalii Tartras; Tartar Emetic; Tartarus Stibiatus. Dipotassium bis{μ-[2,3-dihydroxybutanedioato(4-)-*O*^{1},*O*^{2}:*O*^{3},*O*^{4}]}-diantimonate(2-) trihydrate; Dipotassium bis[μ-tartrato(4-)]diantimonate(2-) trihydrate.

Антимонил-тартрат Калия

$C_8H_4K_2O_{12}Sb_2,3H_2O = 667.9.$

CAS — 11071-15-1 (anhydrous antimony potassium tartrate); 28300-74-5 (antimony potassium tartrate trihydrate).



Pharmacopoeias. In *US.*

USP 31 (Antimony Potassium Tartrate). Odourless, colourless, transparent crystals or white powder. The crystals effloresce on exposure to air and do not readily rehydrate even on exposure to high humidity. Soluble 1 in 12 of water, 1 in 3 of boiling water, and 1 in 15 of glycerol; insoluble in alcohol. Its solutions are acid to litmus.

Antimony Sodium Tartrate

Antim. Sod. Tart.; Antimónico sódico, tartrato; Sodium Antimonyltartrate; Stibium Natrium Tartaricum. Disodium bis{μ-[2,3-dihydroxybutanedioato(4-)-*O*^{1},*O*^{2}:*O*^{3},*O*^{4}]}diantimonate(2-); Disodium bis{μ-[L-(+)-tartrato(4-)]}diantimonate(2-).

Антимонил-тартрат Натрия

$C_8H_4Na_2O_{12}Sb_2 = 581.6.$

CAS — 34521-09-0.

Pharmacopoeias. In *Int.* (as $C_4H_4NaO_7Sb = 308.8$) and *US.*

USP 31 (Antimony Sodium Tartrate). Odourless, colourless, transparent crystals or white powder. The crystals effloresce on exposure to air. Freely soluble in water; insoluble in alcohol.

Sodium Stibocaptate *(BAN, rINN)*

Antimony Sodium Dimercaptosuccinate; Estibocaptato de sodio; Natrii Stibocaptas; Ro-4-1544/6; Sb-58; Stibocaptate; Stibocaptate de Sodium; TWSb/6. Antimony sodium *meso*-2,3-dimercaptosuccinate. The formula varies from $C_{12}H_{11}NaO_{12}S_6Sb_2 = 806.1$ to $C_{12}H_6Na_6O_{12}S_6Sb_2 = 916.0.$

Натрия Стибокаптат

CAS — 3064-61-7 ($C_{12}H_6Na_6O_{12}S_6Sb_2$).

Stibophen

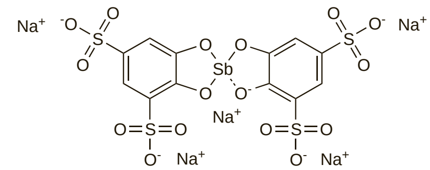
Estibofeno; Fouadin; Stibophenum. Bis[4,5-dihydroxybenzene-1,3-disulphonato(4−)-*O*^{4},*O*^{5}]antimonate(5−) pentasodium heptahydrate.

Стибофен

$C_{12}H_4Na_5O_{16}S_4Sb,7H_2O = 895.2.$

CAS — 15489-16-4 (stibophen heptahydrate).

ATC — P02BX03.



Adverse Effects and Treatment

Trivalent antimony compounds are more toxic than pentavalent antimonials such as sodium stibogluconate, possibly because they are excreted much more slowly. The most serious adverse effects are on the heart and liver. There are invariably ECG changes during treatment, but hypotension, bradycardia, and cardiac arrhythmias are more serious. Sudden death or cardiovascular collapse may occur at any time. Elevated liver enzyme values are common; liver damage with hepatic failure and death is more likely in patients with pre-existing hepatic disease.

Adverse effects immediately after intravenous use of trivalent antimonials, in particular the tartrates, have included coughing, chest pain, pain in the arms, vomiting, abdominal pain, fainting, and collapse, especially after rapid injection. Extravasation during injection is extremely painful because of tissue damage. An anaphylactoid reaction characterised by an urticarial rash, husky voice, and collapse has been reported after the sixth or seventh intravenous injection of a course of treatment.

Numerous less immediate adverse effects have occurred including gastrointestinal disturbances, muscular and joint pains, arthritis, pneumonia, dyspnoea, headache, dizziness, weakness, pruritus, skin rashes, facial oedema, fever, haemolytic anaemia, and kidney damage.

Large oral doses of antimony compounds have an emetic action. Continuous treatment with small doses of antimony may give rise to symptoms of subacute poisoning similar to those of chronic arsenical poisoning.

Treatment of severe poisoning with antimony compounds is similar to that for arsenic poisoning (p.2261); dimercaprol may be of benefit.

◊ References.

1. Stemmer KL. Pharmacology and toxicology of heavy metals: antimony. *Pharmacol Ther* 1976; **1:** 157–60.

Precautions

Trivalent antimony therapy has generally been superseded by less toxic treatment. It is contra-indicated in the presence of lung, heart, liver, or kidney disease. Intravenous injections should be given very slowly and stopped if coughing, vomiting, or substernal pain occurs; extravasation should be avoided.

Some antimony compounds such as the tartrates cause severe pain and tissue necrosis and should not be given by intramuscular or subcutaneous injection.

Breast feeding. The American Academy of Pediatrics[1] states that there have been no reports of any clinical effect on the infant associated with the use of antimony by breast-feeding mothers, and that therefore it may be considered to be usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 02/06/04)

Glucose-6-phosphate dehydrogenase deficiency. In the event of trivalent antimony compounds being used, patients with G6PD deficiency should be excluded. WHO lists stibophen[1] among the anthelmintics to be avoided in patients with this deficiency.

1. WHO. Glucose-6-phosphate dehydrogenase deficiency. *Bull WHO* 1989; **67:** 601–11.

Pharmacokinetics

Antimony compounds are poorly absorbed from the gastrointestinal tract. They are slowly excreted, mainly in the urine, after parenteral doses. Antimony accumulates in the body during treatment and persists for several months afterwards. Trivalent antimony has a greater affinity for cell proteins than for plasma proteins.

Uses and Administration

Trivalent antimony compounds were used in the treatment of the protozoal infection leishmaniasis until the advent of the less toxic pentavalent compounds. They continued to be used in the treatment of schistosomiasis, but have now been superseded by less toxic and more easily given drugs such as praziquantel.

The symbol † denotes a preparation no longer actively marketed

Antimony sodium tartrate was formerly used as an emetic. The sodium tartrate and potassium tartrate have also been used as expectorants.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Thai.:*** Brown Mixture.

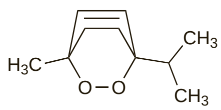
Ascaridole

Ascaridol. 1-Isopropyl-4-methyl-2,3-dioxabicyclo[2.2.2]oct-5-ene.

Аскаридол

$C_{10}H_{16}O_2$ = 168.2.

CAS — 512-85-6.



Profile

Ascaridole is the active principle of chenopodium oil (p.142) and has the same actions.

Handling. Ascaridole is an unstable liquid which is liable to explode when heated or when treated with organic acids.

Bephenium Hydroxynaphthoate *(BAN, rINN)*

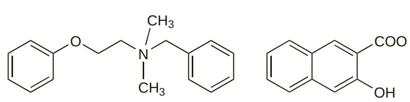
Bephenii Hydroxynaphthoas; Béphénium, Hydroxynaphtoate de; Hidroxinaftoato de befenio; Naphthammonum. Benzyldimethyl(2-phenoxyethyl)ammonium 3-hydroxy-2-naphthoate.

Бефения Гидроксинафтоат

$C_{28}H_{29}NO_4$ = 443.5.

CAS — 7181-73-9 (bephenium); 3818-50-6 (bephenium hydroxynaphthoate).

ATC — P02CX02.



Pharmacopoeias. In *Int.*

Profile

Bephenium hydroxynaphthoate is an anthelmintic formerly used in the treatment of hookworm infections, ascariasis, and trichostrongyliasis.

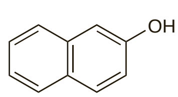
Betanaphthol

β-Naftol; 2-Naftol; Naphthol. Naphth-2-ol.

Бета-нафтол

$C_{10}H_8O$ = 144.2.

CAS — 135-19-3.



Pharmacopoeias. In *Pol.* and *Swiss.*

Profile

Betanaphthol was formerly used as an anthelmintic in hookworm and tapeworm infections, but it has been superseded by less toxic and more efficient drugs.

Betanaphthol has a potent parasiticidal effect and has been used topically in the treatment of scabies, ringworm, and other skin diseases.

Betanaphthyl benzoate has been used in preparations for the treatment of gastrointestinal disorders.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Arg.:*** Hekabetol; ***Austria:*** Salvyl.

Bithionol *(BAN, rINN)*

Bithionololum; Bithionolum; Bitionol; Bitionolol; Bitionololi. 2,2′-Thiobis(4,6-dichlorophenol).

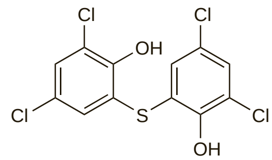
Битионол

$C_{12}H_6Cl_4O_2S$ = 356.1.

CAS — 97-18-7.

ATC — D10AB01; P02BX01.

ATC Vet — QD10AB01; QP52AG07.



Pharmacopoeias. *Fr.* includes bithionol oxide for veterinary use.

Adverse Effects

Adverse effects in patients taking bithionol by mouth include anorexia, nausea, vomiting, abdominal discomfort, diarrhoea, salivation, dizziness, headache, and skin rashes.

Photosensitivity reactions have occurred in persons using soap containing bithionol. Cross-sensitisation with other halogenated disinfectants has also occurred.

Uses and Administration

Bithionol is a chlorinated bis-phenol with bactericidal and anthelmintic properties. It is active against most trematodes (flukes). Bithionol is used in preference to praziquantel in fascioliasis (see Liver Fluke Infections, p.137) and is also used in paragonimiasis (see Lung Fluke Infections, p.137) as an alternative to praziquantel. It may be given in an oral dose of 30 to 50 mg/kg on alternate days for 10 to 15 doses. Alternatively, for fascioliasis, WHO recommends a regimen of 30 mg/kg daily for 5 days.

Bithionol was formerly used topically as a bactericide but this use has declined because of photosensitivity reactions.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Arg.:*** Fonergine.

Bromofenofos *(rINN)*

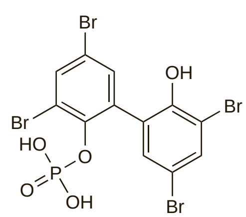
Bromfenofos; Bromofénofos; Bromofenofós; Bromofenofosum; Bromophenophos; Bromphenphos. 3,3′,5,5′-Tetrabromo-2,2′-biphenyldiolmono(dihydrogen phosphate).

Бромофенофос

$C_{12}H_7Br_4O_5P$ = 581.8.

CAS — 21466-07-9.

ATC Vet — QP52AB02.



Profile

Bromofenofos is an organophosphorus compound (see Organophosphorus Insecticides, p.2047) used as an anthelmintic in veterinary medicine for the treatment of fluke infections.

Cambendazole *(BAN, USAN, rINN)*

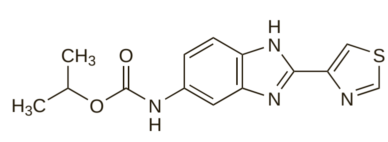
Cambendazol; Cambendazolum; MK-905. Isopropyl 2-(thiazol-4-yl)-1*H*-benzimidazol-5-ylcarbamate.

Камбендазол

$C_{14}H_{14}N_4O_2S$ = 302.4.

CAS — 26097-80-3.

ATC Vet — QP52AC08.



Profile

Cambendazole is a benzimidazole carbamate anthelmintic structurally related to tiabendazole (p.156). It is used in the treatment of strongyloidiasis.

Preparations

Proprietary Preparations (details are given in Part 3)

Braz.: Cambem†.

Multi-ingredient: ***Braz.:*** Exelmin†.

Chenopodium Oil

Aceite de quenopodio; Aetheroleum Chenopodii; Esencia de Quenopodio Vermifuga; Oil of American Wormseed; Wurmsamenöl.

Амброзиевое Масло; Маревое Масло

CAS — 8006-99-3.

Profile

Chenopodium oil is distilled with steam from the fresh flowering and fruiting plants, excluding roots, of *Chenopodium ambrosioides* var. *anthelminticum.* It contains ascaridole. It was formerly used as an anthelmintic for the expulsion of roundworms (*Ascaris*) and hookworms. It is toxic and has caused numerous fatalities.

Handling. Chenopodium oil may explode when heated.

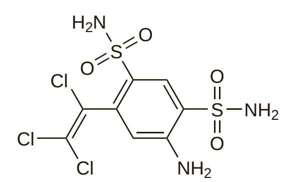
Clorsulon *(BAN, USAN, rINN)*

Clorsulón; Clorsulone; Clorsulonum; MK-401. 4-Amino-6-(trichlorovinyl)benzene-1,3-disulphonamide.

Клорсулон

$C_8H_8Cl_3N_3O_4S_2$ = 380.7.

CAS — 60200-06-8.



Pharmacopoeias. In *US* for veterinary use only.

USP 31 (Clorsulon). A white to off-white powder. Slightly soluble in water; freely soluble in acetonitrile and in methyl alcohol; very slightly soluble in dichloromethane.

Profile

Clorsulon is an anthelmintic used in veterinary medicine for the treatment of liver fluke infections.

Closantel *(BAN, USAN, rINN)*

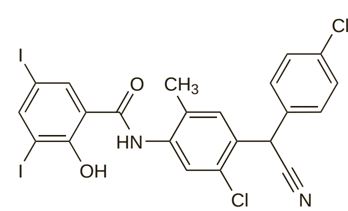
Closantelum; R-31520. 5′-Chloro-4′-(4-chloro-α-cyanobenzyl)-3,5-di-iodosalicyl-*o*-toluidide.

Клозантел

$C_{22}H_{14}Cl_2I_2N_2O_2$ = 663.1.

CAS — 57808-65-8.

ATC Vet — QP52AG09.



Closantel Sodium *(BANM, rINNM)*

Closantel sódico; Closantel sodique; Closantelum natricum; Klosanteelinatrium; Klosantel sodná sůl; Klosantelnatrium; Natrii Closantelum; R-34828.

Натрий Клозантел

$C_{22}H_{14}Cl_2I_2N_2O_2Na$ = 686.1.

Pharmacopoeias. In *Eur.* (see p.vii) as the dihydrate for veterinary use.

Ph. Eur. 6.2 (Closantel Sodium Dihydrate for Veterinary Use; Closantel Sodium Dihydrate BP(Vet) 2008). A yellow, slightly hygroscopic, powder. It exhibits polymorphism. Very slightly soluble in water; freely soluble in alcohol; soluble in methyl alcohol. Store in airtight containers. Protect from light.

Profile

Closantel is an anthelmintic used in veterinary medicine for the treatment of fluke and nematode infections.

Effects on the eyes. Loss of eyesight was reported in 11 women who received closantel (Flukiver) in mistake for a gynaecological product.[1] Sight was restored after closantel was stopped but incapacitating eye pain remained.

1. 't Hoen E, *et al.* Harmful human use of donated veterinary drug. *Lancet* 1993; **342:** 308–9.

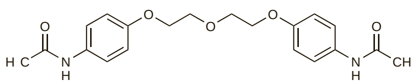
Diamfenetide *(BAN, rINN)*

Diamfenetida; Diamfénétide; Diamfenetidum; Diamphenethide. β,β′-Oxybis(aceto-*p*-phenetidide).

Диамфенетид

$C_{20}H_{24}N_2O_5$ = 372.4.

CAS — 36141-82-9.



Profile

Diamfenetide is an anthelmintic that has been used in veterinary medicine for the control of fascioliasis in sheep.

Dichlorophen *(BAN, rINN)*

Dichlorophène; Dichlorophenum; Diclorofeno; Di-phenthane-70; G-4. 2,2′-Methylenebis(4-chlorophenol).

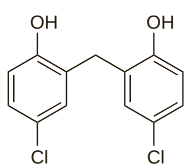
Дихлорофен

$C_{13}H_{10}Cl_2O_2$ = 269.1.

CAS — 97-23-4.

ATC — P02DX02.

ATC Vet — QP52AG01.



Pharmacopoeias. In *Br.* and *Fr.*

BP 2008 (Dichlorophen). A white or slightly cream-coloured powder with a not more than slightly phenolic odour. Practically insoluble in water; freely soluble in alcohol; very soluble in ether.

Profile

Dichlorophen is an anthelmintic that was used in the treatment of infection by tapeworms but has been superseded by praziquantel or niclosamide.

Dichlorophen also has antifungal and antibacterial activity and has been used topically in the treatment of fungal infections and as a germicide in soaps and cosmetics.

Preparations

BP 2008: Dichlorophen Tablets.

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***S.Afr.:*** Mycota†; ***UK:*** Mycota.

Diethylcarbamazine Citrate

(BANM, rINNM)

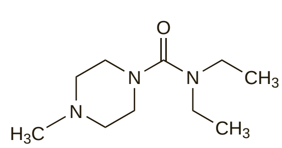
Citrato de dietilcarbamazina; Diethylcarbam. Cit.; Diethylcarbamazine Acid Citrate; Diéthylcarbamazine, citrate de; Diethylcarbamazini citras; Diethylkarbamazin-citrát; Dietilkarbamazin-citrát; Dietilkarbamazino citratas; Dietylkarbamazincitrat; Dietyylikarbamatsiinisitraatti; Ditrazini Citras; RP-3799. *NN*-Diethyl-4-methylpiperazine-1-carboxamide dihydrogen citrate.

Диэтилкарбамазина Цитрат

$C_{10}H_{21}N_3O,C_6H_8O_7$ = 391.4.

CAS — 90-89-1 (diethylcarbamazine); 1642-54-2 (diethylcarbamazine citrate).

ATC — P02CB02.



(diethylcarbamazine)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Diethylcarbamazine Citrate). A white or almost white, crystalline, slightly hygroscopic powder. Very soluble in water; soluble in alcohol; practically insoluble in acetone. Store in airtight containers.

USP 31 (Diethylcarbamazine Citrate). A white, crystalline, slightly hygroscopic powder, odourless or has a slight odour. Very soluble in water; sparingly soluble in alcohol; practically insoluble in acetone, in chloroform, and in ether. Store in airtight containers.

Adverse Effects

Adverse effects directly attributable to diethylcarbamazine include nausea and vomiting. Headache, dizziness, and drowsiness may occur.

Hypersensitivity reactions arise from the death of the microfilariae. These can be serious, especially in onchocerciasis where there may also be sight-threatening ocular toxicity; fatalities have been reported. Encephalitis may be exacerbated in patients with loiasis and fatalities have occurred.

◊ Reactions occurring during diethylcarbamazine treatment of **lymphatic filariasis** are basically of 2 types: pharmacological dose-dependent responses and a response of the infected host to the destruction and death of parasites.[1]

- Reactions of the first type include weakness, dizziness, lethargy, anorexia, and nausea. They begin within 1 to 2 hours of taking diethylcarbamazine, and persist for a few hours.
- Reactions of the second type are less likely to occur and are less severe in bancroftian than in brugian filariasis. They may be systemic or local, both with or without fever.

  Systemic reactions may occur a few hours after the first oral dose of diethylcarbamazine and generally do not last for more than 3 days. They include headache, aches in other parts of the body, joint pain, dizziness, anorexia, malaise, transient haematuria, allergic reactions, vomiting, and sometimes attacks of bronchial asthma in asthmatic patients. Fever and systemic reactions are positively associated with microfilaraemia. Systemic reactions are reduced if diethylcarbamazine is given in spaced doses or in repeated small doses. They eventually cease spontaneously and interruption of treatment is rarely necessary; symptomatic treatment with antipyretics or analgesics may be helpful.

  Local reactions tend to occur later in the course of treatment and last longer; they also disappear spontaneously and interruption of treatment is not necessary. Local reactions include lymphadenitis, abscess, ulceration, and transient lymphoedema; funiculitis and epididymitis may also occur in bancroftian filariasis.

It has been suggested that the release of interleukin-6 may be implicated in diethylcarbamazine's adverse effects in patients with lymphatic filariasis.[2]

In most patients with **onchocerciasis**, the microfilaricidal activity of diethylcarbamazine leads to a series of events with dermal, ocular, and systemic components, known as the *Mazzotti reaction*, within minutes to hours after its use.[3]

- Clinical manifestations can be severe, dangerous, and debilitating. Systemic reactions include increased itching, rash, headache, aching muscles, joint pain, painful swollen and tender lymph nodes, fever, tachycardia and hypotension, and vertigo. Most patients have eye discomfort in the first few hours after diethylcarbamazine treatment. Punctate keratitis can develop as can optic neuritis and visual field loss.

WHO no longer recommends the use of diethylcarbamazine in onchocerciasis as safer alternatives exist.

2. Yazdanbakhsh M, *et al.* Serum interleukin-6 levels and adverse reactions to diethylcarbamazine in lymphatic filariasis. *J Infect Dis* 1992; **166:** 453–4.
3. WHO. WHO expert committee on onchocerciasis: third report. *WHO Tech Rep Ser 752* 1987.

Precautions

Treatment with diethylcarbamazine should be closely supervised since hypersensitivity reactions are common and may be severe, especially in patients with onchocerciasis or loiasis. Patients with onchocerciasis should be monitored for eye changes. (The use of diethylcarbamazine to treat onchocerciasis is no longer recommended.) In patients with heavy *Loa loa* infection there is a small risk of encephalopathy and diethylcarbamazine should be stopped at the first sign of cerebral involvement.

Infants, pregnant women, the elderly, and the debilitated, especially those with cardiac or renal disease, are normally excluded when diethylcarbamazine is used in mass treatment schedules.

Pregnancy. Pregnant women are normally excluded when diethylcarbamazine is used in mass treatment schedules.

Animal studies[1] suggest that the uterine hypermotility induced by diethylcarbamazine is mediated via prostaglandin synthesis; this might explain the mechanism of the abortifacient action previously reported.[2]

1. Joseph CA, Dixon PAF. Possible prostaglandin-mediated effect of diethylcarbamazine on rat uterine contractility. *J Pharm Pharmacol* 1984; **36:** 281–2.

Renal impairment. For a study on the effects of renal impairment on the pharmacokinetics of diethylcarbamazine, see under Pharmacokinetics, below.

Pharmacokinetics

Diethylcarbamazine is readily absorbed from the gastrointestinal tract and also through the skin and conjunctiva. It is widely distributed in tissues and is mainly excreted in the urine unchanged and as the *N*-oxide metabolite. Urinary excretion and hence plasma half-life is dependent on urinary pH. About 5% of a dose is eliminated in the faeces.

Disposition. A pharmacokinetic study in 6 patients with onchocerciasis[1] indicated that diethylcarbamazine is absorbed quickly and almost completely from the gastrointestinal tract, and is eliminated largely as unchanged drug in urine, with relatively small amounts being excreted as the *N*-oxide metabolite. After a single radioactively labelled oral dose of diethylcarbamazine citrate 0.5 mg/kg given as an aqueous solution, peak plasma concentrations of 100 to 150 nanograms/mL were achieved in 1 to 2 hours, followed by a sharp decline, then a marked secondary rise 3 to 6 hours after dosing, followed by a steady decline. The half-life ranged from 9 to 13 hours. Urinary excretion of diethylcarbamazine and diethylcarbamazine *N*-oxide was complete within 96 hours; between 4 and 5% of the dose was recovered in the faeces. Disposition was similar in 5 healthy subjects given a single 50-mg tablet of diethylcarbamazine citrate. Peak plasma concentrations were initially 80 to 200 nanograms/mL, with a secondary rise 3 to 9 hours after dosing, the terminal half-life ranged from 5 to 13 hours, and urinary excretion of unchanged diethylcarbamazine and the *N*-oxide was complete within 48 hours.

When an alkaline urinary pH was maintained, the elimination half-life of diethylcarbamazine and the area under the plasma concentration versus time curve were significantly increased compared with when an acidic urinary pH was maintained.[2]

2. Edwards G, *et al.* The effect of variations in urinary pH on the pharmacokinetics of diethylcarbamazine. *Br J Clin Pharmacol* 1981; **12:** 807–12.

Renal impairment. Results in patients with chronic renal impairment and in healthy subjects, given a single 50-mg oral dose of diethylcarbamazine citrate, indicated that the plasma half-life of diethylcarbamazine is prolonged and its 24-hour urinary excretion considerably reduced in those with moderate and severe degrees of renal impairment.[1] Mean plasma half-lives in 7 patients with severe renal impairment (creatinine clearance less than 25 mL/minute), in 5 patients with moderate renal impairment (creatinine clearance between 25 and 60 mL/minute), and in 4 healthy subjects, were 15.1, 7.7, and 2.7 hours, respectively. The patient with the longest plasma half-life of 32 hours did not have the poorest renal function, but it was considered likely that the abnormally slow elimination of diethylcarbamazine was due to the high urinary pH (7) resulting from sodium bicarbonate therapy. A further patient with a half-life longer than expected also had a less acidic urine.

1. Adjepon-Yamoah KK, *et al.* The effect of renal disease on the pharmacokinetics of diethylcarbamazine in man. *Br J Clin Pharmacol* 1982; **13:** 829–34.

Uses and Administration

Diethylcarbamazine is an anthelmintic used in the treatment of lymphatic filariasis due to *Wuchereria bancrofti* (bancroftian filariasis), *Brugia malayi*, or *B. timori* (both known as brugian filariasis and as Malayan and Timorian filariasis respectively). It is also used in loiasis due to *Loa loa*. It was used in onchocerciasis due to *Onchocerca volvulus* before ivermectin became available. Diethylcarbamazine is active against both the microfilariae and adult worms of *W. bancrofti*, *B. malayi*, and *Loa loa*, but only against the microfilariae of *O. volvulus*. It has been tried in *Mansonella* infections and may be most effective against *M. streptocer-*

ca. Diethylcarbamazine is also used in the treatment of toxocariasis (visceral larva migrans). For discussions of these infections and their treatment, see under Choice of Anthelmintic, p.134, and under the individual headings below.

Diethylcarbamazine is usually given orally as the citrate.

In the treatment of **lymphatic filariasis** the recommended dose of diethylcarbamazine citrate is 6 mg/kg daily in 3 divided doses for 3 weeks, given in an initial dosage of 1 mg/kg daily and then gradually increased to 6 mg/kg daily over 3 days to reduce the incidence and severity of hypersensitivity reactions due to the destruction of microfilariae. However, adverse effects of diethylcarbamazine may be reduced, without loss of efficacy, by giving a single dose of 6 mg/kg at weekly or monthly intervals. In areas where lymphatic filariasis is endemic, mass treatment campaigns can reduce the intensity of transmission and incidence of disease. Diethylcarbamazine may also be used in the form of medicated salt to control lymphatic filariasis. For further details, see below.

In the treatment of **loiasis** diethylcarbamazine citrate 6 mg/kg daily in 3 divided doses for 2 to 4 weeks has been given. In heavy infections rapid killing of microfilariae can cause severe adverse effects including encephalitis and treatment should start with very small doses, increasing gradually over 4 days. A corticosteroid has been given concurrently. In the prophylaxis of loiasis, a dose of 300 mg weekly is recommended by WHO.

In the treatment of **toxocariasis** diethylcarbamazine citrate 9 mg/kg daily in 3 divided doses for 21 days has been given. Diethylcarbamazine is considered by some to be the treatment of choice while others do not recommend its use due to higher rates of severe adverse effects.

Administration. Diethylcarbamazine was first used as the chloride, but was subsequently produced as the dihydrogen citrate which contains only half its weight as base. In reporting doses it was therefore important to indicate whether they referred to a specific salt or to the base; unless otherwise stated, it could generally be assumed that the dose referred to the citrate.[1]

1. WHO. Lymphatic filariasis: fourth report of the WHO expert committee on filariasis. *WHO Tech Rep Ser 702* 1984. Available at: http://libdoc.who.int/trs/WHO_TRS_702.pdf (accessed 16/07/08)

Loiasis. Diethylcarbamazine is the main drug used in the management of loiasis (p.137).

Lymphatic filariasis. Diethylcarbamazine is used in the management of lymphatic filariasis (p.137). In endemic areas mass treatment of the entire population (excluding neonates, pregnant women, and debilitated individuals) can reduce the intensity of transmission and the incidence of disease. In countries where there is no co-endemic loiasis or onchocerciasis, the Global Programme to Eliminate Lymphatic Filariasis launched by WHO together with other international agencies, advocates a single dose of diethylcarbamazine citrate 6 mg/kg with a single dose of albendazole 400 mg, given once each year for at least 5 years. If diethylcarbamazine-medicated salt is to be employed then intake of salt needs to be on a daily basis for 6 to 12 months.

Preparations

BP 2008: Diethylcarbamazine Tablets;
USP 31: Diethylcarbamazine Citrate Tablets.

Proprietary Preparations (details are given in Part 3)

Fr.: Notezine; ***Gr.:*** Hetrazan†; Notezine; ***India:*** Banocide; Hetrazan; ***Thai.:*** Diethizine.

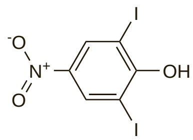
Multi-ingredient: ***India:*** Helmazan†; Unicarbazan.

Disophenol

Disofenol. 2,6-Diiodo-4-nitrophenol.

$C_6H_3I_2NO_3$ = 390.9.

CAS — 305-85-1.



Profile

Disophenol is an anthelmintic used in veterinary medicine.

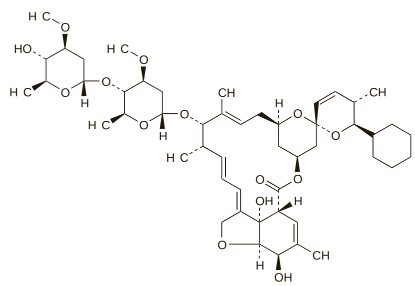
Doramectin *(BAN, USAN, rINN)*

Doramectina; Doramectine; Doramectinum; Doramektiini; Doramektin; UK-67994.

Дорамектин

CAS — 117704-25-3.

ATC Vet — QP54AA03.



Profile

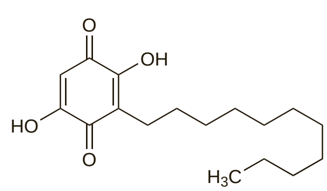
Doramectin is an avermectin anthelmintic used in veterinary medicine for nematode infections. It is also used as a systemic veterinary ectoparasiticide.

Embelia

Vidang.

Виданга

CAS — 550-24-3 (embelic acid).



(embelic acid)

Profile

Embelia consists of the dried fruits of *Embelia ribes* and *E. robusta* (= *E. tsjeriamcottam*) (Myrsinaceae), containing about 2.5% of embelic acid (embelin). It has been used in India and other Asian countries for the expulsion of tapeworms.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***India:*** Happy'tizer.

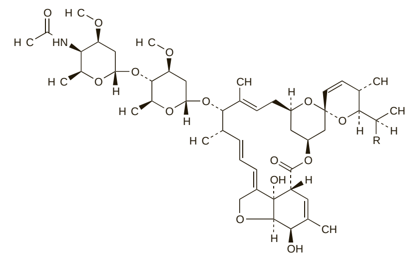
Eprinomectin *(USAN, rINN)*

Eprinomectina; Éprinomectine; Eprinomectinum; Eprinomektiini; Eprinomektin; MK-397. A mixture of eprinomectin component B_{1a} and eprinomectin component B_{1b}.

Эприномектин

CAS — 159628-36-1 (eprinomectin); 123997-26-2 (eprinomectin); 133305-88-1 (component B_{1a}); 133305-89-2 (component B_{1b}).

ATC Vet — QP54AA04.



Pharmacopoeias. In *US.*

USP 31 (Eprinomectin). Eprinomectin is a mixture of component B_{1a} ($C_{50}H_{75}NO_{14}$ = 914.1) and component B_{1b} ($C_{49}H_{73}NO_{14}$ = 900.1). It contains not less than 90% of component B_{1a} and not less than 95% of components B_{1a} and B_{1b}, calculated on the anhydrous, solvent-free, and antioxidant-free basis. Antoxidants may be added. A white to off-white powder. Insoluble in cold water. Store in airtight containers at 2° to 8°.

Profile

Eprinomectin is an avermectin anthelmintic used in veterinary medicine for nematode infections. It is also used as a systemic veterinary ectoparasiticide.

Epsiprantel *(BAN, rINN)*

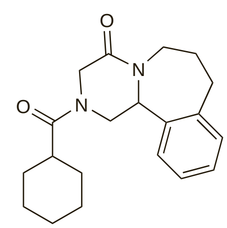
BRL-38705; Epsipranteeli; Epsiprantelum. 2-Cyclohexylcarbonyl-1,2,3,4,6,7,8,12b-octahydropyrazino[2,1-*a*][2]benzazepin-4-one.

Эпсипрантел

$C_{20}H_{26}N_2O_2$ = 326.4.

CAS — 98123-83-2.

ATC Vet — QP52AA04.



Profile

Epsiprantel is an anthelmintic closely related to praziquantel. It is used in veterinary medicine.

Febantel *(BAN, USAN, rINN)*

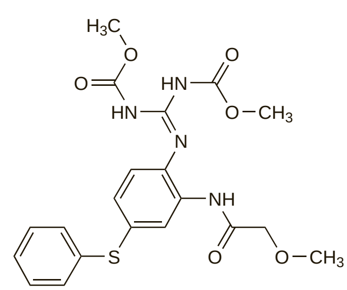
Bay-h-5757; Bay-Vh-5757; Febanteeli; Fébantel; Febantelum. 2′-[2,3-Bis(methoxycarbonyl)guanidino]-5′-phenylthio-2-methoxyacetanilide; Dimethyl {2-[2-(2-methoxyacetamido)-4-(phenylthio)phenyl]imidocarbonyl}dicarbamate.

Фебантел

$C_{20}H_{22}N_4O_6S$ = 446.5.

CAS — 58306-30-2.

ATC Vet — QP52AC05.



Pharmacopoeias. In *Eur.* (see p.vii) for veterinary use only.

Ph. Eur. 6.2 (Febantel for Veterinary Use; Febantel BP(Vet) 2008). A white or almost white, crystalline powder. It exhibits polymorphism. Practically insoluble in water; slightly soluble in dehydrated alcohol; soluble in acetone.

Profile

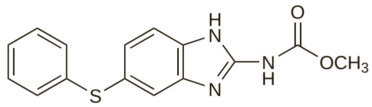
Febantel is an anthelmintic used in veterinary medicine for the treatment of nematode infections of the gastrointestinal tract and lungs and in tapeworm infections.

Fenbendazole *(BAN, USAN, rINN)*

Fenbendatsoli; Fenbendazol; Fenbendazolum; Hoe-881V. Methyl 5-phenylthio-1*H*-benzimidazol-2-ylcarbamate.

Фенбендазол

$C_{15}H_{13}N_3O_2S$ = 299.3.
CAS — 43210-67-9.
ATC — P02CA06.
ATC Vet — QP52AC13.



Pharmacopoeias. In *Eur.* (see p.vii) and *US* for veterinary use only.

Ph. Eur. 6.2 (Fenbendazole for Veterinary Use; Fenbendazole BP(Vet) 2008). A white or almost white powder. Practically insoluble in water; sparingly soluble in dimethylformamide; very slightly soluble in methyl alcohol. Protect from light.

USP 31 (Fenbendazole). A white to off-white powder. Practically insoluble in water; sparingly soluble in dimethylformamide; very slightly soluble in methyl alcohol. Store at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Profile

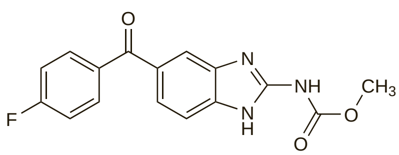
Fenbendazole is a benzimidazole carbamate anthelmintic structurally related to mebendazole (p.148). It is used in veterinary medicine.

Flubendazole *(BAN, USAN, rINN)*

Flubendatsoli; Flubendazol; Flubendazolas; Flubendazolum; Fluorомebendazole; R-17889. Methyl 5-(4-fluorobenzoyl)-1*H*-benzimidazol-2-ylcarbamate.

Флубендазол

$C_{16}H_{12}FN_3O_3$ = 313.3.
CAS — 31430-15-6.
ATC — P02CA05.
ATC Vet — QP52AC12.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Flubendazole). A white or almost white powder. It exhibits polymorphism. Practically insoluble in water, in alcohol, and in dichloromethane. Protect from light.

Profile

Flubendazole, a benzimidazole carbamate anthelmintic, is an analogue of mebendazole (p.148) and has similar actions and uses.

For the treatment of enterobiasis in adults and children, flubendazole 100 mg is given as a single oral dose, repeated after 2 to 3 weeks. For ascariasis, hookworm infections, and trichuriasis 100 mg is given twice daily for 3 days. For discussions of these infections and their treatment, see under Choice of Anthelmintic, p.134.

Preparations

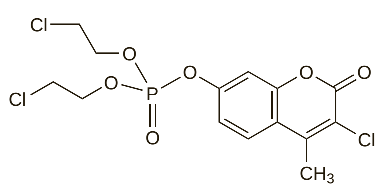
Proprietary Preparations (details are given in Part 3)
Arg.: Flumoxal; ***Fr.:*** Fluvermal; ***Port.:*** Fluvermal; Teniverme; ***Spain:*** Flicum; ***Venez.:*** Fluvermox.

Haloxon *(BAN, rINN)*

Haloxón; Haloxone; Haloxonum. Bis(2-chloroethyl) 3-chloro-4-methylcoumarin-7-yl phosphate.

Галоксон

$C_{14}H_{14}Cl_3O_6P$ = 415.6.
CAS — 321-55-1.
ATC Vet — QP52AB04.



Profile

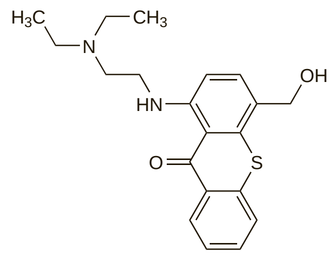
Haloxon is an organophosphorus compound (see Organophosphorus Insecticides, p.2047) used as an anthelmintic in veterinary medicine.

Hycanthone *(USAN, rINN)*

Hicantona; Hycanthonum; NSC-134434; Win-24933. 1-(2-Diethylaminoethylamino)-4-hydroxymethylthioxanthen-9-one.

Гикантон

$C_{20}H_{24}N_2O_2S$ = 356.5.
CAS — 3105-97-3.



Hycanthone Mesilate *(rINNM)*

Hycanthone, Mésilate d'; Hycanthone Mesylate; Hycanthoni Mesilas; Hydroxylucanthone Methanesulphonate; Mesilato de hicantona.

Гикантона Мезилат

$C_{20}H_{24}N_2O_2S,CH_3SO_3H$ = 452.6.
CAS — 23255-93-8.

Profile

Hycanthone has been used as a schistosomicide in the individual or mass treatment of infection with *Schistosoma haematobium* and *S. mansoni*.

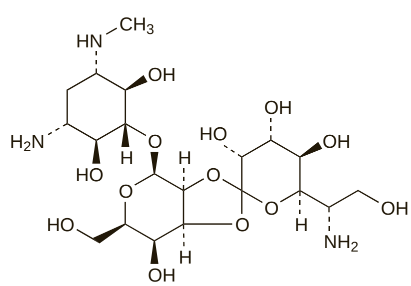
Owing to its toxicity and concern about possible carcinogenicity, mutagenicity, and teratogenicity, hycanthone has been replaced by other drugs such as praziquantel.

Hygromycin B

Higromicina B. *O*-6-Amino-6-deoxy-L-glycero-D-galacto-heptopyranosylidene-(1→2-3)-*O*-β-D-talopyranosyl-(1→5)-2-deoxy-N^3-methyl-D-streptamine.

Гигромицин Б

$C_{20}H_{37}N_3O_{13}$ = 527.5.



Profile

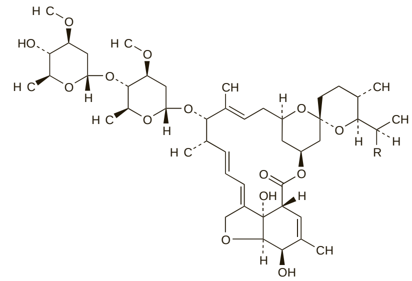
Hygromycin B is an anthelmintic used in veterinary medicine for nematode infections.

Ivermectin *(BAN, USAN, rINN)*

Ivermectina; Ivermectine; Ivermectinum; Ivermektiini; Ivermektin; Ivermektinas.

Ивермектин

CAS — 70288-86-7 (ivermectin); 70161-11-4 (component B_{1a}); 70209-81-3 (component B_{1b}).
ATC — P02CF01.
ATC Vet — QP54AA01; QS02QA03.



Pharmacopoeias. In *Eur.* (see p.vii) and *US*.

Ph. Eur. 6.2 (Ivermectin). A mixture of ivermectin component H_2B_{1a} (5-*O*-demethyl-22,23-dihydroavermectin A_{1a}; $C_{48}H_{74}O_{14}$ = 875.1) and ivermectin component H_2B_{1b} (5-*O*-demethyl-25-de(1-methylpropyl)-25-(1-methylethyl)-22,23-dihydroavermectin A_{1a}; $C_{47}H_{72}O_{14}$ = 861.1).

A white or yellowish-white, slightly hygroscopic, crystalline powder. Practically insoluble in water; soluble in alcohol; freely soluble in dichloromethane. Store in airtight containers.

USP 31 (Ivermectin). A mixture of component H_2B_{1a} (5-*O*-demethyl-22,23-dihydro-avermectin A_{1a}; $C_{48}H_{74}O_{14}$ = 875.1) and component H_2B_{1b} (5-*O*-demethyl-25-de(1-methylpropyl)-22,23-dihydro-25-(1-methylethyl)-avermectin A_{1a}; $C_{47}H_{72}O_{14}$ = 861.1). It may contain small amounts of suitable antoxidant and chelating agents.

A white to yellowish-white, slightly hygroscopic, crystalline powder. Practically insoluble in water and in petroleum spirit; soluble in acetone and in acetonitrile; freely soluble in dichloromethane and in methyl alcohol. Store in airtight containers at a temperature of 2° to 8°. Where the use of an antoxidant is allowed, store at 25°, excursions permitted between 15° and 30°.

Adverse Effects and Precautions

The adverse effects reported with ivermectin in patients with filariasis are generally consistent with a mild Mazzotti reaction arising from its effect on microfilariae. They include fever, pruritus, skin rashes, arthralgia, myalgia, asthenia, orthostatic hypotension, tachycardia, oedema, lymphadenopathy, gastrointestinal symptoms, sore throat, cough, and headache. The effects tend to be transient and if treatment is required they respond to analgesics and antihistamines.

Ivermectin may cause mild ocular irritation. Somnolence, transient eosinophilia, and raised liver enzyme values have also been reported.

Ivermectin is not recommended during pregnancy. Mass treatment is generally withheld from pregnant women (see Pregnancy, below), children under 15 kg, and the seriously ill.

Incidence of adverse effects. Some studies have shown quite a high incidence of adverse effects with ivermectin and have associated the effects with the severity of infection.[1-3] However, in none of these studies were the reactions considered to be life-threatening and only symptomatic treatment was required. The severity, incidence, and duration of adverse reactions was reported to be reduced after repeated annual administration.[4] When larger groups of patients were considered in the Onchocerciasis Control Programme (OCP) in West Africa, a much lower incidence of adverse reactions was seen in patients given ivermectin for the first time[5] and when treatment was repeated a year later that incidence was reduced even further. The results from several studies in this programme[6] showed 93 severe reactions in 50 929 patients (1.83%), most of the reactions being orthostatic hypotension or dizziness (53). In a 3-year randomised, double-blind, controlled study of ivermectin for onchocerciasis control in 572 patients,[7] 3-monthly treatment with the standard dose of 150 micrograms/kg was associated with a reduced risk of adverse reactions, especially oedema, pruritus, and back pain, when compared with the same dose given annually. Higher doses of 400 then 800 micrograms/kg, given either 3-monthly or annually, were associated with subjective ocular problems. Another study[8] found 22 severe reactions in 17 877 patients treated for onchocerciasis in an area also endemic for *Loa loa* infection, and demonstrated a relationship to heavy *L. loa* microfilaraemia. The Mectizan® Expert Committee and the Technical Consultative Committee have reported the incidence of encephalopathy after ivermectin treatment of onchocerciasis in *Loa loa* endemic areas to be less than 1 case in 10 000 treatments[9] and have implemented recommendations for ivermectin mass treatment programmes of onchocerciasis in areas co-endemic for loiasis to reduce the risk of serious adverse events, especially in areas where the population is ivermectin naive.

Some supervision is considered necessary after doses of ivermectin;[2,6] the OCP recommendation[6] is for resident nurses to monitor patients for a period of 36 hours after treatment, whatever the level of endemicity. However, the incidence of adverse reactions reported after repeated doses appears to be lower than after the first dose and the need for supervision on re-treatment has been questioned.[10]

Neurotoxicity seen in some breeds of *dogs* has not been seen in *cattle* or *horses*[11] and nor was it reported in man in the above studies. Another potential concern was the prolongation of prothrombin times observed in 28 patients given ivermectin,[12] but others have not confirmed this effect[13] or observed any bleeding disorders.[14]

There has been some concern over the use of ivermectin to treat scabies in elderly patients after a report suggesting a possible link to an increased incidence of death among a cohort of 47 patients.[15] It has, however, been argued that no such association has been seen in other populations of elderly patients and that the statistical methods used by the original authors were deficient.[16-18] There was no evidence of an increase in death rate associated with ivermectin in a community-based trial in Papua New Guinea of diethylcarbamazine with or without ivermectin for lymphatic filariasis.[19]

Breast feeding. Mean ivermectin concentrations in the breast milk of 4 healthy women who had been given a standard dose of ivermectin were 14.13 nanograms/mL.[1] It was felt that in view of this low concentration the precaution of excluding lactating mothers from ivermectin mass treatment programmes should be reconsidered. Some authorities have recommended that ivermectin should not be given to mothers who are breast feeding until the infant is at least one week old. The American Academy of Pediatrics states that, since no adverse effects have been seen in breast-fed infants whose mothers were receiving ivermectin, it may be considered to be usually compatible with breast feeding.[2]

Encephalopathy. For information on encephalopathy following Ivermectin treatment of onchocerciasis in *Loa loa* endemic areas, see Incidence of Adverse Effects, above.

Pregnancy. Ivermectin is teratogenic in *animals* and there are no adequate and well controlled studies in human pregnancy. Ivermectin treatment is therefore usually contra-indicated during pregnancy and pregnant women should be excluded from mass treatment schedules with ivermectin. However, women not yet diagnosed as pregnant or unwilling to admit their pregnancy have been treated. An assessment[1] of 203 pregnancy outcomes to women who had taken ivermectin during pregnancy, mostly during the first 12 weeks, found that the rates of major congenital malformation, miscarriage, and still-birth associated with ivermectin were similar to those in untreated mothers. In another study, 110 women also inadvertently given ivermectin during pregnancy experienced a similar lack of adverse effect on pregnancy outcome;[2] it was considered that the precaution of avoiding the use of ivermectin in women notifying a pregnancy should be adequate.

Pharmacokinetics

Ivermectin is absorbed after oral doses, with peak plasma concentrations being obtained after about 4 hours. Ivermectin is reported to be about 93% bound to plasma proteins and has a plasma elimination half-life of about 12 hours. It undergoes metabolism and is excreted largely as metabolites over a period of about 2 weeks, chiefly in the faeces, with less than 1% appearing in the urine and less than 2% in breast milk (see also Breast Feeding, above).

Uses and Administration

Ivermectin is a semisynthetic derivative of one of the avermectins, a group of macrocyclic lactones produced by *Streptomyces avermitilis*.

It has a microfilaricidal action in onchocerciasis and reduces the microfilarial load without the toxicity seen with diethylcarbamazine. Ivermectin also has a microfilaricidal action in lymphatic filariasis and is used in its management. Ivermectin is active in some other worm infections. It is used in the treatment of strongyloidiasis and has been tried in some *Mansonella* infections. For details of these infections and their treatment, see under Choice of Anthelmintic, p.134, and under the individual headings below.

In the treatment of onchocerciasis, a single oral dose of 3 to 12 mg of ivermectin, based roughly on 150 micrograms/kg for patients weighing more than 15 kg and over 5 years of age, is given annually or every 6 months. This schedule has been adopted for mass treatment in infected areas. No food should be taken for 2 hours before or after the dose.

Ivermectin 200 micrograms/kg as a single dose, or daily on two consecutive days, is used for the treatment of strongyloidiasis.

Cutaneous larva migrans. There are some reports[1,2] of ivermectin being effective in the treatment of cutaneous larva migrans (p.135). An oral dose of 200 micrograms/kg daily for 1 to 2 days has been recommended.[3]

Intestinal nematode infections. Ivermectin activity has been seen in man against *Ascaris lumbricoides*, *Strongyloides stercoralis*, and *Trichuris trichiura*;[1] although some have failed to detect activity against *Trichuris*,[2] ivermectin given with albendazole has been studied for the treatment of trichuriasis (p.139) and may prove useful. Roundworm expulsion has been reported as a 'side-effect' of ivermectin when used in community-based treatment of onchocerciasis.[3] In a controlled study,[4] single doses of ivermectin 150 or 200 micrograms/kg produced cure rates of 94% in strongyloidiasis (see below) and above 67% in ascariasis, trichuriasis, and enterobiasis. Although some activity has been observed against *Necator americanus*,[1] cure rates for hookworm were considered unsatisfactory.[4]

Loiasis. There is evidence of reduced microfilaraemia after ivermectin treatment[1-5] in patients with loiasis (p.137), but concern exists over its potential for neurotoxicity in patients with a high microfilarial burden.[6,7] Low-dose regimens (about 25 micrograms/kg) have been investigated[8] but did not seem to offer much advantage in reducing neurotoxicity.

Lymphatic filariasis. Ivermectin is used in the management of lymphatic filariasis (p.137). In endemic areas mass treatment of the entire population (excluding neonates, pregnant women, and debilitated individuals) can reduce the intensity of transmission and the incidence of disease. In countries where there is co-endemic loiasis or onchocerciasis, the Global Programme to Eliminate Lymphatic Filariasis launched by WHO, with other international agencies, advocates a single oral dose of ivermectin 150 to 200 micrograms/kg with a single oral dose of albendazole 400 mg given once each year for at least 5 years.

Mansonella infections. The response of *Mansonella* infections (p.137) to ivermectin depends on the species. It may be effective against *Mansonella ozzardi*, but studies in *M. perstans* infection have not shown ivermectin to produce a substantial reduction in microfilaraemia.[1,2] A good response to ivermectin has been reported in infections with *M. streptocerca*.[3,4]

Onchocerciasis. Ivermectin has a microfilaricidal action against *Onchocerca volvulus* and is the main drug used in the control of onchocerciasis (p.137). A single oral dose rapidly eliminates microfilariae from the skin, with maximum effect after 1 to 2 months,[1] and gradually eliminates them from the cornea and anterior chamber of the eye.[2] Ivermectin has little effect on the adult worms but does suppress the release of microfilariae from the adult worm for several cycles which accounts for its prolonged activity. Ivermectin therefore only controls the disease; it does not cure or eradicate it. Its action against *O. volvulus* has been attributed to a GABA-agonist effect. Studies have also indicated that ivermectin inhibits the transmission of microfilariae by reducing their uptake from man by the insect vector.[3-6]

Ivermectin is donated by *Merck* through the Mectizan Expert Committee (MEC) for human use in community-wide mass treatment programmes in all countries in which onchocerciasis is endemic, where it is given at a standard dose of 150 micrograms/kg once or twice a year to all but pregnant women, breast-feeding mothers of recently born babies, children weighing less than 15 kg, and those unable to walk or otherwise seriously ill.[7] The adult worms live for about 15 years, therefore treatment will need to be continued for many years. Several studies have confirmed the long-term safety and efficacy of such programmes.[8-12] Studies have reported that increasing the frequency of the standard doses of ivermectin to every 3 or 6 months appears to increase efficacy compared with annual treatments[13,14] and that 3-monthly regimens may also reduce risk of adverse effects.[14,15] No additional benefit was noted by increasing the dose of ivermectin to 400 or 800 micrograms/kg given either 3-monthly or annually.

In non-endemic areas, repeated doses may be necessary to reduce recurrence; a study in the UK found that patients given three doses at monthly intervals had fewer relapses at 6 months than patients who received a single dose, but relapses were nevertheless seen in 50% of patients at 12 months.[16]

The ocular microfilarial load can be safely reduced by ivermectin[2,17] and early lesions of the anterior segment of the eye have improved.[17] A reduction in the incidence[18] and progression[19] of optic nerve damage has also been reported, but the effect on posterior segment disease is less certain.[20] A systematic review of 5 placebo-controlled studies, with data from 3810 individuals, found no statistically significant difference between ivermectin and placebo groups for preventing visual acuity loss.[21] Improvements in skin lesions have been reported.[22]

Scabies and pediculosis. Scabies (p.2035) is usually treated with a topically applied acaricide. However, a single oral dose of ivermectin has been reported to be effective.[1,2] In a study of 11 patients with uncomplicated scabies, a single oral dose of ivermectin 200 micrograms/kg was effective in curing infection after 4 weeks. In a group of 11 patients, also infected with HIV, scabies was cured in 8 after 2 weeks.[1] Two of the remaining 3 patients received a second dose of ivermectin which cured the scabies infection by the fourth week. A single oral dose of ivermectin 150 micrograms/kg was partially effective in an outbreak of scabies in 1153 Tanzanian patients.[3] Crusted (Norwegian) scabies has also been reported to be effectively treated by a single oral dose of 12 mg of ivermectin in addition to topical application of 3% salicylic acid ointment in 2 patients; the treatment was effective in under one week.[2] A single oral dose of ivermectin 200 micrograms/kg was effective for crusted scabies in a 2-year-old infant who had contracted the disease following long-term corticosteroid use.[4]

Ivermectin has also been investigated[5] as a possible treatment for pediculosis (p.2034) although, again, topically applied insecticides are the usual method of control. A study *in vitro* and in *animals* showed that ivermectin killed nymphs and females of the human body louse (*Pediculus humanus humanus*). Ivermectin was known to be effective against other louse species that infect a range of *animals*.[6]

Preparations

USP 31: Ivermectin Tablets.

Proprietary Preparations (details are given in Part 3)

Arg.: Dermopero; Securo; ***Austral.:*** Stromectol; ***Braz.:*** Ivermec†; Leverctin; Revectina; Vermectil; ***Fr.:*** Mectizan; Stromectol; ***Jpn:*** Stromectol; ***Mex.:*** Ivexterm; ***Neth.:*** Stromectol; ***NZ:*** Stromectol; ***USA:*** Mectizan; Stromectol.

Levamisole *(BAN, rINN)*

Levamisol; Lévamisole; Levamisoli; Levamisolum; Levamizol. (*S*)-2,3,5,6-Tetrahydro-6-phenylimidazo[2,1-*b*][1,3]thiazole.

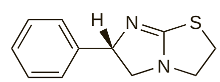
Левамизол

$C_{11}H_{12}N_2S$ = 204.3.

CAS — 14769-73-4.

ATC — P02CE01.

ATC Vet — QP52AE01.



Pharmacopoeias. In *Eur.* (see p.vii) for veterinary use only.

Ph. Eur. 6.2 (Levamisole for Veterinary Use; Levamisole BP(Vet) 2008). A white or almost white powder. It exhibits polymorphism. Slightly soluble in water; freely soluble in alcohol and in methyl alcohol. Store in airtight containers. Protect from light.

Levamisole Hydrochloride *(BANM, USAN, rINNM)*

Cloridrato de Levamizol; Hidrocloruro de levamisol; ICI-59623; Lévamisole, chlorhydrate de; Levamisol-hydrochlorid; Levamisolhydroklorid; Levamisoli hydrochloridum; Levamisolihydrokloridi; Levamizol-hidroklorid; Levamizolio hidrochloridas; Lewamizolu chlorowodorek; NSC-177023; R-12564; RP-20605; *l*-Tetramisole Hydrochloride; *l*-Tetramisole Hydrochloride.

Левамизола Гидрохлорид

$C_{11}H_{12}N_2S,HCl$ = 240.8.

CAS — 16595-80-5.

ATC — P02CE01.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., US,* and *Viet.*

Ph. Eur. 6.2 (Levamisole Hydrochloride). A white to almost white crystalline powder. Freely soluble in water; soluble in alcohol; slightly soluble in dichloromethane. A 5% solution in water has a pH of 3.0 to 4.5. Protect from light.

USP 31 (Levamisole Hydrochloride). A white or almost white crystalline powder. Freely soluble in water; soluble in alcohol; slightly soluble in dichloromethane; practically insoluble in ether. pH of a 5% solution in water is between 3.0 and 4.5. Protect from light.

Adverse Effects

When given in single doses for the treatment of ascariasis or other worm infections, levamisole is generally well tolerated and adverse effects are usually limited to nausea, vomiting, diarrhoea, abdominal pain, dizziness, and headache.

When levamisole is used as an immunostimulant and given for longer periods, adverse effects are more frequent and diverse and, in common with other immunomodulators, may sometimes result from exacerbation of the primary underlying disease. Adverse effects associated especially with the more prolonged use of levamisole have included: hypersensitivity reactions such as fever, a flu-like syndrome, arthralgia, muscle pain, skin rashes, and cutaneous vasculitis; CNS effects including headache, insomnia, dizziness, and convulsions; haematological abnormalities such as agranulocytosis, leucopenia, and thrombocytopenia; and gastrointestinal disturbances, including an abnormal taste in the mouth.

Incidence of adverse effects. In a review[1] (by the manufacturers) of 46 controlled studies in which 2635 cancer patients received adjuvant levamisole treatment, most patients received levamisole on 3 consecutive days every 2 weeks (1102 patients) or on 2 consecutive days every week (1156 patients), usually in a daily dose of 150 mg. Levamisole caused several adverse effects, such as skin rash, nausea, vomiting, and a metallic or bitter taste in the mouth, which although troublesome were relatively trivial and often regressed during therapy or disappeared on cessation of therapy. A total of 38 patients developed agranulocytosis and of these 36 had received weekly treatment. Several contracted possible life-threatening infections and 2 died of septic shock.

1. Amery WK, Butterworth BS. Review/commentary: the dosage regimen of levamisole in cancer: is it related to efficacy and safety? *Int J Immunopharmacol* 1983; **5:** 1–9.

Effects on the endocrine system. Rechallenge confirmed that levamisole was responsible for inappropriate antidiuretic hormone syndrome in a patient receiving levamisole with fluorouracil.[1]

1. Tweedy CR, *et al.* Levamisole-induced syndrome of inappropriate antidiuretic hormone. *N Engl J Med* 1992; **326:** 1164.

Effects on the liver. Elevated aspartate aminotransferase concentrations in 2 of 11 patients given levamisole for recurrent pyoderma suggested liver toxicity, a very rarely occurring adverse effect.[1] In a later report, liver enzyme concentrations were raised in a 14-year-old boy treated with levamisole for minimal change nephrotic syndrome.[2]

2. Bulugahapitiya DTD. Liver toxicity in a nephrotic patient treated with levamisole. *Arch Dis Child* 1997; **76:** 289.

Effects on the nervous system. Reports[1,2] of inflammatory leukoencephalopathy were associated with the use of fluorouracil and levamisole in 4 patients being treated for adenocarcinoma of the colon. Active demyelination was demonstrated in 2 patients.[1] Clinical improvement occurred when chemotherapy was stopped; 3 patients were treated with corticosteroids.[1] A similar syndrome has been reported in a patient with a history of hepatitis C given levamisole alone.[3]

2. Kimmel DW, Schutt AJ. Multifocal leukoencephalopathy: occurrence during 5-fluorouracil and levamisole therapy and resolution after discontinuation of chemotherapy. *Mayo Clin Proc* 1993; **68:** 363–5.
3. Lucia P, *et al.* Multifocal leucoencephalopathy induced by levamisole. *Lancet* 1996; **348:** 1450.

Precautions

The use of levamisole should be avoided in patients with pre-existing blood disorders. Patients given levamisole with fluorouracil should undergo appropriate monitoring of haematological and hepatic function.

Rheumatoid arthritis. The presence of HLA B27 in seropositive rheumatoid arthritis is an important predisposing factor to the development of agranulocytosis with levamisole; it is recommended that the use of levamisole in this group should be avoided.[1]

1. Mielants H, Veys EM. A study of the hematological side effects of levamisole in rheumatoid arthritis with recommendations. *J Rheumatol* 1978; **5** (suppl 4): 77–83.

Sjögren's syndrome. The appearance of adverse effects in 9 of 10 patients with rheumatoid arthritis and Sjögren's syndrome while being treated with levamisole led to abandonment of the study.[1] Levamisole should be given with caution, if at all, to patients with Sjögren's syndrome.

1. Balint G, *et al.* Sjögren's syndrome: a contraindication to levamisole treatment? *BMJ* 1977; **2:** 1386–7.

Interactions

Alcohol. US licensed product information states that levamisole can produce a disulfiram-like reaction with *alcohol.*

Anticoagulants. For an increase in the activity of *warfarin* when given with levamisole and fluorouracil, see Interactions, Levamisole, under Warfarin, p.1431.

Antiepileptics. For increased *phenytoin* concentrations when given with levamisole and fluorouracil, see Interactions, Antineoplastics, under Phenytoin, p.499.

Pharmacokinetics

Levamisole is rapidly absorbed from the gastrointestinal tract. Maximum plasma concentrations are attained within 1.5 to 2 hours. It is extensively metabolised in the liver. The plasma half-life for levamisole is 3 to 4 hours and for the metabolites is 16 hours. It is excreted mainly in the urine as metabolites and a small proportion in the faeces. About 70% of a dose is excreted in the urine over 3 days, with about 5% as unchanged levamisole.

Uses and Administration

Levamisole hydrochloride is the active laevo-isomer of tetramisole hydrochloride. It is used as an anthelmintic and as an adjuvant in malignant disease. It has also been tried in several conditions where its stimulant effect on the depressed immune response might be useful.

Levamisole is active against intestinal nematode worms and appears to act by paralysing susceptible worms which are subsequently eliminated from the intestines. In particular, levamisole is effective in the treatment of ascariasis (p.134). It is also used in hookworm infections (p.136).

Doses of levamisole hydrochloride are expressed in terms of the equivalent amount of levamisole. Levamisole hydrochloride 1.18 g is equivalent to about 1 g of levamisole. The usual adult dose in ascariasis is 150 mg of levamisole orally as a single dose; children have been given 3 mg/kg as a single dose. For the hookworm infection ancylostomiasis or for mixed ascariasis-hookworm infections, both adults and children may be given 2.5 mg/kg as a single dose, repeated after 7 days in cases of severe hookworm infection.

Levamisole influences host defences by modulating cell-mediated immune responses; it restores depressed T-cell functions and has been described as an immunostimulant, although stimulation above normal levels does not seem to occur. It has been tried in many disorders, including bacterial and viral infections and rheumatic disorders, although in these conditions results have not been encouraging.

Levamisole has also been used as an adjunct in patients with malignant disease, although it is not clear that any response is due to its action on the immune system. Adjuvant treatment with levamisole and fluorouracil has been given to reduce recurrence after resection of adenocarcinoma of the colon with regional lymph node involvement (but see Malignant Neoplasms, below).

Malignant neoplasms. Levamisole has been tried in the adjuvant treatment of various malignant neoplasms[1,2] with conflicting results. Based on the results of early adjuvant trials,[3-5] levamisole was used as standard therapy to modulate fluorouracil in patients with colorectal cancer (p.665), particularly in the USA. However, whether levamisole actually added to the beneficial effect of adjuvant fluorouracil was unclear. Adjuvant levamisole alone was no more effective than placebo in 1 study,[6] and more recent trials have indicated that levamisole is no more effective than placebo when added to fluorouracil,[7] or to fluorouracil plus folinic acid.[8]

Mouth ulceration. Levamisole might be beneficial in severe mouth ulceration (p.1700) but is limited by its adverse effects. A review[1] of its use in recurrent aphthous stomatitis indicated that beneficial results have been reported with levamisole in open studies, but results of double-blind studies have been conflicting. Nevertheless, there have been patients with severe recurrent aphthous stomatitis refractory to all other modes of treatment who have responded to levamisole. Dosage has been with 150 mg daily in divided doses given for 3 days at the first sign of ulceration, followed by 11 days without treatment, repeated as necessary.

1. Miller MF. Use of levamisole in recurrent aphthous stomatitis. *Drugs* 1980; **20:** 131–6.

Renal disorders. In a randomised double-blind study, children with frequently relapsing corticosteroid-sensitive and corticosteroid-dependent nephrotic syndrome were given placebo or levamisole 2.5 mg/kg on alternate days and steroid therapy was gradually withdrawn.[1] Of 31 children being treated with levamisole, 14 were still in remission 112 days after the start of the study compared with 4 of 30 receiving placebo. There have been subsequent reports of adjunctive use in children with nephrotic syndrome,[2-6] but its place in therapy remains to be established. For a discussion of the treatment of glomerular kidney disorders, including the nephrotic syndrome, see p.1504.

6. Boyer O, *et al.* Short- and long-term efficacy of levamisole as adjunctive therapy in childhood nephrotic syndrome. *Pediatr Nephrol* 2008; **23:** 575–80.

Vitiligo. In a study[1] involving 36 patients with limited slow-spreading vitiligo, response to levamisole treatment occurred in 34 within 2 to 4 months. Patients received 150 mg of oral levamisole daily on 2 consecutive days each week. Patients who were additionally treated with topical fluocinolone or clobetasol had higher rates of repigmentation. A later controlled study[2] involving 43 patients reported less benefit.

The usual treatment of vitiligo is discussed under Pigmentation Disorders, p.1582.

Male Fern

Aspidium; Farnwurzel; Felce Maschio; Feto Macho; Filix Mas; Fougère Mâle; Helecho macho; Rhizoma Filicis Maris.

Щитовник Мужской

Pharmacopoeias. In *Chin.*

Profile

Male fern consists of the rhizome, frond-bases, and apical bud of *Dryopteris filix-mas* agg. (Polypodiaceae), collected late in the autumn, divested of the roots and dead portions and carefully dried, retaining the internal green colour. It contains not less than 1.5% of filicin. During storage the green colour of the interior gradually disappears, often after a lapse of 6 months, and such material is unfit for medicinal use.

Filicin is the mixture of ether-soluble substances obtained from male fern. Its activity is chiefly due to flavaspidic acid, a phloroglucinol derivative.

Male fern has anthelmintic properties and was formerly used as male fern extract (aspidium oleoresin) for the expulsion of tapeworms. However, male fern is highly toxic and has been superseded by other drugs.

Adverse effects include headache, nausea and vomiting, severe abdominal cramp, diarrhoea, dyspnoea, albuminuria, hyperbilirubinaemia, dizziness, tremors, convulsions, visual disturbances including blindness (possibly permanent), stimulation of uterine muscle, coma, respiratory failure, bradycardia, and cardiac failure. Fatalities have occurred.

Mebendazole *(BAN, USAN, rINN)*

Mebendatsoli; Mebendazol; Mebendazolas; Mébendazole; Mebendazolum; R-17635. Methyl 5-benzoyl-1*H*-benzimidazol-2-ylcarbamate.

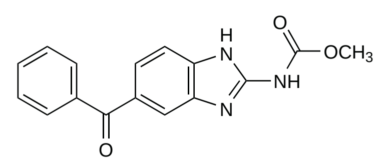
Мебендазол

$C_{16}H_{13}N_3O_3$ = 295.3.

CAS — 31431-39-7.

ATC — P02CA01.

ATC Vet — QP52AC09.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., US,* and *Viet.*

Ph. Eur. 6.2 (Mebendazole). A white or almost white powder. It shows polymorphism. Practically insoluble in water, in alcohol, and in dichloromethane. Protect from light.

USP 31 (Mebendazole). A white to slightly yellow, almost odourless, powder. Practically insoluble in water, in alcohol, in chloroform, in ether, and in dilute mineral acids; freely soluble in formic acid.

Adverse Effects

Since mebendazole is poorly absorbed from the gastrointestinal tract at the usual therapeutic doses, adverse effects have generally been restricted to gastrointestinal disturbances, such as transient abdominal pain and diarrhoea, and have tended to occur in patients being treated for heavy intestinal infection. Headache and dizziness have been reported. Adverse effects have been reported more frequently with the high doses tried in echinococcosis and have included allergic reactions, raised liver enzyme values, alopecia, and bone marrow depression.

Incidence of adverse effects. In the first phase[1] of WHO-coordinated multicentre studies on the treatment of echinococcosis (hydatid disease) involving *Echinococcus granulosus* or *E. multilocularis*, the most frequent adverse effects in the 139 patients given *high-dose* mebendazole, generally for 3 months, were reduced leucocyte count (25 patients), gastrointestinal symptoms (22), and raised serum-transaminase values (22). Other adverse effects were allergic conditions such as fever and skin reactions (4), CNS symptoms including headache (6), and loss of hair (7). Seven patients stopped treatment because of adverse effects.

The second phase of studies[2] compared albendazole with mebendazole in more prolonged high-dosage schedules for cystic *E. granulosus* infection. Adverse effects were similar to those reported with the first phase. However, in the first phase the allergic consequences of the 14 ruptured lung cysts and the 4 ruptured liver cysts that occurred with mebendazole were not reported. In the second phase, 2 patients suffered anaphylactic shock as a result of rupture of a lung cyst and a cyst in the abdominal cavity. These 2 patients were withdrawn from mebendazole treatment, as were another 4 patients as a consequence of their adverse reactions, although in 3 the withdrawal was only temporary.

Although albendazole is preferred to mebendazole in the treatment of echinococcosis, if either drug is used there should be constant medical supervision with regular monitoring of serum-transaminase concentrations and of leucocyte and platelet counts. Patients with liver damage should be treated with reduced doses of benzimidazole carbamates, if at all.[2]

1. Davis A, *et al.* Multicentre clinical trials of benzimidazolecarbamates in human echinococcosis. *Bull WHO* 1986; **64:** 383–8.
2. Davis A, *et al.* Multicentre clinical trials of benzimidazolecarbamates in human cystic echinococcosis (phase 2). *Bull WHO* 1989; **67:** 503–8.

Overdosage. Respiratory arrest and tachyarrhythmia associated with continuous convulsions were reported[1] in an 8-week-old infant after accidental poisoning with mebendazole. Treatment by exchange transfusion and anticonvulsants was successful.

1. el Kalla S, Menon NS. Mebendazole poisoning in infancy. *Ann Trop Paediatr* 1990; **10:** 313–14.

Precautions

Patients given high doses of mebendazole, such as those with echinococcosis, should be supervised closely with blood counts and liver function being monitored; such high-dose therapy may be inappropriate in those with hepatic impairment (see under Incidence of Adverse Effects, above).

Monitoring drug concentrations. In a retrospective analysis of patients given high doses of mebendazole for echinococcosis,[1] no relationship was found between dose and plasma concentration of mebendazole and considerable intra- and interindividual variation in plasma concentrations was observed, emphasising the need for repeated monitoring. Several patients appeared to have what were considered to be subtherapeutic plasma concentrations.

1. Luder PJ, *et al.* Treatment of hydatid disease with high oral doses of mebendazole: long-term follow-up of plasma mebendazole levels and drug interactions. *Eur J Clin Pharmacol* 1986; **31:** 443–8.

Pregnancy. Mebendazole is teratogenic in *rats* and there are no adequate and well controlled studies in human pregnancy. Mebendazole is therefore usually contra-indicated during pregnancy. However, it was noted that in a survey of a limited number of pregnant women who had inadvertently taken mebendazole during the first trimester, the incidence of malformation and spontaneous abortion was no greater than that observed in the general population.

Interactions

Antiepileptics. *Phenytoin* or *carbamazepine* have been reported to lower plasma-mebendazole concentrations in patients receiving high doses for echinococcosis, presumably as a result of enzyme induction; *valproate* had no such effect.[1]

1. Luder PJ, *et al.* Treatment of hydatid disease with high oral doses of mebendazole: long-term follow-up of plasma mebendazole levels and drug interactions. *Eur J Clin Pharmacol* 1986; **31:** 443–8.

Histamine H_2-antagonists. Plasma concentrations of mebendazole have been raised when the enzyme inhibitor *cimetidine* was also given, and this has resulted in the resolution of previously unresponsive hepatic hydatid cysts.[1]

1. Bekhti A, Pirotte J. Cimetidine increases serum mebendazole concentrations: implications for treatment of hepatic hydatid cysts. *Br J Clin Pharmacol* 1987; **24:** 390–2.

Pharmacokinetics

Mebendazole is poorly absorbed from the gastrointestinal tract and undergoes extensive first-pass elimination, being metabolised in the liver, eliminated in the bile as unchanged drug and metabolites, and excreted in the faeces. Only about 2% of a dose is excreted unchanged or as metabolites in the urine.

Mebendazole is highly protein bound.

Uses and Administration

Mebendazole, a benzimidazole carbamate derivative, is an anthelmintic with activity against most nematodes and some other worms; activity against some larval stages and ova has also been demonstrated. It inhibits or destroys cytoplasmic microtubules in the worm's intestinal or absorptive cells. Inhibition of glucose uptake and depletion of glycogen stores follow as do other inhibitory effects leading to death of the worm within several days.

Mebendazole, being poorly absorbed from the gastrointestinal tract, is used principally in the treatment of the intestinal nematode infections ascariasis (roundworm infection), enterobiasis (pinworm or threadworm infections), hookworm (ancylostomiasis and necatoriasis), and trichuriasis (whipworm infection); it is useful in mixed infections. During treatment with mebendazole, migration of worms with expulsion through the mouth and nose has occurred in some patients heavily infected with *Ascaris*. Mebendazole is also used in the treatment of capillariasis and trichostrongyliasis and has been used in strongyloidiasis. Other nematode infections which may respond to mebendazole are infection with the filarial nematode *Mansonella perstans*, and the tissue infections toxocariasis and trichinosis. Mebendazole has also been tried in high doses in the treatment of echinococcosis (hydatid disease). For discussions of these infections and their treatment, see under Choice of Anthelmintic, p.134, and under the individual headings below.

Mebendazole is given orally. The usual dose for adults and children aged over 2 years with enterobiasis is 100 mg as a single dose, repeated if necessary after 2 to 3 weeks; for ascariasis, hookworm infections, and trichuriasis the usual dose in adults and children over 1 year is 100 mg twice daily for 3 days, although a single dose of 500 mg may be effective.

Angiostrongyliasis. Mebendazole was formerly used for the treatment of angiostrongyliasis (p.134) but current opinion is that there is no convincing evidence to support its use.

Capillariasis. Mebendazole in a dose of 200 mg twice daily for 20 days has been used[1] for the treatment of capillariasis (p.135).

1. Abramowicz M, ed. *Drugs for parasitic infections*. 1st ed. New Rochelle NY: The Medical Letter, 2007.

Echinococcosis. Mebendazole has been used[1-9] in echinococcosis (p.136), but albendazole is generally preferred. The usual dose of mebendazole in cystic echinococcosis is 40 to 50 mg/kg daily for at least 3 to 6 months.[8] A similar dose is used as an adjuvant to surgery. For alveolar echinococcosis, the dose is adjusted after 4 weeks to produce a plasma concentration of at least 250 nanomoles/litre (74 nanograms/mL), although adults should not be given more than 6 g daily. Treatment is continued for at least 2 years after radical surgery, or indefinitely in inoperable cases.

Giardiasis. For mention of the use of mebendazole for the treatment of giardiasis, see p.824.

Mansonella infections. Mebendazole is one of the drugs that has been suggested for the treatment of infections with *Mansonella perstans* (p.137). Some patients have responded to mebendazole with levamisole,[1,2] diethylcarbamazine,[3] or to mebendazole alone.[3,4]

1. Maertens K, Wery M. Effect of mebendazole and levamisole on Onchocerca volvulus and Dipetalonema perstans. *Trans R Soc Trop Med Hyg* 1975; **69:** 359–60.
2. Bernberg HC, *et al.* The combined treatment with levamisole and mebendazole for a perstans-like filarial infection in Rhodesia. *Trans R Soc Trop Med Hyg* 1979; **73:** 233–4.
3. Bregani ER, *et al.* Comparison of different anthelmintic drug regimens against Mansonella perstans filariasis. *Trans R Soc Trop Med Hyg* 2006; **100:** 458–63.
4. Wahlgren M, Frolov I. Treatment of Dipetalonema perstans infections with mebendazole. *Trans R Soc Trop Med Hyg* 1983; **77:** 422–3.

Strongyloidiasis. Mebendazole has been used for the treatment of strongyloidiasis (p.138), but needs to be given for longer periods than albendazole to control auto-infection, so that, of the two, albendazole is preferred.[1-3]

1. Wilson KH, Kauffman CA. Persistent Strongyloides stercoralis in a blind loop of the bowel: successful treatment with mebendazole. *Arch Intern Med* 1983; **143:** 357–8.

Toxocariasis. Mebendazole has been used in the treatment of toxocariasis (p.139). In comparative studies, mebendazole has been reported to produce similar improvements to those obtained with tiabendazole[1] and with diethylcarbamazine,[2] in each case with a lower incidence of adverse effects.

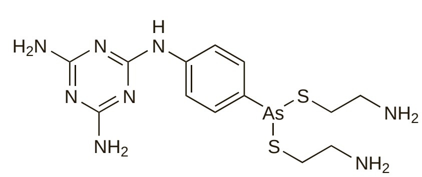
Melarsomine *(rINN)*

Melarsomina; Mélarsomine; Melarsominum. Bis(2-aminoethyl) *p*-[(4,6-diamino-*s*-triazin-2-yl)amino]dithiobenzenearsonite.

Меларсомин

$C_{13}H_{21}AsN_8S_2$ = 428.4.
CAS — 128470-15-5.
ATC Vet — QP51AD06.



Profile

Melarsomine is a trivalent arsenical derivative used in veterinary practice for the control of canine heartworm (dirofilariasis).

Metrifonate *(BAN, rINN)*

Bayer-L-1359; DETF; Metrifonaatti; Metrifonát; Metrifonat; Metrifonatas; Métrifonate; Metrifonato; Metrifonatum; Metriphonate; Trichlorfon *(USAN)*; Trichlorphon. Dimethyl 2,2,2-trichloro-1-hydroxyethylphosphonate.

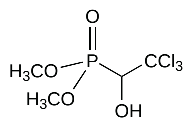
Метрифонат

$C_4H_8Cl_3O_4P$ = 257.4.

CAS — 52-68-6.

ATC — P02BB01.

ATC Vet — QP52AB01; QP53AF02.



Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Metrifonate). A white or almost white, crystalline powder. M.p. is between 76° and 81°. Freely soluble in water, in alcohol, and in acetone; very soluble in dichloromethane. Protect from light.

USP 31 (Metrifonate). A white crystalline powder. M.p. about 78° with decomposition. Freely soluble in water, in alcohol, in acetone, in chloroform, in ether, and in benzene; very soluble in dichloromethane; very slightly soluble in hexane and in pentane. Decomposed by alkali. Store at a temperature not exceeding 25°.

Adverse Effects, Treatment, and Precautions

Metrifonate is generally well tolerated, but may cause nausea, vomiting, abdominal pain, diarrhoea, headache, dizziness, and weakness.

It is an organophosphorus compound and because of its anticholinesterase properties depresses plasma-cholinesterase concentrations. For a description of the toxic effects of organophosphorus compounds and the treatment of acute poisoning, see Organophosphorus Insecticides, p.2047. Atropine has been used to relieve cholinergic adverse effects without affecting metrifonate's activity against *Schistosoma haematobium*.

Anticholinesterase effects. Metrifonate depresses cholinesterase activity and there has been the occasional report of severe cholinergic adverse effects.[1] However, it does not usually give rise to troublesome effects at doses normally used, even though there may temporarily be almost complete inhibition of plasma cholinesterase and considerable inhibition of erythrocyte cholinesterase[2] (but see also under Alzheimer's Disease, below).

The environmental aspects of metrifonate usage have been considered by WHO.[3]

Handling. Bulk metrifonate is very toxic when inhaled, swallowed, or spilled on the skin. It can be removed from the skin by washing with soap and water. Contaminated material should be immersed in a 2% aqueous solution of sodium hydroxide for several hours.

Pregnancy. WHO reported[1] that metrifonate had not shown embryotoxicity or teratogenicity, but did not recommend the use of metrifonate in pregnant patients unless immediate intervention was essential. There has been a report of an infant born with massive hydrocephalus and a large meningomyelocele whose mother had been treated twice with metrifonate during the second month of pregnancy.[2] A possible link between congenital abnormalities and the use of metrifonate to eradicate fish parasites has also been postulated.[3]

3. Czeizel AE, *et al.* Environmental trichlorfon and cluster of congenital abnormalities. *Lancet* 1993; **341:** 539–42.

Interactions

Patients treated with metrifonate should not be given depolarising neuromuscular blockers such as suxamethonium for at least 48 hours.The use of metrifonate should be avoided in those recently exposed to insecticides or other agricultural chemicals with anticholinesterase activity.

Pharmacokinetics

Metrifonate is absorbed after oral doses and some is converted to dichlorvos which is considered to be the active moiety. Plasma concentrations of dichlorvos are about 1% of those of metrifonate with peak concentrations of both substances occurring within 2 hours. Excretion is via the kidney, mainly as glucuronides.

3. Pettigrew LC, *et al.* Pharmacokinetics, pharmacodynamics, and safety of metrifonate in patients with Alzheimer's disease. *J Clin Pharmacol* 1998; **38:** 236–45.

Uses and Administration

Metrifonate is an organophosphorus compound and is converted in the body to the active metabolite dichlorvos (p.2040), an anticholinesterase.

Metrifonate has anthelmintic activity against *Schistosoma haematobium* and has been given orally as an alternative to praziquantel in the treatment of schistosomiasis due to *S. haematobium*. It has usually been given in three doses of 7.5 to 10 mg/kg at intervals of 2 weeks.

Metrifonate has also been used as an insecticide and as a parasiticide in fish and domestic animals.

Alzheimer's disease. Metrifonate, like a number of other cholinesterase inhibitors, has been tried in the treatment of Alzheimer's disease (see Dementia, p.362). Clinical studies[1,2] produced modest benefits but research was stopped after reports of muscle weakness, sometimes requiring respiratory support.

2. Morris JC, *et al.* Metrifonate benefits cognitive, behavioral, and global function in patients with Alzheimer's disease. *Neurology* 1998; **50:** 1222–30.

Schistosomiasis. While praziquantel is now the main treatment for schistosomiasis (p.138), metrifonate is an alternative for infection due to *Schistosoma haematobium*. Cure rates with standard doses in schistosomiasis control programmes range from 40 to more than 80%, with a reduction of more than 80% in egg counts among those not cured, but a comparison with praziquantel has shown praziquantel to be the more effective drug.[1] In addition, metrifonate's dosage schedule of 3 doses at intervals of 2 weeks has caused problems of patient compliance;[2] giving 5 mg/kg three times in one day has produced similar results to a standard dosage schedule.[3]

Milbemycin Oxime

CGA-179246; Milbemicina oxima. A mixture of milbemycin A_4 5-oxime and milbemycin A_3 5-oxime.

Мильбемицин Оксим

CAS — 129496-10-2.

ATC Vet — QP54AB01.

Profile

Milbemycin oxime is an anthelmintic used in veterinary medicine.

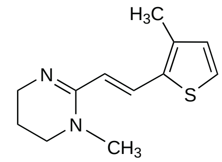
Morantel Citrate *(BANM, pINNM)*

Citrato de morantel; Morantel, Citrate de; Moranteli Citras. (*E*)-1,4,5,6-Tetrahydro-1-methyl-2-[2-(3-methyl-2-thienyl)vinyl]pyrimidine citrate monohydrate.

Морантела Цитрат

$C_{12}H_{16}N_2S,C_6H_8O_7,H_2O$ = 430.5.

CAS — 20574-50-9 (morantel); 69525-81-1 (morantel citrate).



(morantel)

Morantel Tartrate *(BANM, USAN, pINNM)*

CP-12009-18; Moranteelivetytartraatti; Morantel, hydrogénotartrate de; Morantel, Tartrate de; Morantel-hidrogén-tartarát; Morantel-hydrogen-tartarát; Moranteli hydrogenotartras; Moranteli Tartras; Morantelvätetartrat; Tartrato de morantel; UK-2964-18.

Морантела Тартрат

$C_{12}H_{16}N_2S,C_4H_6O_6$ = 370.4.

CAS — 20574-50-9 (morantel); 26155-31-7 (morantel tartrate).

Pharmacopoeias. In *Eur.* (see p.vii) and *US* for veterinary use only.

Ph. Eur. 6.2 (Morantel Hydrogen Tartrate for Veterinary Use; Morantel Tartrate BP(Vet) 2008). A white or pale yellow, crystalline powder. Very soluble in water and in alcohol; practically insoluble in ethyl acetate. A 1% solution in water has a pH of 3.3 to 3.9. Protect from light.

USP 31 (Morantel Tartrate). A white or pale yellow, crystalline powder. Very soluble in water and in alcohol; practically insoluble in ethyl acetate. pH of a 1% solution in water is between 2.8 and 3.9. Store at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Profile

Morantel is an analogue of pyrantel. The citrate and the tartrate are used as anthelmintics in veterinary medicine for the treatment of gastrointestinal roundworms.

Moxidectin *(BAN, USAN, rINN)*

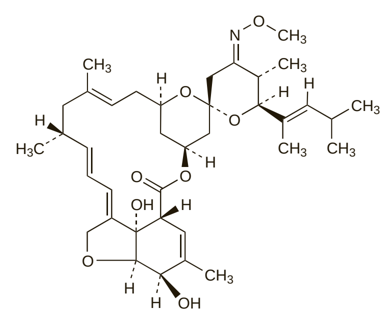
CL-301423; Moksidektiini; Moxidectina; Moxidectine; Moxidectinum; Moxidektin. (6*R*,15*S*)-5-*O*-Demethyl-28-deoxy-25-[(*E*)-1,3-dimethylbut-1-enyl]-6,28-epoxy-23-oxomilbemycin B (*E*)-23-*O*-methyloxime.

Моксидектин

$C_{37}H_{53}NO_8$ = 639.8.

CAS — 113507-06-5.

ATC Vet — QP54AB02.



Pharmacopoeias. In *Eur.* (see p.vii) for veterinary use.

Ph. Eur. 6.2 (Moxidectin for Veterinary Use). A white or pale yellow, amorphous powder. Practically insoluble in water; very soluble in alcohol; slightly soluble in hexane.

Profile

Moxidectin is an anthelmintic used in veterinary medicine. It is also used as a systemic veterinary ectoparasiticide and is under investigation for the treatment of human onchocerciasis.

◊ References.

Naftalofos *(BAN, USAN, rINN)*

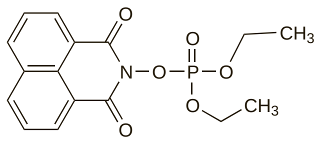
Bay-9002; E-9002; ENT-25567; Naftalofós; Naftalofosum; Naphthalophos; Phthalophos; S-940. Diethyl naphthalimido-oxyphosphonate.

Нафталофос

$C_{16}H_{16}NO_6P$ = 349.3.

CAS — 1491-41-4.

ATC Vet — QP52AB06.



Profile

Naftalofos is an organophosphorus compound (see Organophosphorus Insecticides, p.2047) used as an anthelmintic in veterinary medicine.

Netobimin *(BAN, USAN, rINN)*

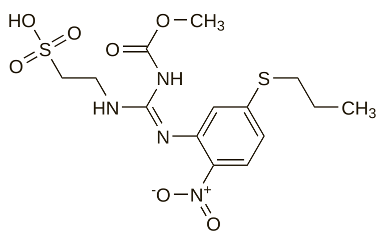
Netobimina; Nétobimine; Netobiminum; Sch-32481. 2-{3-Methoxycarbonyl-2-[2-nitro-5-(propylthio)phenyl]guanidino}ethanesulphonic acid.

Нетобимин

$C_{14}H_{20}N_4O_7S_2$ = 420.5.

CAS — 88255-01-0.

ATC Vet — QP52AC06.



Profile

Netobimin is an anthelmintic used in veterinary medicine.

Niclosamide *(BAN, USAN, rINN)*

Anhydrous Niclosamide; Bay-2353; Niclosamida; Niclosamida Anidra; Niclosamide anhydre; Niclosamidum; Niclosamidum anhydricum; Niklosamid; Niklosamid, vattenfri; Niklosamidi; Niklosamidi, vedetön; Niklozamid; Niklozamid bezwodny; Niklozamidas, bevandenis; Phenasale; Vízmentes niklozamid. 2′,5-Dichloro-4′-nitrosalicylanilide; 5-Chloro-*N*-(2-chloro-4-nitrophenyl)-2-hydroxybenzamide.

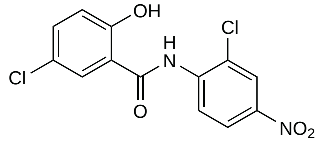
Никлозамид

$C_{13}H_8Cl_2N_2O_4$ = 327.1.

CAS — 50-65-7.

ATC — P02DA01.

ATC Vet — QP52AG03.



Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Int. permits the anhydrous substance or the monohydrate under the title Niclosamide.

Ph. Eur. 6.2 (Niclosamide, Anhydrous). Yellowish-white to yellowish, fine crystals. Practically insoluble in water; slightly soluble in dehydrated alcohol; sparingly soluble in acetone. Store in airtight containers. Protect from light.

Niclosamide Monohydrate *(BANM)*

Niclosamida Mono-hidratada; Niclosamida monohidrato; Niclosamide monohydraté; Niclosamidum monohydricum; Niklosamid monohydrát; Niklosamidimonohydraatti; Niklosamidmonohydrat; Niklozamidas monohidratas; Niklozamid-monohidrát.

Никлозамид Моногидрат

$C_{13}H_8Cl_2N_2O_4,H_2O$ = 345.1.

ATC — P02DA01.

Pharmacopoeias. In *Eur.* (see p.vii).

Int. permits the monohydrate or the anhydrous substance under the title Niclosamide.

Ph. Eur. 6.2 (Niclosamide Monohydrate). Yellowish, fine crystals. Practically insoluble in water; slightly soluble in dehydrated alcohol; sparingly soluble in acetone. Protect from light.

Adverse Effects

Gastrointestinal disturbances may occur occasionally with niclosamide. Lightheadedness and pruritus have been reported less frequently.

Pharmacokinetics

Niclosamide is not significantly absorbed from the gastrointestinal tract.

Uses and Administration

Niclosamide is an anthelmintic which is active against most tapeworms, including the beef tapeworm (*Taenia saginata*), the pork tapeworm (*T. solium*), the fish tapeworm (*Diphyllobothrium latum*) and the dog tapeworm (*Dipylidium caninum*); it has also been given for infections with the dwarf tapeworm, *Hymenolepis nana*. For discussions of the treatment of tapeworm infections, see Diphyllobothriasis, p.136, Hymenolepiasis, p.136, and Taeniasis, p.139. The activity of niclosamide against these worms appears to be due to inhibition of mitochondrial oxidative phosphorylation; anaerobic ATP production is also affected.

Niclosamide is given as tablets, which must be chewed thoroughly before swallowing and washed down with water.

For infections with pork tapeworm a single 2-g dose is given after a light breakfast. Niclosamide is not active against the larval form (cysticerci) and, although the risk of inducing cysticercosis appears to be theoretical, a laxative is given about 2 hours after the dose to expel the killed worms and minimise the possibility of the migration of ova of *T. solium* into the stomach; an antiemetic may also be given before treatment.

For infections with beef or fish tapeworms the 2-g dose of niclosamide may be divided, with 1 g taken after breakfast and 1 g an hour later.

In dwarf-tapeworm infections an initial dose of 2 g has been given on the first day followed by 1 g daily for 6 days.

Children aged 2 to 6 years are given half the above doses and those under 2 years of age are given one-quarter the above doses.

Unless expulsion of the worm is aided by a laxative, portions are voided in a partially digested form after treatment with niclosamide; the scolex is rarely identifiable.

In schistosomiasis (p.138), niclosamide is used as a molluscicide in water-treatment control programmes.

Preparations

BP 2008: Niclosamide Tablets.

Proprietary Preparations (details are given in Part 3)

Nitroscanate *(BAN, USAN, rINN)*

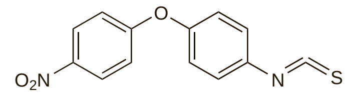
CGA-23654; Nitroscanato; Nitroscanatum; Nitroskanaatti; Nitroskanat. 4-(4-Nitrophenoxy)phenyl isothiocyanate.

Нитросканат

$C_{13}H_8N_2O_3S$ = 272.3.

CAS — 19881-18-6.

ATC Vet — QP52AX01.



Profile

Nitroscanate is an isothiocyanate anthelmintic used in veterinary medicine.

Nitroxinil *(BAN, rINN)*

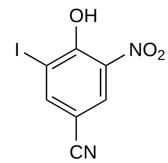
Nitroxinilo; Nitroxinilum; Nitroxynil. 4-Hydroxy-3-iodo-5-nitrobenzonitrile.

Нитроксинил

$C_7H_3IN_2O_3$ = 290.0.

CAS — 1689-89-0 (nitroxinil); 27917-82-4 (nitroxinil eglumine).

ATC Vet — QP52AG08.



Pharmacopoeias. In *BP(Vet)*. Also in *Fr.* for veterinary use only.

BP(Vet) 2008 (Nitroxinil). A yellow to yellowish brown powder. Practically insoluble in water; slightly soluble in alcohol; sparingly soluble in ether; it dissolves in solutions of alkali hydroxides. Protect from light.

Profile

Nitroxinil is an anthelmintic used in veterinary medicine for the treatment of fascioliasis and some gastrointestinal roundworms in cattle and sheep.

Oxamniquine *(BAN, USAN, rINN)*

Oxamniquina; Oxamniquinum; UK-4271. 1,2,3,4-Tetrahydro-2-isopropylaminomethyl-7-nitro-6-quinolylmethanol.

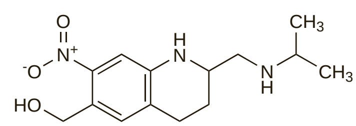
Оксамнихин

$C_{14}H_{21}N_3O_3$ = 279.3.

CAS — 21738-42-1.

ATC — P02BA02.

ATC Vet — QP52AA02.



Pharmacopoeias. In *Fr.* and *Int.*

Adverse Effects

Oxamniquine causes severe pain at the injection site when given intramuscularly and is no longer given by this route.

It is generally well tolerated after oral doses, although dizziness with or without drowsiness occurs in at least a third of patients, beginning up to 3 hours after a dose and usually lasting for up to 6 hours. Headache and gastrointestinal effects such as nausea, vomiting, and diarrhoea are also common.

Allergic-type reactions including urticaria, pruritic skin rashes, and fever may occur. Liver enzyme values have been raised transiently in some patients. Epileptiform convulsions have been reported, especially in patients with a history of convulsive disorders. Hallucinations and excitement have occurred rarely.

A reddish discoloration of urine, probably due to a metabolite of oxamniquine, has been reported.

Effects on body temperature. A review[1] in 1987 noted that although a modest post-treatment rise in temperature had been reported occasionally, fever was not a common adverse effect of oxamniquine, except in Egypt where it appeared to be characteristic. The cause was not known. Increased immune complexes and excretion of antigens occurred in only half the cases, there was no evidence that Egyptian patients metabolised the drug differently to produce a pyrogenic metabolite, and the effect had not been seen in other areas where a similar high-dose regimen was used.[1]

1. Foster R. A review of clinical experience with oxamniquine. *Trans R Soc Trop Med Hyg* 1987; **81:** 55–9.

Effects on the nervous system. In 37 patients with *Schistosoma mansoni* infection treated successfully with oxamniquine,[1] dizziness and drowsiness were most common, but the most significant adverse effect was the development of EEG abnormalities in 6 of 34 patients whose pre-treatment EEG was normal. Of the 3 patients with pre-existing EEG abnormalities, 1 suffered a tonic-clonic seizure during therapy as previously reported,[2] 1 did not suffer seizures, and the third received phenytoin prophylaxis during oxamniquine therapy. It was considered prudent to give antiepileptics before starting oxamniquine in patients with a history of seizure disorder. After completion of this study, a patient with no history of seizures suffered a tonic-clonic seizure 2 hours after each of the second and third doses of oxamniquine.

The main neuropsychiatric adverse effects seen in 180 Brazilian patients with *Schistosoma mansoni* infection treated with single oral doses of oxamniquine were: drowsiness (50.6%), dizziness (41.1%), headache (16.1%), temporary amnesia (2.2%), behavioural disturbances (1.7%), chills (1.1%), and seizures (1.1%).[3] An EEG was performed before and after treatment in 20 patients; there were alterations in 3 but they were not associated with neuropsychiatric changes.

1. Krajden S, *et al*. Safety and toxicity of oxamniquine in the treatment of Schistosoma mansoni infections, with particular reference to electroencephalographic abnormalities. *Am J Trop Med Hyg* 1983; **32:** 1344–6.
2. Keystone JS. Seizures and electroencephalograph changes associated with oxamniquine therapy. *Am J Trop Med Hyg* 1978; **27:** 360–2.
3. de Carvalho SA, *et al*. Neurotoxicidade do oxamniquine no tratamento da infeçáo humana pelo Schistosoma mansoni. *Rev Inst Med Trop Sao Paulo* 1985; **27:** 132–42.

Precautions

Oxamniquine should be used with caution in patients with epilepsy or a history of convulsive disorders. Patients should be warned that oxamniquine can cause dizziness or drowsiness and if affected they should not drive or operate machinery.

Pharmacokinetics

Oxamniquine is readily absorbed after oral doses. Peak plasma concentrations are achieved 1 to 3 hours after a dose and the plasma half-life is 1 to 2.5 hours.

It is extensively metabolised to inactive metabolites, principally the 6-carboxy derivative, which are excreted in the urine. About 70% of a dose of oxamniquine is excreted as the 6-carboxy metabolite within 12 hours of a dose; traces of the 2-carboxy metabolite have also been detected in the urine.

Uses and Administration

Oxamniquine is an anthelmintic used in the treatment of schistosomiasis caused by *Schistosoma mansoni*, but not by other *Schistosoma* spp. It causes worms to shift from the mesenteric veins to the liver where the male worms are retained; the female worms return to the mesentery, but can no longer release eggs. Resistance may occur.

Oxamniquine is given orally, preferably after food. Dosage depends on the geographical origin of the infection and total doses range from 15 mg/kg as a single dose to 60 mg/kg given over 2 to 3 days. A single dose should not exceed 20 mg/kg.

Schistosomiasis. Oxamniquine is an alternative to praziquantel for the treatment of schistosomiasis (p.138) due to *Schistosoma mansoni*, although resistance has occurred, particularly in South America,[1] and it is somewhat less effective than praziquantel.[2]

The dose ranges between a single dose of 15 mg/kg and 60 mg/kg given over 2 or 3 days.[1,3] Doses in the low range have been used effectively in South America, the Caribbean, and West Africa while patients in Egypt, South Africa, and Zimbabwe require doses at the top end of the range; intermediate doses may be effective in other parts of Africa.[3]

After the appropriate therapeutic dose of oxamniquine, cure rates of at least 60%, and often more than 90%, can be expected. Egg excretion in those not cured will be reduced by over 80%, and usually by over 90%, one year after treatment.[3]

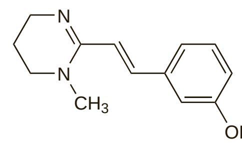
Oxantel Embonate *(BANM, rINNM)*

CP-14445-16; Embonato de oxantel; Oxantel, Embonate d'; Oxantel Pamoate *(USAN)*; Oxanteli Embonas. (*E*)-3-[2-(1,4,5,6-Tetrahydro-1-methylpyrimidin-2-yl)vinyl]phenol 4,4′-methylenebis(3-hydroxy-2-naphthoate).

Оксантела Эмбонат

$C_{13}H_{16}N_2O,C_{23}H_{16}O_6$ = 604.6.
CAS — 36531-26-7 (oxantel); 68813-55-8 (oxantel embonate); 42408-84-4 (oxantel embonate).
ATC — P02CC02.



(oxantel)

Profile

Oxantel is an analogue of pyrantel that has been used as the embonate in the treatment of trichuriasis. It is used with pyrantel for various intestinal nematode infections.

Preparations

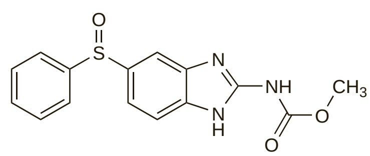
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Indon.:*** Quantrel; ***Philipp.:*** Quantrel; ***Venez.:*** Dualid; Quantrel.

Oxfendazole *(BAN, USAN, rINN)*

Oksfendatsoli; Oxfendazol; Oxfendazolum; RS-8858. Methyl 5-phenylsulphinyl-1*H*-benzimidazol-2-ylcarbamate.

Оксфендазол

$C_{15}H_{13}N_3O_3S$ = 315.3.
CAS — 53716-50-0.
ATC Vet — QP52AC02.



Pharmacopoeias. In *Eur.* (see p.vii) and *US* for veterinary use only.

Ph. Eur. 6.2 (Oxfendazole for Veterinary Use; Oxfendazole BP(Vet) 2008). A white or almost white powder. It shows polymorphism. Practically insoluble in water; slightly soluble in alcohol and in dichloromethane. Protect from light.

USP 31 (Oxfendazole). A white or almost white powder. Practically insoluble in water; slightly soluble in alcohol and in dichloromethane. Protect from light.

Profile

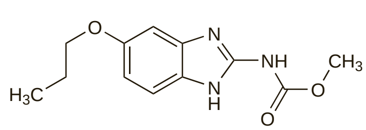
Oxfendazole is a benzimidazole carbamate anthelmintic structurally related to mebendazole (p.148). It is used in veterinary medicine.

Oxibendazole *(BAN, USAN, rINN)*

Oxibendazol; Oxibendazolum; SKF-30310. Methyl 5-propoxy-1*H*-benzimidazol-2-ylcarbamate.

Оксибендазол

$C_{12}H_{15}N_3O_3$ = 249.3.
CAS — 20559-55-1.
ATC Vet — QP52AC07.



Profile

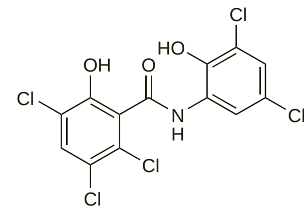
Oxibendazole is a benzimidazole carbamate anthelmintic structurally related to mebendazole (p.148). It is used in veterinary medicine.

Oxyclozanide *(BAN, rINN)*

ICI-46683; Oxiclozanida; Oxyclozanidum. 3,3′,5,5′,6-Pentachloro-2′-hydroxysalicylanilide.

Оксиклозанид

$C_{13}H_6Cl_5NO_3$ = 401.5.
CAS — 2277-92-1.
ATC Vet — QP52AG06.



Pharmacopoeias. In *BP(Vet).*

BP(Vet) 2008 (Oxyclozanide). A pale cream or cream-coloured powder. Very slightly soluble in water; soluble in alcohol; freely soluble in acetone; slightly soluble in chloroform.

Profile

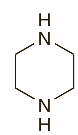
Oxyclozanide is an anthelmintic used in veterinary medicine for the control of fascioliasis in cattle and sheep.

Piperazine

Piperatsiini; Piperazin; Piperazina; Piperazinum.

Пиперазин

$C_4H_{10}N_2$ = 86.14.
CAS — 110-85-0.
ATC — P02CB01.
ATC Vet — QP52AH01.



Pharmacopoeias. In *US.*

USP 31 (Piperazine). White to off-white lumps or flakes having an ammoniacal odour. Soluble in water and in alcohol; insoluble in ether. Store in airtight containers. Protect from light.

Piperazine Adipate

Piperatsiiniadipaatti; Piperaz. Adip.; Piperazina, adipato de; Piperazinadipat; Piperazin-adipát; Pipérazine, adipate de; Piperazini adipas; Piperazino adipatas; Piperazinum Adipicum.

Пиперазина Адипат

$C_4H_{10}N_2,C_6H_{10}O_4$ = 232.3.
CAS — 142-88-1.
ATC — P02CB01.

Pharmacopoeias. In *Eur.* (see p.vii), *Int., Jpn,* and *Viet.*

Ph. Eur. 6.2 (Piperazine Adipate). A white or almost white, crystalline powder. Soluble in water; practically insoluble in alcohol.

Piperazine Citrate

Hydrous Tripiperazine Dicitrate; Piperatsiinisitraatti; Piperazina, citrato de; Piperazincitrat; Piperazin-citrát; Piperazin-citrát hydrát; Pipérazine, citrate de; Piperazini citras; Piperazini Citras Hydricus; Piperazino citratas.

Пиперазина Цитрат

$(C_4H_{10}N_2)_3,2C_6H_8O_7,xH_2O$ = 642.7 (anhydrous substance).
CAS — 144-29-6 (anhydrous piperazine citrate); 41372-10-5 (piperazine citrate hydrate).
ATC — P02CB01.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., US,* and *Viet.*

Ph. Eur. 6.2 (Piperazine Citrate). A white or almost white granular powder. It contains a variable amount of water. Freely soluble in water; practically insoluble in alcohol.

USP 31 (Piperazine Citrate). A white, crystalline powder having not more than a slight odour. Soluble in water; insoluble in alcohol and in ether. pH of a 10% solution in water is about 5.

Stability. A decrease in the content of piperazine [as citrate] in syrups on storage was attributed to interaction with fructose and glucose formed by hydrolysis of sucrose.[1] A syrup prepared with sorbitol lost no potency when stored at 25° for 14 months.

1. Nielsen A, Reimer P. The stability of piperazine in syrup. *Arch Pharm Chemi (Sci)* 1975; **3:** 73–8.

Piperazine Hydrate

Piperatsiinihydraatti; Piperazin Heksahidrat; Piperazin hexahydrát; Piperazina hexahidrato; Piperazinas hidratas; Pipérazine, hydrate de; Piperazin-hidrát; Piperazinhydrat; Piperazini Hydras; Piperazinium Hexahydricum; Piperazinum hydricum; Piperazyna uwodniona. Piperazine hexahydrate.

Пиперазина Гидрат

$C_4H_{10}N_2,6H_2O$ = 194.2.
CAS — 142-63-2.
ATC — P02CB01.

Pharmacopoeias. In *Eur.* (see p.vii) and *Viet.*
Ph. Eur. 6.2 (Piperazine Hydrate). Colourless deliquescent crystals. M.p. about 43°. Freely soluble in water and in alcohol. A 5% solution in water has a pH of 10.5 to 12.0. Store in airtight containers. Protect from light.

Piperazine Phosphate

Piperazina, fosfato de; Piperazini Phosphas.

Пиперазина Фосфат

$C_4H_{10}N_2,H_3PO_4,H_2O$ = 202.1.
CAS — 14538-56-8 (anhydrous piperazine phosphate); 18534-18-4 (piperazine phosphate monohydrate).
ATC — P02CB01.

Pharmacopoeias. In *Br., Chin., Jpn,* and *Viet.*
BP 2008 (Piperazine Phosphate). A white odourless or almost odourless crystalline powder. Sparingly soluble in water; practically insoluble in alcohol. A 1% solution in water has a pH of 6.0 to 6.5.

Adverse Effects

Serious adverse effects are rare with piperazine and generally indicate overdosage or impaired excretion. Nausea, vomiting, diarrhoea, abdominal pain, headache, skin rashes, and urticaria occasionally occur. Severe neurotoxicity and EEG abnormalities have been reported with symptoms including somnolence, dizziness, nystagmus, muscular incoordination and weakness, ataxia, paraesthesia, myoclonic contractions, choreiform movements, tremor, convulsions, and loss of reflexes.

Transient visual disturbances such as blurred vision have occurred occasionally and there were reports of cataract formation after treatment with piperazine although they do not appear to have been substantiated.

Hypersensitivity reactions such as bronchospasm, Stevens-Johnson syndrome, and angioedema have occurred in some individuals.

◊ Piperazine has been taken off the market in some European countries because of general concern about its safety.[1] A study carried out in Sweden on 2 healthy subjects had indicated that mononitrosation of piperazine can occur in the stomach to produce the potential carcinogen *N*-mononitrosopiperazine; the more potent *N,N*-dinitrosopiperazine was not found.[2] However, the disease risk to man from such *N*-nitroso compounds has been questioned[3] and certainly reports of tumours associated with the use of piperazine have not been traced. Also, in the UK the CSM concluded that the incidence of serious adverse effects associated with piperazine was low and that, with appropriate pack warnings, piperazine products could remain as medicines available to the public through pharmacies.[1]

1. Anonymous. Data sheet changes for piperazine in pregnancy. *Pharm J* 1988; **240:** 367.
2. Bellander BTD, *et al.* Nitrosation of piperazine in the stomach. *Lancet* 1981; **ii:** 372.
3. Tannenbaum SR. N-nitroso compounds: a perspective on human exposure. *Lancet* 1983; **i:** 629–32.

Abuse. Derivatives of piperazine have been developed and abused as 'designer drugs'—see Benzylpiperazine (p.2152).

Effects on the blood. A 4-year-old African boy with G6PD deficiency developed haemolytic anaemia; no cause for the haemolysis was found except that 2 days previously he had taken *Pripsen* (piperazine and senna).[1] Severe thrombocytopenia with epistaxis and haemoptysis, which developed in a 61-year-old man after piperazine self-medication, was probably the result of sensitisation to piperazine 15 years earlier.[2]

1. Buchanan N, *et al.* G-6-PD deficiency and piperazine. *BMJ* 1971; **2:** 110.
2. Cork MJ, *et al.* Pruritus ani, piperazine, and thrombocytopenia. *BMJ* 1990; **301:** 1398.

Effects on the liver. A reaction resembling viral hepatitis occurred on 2 occasions in a 25-year-old woman after use of piperazine; it appeared to be a hypersensitivity reaction.[1]

1. Hamlyn AN, *et al.* Piperazine hepatitis. *Gastroenterology* 1976; **70:** 1144–7.

Hypersensitivity. A patient experienced a serum-sickness-like illness associated with piperazine,[1] which was followed by a delayed hypersensitivity vasculitis.

See also Effects on the Blood and Effects on the Liver, above.

1. Balzan M, Cacciottolo JM. Hypersensitivity vasculitis associated with piperazine therapy. *Br J Dermatol* 1994; **131:** 133–4.

Precautions

Piperazine is contra-indicated in patients with epilepsy or severe renal impairment and should be given with care to patients with neurological disturbances or mild to moderate renal impairment. It should also be avoided or given with extreme caution in patients with hepatic impairment.

Breast feeding. The UK licensed product information for *Pripsen* (piperazine and senna) states that piperazine is distributed into breast milk. Mothers should be advised to take a dose after breast feeding then not to breast feed for 8 hours during which period milk should be expressed and discarded at the regular feeding times.

Pregnancy. It has been reported that piperazine is teratogenic in *rabbits* and that there have been isolated reports of fetal malformations after clinical use, though no causal relationship has been established. Two infants with malformations have been described briefly:[1] one had bilateral hare lip, cleft palate, and anophthalmia; the other had an abnormality of one foot. Both mothers had taken *Pripsen* (piperazine and senna). UK licensed product information for *Pripsen* advises against use in pregnancy, especially during the first trimester, unless immediate treatment with piperazine is essential.

1. Leach FN. Management of threadworm infestation during pregnancy. *Arch Dis Child* 1990; **65:** 399–400.

Interactions

The anthelmintic effects of piperazine and pyrantel may be antagonised when the two compounds are used together. The possibility that piperazine may enhance the adverse effects of phenothiazines such as chlorpromazine is discussed on p.975.

Pharmacokinetics

Piperazine is readily absorbed from the gastrointestinal tract and is excreted in the urine within 24 hours, partly as metabolites. The rate at which different individuals excrete piperazine has been reported to vary widely. It is distributed into breast milk.

Uses and Administration

Piperazine is an anthelmintic effective against the intestinal nematodes *Ascaris lumbricoides* (roundworm) and *Enterobius vermicularis* (pinworm, threadworm), although other anthelmintics are usually preferred (see the discussions on the treatment of ascariasis and enterobiasis on p.134 and p.136). In roundworms piperazine produces a neuromuscular block leading to a flaccid muscle paralysis in susceptible worms, which are then easily dislodged by the movement of the gut and expelled in the faeces.

Piperazine is usually given as the citrate or phosphate, but the adipate may also be used. The dosage of the salts of piperazine is usually expressed in terms of piperazine hydrate; 100 mg of piperazine hydrate is equivalent to about 44.4 mg of piperazine, 120 mg of piperazine adipate, 125 mg of piperazine citrate (110 mg of anhydrous piperazine citrate), and to 104 mg of piperazine phosphate.

For the treatment of ascariasis, a single dose, repeated once after 14 days, has been used. In adults and children over 12 years of age, a dose equivalent to 4.5 g of piperazine hydrate is given orally. Children aged 9 to 12 years may be given the equivalent of 3.75 g, those aged 6 to 8 years the equivalent of 3 g, those aged 4 to 5 years the equivalent of 2.25 g, and those aged 1 to 3 years the equivalent of 1.5 g. Children under 1 year should receive piperazine on medical advice only; a dose equivalent to 120 mg/kg has been suggested.

For enterobiasis, piperazine has been given for 7 days. A second course after a 7-day interval may be required. Adults and children over 12 years of age are given the equivalent of 2.25 g of the hydrate once daily, children aged 7 to 12 years the equivalent of 1.5 g daily, those aged 4 to 6 years the equivalent of 1.125 g daily, and those aged 1 to 3 years the equivalent of 750 mg daily. Children under 1 year should receive piperazine on medical advice only; a dose equivalent to 45 to 75 mg/kg has been suggested.

Piperazine is also used as a preparation with senna in a single dose of 4 g of the phosphate for adults and children over 6 years of age, repeated after 14 days for enterobiasis, or repeated monthly if necessary for up to 3 months to treat and prevent ascariasis.

Preparations

BP 2008: Piperazine Citrate Elixir; Piperazine Phosphate Tablets;
USP 31: Piperazine Citrate Syrup; Piperazine Citrate Tablets.

Pomegranate Bark

Granado; Granati Cortex; Granatrinde; Granatum; Grenadier; Melograno; Pomegranate; Pomegranate Root Bark; Romeira.

Кора Гранатового Дерева

Profile

Pomegranate bark, the dried bark of the stem and root of *Punica granatum* (Punicaceae) containing about 0.4 to 0.9% of alkaloids,, has been used for the expulsion of tapeworms.

Preparations

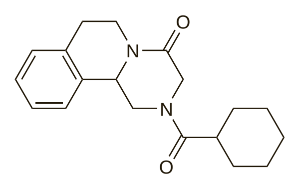
Proprietary Preparations (details are given in Part 3)
Fr.: Hexaporine.

Praziquantel *(BAN, USAN, rINN)*

EMBAY-8440; Pratsikvanteli; Prazicuantel; Prazikvantel; Prazikvantelis; Praziquantelum. 2-Cyclohexylcarbonyl-1,2,3,6,7,11b-hexahydropyrazino[2,1-*a*]isoquinolin-4-one.

Празиквантел

$C_{19}H_{24}N_2O_2$ = 312.4.
CAS — 55268-74-1.
ATC — P02BA01.
ATC Vet — QP52AA01.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int.*, and *US.*
Ph. Eur. 6.2 (Praziquantel). White or almost white crystalline powder. It exhibits polymorphism. Very slightly soluble in water; freely soluble in alcohol and in dichloromethane. Protect from light.
USP 31 (Praziquantel). A white or practically white crystalline powder; odourless or with a faint characteristic odour. Very slightly soluble in water; freely soluble in alcohol and in chloroform. Protect from light.

Adverse Effects

Adverse effects with praziquantel may be common but are usually mild and transient. Headache, diarrhoea, dizziness, drowsiness, malaise, abdominal discomfort, nausea, and vomiting have been reported most frequently. Hypersensitivity reactions such as fever, urticaria, pruritic skin rashes, and eosinophilia can occur; they may be due to death of the infecting parasites. Raised liver enzyme values have been reported rarely.

Most patients with neurocysticercosis who are given praziquantel suffer CNS effects, including headache, hyperthermia, seizures, and intracranial hypertension, which are thought to result from an inflammatory response to dead and dying parasites in the CNS. Use with corticosteroids is advised in such patients.

Effects on the gastrointestinal tract. Colicky abdominal pain and bloody diarrhoea occurred in a small community in Zaire shortly after treatment for *Schistosoma mansoni* infection with single oral doses of praziquantel 40 mg/kg.[1] A similar syndrome has been reported in some patients with *Schistosoma japonicum* infection given praziquantel.[2] The abdominal pain occurring in these patients was very different from the mild abdominal discomfort much more commonly reported with praziquantel therapy.

1. Polderman AM, *et al.* Side effects of praziquantel in the treatment of Schistosoma mansoni in Maniema, Zaire. *Trans R Soc Trop Med Hyg* 1984; **78:** 752–4.
2. Watt G, *et al.* Bloody diarrhoea after praziquantel therapy. *Trans R Soc Trop Med Hyg* 1986; **80:** 345–6.

Effects on the nervous system. Adverse nervous system effects are common in patients with neurocysticercosis given praziquantel. Neurological symptoms have also been reported[1] with the much lower doses of praziquantel used in the treatment of taeniasis in a patient with undiagnosed neurocysticercosis.

1. Flisser A, *et al.* Neurological symptoms in occult neurocysticercosis after single taenicidal dose of praziquantel. *Lancet* 1993; **342:** 748.

Precautions

Praziquantel should not be used in patients with ocular cysticercosis because of the risk of severe eye damage resulting from destruction of the parasite.

Patients should be warned that praziquantel may cause dizziness or drowsiness and if affected they should not drive or operate machinery during or for 24 hours after treatment.

Breast feeding. Praziquantel is distributed into breast milk and mothers should not breast feed during treatment or for 72 hours thereafter.

Pregnancy. In a review of 637 women given praziquantel in a mass distribution programme, 88 had had a single oral dose during pregnancy, including 37 in their first trimester. All pregnancies ended in full-term babies and there was no evidence of clinical abnormality. No difference was found in the rates of preterm delivery or abortion compared with a control group.[1]

1. Adam I,*et al.* Is praziquantel therapy safe during pregnancy? *Trans R Soc Trop Med Hyg* 2004; **98:** 540–3.

Interactions

Anthelmintics. For reference to plasma concentrations of the active metabolite of *albendazole* being increased by praziquantel, see p.139.

Antibacterials. A study[1] in healthy subjects found that oral *rifampicin* decreased plasma concentrations after single and multiple doses of oral praziquantel to subtherapeutic levels.

1. Ridtitid W, *et al.* Rifampin markedly decreases plasma concentrations of praziquantel in healthy volunteers. *Clin Pharmacol Ther* 2002; **72:** 505–13.

Antiepileptics. *Carbamazepine* and *phenytoin* have been reported to reduce the bioavailability of praziquantel.[1]

1. Quinn DI, Day RO. Drug interactions of clinical importance: an updated guide. *Drug Safety* 1995; **12:** 393–452.

Antimalarials. *Chloroquine* has been reported to reduce the bioavailability of praziquantel.[1]

1. Masimirembwa CM, *et al.* The effect of chloroquine on the pharmacokinetics and metabolism of praziquantel in rats and in humans. *Biopharm Drug Dispos* 1994; **15:** 33–43.

Corticosteroids. Corticosteroids may be used to reduce the inflammatory reactions that often occur within 2 to 3 days of starting cysticidal therapy. However, use is complicated by the fact that dexamethasone roughly halves the plasma concentration of praziquantel. It has therefore been suggested that when praziquantel is given in the 2-week treatment regimen, corticosteroids should not be given prophylactically but only if an inflammatory reaction develops. Dexamethasone is then given daily for 2 or 3 days and most of the treatment period will be free of pharmacokinetic interaction. When the short course praziquantel regimen is used (3 doses given 2 hours apart), the corticosteroid may be given prophylactically. The first dose of dexamethasone is given 4 hours after the last dose of praziquantel (when the concentration of praziquantel is starting to decrease and the pharmacological action is assumed to have been accomplished) and then daily for 2 to 3 days. No pharmacokinetic interaction would be expected at this point.[1]

1. Sotelo J, Jung H. Pharmacokinetic optimisation of the treatment of neurocysticercosis. *Clin Pharmacokinet* 1998; **34:** 503–15.

Histamine H_2-antagonists. *Cimetidine* has been reported to increase praziquantel bioavailability.[1,2]

1. Metwally A, *et al.* Effect of cimetidine, bicarbonate and glucose on the bioavailability of different formulations of praziquantel. *Arzneimittelforschung* 1995; **45:** 516–18.
2. Jung H, *et al.* Pharmacokinetic study of praziquantel administered alone and in combination with cimetidine in a single-day therapeutic regimen. *Antimicrob Agents Chemother* 1997; **41:** 1256–9.

Pharmacokinetics

Praziquantel is rapidly absorbed after oral doses; more than 80% of a dose is reported to be absorbed. Peak plasma concentrations occur 1 to 3 hours after a dose, but there is a pronounced first-pass effect and praziquantel undergoes rapid and extensive metabolism in the liver, being hydroxylated to metabolites that are thought to be inactive. It is distributed into the CSF. The plasma elimination half-life of praziquantel is about 1 to 1.5 hours and that of the metabolites about 4 hours.

It is excreted in the urine, mainly as metabolites, about 80% of the dose being eliminated within 4 days and more than 90% of this in the first 24 hours.

Praziquantel is distributed into breast milk.

4. Mandour M El M, *et al.* Pharmacokinetics of praziquantel in healthy volunteers and patients with schistosomiasis. *Trans R Soc Trop Med Hyg* 1990; **84:** 389–93.

Uses and Administration

Praziquantel is an anthelmintic with a broad spectrum of activity against trematodes (flukes) including all species of *Schistosoma* pathogenic to man, and against cestodes (tapeworms). It is used in the treatment of cysticercosis, diphyllobothriasis, hymenolepiasis, schistosomiasis, taeniasis, and intestinal, liver, and lung fluke infections. For discussions of these infections and their treatment, see under Choice of Anthelmintic, p.134, and under the individual headings below.

Praziquantel is given orally with food.

In the treatment of schistosomiasis in adults and children over 4 years it is given on one day as three doses of 20 mg/kg at intervals of 4 to 6 hours or it is given as a single dose of 40 to 60 mg/kg (but see below).

Doses in adults and children over 4 years in the liver fluke infections clonorchiasis and opisthorchiasis are 25 mg/kg three times daily for one or two days or a single dose of 40 mg/kg. Similar doses may be used in intestinal fluke and lung fluke infections (see below).

Single doses of 5 to 25 mg/kg are used in adults and children over 4 years in tapeworm infections.

Praziquantel is used in adults and children over 4 years in the treatment of neurocysticercosis in a dose of 50 mg/kg daily in 3 divided doses for 14 days. An alternative regimen of 3 doses of 25 mg/kg every 2 hours has been proposed.

Echinococcosis. Praziquantel may be used as an adjunct to surgery in echinococcosis (p.136). Praziquantel has been reported to possess a scolicidal effect *in vitro* against *Echinococcus granulosus*[1] and there has been a report of the successful treatment of disseminated peritoneal hydatid disease with praziquantel and surgery.[2] In this case praziquantel was effective against the small cysts; 2 large cysts were removed surgically, one before praziquantel was started. However, activity in 9 other patients given praziquantel was disappointing.[3] A combination of praziquantel with albendazole may be effective.[4]

Intestinal fluke infections. Praziquantel is used in the treatment of intestinal fluke infections (p.136). In the treatment of fasciolopsiasis, heterophyiasis, and metagonimiasis, the usual recommended dose is 25 mg/kg three times daily for one day.[1] However, a single dose of 25 mg/kg has also been recommended.[2] Single doses of 15 mg/kg, 25 mg/kg, or 40 mg/kg all yielded a cure rate of 100% in a study in 72 primary-school children in Thailand who were harbouring *Fasciolopsis buski*, suggesting that a single dose of 15 mg/kg at bedtime might be tried.[3] In another study, 9 patients infected with the trematode *Nanophyetus salmincola* were treated with praziquantel 20 mg/kg three times daily for one day and were negative for eggs in their stools 2 to 12 weeks later,[4] and this has become the usual recommended dose.[1]

Liver fluke infections. Praziquantel is used in the treatment of clonorchiasis and opisthorchiasis, and has also been used in the treatment of fascioliasis (p.137) although in this latter infection bithionol or triclabendazole are preferred.

Various studies have shown praziquantel to be effective in clonorchiasis[1-4] and opisthorchiasis,[5,6] although one study in opisthorchiasis[7] showed that re-infection was common despite praziquantel therapy, particularly in those with heavy initial infection. A study in Thailand[8] confirmed that mass treatment for opisthorchiasis with a single dose of praziquantel was beneficial, although it was suggested that ideally treatment should be given twice a year.

While praziquantel is not the drug of choice for fascioliasis, there has been a report[9] of successful treatment of a patient with severe infection. Subsequent studies[10-12] have, however, shown praziquantel to be of little benefit.

Schistosomiasis. Praziquantel is the main drug[1,2] used in the treatment of schistosomiasis (p.138). It is effective against all species of schistosomes.[1] Doses are either 20 mg/kg given three times in one day or a single dose of 40 mg/kg. WHO considers[1] that in the field such a single-dose treatment will produce a cure rate of 60 to 90% with a reduction in egg count in those not cured of 90 to 95%. Good as such results are, a single dose or one day's sole treatment should not be considered to be all that is required to achieve a permanent cure or prevent re-infection, and any treatment plan should be reassessed after 6 or 12 months.[3,4] Such an approach with annual screening and targeted chemotherapy can provide, at least in some endemic areas, successful protection for children against intense infection and consequent hepatic disease.[4]

Several studies indicate that doses lower than those recommended above might be effective and in some control programmes 20 mg/kg might be enough for *S. haematobium*[5-7] or 30 mg/kg for *S. mansoni.*[5] The extent to which low doses contribute to resistance, as has been suggested with oxamniquine,[8] is unclear, but refractory infections have been reported. A 4-day treatment course was needed to produce a complete cure in a patient who relapsed twice following standard one-day treatment regimens.[9] Hepatic impairment, specifically hepatic fibrosis, is a feature of some schistosomal infections and patients with such liver involvement have benefited from treatment with praziquantel.[4,10]

Taeniasis. Praziquantel is used in the treatment of taeniasis (p.139). It has been studied in the mass control of taeniasis when a single dose of 5 mg/kg was used.[1]

Praziquantel is also effective against the larval form of *Taenia solium* and is used to treat neurocysticercosis (see above).

Pyrantel Embonate *(BANM, rINNM)*

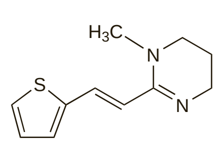
CP-10423-16; Embonato de pirantel; Pirantel Pamoat; Pirantel Pamoate; Pirantelio embonatas; Pyranteeliembonaatti; Pyrantel, embonate de; Pyrantel Pamoate *(USAN)*; Pyrantelembonat; Pyrantel-embonát; Pyranteli embonas; Pyrantelu embonian. 1,4,5,6-Tetrahydro-1-methyl-2-[(*E*)-2-(2-thienyl)vinyl]pyrimidine 4,4′-methylenebis(3-hydroxy-2-naphthoate).

Пирантела Эмбонат

$C_{11}H_{14}N_2S,C_{23}H_{16}O_6$ = 594.7.

CAS — 15686-83-6 (pyrantel); 22204-24-6 (pyrantel embonate); 33401-94-4 (pyrantel tartrate).

ATC — P02CC01.



(pyrantel)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Pyrantel Embonate). A pale yellow or yellow powder. Practically insoluble in water and in methyl alcohol; soluble in dimethyl sulfoxide. Protect from light.

USP 31 (Pyrantel Pamoate). A yellow to tan solid. Practically insoluble in water and in methyl alcohol; soluble in dimethyl sulfoxide; slightly soluble in dimethylformamide. Protect from light.

Adverse Effects and Precautions

The adverse effects of pyrantel embonate are generally mild and transient. The most frequent are gastrointestinal effects such as nausea and vomiting, anorexia, abdominal pain, and diarrhoea. Other adverse effects reported include headache, dizziness, drowsiness, insomnia, skin rashes, and raised liver enzyme values.

Pyrantel embonate should be used with caution in patients with hepatic impairment.

Interactions

The anthelmintic effects of both pyrantel and piperazine may be antagonised when the two drugs are used together.

Pharmacokinetics

Only a small proportion of a dose of pyrantel embonate is absorbed from the gastrointestinal tract. Up to about 7% is excreted as unchanged drug and metabolites in the urine but over half of the dose is excreted unchanged in the faeces.

Uses and Administration

Pyrantel embonate is an anthelmintic effective against intestinal nematodes including roundworms (*Ascaris lumbricoides*), threadworms (*Enterobius vermicularis*), and *Trichostrongylus* spp., the tissue nematode *Trichinella spiralis*, and hookworms, although it is possibly less effective against *Necator americanus* hookworms than against *Ancylostoma duodenale*. Pyrantel embonate is one of the anthelmintics that may be used in the treatment of infections with these worms, as discussed under Choice of Anthelmintic, p.134. It appears to act by paralysing susceptible worms which are then dislodged by peristaltic activity.

Pyrantel is given orally as the embonate, but doses are described in terms of the base. Pyrantel embonate 2.9 g is equivalent to about 1 g of pyrantel.

Single or mixed infections due to susceptible worms in adults and children may be treated with the equivalent of pyrantel 10 mg/kg as a single oral dose. Ascariasis occurring alone may only require 5 mg/kg; a single dose of 2.5 mg/kg given three or four times a year has been used in mass treatment programmes. In necatoriasis, 10 mg/kg daily for 3 or 4 days or 20 mg/kg daily for 2 days may be necessary. The response in enterobiasis may be improved by repeating the 10 mg/kg dose after 2 to 4 weeks. In trichinosis, a dose of 10 mg/kg daily for 5 days has been used.

Pyrantel tartrate has been used as a veterinary anthelmintic.

Preparations

USP 31: Pyrantel Pamoate Oral Suspension.

Proprietary Preparations (details are given in Part 3)

Pyrvinium Embonate *(rINNM)*

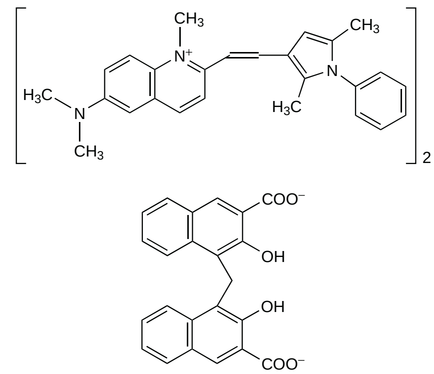
Embonato de pirvinio; Pirvinyum Pamoat; Pyrvinii Embonas; Pyrvinium, Embonate de; Pyrvinium Pamoate *(BAN)*; Viprynium Embonate; Viprynium Pamoate. Bis{6-dimethylamino-2-[2-(2,5-dimethyl-1-phenylpyrrol-3-yl)vinyl]-1-methylquinolinium} 4,4′-methylenebis(3-hydroxy-2-naphthoate).

Пирвиния Эмбонат

$C_{52}H_{56}N_6,C_{23}H_{14}O_6$ = 1151.4.

CAS — 3546-41-6.

ATC — P02CX01.



Pharmacopoeias. In *US.*

USP 31 (Pyrvinium Pamoate). A bright orange or orange-red to practically black crystalline powder. Practically insoluble in water and in ether; slightly soluble in chloroform and in methoxyethanol; freely soluble in glacial acetic acid; very slightly soluble in methyl alcohol. Store in airtight containers. Protect from light.

Adverse Effects

Pyrvinium occasionally causes nausea, vomiting, abdominal pain, and diarrhoea. Hypersensitivity reactions and photosensitivity have been reported. Headache may occur.

Pyrvinium stains the stools bright red and may stain clothing if vomiting occurs.

Pharmacokinetics

Pyrvinium embonate is not significantly absorbed from the gastrointestinal tract.

Uses and Administration

Pyrvinium embonate is an effective anthelmintic in the treatment of enterobiasis (p.136), but has generally been superseded by other drugs.

Pyrvinium is given as the embonate but doses are described in terms of the base. Pyrvinium embonate 7.5 mg is equivalent to about 5 mg of pyrvinium.

It has been given orally in a single dose equivalent to pyrvinium 5 mg/kg, repeated after 2 to 3 weeks.

Preparations

USP 31: Pyrvinium Pamoate Oral Suspension; Pyrvinium Pamoate Tablets.

Proprietary Preparations (details are given in Part 3)

Arg.: Tru; ***Austria:*** Molevac; ***Braz.:*** Enterocid†; Pyr-Pam†; Pyverm; ***Canad.:*** Vanquin†; ***Denm.:*** Vanquin; ***Fin.:*** Pyrvin; ***Fr.:*** Povanyl; ***Ger.:*** Molevac; Pyrcon; ***Norw.:*** Vanquin; ***Spain:*** Pamoxan; ***Swed.:*** Vanquin; ***Turk.:*** Pirok.

Rafoxanide *(BAN, USAN, rINN)*

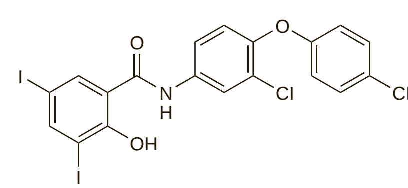
MK-990; Rafoxanida; Rafoxanidum. 3′-Chloro-4′-(4-chlorophenoxy)-3,5-di-iodosalicylanilide.

Рафоксанид

$C_{19}H_{11}Cl_2I_2NO_3$ = 626.0.

CAS — 22662-39-1.

ATC Vet — QP52AG05.



Profile

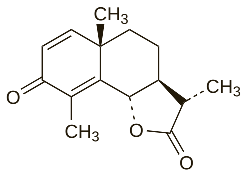
Rafoxanide is an anthelmintic used in veterinary medicine for the treatment of fascioliasis in cattle and sheep.

Santonin

Santoniini; Santonina; Santoninum. (3*S*,3a*S*,5a*S*,9b*S*)-3a,5,5a,9b-Tetrahydro-3,5a,9-trimethylnaphtho[1,2-*b*]furan-2,8(3*H*,4*H*)-dione.

Сантонин

$C_{15}H_{18}O_3$ = 246.3.
CAS — 481-06-1.



Pharmacopoeias. In *Jpn.*

Profile

Santonin is a crystalline lactone obtained from the dried unexpanded flowerheads of *Artemisia cina* (santonica, wormwood) and other species of *Artemisia* (Compositae). It was formerly used as an anthelmintic in the treatment of roundworm (*Ascaris*) infection, but has been superseded by other less toxic anthelmintics.

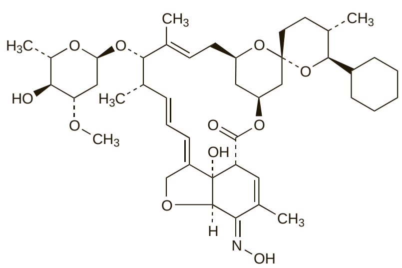
It is used as a flavour in food.

Selamectin *(USAN, rINN)*

Selamectina; Sélamectine; Selamectinum; Selamektiini; Selamektin; UK-124114. (2a*E*,4*E*,5′*S*,6*S*,6′*S*,7*S*,8*E*,11*R*,13*R*,15*S*,17a*R*,20a*R*,20b*S*)-6′-Cyclohexyl-7-[(2,6-dideoxy-3-*O*-methyl-α-L-*arabino*-hexopyranosyl)oxy]-3′,4′,5′,6,6′,7,10,11,14,15,20a,20b-dodecahydro-20b-hydroxy-5′,6,8,19-tetramethylspiro(11,15-methano-2*H*,13*H*,17*H*-furo[4,3,2-*p*,*q*][2,6]benzodioxacyclooctadecin-13,2′-[2*H*]pyran)-17,20(17a*H*)-dione 20-oxime.

Селамектин

$C_{43}H_{63}NO_{11}$ = 770.0.
CAS — 165108-07-6.
ATC Vet — QP54AA05.



Pharmacopoeias. In *Eur.* (see p.vii) for veterinary use only.

Ph. Eur. 6.2 (Selamectin for Veterinary Use). A semi-synthetic product derived from a fermentation product. A white or almost white, hygroscopic powder. Practically insoluble in water; soluble in acetone and in dichloromethane; freely soluble in isopropyl alcohol; sparingly soluble in methyl alcohol. Store in airtight containers.

Profile

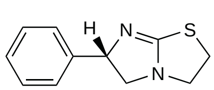
Selamectin is an avermectin anthelmintic and ectoparasiticide used in veterinary medicine.

Tetramisole Hydrochloride *(BANM, USAN, rINNM)*

Hidrocloruro de tetramisol; ICI-50627; McN-JR-8299-11; R-8299; Tétramisole, Chlorhydrate de; Tetramisoli Hydrochloridum. (±)-2,3,5,6-Tetrahydro-6-phenylimidazo[2,1-*b*]thiazole hydrochloride.

Тетрамизола Гидрохлорид

$C_{11}H_{12}N_2S,HCl$ = 240.8.
CAS — 5036-02-2 (tetramisole); 5086-74-8 (tetramisole hydrochloride).



(tetramisole)

Pharmacopoeias. In *Fr.* for veterinary use only.

Profile

Tetramisole hydrochloride is an anthelmintic used in veterinary medicine for the control of nematode infections. It is a racemic mixture and the laevo-isomer, levamisole hydrochloride (p.147), accounts for most of its activity.

Preparations

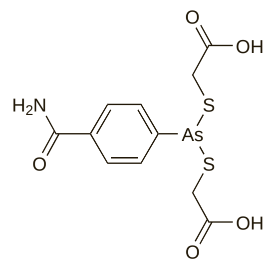
Proprietary Preparations (details are given in Part 3)
Braz.: Ascarizole†; Tetramizotil†.
Multi-ingredient: *India:* Jetomisol-P.

Thiacetarsamide *(rINNM)*

Thiacétarsamide; Thiacetarsamidum; Tiacetarsamida. *p*-[Bis(carboxymethylmercapto)arsino]benzamide; 4-Carbamylphenyl bis[carboxymethylthio]arsenite.

Тиацетарсамид

$C_{11}H_{12}AsNO_5S_2$ = 377.3.
CAS — 531-72-6.
ATC Vet — QP52AX08.



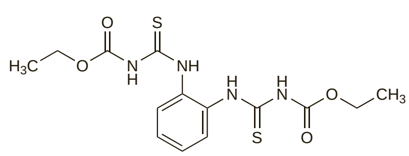
Profile

Thiacetarsamide is an anthelmintic used in veterinary medicine.

Thiophanate *(BAN)*

Tiofanato. 4,4′-*o*-Phenylenebis(ethyl 3-thioallophanate).

$C_{14}H_{18}N_4O_4S_2$ = 370.4.
CAS — 23564-06-9.
ATC Vet — QP52AC04.



Profile

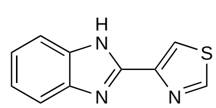
Thiophanate is an anthelmintic used in veterinary medicine for the control of nematode infections.

Tiabendazole *(BAN, rINN)*

E233; MK-360; Thiabendazole *(USAN)*; Tiabendatsoli; Tiabendazol; Tiabendazolas; Tiabendazolum. 2-(Thiazol-4-yl)-1*H*-benzimidazole.

Тиабендазол

$C_{10}H_7N_3S$ = 201.2.
CAS — 148-79-8.
ATC — D01AC06; P02CA02.
ATC Vet — QD01AC06; QP52AC10.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Tiabendazole). A white or almost white crystalline powder. Practically insoluble in water; slightly soluble in alcohol and in dichloromethane; it dissolves in dilute mineral acids. Protect from light.

USP 31 (Thiabendazole). A white to practically white, odourless or practically odourless, powder. Practically insoluble in water; slightly soluble in alcohol and in acetone; very slightly soluble in chloroform and in ether.

Adverse Effects

Dizziness and gastrointestinal disturbances, especially anorexia, nausea and vomiting, diarrhoea, and abdominal pain are common during treatment with tiabendazole. Other adverse effects occurring occasionally include pruritus, skin rashes, headache, fatigue, drowsiness, drying of mucous membranes, hyperglycaemia, disturbance of vision including colour vision, leucopenia, tinnitus, effects on the liver including cholestasis and parenchymal damage (in some cases severe and irreversible), enuresis, crystalluria, and bradycardia and hypotension. There have also been reports of erythema multiforme, fatal Stevens-Johnson syndrome, toxic epidermal necrolysis, convulsions, and effects on mental state.

Fever, chills, angioedema, and lymphadenopathy have been reported, but may represent allergic response to dead parasites rather than to tiabendazole.

The urine of some patients taking tiabendazole may have a characteristic odour similar to that after eating asparagus; it is attributed to the presence of a tiabendazole metabolite.

Effects on the salivary glands. Dry mouth with swollen parotid and salivary glands suggestive of the sicca complex preceded the development of cholestatic jaundice in a 17-year-old boy given tiabendazole.[1]

1. Davidson RN, *et al.* Intrahepatic cholestasis after thiabendazole. *Trans R Soc Trop Med Hyg* 1988; **82:** 620.

Hypersensitivity. Severe erythema multiforme developed in a patient 16 days after a course of tiabendazole.[1] Many of the lesions encircled pre-existing melanocytic naevi.

1. Humphreys F, Cox NH. Thiabendazole-induced erythema multiforme with lesions around melanocytic naevi. *Br J Dermatol* 1988; **118:** 855–6.

Precautions

Tiabendazole should be used with caution in patients with hepatic or renal impairment. Tiabendazole causes drowsiness in some patients and those affected should not drive or operate machinery.

Tiabendazole should not be used in mixed worm infections involving *Ascaris lumbricoides* as it can cause these roundworms to migrate; live roundworms have emerged through the mouth or nose.

Pregnancy. Tiabendazole is teratogenic in *mice* although there are no adequate and well controlled studies in human pregnancy.

Renal impairment. Tiabendazole and its 5-hydroxy metabolite did not accumulate in an anephric patient on haemodialysis and haemoperfusion who was treated for severe strongyloidiasis.[1] However, the potentially toxic conjugated glucuronide and sulfate metabolites did accumulate. The clearance of all 3 metabolites was poor by haemodialysis; haemoperfusion was much more efficient, although for rapid removal the haemoperfusion columns should be changed every hour.

1. Bauer L, *et al.* The pharmacokinetics of thiabendazole and its metabolites in an anephric patient undergoing hemodialysis and hemoperfusion. *J Clin Pharmacol* 1982; **22:** 276–80.

Interactions

Xanthines. For the effect of tiabendazole on serum concentrations of *theophylline*, see p.1145.

Pharmacokinetics

Tiabendazole is readily absorbed from the gastrointestinal tract and reaches peak concentrations in the plasma after 1 to 2 hours. It is metabolised to 5-hydroxythiabendazole and excreted principally in the urine as glucuronide or sulfate conjugates; about 90% is recovered in the urine within 48 hours of ingestion, but only 5% in the faeces. Absorption may occur from preparations applied to the skin or eyes.

◊ References.

1. Tocco DJ, *et al.* Absorption, metabolism, and excretion of thiabendazole in man and laboratory animals. *Toxicol Appl Pharmacol* 1966; **9:** 31–9.

Uses and Administration

Tiabendazole, a benzimidazole derivative, is an anthelmintic with activity against most nematode worms; activity against some larval stages and ova has also been demonstrated. The mode of action is not certain, but tiabendazole may inhibit the fumarate-reductase system of worms thereby interfering with their source of energy.

Tiabendazole is used in the treatment of cutaneous larva migrans, dracunculiasis (guinea worm infection), and toxocariasis. It may also be used in the treatment of strongyloidiasis, and can provide symptomatic relief during the larval invasion stage of trichinosis. Tiabendazole is also active against some intestinal nematodes, but should not be used as primary therapy; the treatment of mixed infections including ascariasis is not recommended since tiabendazole may cause the worms to migrate to other body organs causing serious complications. For discussions of the treatment of the above infections see under Choice of Anthelmintic, p.134, and under the individual headings below.

Tiabendazole is given orally, with meals, usually in a dose of 25 mg/kg twice daily for 2 or more days, the duration depending on the type of infection; the daily dose should not exceed 3 g. For those unable to tolerate 2 doses daily, 25 mg/kg may be given after the largest meal on day 1 and repeated 24 hours later after a similar meal on day 2. For mass treatment, a single dose of 50 mg/kg after the evening meal is suggested although the incidence of adverse effects may be higher than with 2 doses of 25 mg/kg.

In cutaneous larva migrans, 25 mg/kg may be given twice daily for 2 days, repeated after 2 days if necessary; topical treatment with a 10 to 15% suspension intended for oral use has also been advocated as an alternative or adjunct to oral treatment.

In dracunculiasis, 25 to 50 mg/kg may be given twice daily for one day; in massive infection a further 50 mg/kg may be given after 5 to 8 days.

In strongyloidiasis, 25 mg/kg may be given twice daily for 2 or 3 days or 50 mg/kg as a single dose; when the infection is disseminated treatment for at least 5 days may be necessary.

In trichinosis, 25 mg/kg may be given twice daily for 2 to 4 successive days.

In toxocariasis, 25 mg/kg may be given twice daily for 5 to 7 days.

Tiabendazole also has some antifungal activity. It is used as a fungicidal preservative for certain foods.

Dracunculiasis. Tiabendazole[1,2] may be used for symptomatic treatment of dracunculiasis (p.136), although it has no direct anthelmintic effect. It is used to facilitate removal of the worm from subcutaneous tissues.

1. Muller R. Guinea worm disease: epidemiology, control, and treatment. *Bull WHO* 1979; **57:** 683–9.
2. Kale OO, *et al.* Controlled comparative trial of thiabendazole and metronidazole in the treatment of dracontiasis. *Ann Trop Med Parasitol* 1983; **77:** 151–7.

Strongyloidiasis. Tiabendazole may be used in the treatment of strongyloidiasis (p.138), but albendazole or ivermectin are generally preferred.

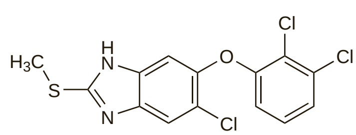
Triclabendazole *(BAN, rINN)*

Triclabendazol; Triclabendazolum. 5-Chloro-6-(2,3-dichlorophenoxy)-2-(methylthio)benzimidazole.

Триклабендазол

$C_{14}H_9Cl_3N_2OS$ = 359.7.
CAS — 68786-66-3.
ATC — P02BX04.
ATC Vet — QP52AC01.



Profile

Triclabendazole is a benzimidazole anthelmintic used in veterinary medicine for the treatment of fascioliasis. It is also increasingly being used in the treatment of human fascioliasis, and is under investigation for the treatment of human paragonimiasis.

Liver fluke infections. Although bithionol or praziquantel are used to treat fascioliasis (p.137), some consider triclabendazole to be the drug of choice.[1] A suggested oral dose is 10 mg/kg, given as a single dose after food; the dose may be repeated once.[1] Several studies[2-7] have demonstrated the efficacy of triclabendazole in fascioliasis.

Lung fluke infections. Encouraging results were reported from a pilot study of triclabendazole[1] in the treatment of paragonimiasis (p.137). In an open comparative study[2] in 62 patients, a more rapid parasitological response was obtained with triclabendazole in oral doses of 5 mg/kg once daily for 3 days, 10 mg/kg twice on one day, or 10 mg/kg as a single dose, than with praziquantel. Clinical symptoms resolved at a comparable rate in all groups. A later study compared the two one-day regimens in 154 patients.[3] After 3 months, the cure rates (assessed by clearance of eggs from sputum) were 84.4% in those given a single dose of 10 mg/kg, and 90.9% in those given two such doses on the same day. In those who were still infected at 3 months, a second two-dose course resulted in complete parasitological clearance at 1 year.

This chapter includes antimicrobial drugs whose main use is the treatment and prophylaxis of bacterial infections. In practice the term 'antibiotics' is often, and in some instances erroneously, used to encompass all of these drugs. In *Martindale* the term antibacterial is preferred for the drugs in this chapter. The groups into which these drugs may be categorised are described below. Antibacterials described elsewhere in *Martindale* include metronidazole (p.837), nitazoxanide (p.842), and tinidazole (p.848), which, as well as being antiprotozoals, are used in the treatment of anaerobic bacterial infections.

Immunological approaches to the treatment and prophylaxis of bacterial infections are discussed under Vaccines Immunoglobulins and Antisera, p.2201.

In addition, disinfectants and preservatives (p.1622) are used to kill or inhibit the growth of micro-organisms.

Drug Groups

Although antibacterials are very diverse compounds they are often classified and discussed in groups. They may be classified according to their mode of action or spectrum of antimicrobial activity, but generally those with similar chemical structures are grouped together.

Aminoglycosides

The aminoglycosides are a closely related group of bactericidal antibacterials derived from bacteria of the order Actinomycetales or, more specifically, the genus *Streptomyces* (framycetin, kanamycin, neomycin, paromomycin, streptomycin, and tobramycin) and the genus *Micromonospora* (gentamicin and sisomicin). They are polycationic compounds that contain an aminocyclitol, usually 2-deoxystreptamine, or streptidine in streptomycin and related compounds, with cyclic amino-sugars attached by glycosidic linkages. Therefore, they have also been termed aminoglycosidic aminocyclitols. The sulfate salts are generally used.

The aminoglycosides have broadly similar toxicological features. Ototoxicity is a major limitation to their use; streptomycin and gentamicin are generally considered to be more toxic to the vestibular branch of the eighth cranial nerve and neomycin and kanamycin to be more toxic to the auditory branch. Other adverse effects common to the group include nephrotoxicity, neuromuscular blockade, and allergy, including cross-reactivity.

The pharmacokinetics of the aminoglycosides are very similar. Little is absorbed from the gastrointestinal tract but they are generally well distributed in the body after parenteral dosage although penetration into the CSF is poor. They are excreted unchanged in the urine by glomerular filtration.

The aminoglycosides have a similar antimicrobial spectrum and appear to act by interfering with bacterial protein synthesis, possibly by binding irreversibly to the 30S and to some extent the 50S portions of the bacterial ribosome. The manner in which they bring about cell death is not fully understood. They are most active against Gram-negative rods. *Staphylococcus aureus* is susceptible to the aminoglycosides but otherwise most Gram-positive bacteria, and also anaerobic bacteria, are naturally resistant. Aminoglycosides show enhanced activity with penicillins against some enterococci and streptococci. Bacterial resistance to streptomycin may occur by mutation, whereas with the other aminoglycosides it is usually associated with the plasmid-mediated production of inactivating enzymes which are capable of phosphorylation, acetylation, or adenylation. The aminoglycosides have a postantibiotic effect, that is antibacterial activity persisting after concentrations have dropped below minimum inhibitory concentrations.

Streptomycin was the first aminoglycoside to become available commercially and was isolated from a strain of *Streptomyces griseus* in 1944. Its use is now restricted mainly to the treatment of tuberculosis when it is always given with other antituberculous drugs because of the rapid development of resistance. *Dihydrostreptomycin*, a reduction product of streptomycin, is only rarely used because of its toxicity. The *neomycin* complex of antibacterials were the next to be isolated; neomycin itself is mainly a mixture of the B and C isomers and neomycin B is considered to be identical with *framycetin*. Because of their toxicity they are not given systemically. The related compound *paromomycin* (p.843) also has antiprotozoal and anthelmintic properties and may be used in the treatment of intestinal amoebiasis, cestode infections, cryptosporidiosis, and leishmaniasis. *Kanamycin* is less toxic than neomycin and can be used systemically. Although it has been used in penicillin-resistant gonorrhoea, it is not active against *Pseudomonas aeruginosa* and has generally been replaced by gentamicin and other newer aminoglycosides.

Gentamicin was isolated from *Micromonospora purpurea* in 1963 and, being active against *Ps. aeruginosa* and *Serratia marcescens*, is widely used in the treatment of life-threatening infections. *Tobramycin* is one of several components of the nebramycin complex of aminoglycosides produced by *Streptomyces tenebrarius*. It has an antimicrobial spectrum very similar to that of gentamicin and is reported to be more active against *Ps. aeruginosa*. *Amikacin*, a semisynthetic derivative of kanamycin, has a side-chain rendering it less susceptible to inactivating enzymes. It has a spectrum of activity like that of gentamicin but Gram-negative bacteria resistant to gentamicin, tobramycin, and kanamycin are often sensitive. *Sisomicin* is closely related structurally to gentamicin. *Netilmicin*, the *N*-ethyl derivative of sisomicin, may be active against some gentamicin-resistant strains of bacteria although not to the same extent as amikacin. Other aminoglycosides include *apramycin*, *arbekacin*, *astromicin*, *bekanamycin*, *dibekacin*, *etimicin*, *isepamicin*, and *micronomicin*.

Aminoglycosides should in general only be used for the treatment of serious infections because of their potential toxicity and antimicrobial spectrum. Doses must be carefully regulated to maintain plasma concentrations within the therapeutic range but avoid accumulation, especially in patients with renal impairment. Neomycin and framycetin, which are considered too toxic to be given parenterally, have been given orally to suppress the intestinal flora. The topical use of neomycin and gentamicin has been associated with allergic reactions and the emergence of resistant bacteria. Gentamicin or tobramycin are the drugs of choice in the treatment of life-threatening infections due to aminoglycoside-sensitive organisms and are often used with other antibacterials. With the continuing emergence of resistant strains, amikacin and netilmicin should be reserved for severe infections resistant to gentamicin and the other aminoglycosides.

Described in this chapter are

Amikacin, p.200	Gentamicin, p.282
Apramycin, p.205	Isepamicin, p.288
Arbekacin, p.206	Kanamycin, p.291
Astromicin, p.206	Micronomicin, p.300
Bekanamycin, p.211	Neomycin, p.305
Dibekacin, p.265	Netilmicin, p.306
Dihydrostreptomycin, p.266	Sisomicin, p.332
Etimicin, p.276	Streptomycin, p.333
Framycetin, p.279	Tobramycin, p.354

Antimycobacterials

The antimycobacterials are a miscellaneous group of antibacterials whose spectrum of activity includes *Mycobacterium* spp. and which are used in the treatment of tuberculosis, leprosy, and other mycobacterial infections. They include the rifamycins, also known as ansamycins or rifomycins, a group of antibacterials isolated from a strain of *Amycolatopsis mediterranei* (*Nocardia mediterranei*; *Streptomyces mediterranei*). The main antibacterial in this group, *rifampicin,* is a mainstay of regimens for the treatment of tuberculosis and leprosy, and is increasingly being used for other infections. The related drug *rifabutin* is also used in mycobacterial disease, especially nontuberculous mycobacterial infections due to *Mycobacterium avium* complex (MAC). Other rifamycins described in this chapter include *rifapentine*, *rifaximin* which is poorly absorbed and is mainly used for a local effect on the gastrointestinal tract, and *rifamycin sodium,* a rifamycin rarely used as it has been superseded by more effective drugs.

Another antimycobacterial widely used for tuberculosis is *isoniazid*, a derivative of isonicotinic acid; it is invariably used with other drugs to avoid or delay emergence of resistance. *Pyrazinamide,* a nicotinamide derivative, is also an important component of regimens for tuberculosis, while *ethambutol* and the aminoglycoside *streptomycin* are added when resistance to first-line drugs is likely. The thiosemicarbazone derivative *thioacetazone* is now less widely used in tuberculosis because of its toxicity and because more effective drugs are available, but is sometimes used in developing countries. Other drugs that have been used to treat tuberculosis including *aminosalicylic acid* and its salts, *capreomycin, cycloserine*, *ethionamide, protionamide*, and *kanamycin* are regarded as secondary drugs and are reserved for patients in whom resistance or toxicity to first-line drugs is a problem.

The sulfones have been used since the 1940s in the treatment of leprosy, but the only one widely used now is *dapsone*, an important component of multidrug regimens. Its action is thought to involve inhibition of folate metabolism, similarly to the sulfonamides, and dapsone is also used for the prophylaxis of malaria and for prophylaxis and treatment of pneumocystis pneumonia. Also important in the treatment of leprosy is the phenazine dye *clofazimine*. Additionally, it has a role in the treatment of type 2 lepra reactions and has been used in other mycobacterial infections. The thioamides *ethionamide* and *protionamide* have been used in the treatment of leprosy and tuberculosis, but have generally been replaced by less toxic drugs, for example *clarithromycin*, *ofloxacin*, *minocycline,* or *pefloxacin*, in alternative antileprotic regimens.

Described in this chapter are

Aminosalicylic Acid, p.201	Methaniazide, p.298
Capreomycin, p.215	Morinamide, p.302
Clofazimine, p.254	Protionamide, p.320
Cycloserine, p.260	Pyrazinamide, p.320
Dapsone, p.261	Rifabutin, p.323
Ethambutol, p.274	Rifampicin, p.325
Ethionamide, p.275	Rifamycin, p.329
Ftivazide, p.279	Rifapentine, p.329
Isoniazid, p.288	Rifaximin, p.330
	Thioacetazone, p.351

Cephalosporins and related beta lactams

The cephalosporins or cephem antibacterials are semisynthetic antibacterials derived from cephalosporin C, a natural antibacterial produced by the mould *Cephalosporium acremonium*. The active nucleus, 7-aminocephalosporanic acid, is very closely related to the penicillin nucleus, 6-aminopenicillanic acid, and consists of a beta-lactam ring fused with a 6-membered dihydrothiazine ring and having an acetoxymethyl group at position 3. Cephalosporin C has a side-chain at position 7 derived from D-α-aminoadipic acid. Chemical modification of positions 3 and 7 has resulted in a series of drugs with different characteristics. Substitution at the 7-amino group tends to affect antibacterial action whereas at position 3 it may have more of an effect on pharmacokinetic properties.

The cephalosporins are bactericidal and, like the penicillins, they act by inhibiting synthesis of the bacterial cell wall. The most widely used system of classification of cephalosporins is by generations and is based on the general features of their antibacterial activity, but may depend to some extent on when they were introduced. Succeeding generations generally have increasing activity against Gram-negative bacteria. *Cefalotin* was one of the first cephalosporins to become available and is representative of the **first-generation** cephalosporins. It has good activity against a wide spectrum of Gram-positive bacteria including penicillinase-producing, but not meticillin-resistant, staphylococci; enterococci are, however, resistant. Its activity against Gram-negative bacteria is modest. Cefalotin is not absorbed from the gastrointestinal tract and must be given parenterally although intramuscular dosage is painful. Cefalotin has generally been replaced by *cefazolin* or *cefradine*. *Cefaloridine* is now rarely used because of its nephrotoxicity. Cefradine is absorbed from the gastrointestinal tract and can be given both orally and by injection. *Cefadroxil, cefatrizine*, and *cefalexin* are all given orally. All of these drugs have a very similar spectrum of antimicrobial activity to cefalotin. *Cefaclor* is also given orally. It has similar activity to cefalotin against Gram-positive cocci, but because of its greater activity against Gram-negative bacteria, particularly *Haemophilus influenzae*, it is often classified as a second-generation drug. *Cefprozil* is an oral cephalosporin with a longer half-life than cefaclor.

Cefamandole was the first available **second-generation** cephalosporin. It has similar or slightly less activity than cefalotin against Gram-positive bacteria, but greater stability to hydrolysis by beta lactamases produced by Gram-negative bacteria and enhanced activity against many of the Enterobacteriaceae and *Haemophilus influenzae*. It is given parenterally. *Cefuroxime* has a similar spectrum of activity to cefamandole although it is even more resistant to hydrolysis by beta lactamases. It is given parenterally but, *cefuroxime axetil*, the acetoxyethyl ester of cefuroxime, is given orally. Other drugs classified as second-generation cephalosporins and given parenterally include *cefonicid, ceforanide*, and *cefotiam*; these all have spectra of activity similar to cefamandole. Cephamycins (see below) are also classified with second-generation cephalosporins.

The **third-generation** cephalosporins, sometimes referred to as **extended-spectrum** cephalosporins, are even more stable to hydrolysis by beta lactamases than cefamandole and cefuroxime. Compared with the earlier generations of cephalosporins they have a wider spectrum and greater potency of activity against Gram-negative organisms, including most clinically important Enterobacteriaceae. Their activity against Gram-positive organisms is said to be less than that of the first-generation drugs, but they are very active against streptococci. *Cefotaxime* was the first of this group to become available and it has relatively modest activity against *Pseudomonas aeruginosa*. *Cefmenoxime*, *cefodizime*, *ceftizoxime*, and *ceftriaxone* are all very similar to cefotaxime in their antimicrobial activity. These drugs are all given parenterally and differ mainly in their pharmacokinetic characteristics. *Cefixime* is a third-generation cephalosporin given by mouth; others include *cefdinir*, *cefetamet pivoxil*, *cefpodoxime proxetil*, and *ceftibuten*. *Ceftazidime* is typical of a group of parenteral third-generation cephalosporins with enhanced activity against *Ps. aeruginosa*. *Cefoperazone* is similar in its activity to ceftazidime. *Cefpiramide* is structurally related to cefoperazone and has comparable activity. Although *cefsulodin* is classified as a third-generation cephalosporin its activity against Gram-negative bacteria is confined to *Ps. aeruginosa*. *Latamoxef* is an **oxacephalosporin** which differs from the true cephalosporins in that the sulfur atom of the 7-aminocephalosporanic acid nucleus is replaced by an oxygen atom. It differs from cefotaxime mainly in its enhanced activity against *Bacteroides fragilis*.

The newer cephalosporins *cefepime* and *cefpirome* are generally considered to be **fourth-generation** because of their broad spectrum of activity. *Ceftobiprole* is active against meticillin-resistant staphylococci.

The semisynthetic **cephamycins** are chemical modifications of cephamycin C, a beta-lactam antibacterial produced naturally by *Streptomyces* spp. They differ from the cephalosporins by the addition of a 7-α-methoxy group to the 7-aminocephalosporanic acid nucleus. Steric hindrance by this methoxy group is considered to be responsible for their greater stability to beta lactamases. For practical purposes they are generally classified with the second-generation cephalosporins, but are more active against anaerobic bacteria, especially *Bacteroides fragilis*. *Cefoxitin* was one of the first cephamycins available; *cefmetazole* and *cefotetan* have been introduced more recently. Another is *cefminox*. All these cephamycins must be given parenterally.

Imipenem was the first of the **carbapenem** group of antibacterials to become available; it is the *N*-formimidoyl derivative of thienamycin which is produced by *Streptomyces cattleya*. It is bactericidal, and, similarly to the cephalosporins, acts by inhibiting synthesis of the bacterial cell wall. It has a very broad spectrum of antimicrobial activity including Gram-positive and Gram-negative aerobic and anaerobic organisms; it has good activity against both *Ps. aeruginosa* and *B. fragilis*. Imipenem is given parenterally with cilastatin, a dehydropeptidase I inhibitor that inhibits the renal metabolism of imipenem. Similarly, the carbapenem panipenem is given with the renal protectant betamipron. Two other carbapenems, *ertapenem* and *meropenem*, are relatively stable to renal dehydropeptidase and can be used without such an inhibitor. Ertapenem has a narrower spectrum of activity than other carbapenems, including no activity against *Ps. aeruginosa*. *Doripenem* is a carbapenem claimed to have particular activity against *Ps. aeruginosa*.

The **monobactams** were first identified as monocyclic beta lactams isolated from bacteria; they are now produced synthetically. *Aztreonam* was the first commercially available monobactam. It is bactericidal with a similar action on bacterial cell-wall synthesis to the cephalosporins. Its antimicrobial activity, however, differs from imipenem and the newer cephalosporins in that it is restricted to Gram-negative aerobic organisms. It has good activity against *Ps. aeruginosa*. Aztreonam is given parenterally. Other monobactams include *carumonam*.

Carbacephems are structurally related to the cephalosporins, but the sulfur atom of the 7-aminocephalosporanic acid nucleus is replaced by a methylene group. *Loracarbef* is an oral carbacephem.

Described in this chapter are

Aztreonam, p.209	Cefotiam, p.230
Betamipron, p.215	Cefovecin, p.230
Biapenem, p.215	Cefoxitin, p.230
Carumonam, p.217	Cefozopran, p.231
Cefaclor, p.217	Cefpiramide, p.231
Cefadroxil, p.218	Cefpirome, p.231
Cefalexin, p.218	Cefpodoxime, p.232
Cefalonium, p.219	Cefprozil, p.232
Cefaloridine, p.219	Cefquinome, p.233

Chloramphenicols

Chloramphenicol is an antibacterial which was first isolated from cultures of *Streptomyces venezuelae* in 1947 but is now produced synthetically. It has a relatively simple structure and is a derivative of dichloroacetic acid with a nitrobenzene moiety. Chloramphenicol was the first broad-spectrum antibacterial to be discovered; it acts by interfering with bacterial protein synthesis and is mainly bacteriostatic. Its range of activity is similar to that of tetracycline and includes Gram-positive and Gram-negative bacteria, Rickettsia spp., and Chlamydiaceae. The sensitivities of *Salmonella typhi, Haemophilus influenzae*, and

Bacteroides fragilis to chloramphenicol have dictated the principal indications for its use.

Shortly after its introduction chloramphenicol was found to have a serious and sometimes fatal depressant effect on the bone marrow. The 'grey syndrome', another potentially fatal adverse effect, was reported later in neonates. As a result of this toxicity the systemic use of chloramphenicol has been restricted in many countries; it should only be given when there is no suitable alternative and never for minor infections.

Chloramphenicol is active when given orally and, unlike most other antibacterials, it diffuses into the CSF even when the meninges are not inflamed. The majority of a dose is inactivated in the liver, only a small proportion appearing unchanged in the urine.

Chloramphenicol is widely used for typhoid fever, although resistance is a problem in some countries. For *Haemophilus influenzae* infections, especially meningitis, the emergence of ampicillin-resistant strains led to a reappraisal of the use of chloramphenicol, and suggestions that ampicillin and chloramphenicol should both be given empirically to patients with meningitis until the sensitivity of the infecting organisms was known, but the newer third-generation cephalosporins are increasingly preferred because of resistance. For proven *H. influenzae* meningitis, chloramphenicol is used as an alternative to the third-generation cephalosporins, which are now regarded as treatment of choice. Chloramphenicol is also effective against many anaerobic bacteria and may be valuable in such conditions as cerebral abscess where anaerobes such as *Bacteroides fragilis* are often involved, although metronidazole may be preferred.

Chloramphenicol sodium succinate is used parenterally and the palmitate is given orally. Ophthalmic and other topical preparations of chloramphenicol are used widely in some countries.

Thiamphenicol is a semisynthetic derivative of chloramphenicol in which the nitro group on the benzene ring has been replaced by a methylsulfonyl group, resulting, in general, in a loss of activity *in vitro*. It has been claimed that thiamphenicol is less toxic than chloramphenicol and there have been fewer reports of aplastic anaemia but reversible bone-marrow depression may occur more frequently. It is also less likely to cause the 'grey syndrome'. Unlike chloramphenicol, thiamphenicol is not metabolised in the liver to any extent and is excreted largely unchanged in the urine. It has been used similarly to chloramphenicol in some countries.

Azidamfenicol is another analogue of chloramphenicol that has been used topically in the treatment of eye infections.

Described in this chapter are

Azidamfenicol, p.206
Chloramphenicol, p.239
Florfenicol, p.277
Thiamphenicol, p.351

Glycopeptides

Vancomycin has a glycopeptide structure; it acts by interfering with bacterial cell wall synthesis and is very active against Gram-positive cocci. Intravenous vancomycin is reserved for the treatment of severe staphylococcal infections and for the treatment and prophylaxis of endocarditis when other antibacterials cannot be used, either because of patient sensitivity or bacterial resistance. It is the treatment of choice for infections caused by meticillin-resistant staphylococci. Vancomycin hydrochloride is poorly absorbed when taken orally; it is used in the treatment of pseudomembranous colitis. *Teicoplanin* is a glycopeptide with similar properties to vancomycin, but a longer duration of action. It can be given intramuscularly as well as intravenously. *Ramoplanin* is under investigation, especially for the treatment of *Clostridium difficile*-associated diarrhoea. It has also been investigated for the prevention of infection due to vancomycin-resistant enterococci. Also under investigation are *dalbavancin* and *oritavancin*.

Norvancomycin, p.310
Oritavancin, p.311
Ramoplanin, p.323
Teicoplanin, p.344
Vancomycin, p.358

Lincosamides

Lincomycin is an antibacterial produced by a strain of *Streptomyces lincolnensis* and was first described in 1962; *clindamycin* is the 7-chloro-7-deoxy derivative of lincomycin.

Although not related structurally to erythromycin and the other macrolide antibacterials, the lincosamides have similar antimicrobial activity and act at the same site on the bacterial ribosome to suppress protein synthesis.

The lincosamides are bacteriostatic or bactericidal, depending on the concentration, and are active mainly against Gram-positive bacteria, and against *Bacteroides* spp. They also appear to have some antiprotozoal activity. Clindamycin and lincomycin have qualitatively similar activity but clindamycin is more active than lincomycin *in vitro*. Cross-resistance occurs between the lincosamides, macrolides, and streptogramins.

The lincosamides have been used, like erythromycin, as an alternative to penicillin, but reports of severe and sometimes fatal pseudomembranous colitis in association with lincomycin and clindamycin have led to the recommendation that they should only be used when there is no suitable alternative.

Both lincomycin and clindamycin can be given orally and parenterally, but clindamycin is much better absorbed from the gastrointestinal tract and less affected by the presence of food in the stomach. They both penetrate well into bone and have been used successfully in osteomyelitis. They have also been used topically in the treatment of acne vulgaris.

The main indication for the use of lincosamides is now in the treatment of severe anaerobic infections, although metronidazole (p.839) or some beta lactams may be a more suitable choice in such infections. Clindamycin also has a role in the prophylaxis of endocarditis in penicillin-allergic patients and has been used, usually with other antiprotozoals, in babesiosis, chloroquine-resistant malaria, toxoplasmosis, and pneumocystis pneumonia.

Described in this chapter are

Clindamycin, p.251
Lincomycin, p.293
Pirlimycin, p.316

Macrolides

The macrolides are a large group of antibacterials mainly derived from *Streptomyces* spp. and having a common macrocyclic lactone ring to which one or more sugars are attached. They are all weak bases and only slightly soluble in water. Their properties are very similar and in general they have low toxicity and a similar spectrum of antimicrobial activity with cross-resistance between individual members of the group. The macrolides are bacteriostatic or bactericidal, depending on the concentration and the type of micro-organism, and are thought to interfere with bacterial protein synthesis. Their antimicrobial spectrum is similar to that of benzylpenicillin but they are also active against such organisms as *Legionella pneumophila*, *Mycoplasma pneumoniae*, and some rickettsias, chlamydias, and chlamydophilas. Macrolides and related drugs have a postantibiotic effect: that is, antibacterial activity persists after concentrations have dropped below the minimum inhibitory concentration.

Erythromycin was discovered in 1952 and is the macrolide used most widely. It is destroyed by gastric acid and must therefore be given as enteric-coated formulations or as one of its more stable salts or esters such as the stearate or ethyl succinate. Hepatotoxicity has been reported after the use of erythromycin, most commonly as the estolate. Erythromycin lactobionate or gluceptate may be given intravenously. Cardiac arrhythmias have been reported occasionally after intravenous use. Erythromycin is used as an alternative to penicillin in many infections, especially in patients who are allergic to penicillin. It has similar uses to tetracycline in the treatment of infections due to *Mycoplasma pneumoniae* and *Chlamydia trachomatis*, and in acne vulgaris. It is also used in the treatment of infections caused by *Legionella pneumophila*.

More recently developed macrolides include *azithromycin*, *clarithromycin*, *dirithromycin*, and *roxithromycin*. These drugs all appear to have similar properties to erythromycin although they may differ in their pharmacokinetics. Clarithromycin and, to a lesser extent, azithromycin are more active than erythromycin against opportunistic mycobacteria such as *Mycobacterium avium* complex. Clarithromycin is also used in the treatment of leprosy and in regimens for the eradication of *Helicobacter pylori* in peptic ulcer disease. Both azithromycin and clarithromycin have activity against protozoa including *Toxoplasma gondii*.

Flurithromycin is another newer macrolide in use.

Other macrolides include *spiramycin*, which has been used extensively in Europe and has also been used in the treatment and prophylaxis of toxoplasmosis. It may be useful in the treatment of cryptosporidiosis.

Oleandomycin has been used orally and parenterally as the phosphate. Its ester, *troleandomycin*, is better absorbed from the gastrointestinal tract but, like erythromycin estolate, has proved hepatotoxic and more effective antibacterials are generally preferred. *Josamycin*, *kitasamycin*, *midecamycin*, and *rokitamycin* have been used in Europe and/or Japan. *Meleumycin* has been used in China.

Tilmicosin, *tulathromycin*, and *tylosin* are used in veterinary practice.

The **streptogramin** group of antibacterials are also derived from *Streptomyces* spp. and include *pristinamycin* and *virginiamycin*. They consist of two components that act synergistically and are therefore also known as synergistins. One of the components is structurally related to the macrolides, and they have a similar spectrum of antimicrobial activity to erythromycin. Semisynthetic derivatives such as *quinupristin/dalfopristin* may be useful in the treatment of infections with multidrug-resistant organisms including meticillin-resistant *Staphylococcus aureus* and vancomycin-resistant enterococci.

Cross-resistance is often observed between the macrolides, lincosamides, and streptogramins. The **ketolide** antibacterials *telithromycin* and *cethromycin* are semisynthetic derivatives of erythromycin A that have been developed to overcome macrolide resistance in respiratory-tract pathogens.

Penicillins

Penicillin was the first antibacterial to be used therapeutically and was originally obtained, as a mixture of penicillins known as F, G, X, and K, from the mould *Penicillium notatum*. Better yields were achieved using *P. chrysogenum* and benzylpenicillin (penicillin G) was selectively produced by adding the precursor phenylacetic acid to the fermentation medium. The term 'penicillin' is now used generically for the entire group of natural and semisynthetic penicillins. Penicillins are still widely used; they are generally well tolerated, apart from hypersensitivity reactions, and are usually bactericidal by virtue of their inhibitory action on the synthesis of the bacterial cell wall.

Penicillins all have the same ring structure and are monobasic acids that readily form salts and esters; 6-aminopenicillanic acid, the penicillin nucleus, consists of a fused thiazolidine ring and a beta-lactam ring with an amino group at the 6-position.

The earlier or so-called 'natural' penicillins were produced by adding different side-chain precursors to fermentations of the *Penicillium* mould; *benzylpenicillin*, with a phenylacetamido side-chain at the 6-position, and *phenoxymethylpenicillin* (penicillin V), with a phenoxyacetamido side-chain, were 2 of the first and are still widely used. Benzylpenicillin can be considered the parent compound of the penicillins and is active mainly against Gram-positive bacteria and *Neisseria* spp. It is inactivated by penicillinase-producing bacteria and because of its instability in gastric acid it is usually injected. Long-acting preparations include *procaine benzylpenicillin* and *benzathine benzylpenicillin*, which slowly release benzylpenicillin after injection. Phenoxymethylpenicillin is acid-stable and is therefore given orally but it is also inactivated by penicillinase. It is generally used for relatively mild infections.

When no side-chain precursor is added to the fermentation medium, 6-aminopenicillanic acid itself is obtained. A range of penicillins has been synthesised from 6-aminopenicillanic acid by substitution at the 6-amino position in an effort to improve on the instability of benzylpenicillin to gastric acid and penicillinases, to widen its antimicrobial spectrum, and to reduce its rapid rate of renal excretion. Phenoxypenicillins with an α-phenoxypropionamido (*pheneticillin*) or α-phenoxybutyramido (*propicillin*) side-chain are more stable to acid than benzylpenicillin but offer no advantage over phenoxymethylpenicillin.

Meticillin has a 2,6-dimethoxybenzamido group at the 6-position and was the first penicillin found to be resistant to destruction by staphylococcal penicillinase. However, it is not acid-resistant and has to be injected. The isoxazolyl penicillins, *cloxacillin*, *dicloxacillin*, *flucloxacillin*, and *oxacillin*, are resistant to penicillinase and gastric acid. They have very similar chemical structures and differ mainly in their absorption characteristics. *Nafcillin* is a similar penicillinase-resistant antibacterial but is irregularly absorbed when taken orally.

Ampicillin has a D(−)-α-aminophenylacetamido side-chain and a broader spectrum of activity than benzylpenicillin; although generally less active against Gram-positive bacteria, some Gram-negative organisms including *Escherichia coli*, *Haemophilus influenzae*, and *Salmonella* spp. are sensitive although resistance is being reported increasingly. *Pseudomonas* spp. are not sensitive. Ampicillin is acid-stable and can be given orally but is destroyed by penicillinase. A number of prodrugs including *bacampicillin*, *metampicillin*, and *pivampicillin* are also said to be better absorbed and are hydrolysed to ampicillin *in vivo*. *Amoxicillin*, with a D(−)-α-aminohydroxyphenylacetamido side-chain, only differs from ampicillin by the addition of a hydroxyl group, but is better absorbed from the gastrointestinal tract.

Carbenicillin, with an α-carboxyphenylacetamido side-chain, has marked activity against *Pseudomonas aeruginosa* and some *Proteus* spp. but otherwise is generally less active than ampicillin. It has to be given by injection and large doses are required. *Carfecillin* and *carindacillin* are the phenyl and indanyl esters of carbenicillin respectively and are hydrolysed to carbenicillin *in vivo* when taken orally. *Sulbenicillin* has an α-phenylsulfoacetamido side-chain and *ticarcillin* an α-carboxythienylacetamido side-chain and both have similar activity to carbenicillin; ticarcillin is more active against *Ps. aeruginosa*. The ureidopenicillins *azlocillin* and *mezlocillin*, and the closely related drug *piperacillin* are more active than carbenicillin against *Ps. aeruginosa* and have a wider range of activity against Gram-negative bacteria.

Temocillin, a 6-α-methoxy derivative of ticarcillin, is resistant to many beta lactamases and is active against most Gram-negative aerobic bacteria, but not *Ps. aeruginosa*.

Mecillinam is a penicillanic acid derivative with a substituted amidino group in the 6-position. Unlike the 6-aminopenicillanic acid derivatives it is active mainly against Gram-negative bacteria, although *Ps. aeruginosa*, and *Bacteroides* spp. are considered resistant. Mecillinam itself is not active orally; it is given as *pivmecillinam*, which is hydrolysed to mecillinam on absorption.

The beta-lactamase inhibitors *clavulanic acid*, *sulbactam*, and *tazobactam* are used to extend the antimicrobial range of certain beta-lactam antibacterials.

Quinolones

The quinolonecarboxylic acids, carboxyquinolones, or 4-quinolones are a group of synthetic antibacterials structurally related to nalidixic acid. The term 4-quinolone has been used as a generic name for the common 4-oxo-1,4-dihydroquinoline skeleton. Under this system nalidixic acid, a naphthyridene derivative, is an 8-aza-4-quinolone, cinoxacin, a cinnoline derivative, is a 2-aza-4-quinolone, and pipemidic and piromidic acids, pyrido-pyrimidine derivatives, are 6,8-diaza-4-quinolones.

Nalidixic acid is active against Gram-negative bacteria but has little activity against *Pseudomonas* and Gram-positive organisms. Because bactericidal concentrations can only be achieved in urine its use has generally been limited to the treatment of urinary-tract infections.

Modification of the structure of nalidixic acid has produced related antibacterials such as *oxolinic acid*, *cinoxacin*, and *rosoxacin*. Although some of these have a greater activity *in vitro* against Gram-negative organisms and activity against some Gram-positive organisms, none has been considered to represent a significant clinical advance over nalidixic acid; rosoxacin is only used in the treatment of gonorrhoea. Addition of a piperazinyl radical at position 7, as in *pipemidic acid*, appears to confer some activity against *Pseudomonas*. *Flumequine* was the first fluorinated 4-quinolone to be synthesised, but has no piperazinyl group. Addition of the 7-piperazinyl group and a fluorine atom at position 6 has produced a group of fluorinated piperazinyl quinolones or **fluoroquinolones** with a broader spectrum of activity than nalidixic acid and pharmacokinetic properties more suitable for the treatment of systemic infections. They include *ciprofloxacin*, *enoxacin*, *fleroxacin*, *gatifloxacin*, *gemifloxacin*, *levofloxacin*, *lomefloxacin*, *moxifloxacin*, *nadifloxacin*, *norfloxacin*, *ofloxacin*, *pazufloxacin*, *pefloxacin*, *rufloxacin*, *sparfloxacin*, and *trovafloxacin*. Trovafloxacin and its prodrug, *alatrofloxacin*, have been withdrawn worldwide after reports of unpredictable hepatotoxicity, including some fatalities. Other fluoroquinolones withdrawn because of toxicity include: *clinafloxacin*, *grepafloxacin*, and *temafloxacin*. *Danofloxacin*, *enrofloxacin*, *ibafloxacin*, *marbofloxacin*, *orbifloxacin*, and *sarafloxacin* are used in veterinary practice. Development of *difloxacin* for human use was suspended because of the high incidence of adverse effects, but it is used in veterinary practice.

The fluoroquinolones are very active against aerobic Gram-negative bacilli and cocci including the Enterobacteriaceae, *Haemophilus influenzae*, *Moraxella catarrhalis* (*Branhamella catarrhalis*), and *Neisseria gonorrhoeae* and are also active against *Pseudomonas aeruginosa*. They are generally less active against Gram-positive organisms such as staphylococci and much less active against streptococci such as *Streptococcus pneumoniae*, although some fluoroquinolones now developed have increased activity against these organisms. They also have activity against mycobacteria, mycoplasmas, and rickettsias. Some, for example ofloxacin, have useful activity against *Chlamydia trachomatis*. Activity against anaerobic bacteria is generally poor. There is concern that the emergence of resistant strains of organisms may limit the usefulness of fluoroquinolones.

One disadvantage of the quinolone antibacterials is that they are generally not recommended for use in children, adolescents, and pregnant or breast-feeding women because of their propensity to cause joint erosions in immature *animals*.

Sulfonamides and diaminopyrimidines

The sulfonamides are analogues of *p*-aminobenzoic acid. The first sulfonamide of clinical importance was *Prontosil*, an azo dye that is metabolised *in vivo* to *sulfanilamide*. It was synthesised in Germany in 1932. Many sulfonamides have since been synthesised; they differ only slightly in their antimicrobial activity, but vary in their pharmacokinetic properties. The sulfonamides have been classified according to their rate of excretion as short-, medium- or intermediate-, long-, and ultra-long-acting. The **short-acting** sulfonamides are excreted in the urine in high concentrations and have therefore been of particular use in the treatment of urinary-tract infections. The solubility in urine of earlier short-acting sulfonamides, such as *sulfapyridine*, and their acetyl metabolites is low and hence crystalluria has been reported frequently. Of the short-acting sulfonamides most commonly used, *sulfadiazine* also has low solubility in urine whereas *sulfadimidine* and *sulfafurazole* and their acetyl conjugates are very soluble. Three short-acting sulfonamides (triple sulfonamides) have been given together to reduce the risk of crystalluria, as the constituent sulfonamides can co-exist in solution in urine without affecting each other's solubility. Preparations of mixed sulfonamides have, however, generally been replaced by the more soluble sulfonamides. The **medium-acting** sulfonamides such as *sulfamethoxazole*, the **long-acting** sulfonamides such as *sulfadimethoxine*, *sulfamethoxypyridazine*, and *sulfametoxydiazine*, and the **ultra-long-acting** sulfonamides such as *sulfadoxine* and *sulfametopyrazine* do not attain such high concentrations in the urine and rarely cause crystalluria. Sulfonamides that are slowly excreted from the body do appear, however, to have been more commonly implicated in the development of reactions such as the Stevens-Johnson syndrome.

The sulfonamides are usually bacteriostatic, and interfere with folic acid synthesis of susceptible organisms; their broad spectrum of antimicrobial activity has, however, been limited by the development of resistance. The clinical use of sulfonamides has therefore been greatly reduced; in general they are indicated only in the treatment of urinary-tract infections and a few other disorders such as nocardiosis. Sulfonamides such as *sulfaguanidine*, *succinylsulfathiazole*, *phthalysulfacetamide*, and *phthalylsulfathiazole* are poorly absorbed from the gastrointestinal tract and have been used for the treatment of gastrointestinal infections although they are now rarely indicated. *Sulfadiazine silver*, *sulfathiazole silver*, and *mafenide* are applied topically for their antibacterial action in patients with burns. *Sulfasalazine* (p.1773), a conjugate of 5-aminosalicylic acid (mesalazine) and sulfapyridine, is used in the treatment of inflammatory bowel diseases and in rheumatoid arthritis.

Trimethoprim is a diaminopyrimidine that also inhibits folic acid synthesis but at a different stage in the metabolic pathway to that inhibited by the sulfonamides. It has a similar spectrum of antimicrobial activity to sulfonamides and often shows synergy *in vitro* with these drugs. Trimethoprim was initially available only in combination with sulfonamides, most commonly with sulfamethoxazole as co-trimoxazole. It is now used alone particularly in the treatment of infections of the urinary and respiratory tracts. Analogues of trimethoprim include *baquiloprim*, *brodimoprim*, *ormetoprim*, and *tetroxoprim*.

Co-trimoxazole generally replaced use of sulfonamides alone in the treatment of systemic infections, although its use has also been restricted in some countries and trimethoprim may be preferred. Co-trimoxazole is however indicated for pneumocystis pneumonia and nocardiosis and may be useful in protozoal infections such as toxoplasmosis. Other sulfonamides which have been combined with trimethoprim include sulfadiazine (see *co-trimazine*), sulfamethoxypyridazine, sulfametopyrazine, sulfametrole, and sulfamoxole (see *co-trifamole*). Sulfadiazine has been used with tetroxoprim (see *co-tetroxazine*).

Sulfonamides have also been used with pyrimethamine (p.610) in the treatment or prophylaxis of some protozoal infections. Common combinations are sulfadoxine and pyrimethamine for malaria, and sulfadiazine and pyrimethamine for the treatment of toxoplasmosis.

Tetracyclines

The tetracyclines are a group of antibacterials, originally derived from certain *Streptomyces* spp., having the same tetracyclic nucleus, naphthacene, and similar properties. Unlike the penicillins and aminoglycosides they are usually bacteriostatic at the concentrations achieved in the body but act similarly to the aminoglycosides by interfering with protein synthesis in susceptible organisms.

Tetracyclines all have a broad spectrum of activity which includes Gram-positive and Gram-negative bacteria, chlamydias and chlamydophilas, rickettsias, mycoplasmas, spirochaetes, some mycobacteria, and some protozoa, but the emergence of resistant strains and the development of other antimicrobials has often reduced their value. Adverse effects have also restricted their usefulness. Gastrointestinal disturbances are common and other important toxic effects include deposition in bones and teeth, precluding their use in pregnancy and young children; antianabolic effects, especially in patients with renal impairment; fatty changes in the liver; and photosensitivity, especially with demeclocycline. Allergic reactions are relatively uncommon. Because of these adverse effects tetracyclines should be avoided in pregnant women, children, and, apart from doxycycline and minocycline, patients with renal impairment.

The first tetracycline to be introduced was *chlortetracycline* in 1948 and, like chloramphenicol which was discovered at about the same time, it was found to have a broad spectrum of activity and to be active orally unlike benzylpenicillin or streptomycin, the only other antibacterials then in use. The discovery of chlortetracycline was followed closely by that of *oxytetracycline* and then *tetracycline*, a reduction product of chlortetracycline which may be produced semisynthetically. All three have very similar properties, although chlortetracycline is less well absorbed and oxytetracycline may cause less staining of teeth. *Demeclocycline*, demethylated chlortetracycline, has a longer half-life than tetracycline but is more often associated with phototoxic reactions. It has been used with some success in patients with the syndrome of inappropriate secretion of antidiuretic hormone.

These four tetracyclines are all natural products that have been isolated from *Streptomyces* spp. The more recent tetracyclines, namely methacycline, doxycycline, and minocycline, are semisynthetic derivatives. *Methacycline*, like demeclocycline, has a longer half-life than tetracycline and has been given twice daily. *Doxycycline* and *minocycline* are both more active *in vitro* than tetracycline against many species. More importantly, minocycline is active against some tetracycline-resistant bacteria, including strains of staphylococci. Both are well absorbed and, unlike the other tetracyclines, absorption is not significantly affected by the presence of food. They can be given in lower doses than the older members of the group and, having long half-lives, doxycycline is usually given once daily and minocycline twice daily. Also, they do not accumulate significantly in patients with renal impairment and can, with care, be given to such patients; however, usual doses of minocycline can lead to higher serum concentrations resulting in possible liver toxicity. Both doxycycline and minocycline are more lipid-soluble than the other tetracyclines and they penetrate well into tissues. The use of minocycline may, however, be limited by its vestibular adverse effects.

Tetracyclines are not generally the antibacterials of choice in Gram-positive or Gram-negative infections because of the emergence of resistant organisms and the discovery of drugs with narrower antimicrobial spectra. However, they have a place in the treatment of chlamydial infections, rickettsial infections such as typhus and the spotted fevers, mycoplasmal infections such as atypical pneumonia, pelvic inflammatory disease, Lyme disease, brucellosis, tularaemia, plague, cholera, periodontal disease, and acne. The tetracyclines have also been useful in the treatment of penicillin-allergic patients suffering from venereal diseases, actinomycosis, bronchitis, and leptospirosis. Minocycline may sometimes be used in multidrug regimens for leprosy. Doxycycline may be used for the treatment and prophylaxis of malaria; it is also used in the management of anthrax.

Oxytetracycline, p.312
Rolitetracycline, p.330
Tetracycline, p.347

Miscellaneous Antibacterials

Spectinomycin is an aminocyclitol antibacterial with some similarities to streptomycin although it is not an aminoglycoside. Spectinomycin is active against a wide range of bacteria but its clinical use is restricted to the treatment of chancroid and gonorrhoea. Trospectomycin, a water-soluble derivative, has been investigated.

Mupirocin is an antibacterial produced by *Pseudomonas fluorescens* with activity against most strains of staphylococci and streptococci and also some Gram-negative bacteria. It is applied topically.

Fosfomycin is a derivative of phosphonic acid; it is active against a range of Gram-positive and Gram-negative bacteria and is given by mouth or parenterally.

The fusidane antibacterial *fusidic acid* is derived from *Fusidium coccineum* and has a narrow spectrum of antibacterial activity, but it is very active against *Staphylococcus aureus* and has been used both topically and systemically in the treatment of staphylococcal infections. Resistance develops readily and it is often used with other antibacterials.

The polymyxins are basic antibacterials produced by the growth of different strains of *Bacillus polymyxa* (*B. aerosporus*). *Polymyxin B* and *colistin* have been used clinically, but their systemic use has been more or less abandoned because of their toxicity, notably to the kidneys and nervous system. They are not absorbed when taken orally and have therefore been given in gastrointestinal infections for their bactericidal activity against Gram-negative bacteria. They continue to be widely used as components of topical preparations.

Bacitracin, gramicidin, gramicidin S, and *tyrothricin* are polypeptide antibacterials also produced by certain strains of *Bacillus* spp. but they are active against Gram-positive bacteria. Like the polymyxins, they are toxic when used systemically and are therefore mainly used topically.

The halogenated hydroxyquinoline *clioquinol* has antibacterial, antifungal, and antiprotozoal activity. It was formerly used in gastrointestinal infections including amoebiasis but is of little value and can produce severe neurotoxicity. It is now mainly used locally for superficial infections of the skin and external ear. *Chlorquinaldol* and *halquinol* are used similarly.

Urinary antimicrobials such as *nitrofurantoin*, and also *methenamine* which has generally been given as the hippurate or mandelate, may be used in the treatment and prophylaxis of infections of the lower urinary tract. They are concentrated in the urine, but do not usually achieve antimicrobial concentrations in the blood.

The oxazolidinone *linezolid* has activity against Gram-positive organisms including vancomycin-resistant enterococci and meticillin-resistant *Staphylococcus aureus*. It is used in infections of the skin and respiratory tract due to these organisms.

The glycylcycline *tigecycline* has activity against Gram-positive bacteria, including meticillin-resistant *Staph. aureus*, and also against some Gram-negative and some anaerobic bacteria. It is used in the treatment of complicated skin and skin structure infections and complicated intra-abdominal infections.

The pleuromutilin antibacterial *retapamulin* is derived from the fungus *Clitopilus passeckerianus*; it has activity against *Staphylococcus aureus* and *Streptococcus pyogenes*. It is applied topically.

Choice of Antibacterial

Ideally, antibacterial treatment of infections should be chosen after the infecting organisms have been identified and the results of sensitivity tests are known. In practice, empirical treatment is often necessary initially, bearing in mind local patterns of infection and resistance. Other factors such as site of infection and tissue penetration are also important in deciding which antibacterial to give.

The prophylactic use of antibacterials is restricted mainly to patients undergoing some types of surgery. Other groups requiring infection prophylaxis include patients at special risk of developing endocarditis and those who have had rheumatic fever, who are splenectomised, or who are immunocompromised.

Abscess, abdominal

See under Abscess, Liver, below, and under Peritonitis, p.184.

Abscess, brain

Brain abscesses can result from otitis media, sinusitis, trauma, or dental sepsis, or they may be metastatic secondary to, for example, lung abscesses. Opportunistic infections in immunocompromised patients may present as brain abscesses.

Treatment of brain abscesses entails removal of pus or excision and use of high doses of antibacterials. Ideally the choice of antibacterial depends on the infecting organisms and penetration by the antibacterial into brain tissue and abscess pus. Until organisms can be cultured empirical treatment should be given.

There is very little good quality published information on the treatment of brain abscess. For many years, combined treatment with benzylpenicillin and chloramphenicol was the mainstay of empirical therapy, but a report by the British Society for Antimicrobial Chemotherapy,[1] based on published information and the authors' expertise, recommended the following regimens for first-line empirical treatment, according to the site of the abscess and origin of the infection:

- for frontal lobe abscesses originating from infection of the paranasal sinuses or teeth, a combination of metronidazole with one of cefuroxime, cefotaxime, or ceftriaxone
- for temporal lobe or cerebellar abscesses originating from infection of the middle ear or sphenoidal sinuses, ampicillin and metronidazole with either ceftazidime or gentamicin
- for abscesses associated with penetrating trauma, flucloxacillin, cefuroxime, cefotaxime, or ceftriaxone
- for metastatic abscesses, usually in the area supplied by the middle cerebral artery, one of cefuroxime, cefotaxime, or ceftriaxone, with or without metronidazole, or, if associated with endocarditis or cyanotic congenital heart disease, benzylpenicillin

Similar suggestions have been made by a more recent review,[2] which also suggested the use of oxacillin with metronidazole and a third-generation cephalosporin for empirical management of abscesses associated with penetrating trauma, and vancomycin plus a third-generation cephalosporin for abscess occurring postoperatively.

Abscess, liver

Bacteria commonly responsible for pyogenic liver abscesses include Enterobacteriaceae, especially *Escherichia coli* and in some countries[1] *Klebsiella pneumo-*

niae; anaerobes, especially *Bacteroides fragilis*; and *Streptococcus milleri* (these can be microaerophilic). As elsewhere in the abdomen (see under Peritonitis, p.184), infections are often mixed. Treatment involves percutaneous aspiration and drainage of pus and the use of high doses of antibacterials.[2,3] Broad-spectrum empirical therapy should be started immediately; more specific therapy may be possible when the results of cultures following diagnostic percutaneous aspiration of the abscess are known. Gentamicin with clindamycin has been commonly used[4,5] but other antibacterial combinations, involving cefoxitin, chloramphenicol, carboxypenicillins, third-generation cephalosporins, and metronidazole, might be appropriate.[5] A regimen of ampicillin, gentamicin, and metronidazole has become standard in some centres, but may be hazardous in patients with *Klebsiella*-related liver abscess, in whom a combination of an aminoglycoside with either an extended-spectrum beta-lactam such as piperacillin or a second- or third-generation cephalosporin, may be preferred.[1] Antibacterial therapy has been successful without surgical intervention, but may not be consistently so,[6] although this might be due to inadequate treatment against enteric anaerobes, especially *B. fragilis*.[5]

For the treatment of amoebic liver abscess, see under Amoebiasis in Antiprotozoals, p.822.

Abscess, lung

Lung abscesses are often secondary to aspiration pneumonia and are discussed under Pneumonia, p.186. The organisms involved are commonly anaerobic bacteria.

Actinomycosis

Actinomycosis is mainly caused by the oral commensal *Actinomyces israelii*, a Gram-positive anaerobic or microaerophilic bacterium. Other species sometimes responsible include *A. meyeri*, *A. naeslundii*, and *A. viscosus*. One of the commonest forms has been cervicofacial actinomycosis, generally associated with poor oral hygiene and dental procedures.[1] Other forms include abdominal, thoracic,[2] and disseminated actinomycosis; pelvic actinomycosis is associated with the use of intra-uterine contraceptive devices.

The antibacterial of choice is benzylpenicillin given intravenously in high doses for 2 to 6 weeks, followed by an oral penicillin (e.g. phenoxymethylpenicillin or amoxicillin) for 6 to 12 months.[2] There is evidence that actinomycosis can be successfully treated with less prolonged regimens of penicillin; however, short-course treatment regimens are generally not advised for patients with large lesions and/or abdominal disease unless surgical debridement is performed.[2] Tetracycline is an alternative in patients allergic to penicillin; other alternatives include erythromycin or clindamycin. In one patient, actinomycosis resistant to conventional treatment responded to a prolonged course of ciprofloxacin.[3] Other antibacterials used successfully to treat actinomycosis include intravenous imipenem for 6 to 10 weeks and parenteral ceftriaxone for 3 weeks followed by oral ampicillin for 3 months.[2]

Anaerobic bacterial infections

Anaerobic bacteria predominate in the normal microbial flora of man and are a common cause of infections, especially those arising from the gastrointestinal tract, upper respiratory tract, skin, or vagina. Common anaerobic pathogens are *Bacteroides*, *Prevotella* (formerly non-fragilis *Bacteroides*), *Fusobacterium*, *Clostridium*, *Peptostreptococcus*, and *Actinomyces* spp. Apart from single species infections such as tetanus, gas gangrene, pseudomembranous colitis, and actinomycosis, most anaerobic infections are of mixed aetiology. Abscesses are often a feature. Infections include: brain abscess; acute necrotising gingivitis and other periodontal infections; chronic otitis media and chronic sinusitis; aspiration pneumonia and lung abscess; peritonitis and intra-abdominal abscess; bacterial vaginosis and pelvic inflammatory disease; cellulitis, ulcers, bites, and other wound infections.[1]

Sensitivity testing *in vitro* is often impractical and treatment is usually empirical.[1-4] Benzylpenicillin was traditionally considered the antibacterial of choice when *B. fragilis* was unlikely (infections above the diaphragm) although resistance is increasingly a problem. Antibacterials with activity against the *B. fragilis* group and other anaerobic pathogens include metronidazole and other 5-nitroimidazole derivatives, chloramphenicol, clindamycin, cefoxitin, antipseudomonal penicillins, imipenem-cilastatin, and combinations of a beta lactam and a beta-lactamase inhibitor.[2]

Surveys of susceptibility patterns in clinical isolates of anaerobic bacteria have shown increasing resistance of the *B. fragilis* group (including *B. distasonis*, *B. fragilis*, *B. ovatus*, *B. thetaiotaomicron*, and *B. vulgatus*) to clindamycin, continuing penicillin resistance in non-fragilis *Bacteroides* spp. (now reclassified as *Prevotella* spp. and including the type species *P. melaninogenica*), and rare beta-lactamase-mediated resistance of *Fusobacterium* to penicillin. Resistance of some *Clostridium* spp. to penicillin and clindamycin had declined, but no changes were noted for *Cl. perfringens*. The emergence of multi-drug resistant anaerobes has been noted.[5]

The *B. fragilis* group are the most frequently isolated anaerobic bacteria in clinical infections and all members of the group may be pathogenic.[6] Most strains produce beta lactamase and thus are resistant to penicillins and cephalosporins although there is varied susceptibility within the group.[7] In a survey of susceptibility patterns[8] the most active drugs *in vitro* against *B. fragilis* group strains were imipenem, metronidazole, and chloramphenicol; resistance to cefoxitin, clindamycin, and piperacillin was not widespread and combinations of beta-lactamase inhibitors with penicillins or cephalosporins (e.g. ampicillin or cefoperazone with sulbactam; ticarcillin with clavulanate) were also very active. Others have reported similar results.[7] On the basis of activity *in vitro* in another study[9] metronidazole, imipenem, ticarcillin with clavulanate, cefoxitin, and amoxicillin with clavulanate were considered suitable for the treatment of *B. fragilis* group infections. However, a more recent commentary[5] suggested that cefoxitin and clindamycin were no longer drugs of choice due to increasing resistance. A clinical isolate of *B. fragilis*, simultaneously resistant to metronidazole, amoxicillin with clavulanate, and imipenem, was reported in the UK;[10] treatment with clindamycin was successful on this occasion. Tigecycline is considered promising for the management of anaerobic infections; other drugs with potential for oral therapy may include nitazoxanide, ramoplanin, and rifaximin.[5]

Anthrax

Anthrax is caused by *Bacillus anthracis*, a spore-forming Gram-positive aerobe found in the soil. It most commonly infects herbivorous mammals. Humans can become infected by contact with infected animals or infected or contaminated animal products, or by inhalation of anthrax spores. Person-to-person transmission has not been reported. Although rare in western countries it remains a problem in many areas, including Africa, Asia, some southern European countries, the Americas, and parts of Australia. Anthrax has also been used as a weapon for biological warfare.

In humans anthrax presents most often in the cutaneous form. Gastrointestinal or inhalation anthrax can also occur and in these types the prognosis is poor without prompt treatment. In *cutaneous* anthrax symptoms may develop within hours, or up to 12 days, after contact and initially involves a painless, pruritic papule, which enlarges to an ulcer. Later (2 to 6 days) a vesicle with a black eschar develops. The incubation period for *inhalation* anthrax is usually about 10 days. Initial symptoms are non-specific and resemble a flu-like illness with fever, non-productive cough, dyspnoea, fatigue, headache, malaise, sweats, weakness, abdominal pain, and vomiting. This initial stage may last from a few hours to days and is followed in some patients by a short period of recovery while others progress directly to respiratory failure. *Gastrointestinal* anthrax has an incubation period of up to 1 week (usually 2 to 5 days) and initial symptoms are fever, abdominal pain, nausea, vomiting, gastric ulcers, haematemesis, and diarrhoea (usually bloody). Systemic disease progresses rapidly and hypotension, shock, and death may occur 2 to 5 days after initial symptoms.

The **treatment** of naturally occurring anthrax has traditionally been with benzylpenicillin with ciprofloxacin or doxycycline (or other tetracycline) as alternatives. Other drugs with *in vitro* activity are aminoglycosides, amoxicillin, chloramphenicol, clindamycin, imipenem, linezolid, the macrolides, meropenem, rifampicin, and vancomycin.[1-3] There are currently no clinical trial data on the optimal treatment for anthrax and treatment recommendations and guidelines[1-3] are based largely on the experience gained during the 1979 incident in Sverdlovsk (accidental release of biological warfare agents), the 2001 attack in the USA (deliberate release), isolated case reports of naturally occurring disease, and *in vitro* data. Because of the risks of engineered drug-resistant strains of *B. anthracis*, inducible beta-lactamases, and *in vitro* resistance to ofloxacin, guidelines[1-3] for the treatment of anthrax (occurring after deliberate release) recommend the use of 2 or more antibacterials which should be started as soon as possible. Corticosteroids may be given as adjunctive therapy. For the treatment of *inhalation* and *gastrointestinal* anthrax intravenous ciprofloxacin or oral doxycycline plus one or two additional antibacterials with *in vitro* activity are recommended until antimicrobial susceptibility is known. Treatment should be given for 60 days. For *cutaneous* anthrax, oral ciprofloxacin or oral doxycycline is generally recommended. A change to amoxicillin, particularly in pregnant women and children, may be considered if the organism is found to be susceptible or first-line drugs cannot be taken. Treatment for 7 to 10 days is usually recommended for cutaneous anthrax, but in the event of a deliberate release or if concurrent inhalation is suspected then treatment should be continued for 60 days. If there are signs of systemic involvement, extensive oedema, or lesions on the head or neck, intravenous, and a multi-drug approach is recommended.

Anthrax can be **prevented** by controlling and eliminating infected animals and vaccinating livestock. In humans, chemoprophylaxis may be given when exposure to anthrax is suspected. US[4] and UK[3] guidelines recommend antibacterial prophylaxis with oral ciprofloxacin or oral doxycycline for 60 days. UK guidelines suggest that amoxicillin may be considered if the organism is found to be susceptible. Anthrax vaccines may be used for active immunisation and are recommended for persons working with potentially infected animals or animal products (including laboratory workers). The vaccine may also be given with antibacterials as part of a postexposure prophylaxis regimen.[2,3,5] In such situations, antibacterial prophylaxis may be reduced to 4 to 6 weeks.[3,5] In the USA, specific guidelines[5,6] for the use of anthrax vaccine, including its use in response to terrorism, have been developed.

See under Bone and Joint Infections, p.164.

Bacillary angiomatosis

See under Cat Scratch Disease, p.166.

Bacterial vaginosis

Bacterial vaginosis (anaerobic vaginosis; non-specific vaginitis) results from a reduction of the normal vaginal bacteria (*Lactobacillus* spp.) and an overgrowth of anaerobic bacteria (including *Gardnerella vaginalis*, *Mycoplasma hominis*, or *Mobiluncus* or *Prevotella* spp.). It is a common and often distressing condition that is not thought to be sexually transmitted but is generally associated with sexual activity. Infections may be asymptomatic or result in a fishy-smelling vaginal discharge.

Various antibacterial regimens for the **treatment** of bacterial vaginosis are recommended in guidelines issued in the UK,[1] and in the USA[2] and also by WHO[3] but relapse is common after any regimen.

- **WHO:**
  - oral metronidazole 400 or 500 mg twice daily for 7 days

  alternatives are:
  - a single oral dose of metronidazole 2 g
  - intravaginal metronidazole 5 g of a 0.75% gel twice daily for 5 days
  - oral clindamycin 300 mg twice daily for 7 days
  - intravaginal clindamycin 5 g of a 2% cream at bedtime for 7 days
- **UK:**
  - oral metronidazole 400 or 500 mg twice daily for 5 to 7 days *or* a single oral 2-g dose

  alternatives are:
  - intravaginal metronidazole 0.75% gel once daily for 5 days
  - oral clindamycin 300 mg twice daily for 7 days
  - intravaginal clindamycin as a 2% cream once daily for 7 days
  - a single oral dose of tinidazole 2 g
- **USA:**
  - oral metronidazole 500 mg twice daily for 7 days, *or*
  - intravaginal metronidazole 5 g of a 0.75% gel once daily for 5 days, *or*
  - intravaginal clindamycin 5 g of a 2% cream at bedtime for 7 days

  alternatives are:
  - oral clindamycin 300 mg twice daily for 7 days
  - intravaginal clindamycin 100 mg at bedtime for 3 days

An association has been reported between bacterial vaginosis and adverse ***pregnancy*** outcomes, including miscarriage and premature births of low-weight infants, and some have advised treatment early in the second trimester of pregnancy.[4,5] A systematic review[6] of clinical studies has concluded that there is little evidence that screening and treatment of all pregnant women for bacterial vaginosis would prevent premature birth and its consequences, but there is some suggestion that treatment before 20 weeks of gestation may reduce the risk of preterm birth. In women with a history of a previous premature birth, treatment of bacterial vaginosis may reduce the risk of preterm birth.[2] Symptomatic pregnant women should be treated and the following regimens have been recommended:

- **WHO:**
  - oral metronidazole 200 or 250 mg three times daily for 7 days, after the first trimester, *or*
  - a single oral dose of metronidazole 2 g, if treatment is needed in the first trimester

  alternatives are:
  - oral clindamycin 300 mg twice daily for 7 days *or*
  - intravaginal metronidazole 5 g of a 0.75% gel twice daily for 7 days
- **USA:**
  - oral metronidazole 500 mg twice daily *or* 250 mg three times daily for 7 days *or*
  - oral clindamycin 300 mg twice daily for 7 days

Treatment of male sex partners does not prevent the recurrence of bacterial vaginosis.[1-3]

Patients co-infected with HIV should receive the same treatment as those who are HIV-negative.[2]

Biliary-tract infections

Infections of the biliary tract are usually associated with obstructive and inflammatory conditions such as cholecystitis and cholangitis. Complications can include gangrene, hepatic or intraperitoneal abscesses, peritonitis, and septicaemia. The organisms involved are typically gut flora, including Gram-negative aerobes such as *Escherichia coli* and *Klebsiella* spp., and anaerobes including *Bacteroides fragilis*.

Treatment of uncomplicated acute cholecystitis is usually conservative. Antibacterials including cephalosporins, tetracyclines, or broad-spectrum penicillins are commonly given, although some have questioned their use.[1] For more severe infections including suppurative cholangitis, prompt treatment with appropriate antibacterial drugs is necessary. Since biliary obstruction prevents adequate concentrations of many antibacterials being achieved in the bile, the main aim of treatment is to control bacteraemia. Antibacterials used, often in combination, include cephalosporins, aminoglycosides, ampicillin (or amoxicillin), piperacillin, fluoroquinolones, metronidazole, clindamycin, and imipenem or its analogues.[2-5] In most cases of obstruction, definitive treatment depends on restoring drainage of bile by surgical or medical treatment of gallstones (p.2409).

Antibacterial prophylaxis is common in biliary surgery (see Surgical Infection, p.195) to prevent acute cholangitis and wound infections. Cephalosporins are often used for this purpose.[2]

Antibacterials may also have a role as maintenance therapy in recurrent cholangitis.

Bites and stings

Wound infections after cat or dog bites may be due to a mixture of organisms,[1] often including the Gram-negative aerobe *Pasteurella multocida*. The treatment of choice for *P. multocida* is benzylpenicillin[2] and it should be given for infections evident within 24 hours of a bite;[3] alternatives are amoxicillin-clavulanic acid, ampicillin-sulbactam, or a second- or third-generation cephalosporin.[2] A tetracycline such as doxycycline is a further alternative in patients allergic to penicillin.[2] The fluoroquinolone ciprofloxacin has been used successfully to treat *P. multocida* cellulitis associated with a cat bite.[4]

In addition to *P. multocida*, other bacteria involved in cat or dog bite wound infections include *Staphylococcus*, *Streptococcus*, *Bacteroides*, and *Fusobacterium* spp. and their presence will influence the choice of treatment. For example, a penicillinase-resistant penicillin may be necessary if *Staph. aureus* is present. Also, combinations of antibacterials may be necessary in patients allergic to penicillin since tetracycline, the alternative suggested against *P. multocida* infection, has only limited activity against aerobic Gram-positive cocci.

More unusual organisms include *Capnocytophaga canimorsus* (formerly called dysgonic fermenter type 2 or DF-2) which has been associated in particular with dog bites,[5,6] but also with cat bites. It is an opportunistic pathogen especially hazardous to immunocompromised patients including splenectomised patients; the best treatment is benzylpenicillin,[7] amoxicillin-clavulanic acid, or erythromycin.[8] Infection with *C. canimorsus* following dog bites may be severe and has led to fatal septicaemia, disseminated intravascular coagulation, meningitis, or endocarditis,[5] highlighting the importance of early antibacterial treatment and debridement.

See also under Cat Scratch Disease (p.166).

A systematic review[9] has concluded that there is no evidence that the use of prophylactic antibacterials is effective for cat or dog bites, though, if necessary, prophylaxis or treatment for rabies (p.2234) should be instituted. A combined tetanus and diphtheria vaccine (see Tetanus Vaccine, p.2240) should be given to patients whose primary tetanus immunisation is incomplete or unknown, or boosters are not up-to-date.

Among the more unusual infections acquired from animals is seal finger, caused by an as yet unidentified organism and treated with tetracycline.[10] The Gram-negative bacilli *Spirillum minus* (or *minor*) and *Streptobacillus moniliformis* are both causes of rat-bite fever. In each case the treatment of choice is benzylpenicillin;[2] a tetracycline or streptomycin are alternatives.

Envenomation after bites and stings by snakes, scorpions, spiders, and some marine animals is usually treated symptomatically and with specific antivenoms and antisera (see Jellyfish Stings, p.2220, Scorpion Stings, p.2237, Snake Bites, p.2239, Spider Bites, p.2239, and Stone Fish Venom Antisera, p.2239).

Bone and joint infections

In *bacterial arthritis* (septic arthritis) joints may be infected via the blood with a variety of organisms, including staphylococci, streptococci, enterococci, Enterobacteriaceae, *Pseudomonas aeruginosa*, and anaerobes, although the commonest is probably *Staphylococcus aureus*. *Haemophilus influenzae* is a common cause in young children, as is *Neisseria gonorrhoeae* in sexually active young adults. In addition to gonococcal arthritis, other specific types of bacterial arthritis include Lyme disease and meningococcal, salmonellal, and tuberculous arthritis (see under the appropriate disease for further details).

With the exception of *N. gonorrhoeae*, infecting organisms in *osteomyelitis* (infection of bone) are similar to those in bacterial arthritis.[1-3]

In *reactive arthritis* (aseptic arthritis) joint inflammation follows infection elsewhere in the body. It is generally secondary to sexually transmitted, especially chlamydial, infections, or to enteric infections. Reactive arthritis in association with urethritis or cervicitis, or both, is termed Reiter's syndrome.

Empirical treatment regimens for bacterial arthritis or osteomyelitis usually include antistaphylococcal antibacterials such as flucloxacillin, nafcillin, oxacillin, a first-generation cephalosporin,[4] clindamycin, or fusidic acid; vancomycin is used to combat possible meticillin-resistant *Staph aureus*. Linezolid may be used as an alternative in patients unable to take vancomycin.[4] Children under 5 years may be given amoxicillin or cefuroxime because of the likelihood of *H. influenzae* infection. Ceftriaxone may be used for empirical treatment where infection is thought to be caused by *Streptococcus* spp. and *N. gonorrhoeae*.

Empirical antibacterial treatment for infections caused by Gram-negative bacteria includes ceftriaxone, ceftazidime, or ciprofloxacin.[4] Treatment of bone and joint infection is usually started intravenously; if high bone concentrations can be achieved with an appropriate oral antibacterial, patients may be switched to oral therapy. Successful treatment of septic arthritis is generally achieved after 2 to 3 weeks of therapy, while osteomyelitis and prosthetic joint infections may need to be treated for weeks to months.[5]

A systematic review and meta-analysis[6] of antibacterial treatment of bone and joint infections concluded that most studies were methodologically flawed and that there was little high-quality evidence regarding treatment. Rifampicin has also been used, sometimes with other drugs; in one study[7] use of rifampicin with ciprofloxacin improved control of staphylococcal bone infections related to orthopaedic devices in comparison with ciprofloxacin alone.

For reference to infection prophylaxis in orthopaedic patients, see under Surgical Infection, below.

Reactive arthritis is treated with anti-inflammatories; the role of antibacterials is less certain.[8] Results in arthritis associated with chlamydial infections have been more promising than in that triggered by enteric infections.[9] Long-term treatment with a tetracycline in addition to an NSAID has been reported to shorten the duration of reactive arthritis resulting from *Chlamydia trachomatis* infection.[10]

For mention of the use of tetracyclines, usually minocycline, in the treatment of *rheumatoid arthritis*, see under Musculoskeletal and Joint Disorders, p.350.

Botulism

For a discussion of botulism and its management, see p.2207.

Bronchitis

Bronchitis may be defined as inflammation of the bronchi and is associated with excessive sputum production and cough. The bronchi of healthy people are said to be nearly always sterile whereas the upper respiratory tract is often colonised with commensal bacteria including *Streptococcus pneumoniae* and *Haemophilus influenzae*.

Acute bronchitis[1] in previously healthy subjects is commonly associated with viral respiratory infections such as colds and influenza. There may sometimes be secondary bacterial infection that responds to antibacterial therapy as for acute exacerbations of chronic bronchitis (see below). *Acute bronchiolitis* occurs in infants as a result mainly of viral infection and antibacterials are not given routinely (see Respiratory Syncytial Virus Infection, p.860).

Chronic bronchitis and emphysema often occur together and have been termed chronic obstructive pulmonary disease (p.1112). Acute exacerbations of chronic bronchitis may be viral in origin, but bacteria are often present in purulent sputum, the commonest being *Str. pneumoniae* and *H. influenzae*; *Moraxella catarrhalis* (*Branhamella catarrhalis*) is increasingly reported.

The value of antibacterial treatment in both acute bronchitis and acute exacerbation of chronic disease has been controversial and difficult to assess.[1-6] After a comparison of a broad-spectrum antibacterial (amoxicillin, co-trimoxazole, or doxycycline) with placebo,[7] it was considered that antibacterials were justified in exacerbations of chronic obstructive pulmonary disease characterised by increased dyspnoea, sputum production, and sputum purulence. Also, a meta-analysis of randomised studies indicated a small improvement due to therapy in patients with exacerbations of disease.[8] However, a further meta-analysis[9] assessing the use of antibacterials for acute bronchitis concluded that, although there was some benefit to be obtained this did not outweigh the risks of adverse effects and increased resistance and that the use of antibacterials could therefore not be advocated in otherwise healthy patients with no evidence of chronic disease. A systematic review[10] also concluded that the modest benefit associated with antibacterial use in acute disease needed to be considered in the broader context of potential adverse effects, the necessity to treat a self-limiting condition, development of resistance, and cost of treatment. If antibacterials are given it is common practice to give a 7- to 10-day oral course of a broad-spectrum drug such as amoxicillin (alone or with clavulanic acid), ampicillin, an oral cephalosporin such as cefaclor or cefuroxime axetil, co-trimoxazole, erythromycin or a newer macrolide such as azithromycin or clarithromycin, tetracycline, or trimethoprim (preferred to co-trimoxazole in the UK), the choice depending on local patterns of resistance.

Long-term prophylaxis in patients with frequent exacerbations of bronchitis is controversial. A systematic review[11] of the value of antibacterial prophylaxis in chronic bronchitis concluded that it did have a small but significant effect in reducing the number of days of illness, but that it had no place in routine therapy because of concerns over adverse effects and the development of resistance.

Bronchitis associated with *Chlamydophila pneumoniae* (*Chlamydia pneumoniae*) and responding to tetracycline or erythromycin has also been reported.[12]

Brucellosis

Brucellosis (also known as undulant or Mediterranean fever) is caused by *Brucella* spp., aerobic Gram-negative bacteria found primarily in livestock and domestic animals. Humans can become infected by direct contact with infected animals or animal material (such as the placenta), indirectly by consuming infected and unpasteurised milk products, or by inhalation of contaminated dust or droplets. Rarely, human infection has been reported from exposure to some live veterinary vaccines.[1,2] The principal *Brucella* spp. affecting humans are *B. melitensis*, from sheep, goats, camels, and sometimes cattle; *B. abortus*, from cattle, buffalo, camels, and yaks; *B. suis*, from pigs; and rarely *B. canis*, from dogs. Although rare or controlled in countries such as the UK brucellosis remains a problem in many areas, including eastern Europe, the Mediterranean region, South and Central America, Mexico, the Caribbean, the Indian subcontinent, parts of Africa and Asia, and the Middle East.

Symptoms usually develop 2 to 8 weeks after infection and resemble a flu-like illness with anorexia, fever, headache, lethargy, malaise, depression, myalgia and back pain, sweating, and weakness. Laboratory findings include anaemia, leucopenia, lymphocytosis, pancytopenia, and thrombocytopenia. Brucellosis may be acute, relapsing, or chronic (disease duration of more than 1 year) and can affect any part of the body, including joints (peripheral arthritis, sacroiliitis, and spondylitis), heart (endocarditis), liver (hepatitis), the CNS (meningitis, encephalitis, meningoencephalitis, meningovascular disease, brain abscesses, and demyelinating syndrome), and the reproductive system (epididymo-orchitis). Relapses occur in about 10% of patients, usually in the first year after infection, and typically cause milder symptoms.[3]

Treatment of brucellosis shortens the duration of illness, and reduces complications and the risk of relapse. Tetracyclines, although highly active against *Brucella* spp., are associated with high relapse rates when given as monotherapy and therefore combination therapy is now used. Common regimens are: doxycycline and rifampicin both orally for at least 6 weeks;[4,5] doxycycline orally for 6 weeks with a parenteral aminoglycoside (streptomycin,[6,7] gentamicin,[5,8,9] or netilmicin[10]) for the first 1 to 2 weeks. Fewer relapses have been reported with doxycycline and streptomycin than with doxycycline and rifampicin, perhaps due to rifampicin reducing plasma concentrations of doxycycline.[11] Higher relapse rates have been reported with netilmicin than with gentamicin.[10] Studies[12,13] have shown that combination treatment with a fluoroquinolone plus either doxycycline or rifampicin is effective although fluoroquinolone monotherapy is not. A review of the literature on fluoroquinolone-based combination treatment did not support their use as first-line treatment,[13] but they can be considered as part of an alternative regimen for patients who experience relapse or toxicity problems with the usual first-line antibacterials. Co-trimoxazole when used is usually given in triple-drug regimens.[3] A systematic review and meta-analysis[14] of 30 randomised controlled studies on the treatment of brucellosis found that a triple drug regimen of doxycycline, gentamicin, and rifampicin was better than doxycycline plus an aminoglycoside. It also found that 6 weeks of treatment was associated with a lower rate of relapse than treatment regimens of 30 days or less.

Tetracyclines should be avoided in young *children* (usually specified as below 8 years of age in the US and below 12 years in the UK). The preferred regimens for these children appear to be co-trimoxazole with rifampicin both orally for at least 6 weeks or co-trimoxazole orally with parenteral gentamicin for the first 2 weeks.[5,6] Alternative regimens include rifampicin orally for at least 6 weeks with either gentamicin or netilmicin for the first 5 days.[6]

For the treatment of brucellosis during *pregnancy*, WHO recommends rifampicin monotherapy for 6 weeks as the drug of choice and that co-trimoxazole or tetracycline should only be given if rifampicin is unavailable; streptomycin is contra-indicated.[4] Co-trimoxazole with rifampicin for 4 weeks has also been tried.[6]

No one antibacterial combination has been found to be superior for the treatment of *spondylitis* although a 3-month course of doxycycline with ciprofloxacin has been proposed based on an evaluation of the literature.[15] In the treatment of *neurobrucellosis*, the length of therapy appears to be of critical importance; relapses may occur after treatment lasting only 2 to 3 weeks and it is recommended that doxycycline be given with 2 or more other drugs (rifampicin, an aminoglycoside, co-trimoxazole, or ceftriaxone) for several months depending on the response. Corticosteroids are often given but their efficacy is unproven. A similar treatment regimen is used in the management of paediatric neurobrucellosis and a 3-drug regimen (doxycycline, rifampicin, and an aminoglycoside) given for 3 months has been shown to be effective. In young children doxycycline should be replaced with co-trimoxazole.[16] Treatment of *endocarditis* in adults generally requires long-term triple or quadruple drug regimens (a tetracycline, an aminoglycoside, rifampicin, and/or co-trimoxazole) usually with surgical valve replacement.[17,18] Treatment should be continued for 3 months or longer and some recommend the addition of ceftriaxone and/or a fluoroquinolone to reduce the need for surgery. Cardiac complications in children are generally less severe than in adults and treatment with tetracycline for 3 weeks with streptomycin for 2 weeks has been found to be effective.[18]

Brucellosis can be **prevented** by controlling and eliminating infected animals, pasteurising milk products, and vaccinating cattle and other livestock. There is no human vaccine currently available for brucellosis, although many have been tested and some have been available from time to time in various countries.[3]

Campylobacter enteritis

See p.172.

Cat scratch disease

Cat scratch disease usually occurs after a cat scratch or bite. The condition is characterised by regional lymphadenopathy and is often self-limiting, but may be disseminated in immunocompromised patients.

In the 1980s a Gram-negative bacillus presumed to be responsible for cat scratch disease was isolated and subsequently named *Afipia felis.* However, it now appears that *Bartonella henselae* (formerly *Rochalimaea henselae*) is the main cause of cat scratch disease[1] and that *A. felis* causes few, if any, cases, although there is some evidence for a joint role.[2] With uncertainty over aetiology there has been no specific antibacterial therapy and treatment with antibacterials is generally not recommended in patients with mild to moderate infection.[1] There are, however, reports of successful treatment with gentamicin[3] or co-trimoxazole[4] in children and with ciprofloxacin[5] in adults. Azithromycin has also been found to be of benefit in adults[6] and is considered the treatment of choice in both adults and children with extensive lymphadenopathy. Doxycycline with rifampicin may be given as an alternative for these patients and is the recommended treatment for complicated cat scratch disease.[1]

Bacillary angiomatosis, in which both *B. henselae* and *B. quintana*[7] (the causative organism of trench fever) have been implicated, resembles a disseminated form of cat scratch disease but occurs predominantly in HIV-infected patients. Disseminated disease in immunocompromised patients has not responded to ciprofloxacin,[8,9] but has responded to treatment with doxycycline[8-11] or erythromycin[8] or azithromycin. Erythromycin for 3 months is the drug of choice for bacillary angiomatosis; doxycycline may be given as an alternative. Immunocompromised patients with acute, life-threatening infection should be treated with rifampicin plus erythromycin or doxycycline.[1] Care is required in patients with AIDS since the lesions of bacillary angiomatosis closely resemble those of Kaposi's sarcoma, and if the diagnosis is missed, life-saving antibacterial therapy may not be given.[12]

Cellulitis

See under Skin Infections, p.194.

Cervicitis

Gonorrhoea in women occurs mainly as cervicitis, but mucopurulent cervicitis is frequently caused by sexually transmitted *Chlamydia trachomatis*. The two infections often occur together and should be treated concurrently. Guidelines for treatment are given under Gonorrhoea, p.191, and Chlamydial Infections, below.

Chancroid

See under Sexually Transmitted Diseases, p.191

Chlamydial infections

The chlamydia organism belongs to the family Chlamydiaceae. Species that are pathogenic in man are *Chlamydophila pneumoniae*, *Chlamydophila psittaci*, and *Chlamydia trachomatis*; they are generally sensitive to tetracyclines or erythromycin.

C. pneumoniae (formerly classified as a TWAR strain of *C. psittaci*) is a respiratory pathogen. It was first described as a cause of community-acquired pneumonia (see Pneumonia, p.186), but has since been associated with other clinical presentations including pharyngitis (see p.185) and has been implicated in the pathogenesis of ischaemic heart disease (see Atherosclerosis, p.1159).

C. psittaci is transmitted to man from birds and causes psittacosis, which also affects the lungs (see Psittacosis, p.188).

C. trachomatis causes a wide range of diseases. Many are sexually transmitted and the spectrum is similar to that with *Neisseria gonorrhoeae* (see Gonorrhoea, p.191); infections with the two organisms often occur concurrently. In women *C. trachomatis* may cause endometritis, pelvic inflammatory disease, ectopic pregnancy, and infertility. In the USA[1,2] routine screening for *C. trachomatis* infection is recommended in all sexually active women aged 25 years or less, whether or not they are pregnant, and in women aged over 25 years if they are considered to be at increased risk of infection.

Guidelines produced by WHO,[3] by an expert group in the UK,[4] and by the CDC in the USA[2] for the **treatment** of uncomplicated anogenital infection with *C. trachomatis* are as follows:

- **WHO:**
  - oral doxycycline 100 mg twice daily for 7 days, *or*
  - a single oral dose of azithromycin 1 g

  alternatives, given for 7 days, are:
  - oral amoxicillin 500 mg three times daily
  - oral erythromycin 500 mg four times daily
  - oral ofloxacin 300 mg twice daily
  - oral tetracycline 500 mg four times daily
- **UK:**
  - first-line therapy is the same as WHO

  alternatives are:
  - oral erythromycin 500 mg twice daily for 10 to 14 days
  - oral ofloxacin 200 mg twice daily *or* 400 mg once daily for 7 days
- **USA:**
  - first-line therapy is the same as WHO

  alternatives, given for 7 days, are:
  - oral erythromycin 500 mg four times daily
  - oral erythromycin ethylsuccinate 800 mg four times daily
  - oral ofloxacin 300 mg twice daily
  - oral levofloxacin 500 mg once daily

Pregnant women infected with *C. trachomatis* may be at risk of premature rupture of membranes and preterm labour (see Premature Labour, p.188). They may also infect their offspring to cause ophthalmia neonatorum (see Neonatal Conjunctivitis, p.180) or pneumonia (p.186). Infected pregnant women should be treated and the following regimens have been recommended:

- **WHO:** treatment for 7 days with:
  - oral erythromycin 500 mg four times daily *or*
  - oral amoxicillin 500 mg three times daily
- **UK:**
  - as for WHO, *or*
  - oral erythromycin 500 mg twice daily for 14 days, *or*
  - a single oral dose of azithromycin 1 g
- **USA:**
  - a single oral dose of azithromycin 1 g *or*
  - oral amoxicillin 500 mg three times daily for 7 days

  alternatives are:
  - erythromycin-containing regimens

Sexual partners of those infected with *C. trachomatis* should be tested and treated.[2-4]

For further reference to sexually transmitted *C. trachomatis* infections, see under Epididymitis (p.170), Pelvic Inflammatory Disease (p.184), and Urethritis (p.199)

Specific serotypes of *C. trachomatis* are responsible for another sexually transmitted disease, lymphogranuloma venereum (p.192).

Reactive arthritis (see Bone and Joint Infections, p.164) may be secondary to chlamydial infections.

Other *C. trachomatis* infections that are not sexually transmitted include trachoma and inclusion conjunctivitis in adults (see Trachoma, p.196).

Cholera and other vibrio infections

See p.172.

Cystic fibrosis

Cystic fibrosis is a genetic disorder associated with the production of abnormally viscous mucus. The underlying defect is mutation in the gene which codes for cystic fibrosis transmembrane conductance regulator (CFTR), a protein which functions as a chloride channel. Mutations result in defective ion transport with reduced chloride ion secretion and accelerated sodium ion absorption, and related changes in the composition and properties of mucin secreted. Now that patients with cystic fibrosis usually survive into adulthood, it is increasingly seen to be a multisystem disease. However, the main clinical manifestations are still pulmonary disease, with recurrent bacterial infections and the production of copious viscous sputum, and malabsorption due to pancreatic insufficiency. Other complications include male infertility and hepatobiliary disease. There is increased salt loss in sweat.

Pulmonary disease is the major cause of mortality. Cystic fibrosis is an underlying cause of bronchiectasis (chronic dilatation of the bronchi) as a result of excessive secretion of mucus and recurrent infections. Cough and excessive production of sputum are characteristic of cystic fibrosis and the lungs are generally colonised with bacterial pathogens, especially mucoid strains of *Pseudomonas aeruginosa*. Pseudomonal pulmonary infection is the major cause of morbidity and mortality in cystic fibrosis. Monitoring of bacterial pathogens in the sputum, including their sensitivity, is necessary for rational treatment. Apart from *Ps. aeruginosa*, *Staphylococcus aureus* is often present and may be the predominant pathogen in infants. *Burkholderia cepacia* complex (*Pseudomonas cepacia*) has been recognised as a cause of serious lung infection in cystic fibrosis and is readily transmitted by social contact. In a proportion who acquire it, *B. cepacia* has been associated with rapid deterioration and death. Other bacteria isolated include *Haemophilus influenzae* and atypical *Mycobacteria* spp.

Various diagnostic methods are available[1-3] and clinical diagnosis of cystic fibrosis may be confirmed by establishing that chloride concentrations in sweat are raised. This may be done by using the pilocarpine sweat test (see Pilocarpine, p.1885). Identification of gene mutation is possible and may be used for further confirmation of the diagnosis and identification of carrier status.[4] In some areas neonatal screening programs have been instituted, to allow for early intervention.

The reduced morbidity and improved survival in patients with cystic fibrosis are largely due to the management of pulmonary disease with antibacterials and physiotherapy and to nutritional management. Several reviews have discussed both established and experimental therapy.[5-9] Despite the successes, the evidence base for some procedures is scanty,[9] and there may be variations in management between centres. However, the cornerstones of current management are:[8,9]

- mechanical airway clearance, with the use of adjuncts such as dornase alfa and hypertonic saline
- prevention or eradication of pulmonary infections in early disease
- suppression of bacterial load through antibacterial treatment of chronic infection in more advanced disease
- use of ibuprofen or azithromycin to control lung inflammation
- aggressive antibacterial treatment of pulmonary exacerbations
- nutritional support to ensure an adequate intake of calories and salt, with supplementation of pancreatic enzymes and the fat-soluble vitamins A, D, E, and K
- maintaining regular physical activity

Airway clearance by manual chest percussion and mechanical techniques including chest-wall or airway oscillation helps to loosen secretions and aid their removal. Dornase alfa[10] is given by aerosol inhalation and reduces the viscosity of the sputum by breaking down the large quantities of DNA released by degenerating inflammatory cells. The use of dornase alfa has been associated with some improvement in lung function and it might be a useful adjunct to bronchial drainage, although it is unclear whether it prevents the development of progressive lung damage. However, a randomised, multicentre, placebo-controlled study in children showed that dornase alfa maintained lung function and reduced the risk of exacerbations over a period of 96 weeks.[11] Mucolytics such as acetylcysteine are generally not considered to be effective in cystic fibrosis.[12] Inhalation of hypertonic saline has, however, been shown to be of benefit (see p.1687) and has become part of management in many centres.[8,9] The time required for such therapies and their associated monitoring may prove challenging to patients and their families.[8]

In young patients with early disease, **prevention or eradication of infection** for as long as possible is a reasonable aim, in order to maintain good lung function.[9] Staphylococcal infections commonly develop during the first decade of life, and some clinicians start antistaphylococcal antibacterials on diagnosis of cystic fibrosis. Others wait until the first clinical infection occurs before starting treatment. Once started, antistaphylococcal therapy is continued indefinitely in some centres, while others only treat when symptomatic exacerbations or positive sputum cultures occur. Systematic reviews confirmed that antistaphylococcal treatment is effective and also concluded that prophylaxis is likely to be beneficial in young children with cystic fibrosis.[13,14] In the UK, flucloxacillin or co-amoxiclav are commonly given.[9] It is unclear whether intermittent or continuous therapy produces the best clinical outcome. Other potential disadvantages to prophylaxis are the possible early acquisition of *Ps. aeruginosa* infection[15] (this seems to be a risk mainly if broad spectrum cephalosporins are given) and an increased incidence of drug-resistant staphylococci with continuous therapy.[16]

Management of **chronic infection** is aimed at control of bacterial load,[9] since permanent eradication is impossible. Selection of an antibacterial must be individualised, and will depend on the infecting organisms,[9] and local prescribing policies and availability. Long-term intermittent treatment with inhaled antibacterials, particularly tobramycin, is favoured;[8,9,17,18] other nebulised antibacterials that may be of benefit include aztreonam and colistin.[8,19] A systematic review confirmed that inhaled antipseudomonal antibacterials improved lung function and reduced the frequency of exacerbations.[20] Although there is some evidence of an increase in resistance with such treatment,[20] it is claimed to be less frequent than feared.[8] In contrast, oral antipseudomonal therapy has not been conclusively shown to be of benefit in chronic infection,[21] and is generally avoided because of fears of resistance.[8]

The macrolide azithromycin is, however, used orally in chronic infection, but may be acting as an immunomodulator to **reduce inflammation** rather than specifically as an antibacterial.[8,9,22] A systematic review[23] on the use of macrolides in cystic fibrosis found evidence of a small but significant improvement in respiratory function at 6 months with azithromycin compared with placebo; the role of other macrolides was unclear. A small anti-inflammatory benefit has also been reported from treatment with high-dose oral ibuprofen,[24] and this is used in some centres, particularly in the USA.[9] However, there are some concerns about the potential for adverse effects; it has been recommended that if used, such therapy be stopped in patients who require intravenous aminoglycosides, and should be avoided in those with gastrointestinal risk factors.[24] There is no evidence supporting a role for corticosteroid therapy,[25,26] except in the management of patients who develop allergic bronchopulmonary aspergillosis.[9]

Aggressive **management of exacerbations** with appropriate antibacterials is crucial.[8,9,27,28] Treatment should be based on recent culture results, but there appears to be no additional value in combination antibacterial sensitivity testing.[29] In patients with *Ps. aeruginosa* infection a combination of intravenous antibacterials, typically an aminoglycoside such as tobramycin and a beta-lactam with antipseudomonal activity such as ceftazidime, is favoured.[27,28,30] Once-daily dosing with the aminoglycoside is as effective as giving it in divided doses, and may be associated with less nephrotoxicity in children.[31] High doses are necessary because of the poor penetration of these antipseudomonal antibacterials into the site of infection and their increased renal clearance in patients with cystic fibrosis.[32,33] Treatment is generally given for 2 to 3 weeks although there is no good evidence to support a particular length of therapy.[34] Intermittent elective intravenous therapy has become more practical with the development of regimens that enable patients to be treated at home.[30,35]

Infection with *B. cepacia* complex is difficult to treat because the majority of antipseudomonal antibacterials are not effective. Co-trimoxazole has been suggested[36] and can be given orally;[28] meropenem and ceftazidime have some *in-vitro* activity, and temocillin has been tried.[28] Other problems may include meticillin-resistant *Staph. aureus* infections; intravenous teicoplanin has been used, as have oral doxycycline or linezolid where sensitivity patterns permit.[28] The possibility of fungal or viral infections should also be considered.[28]

Nutritional management of cystic fibrosis should ensure adequate calorie intake from a balanced diet in order to counteract malabsorption due to pancreatic insufficiency and the increased metabolic requirements of patients with cystic fibrosis.[37,38] Supplements of the fat-soluble vitamins A, D, and E, and sometimes vitamin K, may be necessary. Investigation of bone mineral density[39] and direct assessment of vitamin status[40] suggest that current supplements may be inadequate. Pancreatic enzymes, as pancreatin or pancrelipase, are taken before or with each meal or snack.[41]

Many **other interventions** have been tried.[42,43]

Bronchodilators including both beta agonists and antimuscarinics may be useful in selected patients although there are few meaningful clinical trial results.[44] A therapeutic trial is often justified in individual patients since it is difficult to predict which patients will respond.[42] While use by nebuliser is regarded as most effective, inhalers may be more practical where compatibility with other nebulised drugs could be a problem.[43] Alpha$_1$-proteinase inhibitor, the main inhibitor of neutrophil elastase in the lung has also been investigated[45] as has pentoxifylline,[46] a drug with anticytokine activity.

Experimental treatment aimed at modifying the pulmonary disease process has also included ion transport therapy. This involves the use of aerosolised drugs that either inhibit sodium ion absorption across airway epithelia (for example the sodium channel blocker amiloride) or induce chloride ion secretion. However, nebulised amiloride was not found to be a useful adjunct in patients on optimal treatment.[47]

In patients with severe lung disease, oxygen therapy may give some relief of symptoms but its effect on mortality and morbidity is uncertain.[48] At present the only available treatment for patients with end stage pulmonary disease is lung transplantation. Although individuals with cystic fibrosis do as well as those referred for transplantation with other lung diseases, the 5-year survival rate after the procedure is reported to be only 50%.[8]

Somatic **gene therapy** represents the nearest approach to a cure for cystic fibrosis.[49] It aims to introduce the normal CFTR gene sequence into cells of affected tissue. Most effort has been directed at gene delivery to the lungs using adenovirus vectors or liposomes, but results have been variable.[50-53] Difficulties encountered include inefficient gene transfer, immunity to viral vectors, and a systemic inflammatory reaction provoked by plasmid DNA.[4] For a discussion of the general principles of gene therapy, see p.2310.

Diarrhoea, infective

See Gastro-enteritis, p.171.

Diphtheria

Diphtheria is caused by infection, usually of the upper respiratory tract or the skin, with the Gram-positive aerobe *Corynebacterium diphtheriae*. It occurs worldwide and, despite the effectiveness of immunisation (see Diphtheria Vaccines, p.2209), is still common in parts of the world, including the tropics. Although the risk to travellers is said to be low, diphtheria should be considered in patients returning from endemic areas with a sore throat.

The most serious manifestations of infection are due to exotoxin produced by toxigenic strains and thus treatment is primarily with diphtheria antitoxin. Erythromycin or benzylpenicillin are also given to eliminate *C. diphtheriae*, thereby terminating toxin production and preventing the spread of infection to contacts. Close contacts of primary cases of diphtheria may be given a 7-day prophylactic course of erythromycin orally or a single intramuscular dose of benzylpenicillin,[1] in addition to boosters or primary immunisation with diphtheria vaccine. Non-toxigenic *C. diphtheriae* is the most common isolate in clinical cases in the UK[1,2] and generally causes a less severe form of the disease; it does, however, have the potential to cause invasive disease in some patients.[3]

Asymptomatic carriers may harbour non-toxigenic strains of *C. diphtheriae* that can be converted to toxigenic strains. A single intramuscular injection of benzathine benzylpenicillin has been less effective than oral erythromycin, but may be used if compliance is uncertain;[4] clindamycin for 7 days by mouth has also eliminated the carrier state,[4] but erythromycin remains the drug of choice. Bacteriological follow-up should be carried out 2 weeks after completing treatment to be certain *C. diphtheriae* has been eradicated from carriers.[5]

Ear infections

See Otitis Externa, and Otitis Media, p.182.

Ehrlichiosis

Ehrlichioses are a group of diseases produced by infection with rickettsia-like bacteria of the family Anaplasmataceae, a family that contains the genera *Anaplasma*, *Ehrlichia*, *Neorickettsia*, and *Wolbachia*. At one time such organisms were considered to be only animal pathogens but it is now recognised that humans may also become infected. One of the earliest human forms of ehrlichiosis identified was Sennetsu fever, a disease found in Japan and Malaysia, and which is caused by *N. sennetsu* (*E. sennetsu*). Subsequently *Anaplasma phagocytophilum* (*E. phagocytophila*), *E. chaffeensis*, *E. ewingii*, and possibly *E. canis* have emerged as tick-borne human pathogens.

E. chaffeensis mainly infects mononuclear cells and in humans the resulting disease is commonly called human monocytic (or monocytotropic) ehrlichiosis (HME) whereas *A. phagocytophilum* mainly infects granulocytes and in humans produces human granulocytic (or granulocytotropic) ehrlichiosis (HGE), now also known as human granulocytic anaplasmosis (HGA). *E. ewingii* and *E. canis* mainly infect granulocytes and mononuclear cells respectively.

Some patients with HGA may also be co-infected with *Borrelia burgdorferi*, the cause of Lyme disease, and/or *Babesia microti*, the cause of babesiosis, as they are all transmitted by tick bites from the same *Ixodes* spp. For details on the treatment of patients with HGA co-infected with Lyme disease, see p.177.

Human ehrlichiosis is characterised by fever, headache, myalgia, and malaise. Laboratory findings include leucopenia, thrombocytopenia, and elevated liver enzymes.[1,2] Symptoms more commonly seen in patients with HME are gastrointestinal disturbances, cough, confusion, and skin rash. HME is a relatively severe infection and patients may require hospitalisation for complications such as acute respiratory distress, coagulopathy, hepatitis, hepatic failure, meningoencephalitis, acute renal failure, and shock. Fulminant infections may give rise to other opportunistic infections, particularly in immunocompromised patients. Fatalities have been reported in 2 to 3% of patients with HME. Clinical symptoms of infections with *E. ewingii* or *A. phagocytophilum* are generally similar to those of *E. chaffeensis*[3,4] although usually less severe. Cough, confusion, and skin rash have not been seen with infections caused by *E. ewingii* and most cases have been diagnosed in immunocompromised patients; no deaths have been reported. HGA is generally a mild, self-limiting disease, but may be severe in about 5 to 7% of patients and reported fatalities are less than 1%. Most severe cases have been diagnosed in immunocompromised patients. Skin rash, gastrointestinal and respiratory disturbances, and CNS involvement are less frequent with HGA.[1]

Prompt **treatment** is recommended due to the potential for serious complications. Treatment for all infections is with a tetracycline, preferably doxycycline, given for 7 to 10 days or for at least 3 days after the patient has become afebrile. Chloramphenicol has been used as an alternative for HME, although its efficacy is controversial and it should not be considered as a first-line treatment.[1,5] It is also not effective against *A. phagocytophilum in vitro*. Despite the known adverse effects of doxycycline in children, the American Academy of Pediatrics[6] and the Infectious Diseases Society of America (IDSA)[7] state that a shortened course may be given to those who are less than 8 years of age who are severely ill and not co-infected with Lyme disease; the dose is 4 mg/kg daily in two divided doses and should be given for at least 3 days after the patient has become afebrile (a total of about 5 to 10 days). Successful treatment of HGA with rifampicin has been reported in pregnancy (gestational age of 10 to 36 weeks)[8] and in 2 children with non-life-threatening infection.[9] The IDSA[7] recommends that patients with mild disease who cannot be given a tetracycline may be given rifampicin 300 mg twice daily for 7 to 10 days; children may be given 10 mg/kg twice daily. Antibacterial susceptibility testing has suggested that rifamycins and fluoroquinolones are promising alternatives in the treatment of HGA.[10]

Endocarditis

Infective endocarditis is an infection of the endocardium after invasion of the bloodstream by bacteria or fungi, and particularly affects the heart valves. Infection has traditionally been classified as acute or subacute; however, changes in the clinical spectrum of infection have meant that some now prefer to classify it into the categories:[1]

- native-valve endocarditis (often associated with congenital or chronic rheumatic heart disease, and classically due to streptococci although cases due to staphylococcal infection are increasingly frequent)
- prosthetic valve endocarditis (which may occur early, within 60 days of surgery, which is often due to staphylococci, or late, in which case it is often due to streptococci or more exotic organisms such as the HACEK group)
- endocarditis in intravenous drug users (usually associated with infection by skin pathogens, especially *Staphylococcus aureus*)
- nosocomial endocarditis (related to catheter implantation or other invasive medical or surgical procedures; it is usually due to staphylococci or enterococci and has a high mortality rate). An increasing incidence is also seen in patients undergoing haemodialysis

Treatment of infective endocarditis is essential, as infection can result in heart failure, embolisation and infarction of major organs, and death. Diagnosis is often difficult as many of the symptoms (which include fever, malaise, headache, petechiae, and splinter haemorrhages under the nails) are nonspecific. A set of diagnostic criteria known as the Duke criteria have been developed, and some modifications subsequently proposed.[2] The Duke criteria identify endocarditis primarily on the basis of microbiological data (blood culture of the infecting organism) and anatomical lesions of the valves (identified by echocardiography or the development of new valvular regurgitation); minor criteria such as development of fever, or presence of predisposing conditions such as heart defects or intravenous drug use, are also considered.[2]

Virtually any organism can cause endocarditis but streptococci, enterococci, and staphylococci continue to be major culprits.

- Among the commonest causes are the alpha-haemolytic *streptococci* originating mainly from the mouth and throat; they have been called viridans streptococci or even '*Streptococcus viridans*' (although this is not a true species) and include *Str. mitis*, *Str. mutans*, *Str. oralis*, *Str. salivarius*, and *Str. sanguis*. Other streptococci originate in the gut and include *Str. bovis*.
- Also increasingly common is endocarditis due to *staphylococci* such as *Staphylococcus aureus*, a common cause in intravenous drug abusers, but endocarditis may also be caused by coagulase-negative *staphylococci*, particularly *Staph. lugdunensis*. Prosthetic valve infection is often caused by *Staph. epidermidis* or other staphylococci.
- *Enterococci* (faecal streptococci) originate in the gut and include *Enterococcus faecalis* and, to a lesser extent, *E. faecium*. Endocarditis due to any of these bacteria is commonly subacute or insidious.

Less common causes of endocarditis include:[3]

- Gram-negative bacteria such as the Enterobacteriaceae and
- *Pseudomonas* spp.
- the HACEK group of slow-growing organisms (*Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, *Kingella*)
- the rickettsia *Coxiella burnetii* (the cause of Q fever, p.188)
- *Bartonella* spp. (also formerly classified as rickettsia)
- fungi such as *Candida* and *Aspergillus* (see p.519).

Guidelines for the treatment and prophylaxis of endocarditis have been issued by bodies in many countries. Although some common principles can be identified, recommendations must be localised because of differences in patterns of infection and drug resistance, variations in the availability of antibacterials and local policies for their use, and differences in medical practice. Countries also vary in the degree to which such guidelines are accepted in practice.

Endocarditis treatment.

Treatment of endocarditis relies on prompt identification of the infecting organisms and their sensitivity to antibacterials. Three sets of blood cultures, each from a separate venepuncture, should be taken before antimicrobial treatment is started; MICs for the causative organism should be measured. As already mentioned, guidelines vary,[4-8] but in general:

- a microbicidal antibacterial, or combination of antibacterials, should be used for treatment; many regimens are based on a beta-lactam or glycopeptide plus an aminoglycoside
- treatment should be given at high doses, and by the intravenous route
- except in the most sensitive infections, treatment should be given for at least 4 weeks (or at least 6 weeks if the patient has prosthetic valves or other prosthetic material implanted in the heart)
- ideally, it is preferable to wait for the results of blood culture before starting therapy; however, empirical treatment is given to patients presenting with acute or severe disease
- associated complications such as heart failure should be managed appropriately; management may include referral for early surgical intervention

If *empirical treatment* is to be given until the laboratory results are known, then it is most likely to be with gentamicin plus benzylpenicillin.[4-6] An isoxazolyl penicillin (cloxacillin, dicloxacillin, flucloxacillin, or oxacillin) may be added, or used instead of benzylpenicillin, in more severe or acute presentations. Vancomycin is likely to be the antibacterial of choice in penicillin-allergic patients requiring empirical treatment,[5] and may be used empirically with an aminoglycoside in patients with prosthetic valves or where penicillin resistance is suspected.[4,6] (UK guidelines also add rifampicin in these situations.[6])

Once the causative organism and its antibiotic susceptibility have been identified, appropriate *pathogen-directed* therapy may be begun.

- **Streptococcal endocarditis**. Streptococci vary in their susceptibility to penicillin, and guidelines generally divide regimens according to whether the organism is of low, intermediate, or high penicillin resistance, although at what MIC these categories are defined varies between guidelines.

  For uncomplicated cases of infection with the most *penicillin sensitive streptococci*, benzylpenicillin may be used, with or without gentamicin.[4-8] Typically, if used alone in native-valve infection it would be given for 4 weeks, whereas the combination regimen is given only for 2 weeks.[6-8] Indicative doses would be 1.2 to 2.4 g of benzylpenicillin every 4 hours, and gentamicin 1 mg/kg every 8 hours. Ceftriaxone or vancomycin may be considered as an alternative,[6] although these are more often given to treat less sensitive strains, or in patients unable to tolerate penicillin.

  For *streptococci less sensitive to penicillin* benzylpenicillin may be given as above but for 4 to 6 weeks,[4,6,7] usually with gentamicin for at least the first 2 weeks. Alternatively, 4 weeks of treatment with ceftriaxone or vancomycin may be considered.[6-8] Typical doses are 2 g daily of ceftriaxone as a single injection, or 30 mg/kg of vancomycin daily (up to a usual maximum of 2 g daily), in 2 divided doses.

  For *penicillin resistant streptococci* treatment is similar to that for enterococcal endocarditis.[6,7] A combination of vancomycin and gentamicin may be given for 4 to 6 weeks. Streptomycin is a possible alternative to gentamicin for *gentamicin resistant* isolates.[6]

  For *streptococci in penicillin-allergic patients*, vancomycin for 4 to 6 weeks may be given; UK guidelines advise 4 weeks of treatment combined with gentamicin for the first 2 weeks.[6] Teicoplanin, typically in doses of 6 to 10 mg/kg daily (higher loading doses should be given initially to establish a suitable trough concentration) is a possible alternative to vancomycin.[6] Some patients may tolerate ceftriaxone.[4]

  For patients with *prosthetic valve endocarditis*, a regimen similar to that for less sensitive streptococci (above) has been suggested, given for at least 6 weeks.[6-8]

- **Staphylococcal endocarditis**. The treatment of staphylococcal endocarditis is based on the use of an isoxazolyl penicillin or a glycopeptide. In contrast to streptococcal or enterococcal endocarditis, the benefits of adding an aminoglycoside are uncertain, and guidelines differ in whether they recommend this. Combination therapy is recommended where prosthetic valves or other intracardiac prostheses are present.

  For *meticillin sensitive staphylococci*, typically cloxacillin, dicloxacillin, or flucloxacillin is given in a dose of 2 g every 4 to 6 hours for at least 4 weeks.[4-8] Some guidelines continue to recommend addition of gentamicin for the first 3 to 5 days of therapy.[7,8] Patients with right-sided endocarditis due to intravenous drug abuse may respond to shorter courses of 2 weeks of combination therapy with an isoxazolyl penicillin plus gentamicin.[4,6-8]

  For *staphylococci resistant to meticillin/oxacillin*, vancomycin may be given alone for 6 weeks,[4,7,8] or with rifampicin or perhaps gentamicin or sodium fusidate (depending on sensitivity) for at least 4 weeks.[5-8] Such combinations may also be appropriate in patients with *penicillin allergy*. Teicoplanin should not be used as the reported incidence of treatment failure is unacceptably high.[6]

  For *staphylococcal endocarditis in the presence of intracardiac prostheses* either an isoxazolyl penicillin or vancomycin may be used with rifampicin or gentamicin or both; an indicative regimen might be intravenous doses of 2 g of the penicillin every 4 to 6 hours, or 1 g of vancomycin every 12 hours, plus rifampicin 300 mg by mouth every 8 hours, both given for 6 to 8 weeks, plus gentamicin 1 mg/kg intravenously every 8 hours for the first 2 weeks.[6-8] Gentamicin may be given for the entire period of treatment if the infection is due to more recalcitrant strains of meticillin-resistant *Staph. aureus* or coagulase-negative staphylococci.[6]

- **Enterococcal endocarditis**. Treatment of enterococcal endocarditis is based on combinations of an aminoglycoside with another antibacterial, usually a beta lactam or a glycopeptide, depending on the sensitivity of the isolated organism.

  For *gentamicin sensitive, penicillin sensitive enterococci*: intravenous bolus injections of ampicillin or amoxicillin 2 g (or benzylpenicillin 2.4 g) every 4 hours and gentamicin 1 mg/kg every 8 or 12 hours, both given for at least 4 weeks.[4,6,8]

  If the patient is *allergic to penicillin*, or the isolate is *penicillin resistant but gentamicin sensitive*, then a combination of vancomycin or teicoplanin with gentamicin may be given for at least 4 weeks.[6-8]

  For *enterococci with high level gentamicin resistance*, a penicillin as above may be used with streptomycin 7.5 mg/kg twice daily (intramuscularly or intravenously) for at least 4 weeks.[6,8] If there is also *penicillin resistance*, or the patient is *penicillin allergic*, streptomycin as above may be given with vancomycin or teicoplanin.[6] If streptomycin cannot be used then treatment should be given for at least 8 weeks.[6]

  Endocarditis due to *multiply resistant enterococci* not susceptible to penicillin, gentamicin, or vancomycin, is still infrequent and there seem to be no established regimens; options may include the use of linezolid or quinupristin/dalfopristin where available.[6,8] A combination of ampicillin with ceftriaxone or imipenem-cilastatin, given for at least 8 weeks, has been suggested for multiply resistant *E. faecalis* infection in US guidelines.[8]

- **HACEK endocarditis**. The HACEK organisms are slow and difficult to culture and treatment must often, therefore, be empirical. Traditionally, treatment for this group of organisms was based on ampicillin and gentamicin. However, because of the emergence of beta-lactamase producing strains, empirical treatment is now based on beta-lactamase-stable cephalosporins.

  Preferred treatment for native-valve endocarditis due to HACEK organisms is therefore with intramuscular or intravenous ceftriaxone (usually in a dose of 2 g once daily) for 4 weeks,[4,6-8] although cefotaxime[4] or other third-generation cephalosporin may be used instead. UK guidelines recommend addition of gentamicin for the first 2 weeks of therapy.[6] Alternatively, if the isolate is penicillin sensitive, ampicillin plus 2 weeks of gentamicin,[6] or ampicillin-sulbactam[8] have been suggested. US guidelines consider that a fluoroquinolone such as ciprofloxacin for 4 weeks, by mouth or intravenously, may also be effective.[8]

- **Endocarditis due to other organisms**. Treatment of endocarditis due to other organisms depends greatly on the organism and its susceptibility; early surgery is often required. For endocarditis due to *Pseudomonas* spp. a combination of an antipseudomonal beta-lactam with tobramycin has been suggested.[5,7] Endocarditis associated with the intracellular pathogen *Coxiella burnetii* requires very prolonged therapy with doxycycline,[6,7] in combination with rifampicin[7] or a fluoroquinolone such as ciprofloxacin.[6] Regimens suggested for *Bartonella* endocarditis have included a penicillin or ceftriaxone in combination with gentamicin, or doxycycline plus gentamicin.[6,8] For other potential causes of culture-negative endocarditis, empirical treatment with a penicillin or vancomycin plus gentamicin, sometimes in combination with a third antibiotic such as rifampicin or ciprofloxacin, has been suggested.[4,7,8]

Endocarditis prophylaxis.

Because of the potentially severe consequences of endocarditis, prophylaxis is widely practised in patients considered to be at increased risk when they are exposed to procedures likely to produce bacteraemia, although much of the evidence to support the practice is circumstantial and the benefits and risks therefore hard to calculate. Patients who have been considered to be at risk of developing endocarditis include those with:[4,7,9]

- acquired valvular heart disease
- congenital heart disease, including septal defects, tetralogy of Fallot, or aortic stenosis
- hypertrophic cardiomyopathy
- mitral valve prolapse with valvular regurgitation
- prosthetic valves or shunts
- a history of endocarditis

Traditionally, these groups have been subdivided into those at moderate and high risk, but some guidelines no longer make such a distinction.

As for treatment, guidelines have been periodically issued to guide the selection of antibacterials for prophylaxis before various procedures in patients at risk.[4,7,9-11] Procedures that have been thought likely to produce bacteraemia and therefore to require prophylactic treatment include any dental intervention likely to cause bleeding, other oral or upper-respiratory tract operations such as tonsillectomy, certain gastrointestinal procedures such as sclerotherapy for oesophageal varices or biliary-tract surgery, and some urinary-tract surgery.[4,7,9] Whether prophylaxis is truly needed before dental procedures is a subject of controversy. US guidelines[10] recommend antibacterial prophylaxis only for dental procedures that involve manipulation of gingival tissues or periapical region of teeth, or perforation of oral mucosa in patients considered to be at the highest risk of developing adverse outcomes from endocarditis (such as those with a history of infective endocarditis, cardiac valve replacement surgery, or some patients with congenital heart disease). US guidelines also recommend antibacterial prophylaxis for high-risk patients for procedures on respiratory tract or infected skin, skin structures, or musculoskeletal tissue, but do not recommend prophylaxis for genitourinary or gastrointestinal tract procedures. Similar recommendations were made in the UK by the British Society for Antimicrobial Chemotherapy in 2006[9] but subsequent guidelines issued by NICE[11] and adopted by the *BNF* essentially abolished the requirement for standard antibacterial prophylaxis in any procedure.

Antibacterial prophylaxis is aimed mainly at viridans streptococci and HACEK organisms before dental, oral, respiratory, and oesophageal procedures, and at enterococci, *Strep. bovis*, and the Enterobacteriaceae before gastrointestinal and genito-urinary procedures.[7] Drugs should be given in a regimen that assures adequate blood concentrations throughout the procedure. They are generally given as a single dose before the procedure, sometimes repeated about 6 hours later; the oral route is used if possible.

- A penicillin such as amoxicillin is the basis for prophylactic therapy, typically in a single dose of 2 to 3 g by mouth or 1 to 2 g intravenously.[4,7,9,10] For *dental* procedures it may be replaced, in patients allergic to penicillin or who have received more than a single dose in the previous month, by clindamycin 600 mg orally or 300 to 600 mg intravenously, or by azithromycin 500 mg orally. All oral drugs should be given 1 hour before the procedure.[4,7,9,10]

- For *gastrointestinal* or *genito-urinary* procedures the penicillin is usually combined with a single dose of gentamicin 1.5 or 2 mg/kg intravenously or intramuscularly before the procedure; a second dose of amoxicillin (typically half the initial dose) may be given after 6 hours. In patients allergic to penicillin, or who have received more than a single dose of penicillin in the previous month, amoxicillin may be substituted with an infusion of 1 g of vancomycin over 1 to 2 hours before the procedure, or injection of 400 mg of teicoplanin immediately beforehand.[4,7,9]
- For *nasal packing and intubation* flucloxacillin 1 g intravenously is given; in penicillin allergic patients clindamycin 600 mg intravenously may be used.[9]
- For *infected skin, skin structure, or musculoskeletal tissue* procedures a penicillin such as amoxicillin is usually given in a single oral or intravenous dose of 2 g, or a cephalosporin such as cefalexin is given in a single oral dose of 2 g. Vancomycin or clindamycin may be given to patients allergic to penicillin or who are known or suspected of having an infection caused by a meticillin-resistant strain of staphylococcus.[10]

Endometritis

Endometritis (or endomyometritis) is a uterine infection that may be a part of pelvic inflammatory disease (p.184) or may be a postoperative complication of caesarean section.

Antibacterial prophylaxis may be given at caesarean section after cord clamping to prevent postpartum endometritis as well as wound infection. While the use of antimicrobial prophylaxis in patients at high risk of infection is well established, prophylaxis in low-risk patients remains controversial. A systematic literature review[1] has shown prophylaxis to be beneficial after both elective and non-elective caesarean section, but USA surgical guidelines do not recommend routine prophylaxis in low-risk patients.[2] A penicillin or first-generation cephalosporin such as cefazolin is often used.[2]

Early postpartum endometritis has a polymicrobial aetiology. In one study the most common organisms isolated included *Gardnerella vaginalis*, *Peptococcus* spp., *Bacteroides* spp., *Staphylococcus epidermidis*, group B streptococci, and *Ureaplasma urealyticum*.[3] *Chlamydia trachomatis* has been implicated more often in late postpartum endometritis, but a wide variety of micro-organisms may also be responsible including genital mycoplasmas and, to a lesser extent, facultative and anaerobic bacteria.[4]

In the USA, standard empirical therapy for postpartum endometritis has been a short course of intravenous antibacterials, often clindamycin with gentamicin, given until the patient has been afebrile and asymptomatic for 24 to 48 hours and sometimes followed by a course of oral treatment, often amoxicillin. A systematic review[5] has confirmed the suitability of clindamycin with gentamicin and indicated that oral therapy is not necessary after successful intravenous therapy. It may, however, be recommended in patients with staphylococcal bacteraemia.[2]

Enterococcal infections

Enterococcal infections are causing increasing concern, particularly with the emergence of drug-resistant strains.[1-6] Enterococci, principally *Enterococcus faecalis* (formerly *Streptococcus faecalis*) but also *E. faecium* and *E. avium*, can cause infections including those of the biliary tract and urinary tract, endocarditis, and peritonitis. Since they are frequently present in the gut flora they are a common cause of nosocomial infections. Enterococci are resistant to cephalosporins, tetracyclines, macrolides, and chloramphenicol. The emergence of resistance to gentamicin, penicillins, and the glycopeptide antimicrobials vancomycin and teicoplanin has compromised the previously standard treatment for enterococcal infections of a penicillin or glycopeptide with gentamicin. Further therapeutic options have more recently emerged with the development of linezolid, daptomycin, tigecycline, and quinupristin/dalfopristin for the treatment of vancomycin-resistant enterococcal infections,[7] although the latter is active against *E. faecium* but not against *E. faecalis.* There has, however, been a report of enterococcal resistance to linezolid.[8] In general, there can be no recommendations for treatment at present and the choice of antibacterial should be made according to local patterns of resistance and antibacterial sensitivity tests. The lack of effective antibacterials has placed emphasis on measures to prevent the spread of vancomycin-resistant enterococci.[9]

Epididymitis

Epididymitis is often associated with urethritis, and in young men (less than 35 years) occurs most commonly as a complication of sexually transmitted infection with *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, but may occur in homosexual males as a result of infection with enteric organisms, particularly *Escherichia coli*.

In men over 35 years and in children, epididymitis is not usually sexually transmitted but generally results from bacteriuria secondary to urinary-tract infection with *Pseudomonas aeruginosa* and other Gram-negative bacilli, urinary-tract instrumentation or surgery, systemic disease, or immunosuppression.

Guidelines produced by WHO,[1] by an expert group in the UK,[2] and by the CDC in the USA[3] for the **treatment** of epididymitis are as follows, although recommendations may need to be localised because of differences in patterns of infection and drug resistance:

- **WHO:**
  for chlamydial epididymitis:
  - oral doxycycline 100 mg twice daily for 7 days, *or*
  - a single dose of oral azithromycin 1 g

  alternatives, given for 7 days, are:
  - oral amoxicillin 500 mg three times daily
  - oral erythromycin 500 mg four times daily
  - oral ofloxacin 300 mg twice daily
  - oral tetracycline 500 mg four times daily

  Unless it can be excluded, patients should also be treated concurrently for gonorrhoea (p.191).
- **UK:**
  for probable chlamydial infections or infections with other non-gonococcal, non-enteric organisms:
  - oral doxycycline 100 mg twice daily for 10 to 14 days is recommended

  for infections with enteric organisms:
  - oral ofloxacin 200 mg twice daily for 14 days, *or*
  - oral ciprofloxacin 500 mg twice daily for 10 days

  for disease most probably due to gonococcal infection:
  - a single intramuscular dose of ceftriaxone 250 mg, *or*
  - a single oral dose of ciprofloxacin 500 mg *plus* oral doxycycline 100 mg twice daily for 10 to 14 days

  in patients allergic to cephalosporins and/or tetracyclines infections from all causes may be treated with:
  - oral ofloxacin 200 mg twice daily for 14 days
- **USA:** empirical treatment recommended:
  likely cause gonococcal or chlamydial infection:
  - a single intramuscular dose of ceftriaxone 250 mg *plus* oral doxycycline 100 mg twice daily for 10 days

  likely cause an enteric organism *or* in patients allergic to cephalosporins and/or tetracyclines:
  - oral ofloxacin 300 mg twice daily for 10 days, *or*
  - oral levofloxacin 500 mg once daily for 10 days

Sexual contacts should also be treated if epididymitis is caused by a sexually transmitted pathogen.[2,3]

Patients co-infected with HIV should receive the same treatment as those who are HIV-negative.[3]

Epiglottitis

In acute epiglottitis rapid swelling of the epiglottis and surrounding soft tissues results in sudden airway obstruction which can be fatal. It is often due to bacteraemic infection with *Haemophilus influenzae* type b (see p.174) and has occurred mainly in young children, although the incidence has decreased in this age group since the introduction of Haemophilus influenzae vaccine.[1] Acute epiglottitis also occurs in adults.[1]

Treatment and prophylaxis is similar to that for Haemophilus influenzae meningitis (see under Meningitis, p.178). Immediate management includes the maintenance of an adequate airway and the intravenous use of antibacterials active against *H. influenzae* type b. Chloramphenicol has been the drug of choice, but third-generation cephalosporins such as cefotaxime and ceftriaxone are increasingly used.[2,3] Prophylaxis with rifampicin may be given to index cases and contacts.

Escherichia coli enteritis

See p.173.

Eye infections

Conjunctivitis is a common superficial eye disorder and may be caused by infection with bacteria, viruses, or, less often, fungi. Acute bacterial conjunctivitis is often caused by staphylococci or streptococci in adults, and *Haemophilus influenzae* and *Moraxella catarrhalis* (*Branhamella catarrhalis*) in children. Other causes of bacterial conjunctivitis include gonococci (see Gonorrhoea, p.191) and *Chlamydia trachomatis* (see Trachoma, p.196). Neonatal chlamydial and gonococcal conjunctivitis are discussed under Neonatal Conjunctivitis, p.180. Uncomplicated bacterial conjunctivitis may be self-limiting but empirical treatment with topical antibacterials is often given. In the UK, topical chloramphenicol remains the treatment of choice despite concerns over the potential risk of aplastic anaemia (see Ocular Use under Precautions of Chloramphenicol, p.240). Alternatives include gentamicin, tobramycin, erythromycin (especially when infection with Gram-positive organisms is suspected), fluoroquinolones including ciprofloxacin and ofloxacin, framycetin, fusidic acid (especially for staphylococcal infections), and polymyxin B in combination with bacitracin, trimethoprim, or neomycin.

Blepharitis is an infection of the lid margins. It usually presents as a chronic condition and may require prolonged treatment, typically involving local hygiene to remove encrustations and topical application of a broad-spectrum antibacterial ointment.

Keratitis may be caused by infection of the cornea by bacteria, fungi, viruses, or protozoa, usually after trauma to the surface of the eye, including that due to contact lens wear (see Contact Lens Care, p.1622). Common bacterial pathogens include staphylococci, streptococci, *Pseudomonas* spp., and Enterobacteriaceae. Bacterial keratitis is potentially sight-threatening and requires prompt aggressive treatment with broad-spectrum antibacterials. It is customary to obtain material for sensitivity testing, but increasingly, empirical treatment is then begun without delay. Frequent or continuous topical application of drops or the use of local drug delivery devices have been used to ensure prolonged elevated drug concentrations. Subconjunctival or systemic therapy may occasionally be necessary. Topical treatment with cefazolin and either gentamicin or tobramycin has traditionally been used when *Pseudomonas* is not suspected. More recently, fluoroquinolones or ceftazidime have been used, and semisynthetic penicillins or vancomycin are other alternatives. For the treatment of Acanthamoeba keratitis, see p.822.

Endophthalmitis is a devastating ocular disease resulting from infection of the ocular cavity, usually after penetrating trauma or surgery. Depending on the route of infection, causative organisms often include staphylococci, streptococci, *H. influenzae*, *Bacillus cereus*, and *Propionibacterium acnes*. Fungal infections occur less commonly. Bacterial endophthalmitis requires immediate aggressive treatment with antibacterials, usually given intravitreally. The value of concurrent parenteral antibacterials is unclear. The choice of antibacterial for intravitreal use depends on the most likely pathogen. Third-generation cephalosporins or vancomycin are used, but aminoglycosides may produce retinal toxicity. Clindamycin may be effective if *B. cereus* is suspected. Adjunctive treatment includes vitrectomy, surgical removal of infected lens structures, and corticosteroids to control inflammatory and immune responses.

For a discussion of fungal infections of the eye, see p.519; for cytomegalovirus retinitis and ocular herpes simplex infections, see under Cytomegalovirus Infections, p.853, and Herpes Simplex Infections, p.854, respectively.

Gas gangrene

Clostridium spp. are anaerobic Gram-positive bacteria some of which cause gas gangrene with muscle necrosis and systemic toxicity as a result of toxin formation. *Cl. perfringens* is the species most frequently responsible. Gas gangrene is usually associated with traumatic or surgical wounds. The main treatment is surgical debridement of all necrotic muscle and large doses of benzylpenicillin. Alternative antibacterials have included clindamycin, metronidazole, imipenem, a tetracycline, or chloramphenicol. Hyperbaric oxygen is used as an adjunct to surgical debridement. Gas-gangrene antitoxins are rarely used nowadays.

Benzylpenicillin is also recommended as prophylaxis against gas gangrene in patients undergoing high amputations of lower limbs or after major trauma; metronidazole is an alternative in patients allergic to penicillin.

Gastro-enteritis

Diarrhoea is a symptom of simple gastro-enteritis and of most intestinal infections. It is a major problem in developing countries, but is common worldwide. Although viruses are often responsible, the severest forms of infectious diarrhoea are generally those due to bacteria. Common bacterial pathogens include *Campylobacter jejuni*, *Escherichia coli*, *Salmonella enteritidis*, *Shigella* spp., *Vibrio cholerae*, and *Yersinia enterocolitica*. Intestinal protozoa also cause diarrhoea and are important in AIDS-associated diarrhoea. For discussions of viral and protozoal gastro-enteritis and their treatment, see p.850 and p.824, respectively.

In acute diarrhoea (p.1694) of any aetiology the priority is to maintain hydration by prevention or treatment of fluid and electrolyte depletion, especially in infants and the elderly. Acute, watery diarrhoea caused by non-invasive pathogens is usually self-limiting and may be treated conservatively. Inflammatory diarrhoea, predominantly caused by invasive pathogens and affecting the colon, often requires treatment with antibacterials. Guidelines published in the UK[1] recommended that empirical treatment of acute diarrhoea with antibacterials should be reserved for patients with symptoms suggesting infection with invasive pathogens and those at high risk of complications. Similarly antibacterial treatment was considered appropriate in tropical regions for diarrhoea due to invasive but not non-invasive organisms.[2] Nevertheless, some clinicians consider such an approach to be unnecessarily conservative in adults with severe acute diarrhoea in developed countries[3] in whom empirical treatment with fluoroquinolones can relieve symptoms and shorten the illness without significant adverse effects. In the USA, empirical therapy is considered for any patients in whom a bacterial cause is suspected; stool samples should be obtained for identification of the causative organism.[4]

In **infants and children** oral rehydration therapy is universally recognised as appropriate initial treatment of acute diarrhoea, but it has been underutilised in both developed and developing countries.[2,5,6] Nutritional support and management of secondary complications, including systemic infections, is also particularly important in this age group.[2] Antibacterials have little place in management in most cases and their inappropriate use has contributed to a high prevalence of resistance in commensal bacteria.[5] WHO[6,7] has stipulated that antibacterials should only be used in children with acute diarrhoea when there is dysentery or suspected cholera; *Shigella* is the most important cause of dysentery in young children. Giardiasis and amoebiasis should also be treated. WHO emphasised[6] that oral preparations containing streptomycin or dihydrostreptomycin, neomycin, halogenated hydroxyquinolines, or nonabsorbable sulfonamides (sulfaguanidine, succinylsulfathiazole, phthalylsulfathiazole) should not be used.

Persistent or prolonged diarrhoea may not have an infective cause and antibacterial treatment should not be started unless a pathogen can be identified. **Tropical sprue**, a syndrome characterised by malabsorption often presenting as chronic diarrhoea, is believed to have an infective component and may respond to tetracycline, although this may be less effective in indigenous populations than in expatriates.[2]

HIV-associated diarrhoea. Diarrhoea is common in HIV infection and AIDS (p.856) and causative organisms may be bacterial, protozoal, or viral. The most common bacterial cause is the *Mycobacterium avium* complex (see Nontuberculous Mycobacterial Infections, p.181); others include *Campylobacter*, *Salmonella*, and *Shigella* spp. Supportive care and appropriate conventional antibacterial therapy may be adequate, as described under the specific infections, below.

'Food poisoning' is generally a self-limiting form of gastro-enteritis, although serious outbreaks of foodborne illness have been associated with bacteria such as *Salmonella enteritidis*. Other common food-poisoning organisms include *Listeria monocytogenes*, *Campylobacter* spp., *Yersinia enterocolitica*, *Vibrio parahaemolyticus*, and *E. coli*. An enterotoxin is responsible for food poisoning associated with *Staphylococcus aureus*, *Clostridium* spp., and *Bacillus* spp.[8,9]

Travellers' diarrhoea. Acute diarrhoea associated with travel occurs worldwide. The most common bacterial pathogen is enterotoxigenic *E. coli*, although enteroadherent *E. coli* is also sometimes involved. Other bacteria include *Campylobacter jejuni*, *Salmonella* and *Shigella* spp., *Vibrio cholerae*, and non-cholera vibrios such as *V. parahaemolyticus*. Viruses and the protozoa *Giardia intestinalis*, *Entamoeba histolytica*, and *Cryptosporidium* may also be responsible. Recommendations for the management of travellers' diarrhoea are published by national and international bodies including WHO, the Department of Health in the UK, and the Centers for Disease Control in the USA. Clinical features depend on the pathogen responsible and treatment varies according to severity and duration of diarrhoea. Onset of diarrhoea is generally delayed with *Giardia* and *Entamoeba* because of the incubation period. Diarrhoea is often mild and self-limiting and increased fluid intake or oral rehydration therapy is usually all that will be required. Symptomatic treatment with antimotility drugs such as loperamide may be of benefit in mild to moderate diarrhoea. Bismuth salicylate may be used to reduce the frequency of diarrhoea. Although antimicrobial therapy is not indicated in most cases of infective diarrhoea, empirical treatment with a fluoroquinolone has been effective for moderate to severe attacks. Co-trimoxazole has also been used, but its use is restricted by its toxicity and increasingly widespread bacterial resistance is of concern. When the infecting bacteria are known, specific therapy may be necessary, as described below.

The risk of developing travellers' diarrhoea can be reduced by avoiding possibly contaminated foods as embodied in the advice to '***cook it, boil it, peel it, or forget it***'. Prophylactic drug regimens have been suggested, including various antibacterials, usually a fluoroquinolone or co-trimoxazole, in addition to bismuth salicylate. However, routine antimicrobial prophylaxis is not generally recommended because of the danger of drug reactions, superinfections, and increasing bacterial resistance; it should be reserved for those at special risk.[10] Many authorities prefer early treatment, including self-medication, with clear instructions on when medical help should be sought.

Antibiotic-associated colitis. Although other organisms, including *Candida* spp.,[1] have been implicated in antibiotic-associated diarrhoea, colonisation of the colon with *Clostridium difficile*, a toxin-producing Gram-positive anaerobe, is the most common identifiable cause of antibiotic-associated colitis and pseudomembranous colitis. Restrictive antibacterial policies have decreased the incidence of *Cl. difficile*-associated diarrhoea in some hospitals[2] but it remains a major hazard of antibacterial use. Antibiotic-associated colitis has been associated with the use of most antibacterials, but particularly with clindamycin, lincomycin, ampicillin, amoxicillin, and cephalosporins and, less frequently, with fluoroquinolones, tetracycline, carbapenems, and trimethoprim. The diarrhoea may be mild and self-limiting or debilitating and persistent and can be life-threatening. Although the diarrhoea generally resolves within a few days of stopping the offending drug, together with fluid and electrolyte replacement, early specific antibacterial therapy should be given to patients with severe illness characterised by high fever, marked abdominal pain, and marked leucocytosis and to elderly, toxic, or debilitated patients, or those unresponsive to supportive therapy.[3,4] Antibacterials are probably unnecessary in mild disease.[5] Antidiarrhoeal drugs should be avoided since they may aggravate the condition and may occasionally increase the possibility of toxic megacolon.[3]

Vancomycin or metronidazole are widely used when antibacterial treatment is necessary.[3,4,6,7] Metronidazole tends to be the drug of first choice and vancomycin is reserved for those who do not respond to, or who cannot tolerate, metronidazole, for those who are severely immunocompromised, and for those with severe illness.[3,4,6-8] This view is also endorsed by expert bodies in the USA whose aim is to provide guidelines for preventing the spread of vancomycin resistance.[9] Metronidazole can be given orally or intravenously as appropriate. Vancomycin is only given orally; it should not be given intravenously since it does not give rise to adequate concentrations of the drug in the bowel lumen.[3] The severity of the diarrhoea often decreases within 48 to 72 hours, but may not stop for a week or more. Treatment is usually continued for 10 days.[6] Relapses are quite common,[8] but usually respond to re-treatment with vancomycin or metronidazole.[3,8]

Other drugs that have been investigated in the treatment of antibiotic-associated colitis include teicoplanin,[10-12] fusidic acid,[12,13] and bacitracin,[14] although experience with their use remains limited. A systematic review[5] found that metronidazole, bacitracin, rifaximin, nitazoxanide, or fusidic acid seemed to be as effective as vancomycin in terms of symptomatic cure, and teicoplanin might be slightly more effective. Bacitracin and fusidic acid seemed to be less effective than vancomycin in terms of bacteriological cure and resolution.[5] Ramoplanin and tiacumicin B (OPT-80) have also been investigated.[7]

The anion-exchange resins colestyramine and colestipol hydrochloride have been shown to bind the *Cl. difficile* toxin *in vitro*, and colestyramine has been used to treat pseudomembranous colitis.[15] The use of vancomycin together with colestyramine has been suggested,[16] but the value of the combination is uncertain. In general, the use of colestyramine is not recommended.[6] An experimental toxin-binding polymer, tolevamer has also been investigated.[7]

Oral immunoglobulin A, used with vancomycin, was effective in controlling severe diarrhoea in a child who had not responded to other therapies.[17] Normal immunoglobulin given intravenously was also effective when added to vancomycin and metronidazole therapy in 2 elderly patients unresponsive to antibacterials alone.[18] Vaccines against *C. difficile* have also been investigated.[7]

Treatment and prevention strategies aimed at colonising the gut with non-pathogenic organisms have included use of lactic-acid-producing organisms such as *Lactobacillus*,[4,19] and the yeasts *Saccharomyces boulardii*,[4] and *S. cerevisiae*.[20]

Campylobacter enteritis. *Campylobacter jejuni* is a major cause of acute diarrhoea. *C. coli* is less common and *C. upsaliensis* has more recently been identified as an enteropathogen.[1,2] Food is a common source of infection.[3,4] In the UK, several sources are responsible[5] including contaminated food and water and one important source is from doorstep deliveries of foil-topped bottled milk that have been pecked by birds.[5-7]

The macrolides erythromycin or azithromycin are of benefit[8] in severely affected patients, but the infection is usually self-limiting and fluid and electrolyte replacement is generally sufficient. A fluoroquinolone, a tetracycline, or gentamicin may be alternative antimicrobials.[8] Treatment with erythromycin can eradicate the organism from the faeces,[9-11] but may not reduce the duration of symptoms unless treatment is started early in the course of the disease.[9-11] Some strains of *Campylobacter* are resistant to erythromycin,[12] and resistance is also an increasing problem with ciprofloxacin.[13,14] Multiple drug resistance has been reported.[15,16]

Severe systemic infections with *C. fetus* require parenteral therapy with a third-generation cephalosporin or gentamicin,[8] depending on susceptibility.

There is some evidence of an association between *C. jejuni* infection and the Guillain-Barré syndrome.[17,18]

Cholera and other vibrio infections. Cholera results from infection with the enterotoxin-producing Gram-negative bacillus *Vibrio cholerae* which causes acute secretory diarrhoea. It can be associated with two serogroups of *V. cholerae*, O1 and O139. Serogroup O1 can then be divided into two biotypes (classical and El Tor) and each of these has three serotypes (Inaba, Ogawa, and Hikojima). The seventh pandemic[1-6] began in 1961 in South East Asia, and reached South America in January 1991. This pandemic is caused by *V. cholerae* O1 biotype El Tor. In late 1992 and 1993 epidemic cholera caused by *V. cholerae* O139 was reported in India and Bangladesh and subsequently identified in Thailand and other Asian countries. *V. cholerae* O139 became the dominant strain in India in less than 2 months and some workers declared it responsible for the eighth cholera pandemic.[2] However, there was some evidence that by 1994 it was abating and that by 1996 O1 was again the prevalent type in India and Bangladesh. There appears to be no cross-immunity between O1 and the O139 serogroup.

Individuals can reduce the risk of contracting cholera by good personal hygiene, avoiding possibly contaminated foodstuffs, and by boiling or otherwise disinfecting drinking water. Methods of preventing or containing cholera epidemics include ensuring a safe water supply, providing good sanitation, and promoting safe handling and preparation of foods. Mass chemoprophylaxis, vaccination, and travel and trade restrictions are not effective[7] although oral vaccines show more promise.

Most cases of vibrio gastro-enteritis are mild to moderate and generally require no therapy other than fluid and electrolyte replacement with an appropriate oral rehydration solution (see Diarrhoea, p.1694). Patients with severe gastro-enteritis, dehydration, and shock should receive vigorous fluid replacement, preferably intravenously.[8] Antimicrobial therapy has been shown to decrease the duration and volume of diarrhoea in cholera and may also decrease the duration of other vibrio diarrhoeas.[9] WHO recommends a single dose of doxycycline as the treatment of choice for adults except pregnant women. Tetracycline, ciprofloxacin, co-trimoxazole, furazolidone, erythromycin, and chloramphenicol are alternatives, with furazolidone being preferred for pregnant women and erythromycin for children. Recommendations from the USA for adults specify a tetracycline as the first choice with co-trimoxazole or a fluoroquinolone such as ciprofloxacin as alternatives.[10] One study has suggested that single-dose ciprofloxacin might be preferred to doxycycline, particularly in areas of tetracycline resistance,[11] and in Bangladesh, ampicillin has been found to be as effective as either erythromycin or tetracycline[12] and may be a useful alternative in children. Studies[13-15] in Bangladesh and India found single-dose azithromycin to be effective in children and adults. The O139 strain is reported to be sensitive to ciprofloxacin,[16] erythromycin,[16] and tetracyclines,[2] but resistant to co-trimoxazole.[2] There has also been some resistance to furazolidone.[2] Multiple drug resistance may be a problem; differing sensitivity and resistance patterns have been reported for the 2 biotypes classical and El Tor *V. cholerae*.[17] The outbreak strain in Rwandan refugees was resistant to tetracycline, doxycycline, co-trimoxazole, chloramphenicol, and ampicillin.[2]

Mass chemoprophylaxis is not recommended but may be justified for household contacts,[1,18] especially those at high risk because of age or pregnancy.[1] The type of cholera vaccines traditionally available are not very effective although promising results have been reported with the use of oral vaccines in areas where cholera is endemic.

Marine or halophilic *Vibrio* spp. known to cause gastro-enteritis include *V. parahaemolyticus* which is responsible for food poisoning from raw or undercooked seafood, especially in Japan.[19,20] Another halophilic sp., *V. vulnificus*, is increasingly associated with wound infection and septicaemia.[19] On the basis of *in-vitro* sensitivity testing[21] and anecdotal clinical experience, empirical therapy with aminoglycosides, ceftazidime, imipenem, or ciprofloxacin should all be effective.[22]

Escherichia coli enteritis. *Escherichia coli* is a normal intestinal commensal and member of the Gram-negative family of bacteria the Enterobacteriaceae. Pathogenic strains causing distinct syndromes of diarrhoeal disease and also associated with foodborne illness include: enteropathogenic *E. coli* (EPEC)—an important cause of infantile diarrhoea in many developing countries; enteroinvasive *E. coli* (EIEC)—producing an invasive type of diarrhoea resembling that of *Shigella* dysentery; enterotoxigenic *E. coli* (ETEC)—an important cause of travellers' diarrhoea (see Gastro-enteritis, above); and enterohaemorrhagic *E. coli* (EHEC)—associated with haemorrhagic colitis, haemolytic-uraemic syndrome, and thrombotic thrombocytopenic purpura.[1] Enteroadherent *E. coli* (EAEC) is a cause of chronic diarrhoea in young children.[2]

Although these organisms are generally sensitive to a wide range of antibacterials only special categories of *E. coli* diarrhoea should be treated.[2]

Neonates with severe EPEC diarrhoea have been given oral non-absorbable antibacterials such as neomycin or gentamicin although in older children or adults this diarrhoea may be self-limiting.[2] Evidence for the efficacy of neomycin is largely limited to uncontrolled studies.[3] However, improvement with antibacterials has been noted beyond the neonatal period;[4] EPEC infection has been reported to be a common treatable cause of life-threatening *chronic* diarrhoea in infancy, possibly associated with travel to a developing country.[5] Symptoms could become persistent and life-threatening in previously healthy infants, requiring intravenous rehydration and parenteral antibacterials such as gentamicin and penicillin.[5]

Vero cytotoxin-producing strains of EHEC (VTEC; Shiga toxin producing *E. coli*; STEC), in particular serotype O157, have been associated with bloody diarrhoea, haemorrhagic colitis, and haemolytic-uraemic syndrome.[6,7] Children and the elderly are at greater risk of severe disease,[6] but the illness is usually self-limiting.[7] Cases have generally been linked with the consumption of foods derived from cattle, especially undercooked beef and unpasteurised milk, although there have been outbreaks associated with the consumption of fresh vegetables and unpasteurised juices, probably as a result of faecal contamination. Person-to-person spread is also common, and direct spread from infected animals may occur. *E. coli* O157 has also been reported as a cause of epidemic haemorrhagic colitis in Africa, where it may be difficult to distinguish from shigellosis.[8,9] Treatment is generally supportive, including correcting and maintaining the fluid and electrolyte balance.[7] Antibacterial treatment is controversial and there is uncertainty as to whether it influences the course of enterohaemorrhagic *E. coli* infection and the development of haemolytic-uraemic syndrome[10] or thrombotic thrombocytopenic purpura;[6,7,11] the non-antibacterial treatment of these two latter complications is discussed in Plasma, under Thrombotic Microangiopathies, p.1076. Oral preparations of Vero cytotoxin-binding resins are under investigation.

Necrotising enterocolitis. Necrotising enterocolitis in the newborn is thought to result from hypoxia or ischaemic injury to the intestinal mucosa with subsequent infection. Bacteria implicated in the disease include *Pseudomonas*, *Escherichia coli*, *Klebsiella*, *Salmonella* spp., and *Clostridium* spp. Treatment involves suspension of oral feeding, intravenous fluid therapy, and surgical excision of the affected gut. References to the use of oral vancomycin for the treatment[1] of neonatal necrotising enterocolitis indicate that it may be of benefit. In a comparison of intravenous regimens to treat the condition it was reported that ampicillin with gentamicin appeared as effective as vancomycin with cefotaxime in neonates over 2.2 kg birth-weight, but in smaller neonates results were better with vancomycin and cefotaxime.[2] A systematic review has concluded that prophylactic oral antibacterials might well reduce the incidence of necrotising enterocolitis in low birth-weight or preterm infants in a high-risk environment,[3] but there are concerns about adverse outcomes, and prophylactic use (particularly of vancomycin) is not generally recommended because of the risk of inducing resistance. It has been suggested[4] that oral immunoglobulins may prevent necrotising enterocolitis in low-birth-weight infants; however, a systematic review[5] concluded that the available evidence did not support this claim. There is, however, some evidence[6] of the value of probiotics in this group. Supplementation with arginine has also been investigated,[7] but there is insufficient evidence to determine its value.

Necrotising enteritis in older children and adults, known as pigbel, has been attributed to toxins produced by *Clostridium perfringens*. Both sporadic and epidemic forms are mainly seen in the highlands of Papua New Guinea, but sporadic cases have been reported elsewhere. Treatment is supportive with surgical intervention where necessary. A vaccine is available for prophylaxis.

Salmonella enteritis. *Salmonella* spp. are Gram-negative bacteria belonging to the Enterobacteriaceae family. They can be divided into those causing enteric fever, namely *S. typhi* and *S. paratyphi*, where infection is systemic although affecting the gastrointestinal tract (see under Typhoid and Paratyphoid Fever, p.198) and non-typhoid *Salmonella*, including *S. enteritidis* and *S. typhimurium* which cause acute gastro-enteritis, usually through food poisoning. There are numerous *Salmonella* serotypes identified with food poisoning and they have often been named according to the place where they were first isolated. The increase in salmonellosis in Great Britain has been almost entirely due to *S. enteritidis*[1] and this reflects an increase internationally.[2] Non-typhoid *Salmonella* spp. can cause invasive salmonellosis which may present as septicaemia or localised infections such as meningitis or osteomyelitis.

Uncomplicated non-typhoid *Salmonella* enteritis is usually managed by fluid and electrolyte replacement. Antibacterial therapy produces no clinical benefit in uncomplicated *Salmonella* enteritis[3] and may prolong *Salmonella* detection in stools.[3] Attempts to eradicate the carrier state with antibacterial therapy (for example fluoroquinolones) appear to have been unsuccessful so far[4] and routine use is not recommended.[5] Patients with underlying debility or evidence of invasive salmonellosis should be given antibacterial therapy. Amoxicillin, ampicillin, or co-trimoxazole have been suggested[6,7] as have trimethoprim, ceftriaxone,[7] azithromycin,[7] a fluoroquinolone[7] such as ciprofloxacin,[8] or chloramphenicol.[7] However, there is concern over the emergence of resistant strains, particularly to the fluoroquinolones.[9,10] Resistance to cephalosporins has also been recognised.[11,12] Multiresistant R-type strains of *S. typhimurium* DT 104 (another common cause of *Salmonella* enteritis in the UK) have severely limited the treatment options for infections with this organism.[13-16]

Shigellosis. Shigellosis (bacillary dysentery) is an enteric infection caused by the *Shigella* spp. *S. dysenteriae*, *S. flexneri*, *S. boydii*, or *S. sonnei*. They are Gram-negative bacteria belonging to the Enterobacteriaceae family and are able to invade the colon. Depending on the species involved, the disease ranges from mild self-limiting secretory diarrhoea to severe colitis and dysentery with blood and mucus in the stools. *S. dysenteriae* is the most common in the developing world and causes the most severe disease. In developed countries *S. flexneri* and *S. sonnei* are more common. Some *S. flexneri* can cause severe colitis and toxic dilatation of the colon has been reported in travellers.[1] *S. sonnei* is the least pathogenic of the species.

As with any form of diarrhoea, rehydration is the key to treatment.[2] Antibacterial therapy may be with ampicillin (amoxicillin appears to be less effective), co-trimoxazole (or trimethoprim), nalidixic acid, or fluoroquinolones such as ciprofloxacin, but will depend on the prevailing resistance patterns (see below) and the severity of the disease. Bacterial resistance is common and some consider that antibacterials should be restricted to the most severe cases, particularly those due to *S. dysenteriae*;[3] in the UK, the Public Health Laboratory Services (PHLS) Working Group has concluded that therapy is seldom indicated for *S. sonnei* infections.[4] WHO[5] has advised that children with *Shigella* dysentery should be given antimicrobial therapy and recommended co-trimoxazole as treatment of choice with nalidixic acid or ampicillin as alternatives; it was noted that resistance to ampicillin is frequent.[6]

The rapid development of resistance and the emergence of multiresistant strains of *Shigella*, particularly in developing countries, has led to some changes in treatment recommendations.[6] In 1992, nalidixic acid had become the preferred drug in developing countries unless ampicillin or co-trimoxazole were known to be effective in the region.[7] For *S. dysenteriae* it might be necessary to use pivmecillinam. It was concluded that the fluoroquinolones should continue to be reserved for infections resistant to nalidixic acid or pivmecillinam.[7] Reduced susceptibility to fluoroquinolones of some strains of *S. sonnei* has been reported from Japan,[8] and fluoroquinolone-resistant *S. dysenteriae* has been reported.[2] Fluoroquinolones are generally not used in children, although a study[9] in Bangladesh has used ciprofloxacin in children with shigellosis and found it to be of similar efficacy to pivmecillinam. In studies from Israel, the third-generation cephalosporins ceftriaxone[10] or cefixime[11] were more effective than ampicillin or co-trimoxazole, respectively, in children with shigellosis. Other studies in adults in Bangladesh found cefixime to be ineffective compared with pivmecillinam[12] and azithromycin to be effective, although slightly less so, than ciprofloxacin.[13] Rifaximin has also been investigated.[2]

Vitamin A may be a useful adjunct to treatment, especially in children in developing countries (see Diarrhoea, under Vitamin A, p.1973).

Oral shigella vaccines are being studied for prophylaxis.

Yersinia enteritis. *Yersinia enterocolitica* is a Gram-negative bacteria of the Enterobacteriaceae family and the species most commonly responsible for yersiniosis. The predominant form of infection is an enteric illness with or without mesenteric adenitis[1] although clinical manifestations can range from self-limited enterocolitis to potentially fatal systemic infection, and post-infection complications can include erythema nodosum and reactive arthritis.[2] *Y. enterocolitica* is a recognised foodborne pathogen[3] and in some temperate countries rivals *Salmonella* and exceeds *Shigella* as a cause of acute gastro-enteritis; pigs are a major reservoir. Increased susceptibility to *Yersinia* infection has occurred in patients with iron overload treated with desferrioxamine (see p.1440).

Isolates of *Y. enterocolitica* are reported to be susceptible to co-trimoxazole, aminoglycosides, chloramphenicol, tetracycline, third-generation cephalosporins, and quinolones *in vitro*.[1,2] As with any form of diarrhoea, rehydration is the key to treatment and most forms of mild uncomplicated enteritis do not require antibacterial treatment. There has been no general consensus concerning the antibacterial of choice when treatment becomes necessary: as with many other enteric infections there is a lack of good clinical evidence. Drugs with good intracellular activity such as trimethoprim, co-trimoxazole, tetracycline, chloramphenicol, or fluoroquinolones may be preferred.[1] Doxycycline or co-trimoxazole have been recommended[2] for complicated gastrointestinal and focal extra-intestinal infections or doxycycline and an aminoglycoside empirically in bacteraemia. Co-trimoxazole as first choice or alternatively a fluoroquinolone, an aminoglycoside, or cefotaxime have also been recommended.[4] A patient with chronic *Yersinia* infection who responded well to tetracycline or co-trimoxazole, but relapsed on withdrawal, was treated successfully with ciprofloxacin.[5]

See under Sexually Transmitted Diseases, p.192.

Haemophilus influenzae infections

Haemophilus influenzae is a Gram-negative bacterium that colonises the upper respiratory tract in the majority of healthy people. Most are carriers of non-encapsulated strains, but a small proportion carry *H. influenzae* type b, the commonest encapsulated strain. Serious invasive infections have usually been caused by type b strains and have occurred mainly in young children. They include the bacteraemic diseases meningitis, pneumonia, epiglottitis, cellulitis, and arthritis. Non-encapsulated strains commonly cause otitis media, sinusitis, and conjunctivitis and infect patients with chronic bronchitis. However, they too can cause invasive infections such as pneumonia, septicaemia, and meningitis and, with the introduction of *H. influenzae* type b vaccines, non-encapsulated strains may be responsible for a greater proportion of invasive *H. influenzae* disease.

For further details of these infections and their management, see under the specific disease side-headings.

Ampicillin and chloramphenicol have been the antibacterials of choice against *H. influenzae*, but increasing resistance, especially to ampicillin, should be borne in mind; there have been several reports of multiresistant strains.[1-4] Injectable cephalosporins are popular alternatives for multiresistant type b organisms although there is controversy over their effectiveness against fully sensitive strains when compared with ampicillin or chloramphenicol or both; experience has been favourable with cefotaxime and ceftriaxone, but there have been treatment failures in *H. influenzae* meningitis with cefuroxime and there is argument over its efficacy.[5] Meropenem is a further alternative.[6]

For serious *H. influenzae* infections cefotaxime or ceftriaxone are currently preferred. For upper respiratory infections and bronchitis, co-trimoxazole (or trimethoprim in the UK) is preferred; ampicillin, amoxicillin (with or without clavulanic acid), oral second- or third-generation cephalosporins, a tetracycline, a fluoroquinolone, or the macrolides azithromycin or clarithromycin are suggested alternatives.[6]

In the UK, secondary prophylaxis with rifampicin is given after *H. influenzae* type b meningitis (see p.178). A vaccine against *H. influenzae* type b is available and vaccination is included in the infant immunisation schedules in some countries including the UK and USA.

Helicobacter pylori infections

Antibacterial therapy is used to eradicate *Helicobacter pylori* infection in peptic ulcer disease (p.1702) and MALT lymphoma of the stomach (p.657). The role of *H. pylori* and the value of its eradication in dyspepsia (p.1695) and gastro-oesophageal reflux disease (p.1696) is less clear.

Infections in immunocompromised patients

Patients with a defective immune system are at increased risk of infection. Primary immune deficiency is rare, whereas secondary deficiency is more common: immunosuppressive therapy, cancer and its treatment, HIV infection, or splenectomy may all cause neutropenia and impaired humoral and cellular immunity in varying degrees. The risk and severity of infections depends upon the duration of compromised immunity, the degree to which immune function is compromised, whether cellular or humoral functions are affected, and upon breaches in physical barriers, for example due to severe mucositis or prolonged vascular access. Thus patients with profound neutropenia or a history of splenectomy are prone to rapidly progressive and potentially life-threatening infections; those with neutropenia induced by cytotoxic chemotherapy or by preparation for transplantation are particularly vulnerable to acute infections whereas those in whom immunosuppression results from viral infections or congenital defects are at lower risk of acute infections.[1] Patients in whom neutropenia persists for more than 10 days are not only at risk of opportunistic bacterial infections but also susceptible to viral, fungal, and parasitic infections.

Infectious diseases are a major cause of morbidity and mortality in patients with AIDS (see HIV-associated Infections, p.857). Some are due to common pathogens, but others are opportunistic and are caused by normally avirulent commensals. Children with HIV infection appear to be at special risk of serious bacterial infections with common encapsulated bacteria. For further reference to some bacterial infections associated with AIDS, see Gastro-enteritis (p.171), Nontuberculous Mycobacterial Infections (p.181), and Tuberculosis (p.196). Fungal, protozoal, and viral infections which can affect immunocompromised patients are discussed in the relevant chapters under Infections in Immunocompromised Patients, p.520, p.824, and p.859, respectively.

Common causative organisms of unexplained fever in neutropenic patients include the Gram-negative bacteria *Pseudomonas aeruginosa*, *Escherichia coli*, and *Klebsiella* spp. and Gram-positive organisms particularly staphylococci, streptococci, enterococci, and *Corynebacterium* spp. Gram-negative organisms have historically been responsible for most immediate life-threatening infections, but Gram-positive infections are increasing in importance and now predominate in many areas.[1,2] Factors influencing this change include the wider use of selective gut decontamination and of central venous catheters,[3] and possibly the prophylactic use of quinolones.

TREATMENT. Onset of fever in neutropenic patients is indicative of potentially serious infection which may progress to septicaemia and death. The severity of infections depends on numerous factors (see above) and it is therefore difficult to produce a standard drug regimen; in addition, the choice of empirical therapy must be adapted according to prevailing local antibacterial susceptibility patterns. Guidelines have been produced in many countries, of which those issued by the Infectious Diseases Society of America[4] for both the initial and subsequent management of febrile neutropenic patients are fairly typical:

- the patient's risk of life-threatening infection should first be assessed. If the risk is considered high, empirical intravenous antibacterial therapy should be started immediately
- secondly, consideration should be given to whether the patient requires vancomycin therapy. If so, treatment should begin with vancomycin plus cefepime, ceftazidime, or a carbapenem, with or without an aminoglycoside.
- if vancomycin is not indicated, intravenous monotherapy should be given with
  - either a cephalosporin (cefepime, although concerns have been raised about its safety,[5] or ceftazidime) or a carbapenem (imipenem-cilastatin or meropenem) for uncomplicated cases
  - in more complicated cases, or where resistance is a problem, combined treatment should be given with an aminoglycoside and one of cefepime, ceftazidime, a carbapenem, or an antipseudomonal penicillin such as ticarcillin with clavulanic acid or piperacillin with tazobactam.
- low-risk patients may be treated empirically either orally with ciprofloxacin and amoxicillin with clavulanic acid, or intravenously as for uncomplicated cases above. Initial treatment with oral antibacterials alone is, however, not recommended for children[4]

The initial regimen usually needs to be given for 3 to 5 days in order to determine its efficacy. In *patients in whom fever resolves* and in whom a causative organism is identified, antibacterial treatment should be modified for the specific organisms and broad-spectrum antibacterials continued for at least 7 days or until culture results are negative and the patient has clinically recovered.[4] In afebrile patients in whom no causative organism is found but who were considered at high risk at the onset of treatment, the same antibacterials should be continued intravenously; those considered at low risk initially may be switched to oral therapy with ciprofloxacin plus either amoxicillin-clavulanic acid (adults) or cefixime (children).[4]

Patients in whom fever persists throughout the first 3 to 5 days but for whom no aetiology is determined may have a non-bacterial infection, a bacterial infection that is refractory to treatment, the emergence of a second infection, or drug fever.[4] Such patients should be reassessed and then one of three options followed. If the patient's condition is clinically stable, the same antibacterial treatment may be continued; if there is still no change in the patient's condition, consideration should be given to stopping vancomycin if it has been given. Alternatively, if there is evidence of progressive disease or drug toxicity, the antibacterials given may be changed; if vancomycin has not been given, it may be added to the regimen. The third option is to add an antifungal drug (amphotericin B) with or without a change to the antibacterial regimen if the patient is febrile through days 5 to 7 and resolution of neutropenia is not imminent.[4]

The optimum *duration of therapy* is governed by the clinical situation. The most important determinant of successfully stopping antibacterials is the neutrophil count:[4]

- if no infection is identified after day 3, the neutrophil count exceeds 500 cells/mm^3 for 2 consecutive days, and the patient has been afebrile for at least 48 hours, then antibacterial treatment may be stopped
- if neutropenia persists in the absence of fever, it is reasonable to stop antibacterial treatment after 5 to 7 days in patients who were initially considered at low risk and who are clinically well, though such patients should be closely monitored and intravenous antibacterials reinstigated immediately on recurrence of fever or evidence of infection.[4] In afebrile patients with profound neutropenia (less than 100 cells/mm^3), or in those with mucositis or other risk factors, continuous antibacterial treatment should be considered throughout the entire neutropenic period
- in patients with persistent fever and prolonged neutropenia in whom haematological recovery cannot be anticipated, consideration may be given to stopping antibacterials after 2 weeks if no infection has been identified and careful observation is possible.[4]
- clinically well patients with persistent fever may have their antibacterials stopped after 4 to 5 days if the neutrophil count remains at least 500 cells/mm^3 throughout this period and there is no sign of infection and no response to therapy; such patients should be closely monitored for subsequent infections which are usually easily treatable, and empirical amphotericin B should be considered despite cessation of antibacterials if fever persists for 5 to 7 days after the start of initial therapy[4]
- patients who remain febrile after recovery from neutropenia and despite broad-spectrum antibacterials should be reassessed for undiagnosed infection which may be fungal, mycobacterial, or viral

The routine use of colony-stimulating factors as an adjunct to antibacterial treatment is not generally recommended[4] but may be indicated in febrile neutropenic patients at high risk of serious infections or infection-related complications; examples include some patients with malignant neoplasms[6,7] and those with persistent severe neutropenia and infections that are not responsive to antibacterials alone.[4] A systematic review[8] of the use of colony-stimulating factors in patients with febrile neutropenia due to cancer chemotherapy concluded that their use did not affect overall mortality but did reduce time spent in hospital and the neutrophil recovery time.

PROPHYLAXIS. Most infections in immunocompromised patients are caused by organisms from their own alimentary tract and in cancer patients, for example, may follow chemotherapy-induced mucosal damage to the tract. Although antibacterial prophylaxis may be effective in afebrile patients likely to be neutropenic, the efficacy of empirical treatment means that prophylaxis is less widely used[9] and the Infectious Diseases Society of America[4] discourages routine use; reasons include toxicity of the antibacterial, potential fungal overgrowth, and problems of bacterial resistance (see below). Most experience with prophylaxis has been in patients with leukaemia. Possible prophylactic regimens have included selective decontamination of the alimentary tract using oral nonabsorbable antibacterials (see also under Intensive Care, below). Co-trimoxazole has also been widely used.[9] More recently, prophylaxis with fluoroquinolones has been commonly used although, generally, prophylaxis with these drugs has resulted in reduction in Gram-negative but not in Gram-positive infections in immunocompromised patients,[10] and improved morbidity and mortality has not been observed.[11] Combination prophylaxis with fluoroquinolones and phenoxymethylpenicillin[12] or rifampicin[13] has been tried to improve cover against Gram-positive organisms. Nevertheless, concern about the emergence of resistant organisms has led to the recommendation that routine prophylaxis should be avoided.[4]

Immunocompromised patients may benefit from appropriate immunisation against common infections, although precautions relating to the use of live vaccines in such patients should be observed (p.2202).

The duration and severity of neutropenia can be reduced by the use granulocyte or granulocyte-macrophage colony-stimulating factors, and this may be a useful adjunct in infection control in selected patients.[6] Bone marrow protective agents such as amifostine are also being studied.

Intensive care

Like immunocompromised patients (above), those in intensive care units are often very susceptible to endogenous infections, especially respiratory and urinary-tract infections, arising from gastrointestinal colonisation by aerobic Gram-negative bacilli acquired in hospital. Selective digestive tract decontamination (SDD), using oral non-absorbable antibacterial regimens, and selective parenteral and enteral antisepsis regimens (SPEAR), incorporating selective decontamination with systemic antibacterial prophylaxis, have been used in an attempt to prevent colonisation and infection in these high-risk patients, although their effectiveness is debated. SDD has generally not been widely adopted in the USA[1] particularly in relation to prevention of nosocomial pneumonia,[2] although benefit of short-term use may be seen in some patient groups.[3] It may be more effective in surgical patients.[4]

Selective decontamination is achieved by elimination of aerobic, potentially pathogenic, organisms from the throat and intestines while preserving the indigenous, mostly anaerobic, flora.[5,6] Regimens commonly include two or three non-absorbable or poorly absorbed antibacterial drugs, for example colistin, neomycin, norfloxacin, or polymyxin, with an antifungal, usually amphotericin B. The drugs are usually applied topically to the oropharyngeal mucosa in addition to oral or intragastric dosage, although local application to the oropharynx alone is also reported to be effective.[7,8] A parenteral third-generation cephalosporin, usually cefotaxime, may be given for a few days until oral medication takes effect.[9,10] Strict adherence to the protocol is reported to be necessary for maximum efficacy[11] and constant monitoring for the emergence of antimicrobial resistance is considered essential[10,11] although this has rarely been seen in practice.[11,12] However, most regimens have little or no activity against potential Gram-positive pathogens such as *Enterococcus* spp., and so their use may increase the risk for colonisation and infection with these organisms.[13] There is particular concern over the emergence of vancomycin-resistant strains.

Despite numerous clinical studies, many of which have shown a reduction in potential Gram-negative pathogens[9,10,14] and in the incidence of respiratory-tract infections,[7,8] it has been difficult to demonstrate that SDD or SPEAR reduces mortality.[15-18] Although meta-analyses[19,20] of randomised controlled trials concluded that a combination of a systemic and topical antibacterial could be beneficial it has been argued that the effect was largely due to the systemic component of the treatment.[21] It has been suggested[22] that equivalent infection control could be achieved more economically by emphasis on high standards of hygiene and avoidance of histamine H_2-receptor antagonists, which could allow overgrowth of potentially pathogenic bacteria as a result of the change in gastric pH. Oral decontamination with chlorhexidine may be useful in preventing ventilator-associated pneumonia.[23]

Another potential source of infection in intensive care is from the use of **intravascular catheters**. The organisms implicated most frequently have been coagulase-negative staphylococci.[24] Prevention and control of infection depend on good aseptic technique and care of the insertion site, and also catheter design;[24-27] guidelines have been produced in the USA for the prevention of infection.[28] Catheters should be removed as soon as possible (often after 48 to 72 hours for peripheral lines) and any infections treated promptly with antibacterials; vancomycin or teicoplanin are appropriate for empirical treatment provided resistance is not a problem.[24] There have been some favourable results with antibacterial prophylaxis, but such use is discouraged because of concern over the emergence of resistant organisms.[29] Topical antiseptics and antibacterials have produced promising results.[24] Antibacterials could also prove useful in reducing or eliminating colonisation of the catheter lumen[30] and catheters coated with antibacterials[31] or heparin[32] are under investigation. Randomised clinical studies have shown that the use of catheters coated with minocycline and rifampicin[33] or with antiseptics (p.1624) can reduce the risk of systemic infections. Some evidence suggests that catheters impregnated with minocycline and rifampicin are more effective in minimising risk of infection than those coated with chlorhexidine or sulfadiazine silver.[34]

The importance of maintaining high standards of infection control, including handwashing, in intensive care units has been reinforced by the increasing incidence of nosocomial infections that are difficult to treat such as those due to vancomycin-resistant enterococci and *Acinetobacter.* In one such outbreak due to *A. baumannii* some strains were resistant to imipenem and all other antibacterials except polymyxin B and sulbactam.[35] Intensive infection control measures and irrigation of all open wounds with polymyxin B solution were used to eliminate infection and colonisation.

Legionnaires' disease

Legionnaires' disease[1] is a legionella pneumonia caused by the Gram-negative bacterium *Legionella pneumophila*. Serious outbreaks have been associated with infected air-conditioning systems or water supplies. Pontiac fever is a milder, usually self-limiting, flu-like illness also caused by *L. pneumophila* as well as by other *Legionella* spp. Legionellosis has been suggested as a broad term to cover pneumonic and non-pneumonic clinical syndromes caused by any *Legionella* spp., which may include *L. bozemanii, L. micdadei* (Pittsburgh pneumonia agent), and *L. wadsworthii*.

The usual treatment for *Legionella* infections is with a macrolide, with erythromycin now increasingly replaced by azithromycin;[2,3] clarithromycin, roxithromycin, or telithromycin may be further acceptable alternative macrolides.[2,3] Fluoroquinolones are also increasingly recommended as alternatives to the macrolides.[1-3] Doxycycline or co-trimoxazole are further alternatives.[4] Rifampicin has been given in addition to fluoroquinolones or doxycycline, especially in severe or deteriorating illness or in immunocompromised patients, although this may be of little further benefit.[3]

Leprosy

Leprosy (Hansen's disease) is a chronic disease caused by the bacillus, *Mycobacterium leprae*; it has a prolonged incubation period (years) and slow onset of symptoms. Disease results from bacillary infiltration of the peripheral nervous system, skin, eyes, respiratory mucosa, bones, and testes. It is not highly infectious and transmission requires both prolonged close contact with an infected patient and an inherent immunological susceptibility to the disease in the exposed person. Clinical leprosy may be regarded as a consequence of deficient cell-mediated immunity in susceptible individuals; most individuals are naturally immune, and symptoms are suppressed. The clinical manifestations depend on the bacillary load and the host's immune response to the mycobacterium. Patients with leprosy may be classified as having:

- **Multibacillary** (or lepromatous) leprosy, which occurs when cellular immunity is largely deficient, and includes the sub-groups lepromatous (LL), borderline lepromatous (BL), and midborderline leprosy (BB), as well as any other types giving a positive skin smear for acid-fast bacilli. Generally the lepromin test (p.2333) is negative.
- **Paucibacillary** (or tuberculoid) leprosy, which results when cellular immunity is only partially deficient, and includes the sub-groups borderline tuberculoid (BT), tuberculoid (TT), and indeterminate leprosy (I) when the skin smear is negative. Generally the lepromin test is positive.

For the purpose of treatment, WHO classifies patients with more than 5 skin lesions as having multibacillary leprosy, and those with 1 to 5 skin lesions as having paucibacillary leprosy. The use of this clinical classification avoids the necessity to provide facilities for bacteriological examination of skin smears.

Changes in the hosts immune response to the mycobacteria may result in **lepra reactions** and unless treated these may lead to severe nerve and tissue damage.[1] Most reactions belong to one of two main types:

- **Type 1** lepra reactions, or reversal reactions, are caused by spontaneous increases in T-cell reactivity to mycobacterial antigens (type IV hypersensitivity) and occur in patients with borderline forms of leprosy. These reactions are characterised by erythema and oedema of the skin and tenderness of peripheral nerves. Prompt treatment with corticosteroids is necessary to prevent permanent nerve damage.[2-5] Treatment is usually continued for 3 to 6 months. Adding azathioprine may permit the use of lower cumulative doses of corticosteroid.[6] Methotrexate was found to be effective in treating a patient intolerant to corticosteroids,[7] while ciclosporin is considered to be effective for chronic neuritis.[2,8] Prophylactic use of low-dose corticosteroids during the first 4 months of standard multidrug treatment for leprosy has also been investigated, and found to decrease the number of reactional episodes by 75%; but the protective effect was lost by the end of 12 months.[9]
- **Type 2** lepra reactions, also known as erythema nodosum leprosum (ENL), represent a systemic inflammatory response (type III hypersensitivity) to dead bacteria and are accompanied by high levels of circulating tumour necrosis factor alpha (TNFα). This reaction occurs only in patients with borderline lepromatous or lepromatous leprosy. Mild type 2 reactions may be treated with anti-inflammatories but moderate or severe reactions should be treated with corticosteroids or thalidomide (in males and post menopausal women).[2-4] The incidence and severity of ENL has decreased since the inclusion of clofazimine in multidrug regimens, probably owing to the drug's anti-inflammatory action.[2] Clofazimine does not act as rapidly as either corticosteroids or thalidomide, nor is it as effective.[2,3] Other TNFα inhibiting drugs that have been tried include pentoxifylline[5,10] and infliximab.[11] Chloroquine has also been used with limited effect.[1] Antileprotic drug therapy is generally continued during lepra reactions.

Although measures to manage the consequences of nerve damage and lepra reactions are an important part of the management of leprosy, curative antibacterial therapy is the mainstay of **treatment**. Dapsone monotherapy, long the basis of this, has been replaced since the 1980s with multidrug oral regimens designed to overcome the development of resistance. Dapsone, rifampicin, and clofazimine form the elements of the standard combinations.[5,12] Newer alternatives include clarithromycin, minocycline, and fluoroquinolones such as ofloxacin and pefloxacin. These may be used as second-line therapy for patients unable to tolerate dapsone or clofazimine. Ethionamide or protionamide have been used in light-skinned patients to avoid clofazimine's tendency to pigment the skin, but are no longer recommended because of their risk of hepatotoxicity.

The most widely used multidrug regimens are those recommended by WHO[3] and in these the choice of drugs and length of treatment are based on the clinical classification outlined above.

- MULTIBACILLARY LEPROSY

  The standard regimen recommended by WHO for multibacillary leprosy[3,4] is rifampicin 600 mg and clofazimine 300 mg both given once a month, with clofazimine 50 mg and dapsone 100 mg both daily. Treatment is continued for 12 months.[4]

  A 2-year treatment duration was chosen originally because it is highly effective in the majority of cases and avoids the need to assess response with skin smears. However, such a long treatment duration is an obstacle to implementing treatment programmes in areas where healthcare is inaccessible or the infrastructure is poor. Ongoing clinical studies and experience with patients defaulting from treatment have encouraged WHO to now recommend that treatment for 12 months is adequate.[4] Early hopes that reducing duration of treatment to as little as one month would be possible have not been supported by a study using daily rifampicin and ofloxacin.[13]

  In patients for whom rifampicin is unsuitable because of resistance or intolerance, WHO recommends[3] daily treatment with clofazimine 50 mg, ofloxacin 400 mg, and minocycline 100 mg for the first 6 months; treatment is then continued for at least a further 18 months with clofazimine together with either minocycline or ofloxacin.

  When clofazimine cannot be given ofloxacin 400 mg daily or minocycline 100 mg daily may be substituted in the standard regimen.[14]

  Rifampicin 600 mg, ofloxacin 400 mg, and minocycline 100 mg (ROM) given once a month for 24 months was found to be as effective as the WHO standard regimen given for 24 months[15] and has been suggested as an alternative regimen.[3]

- PAUCIBACILLARY LEPROSY

  The WHO recommended regimen[3,4] for paucibacillary leprosy is rifampicin 600 mg monthly and dapsone 100 mg daily. Treatment is continued for 6 months. If there are severe toxic effects with dapsone it should be substituted with clofazimine.[14]

  On the basis of a clinical study[16] showing that a single dose each of rifampicin 600 mg, ofloxacin 400 mg, and minocycline 100 mg given in combination is only slightly less effective than standard multidrug treatment, WHO has suggested that this is a suitable alternative for patients with single-lesion paucibacillary leprosy.[3] However, reservations have been expressed about the study, including concerns regarding the short follow-up[17] and poor microbiological rationale.[18]

- RELAPSE

  Relapse after a recommended course of multidrug therapy for multibacillary or paucibacillary leprosy can occur and WHO recommends re-treatment with the initial regimen.[3,4] Although the relapse rate after standard multidrug therapy for multibacillary leprosy is generally low,[3,19] there is insufficient information on the long-term efficacy of shorter treatment courses.[13]

- PREGNANCY

  Standard multidrug therapy is safe during pregnancy.[4,5] Leprosy patients who are pregnant or breast feeding may experience clinical deterioration and, in general, antileprotic therapy is continued in such patients.

• PROPHYLAXIS

Leprosy is spread from person to person through respiratory droplets, so household contacts may become infected. A systematic review and meta-analysis[20] has concluded that prophylaxis, usually with dapsone, in some household contacts may prevent disease in this high-risk group. A large randomised placebo-controlled study[21] found that a single dose of rifampicin given to contacts of new patients with leprosy significantly reduced the incidence of developing leprosy in the first 2 years but no difference was noted beyond 2 years. WHO[3] suggests that contacts of newly diagnosed cases should be examined for evidence of leprosy and then advised how to watch for early signs of the disease; prophylaxis with rifampicin or other antileprotics is not recommended in leprosy control programmes. BCG vaccine appears to be protective. Vaccines specifically against leprosy are under investigation.

• ELIMINATION

The multidrug therapy regimens recommended by WHO have been widely implemented in recent years raising the possibility of eliminating leprosy as a public health problem: that is, reducing the prevalence to less than 1 case per 10 000 population in endemic areas. Considerable progress towards this target has been made, and it was announced in 2001 that the global level of leprosy had decreased by over 90%. Full control of leprosy, however, has still not been attained in several countries and continued efforts are necessary. WHO has since developed a global strategy for the further reduction of the leprosy burden and sustained leprosy control.[22]

Leptospirosis

Leptospirosis[1] is an infectious disease caused by serovars of the spirochaete *Leptospira interrogans*, the commonest in the UK being *L. hardjo* and *L. icterohaemorrhagiae*.[2] *Leptospira* are widely distributed in wild and domestic animals, including cattle. Rats are a common source of infection in man and transmission is often by contact with water or soil contaminated with infected urine. The main occupational group at risk in the UK has been farmers and agricultural workers, although there have been outbreaks elsewhere among recreational water users such as canoeists.[3] The majority of symptomatic patients have no more than a mild flu-like illness, although a small proportion develop Weil's disease with haemorrhagic complications and severe hepatic and renal impairment.

The use of antibacterials is controversial since many patients recover without treatment. There is insufficient evidence to conclude whether treatment with antibacterials is worthwhile.[4] However, treatment for suspected leptospirosis within 4 to 7 days has been recommended to prevent complications.[5,6] The intravenous use of either benzylpenicillin 900 mg, ampicillin 1 g, or erythromycin 500 mg every 6 hours, or the oral use of amoxicillin 500 mg every 8 hours or doxycycline 100 mg twice daily has been suggested;[6] treatment is continued for 7 days. Benzylpenicillin has been given intravenously in higher doses for severe leptospirosis; 7.2 to 9.6 g daily for 5 days followed by 1.44 g daily for a further 5 days has been advocated.[7] However, intravenous doses of 900 mg every 6 hours for 7 days have proved successful even when given late in the course of illness.[8] Intravenous ceftriaxone 1 g daily,[9] intravenous cefotaxime 1 g every 6 hours (followed by a switch to oral amoxicillin),[10] and intravenous doxycycline given as an initial dose of 200 mg, then 100 mg every 12 hours (followed by a switch to oral doxycycline),[10] each regimen given for a total of 7 days, have also been found to be effective for treatment of severe leptospirosis. In severe infections, supportive therapy with analgesics and antiemetics may be required. Renal function should be monitored and dialysis instigated if necessary, and blood products may be necessary to control haemorrhagic complications.[5]

The incidence of leptospirosis in US soldiers in Panama was reduced when they were given prophylaxis with oral doxycycline 200 mg weekly throughout the period of exposure.[11] Leptospirosis vaccines are available in some countries.

Listeriosis

Listeriosis is caused by *Listeria monocytogenes*, a Gram-positive bacterium widespread in the environment and capable of growing at low temperatures. Increased awareness of *L. monocytogenes* as a human pathogen has followed epidemics of listeriosis associated with the consumption of contaminated food products including soft cheeses, coleslaw, and milk. *L. monocytogenes* has since been detected in many types of food, especially uncooked hot dogs, undercooked chicken, and pâté. It has been acknowledged[1-3] that it is a relatively rare infection and that despite epidemics associated with identified food products it typically occurs sporadically and the source is usually not certain. Infection occurs primarily in pregnant women, neonates, the elderly, and immunocompromised patients. Clinical manifestations vary. Pregnant women may have relatively mild flu-like symptoms, but infection may result in spontaneous abortion, fetal death, or perinatal sepsis or meningitis in the neonate. Non-perinatal listeriosis may cause sepsis but commonly presents as meningitis. Endocarditis has occurred in patients with cardiac lesions. Focal infections after initial bacteraemia occur mainly in immunocompromised patients.

The treatment of choice is generally ampicillin with gentamicin,[1,2,4,5] although some have advocated ampicillin alone;[6] synergy has been reported *in vitro*. Ampicillin or amoxicillin alone may be used in pregnant women.[7] In penicillin-allergic patients co-trimoxazole, vancomycin or teicoplanin, erythromycin, and tetracycline are alternatives,[1,3] but the choice of treatment in these patients is more difficult. Gentamicin with chloramphenicol or with vancomycin has been used[4] as has erythromycin plus gentamicin.[8] According to some,[4] tetracycline should not be used to treat listeriosis in the UK because of bacterial resistance. Others[3] recommend against use of cephalosporins.

Further details specifically concerning neonatal listerial meningitis and its treatment can be found under Meningitis, p.178.

Lyme disease

Lyme disease is a seasonal infectious disease caused by the spirochaete *Borrelia burgdorferi* and transmitted primarily by *Ixodes* ticks. *I. scapularis*, one of the species of ticks that may cause Lyme disease, may also be infected with, and transmit, *Anaplasma phagocytophilum* and/or *Babesia microti* and therefore the bite from this tick may lead to Lyme disease, human granulocytic anaplasmosis (see Ehrlichiosis, p.168), or babesiosis (p.823) as a single infection or as a co-infection.[1] Lyme disease was first recognised in the 1970s in Lyme, Connecticut, but when the spirochaete responsible was later identified, it was found to occur worldwide with regional variations. Lyme disease is a multisystem disease characterised by inflammatory reactions that principally affects the skin, nervous system, heart, and joints, and can be divided into 3 stages. In the early stage a characteristic skin lesion (erythema migrans) occurs at the site of the tick bite and may be accompanied by flu-like or meningitis-like symptoms. This may be followed weeks or months later by signs of disseminated infection, including neurological and cardiac abnormalities, and even years later by chronic arthritis and the late skin manifestation acrodermatitis chronica atrophicans, both signs of persistent infection.

Appropriate **treatment** should prove curative, especially in the early stages. Recommendations for treatment[1-4] give oral tetracyclines (doxycycline or tetracycline) and the beta-lactam antibacterials (amoxicillin, phenoxymethylpenicillin, or cefuroxime) as the antibacterials of choice for *early* Lyme disease in the absence of neurological symptoms or advanced AV block. Treatment is usually for 14 days (range 10 to 21 days for doxycycline and 14 to 21 days for amoxicillin or cefuroxime). The macrolides (azithromycin, clarithromycin, erythromycin, and roxithromycin) are less effective and should only be used in patients allergic to, or who cannot be given, the first-line agents.[2,3] Young children (usually specified as below 8 years of age in the US and below 12 years in the UK) may be given amoxicillin or cefuroxime.[1,3] Pregnant women should avoid tetracyclines but may be given any of the other oral regimens.[1,3]

Adults and children presenting with *neurological symptoms*, either early or late, should be treated with intravenous ceftriaxone, cefotaxime, or benzylpenicillin for 14 to 28 days. Patients allergic to cephalosporins or penicillins may be given oral doxycycline 200 to 400 mg daily in 2 divided doses.[1,3] Early Lyme disease with *cardiac* complications may be treated with either an oral or intravenous antibacterial for 14 to 21 days. Lyme *arthritis* can generally be effectively treated with one of the oral regimens given for 28 days. Patients with ongoing or recurrent joint pain after the initial treatment course may be re-treated with either another 4-week course of oral antibacterials or with intravenous ceftriaxone for 2 to 4 weeks. *Acrodermatitis chronica atrophicans* may be treated with an oral antibacterial for 21 days.[3]

A small percentage of patients continue to experience non-specific symptoms after appropriate treatment of Lyme disease; there is some controversy over whether prolonged treatment is effective in these patients and studies have suggested otherwise.[5-7] The use of antibacterials in patients with chronic (more than 6 months) subjective symptoms after recommended treatment is hotly debated[8,9] but the Infectious Diseases Society of America (IDSA) does not support such therapy.[3]

Adults and older children *co-infected* with *A. phagocytophilum* should be treated with doxycycline for 10 days. In the US, recommended treatment for severely ill children less than 8 years of age is doxycycline for 4 to 5 days followed by amoxicillin or cefuroxime to complete a 14-day course. Patients with mild illness and who cannot be given a tetracycline may be given rifampicin 300 mg twice daily for 7 to 10 days plus amoxicillin or cefuroxime.[3]

Preventive measures against Lyme disease include the use of tick repellents, physical protection,[3,10,11] and prompt removal of attached ticks.[3] Most guidelines[3,10] do not support the use of empirical antibacterial therapy or serologic testing after tick bites as generally the risk of infection is low,[12] particularly if the tick is removed promptly. The risk of infection may, however, be greater if the tick has fed to repletion.[13] A study[14] has shown that empirical treatment with a single dose of doxycycline given within 72 hours of a tick bite may be warranted in endemic areas where the probability of infection is high. Although routine antibacterial prophylaxis is not recommended by the IDSA,[3] they recommend that a single dose of doxycycline may be given provided that the tick has been attached for 36 hours or more, prophylaxis can be started within 72 hours of the time of tick removal, and the tick species can be identified as *I. scapularis*. Lyme disease vaccines are available in some countries.

Lymphogranuloma venereum

See under Sexually Transmitted Diseases, p.192.

Melioidosis

Melioidosis is caused by the Gram-negative aerobic bacterium *Burkholderia pseudomallei* (*Pseudomonas pseudomallei*), and has been found mainly in south-east Asia and northern Australia.[1] Its true incidence and distribution may be much wider than originally thought;[2] diagnosis is difficult because of the broad spectrum of clinical manifestations. Pulmonary melioidosis is probably the commonest form and has been treated with doxycycline for 3 to 6 months.[3] Chronic or subacute non-bacteraemic melioidosis has also been treated long term with tetracycline or co-trimoxazole.[3]

Septicaemic melioidosis is an important cause of death in Thailand. Because *B. pseudomallei* is intrinsically resistant to many antibacterials, including aminoglycosides and the early beta lactams, it has been unresponsive to many empirical regimens for septicaemia.[2] Treatment was based on anecdotal regimens until, in a study from Thailand,[4] intravenous ceftazidime halved the mortality of severe melioidosis when compared with conventional parenteral treatment with high doses of chloramphenicol intravenously, doxycycline, and co-trimoxazole. As a result ceftazidime came to be considered the treatment of choice for septicaemic melioidosis.[2] A systematic review[5] of treatment of acute melioidosis has also concluded that regimens should contain ceftazidime or imipenem parenterally. Parenteral treatment for a minimum of 7 days is followed by oral maintenance therapy with amoxicillin-clavulanic acid or the conventional regimen (chloramphenicol, doxycycline, and co-trimoxazole);[1,4] amoxicillin-clavulanic acid has shown promise[4] and appears to be a safe alternative to the conventional regimen for the oral treatment of melioidosis.[6] However, resistance to ceftazidime and amoxicillin-clavulanic acid has been reported,[7] emphasising the importance of careful monitoring for the emergence of resistance during treatment. Ceftazidime plus co-trimoxazole, both given intravenously, has been advocated by some for severe melioidosis, especially in patients with septicaemia.[8]

B. pseudomallei has the potential for prolonged latency as demonstrated by a Vietnam war veteran who presented with melioidosis of the bone 18 years after exposure to the organism.[9] He was treated with ceftriaxone intravenously for 8 weeks followed by oral ciprofloxacin.

Meningitis

Meningitis refers to infection of the subarachnoid space and meninges, which may be caused by viruses, bacteria, protozoa, or fungi. The symptoms and signs of meningitis result from the host inflammatory response to infection. Whereas viruses cause the majority of generally mild cases of infectious meningitis, bacterial meningitis is usually a more serious condition. Meningitis may occasionally be a manifestation of non-infectious (auto-immune or neoplastic) disease. This section discusses bacterial meningitis and its management. For reference to fungal meningitis, see p.520.

The bacteria most often encountered in adult or childhood meningitis are *Neisseria meningitidis* (meningococci) and *Streptococcus pneumoniae* (pneumococci). *N. meningitidis* A, C, and W135 are the main subtypes involved in epidemics in the African meningitis belt, whereas B and C subtypes are responsible for outbreaks in Europe and North America. In neonates, infants, pregnant women, immunocompromised patients, and the elderly, *Listeria monocytogenes* and Gram-negative bacilli may also be encountered, and *Str. agalactiae* may cause meningitis in neonates and infants. *Haemophilus influenzae* meningitis was a common cause of meningitis in infants and young children before the availability of *H. influenzae* type b vaccine, and this pathogen is still encountered in non-vaccinated young children, particularly in resource-poor countries. Meningitis after head trauma, neurosurgery, or in the presence of CSF shunts is not infrequently caused by staphylococci (both *Staphylococcus aureus* and coagulase-negative staphylococci) or Gram-negative bacilli.

The bacteria are transmitted from person to person through droplets of respiratory or throat secretions. Infection is spread by prolonged close contact (such as kissing, sneezing and coughing, living in close quarters or dormitories, and sharing eating or drinking utensils). The average incubation period is 4 days, ranging between 2 and 10 days. The clinical presentation of acute bacterial meningitis is largely dependent on the patient's age. The classic manifestations of meningitis in older children and adults, including fever, headache, neck stiffness, photophobia, confusion, and vomiting, are rarely present in infants. In general, the younger the patient, the more subtle and atypical are the signs and symptoms. Fatality rates can be as low as 2% in infants and children, and as high as 20 to 30% in neonates and adults depending on the causative bacteria and patient's age. Brain damage, transient or permanent deafness, or learning disability may occur in up to one-third of survivors.[1,2] A less common but more severe (often fatal) form of meningococcal disease is meningococcal septicaemia which is characterised by a widespread haemorrhagic rash, acute adrenal insufficiency, and rapid circulatory collapse.[1] (For further information see Meningococcal Infections, below p.179.)

Choice of treatment. Bacterial meningitis is a medical emergency and almost universally requires hospitalisation. Death may occur in a matter of hours if left untreated. Outcome is worse if treatment is delayed and therefore doctors in the UK are advised[3,4] to give emergency treatment with parenteral benzylpenicillin in all suspected cases of meningitis before transfer to hospital. Alternative antibacterials include a third generation cephalosporin or chloramphenicol.[3,5] Patients with suspected or confirmed bacterial meningitis should have blood and/or CSF samples taken for culture and receive *empirical* therapy until the causative organism has been identified and susceptibility patterns have become available.[4,6,7] Empiric antibacterials are given intravenously in relatively high doses, and treatment should be targeted at specific organisms as soon as the results of blood and/or CSF cultures are known. The choice of empirical therapy depends on the bacterial pathogens (and their antibacterial susceptibility patterns) that are most likely to have caused meningitis and varies with age and the presence of predisposing factors such as trauma or neurosurgery. Guidelines have been published for the UK[4,6,8] and the USA,[7] and country specific guidelines should be consulted where available. In most countries, a third generation cephalosporin (high-dose ceftriaxone or cefotaxime) is recommended as empirical treatment for bacterial meningitis in adults and children. These drugs are active against *N. meningitidis*, most *Str. pneumoniae* strains, and *H. influenzae*, and penetrate CSF well. However, in situations where ceftriaxone or cefotaxime are not available or are unaffordable, a combination of ampicillin and chloramphenicol or chloramphenicol alone may be used as an alternative.[9] For those patients allergic to both penicillins and cephalosporins, a combination of vancomycin and chloramphenicol may be given.[4] In patients over 55 years ampicillin should be added to cover *Listeria*.[6] Empirical treatment in neonates may include cefotaxime, ampicillin to cover *Listeria*, and an aminoglycoside to cover Gram-negative organisms.[7,10] In the USA and other areas where penicillin and cephalosporin-resistant pneumococci or meticillin-resistant staphylococci are encountered, vancomycin (with or without rifampicin) should be given with a third-generation cephalosporin to children or adults with bacterial meningitis.[4,6-8] Vancomycin together with ceftazidime (or/cefepime or meropenem) should be given to patients with meningitis complicating neurosurgery, head trauma, or CSF shunts. Because of concern of suboptimal CSF penetration, vancomycin should not be used alone in patients with meningitis due to resistant pneumococci or staphylococci, especially when dexamethasone is given as well. The duration of antibacterial treatment depends on the organism isolated. For *Str. pneumoniae* 10 to 14 days of treatment is recommended and for *H. influenzae* 7 to 14 days. For *N. meningitidis* 7 days, treatment is sufficient. In *L. monocytogenes* and group B streptococcal meningitis, antibacterials should be given for a minimum of 14 to 21 days while Gram-negative bacilli should be treated for a minimum of 3 weeks.[7,11]

Chloramphenicol is effective for the treatment of epidemic meningococcal meningitis and is the drug of choice for patients over 1 year of age in areas with limited health facilities.[1,12] An intramuscular dose of ceftriaxone (100 mg/kg to a maximum of 4 g) was found to be as effective as an intramuscular dose of oily chloramphenicol (100 mg/kg to a maximum of 3 g) for the treatment of meningococcal meningitis during epidemics in resource-poor settings.[13] For children under 2 months, intravenous ampicillin for 7 days is recommended to cover *Listeria*, while for children aged between 2 months and 1 year, intramuscular ceftriaxone for 5 days or intravenous ampicillin for 7 days may be used.[12]

Prophylaxis. Immunisation is the most effective way of preventing bacterial meningitis in children. Vaccination is also recommended for travellers to areas affected by meningococcal outbreaks and is compulsory for pilgrims going to Saudi Arabia. Several vaccines are available to prevent bacterial meningitis. Unconjugated polysaccharide vaccines against *N. meningitidis* subtypes A, C, Y, and/ or W135, in various combinations, have been available for many years and are recommended for children older than 2 years who are at high risk of infection, such as those with asplenia and with terminal complement deficiencies, and students living in dormitories. A newer conjugated tetravalent ACWY meningococcal vaccine protects against A, C, W135 and Y meningococcal subtypes and is now a visa requirement for pilgrims to Saudi Arabia. A monovalent conjugate vaccine against *N. meningitidis* subtype C has recently been licensed in developed countries for use in children and adolescents. This conjugate vaccine produces better protection than unconjugated polysaccharide vaccine, in children under 2 years of age.[1,3] For further information on meningococcal vaccines see, p.2224. The newer conjugate *Haemophilus* vaccines (see p.2213) are similarly more immunogenic than the polysaccharide vaccine, and universal immunisation of infants with these conjugate vaccines has been associated with more than 99% reduction in invasive *H. influenzae* type b diseases in developed countries.[2] In 2000, a conjugate vaccine, directed against the seven most prevalent invasive pneumococcal strains in the USA, was approved for routine childhood immunisation. Three doses of this vaccine, given at 2, 4, and 6 months of age, were associated with a reduction of more than 90% in invasive pneumococcal infections, including sepsis and meningitis.[2] For further information on pneumococcal vaccines see, p.2231.

Close contacts of patients infected with meningococcus A, C, Y, or W135 and aged over 2 years should be offered tetravalent meningococcal vaccine.[2-4,11] Those over 3 months and exposed to serogroup A infection may also be given a tetravalent meningococcal vaccine, while those over 2 months of age and exposed to serogroup C infection who are unimmunised or incompletely immunised may be vaccinated with a meningococcal C vaccine. Those who completed a course more than one year before should be offered a booster.[3] All unimmunised index cases under the age of 25 years should also be offered a meningococcal C vaccine. Cases of confirmed serogroup C disease who have previously been immunised with meningococcal C or tetravalent vaccines should be offered a meningococcal C vaccine before discharge from hospital.[3]

Antibacterial treatment does not eliminate nasopharyngeal carriage of *N. meningitidis* and **chemoprophylaxis** should be given to close contacts of the index case (irrespective of vaccination status) to reduce the risk of invasive disease.[3] A systematic review[14] found that ceftriaxone, ciprofloxacin, and rifampicin were all effective at eradicating carriage for up to 2 weeks although resistance to rifampicin may occur after prophylactic treatment; penicillin was less effective. Oral rifampicin twice daily for 2 days (or a single oral dose of ciprofloxacin or a single dose of intramuscular ceftriaxone) should be started in the close contacts within 24 hours or as soon as possible after diagnosis of the index case. If further cases occur within a group of close contacts within 4 weeks of receiving prophylaxis with rifampicin, then repeat prophylaxis should be with either ciprofloxacin or ceftriaxone. Index cases (except those whose disease was treated with ceftriaxone) should be given antibacterial prophylaxis before discharge from hospital.[3] Chemoprophylaxis is also recommended for health care workers whose mouth or nose is directly exposed to large particle droplets or secretions from the respiratory tract of a probable or confirmed index case of meningococcal disease during acute illness and until 24 hours of systemic antibacterial treatment has been completed.[3] Similarly, treatment of *H. influenzae* meningitis does not eliminate nasopharyngeal carriage of the organism and rifampicin should be given to index cases for 4 days before discharge from hospital. Anyone who has been in direct or prolonged close contact with the infected persons should also be given rifampicin for 4 days. Unvaccinated children should be immunised. Chemoprophylaxis is not normally indicated for close contacts of pneumococcal and other types of bacterial meningitis.[4,11]

The WHO recommendation for outbreak control is mass vaccination of persons residing in districts in the epidemic phase as well as surrounding districts in an alert phase. It is estimated that a mass immunisation campaign, promptly implemented, can avoid 70% of cases.[1]

Adjunctive treatment. Mortality and morbidity, including deafness in children, remain high in meningitis despite effective antibacterial therapy. Endotoxins and other microbial products, released from bacteria after antibacterial treatment, are able to elicit a severe inflammatory response, suggesting that anti-inflammatory drugs may be of benefit. A systematic review[15] of adjunctive corticosteroid therapy concluded that corticosteroids reduce mortality, neurological sequelae, and especially the risk of severe hearing loss in both children and adults. This systematic review concludes that corticosteroids should be given before, or with the first dose of antibacterial in adults; the same recommendations apply to children living in high-income countries. However, results from a study in sub-Saharan Africa[16] did not support the routine use of adjunctive corticosteroids in the treatment of adults with bacterial meningitis in resource-poor countries where *Strep. pneumoniae* is the main pathogen and where a large number of patients are also likely to have advanced HIV disease. Another study[17] of dexamethasone in Vietnamese patients over 14 years of age with suspected bacterial meningitis reported that dexamethasone did not improve survival in all patients; significant benefit was only seen in patients with proven bacterial meningitis, including those given prior treatment with antibacterials. This finding was thought to be due to patients with tuberculosis meningitis in the treatment group.

Careful management of fluid and electrolyte balance may be important in the treatment of meningitis and fluid restriction to prevent cerebral oedema has been widely advocated and used in children.[18,19] This practice was based on reports of hyponatraemia which were attributed to inappropriately increased concentrations of antidiuretic hormone. However, subsequent studies have suggested that the raised concentration of antidiuretic hormone may be an appropriate host response to hypovolaemia, and that more liberal use of parenteral fluids may be beneficial.[2] A systematic review[18] concluded that there is some evidence to support the use of intravenous fluids, in preference to restricted fluid intake, particularly in the first 48 hours in settings with high mortality rates. However, where children present early and mortality rates are lower, there is probably little benefit and insufficient evidence to guide practice; it has been suggested that fluids should not be restricted in children.[11] The British Infection Society working party[4,6] recommends that adult patients with meningitis should not be fluid restricted in an attempt to reduce cerebral oedema.

Meningococcal infections

Meningococcal disease[1-3] refers to systemic infection with *Neisseria meningitidis* and may present clinically either as meningitis or septicaemia, or both. Less common forms of metastatic meningococcal infection include polyarthritis, pericarditis, pneumonitis, and genito-urinary-tract infections. *N. meningitidis* is a Gram-negative bacterium, occurring worldwide, and is classified into several serotypes. Serotypes A, C, and W135 are responsible for epidemic meningitis in sub-Saharan Africa, while serotypes B and C are the cause of outbreaks in Europe and North America. The number of cases of meningococcal disease due to serotype C has decreased significantly after the introduction of vaccination in developed countries.

Infections are more common in young children under 5 years of age and in adolescents. *N. meningitidis* only infects humans and about 10 to 25% of the population may be carriers of the organism. The bacteria are carried in the pharynx and may sometimes penetrate the mucosa and spread through the bloodstream causing systemic disease that may rapidly progress to shock and death. Patients with meningococcal disease and asymptomatic nasopharyngeal carriers may spread meningococcal infection via respiratory droplets or throat secretions. Close and prolonged contact such as kissing, sneezing and coughing, living in close quarters, and sharing eating or drinking utensils are established risk factors.[1,2,4] Symptoms and signs during the early stage of meningococcal disease are non-specific and include fever, vomiting, malaise, and lethargy. Most patients with meningococcal septicaemia develop a vasculitic rash (petechiae or purpura) which is often scant or absent in patients with meningitis. Purpuric rash, drowsiness or impaired consciousness, and shock are late presentations and associated with high mortality rates, which may be up to 50% in severe forms. Meningococcal meningitis usually presents with headache, neck stiffness, photophobia, and drowsiness. Mortality from meningococcal meningitis is less than in septicaemia and may be below 5% with prompt treatment.[1,2,5]

Guidelines for prevention and control of meningococcal disease have been developed for the UK[6] and the USA.[7,8]

Choice of treatment. Mortality is reduced by early recognition of the disease and prompt treatment with antibacterials. In the UK doctors are advised that if meningococcal disease is suspected, benzylpenicillin should be given parenterally, preferably intravenously, before transfer to hospital.[1,5,6] Alternative antibacterials include a third generation cephalosporin or chloramphenicol.[6] Both initial empiric and later treatment may be with benzylpenicillin, ampicillin, chloramphenicol, or third-generation cephalosporins such as cefotaxime or ceftriaxone. Oily chloramphenicol or ceftriaxone are used during epidemics in Africa and in areas with limited health facilities. Uncomplicated meningococcal disease usually requires 7 days of antibacterial treatment.[4,5,9,10] For further details of the treatment of meningococcal meningitis, including the treatment of close contacts, see Meningitis, above. Immunisation is the most effective way of preventing meningococcal meningitis and several vaccines are available (see Meningococcal Vaccines, p.2224).

Mouth infections

Infections of the mouth include those of dental origin such as dental caries, abscesses, gingivitis, and periodontal infections, and those without a dental origin. Infections arising in the nasal cavity, middle ear, oropharynx, and paranasal sinuses can also affect the oral cavity. Emphasis has shifted from treatment to prevention of oral diseases.[1] This discussion deals mainly with infections of dental origin.

The organisms most often encountered in oral infections are viridans streptococci, a variety of anaerobes, and facultative streptococci.[2]

Dental caries[3] is caused by the erosion of tooth enamel due to acid produced by bacteria (usually *Streptococcus mutans*) in plaque. Fluoride in various forms is used in dental caries prophylaxis, where it may promote remineralisation or reduce acid production by plaque bacteria.[1] Sugar-free chewing gum can help prevent caries by stimulating the production of saliva.[4] Dental caries vaccines have also been investigated.

The term **periodontal disease**[5] encompasses specific conditions affecting the gingiva and the supporting connective tissue and alveolar bone. **Gingivitis** is thought to be caused by a non-specific bacterial plaque flora that gradually changes from predominantly Gram-positive to more Gram-negative. Gingivitis may or may not develop into periodontitis, but periodontitis is always preceded by gingivitis. **Periodontitis** is associated with a Gram-negative anaerobic microflora. Most gingivitis and periodontitis can be prevented and treated by adequate oral hygiene and plaque removal using mechanical means such as toothbrushing. Mechanical removal of calculus is necessary where the build up is significant. Antiseptics may also help to reduce plaque accumulation and several, but most notably chlorhexidine, have been used.[6,7]

Penicillin has continued to be an effective drug in combating oral pathogens, and erythromycin or metronidazole are alternatives. In the UK, the *BNF* advises against the routine use of clindamycin in oral infections, but notes that it can be used for the treatment of dentoalveolar abscess that has not responded to penicillin or metronidazole. Fusiform bacteria and spirochaetes have been linked with acute necrotising ulcerative gingivitis (also called Vincent's infection or trench mouth);[8] systemic metronidazole is often the treatment of choice. Tinidazole has also been used. Tetracyclines or metronidazole have been used for chronic periodontal disease.[9] Antibacterials and antiseptics delivered locally to the periodontal pocket may be of value.[7]

Mycetoma

Mycetoma is a localised chronic infection seen especially in the tropics and subtropics and involving subcutaneous tissue, bone, and skin. It has been termed Madura foot when affecting the sole of the foot. Mycetomas caused by fungi (p.520) such as *Madurella mycetomatis* are called eumycetomas and those caused by the filamentous bacteria, actinomycetes, are called actinomycetomas. *Nocardia brasiliensis* is the commonest actinomycete responsible; others include *Actinomadura madurae*, *A. pelletieri*, and *Streptomyces somaliensis*. For details of systemic infections caused by *Nocardia* spp., see under Nocardiosis, p.181.

Various treatment regimens for actinomycetomas have been tried. Combined drug treatment is preferred so as to avoid resistance and eradicate residual infection.[1] The most common regimen is streptomycin and dapsone; co-trimoxazole may replace dapsone in patients who have not responded to initial treatment after a few months and in those who cannot tolerate dapsone. Successful treatment has been reported with amikacin, either as monotherapy or with co-trimoxazole.[1] Rifampicin, pyrimethamine-sulfadoxine, and sulfonamides have also been tried in resistant infections and are considered suitable for second-line therapy.[1] Cures were achieved after treatment for 4 to 24 months. In a study of antibacterial activity *in vitro* against strains of *S. somaliensis* isolated from mycetoma patients, rifampicin was the most effective followed in decreasing order of activity by erythromycin, tobramycin, fusidic acid, and streptomycin; all strains were resistant to trimethoprim.[2] The successful use of hyperbaric oxygen in addition to co-trimoxazole[3] or of amoxicillin-clavulanic acid[4] in the treatment of *N. brasiliensis* actinomycetoma previously resistant to conventional therapy has been described.

Necrotising enterocolitis

See p.173.

Necrotising fasciitis

Necrotising fasciitis is a severe soft-tissue infection resulting in necrosis of the subcutaneous tissue and adjacent fascia, together with severe systemic illness. It may be caused by a mixture of aerobic and anaerobic organisms, but can be due to group A streptococci or staphylococci alone and may be associated with a toxic shock syndrome (p.196).

Complete debridement of the infected tissue is considered essential for treatment. Antibacterial therapy is given as an adjunct and should be continued until no further debridements are needed.[1] Antibacterial treatment regimens should cover Gram-positive, Gram-negative, and anaerobic organisms. The possibility of infection with group A *Streptococcus* or *Clostridium* species should also be considered. Possible treatment regimens include monotherapy with ertapenem, imipenem, meropenem, piperacillin-tazobactam, or tigecycline; multidrug regimens include high-dose benzylpenicillin and clindamycin plus a fluoroquinolone or an aminoglycoside. Until meticillin-resistant staphylococcal infection has been ruled out, treatment regimens should also include vancomycin, daptomycin, or linezolid.[1] Hyperbaric oxygen therapy has also been beneficial although prospective controlled studies are lacking.[2] Intravenous normal immunoglobulins have also been tried in patients with necrotising fasciitis caused by group A streptococcus.[3]

Neonatal conjunctivitis

Conjunctivitis of the newborn, also known as ophthalmia neonatorum, is defined as any conjunctivitis with discharge occurring during the first 28 days of life.[1] That due to *Neisseria gonorrhoeae* is the most serious; it usually appears by the third day after birth and can rapidly result in blindness; systemic infections, especially severe septicaemia, may occur. *Chlamydia trachomatis* is another major cause of neonatal conjunctivitis (inclusion conjunctivitis); it characteristically occurs 5 to 14 days after birth and is less threatening to sight than gonococcal infection, but may also infect the nasopharynx and can cause pneumonia. Chlamydial conjunctivitis is more common than gonococcal conjunctivitis in developed countries. Both organisms are sexually transmitted and the infants of mothers with such genital-tract infections are infected during their passage through the birth canal. Other less serious bacterial causes of neonatal conjunctivitis include *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus* spp., and *Pseudomonas* spp.; they are often hospital-acquired.[1]

The management of gonococcal and chlamydial neonatal conjunctivitis varies from country to country depending on the prevalence of gonorrhoea and *C. trachomatis* infection and on bacterial resistance.

- PROPHYLAXIS

  The ideal method of prophylaxis is to treat the infected mother during pregnancy, but this is not always possible. Where the risk of *gonococcal infection* is high, ocular prophylaxis at birth is particularly important because of the rapid onset of conjunctivitis and its potential seriousness and is preferable to early diagnosis and treatment of the neonate.[2] Cleansing of the neonate's eyes immediately after birth followed by the topical application of either tetracycline 1% eye ointment,[3,4] erythromycin 0.5% eye ointment,[3] or silver nitrate 1% eye drops is advised[4] and is sometimes required by law.[3] Silver nitrate[1] is active against all strains of *N. gonorrhoeae* regardless of their susceptibility to antibacterials; it is inexpensive and widely available, but may cause chemical conjunctivitis and has been ineffective in preventing chlamydial conjunctivitis (see below). Tetracycline has been reported to be as effective as silver nitrate in protecting against gonococcal conjunctivitis caused by multiresistant strains[5] and WHO now lists both drugs as the drugs of choice.[4]

  The value of prophylaxis against *chlamydial neonatal conjunctivitis* is less certain. Tetracycline ointment has been reported to be less effective in preventing chlamydial infection than gonococcal infection[5] and erythromycin ointment has also been unreliable.[6] Silver nitrate is generally considered ineffective,[1] despite an unexpected reduction in the incidence of chlamydial conjunctivitis in one study.[5] The CDC[3] does not recommend prophylactic antibacterial treatment for infants born to mothers with untreated chlamydial infection. Screening and treatment of pregnant women for *C. trachomatis* infection may be a more effective method of control than ocular prophylaxis.[5,7] This approach also tackles the more serious problem of pneumonia.[8]

  Neonatal conjunctivitis continues to cause blindness, especially in developing countries. Povidone-iodine is less expensive and perhaps more readily available in such countries than silver nitrate or erythromycin. In a study in Kenya involving more than 3000 infants[9] a 2.5% ophthalmic solution of povidone-iodine appeared to be a more effective prophylactic than either a 1% ophthalmic solution of silver nitrate or erythromycin 0.5% eye ointment. In particular, there were fewer cases of chlamydial conjunctivitis with povidone-iodine.

- TREATMENT

  All cases of neonatal conjunctivitis should be treated for both *N. gonorrhoeae* and *C. trachomatis* because of the possibility of mixed infection.[4] *Gonococcal neonatal conjunctivitis* must be treated systemically. WHO[4] recommends ceftriaxone 50 mg/kg by intramuscular injection as a single dose (to a maximum of 125 mg) or, if ceftriaxone is not available, spectinomycin 25 mg/kg (to a maximum of 75 mg) or kanamycin 25 mg/kg (to a maximum of 75 mg) by intramuscular injection as a single dose.

  In the USA, CDC[3] recommends a single intravenous or intramuscular injection of ceftriaxone 25 to 50 mg/kg (up to 125 mg) when there is no evidence of disseminated infection.

  See also under Gonorrhoea (p.191) for the treatment of infants exposed to gonorrhoea at birth or with established gonococcal infection at any site.

  For *nongonococcal neonatal conjunctivitis* WHO[4] and CDC[3] recommend erythromycin 50 mg/kg daily in 4 divided doses orally for 14 days; WHO[4] recommend co-trimoxazole 240 mg twice daily for 14 days as an alternative. There is no indication that topical therapy is of additional benefit.[3,4]

Nocardiosis

Nocardia spp. are Gram-positive aerobic branching bacteria that cause systemic or localised infection. The principal pathogenic species in man is *N. asteroides*; others include *N. brasiliensis*, *N. pseudobrasiliensis*, and *N. caviae*. Localised chronic infection or actinomycetoma is described under Mycetoma (p.180). Systemic nocardiosis is mainly a lung infection and often involves abscess formation; it occurs especially in immunocompromised patients and may be disseminated with abscesses in the brain and subcutaneous tissues.

The treatment of choice has been a sulfonamide such as sulfadiazine or co-trimoxazole,[1-5] although a study *in vitro* indicated that the fixed ratio of trimethoprim:sulfamethoxazole in co-trimoxazole might contain too little trimethoprim for optimal activity.[6] Sulfafurazole[7] has been used successfully. There have been reports of the effective treatment of nocardiosis with amikacin,[8,9] linezolid,[10] minocycline,[11,12] or ciprofloxacin with doxycycline.[13] Other suggested alternatives include ceftriaxone, imipenem or meropenem.[14] Treatment needs to be prolonged and may continue for 6 to 12 months.

Nontuberculous mycobacterial infections

Environmental mycobacteria are widespread, and a number of species other than those responsible for leprosy (p.176) and tuberculosis (p.196) are facultative parasites capable of producing disease in man. These organisms, which have been referred to as atypical, nontuberculous (NTM), tuberculoid, opportunistic, or MOTT (mycobacteria other than tuberculous), are rarely, if ever, transmitted from person to person but are acquired from the environment. Symptomatic infections are usually associated with focal or generalised defects in the host's immune system. The diseases produced include localised skin and soft tissue lesions, pulmonary infections, lymphadenitis, and disseminated infections.

Cutaneous disease may follow traumatic inoculation with *Mycobacterium marinum* ('swimming pool' or 'fish-tank' granuloma), *M. ulcerans* (Buruli ulcer), *M. chelonae* (*M. chelonei*), *M. abscessus* (formerly *M. chelonae* subspecies), or *M. fortuitum*. Ulcerated lesions due to *M. haemophilum* have been described mainly in immunocompromised patients.

Pulmonary disease may be clinically indistinguishable from pulmonary tuberculosis, and has most frequently been attributed to the *M. avium* complex (MAC), which includes *M. avium* and *M. avium-intracellulare*, or to *M. kansasii*, and to a lesser extent *M. xenopi*; less common causes include *M. abscessus*, *M. asiaticum*, *M. celatum*, *M. chelonae*, *M. fortuitum*, *M. malmoense*, *M. scrofulaceum*, *M. simiae*, and *M. szulgai*.

Lymphadenitis, which is usually self-limiting and occurs particularly in children under 5 years of age, may be caused by many species but the great majority of cases are due to *M. avium* complex, *M. genavense*, *M. malmoense*, and *M. scrofulaceum* (sometimes collectively known as the MAIS complex).

Dissemination of opportunistic mycobacterial infections may occur rapidly in immunocompromised patients. The majority of cases have been attributed to the *M. avium* complex; other species implicated include *M. abscessus*, *M. celatum*, *M. chelonae*, *M. genavense*, *M. haemophilum*, *M. kansasii*, *M. malmoense*, *M. scrofulaceum*, and *M. simiae*.

The treatment depends on the site and nature of the infection and whether immunodeficiency is present. Both HIV-negative and HIV-positive patients may be affected and the possibility of drug interactions should be borne in mind in patients receiving antiretroviral therapy. For further information on drug interactions with antiretrovirals see Table 1, p.917, and Table 2, p.944, in Antivirals.

- MYCOBACTERIUM AVIUM COMPLEX (MAC).

  US guidelines[1,2] produced by the CDC, National Institutes of Health, HIV Medicine Association, and Infectious Diseases Society of America recommend that the **treatment** of **HIV-positive patients** with MAC should consist of at least 2 antimycobacterial drugs. Clarithromycin is the preferred first drug (with azithromycin as an alternative) and is given with ethambutol. Rifabutin may be added as a third drug in patients with advanced immunosuppression, high mycobacterial loads, or if the patient is not taking effective HAART. The fluoroquinolones (ciprofloxacin or levofloxacin) or amikacin may be given when rifabutin is contra-indicated or not tolerated. In ***disseminated*** disease, patients who are not taking HAART should start antiretroviral treatment at the same time as starting treatment for MAC or at least 1 to 2 weeks thereafter. Those already on HAART should continue this treatment.

  UK guidelines from the British Thoracic Society (1999)[3] for treatment of HIV-positive patients with MAC broadly concur with the US recommendations. Rifampicin or rifabutin, ethambutol, and clarithromycin or azithromycin are recommended. A fluoroquinolone such as ciprofloxacin, or even amikacin, may be added for patients who are intolerant of first-line drugs or who fail to respond. UK guidelines recommend lifelong treatment; the US considers that treatment may be stopped in selected patients (see Chemoprophylaxis, below). In ***disseminated*** disease, the same treatment should be given and continued indefinitely.

  A prospective, randomised study[4] undertaken to compare 3 regimens (clarithromycin and ethambutol, clarithromycin and rifabutin, and all 3 drugs) for the treatment of disseminated MAC in patients with AIDS found that all regimens appeared to provide effective treatment and the differences were not statistically significant. However, patients taking the 3-drug regimen had greater overall clinical efficacy, a lower relapse rate, and a lower risk of death.

  The British Thoracic Society guidelines (1999)[3] state that treatment for **HIV-negative patients** with MAC pulmonary disease should consist of rifampicin and ethambutol for 24 months, with or without isoniazid. In extrapulmonary disease affecting lymph nodes, surgical excision of the nodes should be undertaken; chemotherapy with rifampicin, ethambutol, and clarithromycin for up to 2 years should be considered if disease recurs or where the excision is incomplete or impossible. In sites other than lymph nodes, chemotherapy should be given for 18 to 24 months.

  Prophylactic treatment is used to reduce the incidence of disseminated MAC disease in patients with HIV infection. There appears to be a tendency to delay starting prophylaxis until later in the disease process; the guidelines[5] from the US Public Health Service and the Infectious Diseases Society of America (USPHS/IDSA) recommend starting prophylaxis at a CD4+ count of less than 50 cells/microlitre with either azithromycin or clarithromycin. If these drugs cannot be tolerated then rifabutin may be given as an alternative. Combination therapy with one of the macrolides and rifabutin is not recommended. The US guidelines state that prophylaxis need not be lifelong in patients responding to HAART; specifically, primary prophylaxis may be stopped in patients whose CD4+ count has increased to more than 100 cells/microlitre for 3 months or more, but should be restarted if the CD4+ count falls to below 50 to 100 cells/microlitre again. Observational data from a large cohort of patients in the USA found no evidence of increased risk of MAC in patients who had stopped primary prophylaxis in accordance with the USPHS/IDSA guidelines.[6]

  The US guidelines[5] also state that it may be possible to stop secondary prophylaxis (chronic maintenance therapy) in HIV-infected patients who have completed at least 12 months of treatment for MAC, who remain asymptomatic with respect to MAC, and who have a sustained response to HAART (CD4+ count greater than 100 cells/microlitre). Secondary prophylaxis should be restarted if CD4+ count falls below 100 cells/microlitre.

  In the UK, however, the British Thoracic Society guidelines note there is no general agreement about when prophylaxis should be used. If prophylaxis is to be given to patients with a CD4+ count below 50 cells/microlitre the first drug of choice would be azithromycin; clarithromycin is an alternative and azithromycin with rifabutin would be a third choice.[3] The UK guidelines, partly based on studies which predate the wide use of HAART, recommend that prophylaxis be continued indefinitely.[3]

- MYCOBACTERIUM KANSASII INFECTION.

  UK guidelines state that infections with *M. kansasii* may be treated with rifampicin (or rifabutin) and ethambutol.[3] Pulmonary disease in HIV-negative patients is usually treated for 9 months whereas HIV-positive patients should receive therapy for 2 years or until the sputum has been negative for 12 months. For disseminated infection in HIV-positive patients, clarithromycin should be added and possibly also isoniazid. The place of macrolides and fluoroquinolones in pulmonary or disseminated *M. kansasii* infection remain to be established. In extrapulmonary disease in HIV-negative patients, chemotherapy with rifampicin and ethambutol may be used before excision of an infected lymph node. In other extrapulmonary disease the guidelines state that the data are insufficient to make recommendations, but consider that rifampicin and ethambutol for 9 months appears sensible with the addition of protionamide and streptomycin and/or a macrolide if the condition is not responding.[3]

- OTHER OPPORTUNISTIC MYCOBACTERIA.

  In *M. malmoense* and *M. xenopi* **pulmonary** disease, the UK guidelines recommend that rifampicin and ethambutol should be given for 2 years in HIV-negative patients. Extrapulmonary *M. malmoense* infections should be treated in the same manner as extrapulmonary MAC or *M. kansasii* infections. *M. malmoense* infection rarely occurs in AIDS patients, but if necessary, treatment with rifampicin, ethambutol, and clarithromycin, and possibly isoniazid should be used. For *M. xenopi* in HIV-positive patients the guidelines state that there is no evidence on which to base recommendations; treatment as for pulmonary or disseminated MAC infection is suggested.[3]

  For pulmonary disease due to rapidly growing bacteria (*M. abcessus*, *M. chelonae*, *M. fortuitum*, and *M. gordonae*) and other species (*M. genavense*, *M. haemophilum*, *M. simiae*, *M. szulgai*, and *M. ulcerans*) surgery should be used if possible. Drug therapy should probably include rifampicin, ethambutol, and clarithromycin. Amikacin, cefoxitin, imipenem, quinolones, and sulfonamides may have a place in treatment. For extrapulmonary disease due to these organisms, there have been several anecdotal reports outlining treatment but there is no evidence from controlled clinical studies.[3] Successful treatment of *M. simiae* infection in patients with AIDS was reported with clarithromycin, ethambutol, and ciprofloxacin.[7] Surgical treatment and intensive antibacterial regimens have been used for *M. scrofulaceum* infections.[8] Symptomatic improvement was achieved in an AIDS patient with *M. celatum* infection with a regimen of isoniazid, rifampicin, and ethambutol.[9]

For **cutaneous** infections due to *M. marinum* (swimming-pool granuloma or fish-tank granuloma) numerous antibacterial regimens have been used,[10] including rifampicin with ethambutol[11] or isoniazid, rifabutin with ciprofloxacin,[12] minocycline with co-trimoxazole,[13] clarithromycin with rifabutin[14] or ciprofloxacin[12] or ethambutol.[12] Monotherapy with clarithromycin, minocycline, doxycycline, or co-trimoxazole[15] have each been tried, mainly in small series of patients.

Buruli ulcer, due to *M. ulcerans*, is difficult to treat and usually requires surgery; responses to antimycobacterial monotherapies have been generally disappointing. However, recent evidence suggests that combination antibacterial therapy may reduce the healing time and recurrence rates of ulcers, and minimise or avoid the need for surgery.[16] Treatment of nodules and plaques of early Buruli ulcers with rifampicin and streptomycin for up to 12 weeks, showed inhibition of growth 4 weeks after starting treatment.[17] Furthermore, no lesions enlarged during the treatment period. WHO therefore recommends the use of rifampicin and streptomycin or amikacin for 8 weeks.[18] Consensus recommendations issued by practitioners in Victoria, Australia[19] consider surgery to be the best treatment for Buruli ulcer, with antibacterial therapy being indicated for more extensive disease. Use of antibacterial may also possibly allow more conservative resection and reduce the risk of relapse. The recommended oral regimens were: at least 3 months of rifampicin given with clarithromycin, ciprofloxacin, or moxifloxacin. For more severe or extensive disease patients may also require intravenous amikacin for 4 to 8 weeks in addition to oral therapy. Reports of other therapies include a beneficial response with topical nitrogen oxides in a small pilot study of 37 patients with Buruli ulcer,[20] and healing after local application of phenytoin.[21]

Cutaneous disease due to *M. haemophilum* infection has been treated with an initial treatment course of rifabutin, ciprofloxacin, and clarithromycin, followed by clarithromycin for 2 years.[22] *M. chelonae* was successfully treated with clarithromycin and linezolid for one month, followed by a further 5 months of treatment with clarithromycin.[23]

Otitis externa

Otitis externa is a general term used to describe inflammation of the skin of the external auditory canal that may be due to infection with bacteria, viruses, or fungi or secondary to skin disorders such as eczema. Otitis externa is associated with high humidity, warmer temperatures, swimming, local trauma, or obstruction of the ear canal. Subtypes include acute localised otitis externa, acute diffuse otitis externa (swimmer's ear), chronic otitis externa, and necrotising (malignant) otitis externa. Acute diffuse disease is characterised by erythema, itching, pain, purulent discharge, oedema, fullness, and deafness. If left untreated or if treated inadequately it may progress to chronic otitis externa. Chronic otitis externa may also result from allergic contact dermatitis or other underlying skin conditions, such as eczema. Malignant otitis externa is rare and occurs mainly in immunocompromised persons and in diabetics and can be life-threatening if temporal bone infections occur.

The **treatment** of both acute and chronic otitis externa includes thorough cleansing and the use of appropriate acidifying and/or antibacterial ear drops, with or without a corticosteroid, even though some have doubted the value of topical antibacterials. Ear drops containing aminoglycosides, such as gentamicin, neomycin, or framycetin, or polymyxins should not be used when the ear drum is perforated because of the risk of ototoxicity.

The management of the various subtypes of otitis externa has been described.[1-4]

Acute localised otitis externa is an infection of the hair follicle (furunculosis), commonly due to *Staphylococcus aureus*. It may cause severe pain, which may be treated with an analgesic such as paracetamol or ibuprofen. If the furuncle is not pointing (ready to rupture spontaneously), local heat application and systemic treatment with a penicillinase-resistant penicillin such as flucloxacillin or a first-generation cephalosporin such as cefalexin may be used.[1] Others have suggested application of topical antibacterials using wicks which are left in the ear canal for 3 to 5 days.[3] Pointed furuncles require incision and drainage followed by a course of topical and/or oral antibacterials.[1,3]

In *acute diffuse otitis externa*, *Staphylococcus aureus*, *S. epidermidis*, and *Pseudomonas* spp. are often present. Treatment includes thorough cleansing of the ear canal and instillation of ear drops including acidifying agents (2% acetic acid) and antibacterials such as aminoglycosides, fluoroquinolones (ciprofloxacin and ofloxacin), chloramphenicol, or polymyxin B, with or without corticosteroids such as dexamethasone.[1,3] Antifungals may sometimes be required. A wick may be used if instillation proves difficult.[1] Systemic antibacterials may be necessary in severe cases of otitis externa.[1,3]

Chronic otitis externa is treated similarly, although the topical antibacterials and corticosteroids used should not be the same as those used previously for the treatment of acute disease.[1]

Necrotising (malignant) otitis externa, due to fulminating infection, especially with *Pseudomonas*, is uncommon but can occur in susceptible patients. Topical antibacterials are not effective and systemic treatment with antipseudomonal drugs such as gentamicin, ceftazidime, a carbapenem, or a fluoroquinolone is needed for about 4 to 8 weeks.[1,3] However, resistance to ciprofloxacin has been reported.[5] Combination treatment with an aminoglycoside and another antipseudomonal drug or a penicillin (such as azlocillin, piperacillin, or ticarcillin) may also be used.[1,3]

Otitis media

Otitis media is a general term used to describe inflammation of the middle ear that usually results from dysfunction of the Eustachian tube after a viral infection of the nasopharynx. It is one of the most frequent childhood illnesses seen in general practice. Subtypes of otitis media may be classified as follows:

- *acute otitis media (AOM)* is seen especially in young children and is often due to bacterial and/or viral infection and is sometimes associated with upper respiratory-tract infection. It is characterised by rapid onset, ear discomfort, and pain. Common bacterial pathogens include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* (*Branhamella catarrhalis*)
- *recurrent acute otitis media* refers to frequent episodes of AOM (3 or more episodes within 6 months or 4 episodes within 12 months) and may be due to relapse or re-infection
- *otitis media with effusion (OME) or serous otitis media*, commonly known as 'glue ear', is defined as the accumulation of fluid in the middle ear without local or systemic illness. It may be associated with recurrent upper respiratory-tract infection and is characterised by deafness although some episodes may be asymptomatic
- *chronic suppurative otitis media (CSOM)* is often preceded by one or more episodes of AOM and is associated with perforation of the ear drum, and continued infection and inflammation in the middle ear causing persistent or recurrent discharge and deafness. The condition has been divided into inactive or active. Inactive disease (tubo-tympanic disease) is typically characterised by perforation of the ear drum, deafness, and a profuse mucoid discharge associated with upper respiratory-tract infection. In active disease (attico-antral disease) there may be cholesteatoma with bone involvement. The commonest infecting organisms are *Pseudomonas aeruginosa* and anaerobes. Other common infecting aerobic organisms are diphtheroids, *Staphylococcus aureus*, and *Klebsiella*.[1]

TREATMENT Treatment of *acute otitis media* aims to relieve symptoms, avoid complications, and prevent relapse, recurrence, and progression to the chronic state. Sometimes an analgesic such as paracetamol may be all that is required as long as frequent inspection is possible. However, it is common practice to prescribe a systemic antibacterial as well as an analgesic,[2] although the need for routine antibacterial treatment is questionable.[3-5] Systemic antibacterial treatment aims to speed resolution and prevent complications. However, meta-analyses and reviews have shown only modest benefits from routine use of antibacterials[6-8] and experience from studies where antibacterials are not given routinely for AOM suggested that there is no consequent increase in complications.[4,8,9] Another meta-analysis[10] to estimate the natural history of AOM found that about 60% of children not initially treated with an antibacterial showed symptomatic improvement within 24 hours, and that symptoms resolved within 3 days in about 80% of these children. Suppurative complications occurred in about 0.12% of children not immediately treated with antibacterials and in 0.24% of those given immediate treatment. A systematic review[9] reported that clinical signs and symptoms resolved within 4 to 7 days in 78% of children not initially treated with an antibacterial. However, some clinicians have argued that although the benefit is modest, it is significant and therefore the routine use of antibacterials is clinically justifiable.[6] A later systematic review[11] concluded that antibacterials do provide a small benefit in very young children and a further meta-analysis[12] reported that most benefit was seen in children under 2 years of age with bilateral AOM, and in children with both AOM and discharge. Another suggested approach has been to delay the start of antibacterials for 72 hours and to then only give them if the patient remains unwell.[8,13,14] No one antibacterial has been found to be superior to another in the treatment of AOM.[9] Adjunctive treatment with topical and systemic decongestants and antihistamines has not been found to be beneficial[15] and there is insufficient information to conclude whether there is any benefit from the use of topical analgesics (including corticosteroids, local anaesthetics, and NSAIDs).[16]

The American Academy of Pediatrics has produced guidelines[17] for the diagnosis and management of uncomplicated AOM in children from 2 months to 12 years of age. They suggest that in a select group of children an observation period may be recommended depending on the patient's age, the diagnostic certainty, and the severity of illness. These children should be given symptomatic treatment and observed for 48 to 72 hours; if the illness worsens during the observation period or there is no improvement then systemic antibacterials should be considered. Pain management is important, and appropriate analgesics should be offered. If antibacterial treatment is given high-dose amoxicillin (80 to 90 mg/kg daily) is recommended for most children. In children with severe illness or those not responding to amoxicillin and thought to be infected with *H. influenzae* or *M. catarrhalis* high-dose amoxicillin with clavulanic acid should be given. Alternatives in penicillin-allergic children include cephalosporins, azithromycin, or clarithromycin. Similar recommendations have been made for the treatment of AOM in the UK.[18]

Duration of therapy for AOM has varied from 5 to 10 or more days. A systematic review[19] of published clinical studies suggests that a 5-day treatment course may be given to children with uncomplicated AOM. The American Academy of Pediatrics recommends treatment with antibacterials for 10 days in younger children (up to 6 years of age) and for children with severe disease; those aged 6 years or older with mild to moderate disease may be given treatment for 5 to 7 days.[17]

Penicillin-resistant strains of *Str. pneumoniae* have been reported in children with otitis media and are reported to be increasingly prevalent.[20] About one-quarter of *Str. pneumoniae* isolates, one third of *H. influenzae* isolates, and nearly all *M. catarrhalis* isolates are resistant to penicillin and amoxicillin.[2] However, resistance rates vary between countries[21] and many penicillin-resistant strains remain sensitive *in vivo* to high-dose amoxicillin.[20,22,23]

Optimal treatment of *otitis media with effusion* is controversial and the majority of cases will resolve spontaneously within 3 months. Guidelines have been developed in the USA[24] for the diagnosis and management of uncomplicated disease in children from 2 months to 12 years of age. They suggest careful assessment and observation for at least 3 months before considering surgery. Those at increased risk of developmental difficulties such as children with cleft palate or Down's syndrome should be referred to a specialist. Similar recommendations have been made for the treatment of OME in the UK.[25] Antihistamines, decongestants, and mucolytics are ineffective.[24-26] Oral or topical intranasal corticosteroids alone or with an antibacterial have only short-term benefit[27] and their use is not recommended as routine treatment.[24,25] A meta-analysis[28] on the use of antibacterials for the treatment of OME failed to find any benefit and their use cannot be justified.[24,25]

Treatment of *chronic suppurative otitis media* aims to stop the discharge, eradicate the infection, heal the ear drum, and to prevent serious complications. Treatment options for uncomplicated cases include aural toilet (thorough cleansing and mopping of the ear), systemic antibacterials, and topical treatments with either an antiseptic or antibacterial, sometimes also with a corticosteroid. Surgery may be needed if complications develop.[1,29] There is controversy over the use of ear drops containing aminoglycosides or polymyxins in the presence of a perforated ear drum, as they are potentially ototoxic. However, it is considered that untreated disease is more likely to result in deafness than a short course of these ear drops. A systematic review[29] found that treatment with topical fluoroquinolone ear drops was more effective at drying the ear than no drug treatment or topical antiseptics; effects of topical non-fluoroquinolone antibacterials when compared with no drug treatment or topical antiseptics were less clear. Another systematic review[30] found that ear drops containing fluoroquinolones were also more effective than systemic antibacterials at drying the ear. Effects of topical non-fluoroquinolone antibacterials or antiseptics were less clear and no additional benefit was noted by adding a systemic antibacterial to topical antibacterial treatment.

PREVENTION Long-term antibacterial prophylaxis has been tried in children at high risk including those with *recurrent acute otitis media*,[31,32] but the evidence for its benefit is inconsistent. A meta-analysis[33] on the use of antibacterials to prevent recurrent AOM concluded that they appeared to have limited benefit and that 9 children would need to be treated to show an improved outcome in one. A later meta-analysis[34] concluded that antibacterials reduced the probability of disease recurring during the treatment period, but that the long-term benefits of treatment were unclear and that 5 children would need to be treated to show an improved outcome in one.

The use of xylitol, which inhibits the growth of *Str. pneumoniae*, as chewing gum[35,36] or as syrup for very young children[36,37] has been reported to reduce the incidence of AOM. Randomised studies[35,36] with xylitol chewing gum reported a 40% reduction in the incidence of AOM in children with recurrent AOM. However, xylitol was found to be ineffective when it was used only during an acute respiratory-tract infection[38] and the need for use 5 times a day may make this treatment impractical.[35,36]

Vaccination against AOM with pneumococcal vaccines has also been tried but unconjugated multivalent polysaccharide vaccines do not prevent AOM in children under 2 years of age[23,39] and their benefit in older children is minimal.[39] A meta-analysis[39] found that starting immunisation with the 7-valent pneumococcal conjugate vaccine by 2 months of age reduces the incidence of recurrent AOM. No benefit was noted in children with recurrent infections who received their first vaccination after 1 year of age. In a later study[40] in children 2 to 8 years of age with recurrent OME, vaccination with the 7-valent conjugated vaccine before, and the 23-valent polysaccharide vaccine after, insertion of a tympanostomy tube did not prevent recurrences.

Vaccination may also have a role in reducing the incidence and in preventing the development of antibacterial resistance[23] but use of conjugated pneumococcal vaccines was found to cause a shift in the pathogens responsible for AOM from vaccine-type pneumococci to nonvaccine-type strains and to *H. influenzae*.[23]

Pancreatitis

The overall management of pancreatitis is discussed on p.2361. Although there has been some uncertainty about the value of prophylactic antibacterials in acute pancreatitis, a meta-analysis[1] of 8 prospective studies showed a positive benefit in reducing mortality. The advantage was limited to patients with severe pancreatitis given broad-spectrum drugs that achieved therapeutic levels in pancreatic tissue, such as imipenem or a fluoroquinolone. A retrospective study[2] reported a reduction in the incidence, but not in the time of onset, of infection in those given antibacterial prophylaxis in severe disease. However, a systematic review[3] of the value of antibacterial prophylaxis in patients with severe acute necrotising pancreatitis concluded that, despite variations in drugs used (cefuroxime, imipenem, or metronidazole with ciprofloxacin or ofloxacin) and in the quality and methodology of studies conducted, antibacterial prophylaxis appeared to reduce the risk of death in patients with pancreatic necrosis but not, overall, the rate of infected pancreatic necrosis. However, there was some evidence that beta lactams were associated with both a reduction in risk of death, and risk of infected pancreatic necrosis whereas quinolone plus imidazole regimens were not.

Pelvic inflammatory disease

Pelvic inflammatory disease (PID) is a broad term for infectious disorders of the upper genital tract in women and may include endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. It is generally due to ascending infection through the cervix and uterus to the fallopian tubes, resulting in salpingitis, and from there may extend to the ovaries and peritoneum. Long-term complications include infertility and ectopic pregnancy. The use of intrauterine contraceptive devices might increase the likelihood of PID although the risk may have been overstated;[1] it appears to be greatest during the first 20 days after insertion of the device.[2]

The majority of these infections are probably sexually transmitted and at one time were mainly due to *Neisseria gonorrhoeae*, but *Chlamydia trachomatis* is increasingly responsible and may be the commonest cause of PID in some areas. Other organisms that have been isolated include *Mycoplasma hominis*; *Ureaplasma urealyticum*; anaerobes such as *Bacteroides*, *Peptococcus*, and *Peptostreptococcus* spp.; Gram-negative enteric aerobes such as *Escherichia coli*; and Gram-positive aerobes such as group B streptococci. Some of these organisms occur in the abnormal vaginal flora associated with bacterial vaginosis (p.164). Thus, the aetiology of PID appears to be polymicrobial; some think that primary infection with *N. gonorrhoeae* or *C. trachomatis*, or both, allows opportunistic infection with aerobic and anaerobic bacteria.[1]

Treatment regimens are of necessity broad spectrum and empirical and should include antibacterials active against the major pathogens. Many consider that treatment should be started in hospital so that drugs can be given parenterally. Guidelines produced by WHO,[3] by an expert group in the UK,[4] and by the CDC in the USA[5] are as follows, although recommendations may need to be localised because of differences in patterns of infection and drug resistance:

- **WHO**
  - *inpatients*:
    - intramuscular ceftriaxone 250 mg daily, *plus*
      oral or intravenous doxycycline 100 mg twice daily (or oral tetracycline 500 mg four times a day), *plus*
      oral or intravenous metronidazole 400 to 500 mg twice daily or chloramphenicol 500 mg four times daily
    - intravenous clindamycin 900 mg every 8 hours, *plus*
      intravenous gentamicin 1.5 mg/kg every 8 hours
    - oral ciprofloxacin 500 mg twice daily or intramuscular spectinomycin 1 g four times daily, *plus*
      oral or intravenous doxycycline 100 mg twice daily (or oral tetracycline 500 mg four times a day), *plus*
      oral or intravenous metronidazole 400 to 500 mg twice daily or chloramphenicol 500 mg four times daily

    Therapy should be continued for at least 48 hours after clinical improvement, and *then* followed by doxycycline or tetracycline orally for 14 days.
  - *outpatients*:
    - a single-dose treatment for uncomplicated gonorrhoea such as a single intramuscular dose of ceftriaxone 125 mg is recommended (see Gonorrhoea, p.191) *plus*
      oral metronidazole 400 to 500 mg twice daily *and* oral doxycycline 100 mg twice daily (or oral tetracycline 500 mg four times a day) for 14 days.
- **UK**:
  - *inpatients*:
    with the regimens below intravenous therapy is continued until 24 hours after clinical improvement, and the oral regimen is *then* substituted until therapy has been given for at least 14 days.
    - intravenous cefoxitin 2 g three times daily *plus* intravenous (or oral if tolerated) doxycycline 100 mg twice daily, until clinical improvement, *then*
      oral doxycycline 100 mg twice daily, *plus* oral metronidazole 400 mg twice daily
    - intravenous clindamycin 900 mg three times daily *plus* intravenous gentamicin (2 mg/kg as a loading dose, *then* 1.5 mg/kg three times daily *or* a single daily dose of 7 mg/kg) until clinical improvement, *then*
      oral clindamycin 450 mg four times daily or oral doxycycline 100 mg twice daily *plus* oral metronidazole 400 mg twice daily

    alternative regimens, given for a total of 14 days, are:
    - intravenous ofloxacin 400 mg twice daily *plus*
      intravenous metronidazole 500 mg three times daily
    - intravenous ciprofloxacin 200 mg twice daily *plus*
      intravenous metronidazole 500 mg three times daily, *plus*
      intravenous or oral doxycycline 100 mg twice daily

    Metronidazole may be stopped in women with mild or moderate disease who tolerate it poorly, but the improved coverage of anaerobic infection that it provides is more important in women with severe disease.
  - *outpatients*:
    - a single intramuscular dose of ceftriaxone 250 mg *or* cefoxitin 2 g with oral probenecid 1 g, *then*
      oral doxycycline 100 mg twice daily plus oral metronidazole 400 mg twice daily for 14 days, *or*
    - oral ofloxacin 400 mg plus oral metronidazole 400 mg both twice daily for 14 days
- **USA:**
  - *parenteral* treatment:
    - (regimen A): intravenous cefoxitin 2 g every 6 hours or cefotetan 2 g every 12 hours *plus*
      oral or intravenous doxycycline 100 mg every 12 hours
    - (regimen B): intravenous clindamycin 900 mg every 8 hours *plus*
      parenteral gentamicin 2 mg/kg as a loading dose *then* 1.5 mg/kg every 8 hours

    In each case parenteral treatment is continued for 24 hours after substantial clinical improvement has occurred and *then* followed by oral therapy to complete a total of 14 days of treatment.
    - in regimen A, continuation is usually with oral doxycycline 100 mg twice daily; in patients with tubo-ovarian abscesses oral clindamycin *or* oral metronidazole may be added to doxycycline
    - in regimen B, continuation may be with oral clindamycin 450 mg four times a day *or* doxycycline; oral clindamycin is preferred in patients with tubo-ovarian abscesses

    Another parenteral regimen which has been tried is:
    - ampicillin/sulbactam 3 g every 6 hours *plus*
      oral or intravenous doxycycline 100 mg every 12 hours.
  - *oral* treatment:
    - a single intramuscular dose of cefoxitin 2 g *plus* oral probenecid 1 g, *or* a single intramuscular dose of ceftriaxone 250 mg (*or* equivalent third-generation cephalosporin), *plus*
      oral doxycycline 100 mg twice daily, with or without oral metronidazole 500 mg twice daily, for 14 days

Pregnant women who have suspected PID disease should be hospitalised and treated with a parenteral regimen.[5]

Sexual partners of patients with PID should be tested and treated.[5]

Women co-infected with HIV appear to be more likely to develop tubo-ovarian abscesses but respond similarly to treatment compared to women who are HIV-negative.[5]

Peptic ulcer disease

The Gram-negative bacterium *Helicobacter pylori* is involved in the aetiology of gastritis and peptic ulceration, and treatment regimens to eradicate the organism are recommended in peptic ulcer disease (p.1702).

Perinatal streptococcal infections

Group B streptococci are a major cause of perinatal infections, often leading to neonatal pneumonia or septicaemia, sometimes with meningitis, although the incidence varies in different parts of the world. Infections are acquired through maternal genital carriage during pregnancy. *Prevention* of group B streptococcal infection in infants may be achieved by giving appropriate antibacterials to the mother during labour.[1] Ideally maternal carriers of group B streptococci would be identified during pregnancy, but this may not be practical. Factors that increase the risk of acquiring neonatal infection include premature labour, prolonged rupture of membranes, maternal fever, a previous child with neonatal group B streptococcal infection, and multiple pregnancy and they will influence the decision of whether or not to give intrapartum antibacterial prophylaxis to the mother. A penicillin is the preferred drug.

Guidelines from the USA[1] recommend prophylaxis based on universal prenatal screening. Where required, they recommend benzylpenicillin or, alternatively, ampicillin, given intravenously during labour. In women allergic to penicillin but who are not considered to be at high risk of anaphylaxis, intravenous cefazolin is recommended as an alternative; those considered to be at high risk of anaphylaxis should be given clindamycin or erythromycin intravenously or, where there is resistance to clindamycin and erythromycin or susceptibility is unknown, intravenous vancomycin.

In other parts of the world, including Europe, the incidence of neonatal streptococcal infections is much lower and the US model for prophylaxis may not be appropriate.[2,3]

Another strategy suggested for areas with a high incidence of neonatal group B streptococcal disease (above 1.5 per 1000 live births) is to give a single dose of penicillin to all neonates at birth.[4]

As mentioned under Premature Labour, p.188, the elimination of bacteria such as group B streptococci in pregnant women might also reduce the risk of premature labour.

Streptococcus group B vaccines are under investigation for use in pregnant women to prevent neonatal infection.

Peritonitis

Intra-abdominal infections include peritonitis, which may be complicated by intraperitoneal abscesses, and abscesses of the intra-abdominal viscera such as those of the liver (see under Abscess, Liver, p.162), pancreas, and spleen. Infective peritonitis may be primary or secondary or may be a complication of continuous ambulatory peritoneal dialysis (CAPD).

Primary peritonitis. In primary or spontaneous bacterial peritonitis there is no specific focus of infection and it occurs most often as a complication of ascites. Infecting bacteria include *Escherichia coli*, other Enterobacteriaceae, and streptococci. Initial empirical treatment has been with broad-spectrum chemotherapy such as ampicillin plus an aminoglycoside, but third-generation cephalosporins such as cefotaxime are considered by some to be the treatment of choice.[1-3] Other alternatives include other broad-spectrum penicillins, carbapenems, and combinations of penicillins with beta-lactamase inhibitors.[2,3] Oral ofloxacin has been reported to be as effective as intravenous cefotaxime in uncomplicated infections.[4] If infection with anaerobic organisms is suspected, metronidazole or clindamycin may be added to the chosen regimen.[2] In cirrhotic patients with low levels of ascitic fluid protein[5] the use of oral norfloxacin for selective intestinal decontamination appeared to prevent spontaneous bacterial peritonitis and prophylaxis with norfloxacin has been recommended to decrease the recurrence of spontaneous bacterial peritonitis.[1] However, prophylaxis with norfloxacin will not prevent infection by Gram-positive bacteria including *Staphylococcus aureus* or quinolone-resistant Gram-negative bacteria.[2] Co-trimoxazole has also been reported to be an effective prophylactic.[6]

Secondary peritonitis. Secondary peritonitis is associated with perforation of the gastrointestinal tract, conditions such as appendicitis and diverticulitis, and contamination at surgery. Infections are generally mixed and originate from the gastrointestinal tract. Bacteria responsible include *E. coli* and other Enterobacteriaceae, anaerobes (especially *Bacteroides fragilis*), enterococci, and sometimes *Pseudomonas aeruginosa*. Broad-spectrum antibacterial therapy is therefore usually used, at least until the infecting organisms are known, and a combination of two or three drugs is often given. The intravenous route is generally preferred. Nevertheless, it is difficult to assess the relative merits of surgical therapy against medical management that includes antibacterial therapy.[2] An aminoglycoside such as gentamicin or a cephalosporin, plus metronidazole or clindamycin, have often been used, but many other regimens have been tried. Patterns of resistance further complicate the choice of antibacterial: resistance to beta lactams may emerge among some Gram-negative organisms, which are most likely to infect patients with prolonged hospital stays, previous antibacterial treatment, postoperative peritonitis, or recurrent peritonitis. Such patients are best treated with a regimen that includes a carbapenem, cefepime, a fluoroquinolone, or an aminoglycoside.[2] Resistant isolates of *B. fragilis* and *Clostridium difficile* (with associated diarrhoea) are more common after clindamycin than after metronidazole.[2] Microaerophilic Gram-positive cocci are resistant to metronidazole but not to clindamycin,[2] so metronidazole should be used with a beta lactam other than aztreonam.[2]

For reference to the prevention of postoperative infection, see under Surgical Infection, p.195.

CAPD peritonitis. Peritonitis is the main complication of CAPD, a technique widely used in end-stage renal failure. Unlike secondary peritonitis, above, a single infecting organism is often responsible. The most common infections have usually been due to Gram-positive organisms, especially staphylococci, but infections with Gram-negative bacteria (typically Enterobacteriaceae) are becoming more common, and fungi are an increasingly important cause of peritonitis in CAPD.[2] The International Society for Peritoneal Dialysis recommends[7] that the choice of antibacterial for empirical therapy be based on the history of sensitivities of organisms causing peritonitis in the particular hospital or centre involved. In some cases a first-generation cephalosporin (such as cefalotin or cefazolin) for Gram-positive organisms, with a third-generation cephalosporin or an aminoglycoside for Gram-negative coverage, may be suitable; however, many centres have a high rate of meticillin-resistant infections and vancomycin for Gram-positive coverage may be necessary. Quinolones for Gram-negative organisms should only be used if local sensitivity is demonstrated. Aztreonam can be used in patients with cephalosporin hypersensitivity. The antibacterials are given intraperitoneally by mixing with the dialysate. Once-daily dosing regimens for aminoglycosides are considered appropriate for CAPD patients. Once the infecting organism is identified, an appropriate narrow-spectrum antibacterial can be substituted. Treatment is generally continued for 14 days in patients who have a clinical response. Treatment should be extended to 21 days in patients with severe infections (such as *Staph. aureus*, Gram-negative, or enterococcal peritonitis).

Exit-site infections can be treated with an oral penicillinase-resistant penicillin, a first-generation cephalosporin such as cefalexin, or co-trimoxazole for Gram-positive infections. Vancomycin should be avoided for routine use but may be needed if there is meticillin resistance. Rifampicin may be added in severe *Staph. aureus* infections. An oral fluoroquinolone such as ciprofloxacin may be used for Gram-negative infections.[7] Intraperitoneal ceftazidime may be added in cases of pseudomonal infection where resolution of infection is slow or where there is recurrence.

Long-term antibacterial prophylaxis is not generally effective, but *Staph. aureus* nasal carriage is associated with increased risk of exit-site infections and intranasal or exit-site mupirocin (cream, as ointment may damage the catheter) or exit-site gentamicin cream have been used to reduce them.[7] Dramatic reductions in peritonitis rates have been achieved with programmes based on stringent aseptic wound care and on minimising contact of the CAPD system with domestic water.[8]

Pertussis

Pertussis or whooping cough[1] is caused by infection with the respiratory pathogen *Bordetella pertussis*, a Gram-negative aerobic bacterium. The related species *B. parapertussis* causes a similar but generally milder illness. Pertussis is very infectious and occurs most frequently in children, but may be more common in adults than once thought. The incidence of pertussis has been greatly reduced by the active immunisation of infants (see under Pertussis Vaccines, p.2231) and effective prevention by the adequate uptake of vaccine remains the ultimate objective.

Erythromycin has been the antibacterial of choice, but the newer macrolides, clarithromycin and azithromycin, have similar effectiveness and are also recommended for the **treatment** of pertussis.[1-3] Once infection has occurred antibacterial therapy is thought to render the patient non-infectious by eliminating nasopharyngeal carriage of *B. pertussis*. Such treatment is unlikely to affect the clinical course of pertussis because diagnosis is difficult until the paroxysmal stage, by which time the bacteria have already damaged the respiratory tract and released their toxins. Effective regimens include:[2,3]

- oral azithromycin 500 mg daily on the first day of treatment then 250 mg for 4 days; infants and children may be given oral azithromycin 10 mg/kg daily for 3 to 5 days, or 10 mg/kg daily on the first day of treatment then 5 mg/kg daily for 4 days
- oral clarithromycin 500 mg twice daily for 7 days; infants and children may be given oral clarithromycin 7.5 mg/kg twice daily for 7 days
- oral erythromycin 500 mg four times daily for 14 days; infants and children may be given oral erythromycin 40 to 50 mg/kg daily in 3 to 4 divided doses for 7 to 14 days, or 60 mg/kg daily in 3 divided doses for 14 days

Oral co-trimoxazole for 7 to 14 days may be given as an alternative treatment for patients unable to tolerate macrolides. Oxytetracycline or chloramphenicol are not recommended because of their potential side effects.

Macrolide antibacterials, given in the same doses as for treatment and within 3 weeks of onset of cough in the index patients, may also be given **prophylactically** to close contacts.[2] However, protection is limited and a systematic review[3] concluded there was insufficient evidence to determine the benefit of prophylactic treatment of healthy pertussis contacts.

Pharyngitis

Pharyngitis and tonsillitis are upper respiratory-tract infections with similar causes and occur especially in children. Acute pharyngitis is an inflammatory syndrome of the oropharynx that may include the tonsils whereas tonsillitis is, strictly speaking, a more localised infection. The commonest causes are viral and a sore throat is often a symptom of the common cold as well as influenza and infectious mononucleosis. For further details of these viral infections, see under Choice of Antiviral, p.850.

The most important bacterial cause of acute pharyngitis and tonsillitis is the group A beta-haemolytic streptococcus, *Streptococcus pyogenes*. An erythrogenic toxin-producing strain causes pharyngitis and tonsillitis in scarlet fever.

In view of the prevalence of a viral cause, opinions have differed over whether and when to treat pharyngitis with antimicrobial drugs. Some have advocated waiting until a definite diagnosis of *Str. pyogenes* infection is made, but others treat immediately if streptococcal pharyngitis is suspected because of the risk of longer term complications such as rheumatic fever and the need to eradicate *Str. pyogenes* from the throat.[1-3] The incidence of rheumatic fever has been low for many years in developed countries, but there was evidence of a resurgence in parts of the USA in the mid-1980s. Thus, in addition to shortening the illness and interrupting transmission, the antibacterial treatment of streptococcal pharyngitis also serves as primary prevention of rheumatic fever (see below). However, in countries in which the incidence of rheumatic fever remains low the routine use of antibacterials for the management of sore throats is discouraged.[4,5]

Penicillin is the standard treatment for streptococcal pharyngitis or tonsillitis,[6-8] generally as phenoxymethylpenicillin by mouth for 10 days; benzylpenicillin may be given by injection initially. A single intramuscular injection of benzathine benzylpenicillin is perhaps the treatment of choice, especially if compliance with a 10-day course of oral penicillin is unlikely, and is advocated by WHO and the American Heart Association for the primary prevention of rheumatic fever (see under Rheumatic Fever, p.189), but the injection may not be available in some countries. Ampicillin should probably be avoided because of the risk of maculopapular rash if the patient proves to have infectious mononucleosis.[9] Erythromycin or another macrolide may be given to penicillin-allergic patients, except where there is evidence of significant resistance, as in some parts of Europe,[6] the USA,[10] Japan,[11] and Finland;[12] it may also be a better choice than penicillin if there is a likelihood of infection with *Arcanobacterium haemolyticum* (*Corynebacterium haemolyticum*) (see below). Oral cephalosporins are another alternative, and a meta-analysis[13] has shown that the likelihood of treatment failure with oral cephalosporins may be approximately half that with penicillin.

Despite the general effectiveness of penicillin a trend of increasing numbers of relapses and recurrent infections has been noted.[14] Some treatment failures have been attributed to poor patient compliance with a 10-day course of penicillin and attempts to overcome this have included giving fewer daily doses or shortening the length of treatment. Meta-analysis of studies supports the use of twice-daily dosing of phenoxymethylpenicillin which appears to be as effective as doses three or four times daily,[15] but a single daily dose is less effective. Courses of phenoxymethylpenicillin shorter than 10 days have not proved effective.[16,17] There is some evidence that shorter courses may be possible with some alternative antibacterials. Studies have shown that courses of 5 days or less of erythromycin,[18] cefotiam hexetil,[19] azithromycin,[20,21] clarithromycin,[22] or cefuroxime axetil[23,24] may be as effective as a 10-day course of phenoxymethylpenicillin. However, definitive studies have not been done, and the broader spectrum and higher cost of these regimens are drawbacks.[6,7]

Penicillin resistance in *Str. pyogenes* remains rare. In addition to poor compliance, treatment failures with penicillin, leading to recurrent infection, might be explained by the presence of beta-lactamase-producing oropharyngeal bacteria that are able to protect *Str. pyogenes* against penicillin,[25] although this theory was not supported by a study in 462 children.[26] Antibacterials less susceptible to beta lactamase have been effective, sometimes more so than phenoxymethylpenicillin. They include the oral cephalosporins cefaclor,[27] cefuroxime axetil,[28] cefixime,[29] cefprozil,[30] and cefadroxil[31] and the combined preparation amoxicillin with clavulanic acid[32,33] (like ampicillin, amoxicillin should perhaps be avoided because of the risk of maculopapular rash if the patient proves to have infectious mononucleosis). Clindamycin has eradicated *Str. pyogenes* and beta-lactamase-producing bacteria in children of 12 years and under with recurrent tonsillitis, but might be less effective in older patients.[34] It was also effective where penicillin and erythromycin had failed in an outbreak of streptococcal pharyngitis.[35]

Pharyngeal carriage of *Str. pyogenes* is common, especially in primary-school children and thus its presence does not necessarily reflect acute infection. Eradication may be beneficial in selected cases and has been achieved by a single intramuscular injection of benzathine benzylpenicillin together with a 4-day course of oral rifampicin;[36] a 10-day course of oral clindamycin has also been effective.[37] In order to ensure that outbreaks of *Str. pyogenes* are prevented in closely confined populations, some have recommended prophylactic antibacterials for *all* members of these populations, without exception.[38]

Other bacterial causes of pharyngitis include *Arcanobacterium haemolyticum* (*Corynebacterium haemolyticum*), *Chlamydophila pneumoniae* (*Chlamydia pneumoniae*), *Corynebacterium diphtheriae* (see under Diphtheria, p.168), *Neisseria gonorrhoeae* (see under Gonorrhoea, p.191), group C beta-haemolytic streptococci, and anaerobic bacteria.

A. haemolyticum is thought to be an important cause of pharyngitis in adolescents and young adults; there is often an accompanying scarlatiniform rash. It has been reported to respond to a single injection of benzathine benzylpenicillin or a 10-day course of oral erythromycin, but not to phenoxymethylpenicillin.[7]

Pharyngitis is often associated with *Chlamydophila pneumoniae* infection and tetracycline or erythromycin are effective antibacterials.[39]

Plague

Plague[1] is caused by the Gram-negative bacillus *Yersinia pestis* (*Yersinia pseudotuberculosis* subsp. *pestis*) and is usually transmitted to man via rodents and their infected fleas. It has occurred as worldwide pandemics, for example, the Black Death in Europe in the Middle Ages. In the 1980s the largest numbers of cases reported were in Tanzania, Vietnam, Brazil, Peru and more recently in Madagascar. Plague may take several forms of which bubonic plague is the most common; others include pneumonic, septicaemic, and meningitic plague. Streptomycin, tetracycline, and chloramphenicol have traditionally been used in the treatment of plague[2] with streptomycin being the treatment of choice, although the possibility of a Jarisch-Herxheimer reaction resulting from the bactericidal effect of streptomycin must be borne in mind; it is also contra-indicated in pregnancy. Success has also been reported with aminoglycosides such as gentamicin and kanamycin. Although there is no clinical experience with fluoroquinolones, *in-vitro* susceptibilities and *animal* studies suggest that they would be effective.[2]

In the UK, the recommended treatment for adults is gentamicin (first choice in pregnancy); ciprofloxacin or doxycycline may be used if aminoglycosides are unsuitable and may also be used for first-line therapy in children, but doxycycline is only suitable for children over 8 years of age. If plague meningitis is suspected chloramphenicol should be used as it crosses the blood-brain barrier.[2] Similar information is provided by WHO,[3] with sulfonamides being mentioned as alternatives. In UK guidelines[2] ciprofloxacin is considered to be the drug of choice for prophylaxis in adults and children considered to be at risk after close contact with cases of pneumonic disease or after a deliberate release of *Y. pestis*; doxycycline may be used as an alternative in those over 12 years of age. Other suggested antibacterials include chloramphenicol and co-trimoxazole.

Commenting on the plague epidemic that occurred in India in 1994, workers from the US CDC[4] also noted that streptomycin continues to be the drug of choice for treating plague, that tetracycline and gentamicin are alternatives, and that chloramphenicol is preferred for plague meningitis. They considered that prophylaxis should be given to those who have had face-to-face contact or who have occupied a closed space with someone who has pneumonic plague. For prophylaxis, tetracycline can be given to adults and older children or sulfonamides to children of 8 years or less; chloramphenicol is also effective.[4]

Infection with a strain of *Y. pestis* resistant to all the drugs usually effective against plague identified in a patient from Madagascar[5] responded to treatment with co-trimoxazole and streptomycin.

A vaccine is available for active immunisation.

Pneumonia

Pneumonia[1] is a respiratory disease characterised by inflammation of the lung parenchyma with congestion. It is mostly due to bacterial or viral infection, but may be caused by fungi in immunocompromised patients or by the aspiration of chemical irritants. Pneumonia is a common illness occurring in all age groups and throughout the world; it is a major cause of death among the elderly and those who are chronically and/or terminally ill. Symptoms and signs of pneumonia include chills, cough, dyspnoea, fever, headache, myalgia, pleuritic chest pain, and sputum production. Treatment of pneumonia relies on prompt use of antibacterials and identification of the infecting organisms and their sensitivity to antibacterials. Cases of pneumonia are usually classified as community-acquired or hospital-acquired (nosocomial) pneumonia. Cases of community-acquired pneumonia can also be further sub-divided into those who can be treated in an ambulatory (outpatient) setting and those that need hospitalisation. Patients who need hospitalisation are generally infected with unusual pathogens and/or have more severe disease. Pneumonia occurring in long-term-care facilities can be treated as either community-acquired or hospital-acquired pneumonia. Cases of hospital-acquired pneumonia are divided according to whether ventilator assistance is needed. These categories also provide a rough guide as to the likely pathogen and severity of the disease.

Other types of pneumonia include aspiration pneumonia and the various forms of interstitial pneumonia or pneumonitis (see also Aspiration Syndromes, p.1693, and Diffuse Parenchymal Lung Disease, p.1502). Interstitial pneumonitis is a common complication in cancer patients and has also been associated with certain drugs, for example amiodarone, bleomycin, and nitrofurantoin.

Community-acquired pneumonia. In community-acquired pneumonia[2-7] the commonest pathogen in previously healthy subjects is *Streptococcus pneumoniae* (pneumococcus). Other common pathogens include *Haemophilus influenzae* and atypical pathogens such as *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, and *Legionella pneumophila* (see Legionnaires' Disease, p.176).[2,4] Less common causes include *Staphylococcus aureus*, which usually occurs as a secondary bacterial infection after influenza and is associated with high mortality; *Moraxella catarrhalis* (*Branhamella catarrhalis*) occurs especially in patients with chronic lung disease; Gram-negative enteric bacilli; *Pseudomonas aeruginosa*; *Chlamydophila psittaci* (*Chlamydia psittaci*) (see Psittacosis, p.188); and *Coxiella burnetii* (see Q Fever, p.188). Gram-negative bacilli rarely cause pneumonia in the community, especially in previously healthy patients, although the frequency of such infections is increasing.[8] Anaerobic bacteria are associated with aspiration pneumonia. Viruses are the commonest pathogens in young children.

Pneumococcal pneumonia usually develops over a number of days and in elderly patients onset may be insidious. *Str. pneumoniae* has usually been considered to be sensitive to penicillins (benzylpenicillin, amoxicillin, or ampicillin), cephalosporins, erythromycin, or co-trimoxazole, but there is increasing prevalence of global resistance although there are marked geographical differences.[9,10] A survey[10] which, during 1999 to 2000, collected data from 69 centres in 25 countries found 22.1% resistance overall to benzylpenicillin (but 71.5% in South Korea, 46.2% in France, 42.1% in Spain, 32.6% in the USA, 15.3% in Latin America, 5.5% in the UK, 4.4% in Australia, and 0% in the Netherlands); resistance overall to erythromycin was 31.0% (87.6% in South Korea, 57.6% in France, 28.6% in Spain, 30.9% in the USA, 15.3% in Latin America, 13.2% in the UK, 12.3% in Australia, and 7.8% in the Netherlands). Macrolide resistance as high as 35% has been reported in some areas of the USA and Europe; 96% resistance has been reported in Taiwan. Fluoroquinolone resistance was low overall (1%) although 14.3% of isolates were resistant in Hong Kong.[9,10] However, in clinical practice pneumococcal pneumonia frequently responds to high doses of penicillins or cephalosporins and the routine use of penicillin for community-acquired pneumonia may still be reasonable in many countries.

The treatment of community-acquired pneumonia is complicated by the increasing spectrum of causative organisms and prevalence of antibacterial resistance. Furthermore, since the causative pathogen is often unknown, initial antibacterial therapy is usually empirical. Guidelines for the treatment of pneumonia have been issued by bodies in many countries.[8,11-18] Although common principles can be identified, recommendations must be localised because of differences in patterns of infection and drug resistance, variations in the availability of antibacterials and local policies for their use, and differences in medical practice. Countries also vary in the degree to which such guidelines are accepted in practice. These guidelines generally give advice for differences associated with age, the severity of the infection and the presence or absence of underlying or co-existent disorders.

In the UK, guidelines for the management of community-acquired pneumonia have been produced by the British Thoracic Society (BTS).[8] For initial ***empirical treatment in the community*** amoxicillin is usually preferred. Erythromycin is an alternative in penicillin-allergic patients and should also be given during epidemics of mycoplasmal pneumonia and when *Legionella* is suspected; clarithromycin may be given if there is gastrointestinal intolerance to erythromycin.

In those patients ***hospitalised with non-severe community-acquired pneumonia*** there is an increased likelihood of infection with atypical pathogens, or with *Legionella* spp.; consequently, combined empirical treatment orally with amoxicillin plus either erythromycin or clarithromycin is preferred.[8] When oral therapy is inappropriate, intravenous ampicillin or benzylpenicillin is given, together with intravenous erythromycin or, preferably, clarithromycin. For those intolerant of beta-lactams and macrolides or when there are local concerns over *Clostridium difficile*-associated diarrhoea, a fluoroquinolone with enhanced activity against pneumococci may be given as an alternative (levofloxacin orally or intravenously or moxifloxacin orally).[8] In practice, however, many patients with non-severe community-acquired pneumonia are admitted to hospital for non-clinical reasons such as old age, family preference, inadequate home care, or adverse social circumstances, and in these patients it is considered appropriate to treat with monotherapy as for patients treated in the community (see above).[8]

Patients ***hospitalised with severe community-acquired pneumonia*** should receive parenteral empirical treatment regardless of their ability to take oral medication. Since community-acquired pneumonia caused by *Legionella* spp. is more likely to result in severe disease, the initial empirical regimen should include appropriate therapy. Current recommendations[8] are for combined intravenous treatment with a broad-spectrum beta-lactamase-stable antibacterial such as amoxicillin with clavulanic acid or a second- or third-generation cephalosporin such as cefuroxime, cefotaxime, or ceftriaxone, together with a macrolide (clarithromycin or erythromycin). For life-threatening infection where *Legionella* is suspected, the further addition of rifampicin is recommended;[8] although rifampicin may result in reduced serum concentrations of macrolides, this is not known to be of clinical significance when treating community-acquired pneumonia. As in non-severe infection, in patients who are intolerant of beta-lactams and macrolides or when there are local concerns over *C. difficile*-associated diarrhoea, levofloxacin may be given as an alternative, but with the addition of benzylpenicillin for severe infection.[8]

The following treatments are recommended in the UK,[8] in conjunction with local microbiological advice, for the minority of patients with community-acquired pneumonia in whom the ***causative organism*** has been identified, usually in hospital:

- *Str. pneumoniae*: preferred treatment, oral amoxicillin or intravenous benzylpenicillin; alternatives, oral erythromycin or clarithromycin, or intravenous cefuroxime, cefotaxime, or ceftriaxone
- *M. pneumoniae* or *C. pneumoniae*: preferred treatment, oral or intravenous erythromycin or clarithromycin; alternatives, oral tetracycline or oral or intravenous fluoroquinolone
- *C. psittaci* or *C. burnetii*: preferred treatment, oral or intravenous tetracycline; alternatives, oral or intravenous erythromycin or clarithromycin
- *Legionella* spp.: preferred treatment, oral or intravenous clarithromycin with or without oral or intravenous rifampicin; alternative, oral or intravenous fluoroquinolone
- *H. influenzae* (non-beta-lactamase-producing): preferred treatment, oral amoxicillin or intravenous ampicillin; alternatives, intravenous cefuroxime, cefotaxime, or ceftriaxone, or oral or intravenous fluoroquinolone
- *H. influenzae* (beta-lactamase-producing): preferred treatment, oral or intravenous amoxicillin with clavulanic acid; alternatives, intravenous cefuroxime, cefotaxime, or ceftriaxone, or oral or intravenous fluoroquinolone
- Gram-negative enteric bacilli: preferred treatment, intravenous cefuroxime, cefotaxime, or ceftriaxone; alternatives, intravenous fluoroquinolone, imipenem, or meropenem
- *Ps. aeruginosa*: preferred treatment, intravenous ceftazidime plus either gentamicin or tobramycin; alternatives, intravenous ciprofloxacin or piperacillin plus either gentamicin or tobramycin
- *Staph. aureus* (non-meticillin-resistant): preferred treatment, intravenous flucloxacillin with or without oral or intravenous rifampicin; alternative, intravenous teicoplanin with or without oral or intravenous rifampicin
- *Staph. aureus* (meticillin-resistant): preferred treatment, intravenous vancomycin; alternative, intravenous teicoplanin with or without oral or intravenous rifampicin

In the USA, guidelines for the management of community-acquired pneumonia in adults have been jointly produced by the Infectious Diseases Society of America (IDSA) and by the American Thoracic Society (ATS).[12] For previously healthy ***outpatients*** with no risk factors for drug-resistant *Str. pneumoniae* (DRSP) infection they recommend a macrolide (such as erythromycin, azithromycin, or clarithromycin); doxycycline may be given as an alternative. In those with co-existing cardiopulmonary disease and/or other complicating factors (such as renal disease, diabetes mellitus, alcoholism, malignancies, or asplenia), taking immunosuppressive drugs, those who have received antibacterial therapy within the previous 3 months, or those with other risks for DRSP infection a 'respiratory fluoroquinolone' (gemifloxacin, levofloxacin, or moxifloxacin) is recommended. Alternatively a beta-lactam (high dose amoxicillin with or without clavulanic acid, or ceftriaxone, cefpodoxime, or cefuroxime) plus a macrolide (or doxycycline) may be given.

In ***hospitalised*** patients who are not in intensive care the preferred treatment is a beta-lactam (cefotaxime, ceftriaxone, ampicillin, or ertapenem) plus a macrolide (or doxycycline). In penicillin-allergic patients a respiratory fluoroquinolone is recommended. In hospitalised patients who are in intensive care the preferred treatment is a beta-lactam (cefotaxime, ceftriaxone, or ampicillin/sulbactam) plus either azithromycin or a respiratory fluoroquinolone. In penicillin-allergic patients a respiratory fluoroquinolone and aztreonam are recommended. For *Pseudomonas* infection, an antipneumococcal, antipseudomonal beta-lactam (such as piperacillin/tazobactam, cefepime, imipenem, or meropenem) plus either ciprofloxacin or levofloxacin are recommended. Alternative regimens include an antipneumococcal, antipseudomonal beta-lactam plus an aminoglycoside and azithromycin, or an antipneumococcal, antipseudomonal beta-lactam plus an aminoglycoside and an antipneumococcal fluoroquinolone. In penicillin-allergic patients aztreonam should be used in place of the beta-lactam. For community-acquired meticillin-resistant *Staph. aureus* infection, vancomycin or linezolid should be added.

In **children** pneumonia is caused by a wider spectrum of organisms than in adults. Viruses, especially respiratory syncytial virus, are very common pathogens in infants and children up to 4 years of age and, as in adults, pneumococci are very common bacterial pathogens. Guidelines for the management of community-acquired pneumonia in children have been produced by the BTS.[11] Amoxicillin is considered the antibacterial of first choice for empirical oral therapy in children under 5 years of age because it is effective against the majority of causative organisms. Alternatives are amoxicillin with clavulanic acid, cefaclor, erythromycin, clarithromycin, or azithromycin. Macrolides should be given as first-line empirical therapy in children over 5 years since *M. pneumoniae* pneumonia is more prevalent in older children. Macrolides should also be used in children of any age if either *M. pneumoniae* or *C. pneumoniae* are suspected. Amoxicillin should be used as first-line treatment at any age if *Str. pneumoniae* is thought to be the likely pathogen. If *Staph. aureus* is suspected then a macrolide or a combination of flucloxacillin with amoxicillin is appropriate. Intravenous therapy should be given in severe infection or when the child is unable to absorb oral antibacterials, for example due to vomiting; appropriate intravenous drugs for severe pneumonia include amoxicillin with clavulanic acid, cefuroxime, or cefotaxime. If the causative organism is known to be *Str. pneumoniae* a penicillin may be used alone. *Chlamydia trachomatis* is another common cause in infants up to 3 months of age for which erythromycin may be used or, alternatively, sulfafurazole.

Pneumonia in neonates is usually due to organisms acquired from the mother's genital tract, especially group B streptococci, *Escherichia coli*, and *Klebsiella pneumoniae*; initial treatment with gentamicin and benzylpenicillin or ampicillin has been suggested. For prophylaxis against group B streptococci in neonates, see under Perinatal Streptococcal Infections, p.184.

Similar guidelines for the empirical management of community-acquired pneumonia in children have been developed in South Africa.[15] Additional recommendations have been made to take into account the high prevalence of HIV infection. The drug of choice is amoxicillin; although standard doses of amoxicillin will treat most cases of pneumococcal pneumonia the use of high-dose amoxicillin (30 mg/kg given 3 times daily) is recommended in order to overcome and limit the emergence of resistant pneumococci, and to successfully treat those few children with high-level pneumococcal resistance the following additional factors should be considered:

- children younger than 2 months have more Gram-negative infections and therefore need an intravenous aminoglycoside or an intravenous cephalosporin, while children older than 5 years have more infections caused by *M. pneumoniae* and *C. pneumoniae* and need a macrolide (erythromycin, clarithromycin, or azithromycin)
- HIV-infected children requiring hospitalisation and those with a high risk of being HIV-infected or who have symptomatic HIV disease or who are severely malnourished should be given an aminoglycoside plus their empirical antibacterial regimen; alternatively they may be given a regimen that provides effective treatment against Gram-negative bacteria
- if pneumocystis pneumonia is suspected, co-trimoxazole should be added. All hospitalised HIV-exposed children less than 6 months of age should be treated empirically with co-trimoxazole, unless HIV infection status is negative and the child is not being breast-fed. Empirical treatment with co-trimoxazole plus amoxicillin and an aminoglycoside should also be given to older HIV-infected children with features of AIDS who are not on co-trimoxazole prophylaxis
- when *Staph. aureus*, is suspected, cloxacillin is the drug of choice. In HIV-infected children, about 60% of community-acquired *Staph. aureus* may be resistant to cloxacillin and vancomycin should be given

Hospital-acquired pneumonia. Most reports on hospital-acquired or nosocomial pneumonia have been from the USA. The organisms most commonly responsible for hospital-acquired pneumonia are Gram-negative enteric bacilli, *Staph. aureus*, *Str. pneumoniae*, Enterobacteriaceae, and *H. influenzae*; others that may need to be considered, particularly in the presence of specific risk factors, are *Legionella* spp., *Ps. aeruginosa*, anaerobes and, in severe infection, *Acinetobacter* spp. Hospital-acquired pneumonia occurring 48 hours after mechanical ventilation is termed ventilator-associated pneumonia; cases usually result from aspiration of pathogenic material that commonly colonises the oropharynx. The organisms often responsible for early onset ventilator-associated pneumonia are *Staph. aureus*, *Str. pneumoniae*, and *H. influenzae* while late-onset ventilator-associated pneumonia is often caused by resistant nosocomial pathogens such as *Ps. aeruginosa*, meticillin resistant *Staph. aureus*, *Klebsiella* spp., and *Acinetobacter baumannii*.[19]

Broad spectrum antibacterial therapy is essential for hospital-acquired pneumonia and most initial therapy is empirical. As in the treatment of community-acquired pneumonia selection of antibacterials must be localised. For initial empirical treatment of early-onset hospital-acquired pneumonia or ventilator-associated pneumonia in patients with no known risk factors for multidrug-resistant pathogens, and any disease severity, ATS recommends[20] the following drugs: ceftriaxone; levofloxacin, moxifloxacin, or ciprofloxacin; ampicillin/sulbactam; or ertapenem. Where there is late-onset infection or risk factors for multidrug resistance the following are recommended: an antipseudomonal cephalosporin (cefepime or ceftazidime) or an antipseudomonal carbapenem (imipenem or meropenem) or piperacillin-tazobactam together with an antipseudomonal fluoroquinolone (ciprofloxacin or levofloxacin) or an aminoglycoside (amikacin, gentamicin, or tobramycin); if MRSA is likely then linezolid or vancomycin should also be used. Intravenous therapy should be given to all patients initially, and changed to the oral or enteral route as soon as possible. Efforts should be made to shorten the duration of therapy from the traditional 14 to 21 days to as little as 7 days provided *Ps. aeruginosa* is absent and that the patient shows a good clinical response.

Nosocomial pneumonia is especially likely in immunocompromised or neutropenic patients. Prophylactic measures in ventilated patients are those mentioned under Intensive Care, p.175.

Immunocompromised patients. Immunosuppressed patients are at increased risk of pneumonia. In addition to the bacteria mentioned above they are susceptible to opportunistic infections with *Mycobacterium tuberculosis* (see under Tuberculosis, p.196); viruses such as *Cytomegalovirus* and fungi, in particular *Pneumocystis jirovecii* (see p.521), are also causes of pneumonia in these patients.

Aspiration pneumonia. Aspiration of organisms present in the upper respiratory tract into the lungs, often as a result of loss of consciousness or difficulty in swallowing, can cause aspiration pneumonia.[21] When community acquired the organisms responsible are predominantly anaerobes, but in hospital-acquired aspiration pneumonia Gram-negative bacilli and *Staph. aureus* are also found. Confusion has arisen over the term 'aspiration pneumonia' because it has also been applied more generally to aspiration, for example, of gastric acid (Mendelson's syndrome), resulting in chemical pneumonitis and not associated with bacterial infection. *Lung abscess* generally characterises late-stage aspiration pneumonia involving anaerobic bacteria. The aetiology is rarely established, but specific anaerobic bacteria involved include *Peptostreptococcus*, *Prevotella melaninogenica* (*Bacteroides melaninogenicus*), and *Fusobacterium nucleatum*. Nearly all patients with anaerobic pulmonary infections are treated empirically. Some[21] have expressed the view that penicillin and clindamycin are inadequate and that antibacterials with activity against Gram-negative organisms, such as third-generation cephalosporins, fluoroquinolones, and piperacillin are usually required even in community-acquired aspiration pneumonia. Most patients with lung abscess receive parenteral therapy until they become afebrile and show clinical improvement; oral therapy may then continue for weeks or months if necessary.

Pregnancy and the neonate

For infections associated specifically with pregnancy, see under Endometritis (p.170), Perinatal Streptococcal Infections (p.184), and Premature Labour (below).

Premature labour

Preterm birth, with or without rupture of membranes, causes significant perinatal morbidity and mortality. There is evidence that infection appears to have an important role in the cause or as a consequence of ruptured membranes[1,2] and as many as 50% of spontaneous preterm births are due to infection, with *Mycoplasma* spp. being the most commonly isolated organisms from the amniotic cavity.[3] Other bacteria that have been implicated include group B streptococci, *Chlamydia trachomatis*, and those associated with bacterial vaginosis. The role of antibacterial treatment has been evaluated. However, it is possible that maternal antibacterial treatment may suppress the stimulation of labour without effectively treating fetal infection[2] and concerns have been expressed that delaying delivery in the presence of a subclinical infection may not produce the best outcome for the neonate.[4]

A meta-analysis[5] and a systematic review[1] of studies of the routine use of antibacterials as adjuncts in the management of premature labour in women with *intact membranes* have failed to demonstrate an overall improvement in neonatal morbidity; indeed, an increase in neonatal mortality was actually noted.[5]

In women with preterm premature *rupture of membranes*, meta-analyses[6,7] and a systematic review[2] have shown that antibacterials could delay delivery, and reduce both maternal morbidity (chorioamnionitis and postpartum infections) and some aspects of neonatal morbidity (sepsis, pneumonia, and intraventricular haemorrhage). No effects on neonatal mortality or gestational age-related morbidity were noted.[2,7] An increased incidence of neonatal necrotising enterocolitis has been found after maternal use of amoxicillin with clavulanic acid and it is considered best avoided in women at risk of premature delivery; erythromycin may be the antibacterial of choice.[2] A systematic review and meta-analysis[3] evaluated the effect of antibacterials on the rate of preterm births when given in the second trimester of pregnancy to women at risk of preterm births. Giving macrolides or clindamycin was associated with a lower rate of preterm delivery, whereas giving metronidazole alone in the second trimester was associated with a greater risk of preterm delivery in a high-risk population.

Clinical infections of the genito-urinary tract during pregnancy are a cause of significant morbidity in the neonate and antimicrobial treatment is necessary (see Bacterial Vaginosis, p.164, Chlamydial Infections, p.166, and Perinatal Streptococcal Infections, p.184).

Proctitis

Proctitis is inflammation of the rectum that may be caused by sexually transmitted pathogens, most commonly *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Treponema pallidum*, or herpes simplex virus.

For empirical **treatment** of sexually transmitted proctitis the CDC[1] in the USA recommends a single intramuscular dose of ceftriaxone 125 mg, plus oral doxycycline 100 mg twice daily for 7 days.

The specific treatment of rectal infections caused by *C. trachomatis* and *N. gonorrhoeae* is discussed under Chlamydial Infections (p.166) and Gonorrhoea (p.191) respectively. Patients with herpes proctitis should be treated in the same way as those with genital herpes (p.854).

Prostatitis

See under Urinary-tract Infections, p.199.

Psittacosis

The causative organism of psittacosis (ornithosis) is *Chlamydophila psittaci* (*Chlamydia psittaci*). It is usually transmitted to humans by direct or indirect contact with infected birds and the primary site of infection is the lung.[1] The clinical presentation of psittacosis can vary widely from a mild 'flu-like' illness to a fulminating toxic state with multiple organ involvement.[1] Most patients will have a cough, although this is not always prominent. Tetracyclines are the treatment of choice[1,2] and early therapy may be life-saving; a 21-day course has been recommended since relapses have occurred after shorter periods.[1] An alternative is chloramphenicol.[2] Erythromycin or a similar macrolide have also been used successfully.[3,4]

Q fever

Q fever[1,2] (or query fever) is a rickettsial infection (p.190) caused by *Coxiella burnetii*. It is a zoonosis occurring worldwide and is transmitted to humans from domestic animals such as cattle and sheep, mainly by inhalation of infected dust. Q fever is asymptomatic in about 50 to 60% of infected persons. Symptomatic acute infection generally presents as a febrile flu-like illness and many patients may also have hepatitis or pneumonia that can progress to acute respiratory distress syndrome. Endocarditis is the most frequent form of chronic infection and the most serious form of Q fever; infection may be difficult to eradicate and prolonged treatment is generally needed. There is also evidence of long-term sequelae including lethargy and fatigue in patients who have not had cardiac involvement.

Subclinical **acute infections** should be treated if recognised and if possible treatment should be started within 3 days of the onset of symptoms. A tetracycline such as doxycycline for 14 days is the treatment of choice for acute Q fever. The role of macrolides in acute infection is unclear and clinical data on the use of fluoroquinolones are limited.[1,2] Co-trimoxazole is recommended for children younger than 8 years of age.[1] **Q fever endocarditis** is more difficult to treat and surgery may be required in addition to antibacterial treatment.[2] Monotherapy with tetracycline decreases symptoms but fails to eradicate *C. burnetii* and combination antibacterial therapy has been evaluated. Long-term treatment with doxycycline plus rifampicin or with ciprofloxacin alone[3] has been successful in individual patients with endocarditis, whereas pefloxacin alone[4] was not. A retrospective comparison of doxycycline alone or with rifampicin, fluoroquinolones (ofloxacin or pefloxacin), or co-trimoxazole, recommended treatment for at least 3 years with doxycycline plus a fluoroquinolone;[5] doxycycline plus rifampicin also appeared effective, but in most cases rifampicin had been stopped after a few months because of interactions with anticoagulants often prescribed at the same time. Patients given doxycycline plus hydroxychloroquine needed a shorter treatment course and had fewer relapses than those treated with doxycycline plus ofloxacin; mortality rate for both groups was 5%.[6] Successful treatment with doxycycline and chloroquine for 2 years has been reported in a patient with a biological prosthetic aortic valve and aortic homograft.[7] The combination of doxycycline 100 mg twice daily and hydroxychloroquine 200 mg three times daily, both given orally for at least 18 months, is considered to be the treatment of choice for Q fever endocarditis.[1,2] An alternative regimen for patients unable to tolerate hydroxychloroquine is doxycycline plus a fluoroquinolone for at least 3 to 4 years.[2]

Q fever during **pregnancy** may result in obstetric complications, such as spontaneous abortion, intra-uterine growth retardation, intra-uterine fetal death, and premature delivery.[8] Treatment with co-trimoxazole for at least 5 weeks during pregnancy was reported to protect against maternal chronic Q fever, placental infection, and obstetric complications (in particular intra-uterine fetal death).[8]

A vaccine is available in some countries for **prophylaxis** in occupational groups who regularly handle potentially infected animal tissues.

Relapsing fever

Relapsing fever is caused by spirochaetes of the *Borrelia* genus that are transmitted to humans by body lice or *Ornithodoros* ticks. *B. recurrentis* causes louse-borne relapsing fever and can occur widely, but is endemic especially in Ethiopia. Many species of *Borrelia* may cause tick-borne relapsing fever.

The treatment of choice for infection due to *B. recurrentis* is a tetracycline; benzylpenicillin or erythromycin are alternatives.[1] Therapy with single oral doses of tetracycline,[2,3] erythromycin,[2,3] or chloramphenicol[3] has been effective. Antibacterial treatment often causes a Jarisch-Herxheimer reaction characterised by rigor, fever and hypotension, which may be fatal.[2,4] Attempts to prevent this reaction include use of paracetamol and corticosteroids;[2,4] antibodies against tumour necrosis factor α have shown promise.[5]

Tick-borne relapsing fever is milder than the louse-borne variety, but has been treated similarly.

Respiratory-tract infections

Principal community-acquired bacterial pathogens in the respiratory tract are *Streptococcus pneumoniae* and *Haemophilus influenzae*, although *Moraxella catarrhalis* (*Branhamella catarrhalis*)[1] is increasingly important in some areas. Other respiratory pathogens include *Chlamydophila pneumoniae* (*Chlamydia pneumoniae*), *Legionella pneumophila*, and *Mycoplasma pneumoniae*. *Streptococcus pyogenes* is the predominant cause of pharyngitis. *Staphylococcus aureus* and aerobic Gram-negative bacilli such as *Pseudomonas aeruginosa* and *Klebsiella* spp. may be responsible for hospital-acquired (nosocomial) infections.

Community-acquired lower respiratory-tract infections are very common and are traditionally considered to be viral in origin, but bacterial pathogens similar to those causing pneumonia are commonly isolated from patients with these milder respiratory infections;[2] even so, about one-quarter of patients fail to respond satisfactorily to empirical antibacterial treatment. For previously healthy adults with non-specific upper respiratory-tract infection, US guidelines[3] recommend that antibacterials are not given.

Broad-spectrum antibacterials such as a penicillin or erythromycin may be necessary in some cases of uncomplicated upper or lower respiratory-tract infection. First line empirical treatment with a fluoroquinolone has been avoided in the past because of poor activity against streptococci,[4,5] although some newer fluoroquinolones have much greater activity against streptococci.[6]

In respiratory-tract infections complicating chronic obstructive pulmonary disease, amoxicillin has been recommended for first-line treatment.[7] If a further course is necessary, drugs with activity against penicillin-resistant *H. influenzae* and *M. catarrhalis* should probably be given, such as amoxicillin with clavulanic acid, a fluoroquinolone (bearing in mind that some are not very active against *Str. pneumoniae*), or a second-generation cephalosporin. Ofloxacin has been reported to be beneficial in patients with chronic obstructive pulmonary disease who require mechanical ventilation.[8]

For details on infections of the upper respiratory tract, see under Epiglottitis (p.170), Pharyngitis (p.185), and Sinusitis (p.193); see also Otitis Media (p.182). For infections of the lower respiratory tract, see under Bronchitis (p.165), Cystic Fibrosis (p.166), and Pneumonia (p.186); those with a specific cause include Legionnaires' Disease (p.176), Nocardiosis (p.181), Pertussis (p.185), and Tuberculosis (p.196).

Rheumatic fever

Acute rheumatic fever occurs especially in children aged 6 to 15 years as a consequence of upper respiratory-tract infections, such as pharyngitis or tonsillitis, with rheumatogenic strains of the group A beta-haemolytic streptococcus, *Streptococcus pyogenes*. The pathogenesis of rheumatic fever is not known, but an immune mechanism may be involved. There may be a latent period of 1 to 5 weeks after the initial infection, before clinical manifestations of rheumatic fever appear. The major ones are arthritis, carditis, chorea, erythema marginatum, and subcutaneous nodules. Those affecting the heart are the most serious and are a major cause of cardiovascular death in children and young adults in developing countries. Rheumatic fever has been associated with poverty and overcrowding and has declined dramatically in developed countries, but is still a major problem in the developing world. However, in the 1980s there was evidence of a resurgence in the USA with outbreaks of rheumatic fever reported in middle-class children[1] and military recruits.[2] Increased pathogenicity of *Str. pyogenes* serotypes might have contributed to this resurgence.[3] A high incidence is also seen among indigenous populations in Australia and New Zealand.[4]

Guidelines for the management and prevention of rheumatic fever have been published by sources including the American Heart Association (AHA),[5] WHO,[6] and an expert group from Australia and New Zealand.[7] Rheumatic fever can usually be prevented by *primary prophylaxis*, that is, by the prompt treatment of streptococcal upper respiratory-tract infection with eradication of group A streptococci from the throat. Penicillin is the drug of choice, either as a single intramuscular injection of benzathine benzylpenicillin or as a course of phenoxymethylpenicillin by mouth for 10 days. An injection containing benzathine benzylpenicillin and procaine benzylpenicillin has been used in children.[5] Erythromycin may be given to patients allergic to penicillin. Other macrolides or oral cephalosporins may also be used. For further details on the treatment of streptococcal sore throat, see under Pharyngitis, p.185. Treatment failure is more common after oral antibacterials and in the USA most of these patients are streptococcal carriers.[5] Treatment of chronic carriers is not usually necessary, but eradication of pharyngeal carriage has been achieved by an injection of benzathine benzylpenicillin plus rifampicin by mouth for 4 days;[8] a 10-day course of oral clindamycin has also been effective.[9] Broad-based primary prophylaxis in communities rather than individuals is controversial and requires careful planning, but, for example, penicillin prophylaxis did control an epidemic of acute tonsillitis associated with *Str. pyogenes* in a junior detention centre.[10] However, a study in military recruits demonstrated that *Str. pyogenes* infection could not be prevented in closely confined communities unless all individuals in the population received prophylaxis.[11]

If acute rheumatic fever occurs, a full therapeutic course of penicillin should be given initially, as for primary prevention, to eradicate group A streptococci.[5] Treatment then comprises bed rest and anti-inflammatory drugs, usually corticosteroids or salicylates, in an attempt to prevent valvular scarring. However, it is unclear whether anti-inflammatory treatment has any influence on such long-term sequelae.[12] Carbamazepine or valproate may be given for severe and distressing chorea.[7] *Secondary prevention* is then continued with prolonged antibacterial prophylaxis because of the high risk of recurrent attacks of rheumatic fever after subsequent streptococcal upper respiratory-tract infections. Again, penicillin is the preferred antibacterial, the usual recommendation being an intramuscular injection of benzathine benzylpenicillin every 4 weeks, although injections every 3 weeks may be warranted where the risk of recurrence is high.[5-7] This advice has been influenced by reports of high recurrence rates with the monthly regimen in such situations.[13] A 12-year study in Taiwan[14] confirmed that prophylaxis with benzathine benzylpenicillin injections every 3 weeks is more effective than injections every 4 weeks and it was recommended that the 3-week regimen should be used in adults and children with a recent episode of rheumatic fever, especially in developing countries where exposure to streptococci is still intense. In addition, pharmacokinetic studies have indicated relatively low serum concentrations of penicillin in the fourth week after an intramuscular injection of benzathine benzylpenicillin,[15,16] despite the successful use of monthly injections in most patients. However, Australian and New Zealand guidelines consider the 4-week regimen suitable in most patients.[7] Alternatively, oral prophylaxis with phenoxymethylpenicillin or sulfadiazine may be given, although, over the long time scale involved, compliance is likely to be a problem;[4,6,7] erythromycin is suggested for the rare patient who is allergic to penicillin and sulfonamides. Sulfonamides should *not* be used for primary prevention because they do not eradicate the streptococci. The duration of secondary prophylaxis depends on the individual patient, but in those who have not had rheumatic carditis it should generally continue for a minimum of 5 years after the last attack of rheumatic fever,[5,6] and at least until the age of 18 or early 20s. A study from Chile supported this view.[17] Those who have had rheumatic carditis but without residual valvular disease should perhaps receive prophylaxis for 10 years[5] or at least until the age of 25 years.[6] For those with carditis and persistent valvular disease, prophylaxis should continue at least until the age of 40 years, or sometimes for life.[5,6] Fears of serious allergic reactions associated with long-term benzathine benzylpenicillin prophylaxis appear to be unfounded.[18]

Household contacts of rheumatic fever patients who themselves have positive streptococcal cultures should be treated.[5]

Patients with rheumatic valvular heart disease as a result of rheumatic fever are at risk of developing infective endocarditis and may need additional appropriate short-term antibacterial prophylaxis when undergoing dental and some surgical procedures (see Endocarditis, p.168).

Rickettsial infections

Bacteria of the Rickettsiaceae family that infect man include *Rickettsia* spp. (see under Spotted Fevers, p.194 and Typhus, p.198) and *Coxiella burnetii* (see under Q fever, p.188). *Ehrlichia* spp. (see under Ehrlichiosis, p.168) and *Bartonella quintana* (*Rochalimaea quintana*) (see under Trench Fever, p.196) are no longer classified as a rickettsia. The treatment of choice for rickettsial infections is usually doxycycline; chloramphenicol or a fluoroquinolone are alternatives.[1]

Septicaemia

Traditionally, transient bacteraemia (the presence of bacteria in the blood) has been regarded as a fairly common condition which does not usually cause complications, whereas uncontrolled bacteraemia leads to septicaemia with serious symptoms such as fever and shock. This distinction has not always been adhered to in published sources and the terms have sometimes been used interchangeably. Added to this, the identification of the cascade of inflammatory mediators involved and the realisation that what had been called 'sepsis' could arise in the absence of infection have prompted reassessment of the terminology used both in the UK and in the USA.[1] In the UK, some authorities[2] considered that the term 'septicaemia' should no longer be used since it does not distinguish between mild and severe disease. The term 'sepsis syndrome' was preferred for patients with a generalised systemic response together with evidence of organ dysfunction and 'septic shock' to describe patients who also have hypotension not due to hypovolaemia or cardiac causes. The American College of Chest Physicians and Society of Critical Care Medicine proposed the following series of definitions to cover the spectrum of syndromes resulting from this inflammatory response:[1,3]

- **systemic inflammatory response syndrome** (SIRS), the systemic inflammatory response to infection or various other severe clinical insults including pancreatitis, ischaemia, trauma, and haemorrhagic shock
- **sepsis**, the SIRS caused specifically by infection
- **severe sepsis**, sepsis associated with organ dysfunction, perfusion abnormalities (such as lactic acidosis, oliguria, or an acute alteration in mental status), or hypotension
- **septic shock**, sepsis with hypotension, despite adequate fluid resuscitation, together with perfusion abnormalities
- **multiple organ dysfunction syndrome** (MODS), the presence of altered organ function in an acutely ill patient such that homoeostasis cannot be maintained without intervention; it may be a cause as well as a consequence of SIRS.

Septicaemia can be caused by many bacteria.[4] **Community-acquired** primary septicaemia is often associated with a specific infectious disease, such as meningococcal septicaemia with meningococcal meningitis (p.178) or streptococcal septicaemia with pneumonia (p.186). *Streptococcus pneumoniae* and *Haemophilus influenzae* are common causes of primary septicaemia in children (although this pattern is changing in countries where immunisation against *H. influenzae* type b is routine); Gram-negative rods and group B streptococci are commonest in neonates. **Hospital-acquired** septicaemia is often iatrogenic and may occur as a complication of surgery or indwelling catheters[5] or may be associated with neutropenia in immunocompromised patients (see under Infections in Immunocompromised Patients, p.174). Gram-positive organisms have been reported to be responsible for most infections.[6] Hospital-acquired septicaemia is often associated with acute respiratory distress syndrome (p.1498).

Whatever the cause, septicaemia requires prompt treatment without waiting for the results of laboratory tests. Choice of antibacterial depends on the probable source of infection. For example, urinary-tract infection is likely to be associated with Gram-negative septicaemia due to *Escherichia coli*; abdominal sepsis with Gram-negative septicaemia due to mixed infection with *E. coli*, enterococci, and anaerobic bacteria; and skin sepsis, bacterial arthritis, acute osteomyelitis, and cardiovascular shunts with Gram-positive septicaemia due to staphylococci. The antibacterials used should also reflect current patterns of bacterial resistance in the community or hospital. International guidelines[7] have recommended starting intravenous antibacterial therapy as early as possible, and within the first hour of recognition of septic shock; the initial choice of therapy should be broad enough to cover all likely pathogens, and it should be reassessed daily to optimise activity and prevent the development of resistance. De-escalation of combination therapy to the most appropriate single therapy should be carried out as soon as susceptibility of the infection is known. The typical duration of therapy will be 7 to 10 days. *Empirical treatment* has often begun with a penicillin and an aminoglycoside, metronidazole being added if anaerobic infection is suspected. In the UK, the *BNF* recommends that initial empirical treatment for community-acquired septicaemia is with either a broad-spectrum antipseudomonal penicillin (such as ticarcillin-clavulanic acid or piperacillin-tazobactam) or a broad-spectrum cephalosporin (such as ceftazidime or cefotaxime); for hospital-acquired septicaemia a broad-spectrum antipseudomonal beta-lactam antibacterial (such as ceftazidime, ticarcillin-clavulanic acid, piperacillin-tazobactam, imipenem-cilastatin, or meropenem) is recommended. In both cases, an aminoglycoside should be added if *Pseudomonas* is suspected or if sepsis is severe, metronidazole if anaerobic organisms are suspected, and vancomycin (or teicoplanin) if meticillin-resistant staphylococci are suspected. US guidelines[8] recommend a third- or fourth-generation cephalosporin (cefotaxime, ceftriaxone, ceftazidime, or cefepime), or piperacillin-tazobactam, or imipenem-cilastatin, or meropenem, in each case with an aminoglycoside (gentamicin, tobramycin, or amikacin) for the initial treatment of life-threatening sepsis in adults. When there is some information on which to base choice of treatment, but before the infecting organisms are definitely known, the following treatment is suggested:

- suspected bacterial endocarditis—ceftriaxone with vancomycin, possibly with gentamicin as well
- suspected meticillin-resistant staphylococci—vancomycin, alone or with gentamicin and/or rifampicin

Once the infecting organisms have been identified, choice of treatment will again depend on their sensitivity and current patterns of resistance in the community or hospital. For comments on the consequences of emerging multidrug-resistant strains of enterococci and staphylococci, see Enterococcal Infections, p.170, and Staphylococcal Infections, p.195.

In addition to antimicrobial therapy, patients with sepsis or septic shock[9,10] require rigorous supportive measures (p.1183).

Septicaemia is generally most lethal in the very old and the very young.

Neonatal septicaemia may be divided into **early-onset**, which is acquired from the mother's genital tract and manifests itself during the first few days after birth, and **late-onset** which may be nosocomially acquired. Bacteria commonly causing early-onset sepsis include enterococci, *E. coli*, *H. influenzae*, *Listeria monocytogenes*, and streptococci. Some of these organisms may also produce meningitis in the neonate (p.178). Empirical treatment for both early- and late-onset sepsis is based on similar principles to those in other patients, giving consideration to local patterns of infection and resistance and to the suitability of individual antibacterials for this age group. However, early-onset sepsis is usually best controlled by prenatal treatment of the mother or by perinatal prophylaxis. Prophylaxis for group B streptococcal infections is discussed under Perinatal Streptococcal Infections, p.184. While vancomycin has been shown to prevent infections with coagulase-negative staphylococci and to reduce the incidence of neonatal sepsis, widespread prophylactic use of this drug is not recommended.[11] Intravenous normal immunoglobulin (see Neonatal Infection, p.2229) and filgrastim (see Neutropenia, p.1071) have been tried for the prevention of septicaemia in preterm neonates with variable results.

Treatment failure in patients with sepsis or septic shock, occurring despite apparently adequate anti-infective therapy, might be due in part to a continuing **inflammatory process** and attempts to modify this are under investigation.[10,12] Endotoxin, a lipopolysaccharide associated with the cell membrane of Gram-negative bacteria, is an important mediator in the septic syndrome. Endotoxin release may occur spontaneously or during antibacterial therapy.[13] When in the circulation it stimulates the release of endogenous mediators such as interleukin-1, interleukin-6, tumour necrosis factor alpha, and other cytokines.[14] These in turn induce a cascade of secondary inflammatory mediators resulting eventually in endothelial damage and severe haemodynamic and metabolic derangements. It is now understood that a similar inflammatory response also occurs after non-infective insults. However, adjunctive therapy with endotoxin antibodies, anticytokines such as anakinra and tumour necrosis factor antibodies, soluble tumour necrosis factor receptor, bactericidal permeability increasing protein, nitric oxide synthase inhibitors, guanylate cyclase inhibitors such as methylthioninium chloride, and platelet-activating factor antagonists has generally produced disappointing results.[12,15,16] A systematic review[17] of the use of intravenous polyclonal immunoglobulin concluded that it had a promising role as adjuvant therapy in sepsis and septic shock. Specific monoclonal immunoglobulins were not effective.[17] Recent theories suggest that a more complex interplay of pro- and anti-inflammatory responses may be involved in the pathophysiology of SIRS and MODS and this may explain the failure of many of these mainly anti-inflammatory treatment modalities.[18] Reduced mortality has been reported[19] after the treatment of patients with severe sepsis with recombinant activated protein C (drotrecogin alfa) which has antithrombotic, anti-inflammatory, and pro-fibrinolytic properties, but its benefits appear to be limited to those at high risk of death. Studies with other physiological anticoagulants such as antithrombin III[20] and tissue factor pathway inhibitor (tifacogin)[21] have not been successful.

Sexually transmitted diseases

The sexually transmitted diseases, formerly termed venereal diseases, are defined as a group of communicable diseases that are transferred mainly by sexual contact. Many pathogens are known to be transmitted sexually including:

- bacteria:
  - *Chlamydia trachomatis* (see Lymphogranuloma Venereum, p.192 and Chlamydial Infections, p.166)
  - *Haemophilus ducreyi* (see Chancroid, p.191)
  - *Klebsiella granulomatis* (see Granuloma Inguinale, p.192)
  - *Neisseria gonorrhoeae* (see Gonorrhoea, p.191)
  - *Treponema pallidum* (see Syphilis, p.192)
  - *Ureaplasma urealyticum*
- protozoa:
  - *Trichomonas vaginalis* (see Trichomoniasis, p.827).
- viruses:
  - human immunodeficiency virus (see HIV Infection and AIDS, p.856)
  - hepatitis viruses (see Hepatitis, p.851)
  - herpesviruses (see Herpesvirus Infections, p.853)

Clinical syndromes associated with sexually transmitted diseases, and which are discussed in this section, include urethritis (p.199) and epididymitis (p.170) in men; cervicitis (p.166), pelvic inflammatory disease (p.184), and bacterial vaginosis (p.164) in women; and proctitis (p.188). Perinatal transmission of sexually transmitted pathogens from the mother can result in neonatal conjunctivitis (p.180) or pneumonia (p.186).

General guidelines for the management of sexually transmitted diseases have been published[1-3] although recommendations may need to be localised because of differences in patterns of infection and drug resistance. Early detection and treatment are required to prevent long-term complications, including infertility, still-births and neonatal infections, genital cancers, and an increased risk of acquiring and transmitting HIV.

The suggestion that spermicidal contraceptives may provide some protection against sexually transmitted diseases is discussed under Nonoxinols, p.1917.

1. CDC. Sexually transmitted diseases treatment guidelines 2006. *MMWR* 2006; **55** (RR-11): 1–94. Also available at: http://www.cdc.gov/mmwr/PDF/rr/rr5511.pdf (accessed 23/03/07)
2. WHO. Guidelines for the management of sexually transmitted infections. Geneva: WHO, 2003. Also available at: http://whqlibdoc.who.int/publications/2003/9241546263.pdf (accessed 23/03/07)
3. Clinical Effectiveness Group (Association for Genitourinary Medicine and the Medical Society for the Study of Venereal Diseases - now British Association for Sexual Health and HIV). National guideline on the management of suspected sexually transmitted infections in children and young people. Available at: http://www.bashh.org/documents/41/41.pdf (accessed 18/08/08)

Chancroid. Chancroid is a sexually transmitted disease caused by the Gram-negative bacterium *Haemophilus ducreyi*. It occurs worldwide, but is endemic in parts of Africa and South East Asia, where it is a frequent cause of painful genital ulcers and a risk factor in the transmission of HIV.

Specific **treatment** guidelines have been provided by WHO,[1] by expert groups in the UK,[2] and by the CDC in the USA.[3] Treatment failure may be more common in patients also infected with HIV[1] (see below), but in other patients single-dose treatment regimens might be preferable if compliance is a problem. Guideline regimens are as follows:

- **WHO:**
  - oral ciprofloxacin 500 mg twice daily for 3 days, *or*
  - oral erythromycin 500 mg four times daily for 7 days, *or*
  - a single oral dose of azithromycin 1 g

  an alternative regimen is:
  - a single intramuscular injection of ceftriaxone 250 mg
- **UK:**
  - a single oral dose of azithromycin 1 g, *or*
  - a single intramuscular dose of ceftriaxone 250 mg, *or*
  - oral ciprofloxacin 500 mg twice daily for 3 days *or* as a single oral dose

  further alternatives are:
  - oral erythromycin 500 mg four times daily for 7 days
  - single oral doses of other fluoroquinolones such as fleroxacin 400 mg *or* norfloxacin 800 mg
  - a single intramuscular injection of spectinomycin 2 g
- **USA:**
  - a single oral dose of azithromycin 1 g, *or*
  - a single intramuscular dose of ceftriaxone 250 mg, *or*
  - oral ciprofloxacin 500 mg twice daily for 3 days

  a further alternative is:
  - oral erythromycin 500 mg three times daily for 7 days

Sexual partners of patients with chancroid should also be tested and treated.[2,3]

Patients co-infected with HIV have ulcers that heal more slowly and may need to be treated for longer to prevent treatment failure;[3] treatment failure is common with single-dose regimens.[1]

1. WHO. Guidelines for the management of sexually transmitted infections. Geneva: WHO, 2003. Also available at: http://whqlibdoc.who.int/publications/2003/9241546263.pdf (accessed 23/03/07)
2. Clinical Effectiveness Group (Association for Genitourinary Medicine and the Medical Society for the Study of Venereal Diseases – now British Association for Sexual Health and HIV). 2001 National guideline for the management of chancroid. Available at: http://www.bashh.org/documents/85/85.pdf (accessed 18/08/08)
3. CDC. Sexually transmitted diseases treatment guidelines 2006. *MMWR* 2006; **55**(RR-11): 1–94. Also available at: http://www.cdc.gov/mmwr/PDF/rr/rr5511.pdf (accessed 23/03/07)

Gonorrhoea. Gonorrhoea is a sexually transmitted disease caused by infection of mucosa with *Neisseria gonorrhoeae* (gonococcus), a Gram-negative bacterium. It occurs mainly in the lower genital tract as urethritis (p.199) in men and cervicitis (p.166) in women, but also as pharyngitis, proctitis (p.188), or conjunctivitis. Infection may sometimes ascend to the upper genital tract to cause complications such as pelvic inflammatory disease (p.184) in women and epididymitis (p.170) in men. In the USA[1] routine screening is recommended for all sexually active women with an increased risk of infection. Disseminated gonococcal infection resulting from gonococcal bacteraemia is rare and may lead to septic arthritis, an arthritis-dermatitis syndrome (not to be confused with Reiter's disease which has been associated with non-gonococcal or nonspecific urethritis), and more rarely to conditions such as endocarditis or meningitis. Gonorrhoea in pregnant women may cause neonatal gonococcal conjunctivitis (ophthalmia neonatorum).

Antibacterial drug resistance is a problem in the management of gonococcal infection. Penicillins were once the treatment of choice for *N. gonorrhoeae* but are no longer recommended. High-level plasmid-mediated and chromosomally mediated resistances have also been reported with tetracycline, and chromosomally mediated resistance to other antibiotics may occur. Gonococcal resistance is now monitored in England and Wales via the Gonococcal Resistance to Antimicrobials Surveillance Programme (GRASP)[2] and in the USA by the Gonococcal Isolate Surveillance Project (GISP).[3] Of concern are the increasing number of reports worldwide of resistance to fluoroquinolones which has resulted in revision of treatment guidelines. In the UK fluoroquinolones are no longer recommended as first-line drugs, while in the USA they are no longer recommended for gonococcal infections.

Infection with *Chlamydia trachomatis* (see under Chlamydial Infections, p.166) often occurs along with gonorrhoea and should be tested for or treated presumptively.

Guidelines produced by WHO,[4] by an expert group in the UK,[5] and by the CDC in the USA[1] for the **treatment** of gonorrhoea are as follows, although recommendations may need to be localised because of differences in patterns of infection and drug resistance:

- UNCOMPLICATED ANOGENITAL GONOCOCCAL INFECTIONS IN ADULTS.
  - **WHO**:
    - a single oral dose of ciprofloxacin 500 mg, *or*
    - a single oral dose of cefixime 400 mg, *or*
    - a single intramuscular dose of ceftriaxone 125 mg, *or*
    - a single intramuscular dose of spectinomycin 2 g
  - **UK:**
    - a single intramuscular dose of ceftriaxone 250 mg, *or*
    - a single intramuscular dose of spectinomycin 2 g, *or*
    - a single oral dose of cefixime 400 mg

    alternative regimens are:
    - a single oral dose of ciprofloxacin 500 mg
    - a single oral dose of ofloxacin 400 mg
    - a single oral dose of ampicillin 2 or 3 g *plus* probenecid 1 g
    - a single intramuscular dose of cefotaxime 500 mg
    - a single intramuscular dose of cefoxitin 2 g plus oral probenecid 1 g
  - **USA:**
    - a single oral dose of cefixime 400 mg, *or*
    - a single intramuscular dose of ceftriaxone 125 mg

    Other single dose cephalosporins may be substituted. A single intramuscular dose of spectinomycin 2 g is an alternative in patients who cannot tolerate cephalosporins.
- PHARYNGEAL INFECTIONS.
  - **UK:**
    - a single oral dose of ciprofloxacin 500 mg, *or*
    - a single oral dose of ofloxacin 400 mg, *or*
    - a single intramuscular dose of ceftriaxone 250 mg
  - **USA:**
    - a single intramuscular dose of ceftriaxone 125 mg
- GONOCOCCAL INFECTIONS IN PREGNANT WOMEN.
  - **WHO:**
    - a single oral dose of cefixime 400 mg, *or*
    - a single intramuscular dose of ceftriaxone 125 mg, *or*
    - a single intramuscular dose of spectinomycin 2 g
  - **UK:**
    - a single intramuscular dose of ceftriaxone 250 mg, *or*
    - a single intramuscular dose of spectinomycin 2 g, *or*
    - a single oral dose of cefixime 400 mg, *or*
    - a single oral dose of amoxicillin 3 g (*or* ampicillin 2 or 3 g) plus probenecid 1 g
  - **USA:**
    - a cephalosporin or spectinomycin
- GONOCOCCAL EYE INFECTIONS IN ADULTS.
  - **WHO:** frequent irrigation of the infected eye with saline together with:
    - a single intramuscular dose of ceftriaxone 125 mg, *or*
    - a single intramuscular dose of spectinomycin 2 g, *or*
    - a single oral dose of ciprofloxacin 500 mg

    a further alternative is:
    - a single intramuscular dose of kanamycin 2 g
  - **USA:** irrigation of the infected eye with saline together with:
    - a single intramuscular dose of ceftriaxone 1 g
- DISSEMINATED GONOCOCCAL INFECTIONS IN ADULTS.
  - **WHO:**
    - parenteral ceftriaxone 1 g once daily for 7 days, *or*
    - intramuscular spectinomycin 2 g twice daily for 7 days

    Another third-generation cephalosporin may be substituted if neither of these drugs is available. Treatment for endocarditis should continue for 28 days.
  - **USA:**
    - parenteral ceftriaxone 1 g every 24 hours

    alternatives are:
    - intravenous ceftizoxime 1 g every 8 hours
    - cefotaxime 1 g every 8 hours
    - intramuscular spectinomycin 2 g every 12 hours

    Once improvement has been established for 24 to 48 hours, oral therapy with cefixime 400 mg twice daily, *or* cefpodoxime 400 mg twice daily may be substituted until at least a 1-week treatment period is complete. Provided antimicrobial susceptibility is documented fluoroquinolones may be given as an alternative treatment.

    For gonococcal meningitis and endocarditis, intravenous ceftriaxone 1 to 2 g every 12 hours is recommended; treatment for meningitis should continue for 10 to 14 days and for endocarditis for at least 4 weeks.

- GONOCOCCAL INFECTIONS IN NEONATES AND CHILDREN.

Neonates born to mothers with gonorrhoea are at high risk of infection and require *prophylaxis*:

- **WHO:**
  - a single intramuscular injection of ceftriaxone 50 mg/kg (maximum 125 mg)

  alternatives are:
  - a single intramuscular dose of spectinomycin 25 mg/kg (maximum 75 mg)
  - a single intramuscular dose of kanamycin 25 mg/kg (maximum 75 mg)
- **USA:**
  - a single parenteral dose of ceftriaxone 25 to 50 mg/kg (maximum 125 mg)

For those neonates with *disseminated gonococcal infection* (sepsis, arthritis, meningitis), US recommendations are:

- parenteral ceftriaxone 25 to 50 mg/kg once daily for 7 days, *or*
- parenteral cefotaxime 25 mg/kg every 12 hours for 7 days

Treatment should be extended to 10 to 14 days if meningitis is present.

Treatment for *children* with uncomplicated gonococcal infections, most commonly due to sexual abuse in preadolescents, is as for adults in those weighing 45 kg or more. For those weighing less than 45 kg a single intramuscular dose of ceftriaxone 125 mg *or* spectinomycin 40 mg/kg (maximum 2 g) is recommended. For disseminated infection in all children an intramuscular or intravenous dose of ceftriaxone 50 mg/kg once daily for 7 days, up to a maximum dose of 1 g in those weighing less than 45 kg is recommended.

The prevention and treatment of neonatal gonococcal conjunctivitis is discussed under Neonatal Conjunctivitis, p.180.

Sexual partners of patients with gonococcal infection should be tested and treated.[1]

Patients co-infected with HIV should receive the same treatment as those who are HIV-negative.[1]

4. WHO. Guidelines for the management of sexually transmitted infections. Geneva: WHO, 2003. Also available at: http://whqlibdoc.who.int/publications/2003/9241546263.pdf (accessed 20/06/07)
5. Clinical Effectiveness Group (British Association for Sexual Health and HIV). National guideline on the diagnosis and treatment of gonorrhoea in adults 2005. Available at: http://www.bashh.org/documents/116/116.pdf (accessed 18/08/08)

Granuloma inguinale. Granuloma inguinale or donovanosis is caused by the Gram-negative bacterium *Klebsiella granulomatis* (formerly known as *Calymmatobacterium granulomatis*) and occurs most commonly in the tropics and subtropics, especially Papua New Guinea and India. It is characterised by genital ulcers and is generally considered to be a sexually transmitted disease.

Guidelines produced by WHO,[1] by an expert group in the UK,[2] and by the CDC in the USA[3] for the **treatment** of granuloma inguinale are as follows:

- **WHO:**
  - oral azithromycin 1 g on the first day then 500 mg once daily, *or*
  - oral doxycycline 100 mg twice daily

  alternatives include:
  - oral erythromycin 500 mg four times daily
  - oral tetracycline 500 mg four times daily
  - oral co-trimoxazole 960 mg twice daily

  Treatment is continued until all lesions have completely resolved. The addition of parenteral gentamicin should be considered for HIV-infected patients. Streptomycin is no longer recommended because of its toxicity and the need to reserve it for tuberculosis.
- **UK:**
  - oral azithromycin 1 g once weekly or 500 mg daily, *or*
  - parenteral ceftriaxone 1 g once daily, *or*
  - oral co-trimoxazole 960 mg twice daily, *or*
  - oral doxycycline 100 mg twice daily, *or*
  - oral erythromycin 500 mg four times daily, *or*
  - oral norfloxacin 400 mg twice daily

  The addition of parenteral gentamicin 1 mg/kg every 8 hours should be considered if lesions do not respond during the first few days of treatment.
- **USA:**
  - oral doxycycline 100 mg twice daily for a minimum of 3 weeks

  alternatives are:
  - oral ciprofloxacin 750 mg twice daily, *or*
  - oral erythromycin 500 mg four times daily, *or*
  - oral azithromycin 1 g once weekly, *or*
  - oral co-trimoxazole 960 mg twice daily

  In each case treatment is for 3 weeks. The addition of an aminoglycoside may be considered if lesions do not respond during the first few days of treatment, in pregnant women, and in those co-infected with HIV.

Sexual partners of patients with granuloma inguinale should be tested and treated.[2,3]

Patients co-infected with HIV should receive the same treatment as those who are HIV-negative.[3]

1. WHO. Guidelines for the management of sexually transmitted infections. Geneva: WHO, 2003. Also available at: http://whqlibdoc.who.int/publications/2003/9241546263.pdf (accessed 23/03/07)

3. CDC. Sexually transmitted diseases treatment guidelines 2006. *MMWR* 2006; **55**(RR-11): 1–94. Also available at: http://www.cdc.gov/mmwr/PDF/rr/rr5511.pdf (accessed 23/03/07)

Lymphogranuloma venereum. Lymphogranuloma venereum or chlamydial lymphogranuloma is an invasive, systemic infection caused by certain serotypes of *Chlamydia trachomatis* and is endemic in tropical and subtropical areas, but may also occur in the developed world. It is a sexually transmitted disease and in the early phase may cause genital ulceration although the commonest clinical manifestation is unilateral inguinal and/or femoral lymphadenopathy. There is multisystem involvement and late complications, including those related to fibrosis and abnormal lymphatic drainage, may require surgery.

Guidelines produced by WHO,[1] by an expert group in the UK,[2] and by the CDC in the USA[3] for the **treatment** of lymphogranuloma venereum are as follows:

- **WHO:** treatment for 2 weeks with:
  - oral doxycycline 100 mg twice daily, *or*
  - oral erythromycin 500 mg four times daily

  an alternative is:
  - oral tetracycline 500 mg four times daily
- **UK** and **USA:** treatment for 3 weeks with:
  - oral doxycycline 100 mg twice daily, *or*
  - oral tetracycline 2 g daily, *or*
  - oral minocycline 300 mg as a loading dose *then* 200 mg twice daily, *or*
  - oral erythromycin 500 mg four times daily

  Sexual partners of patients with lymphogranuloma venereum should be treated with:
  - a single oral dose of azithromycin 1 g *or*
  - oral doxycycline 100 mg twice daily for 7 days

Patients co-infected with HIV should receive the same treatment as those who are HIV-negative, although longer therapy may be required.[3]

1. WHO. Guidelines for the management of sexually transmitted infections. Geneva: WHO, 2003. Also available at: http://whqlibdoc.who.int/publications/2003/9241546263.pdf (accessed 23/03/07)

3. CDC. Sexually transmitted diseases treatment guidelines 2006. *MMWR* 2006; **55**(RR-11): 1–94. Also available at: http://www.cdc.gov/mmwr/PDF/rr/rr5511.pdf (accessed 23/03/07)

Syphilis. Syphilis is a sexually transmitted disease caused by the spirochaete *Treponema pallidum* and occurs worldwide. Non-venereal treponematoses include endemic syphilis or bejel, also caused by *T. pallidum*; pinta, caused by *T. carateum*; and yaws, caused by *T. pertenue*.

Syphilis may be **classified** as acquired or congenital and in each case has early and late stages. Syphilis may be described as latent, when serological and CSF tests are positive but the patient is asymptomatic.

- In acquired sexually transmitted disease the *early* stage includes primary and secondary syphilis and early latent infection; early latent infection is defined in the UK[1] and by WHO[2] as of not more than 2 years' duration or of less than 1 year's duration by the CDC in the USA.[3]
- *Late* stage disease includes late latent infection and all late clinical stages. The late clinical stages fall broadly into three types: *neurosyphilis* manifesting as neurological symptoms, commonly including dorsal column loss (tabes dorsalis), dementia, or meningovascular involvement; *cardiovascular* syphilis, characterised by aortitis which may manifest as aortic regurgitation, aortic aneurysm, or angina; and *gummata*, inflammatory fibrous nodules or plaques which may be locally destructive and which commonly affect the bone and skin but may occur in any organ. Some term all these late clinical stages tertiary syphilis whereas others use tertiary for benign gummatous syphilis and quaternary for the more serious complications of cardiovascular syphilis and neurosyphilis. The term neurosyphilis has generally been applied to late-stage symptomatic neurological disease, although it is recognised that CNS invasion by *T. pallidum* is common in early syphilis and that CNS involvement may occur at any stage.
- *Congenital syphilis* may result from transplacental infection at any stage of pregnancy and any stage of maternal syphilis.

The incidence of syphilis fell dramatically after the introduction of penicillin and *T. pallidum* remains sensitive to it. There has, however, been a resurgence of syphilis, linked in part with HIV infection. In HIV-infected patients syphilis appears more virulent and neurosyphilis occurs more quickly. Like other diseases causing genital ulcers, syphilis is a risk factor for HIV infection.

The **treatment** of choice for both early and late syphilis is still penicillin and long-acting injections are generally used. Treatment for late syphilis is less well-established than that for early disease and is usually given for longer. A Jarisch-Herxheimer reaction may occur after the first dose of antibacterial, especially in patients with early syphilis, and corticosteroid cover may be beneficial, especially in patients with cardiovascular or neurological involvement.

Guidelines produced by WHO,[2] by an expert group in the UK,[1] and by the CDC in the USA[3] for the treatment of acquired and congenital syphilis are as follows:

- EARLY SYPHILIS
  - **WHO**:
    - intramuscular benzathine benzylpenicillin 1.8 g (2.4 million units) usually given as 2 injections at separate sites in a single session, *or*
    - intramuscular procaine benzylpenicillin 1.2 g (1.2 million units) daily for 10 days

    alternatives for non-pregnant penicillin-allergic patients are:
    - oral doxycycline 100 mg twice daily for 14 days, *or*
    - oral tetracycline 500 mg four times daily for 14 days

    Pregnant women allergic to penicillin may be given:
    - oral erythromycin 500 mg four times daily for 14 days (but see Syphilis in Pregnancy, below)
  - **UK**:
    - intramuscular benzathine benzylpenicillin 1.8 g (2.4 million units) as a single dose, *or*
    - intramuscular procaine benzylpenicillin 600 mg (600 000 units) daily for 10 days

    An additional alternative if parenteral therapy is refused is:
    - oral amoxicillin 500 mg *plus* oral probenecid 500 mg, both four times daily for 14 days

    alternatives for penicillin-allergic patients are:
    - oral doxycycline 100 mg twice daily for 14 days
    - oral erythromycin 500 mg four times daily for 14 days
    - oral azithromycin 2 g as a single dose
    - oral azithromycin 500 mg daily for 10 days
    - intramuscular ceftriaxone 500 mg daily for 10 days (in the absence of anaphylaxis to penicillin)
  - **USA**:
    - a single intramuscular dose of benzathine benzylpenicillin 1.8 g (2.4 million units)

    alternatives for penicillin-allergic patients are:
    - oral doxycycline 100 mg twice daily for 14 days
    - oral tetracycline 500 mg four times daily for 14 days

    Preliminary data suggest that azithromycin 2 g orally as a single dose may also be effective, *or* parenteral ceftriaxone 1 g daily for 8 to 10 days may also be considered.

- LATE SYPHILIS
  - **WHO**:
    - intramuscular benzathine benzylpenicillin 1.8 g (2.4 million units) once weekly for 3 consecutive weeks, *or*
    - intramuscular procaine benzylpenicillin 1.2 g (1.2 million units) daily for 20 consecutive days

    alternatives for non-pregnant penicillin-allergic patients are:
    - oral doxycycline 100 mg twice daily for 30 days, *or*
    - oral tetracycline 500 mg four times daily for 30 days

    Pregnant women allergic to penicillin may be given:
    - oral erythromycin 500 mg four times daily for 30 days

    For those with *neurosyphilis*:
    - intravenous benzylpenicillin 1.2 to 2.4 g (2 to 4 million units) every 4 hours for 14 days, *or*
    - if outpatient compliance can be ensured, intramuscular procaine benzylpenicillin 1.2 g (1.2 million units) daily *plus* oral probenecid 500 mg four times daily each for 10 to 14 days

    alternatives for non-pregnant penicillin-allergic patients are:
    - oral doxycycline 200 mg twice daily for 30 days
    - oral tetracycline 500 mg four times daily for 30 days
  - **UK**:
    - intramuscular benzathine benzylpenicillin 1.8 g (2.4 million units) weekly for 3 doses, *or*
    - intramuscular procaine benzylpenicillin 600 mg (600 000 units) daily for 17 days

    alternatives for patients allergic to penicillin and those declining parenteral therapy are:
    - oral doxycycline 100 mg twice daily for 28 days, *or*
    - if penicillin can be tolerated, oral amoxicillin 2 g three times daily *plus* oral probenecid 500 mg four times daily, both for 28 days

    For those with *neurosyphilis* recommendations are:
    - intramuscular procaine benzylpenicillin 1.8 to 2.4 g (1.8 to 2.4 million units) once daily *plus* oral probenecid 500 mg four times daily for 17 days, *or*
    - intravenous benzylpenicillin 1.8 to 2.4 g (3 to 4 million units) every 4 hours for 17 days

    alternatives are:
    - oral doxycycline 200 mg twice daily for 28 days
    - oral amoxicillin 2 g three times daily *plus* oral probenecid 500 mg four times daily, both for 28 days
    - intramuscular or intravenous ceftriaxone 2 g daily for 10 to 14 days (in the absence of anaphylaxis to penicillin)
  - **USA**:
    - intramuscular benzathine benzylpenicillin 1.8 g (2.4 million units) weekly for 3 consecutive weeks

    alternatives in penicillin-allergic patients are:
    - oral doxycycline 100 mg twice daily for 28 days, *or*
    - oral tetracycline 500 mg four times daily for 28 days

    For those with *neurosyphilis*:
    - intravenous benzylpenicillin 1.8 to 2.4 g (3 to 4 million units) every 4 hours for 10 to 14 days (or the total daily dose may be given by continuous infusion), *or*
    - if outpatient compliance can be ensured, then intramuscular procaine benzylpenicillin 2.4 g (2.4 million units) daily *plus* oral probenecid 500 mg four times daily, both for 10 to 14 days

    Since the duration of treatment for neurosyphilis is shorter than that for late syphilis in the absence of neurosyphilis, some clinicians give intramuscular benzathine benzylpenicillin 1.8 g (2.4 million units) once weekly for up to 3 weeks after completion of neurosyphilis treatment to provide a comparable total duration of treatment.
- SYPHILIS IN PREGNANCY

  All guidelines recommend penicillin as under early and late syphilis, together with close surveillance. In the USA, CDC[3] note that some recommend a second dose of benzathine benzylpenicillin a week after the initial dose for patients with early syphilis. In the UK[1] it is recommended that when the first dose is given in the third trimester a second dose should be given one week later. According to CDC,[3] pregnant patients who are allergic to penicillin should be given penicillin, after desensitisation if necessary, since the alternatives, tetracyclines, are contra-indicated during pregnancy and erythromycin cannot be relied upon to cure an infected fetus. WHO,[2] on the other hand, advise against desensitisation in a primary care setting and suggest that erythromycin, although inferior, should be given in these circumstances; consideration should probably be given to use of a third-generation cephalosporin in the absence of anaphylaxis. After treatment, the mother should be re-treated if there is serological evidence of re-infection or relapse, and the infant treated.[2] UK guidelines[1] list alternative antibacterials that may be given as: amoxicillin, ceftriaxone, erythromycin or azithromycin. they also state that desensitisation should be considered in those allergic to penicillin.
- CONGENITAL SYPHILIS
  - **WHO**:

    for early congenital syphilis, infants up to 2 years of age and having abnormal CSF may be given:
    - intravenous benzylpenicillin 30 mg/kg (50 000 units/kg) twice daily for the first 7 days of life and then three times daily for a total of 10 days, *or*
    - intramuscular procaine benzylpenicillin 50 mg/kg (50 000 units/kg) once daily for 10 days

    For infants with normal CSF (although some treat all infants as if the CSF were abnormal):
    - a single intramuscular dose of benzathine benzylpenicillin 37.5 mg/kg (50 000 units/kg)

    Children older than 2 years may be given:
    - parenteral benzylpenicillin 30 mg/kg (50 000 units/kg) every 4 to 6 hours for 10 to 14 days

    For penicillin-allergic infants aged over 1 month:
    - oral erythromycin 7.5 to 12.5 mg/kg four times daily for 30 days
  - **UK**: recommended doses are as for infants up to 2 years with abnormal CSF in WHO guidelines, above.
  - **USA**:

    Neonates (up to 4 weeks of age) and having proven or probable disease:
    - intravenous benzylpenicillin 30 mg/kg (50 000 units/kg) twice daily for the first 7 days of life and then three times daily for a total of 10 days, *or*
    - intramuscular procaine benzylpenicillin 50 mg/kg (50 000 units/kg) once daily for 10 days

    Neonates who have a normal physical and a non-treponemal serum titre the same as or less than 4 times the maternal titre may be given, depending on how successfully the mother was treated during pregnancy:
    - one of the above treatment regimens *or*
    - a single intramuscular dose of benzathine benzylpenicillin 37.5 mg/kg (50 000 units/kg)

    Infants and children may be given:
    - intravenous benzylpenicillin 30 mg/kg (50 000 units/kg) every 4 to 6 hours for 10 days.

    Those who are allergic to penicillin should be desensitised if necessary.

Sexual partners of patients with syphilis in any stage should be examined, tested, and treated.[2,3]

In the UK,[1] it is advised that all cases of syphilis in HIV-infected patients be treated as for the appropriate stage of infection as in HIV-negative patients; some experts recommend treatment as for neurosyphilis but the UK guidelines note that evidence for this policy is lacking. The CDC[3] and WHO[2] consider that standard treatment with a single intramuscular dose of benzathine benzylpenicillin 1.8 g (2.4 million units) is sufficient, but acknowledge that some authorities recommend more intensive treatment regimens.

Sinusitis

Sinusitis or inflammation of the paranasal sinuses can be caused by viral, bacterial, or fungal infection or may be secondary to other disorders such as allergy. Serious complications include bacterial meningitis and brain abscess.

Acute sinusitis often results from viral upper respiratory-tract infections. As in acute otitis media the most frequent bacterial pathogens are *Streptococcus pneumoniae* and unencapsulated *Haemophilus influenzae*, with *Moraxella catarrhalis* (*Branhamella catarrhalis*) increasingly important in children. Other bacterial causes, especially in adults, include mixed anaerobic bacteria (usually associated with dental disease and more frequent in chronic sinusitis), *Staphylococcus aureus*, *Streptococcus pyogenes*, and Gram-negative bacteria including Enterobacteriaceae and *Pseudomonas aeruginosa* (in nosocomial sinusitis). About 5% of primary sinusitis in young adults has been associated with *Chlamydophila pneumoniae* (*Chlamydia pneumoniae*).

Acute sinusitis may resolve spontaneously. In an evidence-based report on the diagnosis and treatment of rhinosinusitis,[1] the Agency for Health Care Policy and Research in the USA has stated that most patients with the acute condition will recover without antibacterial therapy, although they will recover faster if antibacterials are given. However, a systematic review concluded that any treatment effect of antibacterials was small.[2] The Agency also considered[1] that the use of new antibacterials for treating uncomplicated community-acquired acute bacterial rhinosinusitis was not justified and that amoxicillin or folate inhibitors were sufficiently effective. This view was supported by a meta-analysis.[3] US guidelines for the management of sinusitis in adults[4] state that most cases will resolve without antibacterial treatment and recommend that antibacterials should be reserved for those patients with persistent moderate or severe symptoms. However, a later meta-analysis[5] considered that antibacterials could not be justified, even in patients who reported symptoms for longer than 7 to 10 days; the only reason for antibacterial treatment was the presence of signs suggestive of a serious complication (such as high fever, periorbital swelling, erythema, or intense facial pain). Guidelines from the American Academy of Pediatrics for the management of sinusitis in children[6] recommend that antibacterials be given to children clinically diagnosed with persistent or severe acute bacterial sinusitis in order to achieve a more rapid clinical cure.

If antibacterials are considered necessary, treatment should be given for an adequate length of time, usually 2 weeks.[6-8] Topical decongestants may also be used to promote drainage and ventilation.[7,8] The choice of antibacterial is similar to that for acute otitis media (p.182). Effective antibacterials include amoxicillin with or without clavulanic acid, cefuroxime, clarithromycin, clindamycin and azithromycin;[6] the emergence of penicillin-resistant strains of *H. influenzae*, *M. catarrhalis*, and *Str. pneumoniae* is of concern.[9] Co-trimoxazole or erythromycin with sulfafurazole have also been used although pneumococcal resistance has been reported to be substantial.[6] Patients with evidence of severe infections may need initial intravenous therapy with vancomycin and ceftriaxone or cefotaxime.[9] Tetracycline or erythromycin are the most effective antibacterials against *Chlamydophila pneumoniae*.[10]

Failure to treat acute sinusitis that does not resolve spontaneously can result in chronic sinusitis or occasionally in complications such as brain abscess or meningitis. Exacerbations of chronic sinusitis are treated as for acute infection. Management of chronic sinusitis is based on reducing obstruction of the sinus cavity using antihistamines, decongestants, anti-inflammatory drugs (including corticosteroids), and saline washes as appropriate.[7,11,12] The usefulness of antibacterials is more contentious,[11] although some clinicians advocate prolonged courses as part of initial treatment.[7,12] As well as their established antibacterial effect, it has been suggested that macrolides also have immunomodulatory effects that could be useful in the management of respiratory diseases including chronic sinusitis but large placebo-controlled studies are needed. Surgical intervention may be necessary if medical treatment fails.

Skin infections

Bacterial infections of the skin may result from invasion of skin structures by endogenous skin flora or by exogenous pathogenic organisms. They include the primary pyodermas (for example, impetigo, folliculitis, furunculosis, erysipelas, cellulitis, and ecthyma) and secondary infections complicating pre-existing skin lesions, for example diabetic or other chronic superficial skin ulcers, burns, bites and stings (p.164), eczema, or may occur as opportunistic infections after skin trauma in immunocompromised patients.

The pyodermas are commonly caused by *Staphylococcus aureus* or, less commonly, by beta-haemolytic streptococci. Skin ulcers and burns may typically be colonised by *Staph. aureus* or *Pseudomonas aeruginosa*; chronic ulcers and fungating tumours may also be colonised by anaerobes which can cause an offensive odour.

Skin disorders of uncertain or mixed aetiology that are treated with antibacterials include acne (p.1577) and rosacea (p.1583). Systemic infections with cutaneous involvement include anthrax (p.163), diphtheria (p.168), and mycetoma (p.180).

Topical antibacterials and antiseptics may be useful for superficial skin infections, but antibacterials should only be used short term because of the risks of inducing bacterial resistance and contact allergy. Topical use of antibacterials that are of value systemically, such as gentamicin, is best avoided, although fusidic acid is used topically in the UK. Application of topical antibacterials to extensive areas of damaged skin can result in systemic toxicity.

Serious infections are treated systemically. Treatment of skin infections is increasingly based on knowledge of the likely infecting organisms and patterns of resistance; empirical treatment with broad-spectrum antibacterials is now discouraged in an attempt to minimise the emergence of resistant organisms.[1] For burns, however, control of infection is important to reduce the risk of sepsis. Topical application of sulfadiazine silver or mafenide acetate has been used in addition to aggressive systemic antibacterial therapy.

Gram-positive pathogens, especially staphylococci and beta-haemolytic streptococci, are commonly associated with primary pyodermas. *Staphylococcus aureus* is implicated in impetigo, cellulitis, folliculitis, furunculosis, and occasionally erysipelas and necrotising fasciitis (p.180), and may colonise burns. Staphylococcal scalded skin syndrome is a severe manifestation of bullous impetigo caused by infection with strains of *Staph. aureus* producing exfoliative exotoxins. The term toxic epidermal necrolysis is used to cover both this syndrome and a morphologically identical syndrome due to various aetiologies. A syndrome resembling scarlet fever may also occur. Staphylococcal infections are usually treated systemically with a penicillinase-resistant penicillin or a first-generation cephalosporin.[2] Erythromycin is an alternative for patients unable to tolerate penicillin. Multidrug-resistant staphylococci are becoming increasingly common, particularly in hospitals, and treatment alternatives for infections with these organisms are discussed under Staphylococcal Infections, p.195. Less severe infections in folliculitis or furunculosis may respond to the application of moist heat without the need for antibacterials. In patients at risk of recurrent staphylococcal infections, nasal application of chlorhexidine plus neomycin or mupirocin alone is used to eliminate nasal carriage of staphylococci.

Beta-haemolytic streptococci are also implicated in pyodermas including impetigo, erysipelas, and cellulitis. Necrotising fasciitis (p.180) may be caused by group A streptococci. Streptococcal infections continue to respond to phenoxymethylpenicillin or benzylpenicillin. Erythromycin is an alternative in patients unable to tolerate penicillins, but increasing resistance may be a problem;[1] clindamycin may be effective in patients with aggressive infections not responding to penicillin.[3] Topical retapamulin is licensed for the treatment of impetigo due to either *Staph. aureus* or *Str. pyogenes*. For community-acquired mixed infections associated with necrotising fasciitis a combination of ampicillin-sulbactam, clindamycin, and ciprofloxacin has been advocated.[2]

Resistance is also emerging in *Propionibacterium acnes*; strains resistant to erythromycin, clindamycin, and tetracycline are reported to be common in patients after treatment for acne.[1]

Gram-negative bacteria are less frequently implicated in skin infections, but *Pseudomonas aeruginosa* and *Proteus* spp. can cause infections, especially if the skin is subjected to damp conditions. These organisms produce proteolytic enzymes that cause the resulting skin damage. *Ps. aeruginosa* may colonise burns and skin ulcers. Pseudomonal infections are treated with aminoglycosides and the antipseudomonal penicillins.

Anaerobic organisms may colonise wounds, particularly chronic ulcers and fungating tumours. Topical metronidazole has been used to control the offensive odour caused by these infections.

Spleen disorders

Splenectomised patients and those with hyposplenism associated with, for example, sickle-cell disease have impaired immunity and, like other immunocompromised patients (p.174), are at increased risk of infection. Children are at special risk. *Streptococcus pneumoniae* is the commonest infecting bacterium and may cause severe overwhelming infection that is rapid in onset and sometimes fatal. Hence, prophylaxis with an oral penicillin such as phenoxymethylpenicillin is advocated. Pneumococcal vaccine is also used; the newer ones may be more effective than earlier vaccines. Other organisms implicated include *Neisseria meningitidis*, *Haemophilus influenzae*, and *Escherichia coli* in splenectomised patients and *Salmonella* in children with sickle-cell disease. More unusual organisms include *Capnocytophaga canimorsus* (formerly called DF-2) which may cause opportunistic infections in splenectomised patients after animal bites. There may also be an increased risk of falciparum malaria and babesiosis.

- SPLENECTOMISED PATIENTS

  Guidelines for prophylaxis based on published evidence and expert opinion have been published in a number of countries including the UK.[1] Immunisation with polyvalent pneumococcal vaccine is recommended for all asplenic patients and those with functional hyposplenism. *Haemophilus influenzae* (Hib) vaccine is recommended for all patients who have not previously received this vaccine. Influenza vaccination should be given. Meningococcal group C conjugate vaccine is recommended; however, the vaccine currently available does not protect against the group B strain of *N. meningitidis* causing the majority of infections in the UK. In addition, patients travelling abroad should receive a meningococcal vaccine which protects against group A infections. Lifelong prophylaxis with a suitable antibacterial should be offered. Phenoxymethylpenicillin is usually given, but amoxicillin may be preferred, particularly in adults, as it is better absorbed after oral doses and has a broader spectrum of activity. Erythromycin is a suitable alternative in those unable to tolerate penicillins. On a practical level, compliance with lifelong prophylaxis is difficult, but is particularly important in patients with underlying immunodeficiency, in children up to the age of 16 years, and for the first 2 years after splenectomy. Patients should keep a supply of a suitable antibacterial for immediate use should symptoms of infection occur, and be instructed to seek medical advice urgently.

- SICKLE-CELL DISEASE

  Children with sickle-cell disease are particularly susceptible to severe pneumococcal infection which may present as septicaemia, meningitis, or pneumonia.

  Penicillin prophylaxis is usually combined with early immunisation with a polyvalent pneumococcal vaccine. Phenoxymethylpenicillin 125 mg twice daily is effective in young children but amoxicillin may be preferred in adults since it is better absorbed and has a broader spectrum. There is evidence to suggest that, in children who have received pneumococcal immunisation, there is no benefit in continuing penicillin prophylaxis beyond the age of 5 years,[2] although indefinite prophylaxis has been recommended for those who have had a previous pneumococcal septic event.[3] Fears that prolonged prophylaxis could encourage the emergence of resistant pneumococci have not been substantiated,[4] although the prevalence of beta-lactam-resistant pneumococci continues to increase. Neonatal screening for sickle-cell disease is advocated, but compliance with regular penicillin prophylaxis may be poor and effective follow-up is necessary if the full benefit of such screening is to be achieved.[5,6] Nevertheless, availability of penicillin in the home, even if not taken regularly, means that it can be readily used if febrile illness occurs.[5] If children with sickle-cell disease develop a febrile illness they are generally treated in hospital with intravenous antibacterials, although outpatient management may often be possible.[7]

Spotted fevers

Rickettsial infections of the spotted fever group are transmitted to man by ticks and have also been called tick typhus. They include Rocky Mountain spotted fever, due to *Rickettsia rickettsii* and occurring especially in the USA; boutonneuse or Mediterranean spotted fever, due to *R. conorii* and occurring in Mediterranean countries including the Middle East, Africa, and India; Queensland tick typhus, due to *R. australis* and occurring in Australia; north Asian tick typhus, due to *R. sibirica* and occurring in Siberia and Mongolia; and oriental spotted fever, due to *R. japonica* and occurring in Japan. Rickettsialpox, due to *R. akari* is transmitted from mice by mites and occurs in the USA, Russia, and Africa.

Spotted fevers are recognised increasingly as a cause of febrile illness associated usually, but not always, with a purpuric rash and are becoming an important cause of imported fevers in non-endemic areas.[1,2] Rocky Mountain spotted fever has been one of the most severe of these fevers, but others are potentially serious. A tetracycline, often doxycycline, or chloramphenicol is the treatment of choice for all the spotted fevers. In Rocky Mountain spotted fever, doxycycline 100 mg every 12 hours or chloramphenicol 500 mg every 6 hours for 5 to 10 days may be used. Because tetracyclines are generally contra-indicated in young children, chloramphenicol has been recommended for children with Rocky Mountain spotted fever under the age of 9, but doxycycline is considered the treatment of choice for this and other potentially life-threatening tick-borne rickettsioses, even in young children.[2] The risk of tooth staining with a single short course of doxycycline is considered negligible,[2] and there is evidence that short courses of tetracycline are effective in some of these diseases.[3] Relapses have occurred in patients with Mediterranean spotted fever treated with chloramphenicol.[4] Other alternatives to tetracycline used in Mediterranean spotted fever have included the macrolides azithromycin,[2,5] clarithromycin,[2,5] and erythromycin,[6] or ciprofloxacin[7] or rifampicin. Erythromycin was effective, but less so than tetracycline, in children with Mediterranean spotted fever.[6] Short 2-day courses of ciprofloxacin or doxycycline were curative in adults whose disease was not severe, although there was a more rapid response to doxycycline.[7] A 5-day course of ciprofloxacin has also been used successfully to treat infection with *R. australis*.[8]

Rickettsialpox can be mistaken for chickenpox. However, it will respond to tetracycline although patients have generally recovered without treatment.[9]

Staphylococcal infections

Staphylococci are Gram-positive bacteria pathogenic to man. Species may be differentiated by various methods, including the coagulase test. Those species of clinical importance are *Staphylococcus aureus*, which is usually coagulase-positive, and *Staph. epidermidis* and *Staph. saprophyticus*, which are coagulase-negative.

Staph. aureus colonises the skin and mucous membranes naturally and many people, including neonates, may be staphylococcal carriers from time to time. Localised *Staph. aureus* infections may follow surgery or trauma and commonly result in abscess formation. Staphylococcal skin infections include impetigo and furunculosis. Conditions associated with staphylococcal extracellular toxin production include staphylococcal scalded skin syndrome, toxic shock syndrome, and staphylococcal food poisoning. Staphylococcal septicaemia is usually a consequence of local infection and may sometimes be associated with intravascular or intraperitoneal catheters or with intravenous drug abuse. Septicaemia often results in staphylococcal endocarditis. Other possible complications of septicaemia are pneumonia and bone and joint infections, although in these cases aspiration or local trauma, respectively, may be the cause.

Staph. epidermidis is also a natural inhabitant of skin and mucous membranes and an increasingly important nosocomial pathogen. Many infections are hospital-acquired and are often associated with indwelling catheters. There has been an increased incidence of bacteraemia due to *Staph. epidermidis* in neonatal units.

Staph. saprophyticus is a common cause of urinary-tract infections in young women.

Staphylococci were sensitive to benzylpenicillin when it was first introduced, but the majority of strains are now resistant as a result of penicillinase production. Meticillin and other penicillinase-resistant penicillins such as flucloxacillin were developed because of their activity against these resistant staphylococci. However, meticillin-resistant staphylococci soon emerged. Both coagulase-negative staphylococci and *Staph. aureus* resistant to meticillin are generally resistant to all beta lactams and often exhibit multiple resistance to other antibacterials (see Meticillin, Antimicrobial Action, p.299). More studies have been published on meticillin-resistant *Staph. aureus* (MRSA) than meticillin-resistant coagulase-negative staphylococci, but both types are a serious problem in hospitals around the world. Resistant strains may be endemic to a single hospital or may be epidemic causing outbreaks of infection at more than one hospital. Colonisation of hospital staff and patients with meticillin-resistant staphylococci is an important factor in the spread of these infections. Current trends are towards health care at home rather than in hospital and there are reports suggesting that MRSA is becoming more prevalent in the community.[1-5]

Guidelines for the control of MRSA are available in many countries.[6] In the UK, revised guidelines[7] for the control of MRSA in healthcare facilities were produced by a joint working party of the British Society for Antimicrobial Chemotherapy, the Hospital Infection Society, and the Infection Control Nurses Association in 2006. They advise prompt isolation of infected or colonised patients, screening of patients and staff in contact with such patients, the use of protective clothing, handwashing with an antiseptic detergent, and the use by all patients of an antiseptic detergent for washing and bathing. For eradication of nasal carriage they recommend mupirocin nasal ointment. Eradication at other colonised sites is more difficult: antiseptic detergents may be used for skin and hair washing. A systematic review[8] has concluded that there is insufficient evidence to support the use of topical or systemic antimicrobial therapy for eradicating nasal or extra-nasal MRSA.

Although ciprofloxacin may be used the emergence of widespread resistance in meticillin-sensitive and meticillin-resistant *Staph. aureus* limits its usefulness (see p.246). Combination therapy may be helpful. Rifampicin is highly active against MRSA, but it must always be used with another drug to prevent the emergence of resistance. Combinations of rifampicin with gentamicin, vancomycin, co-trimoxazole, fusidic acid, quinolones, or novobiocin have been tried. Newer antibacterials such as daptomycin, linezolid, or quinupristin/dalfopristin may be effective and may assume increasing importance.

Isolated reports from around the world of MRSA with intermediate resistance or reduced susceptibility to vancomycin initially emerged in the late 1990s,[9-11] and in response the CDC produced interim[12] and later[13] guidelines for preventing the spread of vancomycin-intermediate *Staph. aureus* (VISA) and vancomycin-resistant *Staph. aureus* (VRSA).

Staphylococcal vaccines have been used for the prophylaxis and treatment of staphylococcal infections.

For the management of staphylococcal infections in general, see under the specific disease headings.

Surgical infection

Infection is an important cause of postoperative surgical morbidity and mortality and *antimicrobial prophylaxis* is one of several strategies used to reduce the risk of infection. The value of infection prophylaxis is well established in certain types of surgery, especially abdominal surgery and where prostheses are implanted, although recommendations as to the choice of antibacterial and the route, timing, and duration of treatment may vary. Surgical wounds are classified as following clean, clean-contaminated (potentially contaminated), contaminated, and dirty operations. Clean operations exclude those involving the gastrointestinal, genital, urinary, or respiratory tracts. Clean-contaminated operations include those where the gastrointestinal, genital, urinary, or respiratory tracts are opened, but without unusual contamination. Contaminated operations include those where there is acute inflammation or spillage from a hollow viscus. Dirty operations include those where there is pus, gangrene, or perforated viscera. In addition, surgery to repair compound fractures and lacerations due to animal or human bites is considered dirty. The use of antibacterials for the management of contaminated or dirty surgery is considered to be therapeutic rather than prophylactic[1,2] and should continue for several days postoperatively.[3]

Guidelines for the *treatment* of intra-abdominal infections have been produced in the USA by the Surgical Infection Society[4] and by the Infectious Disease Society of America.[5]

ANTIMICROBIAL PROPHYLAXIS. Strictly speaking the term 'prophylaxis' should be confined to elective procedures with no evidence of sepsis at the time of operation. If possible any pre-existing infections should be treated before admission for surgery. For prophylaxis it is customary to give antibacterials systemically as a single pre-operative dose whereas more prolonged use is necessary when they are given therapeutically. Antimicrobial prophylaxis is used in clean-contaminated operations and in clean operations that involve the insertion of prosthetic materials or when an infection, however unlikely, would be catastrophic.[1]

Contaminating organisms. The choice of prophylactic antibacterial will be influenced by the likely contaminants for a particular surgical procedure. The most frequently isolated pathogens include *Staphylococcus aureus*, coagulase-negative staphylococci, *Enterococcus* spp., and *Escherichia coli*. Infections with antimicrobial-resistant pathogens including *Candida albicans* and meticillin-resistant *Staph. aureus* (MRSA) are increasing in some hospitals.[1] The most common source of infection is the endogenous flora of the patient's skin, mucous membranes, or viscera. Thus, aerobic Gram-positive organisms (for example staphylococci) are common infecting organisms when the source is the skin and mucous membranes, while infections with enterococci, Gram-negative aerobes (for example *E. coli*), and anaerobic bacteria (for example *Bacteroides fragilis*) can arise from the gastrointestinal tract.

Route of administration. Systemic dosage, usually by the intravenous route, is generally preferred. The chosen antibacterial is usually given as a single dose intravenously just before operation at the induction of anaesthesia. The pharmacokinetic properties should be such that adequate serum concentrations are maintained throughout the surgical procedure.[1] Additional doses may be necessary when surgery is prolonged, when there is massive blood loss, or when an antibacterial with a short half-life is used. More controversial routes have included topical or intra-incisional use and peritoneal lavage. Giving non-absorbable antibacterials orally to suppress the intestinal flora was traditional before large bowel surgery, and neomycin with erythromycin is still given for this purpose in the USA. For reference to selective digestive tract decontamination (SDD), see under Intensive Care, p.175. Other dosage forms include bone cement and chains of beads for implantation, both containing gentamicin and used prophylactically in orthopaedic surgery,[6,7] and topical and sometimes subconjunctival antibacterials for ophthalmic surgery.[3]

Choice of antibacterial. The most commonly used antibacterials are cephalosporins, aminoglycosides, and metronidazole. In the UK, the *BNF* recommends that gentamicin or cefuroxime is given before abdominal surgery; before colorectal surgery or hysterectomy metronidazole is given in addition, or amoxicillin with clavulanic acid may be given alone; before endoscopic retrograde cholangiopancreatography gentamicin or ciprofloxacin may be given; before transrectal prostate biopsy ciprofloxacin or gentamicin is given with metronidazole, although for transurethral resection ciprofloxacin, gentamicin, or cefuroxime may be given alone; and before joint replacements, including the hip and knee, cefuroxime or flucloxacillin is recommended. In the USA, cefazolin is commonly given before surgery, except that involving the lower gastrointestinal tract, for which cefoxitin or cefotetan are used to provide activity against anaerobes.[1,2,8] Alternatively, cefazolin may be given with metronidazole in colorectal surgery.[3] The choice of prophylaxis for patients unable to tolerate cephalosporins is less well established. Aztreonam has been suggested as an alternative to cefazolin with the addition of clindamycin or metronidazole if activity against anaerobes is necessary.[1] However, the use of aztreonam plus metronidazole may provide inadequate activity against Gram-positive cocci.[8] Another suggested alternative to cefazolin is vancomycin,[3] but the routine use of vancomycin should be avoided because of the risk of inducing resistance.[9] Vancomycin may be indicated for high-risk procedures if MRSA infections are prevalent,[9] and combination with aztreonam or an aminoglycoside has been suggested to provide activity against Gram-negative organisms.[8] If vancomycin is used for prophylaxis, no more than two doses should be given.[9] Other alternatives for colorectal procedures include an aminoglycoside with either clindamycin or metronidazole.[8]

The necessity for antibacterial prophylaxis in minimally invasive procedures such as laparoscopy and endoscopy is often not clear.[10] US guidelines[1,8] suggest that standard prophylaxis should be used pending further evidence.

Certain categories of patient continue to be at long-term risk of infection after surgery and include splenectomised patients who have impaired immunity and are at risk of pneumococcal and other infections (see under Spleen Disorders, p.194). Opinion is changing as to whether patients at special risk of endocarditis require prophylaxis before dental and surgical procedures (see Endocarditis, p.168). Some have advocated prophylaxis in patients with joint prostheses undergoing dental treatment,[11] but a working party for the British Society for Antimicrobial Chemotherapy considers such prophylaxis to be unjustified.[12]

Syphilis

See under Sexually Transmitted Diseases, p.192.

Tetanus

Clostridium tetani is a Gram-positive anaerobic spore-forming bacillus present in soil and faeces. The toxin it produces, tetanospasmin, causes tetanus or lockjaw, with uncontrolled muscle spasm.[1] Tetanus can be prevented by active immunisation with tetanus vaccine or passive immunisation with tetanus immunoglobulin. Nowadays it occurs mostly in developing countries and especially in neonates. In developed countries immunity may be relatively low in the elderly.

In addition to the control of muscle spasm with drugs such as diazepam (see p.1901 for the symptomatic treatment of tetanus), treatment includes the use of tetanus immunoglobulin to neutralise any circulating toxin and the use of antibacterials. Benzylpenicillin has traditionally been used, with a tetracycline or metronidazole as possible alternatives, but some now consider metronidazole to be preferable to benzylpenicillin.[2-4]

In rural developing countries where tetanus is common and active immunisation little practised, pre-operative metronidazole or penicillin might be used for patients undergoing emergency operations who have not been immunised against tetanus; the duration of antibacterial cover depends on the contamination risk.[5]

Tonsillitis

See under Pharyngitis, p.185.

Toxic shock syndrome

Toxic shock syndrome is an acute febrile illness associated with multisystem failure and caused by a toxin, usually toxic shock syndrome toxin-1 (TSST-1), produced by *Staphylococcus aureus*.[1,2] Bacteraemia has been reported to be absent in most cases.[3] In the early 1980s, toxic shock syndrome was reported predominantly in menstruating women using high-absorbency tampons, but it is now appreciated that foci of staphylococcal infection such as surgical wounds, burns, abscesses, and sinuses are often responsible;[1,2] mortality may be higher in non-menstrual than menstrual cases.[4] Treatment of the acute phase requires prevention of further production or absorption of toxin by local measures such as removal of tampons or packing, wound debridement, or drainage of abscesses; elimination of the toxin-producing bacteria by antistaphylococcal antibacterials given intravenously initially; fluid replacement; and sometimes corticosteroids.[1,2] Drotrecogin alfa has also been tried.[5] Continuing antibacterial treatment for 10 days during the convalescent phase to reduce the risk of recurrence has been recommended.[1] The use of prophylactic antibacterial therapy has been suggested in burns patients,[6] but this is controversial.

Group A beta-haemolytic streptococci (*Streptococcus pyogenes*) have been associated with a similar toxin-related syndrome.[7,8] Benzylpenicillin is the treatment of choice[9] but, since it may be difficult to exclude staphylococcal toxic shock syndrome, an antistaphylococcal drug such as flucloxacillin should also be given.[9] Clinical improvement has been reported with intravenous normal immunoglobulins.[10,11]

Toxic shock syndromes may be associated with necrotising fasciitis (see p.180).

Trachoma

Trachoma[1] results from chronic eye infection with certain *Chlamydia trachomatis* serotypes and is endemic in parts of Africa, the Middle East, and India where it is an important cause of blindness. It is not a sexually transmitted disease, but is associated with poverty, poor sanitation, and poor personal hygiene. The reservoir is chronic eye infection and transmission may be via fingers, fomites, and flies. Inclusion conjunctivitis in infants (see under Neonatal Conjunctivitis, p.180) and in adults is associated with sexually transmitted genital *C. trachomatis* infection and can progress to trachoma when there is persistent or recurrent eye infection.

Guidelines for trachoma control published by WHO in 1981 outlined topical or oral treatment with a tetracycline or alternatively with erythromycin or a sulfonamide.[2] However, topical chemotherapy for trachoma must be intensive and prolonged, 6 weeks being the minimum recommended duration for continuous intensive treatment with tetracycline 1% ophthalmic ointment. With less frequent applications, the duration of treatment must be prolonged and may need to be extended to months or even years. A single oral dose of azithromycin produces a similar rate of resolution to conventional treatment with topical tetracycline for 6 weeks.[3] Mass treatment of African village communities with oral azithromycin once weekly for 3 weeks has resulted in a lower incidence of trachoma at follow-up after one year than a standard course of topical tetracycline.[4,5] Azithromycin has therefore been recommended[6] as the treatment of choice for trachoma, with combined oral and topical treatment with either a tetracycline or a sulfonamide as an alternative.

The SAFE strategy (surgery, antibacterials, facial cleanliness, and environmental improvements) is the cornerstone of efforts by WHO[7] and the International Trachoma Initiative.[8] The aim is to eliminate trachoma by 2020. Tetracycline is still, however, the antibacterial treatment of choice in those countries that are not yet part of the initiative program and for patients in whom azithromycin is contra-indicated.

Trench fever

Trench fever is a louse-borne bacterial infection so named because of its prevalence among soldiers in the First World War. It is caused by *Bartonella quintana* (formerly *Rochalimaea quintana*) which was until recently classified as a rickettsia. *B. quintana* and *B. henselae* have also been implicated in bacillary angiomatosis, especially in immunocompromised patients, and *B. henselae* is considered to be a cause of cat scratch disease (p.166).

Reports from France[1,2] and the USA[3] of *B. quintana* bacteraemia, sometimes with endocarditis, in the urban poor prompted the suggestion that trench fever has returned.[4,5] Cases of trench fever in Marseilles have been reported[2] and might herald an increasing incidence as a result of migration from endemic areas, poverty, and louse infestation.

Treatment of trench fever has usually been with a tetracycline such as doxycycline or with a macrolide such as erythromycin. Other antibacterials, for example ceftriaxone, were also used in cases of bacteraemia,[3] but there was limited follow-up and clear recommendations could not be given. A review[6] has suggested that gentamicin plus doxycycline should be used in patients with trench fever or chronic *B. quintana* bacteraemia. Similarly, optimal therapy for *Bartonella* endocarditis has not been identified; however, it has been suggested that the usual treatment for blood culture-negative endocarditis (a penicillin plus an aminoglycoside) should be effective.[7] Again, treatment with gentamicin plus doxycycline has also been suggested.[6]

Tuberculosis

Tuberculosis[1] refers to disease caused primarily by *Mycobacterium tuberculosis* and occasionally by *M. bovis* or *M. africanum*. Infection results from inhalation of infected droplet nuclei. Primary infection is usually asymptomatic and in more than 95% of immune competent individuals is controlled by acquired (cell mediated) immunity. The immune response, however, is unable to eradicate the tubercle bacilli, and these bacilli may give rise to progressive primary infection (if disease occurs within 2 years of initial infection) or post-primary (reactivated) tuberculosis (if disease occurs years to decades after initial infection). Young children and immunocompromised patients are at increased risk of developing active disease. The most common manifestation of tuberculosis is pulmonary disease, although almost any organ may be affected. Patients usually present with cough, fever, night sweats, and weight loss.

During recent years the incidence of tuberculosis in many countries has increased in association with the increasing prevalence of HIV infection. Supervised rifampicin-based (short-course) therapy, using fixed-dose combination tablets, is recommended by WHO to improve cure rates and reduce the emergence of drug-resistant tuberculosis.[2] WHO applies the term **DOTS** (Directly Observed Therapy – Short Course) to its tuberculosis control strategy, which includes standards for diagnosis, supervised therapy, ensuring secure drug supplies, and regular evaluation of the tuberculosis control programme. The feasibility of implantable dosage forms has also been investigated.

• **First-line treatment.** Multidrug treatment for 6 to 8 months is required to cure tuberculosis, reduce the risk of relapse, and prevent the emergence of drug-resistant disease. Treatment regimens recommend an initial intensive phase of 2 to 3 months that is aimed at achieving rapid sputum conversion followed by a continuation phase of 4 to 6 months to eliminate residual bacilli and prevent relapse. The choice of regimen depends on local patterns of drug resistance and the availability of drugs, and are embodied in national and regional treatment protocols in many countries including those in Europe,[3] the UK,[4] and USA.[5] WHO recommended treatment regimens[6,7] are based on disease severity and history of previous tuberculosis treatment.

- **New cases** of pulmonary or extrapulmonary tuberculosis are treated with an initial phase consisting of rifampicin (R), isoniazid (H), pyrazinamide (Z), and ethambutol (E) for 2 months, followed by a continuation phase with rifampicin and isoniazid for 4 months, such a regimen being described as: RHZE2/RH4. Rifampicin may be substituted with ethambutol in the continuation phase to reduce costs, although this regimen needs to be given for a total of 8 months and is associated with an increased risk of relapse (RHZE2/HE6). In tuberculous meningitis ethambutol should be replaced with streptomycin (S) (RHZS2) and a 6- to 10-month continuation phase with rifampicin and isoniazid is often recommended. Ethambutol may be omitted from the intensive phase in patients with less severe forms of extrapulmonary tuberculosis or with limited non-cavitary smear-negative pulmonary tuberculosis if drug resistance has been excluded or the risk of drug resistance is deemed to be low (RHZ2/RH4). Cure rates of greater than 90% are typically achieved in patients infected with drug-susceptible organisms who adhere to therapy.
- In patients **previously treated** for tuberculosis, the initial treatment phase is rifampicin, isoniazid, pyrazinamide, and ethambutol given for 3 months with streptomycin being added for the first 2 months. The continuation phase includes 3 drugs (rifampicin, isoniazid, and ethambutol) and is extended to 5 months (RHZES2/RHZE1/RHE5). Because it is relatively cheap thioacetazone has been used in some countries with limited resources but its use is strongly discouraged because of its weak antimycobacterial activity and associated risk of fatal skin toxicity, particularly in HIV patients. All first-line drugs can be given intermittently (at double doses 3 times each week) as an alternative to daily use. Patients who remain smear-positive at the end of supervised short-course chemotherapy may have drug-resistant tuberculosis and treatment usually requires the introduction of second-line drugs (see below).

First-line drugs such as isoniazid, rifampicin, and particularly pyrazinamide may cause severe and possibly fatal drug-induced hepatitis. Further details covering hepatotoxicity and special precautions for use in patients with liver disorders are given in the respective drug monographs—see, Isoniazid p.289; Rifampicin p.326; and Pyrazinamide p.320. UK[4] and US[5] guidelines recommend stopping all potentially hepatotoxic drugs if serum transaminases rise to more than 5 times the upper limit of normal or 3 times in the presence of symptoms of hepatitis or elevated bilirubin. Cautious sequential re-introduction of the same drugs (with or without pyrazinamide) after resolution of the biochemical abnormalities is often possible.[4-6] Patients in whom therapy is interrupted may be given streptomycin, ethambutol, and/or a fluoroquinolone until hepatotoxicity has resolved.

Management of drug-resistant disease. The incidence of drug resistance amongst *M. tuberculosis* strains has increased over recent years typically in countries with poor tuberculosis control programmes.[8,9] Isoniazid and streptomycin resistance are the most prevalent. Multidrug-resistant tuberculosis (caused by strains resistant to both isoniazid and rifampicin) requires a combination of first- and second-line drugs for at least 18 to 24 months (see below).[4,5,8] Drug-resistant tuberculosis is a reflection of poor tuberculosis management, control, and unreliable drug supply; it is difficult to treat, and not infrequently fatal, particularly in HIV-infected patients. Whereas the WHO DOTS programme may limit the development of multidrug-resistant tuberculosis, different strategies are required in areas where multidrug resistance is already established. These have been formulated by the WHO in the **DOTS-plus** strategy for countries with well functioning tuberculosis control programmes.[10]

Patients with multidrug-resistant tuberculosis and those who relapse after completing the WHO standard treatment regimens should receive a DOTS-plus regimen, which includes second-line antituberculous drugs. Drugs used in the treatment of drug-resistant tuberculosis are generally less effective and more toxic than standard therapy and need to be taken daily. They include the aminoglycosides (amikacin, capreomycin, and kanamycin), aminosalicylates, cycloserine, ethionamide, fluoroquinolones (ciprofloxacin, levofloxacin, and ofloxacin), protionamide, and terizidone. The DOTS-plus regimen should consist of at least 3 or 4 oral drugs plus an injectable aminoglycoside, to which the patient has not been exposed and which do not share cross-resistance with drugs given previously. These drugs should be given under direct observation for at least 6 months, and followed by a continuation phase of 12 to 18 months with at least 3 drugs.[5,8] Cross-resistance between rifampicin and rifabutin is common and rifabutin is therefore not recommended as a second-line drug. Cross-resistance among aminoglycosides is uncommon, while cross-resistance is variable within the fluoroquinolones. Cross-resistance is complete between ethionamide and protionamide, and between cycloserine and terizidone. Where available, *M. tuberculosis* resistance testing should be performed to guide the choice of therapy. Single drugs should never be added to a failing regimen.

Extensively drug-resistant tuberculosis (XDR-TB) is defined as tuberculosis that is resistant to isoniazid and rifampicin and also resistant to fluoroquinolones and at least one of three injectable second-line drugs (amikacin, capreomycin, or kanamycin).[11] XDR-TB can develop when the second-line drugs are misused or mismanaged and by early 2006 cases were being reported from every region in the world.[12] A report from the KwaZulu-Natal province of South Africa highlighted the risk for rapid death in HIV-infected persons with extensively-drug resistant tuberculosis.[13] In this local case series, all but one of 53 patients died, and where the date of death could be confirmed the median survival was 16 days from the time of diagnosis.

• **Children and infants** can be treated with regimens similar to adults but with appropriate dose adjustments for age or body-weight.[4-7] While ethambutol is not usually given to young children because of the perceived difficulty in detecting ocular toxicity (see p.274), a literature review[14] on its use in children found almost no ocular toxicity at daily doses of 15 to 30 mg/kg and it was considered safe in children of all ages.

• **Pregnancy, breast feeding, and the neonate.** Tuberculosis, and especially drug-resistant tuberculosis, during pregnancy poses a serious risk to the mother, fetus, and neonate if not detected early and treated properly.[15] The WHO recommends that pregnant women with tuberculosis are treated similarly to non-pregnant patients (RHZE2/RH4 or RHZ2/RH4). Fluoroquinolones, aminoglycosides, ethionamide, and protionamide are best avoided. Liver enzymes and symptoms of drug-induced hepatitis should be monitored.[4,5,15] Most antituberculous drugs may be used during breast feeding. Drug concentrations in the breast milk are too low to prevent or treat tuberculosis in infants. In the UK it is recommended that neonates of mothers with tuberculosis should receive isoniazid for 3 months[16] after which time the infant should be re-evaluated. BCG vaccination is recommended by WHO and in the UK when isoniazid is stopped.[16]

• **Co-infection with HIV** increases the risk of patients developing both pulmonary and extrapulmonary tuberculosis, and mortality is higher than in HIV-negative patients in the absence of antiretroviral therapy. HIV patients (including children) with tuberculosis have a similar response to short-course chemotherapy as HIV-negative tuberculosis patients and most can be treated with the standard 6-month regimen (RHZE2/RH4).[4,17-20] In children and patients whose clinical or bacteriological response is slow, treatment should be extended to a total of 9 months.[18-20] Children with extrapulmonary tuberculosis involving the bones or CNS, or in those with miliary disease, should be given treatment for a minimum of 12 months.[18] Treatment failures in HIV-infected patients have been associated with reduced drug concentrations due to malabsorption of antimycobacterials.[21]

Most clinicians would defer starting antiretroviral therapy in HIV co-infected patients with CD4+ counts greater than 200/microlitre until the tuberculosis treatment has been completed. Patients with more severe immunodeficiency benefit from co-administration of HIV and tuberculosis therapy. In these patients, tuberculosis therapy is started first, and HIV treatment added once the patient tolerates tuberculosis therapy, or after 2 months when tuberculosis therapy is simplified. The use of rifamycin-based regimens to treat tuberculosis is recommended as response rates are better compared to non-rifamycin-based regimens. However, drug interactions between rifamycins and antiretrovirals complicate the co-administration of HIV and tuberculosis treatment,[19,20,22] and certain combinations may require dose adjustment or be contra-indicated (for details of the interactions of rifampicin and antiretrovirals see p.327 and for those with rifabutin see p.324). It is important to note that guideline recommendations are based on pharmacokinetic studies, often performed in healthy subjects, rather than on studies of treatment outcome in patients.

Directly observed therapy improves outcome and is recommended wherever possible. Due to the risk for acquired rifamycin resistance highly intermittent (once or twice weekly) tuberculosis regimens should not be used for co-infected patients with CD4+ cell counts less than 100 cells/microlitre.[18-20,22] All HIV and tuberculosis co-infected patients should receive co-trimoxazole if CD4+ counts are below 200 cells/microlitre.[23] Thioacetazone should not be used in HIV-positive patients because of the potential for severe skin toxicity. Paradoxical worsening of tuberculosis symptoms is common in HIV-infected patients who start antiretroviral therapy[24] and incidences of up to 35% have been noted.[22]

• **Adjunctive therapy.** The inflammatory response to tuberculosis can cause considerable tissue damage and adjunctive steroid therapy may be used to counter this. Corticosteroids are of little benefit in uncomplicated pulmonary tuberculosis. However, a study[25] found adjunctive dexamethasone improved survival, but probably not severe disability, in adolescents and adults with tuberculous meningitis. Systematic reviews of tuberculous pleurisy[26] and pericarditis,[27] have concluded that there is insufficient evidence to support the use of corticosteroids in these conditions. WHO[17] suggests that corticosteroids may be useful adjuvants to antituberculous therapy for the management of tuberculous meningitis, pericarditis, pleural effusion, laryngitis, tuberculosis of the renal tract, adrenocortical insufficiency due to adrenal gland tuberculosis, and massive lymph node enlargement in both HIV-positive and -negative patients. Corticosteroids may also be useful for hypersensitivity reactions to antituberculosis drugs. For further details on the possible role of corticosteroids as an adjunct to antituberculous therapy, see p.1514.

Studies have suggested that injection of suspensions of killed *Mycobacterium vaccae* improved immune responsiveness in patients with pulmonary tuberculosis, although a systematic review[28] concluded that *M. vaccae* immunotherapy was of no benefit.

• **Prevention.** Studies have found that *BCG vaccine* offers protection against serious forms of tuberculosis in children, such as miliary and meningeal tuberculosis, but has variable efficacy against pulmonary tuberculosis in adults. In high prevalence areas, vaccination is recommended for children at birth, except for children with HIV infection. For further information on BCG vaccine see, p.2205.

Tuberculosis skin testing may identify persons with *latent M. tuberculosis* infection. Treatment of tuberculosis skin test-positive persons (also referred to as preventative therapy or chemoprophylaxis) reduces the risk of developing (reactivation) tuberculosis. Treatment is beneficial in HIV-infected patients, contacts of active cases, persons who have recently become tuberculosis skin test positive, and persons at high risk of disease. Chemoprophylaxis is not recommended routinely in developing countries where the priority is to detect and treat patients with active tuberculosis.[17,29] Latent tuberculosis has been treated with isoniazid or rifampicin given alone, or with rifampicin given with either isoniazid or pyrazinamide. Daily isoniazid for 6 to 12 months reduces the risk of active tuberculosis by 60 to 90%[1,30] and in HIV-infected, tuberculosis skin test-positive persons isoniazid for 6 months has also been shown to provide short-term protection against tuberculosis.[31] However, the combination of rifampicin and pyrazinamide has resulted in severe and fatal liver damage in HIV-negative persons and is no longer recommended for tuberculosis prophylaxis.[30,32,33] The American Thoracic Society and the CDC,[30,32] and NICE[16] have issued detailed recommendations for treatment of latent tuberculosis infection. Briefly, UK recommendations for HIV-negative adults and children over 2 years old are for either isoniazid alone for 6 months or isoniazid with rifampicin for 3 months; isoniazid alone for 6 months should be given to all HIV-positive patients. In the USA either isoniazid alone for 9 months (or 6 months in HIV-negative patients) or rifampicin alone for 4 months is recommended.

Tularaemia

Tularaemia is caused by the Gram-negative bacillus *Francisella tularensis*, an organism that primarily affects rodents and rabbits but may be transmitted to man, usually by handling infected animals or carcasses, or by the bites of insect vectors. It may take several forms, the most common of which is the ulceroglandular form, characterised by rash and ulceration at the site of inoculation accompanied by fever and lymphadenopathy; other forms include the typhoidal and pneumonic forms, which have a higher mortality rate. There has been some concern about its potential use as a biological weapon.[1,2]

Streptomycin is still considered the antibacterial of choice in severe disease, although gentamicin is an alternative.[1,2] A tetracycline or chloramphenicol may be given orally; clinical relapses are more frequent than with the aminoglycosides,[1,2] although relapsed disease will respond to a further course. Ciprofloxacin has also been used successfully.[1] Some patients have also responded to high-dose intravenous erythromycin.[3]

A tularaemia vaccine is available in some countries for active immunisation against the disease.

Typhoid and paratyphoid fever

Typhoid and paratyphoid fever are systemic infections caused respectively by *Salmonella typhi* and *S. paratyphi* A, B, or C, Gram-negative bacteria belonging to the Enterobacteriaceae family. They are sometimes termed collectively 'enteric fever' but, although initial infection is intestinal, dissemination in the blood leads to more widespread systemic effects. Typhoid and paratyphoid are endemic in many countries and, in most, typhoid is more common. Most cases occurring in the UK are contracted abroad.

Treatment of typhoid fever has traditionally been with chloramphenicol or alternatively amoxicillin, ampicillin, or co-trimoxazole.[1] However, there has been a spread of strains of *S. typhi* resistant to chloramphenicol, ampicillin, amoxicillin, trimethoprim, and co-trimoxazole,[2,3] especially in the Indian subcontinent, in the Middle East, and in South and South-East Asia. Current recommendations therefore emphasise the use of a fluoroquinolone such as ciprofloxacin or ofloxacin for initial treatment of typhoid fever.[3,4] In strains that remain sensitive, chloramphenicol, amoxicillin, or co-trimoxazole are alternatives, while in multidrug-resistant strains a third-generation cephalosporin such as cefixime, cefotaxime, or ceftriaxone may be given. The latter are also an alternative where fluoroquinolone resistance exists;[3,4] this is an increasing problem, particularly in Asia, but most fluoroquinolone-resistant strains seen in the UK retain their sensitivity to cephalosporins, and to azithromycin, which is another alternative.[5] Combination regimens have been investigated,[4] but a study in patients infected with strains showing both multidrug resistance and reduced susceptibility to fluoroquinolones found that azithromycin alone was preferable to azithromycin plus ofloxacin.[6] Interestingly, there is some evidence that as fluoroquinolone resistance spreads, sensitivity to some of the older drugs used to treat the disease, such as chloramphenicol, may be returning.[7,8]

Although fluoroquinolones are not generally indicated in children because of potential toxicity, WHO considers that their benefits in typhoid fever outweigh any putative risk.[3] Azithromycin may also be given.[3] In pregnancy a beta-lactam such as ampicillin or one of the cephalosporins may be preferable,[3] although there are reports of the successful use of fluoroquinolones. WHO also suggests that although there is no evidence to suggest harm, azithromycin should not be used in pregnant or nursing women if alternatives are available.[3]

Patients who develop mental changes should be evaluated for meningitis; if typhoid meningitis is suspected, high-dose intravenous dexamethasone should be given in addition to antibacterial treatment.[3]

On recovery, typhoid patients may continue to excrete *S. typhi* in the faeces or urine for several weeks. Unlike these convalescent carriers, some 1 to 5% of patients become chronic carriers[3] who may excrete *S. typhi* for years without any symptoms; eradication is difficult and prolonged treatment is necessary. An increased risk of biliary-tract and bile-related cancers has been associated with chronic carriage of *S. typhi*, and the importance of eradication has been emphasised.[9]

Typhoid vaccines are used for the prevention of typhoid fever.

Paratyphoid fever is less common and generally milder than typhoid fever. Treatment is similar.

Typhus

Rickettsial infections or fevers of the typhus group are transmitted to man by various insect vectors. Louse-borne or epidemic typhus, due to *Rickettsia prowazekii*, and flea-borne or murine typhus, due to the closely related *R. typhi* (*R. mooseri*), have occurred worldwide. Scrub typhus is due to *Orientia tsutsugamushi* (*R. tsutsugamushi*), transmitted by mites, and occurs mainly in Asia, Australia, and the Pacific Islands.

A tetracycline, often doxycycline, or chloramphenicol is the treatment of choice for these infections although strains of *O. tsutsugamushi* resistant to doxycycline and chloramphenicol have been reported in Thailand.[1,2] Ciprofloxacin may be an effective alternative,[3] and rifampicin has been shown to be more effective against scrub typhus than doxycycline.[4] Azithromycin is also effective.[5] Prophylaxis for scrub typhus with doxycycline has shown promise when started before exposure to infection.[6]

Urethritis

Urethritis or urethral inflammation can result from infectious or noninfectious conditions. Infectious urethritis is a sexually transmitted disease seen most frequently in men. The most common causes are *Neisseria gonorrhoeae* and *Chlamydia trachomatis* (termed nongonococcal urethritis or non-specific urethritis). Other organisms implicated have included *Mycoplasma genitalium* and *Ureaplasma urealyticum*. Gonococcal and chlamydial infections frequently occur together and if a specific clinical diagnosis cannot be made treatment for both infections should be given together otherwise postgonococcal urethritis due to *C. trachomatis* may follow the cure of gonorrhoea. For the treatment of gonococcal urethritis see Gonorrhoea (p.191). For general management of chlamydial infections see p.166.

Guidelines produced by WHO,[1] by an expert group in the UK,[2] and by the CDC in the USA[3] for the **treatment** of urethritis are as follows:

- **WHO:** for chlamydial urethritis:
  - oral doxycycline 100 mg twice daily for 7 days, *or*
  - a single oral dose of azithromycin 1 g

  alternative regimens for 7 days, are:
  - oral amoxicillin 500 mg three times daily
  - oral erythromycin 500 mg four times daily
  - oral ofloxacin 300 mg twice daily
  - oral tetracycline 500 mg four times daily

  Unless it can be excluded, patients should also be treated concurrently for gonorrhoea (p.191)
- **UK:** for nongonococcal urethritis:
  - a single oral dose of azithromycin 1 g, *or*
  - oral doxycycline 100 mg twice daily for 7 days

  alternative regimens are:
  - oral erythromycin 500 mg twice daily for 14 days
  - oral ofloxacin 400 mg daily in one single or two divided doses for 7 days

  Persistent or recurrent nongonococcal urethritis should be treated with:
  - oral azithromycin 500 mg to start then 250 mg daily for 4 days *plus* oral metronidazole 400 mg twice daily for 5 days
  - oral erythromycin 500 mg four times daily for 21 days *plus* oral metronidazole 400 mg twice daily for 5 days
  - oral moxifloxacin 400 mg once daily for 10 days
- **USA:** nongonococcal urethritis:
  - as for the UK

  alternative regimens for 7 days, are:
  - oral erythromycin 500 mg four times daily
  - oral erythromycin ethylsuccinate 800 mg four times daily
  - oral ofloxacin 300 mg twice daily
  - oral levofloxacin 500 mg once daily

  Persistent or recurrent nongonococcal urethritis should be treated with:
  - a single oral dose of either metronidazole 2 g or tinidazole 2 g *plus* oral azithromycin 1 g (if it was not used in the initial treatment regimen)

Sexual partners of patients with urethritis should be tested and treated.[2,3]

Urinary-tract infections

Infections of the urinary tract are especially common in women. They are frequently due to enteric bacteria, in particular *Escherichia coli*, although a common cause in young women is *Staphylococcus saprophyticus*, a coagulase-negative staphylococcus. Other urinary pathogens include *Staph. epidermidis*, enterococci, and *Pseudomonas* spp. An arbitrary definition of urinary-tract infection has been significant bacteriuria with 10^5 or more colony-forming units/mL of a midstream urine specimen; some also consider lower counts to be indicative of infection. Most urinary-tract infections are isolated uncomplicated infections of the lower urinary tract. Recurrent infections may be due to relapse, or more often, re-infection, and are more serious. Patients with complicated urinary-tract infections associated with urinary-tract abnormalities or diseases such as diabetes mellitus may be at risk of kidney damage.

Infections of the lower urinary tract in *women* generally present as cystitis (inflammation of the bladder) and symptoms include dysuria, frequency, and urgency together with pyuria and significant bacteriuria; the urethral syndrome is similar, but there is no significant bacteriuria. In the upper urinary tract, acute pyelonephritis may occur as a complication of cystitis or, more rarely, may result from septicaemia. Asymptomatic bacteriuria may progress to acute pyelonephritis in *pregnant women* and should therefore be treated.

Urinary-tract infections in *men* are less common and are often associated with abnormalities of the genito-urinary tract such as prostatic hyperplasia. Acute bacterial prostatitis is usually caused by organisms similar to those responsible for cystitis in women. Chronic bacterial prostatitis is difficult to treat; the antibacterials used must be able to penetrate into the prostatic fluid. For other genito-urinary infections in men, see under Epididymitis, p.170, and under Urethritis, above.

In preschool *children*, especially girls, asymptomatic bacteriuria together with vesicoureteric reflux can result in renal scarring and should be treated; the use of prophylactic antibacterials is complex and controversial. Long-term follow-up of girls who have had asymptomatic bacteriuria suggests that new kidney damage does not occur after 4 years of age, but highlights the importance of diagnosis and treatment in younger children.

The significance of asymptomatic bacteriuria in *old age* is disputed, but most consider treatment to be unnecessary.

Infections associated with *indwelling bladder catheters* occur in both men and women and probably account for the majority of hospital-acquired urinary-tract infections.

Treatment. Antibacterials used to treat urinary-tract infections need to be excreted in adequate concentrations in the urine. For *acute uncomplicated infections* oral amoxicillin, ampicillin, co-trimoxazole, nalidixic acid, nitrofurantoin, or trimethoprim (preferred to co-trimoxazole in the UK) have been given, although the choice will depend on local patterns of bacterial resistance; *E. coli* resistant to ampicillin and amoxicillin is widespread. Alternatives when resistance is prevalent include amoxicillin with clavulanic acid, oral cephalosporins, fluoroquinolones, or fosfomycin. In pregnant women, nitrofurantoin or a beta lactam can be used. Standard treatment schedules have been for 5 to 7 days; 3-day or single-dose regimens can also be effective and may be preferred in women. Single-dose treatment may be associated with reduced efficacy compared with 3-day regimens. Urinary alkalinising agents such as potassium citrate and sodium citrate have been given by mouth to relieve the pain of cystitis caused by lower urinary-tract infections. Recurrent infections may require long-term low-dose antibacterial prophylaxis.

Acute pyelonephritis may require broad-spectrum parenteral treatment initially with, for example, aztreonam, ceftazidime, cefuroxime, ciprofloxacin, or gentamicin.

Chronic bacterial prostatitis may require treatment for several weeks with trimethoprim, erythromycin, or a fluoroquinolone.

Catheter-related bladder infections may sometimes respond to localised treatment with bladder washouts containing chlorhexidine.

Whipple's disease

Whipple's disease is a rare chronic systemic condition associated with infection with *Tropheryma whippelii*.[1-4] It was once considered to be a disease predominantly involving the small intestine and resulting in malabsorption, but may affect virtually all organs. There is probably CNS involvement in all patients with Whipple's disease, although it may only be evident in 10 to 20%. Before the use of antibacterial therapy the disease was invariably fatal. The treatment generally recommended is either benzylpenicillin (sometimes given as procaine benzylpenicillin) and streptomycin, or ceftriaxone, parenterally for two weeks, followed by co-trimoxazole orally for at least one year.[2,3,5,6] Such long-term treatment with co-trimoxazole, a drug that crosses the blood-brain barrier, is advisable because of the relatively high frequency and seriousness of CNS relapse. These relapses respond less well to antibacterial treatment; chloramphenicol has been used in those not responding to the above regimen and a patient with CNS relapse improved on ceftriaxone given intravenously.[7] Further alternatives may be a tetracycline[8] or cefixime.[6] A patient intolerant of co-trimoxazole was given phenoxymethylpenicillin and probenecid after the initial 14-day course of benzylpenicillin and streptomycin.[9] There has also been a report of benefit in a penicillin-allergic patient treated with erythromycin.[10] A combination of doxycycline with hydroxychloroquine may be tried in patients without neurological involvement.[3]

Amikacin *(BAN, rINN)*

Amicacina; Amikacina; Amikacinas; Amikacine; Amikacinum; Amikacyna; Amikasiini. 6-*O*-(3-Amino-3-deoxy-α-D-glucopyranosyl)-4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-N^1-[(2*S*)-4-amino-2-hydroxybutyryl]-2-deoxystreptamine.

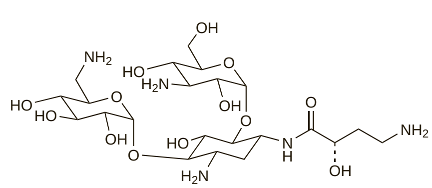
Амикацин

$C_{22}H_{43}N_5O_{13}$ = 585.6.

CAS — 37517-28-5.

ATC — D06AX12; J01GB06; S01AA21.

ATC Vet — QD06AX12; QJ01GB06; QS01AA21.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int.,* and *US.*

Ph. Eur. 6.2 (Amikacin). An antimicrobial substance obtained from kanamycin A. A white or almost white powder. Sparingly soluble in water; practically insoluble in alcohol and in acetone; slightly soluble in methyl alcohol. A 1% solution in water has a pH of 9.5 to 11.5.

USP 31 (Amikacin). A white crystalline powder. Sparingly soluble in water. pH of a 1% solution in water is between 9.5 and 11.5. Store in airtight containers.

Amikacin Sulfate *(USAN, rINNM)*

Amikacin Sulphate *(BANM)*; Amikacin-disulfát; Amikacine, sulfate d'; Amikacini Disulfas; Amikacini sulfas; Amikacino sulfatas; Amikacinsulfat; Amikacin-szulfát; Amikacyny siarczan; Amikasiinisulfaatti; Amikasin Sülfat; BB-K8; Sulfato de amikacina.

Амикацина Сульфат

$C_{22}H_{43}N_5O_{13},2H_2SO_4$ = 781.8.

CAS — 39831-55-5.

ATC — D06AX12; J01GB06; S01AA21.

ATC Vet — QD06AX12; QJ01GB06; QS01AA21.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Amikacin Sulphate). A white or almost white powder. It loses not more than 13.0% of its weight on drying. Freely soluble in water; practically insoluble in alcohol and in acetone. The pH of a 1% solution in water is between 2.0 and 4.0. Store in airtight containers.

USP 31 (Amikacin Sulfate). Amikacin sulfate having a molar ratio of amikacin to H_2SO_4 of 1:2 contains the equivalent of not less than 674 micrograms and not more than 786 micrograms of amikacin per mg, calculated on the dried basis. Amikacin sulfate having a molar ratio of amikacin to H_2SO_4 of 1:1.8 contains the equivalent of not less than 691 micrograms and not more than 806 micrograms of amikacin per mg, calculated on the dried basis.

A white crystalline powder. Freely soluble in water. pH of a 1% solution in water is between 2.0 and 4.0 (1:2 salt) and 6.0 to 7.3 (1:1.8 salt). Store in airtight containers.

Incompatibility. For discussion of the incompatibility of aminoglycosides, including amikacin, with beta lactams, see under Gentamicin Sulfate, p.282. Amikacin is also reported to be incompatible with various other drugs. However, reports are contradictory in many cases, and other factors, such as the strength and composition of the vehicles used, may play a role.

Stability. Solutions may darken from colourless to pale yellow but this does not indicate a loss of potency.

Adverse Effects, Treatment, and Precautions

As for Gentamicin Sulfate, p.282. Peak plasma concentrations of amikacin greater than 30 to 35 micrograms/mL or trough concentrations greater than 5 to 10 micrograms/mL should be avoided. Amikacin affects auditory (cochlear) function to a greater extent than gentamicin.

Effects on the eyes. A report of retinal damage after intravitreal injection of amikacin.[1]

1. Jackson TL, Williamson TH. Amikacin retinal toxicity. *Br J Ophthalmol* 1999; **83:** 1199–1200.

Interactions

As for Gentamicin Sulfate, p.283.

Antimicrobial Action

As for Gentamicin Sulfate, p.283. Amikacin is active against a similar range of organisms although it is also reported to have some activity against *Nocardia asteroides*, *Mycobacterium tuberculosis*, and some atypical mycobacterial strains. Amikacin is not degraded by many of the common enzymes often responsible for acquired aminoglycoside resistance. In consequence, cross-resistance with gentamicin and other aminoglycosides is infrequent and amikacin may be effective against strains resistant to other aminoglycosides. However, resistant strains of Gram-negative bacteria and staphylococci have been reported, and it is generally reserved for infections resistant to other aminoglycosides, although reports differ as to the extent and speed of the development of amikacin resistance where it has been widely used.

◊ References.

1. Ho YII, *et al.* In-vitro activities of aminoglycoside-aminocyclitols against mycobacteria. *J Antimicrob Chemother* 1997; **40:** 27–32.

Pharmacokinetics

As for Gentamicin Sulfate, p.284.

On intramuscular injection, peak plasma-amikacin concentrations of about 20 micrograms/mL are achieved 1 hour after a 500-mg dose, reducing to about

2 micrograms/mL 10 hours after injection. A plasma concentration of 38 micrograms/mL has been reported after the intravenous infusion of 500 mg over 30 minutes, reducing to 18 micrograms/mL 1 hour later. Amikacin has been detected in body tissues and fluids after injection; it crosses the placenta but does not readily penetrate into the CSF, although substantial penetration of the blood-brain barrier has been reported in children with meningitis.

A plasma half-life of about 2 to 3 hours has been reported in patients with normal renal function. Most of a dose is excreted by glomerular filtration in the urine within 24 hours.

Uses and Administration

Amikacin is a semisynthetic aminoglycoside antibiotic derived from kanamycin and is used similarly to gentamicin (p.284) in the treatment of severe Gram-negative and other infections. It is given as the sulfate, and is generally reserved for the treatment of severe infections caused by susceptible bacteria that are resistant to gentamicin and tobramycin. Amikacin has also been given with antimycobacterials in the treatment of non-tuberculous mycobacterial infections (p.181). As with gentamicin, amikacin may be used with penicillins and with cephalosporins; the injections should be given at separate sites.

Doses of amikacin sulfate are expressed in terms of amikacin base; 1.3 g of amikacin sulfate is equivalent to about 1 g of amikacin. Adults and children may be given 15 mg/kg daily in equally divided doses every 8 or 12 hours by intramuscular injection. In life-threatening infections, the dose may be increased in adults up to a maximum of 500 mg every 8 hours. A dose of 7.5 mg/kg daily in two divided doses (equivalent to 250 mg twice daily in adults) may be given for the treatment of uncomplicated urinary-tract infections. The same doses may be given by slow intravenous injection over 2 to 3 minutes, or by intravenous infusion. In adults, 500 mg in 100 to 200 mL of diluent has been infused over 30 to 60 minutes; proportionately less fluid should be given to children.

Neonates may be given 10 mg/kg as a loading dose, followed by 15 mg/kg daily in two divided doses. If given by intravenous infusion, an infusion period of 1 to 2 hours is recommended. It has been suggested that doses may need to be adjusted in preterm neonates.

Treatment should preferably not continue for longer than 7 to 10 days, and the total dose given to adults should not exceed 15 g. Peak plasma concentrations greater than 30 to 35 micrograms/mL or trough plasma concentrations greater than 5 to 10 micrograms/mL should be avoided. Dosage should be adjusted in all patients according to plasma-amikacin concentrations, and this is particularly important where factors such as age, renal impairment, or prolonged therapy may predispose to toxicity, or where there is a risk of subtherapeutic concentrations. For discussion of the methods of calculating aminoglycoside dosage requirements, see Administration and Dosage, under Gentamicin, p.284. As with some other aminoglycosides, once-daily dosage has been used successfully with amikacin without increasing toxicity, but local guidelines should be consulted (see also Once-daily Dosage, p.285).

A 0.25% solution has been instilled into body cavities in adults.

A liposomal formulation of amikacin is under investigation.

Pharmacopoeias. *Jpn* includes the heptahydrate.

Sodium Aminosalicylate

Aminosalicilato sódico; Aminosalicylan sodný dihydrát; Aminosalicylate Sodium; Aminosalylnatrium; Monosodium 4-Aminosalicylate Dihydrate; Natrii Aminosalicylas; Natrii aminosalicylas dihydricus; Natrii Paraaminosalicylas; Natrii Para-aminosalicylas; Natrio aminosalicilatas dihidratas; Natriumaminosalicylat; Natriumaminosalicylatdihydrat; Natriumaminosalisylaatti; Natriumaminosalisylaattidihydraatti; Pasalicylum Solubile; Sodium (aminosalicylate de) dihydraté; Sodium Para-aminosalicylate; Sodium PAS; Sodu aminosalicylan. Sodium 4-amino-2-hydroxybenzoate dihydrate.

Аминосалицилат Натрия

$C_7H_6NNaO_3,2H_2O$ = 211.1.
CAS — 133-10-8 (anhydrous sodium aminosalicylate); 6018-19-5 (sodium aminosalicylate dihydrate).
ATC — J04AA02.
ATC Vet — QJ04AA02.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Sodium Aminosalicylate Dihydrate). A slightly hygroscopic, white or almost white, crystalline powder, or white or almost white crystals. Freely soluble in water; sparingly soluble in alcohol, practically insoluble in dichloromethane. A 2% solution in water has a pH of 6.5 to 8.5. Store in airtight containers. Protect from light.

USP 31 (Aminosalicylate Sodium). A white to cream-coloured, practically odourless crystalline powder. Soluble 1 in 2 of water; sparingly soluble in alcohol; very slightly soluble in chloroform and in ether. Its solutions decompose slowly and darken in colour. Prepare solutions within 24 hours of use. Under no circumstances should a solution be used if its colour is darker than that of a freshly prepared solution. pH of a 2% solution in water is between 6.5 and 8.5. Store in airtight containers at a temperature not exceeding 40°. Protect from light.

Stability. Aqueous solutions of aminosalicylates are unstable and should be freshly prepared.

Solutions of sodium aminosalicylate in sorbitol or syrup degraded more quickly to *m*-aminophenol than those in glycerol or propylene glycol.[1] Colour developed in all solutions but was not found to be an accurate indicator of decomposition of sodium aminosalicylate as it reflected only oxidation of *m*-aminophenol.

1. Blake MI, *et al.* Effect of vehicle on the stability of sodium aminosalicylate in liquid dosage forms. *Am J Hosp Pharm* 1973; **30:** 441–3.

Adverse Effects and Treatment

Aminosalicylic acid and its salts may cause the adverse effects of salicylates (see Aspirin, p.20).

Gastrointestinal effects are common and include nausea, vomiting, and diarrhoea; they may be reduced by giving doses with food or with an antacid but occasionally may be severe enough that therapy has to be withdrawn. Alteration of gastrointestinal function may lead to malabsorption of vitamin B_{12}, folate, and lipids.

Hypersensitivity reactions have been reported in 5 to 10% of adults, usually during the first few weeks of treatment, and include fever, skin rashes; less commonly, arthralgia, lymphadenopathy, and hepatosplenomegaly may occur and, rarely, a syndrome resembling infectious mononucleosis. Other adverse effects which have been attributed to a hypersensitivity reaction to aminosalicylate include jaundice and encephalitis. Blood disorders reported include haemolytic anaemia in patients with G6PD deficiency, agranulocytosis, eosinophilia, leucopenia, and thrombocytopenia. Psychosis may occasionally occur. Prolonged treatment may induce goitre and hypothyroidism. Crystalluria may occur.

Effects on the liver. Drug-induced hepatitis occurred in 0.32% of 7492 patients receiving antituberculous drugs; aminosalicylic acid was the most common cause.[1]

1. Rossouw JE, Saunders SJ. Hepatic complications of antituberculous therapy. *Q J Med* 1975; **44:** 1–16.

Precautions

Aminosalicylic acid and its salts should be used with great care in patients with hepatic or renal impairment and in patients with gastric ulcer. They should be given with caution to patients with G6PD deficiency. The sodium salt should be used with caution in patients with heart failure.

Aminosalicylates interfere with tests for glycosuria using copper reagents and for urobilinogen using Ehrlich's reagent.

Breast feeding. Small amounts of aminosalicylic acid are present in breast milk. A maximum concentration of 1.1 microgram/mL has been reported in the breast milk of a lactating woman 3 hours after a 4-g dose of aminosalicylic acid.[1]

1. Holdiness MR. Antituberculosis drugs and breast feeding. *Arch Intern Med* 1984; **144:** 1888.

Pregnancy. The use of aminosalicylic acid or its salts is not recommended in pregnant patients due to gastrointestinal intolerance.[1] In addition it has been noted that, a study published in 1964 suggested that first-trimester exposure may be associated with congenital defects although other studies had not found similar effects.[2]

1. Snider D. Pregnancy and tuberculosis. *Chest* 1984; **86:** 10S–13S.
2. Briggs GG, *et al. Drugs in pregnancy and lactation.* 7th ed. Philadelphia: Lippincott Williams and Wilkins, 2005: 59.

Interactions

The adverse effects of aminosalicylates and salicylates may be additive. Probenecid may also increase toxicity by delaying renal excretion and enhancing plasma concentrations of aminosalicylate. The activity of aminosalicylic acid may be antagonised by ester-type local anaesthetics such as procaine.

Antimicrobial Action

Aminosalicylic acid is bacteriostatic and is active against *M. tuberculosis*. Other mycobacteria are usually resistant. It has a relatively weak action compared with other antituberculous drugs. Resistance develops quickly if aminosalicylic acid is used alone.

◊ References.

1. Rengarajan J, *et al.* The folate pathway is a target for resistance to the drug para-aminosalicylic acid (PAS) in mycobacteria. *Mol Microbiol* 2004; **53:** 275–82.

Pharmacokinetics

When given orally, aminosalicylic acid and its salts are readily absorbed, and peak plasma concentrations occur after about 1 to 4 hours.

Aminosalicylate diffuses widely through body tissues and fluids, although diffusion into the CSF occurs only if the meninges are inflamed. About 15% of the sodium salt, and 50 to 70% of the acid, is bound to plasma proteins.

Aminosalicylate is metabolised in the intestine and liver primarily by acetylation. Urinary excretion is rapid, and 80% or more of a dose is excreted within 24 hours; 50% or more of the dose is excreted as the acetylated metabolite. The half-life of aminosalicylic acid is about 1 hour.

Aminosalicylate is distributed into breast milk (see under Precautions, above, for more details).

Uses and Administration

Aminosalicylic acid and its salts are second-line antimycobacterials given orally in the treatment of multidrug-resistant **tuberculosis** (p.196). They should always be given with other antituberculous drugs.

Aminosalicylic acid may be given as the acid or as the sodium salt. Sodium aminosalicylate 1.38 g is equivalent to about 1 g of aminosalicylic acid. However, a usual daily oral dose is 12 g in 3 divided doses and has been recommended for products containing the acid as well as for those containing the sodium salt.

For details of doses in infants, children, and adolescents, see below.

Aminosalicylate sodium is also given rectally in the treatment of **ulcerative colitis** in a usual dose of 2 g once daily.

Attempts have been made in formulation to overcome the bulk and exceedingly unpleasant taste of the aminosalicylates. The salts appear to be better tolerated than the free acid and solutions in iced water prepared immediately before use may be less unpleasant to take.

Administration. A small study suggested that giving aminosalicylic acid in a dose of 4 g twice daily produced adequate serum concentrations (well in excess of 1 microgram/mL, a typical MIC against *Mycobacterium tuberculosis*) for up to 12 hours after each dose.[1] The drug was taken with an acidic beverage such as fruit juice to prevent early release in the stomach. A single 4-g dose was not sufficient to maintain serum concentrations for the full 24-hour dosage interval. The authors had subsequently changed their practice to use a twice-daily regimen for aminosalicylic acid in patients with multidrug-resistant tuberculosis.

1. Peloquin CA, *et al*. Once-daily and twice-daily dosing of p-aminosalicylic acid granules. *Am J Respir Crit Care Med* 1999; **159:** 932–4.

Administration in children. For the treatment of drug-resistant tuberculosis in infants, children, and adolescents the American Academy of Pediatrics (AAP) and WHO suggest an oral dose of para-aminosalicylic acid 200 to 300 mg/kg 2 to 4 times daily, to a maximum dose of 10 g daily.

Administration in renal impairment. It has been recommended that aminosalicylic acid should be avoided in patients with renal impairment.[1] An increase in plasma clearance of aminosalicylic acid (attributed to increased hepatic metabolism) has been noted in patients with renal impairment, hence attempting to give aminosalicylate in reduced doses to such patients may lead to subtherapeutic serum concentrations.[2]

2. Holdiness MR. Clinical pharmacokinetics of the antituberculosis drugs. *Clin Pharmacokinet* 1984; **9:** 511–44.

Inflammatory bowel disease. Together with corticosteroids, derivatives of 5-aminosalicylic acid are one of the mainstays of the treatment of inflammatory bowel disease (p.1697). However, aminosalicylic acid (4-aminosalicylic acid) has also been investigated, and beneficial results have been reported with both enemas[1-4] and oral dose forms[5] in ulcerative colitis. Three patients who developed acute pancreatitis while taking mesalazine (5-aminosalicylic acid) for inflammatory bowel disease, later tolerated treatment with 4-aminosalicylic acid enemas.[6]

Manganese toxicity. Intravenous aminosalicylic acid, given in a course of 6 g daily for 4 days a week, for fifteen courses, produced significant benefit in a patient with parkinsonism induced by chronic occupational manganese exposure.[1] The patient remained well on prolonged follow-up. Other cases of benefit had been reported in the Chinese literature.

Amoxicillin *(BAN, rINN)*

Amoksisilin; Amoksisilliini; Amoxicilina; Amoxicilline; Amoxicillinum; Amoxycillin. (6*R*)-6-[α-D-(4-Hydroxyphenyl)glycylamino]penicillanic acid.

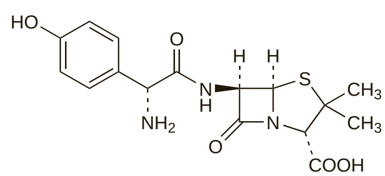
Амоксициллин

$C_{16}H_{19}N_3O_5S$ = 365.4.

CAS — 26787-78-0.

ATC — J01CA04.

ATC Vet — QG51AX01; QJ01CA04.



Amoxicillin Sodium *(BANM, USAN, rINNM)*

Amoksicilino natrio druska; Amoksisilin Sodyum; Amoksisilliininatrium; Amoksycylina sodowa; Amoxicilin sodná sůl; Amoxicilina sódica; Amoxicilline sodique; Amoxicillinnatrium; Amoxicillinnátrium; Amoxicillinum natricum; Amoxycillin Sodium; BRL-2333AB-B; Natrii Amoxicillinum.

Натрий Амоксициллин

$C_{16}H_{18}N_3NaO_5S$ = 387.4.

CAS — 34642-77-8.

ATC — J01CA04.

ATC Vet — QJ01CA04.

Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Amoxicillin Sodium). A white or almost white, very hygroscopic powder. Very soluble in water; sparingly soluble in dehydrated alcohol; very slightly soluble in acetone. A 10% solution in water has a pH of 8.0 to 10.0. Store in airtight containers.

Amoxicillin Trihydrate *(BANM, rINNM)*

Amoksicilinas trihidratas; Amoksisilin Trihidrat; Amoksisilliinitrihydraatti; Amoksycylina trójwodna; Amoxicilin trihydrát; Amoxicilina trihidrato; Amoxicillin *(USAN)*; Amoxicilline trihydratée; Amoxicillin-trihidrát; Amoxicillintrihydrat; Amoxicillinum trihydricum; Amoxycillin Trihydrate; BRL-2333.

Амоксициллин Тригидрат

$C_{16}H_{19}N_3O_5S,3H_2O$ = 419.4.

CAS — 61336-70-7.

ATC — J01CA04.

ATC Vet — QJ01CA04.

NOTE. Compounded preparations of amoxicillin may be represented by the following names:

- Co-amoxiclav *x/y* (*BAN*)—amoxicillin (as the trihydrate or the sodium salt) and potassium clavulanate; *x* and *y* are the strengths in milligrams of amoxicillin and clavulanic acid respectively
- Co-amoxiclav (*PEN*)—amoxicillin trihydrate and potassium clavulanate.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Amoxicillin Trihydrate). A white or almost white, crystalline powder. Slightly soluble in water; very slightly soluble in alcohol; practically insoluble in fatty oils. It dissolves in dilute acids and in dilute solutions of alkali hydroxides. A 0.2% solution in water has a pH of 3.5 to 5.5. Store in airtight containers.

USP 31 (Amoxicillin). A white, practically odourless crystalline powder. Slightly soluble in water and in methyl alcohol; insoluble in carbon tetrachloride, in chloroform, and in benzene. pH of a 0.2% solution in water is between 3.5 and 6.0. Store in airtight containers.

Adverse Effects and Precautions

As for Ampicillin, p.204.

The incidence of diarrhoea is less with amoxicillin than ampicillin.

Hepatitis and cholestatic jaundice have been reported with amoxicillin plus clavulanic acid; the clavulanic acid component has been implicated. Erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis, and exfoliative dermatitis have also been attributed occasionally to the use of amoxicillin with clavulanic acid.

Breast feeding. Although amoxicillin is excreted in breast milk in small amounts,[1] the American Academy of Pediatrics considers that it is usually compatible with breast feeding.[2]

1. Kafetzis DA, *et al*. Passage of cephalosporins and amoxicillin into the breast milk. *Acta Paediatr Scand* 1981; **70:** 285–8.

Effects on the liver. Hepatitis and cholestatic jaundice associated with the combination amoxicillin with clavulanic acid (co-amoxiclav) have been reported[1-4] and by 1993 the UK CSM had received 138 reports of hepatobiliary disorders, 3 of which were fatal.[5] It warned that, although usually reversible, the reaction often occurred after stopping therapy with a delay of up to 6 weeks. It appeared that the clavulanic acid was probably responsible. Retrospective analysis of cases reported in Australia[6] and a cohort study in the UK[7] found increasing age and prolonged treatment to be major risk factors for jaundice after co-amoxiclav; male sex is also a risk factor. By 1997 the CSM considered that cholestatic jaundice occurred with a frequency of about 1 in 6000 adult patients and that the risk of acute liver injury was about 6 times greater with co-amoxiclav than with amoxicillin alone. Therefore it recommended that co-amoxiclav should be reserved for bacterial infections likely to be caused by amoxicillin-resistant strains, and that treatment should not usually exceed 14 days.[8]

Effects on the teeth. A report of tooth discoloration in 3 children associated with the use of amoxicillin with clavulanic acid.[1]

1. Garcia-López M, *et al*. Amoxycillin-clavulanic acid-related tooth discoloration in children. *Pediatrics* 2001; **108:** 819–20.

Sodium content. Each g of amoxicillin sodium contains about 2.6 mmol of sodium.

Interactions

As for Ampicillin, p.204.

Antimicrobial Action

As for Ampicillin, p.204.

Amoxicillin has been reported to be more active *in vitro* than ampicillin against *Enterococcus faecalis, Helicobacter pylori,* and *Salmonella* spp., but less active against *Shigella* spp.

Amoxicillin is inactivated by beta lactamases and complete cross-resistance has been reported between amoxicillin and ampicillin. The spectrum of activity of amoxicillin may be extended by use with a beta-lactamase inhibitor such as clavulanic acid (p.250). As well as reversing resistance to amoxicillin in beta-lactamase-producing strains of species otherwise sensitive, clavulanic acid has also been reported to enhance the activity of amoxicillin against several species not generally considered sensitive. These have included *Bacteroides*, *Legionella*, and *Nocardia* spp., *Haemo-*

philus influenzae, *Moraxella catarrhalis* (*Branhamella catarrhalis*), and *Burkholderia pseudomallei* (*Pseudomonas pseudomallei*). However, *Ps. aeruginosa*, *Serratia marcescens*, and many other Gram-negative bacteria remain resistant. Transferable resistance has been reported in *H. pylori*.

Pharmacokinetics

Amoxicillin is resistant to inactivation by gastric acid. It is more rapidly and more completely absorbed than ampicillin when given orally. Peak plasma-amoxicillin concentrations of about 5 micrograms/mL have been observed 1 to 2 hours after a dose of 250 mg, with detectable amounts present for up to 8 hours. Doubling the dose can double the concentration. The presence of food in the stomach does not appear to diminish the total amount absorbed.

Concentrations of amoxicillin after intramuscular injection are similar to those achieved with oral doses.

About 20% is bound to plasma proteins and plasma half-lives of 1 to 1.5 hours have been reported. The half-life may be prolonged in neonates, the elderly, and patients with renal impairment; in severe renal impairment the half-life may be 7 to 20 hours. Amoxicillin is widely distributed at varying concentrations in body tissues and fluids. It crosses the placenta; small amounts are distributed into breast milk. Little amoxicillin passes into the CSF unless the meninges are inflamed.

Amoxicillin is metabolised to a limited extent to penicilloic acid which is excreted in the urine. About 60% of an oral dose of amoxicillin is excreted unchanged in the urine in 6 hours by glomerular filtration and tubular secretion. Urinary concentrations above 300 micrograms/mL have been reported after a dose of 250 mg. Probenecid reduces renal excretion. Amoxicillin is removed by haemodialysis. High concentrations have been reported in bile; some may be excreted in the faeces.

Amoxicillin with clavulanic acid. The pharmacokinetics of amoxicillin and clavulanic acid are broadly similar and neither appears to affect the other to any great extent.

Uses and Administration

Amoxicillin is the 4-hydroxy analogue of ampicillin (p.205) and is used similarly in susceptible infections. These include actinomycosis, anthrax, biliary-tract infections, bronchitis, endocarditis (particularly for prophylaxis), gastro-enteritis (including salmonella enteritis, but not shigellosis), gonorrhoea, Lyme disease, mouth infections, otitis media, pneumonia, spleen disorders (pneumococcal infection prophylaxis), typhoid and paratyphoid fever, and urinary-tract infections. The beta-lactamase inhibitor clavulanic acid (p.250) widens amoxicillin's antimicrobial spectrum and a combined preparation (co-amoxiclav) can be used when resistance to amoxicillin is prevalent, for example in respiratory-tract infections due to *Haemophilus influenzae* or *Moraxella catarrhalis* (*Branhamella catarrhalis*), in the empirical treatment of animal bites, or in melioidosis. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Amoxicillin is also given as part of treatment regimens to eradicate *Helicobacter pylori* infection in patients with peptic ulcer disease (p.1702).

Administration and dosage. Amoxicillin is given orally as the trihydrate and by injection as the sodium salt. Doses are expressed in terms of the equivalent amount of amoxicillin; 1.06 g of amoxicillin sodium and 1.15 g of amoxicillin trihydrate are each equivalent to about 1 g of amoxicillin.

The usual oral dose is 250 to 500 mg every 8 hours, or 500 to 875 mg every 12 hours. Children up to 10 years of age may be given 125 to 250 mg every 8 hours; for those under 40 kg, a dose of 20 to 40 mg/kg daily in divided doses every 8 hours, or 25 to 45 mg/kg daily in divided doses every 12 hours, may be used; in infants less than 3 months old, the maximum dose should be 30 mg/kg daily in divided doses every 12 hours.

Higher oral doses of amoxicillin, either as a single dose or in short courses, are used in some conditions. For example, a dose of 3 g repeated once after 8 hours may be used for dental abscesses. A 3-g dose may be given for uncomplicated acute urinary-tract infections, and repeated once after 10 to 12 hours.

A high-dose regimen of 3 g twice daily may be used in patients with severe or recurrent infections of the respiratory tract. If necessary, children aged 3 to 10 years with otitis media may be given 750 mg twice daily for 2 days. Amoxicillin has also been given as a single dose of 3 g, with probenecid 1 g, in the treatment of uncomplicated gonorrhoea in areas where gonococci remain sensitive.

For the prophylaxis of endocarditis in patients at risk, amoxicillin 2 or 3 g is given about 1 hour before dental procedures.

For the eradication of *H. pylori*, amoxicillin is given with either metronidazole or clarithromycin and a proton pump inhibitor; usual doses of amoxicillin are 0.75 or 1 g twice daily or 500 mg three times daily.

An extended release formulation containing 775 mg of amoxicillin as the trihydrate is available in the USA for the treatment of tonsillitis and pharyngitis due to *Streptococcus pyogenes* in patients aged 12 years or older. It is given orally in a dose of 775 mg daily for 10 days.

Amoxicillin is given by intramuscular or slow intravenous injection in doses of 500 mg every 8 hours. In severe infections, 1 g of amoxicillin may be given every 6 hours by slow intravenous injection over 3 to 4 minutes or by infusion over 30 to 60 minutes. Children up to 10 years of age may be given 50 to 100 mg/kg daily by injection in divided doses.

Doses may need to be reduced in moderate to severe renal impairment (see below).

Amoxicillin with clavulanic acid. Amoxicillin combined with clavulanic acid (co-amoxiclav) is given by mouth in a ratio of amoxicillin (as the trihydrate) 2, 4, 7, or 14 parts to 1 part of clavulanic acid (as the potassium salt), or intravenously in a ratio of 5 parts of amoxicillin (as the sodium salt) to 1 part of clavulanic acid (as the potassium salt). Doses of the combination, calculated on amoxicillin content, are similar to those for amoxicillin used alone.

Administration in renal impairment. Doses of amoxicillin should be reduced in patients with moderate to severe renal impairment according to creatinine clearance (CC):

- CC 10 to 30 mL/minute: 250 to 500 mg every 12 hours
- CC less than 10 mL/minute: 250 to 500 mg every 24 hours
- haemodialysis patients: 250 to 500 mg every 24 hours and an additional dose both during and after the dialysis session.

Ampicillin *(BAN, USAN, rINN)*

Aminobenzylpenicillin; Ampicilin; Ampicilina; Ampicilinas, bevandenis; Ampicillin, vattenfritt; Ampicilline; Ampicilline anhydre; Ampicillinum; Ampicillinum anhydricum; Ampicylina bezwodna; Ampisilin; Ampisilliini; Ampicillin, vedetön; Anhydrous Ampicillin; AY-6108; BRL-1341; NSC-528986; P-50; Vízmentes ampicillin. (6*R*)-6-(α-D-Phenylglycylamino)penicillanic acid.

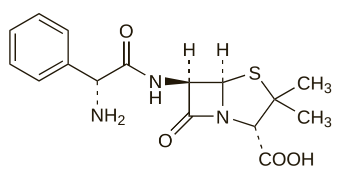
Ампициллин

$C_{16}H_{19}N_3O_4S = 349.4.$

CAS — 69-53-4.

ATC — J01CA01; S01AA19.

ATC Vet — QJ01CA01; QJ51CA01; QS01AA19.



NOTE. Compounded preparations of ampicillin may be represented by the following names:

- Co-fluampicil (*BAN*)—flucloxacillin 1 part and ampicillin 1 part (w/w).

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *Viet.*
Int. and *US* permit anhydrous or the trihydrate.

Ph. Eur. 6.2 (Ampicillin, Anhydrous; Ampicillin BP 2008). A white or almost white, crystalline powder. It exhibits polymorphism. Sparingly soluble in water; practically insoluble in alcohol, in acetone, and in fatty oils. It dissolves in dilute solutions of acids and of alkali hydroxides. A 0.25% solution in water has a pH of 3.5 to 5.5. Store at a temperature not exceeding 30° in airtight containers.

USP 31 (Ampicillin). It is anhydrous or contains three molecules of water of hydration. A white, practically odourless crystalline powder. Slightly soluble in water and in methyl alcohol; insoluble in carbon tetrachloride, in chloroform, and in benzene. pH of a 1% solution in water is between 3.5 and 6.0. Store in airtight containers.

Ampicillin Sodium *(BANM, USAN, rINNM)*

Aminobenzylpenicillin Sodium; Ampicilin sodná sůl; Ampicilina sódica; Ampicilino natrio druska; Ampicilline sodique; Ampicillinnatrium; Ampicillin-nátrium; Ampicillinum natricum; Ampicylina sodowa; Ampisilliininatrium; Natrii Ampicillinum; Sodyum Ampisilin.

Натрий Ампициллин

$C_{16}H_{18}N_3NaO_4S = 371.4.$

CAS — 69-52-3.

ATC — J01CA01; S01AA19.

ATC Vet — QJ01CA01; QS01AA19.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn*, and *US.*

Ph. Eur. 6.2 (Ampicillin Sodium). A white or almost white hygroscopic powder. Freely soluble in water; sparingly soluble in acetone; practically insoluble in liquid paraffin and in fatty oils. A 10% solution in water has a pH of 8.0 to 10.0. Store in airtight containers.

USP 31 (Ampicillin Sodium). A white to off-white, odourless or practically odourless, hygroscopic, crystalline powder. Very soluble in water and in isotonic sodium chloride and glucose solutions. pH of a solution in water containing the equivalent of ampicillin 1% is between 8.0 and 10.0. Store in airtight containers.

Incompatibility. The incompatibility of ampicillin sodium and aminoglycosides is well established. Incompatibilities have also been reported with a wide range of other drugs, including other antibacterials, and appear to be more pronounced at higher concentrations and in solutions also containing glucose.

Stability. The stability of solutions of ampicillin sodium is dependent on many factors including concentration, pH, temperature, and the nature of the vehicle. Stability decreases in the presence of glucose, fructose, invert sugar, dextrans, hetastarch, sodium bicarbonate, and lactate. It is recommended that reconstituted solutions of ampicillin sodium for injection should be given within 24 hours of preparation, and should be stored at 2° to 8° but should not be frozen. Solutions for infusion are stable for varying periods and details are given in licensed product information.

ATC Vet — QJ01CA01; QS01AA19.

Pharmacopoeias. In *Eur.* (see p.vii) and *Viet.* In *Chin.* and *Jpn* under the title Ampicillin. *Int.* and *US* permit anhydrous or the trihydrate under the title Ampicillin.

Ph. Eur. 6.2 (Ampicillin Trihydrate). A white or almost white, crystalline powder. Slightly soluble in water; practically insoluble in alcohol and in fatty oils. It dissolves in dilute solutions of acids and of alkali hydroxides. A 0.25% solution in water has a pH of 3.5 to 5.5. Store in airtight containers.

USP 31 (Ampicillin). It is anhydrous or contains three molecules of water of hydration. A white, practically odourless crystalline powder. Slightly soluble in water and in methyl alcohol; insoluble in carbon tetrachloride, in chloroform, and in benzene. pH of a 1% solution in water is between 3.5 and 6.0. Store in airtight containers.

Adverse Effects

As for Benzylpenicillin, p.213.

Skin rashes are among the most common adverse effects and are generally either urticarial or maculopapular; the urticarial reactions are typical of penicillin hypersensitivity, while the erythematous maculopapular eruptions are characteristic of ampicillin and amoxicillin and often appear more than 7 days after commencing treatment. Such rashes may be due to hypersensitivity to the beta-lactam moiety or to the amino group in the side-chain, or to a toxic reaction. The occurrence of a maculopapular rash during ampicillin use does not necessarily preclude the subsequent use of other penicillins. However, since it may be difficult in practice to distinguish between hypersensitive and toxic responses, skin testing for hypersensitivity may be advisable before another penicillin is used in patients who have had ampicillin rashes. Most patients with infectious mononucleosis develop a maculopapular rash when treated with ampicillin, and patients with other lymphoid disorders such as lymphatic leukaemia, and possibly those with HIV infection, also appear to be at higher risk. More serious skin reactions may occur and erythema multiforme associated with ampicillin has occasionally been reported.

Gastrointestinal adverse effects, particularly diarrhoea and nausea and vomiting, occur quite often, usually after oral use. Pseudomembranous colitis has also been reported.

Precautions

As for Benzylpenicillin, p.214.

Ampicillin should be stopped if a skin rash occurs. It should preferably not be given to patients with infectious mononucleosis since they are especially susceptible to ampicillin-induced skin rashes; patients with lymphatic leukaemia or possibly HIV infection may also be at increased risk of developing skin rashes.

Myasthenia gravis. The symptoms of a woman with myasthenia gravis were exacerbated when she was given ampicillin.[1]

1. Argov Z, *et al.* Ampicillin may aggravate clinical and experimental myasthenia gravis. *Arch Neurol* 1986; **43**: 255–6.

Sodium content. Each g of ampicillin sodium contains about 2.7 mmol of sodium.

Interactions

As for Benzylpenicillin, p.214.

Allopurinol. An increased frequency of skin rashes has been reported in patients receiving ampicillin or amoxicillin, with allopurinol, compared with those receiving the antibacterial alone,[1] but this could not be confirmed in a subsequent study.[2]

1. Jick H, Porter JB. Potentiation of ampicillin skin reactions by allopurinol or hyperuricemia. *J Clin Pharmacol* 1981; **21:** 456–8.
2. Hoigné R, *et al.* Occurrence of exanthems in relation to aminopenicillin preparations and allopurinol. *N Engl J Med* 1987; **316**: 1217.

Chloroquine. The absorption of ampicillin has been reduced in healthy subjects taking chloroquine.[1]

1. Ali HM. Reduced ampicillin bioavailability following oral coadministration with chloroquine. *J Antimicrob Chemother* 1985; **15:** 781–4.

Antimicrobial Action

Ampicillin is a beta-lactam antibiotic. It is bactericidal and has a similar mode of action to that of benzylpenicillin (p.214), but as an aminopenicillin with an amino group side-chain attached to the basic penicillin structure, ampicillin is better able to penetrate the outer membrane of some Gram-negative bacteria and has a broader spectrum of activity.

Spectrum of activity. Ampicillin resembles benzylpenicillin in its action against Gram-positive organisms, including *Streptococcus pneumoniae* and other streptococci, but, with the possible exception of activity against *Enterococcus faecalis*, it is slightly less potent than benzylpenicillin. *Listeria monocytogenes* is highly sensitive. The Gram-negative cocci *Moraxella catarrhalis* (*Branhamella catarrhalis*), *Neisseria gonorrhoeae*, and *N. meningitidis* are sensitive. Ampicillin is more active than benzylpenicillin against some Gram-negative bacilli, including *Haemophilus influenzae* and Enterobacteriaceae such as *Escherichia coli*, *Proteus mirabilis*, *Salmonella* and *Shigella* spp. It is inactive against *Pseudomonas aeruginosa*. Ampicillin also has activity similar to benzylpenicillin against other organisms including many anaerobes and *Actinomyces* spp.

Activity with other antimicrobials. There is synergy against some beta-lactamase-producing organisms between ampicillin and beta-lactamase inhibitors such as clavulanic acid or sulbactam, and also penicillinase-stable drugs such as cloxacillin or flucloxacillin. Synergy has also been shown between ampicillin and aminoglycosides against a range of organisms, including enterococci. Variable effects ranging from synergy to antagonism have been reported between ampicillin and other beta lactams, bacteriostatic drugs such as chloramphenicol, and rifampicin.

Resistance. Like benzylpenicillin, ampicillin is inactivated by beta lactamases, although other mechanisms may be responsible for resistance in some species. There are geographical variations in the incidence of resistance, but most staphylococci and many strains of *E. coli*, *H. influenzae*, *M. catarrhalis*, *N. gonorrhoeae*, and *Salmonella* and *Shigella* spp. are resistant.

Pharmacokinetics

Ampicillin is relatively resistant to inactivation by gastric acid and is moderately well absorbed from the gastrointestinal tract after oral doses. Food can interfere with the absorption of ampicillin so doses should preferably be taken at least 30 minutes before meals. Peak concentrations in plasma are attained in about 1 to 2 hours and after a 500-mg oral dose are reported to range from 3 to 6 micrograms/mL.

Peak plasma concentrations of ampicillin after a 500-mg intramuscular dose given as the sodium salt occur within about 1 hour and are reported to range from 7 to 14 micrograms/mL.

Ampicillin is widely distributed and therapeutic concentrations can be achieved in ascitic, pleural, and joint fluids. It crosses the placenta and small amounts are distributed into breast milk. There is little diffusion into the CSF except when the meninges are inflamed. About 20% is bound to plasma proteins and the plasma half-life is about 1 to 1.5 hours, but this may be increased in neonates, the elderly, and patients with renal impairment; in severe renal impairment half-lives of 7 to 20 hours have been reported.

Ampicillin is metabolised to some extent to penicilloic acid which is excreted in the urine.

Renal clearance of ampicillin occurs partly by glomerular filtration and partly by tubular secretion; it is reduced by probenecid. About 20 to 40% of an oral dose may be excreted unchanged in the urine in 6 hours; urinary concentrations have ranged from 0.25 to 1 mg/mL after a dose of 500 mg. After parenteral use about 60 to 80% is excreted in the urine within 6 hours. Ampicillin is removed by haemodialysis. High concentrations are reached in bile; it undergoes enterohepatic recycling and some is excreted in the faeces.

Ampicillin with sulbactam. The pharmacokinetics of ampicillin and sulbactam are broadly similar and neither appears to affect the other to any great extent.

Uses and Administration

Ampicillin is used in the treatment of a variety of infections due to susceptible organisms (see Antimicrobial Action, above). They include biliary-tract infections, bronchitis, endocarditis, gastro-enteritis (including salmonella enteritis and shigellosis), gonorrhoea, listeriosis, meningitis, perinatal streptococcal infections (intrapartum prophylaxis against group B streptococci), peritonitis, pneumonia, septicaemia, typhoid and paratyphoid fever, and urinary-tract infections. Resistance to ampicillin is increasingly a problem in some infections, for example, gonorrhoea, pneumococcal infections, respiratory-tract infections due to *Haemophilus influenzae* or *Moraxella catarrhalis* (*Branhamella catarrhalis*), *Salmonella* infections, shigellosis, and infections due to *Escherichia coli*. For details of these infections and their treatment, see under Choice of Antibacterial, p.162. If beta-lactamase-producing organisms are present, ampicillin can be given with a beta-lactamase inhibitor such as sulbactam (see below) or a penicillinase-resistant drug such as cloxacillin, dicloxacillin, or flucloxacillin (known as co-fluampicil). It may also be used with an aminoglycoside to increase the spectrum of organisms covered; it is advisable to give the injections separately.

Administration and dosage. The dosage of ampicillin will depend on the severity of the disease, the age of the patient, and renal function. Ampicillin is usually given orally as the trihydrate and by injection as the sodium salt. Doses are expressed in terms of the equivalent amount of ampicillin; 1.06 g of ampicillin sodium and 1.15 g of ampicillin trihydrate are each equivalent to about 1 g of ampicillin.

The usual adult oral dose is 0.25 to 1 g every 6 hours taken at least 30 minutes before or 2 hours after food. Children may be given half the adult dose. The usual adult dose by injection is 500 mg every 4 to 6 hours intramuscularly or by slow intravenous injection over 3 to 5 minutes or by infusion. Again, children may be given half the adult dose.

For urinary-tract infections, ampicillin 500 mg is given orally every 8 hours.

For typhoid and paratyphoid fever where *Salmonella typhi* strains remain sensitive to ampicillin, an oral dose of 1 to 2 g may be given every 6 hours for 2 weeks for acute infections, and for 4 to 12 weeks in carriers. An intramuscular dose of 10 mg/kg (maximum dose 250 mg) every 6 hours for 4 to 6 weeks has been suggested for children who are chronic carriers.

Ampicillin 2 g given with probenecid 1 g, as a single oral dose, has been used in the treatment of uncomplicated gonorrhoea in areas where gonococci remain sensitive; repeated doses are recommended in females.

In meningitis, higher parenteral doses of 2 to 3 g given intravenously every 4 or 6 hours have been suggested. For infants and children with meningitis, an intravenous dose of 150 mg/kg daily in divided doses may be given; a dose of 50 mg/kg (maximum 3 g) every 4 to 6 hours has also been suggested. Neonates may be given a dose of 50 mg/kg every 12 hours for those under 1 week of age, or every 8 hours for older neonates.

For intrapartum prophylaxis against group B streptococcal infection in the neonate, a maternal dose of 2 g by intravenous injection initially then 1 g every 4 hours until delivery has been suggested.

Ampicillin may also be given by other routes, usually as a supplement to systemic therapy. Intraperitoneal or intrapleural injections are given in a dose of 500 mg daily dissolved in 5 to 10 mL of water. For intra-articular injection, ampicillin 500 mg daily is given dissolved in up to 5 mL of water or a solution of procaine hydrochloride 0.5%.

Ampicillin benzathine has also been given by intramuscular injection.

Ampicillin with sulbactam. The sodium salts of ampicillin and sulbactam (p.335) may be given intramuscularly or intravenously in the treatment of infections due to beta-lactamase-producing organisms. Doses are expressed in terms of the equivalent amounts of ampicillin and sulbactam; available injections contain ampicillin and sulbactam in the ratio 2:1, respectively. The usual dose is ampicillin 1 g with sulbactam 500 mg every 6 hours; doses may be doubled in severe infections.

For oral use sultamicillin (p.344), a mutual prodrug of ampicillin and sulbactam, may be given.

Administration in renal impairment. The dose of ampicillin should be reduced, or the dose interval increased, in severe renal impairment (creatinine clearance less than 10 mL/minute). Patients undergoing dialysis should receive an additional dose after the session.

Preparations

BP 2008: Ampicillin Capsules; Ampicillin Injection; Ampicillin Oral Suspension; Co-fluampicil Capsules; Co-fluampicil Oral Suspension;
USP 31: Ampicillin and Probenecid for Oral Suspension; Ampicillin and Sulbactam for Injection; Ampicillin Capsules; Ampicillin for Injectable Suspension; Ampicillin for Injection; Ampicillin for Oral Suspension; Ampicillin Tablets.

Proprietary Preparations (details are given in Part 3)

Apramycin *(BAN, USAN, rINN)*

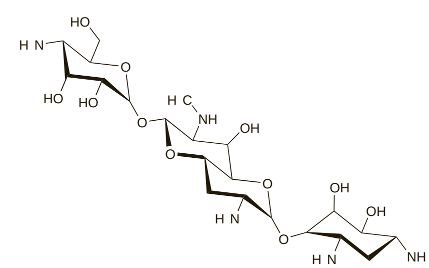
47657; Apramicina; Apramycine; Apramycinum; EL-857; EL-857/820; Nebramycin Factor 2. 4-*O*-[(2*R*,3*R*,4a*S*,6*R*,7*S*,8*R*,8a*R*)-3-Amino-6-(4-amino-4-deoxy-α-D-glucopyranosyloxy)-8-hydroxy-7-methylaminoperhydropyrano[3,2-*b*]pyran-2-yl]-2-deoxystreptamine.

Апрамицин

$C_{21}H_{41}N_5O_{11}$ = 539.6.

CAS — 37321-09-8.

ATC Vet — QA07AA92; QJ01GB90; QJ51GB90.



Apramycin Sulfate *(rINNM)*

Apramycin Sulphate *(BANM)*; Apramycine, Sulfate d'; Apramycini Sulfas; Apramycinsulfat; Apramysiinisulfaatti; Sulfato de apramicina.

Апрамицина Сульфат

$C_{21}H_{41}N_5O_{11}.2 \frac{1}{2}H_2SO_4$ = 784.8.

CAS — 41194-16-5.

Pharmacopoeias. In *BP(Vet).*

BP(Vet) 2008 (Apramycin Sulphate). The sulfate of an antibiotic produced by certain strains of *Streptomyces tenebrarius* or by other means. The potency is not less than 430 units per mg, calculated with reference to the anhydrous substance. A light brown hygroscopic powder or granular material. Freely soluble in water; practically insoluble in alcohol, in acetone, in ether, and in methyl alcohol.

Profile

Apramycin is an aminoglycoside antibiotic used as the sulfate in veterinary practice for the treatment of susceptible infections.

The symbol † denotes a preparation no longer actively marketed

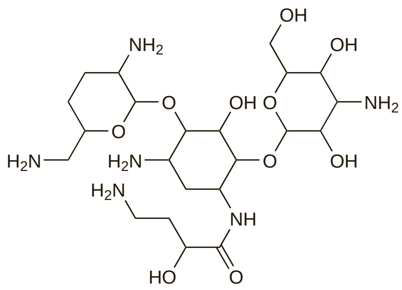
Arbekacin Sulfate *(rINNM)*

ABK (arbekacin); AHB-DBK (arbekacin); Arbekacin Sulphate; Arbékacine, Sulfate d'; Arbekacini Sulfas; HABA-Dibekacin (arbekacin); Sulfato de arbekacina. *O*-3-Amino-3-deoxy-α-D-glucopyranosyl-(1→4)-*O*-[2,6-diamino-2,3,4,6-tetradeoxy-α-D-*erythro*-hexopyranosyl-(1→6)]-*N*′-[(2*S*)-4-amino-2-hydroxybutyryl]-2-deoxy-L-streptamine sulphate.

Арбекацина Сульфат

$C_{22}H_{44}N_6O_{10},xH_2SO_4$.

CAS — 51025-85-5 (arbekacin).



(arbekacin)

Pharmacopoeias. In *Jpn*.

Profile

Arbekacin is an aminoglycoside derived from dibekacin and has general properties similar to those of gentamicin (p.282). It has been used as the sulfate in the treatment of serious infections due to meticillin-resistant *Staphylococcus aureus*.

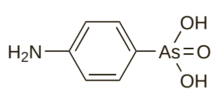
Arsanilic Acid *(BAN, rINN)*

Acide Arsanilique; Ácido arsanílico; Acidum Arsanilicum; Aminarsonic Acid; AS-101. *p*-Aminobenzenearsonic acid; 4-Aminophenylarsonic acid.

Арсаниловая Кислота

$C_6H_8AsNO_3$ = 217.1.

CAS — 98-50-0.



NOTE. The code AS-101 has also been used for an immunomodulator investigated as an antineoplastic and antiviral.

Pharmacopoeias. In *US* for veterinary use only.

USP 31 (Arsanilic Acid). A white to off-white crystalline powder. Soluble in hot water, in amyl alcohol, and in solutions of alkali carbonates; slightly soluble in cold water, in alcohol, and in acetic acid; insoluble in acetone, in chloroform, in ether, in benzene, and in dilute mineral acids; sparingly soluble in concentrated mineral acids.

Sodium Arsanilate *(BANM, rINNM)*

Arsanilate de Sodium; Arsanilato sódico; Natrii Arsanilas; Sodium Aminarsonate; Sodium Anilarsonate. Sodium 4-aminophenylarsonate.

Натрий Арсанилат

$C_6H_7AsNNaO_3$ = 239.0.

CAS — 127-85-5.

Pharmacopoeias. *Fr.* includes the anhydrous substance and the trihydrate.

Profile

Arsanilic acid and sodium arsanilate are used in veterinary medicine for the prophylaxis and treatment of enteric infections in pigs and also as growth-promoting agents.

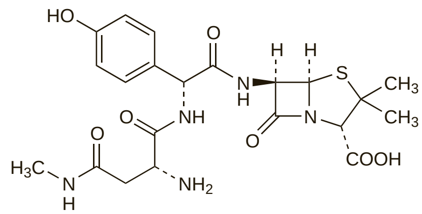
Aspoxicillin *(rINN)*

Aspoxicilina; Aspoxicilline; Aspoxicillinum; TA-058. (2*S*,5*R*,6*R*)-6-{(2*R*)-2-[(2*R*)-2-Amino-3-(methylcarbamoyl)propionamido]-2-(*p*-hydroxyphenyl)acetamido}-3,3-dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0]-heptane-2-carboxylic acid.

Аспоксициллин

$C_{21}H_{27}N_5O_7S$ = 493.5.

CAS — 63358-49-6.



Pharmacopoeias. *Jpn* includes the trihydrate.

Profile

Aspoxicillin is a ureidopenicillin that has been given intravenously in the treatment of susceptible infections.

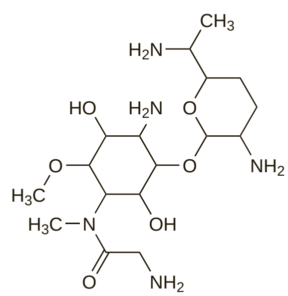
Astromicin Sulfate *(USAN, pINNM)*

Abbott-44747; Astromicin Sulphate; Astromicine, Sulfate d'; Astromicini Sulfas; Fortimicin A Sulphate; KW-1070; Sulfato de astromicina. 4-Amino-1-(2-amino-*N*-methylacetamido)-1,4-dideoxy-3-*O*-(2,6-diamino-2,3,4,6,7-pentadeoxy-β-L-*lyxo*-heptopyranosyl)-6-*O*-methyl-L-*chiro*-inositol sulphate.

Астромицина Сульфат

$C_{17}H_{35}N_5O_6,2H_2SO_4$ = 601.6.

CAS — 55779-06-1 (astromicin); 72275-67-3 (astromicin sulfate); 66768-12-5 (xH_2SO_4).



(astromicin)

Pharmacopoeias. In *Jpn*.

Profile

Astromicin is an aminoglycoside antibiotic produced by *Micromonospora* spp. and with actions and uses similar to those of gentamicin (p.282). Astromicin sulfate has been given by intramuscular injection or intravenous infusion. Dosage should be adjusted based on serum-astromicin concentration monitoring.

Preparations

Proprietary Preparations (details are given in Part 3)
Jpn: Fortimicin.

Avilamycin *(BAN, USAN, rINN)*

Avilamicina; Avilamycine; Avilamycinum; LY-048740 (avilamycin or avilamycin A).

Авиламицин

$C_{61}H_{88}Cl_2O_{32}$ (avilamycin A) = 1404.2.

CAS — 11051-71-1 (avilamycin); 69787-79-7 (avilamycin A); 69787-80-0 (avilamycin C).

Profile

Avilamycin is an antibacterial that has been used in veterinary medicine as a growth promotor.

Avoparcin *(BAN, USAN, rINN)*

Avoparcina; Avoparcine; Avoparcinum; Compound 254.

Авопарцин

CAS — 37332-99-3.

Profile

Avoparcin is a glycopeptide antibiotic usually produced by *Amycolatopsis coloradensis* (*Streptomyces candidus*). It has been incorporated into animal feedstuffs to promote growth.

◊ There is evidence of cross-resistance between avoparcin and vancomycin.[1] Suggestions that vancomycin-resistant organisms could enter the human population from the food chain as a result of the use of avoparcin as a growth promotor in animals[2,3] were disputed by the manufacturers of avoparcin.[4,5] After a ban in the EU on the use of avoparcin as a growth promotor in animals there has been some evidence[6] of a decrease in the occurrence of vancomycin-resistant enterococci in poultry meat.

6. Pantosti A, *et al.* Decrease of vancomycin-resistant enterococci in poultry meat after avoparcin ban. *Lancet* 1999; **354:** 741–2.

Azidamfenicol *(BAN, rINN)*

Azidamfénicol; Azidamfenicolum; Azidamphenicol; Azidanfenicol; Azidoamphenicol; Bayer-52910. 2-Azido-*N*-[(α*R*,β*R*)-β-hydroxy-α-hydroxymethyl-4-nitrophenethyl]acetamide.

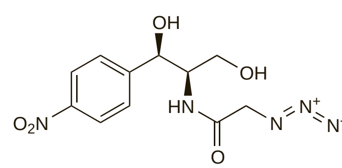
Азидамфеникол

$C_{11}H_{13}N_5O_5$ = 295.3.

CAS — 13838-08-9.

ATC — S01AA25.

ATC Vet — QS01AA25.



Profile

Azidamfenicol is an antibiotic that is related structurally to chloramphenicol (p.239). It is used as 1% eye drops or eye ointment in the treatment of bacterial eye infections.

Preparations

Proprietary Preparations (details are given in Part 3)
Cz.: Ophthalmo-Azaphenicol†; ***Ger.:*** Berlicetin; Posifenicol; Thilocanfol; ***Gr.:*** Thilocof.

Azidocillin Sodium *(BANM, rINNM)*

Azidobenzylpenicillin Sodium; Azidocilina sódica; Azidocilline Sodique; Natrii Azidocillinum. Sodium (6*R*)-6-(D-2-azido-2-phenylacetamido)penicillanate.

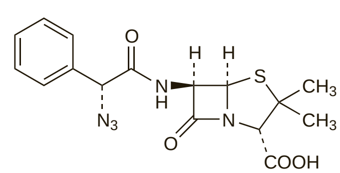
Натрий Азидоциллин

$C_{16}H_{16}N_5NaO_4S$ = 397.4.

CAS — 17243-38-8 (azidocillin); 35334-12-4 (azidocillin sodium).

ATC — J01CE04.

ATC Vet — QJ01CE04.



(azidocillin)

Profile

Azidocillin is a semisynthetic penicillin with actions and uses similar to those of phenoxymethylpenicillin (p.314). It is given orally as the sodium salt; doses, expressed in terms of the base, are 750 mg twice daily in the treatment of susceptible infections. The potassium salt has also been used.

Preparations

Proprietary Preparations (details are given in Part 3)
Ger.: InfectoBicillin H.

Azithromycin *(BAN, USAN, rINN)*

Atsitromysiini; Azithromycine; Azithromycinum; Azitromicina; Azitromicinas; Azitromisin; Azitromycin; Azytromycyna; CP-62993; XZ-450. (2*R*,3*S*,4*R*,5*R*,8*R*,10*R*,11*R*,12*S*,13*S*,14*R*)-13-(2,6-Dideoxy-3-*C*-3-*O*-dimethyl-α-L-*ribo*-hexopyranosyloxy)-2-ethyl-3,4,10-trihydroxy-3,5,6,8,10,12,14-heptamethyl-11-(3,4,6-trideoxy-3-dimethylamino-β-D-*xylo*-hexopyranosyloxy)-1-oxa-6-azacyclopentadecan-15-one dihydrate; 9-Deoxo-9a-aza-9a-methyl-9a-homoerythromycin A dihydrate.

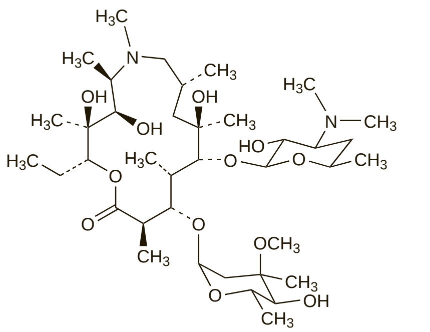
Азитромицин

$C_{38}H_{72}N_2O_{12},2H_2O = 785.0.$

CAS — 83905-01-5 (anhydrous azithromycin); 117772-70-0 (azithromycin dihydrate).

ATC — J01FA10; S01AA26.

ATC Vet — QJ01FA10; QS01AA26.



Pharmacopoeias. In *Chin.* and *Jpn.*
Eur. (see p.vii) includes the anhydrous form.
US includes the monohydrate and the dihydrate.

Ph. Eur. 6.2 (Azithromycin). A white or almost white powder. Practically insoluble in water; freely soluble in dehydrated alcohol and in dichloromethane. A 0.2% solution in a mixture of methyl alcohol and water (1:1) has a pH of 9.0 to 11.0. Store in airtight containers.

USP 31 (Azithromycin). It is anhydrous or contains one or two molecules of water of hydration. pH of a 0.2% solution in a mixture of methyl alcohol and water (1:1) is between 9.0 and 11.0. Store in airtight containers.

Adverse Effects and Precautions

As for Erythromycin, p.270.

Gastrointestinal disturbances are the most frequent adverse effect of azithromycin but are usually mild and less frequent than with erythromycin. Headache, somnolence, and taste disturbances may occur. Severe hypersensitivity reactions occur rarely but may be prolonged. Thrombocytopenia and mild transient neutropenia have been rarely reported in patients receiving azithromycin. Pain and inflammation may occur at the site of intravenous infusions particularly at high concentrations.

Licensed product information states that azithromycin should be used with caution in patients with hepatic or renal impairment. It should not be given to those with severe hepatic impairment as safety has not been established. Although plasma concentrations may be increased in renal impairment dosage adjustment is not usually required.

Incidence of adverse effects. In patients receiving azithromycin daily long-term for mycobacterial infections,[1] gastrointestinal disorders occurred in 32 of 39 patients (82%), hearing impairment in 10 patients (26%), tinnitus in 18 patients (46%), and poor balance or dizziness in 11 patients (28%). In general, adverse effects were associated with higher serum-azithromycin concentrations.

1. Brown BA, *et al.* Relationship of adverse events to serum drug levels in patients receiving high-dose azithromycin for mycobacterial lung disease. *Clin Infect Dis* 1997; **24:** 958–64.

Effects on the ears. Reversible sensorineural hearing loss was reported in 3 patients given oral azithromycin 500 mg daily with clofazimine and ethambutol for the treatment of disseminated *Mycobacterium avium* complex infection.[1] Irreversible hearing loss has also been reported after low-dose exposure to oral azithromycin.[2,3] A patient who had had 8 days of treatment with intravenous azithromycin 500 mg daily for pneumonia reported complete deafness, which had resolved 20 days after stopping the drug.[4]

See also Incidence of Adverse Effects, above.

1. Wallace MR, *et al.* Ototoxicity with azithromycin. *Lancet* 1994; **343:** 241.
2. Ress BD, Gross EM. Irreversible sensorineural hearing loss as a result of azithromycin ototoxicity: a case report. *Ann Otol Rhinol Laryngol* 2000; **109:** 435–7.
3. Mick P, Westerberg BD. Sensorineural hearing loss as a probable serious adverse drug reaction associated with low-dose oral azithromycin. *J Otolaryngol* 2007; **36:** 257–63.
4. Bizjak ED, *et al.* Intravenous azithromycin-induced ototoxicity. *Pharmacotherapy* 1999; **19:** 245–8.

Effects on fluid and electrolyte homoeostasis. The syndrome of inappropriate antidiuretic hormone secretion was associated with azithromycin treatment in a patient.[1,2]

1. Cadle RM, *et al.* Symptomatic syndrome of inappropriate antidiuretic hormone secretion associated with azithromycin. *Ann Pharmacother* 1997; **31:** 1308–10.
2. Kintzel PE. Correction: symptomatic syndrome of inappropriate antidiuretic hormone secretion associated with azithromycin. *Ann Pharmacother* 1998; **32:** 388.

Effects on the kidneys. Acute interstitial nephritis leading to irreversible renal failure has been reported[1] in a patient who received azithromycin for 9 days. A later report[2] described a patient who developed recurrent acute interstitial nephritis after courses of azithromycin. Repeated exposure resulted in persistent renal damage; leucocytosis and eosinophilia were still present 1 year later.

1. Mansoor GA, *et al.* Azithromycin-induced acute interstitial nephritis. *Ann Intern Med* 1993; **119:** 636–7.
2. Soni N, *et al.* Recurrent acute interstitial nephritis induced by azithromycin. *Pediatr Infect Dis J* 2004; **23:** 965–6.

Eosinophilia. A syndrome characterised by eosinophilia, arthralgia, fever, and rash was associated with azithromycin or roxithromycin treatment in a patient on separate occasions.[1] The original authors believed the condition represented the Churg-Strauss syndrome, although this was disputed in correspondence[2] and attributed to the eosinophilia-myalgia syndrome.

1. Hübner C, *et al.* Macrolide-induced Churg-Strauss syndrome in a patient with atopy. *Lancet* 1997; **350:** 563.
2. Kränke B, Aberer W. Macrolide-induced Churg-Strauss syndrome in patient with atopy. *Lancet* 1997; **350:** 1551–2.

Overdosage. Bradycardia with complete heart block was reported[1] in a 9-month-old infant who had been inadvertently given about 50 mg/kg of azithromycin intravenously.

1. Tilelli JA, *et al.* Life-threatening bradyarrhythmia after massive azithromycin overdose. *Pharmacotherapy* 2006; **26:** 147–50.

Interactions

For a discussion of drug interactions of macrolide antibacterials, see Erythromycin, p.271.

Giving azithromycin with antacids containing aluminium or magnesium salts can reduce the rate, but not the extent, of its absorption; azithromycin should be given at least 1 hour before or 2 hours after the antacid.

Nelfinavir. Azithromycin serum concentrations are markedly increased when it is given with nelfinavir,[1] but the clinical significance of this is uncertain. US licensed product information for azithromycin states that dosage adjustment is not required although the patient should be closely monitored for adverse effects.

1. Amsden GW, *et al.* A study of the pharmacokinetics of azithromycin and nelfinavir when coadministered in healthy volunteers. *J Clin Pharmacol* 2000; **40:** 1522–7.

Antimicrobial Action

As for Erythromycin, p.271. Azithromycin is less active than erythromycin against streptococci and staphylococci, but has greater activity than erythromycin *in vitro* against some Gram-negative organisms such as *Haemophilus influenzae* and *Moraxella catarrhalis* (*Branhamella catarrhalis*), as well as having activity against some of the Enterobacteriaceae such as *Escherichia coli* and *Salmonella* and *Shigella* spp. Azithromycin is also more active than erythromycin against *Chlamydia trachomatis* and *Ureaplasma urealyticum*, and some opportunistic mycobacteria, including *Mycobacterium avium* complex. It has activity against the protozoa *Toxoplasma gondii* and *Plasmodium falciparum*.

Resistance. The pattern of resistance to azithromycin is similar to that seen with clarithromycin (p.249).

Pharmacokinetics

Azithromycin given orally is rapidly absorbed and about 40% bioavailable. Absorption from capsules, but not tablets or suspension, is reduced by food. Peak plasma concentrations occur 2 to 3 hours after an oral dose and 1 to 2 hours after intravenous dosage. However, azithromycin is extensively distributed into the tissues, and tissue concentrations subsequently remain much higher than those in the blood; in contrast to most other antibacterials, plasma concentrations are therefore of little value as a guide to efficacy. High concentrations are taken up into white blood cells. There is little diffusion into the CSF when the meninges are not inflamed. Data from *animal* studies indicate that azithromycin crosses the placenta. Small amounts of azithromycin are demethylated in the liver, and it is excreted in bile mainly as unchanged drug and a number of inactive metabolites have also been detected. About 6% of an oral dose (representing about 20% of the amount in the systemic circulation) is excreted in the urine. The terminal elimination half-life is about 68 hours.

Uses and Administration

Azithromycin is a nitrogen-containing macrolide (azalide) with actions and uses similar to those of erythromycin (p.272). It is given in the treatment of respiratory-tract infections (including otitis media), in skin and soft-tissue infections, and in uncomplicated genital infections. Azithromycin may also be used for the prophylaxis, and as a component of regimens in the treatment, of *Mycobacterium avium* complex (MAC) infections. It is used in some countries for the prophylaxis of endocarditis in at-risk patients unable to take penicillin. It is also used in the management of trachoma and typhoid.

For details of all these infections and their treatment, see under Choice of Antibacterial, p.162.

Azithromycin has been tried in protozoal infections such as babesiosis (below), crytosporidiosis (p.823), and toxoplasmosis (p.826).

It is given orally or by intravenous infusion usually as the dihydrate; doses are expressed in terms of the anhydrous substance. Azithromycin dihydrate 524 mg is equivalent to about 500 mg of anhydrous azithromycin. The capsule formulation should be given at least 1 hour before, or 2 hours after, meals.

The usual oral adult dose of azithromycin is 500 mg as a single dose daily for 3 days. Alternatively, an initial dose of 500 mg may be followed by 250 mg daily for a further 4 days.

For uncomplicated genital infections caused by *Chlamydia trachomatis* and for chancroid, 1 g of azithromycin is given as a single dose. A single dose of 2 g has been given for uncomplicated gonorrhoea. For the treatment of granuloma inguinale, an initial dose of 1 g followed by 500 mg daily may be given, or 1 g may be given once a week for at least 3 weeks, until all lesions have completely healed.

In the USA, a modified-release preparation given as an oral suspension is available. The product delivers a single dose of 2 g and should also be taken on an empty stomach. It is licensed for the treatment of acute bacterial sinusitis or community-acquired pneumonia in adults.

For prophylaxis of disseminated MAC infections, azithromycin 1.2 g may be given once weekly. For treatment or secondary prophylaxis, 500 mg once daily should be given with other antimycobacterials.

For mild or moderate typhoid caused by multidrug-resistant strains, 500 mg once daily may be given for 7 days.

For details of doses in infants and children, see below.

Azithromycin dihydrate may also be given initially by intravenous infusion to adults in doses equivalent to 500 mg of azithromycin as a single daily dose in the treatment of community-acquired pneumonia and pelvic inflammatory disease; treatment should be changed to the oral route after at least 2 days in pneumonia and after 1 or 2 days in pelvic inflammatory disease. It may be given either in a solution containing 1 mg/mL over 3 hours or in a solution containing 2 mg/mL over 1 hour.

In the USA, azithromycin is available as 1% eye drops for the topical treatment of conjunctivitis caused by susceptible strains of bacteria.

Administration in children. Azithromycin is licensed for use in infants and children and the usual oral dose in those over 6 months of age is 10 mg/kg once daily for 3 days, or an initial dose of 10 mg/kg may be followed by 5 mg/kg daily for a further 4 days; those who weigh over 45 kg may be given the usual adult dose (see above). A single dose of 30 mg/kg may also be given for acute otitis media. For pharyngitis or tonsillitis in children aged over 2 years, 12 mg/kg once daily for 5 days may be given.

US official guidelines suggest that for prophylaxis of disseminated *Mycobacterium avium* complex infections, azithromycin 20 mg/kg (to a maximum of 1.2 g) once weekly or 5 mg/kg (to a maximum of 250 mg) once daily may be given.[1] For treatment, 10 to 12 mg/kg (to a maximum of 500 mg) once daily should be given with other antimycobacterials.[2]

In the UK, the *BNFC* suggests that azithromycin may be used in penicillin allergic children for the prevention of secondary cases of group A streptococcal infection; those 6 months and older may be given an oral dose of 12 mg/kg (to a maximum of 500 mg) once daily for 5 days.

The *BNFC* also suggests giving azithromycin 10 mg/kg once daily for 7 days in the treatment of mild to moderate typhoid caused by multidrug-resistant strains in those aged 6 months and over.

Babesiosis. In a prospective, randomised study[1] involving 58 patients with babesiosis (p.823), azithromycin with atovaquone was found to be as effective as, and associated with fewer adverse effects than, standard therapy with quinine and clindamycin. Azithromycin 600 mg once daily, or 500 to 1000 mg on day 1 followed by 250 mg once daily thereafter, with atovaquone 750 mg twice daily, both orally for 7 to 10 days, has been recommended by some experts[2,3] in the USA for the treatment of *Babesia microti* infections. Immunocompromised patients may be given higher doses of azithromycin (600 to 1000 mg daily). Children may be given azithromycin 12 mg/kg once daily, or 10 mg/kg on day 1 followed by 5 mg/kg once daily thereafter, with atovaquone 20 mg/kg twice daily, both orally for 7 to 10 days. Azithromycin with quinine was reported to be effective in 2 patients who had not responded to quinine plus clindamycin.[4,5]

Hyperplasia. For reference to the use of azithromycin to control ciclosporin-induced gingival hyperplasia, see p.1824.

Ischaemic heart disease. Macrolide antibacterials, including azithromycin,[1-4] clarithromycin,[5-9] and roxithromycin,[10-14] have been investigated in the prevention of ischaemic heart disease, based on a suggested link between atherosclerosis and infection with *Chlamydophila pneumoniae* (*Chlamydia pneumoniae*) (see p.166). Although preliminary results from some pilot studies were promising, longer-term studies in large numbers of patients were disappointing and none of the three macrolides decreased ischaemic events or provided clinical benefit; indeed, in one study[9] an unexpected increase in cardiovascular mortality was seen in those taking clarithromycin.

Malaria. Azithromycin has been studied[1-7] in the management of malaria. Studies[1,4] have shown that an initial loading dose of 750 mg of azithromycin on the first day followed by 250 mg daily thereafter for 20 weeks was effective in the prophylaxis of *Plasmodium vivax* malaria; the drug was well tolerated and the most frequently reported adverse effects were heartburn, paraesthesia, and itching.[3] In the treatment of *P. vivax* malaria, a study[5] found that azithromycin 1 g daily for 3 days resulted in an 88% clinical response rate by day 7, but with a slower onset of action, when compared with chloroquine 600 mg daily for 2 days then 300 mg on day 3 which resulted in a rate of 99%.

Azithromycin in a dose of 0.5 g once daily up to 1.5 g daily in divided doses together with other antimalarials, such as artesunate 200 mg daily[2,7] or quinine 10 mg/kg 3 times daily,[6,7] given for 3 days was found to be effective in the treatment of uncomplicated multidrug-resistant *P. falciparum* malaria.

However, further studies are warranted, especially in children and pregnant women.

Azlocillin *(BAN, USAN, rINN)*

Atslosilliini; Azlocilina; Azlocilline; Azlocillinum. 6-[*N*-(2-Oxoimidazolidin-1-ylcarbonyl)-D-phenylglycylamino]penicillanic acid.

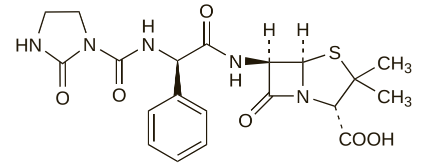
Азлоциллин

$C_{20}H_{23}N_5O_6S$ = 461.5.

CAS — 37091-66-0.

ATC — J01CA09.

ATC Vet — QJ01CA09.



Azlocillin Sodium *(BANM, rINNM)*

Azlocilina sódica; Azlocilline Sodique; Azlocillinum Natricum; Azlocylina sodowa; Bay-e-6905; Natrii Azlocillinum. Sodium (6*R*)-6-[D-2-(2-oxoimidazolidine-1-carboxamido)-2-phenylacetamido]penicillanate.

Натрий Азлоциллин

$C_{20}H_{22}N_5NaO_6S = 483.5.$

CAS — 37091-65-9.

ATC — J01CA09.

ATC Vet — QJ01CA09.

Pharmacopoeias. In *Pol.*

Incompatibility. Azlocillin sodium has been reported to be incompatible with aminoglycosides, ciprofloxacin, metronidazole, and tetracyclines.

Adverse Effects and Precautions

As for Carbenicillin Sodium, p.216.

Prolongation of bleeding time has been less frequent and less severe with azlocillin than with carbenicillin.

Hypouricaemia. Reports of transient asymptomatic decreases in serum-uric acid concentrations during treatment with azlocillin.[1,2]

1. Faris HM, Potts DW. Azlocillin and serum uric acid. *Ann Intern Med* 1983; **98:** 414.
2. Ernst JA, Sy ER. Effect of azlocillin on uric acid levels in serum. *Antimicrob Agents Chemother* 1983; **24:** 609–10.

Sodium content. Each g of azlocillin sodium contains about 2.1 mmol of sodium. As azlocillin sodium has a lower sodium content than carbenicillin sodium, hypernatraemia and hypokalaemia are less likely to occur.

Interactions

As for Benzylpenicillin, p.214.

Antibacterials. For the effect of azlocillin on the clearance of *cefotaxime*, and a report of neurotoxicity, see p.228. For reference to azlocillin affecting the disposition of *ciprofloxacin*, see p.246.

Antimicrobial Action

Azlocillin has an antimicrobial action similar to that of piperacillin (p.315). Its activity *in vitro* against Enterobacteriaceae is generally less than that of mezlocillin or piperacillin, but it has comparable activity to piperacillin against *Pseudomonas aeruginosa*.

Pharmacokinetics

Azlocillin is not absorbed from the gastrointestinal tract to any significant extent. It has nonlinear dose-dependent pharmacokinetics. Doubling an intravenous dose results in more than double the plasma concentration. Between 20 and 46% of azlocillin in the circulation is bound to plasma proteins. The plasma half-life is usually about 1 hour, but is longer in neonates; in patients with renal impairment half-lives of 2 to 6 hours have been reported.

Azlocillin is widely distributed in body tissues and fluids. It crosses the placenta into the fetal circulation and small amounts are distributed into breast milk. There is little diffusion into the CSF except when the meninges are inflamed.

Azlocillin is metabolised to a limited extent. About 50 to 70% of a dose is excreted unchanged in the urine by glomerular filtration and tubular secretion within 24 hours of a dose, resulting in high urinary concentrations. Azlocillin is partly excreted in the bile where it is also found in high concentrations.

Plasma concentrations are enhanced if probenecid is given.

Azlocillin is removed by haemodialysis.

Uses and Administration

Azlocillin is a ureidopenicillin and, like piperacillin (p.316), is used mainly for the treatment of infections caused by *Pseudomonas aeruginosa*. It has been used particularly for septicaemia, and infections of the respiratory and urinary tracts, and also for peritonitis; for details of these infections, see under Choice of Antibacterial, p.162.

Azlocillin is commonly used with an aminoglycoside; however, they should be given separately as they have been shown to be incompatible (see Incompatibility, above).

Administration and dosage. Azlocillin is given intravenously as the sodium salt. Doses are expressed in terms of the equivalent amount of azlocillin; 1.05 g of azlocillin sodium is equivalent to about 1 g of azlocillin. A 10% solution in a suitable diluent is given by slow injection for doses of 2 g or less; higher doses should be infused over 20 to 30 minutes.

The usual adult dose is 5 g every 8 hours for life-threatening infections, or 2 g every 8 hours for less severe infections and urinary-tract infections.

The following doses may be used for children: premature infants, 50 mg/kg twice daily; neonates less than 7 days old, 100 mg/kg twice daily; infants between 7 days and 1 year, 100 mg/kg three times daily; children up to 14 years, 75 mg/kg three times daily.

Dosage of azlocillin may need to be adjusted in patients with hepatic or renal impairment (see below).

Administration in hepatic or renal impairment. The interval between doses of azlocillin may need to be increased to every 12 hours in moderate to severe renal impairment (creatinine clearance less than 30 mL/minute); additional dosage reductions may be needed in patients with both severe renal and hepatic impairment.

Aztreonam *(BAN, USAN, rINN)*

Atstreonaami; Azthreonam; Aztréonam; Aztreonamum; SQ-26776. (*Z*)-2-{2-Aminothiazol-4-yl-[(2*S*,3*S*)-2-methyl-4-oxo-1-sulphoazetidin-3-ylcarbamoyl]methyleneamino-oxy}-2-methylpropionic acid.

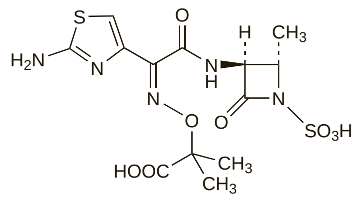
Азтреонам

$C_{13}H_{17}N_5O_8S_2 = 435.4.$

CAS — 78110-38-0.

ATC — J01DF01.

ATC Vet — QJ01DF01.



Pharmacopoeias. In *Jpn* and *US*, which allows the anhydrous or hydrated forms.

USP 31 (Aztreonam). A white, odourless crystalline powder. Very slightly soluble in dehydrated alcohol; practically insoluble in chloroform, in ethyl acetate, and in toluene; soluble in dimethylformamide and in dimethyl sulfoxide; slightly soluble in methyl alcohol. Store in airtight containers.

Incompatibility and stability. Aztreonam has been reported to be incompatible with cefradine, metronidazole, nafcillin, and vancomycin.

Adverse Effects

The adverse effects of aztreonam are similar to those of other beta lactams (see Benzylpenicillin, p.213, and Cefalotin, p.219). Hypersensitivity reactions, including skin rashes, urticaria, angioedema, exfoliative dermatitis, eosinophilia, bronchospasm, and rarely anaphylaxis and toxic epidermal necrolysis, may occur in patients receiving aztreonam, although it has been reported to be only weakly immunogenic. Gastrointestinal effects include diarrhoea, nausea, vomiting, mouth ulcer, and an abnormal taste.

Phlebitis or thrombophlebitis has been reported after the intravenous use of aztreonam, and pain or swelling after intramuscular injection.

Use of aztreonam may result in the overgrowth of non-susceptible organisms, including Gram-positive cocci. Pseudomembranous colitis or gastrointestinal bleeding may develop.

Other adverse effects that have been reported with aztreonam include jaundice and hepatitis, increases in liver enzymes, and prolongation of prothrombin and partial thromboplastin times.

Effects on the skin. References.

1. McDonald BJ, *et al.* Toxic epidermal necrolysis possibly linked to aztreonam in bone marrow transplant patients. *Ann Pharmacother* 1992; **26:** 34–5.

Precautions

Aztreonam should not be given to patients who are hypersensitive to it and should be used with caution in those known to be hypersensitive to other beta lactams, although the incidence of cross-sensitivity appears to be low (but see below).

Aztreonam should be used with caution in patients with renal or hepatic impairment.

Breast feeding. In a study in 12 healthy women given aztreonam, peak concentrations in breast milk were found to be less than 1% of those in serum and this was considered suggestive of a low risk of adverse effects in breast-fed infants.[1] The American Academy of Pediatrics states that no adverse effects have been seen in breast-fed infants whose mothers received aztreonam and considers it to be usually compatible with breast feeding,[2] although UK licensed product information recommends that mothers should refrain from breast feeding while receiving aztreonam.

Hypersensitivity. Aztreonam is said to show little cross-reactivity with other beta lactams,[1,2] but there have been isolated reports of immediate hypersensitivity to aztreonam in patients with a history of hypersensitivity to penicillin.[3,4]

1. Saxon A, *et al.* Lack of cross-reactivity between aztreonam, a monobactam antibiotic, and penicillin in penicillin-allergic subjects. *J Infect Dis* 1984; **149:** 16–22.
2. Adkinson NF. Immunogenicity and cross-allergenicity of aztreonam. *Am J Med* 1990; **88** (suppl 3C): 12S–15S.
3. Alvarez JS, *et al.* Immediate hypersensitivity to aztreonam. *Lancet* 1990; **335:** 1094.
4. Hantson P, *et al.* Immediate hypersensitivity to aztreonam and imipenem. *BMJ* 1991; **302:** 294–5.

Interactions

Caution is recommended in patients receiving aztreonam and oral anticoagulants because of the possibility of increased prothrombin time.

Antimicrobial Action

Aztreonam is bactericidal and acts similarly to the penicillins by inhibiting synthesis of the bacterial cell wall; it has a high affinity for the penicillin-binding protein 3 (PBP-3) of Gram-negative bacteria. The activity of aztreonam is restricted to Gram-negative aerobic organisms, including beta-lactamase-producing strains, with poor or no activity against Gram-positive aerobes or anaerobic organisms. It is active against most Enterobacteriaceae including *Escherichia coli*, *Klebsiella*, *Proteus*, *Providencia*, *Salmonella*, *Serratia*, *Shigella*, and *Yersinia* spp. Some strains of *Enterobacter* and *Citrobacter* spp. are resistant. Aztreonam has some activity against *Pseudomonas aeruginosa*, although most strains of other *Pseudomonas* spp. are insensitive. Aztreonam has good activity against *Haemophilus influenzae* and *Neisseria* spp.

Synergy has been reported *in vitro* between aztreonam and aminoglycosides against *Ps. aeruginosa* and some *Enterobacteriaceae.*

Aztreonam is stable to hydrolysis by many beta-lactamases and appears to be a poor inducer of beta-lactamase production. Acquired resistance has occasionally been reported.

Pharmacokinetics

Aztreonam is poorly absorbed from the gastrointestinal tract and is therefore given parenterally. Absorption after intramuscular injection is good; peak plasma concentrations of about 46 micrograms/mL have been achieved within 1 hour of a 1-g dose. Aztreonam has a plasma half-life of about 1.7 hours. The half-life may be prolonged in neonates, in the elderly, in patients with renal impairment, and to some extent in those with hepatic impairment. Aztreonam is about 56% bound to plasma proteins. It is widely distributed in body tissues and fluids, including bile. Diffusion into the CSF is poor unless the meninges are inflamed. It crosses the placenta and enters the fetal circulation; small amounts are distributed into breast milk.

Aztreonam is not extensively metabolised. The principal metabolite, SQ-26992, is inactive and is formed by opening of the beta-lactam ring; it has a much longer half-life than the parent compound. Aztreonam is excreted mainly in the urine, by renal tubular secretion and glomerular filtration; about 60 to 70% of a dose appears within 8 hours as unchanged drug with only small quantities of metabolites. Only small amounts of unchanged drug and metabolites are excreted in the faeces.

Aztreonam is removed by haemodialysis and to a lesser extent by peritoneal dialysis.

◊ Reviews.

1. Mattie H. Clinical pharmacokinetics of aztreonam: an update. *Clin Pharmacokinet* 1994; **26:** 99–106.

Uses and Administration

Aztreonam is a monobactam or monocyclic beta-lactam antibacterial used parenterally as an alternative to aminoglycosides or third-generation cephalosporins for the treatment of infections caused by susceptible Gram-negative aerobic organisms. These have included bone and joint infections, gonorrhoea, intra-abdominal and pelvic infections, lower respiratory-tract infections including pseudomonal infections in patients with cystic fibrosis, meningitis, septicaemia, skin and soft-tissue infections, and urinary-tract infections. For details of these infections and their treatment, see under Choice of Antibacterial, p.162. To broaden the spectrum of activity for empirical treatment of infections, aztreonam should be used with other antibacterials. Use with an aminoglycoside may be of benefit in serious *Pseudomonas aeruginosa* infections.

Aztreonam is usually given parenterally by deep intramuscular injection, by slow intravenous injection over 3 to 5 minutes, or by intravenous infusion over 20 to 60 minutes. It is given to adults, in usual doses ranging from 1 to 8 g daily, in divided doses every 6 to 12 hours, according to the severity of the infection. Single doses over 1 g should be given by the intravenous route.

UK licensed product information recommends that infants older than one week and children be given aztreonam 30 mg/kg every 6 or 8 hours. For severe infections, children of 2 years or older may be given 50 mg/kg every 6 or 8 hours up to a maximum total daily dose of 8 g. Although not licensed in the UK for neonates less than one week old, the *BNFC* suggests a dose of 30 mg/kg every 12 hours. In the USA the dose for children from 9 months of age is 30 mg/kg every 8 hours for mild to moderate infection, or every 6 to 8 hours in moderate to severe infection up to a maximum total daily dose of 120 mg/kg.

For details of dosage in patients with renal impairment, see below.

A single intramuscular dose of 1 g has been recommended for the treatment of gonorrhoea or cystitis.

Aztreonam lysine is under investigation for inhalational use in respiratory-tract infections.

Administration in renal impairment. Dosage of aztreonam should be reduced in moderate to severe renal impairment. Patients with renal impairment may be given a usual initial dose followed by a maintenance dose adjusted according to creatinine clearance (CC):

- CC 10 to 30 mL/minute: half the initial dose
- CC less than 10 mL/minute: one-quarter of the initial dose
- haemodialysis patients: a supplementary dose of one-eighth of the initial dose may be given after each dialysis session

Bacampicillin Hydrochloride *(BANM, USAN, rINNM)*

Ampicillin Ethoxycarbonyloxyethyl Hydrochloride; Bacampicilline, chlorhydrate de; Bacampicillini hydrochloridum; Bakampicilin-hydrochlorid; Bakampicilino hidrochloridas; Bakampicillin-hidroklorid; Bakampicillinhydroklorid; Bakampisilin Hidroklorür; Bakampisilliinihydrokloridi; Carampicillin; EPC-272; Hidrocloruro de bacampicilina. 1-(Ethoxycarbonyloxy)ethyl (6*R*)-6-(α-D-phenylglycylamino)penicillanate hydrochloride.

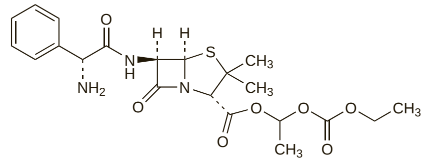
Бакампициллина Гидрохлорид

$C_{21}H_{27}N_3O_7S,HCl = 502.0.$

CAS — 50972-17-3 (bacampicillin); 37661-08-8 (bacampicillin hydrochloride).

ATC — J01CA06.

ATC Vet — QJ01CA06.



(bacampicillin)

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Bacampicillin Hydrochloride). A white or almost white hygroscopic powder or granules. Soluble in water and in dichloromethane; freely soluble in alcohol. A 2% solution in water has a pH of 3.0 to 4.5. Store in airtight containers.

USP 31 (Bacampicillin Hydrochloride). A white or practically white, hygroscopic, powder. Soluble in water and in dichloromethane; freely soluble in alcohol and in chloroform; very slightly soluble in ether. pH of a 2% solution in water is between 3.0 and 4.5. Store in airtight containers.

Adverse Effects and Precautions

As for Ampicillin, p.204. Diarrhoea has been reported to occur less frequently with bacampicillin.

Interactions

As for Benzylpenicillin, p.214.

Antimicrobial Action

Bacampicillin has the antimicrobial action of ampicillin *in vivo* (p.204). It possesses no intrinsic activity and needs to be hydrolysed to ampicillin.

Pharmacokinetics

Bacampicillin is more rapidly and completely absorbed from the gastrointestinal tract than ampicillin, to which it is hydrolysed in the intestinal wall and plasma. Peak plasma-ampicillin concentrations occur about 30 to 60 minutes after oral doses, and are about 2 to 3 times those after an equivalent dose of ampicillin. The absorption of bacampicillin from tablets does not appear to be affected by the presence of food in the stomach. About 75% of a dose is excreted in the urine as ampicillin within 8 hours.

Uses and Administration

Bacampicillin has actions and uses similar to those of ampicillin (p.205) to which it is rapidly hydrolysed in the body. It is given orally as the hydrochloride in adult doses of 0.8 to 2.4 g daily, in 2 divided doses; children over 5 years of age have been given 25 to 50 mg/kg daily in 2 divided doses.

In uncomplicated gonorrhoea a single dose of bacampicillin hydrochloride 1.6 g with probenecid 1 g may be given in areas where gonococci remain sensitive.

Preparations

USP 31: Bacampicillin Hydrochloride for Oral Suspension; Bacampicillin Hydrochloride Tablets.

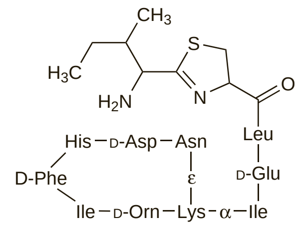
ATC — D06AX05; R02AB04.

ATC Vet — QA07AA93; QD06AX05; QR02AB04.



(bacitracin A)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn*, and *US.*

Ph. Eur. 6.2 (Bacitracin). Mixture of antimicrobial polypeptides produced by certain strains of *Bacillus licheniformis* or *B. subtilis*. The potency is not less than 60 units/mg, calculated with reference to the dried substance. A white or almost white hygroscopic powder. Freely soluble in water and in alcohol. A 1% solution in water has a pH of 6.0 to 7.0. Store at a temperature of 8° to 15° in airtight containers.

USP 31 (Bacitracin). A mixture of polypeptides produced by the growth of an organism of the *licheniformis* group of *Bacillus subtilis* (Bacillaceae). The main components are bacitracins A, B1, B2, and B3. It has a potency of not less than 65 units/mg, calculated with reference to the dried substance. It is a white to pale buff, hygroscopic powder, odourless or having a slight odour. Freely soluble in water; soluble in alcohol, in glacial acetic acid, and in methyl alcohol, the solution in the organic solvents usually showing some insoluble residue; insoluble in acetone, in chloroform, and in ether. Its solutions deteriorate rapidly at room temperature. It is precipitated from its solutions and is inactivated by salts of many of the heavy metals. pH of a solution in water containing 10 000 units/mL is between 5.5 and 7.5. Store in airtight containers at a temperature of 8° to 15°.

Bacitracin Zinc *(BANM, rINNM)*

Bacitracin zinečnatý komplex; Bacitracina zinc; Bacitracin-cink; Bacitracine Zincique; Bacitracine-zinc; Bacitracino cinko kompleksas; Bacitracins Zinc Complex; Bacitracinum Zincicum; Bacitracinum zincum; Bacytracyna cynkowa; Sinkkibasitrasiini; Zinc Bacitracin; Zinci Bacitracinum; Zinkbacitracin.

Цинка Бацитрацин

CAS — 1405-89-6.

ATC — D06AX05; R02AB04.

ATC Vet — QD06AX05; QR02AB04.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Bacitracin Zinc). The zinc complex of bacitracin. The potency is not less than 60 units/mg, calculated with reference to the dried substance. A white or light-yellowish-grey hygroscopic powder. Slightly soluble in water and in alcohol. The filtrate of a saturated solution has a pH of 6.0 to 7.5. Store in airtight containers.

USP 31 (Bacitracin Zinc). The zinc complex of bacitracin, which consists of a mixture of antimicrobial polypeptides, the main components being bacitracins A, B1, B2, and B3. It has a potency of not less than 65 units/mg, calculated with reference to the dried substance. It contains not less than 4% and not more than 6% of zinc, calculated with reference to the dried substance. A white or pale tan, hygroscopic powder, odourless or having a slight odour. Sparingly soluble in water. pH of a saturated solution in water is between 6.0 and 7.5. Store in airtight containers at a temperature of 8° to 15°.

Incompatibility. Bacitracin was slowly inactivated in bases containing stearyl alcohol, cholesterol, polyoxyethylene derivatives, and sodium laurilsulfate, and was rapidly inactivated in bases containing water, macrogols, propylene glycol, glycerol, cetylpyridinium chloride, benzalkonium chloride, ichthammol, phenol, and tannic acid.[1]

1. Plaxco JM, Husa WJ. The effect of various substances on the antibacterial activity of bacitracin in ointments. *J Am Pharm Assoc (Sci)* 1956; **45:** 141–5.

Stability. Bacitracin zinc was more stable than bacitracin and could be stored for 18 months at temperatures up to 40° without appreciable loss of activity. Lozenges of bacitracin zinc and ointments and tablets containing bacitracin zinc with neomycin were more stable than the corresponding bacitracin preparations. Bacitracin zinc was less bitter than bacitracin and the taste was more readily disguised.[1]

1. Gross HM, *et al.* Zinc bacitracin in pharmaceutical preparations. *Drug Cosmet Ind* 1954; **75:** 612–13.

Units

The second International Standard Preparation (1964) of bacitracin zinc contains 74 units/mg.

Adverse Effects and Precautions

Systemic bacitracin may produce severe nephrotoxicity, resulting in renal failure due to tubular and glomerular necrosis. Renal function should be determined before, and daily during, therapy. Fluid intake and urinary output should be maintained to avoid kidney toxicity. If renal toxicity occurs, bacitracin should be stopped. Use with other nephrotoxic drugs should be avoided (see Interactions, below).

Nausea and vomiting may occur, as well as pain at the site of injection. Hypersensitivity reactions, including rashes and anaphylaxis, have occurred with both systemic, and more rarely with topical, use.

Interactions

Additive nephrotoxicity would be anticipated if bacitracin were given systemically with other nephrotoxic drugs, particularly colistin, kanamycin, neomycin, polymyxin B, and streptomycin; such use should be avoided.. Bacitracin is reported to enhance the neuromuscular blocking action of certain drugs, such as neuromuscular blockers and anaesthetics, if given during surgery or postoperatively.

Antimicrobial Action

Bacitracin interferes with bacterial cell wall synthesis by blocking the function of the lipid carrier molecule that transfers cell wall subunits across the cell membrane. It is active against many Gram-positive bacteria including staphylococci, streptococci (particularly group A streptococci), corynebacteria, and clostridia. It is also active against *Actinomyces*, *Treponema pallidum*, and some Gram-negative species such as *Neisseria* and *Haemophilus influenzae*, although most Gram-negative organisms are resistant.

Acquired bacterial resistance to bacitracin rarely occurs, but resistant strains of staphylococci have been detected.

Pharmacokinetics

Bacitracin is not appreciably absorbed from the gastrointestinal tract or from intact or denuded skin, wounds, or mucous membranes; however, systemic absorption has been reported after peritoneal lavage. It is rapidly absorbed when given by intramuscular injection. Bacitracin readily diffuses into pleural and ascitic fluids but little passes into the CSF. About 10 to 40% of a single injected dose is excreted slowly by glomerular filtration and appears in the urine within 24 hours.

Uses and Administration

Bacitracin and bacitracin zinc are applied **topically** (as a cream, ointment, dusting powder, or ophthalmic ointment), often with other antibacterials such as neomycin and polymyxin B, and sometimes with corticosteroids, in the treatment of local infections due to susceptible organisms. Typical concentrations of bacitracin or bacitracin zinc in such products are 250 to 500 units/g. Absorption from open wounds and from the bladder or peritoneal cavity may lead to adverse effects, although the dose-limiting toxicity of combined preparations is considered to be due to neomycin.

Parenteral use of bacitracin is usually avoided because of nephrotoxicity but it may be given intramuscularly for the treatment of infants with staphylococcal pneumonia and empyema due to susceptible organisms. For details of doses, see below.

Bacitracin has been given **orally** in the treatment of antibiotic-associated colitis due to *Clostridium difficile*.

Administration in children. In the USA, bacitracin may be given intramuscularly for the treatment of infants with staphylococcal pneumonia and empyema due to susceptible organisms. Infants weighing less than 2.5 kg may be given a dose of 900 units/kg daily in 2 or 3 divided doses; those weighing more than 2.5 kg may be given 1000 units/kg daily in 2 or 3 divided doses.

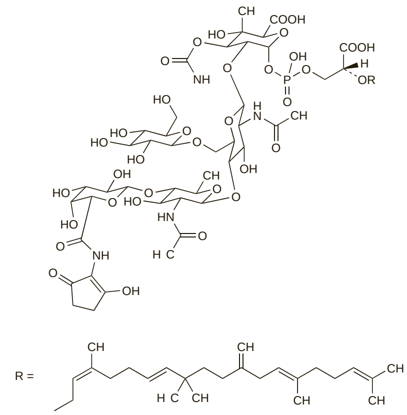
Бамбермицин

$C_{69}H_{108}N_5O_{34}P$ = 1582.6 (moenomycin A).
CAS — 11015-37-5 (bambermycin); 76095-39-1 (moenomycin A).



(moenomycin A)

Profile

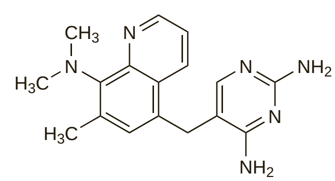
Bambermycin is an antibacterial complex containing mainly moenomycin A and moenomycin C and which may be obtained from cultures of *Streptomyces bambergiensis* or by other means. It is used as a growth promotor in veterinary practice.

Baquiloprim *(BAN, rINN)*

Bakilopriimi; Bakiloprim; Baquiloprima; Baquiloprime; Baquiloprimum; 138OU. 5-(8-Dimethylamino-7-methyl-5-quinolylmethyl)pyrimidin-2,4-diyldiamine.

Бахилоприм

$C_{17}H_{20}N_6$ = 308.4.
CAS — 102280-35-3.



Profile

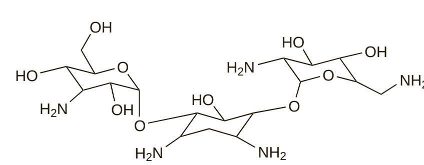
Baquiloprim is a diaminopyrimidine antibacterial used in veterinary medicine with sulfadimethoxine or sulfadimidine.

Bekanamycin Sulfate *(rINNM)*

Aminodeoxykanamycin Sulphate; Bekanamycin Sulphate; Békanamycine, Sulfate de; Bekanamycini Sulfas; Kanamycin B Sulphate; KDM; NK-1006; Sulfato de bekanamicina. 6-*O*-(3-Amino-3-deoxy-α-D-glucopyranosyl)-2-deoxy-4-*O*-(2,6-diamino-2,6-dideoxy-α-D-glucopyranosyl)-D-streptamine sulphate.

Беканамицина Сульфат

$C_{18}H_{37}N_5O_{10},2/_{}H_2SO_4$ = 728.7.
CAS — 4696-76-8 (bekanamycin); 70550-99-1 (bekanamycin sulfate).



(bekanamycin)

Pharmacopoeias. In *Jpn.*

Profile

Bekanamycin is an aminoglycoside and is a congener of kanamycin. It has properties similar to those of gentamicin (p.282).

It is given topically as the sulfate for the treatment of eye infections. It has also been given intramuscularly and orally. It is reported to be more toxic than kanamycin.

Preparations

Proprietary Preparations (details are given in Part 3)
Port.: Kanacyl†.
Multi-ingredient: ***Ital.:*** Visucloben Antibiotico; Visumetazone Antibiotico.

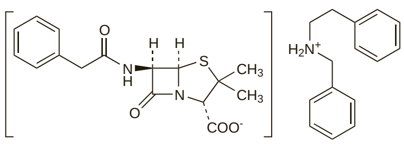
Benethamine Penicillin *(BAN, rINN)*

Bénéthamine Pénicilline; Benethaminum Penicillinum; Penicilina-benetamina. Benzyl(phenethyl)ammonium (6*R*)-6-(2-phenylacetamido)penicillanate.

Бенетамин Пенициллин

$C_{15}H_{17}N,C_{16}H_{18}N_2O_4S = 545.7.$

CAS — 751-84-8.



Profile

Benethamine penicillin is a poorly soluble derivative of benzylpenicillin (p.213) with similar actions and uses, although it is not recommended for chronic, severe, or deep-seated infections. After deep intramuscular injection it forms a depot from which it is slowly absorbed and hydrolysed to benzylpenicillin. Benethamine penicillin is usually given with benzylpenicillin sodium and also sometimes procaine benzylpenicillin to produce both an immediate and a prolonged effect; overall, the effect lasts for 2 to 3 days.

Preparations

Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Fr.:*** Biclinocilline; ***Port.:*** Atralmicina.

Benzathine Benzylpenicillin *(BAN, rINN)*

Bensylpenicillinbensatin; Bensylpenicillinbenzatin; Bentsyylipenisilliinibentsatiini; Benzathin-benzylpenicilin; Benzathine benzylpénicilline; Benzathine Penicillin; Benzathini Benzylpenicillinum; Benzatin Penisilin; Benzatina bencilpenicilina; Benzethacil; Benzilpenicilinas benzatinas; Benzilpenicillina Benzatinica; Benzilpenicillin-benzantin; Benzylopenicylina benzatynowa; Benzylpenicillinum Benzanthinum; Benzylpenicillinum benzathinum; Penicillin G Benzathine; Penisilin G Benzatin; Penzaethinum G. *NN*′-Dibenzylethylenediammonium bis[(6*R*)-6-(2-phenylacetamido)penicillanate].

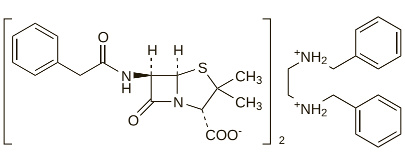
Бензатина Бензилпенициллин

$C_{16}H_{20}N_2(C_{16}H_{18}N_2O_4S)_2 = 909.1.$

CAS — 1538-09-6 (anhydrous benzathine benzylpenicillin); 5928-83-6 (benzathine benzylpenicillin monohydrate); 41372-02-5 (benzathine benzylpenicillin tetrahydrate).

ATC — J01CE08.

ATC Vet — QJ01CE08.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *Int.* *Jpn* and *US* include the tetrahydrate.

Ph. Eur. 6.2 (Benzylpenicillin, Benzathine). It contains a variable quantity of water. A white or almost white powder. Very slightly soluble in water; slightly soluble in alcohol; freely soluble in dimethylformamide and in formamide. Store in airtight containers.

USP 31 (Penicillin G Benzathine). The tetrahydrate is a white, odourless, crystalline powder. Soluble 1 in 5000 of water and 1 in 65 of alcohol. pH in a solution prepared by dissolving 50 mg in 50 mL of dehydrated alcohol, and adding 50 mL of water is between 4.0 and 6.5. Store in airtight containers.

Adverse Effects and Precautions

As for Benzylpenicillin, p.213.

Non-allergic (embolic-toxic) reactions similar to those associated with procaine benzylpenicillin, p.319, have been reported rarely with benzathine benzylpenicillin.

Benzathine benzylpenicillin should not be injected intravascularly since ischaemic reactions may occur.

Interactions

As for Benzylpenicillin, p.214.

Pharmacokinetics

When benzathine benzylpenicillin is given by intramuscular injection, it forms a depot from which it is slowly released and hydrolysed to benzylpenicillin. Peak plasma concentrations are produced in about 24 hours and are lower than those after an equivalent dose of benzylpenicillin potassium or sodium. However, depending on the dose, benzylpenicillin is usually detectable in plasma for up to 4 weeks (but see below).

Distribution into the CSF is reported to be poor.

Due to the slow absorption from the site of injection, benzylpenicillin has been detected in the urine for up to 12 weeks after a single dose.

Benzathine benzylpenicillin is relatively stable in the presence of gastric juice, but absorption from the gastrointestinal tract is variable. Plasma concentrations of benzylpenicillin after an oral dose are lower than those from the same dose of a soluble penicillin; peak concentrations are also produced less rapidly, but may persist for longer.

Plasma concentrations. Benzathine benzylpenicillin has been given every 4 weeks for secondary prophylaxis against rheumatic fever, although some advocate giving it every 3 weeks to ensure adequate plasma concentrations of benzylpenicillin. Typical concentrations achieved after a single intramuscular injection of benzathine benzylpenicillin 900 mg have been cited as about 100, 20, and 2 nanograms/mL on days 1, 14, and 32 respectively. In one study[1] adequate concentrations (defined as 20 nanograms or more per mL) were seen in more than 80% of serum samples at 3 weeks, but in only 36% at 4 weeks. In a further study,[2] in which single doses of 900 mg, 1.35 g and 1.8 g were compared, it appeared that doses higher than the 900-mg dose of benzathine benzylpenicillin usually recommended might prolong the duration of protective plasma concentrations of benzylpenicillin (defined as above 25 nanograms/mL) and improve the efficacy of dosing every 4 weeks for prophylaxis against rheumatic fever.

1. Kaplan EL, *et al.* Pharmacokinetics of benzathine penicillin G: serum levels during the 28 days after intramuscular injection of 1 200 000 units. *J Pediatr* 1989; **115:** 146–50.
2. Currie BJ, *et al.* Penicillin concentrations after increased doses of benzathine penicillin G for prevention of secondary rheumatic fever. *Antimicrob Agents Chemother* 1994; **38:** 1203–4.

Pregnancy. The pharmacokinetics of benzathine benzylpenicillin appear to be altered in late pregnancy. Of 10 healthy pregnant women given benzathine benzylpenicillin 1.8 g intramuscularly before caesarean section, only 4 achieved adequate serum concentrations of benzylpenicillin (for syphilis, at least 18 nanograms/mL) for 7 days.[1]

1. Nathan L, *et al.* Penicillin levels following the administration of benzathine penicillin G in pregnancy. *Obstet Gynecol* 1993; **82:** 338–42.

Uses and Administration

Benzathine benzylpenicillin has the same antimicrobial action as benzylpenicillin (p.214), to which it is hydrolysed gradually after deep intramuscular injection. This results in a prolonged effect, but because of the relatively low blood concentrations of benzylpenicillin produced, its use should be restricted to micro-organisms that are highly susceptible to benzylpenicillin. In acute infections, and when bacteraemia is present, the initial treatment should be with benzylpenicillin by injection.

Infections treated with benzathine benzylpenicillin include diphtheria (asymptomatic carriers), pharyngitis (*Streptococcus pyogenes; Arcanobacterium haemolyticum* (*Corynebacterium haemolyticum*)), and syphilis (including non-venereal treponematoses). It is also used for primary and secondary prophylaxis of rheumatic fever. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Administration and dosage. Benzathine benzylpenicillin is given by deep intramuscular injection, sometimes with procaine benzylpenicillin and benzylpenicillin itself. It has been given orally for mild infections, although phenoxymethylpenicillin is usually preferred. Benzathine benzylpenicillin 900 mg is equivalent to about 720 mg of benzylpenicillin (1.2 million units).

For early syphilis, a single dose of benzathine benzylpenicillin 1.8 g by deep intramuscular injection is given, usually as 2 injections at separate sites. In late syphilis, 1.8 g is given at weekly intervals for 3 consecutive weeks. Benzathine benzylpenicillin is not usually recommended for the treatment of neurosyphilis because of reports of inadequate penetration into the CSF. Infants up to 2 years of age may be given a single intramuscular dose of 37.5 mg/kg for the treatment of congenital syphilis, provided there is no evidence of infection in the CSF.

For the treatment of other treponemal infections, such as yaws, pinta, and endemic syphilis (bejel), a single intramuscular dose of benzathine benzylpenicillin 900 mg is given; a dose of 450 mg may be used in children.

For streptococcal pharyngitis and the primary prevention of rheumatic fever, the adult dose is a single intramuscular injection of 900 mg; children under 30 kg may be given 225 to 675 mg. To prevent recurrences of acute rheumatic fever, 900 mg is given intramuscularly every 3 or 4 weeks to adults; a dose of 450 mg has been used for children under 30 kg.

Preparations

Benzylpenicillin *(BAN, rINN)*

Bencilpenicilina; Bensylpenicillin; Bentsyylipenisilliini; Benzil Penisiliin; Benzylpénicilline; Benzylpenicillinum; Crystalline Penicillin G; Penicillin; Penicillin G; Penisilin G. (2*S*,5*R*,6*R*)-3,3-Dimethyl-7-oxo-6-(2-phenylacetamido)-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylic acid; (6*R*)-6-(2-Phenylacetamido)penicillanic acid.

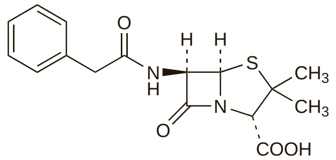
Бензилпенициллин

$C_{16}H_{18}N_2O_4S$ = 334.4.

CAS — 61-33-6.

ATC — J01CE01; S01AA14.

ATC Vet — QJ01CE01; QJ51CE01; QS01AA14.



Description. The name benzylpenicillin is commonly used to describe either benzylpenicillin potassium or benzylpenicillin sodium as these are the forms in which benzylpenicillin is used. In *Martindale*, benzylpenicillin means either the potassium or sodium salt.

Benzylpenicillin Potassium *(BANM, rINNM)*

Bencilpenicilina potásica; Bensylpenicillinkalium; Bentsyylipenisilliinikalium; Benzilpenicilino kalio druska; Benzilpenicillin-kálium; Benzylopenicylina potasowa; Benzylpenicilin draselná sůl; Benzylpénicilline potassique; Benzylpenicillinum kalicum; Kalii Benzylpenicillinum; Penicillin G Potassium; Penisilin G Potasyum.

Калия Бензилпенициллин

$C_{16}H_{17}KN_2O_4S$ = 372.5.

CAS — 113-98-4.

ATC — J01CE01; S01AA14.

ATC Vet — QJ01CE01; QS01AA14.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Benzylpenicillin Potassium). The potassium salt of a substance produced by growing certain strains of *Penicillium notatum* or related organisms or obtained by any other means. A white or almost white crystalline powder. Very soluble in water; practically insoluble in fatty oils and in liquid paraffin. A 10% solution in water has a pH of 5.5 to 7.5. Store in airtight containers.

USP 31 (Penicillin G Potassium). Colourless or white crystals, or white crystalline powder. It is odourless or practically so, and is moderately hygroscopic. Very soluble in water, in sodium chloride 0.9%, and in glucose solutions; sparingly soluble in alcohol. Its solutions retain substantially full potency for several days at temperatures below 15°, but are rapidly inactivated by acids, by alkali hydroxides, by glycerol, and by oxidising agents. pH of a 6% solution in water is between 5.0 and 7.5. Store in airtight containers.

Incompatibility and stability. As for Benzylpenicillin Sodium, below.

Benzylpenicillin Sodium *(BANM, rINNM)*

Bencilpenicilina sódica; Bensylpenicillinnatrium; Bentsyylipenisilliininatrium; Benzilpenicilino natrio druska; Benzilpenicillin-nátrium; Benzylopenicylina sodowa; Benzylpenicilin sodná sůl; Benzylpénicilline sodique; Benzylpenicillinum natricum; Natrii Benzylpenicillinum; Penicillin G Sodium; Sodyum Penisilin G.

Натрий Бензилпенициллин

$C_{16}H_{17}N_2NaO_4S$ = 356.4.

CAS — 69-57-8.

ATC — J01CE01; S01AA14.

ATC Vet — QJ01CE01; QS01AA14.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., US,* and *Viet.*

Ph. Eur. 6.2 (Benzylpenicillin Sodium). The sodium salt of a substance produced by growing certain strains of *Penicillium notatum* or related organisms or obtained by any other means. A white or almost white crystalline powder. Very soluble in water; practically insoluble in fatty oils and in liquid paraffin. A 10% solution in water has a pH of 5.5 to 7.5. Store in airtight containers.

USP 31 (Penicillin G Sodium). Colourless or white crystals, or white to slightly yellow crystalline powder. It is odourless or practically so, and is moderately hygroscopic. Its solutions lose potency fairly rapidly at room temperature, but retain substantially full potency for several days at temperatures below 15°. Its solutions are rapidly inactivated by acids, by alkali hydroxides, by oxidising agents, and by penicillinase. pH of a 6% solution in water is between 5.0 and 7.5. Store in airtight containers.

Incompatibility. Benzylpenicillin has been reported to be incompatible with metal ions and some rubber products. Its stability may be affected by ionic and nonionic surfactants, oxidising and reducing agents, alcohols, glycerol, glycols, macrogols and other hydroxy compounds, some paraffins and bases, some preservatives such as chlorocresol or thiomersal, carbohydrate solutions in an alkaline pH, fat emulsions, blood and blood products, and viscosity modifiers. Benzylpenicillin is incompatible with a wide range of acidic and basic drugs (see Stability, below) and with a number of other antimicrobials, including amphotericin B, some cephalosporins, and vancomycin. Benzylpenicillin and aminoglycosides are mutually incompatible and injections should be given at separate sites.

Stability. Benzylpenicillin is hydrolysed in aqueous solutions by degradation of the beta-lactam ring and hydrolysis is accelerated by increased temperature or alkaline conditions; inactivation also occurs under acid conditions. Degradation products include penillic, penicillenic, and penicilloic acids which lower the pH and cause a progressive increase in the rate of deterioration; *N*-formylpenicillamine and very small amounts of penicillamine have also been detected. Degradation is minimal at about pH 6.8 and deterioration of benzylpenicillin in solution may be retarded by using a citrate buffer. Dilute solutions are more stable than concentrated ones.

Units

The second International Standard Preparation (1952) of benzylpenicillin sodium contained 1670 units of penicillin per mg but was withdrawn in 1968 since penicillin can now be characterised completely by chemical tests. Despite this, doses of benzylpenicillin are still expressed in units in some countries.

Benzylpenicillin potassium 600 mg or benzylpenicillin sodium 600 mg have generally been considered to be equivalent to about 1 million units (1 mega unit).

Adverse Effects

The most common adverse effects of benzylpenicillin are hypersensitivity reactions, especially skin rashes; anaphylaxis occasionally occurs and has sometimes been fatal.

Gastrointestinal effects such as diarrhoea and nausea are the most common adverse effects after oral use of benzylpenicillin; a sore mouth or tongue or a black hairy tongue have occasionally been reported. Pseudomembranous colitis has been associated with the use of most antibiotics; ampicillin or amoxicillin are the most frequently implicated penicillins (see Antibiotic-associated Colitis, p.171).

Other adverse effects have generally been associated with large intravenous doses of benzylpenicillin; patients with renal impairment are also at increased risk. These adverse effects include haemolytic anaemia and neutropenia, both of which might have some immunological basis; prolongation of bleeding time and defective platelet function; convulsions and other signs of CNS toxicity (encephalopathy has followed intrathecal dosage and can be fatal); and electrolyte disturbances because of the large amounts of potassium or sodium given when benzylpenicillin potassium or sodium, respectively, are used.

Hepatitis and cholestatic jaundice have been reported rarely with some penicillins, notably penicillinase-resistant penicillins such as flucloxacillin and oxacillin, and also combinations of amoxicillin or ticarcillin with clavulanic acid.

Nephropathy and interstitial nephritis, which may have some immunological basis, have been especially associated with meticillin, but may be produced by other penicillins.

Some patients with syphilis and other spirochaete infections may experience a Jarisch-Herxheimer reaction shortly after starting treatment with penicillin, which is probably due to the release of endotoxins from the killed treponemes and should not be mistaken for a hypersensitivity reaction. Symptoms include fever, chills, headache, and reactions at the site of the lesions. The reaction can be dangerous in cardiovascular syphilis, or where there is a serious risk of increased local damage, such as with optic atrophy.

Hypersensitivity. The overall incidence of allergic reactions to penicillin has been reported to vary from about 1 to 10% although some patients may have been incorrectly labelled 'allergic to penicillin'. Anaphylactic reactions occur in about 0.05% of patients, usually after parenteral use, but they have also been reported after taking oral penicillin.

Hypersensitivity to penicillin gives rise to immediate reactions including anaphylaxis, angioedema, urticaria, and some maculopapular rashes. Late reactions may include serum sickness-like reactions and haemolytic anaemia. Reactions are considered to be due mainly to breakdown products produced *in vitro* before use or to metabolites of penicillin, and possibly penicillin itself. These act as haptens which, when combined with proteins and other macromolecules, produce potential antigens. As the hypersensitivity is related to the basic penicillin structure, patients who are genuinely allergic to benzylpenicillin must be assumed to be allergic to all penicillins; sensitised patients may also react to the cephalosporins and other beta-lactam antibiotics.

Tests for hypersensitivity may be used to determine those patients most likely to develop serious allergic reactions to penicillins. Skin tests are used to evaluate the current risk of immediate or accelerated IgE-mediated reactions, the most serious being anaphylaxis. Both the major and minor determinants of penicillin hypersensitivity should be used; the major determinant is available as penicilloyl-polylysine (p.2364) and a minor-determinant mixture consisting of benzylpenicillin and its derivatives, including penicilloic acid and benzylpenicilloylamine, can be used, although if this is not available a solution of benzylpenicillin may be substituted. Adrenaline should be available in case an anaphylactic reaction develops. The results of skin tests are unreliable if a significant time has elapsed before beginning therapy. A number of *in-vitro* tests including the radioallergosorbent test (RAST) have been developed.

Desensitisation may be attempted in patients allergic to penicillin when treatment with penicillin is considered essential. It involves very small doses of penicillin given at relatively short intervals of 15 minutes or more, and gradually increased to therapeutic concentrations. However, desensitisation may be hazardous and should only be carried out if the patient can be monitored continuously and adrenaline and resuscitation equipment are immediately available. Desensitisation should be regarded as temporary, and allergic reactions may recur during the next exposure to penicillin.

Neutropenia. Neutropenia has been widely reported in patients given high doses of beta lactams and an incidence of from 5 to more than 15% has been reported in patients treated for 10 days or more. Warning signs include fever, rash, and eosinophilia. Monitoring of the leucocyte count is recommended during long-term treatment with high doses. Some have proposed a direct toxic effect whereas others have postulated an immune mechanism.

Precautions

Patients known to be hypersensitive to penicillins should be given an antibacterial of another class. However, sensitised patients may also react to the cephalosporins and other beta lactams. Desensitisation may be attempted if treatment with a penicillin is considered essential (see Adverse Effects, above). Penicillins should be given with caution to patients with a history of allergy, especially to drugs.

Care is necessary if very high doses of penicillins are given, especially if renal function is poor, because of the risk of neurotoxicity. The intrathecal route should be avoided. Renal, hepatic, and haematological status should be monitored during prolonged and high-dose therapy. Because of the Jarisch-Herxheimer reaction, care is also necessary when treating patients with spirochaete infections, particularly syphilis.

Skin contact with penicillins should be avoided since sensitisation may occur.

Penicillin therapy changes the normal bacterial flora and can lead to superinfection with penicillin-resistant organisms including *Clostridium difficile* or *Candida*, particularly with prolonged use.

Penicillins may interfere with some diagnostic tests such as those for urinary glucose using copper sulfate, direct antiglobulin (Coombs') tests, and some tests for urinary or serum proteins. Penicillins may interfere with tests that use bacteria, for example the Guthrie test for phenylketonuria using *Bacillus subtilis* organisms.

Potassium and sodium content. Each g of benzylpenicillin potassium contains about 2.7 mmol of potassium and each g of benzylpenicillin sodium contains about 2.8 mmol of sodium. Care is necessary if large doses of the potassium or sodium salts are given to patients with renal impairment or heart failure. High doses of benzylpenicillin potassium should also be used with caution in patients receiving potassium-containing drugs or potassium-sparing diuretics.

Interactions

Probenecid prolongs the half-life of benzylpenicillin by competing with it for renal tubular secretion and may be used therapeutically for this purpose. Benzylpenicillin may also interact with bacteriostatic antibacterials such as chloramphenicol and tetracyclines (see Antimicrobial Action, below), and may be incompatible *in vitro* with other drugs, including some other antibacterials (see above).

The possibility of a prolonged bleeding time after oral treatment with a broad-spectrum drug like ampicillin should be borne in mind in patients receiving anticoagulants.

Hormonal contraceptives. For the effect of penicillins on oral contraceptives, see p.2068.

Methotrexate. For the effect of penicillins on methotrexate, see p.748.

Antimicrobial Action

Benzylpenicillin is a beta-lactam antibiotic and has a bactericidal action against Gram-positive bacteria, Gram-negative cocci, some other Gram-negative bacteria, spirochaetes, and actinomycetes.

Mechanism of action. It exerts its killing action on growing and dividing bacteria by inhibiting bacterial cell-wall synthesis, although the mechanisms involved are still not precisely understood. Bacterial cell walls are held rigid and protected against osmotic rupture by peptidoglycan. Benzylpenicillin inhibits the final cross-linking stage of peptidoglycan production by binding to and inactivating transpeptidases, penicillin-binding proteins on the inner surface of the bacterial cell membrane. However, it is now realised that other earlier stages in cell-wall synthesis can also be inhibited. Other mechanisms involved include bacterial lysis by the inactivation of endogenous inhibitors of bacterial autolysins.

Its action is inhibited by penicillinase and other beta-lactamases that are produced during the growth of certain micro-organisms.

Many Gram-negative organisms are intrinsically resistant by virtue of the inability of benzylpenicillin to penetrate their outer membranes. Intrinsic resistance can also be due to structural differences in the target penicillin-binding proteins. See under Resistance, below, for reference to acquired resistance.

Spectrum of activity. The following pathogenic organisms are usually sensitive to benzylpenicillin:

- Gram-positive aerobes and anaerobes including *Bacillus anthracis*, *Clostridium perfringens*, *Cl. tetani*, *Corynebacterium diphtheriae*, *Erysipelothrix rhusiopathiae*, *Listeria monocytogenes*, *Peptostreptococcus* spp., non-beta-lactamase-producing staphylococci, and streptococci including *Streptococcus agalactiae* (group B), *Str. pneumoniae* (pneumococci), *Str. pyogenes* (group A), and some viridans streptococci; enterococci are relatively insensitive.
- Gram-negative cocci including *Neisseria meningitidis* (meningococci) and *Neisseria gonorrhoeae* (gonococci), although beta-lactamase-producing strains are common.
- Gram-negative bacilli including *Pasteurella multocida*, *Streptobacillus moniliformis*, and *Spirillum minus* (or *minor*); most Gram-negative bacilli, including *Pseudomonas* spp. and Enterobacteriaceae, are insensitive although some strains of *Proteus mirabilis* and *Escherichia coli* may be inhibited by high concentrations of benzylpenicillin.
- Gram-negative anaerobes including *Prevotella* (non-fragilis *Bacteroides*) and *Fusobacterium* spp.
- Other organisms including *Actinomyces* and the spirochaetes, *Borrelia*, *Leptospira*, and *Treponema* spp.
- Mycobacteria, fungi, mycoplasmas, and rickettsias are not sensitive.

Activity with other antimicrobials. Benzylpenicillin may exhibit synergy with other antimicrobials, particularly the aminoglycosides, and such combinations have been used against enterococci and other relatively insensitive bacteria. Its activity may be enhanced by clavulanic acid and other beta-lactamase inhibitors, and both enhancement and antagonism have been demonstrated for beta-lactam combinations. Antagonism has been reported to occur with some bacteriostatic drugs, such as chloramphenicol or tetracyclines, that interfere with active bacterial growth necessary for benzylpenicillin to achieve its effect.

Resistance. Susceptible Gram-positive bacteria acquire resistance to beta lactams mainly through the induction of beta-lactamases, including penicillinases. These enzymes are liberated extracellularly and hydrolyse the beta-lactam ring. This resistance is usually plasmid-mediated and can be transferred from one bacterium to another. Gram-negative bacteria produce beta-lactamases within their cell membranes which may be chromosomally or plasmid-mediated; all Gram-negative species probably contain small amounts of beta-lactamases. Resistance in Gram-negative species may also be due to changes in their outer membrane resulting in the failure of beta lactams to reach their target penicillin-binding proteins. Changes in the binding characteristics of penicillin-binding proteins may also result in resistance in Gram-positive and Gram-negative bacteria.

Most strains of *Staphylococcus aureus* are now resistant to benzylpenicillin. *Streptococcus pneumoniae* with reduced susceptibility or complete resistance to benzylpenicillin have increasingly been reported. Strains of *Neisseria meningitidis* with reduced sensitivity to benzylpenicillin have been identified. Penicillinase-producing *Neisseria gonorrhoeae* are widespread; reduced sensitivity of gonococci to benzylpenicillin may also result from alterations in penicillin-binding proteins. Most strains of *Haemophilus influenzae* and *Moraxella catarrhalis* (*Branhamella catarrhalis*) are now resistant.

Some organisms, usually Gram-positive cocci such as staphylococci or streptococci, may develop tolerance and are inhibited but not killed by benzylpenicillin; in such cases the minimum bactericidal concentration is much greater than the minimum inhibitory concentration.

Pharmacokinetics

Benzylpenicillin rapidly appears in the blood after intramuscular injection of water-soluble salts, and maximum concentrations are usually reached in 15 to 30 minutes; peak plasma concentrations of about 12 micrograms/mL have been reported after single doses of 600 mg.

When given orally, benzylpenicillin is inactivated fairly rapidly by gastric acid and only up to about 30% is absorbed, mainly from the duodenum; maximum plasma-penicillin concentrations usually occur in about 1 hour. In order to attain plasma-penicillin concentrations after oral use similar to those after intramuscular injection, up to 5 times as much benzylpenicillin may be necessary. Absorption varies greatly in different individuals and is better in patients with reduced gastric acid production, including neonates and the elderly. Food decreases the absorption of benzylpenicillin and oral doses are best given at least half an hour before or 2 to 3 hours after a meal.

Benzylpenicillin is widely distributed at varying concentrations in body tissues and fluids. It appears in pleural, pericardial, peritoneal, and synovial fluids, but in the absence of inflammation diffuses only to a small extent into abscess cavities, avascular areas, the eye, the middle ear, and the CSF. Inflamed tissue is, however, more readily penetrated and, for example, in meningitis higher concentrations of benzylpenicillin are achieved in the CSF. Active transport out of the CSF is reduced by probenecid. In patients with uraemia, other organic acids may accumulate in the CSF and compete with benzylpenicillin for active transport; toxic concentrations of benzylpenicillin sufficient to cause convulsions can result.

Benzylpenicillin diffuses across the placenta into the fetal circulation, and small amounts appear in breast milk.

The plasma half-life is about 30 minutes, although it may be longer in neonates and the elderly because of reduced renal function. In renal impairment the half-life may be increased to about 10 hours. Approximately 60% is reported to be bound to plasma protein.

Benzylpenicillin is metabolised to a limited extent and the penicilloic acid derivative has been recovered in the urine. Benzylpenicillin is rapidly excreted in the urine, principally by tubular secretion and about 20% of a dose given by mouth appears unchanged in the urine; about 60 to 90% of a dose of aqueous benzylpenicillin given intramuscularly appears in the urine, mainly within the first hour. Significant concentrations are achieved in bile, but in patients with normal renal function only small amounts are excreted via the bile. Benzylpenicillin is removed by haemodialysis.

Renal tubular secretion is inhibited by probenecid (p.558), which is sometimes given to increase plasma-penicillin concentrations.

Uses and Administration

Benzylpenicillin is used in the treatment of infections due to susceptible organisms (see Antimicrobial Action, above). They include abscess, actinomycosis, anthrax, bites and stings, diphtheria, endocarditis, gas gangrene, leptospirosis, Lyme disease, meningitis, meningococcal infections, necrotising enterocolitis, necrotising fasciitis, neonatal conjunctivitis (if gonococci are sensitive), perinatal streptococcal infections (intrapartum prophylaxis against group B streptococci), pharyngitis (or tonsillitis), pneumonia, skin infections, syphilis (neurosyphilis and congenital syphilis), tetanus, toxic shock syndrome, and Whipple's disease. It is also used for surgical infection prophylaxis in first trimester abortion in women at high risk of pelvic infection. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Administration and dosage. Benzylpenicillin is usually given intramuscularly or intravenously. For some indications benzathine benzylpenicillin (p.212) or procaine benzylpenicillin (p.319), which provide a prolonged effect, are preferred; they are given intramuscularly. Benzylpenicillin is sometimes given orally for infections of moderate severity, but one of the acid-resistant penicillins such as phenoxymethylpenicillin (p.314) is preferable.

Benzylpenicillin is available as the potassium or sodium salt. The dose of benzylpenicillin should be sufficient to achieve an optimum bactericidal concentration in the blood as rapidly as possible; concentrations may be increased by giving it with probenecid (p.559). In some countries, doses are still expressed in units. Benzylpenicillin potassium 600 mg or benzylpenicillin sodium 600 mg have generally been considered to be equivalent to about 1 million units (1 mega unit).

For some infections, adult doses of 0.6 to 4.8 g of benzylpenicillin daily in 2 to 4 divided doses by intramuscular or slow intravenous injection or intravenous infusion may be adequate, but higher doses given intravenously, often by infusion, are more usual for severe infections. For example, in endocarditis, benzylpenicillin 7.2 g daily (1.2 g every 4 hours) intravenously, usually with an aminoglycoside, is recommended; doses of up to 18 g daily are not unusual for less sensitive streptococci and enterococci. In meningococcal and pneumococcal meningitis, benzylpenicillin 14.4 g daily (2.4 g every 4 hours) intravenously is recommended; up to 18 g daily has been recommended for meningococcal meningitis. High doses should be given slowly to avoid irritation of the CNS and electrolyte imbalance, and a rate of not more than 300 mg/minute is recommended for intravenous doses above 1.2 g. High doses may need to be reduced in patients with renal impairment.

Infants and children from 1 month to 12 years may be given 100 mg/kg daily in 4 divided doses; infants aged 1 to 4 weeks, 75 mg/kg daily in 3 divided doses; and neonates 50 mg/kg daily in 2 divided doses.

As in adults, higher paediatric doses may be necessary in severe infections. A dose of 180 to 300 mg/kg daily given intravenously in 4 to 6 divided doses is recommended for meningococcal meningitis in infants and children from 1 month to 12 years of age; infants aged 1 to 4 weeks may be given 150 mg/kg daily in 3 divided doses; neonates up to 7 days old may be given 100 mg/kg daily in 2 divided doses.

In patients with suspected meningococcal infection, an intravenous or intramuscular injection of benzylpenicillin should be given before transfer to hospital. Doses are: adults and children aged 10 years or more, 1.2 g; children aged 1 to 9 years, 600 mg; children under 1 year, 300 mg.

A dose for intrapartum prophylaxis against group B streptococcal infection is benzylpenicillin 3 g intravenously initially, then 1.5 g every 4 hours until delivery.

Other routes. Benzylpenicillin eye drops and eye ointment are used in the treatment of susceptible eye infections. For subconjunctival injection, 300 or 600 mg of benzylpenicillin has been dissolved in 0.5 to 1.0 mL of water, or another suitable solvent such as lidocaine 2% with or without adrenaline 1 in 200 000 or similar.

Benzylpenicillin has also been given orally on an empty stomach in adult doses of 125 to 312 mg every 4 to 6 hours.

Intrathecal injections are no longer recommended.

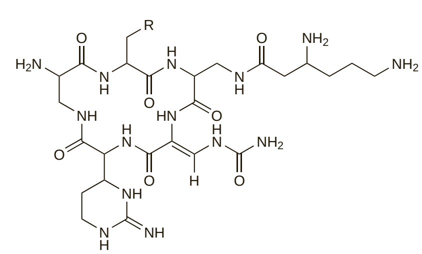
Capreomycin Sulfate *(USAN, rINNM)*

34977; Capreomycin Sulphate *(BANM)*; Capréomycine, Sulfate de; Capreomycini Sulfas; Capromycin Sulphate; Sulfato de capreomicina.

Капреомицина Сульфат

CAS — 11003-38-6 (capreomycin); 1405-37-4 (capreomycin sulfate).
ATC — J04AB30.
ATC Vet — QJ04AB30.



Capreomycin IA R = OH
Capreomycin IB R = H

(capreomycin)

The symbol † denotes a preparation no longer actively marketed

Description. Capreomycin I consists of capreomycin IA ($C_{25}H_{44}N_{14}O_8$ = 668.7) and capreomycin IB ($C_{25}H_{44}N_{14}O_7$ = 652.7), which predominates. Capreomycin II, which makes up about 10% of the mixture, consists of capreomycin IIA and capreomycin IIB.

Pharmacopoeias. In *Chin.* and *US.*
USP 31 (Capreomycin Sulfate). The disulfate of capreomycin, a polypeptide mixture produced by the growth of *Streptomyces capreolus*. It contains not less than 90% of capreomycin I. A white to practically white amorphous powder. Freely soluble in water; practically insoluble in most organic solvents. pH of a 3% solution in water is between 4.5 and 7.5. Store in airtight containers.

Adverse Effects and Treatment

The effects of capreomycin on the kidney and eighth cranial nerve are similar to those of aminoglycosides such as gentamicin (p.282). Nitrogen retention, renal tubular dysfunction, and progressive renal damage may occur. Hypokalaemia and other electrolyte abnormalities have been reported. Vertigo, tinnitus, and hearing loss may also occur and are sometimes irreversible. Abnormalities in liver function have been reported when capreomycin has been used with other antituberculous drugs. Hypersensitivity reactions including urticaria, maculopapular rashes, and sometimes fever have been reported. Leucocytosis and leucopenia have also been observed. Thrombocytopenia has been reported rarely. Eosinophilia commonly occurs with capreomycin. Capreomycin also has a neuromuscular blocking action. There may be pain, induration, and excessive bleeding at the site of intramuscular injection; sterile abscesses may also form.

Teratogenicity has been seen after high doses in *rodents*.

Treatment of overdose is generally supportive. Patients with normal renal function should be hydrated to maintain adequate urine output. Capreomycin may be removed by haemodialysis in patients with significant renal impairment.

Impurities. The manufacturer of a highly-purified capreomycin product (*Capacin; Cheiljedang, Kor.*) has claimed that such purification reduces the toxicity and alters the pharmacokinetics in *animal* studies, suggesting that some of the toxicity of capreomycin is due to such impurities.[1]

1. Lee SH, *et al.* The impurities of capreomycin make a difference in the safety and pharmacokinetic profiles. *Int J Antimicrob Agents* 2003; **22:** 81–3.

Precautions

Capreomycin should be given with care and in reduced dosage to patients with renal impairment. Care is also essential in patients with signs of eighth cranial nerve damage. It is advisable to monitor renal and auditory function and serum-potassium concentrations in patients before and during therapy. Periodic assessment of hepatic function is also recommended.

Interactions

Care should be taken when capreomycin is used with other drugs that have neuromuscular blocking activity. It should not be given with other drugs that are ototoxic or nephrotoxic.

Antimicrobial Action

Capreomycin has activity against various mycobacteria. Resistance develops readily if capreomycin is used alone. It shows cross-resistance with kanamycin and neomycin.

◊ References.

1. Ho YII, *et al.* In-vitro activities of aminoglycoside-aminocyclitols against mycobacteria. *J Antimicrob Chemother* 1997; **40:** 27–32.
2. Maus CE, *et al.* Molecular analysis of cross-resistance to capreomycin, kanamycin, amikacin, and viomycin in Mycobacterium tuberculosis. *Antimicrob Agents Chemother* 2005; **49:** 3192–7.

Pharmacokinetics

Capreomycin is poorly absorbed from the gastrointestinal tract. An intramuscular dose of 1 g has been reported to give a peak serum concentration of about 30 micrograms/mL after 1 or 2 hours. About 50% of a dose is excreted unchanged in the urine by glomerular filtration within 12 hours. Capreomycin is removed by haemodialysis.

Uses and Administration

Capreomycin is a second-line antimycobacterial that may be used in the treatment of tuberculosis (p.196) as part of a multidrug regimen when resistance to primary drugs has developed.

Capreomycin is given as the sulfate by deep intramuscular injection or by intravenous infusion. The usual dose is the equivalent of 1 g of capreomycin base (maximum 20 mg/kg) given daily for 2 to 4 months, then 2 or 3 times weekly for the remainder of therapy.

For details of doses in infants, children, and adolescents, see below.

Administration in children. For the treatment of drug-resistant tuberculosis in infants, children, and adolescents the American Academy of Pediatrics (AAP) suggests an intramuscular dose of capreomycin 15 to 30 mg/kg daily, to a maximum dose of 1 g daily.

Administration in renal impairment. As with aminoglycosides, the dose of capreomycin in patients with renal impairment must be reduced based on creatinine clearance; the desired steady-state serum capreomycin level is 10 micrograms/mL.

Preparations

USP 31: Capreomycin for Injection.

Proprietary Preparations (details are given in Part 3)

Austral.: Capastat; ***Austria:*** Capastat; ***Cz.:*** Capastat†; ***Gr.:*** Capastat; ***Rus.:*** Capastat (Капастат); Lykocin (Лайкоцин); ***Spain:*** Capastat; ***UK:*** Capastat; ***USA:*** Capastat.

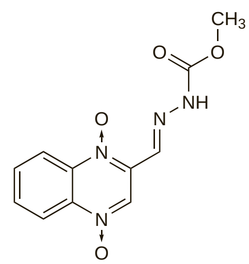
Carbadox *(BAN, USAN, pINN)*

Carbadoxum; GS-6244. Methyl 3-quinoxalin-2-ylmethylenecarbazate 1,4-dioxide.

Карбадокс

$C_{11}H_{10}N_4O_4$ = 262.2.

CAS — 6804-07-5.



Profile

Carbadox is an antibacterial that has been used in veterinary practice for treating swine dysentery and enteritis and for promoting growth. However, its use has been prohibited in the EU and some other countries after reports of carcinogenicity.

Carbenicillin Sodium *(BANM, rINNM)*

BRL-2064; Carbenicilina sódica; Carbenicillin Disodium *(USAN)*; Carbénicilline sodique; Carbenicillinum natricum; α-Carboxybenzylpenicillin Sodium; CP-15-639-2; GS-3159 (carbenicillin potassium); Karbenicillin-nátrium; Karbenicylina sodowa; Natrii Carbenicillinum; NSC-111071. The disodium salt of (6*R*)-6-(2-carboxy-2-phenylacetamido)penicillanic acid .

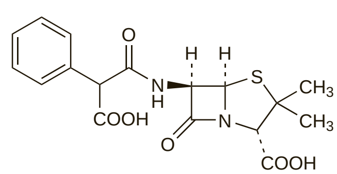
Натрий Карбенициллин

$C_{17}H_{16}N_2Na_2O_6S$ = 422.4.

CAS — 4697-36-3 (carbenicillin); 4800-94-6 (carbenicillin disodium); 17230-86-3 (carbenicillin potassium).

ATC — J01CA03.

ATC Vet — QJ01CA03.



(carbenicillin)

Pharmacopoeias. In *Pol.* and *US.*
USP 31 (Carbenicillin Disodium). A white to off-white crystalline powder. Freely soluble in water; soluble in alcohol; practically insoluble in chloroform and in ether. pH of a solution in water containing the equivalent of carbenicillin 1% is between 6.5 and 8.0. Store in airtight containers.

Incompatibility. Carbenicillin sodium has been reported to be incompatible with aminoglycosides, tetracyclines, and a number of other drugs including other antimicrobials and these drugs should therefore be given separately.

Adverse Effects

As for Benzylpenicillin, p.213.

Hypersensitivity reactions have been reported to be less frequent and less severe with carbenicillin than with benzylpenicillin. Pain at the injection site and phlebitis may occur. Electrolyte disturbances, particularly hypokalaemia or hypernatraemia, may follow large doses of carbenicillin sodium.

A dose-dependent coagulation defect has been reported, especially in patients with renal impairment. Carbenicillin appears to interfere with platelet function thereby prolonging bleeding time; purpura and haemorrhage from mucous membranes and elsewhere may result.

Precautions

As for Benzylpenicillin, p.214.

Sodium content. Each g of carbenicillin sodium contains about 4.7 mmol of sodium. Carbenicillin sodium should therefore be given with caution to patients on a restricted sodium diet.

Interactions

As for Benzylpenicillin, p.214.

Antimicrobial Action

Carbenicillin has a bactericidal mode of action similar to that of benzylpenicillin, but with an extended spectrum of activity against Gram-negative bacteria. The most important feature of carbenicillin is its activity against *Pseudomonas aeruginosa*, although high concentrations are generally necessary. Activity against *Ps. aeruginosa* and some other organisms can be enhanced by gentamicin and other aminoglycosides. Carbenicillin is also active against *Proteus*, including indole-positive spp. such as *Pr. vulgaris*. It is comparable with ampicillin against other Gram-negative bacteria. Sensitive organisms include some Enterobacteriaceae, for example *Escherichia coli* and *Enterobacter* spp.; *Haemophilus influenzae*; and *Neisseria* spp. *Klebsiella* spp. are usually not susceptible. Its activity against Gram-positive bacteria is less than that of benzylpenicillin. Anaerobic organisms are generally susceptible to carbenicillin, but high concentrations are required for *Bacteroides fragilis*.

Resistance. Carbenicillin is inactivated by penicillinases and some other beta-lactamases, although it is more stable to the chromosomally mediated beta-lactamases produced by some Gram-negative organisms, including *Ps. aeruginosa* and some *Proteus* spp. Resistance to carbenicillin may develop in *Ps. aeruginosa* during treatment with carbenicillin or other beta lactams. This resistance may be intrinsic where there are changes in cell wall permeability or penicillin-binding proteins, or it may be due to plasmid-mediated beta-lactamase production that may be transferred to and from certain strains of Enterobacteriaceae.

There may be cross-resistance between carbenicillin and other antipseudomonal penicillins.

Outbreaks of pseudomonal resistance to carbenicillin have been associated with extensive use in, for example, hospital burns units.

Pharmacokinetics

Carbenicillin is not absorbed from the gastrointestinal tract and has therefore been given either intramuscularly or intravenously.

The half-life of carbenicillin is reported to be about 1 to 1.5 hours; it is increased in patients with renal impairment, especially if there is also hepatic impairment, and also in neonates. Half-lives of 10 to 18 hours have been reported in renal impairment. Clearance is enhanced in patients with cystic fibrosis. Carbenicillin is about 50% bound to plasma proteins. Distribution of carbenicillin in the body is similar to that of other penicillins. Small amounts have been detected in breast milk. There is little diffusion into the CSF except when the meninges are inflamed.

Relatively high concentrations have been reported in bile, but carbenicillin is excreted principally by renal tubular secretion and glomerular filtration.

Probenecid increases and prolongs plasma concentrations of carbenicillin.

Carbenicillin is removed by haemodialysis and, to some extent, by peritoneal dialysis.

Uses and Administration

Carbenicillin is a carboxypenicillin that has been given by injection as the disodium salt, often with gentamicin, in the treatment of infections due to *Pseudomonas aeruginosa*; however, other antipseudomonal penicillins such as ticarcillin (p.352) or piperacillin (p.315) are now preferred. It has also been given to treat serious infections due to non-penicillinase-producing strains of *Proteus* spp.

Esters of carbenicillin, such as carfecillin (p.217) and carindacillin (p.217), have been given orally in the treatment of urinary-tract infections.

Preparations

USP 31: Carbenicillin for Injection.

Proprietary Preparations (details are given in Part 3)

Mex.: Carbecin†.

Carfecillin Sodium *(BANM, pINNM)*

BRL-3475; Carbenicillin Phenyl Sodium *(USAN)*; Carfecilina sódica; Carfécilline Sodique; Natrii Carfecillinum. Sodium (6*R*)-6-(2-phenoxycarbonyl-2-phenylacetamido)penicillanate.

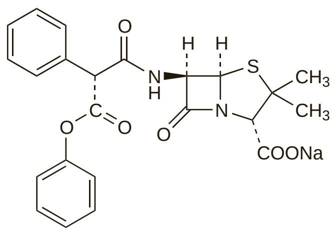
Натрий Карфециллин

$C_{23}H_{21}N_2NaO_6S$ = 476.5.

CAS — 27025-49-6 (carfecillin); 21649-57-0 (carfecillin sodium).

ATC — G01AA08.

ATC Vet — QG01AA08.



Profile

Carfecillin is the phenyl ester of carbenicillin (p.216) to which it is hydrolysed after absorption from the gastrointestinal tract. Its use has been restricted to the treatment of urinary-tract infections due to *Pseudomonas* spp. and other sensitive bacteria including *Proteus* spp.

Carindacillin Sodium *(BANM, pINNM)*

Carbenicillin Indanyl Sodium *(USAN)*; Carindacilina sódica; Carindacilline Sodique; CP-15464-2; Natrii Carindacillinum. Sodium (6*R*)-6-[2-(indan-5-yloxycarbonyl)-2-phenylacetamido]penicillanate.

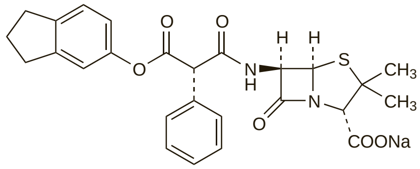
Натрий Кариндациллин

$C_{26}H_{25}N_2NaO_6S$ = 516.5.

CAS — 35531-88-5 (carindacillin); 26605-69-6 (carindacillin sodium).

ATC — J01CA05.

ATC Vet — QJ01CA05.



Pharmacopoeias. In *US*.

USP 31 (Carbenicillin Indanyl Sodium). A white to off-white powder. Soluble in water and in alcohol. pH of a 10% solution in water is between 5.0 and 8.0. Store in airtight containers.

Profile

Carindacillin is the indanyl ester of carbenicillin (p.216) to which it is hydrolysed after absorption from the gastrointestinal tract. Its use is restricted to the treatment of urinary-tract infections due to *Pseudomonas* spp. and other sensitive bacteria including *Proteus* spp.

Carindacillin is given orally as the sodium salt; 535 mg of carindacillin sodium is equivalent to about 382 mg of carbenicillin. Usual doses, expressed in terms of carbenicillin, are 382 to 764 mg four times daily.

Sodium content. Each g of carindacillin sodium contains about 1.9 mmol of sodium.

Preparations

USP 31: Carbenicillin Indanyl Sodium Tablets.

Proprietary Preparations (details are given in Part 3)
USA: Geocillin†.

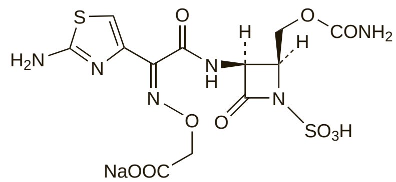
Carumonam Sodium *(BANM, USAN, rINNM)*

AMA-1080 (carumonam); Carumonam sódico; Carumonam Sodique; Natrii Carumonamum; Ro-17-2301 (carumonam); Ro-17-2301/006 (carumonam sodium). (*Z*)-(2-Aminothiazol-4-yl){[(2*S*,3*S*)-2-carbamoyloxymethyl-4-oxo-1-sulphoazetidin-3-yl]carbamoyl}methyleneamino-oxyacetic acid, disodium salt.

Натрий Карумонам

$C_{12}H_{12}N_6Na_2O_{10}S_2$ = 510.4.

CAS — 87638-04-8 (carumonam); 86832-68-0 (carumonam sodium).



(carumonam)

Pharmacopoeias. In *Jpn*.

Profile

Carumonam is a monobactam antibacterial with a spectrum of antimicrobial action *in vitro* similar to that of aztreonam (p.209). It is given by intramuscular or intravenous injection as the sodium salt and doses are expressed in terms of carumonam; 1.09 g of carumonam sodium is equivalent to about 1 g of carumonam. The usual dose is 1 to 2 g daily in two divided doses.

Sodium content. Each g of carumonam sodium contains about 3.92 mmol of sodium.

Preparations

Proprietary Preparations (details are given in Part 3)
Jpn: Amasulin.

Cefaclor *(BAN, USAN, pINN)*

Céfaclor; Cefaclorum; Cefaclorum Monohydricum; Cefaklór; Cefaklor; Cefaklor monohydrát; Cefakloras; Compound 99638; Kefakloori; Sefaklor. (7*R*)-3-Chloro-7-(α-D-phenylglycylamino)-3-cephem-4-carboxylic acid monohydrate.

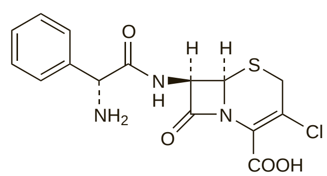
Цефаклор

$C_{15}H_{14}ClN_3O_4S,H_2O$ = 385.8.

CAS — 53994-73-3 (anhydrous cefaclor); 70356-03-5 (cefaclor monohydrate).

ATC — J01DC04.

ATC Vet — QJ01DC04.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US. Jpn* includes the anhydrous substance.

Ph. Eur. 6.2 (Cefaclor). A white or slightly yellow powder. Slightly soluble in water; practically insoluble in dichloromethane and in methyl alcohol. A 2.5% suspension in water has a pH of 3.0 to 4.5.

USP 31 (Cefaclor). A white to off-white crystalline powder. Slightly soluble in water; practically insoluble in chloroform, in methyl alcohol, and in benzene. pH of a 2.5% suspension in water is between 3.0 and 4.5. Store in airtight containers.

Adverse Effects and Precautions

As for Cefalexin, p.218.

Hypersensitivity. Serum-sickness-like reactions may be more common with cefaclor than several other oral antibacterials[1] especially in young children who have received a number of courses of cefaclor;[2] typical features include skin reactions and arthralgia. A relatively high incidence of anaphylactic reactions has been reported from Japan.[3]

There has been a report of myocarditis that developed as a hypersensitivity reaction to cefaclor in a 12-year-old child.[4]

1. McCue JD. Delayed detection of serum sickness caused by oral antimicrobials. *Adv Therapy* 1990; **7**: 22–7.
2. Vial T, *et al.* Cefaclor-associated serum sickness-like disease: eight cases and review of the literature. *Ann Pharmacother* 1992; **26:** 910–14.
3. Hama R, Mori K. High incidence of anaphylactic reactions to cefaclor. *Lancet* 1988; **i**: 1331.
4. Beghetti M, *et al.* Hypersensitivity myocarditis caused by an allergic reaction to cefaclor. *J Pediatr* 1998; **132:** 172–3.

Interactions

As for Cefalexin, p.218.

Anticoagulants. UK licensed product information recommends that monitoring of prothrombin time should be considered in patients receiving cefaclor and *warfarin* after rare reports of increased prothrombin times. It is not known whether this interaction is related to the vitamin K-related hypoprothrombinaemia observed with some cephalosporins (see Adverse Effects of Cefamandole, p.221), but cefaclor does not contain the side-chain usually implicated in this reaction.

Antimicrobial Action

Cefaclor is bactericidal and has antimicrobial activity similar to that of cefalexin (p.218) but is reported to be more active against Gram-negative bacteria including *Escherichia coli*, *Klebsiella pneumoniae*, *Neisseria gonorrhoeae*, and *Proteus mirabilis*, and especially against *Haemophilus influenzae*. It is active against some beta-lactamase-producing strains of *H. influenzae*. It may be less resistant to staphylococcal penicillinase than cefalexin or cefradine and a marked inoculum effect has been reported *in vitro*.

Pharmacokinetics

Cefaclor is well absorbed from the gastrointestinal tract. Oral doses of 250 mg, 500 mg, and 1 g produce peak plasma concentrations of about 7, 13, and 23 micrograms/mL respectively after 0.5 to 1 hour. The presence of food may delay the absorption of cefaclor, but the total amount absorbed is unchanged. A plasma half-life of 0.5 to 1 hour has been reported; it may be slightly prolonged in patients with renal impairment. About 25% is bound to plasma proteins.

Cefaclor appears to be widely distributed in the body; it crosses the placenta and low concentrations have been detected in breast milk. It is rapidly excreted by the kidneys; up to 85% of a dose appears unchanged in the urine within 8 hours, the greater part within 2 hours. High concentrations of cefaclor are achieved in the urine within 8 hours of a dose; peak concentrations of 600, 900, and 1900 micrograms/mL have been reported after doses of 0.25, 0.5, and 1 g respectively. Probenecid delays excretion. Some cefaclor is removed by haemodialysis.

2. Sourgens H, *et al.* Pharmacokinetic profile of cefaclor. *Int J Clin Pharmacol Ther* 1997; **35:** 374–80.

Uses and Administration

Cefaclor is a cephalosporin antibacterial given orally similarly to cefalexin in the treatment of susceptible infections including upper and lower respiratory-tract infections, skin infections, and urinary-tract infections. Some classify cefaclor as a second-generation cephalosporin and its greater activity against *Haemophilus influenzae* makes it more suitable than cefalexin for the treatment of infections such as otitis media. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Cefaclor is given as the monohydrate. Doses are expressed in terms of the equivalent amount of anhydrous cefaclor; 1.05 g of cefaclor monohydrate is equivalent to about 1 g of anhydrous cefaclor. The usual adult dose is 250 to 500 mg every 8 hours; up to 4 g daily has been given. A suggested dose for children over 1 month of age is 20 mg/kg daily in three divided doses, increased if necessary to 40 mg/kg daily, but not exceeding a total daily dose of 1 g. A common dosage regimen is: children over 5 years, 250 mg three times daily; 1 to 5 years, 125 mg three times daily; under 1 year, 62.5 mg three times daily.

Modified-release formulations of cefaclor are available in some countries.

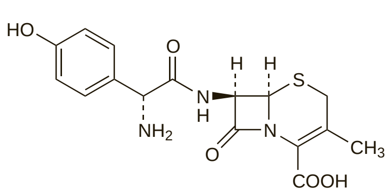
CAS — 50370-12-2 (anhydrous cefadroxil); 119922-85-9 (cefadroxil hemihydrate); 66592-87-8 (cefadroxil monohydrate).

ATC — J01DB05.

ATC Vet — QJ01DB05.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US. Jpn* includes the anhydrous substance.

Ph. Eur. 6.2 (Cefadroxil Monohydrate). A white or almost white powder. Slightly soluble in water; very slightly soluble in alcohol. A 5% suspension in water has a pH of 4.0 to 6.0. Protect from light.

USP 31 (Cefadroxil). A white to off-white crystalline powder. Slightly soluble in water; practically insoluble in alcohol, in chloroform, and in ether. pH of a 5% suspension in water is between 4.0 and 6.0. Store in airtight containers.

Adverse Effects and Precautions

As for Cefalexin, p.218.

Breast feeding. Although higher concentrations of cefadroxil were reported in breast milk compared with cefalexin, cefalotin, cefapirin, and cefotaxime,[1] no detectable cefadroxil would be expected in breast-fed infants and no adverse effects have been seen in infants whose mothers were receiving cefadroxil. Accordingly, the American Academy of Pediatrics considers[2] that cefadroxil is usually compatible with breast feeding.

2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 25/05/04)

Interactions

As for Cefalexin, p.218.

Antimicrobial Action

As for Cefalexin, p.218.

Pharmacokinetics

Cefadroxil is almost completely absorbed from the gastrointestinal tract. After oral doses of 500 mg and 1 g, peak plasma concentrations of about 16 and 30 micrograms/mL respectively are obtained after 1.5 to 2 hours. Although peak concentrations are similar to those of cefalexin, plasma concentrations are more sustained. Dosage with food does not appear to affect the absorption of cefadroxil. About 20% of cefadroxil is reported to be bound to plasma proteins. The plasma half-life of cefadroxil is about 1.5 hours and is prolonged in patients with renal impairment.

Cefadroxil is widely distributed to body tissues and fluids. It crosses the placenta and appears in breast milk.

More than 90% of a dose of cefadroxil may be excreted unchanged in the urine within 24 hours by glomerular filtration and tubular secretion; peak urinary concentrations of 1.8 mg/mL have been reported after a dose of 500 mg. Cefadroxil is removed by haemodialysis.

◊ References.

3. Garrigues TM, *et al.* Dose-dependent absorption and elimination of cefadroxil in man. *Eur J Clin Pharmacol* 1991; **41**: 179–83.

Uses and Administration

Cefadroxil is a first-generation cephalosporin antibacterial that is the para-hydroxy derivative of cefalexin (p.219), and is used similarly in the treatment of mild to moderate susceptible infections. It is given orally, and doses are expressed in terms of the anhydrous substance; 1.04 g of cefadroxil monohydrate is equivalent to about 1 g of anhydrous cefadroxil. The usual adult dose is 1 to 2 g daily as a single dose or in two divided doses. The following doses are used in children weighing less than 40 kg: 500 mg twice daily for those over 6 years of age, 250 mg twice daily for those aged 1 to 6 years, and 25 mg/kg daily in divided doses for infants under 1 year. For details of reduced doses of cefadroxil in patients with renal impairment, see below.

Cefadroxil has also been used as the lysine derivative.

Administration in renal impairment. Following an initial loading dose of 0.5 to 1 g, dosage of cefadroxil should be adjusted in patients with renal impairment according to creatinine clearance (CC):

- CC 26 to 50 mL/minute per 1.73 m^2: 0.5 to 1 g every 12 hours
- CC 11 to 25 mL/minute per 1.73 m^2: 0.5 to 1 g every 24 hours
- CC 10 mL/minute per 1.73 m^2 or less: 0.5 to 1 g every 36 hours.

Porphyria. Cefalexin is considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity.

Interactions

The renal excretion of cefalexin, and many other cephalosporins, is delayed by probenecid.

Hormonal contraceptives. There have been isolated reports of cefalexin decreasing the efficacy of oestrogen-containing oral contraceptives.[1] For a discussion of decreased efficacy of oral contraceptives and the need for additional contraceptive methods in patients taking broad-spectrum antibacterials, see under Hormonal Contraceptives, p.2068.

1. Friedman M, *et al.* Cephalexin and Microgynon-30 do not go well together. *J Obstet Gynaecol* 1982; **2**: 195–6.

Antimicrobial Action

As for Cefalotin Sodium, p.220, although cefalexin is generally less potent. Some strains of Gram-negative bacteria may be inhibited only by the high concentrations achievable in the urinary tract. *Haemophilus influenzae* is moderately resistant to cefalexin.

Pharmacokinetics

Cefalexin is almost completely absorbed from the gastrointestinal tract and produces a peak plasma concentration of about 18 micrograms/mL 1 hour after a 500-mg oral dose. If cefalexin is taken with food, absorption may be delayed, but the total amount absorbed is not appreciably altered. Up to 15% of a dose is bound to plasma proteins. The plasma half-life is about 1 hour; it increases with reduced renal function.

Cefalexin is widely distributed in the body but does not enter the CSF in significant quantities. It crosses the placenta and small quantities are found in breast milk. Cefalexin is not metabolised. About 80% or more of a dose is excreted unchanged in the urine in the first 6 hours by glomerular filtration and tubular secretion; urinary concentrations greater than 1 mg/mL have been achieved after a dose of 500 mg. Probenecid delays urinary excretion. Therapeutically effective concentrations may be found in the bile and some may be excreted by this route.

Cefalexin is removed by haemodialysis and peritoneal dialysis.

◊ References.

1. Wise R. The pharmacokinetics of the oral cephalosporins—a review. *J Antimicrob Chemother* 1990; **26** (suppl E): 13–20.

Uses and Administration

Cefalexin is a first-generation cephalosporin antibacterial. It is given orally for the treatment of susceptible infections including those of the respiratory and urinary tracts and of the skin (see under Choice of Antibacterial, p.162). For severe infections, treatment with parenteral cephalosporins is to be preferred.

Cefalexin is usually given as the monohydrate although the hydrochloride is sometimes used. Doses are expressed in terms of the equivalent amount of anhydrous cefalexin; 1.05 g of cefalexin monohydrate and 1.16 g of cefalexin hydrochloride are each equivalent to about 1 g of anhydrous cefalexin.

The usual dose for adults is 1 to 2 g daily given in divided doses at 6-, 8-, or 12-hourly intervals; in severe or deep-seated infections the dose can be increased to up to 6 g daily but when high doses are required the use of a parenteral cephalosporin should be considered. Children may be given 25 to 100 mg/kg daily in divided doses to a maximum of 4 g daily.

For the prophylaxis of recurrent urinary-tract infection, cefalexin may be given in a dose of 125 mg at night.

Cefalexin sodium or cefalexin lysine have been used parenterally.

The dose of cefalexin may need to be reduced in renal impairment, see below.

Administration in renal impairment. Doses of cefalexin may need to be reduced in patients with renal impairment. The *BNF* recommends the following maximum daily doses according to creatinine clearance (CC):

- CC 40 to 50 mL/minute: maximum 3 g daily
- CC 10 to 40 mL/minute: maximum 1.5 g daily
- CC less than 10 mL/minute: maximum 750 mg daily

Preparations

Cefalonium *(BAN, pINN)*

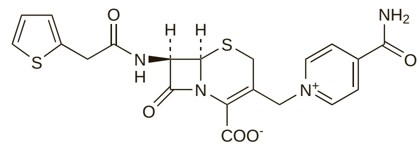
41071; Carbamoylcefaloridine; Cefalonio; Céfalonium; Cephalonium. (7*R*)-3-(4-Carbamoyl-1-pyridiniomethyl)-7-[2-(2-thienyl)-acetamido]-3-cephem-4-carboxylate.

Цефалоний

$C_{20}H_{18}N_4O_5S_2$ = 458.5.

CAS — 5575-21-3.

ATC Vet — QJ51DA90.



Pharmacopoeias. *BP(Vet)* includes the dihydrate.

BP(Vet) 2008 (Cefalonium). The dihydrate is a white or almost white crystalline powder. Very slightly soluble in water and in methyl alcohol; insoluble in alcohol, in dichloromethane, and in ether; soluble in dimethyl sulfoxide. It dissolves in dilute acids and in alkaline solutions. Store at temperature not exceeding 30°. Protect from light.

Profile

Cefalonium is a cephalosporin antibacterial used in veterinary practice.

Cefaloridine *(BAN, pINN)*

40602; Cefaloridin; Cefaloridina; Céfaloridine; Cefaloridinum; Cephaloridine *(USAN)*; Kefaloridiini. (7*R*)-3-(1-Pyridiniomethyl)-7-[(2-thienyl)acetamido]-3-cephem-4-carboxylate.

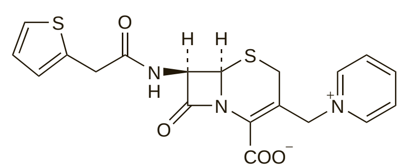
Цефалоридин

$C_{19}H_{17}N_3O_4S_2$ = 415.5.

CAS — 50-59-9.

ATC — J01DB02.

ATC Vet — QJ01DB02.



Profile

Cefaloridine was one of the first cephalosporin antibacterials to be available clinically. It has properties similar to those of cefalotin (below), but is more nephrotoxic and is seldom used now.

Cefalotin Sodium *(BANM, pINNM)*

38253; Cefalotin sodná sůl; Cefalotina sódica; Céfalotine sodique; Cefalotinnatrium; Cefalotin-nátrium; Cefalotino natrio druska; Cefalotinum natricum; Cefalotyna sodowa; Cephalothin Sodium *(USAN)*; Kefalotiininatrium; Natrii Cefalotinum; Sodium Cephalothin. Sodium (7*R*)-7-[2-(2-thienyl)acetamido]cephalosporanate; Sodium (7*R*)-3-acetoxymethyl-7-[2-(2-thienyl)acetamido]-3-cephem-4-carboxylate.

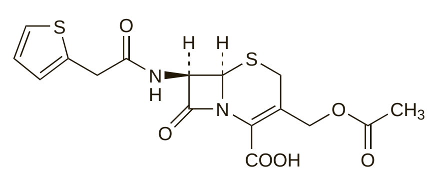
Натрий Цефалотин

$C_{16}H_{15}N_2NaO_6S_2$ = 418.4.

CAS — 153-61-7 (cefalotin); 58-71-9 (cefalotin sodium).

ATC — J01DB03.

ATC Vet — QJ01DB03.



(cefalotin)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Cefalotin Sodium). A white or almost white powder. Freely soluble in water; slightly soluble in dehydrated alcohol. A 10% solution in water has a pH of 4.5 to 7.0. Protect from light.

USP 31 (Cephalothin Sodium). A white to off-white, practically odourless, crystalline powder. Freely soluble in water, in sodium chloride 0.9%, and in glucose solutions; insoluble in most organic solvents. pH of a 25% solution in water is between 4.5 and 7.0. Store in airtight containers.

Incompatibility and stability. Cefalotin sodium has been reported to be incompatible with aminoglycosides and with many other drugs. Precipitation may occur in solutions with a pH of less than 5.

Adverse Effects

The adverse effects associated with cefalotin and other cephalosporins are broadly similar to those described for penicillins (see Benzylpenicillin, p.213). The most common are hypersensitivity reactions, including skin rashes, urticaria, eosinophilia, fever, reactions resembling serum sickness, and anaphylaxis.

There may be a positive response to the Coombs' test although haemolytic anaemia rarely occurs. Neutropenia and thrombocytopenia have occasionally been reported. Agranulocytosis has been associated rarely with some cephalosporins. Bleeding complications related to hypoprothrombinaemia and/or platelet dysfunction have occurred especially with cephalosporins and cephamycins having an *N-methylthiotetrazole* side-chain, including

- cefamandole
- cefbuperazone
- cefmenoxime
- cefmetazole
- cefonicid
- cefoperazone
- ceforanide
- cefotetan
- cefpiramide
- latamoxef.

The presence of a *methylthiadiazolethiol* side-chain, as in cefazolin, or an *N-methylthiotriazine* ring, as in ceftriaxone, might also be associated with such bleeding disorders. Hypoprothrombinaemia which is usually reversible with vitamin K, was once thought to be due to an alteration in intestinal flora but interference with prothrombin synthesis now seems more likely.

Nephrotoxicity has been reported with cefalotin although it is less toxic than cefaloridine. Acute renal tubular necrosis has followed excessive dosage and has also been associated with its use in older patients or those with pre-existing renal impairment, or when used with nephrotoxic drugs such as aminoglycosides. Acute interstitial nephritis is also a possibility as a manifestation of hypersensitivity.

Transient increases in liver enzyme values have been reported. Hepatitis and cholestatic jaundice have occurred rarely with some cephalosporins.

Convulsions and other signs of CNS toxicity have been associated with high doses, especially in patients with severe renal impairment.

Gastrointestinal adverse effects such as nausea, vomiting, and diarrhoea have been reported rarely. Prolonged use may result in overgrowth of non-susceptible organisms and, as with other broad-spectrum antibiotics, pseudomembranous colitis may develop (see also below).

There may be pain at the injection site after intramuscular use, and thrombophlebitis has occurred on intravenous infusion of cephalosporins. Cefalotin appears to be more likely to cause such local reactions than other cephalosporins.

Antibiotic-associated colitis. Pseudomembranous colitis has occurred with many antibacterials, including broad-spectrum cephalosporins.[1-3] In 1991 the UK CSM warned[4] of the dangers of pseudomembranous colitis with the newer, as well as the older, oral cephalosporins. In addition to 33 reports of pseudomembranous colitis associated with cefalexin, cefradine, cefadroxil, and cefaclor, 6 of which proved fatal, they had received 12 reports of probable or confirmed cases with cefuroxime axetil and 15 with cefixime, one of them fatal. In clinical trials of cefuroxime axetil and cefixime, diarrhoea and pseudomembranous colitis appeared to be dose-related and therefore the CSM recommended that higher doses should be reserved for severe infections. In any event they advised that treatment should be stopped if symptoms suggestive of pseudomembranous colitis arose.

For further discussion of the management of this condition, see p.171.

Precautions

Cefalotin should not be given to patients who are hypersensitive to it or to other cephalosporins. Immunological studies have suggested that up to 20% of penicillin-sensitive patients may also be allergic to cephalosporins although clinical studies indicate a lower frequency and the true incidence is uncertain; great care should be taken if cefalotin is to be given to such patients. Care is also necessary in patients with a history of allergy.

Cefalotin should be given with caution to patients with renal impairment; dosage reduction may be necessary. Renal and haematological status should be monitored especially during prolonged and high-dose therapy. Cefalotin and some other cephalosporins and cephamycins (ceforanide, cefotetan, cefoxitin, and cefpirome) may interfere with the Jaffé method of measuring creatinine concentrations and may produce falsely high values; this should be borne in mind when measuring renal function. Positive results to the direct Coombs' test have been found during treatment with cefalotin and these can interfere with blood cross-matching. The urine of patients being treated with cefalotin may give false-positive reactions for glucose using copper-reduction reactions.

Porphyria. Cephalosporins are considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity.

Sodium content. Each g of cefalotin sodium contains about 2.39 mmol of sodium.

Interactions

The use of nephrotoxic drugs such as the aminoglycosides gentamicin and tobramycin may increase the risk of kidney damage with cefalotin. There is also some evidence for enhanced nephrotoxicity with the loop diuretic furosemide, but this is less certain than for furosemide with cefaloridine. As with penicillins, the renal excretion of cefalotin and many other cephalosporins is inhibited by probenecid. There may be antagonism between cefalotin and bacteriostatic antibacterials.

Antimicrobial Action

Cefalotin is a beta-lactam antibacterial. It is bactericidal and acts similarly to benzylpenicillin (p.214) by inhibiting synthesis of the bacterial cell wall. It is most active against Gram-positive cocci, and has moderate activity against some Gram-negative bacilli.

Sensitive Gram-positive cocci include both penicillinase- and non-penicillinase-producing staphylococci, although meticillin-resistant staphylococci are resistant; most streptococci are also sensitive, but not penicillin-resistant *Streptococcus pneumoniae;* enterococci are usually resistant. Some Gram-positive anaerobes are also susceptible. Cefalotin is usually inactive against *Listeria monocytogenes*.

Among Gram-negative bacteria cefalotin has activity against some Enterobacteriaceae including strains of *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus mirabilis*, *Salmonella*, and *Shigella* spp., but not against *Enterobacter*, indole-positive *Proteus*, or *Serratia* spp. It is also active against *Moraxella catarrhalis* (*Branhamella catarrhalis*) and *Neisseria* spp., though *Haemophilus influenzae* is moderately resistant. *Bacteroides fragilis* and *Pseudomonas aeruginosa* are not sensitive and neither are mycobacteria, mycoplasma, and fungi.

Resistance of bacteria to cefalotin may be due to several mechanisms: the drug may be prevented from reaching its site of action, for example in some Gram-negative organisms the cell wall may be a potential barrier; the target penicillin-binding proteins may be altered so that cefalotin cannot bind with these proteins; or, most importantly, the organism may produce beta-lactamases (cephalosporinases). Cefalotin is relatively resistant to hydrolysis by staphylococcal beta-lactamase, but is inactivated by a variety of beta-lactamases produced by Gram-negative organisms; resistance of Gram-negative organisms often depends on more than one factor. Resistance can be chromosomally or plasmid-mediated and may sometimes be inducible by cephalosporins.

Certain strains of bacteria may be inhibited but not killed by cephalosporins or penicillins and in such cases the minimum bactericidal concentration is much greater than the minimum inhibitory concentration; this is known as tolerance.

As well as with other cephalosporins, some cross-resistance may occur between cefalotin and the penicillinase-resistant penicillins.

Pharmacokinetics

Cefalotin is poorly absorbed from the gastrointestinal tract. After intramuscular injection peak plasma concentrations of about 10 and 20 micrograms/mL are achieved within 30 minutes of doses of 0.5 and 1 g, respectively. A concentration of 30 micrograms/mL has been reported 15 minutes after the intravenous injection of a 1-g dose; a range of 14 to 20 micrograms/mL has been achieved by the continuous intravenous infusion of 500 mg/hour.

Cefalotin is widely distributed in body tissues and fluids except the brain and CSF where the concentrations achieved are low and unpredictable. It crosses the placenta and low concentrations have been detected in breast milk. The plasma half-life varies from about 30 to 50 minutes, but may be longer in patients with renal impairment, especially that of the metabolite. About 70% of cefalotin is bound to plasma proteins.

About 20 to 30% of cefalotin is rapidly deacetylated in the liver and about 60 to 70% of a dose is excreted in the urine by the renal tubules within 6 hours as cefalotin and the less active metabolite, desacetylcefalotin. High urine concentrations of 0.8 and 2.5 mg/mL have been observed after intramuscular doses of 0.5 and 1 g, respectively. Probenecid blocks the renal excretion of cefalotin. A very small amount is excreted in bile.

Uses and Administration

Cefalotin is a first-generation cephalosporin antibacterial that has been used in the treatment of infections due to susceptible bacteria, particularly staphylococci, but has generally been replaced by newer cephalosporins.

Cefalotin is given as the sodium salt by slow intravenous injection over 3 to 5 minutes or by intermittent or continuous infusion. It may be given intramuscularly but this route is painful. Doses are expressed in terms of the equivalent amount of cefalotin; 1.06 g of cefalotin sodium is equivalent to about 1 g of cefalotin. The usual dose is 0.5 to 1 g of cefalotin every 4 to 6 hours; up to 12 g daily has been given in severe infections.

Administration in renal impairment. Reduced doses are recommended if cefalotin is given to patients with renal impairment. After an intravenous loading dose of 1 to 2 g patients may be given the following maximum doses according to their creatinine clearance (CC):

- CC 50 to 80 mL/minute: 2 g every 6 hours
- CC 25 to 50 mL/minute: 1.5 g every 6 hours
- CC 10 to 25 mL/minute: 1 g every 6 hours
- CC 2 to 10 mL/minute: 500 mg every 6 hours
- CC less than 2 mL/minute: 500 mg every 8 hours

Цефамандола Нафат

$C_{19}H_{17}N_6NaO_6S_2$ = 512.5.
CAS — 42540-40-9.
ATC — J01DC03.
ATC Vet — QJ01DC03.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Cefamandole Nafate). A white, or almost white powder. Freely soluble in water; sparingly soluble in methyl alcohol. A 10% solution in water has a pH, measured after 30 minutes, of 6.0 to 8.0. Store in airtight containers. Protect from light.

USP 31 (Cefamandole Nafate). A white, odourless, crystalline solid. Soluble in water and in methyl alcohol; practically insoluble in chloroform, in cyclohexane, in ether, and in benzene. pH of a 10% solution in water is between 3.5 and 7.0. Store in airtight containers.

Incompatibility and stability. Cefamandole nafate has been reported to be incompatible with aminoglycosides and with metronidazole. Formulations of cefamandole nafate available for injection contain sodium carbonate and are incompatible with solutions containing calcium or magnesium salts. When reconstituted with water the sodium carbonate rapidly hydrolyses about 30% of the ester to cefamandole sodium; during storage of the reconstituted solution at room temperature carbon dioxide is produced.

Cefamandol sódico; Céfamandole Sodique; Cephamandole Sodium; Natrii Cefamandolum.

Натрий Цефамандол

$C_{18}H_{17}N_6NaO_5S_2$ = 484.5.
CAS — 30034-03-8.
ATC — J01DC03.
ATC Vet — QJ01DC03.

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219.

As mentioned under Cefalotin, cephalosporins with an *N*-methylthiotetrazole side-chain such as cefamandole (and possibly those with methylthiadiazolethiol or *N*-methylthiotriazine side-chains as well) may produce bleeding disorders associated with hypoprothrombinaemia and/or platelet disorders.

Sodium content. 1.05 g of cefamandole sodium and 1.11g of cefamandole nafate each contain about 2.2 mmol of sodium.

Interactions

A disulfiram-like interaction with alcohol may occur and has been attributed to the *N*-methylthiotetrazole side-chain of cefamandole; patients should avoid alcohol during, and for at least several days after, cefamandole treatment. Interactions are also possible with preparations containing significant amounts of alcohol.

Cefamandole, and other cephalosporins with an *N*-methylthiotetrazole side-chain, may enhance the hypoprothrombinaemic response to anticoagulants as discussed under Warfarin (p.1428).

Probenecid reduces the renal clearance of cefamandole and many other cephalosporins.

◊ References.

2. Drummer S, *et al.* Antabuse-like effect of β-lactam antibiotics. *N Engl J Med* 1980; **303:** 1417–18.

Antimicrobial Action

Cefamandole is bactericidal and acts similarly to cefalotin, but has a broader spectrum of activity. It generally has similar or less activity against Gram-positive staphylococci and streptococci, but is resistant to some beta-lactamases produced by Gram-negative bacteria. It is more active than cefalotin against many of the Enterobacteriaceae including some strains of *Enterobacter, Escherichia coli, Klebsiella, Salmonella*, and some *Proteus* spp. However, resistance to cefamandole and other beta lactams has emerged in some species, notably *Enterobacter*, during treatment with cefamandole. Cefamandole is very active *in vitro* against *Haemophilus influenzae* although an inoculum effect has been reported for beta-lactamase-producing strains. Like cefalotin, most strains of *Bacteroides fragilis* are resistant to cefamandole, as are *Pseudomonas* spp.

◊ References.

1. Sabath LD. Reappraisal of the antistaphylococcal activities of first-generation (narrow-spectrum) and second-generation (expanded-spectrum) cephalosporins. *Antimicrob Agents Chemother* 1989; **33:** 407–11.

Pharmacokinetics

Cefamandole is poorly absorbed from the gastrointestinal tract. It is given intramuscularly or intravenously, usually as the nafate which is rapidly hydrolysed to release cefamandole *in vivo*. Peak plasma concentrations for cefamandole of about 13 and 25 micrograms/mL have been achieved 0.5 to 2 hours after intramuscular doses of 0.5 and 1 g respectively; concentrations are very low after 6 hours. About 70% is bound to plasma proteins. The plasma half-life varies from about 0.5 to 1.2 hours depending on the route of injection; it is prolonged in patients with renal impairment.

Cefamandole is widely distributed in body tissues and fluids including bone, joint fluid, and pleural fluid; it diffuses into the CSF when the meninges are inflamed, but concentrations are unpredictable. Cefamandole has also been detected in breast milk. It is rapidly excreted unchanged by glomerular filtration and renal tubular secretion; about 80% of a dose is excreted within 6 hours and high urinary concentrations are achieved. Probenecid competes for renal tubular secretion with cefamandole resulting in higher and prolonged plasma concentrations of cefamandole. Therapeutic concentrations of cefamandole are achieved in bile.

Cefamandole is removed by haemodialysis to some extent.

Uses and Administration

Cefamandole is a second-generation cephalosporin antibacterial used in the treatment of infections due to susceptible bacteria and for surgical infection prophylaxis.

It is given principally as cefamandole nafate (the sodium salt of cefamandole formyl ester). Doses are expressed in terms of the equivalent amount of cefamandole; 1.05 g of cefamandole sodium and 1.11 g of cefamandole nafate are each equivalent to about 1 g of cefamandole. It is given by deep intramuscular injection, by slow intravenous injection over 3 to 5 minutes, or by intermittent or continuous infusion in doses of 0.5 to 2 g every 4 to 8 hours for adults depending on the severity of the infection. Children over 1 month of age may be given 50 to 100 mg/kg daily in equally divided doses; 150 mg/kg daily may be given in severe infections, but this dose should not be exceeded. For details of reduced doses in patients with renal impairment, see below. If cefamandole is used with an aminoglycoside, the drugs should be given separately.

For surgical infection prophylaxis, a dose of 1 or 2 g intravenously or intramuscularly 30 to 60 minutes before surgical incision, followed by 1 or 2 g every 6 hours for 24 to 48 hours, is recommended. For patients undergoing procedures involving implantation of prosthetic devices, cefamandole should be continued for up to 72 hours. Children over 3 months of age may be treated similarly to adults and given 50 to 100 mg/kg daily in equally divided doses.

Administration in renal impairment. Doses of cefamandole should be reduced for patients with renal impairment. After an initial dose of 1 to 2 g the following maintenance doses have been recommended based on creatinine clearance (CC):

- CC 50 to 80 mL/minute: 0.75 to 2 g every 6 hours
- CC 25 to 50 mL/minute: 0.75 to 2 g every 8 hours
- CC 10 to 25 mL/minute: 0.5 to 1.25 g every 8 hours
- CC 2 to 10 mL/minute: 0.5 to 1 g every 12 hours
- CC less than 2 mL/minute: 0.25 to 0.75 g every 12 hours

Preparations

USP 31: Cefamandole Nafate for Injection.

Proprietary Preparations (details are given in Part 3)

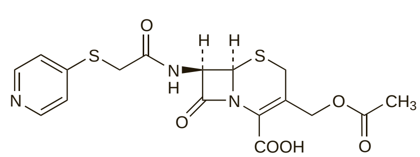
Cefapirin Sodium *(BANM, pINNM)*

BL-P-1322; Cefapirin sodná sůl; Cefapirina sódica; Céfapirine sodique; Cefapirinnatrium; Cefapirin-nátrium; Cefapirino natrio druska; Cefapirinum natricum; Cephapirin Sodium *(USAN)*; Kefapiriininatrium; Natrii Cefapirinum. Sodium (7*R*)-7-[2-(4-pyridylthio)acetamido]cephalosporanate; Sodium (7*R*)-3-acetoxymethyl-7-[2-(4-pyridylthio)acetamido]-3-cephem-4-carboxylate.

Натрий Цефапирин

$C_{17}H_{16}N_3NaO_6S_2$ = 445.4.
CAS — 21593-23-7 (cefapirin); 24356-60-3 (cefapirin sodium).
ATC — J01DB08.
ATC Vet — QJ01DB08.



(cefapirin)

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US*.
US also includes Cephapirin Benzathine for veterinary use.

Ph. Eur. 6.2 (Cefapirin Sodium). A white or pale yellow powder. Soluble in water; practically insoluble in dichloromethane. A 1% solution in water has a pH of 6.5 to 8.5. Protect from light.

USP 31 (Cephapirin Sodium). A white to off-white crystalline powder, odourless or having a slight odour. Very soluble in water; insoluble in most organic solvents. pH of a solution in water containing the equivalent of cefapirin 1% is between 6.5 and 8.5. Store in airtight containers.

Profile

Cefapirin is a first-generation cephalosporin antibacterial with actions and uses very similar to those of cefalotin (p.219). It is used as the sodium salt but doses are expressed in terms of cefapirin base; 1.05 g of cefapirin sodium is equivalent to about 1 g of cefapirin. The usual dose is the equivalent of 0.5 to 1 g of cefapirin every 4 to 6 hours by intramuscular injection or intravenously. In severe infections up to 12 g daily may be given, preferably intravenously.

Administration in renal impairment. Reduced doses of cefapirin sodium may be necessary in patients with renal impairment. One regimen, based on creatinine clearance (CC), that has been suggested is:

- CC 5 to 20 mL/minute: 1 g every 12 hours
- CC less than 5 mL/minute: 1 g every 24 hours

Patients undergoing haemodialysis may receive 7.5 to 15 mg/kg after each dialysis.

Sodium content. Each g of cefapirin sodium contains about 2.2 mmol of sodium.

Preparations

USP 31: Cephapirin for Injection.

Proprietary Preparations (details are given in Part 3)
Cz.: Cefatrexyl†; ***Fr.:*** Cefaloject; ***Gr.:*** Cefatrex†; ***Spain:*** Brisfirina.

Cefatrizine *(BAN, USAN, pINN)*

BL-S640; Cefatrizina; Céfatrizine; Cefatrizinum; SKF-60771; S-640P. (7*R*)-7-(α-D-4-Hydroxyphenylglycylamino)-3-(1*H*-1,2,3-triazol-4-ylthiomethyl)-3-cephem-4-carboxylic acid.

Цефатризин

$C_{18}H_{18}N_6O_5S_2$ = 462.5.
CAS — 51627-14-6.
ATC — J01DB07.
ATC Vet — QJ01DB07.

(7*R*)-7-(α-D-4-Hydroxyphenylglycylamino)-3-(1*H*-1,2,3-triazol-4-ylthiomethyl)-3-cephem-4-carboxylate propylene glycol.

Цефатризин Пропиленгликол

$C_{18}H_{18}N_6O_5S_2$, $(C_3H_8O_2)_n$.
CAS — 64217-62-5.
ATC — J01DB07.
ATC Vet — QJ01DB07.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn*.

Ph. Eur. 6.2 (Cefatrizine Propylene Glycol). A white or almost white powder. Slightly soluble in water; practically insoluble in alcohol and in dichloromethane.

Profile

Cefatrizine is a cephalosporin antibacterial with actions and uses similar to those of cefalexin (p.218), although it might be more active *in vitro*. It is given orally as the base or, more often, as a compound with propylene glycol, in usual doses equivalent to 500 mg twice daily of cefatrizine.

Preparations

Proprietary Preparations (details are given in Part 3)
Belg.: Cefaperos; ***Fr.:*** Cefaperos†; ***Gr.:*** Anfagladin; Axelorax; Banadroxin†; Ceftazin; Cetrizin; Clomin†; Fica-F; Gertemycin; Izerin; Kentacef; Klevasin; Liamycin; Liferost; Lingopen; Mekan†; Nibocin; Northiron; Phacobiotic†; Relyovix; Specicef-N; Trixilan; ***Ital.:*** Biotrixina†; Cefatrix†; Cetrazil†; Cetrinox†; Faretrizin; Ipatrizina†; Ketrizin; Miracef†; Novacef†; Tamyl†; Tricef†; Trizina; ***Port.:*** Macropen; Supracefa.

Cefazolin *(BAN, pINN)*

Cefazolina; Céfazoline; Cefazolinum; Cephazolin; Kefatsoliini; Sefazolin. 3-[(5-Methyl-1,3,4-thiadiazol-2-yl)thiomethyl]-7-(tetrazol-1-ylacetamido)-3-cephem-4-carboxylic acid.

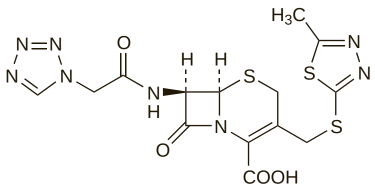
Цефазолин

$C_{14}H_{14}N_8O_4S_3$ = 454.5.

CAS — 25953-19-9.

ATC — J01DB04.

ATC Vet — QJ01DB04; QJ51DA04.



Pharmacopoeias. In *US.*

USP 31 (Cefazolin). A white to slightly off-white, odourless crystalline powder. Slightly soluble in water, in alcohol, and in methyl alcohol; sparingly soluble in acetone; practically insoluble in chloroform, in dichloromethane, in ether, and in benzene; soluble in dimethylformamide and in pyridine; very slightly soluble in ethyl acetate, in isopropyl alcohol, and in methyl isobutyl ketone. Store in airtight containers.

Cefazolin Sodium *(BANM, USAN, pINNM)*

46083; Cefazolin sodná sůl; Cefazolina sódica; Céfazoline sodique; Cefazolinnatrium; Cefazolin-nátrium; Cefazolino natrio druska; Cefazolinum natricum; Cephazolin Sodium; Kefatsoliininatrium; Natrii Cefazolinum; Sefazolin Sodyum; SKF-41558.

Натрий Цефазолин

$C_{14}H_{13}N_8NaO_4S_3$ = 476.5.

CAS — 27164-46-1.

ATC — J01DB04.

ATC Vet — QJ01DB04.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Jpn also includes the pentahydrate.

Ph. Eur. 6.2 (Cefazolin Sodium). A white or almost white, very hygroscopic powder. It exhibits polymorphism. Freely soluble in water; very slightly soluble in alcohol. A 10% solution in water has a pH of 4.0 to 6.0. Store in airtight containers. Protect from light.

USP 31 (Cefazolin Sodium). A white to off-white, practically odourless, crystalline powder, or a white to off-white solid. Freely soluble in water, in sodium chloride 0.9%, and in glucose solutions; very slightly soluble in alcohol; practically insoluble in chloroform and in ether. pH of a solution in water containing the equivalent of cefazolin 10% is between 4.0 and 6.0. Store in airtight containers.

Incompatibility and stability. Cefazolin sodium has been reported to be incompatible with aminoglycosides and many other drugs. When the pH of a solution exceeds 8.5 there may be hydrolysis and when it is below 4.5 insoluble cefazolin may be precipitated.

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219. Stevens-Johnson syndrome has occurred.

Like cephalosporins with an *N*-methylthiotetrazole side-chain, cefazolin has been associated with hypoprothrombinaemia.

Breast feeding. In a study[1] of 20 lactating women receiving cefazolin, the amount of cefazolin in breast milk was found to be extremely small (equivalent to less than 0.075% of the dose). No adverse effects have been seen in breast-fed infants whose mothers were receiving cefazolin, and the American Academy of Pediatrics considers[2] that it is therefore usually compatible with breast feeding.

Sodium content. Each g of cefazolin sodium contains about 2.1 mmol of sodium.

Interactions

Cefazolin contains a methylthiadiazolethiol side-chain; like cephalosporins containing the related *N*-methylthiotetrazole side-chain (see Cefamandole, p.221), it may have the potential to cause a disulfiram-like reaction with alcohol, and enhance the effects of warfarin.

The renal excretion of cefazolin and many other cephalosporins is delayed by probenecid.

Antimicrobial Action

As for Cefalotin Sodium, p.220, although cefazolin is more sensitive to staphylococcal beta-lactamase.

Pharmacokinetics

Cefazolin is poorly absorbed from the gastrointestinal tract and is given by the intramuscular or intravenous routes. After a 500-mg dose given intramuscularly, peak plasma concentrations of 30 micrograms or more per mL are obtained after 1 hour. About 85% of cefazolin is bound to plasma proteins. The plasma half-life of cefazolin is about 1.8 hours, and is increased in patients with renal impairment. Cefazolin diffuses into bone and into ascitic, pleural, and synovial fluid but not appreciably into the CSF. It crosses the placenta; only low concentrations are detected in breast milk.

Cefazolin is excreted unchanged in the urine, mainly by glomerular filtration with some renal tubular secretion, at least 80% of a dose given intramuscularly being excreted within 24 hours. Peak urine concentrations of more than 2 and 4 mg/mL have been reported after intramuscular doses of 0.5 and 1 g respectively. Probenecid delays excretion. Cefazolin is removed to some extent by haemodialysis.

High biliary concentrations have been reported, although the amount excreted by this route is small.

Uses and Administration

Cefazolin is a first-generation cephalosporin antibacterial used to treat infections due to susceptible organisms, including biliary-tract infections, endocarditis (staphylococcal), and peritonitis (associated with continuous ambulatory peritoneal dialysis). It is also used for surgical infection prophylaxis, including prophylaxis of endometritis at caesarean section. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Administration and dosage. Cefazolin is given as the sodium salt by deep intramuscular injection, by slow intravenous injection over 3 to 5 minutes, or by intravenous infusion. Doses are expressed in terms of the equivalent amount of cefazolin; 1.05 g of cefazolin sodium is equivalent to about 1 g of cefazolin. The usual adult dose is the equivalent of 0.5 to 1 g of cefazolin every 6 to 12 hours. The usual maximum daily dose is 6 g, although up to 12 g has been used in severe life-threatening infections. Children over 1 month of age may be given 25 to 50 mg/kg daily in 3 or 4 divided doses, increased in severe infections to a maximum of 100 mg/kg daily.

For the prophylaxis of infection during surgery, a 1-g dose is given half to one hour before the operation, followed by 0.5 to 1 g during surgery for lengthy procedures. A dose of 0.5 to 1 g is given every 6 to 8 hours postoperatively for 24 hours, or up to 5 days in certain cases.

For details of reduced doses of cefazolin in patients with renal impairment, see below.

Other routes used for cefazolin sodium include intraperitoneal use in peritoneal dialysis solutions, and intra-ocular injection.

In some countries a modified-release intramuscular formulation of cefazolin sodium with the less soluble dibenzylamine salt of cefazolin, in the ratio of 1:4, has been used.

Administration in renal impairment. Dosage of cefazolin should be reduced in patients with renal impairment and various modifications have been recommended. After a loading dose the licensed product information suggests the following doses based on creatinine clearance (CC):

Adults

- CC 55 mL or more per minute: usual doses
- CC 35 to 54 mL/minute: usual doses but at intervals of at least 8 hours
- CC 11 to 34 mL/minute: half the usual dose every 12 hours
- CC 10 mL or less per minute: half the usual dose every 18 to 24 hours

Children

- CC 40 to 70 mL/minute: 60% of the normal daily dose in 2 divided doses
- CC 20 to 40 mL/minute: 25% of the normal daily dose in 2 divided doses
- CC 5 to 20 mL/minute: 10% of the normal daily dose every 24 hours.

One report[1] indicated that, for patients on long-term haemodialysis, a dose of 20 mg/kg given 3 times weekly after dialysis maintained therapeutic cefazolin concentrations.

Натрий Цефбуперазон

$C_{22}H_{28}N_9NaO_9S_2$ = 649.6.

Pharmacopoeias. In *Jpn.*

Profile

Cefbuperazone is a cephamycin antibiotic similar to cefoxitin (p.230) but with an *N*-methylthiotetrazole side-chain like cefamandole (p.220). It is given by injection as the sodium salt. Its spectrum of activity includes Enterobacteriaceae, but more especially anaerobic bacteria such as *Bacteroides fragilis.* Cefbuperazone does not appear to be active against cefoxitin-resistant strains of *B. fragilis.*

Preparations

Proprietary Preparations (details are given in Part 3)
Jpn: Tomiporan.

Cefcapene Pivoxil Hydrochloride *(rINNM)*

Cefcapène Pivoxil, Chlorhydrate de; Cefcapeni Pivoxili Hydrochloridum; Hidrocloruro de cefcapeno pivoxilo. Cefdinir *(BAN, USAN, rINN)*

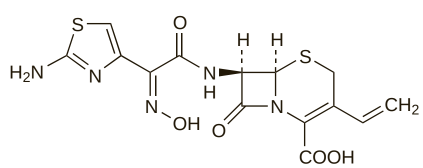
Cefdinirum; CI-983; FK-482; Kefdiniiri. (−)-(6*R*,7*R*)-7-[2-(2-Amino-4-thiazolyl)glyoxylamido]-8-oxo-3-vinyl-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid, 7^2-(*Z*)-oxime; 7-{(2-Amino-1,3-thiazol-4-yl)-2-[(*Z*)-hydroxyimino]acetamido}-3-vinylcephem-4-carboxylic acid.

Цефдинир

$C_{14}H_{13}N_5O_5S_2 = 395.4.$

CAS — 91832-40-5.
ATC — J01DD15.
ATC Vet — QJ01DD15.



Pharmacopoeias. In *Chin.* and *Jpn.*

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219. There have been reports of reddish stools in patients given cefdinir with iron supplements (see also Interactions, below).

Interactions

Absorption of cefdinir is decreased by antacids or iron supplements and doses should be separated by an interval of at least 2 hours. Probenecid reduces the renal excretion of cefdinir.

Iron. A report[1] of red stools in an infant given cefdinir whilst being fed with an infant formula containing supplemental iron. It was considered important to be aware of the interaction because of the risk that it might be mistaken for a sign of gastrointestinal bleeding.

1. Lancaster J, *et al.* Nonbloody, red stools from coadministration of cefdinir and iron-supplemented infant formulas. *Pharmacotherapy* 2008; **28:** 678–81.

Antimicrobial Action

As for Cefixime, p.224. However, cefdinir is reported to be much more active *in vitro* than cefixime against *Staphylococcus aureus*, but not meticillin-resistant strains, and it is less active against some Enterobacteriaceae.

Pharmacokinetics

Cefdinir is absorbed from the gastrointestinal tract after oral doses, peak plasma concentrations occurring 2 to 4 hours after a dose. Oral bioavailability has been estimated to range from 16 to 25%. It is widely distributed into tissues and is 60 to 70% bound to plasma proteins. Cefdinir is not appreciably metabolised and is excreted in the urine with an elimination half-life of 1.7 hours. Cefdinir is removed by dialysis.

Uses and Administration

Cefdinir is a third-generation oral cephalosporin antibacterial with actions and uses similar to those of cefixime (p.224). It is given orally in a usual adult dose of 600 mg daily as a single dose or in two divided doses. Children may be given 14 mg/kg daily up to a maximum of 600 mg daily. Doses may need to be reduced in patients with renal impairment (see below).

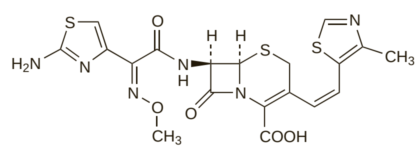
Cefditoren Pivoxil *(rINNM)*

Cefditorène, Pivoxil de; Cefditoreni Pivoxil; Cefditoreno pivoxilo; ME-1207; ME-1206 (cefditoren). Pivaloyloxymethyl (+)-(6*R*,7*R*)-7-[2-(2-Amino-4-thiazolyl)glyoxylamido]-3-[(*Z*)-2-(4-methyl-5-thiazolyl)vinyl]-8-oxo-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid 7^2-(*Z*)-(*O*-methyloxime).

Цефдиторена Пивоксил

$C_{25}H_{28}N_6O_7S_3 = 620.7.$

CAS — 104145-95-1 (cefditoren); 117467-28-4 (cefditoren pivoxil).
ATC — J01DD16.
ATC Vet — QJ01DD16.



(cefditoren)

Pharmacopoeias. In *Jpn.*

Adverse Effects and Precautions

As for Cefalotin, p.219.

The most frequently reported adverse effects of cefditoren are gastrointestinal disturbances, especially diarrhoea.

For reference to carnitine deficiency with some pivaloyloxymethyl esters, see Pivampicillin, p.317.

Interactions

Absorption of cefditoren after oral doses is decreased by antacids or histamine H_2-receptor antagonists. Probenecid reduces the renal excretion of cefditoren.

Antimicrobial Action

As for Cefixime, p.224. Cefditoren also has activity against *Staphylococcus aureus.*

Pharmacokinetics

Cefditoren pivoxil is absorbed from the gastrointestinal tract and is hydrolysed to cefditoren by esterases to release active cefditoren in the bloodstream. Peak plasma concentrations average 1.8 micrograms/mL in fasting subjects 1.5 to 3 hours after a 200-mg dose. Bioavailability is about 14% in fasting subjects and is increased when cefditoren pivoxil is given with a high-fat meal. Plasma protein binding is reported to be 88%. The plasma half-life is about 1.6 hours and is prolonged in patients with renal impairment.

Cefditoren is not appreciably metabolised and is excreted mainly in the urine by glomerular filtration and tubular secretion. It is removed by haemodialysis.

Uses and Administration

Cefditoren is a cephalosporin antibacterial with a broad spectrum of activity used in the treatment of susceptible infections, particularly of the respiratory tract and skin. It is given orally as the pivaloyloxymethyl ester, cefditoren pivoxil, but doses are expressed in terms of cefditoren; 245 mg of cefditoren pivoxil is equivalent to about 200 mg of cefditoren. A usual dose is 200 to 400 mg given twice daily.

For details of reduced doses to be used in patients with moderate to severe renal impairment, see below.

◊ Reviews.

1. Wellington K, Curran MP. Cefditoren pivoxil: a review of its use in the treatment of bacterial infections. *Drugs* 2004; **64:** 2597–2618.

Administration in renal impairment. Doses of cefditoren pivoxil should be reduced in patients with moderate to severe renal impairment according to creatinine clearance (CC):

- CC 30 to 49 mL/minute: the dose should not exceed 200 mg twice daily
- CC less than 30 mL/minute: the dose should be 200 mg once daily.

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219.

◊ The safety of cefepime has been reviewed.[1-3] A meta-analysis[2] of studies involving cefepime suggested that there might be an increased risk of all-cause mortality compared with other beta-lactams. The FDA subsequently announced that it would review safety data to further evaluate the risk of death associated with cefepime use.[4]

Antimicrobial Action

Cefepime is a fourth-generation cephalosporin and is active against a wide range of Gram-positive and Gram-negative aerobic organisms. Against Gram-positive cocci, its activity is similar to that of cefotaxime (p.228) and includes staphylococci (but not meticillin-resistant *Staphylococcus aureus*) and streptococci. Against Enterobacteriaceae, it has a broader spectrum of activity than other cephalosporins, including activity against organisms producing chromosomally mediated beta-lactamases such as *Enterobacter* spp. and *Proteus vulgaris*. Against *Pseudomonas aeruginosa*, it has similar or slightly less activity than ceftazidime (p.234), although it may be active against some strains resistant to ceftazidime.

Pharmacokinetics

Cefepime is given by injection as the hydrochloride. It is rapidly and almost completely absorbed on intramuscular injection and mean peak plasma concentrations of about 14 and 30 micrograms/mL have been reported about 1.5 hours after doses of 500 mg and 1 g respectively. Within 30 minutes of similar intravenous doses, peak plasma concentrations of about 40 and 80 micrograms/mL are achieved. The plasma half-life of cefepime is about 2 hours and is prolonged in patients with renal impairment. About 20% of cefepime is bound to plasma proteins.

Cefepime is widely distributed in body tissues and fluids. High concentrations are achieved in bile. Low concentrations have been detected in breast milk.

Cefepime is eliminated principally by the kidneys and about 85% of a dose is recovered unchanged in the urine. Cefepime is substantially removed by haemodialysis.

Uses and Administration

Cefepime is a fourth-generation cephalosporin antibacterial used in the treatment of infections due to susceptible organisms. They include infections of the urinary tract, respiratory tract, and skin. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Cefepime is given as the hydrochloride by deep intramuscular injection, or intravenously by infusion over at least 30 minutes. Doses are expressed in terms of the equivalent amount of cefepime; 1.19 g of cefepime hydrochloride is equivalent to about 1 g of cefepime. The usual adult dose is 1 to 2 g daily in 2 divided doses for mild to moderate infections, increased to 4 g daily in 2 divided doses in severe infections, although up to 6 g daily in 3 divided doses has been given for febrile neutropenia. Children aged over 2 months and weighing up to 40 kg may be given 50 mg/kg twice daily; this dose may be given 3 times daily for febrile neutropenia.

For details of reduced doses to be used in renal impairment, see below.

◊ Reviews.

1. Various. Cefepime: a β-lactamase-stable extended-spectrum cephalosporin. *J Antimicrob Chemother* 1993; **32** (suppl B): 1–214.

6. Roberts JA, *et al.* Cefepime versus ceftazidime: considerations for empirical use in critically ill patients. *Int J Antimicrob Agents* 2007; **29:** 117–28.

Administration in renal impairment. Dosage of cefepime should be modified in renal impairment. After a normal first dose the maintenance dosage should be adjusted according to the patient's creatinine clearance (CC) and the severity of the infection:

- CC 30 to 60 mL/minute: 0.5 to 2 g every 24 hours (2 g every 12 hours for febrile neutropenia)
- CC 11 to 29 mL/minute: 0.5 to 1 g every 24 hours (2 g every 24 hours for febrile neutropenia)
- CC 10 mL/minute or less: 250 to 500 mg every 24 hours (1 g every 24 hours for febrile neutropenia)

Patients undergoing haemodialysis should be given a dose of 1 g on the first day of treatment, followed by 500 mg daily; the dose should be given after haemodialysis on those days. A dose of 1 g daily should be used for febrile neutropenia. Patients undergoing continuous ambulatory peritoneal dialysis should receive normal recommended doses at intervals of 48 hours. A dose of 2 g every 48 hours is used for febrile neutropenia.

Цефетамета Пивоксила Гидрохлорид

$C_{20}H_{25}N_5O_7S_2,HCl$ = 548.0.
CAS — 65243-33-6 (cefetamet pivoxil); 111696-23-2 (cefetamet pivoxil hydrochloride).
ATC — J01DD10.
ATC Vet — QJ01DD10.

Profile

Cefetamet is a third-generation cephalosporin antibacterial similar to cefixime (below). It has been given orally as the hydrochloride of the pivaloyloxymethyl ester, cefetamet pivoxil hydrochloride, which is hydrolysed to cefetamet *in vivo*. The usual dose is 500 mg twice daily.

For reference to carnitine deficiency occurring with some pivaloyloxymethyl esters, see Pivampicillin, p.317.

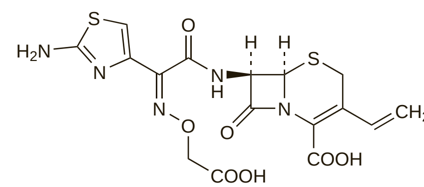
Cefiksimas; Cefixim; Cefixim trihydrát; Cefixima; Céfixime; Cefiximum; Cefiximum Trihydricum; CL-284635; FK-027; FR-17027; Kefiksiimi; Sefiksim. (*Z*)-7-[2-(2-Aminothiazol-4-yl)-2-(carboxymethoxyimino)acetamido]-3-vinyl-3-cephem-4-carboxylic acid trihydrate.

Цефиксим

$C_{16}H_{15}N_5O_7S_2,3H_2O$ = 507.5.
CAS — 79350-37-1.
ATC — J01DD08.
ATC Vet — QJ01DD08.



Pharmacopoeias. In *Eur.* (see p.vii) and *US. Jpn* includes the anhydrous substance.

Ph. Eur. 6.2 (Cefixime). A white or almost white, slightly hygroscopic, powder. Slightly soluble in water; sparingly soluble in dehydrated alcohol; practically insoluble in ethyl acetate; freely soluble in methyl alcohol. A 5% suspension in water has a pH of 2.6 to 4.1. Store in airtight containers. Protect from light.

USP 31 (Cefixime). A white to light yellow crystalline powder. Practically insoluble in water, in ether, in ethyl acetate, and in hexane; slightly soluble in alcohol, in acetone, and in glycerol; soluble in methyl alcohol and in propylene glycol; very slightly soluble in 70% sorbitol and in octanol. pH of a solution in water containing the equivalent of cefixime 0.07% is between 2.6 and 4.1. Store in airtight containers.

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219.

The most frequently reported adverse effects of cefixime are gastrointestinal disturbances, especially diarrhoea. Cefixime should be stopped if diarrhoea is severe.

Although cefixime does not have the *N*-methylthiotetrazole side-chain usually associated with hypoprothrombinaemia increases in prothrombin times have occurred in a few patients.

Antibiotic-associated colitis. For reports of diarrhoea and pseudomembranous colitis associated with cefixime, see Cefalotin, p.219.

Interactions

Care should be exercised in patients receiving anticoagulants and cefixime due to the possibility that cefixime may increase prothrombin times (see above).

Antimicrobial Action

Cefixime is bactericidal and is stable to hydrolysis by many beta-lactamases. It has a mode of action and spectrum of activity similar to those of the third-generation cephalosporin cefotaxime (p.228), but some Enterobacteriaceae are less susceptible to cefixime. *Haemophilus influenzae*, *Moraxella catarrhalis* (*Branhamella catarrhalis*), and *Neisseria gonorrhoeae* are sensitive, including penicillinase-producing strains. Of the Gram-positive bacteria, streptococci are sensitive to cefixime but most strains of staphylococci, enterococci, and *Listeria* spp. are not.

Enterobacter spp., *Pseudomonas aeruginosa*, and *Bacteroides* spp. are resistant to cefixime.

Pharmacokinetics

Only 40 to 50% of an oral dose of cefixime is absorbed from the gastrointestinal tract, whether taken before or after meals, although the rate of absorption may be decreased in the presence of food. Cefixime is better absorbed from oral suspension than from tablets. Absorption is fairly slow; peak plasma concentrations of 2 to 3 micrograms/mL and 3.7 to 4.6 micrograms/mL have been reported between 2 and 6 hours after single doses of 200 and 400 mg, respectively. The plasma half-life is usually about 3 to 4 hours and may be prolonged when there is renal impairment. About 65% of cefixime is bound to plasma proteins.

Information on the distribution of cefixime in body tissues and fluids is limited. It crosses the placenta. Relatively high concentrations may be achieved in bile and urine. About 20% of an oral dose (or 50% of an absorbed dose) is excreted unchanged in the urine within 24 hours. Up to 60% may be eliminated by nonrenal mechanisms; there is no evidence of metabolism but some is probably excreted into the faeces from bile. It is not substantially removed by dialysis.

6. Somekh E, *et al*. Penetration and bactericidal activity of cefixime in synovial fluid. *Antimicrob Agents Chemother* 1996; **40:** 1198–1200.

Uses and Administration

Cefixime is generally classified as a third-generation cephalosporin antibacterial and is given orally in the treatment of susceptible infections including gonorrhoea, otitis media, pharyngitis, lower respiratory-tract infections such as bronchitis, and urinary-tract infections. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Cefixime is available as the trihydrate and doses are expressed in terms of anhydrous cefixime; 1.12 g of cefixime trihydrate is equivalent to about 1 g of anhydrous cefixime. It is given orally in adult doses of 200 to 400 mg daily as a single dose or in two divided doses. Children over 6 months and under 50 kg may be given 8 mg/kg daily as an oral suspension, again as a single dose or in two divided doses. For details of reduced dosage of cefixime in patients with moderate to severe renal impairment, see below.

For uncomplicated gonorrhoea, a single oral dose of 400 mg is given.

Натрий Цефметазол

$C_{15}H_{16}N_7NaO_5S_3$ = 493.5.

CAS — 56796-39-5.

ATC — J01DC09.

ATC Vet — QJ01DC09.

Pharmacopoeias. In *Jpn* and *US*.

USP 31 (Cefmetazole Sodium). A white solid. Very soluble in water and in methyl alcohol; soluble in acetone; practically insoluble in chloroform. pH of a 10% solution in water is between 4.2 and 6.2. Store in airtight containers.

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219.

Cefmetazole contains an *N*-methylthiotetrazole side-chain and has the potential to cause hypoprothrombinaemia and bleeding.

Effects on the blood. References.

1. Breen GA, St Peter WL. Hypoprothrombinemia associated with cefmetazole. *Ann Pharmacother* 1997; **31:** 180–4.

Sodium content. Each g of cefmetazole sodium contains about 2 mmol of sodium.

Interactions

As for Cefamandole, p.221.

Antimicrobial Action

Cefmetazole is a cephamycin antibacterial with a similar spectrum of antibacterial activity to that of cefoxitin (p.230), including the anaerobe *Bacteroides fragilis*.

◊ References.

1. Cornick NA, *et al*. Activity of cefmetazole against anaerobic bacteria. *Antimicrob Agents Chemother* 1987; **31**: 2010–12.

Pharmacokinetics

After cefmetazole sodium 2 g intravenously every 6 hours, peak and trough plasma concentrations of 138 and 6 micrograms/mL have been achieved. Cefmetazole is 65 to 85% bound to plasma proteins, depending on the plasma concentration. A plasma half-life of about 1.1 to 1.5 hours has been reported; it is prolonged in patients with renal impairment. Small amounts have been detected in breast milk. Relatively high concentrations have been achieved in bile.

The majority of a dose is excreted unchanged in the urine resulting in high concentrations; up to 85% of a dose has been recovered within 12 hours. Cefmetazole is partly excreted by renal tubular secretion and probenecid prolongs elimination.

Cefmetazole is removed to some extent by haemodialysis.

Uses and Administration

Cefmetazole is a cephamycin antibacterial generally classified with the second-generation cephalosporins and used similarly to cefoxitin (p.230) in the treatment and prophylaxis of anaerobic and mixed bacterial infections, especially intra-abdominal and pelvic infections. It may also be used in the treatment of gonorrhoea. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Cefmetazole is given intravenously as the sodium salt by infusion over 10 to 60 minutes or by slow injection over 3 to 5 minutes. Cefmetazole sodium is also used intramuscularly in some countries. Doses are expressed in terms of the equivalent amount of cefmetazole; 1.05 g of cefmetazole sodium is equivalent to about 1 g of cefmetazole.

The usual dose is 0.5 to 1 g intramuscularly or intravenously every 12 hours. For severe infections the dose may be increased to 3 to 4 g daily, given in divided doses every 6 to 8 hours.

For details of reduced dosage of cefmetazole in patients with renal impairment, see below.

◊ References.

1. Finch R, *et al*. eds. Cefmetazole: a clinical appraisal. *J Antimicrob Chemother* 1989; **23** (suppl D): 1–142.

Administration in renal impairment. Doses of cefmetazole should be reduced in patients with renal impairment. It has been suggested that the interval between doses should be 12, 16, or 24 hours in patients with mild, moderate, or severe renal impairment, respectively; patients with virtually no renal function might be given cefmetazole every 48 hours, after haemodialysis.

Preparations

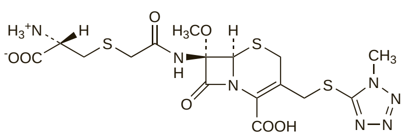
Cefminox Sodium *(pINNM)*

Cefminox sódico; Cefminox Sodique; MT-141; Natrii Cefminoxum. Sodium 7-{2-[(*S*)-2-amino-2-carboxyethyl]thioacetamido}-7-methoxy-3-(1-methyl-1*H*-tetrazol-5-ylthiomethyl)-3-cephem-4-carboxylate.

Натрий Цефминокс

$C_{16}H_{20}N_7NaO_7S_3$ = 541.6.

CAS — 75481-73-1 (cefminox).



(cefminox)

Pharmacopoeias. *Jpn* includes the heptahydrate.

Profile

Cefminox sodium is a cephamycin antibacterial with properties similar to those of cefoxitin (p.230) but with an *N*-methylthiotetrazole side-chain like cefamandole (p.220). It is given intravenously as the sodium salt but doses are expressed in terms of cefminox; 1.04 g of cefminox sodium is equivalent to about 1 g of cefminox. A usual dose is 2 to 4 g daily given in divided doses.

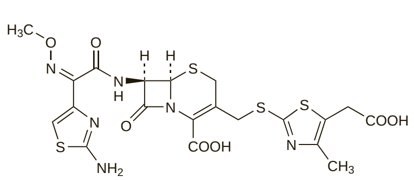
CAS — 69739-16-8 (cefodizime); 86329-79-5 (cefodizime sodium).

ATC — J01DD09.

ATC Vet — QJ01DD09.



(cefodizime)

Pharmacopoeias. In *Jpn.*

Adverse Effects and Precautions

As for Cefotaxime, p.228.

Sodium content. Each g of cefodizime sodium contains about 3.2 mmol of sodium.

Interactions

Probenecid reduces the renal clearance of cefodizime.

Antimicrobial Action

Cefodizime has similar antimicrobial activity to that of cefotaxime (p.228) although cefodizime has no active metabolite. It has variable activity against *Citrobacter* spp., and *Pseudomonas aeruginosa* and *Bacteroides fragilis* are generally resistant.

Pharmacokinetics

Cefodizime is given by injection as the sodium salt. Intramuscular injection of 1 g cefodizime produces peak plasma concentrations of about 60 to 75 micrograms/mL at about 1 to 1.5 hours. Immediately after intravenous doses of 1 or 2 g cefodizime mean peak plasma concentrations of 215 and 394 micrograms/mL, respectively, have been achieved. Cefodizime is about 80% bound to plasma proteins and is widely distributed into body tissues and fluids. It crosses the placenta and small amounts have been detected in breast milk. Plasma elimination is reported to be triphasic with a terminal elimination half-life of about 4 hours. The half-life is prolonged by renal impairment.

The majority of a dose is excreted unchanged in the urine; up to 80% of a dose has been recovered within 24 hours. Cefodizime is mainly excreted by glomerular filtration with some tubular secretion. Probenecid delays excretion. Cefodizime is removed by dialysis.

Uses and Administration

Cefodizime is a third-generation cephalosporin antibacterial with uses similar to those of cefotaxime (p.229).

Cefodizime is given as the disodium salt by intramuscular injection or intravenously by injection or infusion in the treatment of susceptible infections. Doses are expressed in terms of the equivalent amount of cefodizime; 1.08 g of cefodizime sodium is equivalent to about 1 g of cefodizime. Adults are usually given 1 to 2 g every 12 or 24 hours for lower respiratory-tract infections and upper and lower urinary-tract infections. Doses up to 4 g daily may be given in severe infection. In women with uncomplicated lower urinary-tract infections a single dose of 1 to 2 g may be sufficient. For gonorrhoea a single dose of 0.25 to 0.5 g may be given. Doses may need to be reduced in patients with renal impairment (see below).

4. Matsumoto T, *et al.* Single dose of cefodizime completely eradicated multidrug-resistant strain of Neisseria gonorrhoeae in urethritis and uterine cervicitis. *J Infect Chemother* 2006; **12:** 97–9.
5. Matsumoto T, *et al.* Multiple doses of cefodizime are necessary for the treatment of Neisseria gonorrhoeae pharyngeal infection. *J Infect Chemother* 2006; **12:** 145–7.

Administration in renal impairment. Doses of cefodizime should be reduced in patients with renal impairment according to creatinine clearance (CC):

- CC 10 to 30 mL/minute: 1 to 2 g daily
- CC less than 10 mL/minute: 0.5 to 1 g daily

In patients undergoing dialysis, 0.5 to 1 g daily is given after dialysis.

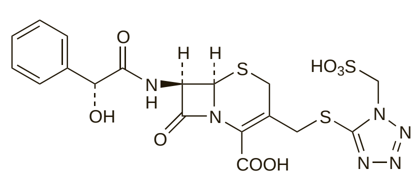
CAS — 61270-58-4 (cefonicid); 61270-78-8 (cefonicid disodium); 71420-79-6 (cefonicid monosodium).

ATC — J01DC06.

ATC Vet — QJ01DC06.



(cefonicid)

Pharmacopoeias. In *US.*

USP 31 (Cefonicid Sodium). A white to off-white solid. Freely soluble in water, in sodium chloride 0.9%, and in glucose 5%; very slightly soluble in dehydrated alcohol; soluble in methyl alcohol. pH of a 5% solution in water is between 3.5 and 6.5. Store in airtight containers.

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219.

Cefonicid contains a substituted *N*-methylthiotetrazole side-chain, a structure associated with hypoprothrombinaemia.

Effects on the blood. References.

1. Riancho JA, *et al.* Life-threatening bleeding in a patient treated with cefonicid. *Ann Intern Med* 1995; **123:** 472–3.

Effects on the liver. References.

1. Famularo G, *et al.* Eosinophilic hepatitis associated with cefonicid therapy. *Ann Pharmacother* 2001; **35:** 1669–71.

Sodium content. Each g of cefonicid sodium contains about 3.4 mmol of sodium.

Interactions

As for Cefamandole, p.221.

Antimicrobial Action

Cefonicid sodium has an antimicrobial action and pattern of resistance similar to those of cefamandole (p.221), although it is generally less active against Gram-positive cocci.

Pharmacokinetics

Cefonicid is given parenterally as the sodium salt. Peak plasma concentrations ranging from 67 to 126 micrograms/mL have been achieved 1 to 2 hours after a 1-g intramuscular dose. Cefonicid is more than 90% bound to plasma proteins. It has a plasma half-life of about 4.5 hours, which is prolonged in patients with renal impairment.

Therapeutic concentrations of cefonicid have been reported in a wide range of body tissues and fluids.

Up to 99% of a dose of cefonicid is excreted unchanged in the urine within 24 hours. Probenecid reduces excretion of cefonicid.

Uses and Administration

Cefonicid is a second-generation cephalosporin antibacterial used similarly to cefamandole (p.221) in the treatment of susceptible infections and for surgical infection prophylaxis.

It is given as the sodium salt by deep intramuscular injection, or intravenously by slow injection over 3 to 5 minutes or by infusion. Doses are expressed in terms of the equivalent amount of cefonicid; 1.08 g of cefonicid sodium is equivalent to about 1 g of cefonicid. The usual dose is cefonicid 1 g once daily. For uncomplicated urinary-tract infections, a dose of 500 mg once daily is recommended; up to 2 g once daily has been given in severe infections. More than 1 g should not be injected intramuscularly into a single site.

For surgical infection prophylaxis, a single dose of 1 g given 1 hour before surgical incision is usually sufficient, but may be given daily for a further 2 days in prosthetic arthroplasty or open-heart surgery.

◊ References.

1. Saltiel E, Brogden RN. Cefonicid: a review of its antibacterial activity, pharmacological properties and therapeutic use. *Drugs* 1986; **32:** 222–59.

Administration in renal impairment. For patients with renal impairment a loading dose equivalent to cefonicid 7.5 mg/kg is recommended, followed by reduced maintenance doses according to the creatinine clearance and the severity of the infection. A dose supplement is not required after dialysis.

Cefoperazone Sodium

(BANM, USAN, rINNM)

Cefoperazon sodná sůl; Cefoperazon sodowy; Cefoperazona sódica; Céfopérazone sodique; Cefoperazonnatrium; Cefoperazon-nátrium; Cefoperazono natrio druska; Cefoperazonum natricum; CP-52640-2; CP-52640 (anhydrous cefoperazone); CP-52640-3 (cefoperazone dihydrate); Kefoperatsoninatrium; Natrii Cefoperazonum; Sefoperazon Sodyum; T-1551 (cefoperazone or cefoperazone sodium). Sodium (7*R*)-7-[(*R*)-2-(4-ethyl-2,3-dioxopiperazin-1-ylcarboxamido)-2-(4-hydroxyphenyl)acetamido]-3-[(1-methyl-1*H*-tetrazol-5-yl)thiomethyl]-3-cephem-4-carboxylate.

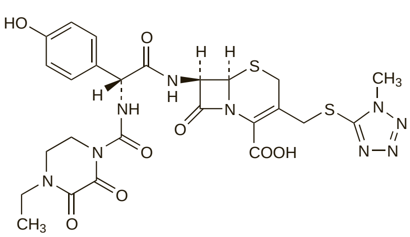
Натрий Цефоперазон

$C_{25}H_{26}N_9NaO_8S_2$ = 667.6.

CAS — 62893-19-0 (cefoperazone); 62893-20-3 (cefoperazone sodium).

ATC — J01DD12.

ATC Vet — QJ01DD12.



(cefoperazone)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US*.

Ph. Eur. 6.2 (Cefoperazone Sodium). A white or slightly yellow, hygroscopic, powder. If crystalline it exhibits polymorphism. Freely soluble in water; slightly soluble in alcohol; soluble in methyl alcohol. A 25% solution in water has a pH of 4.5 to 6.5. Store in airtight containers at a temperature of 2° to 8°. Protect from light.

USP 31 (Cefoperazone Sodium). A white to pale buff crystalline powder. Freely soluble in water and in methyl alcohol; slightly soluble in dehydrated alcohol; insoluble in acetone, in ether, and in ethyl acetate. pH of a 25% solution in water is between 4.5 and 6.5. Store in airtight containers.

Incompatibility. As with most beta lactams, admixture of cefoperazone sodium with aminoglycosides is not recommended because of the potential for inactivation of either drug.

There have been reports of incompatibility with other drugs including diltiazem,[1] doxorubicin,[2] pentamidine,[3] perphenazine,[4] pethidine,[5] promethazine,[6] and remifentanil.[7]

5. Nieves-Cordero AL, *et al*. Compatibility of narcotic analgesic solutions with various antibiotics during simulated Y-site injection. *Am J Hosp Pharm* 1985; **42:** 1108–9.
6. Scott SM. Incompatibility of cefoperazone and promethazine. *Am J Hosp Pharm* 1990; **47:** 519.
7. Trissel LA, *et al*. Compatibility of remifentanil hydrochloride with selected drugs during simulated Y-site administration. *Am J Health-Syst Pharm* 1997; **54:** 2192–6.

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219.

Like cefotaxime (p.228), cefoperazone has the potential for colonisation and superinfection with resistant organisms. Changes in bowel flora may be more marked than with cefotaxime because of the greater biliary excretion of cefoperazone; diarrhoea may occur more often.

Cefoperazone contains an *N*-methylthiotetrazole side-chain, a structure associated with hypoprothrombinaemia. Hypoprothrombinaemia has been reported in patients treated with cefoperazone and has rarely been associated with bleeding episodes. Prothrombin time should be monitored in patients at risk of hypoprothrombinaemia and vitamin K used if necessary.

Sodium content. Each g of cefoperazone sodium contains about 1.5 mmol of sodium.

Interactions

As for Cefamandole, p.221.

Unlike many other cephalosporins, probenecid has no effect on the renal clearance of cefoperazone.

Antimicrobial Action

Cefoperazone has antimicrobial activity similar to that of ceftazidime (p.234), although it is slightly less active against some Enterobacteriaceae. It has good activity against *Pseudomonas aeruginosa*, but is less active than ceftazidime.

Cefoperazone is more susceptible than cefotaxime to hydrolysis by certain beta-lactamases.

Activity, particularly against Enterobacteriaceae and *Bacteroides* spp. has been enhanced in the presence of the beta-lactamase inhibitor sulbactam; resistant *Ps. aeruginosa* are not sensitive to the combination.

◊ References.

1. Fass RJ, *et al*. In vitro activities of cefoperazone and sulbactam singly and in combination against cefoperazone-resistant members of the family Enterobacteriaceae and nonfermenters. *Antimicrob Agents Chemother* 1990; **34:** 2256–9.
2. Clark RB, *et al*. Multicentre study on antibiotic susceptibilities of anaerobic bacteria to cefoperazone-sulbactam and other antimicrobial agents. *J Antimicrob Chemother* 1992; **29:** 57–67.

Pharmacokinetics

Cefoperazone is given parenterally as the sodium salt. With intramuscular doses equivalent to cefoperazone 1 or 2 g, peak plasma concentrations of 65 and 97 micrograms/mL have been reported after 1 to 2 hours. The plasma half-life of cefoperazone is about 2 hours, but may be prolonged in neonates and in patients with hepatic or biliary-tract disease. Cefoperazone is 82 to 93% bound to plasma proteins, depending on the concentration.

Cefoperazone is widely distributed in body tissues and fluids, although penetration into the CSF is generally poor. It crosses the placenta, and low concentrations have been detected in breast milk.

Cefoperazone is excreted mainly in the bile where it rapidly achieves high concentrations. Urinary excretion is primarily by glomerular filtration. Up to 30% of a dose is excreted unchanged in the urine within 12 to 24 hours; this proportion may be increased in patients with hepatic or biliary disease. Cefoperazone A, a degradation product less active than cefoperazone, has been found only rarely *in vivo*.

Uses and Administration

Cefoperazone is a third-generation cephalosporin antibiotic used similarly to ceftazidime (p.235) in the treatment of susceptible infections, especially those due to *Pseudomonas* spp. It is not recommended for the treatment of meningitis because of poor penetration into the CSF.

Cefoperazone is given as the sodium salt by deep intramuscular injection or intravenously by intermittent or continuous infusion. Doses are expressed in terms of the equivalent amount of cefoperazone; 1.03 g of cefoperazone sodium is equivalent to about 1 g of cefoperazone. The usual dose is 2 to 4 g daily in 2 divided doses. In severe infections, up to 12 g daily in 2 to 4 divided doses may be given.

For details of dosage in patients with hepatic and renal impairment, see below.

If cefoperazone is used with an aminoglycoside, the drugs should be given separately.

Cefoperazone has also been given with the beta-lactamase inhibitor sulbactam.

Administration in hepatic and renal impairment. In general, the dose of cefoperazone should not exceed 4 g daily in patients with liver disease or biliary obstruction or 1 to 2 g daily in those with both hepatic and renal impairment; if higher doses are used plasma concentrations of cefoperazone should be monitored.

Ceforanide *(BAN, USAN, rINN)*

BL-S786; Ceforanida; Céforanide; Ceforanidum. 7-[2-(α-Amino-o-tolyl)acetamido]-3-(1-carboxymethyl-1*H*-tetrazol-5-ylthiomethyl)-3-cephem-4-carboxylic acid.

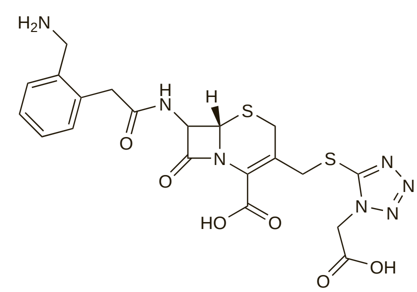
Цефоранид

$C_{20}H_{21}N_7O_6S_2$ = 519.6.

CAS — 60925-61-3.

ATC — J01DC11.

ATC Vet — QJ01DC11.



Pharmacopoeias. In *US*.

USP 31 (Ceforanide). A white to off-white powder. Practically insoluble in water, in chloroform, in ether, and in methyl alcohol; very soluble in 1N sodium hydroxide. pH of a 5% suspension in water is between 2.5 and 4.5. Store in airtight containers.

Profile

Ceforanide is a second-generation cephalosporin antibacterial with actions and uses similar to those of cefamandole (p.220), although it is reported to be less active *in vitro* against some bacteria, including staphylococci and *Haemophilus influenzae.* It is used in the treatment of susceptible infections and for surgical infection prophylaxis.

It is given as the lysine salt ($C_{26}H_{35}N_9O_8S_2$ = 665.7) but doses are expressed in terms of the equivalent amount of ceforanide; 1.28 g of ceforanide lysine is equivalent to about 1 g of ceforanide. It is given by deep intramuscular injection, or intravenously by slow injection over 3 to 5 minutes or by infusion. The usual adult dose is 1 to 2 g every 12 hours. Children may be given 20 mg/kg daily in 2 divided doses. For surgical infection prophylaxis, a dose of 1 to 2 g intravenously 1 hour before surgical incision is used in adults.

Ceforanide contains a substituted *N*-methylthiotetrazole side-chain, a structure associated with hypoprothrombinaemia and alcohol intolerance. Probenecid does not affect the renal excretion of ceforanide.

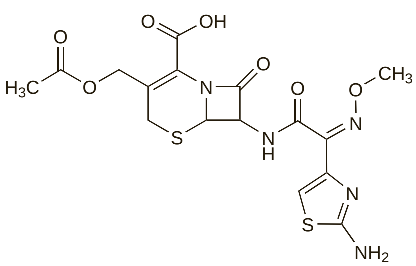
ATC — J01DD01.
ATC Vet — QJ01DD01.



(cefotaxime)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Cefotaxime Sodium). A white or slightly yellow, hygroscopic, powder. Freely soluble in water; sparingly soluble in methyl alcohol. A 10% solution in water has a pH of between 4.5 and 6.5. Store in airtight containers. Protect from light.

USP 31 (Cefotaxime Sodium). An off-white to pale yellow crystalline powder. Freely soluble in water; practically insoluble in organic solvents. pH of a 10% solution in water is between 4.5 and 6.5. Store in airtight containers.

Incompatibility. Cefotaxime sodium has been reported to be incompatible with alkaline solutions such as sodium bicarbonate. Licensed product information recommends that it should be given separately from aminoglycosides.

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219. Arrhythmias have been associated with rapid bolus dosage through a central venous catheter in a few cases.

The broad-spectrum third-generation cephalosporins have the potential for colonisation and superinfection with resistant organisms such as *Pseudomonas aeruginosa*, *Enterobacter* spp., *Candida*, and enterococci, at various sites in the body, although the incidence has generally been low with cefotaxime. Changes in bowel flora are a predisposing factor and have been more marked with cefoperazone and ceftriaxone, possibly because of their greater biliary excretion. Pseudomembranous colitis, associated with *Clostridium difficile* infection, may occasionally be seen with any of the third-generation cephalosporins.

◊ Reviews on adverse effects associated with third-generation cephalosporins.

1. Neu HC. Third generation cephalosporins: safety profiles after 10 years of clinical use. *J Clin Pharmacol* 1990; **30:** 396–403.
2. Fekety FR. Safety of parenteral third-generation cephalosporins. *Am J Med* 1990; **88** (suppl 4A): 38S–44S.

Antibiotic-associated colitis. It has been suggested[1] that cefotaxime is associated with an increased risk of *Clostridium difficile* diarrhoea in elderly patients; however, the manufacturer[2] has disputed this, arguing that cefotaxime compares favourably with alternative third-generation cephalosporins.

Sodium content. Each g of cefotaxime sodium contains about 2.09 mmol of sodium.

Interactions

As for many cephalosporins, probenecid reduces the renal clearance of cefotaxime, resulting in higher and prolonged plasma concentrations of cefotaxime and its desacetyl metabolite.

Antibacterials. The total body clearance of cefotaxime has been reduced in patients with normal and reduced renal function by the ureidopenicillins *azlocillin*[1] or *mezlocillin*.[2] Doses of cefotaxime may need to be reduced if either of these penicillins is being given. Encephalopathy with focal motor status and generalised convulsions have been reported in a patient with renal failure given cefotaxime and high doses of azlocillin.[3]

Antimicrobial Action

Cefotaxime is a third-generation cephalosporin. It has a bactericidal action similar to cefamandole, but a broader spectrum of activity. It is highly stable to hydrolysis by most beta-lactamases and has greater activity than first- or second-generation cephalosporins against Gram-negative bacteria. Although cefotaxime is generally considered to have slightly less activity than first-generation cephalosporins against Gram-positive bacteria, many streptococci are very sensitive.

Desacetylcefotaxime is an active metabolite of cefotaxime and there may be additive or synergistic effects against some species.

Spectrum of activity. Among Gram-negative bacteria, cefotaxime is active *in vitro* against many Enterobacteriaceae including *Citrobacter* and *Enterobacter* spp., *Escherichia coli*, *Klebsiella* spp., both indole-positive and indole-negative *Proteus*, *Providencia*, *Salmonella*, *Serratia*, *Shigella*, and *Yersinia* spp. Other susceptible Gram-negative bacteria, including penicillin-resistant strains, are *Haemophilus influenzae*, *Moraxella catarrhalis* (*Branhamella catarrhalis*), *Neisseria gonorrhoeae*, and *N. meningitidis*. *Brucella melitensis* is also reported to be moderately sensitive. Some strains of *Pseudomonas* spp. are moderately susceptible to cefotaxime, but most are resistant. Desacetylcefotaxime is active against many of these Gram-negative bacteria, but not against *Pseudomonas* spp.

Among Gram-positive bacteria, cefotaxime is active against staphylococci and streptococci. *Staphylococcus aureus*, including penicillinase-producing strains but not meticillin-resistant *Staph. aureus*, is sensitive. *Staph. epidermidis* is also sensitive but penicillinase-producing strains are resistant. *Streptococcus agalactiae* (group B streptococci), *Str. pneumoniae*, and *Str. pyogenes* (group A streptococci) are all very sensitive although truly penicillin-resistant pneumococci are apparently not sensitive. Enterococci and *Listeria monocytogenes* are resistant.

Cefotaxime is active against some anaerobic bacteria. *Bacteroides fragilis* may be moderately sensitive, but many strains are resistant; synergy has been demonstrated with desacetylcefotaxime *in vitro*. *Clostridium perfringens* is sensitive, but most *Cl. difficile* are resistant.

Other organisms sensitive to cefotaxime include the spirochaete *Borrelia burgdorferi* and *Haemophilus ducreyi*.

Activity with other antimicrobials. In addition to possible synergy or additive effects with desacetylcefotaxime, the activity of cefotaxime may be enhanced by aminoglycosides such as gentamicin; synergy has been demonstrated *in vitro* against Gram-negative bacteria including *Pseudomonas aeruginosa*. There have also been reports of enhanced activity *in vitro* with other antibacterials including fosfomycin and ciprofloxacin and variable results with penicillins.

Resistance may develop during treatment with cefotaxime due to derepression of chromosomally mediated beta-lactamases, and has been reported particularly in *Enterobacter* spp., with multiresistant strains emerging during treatment. This type of resistance has also developed in other bacteria including *Citrobacter*, *Serratia*, and *Pseudomonas* spp. Another mechanism of cefotaxime resistance is the development of plasma-mediated, extended-spectrum beta-lactamases, and this has occurred in *Klebsiella* spp. and also other Enterobacteriaceae. Resistance in *Str. pneumoniae* is due to the production of altered penicillin-binding proteins.

Pharmacokinetics

Cefotaxime is given by injection as the sodium salt. It is rapidly absorbed after intramuscular injection and mean peak plasma concentrations of about 12 and 20 micrograms/mL have been reported 30 minutes after doses of 0.5 and 1 g of cefotaxime, respectively. Immediately after intravenous injection of 0.5, 1, or 2 g of cefotaxime, mean peak plasma concentrations of 38, 102, and 215 micrograms/mL, respectively, have been achieved with concentrations ranging from about 1 to 3 micrograms/mL after 4 hours. The plasma half-life of cefotaxime is about 1 hour and that of the active metabolite desacetylcefotaxime about 1.5 hours; half-lives are increased in neonates and in patients with severe renal impairment, especially those of the metabolite, and a reduction in dosage may be necessary. The effects of liver disease on clearance of cefotaxime and its metabolite have been variable, but in general dosage adjustment has not been considered necessary. About 40% of cefotaxime is reported to be bound to plasma proteins.

Cefotaxime and desacetylcefotaxime are widely distributed in body tissues and fluids; therapeutic concentrations are achieved in the CSF particularly when the meninges are inflamed. Cefotaxime crosses the placenta and low concentrations have been detected in breast milk.

After partial metabolism in the liver to desacetylcefotaxime and inactive metabolites, elimination is mainly by the kidneys and about 40 to 60% of a dose has been recovered unchanged in the urine within 24 hours; a further 20% is excreted as the desacetyl metabolite. Relatively high concentrations of cefotaxime and desacetylcefotaxime are achieved in bile and about 20% of a dose has been recovered in the faeces.

Probenecid competes for renal tubular secretion with cefotaxime resulting in higher and prolonged plasma concentrations of cefotaxime and its desacetyl metabolite. Cefotaxime and its metabolites are removed by haemodialysis.

When microbiological assays have been used, reported pharmacokinetic values may relate to cefotaxime plus its active metabolite, desacetylcefotaxime.

Uses and Administration

Cefotaxime is a third-generation cephalosporin antibacterial used in the treatment of infections due to susceptible organisms, especially serious and life-threatening infections. They include brain abscess, endocarditis, gonorrhoea, intensive care (selective parenteral and enteral antisepsis regimens), Lyme disease, meningitis, peritonitis (primary or spontaneous), pneumonia, septicaemia, and typhoid fever. It is also used for surgical infection prophylaxis. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Administration and dosage. Cefotaxime is given as the sodium salt by deep intramuscular injection or intravenously by slow injection over 3 to 5 minutes or by infusion over 20 to 60 minutes. Doses are expressed in terms of the equivalent amount of cefotaxime; 1.05 g of cefotaxime sodium is equivalent to about 1 g of cefotaxime. It is usually given in doses of 2 to 6 g daily in 2 to 4 divided doses to adults. In severe infections up to 12 g may be given daily by the intravenous route in up to 6 divided doses; pseudomonal infections usually require more than 6 g daily, but a cephalosporin with greater antipseudomonal activity, such as ceftazidime, is preferable. Children may be given 100 to 150 mg/kg (50 mg/kg for neonates) daily in 2 to 4 divided doses, increased in severe infections to 200 mg/kg (150 to 200 mg/kg for neonates) daily if necessary.

For details of reduced doses to be used in patients with severe renal impairment, see below.

In the treatment of gonorrhoea, a single dose of 0.5 or 1 g of cefotaxime is given.

For surgical infection prophylaxis, 1 g is given 30 to 90 minutes before surgery. At caesarean section, 1 g is given intravenously to the mother as soon as the umbilical cord is clamped and two further doses intramuscularly or intravenously 6 and 12 hours later.

Cefotaxime may be used with an aminoglycoside as synergy may occur against some Gram-negative organisms, but the drugs should be given separately. It has sometimes been used with another beta lactam to broaden the spectrum of activity. Cefotaxime has also been used with metronidazole in the treatment of mixed aerobic-anaerobic infections.

Administration in renal impairment. Doses of cefotaxime should be reduced in severe renal impairment; after an initial loading dose of 1 g, halving the dose while maintaining the usual frequency of dosing has been suggested.

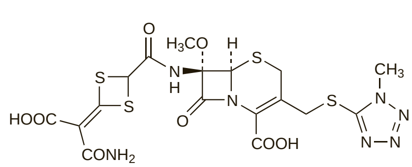
Cefotetan *(BAN, USAN, rINN)*

Céfotétan; Cefotetán; Cefotetanum; ICI-156834 (cefotetan or cefotetan disodium); YM-09330 (cefotetan or cefotetan disodium). (7*S*)-7-[(4-Carbamoylcarboxymethylene-1,3-dithietan-2-yl)carboxamido]-7-methoxy-3-[(1-methyl-1*H*-tetrazol-5-yl)thiomethyl]-3-cephem-4-carboxylic acid.

Цефотетан

$C_{17}H_{17}N_7O_8S_4$ = 575.6.
CAS — 69712-56-7.
ATC — J01DC05.
ATC Vet — QJ01DC05.



Pharmacopoeias. In *Jpn* and *US*.

USP 31 (Cefotetan). Store in airtight containers.

Cefotetan Disodium *(BANM, USAN, rINNM)*

Cefotetán disódico; Céfotétan Disodique; Cefotetanum Dinatricum; ICI-156834 (cefotetan or cefotetan disodium); YM-09330 (cefotetan or cefotetan disodium). (7*S*)-7-[(4-Carbamoylcarboxymethylene-1,3-dithietan-2-yl)carboxamido]-7-methoxy-3-[(1-methyl-1*H*-tetrazol-5-yl)thiomethyl]-3-cephem-4-carboxylic acid, disodium salt.

Динатрий Цефотетан

$C_{17}H_{15}N_7Na_2O_8S_4$ = 619.6.
CAS — 74356-00-6.
ATC — J01DC05.
ATC Vet — QJ01DC05.

Pharmacopoeias. In *US*.

USP 31 (Cefotetan Disodium). pH of a 10% solution in water is between 4.0 and 6.5. Store in airtight containers.

Incompatibility and stability. There may be incompatibility with aminoglycosides. Precipitation has been reported with promethazine hydrochloride.

References.

1. Das Gupta V, *et al*. Chemical stability of cefotetan disodium in 5% dextrose and 0.9% sodium chloride injections. *J Clin Pharm Ther* 1990; **15:** 109–14.
2. Erickson SH, Ulici D. Incompatibility of cefotetan disodium and promethazine hydrochloride. *Am J Health-Syst Pharm* 1995; **52:** 1347.

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219.

Cefotetan contains an *N*-methylthiotetrazole side-chain and has the potential to cause hypoprothrombinaemia and bleeding.

Cefotetan, especially at high doses, may interfere with the Jaffé method of measuring creatinine concentrations to produce falsely elevated values; this should be borne in mind when measuring renal function.

Effects on the blood. Reviews[1,2] and a case report[3] of haemolytic anaemia associated with cefotetan.

1. Moes GS, MacPherson BR. Cefotetan-induced hemolytic anemia: a case report and review of the literature. *Arch Pathol Lab Med* 2000; **124:** 1344–6.

3. Robinson HE, *et al*. Cefotetan-induced life-threatening haemolysis. *Med J Aust* 2006; **184:** 251.

Sodium content. Each g of cefotetan disodium contains about 3.2 mmol of sodium.

Interactions

As for Cefamandole, p.221.

Antimicrobial Action

Cefotetan is a cephamycin antibiotic with a mode of action and spectrum of activity similar to those of cefoxitin (p.230). It is generally much more active *in vitro* than cefoxitin against the Gram-negative Enterobacteriaceae, but has similar activity against *Bacteroides fragilis* and may be less active against some other *Bacteroides* spp.

Pharmacokinetics

On intramuscular injection of cefotetan, peak plasma concentrations of about 70 micrograms/mL at 1 hour and 90 micrograms/mL at 3 hours have been reported after doses of 1 and 2 g, respectively. The plasma half-life of cefotetan is usually in the range of 3.0 to 4.6 hours and is prolonged in patients with renal impairment. About 88% of cefotetan may be bound to plasma proteins, depending on the plasma concentration.

Cefotetan is widely distributed in body tissues and fluids. It crosses the placenta and low concentrations have been detected in breast milk. High concentrations are achieved in bile.

Cefotetan is excreted in the urine, primarily by glomerular filtration, as unchanged drug; 50 to 80% of a dose has been recovered in the urine in 24 hours and high concentrations are achieved. Small amounts of the tautomeric form of cefotetan have been detected in both plasma and urine.

Biliary excretion of cefotetan probably accounts for nonrenal clearance.

Some cefotetan is removed by dialysis.

◊ References.

1. Martin C, *et al*. Clinical pharmacokinetics of cefotetan. *Clin Pharmacokinet* 1994; **26:** 248–58.

Uses and Administration

Cefotetan is a cephamycin antibacterial generally classified with the second-generation cephalosporins and used similarly to cefoxitin (p.230) in the treatment and prophylaxis of anaerobic and mixed bacterial infections, especially intra-abdominal and pelvic infections.

It is given as the disodium salt by deep intramuscular injection or intravenously by slow injection over 3 to 5 minutes or by infusion. Doses are expressed in terms of the equivalent amount of cefotetan; 1.08 g of cefotetan disodium is equivalent to about 1 g of cefotetan. The usual dose is 1 or 2 g every 12 hours. For the treatment of life-threatening infections, 3 g every 12 hours may be given intravenously. Doses of cefotetan should be reduced in patients with moderate to severe renal impairment (see below).

For infection prophylaxis during surgical procedures, an intravenous dose of 1 or 2 g is given 30 to 60 minutes before surgery or, in caesarean section, as soon as the umbilical cord is clamped.

Administration in renal impairment. Dosage of cefotetan should be reduced in patients with moderate to severe renal impairment. US licensed product information gives the following dosing guidelines based on creatinine clearance (CC):

- CC 10 to 30 mL/minute: the usual dose every 24 hours or one-half the usual dose every 12 hours
- CC less than 10 mL/minute: the usual dose every 48 hours or one-quarter the usual dose every 12 hours

In patients undergoing haemodialysis, one-quarter the usual dose may be given every 24 hours on days between dialysis and one-half the usual dose on the day of dialysis.

Preparations

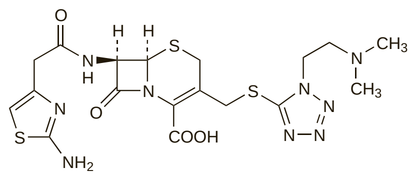
CAS — 61622-34-2 (cefotiam); 66309-69-1 (cefotiam hydrochloride).

ATC — J01DC07.

ATC Vet — QJ01DC07.



(cefotiam)

Pharmacopoeias. In *Jpn* and *US. Jpn* also includes cefotiam hexetil hydrochloride.

USP 31 (Cefotiam Hydrochloride). Store in airtight containers.

Profile

Cefotiam is a third-generation cephalosporin antibacterial with actions and uses similar to those of cefamandole (p.220). It is given intravenously or intramuscularly as the hydrochloride but doses are expressed in terms of the base; 1.14 g of cefotiam hydrochloride is equivalent to about 1 g of cefotiam. The usual dose is the equivalent of up to 6 g of cefotiam daily in divided doses, according to the severity of the infection.

Cefotiam hexetil hydrochloride, a prodrug of cefotiam, is given orally in doses equivalent to 200 to 400 mg of cefotiam twice daily.

(cefoxitin)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Cefoxitin Sodium). A white or almost white, very hygroscopic, powder. Very soluble in water; sparingly soluble in alcohol. A 1% solution in water has a pH between 4.2 and 7.0. Store in airtight containers.

USP 31 (Cefoxitin Sodium). White to off-white, somewhat hygroscopic, granules or powder, having a slight characteristic odour. Very soluble in water; slightly soluble in acetone; insoluble in chloroform and in ether; sparingly soluble in dimethylformamide; soluble in methyl alcohol. pH of a 10% solution in water is between 4.2 and 7.0. Store in airtight containers at a temperature not exceeding 8°.

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219.

Cefoxitin may interfere with the Jaffé method of measuring creatinine concentrations to produce falsely high values; this should be borne in mind when measuring renal function.

Breast feeding. Cefoxitin is distributed into breast milk but is detectable only in low concentrations. In a study[1] in which cefoxitin was given prophylactically in doses of 2 to 4 g to 18 women undergoing caesarean section, only one sample of breast milk contained measurable concentrations of cefoxitin, 19 hours after the last dose. No adverse effects have been observed in breast-fed infants whose mothers were receiving cefoxitin, and the American Academy of Pediatrics considers[2] that it is therefore usually compatible with breast feeding.

1. Roex AJM, *et al.* Secretion of cefoxitin in breast milk following short-term prophylactic administration in caesarean section. *Eur J Obstet Gynecol Reprod Biol* 1987; **25:** 299–302.

Effects on the gastrointestinal tract. Marked changes in anaerobic, facultative, and aerobic faecal flora have been noted with cefoxitin.[1]

1. Mulligan ME, *et al.* Alterations in human fecal flora, including ingrowth of Clostridium difficile, related to cefoxitin therapy. *Antimicrob Agents Chemother* 1984; **26:** 343–6.

Sodium content. Each g of cefoxitin sodium contains about 2.2 mmol of sodium.

Interactions

Probenecid reduces the renal clearance of cefoxitin.

Antimicrobial Action

Cefoxitin is a cephamycin antibacterial which, like the other beta lactams, is bactericidal and is considered to act through the inhibition of bacterial cell wall synthesis.

It has a similar spectrum of activity to cefamandole (p.221) but is more active against anaerobic bacteria, especially *Bacteroides fragilis.*

Cefoxitin can induce the production of beta-lactamases by some bacteria, and use of cefoxitin with other beta lactams have been shown to be antagonistic *in vitro.*

Cefoxitin itself is considered to be resistant to a wide range of beta-lactamases, including those produced by *Bacteroides* spp. However, acquired resistance to cefoxitin has been reported in *B. fragilis* (see Anaerobic Bacterial Infections, p.163) and has been attributed to beta-lactamase as well as to alterations in penicillin-binding proteins or to outer membrane proteins; there may be cross-resistance to other antibacterials.

Pharmacokinetics

Cefoxitin is not absorbed from the gastrointestinal tract; it is given parenterally as the sodium salt. After 1 g by intramuscular injection a peak plasma concentration of up to 30 micrograms/mL at 20 to 30 minutes has been reported whereas concentrations of 125, 72, and 25 micrograms/mL have been achieved after intravenous doses of 1 g over 3, 30, and 120 minutes respectively. Cefoxitin is about 70% bound to plasma proteins. It has a plasma half-life of 45 to 60 minutes which is prolonged in renal impairment. Cefoxitin is widely distributed in the body but there is normally little penetration into the CSF, even when the meninges are inflamed. It crosses the placenta and has been detected in breast milk. Relatively high concentrations are achieved in bile.

The majority of a dose is excreted unchanged by the kidneys, up to about 2% being metabolised to descarbamylcefoxitin which is virtually inactive. Cefoxitin is excreted in the urine by glomerular filtration and tubular secretion and about 85% of a dose is recovered within 6 hours; probenecid slows this excretion. After an intramuscular dose of 1 g, peak concentrations in the urine are usually greater than 3 mg/mL.

Cefoxitin is removed to some extent by haemodialysis.

Uses and Administration

Cefoxitin is a cephamycin antibacterial that differs structurally from the cephalosporins by the addition of a 7-α-methoxy group to the 7-β-aminocephalosporanic acid nucleus.

It is generally classified with the second-generation cephalosporins and can be used similarly to cefamandole (p.221) for the treatment of susceptible infections. However, because of its activity against *Bacteroides fragilis* and other anaerobic bacteria, it is used principally in the treatment and prophylaxis of anaerobic and mixed bacterial infections, especially intra-abdominal and pelvic infections. Indications include endometritis (prophylaxis at caesarean section), pelvic inflammatory disease, and surgical infection (prophylaxis). It may also be used in the treatment of gonorrhoea and urinary-tract infections. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Administration and dosage. Cefoxitin is given as the sodium salt by deep intramuscular injection, by slow intravenous injection over 3 to 5 minutes, or by intermittent or continuous intravenous infusion.

Doses are expressed in terms of the equivalent amount of cefoxitin; 1.05 g of cefoxitin sodium is equivalent to about 1 g of cefoxitin. The usual adult dose is 1 or 2 g every 8 hours although it may be given more frequently (every 4 or 6 hours). In severe infections up to 12 g daily has been recommended. Children and neonates may be given 20 to 40 mg/kg, every 12 hours for neonates up to 1 week old, every 8 hours for those aged 1 to 4 weeks, and every 6 to 8 hours for older infants and children; in severe infections, up to 200 mg/kg daily may be given, to a maximum of 12 g daily.

For the treatment of uncomplicated urinary-tract infections, cefoxitin 1 g twice daily has been given intramuscularly.

For details of reduced doses of cefoxitin in patients with renal impairment, see below.

For the treatment of uncomplicated gonorrhoea, a single dose of 2 g intramuscularly has been given with probenecid 1 g orally.

For surgical infection prophylaxis, the usual adult dose is cefoxitin 2 g intramuscularly or intravenously 30 to 60 minutes before the procedure and then every 6 hours, not usually for more than 24 hours. Infants and children undergoing surgical procedures can be given doses of 30 to 40 mg/kg, at the same time intervals as adults; neonates may be given 30 to 40 mg/kg, but at intervals of 8 to 12 hours.

At caesarean section a single 2-g dose may be given intravenously to the mother as soon as the umbilical cord is clamped. If necessary, a 3-dose regimen, with further 2-g doses 4 and 8 hours after the initial dose, may be used.

◊ Reviews.

Administration in renal impairment. In renal impairment, dosage of cefoxitin should be reduced according to creatinine clearance (CC). After an initial loading dose of 1 to 2 g, maintenance doses are:

- CC 30 to 50 mL/minute: 1 to 2 g every 8 to 12 hours
- CC 10 to 29 mL/minute: 1 to 2 g every 12 to 24 hours
- CC 5 to 9 mL/minute: 0.5 to 1 g every 12 to 24 hours
- CC below 5 mL/minute: 0.5 to 1 g every 24 to 48 hours

In patients undergoing haemodialysis, the loading dose should be repeated after each dialysis session.

Pharmacopoeias. In *Jpn.*

Profile

Cefpiramide is a third-generation cephalosporin antibacterial related to cefoperazone (p.227) and with similar activity against *Pseudomonas aeruginosa*, but possibly less active against Enterobacteriaceae. Cefpiramide is also active against staphylococci and streptococci and marginal activity against enterococci *in vitro* has been reported. Like cefamandole (p.220), cefpiramide contains an *N*-methylthiotetrazole side-chain, a structure associated with hypoprothrombinaemia, alcohol intolerance, and potentiation of anticoagulants.

Cefpiramide is given by intravenous injection or infusion as the sodium salt in the treatment of susceptible infections but doses are expressed in terms of cefpiramide; 1.04 g of cefpiramide sodium is equivalent to about 1 g of cefpiramide. The usual dose is 1 to 2 g daily in 2 divided doses.

◊ References.

1. Wang H, *et al.* In-vitro antibacterial activities of cefpiramide and other broad-spectrum antibiotics against 440 clinical isolates in China. *J Infect Chemother* 2000; **6:** 81–5.

Sodium content. Each g of cefpiramide sodium contains about 1.6 mmol of sodium.

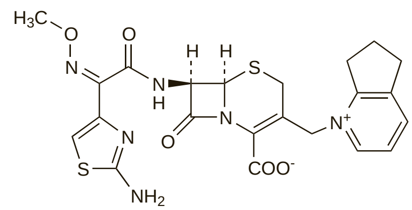
ATC — J01DE02.

ATC Vet — QJ01DE02.



(cefpirome)

Pharmacopoeias. In *Jpn.*

Adverse Effects and Precautions

As for Cefalotin, p.219.

Cefpirome is reported to interfere with the Jaffé method of measuring creatinine concentrations to determine renal function.

◊ References.

1. Rubinstein E, *et al.* A review of the adverse events profile of cefpirome. *Drug Safety* 1993; **9:** 340–5.

Interactions

Probenecid reduces the renal clearance of cefpirome.

Antimicrobial Action

Cefpirome is a fourth-generation cephalosporin that is stable to a wide range of beta-lactamases. It has a spectrum of activity similar to that of the third-generation cephalosporin cefotaxime (p.228), but it appears to be more active *in vitro* against staphylococci, some enterococci, some Enterobacteriaceae, and *Pseudomonas aeruginosa*. Cefpirome may be less active than ceftazidime (p.234) against *Ps. aeruginosa*.

Pharmacokinetics

Cefpirome is given by injection as the sulfate. Mean peak serum concentrations of 80 to 90 micrograms/mL are attained after a single intravenous 1-g dose. The elimination half-life is about 2 hours and is prolonged in patients with renal impairment. Cefpirome is less than 10% bound to plasma proteins.

Cefpirome is widely distributed into body tissues and fluids and appears in breast milk. It is mainly excreted by the kidneys and 80 to 90% of a dose is recovered unchanged in the urine. Significant amounts are removed by haemodialysis.

Uses and Administration

Cefpirome is a fourth-generation cephalosporin antibacterial used in the treatment of infections due to susceptible organisms. They include infections of the urinary tract, respiratory tract, and skin, and also septicaemia and infections in immunocompromised patients. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Cefpirome is given by intravenous injection over 3 to 5 minutes or infusion over 20 to 30 minutes as the sulfate, but doses are expressed in terms of the base; 1.19 g of cefpirome sulfate is equivalent to about 1 g of cefpirome. The usual dose is the equivalent of 1 or 2 g of cefpirome every 12 hours. For details of reduced doses to be used in renal impairment, see below.

◊ References.

1. Brown EM, *et al.* eds. Cefpirome: a novel extended spectrum cephalosporin. *J Antimicrob Chemother* 1992; **29** (suppl A): 1–104.
2. Wiseman LR, Lamb HM. Cefpirome: a review of its antibacterial activity, pharmacokinetic properties and clinical efficacy in the treatment of severe nosocomial infections and febrile neutropenia. *Drugs* 1997; **54:** 117–40.

Administration in renal impairment. Dosage of cefpirome should be modified in renal impairment; after a loading dose of 1 or 2 g depending on the severity of infection, the maintenance dosage should be adjusted according to creatinine clearance (CC) and the severity of infection:

- CC 20 to 50 mL/minute: 0.5 or 1 g twice daily
- CC 5 to 20 mL/minute: 0.5 or 1 g once daily
- CC 5 mL/minute or less (in haemodialysis patients): 0.5 or 1 g once daily plus a half-dose after each dialysis session.

Cefpodoxime Proxetil

(BANM, USAN, rINNM)

Cefpodoxima proxetilo; Cefpodoxime proxétil; Cefpodoxime, Proxétil de; Cefpodoximi Proxetilum; Cefpodoximum proxetili; CS-807; R-3763 (cefpodoxime); U-76252; U-76253 (cefpodoxime). The 1-[(isopropoxycarbonyl)oxy]ethyl ester of (*Z*)-7-[2-(2-amino-1,3-thiazol-4-yl)-2-methoxyiminoacetamido]-3-methoxymethyl-3-cephem-4-carboxylic acid.

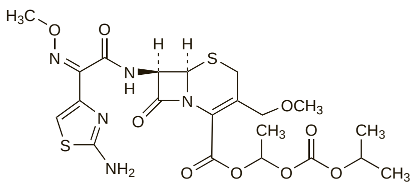
Цефподоксима Проксетил

$C_{21}H_{27}N_5O_9S_2$ = 557.6.

CAS — 80210-62-4 (cefpodoxime); 87239-81-4 (cefpodoxime proxetil).

ATC — J01DD13.

ATC Vet — QJ01DD13.



Pharmacopoeias. In *Jpn* and *US.*

USP 31 (Cefpodoxime Proxetil). A white to light brownish-white powder, odourless or having a faint odour. Very slightly soluble in water; freely soluble in dehydrated alcohol; soluble in acetonitrile and in methyl alcohol; slightly soluble in ether. Store in airtight containers at a temperature not exceeding 25°.

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219.

The most frequently reported adverse effects of cefpodoxime are gastrointestinal disturbances, especially diarrhoea.

Interactions

Absorption of cefpodoxime is decreased by antacids or histamine H_2-receptor antagonists. Probenecid reduces the renal excretion of cefpodoxime.

Antimicrobial Action

As for Cefixime, p.224, but cefpodoxime has greater activity against *Staphylococcus aureus*.

◊ References.

1. Valentini S, *et al.* In-vitro evaluation of cefpodoxime. *J Antimicrob Chemother* 1994; **33:** 495–508.

Pharmacokinetics

Cefpodoxime proxetil is de-esterified in the intestinal epithelium after oral doses, to release active cefpodoxime in the bloodstream. Bioavailability is about 50% in fasting subjects and may be increased in the presence of food. Absorption is decreased in conditions of low gastric acidity. Peak plasma concentrations of about 1.5, 2.5, and 4.0 micrograms/mL have been achieved 2 to 3 hours after oral doses of 100, 200, and 400 mg cefpodoxime respectively. About 20 to 30% of cefpodoxime is bound to plasma proteins. The plasma half-life is about 2 to 3 hours and is prolonged in patients with renal impairment.

Cefpodoxime reaches therapeutic concentrations in the respiratory and genito-urinary tracts and bile. It has been detected in low concentrations in breast milk.

Cefpodoxime is excreted unchanged in the urine. Some is removed by dialysis.

Uses and Administration

Cefpodoxime is a third-generation cephalosporin antibiotic used similarly to cefixime (p.225) in the treatment of susceptible infections. It is given orally as the proxetil ester, which is hydrolysed on absorption to cefpodoxime. Doses are expressed in terms of the equivalent amount of cefpodoxime; 130 mg of cefpodoxime proxetil is equivalent to about 100 mg of cefpodoxime. Absorption may be enhanced if cefpodoxime proxetil is given with food. The usual dose for adults is 100 to 200 mg every 12 hours for respiratory-tract and urinary-tract infections. A dose of 200 or 400 mg every 12 hours may be used for skin and soft-tissue infections. In the USA children aged 2 months and older may be given doses of 5 mg/kg every 12 hours, up to a maximum of 200 mg daily for pharyngitis or tonsillitis or 400 mg daily for acute otitis media or maxillary sinusitis. In the UK cefpodoxime may be given to children and infants aged 15 days and older, in a dose of 4 mg/kg every 12 hours, up to a maximum of 200 mg daily, for infections of the respiratory tract, urinary tract, and skin and soft tissues.

The interval between doses of cefpodoxime may need to be extended in patients with renal impairment (see below).

For uncomplicated gonorrhoea, a single dose of 200 mg may be given.

◊ References.

Administration in renal impairment. The interval between doses of cefpodoxime should be extended in patients with renal impairment to every 24 hours in those with creatinine clearance of 10 to 39 mL/minute, and to every 48 hours when the creatinine clearance is less than 10 mL/minute. In patients on haemodialysis the dose should be given after each dialysis session.

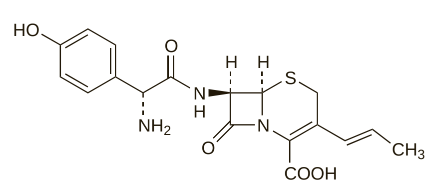
Цефпрозил

$C_{18}H_{19}N_3O_5S,H_2O$ = 407.4.

CAS — 92665-29-7 (anhydrous cefprozil); 121123-17-9 (cefprozil monohydrate).

ATC — J01DC10.

ATC Vet — QJ01DC10.



Pharmacopoeias. In *US.*

USP 31 (Cefprozil). pH of a 0.5% solution in water is between 3.5 and 6.5. Store in airtight containers.

Adverse Effects and Precautions

As for Cefalexin, p.218.

Breast feeding. A study[1] in 9 healthy women found that concentrations of cefprozil in breast milk corresponded to no more than 0.3% of a dose and concluded that cefprozil could be given safely during breast feeding. The American Academy of Pediatrics[2] states that there have been no reports of any clinical effect on the infant associated with the use of cefprozil in breast-feeding mothers, and that it may be considered to be usually compatible with breast feeding.

1. Shyu WC, *et al.* Excretion of cefprozil into human breast milk. *Antimicrob Agents Chemother* 1992; **36:** 938–41.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 25/05/04)

Hypersensitivity. Serum sickness-like reactions were reported in 4 patients, 3 of them children, given cefprozil.[1] Such reactions have been associated with cefaclor (p.217), but whether they represent a class-related hypersensitivity reaction is not clear.

1. Lowery N, *et al.* Serum sickness-like reactions associated with cefprozil therapy. *J Pediatr* 1994; **125:** 325–8.

Interactions

As for Cefalexin, p.218.

Antimicrobial Action

Cefprozil is bactericidal and has a similar but wider range of antimicrobial activity than cefaclor (p.217).

Pharmacokinetics

Cefprozil is well absorbed from the gastrointestinal tract with a reported bioavailability of 90 to 95%. Oral doses of 0.25, 0.5, and 1 g produce peak plasma concentrations of about 6, 10, and 18 micrograms/mL respectively at 1 to 2 hours. The presence of food is reported to have little or no effect on the absorption of cefprozil. A plasma half-life of 1 to 1.4 hours has been reported; it is increased in patients with renal impairment, up to about 6 hours in those with end-stage renal failure. About 35 to 45% of cefprozil is bound to plasma proteins.

Cefprozil is widely distributed in the body tissues. Concentrations of cefprozil in tonsillar and adenoidal tissue are reported to be about 40 to 50% of those in plasma, and less than 0.3% of a 1-g dose has been recovered in breast milk in 24 hours. About 60% of a dose is excreted unchanged in the urine in the first 8 hours by glomerular filtration and tubular secretion. High concentrations of cefprozil are achieved in the urine; concentrations of 700, 1000, and 2900 micrograms/mL have been reported within 4 hours of doses of 0.25, 0.5, and 1 g respectively. Some cefprozil is removed by haemodialysis.

Uses and Administration

Cefprozil is a cephalosporin antibacterial consisting of *cis-* and *trans-* isomers in a ratio of about 90:10. It is used similarly to cefaclor (p.217) in the treatment of susceptible infections, including upper and lower respiratory-tract infections and skin and soft-tissue infections, and should probably be classified as a second-generation cephalosporin.

Cefprozil is given orally as the monohydrate. Doses are expressed in terms of the equivalent amount of anhydrous cefprozil; 523 mg of cefprozil monohydrate is equivalent to about 500 mg of anhydrous cefprozil. The usual adult dose is 500 mg daily (as a single dose or in two divided doses), increased to 500 mg twice daily if necessary. Children may be given up to 20 mg/kg once or twice daily (to a maximum of 500 mg once daily, or twice daily if necessary for otitis media).

For details of reduced dosage of cefprozil in patients with renal impairment, see below.

◊ Reviews.

1. Wiseman LR, Benfield P. Cefprozil: a review of its antibacterial activity, pharmacokinetic properties, and therapeutic potential. *Drugs* 1993; **45:** 295–317.
2. Barriere SL. Review of in vitro activity, pharmacokinetic characteristics, safety, and clinical efficacy of cefprozil, a new oral cephalosporin. *Ann Pharmacother* 1993; **27:** 1082–9.

Administration in renal impairment. Doses of cefprozil should be reduced in patients with renal impairment; half the standard dose should be given to patients with a creatinine clearance of less than 30 mL/minute.

Preparations

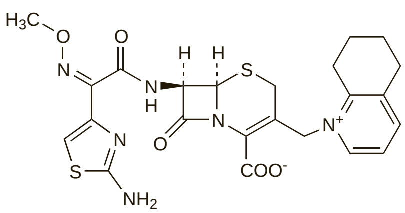
CAS — 84957-30-2 (cefquinome); 118443-89-3 (cefquinome sulfate); 123766-80-3 (cefquinome sulfate).



(cefquinome)

Profile

Cefquinome is a fourth-generation cephalosporin antibacterial used as the sulfate in veterinary medicine.

Cefradine *(BAN, rINN)*

Cefradin; Cefradina; Cefradinas; Céfradine; Cefradinum; Cefradyna; Cephradine *(USAN)*; Kefradiini; Sefradin; SKF-D-39304; SQ-11436; SQ-22022 (cefradine dihydrate). (7*R*)-7-(α-D-Cyclohexa-1,4-dienylglycylamino)-3-methyl-3-cephem-4-carboxylic acid.

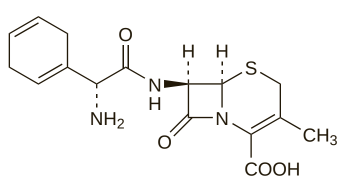
Цефрадин

$C_{16}H_{19}N_3O_4S = 349.4.$

CAS — 38821-53-3 (anhydrous cefradine); 31828-50-9 (non-stoichiometric cefradine hydrate); 58456-86-3 (cefradine dihydrate).

ATC — J01DB09.

ATC Vet — QJ01DB09.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US* (which allows the anhydrous form, the monohydrate, or the dihydrate).

Ph. Eur. 6.2 (Cefradine). A white or slightly yellow, hygroscopic powder. Sparingly soluble in water; practically insoluble in alcohol and in *n*-hexane. A 1% solution in water has a pH of 3.5 to 6.0. Store at 2° to 8° in airtight containers. Protect from light.

USP 31 (Cephradine). A white to off-white crystalline powder. Sparingly soluble in water; very slightly soluble in alcohol and in chloroform; practically insoluble in ether. pH of a 1% solution in water is between 3.5 and 6.0. Store in airtight containers.

Incompatibility and stability. Commercially available injections contain sodium carbonate or arginine as neutralisers. Injections containing sodium carbonate are incompatible with solutions such as compound sodium lactate injection that contain calcium salts.

References.

2. Mehta AC, *et al.* Chemical stability of cephradine injection solutions. *Intensive Therapy Clin Monit* 1988; **9**: 195–6.

Adverse Effects and Precautions

As for Cefalexin, p.218. Intramuscular injections of cefradine can be painful and thrombophlebitis has occurred on intravenous injection.

Porphyria. Cefradine is considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity.

Interactions

As for Cefalexin, p.218.

Antimicrobial Action

As for Cefalexin, p.218.

Pharmacokinetics

Cefradine is rapidly and almost completely absorbed from the gastrointestinal tract after oral doses. Doses of 0.25, 0.5, and 1 g given orally have produced peak plasma concentrations of about 9, 17, and 24 micrograms/mL respectively at 1 hour and are similar to those achieved with cefalexin. Absorption is delayed by the presence of food although the total amount absorbed is not appreciably altered. Following intramuscular injection peak plasma concentrations of about 6 and 14 micrograms/mL have been obtained within 1 to 2 hours of doses of 0.5 and 1 g respectively.

Only about 8 to 12% is reported to be bound to plasma proteins. A plasma half-life of about 1 hour has been reported; this is prolonged in patients with renal impairment. Cefradine is widely distributed to body tissues and fluids, but does not enter the CSF in significant quantities. Therapeutic concentrations may be found in the bile. It crosses the placenta into the fetal circulation and is distributed in small amounts into breast milk.

Cefradine is excreted unchanged in the urine by glomerular filtration and tubular secretion, over 90% of an oral dose or 60 to 80% of an intramuscular dose being recovered within 6 hours. Peak urinary concentrations of about 3 mg/mL have been achieved after a 500-mg oral dose. Probenecid delays excretion.

Cefradine is removed by haemodialysis and peritoneal dialysis.

◊ References.

2. Schwinghammer TL, *et al.* Pharmacokinetics of cephradine administered intravenously and orally to young and elderly subjects. *J Clin Pharmacol* 1990; **30:** 893–9.

Uses and Administration

Cefradine is a first-generation cephalosporin antibacterial given orally similarly to cefalexin (p.219) and by the parenteral route similarly to cefazolin (p.222) in the treatment of susceptible infections and in the prophylaxis of infections during surgical procedures.

Cefradine is given orally in doses of 1 to 2 g daily in 2 to 4 divided doses to adults; up to 4 g daily may be given by this route. In severe infections it should be given parenterally, by deep intramuscular injection or intravenously by slow injection over 3 to 5 minutes or by infusion, in doses of 2 to 4 g daily in 4 divided doses; up to 8 g daily may be given parenterally.

In children, the usual daily oral dose is 25 to 50 mg/kg in 2 to 4 divided doses, although 75 to 100 mg/kg daily may be given for otitis media. By injection, 50 to 100 mg/kg daily may be given in 4 divided doses, increasing to 300 mg/kg daily in severe infections.

For surgical infection prophylaxis, 1 to 2 g may be given pre-operatively by intramuscular or intravenous injection; subsequent parenteral or oral doses are given as appropriate.

For details of reduced doses of cefradine in patients with severe renal impairment, see below.

Administration in renal impairment. Doses of cefradine should be reduced in patients with severe renal impairment. The following oral and parenteral doses are recommended in UK licensed product information according to creatinine clearance (CC):

- CC more than 20 mL/minute: 500 mg every 6 hours
- CC 5 to 20 mL/minute: 250 mg every 6 hours
- CC less than 5 mL/minute: 250 mg every 12 hours

Patients undergoing chronic intermittent haemodialysis may be given a 250-mg dose at the start of the session, repeated after 6 to 12 hours, then again 36 to 48 hours after the initial dose, and again at the start of the next haemodialysis if more than 30 hours have elapsed since the previous dose.

Further dosage modification may be required in children with renal impairment.

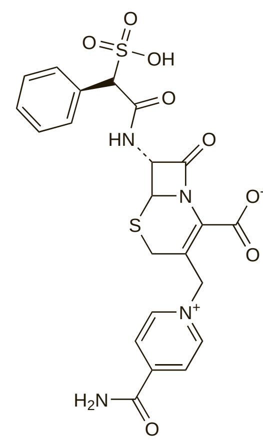
Натрий Цефсулодин

$C_{22}H_{19}N_4NaO_8S_2 = 554.5.$

CAS — 62587-73-9 (cefsulodin); 52152-93-9 (cefsulodin sodium).

ATC — J01DD03.

ATC Vet — QJ01DD03.



(cefsulodin)

Pharmacopoeias. In *Jpn*.

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219.

Sodium content. Each g of cefsulodin sodium contains about 1.8 mmol of sodium.

Antimicrobial Action

Cefsulodin is a bactericidal antibiotic with activity against *Pseudomonas aeruginosa* as great as that of ceftazidime (p.234), but no significant activity against other Gram-negative bacteria. Gram-positive bacteria and anaerobes are not very susceptible. Its activity against *Ps. aeruginosa* may be enhanced by aminoglycosides.

Cefsulodin is stable to hydrolysis by many beta-lactamases, but emergence of resistant *Ps. aeruginosa* has been reported.

Pharmacokinetics

Cefsulodin is given parenterally as the sodium salt. It has a plasma half-life of about 1.6 hours, which is prolonged in renal impairment. Up to 30% of cefsulodin in the circulation is bound to plasma proteins. Therapeutic concentrations have been reported in a wide range of body tissues and fluids. The major route of excretion of cefsulodin is via the urine, mainly by glomerular filtration. Clearance may be enhanced in cystic fibrosis, although there have been conflicting reports.

◊ References.

3. Hedman A, *et al.* Increased renal clearance of cefsulodin due to higher glomerular filtration rate in cystic fibrosis. *Clin Pharmacokinet* 1990; **18:** 168–75.

Uses and Administration

Cefsulodin is a third-generation cephalosporin antibiotic with a narrow spectrum of activity that has been used similarly to ceftazidime (p.235) for the treatment of infections caused by susceptible strains of *Pseudomonas aeruginosa*.

It is given as the sodium salt by intravenous injection. Doses are expressed in terms of the equivalent amount of cefsulodin; 1.04 g of cefsulodin sodium is equivalent to about 1 g of cefsulodin. The usual adult dose is 6 g daily in 4 divided doses; in less severe infections daily doses of 3 to 4 g may be given. Children may be given a usual dose of 100 mg/kg daily; 50 mg/kg daily may be given in less severe infections.

2. Wright DB. Cefsulodin. *Drug Intell Clin Pharm* 1986; **20:** 845–9.

Administration in renal impairment. The dosage of cefsulodin given intravenously should be adjusted in patients with renal impairment according to creatinine clearance (CC):

- CC 20 to 50 mL/minute: a loading dose of 1.5 g then 1 g every 8 hours
- CC 5 to 20 mL/minute: a loading dose of 1.5 g then 1 g every 12 hours
- CC less than 5 mL/minute: a loading dose of 1.5 g then 1 g every 24 hours

In patients undergoing haemodialysis, 1 g is given before and after dialysis.

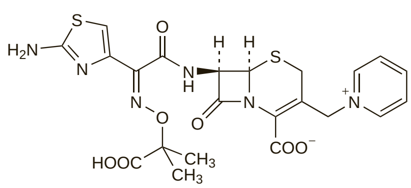
Цефтазидим

$C_{22}H_{22}N_6O_7S_2,5H_2O = 636.7.$

CAS — 72558-82-8 (anhydrous ceftazidime); 78439-06-2 (ceftazidime pentahydrate).

ATC — J01DD02.

ATC Vet — QJ01DD02.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn*, and *US*.

Ph. Eur. 6.2 (Ceftazidime). A white or almost white crystalline powder. Slightly soluble in water and in methyl alcohol; practically insoluble in alcohol and in acetone; it dissolves in acid and alkali solutions. A 0.5% solution in water has a pH of 3.0 to 4.0. Store in airtight containers.

USP 31 (Ceftazidime). A white to cream-coloured crystalline powder. Slightly soluble in water, in dimethylformamide, and in methyl alcohol; insoluble in alcohol, in acetone, in chloroform, in dioxan, in ether, in ethyl acetate, and in toluene; soluble in alkali and in dimethyl sulfoxide. pH of a 0.5% solution in water is between 3.0 and 4.0. Store in airtight containers.

Formulation. Ceftazidime for injection is available as a dry powder containing ceftazidime with sodium carbonate. When reconstituted ceftazidime sodium is formed with the evolution of carbon dioxide. An alternative formulation, ceftazidime with arginine, appears to overcome the problems associated with effervescence.[1] In some countries a frozen injection containing ceftazidime sodium is also used.

1. Stiles ML, *et al.* Gas production of three brands of ceftazidime. *Am J Hosp Pharm* 1991; **48:** 1727–9.

Incompatibility. It has been reported that ceftazidime does not cause decreased activity when incubated in solution with *gentamicin*[1] or *tobramycin*[2] at 37°, or when mixed with tobramycin in serum.[3] Ceftazidime and tobramycin[4] were also stable for up to 16 hours at room temperature when combined in a glucose-containing dialysis solution, and for a further 8 hours at 37°. However, licensed product information recommends that ceftazidime, like most other beta lactams, should not be mixed with an aminoglycoside in the same giving set or syringe because of the potential for inactivation of either drug.

Ceftazidime is generally considered to be compatible with *metronidazole*, but degradation of ceftazidime has been reported.[5] Precipitation has occurred with *vancomycin*[6] and therefore the product information considers it prudent to flush giving sets and intravenous lines between giving the two drugs. However, in one study[7] ceftazidime and/or vancomycin were stable in a glucose-containing peritoneal dialysis solution when kept for 6 days in a refrigerator or 48 to 72 hours at room temperature, and in a further study[8] the two drugs were stable when combined in similar solutions containing 1.5% or 4.25% glucose for up to 12 hours when stored at 37° and for 24 hours when stored at 4° and 24°. Ceftazidime and *teicoplanin*[9] were stable in combination in a peritoneal dialysis solution at 37° for 8 hours when it had been previously stored at 4°, but not when previously stored at 25°. Ceftazidime was not stable when mixed in solution with *aminophylline*.[10] There was some evidence of possible incompatibility with *pentamidine*.[11]

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219.

Like cefotaxime (p.228), ceftazidime has the potential for colonisation and superinfection with resistant organisms. The risk of superinfection with, for example, *Staphylococcus aureus* may be higher than with cefotaxime, since ceftazidime is less active against staphylococci.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving ceftazidime, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding.

Effects on the skin. References.

1. Vinks SATMM, *et al.* Photosensitivity due to ambulatory intravenous ceftazidime in cystic fibrosis patient. *Lancet* 1993; **341:** 1221–2.

Interactions

Unlike many other cephalosporins, probenecid has little effect on the renal clearance of ceftazidime.

◊ References.

1. Verhagen CA, *et al.* The renal clearance of cefuroxime and ceftazidime and the effect of probenecid on their tubular excretion. *Br J Clin Pharmacol* 1994; **37:** 193–7.

Antimicrobial Action

Ceftazidime has a bactericidal action and broad spectrum of activity similar to that of cefotaxime (p.228), but increased activity against *Pseudomonas* spp.; it is less active against staphylococci and streptococci. Unlike cefotaxime it has no active metabolite.

Ceftazidime is highly stable to hydrolysis by most beta-lactamases. It is active *in vitro* against many Gram-negative bacteria including *Pseudomonas aeruginosa*, *Burkholderia pseudomallei* (*Pseudomonas pseudomallei*), and Enterobacteriaceae including *Citrobacter* and *Enterobacter* spp., *Escherichia coli*, *Klebsiella* spp., both indole-positive and indole-negative *Proteus*, *Providencia*, *Salmonella*, *Serratia*, and *Shigella* spp. and *Yersinia enterocolitica*. Other susceptible Gram-negative bacteria include *Haemophilus influenzae*, *Moraxella catarrhalis* (*Branhamella catarrhalis*), and *Neisseria* spp. Among Gram-positive bacteria it is active against some staphylococci and streptococci, but meticillin-resistant staphylococci, enterococci, and *Listeria monocytogenes* are generally resistant. Ceftazidime is active against some anaerobes, although most strains of *Bacteroides fragilis* and *Clostridium difficile* are resistant.

The activity of ceftazidime against *Ps. aeruginosa* and some Enterobacteriaceae may be enhanced by aminoglycosides. Antagonism has been reported *in vitro* between ceftazidime and chloramphenicol.

Resistance. As with cefotaxime, resistance may develop during treatment due to the derepression of chromosomally mediated beta-lactamases. It has been noted particularly in *Pseudomonas* spp. and in Enterobacteriaceae including *Citrobacter*, *Enterobacter* spp. and *Proteus vulgaris*. Resistance may also occur due to the production of plasmid-mediated extended-spectrum beta-lactamases, particularly in *Klebsiella* spp. and *E. coli*.

Pharmacokinetics

Ceftazidime is given by injection as the sodium salt or in solution with arginine. Mean peak plasma concentrations of 17 and 39 micrograms/mL have been reported about 1 hour after intramuscular doses of 0.5 and 1 g of ceftazidime, respectively. Five minutes after intravenous bolus injections of 0.5, 1, and 2 g of ceftazidime, mean plasma concentrations of 45, 90, and 170 micrograms/mL, respectively, have been reported. The plasma half-life of ceftazidime is about 2 hours, but this is prolonged in patients with renal impairment and in neonates. Clearance may be enhanced in patients with cystic fibrosis. It is about 10% bound to plasma proteins.

Ceftazidime is widely distributed in body tissues and fluids; therapeutic concentrations are achieved in the CSF when the meninges are inflamed. It crosses the placenta and is distributed into breast milk.

Ceftazidime is passively excreted in bile, although only a small proportion is eliminated by this route. It is mainly excreted by the kidneys, almost exclusively by glomerular filtration; probenecid has little effect on the excretion. About 80 to 90% of a dose appears unchanged in the urine within 24 hours. It is removed by haemodialysis and peritoneal dialysis.

Uses and Administration

Ceftazidime is a third-generation cephalosporin antibacterial with enhanced activity against *Pseudomonas aeruginosa*. It is used in the treatment of susceptible infections especially those due to *Pseudomonas* spp. They include biliary-tract infections, bone and joint infections, cystic fibrosis (respiratory-tract infections), endophthalmitis, infections in immunocompromised patients (neutropenic patients), melioidosis, meningitis, peritonitis, pneumonia, upper respiratory-tract infections, septicaemia, skin infections (including burns, ecthyma gangrenosum, and ulceration), and urinary-tract infections. It is also used for surgical infection prophylaxis. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Administration and dosage. Ceftazidime is available as the pentahydrate but it is formulated with sodium carbonate, to form the sodium salt in solution, or with arginine. Doses are expressed in terms of anhydrous ceftazidime; ceftazidime pentahydrate 1.16 g is equivalent to about 1 g of anhydrous ceftazidime. It is given by deep intramuscular injection, slow intravenous injection over 3 to 5 minutes, or intravenous infusion over up to 30 minutes. The usual dose for adults ranges from 1 to 6 g daily in divided doses every 8 or 12 hours. The higher doses are used in severe infections especially in immunocompromised patients. In adults with cystic fibrosis who have pseudomonal lung infections, high doses of 90 to 150 mg/kg daily in 3 divided doses are used; up to 9 g daily has been given to those with normal renal function. Single doses of more than 1 g should be given intravenously.

Children are usually given ceftazidime 30 to 100 mg/kg daily in 2 or 3 divided doses, but in severely ill children up to 150 mg/kg daily to a maximum of 6 g daily (9 g in cystic fibrosis with pseudomonal lung infection) may be given in 3 divided doses. Neonates and infants up to 2 months have been given 25 to 60 mg/kg daily in 2 divided doses.

In the elderly the dose should generally not exceed 3 g daily.

Although not licensed for nebulisation in the UK, the *BNFC* suggests a dose of 1 g inhaled twice daily for the management of chronic *Burkholderia cepacia* (*Pseudomonas cepacia*) infection in patients aged 1 month and older with cystic fibrosis.

For details of reduced doses in patients with renal impairment, see below.

For surgical infection prophylaxis in patients undergoing prostatic surgery, a dose of 1 g may be given at induction of anaesthesia and repeated if necessary when the catheter is removed.

Ceftazidime can be used with an aminoglycoside, another beta lactam such as piperacillin, or vancomycin in patients with severe neutropenia, or, if infection with *Bacteroides fragilis* is suspected, with an antimicrobial such as clindamycin or metronidazole. The drugs should generally be given separately (see also Incompatibility, above).

◊ References.

Administration in renal impairment. In patients with renal impairment the dosage of ceftazidime may need to be reduced. After a loading dose of 1 g, maintenance doses are based on the creatinine clearance (CC):

- CC 31 to 50 mL/minute: 1 g every 12 hours
- CC 16 to 30 mL/minute: 1 g every 24 hours
- CC 6 to 15 mL/minute: 500 mg every 24 hours
- CC less than 5 mL/minute: 500 mg every 48 hours

In severe infections these doses may need to be increased by 50%. In these patients ceftazidime trough serum concentrations should not exceed 40 micrograms/mL. In patients undergoing peritoneal dialysis a loading dose of 1 g may be given followed by 500 mg every 24 hours; ceftazidime sodium may also be added to the dialysis fluid, usually 125 to 250 mg of ceftazidime for 2 litres of dialysis fluid. In patients undergoing haemodialysis a loading dose of 1 g is given and then 0.5 to 1 g after each dialysis period.

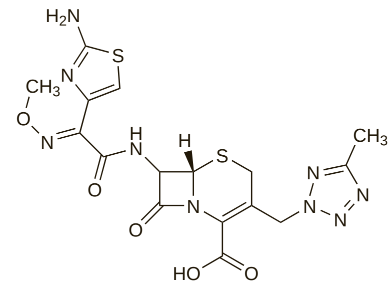
Cefteram Pivoxil *(rINNM)*

Cefteram, Pivoxil de; Cefteram pivoxilo; Cefterami Pivoxil; T-2588. Pivaloyloxymethyl (*Z*)-7-[2-(2-aminothiazol-4-yl)-2-methoxyiminoacetamido]-3-(5-methyl-2*H*-tetrazol-2-ylmethyl)-3-cephem-4-carboxylic acid.

Цефтерама Пивоксил

$C_{22}H_{27}N_9O_7S_2$ = 593.6.

CAS — 82547-58-8 (cefteram); 82547-81-7 (cefteram pivoxil).



(cefteram)

Pharmacopoeias. In *Jpn.*

Profile

Cefteram is a cephalosporin antibacterial used for the treatment of susceptible infections. It is given orally as the pivaloyloxymethyl ester, cefteram pivoxil, and doses are expressed in terms of cefteram; 186 mg of cefteram pivoxil is equivalent to about 150 mg of cefteram. The usual dose is 150 to 300 mg daily in 3 divided doses after meals. For severe infections, up to 600 mg daily may be given.

For reference to carnitine deficiency occurring after the administration of some pivaloyloxymethyl esters, see Pivampicillin, p.317.

Preparations

Proprietary Preparations (details are given in Part 3)
Jpn: Tomiron.

Ceftezole Sodium *(rINNM)*

Ceftezol sódico; Ceftézole Sodique; Natrii Ceftezolum. Sodium (7*R*)-7-[2-(1*H*-tetrazol-1-yl)acetamido]-3-(1,3,4-thiadiazol-2-ylthiomethyl)-3-cephem-4-carboxylate.

Натрий Цефтезол

$C_{13}H_{11}N_8NaO_4S_3$ = 462.5.

CAS — 26973-24-0 (ceftezole); 41136-22-5 (ceftezole sodium).

ATC — J01DB12.

ATC Vet — QJ01DB12.

Pharmacopoeias. In *Chin.*

Profile

Ceftezole is a cephalosporin antibacterial with properties similar to those of cefalotin (p.219). It is given as the sodium salt but doses are expressed in terms of the base; 1.05 g of ceftezole sodium is equivalent to about 1 g of ceftezole. The usual dose is 2 to 4 g daily by intramuscular injection in 2 or 3 divided doses.

Sodium content. Each g of ceftezole sodium contains about 2.16 mmol of sodium.

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Alomen.

Ceftibuten *(BAN, USAN, rINN)*

Ceftibutène; Ceftibuteno; Ceftibutenum; Keftibuteeni; 7432-S; Sch-39720. 7-[2-(2-Amino-1,3-thiazol-4-yl)-4-carboxyisocrotonamide]-3-cephem-4-carboxylic acid.

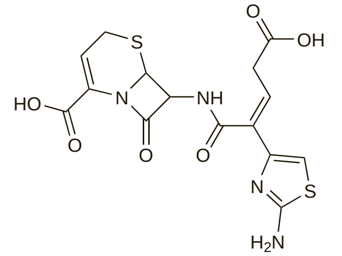
Цефтибутен

$C_{15}H_{14}N_4O_6S_2$ = 410.4.

CAS — 97519-39-6.

ATC — J01DD14.

ATC Vet — QJ01DD14.



Pharmacopoeias. *Jpn* includes the dihydrate.

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219.

The most frequently reported adverse effects of ceftibuten are gastrointestinal disturbances, especially diarrhoea, and headache.

Antimicrobial Action

As for Cefixime, p.224. It is less active *in vitro* against *Streptococcus pneumoniae*.

◊ References.

1. Shawar R, *et al.* Comparative in vitro activity of ceftibuten (Sch-39720) against bacterial enteropathogens. *Antimicrob Agents Chemother* 1989; **33:** 781–4.

3. Wise R, *et al.* Ceftibuten—in-vitro activity against respiratory pathogens, β-lactamase stability and mechanism of action. *J Antimicrob Chemother* 1990; **26:** 209–13.
4. Maioli E, *et al.* In vitro activity of ceftibuten at sub-inhibitory concentrations in comparison with other antibiotics against respiratory and urinary tract pathogens. *J Chemother* 2007; **19:** 152–60.

Pharmacokinetics

Ceftibuten is rapidly absorbed from the gastrointestinal tract, although the rate and extent of absorption are somewhat decreased by the presence of food. Peak plasma concentrations of about 17 micrograms/mL are attained about 2 hours after a 400-mg dose. The plasma half-life of ceftibuten is about 2.0 to 2.3 hours and is prolonged in patients with renal impairment. Ceftibuten is 65 to 77% bound to plasma proteins.

Ceftibuten distributes into middle-ear fluid and bronchial secretions. About 10% of a dose is converted to the *trans*-isomer, which has about one-eighth of the activity of the *cis*-isomer. Ceftibuten is excreted mainly in the urine and also in the faeces. Significant amounts are removed by haemodialysis.

Uses and Administration

Ceftibuten is a third-generation cephalosporin antibacterial used similarly to cefixime (p.225) in the treatment of urinary-tract and respiratory-tract infections. It is given orally as the dihydrate, but doses are expressed in terms of anhydrous ceftibuten; 435 mg of ceftibuten dihydrate is equivalent to about 400 mg of anhydrous ceftibuten. The usual adult dose is 400 mg once daily on an empty stomach. Children over 6 months of age and weighing 45 kg or less may be given 9 mg/kg daily as a single dose. For reduced doses in patients with moderate to severe renal impairment, see below.

Administration in renal impairment. Doses of ceftibuten should be reduced in patients with moderate to severe renal impairment. The following doses based on creatinine clearance (CC) may be used:

- CC 30 to 49 mL/minute: 200 mg once daily
- CC 5 to 29 mL/minute: 100 mg once daily

Patients undergoing haemodialysis 2 or 3 times weekly may be given a dose of 400 mg after each dialysis session.

ATC — J01DD07.

ATC Vet — QJ01DD07.

Pharmacopoeias. In *Jpn* and *US.*

USP 31 (Ceftizoxime Sodium). A white to pale yellow crystalline powder. Freely soluble in water. pH of a 10% solution in water is between 6.0 and 8.0. Store in airtight containers.

Stability. References.

1. Lesko AB, *et al.* Ceftizoxime stability in iv solutions. *DICP Ann Pharmacother* 1989; **23**: 615–18.

Adverse Effects and Precautions

As for Cefotaxime Sodium, p.228.

Sodium content. Each g of ceftizoxime sodium contains about 2.5 mmol of sodium.

Interactions

Probenecid reduces the renal clearance of ceftizoxime.

Antimicrobial Action

As for Cefotaxime Sodium, p.228, although ceftizoxime has no active metabolite.

Pharmacokinetics

After intramuscular injection of 0.5 and 1 g of ceftizoxime, mean peak plasma concentrations of about 14 and 39 micrograms/mL respectively have been reported after 1 hour. The plasma half-life of ceftizoxime is about 1.7 hours and is prolonged in neonates and in renal impairment. Ceftizoxime is 30% bound to plasma proteins.

Ceftizoxime is widely distributed in body tissues and fluids; therapeutic concentrations are achieved in the CSF when the meninges are inflamed. It crosses the placenta and low concentrations have been detected in breast milk.

Nearly all of a dose is excreted unchanged in the urine within 24 hours of dosage, thus achieving high urinary concentrations. Ceftizoxime is excreted by tubular secretion as well as glomerular filtration and giving it with probenecid results in higher and more prolonged plasma concentrations. Some ceftizoxime is removed by haemodialysis.

Neonates. References.

1. Fujii R. Investigation of half-life and clinical effects of ceftizoxime in premature and newborn infants. *Drug Invest* 1990; **2:** 143–9.
2. Reed MD, *et al.* Ceftizoxime disposition in neonates and infants during the first six months of life. *DICP Ann Pharmacother* 1991; **25:** 344–7.

Uses and Administration

Ceftizoxime is a third-generation cephalosporin antibacterial used similarly to cefotaxime (p.229) for the treatment of susceptible infections.

It is given as the sodium salt by deep intramuscular injection, or intravenously as a slow injection over 3 to 5 minutes or as a continuous or intermittent infusion. If 2 g of ceftizoxime is injected intramuscularly the dose should be divided between sites.

Doses are expressed in terms of the equivalent amount of ceftizoxime; 1.06 g of ceftizoxime sodium is equivalent to about 1 g of ceftizoxime. It is usually given in an adult dose of 1 to 2 g every 8 to 12 hours. In severe infections 2 to 4 g may be given intravenously every 8 hours; doses up to 2 g every 4 hours have been given in life-threatening infections.

Children over 6 months of age may be given 50 mg/kg every 6 to 8 hours.

For the treatment of uncomplicated urinary-tract infections, a dose of 500 mg every 12 hours is used.

For details of reduced doses in patients with renal impairment, see below.

A single intramuscular dose of 1 g has been given in uncomplicated gonorrhoea.

◊ References.

1. Richards DM, Heel RC. Ceftizoxime: a review of its antibacterial activity, pharmacokinetic properties and therapeutic use. *Drugs* 1985; **29:** 281–329.

Administration in renal impairment. Doses of ceftizoxime should be modified in renal impairment; after a loading dose of 0.5 to 1 g, the maintenance dosage should be adjusted according to creatinine clearance (CC) and the severity of the infection:

- CC 50 to 79 mL/minute: 0.5 to 1.5 g every 8 hours
- CC 5 to 49 mL/minute: 0.25 to 1 g every 12 hours
- CC less than 5 mL/minute: 250 to 500 mg every 24 hours or 0.5 to 1 g every 48 hours, after dialysis.

Adverse Effects and Precautions

As for Cefotaxime Sodium, p.228.

Changes in bowel flora may be more marked than with cefotaxime because of the greater biliary excretion of ceftriaxone; diarrhoea may occur more often, especially in children. Biliary sludge or pseudolithiasis due to a precipitate of calcium ceftriaxone has been seen occasionally in patients given ceftriaxone. Similarly, deposition of the calcium salt has occurred rarely in the urine. Isolated cases of death in term or premature neonates have been associated with precipitation of calcium ceftriaxone in lungs and kidneys, and in some of these cases a calcium-containing product has been given by a different route or line, or at a different time. US licensed product information therefore contra-indicates the use of ceftriaxone within 48 hours of products or solutions containing calcium, particularly in neonates. Ceftriaxone is highly protein bound and is able to displace bilirubin from albumin binding sites, causing hyperbilirubinaemia; its use should be avoided in jaundiced neonates.

Neutropenia has been reported with most cephalosporins; a complex mechanism has been attributed to that associated with ceftriaxone. There have been rare reports of fatal haemolysis associated with ceftriaxone.

Although ceftriaxone has an *N*-methylthiotriazine ring rather than an *N*-methylthiotetrazole side-chain, it might still have the potential to cause hypoprothrombinaemia.

Breast feeding. A study of drug distribution and protein binding between maternal blood and breast milk post partum in a 26-year-old woman given ceftriaxone 2 g daily by intravenous infusion for 10 days found that penetration of ceftriaxone into breast milk increased at these doses as protein binding capacity was saturated, although no adverse effects occurred in the infant.[1] The authors advised caution in breast-feeding mothers given acidic drugs which also have high protein binding such as ceftriaxone[1] although, on the basis that no adverse effects have been observed in breast-fed infants whose mothers were receiving ceftriaxone, the American Academy of Pediatrics considers[2] that it is therefore usually compatible with breast feeding.

Effects on the biliary tract. Using abdominal ultrasonography, biliary sludge or pseudolithiasis was found in about 40% of severely ill children being treated with high doses of ceftriaxone[1] and was later reported in adults.[2-4] The sludge has been identified as a calcium salt of ceftriaxone.[5] Patients are often asymptomatic and the sludge usually dissolves once ceftriaxone is stopped. Gallstones with ceftriaxone as a major component have been identified in a patient given long-term high-dose treatment.[6] Similarly, a bile-duct stone composed of ceftriaxone occurred with high-dose ceftriaxone in a child.[7] In another report, intractable hiccups were associated with ceftriaxone-related pseudolithiasis in a 10-year-old boy.[8]

Sodium content. Each g of ceftriaxone sodium contains about 3.0 mmol of sodium.

Interactions

Ceftriaxone has an *N*-methylthiotriazine side-chain and may have the potential to increase the effects of anticoagulants and to cause a disulfiram-like reaction with alcohol.

Unlike many cephalosporins, probenecid does not affect the renal excretion of ceftriaxone.

Antimicrobial Action

As for Cefotaxime Sodium, p.228, although ceftriaxone has no active metabolite.

Pharmacokinetics

Ceftriaxone demonstrates nonlinear dose-dependent pharmacokinetics because of its protein binding; about 85 to 95% is bound to plasma proteins depending on the concentration of ceftriaxone.

Mean peak plasma concentrations of about 40 and 80 micrograms/mL have been reported 2 hours after intramuscular injection of 0.5 and 1 g of ceftriaxone respectively. The plasma half-life of ceftriaxone is not dependent on the dose and varies between 6 and 9 hours; it may be prolonged in neonates. The half-life does not change appreciably in patients with moderate renal impairment, but it may be prolonged in severe impairment especially when there is also hepatic impairment.

Ceftriaxone is widely distributed in body tissues and fluids. It crosses both inflamed and non-inflamed meninges, generally achieving therapeutic concentrations in the CSF. It crosses the placenta and low concentrations have been detected in breast milk. High concentrations are achieved in bile.

About 40 to 65% of a dose of ceftriaxone is excreted unchanged in the urine, principally by glomerular filtration; the remainder is excreted in the bile and is ultimately found in the faeces as unchanged drug and microbiologically inactive compounds.

Renal impairment. The pharmacokinetics of ceftriaxone are not markedly altered in mild to moderate renal impairment,[1] but the half-life can be prolonged in severe or end-stage renal disease.[1-4] Ceftriaxone is generally not removed by peritoneal dialysis[4] or by haemodialysis[1-3] although a decrease in half-life has been reported during haemodialysis.[5] In many patients no alteration in dosage is necessary, but some individuals have reduced non-renal clearance despite apparently normal hepatic function.[2,3] It is advisable to monitor plasma ceftriaxone in

patients with severe renal impairment and unknown non-renal clearance.

Uses and Administration

Ceftriaxone is a third-generation cephalosporin antibacterial used similarly to cefotaxime for the treatment of susceptible infections. They include chancroid, endocarditis, gastro-enteritis (invasive salmonellosis; shigellosis), gonorrhoea, Lyme disease, meningitis (including meningococcal meningitis prophylaxis), pneumonia, septicaemia, syphilis, typhoid fever, and Whipple's disease. It is also used for surgical infection prophylaxis. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Administration and dosage. Ceftriaxone is given as the sodium salt by slow intravenous injection over at least 2 to 4 minutes, by intermittent intravenous infusion over at least 30 minutes, or by deep intramuscular injection. If more than 1 g is to be injected intramuscularly then the dose should be divided between more than one site. Doses are expressed in terms of the equivalent amount of ceftriaxone; 1.19 g of ceftriaxone sodium is equivalent to about 1 g of ceftriaxone. The usual adult dose is 1 to 2 g daily as a single dose or in two divided doses; in severe infections up to 4 g daily may be given. Doses for infants and children (under 50 kg) are 20 to 50 mg/kg once daily; for severe infections up to 80 mg/kg daily may be given. In neonates, the maximum dose should not exceed 50 mg/kg daily; intravenous doses in neonates should be given over 60 minutes. Doses above 50 mg/kg should be given by intravenous infusion only.

A single intramuscular dose of 250 mg is recommended for the treatment of uncomplicated gonorrhoea.

For surgical infection prophylaxis, a single dose of 1 g may be given 0.5 to 2 hours before surgery; a 2-g dose is suggested before colorectal surgery.

For the prevention of secondary cases of meningococcal meningitis, a single intramuscular dose of 250 mg may be used for adults and 125 mg for children.

Administration in hepatic and renal impairment. A reduction in dosage of ceftriaxone may be necessary in patients with severe renal impairment (creatinine clearance below 10 mL/minute), in whom the daily dose should not exceed 2 g. In patients undergoing dialysis, and in those with both renal and hepatic impairment, plasma concentrations of ceftriaxone should be monitored to determine whether dose adjustment is needed.

Preparations

BP 2008: Ceftriaxone Injection;

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Cefuroxime Axetil). A white or almost white powder. Slightly soluble in water and in alcohol; soluble in acetone, in ethyl acetate, and in methyl alcohol. Store in airtight containers. Protect from light.

USP 31 (Cefuroxime Axetil). A mixture of the diastereoisomers of cefuroxime axetil. A white or almost white powder. The amorphous form is insoluble in water and in ether; slightly soluble in dehydrated alcohol; freely soluble in acetone; soluble in chloroform, in ethyl acetate, and in methyl alcohol. The crystalline form is insoluble in water and in ether; slightly soluble in dehydrated alcohol; freely soluble in acetone; sparingly soluble in chloroform, in ethyl acetate, and in methyl alcohol. Store in airtight containers.

Cefuroxime Sodium *(BANM, rINNM)*

Cefuroksimo natrio druska; Cefuroksym sodowy; Cefuroxim sodná sůl; Cefuroxima sódica; Céfuroxime sodique; Cefuroximnatrium; Cefuroxim-nátrium; Cefuroximum natricum; Kefuroksiiminatrium; Natrii Cefuroximum; Sefuroksim Sodyum.

Натрий Цефуроксим

$C_{16}H_{15}N_4NaO_8S = 446.4.$

CAS — 56238-63-2.

ATC — J01DC02.

ATC Vet — QJ01DC02.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Cefuroxime Sodium). A white or almost white slightly hygroscopic powder. Freely soluble in water; very slightly soluble in alcohol. A 1% solution in water has a pH of 5.5 to 8.5. Store in airtight containers.

USP 31 (Cefuroxime Sodium). A white or faintly yellow powder. Freely soluble in water; very slightly soluble in alcohol, in chloroform, in ether, and in ethyl acetate; soluble in methyl alcohol. pH of a 10% solution in water is between 6.0 and 8.5. Store in airtight containers.

Incompatibility and stability. Cefuroxime sodium may be incompatible with aminoglycosides.

Adverse Effects and Precautions

As for Cefalotin Sodium, p.219.

Gastrointestinal disturbances, including diarrhoea, nausea, and vomiting, have occurred in some patients receiving cefuroxime axetil. There have been rare reports of erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis. Mild to moderate hearing loss has been reported in some children given cefuroxime for the treatment of meningitis.

Antibiotic-associated colitis. For reports of pseudomembranous colitis associated with cefuroxime axetil, see Cefalotin, p.219.

Hypersensitivity. A report[1] of a serum sickness-like reaction to cefuroxime. Similar reactions have occurred with cefaclor (p.217), although it is unclear whether they represent a class effect.

1. Katta R, Anusuri V. Serum sickness-like reaction to cefuroxime: a case report and review of the literature. *J Drugs Dermatol* 2007; **6:** 747–8.

Porphyria. Cefuroxime is considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity.

Sodium content. Each g of cefuroxime sodium contains about 2.2 mmol of sodium.

Interactions

Probenecid reduces the renal clearance of cefuroxime.

Antimicrobial Action

Cefuroxime is bactericidal and has a similar spectrum of antimicrobial action and pattern of resistance to those of cefamandole (p.221). It is more resistant to hydrolysis by beta-lactamases than cefamandole, and therefore may be more active against beta-lactamase-producing strains of, for example, *Haemophilus influenzae* and *Neisseria gonorrhoeae*. However, treatment failures have occurred in patients with *H. influenzae* meningitis given cefuroxime and might be associated with a relatively high minimum bactericidal concentration when compared with the minimum inhibitory concentration or with a significant inoculum effect. Reduced affinity of penicillin-binding proteins for cefuroxime has also been reported to be responsible for resistance in a beta-lactamase-negative strain of *H. influenzae*.

3. Brown NM, *et al.* Cefuroxime resistance in Haemophilus influenzae. *Lancet* 1992; **340:** 552.

Pharmacokinetics

Cefuroxime axetil is absorbed from the gastrointestinal tract and is rapidly hydrolysed in the intestinal mucosa and blood to cefuroxime; absorption is enhanced in the presence of food. Peak plasma concentrations are reported about 2 to 3 hours after an oral dose. The sodium salt is given by intramuscular or intravenous injection. Peak plasma concentrations of about 27 micrograms/mL have been achieved 45 minutes after an intramuscular dose of 750 mg with measurable amounts present 8 hours after a dose. Up to 50% of cefuroxime in the circulation is bound to plasma proteins. The plasma half-life is about 70 minutes and is prolonged in patients with renal impairment and in neonates.

Cefuroxime is widely distributed in the body including pleural fluid, sputum, bone, synovial fluid, and aqueous humour, but only achieves therapeutic concentrations in the CSF when the meninges are inflamed. It crosses the placenta and has been detected in breast milk.

Cefuroxime is excreted unchanged, by glomerular filtration and renal tubular secretion, and high concentrations are achieved in the urine. On injection, most of a dose of cefuroxime is excreted within 24 hours, the majority within 6 hours. Probenecid competes for renal tubular secretion with cefuroxime resulting in higher and more prolonged plasma concentrations of cefuroxime. Small amounts of cefuroxime are excreted in bile. Plasma concentrations are reduced by dialysis.

Uses and Administration

Cefuroxime is a second-generation cephalosporin antibacterial used in the treatment of susceptible infections. These have included bone and joint infections, bronchitis (and other lower respiratory-tract infections), gonorrhoea, meningitis (although treatment failures have been reported in *H. influenzae* meningitis), otitis media, peritonitis, pharyngitis, sinusitis, skin infections (including soft-tissue infections), and urinary-tract infections. It is also used for surgical infection prophylaxis. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Administration and dosage. Cefuroxime is given orally as the acetoxyethyl ester, cefuroxime axetil, in the form of tablets or suspension with or after food, or by injection as the sodium salt. Cefuroxime sodium may be given by deep intramuscular injection, by slow intravenous injection over 3 to 5 minutes, or by intravenous infusion. Doses of cefuroxime axetil and cefuroxime sodium are expressed in terms of the equivalent amount of cefuroxime; 1.20 g of cefuroxime axetil and 1.05 g of cefuroxime sodium are each equivalent to about 1 g of cefuroxime.

Usual oral doses for adults are 125 mg twice daily for uncomplicated urinary-tract infections and 250 to 500 mg twice daily for respiratory-tract infections. A dose for children more than 3 months of age is 125 mg twice daily or 10 mg/kg twice daily to a maximum of 250 mg daily. Children over 2 years of age with otitis media may be given 250 mg twice daily or 15 mg/kg twice daily to a maximum of 500 mg daily.

By injection the usual adult dose is 750 mg of cefuroxime every 8 hours but in more severe infections 1.5 g may be given intravenously every 8, or in some cases every 6, hours. Infants and children can be given 30 to 60 mg/kg daily, increased to 100 mg/kg daily if necessary, given in 3 or 4 divided doses. Neonates may be given similar total daily doses but in 2 or 3 divided doses.

Adults with pneumonia or with acute exacerbations of chronic bronchitis may respond to sequential therapy with parenteral cefuroxime 1.5 g twice daily or 750 mg twice daily respectively, followed by oral cefuroxime 500 mg twice daily in each case.

For Lyme disease in adults, an oral dose of 500 mg is given twice daily for 20 days.

For details of reduced dosage of cefuroxime in patients with renal impairment, see below.

For the treatment of meningitis due to sensitive strains of bacteria, cefuroxime is given intravenously in adult doses of 3 g every 8 hours. Infants and children are given 200 to 240 mg/kg daily intravenously in 3 or 4 divided doses, which may be decreased to 100 mg/kg daily after 3 days or when there is clinical improvement. For neonates, a dose of 100 mg/kg daily, decreased to 50 mg/kg daily when indicated, may be used.

In the treatment of gonorrhoea, a single dose of 1.5 g by intramuscular injection, divided between 2 injection sites, has been used. A single 1-g oral dose of cefuroxime has been given for uncomplicated gonorrhoea. In each case an oral dose of probenecid 1 g may be given with cefuroxime.

For surgical infection prophylaxis, the usual dose is 1.5 g of cefuroxime intravenously before the procedure; this may be supplemented by 750 mg intramuscularly every 8 hours for up to 24 to 48 hours depending upon the procedure. For total joint replacement, 1.5 g of cefuroxime powder may be mixed with the methylmethacrylate cement.

◊ Reviews.

2. Scott LJ, *et al.* Cefuroxime axetil: an updated review of its use in the management of bacterial infections. *Drugs* 2001; **61:** 1455–1500.

Administration in renal impairment. Parenteral doses of cefuroxime may need to be reduced in renal impairment. Licensed product information suggests the following doses based on creatinine clearance (CC):

- CC 10 to 20 mL/minute: 750 mg twice daily
- CC less than 10 mL/minute: 750 mg once daily

Patients undergoing haemodialysis should receive an additional 750-mg dose following each dialysis; those undergoing continuous peritoneal dialysis may be given 750 mg twice daily.

Preparations

BP 2008: Cefuroxime Axetil Tablets; Cefuroxime Injection;

Chloramphenicol *(BAN, rINN)*

Chloramfenikol; Chloramfenikolis; Chloramphénicol; Chloramphenicolum; Chloranfenicol; Cloranfenicol; Klóramfenikol; Kloramfenikol; Kloramfenikoli; Laevomycetinum. 2,2-Dichloro-*N*-[(α*R*,β*R*)-β-hydroxy-α-hydroxymethyl-4-nitrophenethyl]acetamide.

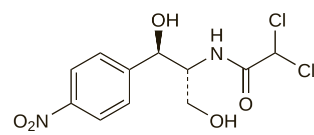
Хлорамфеникол

$C_{11}H_{12}Cl_2N_2O_5$ = 323.1.

CAS — 56-75-7.

ATC — D06AX02; D10AF03; G01AA05; J01BA01; S01AA01; S02AA01; S03AA08.

ATC Vet — QD06AX02; QD10AF03; QG01AA05; QJ01BA01; QJ51BA01; QS01AA01; QS02AA01; QS03AA08.



NOTE. CPL is a code approved by the BP 2008 for use on single unit doses of eye drops containing chloramphenicol where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Chloramphenicol). A substance produced by the growth of certain strains of *Streptomyces venezuelae*, but now mainly prepared synthetically. A white, greyish-white or yellowish-white, fine crystalline powder or fine crystals, needles, or elongated plates. Slightly soluble in water; freely soluble in alcohol and in propylene glycol. Protect from light.

USP 31 (Chloramphenicol). Fine, white to greyish-white or yellowish-white, needle-like crystals or elongated plates. Soluble 1 in 400 of water; freely soluble in alcohol, in acetone, in ethyl acetate, and in propylene glycol. pH of a 2.5% suspension in water is between 4.5 and 7.5. Its solutions are practically neutral to litmus. It is reasonably stable in neutral or moderately acid solutions. Store in airtight containers.

Chloramphenicol Palmitate *(BANM, rINNM)*

Chloramfenikolio palmitatas; Chloramfenikol-palmitát; Chloramfenikolu palmitynian; Chloramphenicol α-Palmitate; Chloramphénicol, palmitate de; Chloramphenicoli palmitas; Kloramfenikolipalmitaatti; Kloramfenikolpalmitat; Klóramfenikol-palmitát; Palmitato de cloranfenicol; Palmitylchloramphenicol.

Хлорамфеникола Пальмитат

$C_{27}H_{42}Cl_2N_2O_6$ = 561.5.

CAS — 530-43-8.

ATC — D06AX02; D10AF03; G01AA05; J01BA01; S01AA01; S02AA01; S03AA08.

ATC Vet — QD06AX02; QD10AF03; QG01AA05; QJ01BA01; QS01AA01; QS02AA01; QS03AA08.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Chloramphenicol Palmitate). A fine, white or almost white, unctuous, powder. M.p. 87° to 95°. Chloramphenicol palmitate shows polymorphism and the thermodynamically stable form has low bioavailability following oral administration. Practically insoluble in water; sparingly soluble in alcohol; freely soluble in acetone; very slightly soluble in hexane. Protect from light.

USP 31 (Chloramphenicol Palmitate). A fine, white, unctuous, crystalline powder, having a faint odour. M.p. 87° to 95°. Insoluble in water; sparingly soluble in alcohol; freely soluble in acetone and in chloroform; soluble in ether; very slightly soluble in hexane. Store in airtight containers.

Chloramphenicol Sodium Succinate

(BANM, rINNM)

Chloramfenikolio natrio sukcinatas; Chloramfenikol-sukcinát sodná sůl; Chloramphenicol α-Sodium Succinate; Chloramphénicol, succinate sodique de; Chloramphenicoli natrii succinas; Kloramfenikol Süksinat Sodyum; Klóramfenikol-hidrogénszukcinát-nátrium; Kloramfenikolinatriumsuksinaatti; Kloramfenikolnatriumsuccinat; Succinato sódico de cloranfenicol.

Хлорамфеникола Натрия Сукцинат

$C_{15}H_{15}Cl_2N_2NaO_8$ = 445.2.

CAS — 982-57-0.

ATC — D06AX02; D10AF03; G01AA05; J01BA01; S01AA01; S02AA01; S03AA08.

ATC Vet — QD06AX02; QD10AF03; QG01AA05; QJ01BA01; QS01AA01; QS02AA01; QS03AA08.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.* *Chin.* includes Chloramphenicol Hydrogen Succinate.

Ph. Eur. 6.2 (Chloramphenicol Sodium Succinate). A white or yellowish-white hygroscopic powder. Very soluble in water; freely soluble in alcohol. A 25% solution in water has a pH of 6.4 to 7.0. Store in airtight containers. Protect from light.

USP 31 (Chloramphenicol Sodium Succinate). A light yellow powder. Freely soluble in water and in alcohol. pH of a solution in water containing the equivalent of chloramphenicol 25% is between 6.4 and 7.0. Store in airtight containers.

Incompatibility. Incompatibility or loss of activity has been reported between chloramphenicol and a wide variety of other substances. Other factors, especially drug concentration, may play a part and many incompatibilities are chiefly seen with concentrated solutions.

Adverse Effects and Treatment

Chloramphenicol may cause serious and sometimes fatal adverse effects. Some of its toxicity is thought to be due to effects on mitochondrial protein synthesis. The most serious adverse effect of chloramphenicol is bone-marrow depression, which can take two different forms. The first is a fairly common dose-related reversible depression occurring usually when plasma-chloramphenicol concentrations exceed 25 micrograms/mL and is characterised by morphological changes in the bone marrow, decreased iron utilisation, reticulocytopenia, anaemia, leucopenia, and thrombocytopenia. This effect may be due to inhibition of protein synthesis in the mitochondria of bone marrow cells.

The second and apparently unrelated form of bone-marrow toxicity is severe irreversible aplastic anaemia. This is fairly rare, with a suggested incidence of about 1:20 000 to 1:50 000, although the incidence varies throughout the world, and is not considered to be dose-related. The aplasia usually develops after a latent period of weeks or even months and has been suggested to be the result of a nitrated benzene radical produced *in vivo*. It is considered that there may be some genetic or biochemical predisposition, but there is no way of identifying susceptible patients. Although the majority of cases were after oral use, aplasia has also occurred after intravenous and topical (eye drops) use of chloramphenicol. Survival is most likely in those with early onset aplasia, but they may subsequently develop acute myeloid leukaemia.

A toxic manifestation—the 'grey syndrome'—characterised by abdominal distension, vomiting, ashen colour, hypothermia, progressive pallid cyanosis, irregular respiration, and circulatory collapse followed by death in a few hours or days, has occurred in premature and other newborn infants given large doses of chloramphenicol. The syndrome is associated with high plasma concentrations of chloramphenicol, due to reduced capacity for glucuronidation and decreased glomerular filtration in children of this age, leading to drug accumulation. Recovery is usually complete if the drug is withdrawn early enough after onset, but up to 40% of infants with the full-blown syndrome may die. The syndrome has also been reported in infants born to mothers given chloramphenicol in late pregnancy. A similar syndrome has been reported in adults and older children given very high doses.

Prolonged oral use of chloramphenicol may induce bleeding, either by bone-marrow depression or by reducing the intestinal flora with consequent inhibition of vitamin K synthesis. Haemolytic anaemia has occurred in some patients with the Mediterranean form of glucose 6-phosphate dehydrogenase deficiency, but is rare in patients with milder forms of the deficiency.

Peripheral as well as optic neuritis has been reported, usually in patients treated over prolonged periods. Although ocular symptoms are often reversible if treatment is withdrawn early, permanent visual impairment or blindness has occurred.

Other neurological symptoms have included encephalopathy with confusion and delirium, mental depression, and headache. Ototoxicity has also occurred, especially after the use of ear drops.

Hypersensitivity reactions including rashes, fever, and angioedema may occur especially after topical use; anaphylaxis has occurred but is rare. Jarisch-Herxheimer reactions may also occur. Gastrointestinal symptoms including nausea, vomiting, and diarrhoea can follow oral use. Disturbances of the oral and intestinal flora may cause stomatitis, glossitis, and rectal irritation. Patients may experience an intensely bitter taste after rapid intravenous use of chloramphenicol sodium succinate.

Aplastic anaemia. A review[1] of the toxicity of chloramphenicol and related drugs, including the potential role of the *p*-nitro group in producing aplastic anaemia, indicated that derivatives such as thiamphenicol, which lack this grouping, are not associated with increased incidence of aplastic anaemia.

1. Yunis AA. Chloramphenicol: relation of structure to activity and toxicity. *Ann Rev Pharmacol Toxicol* 1988; **28:** 83–100.

Overdosage. Charcoal haemoperfusion was found to be far superior to exchange transfusion in the removal of chloramphenicol from blood, although it did not prevent death in a 7-week-old infant with the 'grey syndrome' after a dosage error.[1]

1. Freundlich M, *et al.* Management of chloramphenicol intoxication in infancy by charcoal hemoperfusion. *J Pediatr* 1983; **103:** 485–7.

Precautions

Chloramphenicol is contra-indicated in patients with a history of hypersensitivity or toxic reaction to the drug. It should never be given systemically for minor infections or for prophylaxis. Repeated courses and prolonged treatment should be avoided and it should not be used in patients with pre-existing bone-marrow depression or blood dyscrasias. Routine periodic blood examinations are advisable in all patients, but will not warn of aplastic anaemia.

Use of chloramphenicol with other drugs liable to depress bone-marrow function should be avoided.

Reduced doses should be given to patients with hepatic impairment. Excessive blood concentrations may also occur after usual doses in patients with severe renal impairment and in premature and full-term neonates who have immature metabolic processes. Monitoring of plasma-chloramphenicol concentrations may be desirable in patients with risk factors. A suggested range for peak plasma concentrations is 10 to 25 micrograms/mL and for trough concentrations 5 to 15 micrograms/mL.

Neonates should never be given chloramphenicol systemically, unless it may be life-saving and there is no alternative treatment, because of the risk of the 'grey syndrome'. The use of chloramphenicol is probably best avoided during pregnancy.

Chloramphenicol may interfere with the development of immunity and it should not be given during active immunisation.

Breast feeding. Chloramphenicol is distributed into breast milk[1] and the American Academy of Pediatrics[2] considers that its use by mothers during breast feeding may be of concern, since there have been reports of possible idiosyncratic bone-marrow suppression in the infant.

Ocular use. Ocular chloramphenicol is widely used in the UK for the treatment of superficial eye infections. In view of the potential for serious toxicity, such as aplastic anaemia, after systemic absorption some, particularly in the USA, have advised that its ocular use should be restricted to situations where there is no alternative treatment.[1] However, apart from patients with a personal or family history of blood dyscrasias, the use, particularly of short courses, was defended by several specialists in the UK,[2-4] and the arguments have been the subject of several reviews.[5-7] Prospective case-control studies were considered necessary to clarify the risk.[8] One such study,[9] involving 145 patients with aplastic anaemia and 1226 controls, found that only 3 of the patients had been exposed to ocular chloramphenicol, and calculated that the absolute risk was no more than 0.5 cases per million treatment courses. Similarly, data[10] from 2 other studies revealed that none of 426 patients with aplastic anaemia and 7 of 3118 controls had used chloramphenicol eye drops. In a survey[11] of patients who received prescriptions for chloramphenicol eye drops the risk of serious haematological toxicity was 3 per 442 543 patients or 3 per 674 148 prescriptions.

Porphyria. Chloramphenicol has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Sodium content. Each g of chloramphenicol sodium succinate represents about 2.2 mmol of sodium.

Interactions

Chloramphenicol is inactivated in the liver and may, therefore, interact with drugs that are metabolised by hepatic microsomal enzymes. For example, chloramphenicol enhances the effects of coumarin anticoagulants, such as dicoumarol and warfarin, some hypoglycaemics such as chlorpropamide and tolbutamide, and antiepileptics such as phenytoin. Conversely, the metabolism of chloramphenicol may be increased by inducers of hepatic enzymes such as phenobarbital or rifampicin. Some other interactions affecting the activity of chloramphenicol are discussed below.

Chloramphenicol may decrease the effects of iron and vitamin B_{12} in anaemic patients and has occasionally impaired the action of oral contraceptives.

For the effects of chloramphenicol on the activity of other antibacterials, see Antimicrobial Action, below.

Antiepileptics. Serum concentrations of chloramphenicol are usually reduced by the hepatic enzyme induction that occurs with *phenobarbital*,[1,2] and similar reductions have been reported in a case study during *phenytoin* use.[3] Conversely, elevated and potentially toxic serum-chloramphenicol concentrations have resulted during phenytoin use,[2] apparently due to competition for binding sites, although increased metabolism may alternatively lead to decreased serum-chloramphenicol concentrations.

For reference to the effects of chloramphenicol on phenobarbital and phenytoin, see p.493 and p.498, respectively.

3. Powell DA, *et al.* Interactions among chloramphenicol, phenytoin, and phenobarbital in a pediatric patient. *J Pediatr* 1981; **98:** 1001–3.

Ciclosporin. For the effect of chloramphenicol on ciclosporin, see p.1825.

Cimetidine. Fatal aplastic anaemia of rapid onset has occurred in 2 patients who received intravenous chloramphenicol and cimetidine.[1,2] As there is usually a latent period of 2 weeks to 12 months before aplastic anaemia develops after chloramphenicol therapy it is plausible that an additive or synergistic effect may have occurred between the 2 drugs to cause bone-marrow toxicity.

Cyclophosphamide. For the effect of chloramphenicol on cyclophosphamide, see p.703.

Oral contraceptives. For the effect of chloramphenicol on oral contraceptives, see Hormonal Contraceptives, p.2068.

Paracetamol. A report of an increase in chloramphenicol half-life from 3.25 to 15 hours when intravenous paracetamol was given to 6 patients in intensive care 2 hours after intravenous chloramphenicol[1] has not been confirmed by subsequent studies in patients receiving oral paracetamol. A study in 5 children found that the half-life of intravenous chloramphenicol was reduced from 3 to 1.2 hours, concomitant with an increase in clearance, when oral paracetamol was given 30 minutes beforehand.[2] Furthermore, a study in 26 children found no evidence of altered disposition when oral paracetamol was given to patients receiving intravenous chloramphenicol,[3] and no significant change in chloramphenicol pharmacokinetics was found in 5 patients given oral chloramphenicol and paracetamol.[4]

Tacrolimus. For the effect of chloramphenicol on tacrolimus, see p.1845.

Antimicrobial Action

Chloramphenicol is a bacteriostatic antibiotic with a broad spectrum of action against both Gram-positive and Gram-negative bacteria, as well as some other organisms.

Mechanism of action. Chloramphenicol is thought to enter sensitive cells by an active transport process. Within the cell it binds to the 50S subunit of the bacterial ribosome at a site adjacent to the site of action of the macrolides and clindamycin, and inhibits bacterial protein synthesis by preventing attachment of aminoacyl transfer RNA to its acceptor site on the ribosome, thus preventing peptide bond formation by peptidyl transferase. The block in protein synthesis results in a primarily bacteriostatic action, although it may be bactericidal to some organisms, including *Haemophilus influenzae*, *Neisseria meningitidis*, and *Streptococcus pneumoniae*, at higher concentrations.

Spectrum of activity. Chloramphenicol has activity against many types of bacteria, although in most cases there are less toxic alternatives available. The following pathogens are usually susceptible (but see also Resistance, below).

Gram-positive cocci including staphylococci such as *Staph. epidermidis* and some strains of *Staph. aureus*, and streptococci such as *Str., pneumoniae*, *Str. pyogenes*, and the viridans streptococci. Meticillin-resistant staphylococci and *Enterococcus faecalis* are commonly found to be resistant.

Other Gram-positive species including *Bacillus anthracis*, *Corynebacterium diphtheriae*, and anaerobes such as *Peptococcus* and *Peptostreptococcus* spp. are usually susceptible.

Gram-negative cocci such as *Neisseria meningitidis* and *N. gonorrhoeae* are usually highly sensitive, as are *Haemophilus influenzae* and a variety of other Gram-negative bacteria including *Bordetella pertussis*, *Brucella abortus*, *Campylobacter* spp., *Legionella pneumophila*, *Pasteurella*, and *Vibrio* spp. The Enterobacteriaceae vary in their susceptibility, and many strains have shown acquired resistance, but *Escherichia coli*, and strains of *Klebsiella* spp., *Proteus mirabilis*, *Salmonella*, *Shigella*, and *Yersinia* spp. have been reported to be susceptible. Many strains of *Enterobacter*, indole-positive *Proteus*, and *Serratia* spp. are resistant, or at best moderately susceptible. *Pseudomonas aeruginosa* is invariably resistant, although *Burkholderia* (formerly *Pseudomonas*) spp. may be susceptible.

Some Gram-negative anaerobes are susceptible, or moderately so, including *Bacteroides fragilis*, *Veillonella*, and *Fusobacterium* spp.

Other susceptible organisms include *Actinomyces* spp., *Leptospira* spp., spirochaetes such as *Treponema pallidum*, Chlamydiaceae, Mycoplasma spp., and Rickettsia spp. *Nocardia* spp. are resistant. Chloramphenicol is ineffective against fungi, protozoa, and viruses.

Activity with other antimicrobials. As with other bacteriostatic antimicrobials, the possibility exists of an antagonistic effect if chloramphenicol is given with a bactericidal drug, and some antagonism has been demonstrated *in vitro* between chloramphenicol and various beta lactams and aminoglycosides, but the clinical significance of most of these interactions is usually held to be doubtful. Chloramphenicol may competitively inhibit the effects of macrolides or lincosamides such as clindamycin because of the adjacency of their binding sites on the ribosome.

Resistance. Acquired resistance has been widely reported, although the prevalence of resistance has tended to decline where use of the drug has become less frequent. The most commonly seen form of resistance has been the production of an acetyltransferase that inactivates the drug. Such resistance is usually plasmid-mediated and may be associated with resistance to other drugs such as the tetracyclines. Other mechanisms that may reduce sensitivity to chloramphenicol include reduced permeability or uptake, and ribosomal mutation.

The actual incidence of resistance varies considerably in different countries and different centres. Epidemics of chloramphenicol-resistant *Salmonella* and *Shigella* spp. have occurred in the past, and although the prevalence of resistance in *Salmonella* spp. has been reported to be negligible except in parts of South or South-east Asia, resistant salmonellal infections acquired in these regions are increasingly being seen elsewhere. Resistance among *Haemophilus* and *Neisseria* spp. occurs, and the latter may be problematic in developing countries, although it does not yet seem to be widespread. However, resistant strains of enterococci and pneumococci are reported to be relatively common in some areas, and over 50% of staphylococcal strains have been reported to show resistance in some hospitals.

Pharmacokinetics

Chloramphenicol is readily absorbed when given by mouth. Blood concentrations of 10 micrograms/mL or more may be reached about 1 or 2 hours after a single oral dose of 1 g, and blood concentrations of about 18.5 micrograms/mL have been reported after multiple 1-g doses. Chloramphenicol palmitate is hydrolysed to chloramphenicol in the gastrointestinal tract prior to absorption, and the sodium succinate, which is given parenterally, is probably hydrolysed to free drug mainly in the liver, lungs, kidneys, and plasma; such hydrolysis may be incomplete in infants and neonates, contributing to the variable pharmacokinetics in this age group. Chloramphenicol sodium succinate is, even in adults, only partially and variably hydrolysed, so that blood concentrations of chloramphenicol obtained after the sodium succinate parenterally are often lower than those obtained after oral chloramphenicol, with up to 30% of a dose excreted unchanged in the urine before hydrolysis can take place (but see under Administration, below).

Chloramphenicol is widely distributed in body tissues and fluids; it enters the CSF, giving concentrations of about 50% of those existing in the blood even in the absence of inflamed meninges; it diffuses across the placenta into the fetal circulation, into breast milk, and into the aqueous and vitreous humours of the eye. It also enters the aqueous humour after topical application. Up to about 60% in the circulation is bound to plasma protein. The half-life of chloramphenicol has been reported to range from 1.5 to 4 hours; the half-life is prolonged in patients with severe hepatic impairment and is also much longer in neonates. Renal impairment has relatively little effect on the half-life of the active drug, due to its extensive metabolism, but may lead to accumulation of the inactive metabolites.

Chloramphenicol is excreted mainly in the urine but only 5 to 10% of an oral dose appears unchanged; the remainder is inactivated in the liver, mostly by conjugation with glucuronic acid. About 3% is excreted in the bile. However, most is reabsorbed and only about 1%, mainly in the inactive form, is excreted in the faeces.

The absorption, metabolism, and excretion of chloramphenicol are subject to considerable interindividual variation, especially in infants and children, making monitoring of plasma concentrations necessary to determine pharmacokinetics in a given patient.

Uses and Administration

The risk of life-threatening adverse effects, particularly bone-marrow aplasia, has severely limited the clinical usefulness of chloramphenicol, although it is still widely used in some countries. It should never be given systemically for minor infections and regular blood counts are usually advisable during treatment. The third-generation cephalosporins replaced chloramphenicol for many of its former indications. There are consequently few unambiguous indications for the use of chloramphenicol. It has been used in severe typhoid and other salmonellal infections, although it does not eliminate the carrier state. Chloramphenicol is an alternative to a third-generation cephalosporin in the treatment of bacterial meningitis, both empirically and against sensitive organisms such as *Haemophilus influenzae*. It may be used as part of a multi-drug regimen for the treatment of inhalation and gastrointestinal anthrax. It has been used in the treatment of severe anaerobic infections, particularly in brain abscesses, and in infections below the diaphragm where *Bacteroides fragilis* is often implicated; however, other drugs are usually preferred. Although the tetracyclines remain the treatment of choice in rickettsial infections such as typhus and the spotted fevers, chloramphenicol is also used as an alternative where the tetracyclines cannot be given.

Other bacterial infections in which chloramphenicol may be used as an alternative to other drugs include ehrlichiosis, severe gastro-enteritis (including *Salmonella* enteritis, cholera, and *Yersinia* enteritis), gas gangrene, granuloma inguinale, severe *Haemophilus influenzae* infections (for example in epiglottitis), listeriosis, severe melioidosis, plague (especially if meningitis develops), pneumonia, psittacosis, Q fever, tularaemia (especially when meningitis is suspected), and Whipple's disease. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Chloramphenicol is extensively used in the topical treatment of ear and, in particular, eye infections, despite the fact that many of these are mild and self-limiting. It is also used topically in the treatment of skin infections.

When given orally, chloramphenicol is usually used as capsules or as a suspension of chloramphenicol palmitate. When oral use is not feasible, water-soluble chloramphenicol sodium succinate may be given intravenously, but oral therapy should be substituted as soon as possible; an intravenous dose should be injected over at least 1 minute. Intramuscular injection is controversial because of doubts whether absorption is adequate. In some countries chloramphenicol has been given rectally.

Doses are expressed in terms of chloramphenicol base and are similar whether given orally or intravenously. Chloramphenicol palmitate 1.7 g and chloramphenicol sodium succinate 1.4 g are each equivalent to about 1 g of chloramphenicol base.

For adults and children the usual dose is 50 mg/kg daily in divided doses every 6 hours; up to 100 mg/kg daily may be given in meningitis or severe infections due to moderately resistant organisms, although these higher doses should be reduced as soon as possible. It has been recommended that treatment should be continued after the patient's temperature has returned to normal for a further 4 days in rickettsial diseases, and for 8 to 10 days in typhoid fever, to minimise the risk of relapse.

Where there is no alternative to the use of chloramphenicol, premature and full-term neonates may be given daily doses of 25 mg/kg, in 4 divided doses, and full-term infants over the age of 2 weeks may be given up to 50 mg/kg daily, in 4 divided doses. Monitoring of plasma concentrations is essential to avoid toxicity.

In patients with hepatic impairment or severe renal impairment, the dose of chloramphenicol may need to be reduced because of decreased metabolism or excretion.

In the treatment of eye infections, chloramphenicol is usually applied as a 0.5% solution or as a 1% ointment.

For bacterial infections in otitis externa, chloramphenicol has been given as ear drops in a strength of 5 or 10%.

Chloramphenicol has also been used in the form of other derivatives including the arginine succinate, the cinnamate, the glycinate, the glycinate sulfate, the palmitoylglycolate, the pantothenate, the steaglate, the stearate, and the hydrogen succinate.

Administration. When parenteral use of chloramphenicol is necessary the intravenous route is generally preferred, although the intramuscular route has been advocated. Adequate serum concentrations after intramuscular injection have been reported,[1,2] although this is contrary to the widely held belief that chloramphenicol sodium succinate is poorly absorbed by this route. Pain on injection was also claimed to be minimal.[1] After a study in children with bacterial meningitis,[3] treatment with intramuscular chloramphenicol for 2 or 3 days followed by oral therapy has been suggested, although a later study[2] found that the intramuscular route produced therapeutic concentrations when the oral route did not. However, it has been said[4] that children describe intramuscular chloramphenicol as amongst the worst treatments they ever receive, and certainly much worse than the insertion of intravenous cannulae.

Enterococcal infections. Chloramphenicol has been reported to be effective against vancomycin-resistant *Enterococcus faecium*.[1-3] Although no significant effect of chloramphenicol on mortality was found in one small study,[4] a retrospective analysis[5] of the outcomes of 6 patients with bacteraemia due to vancomycin-resistant *Enterococcus faecium* concluded that chloramphenicol was effective and should be considered as a treatment option.

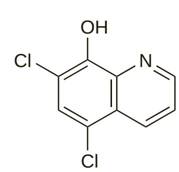
Chloroxine *(USAN)*

Cloroxinum; 5,7-Dichlorochinolin-8-ol; 5,7-Dichloroquinolin-8-ol; Kloroxin.

Хлороксин

$C_9H_5Cl_2NO = 214.0.$
CAS — 773-76-2.



Profile

Chloroxine is a halogenated hydroxyquinoline with antibacterial and antifungal properties similar to those of clioquinol (p.254). It is used topically in the treatment of dandruff and seborrhoeic dermatitis of the scalp. It has also been given orally in preparations for gastrointestinal disorders.

Chloroxine is a component of halquinol (p.286).

Preparations

Proprietary Preparations (details are given in Part 3)
Cz.: Endiaron; ***USA:*** Capitrol.

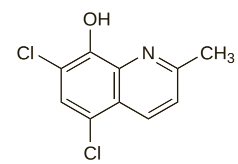
Multi-ingredient: ***Cz.:*** Endiform†; Triaderm; Triamcinolon Compositum†; Triamcinolon E; Triamcinolon-Galena†; ***Ital.:*** Beben Clorossina.

Chlorquinaldol *(BAN, rINN)*

Chlorochinaldol; Chlorquinaldolum; Clorquinaldol; Kloorikinaldoli; Klorkinaldol. 5,7-Dichloro-2-methylquinolin-8-ol.

Хлорхинальдол

$C_{10}H_7Cl_2NO = 228.1.$
CAS — 72-80-0.
ATC — D08AH02; G01AC03; P01AA04; R02AA11.
ATC Vet — QD08AH02; QG01AC03; QR02AA11.



Pharmacopoeias. In *Pol.*

Profile

Chlorquinaldol is a halogenated hydroxyquinoline with properties similar to those of clioquinol (p.254). It is mainly applied topically in infected skin conditions and in vaginal infections.

Preparations

Proprietary Preparations (details are given in Part 3)
Hung.: Chlorosan†; ***Venez.:*** Agel†.

Chlortetracycline Hydrochloride *(BANM, rINNM)*

Chlorotetracykliny chlorowodorek; Chlortetraciklino hidrochloridas; Chlortétracycline, chlorhydrate de; Chlortetracyclini hydrochloridum; Chlortetracyklin-hydrochlorid; Hidrocloruro de clortetraciclina; Klooritetrasykliinihydrokloridi; Klórtetraciklin-hidroklorid; Klortetracyklinhydroklorid.

Хлортетрациклина Гидрохлорид

$C_{22}H_{23}ClN_2O_8,HCl = 515.3.$
CAS — 64-72-2.
ATC — A01AB21; D06AA02; J01AA03; S01AA02.
ATC Vet — QA01AB21; QD06AA02; QJ01AA03; QS01AA02.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, and *US.*
Ph. Eur. 6.2 (Chlortetracycline Hydrochloride). The hydrochloride of a substance produced by the growth of certain strains of *Streptomyces aureofaciens* or by any other means. A yellow powder. Slightly soluble in water and in alcohol; it dissolves in solutions of alkali hydroxides and carbonates. A 1% solution in water has a pH of 2.3 to 3.3. Protect from light.
USP 31 (Chlortetracycline Hydrochloride). A yellow, odourless crystalline powder. Soluble 1 in 75 of water and 1 in 560 of alcohol; practically insoluble in acetone, in chloroform, in dioxan, and in ether; soluble in solutions of alkali hydroxides and carbonates. pH of a 1% solution in water is between 2.3 and 3.3. Store in airtight containers. Protect from light.

Profile

Chlortetracycline is a tetracycline derivative with general properties similar to those of tetracycline (p.347) and is used as the hydrochloride, more often topically than orally. It is used as a 1% ophthalmic ointment and as a 3% ointment for application to the skin. It is poorly absorbed from the gastrointestinal tract compared with other tetracyclines but is sometimes given orally with other tetracycline derivatives.

Preparations

BP 2008: Chlortetracycline Eye Ointment; Chlortetracycline Ointment;
USP 31: Chlortetracycline Hydrochloride Ointment; Chlortetracycline Hydrochloride Ophthalmic Ointment.

Proprietary Preparations (details are given in Part 3)

Ciclacillin *(BAN, rINN)*

Ciclacilina; Ciclacilline; Ciclacillinum; Ciklacillin; Cyclacillin *(USAN)*; Siklasilliini; Wy-4508. (6*R*)-6-(1-Aminocyclohexanecarboxamido)penicillanic acid.

Циклациллин

$C_{15}H_{23}N_3O_4S = 341.4.$
CAS — 3485-14-1.

Pharmacopoeias. In *Jpn.*

Profile

Ciclacillin is an aminopenicillin with properties similar to those of ampicillin (p.204), although it is generally less active *in vitro*.

Preparations

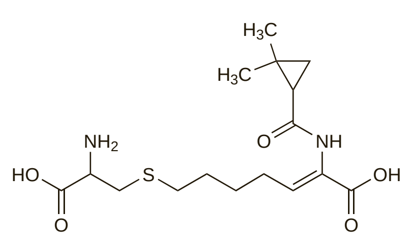
Proprietary Preparations (details are given in Part 3)
Braz.: Cilinase†.

Cilastatin Sodium *(BANM, USAN, rINNM)*

Cilastatin sodná sůl; Cilastatina sódica; Cilastatine sodique; Cilastatinnatrium; Cilastatino natrio druska; Cilastatinum natricum; Cilasztatin-nátrium; L-642957; MK-791; Natrii Cilastatinas; Natrii Cilastatinum; Natriumsilastatinaatti; Natriumsilastatinat; Silastatininatrium; Silastatin Sodyum. (*Z*)-(*S*)-6-Carboxy-6-[(*S*)-2,2-dimethylcyclopropanecarboxamido]hex-5-enyl-L-cysteine, monosodium salt.

Натрий Циластатин

$C_{16}H_{25}N_2NaO_5S = 380.4.$
CAS — 82009-34-5 (cilastatin); 81129-83-1 (cilastatin sodium).



(cilastatin)

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*
Ph. Eur. 6.2 (Cilastatin Sodium). A white or light yellow, hygroscopic, amorphous powder. Very soluble in water and in methyl alcohol; slightly soluble in dehydrated alcohol; practically insoluble in acetone and in dichloromethane; very slightly soluble in dimethyl sulfoxide. A 1% solution in water has a pH of 6.5 to 7.5. Store at a temperature not exceeding 8° in airtight containers.
USP 31 (Cilastatin Sodium). A white to tan-coloured powder. Soluble in water and in methyl alcohol. pH of a 1% solution in water is between 6.5 and 7.5. Store at a temperature less than 8°.

Profile

Cilastatin is an inhibitor of dehydropeptidase I, an enzyme found in the brush border of the renal tubules. It is given as the sodium salt with the antibacterial imipenem (p.286) to prevent its renal metabolism to microbiologically inactive and potentially nephrotoxic products. This increases the concentrations of imipenem achieved in the urine and protects against any nephrotoxic effects, which were seen with high doses of imipenem given experimentally to *animals*.

Cilastatin has no antibacterial activity itself, and does not affect the antibacterial activity of imipenem.

Preparations

USP 31: Imipenem and Cilastatin for Injectable Suspension; Imipenem and Cilastatin for Injection.

Proprietary Preparations (details are given in Part 3)
Pol.: Tienam.

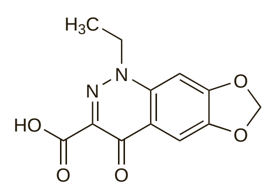
Multi-ingredient: *Arg.:* Dixabiox; Imipecil; Imistatin; Klonam†; Zienam; ***Austral.:*** Primaxin; ***Austria:*** Zienam; ***Belg.:*** Tienam; ***Braz.:*** Penexil†; Tienam; ***Canad.:*** Primaxin; ***Chile:*** Inem; Tienam; ***Cz.:*** Tienam; ***Denm.:*** Tienam; ***Fin.:*** Tienam; ***Fr.:*** Tienam; ***Ger.:*** Zienam; ***Gr.:*** Primaxin; ***Hong Kong:*** Prepenem; Tienam; ***Hung.:*** Tienam; ***India:*** Cilanem; ***Indon.:*** Pelastin; Tienam; ***Israel:*** Tienam; ***Ital.:*** Imipem; Tenacid; Tienam; ***Malaysia:*** Bacqure; Tienam; ***Mex.:*** Arzomeba; Iminen; Tienam; ***Neth.:*** Tienam; ***Norw.:*** Tienam; ***NZ:*** Primaxin; ***Philipp.:*** Anipen; Tienam; ***Port.:*** Tienam; ***Rus.:*** Tienam (Тиенам); ***S.Afr.:*** Tienam; ***Singapore:*** Tienam; ***Spain:*** Tienam; ***Swed.:*** Tienam; ***Switz.:*** Tienam; ***Thai.:*** Tienam; ***Turk.:*** Tienam; ***UK:*** Primaxin; ***USA:*** Primaxin; ***Venez.:*** Zienam.

Cinoxacin *(BAN, USAN, rINN)*

64716; Azolinic Acid; Cinoxacine; Cinoxacino; Cinoxacinum; Compound 64716; Sinoksasiini. 1-Ethyl-1,4-dihydro-4-oxo-1,3-dioxolo[4,5-g]cinnoline-3-carboxylic acid.

Циноксацин

$C_{12}H_{10}N_2O_5 = 262.2.$
CAS — 28657-80-9.
ATC — J01MB06.
ATC Vet — QJ01MB06.



Pharmacopoeias. In *US.*
USP 31 (Cinoxacin). A white to yellowish-white, odourless crystalline solid. Insoluble in water and in most common organic solvents; soluble in alkaline solution. Store in airtight containers.

Adverse Effects and Precautions

As for Nalidixic Acid, p.304.

Cinoxacin should be used in reduced dosage, or not at all, in patients with renal impairment.

◊ References.

1. Stricker BHC, *et al.* Anaphylactic reactions to cinoxacin. *BMJ* 1988; **297:** 1434–5.

Interactions

As for Nalidixic Acid, p.304.

Antimicrobial Action

As for Nalidixic Acid, p.304. Cross-resistance with nalidixic acid has been shown.

Pharmacokinetics

Cinoxacin is rapidly and almost completely absorbed after oral doses. Peak serum concentrations of about 15 micrograms/mL occur 2 to 3 hours after a 500-mg dose. The plasma half-life is about 1 to 2 hours. Cinoxacin is more than 60% bound to plasma proteins.

Cinoxacin appears to be metabolised in the liver and is excreted via the kidney. Over 95% of a dose appears in the urine within 24 hours, over half as unaltered drug and the remainder as inactive metabolites. Mean urinary concentrations of about 300 micrograms/mL have been achieved during the first 4 hours after a 500-mg oral dose. Urinary excretion is reduced by probenecid and in patients with renal impairment.

Uses and Administration

Cinoxacin is a 4-quinolone antibacterial with actions and uses similar to those of nalidixic acid (p.304). In the treatment of urinary-tract infections the usual oral dose is 500 mg twice daily; for prophylaxis 500 mg is given at bedtime.
For advice on use in renal impairment, see below.

Administration in renal impairment. Cinoxacin should be used in reduced dosage, or not at all, in patients with renal impairment.

Preparations

USP 31: Cinoxacin Capsules.

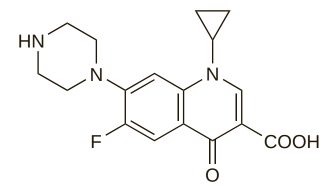
Proprietary Preparations (details are given in Part 3)
Gr.: Cinobactin†; ***Ital.:*** Cinobac; Cinocil; Cinoxen; Nossacin; Noxigram†; Uroc; Uronorm†; Uroxacin†; ***Mex.:*** Gugecin†; ***USA:*** Cinobac†.

Ciprofloxacin *(BAN, USAN, rINN)*

Bay-q-3939; Ciprofloksacinas; Ciprofloxacine; Ciprofloxacino; Ciprofloxacinum; Siprofloksasiini; Siprofloksasin; Siprofloxacin. 1-Cyclopropyl-6-fluoro-1,4-dihydro-4-oxo-7-piperazin-1-ylquinoline-3-carboxylic acid.

Ципрофлоксацин

$C_{17}H_{18}FN_3O_3 = 331.3.$
CAS — 85721-33-1.
ATC — J01MA02; S01AX13; S02AA15; S03AA07.
ATC Vet — QJ01MA02; QS01AX13; QS02AA15; QS03AA07.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, and *US.*
Ph. Eur. 6.2 (Ciprofloxacin). An almost white or pale yellow, slightly hygroscopic, crystalline powder. Practically insoluble in water; very slightly soluble in dehydrated alcohol and in dichloromethane. Store in airtight containers. Protect from light.
USP 31 (Ciprofloxacin). Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Avoid temperatures above 40°. Protect from light.

Ciprofloxacin Hydrochloride *(BANM, USAN, rINNM)*

Bay-o-9867; Ciprofloksacino hidrochloridas; Ciprofloxacine, chlorhydrate de; Ciprofloxacin-hidroklorid; Ciprofloxacin-hydrochlorid; Ciprofloxacinhydroklorid; Ciprofloxacini hydrochloridum; Cyprofloksacyny chlorowodorek; Hidrocloruro de ciprofloxacino; Siprofloksasiinihydrokloridi; Siprofloksasin Hidroklorür. Ciprofloxacin hydrochloride monohydrate.

Ципрофлоксацина Гидрохлорид

$C_{17}H_{18}FN_3O_3,HCl,H_2O = 385.8.$
CAS — 86483-48-9 (anhydrous ciprofloxacin hydrochloride); 86393-32-0 (ciprofloxacin hydrochloride monohydrate).
ATC — S02AA15.
ATC Vet — QS02AA15.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *US*, and *Viet.*
Ph. Eur. 6.2 (Ciprofloxacin Hydrochloride). A pale yellow, slightly hygroscopic, crystalline powder. Soluble in water; very slightly soluble in dehydrated alcohol; practically insoluble in acetone, in dichloromethane, and in ethyl acetate; slightly soluble in methyl alcohol. A 2.5% solution in water has a pH of 3.5 to 4.5. Store in airtight containers. Protect from light.
USP 31 (Ciprofloxacin Hydrochloride). Faintly yellowish to light yellow crystals. Sparingly soluble in water; very slightly soluble in dehydrated alcohol; slightly soluble in acetic acid and in methyl alcohol; practically insoluble in acetone, in acetonitrile, in dichloromethane, in ethyl acetate, and in hexane. pH of a 2.5% solution in water is between 3.0 and 4.5. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Ciprofloxacin Lactate *(BANM, rINNM)*

Ciprofloxacine, Lactate de; Ciprofloxacini Lactas; Lactato de ciprofloxacino.

Ципрофлоксацина Лактат

$C_{17}H_{18}FN_3O_3,C_3H_6O_3 = 421.4.$
CAS — 97867-33-9.
ATC — S02AA15.
ATC Vet — QS02AA15.

Incompatibility. Ciprofloxacin infusion is stated in UK licensed product information to have a pH of 3.9 to 4.5 and to be incompatible with injections chemically or physically unstable at this pH range. Incompatibility has been reported between ciprofloxacin and other drugs including some antibacterials.[1-5]

5. Elmore RL, *et al.* Stability and compatibility of admixtures of intravenous ciprofloxacin and selected drugs. *Clin Ther* 1996; **18:** 246–55.

Stability. For mention of loss of activity in ciprofloxacin solutions exposed to ultraviolet light see under Precautions, below.

Adverse Effects

Ciprofloxacin is generally well tolerated. The range of adverse effects associated with ciprofloxacin and the other fluoroquinolones is broadly similar to that of earlier quinolones such as nalidixic acid (p.304). They most often involve the gastrointestinal tract, CNS, or skin.

Gastrointestinal disturbances include nausea, vomiting, diarrhoea, abdominal pain, and dyspepsia and are the most frequent adverse effects. Pseudomembranous colitis, pancreatitis, and dysphagia have been reported rarely.

Headache, dizziness, confusion, insomnia, and restlessness are among the commonest effects on the CNS. Others include tremor, drowsiness, nightmares, visual and other sensory disturbances, hallucinations, psychotic reactions, depression, convulsions, and intracranial hypertension. Paraesthesia and peripheral neuropathy have also been reported.

In addition to rash and pruritus, hypersensitivity-type reactions affecting the skin have included, rarely, vasculitis, erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis. Photosensitivity has occurred, although it may be more frequent with some other fluoroquinolones such as lomefloxacin and sparfloxacin. Anaphylaxis has been associated with ciprofloxacin and some other quinolones. As with other quinolones, reversible arthralgia or myalgia has sometimes occurred and joint erosions have been documented in immature *animals*. Tendon damage has also been reported.

Other adverse effects reported with ciprofloxacin include crystalluria, transient increases in serum creatinine or blood urea nitrogen and, rarely, acute renal failure secondary to interstitial nephritis. Elevated liver enzyme values, jaundice, and hepatitis have occurred, as have haematological disturbances including eosinophilia, leucopenia, thrombocytopenia and, very rarely, pancytopenia, haemolytic anaemia or agranulocytosis. Cardiovascular adverse effects include tachycardia, hypotension, oedema, syncope, hot flushes, and sweating. Some fluoroquinolones may rarely cause prolongation of the QT interval and ventricular arrhythmias, including torsade de pointes (see below).

As with other antibacterials, superinfection with organisms not very susceptible to ciprofloxacin is possible. Such organisms include *Candida*, *Clostridium difficile*, and *Streptococcus pneumoniae*. There is some evidence that fluoroquinolone use may be associated with an increased risk of colonisation by MRSA.

Pain and irritation may occur at the site of infusion accompanied rarely by phlebitis or thrombophlebitis.

Adverse effects reported after ocular use of ciprofloxacin include local burning or discomfort, keratopathy, corneal staining, corneal precipitates or infiltrates, and photophobia.

Local discomfort, pain, or pruritus have occurred after use of ear drops containing ciprofloxacin.

Effects on the blood. Haematological disturbances including thrombocytopenia,[1] eosinophilia,[2] leucopenia, and, very rarely, pancytopenia,[3] haemolytic anaemia,[4] or agranulocytosis have been reported with ciprofloxacin and some other fluoroquinolones. There has also been a case report[5] of haemolytic-uraemic syndrome associated with ciprofloxacin therapy; the patient recovered with routine supportive treatment (haemodialysis and plasma exchange) after the drug was stopped. In addition, transient reductions in factor VIII and von Willebrand's factor leading to bleeding in 2 patients receiving ciprofloxacin has been reported.[6] Neutropenia that developed in an elderly patient a few days after starting treatment with intravenous moxifloxacin resolved on stopping the drug.[7]

Effects on the cardiovascular system. Prolongation of the QT interval,[1,2] sometimes progressing to torsade de pointes,[3-8] has been associated with ciprofloxacin and other fluoroquinolones although a review[9] considered that ciprofloxacin was least likely to produce this effect. Licensed product information recommends that gatifloxacin, gemifloxacin, levofloxacin, lomefloxacin, moxifloxacin, ofloxacin, and sparfloxacin should be avoided in patients with predisposing factors or who are also receiving other drugs that are known to cause this effect and that norfloxacin should be used with caution in such situations.

Effects on the gastrointestinal tract. There have been case reports and studies of pseudomembranous colitis or superinfection with *Clostridium difficile* in patients given ciprofloxacin[1-6] and other fluoroquinolones[7-10] although some commentators have questioned this association and pointed out that other circumstances, such as poor infection control, may be significant contributory factors.

Effects on glucose metabolism. For the effects of fluoroquinolones, and in particular gatifloxacin, on blood glucose see under Gatifloxacin, p.281.

Effects on the kidneys. A review[1] of case reports of renal toxicity (including interstitial nephritis, acute renal failure, acute tubular necrosis, and crystalluria) associated with ciprofloxacin and other fluoroquinolones indicated that such toxicity, although potentially serious, was rare. It was also noted that nearly all patients developing acute renal failure were over 50 years of age. Another review,[2] confirming that the problem remained rare, noted that risk factors for quinolone-induced nephrotoxicity seemed to include the particular quinolone chosen, with ciprofloxacin the most often involved, as well as the use of high doses, patient age, inadequate hydration, and use of other nephrotoxic drugs or the presence of other processes likely to contribute to renal damage such as diabetes.

Effects on the liver. Fluoroquinolones, including ciprofloxacin, may cause elevated liver enzyme values. In most patients this effect is transient and reversible without stopping the drug.

More serious cases of hepatotoxicity, including fatalities, have been reported both with ciprofloxacin[1-5] and with other fluoroquinolones[4,6-14] but they are rare. In many cases the patients were elderly and had co-morbid conditions.

Effects on the musculoskeletal system. Reversible arthralgia has sometimes occurred with the fluoroquinolones;[1] joint erosions have been documented in immature *animals*. In a report,[2] treatment with pefloxacin may have contributed to the destructive arthropathy that occurred in a 17-year-old youth. For a discussion of the use of fluoroquinolones in children and adolescents, see Administration in Children, under Precautions, below.

There have been reports[3-7] of tendinitis and tendon rupture associated with fluoroquinolones. By July 1995, the UK CSM[5] had received 21 reports of tendon damage, often of the Achilles tendon, associated with these antibacterials—11 with ciprofloxacin and 10 with ofloxacin. In a later case-control study[8] of a cohort of 46 776 users of fluoroquinolones between July 1992 to June 1998, 704 had Achilles tendinitis and 38 had Achilles tendon rupture; the adjusted relative risk of Achilles tendon disorders with current use was 1.9. The risk of tendon damage is increased by use with corticosteroids and is more common with increasing age:[5] the case-control study[8] found that the relative risk for current users rose to 3.2 among those aged 60 and over, and to 6.2 in those in this age group also using corticosteroids. Another case-control study[9] using data from 1988 to 1998 held on a different UK general practice database reported similar findings and concluded that ofloxacin was associated with a higher risk of tendon damage than other fluoroquinolones. A review[10] of the literature between 1966 and 2001 revealed 98 case reports of fluoroquinolone-associated tendon damage. Of these, 36 were associated with pefloxacin therapy and 25 with ciprofloxacin; ofloxacin was associated with 6 cases. Renal disease or impairment was also considered as a risk factor.

Onset may be rapid: rupture has occurred within 48 hours of starting therapy.[11] The CSM[5] warned that at the first sign of pain or inflammation the fluoroquinolone should be withdrawn and the affected limb rested until the tendon symptoms had resolved.

Similar warnings have been issued in other countries, but some cases have continued to be reported.[12] In the USA the FDA has required a warning to be added to prescribing information for the fluoroquinolones stating that there is an increased risk in patients over 60, in kidney, heart, and lung transplant recipients, and with use of concomitant corticosteroid therapy.[13]

There have been reports[14,15] of rhabdomyolysis in patients given fluoroquinolones, including one fatality associated with levofloxacin therapy.[14]

Effects on the nervous system. By 1991 the UK CSM[1] had received 26 reports of convulsions associated with ciprofloxacin, 1 with norfloxacin, and 1 with ofloxacin. It was noted that convulsions could occur both in patients with epilepsy and in those with no history of convulsions. Generalised seizures have been reported in patients given gatifloxacin[2] and levofloxacin.[3,4] Seizures have also been associated with the use of ear drops containing ciprofloxacin.[5] All 5 case reports[2-5] involved patients aged 65 years and over; of these, 1 had a history (although unclear) of seizures,[2] 3 had chronic renal impairment,[3-5] and 1 had neither.[3]

Other reports of CNS toxicity associated with ciprofloxacin have included eosinophilic meningitis,[6] delirium,[7] and acute psychoses.[8,9] Peripheral neuropathy,[10] dysaesthesia,[11] catatonia,[12] hemiparesis,[13] and tinnitus[14] have also been reported. Acute psychosis occurred[15] in a patient using ciprofloxacin eye drops. A review[16] of published and spontaneous reports found an association between adverse manic reactions and the use of certain antibacterials including ciprofloxacin and ofloxacin.

There have also been reports of sleep disturbances[17] and of a Tourette-like syndrome[18] associated with ofloxacin. Ataxia[19] and hallucinations[20] have been reported with the use of gatifloxacin.

Hypersensitivity. Hypersensitivity and skin reactions have been associated with ciprofloxacin and other fluoroquinolones. Reports have included anaphylaxis (which has sometimes been fatal, and may occur after the first dose),[1-7] serum sickness,[8] Stevens-Johnson syndrome,[9] toxic epidermal necrolysis (sometimes fatal),[10-17] laryngeal oedema,[18] and vasculitis.[19-21] Fatal vasculitis has been reported with ofloxacin.[22]

Superinfection. Superinfection with *Streptococcus pneumoniae* has been reported in patients receiving ciprofloxacin.[1-3] For references to superinfection with *Clostridium difficile* and associated pseudomembranous colitis, see under Effects on the Gastrointestinal Tract, above.

Fungal otitis externa is also associated with the use of ear drops containing fluoroquinolones.[4]

Precautions

Ciprofloxacin should be used with caution in patients with epilepsy or a history of CNS disorders. Care is also necessary in those with renal impairment, G6PD deficiency, or myasthenia gravis. An adequate fluid intake should be maintained during treatment with ciprofloxacin and excessive alkalinity of the urine avoided because of the risk of crystalluria.

Since ciprofloxacin and related fluoroquinolones have, like nalidixic acid, been shown to cause degenerative changes in weight-bearing joints of young *animals*, it has been suggested that these drugs should not generally be used in patients aged under 18 years (see also below), pregnant women, or breast-feeding mothers (but see also below) unless the benefits outweigh the risks. Tendon damage may occur rarely with fluoroquinolones (see Effects on the Musculoskeletal System, above) and treatment should be stopped if patients experience tendon pain, inflammation, or rupture; subsequent use of fluoroquinolones is contra-indicated in these patients.

Exposure to strong sunlight or sunlamps should be avoided during treatment with ciprofloxacin. The ability to drive or operate machinery may be impaired, especially when alcohol is also taken.

Some fluoroquinolones have the potential to prolong the QT interval (see Effects on the Cardiovascular System, above) and should be avoided or used with caution in patients with QT prolongation or relevant risk factors such as uncorrected electrolyte disturbances, bradycardia, or pre-existing cardiac disease. Certain drugs may also increase the risk (see Interactions, below).

Ciprofloxacin and other fluoroquinolones should be avoided in MRSA infections because of the high level of resistance.

Administration in children. Since ciprofloxacin and other fluoroquinolones can cause degenerative changes in weight-bearing joints of young *animals* they should only be used in children and adolescents where their use may be justified if the benefits outweigh the risks.[1-3] For example, ciprofloxacin is licensed in some countries for use in the prophylaxis and treatment of inhalational anthrax and also in the treatment of certain infections in those under 18 years of age (see under Uses and Administration, below).

A comparative cohort study[2] involving about 500 children and adolescents found that the incidence of musculoskeletal adverse effects was higher (10 cases out of 264 patients) in those taking fluoroquinolones (ciprofloxacin, ofloxacin, or pefloxacin) than in those taking other antibacterials (1 out of 237). In the former group of patients, these adverse effects, mainly arthralgias, were reversible and were most frequent with pefloxacin therapy.

3. American Academy of Pediatrics Committee on Infectious Diseases. The use of systemic fluoroquinolones. *Pediatrics* 2006; **118:** 1287–92.

Breast feeding. Ciprofloxacin was found to be undetectable in the serum of a breast-fed infant whose mother took ciprofloxacin 500 mg daily for 10 days.[1] In another study[2] involving 30 women who underwent termination of pregnancy, 10 each were given ciprofloxacin, ofloxacin, or pefloxacin respectively, and all 3 drugs were found to be highly concentrated in breast milk with ratios exceeding 75% of the simultaneous serum concentrations 2 hours after a dose. It was concluded that, because fluoroquinolones had been shown to cause arthropathy in young *animals*, their potential benefits should be weighed against the risk to the infant before they were considered for use in breast-feeding women. The American Academy of Pediatrics[3] considers that the use of ciprofloxacin is usually compatible with breast feeding.

Exposure to UV light. Loss of antibacterial activity has been reported after irradiation of ciprofloxacin solutions by UV light.[1] In addition to the possible hazard of photosensitivity reactions, a reduction in both cutaneous and circulating levels of ciprofloxacin was predicted in patients exposed to sunlight through window glass or the longer wavelength UVA radiation from sunbeds.[1]

1. Phillips G, *et al.* The loss of antibiotic activity of ciprofloxacin by photodegradation. *J Antimicrob Chemother* 1990; **26:** 783–9.

Interference with diagnostic tests. Ciprofloxacin did not interfere with determination of urinary-glucose concentrations carried out with *Clinitest*, *Diastix*, or *Tes-Tape*,[1] but pseudoglycosuria, a false-positive reaction for glucose in urine, has been reported with *BM-Test-7* in elderly patients given ciprofloxacin for urinary-tract infections.[2]

1. Tartaglione TA, Flint NB. Effect of imipenem-cilastatin and ciprofloxacin on tests for glycosuria. *Am J Hosp Pharm* 1985; **42:** 602–5.
2. Drysdale L, *et al.* Pseudoglycosuria and ciprofloxacin. *Lancet* 1988; **ii:** 961.

Myasthenia gravis. Caution is advised in patients with myasthenia gravis given fluoroquinolones after reports of the possible exacerbation of symptoms in a patient,[1] and unmasking of subclinical myasthenia gravis in another,[2] by ciprofloxacin. Exacerbation of myasthenia gravis has also been reported with other fluoroquinolones including norfloxacin,[3] ofloxacin,[4] and pefloxacin.[5]

Interactions

Fluoroquinolones, including ciprofloxacin, are known to inhibit the cytochrome P450 isoenzyme CYP1A2 and may increase plasma concentrations of drugs, such as theophylline and tizanidine, that are metabolised by this isoenzyme. Use of ciprofloxacin with tizanidine is contra-indicated, although theophylline may be used providing its dose is reduced and concentrations monitored.

Ciprofloxacin is reported to enhance the effect of oral anticoagulants such as warfarin and the oral antidiabetic glibenclamide. Severe hypoglycaemia, sometimes fatal, has occurred in patients also taking glibenclamide. Renal tubular secretion of methotrexate may be inhibited by ciprofloxacin, potentially increasing its toxicity.

The excretion of ciprofloxacin or related drugs is reduced and plasma concentrations may be increased by probenecid. Cations such as aluminium, calcium, magnesium, or iron reduce the absorption of oral ciprofloxacin or related drugs when given together. Changes in the pharmacokinetics of fluoroquinolones have been reported when given with histamine H_2 antagonists, possibly due to changes in gastric pH, but do not seem to be of much clinical significance.

Transient increases in serum creatinine have occurred when ciprofloxacin is given with ciclosporin; monitoring of serum creatinine concentrations is recommended. Altered serum concentrations of phenytoin have been reported in patients also receiving ciprofloxacin.

Further details concerning some of these interactions, and others, are given below.

Some fluoroquinolones have the potential to prolong the QT interval (see Effects on the Cardiovascular System, above) and should be avoided in patients also receiving class Ia antiarrhythmic drugs (such as quinidine and procainamide) or class III antiarrhythmics (such as amiodarone and sotalol). In addition, caution should be exercised when they are used with other drugs known to have this effect (such as the antihistamines astemizole and terfenadine, cisapride, erythromycin, pentamidine, phenothiazines, or tricyclic antidepressants).

For physical or chemical incompatibilities with ciprofloxacin, see above.

Analgesics. Use of *fenbufen* with fluoroquinolones may increase the incidence of fluoroquinolone CNS adverse effects. Reviews[1,2] have noted cases of convulsions associated with the use of fenbufen and enoxacin reported to the Japanese regulatory authorities. The UK CSM[3] has recognised that convulsions may occur due to an interaction between the fluoroquinolones and *NSAIDs*; by 1991, 3 such interactions had been reported to them. Adverse neurological effects have also been reported in a patient receiving *naproxen* and chloroquine when ciprofloxacin was given, which abated when the antirheumatic drugs were stopped.[4]

Ciprofloxacin also interacts with *opioid analgesics*; peak serum concentrations of ciprofloxacin given by mouth pre-operatively were significantly reduced when intramuscular *papaveretum* was injected.[5] In the UK, licensed product information for ciprofloxacin tablets recommends that opioid premedication should not be used if ciprofloxacin is given for surgical infection prophylaxis.

Antacids and metal ions. The absorption of ciprofloxacin and other fluoroquinolones is reduced by *antacids* containing *aluminium* or *magnesium* and also by *calcium*, *iron*, and *zinc* salts.[1] *Sucralfate* releases aluminium ions in the stomach and thereby reduces the absorption of ciprofloxacin[2,3] and other fluoroquinolones, including norfloxacin,[4] ofloxacin, and sparfloxacin.[5] In addition, antacids or oral iron preparations might antagonise the antibacterial activity of fluoroquinolones within the gut lumen.[6] *Dairy products* with a high calcium content may also interfere with the absorption of some fluoroquinolones.[7-9] *Enteral feeds*, which contain cations, have also been found to reduce absorption of ciprofloxacin.[10] A reduction in ciprofloxacin bioavailability has also been reported after *chewable tablets* of didanosine which contain aluminium and magnesium ion buffering agents.[11]

It is recommended that oral ciprofloxacin should be given at least 2 hours before or 6 hours after such products; similar advice also applies to other fluoroquinolones.

11. Sahai J, *et al.* Cations in the didanosine tablet reduce ciprofloxacin bioavailability. *Clin Pharmacol Ther* 1993; **53:** 292–7.

Antibacterials. The simultaneous use of parenteral ciprofloxacin and *azlocillin* has resulted in higher and more prolonged serum concentrations of ciprofloxacin.[1] Steady-state plasma concentrations of moxifloxacin are significantly reduced when given with *rifampicin* and *isoniazid* for the treatment of tuberculosis.[2]

1. Barriere SL, *et al.* Alteration in the pharmacokinetic disposition of ciprofloxacin by simultaneous administration of azlocillin. *Antimicrob Agents Chemother* 1990; **34:** 823–6.
2. Nijland HMJ, *et al.* Rifampicin reduces plasma concentrations of moxifloxacin in patients with tuberculosis. *Clin Infect Dis* 2007; **45:** 1001–7.

Anticoagulants. For reports of ciprofloxacin and other fluoroquinolones enhancing the effect of oral anticoagulants, see under *Warfarin*, p.1428.

Antidiabetics. For reference to elevated *glibenclamide* concentrations in patients who were also given ciprofloxacin, see p.462.

Antiepileptics. For conflicting reports of the effect of ciprofloxacin on serum-*phenytoin* concentrations, see p.498.

Antifungals. Both *fluconazole* and levofloxacin can prolong the QT interval. The simultaneous use of intravenous levofloxacin and fluconazole resulted in an episode of torsade de pointes in a patient on haemodialysis.[1]

1. Gandhi PJ, *et al.* Fluconazole- and levofloxacin-induced torsades de pointes in an intensive care unit patient. *Am J Health-Syst Pharm* 2003; **60:** 2479–83.

Antimigraine drugs. For a recommendation to reduce the dosage of *zolmitriptan* when given with ciprofloxacin, see p.628.

Antineoplastics. Absorption of oral ciprofloxacin appears to be reduced after cytotoxic chemotherapy.[1]

For reference to the effect of ciprofloxacin on the pharmacokinetics of *cyclophosphamide*, see p.703.

1. Johnson EJ, *et al.* Reduced absorption of oral ciprofloxacin after chemotherapy for haematological malignancy. *J Antimicrob Chemother* 1990; **25:** 837–42.

Antivirals. Both ciprofloxacin and *foscarnet* can cause convulsions and 2 patients developed generalised tonic-clonic seizures while receiving the drugs together.[1]

For reference to reduction of ciprofloxacin bioavailability due to the antacid content of chewable *didanosine* tablets, see under Antacids and Metal Ions, above.

1. Fan-Havard P, *et al.* Concurrent use of foscarnet and ciprofloxacin may increase the propensity for seizures. *Ann Pharmacother* 1994; **28:** 869–72.

Anxiolytics. For reference to the effect of ciprofloxacin on the pharmacokinetics of *diazepam*, *midazolam*, and *temazepam*, see under Diazepam, p.989.

Immunosuppressants. For reference to possible interaction between fluoroquinolones and *ciclosporin*, see Quinolones, p.1825. For a pharmacokinetic study reporting reduced exposure to *mycophenolate mofetil* when given with norfloxacin or norfloxacin plus metronidazole, see p.1837.

Muscle relaxants. For a report of ciprofloxacin increasing the plasma concentrations of *tizanidine*, see p.1898.

Xanthines. Ciprofloxacin and other fluoroquinolones (to a greater or lesser extent) decrease the clearance of *theophylline* (p.1143) and *caffeine* (p.1117) from the body. Seizures have occurred in patients given ciprofloxacin and theophylline and in one such report[1] serum-theophylline concentrations were normal.

1. Bader MB. Role of ciprofloxacin in fatal seizures. *Chest* 1992; **101:** 883–4.

Antimicrobial Action

Ciprofloxacin is bactericidal and acts by inhibiting DNA gyrase and topoisomerase IV, which are essential enzymes in the reproduction of bacterial DNA. It has a broader spectrum of activity and is more potent *in vitro* than the non-fluorinated quinolone nalidixic acid although resistance to many species or strains previously sensitive is emerging. Activity may be reduced in acid media and in the presence of urine but not of serum.

Spectrum of activity. Among Gram-negative aerobic bacteria, ciprofloxacin may be active *in vitro* against Enterobacteriaceae, including *Escherichia coli* and *Citrobacter*, *Enterobacter*, *Klebsiella*, *Proteus*, *Providencia*, *Salmonella*, *Serratia*, *Shigella*, and *Yersinia* spp. It may also exhibit activity against *Pseudomonas aeruginosa* and *Neisseria gonorrhoeae*. *H. influenzae*, *Moraxella catarrhalis* (*Branhamella catarrhalis*), and *N. meningitidis* are all sensitive. Other Gram-negative aerobic bacteria reported to be sensitive to ciprofloxacin have included *Gardnerella vaginalis*, *Helicobacter pylori*, *Legionella* spp., *Pasteurella multocida*, and *Vibrio* spp. Variable activity has been reported against *Acinetobacter* spp., *Brucella melitensis*, and *Campylobacter* spp.

Among Gram-positive aerobic bacteria, ciprofloxacin is active against staphylococci, including penicillinase-producing and penicillinase-nonproducing strains, and against some MRSA. Streptococci, in particular *Streptococcus pneumoniae* and enterococci, are less susceptible. Other Gram-positive bacteria sensitive to ciprofloxacin *in vitro* are *Bacillus* spp.; variable activity has been noted for *Corynebacterium* spp.

Most anaerobic bacteria, including *Bacteroides fragilis* and *Clostridium difficile*, are resistant to ciprofloxacin, although some other *Clostridium* spp. may be susceptible.

Ciprofloxacin has some activity against mycobacteria, mycoplasmas, rickettsias, *Chlamydia trachomatis*, and *Ureaplasma urealyticum*.

Acquired resistance. Resistant strains, particularly of MRSA, *Ps. aeruginosa*, *E. coli*, *Klebsiella pneumoniae*, *C. jejuni*, *N. gonorrhoeae*, and *Str. pneumoniae* have emerged during treatment with ciprofloxacin although there are widely differing patterns of resistance geographically. Resistance to ciprofloxacin has usually been chromosomally mediated although plasma-mediated resistance has recently been noted.

Pharmacokinetics

Ciprofloxacin is rapidly and well absorbed from the gastrointestinal tract. Oral bioavailability is about 70 to 80% and a peak serum concentration of about 2.4 micrograms/mL occurs 1 to 2 hours after a 500-mg oral dose. Absorption of ciprofloxacin tablets may be delayed by the presence of food, but is not substantially affected overall.

Plasma protein binding ranges from 20 to 40%. Ciprofloxacin is widely distributed in the body and tissue penetration is generally good. It appears in the CSF, but concentrations are only about 10% of those in serum when the meninges are not inflamed. Ciprofloxacin crosses the placenta and is also distributed into breast milk. High concentrations are achieved in bile.

The elimination half-life is about 3 to 5 hours and there is evidence of modest accumulation. Half-life may be prolonged in renal impairment (a value of 8 hours has been reported in end-stage renal disease) and to some extent in the elderly. However, no dose adjustment is usually necessary in patients with renal impairment unless it is severe; similarly, usual doses can be given to the elderly except in those with severe renal impairment. There is limited information on the effect of hepatic impairment; the half-life of ciprofloxacin has been reported to be slightly prolonged in patients with severe cirrhosis of the liver. With one or two exceptions, most studies have shown that the pharmacokinetics of ciprofloxacin are not markedly affected by cystic fibrosis.

Ciprofloxacin is eliminated principally by urinary excretion, but non-renal clearance may account for about one-third of elimination and includes hepatic metabolism, biliary excretion, and possibly transluminal secretion across the intestinal mucosa. At least 4 active metabolites have been identified. Oxociprofloxacin appears to be the major urinary metabolite and sulfociprofloxacin the primary faecal metabolite. Urinary excretion is by active tubular secretion as well as glomerular filtration and is reduced by probenecid; it is virtually complete within 24 hours. About 40 to 50% of an oral dose is excreted unchanged in the urine and about 15% as metabolites. Up to 70% of a parenteral dose may be excreted unchanged within 24 hours and 10% as metabolites. Faecal excretion over 5 days has accounted for 20 to 35% of an oral dose and 15% of an intravenous dose.

Only small amounts of ciprofloxacin are removed by haemodialysis or peritoneal dialysis.

General pharmacokinetics. Reviews of the pharmacokinetics of ciprofloxacin[1] and the fluoroquinolones in general.[2,3]

Uses and Administration

Ciprofloxacin is a fluorinated 4-quinolone or fluoroquinolone antibacterial with a wider spectrum of activity than nalidixic acid (see Antimicrobial Action, above) and more favourable pharmacokinetics allowing its use in systemic infections. It has been used in the treatment of infections including anthrax, biliary-tract infections, infected bites and stings, bone and joint infections, cat scratch disease, chancroid, exacerbations of cystic fibrosis, ear, nose, and throat infections (including otitis externa, otitis media, and sinusitis), HACEK endocarditis, gastro-enteritis (including travellers' diarrhoea and campylobacter enteritis, cholera, salmonella enteritis, shigellosis, and yersinia enteritis), gonorrhoea, granuloma inguinale, infections in immunocompromised patients (neutropenia), legionnaires' disease, pelvic inflammatory disease, peritonitis, plague, lower respiratory-tract infections (including pseudomonal infections in cystic fibrosis, but excluding infections due to *Streptococcus pneumoniae* such as pneumococcal pneumonia), rickettsial infections (including Q fever, spotted fevers, and typhus), septicaemia, skin infections (including soft-tissue infections), typhoid and paratyphoid fever, and urinary-tract infections including chronic bacterial prostatitis. Ciprofloxacin is used for meningococcal meningitis prophylaxis. It is also used for surgical infection prophylaxis and in the treatment of nontuberculous mycobacterial infections and tuberculosis. Ciprofloxacin is used topically in the treatment of eye and ear infections.

For details of all these infections and their treatment, see under Choice of Antibacterial, p.162.

Administration and dosage. Ciprofloxacin is given orally as the hydrochloride or base, by intravenous infusion as the lactate, and in eye drops, eye ointment, or ear drops as the hydrochloride. Doses and strengths are expressed in terms of the base. Ciprofloxacin hydrochloride 291.1 mg is equivalent to about 250 mg of ciprofloxacin. Ciprofloxacin lactate 127 mg is equivalent to about 100 mg of ciprofloxacin.

The usual adult oral dose of ciprofloxacin ranges from 250 to 750 mg twice daily depending on the severity and nature of the infection. Modified-release preparations for once-daily dosage are available in some countries. The usual adult intravenous dose is 200 to 400 mg twice daily, given over 30 to 60 minutes as a solution containing the equivalent of 1 to 2 mg/mL.

Women with acute uncomplicated cystitis may be given an oral dose of 100 to 250 mg twice daily for 3 days or 100 mg twice daily by intravenous infusion. A 28-day course of treatment with an oral dose of 500 mg twice daily or an intravenous dose of 400 mg twice daily should be given for chronic bacterial prostatitis. Bone and joint infections should be treated with an oral dose of 500 to 750 mg twice daily or an intravenous dose of 400 mg two or three times daily for 4 to 6 weeks. Intravenous infusions of 400 mg three times daily have also been recommended in severe or complicated lower respiratory tract or skin infections, nosocomial pneumonia, and with piperacillin for empirical treatment of febrile neutropenic patients.

For treatment and postexposure prophylaxis of inhalation anthrax, a 60-day course of treatment with initial intravenous doses of 400 mg twice daily followed by oral doses of 500 mg twice daily is recommended; although unlicensed, the same regimen is recommended by UK and US public health agencies for the treatment of gastrointestinal anthrax. In the treatment of cutaneous anthrax (also unlicensed), a 7- to 10-day course of treatment with an oral dose of 500 to 750 mg twice daily is similarly recommended; treatment may need to be extended to 60 days if infection is due to aerosol exposure.

Doses should be reduced in patients with severe renal impairment (see below).

Single oral doses of 250 or 500 mg or single intravenous doses of 100 mg are used for the treatment of gonorrhoea, depending upon patterns of resistance. A single oral dose of 750 mg is used for surgical infection prophylaxis, given 60 to 90 minutes before the procedure. Although unlicensed in the UK, the *BNF* suggests a single oral dose of 500 mg for meningococcal meningitis prophylaxis.

For details of doses in children, including infants and adolescents, see below.

For corneal ulcers and superficial ocular infections caused by susceptible strains of bacteria ciprofloxacin is given as the hydrochloride in eye drops and eye ointment containing the equivalent of 0.3% of ciprofloxacin.

Ciprofloxacin is also used topically as the hydrochloride in ear drops containing the equivalent of 0.2 or 0.3% of ciprofloxacin, usually with a corticosteroid such as dexamethasone or hydrocortisone, for the treatment of otitis externa and chronic suppurative otitis media caused by susceptible strains of bacteria.

Administration in children. Ciprofloxacin is not recommended for general use in children and adolescents (see under Precautions, above) but, if considered essential, UK licensed product information recommends oral doses of 5 to 15 mg/kg twice daily or intravenous doses of 4 to 8 mg/kg twice daily. The *BNFC* suggests that similar doses may be given to those as young as 1 month of age and that neonates may be given 7.5 mg/kg by mouth twice daily or 5 mg/kg by intravenous infusion twice daily. It is also licensed in different doses for specific indications as outlined below.

Ciprofloxacin is licensed in the UK and the USA for the treatment and postexposure prophylaxis of inhalation ***anthrax*** in children and adolescents. A 60-day course of treatment with initial intravenous doses of 10 mg/kg (to a maximum of 400 mg) twice daily followed by oral doses of 15 mg/kg (to a maximum of 500 mg) twice daily is recommended; the *BNFC* suggests that similar doses may be given to those as young as 1 month of age. Although unlicensed, the same regimen is recommended by UK and US public health agencies for the treatment of gastrointestinal anthrax. In the treatment of cutaneous anthrax (also unlicensed), a 7- to 10-day course of treatment with an oral dose of up to 15 mg/kg twice daily is similarly recommended; treatment may need to be extended to 60 days if infection is due to aerosol exposure.

It is also licensed in the UK for acute exacerbations of ***cystic fibrosis*** associated with *Pseudomonas aeruginosa* infection in those aged 5 to 17 years. An oral dose of 20 mg/kg (to a maximum of 750 mg) twice daily or an intravenous dose of 10 mg/kg (to a maximum of 400 mg) three times daily is recommended. Although not licensed for younger children, the *BNFC* suggests giving those aged 1 month to 5 years an oral dose of 5 to 15 mg/kg twice daily or an intravenous dose of 4 to 8 mg/kg twice daily.

In the USA, ciprofloxacin is also licensed for complicated ***urinary-tract infections*** or ***pyelonephritis*** caused by *Escherichia coli* in those aged 1 to 17 years. An oral dose of 10 to 20 mg/kg (to a maximum of 750 mg) twice daily or an intravenous dose of 6 to 10 mg/kg (to a maximum of 400 mg) three times daily is recommended.

Although unlicensed in the UK, the *BNFC* suggests a single oral dose of 125 mg for ***meningococcal meningitis prophylaxis*** in children aged 2 to 5 years; children aged 5 to 12 years may be given a single oral dose of 250 mg, and those aged over 12 years a single oral dose of 500 mg. Single oral doses of 500 mg have also been suggested for the treatment of gonorrhoea in those over 12 years of age.

Administration in renal impairment. The dose of ciprofloxacin should be reduced in ***adult patients*** with renal impairment by either reducing the total daily dose and/or by increasing the dosage interval in accordance with their creatinine clearance (CC); ideally plasma concentrations of ciprofloxacin should be monitored.

In the UK, halving the usual daily oral or intravenous dose in those with a CC of less than 20 mL/minute is recommended.

In the USA, the following doses are recommended:

- CC 30 to 50 mL/minute: up to 500 mg by mouth every 12 hours or the usual dose by intravenous infusion
- CC 5 to 29 mL/minute: up to 500 mg by mouth every 18 hours or up to 400 mg by intravenous infusion every 18 to 24 hours
- haemodialysis or peritoneal dialysis patients: up to 500 mg by mouth every 24 hours after dialysis

A pharmacokinetic study in 10 critically ill patients undergoing continuous renal replacement therapy with either venovenous haemofiltration or haemodiafiltration suggested that a dose of ciprofloxacin 400 mg every 24 hours would be suitable in such situations.[1]

There appears to be little guidance on the use of ciprofloxacin in ***paediatric patients*** with renal impairment but the *BNFC* states that half the usual dose should be used for those with a CC of less than 20 mL/minute per 1.73 m^2.

1. Malone RS, *et al.* Pharmacokinetics of levofloxacin and ciprofloxacin during continuous renal replacement therapy in critically ill patients. *Antimicrob Agents Chemother* 2001; **45:** 2949–54.

Inflammatory bowel disease. Ciprofloxacin has been given, sometimes with metronidazole, to treat active Crohn's disease[1,2] (see Inflammatory Bowel Disease, p.1697).

1. Prantera C, *et al.* An antibiotic regimen for the treatment of active Crohn's disease: a randomized, controlled clinical trial of metronidazole plus ciprofloxacin. *Am J Gastroenterol* 1996; **91:** 328–32.
2. Ishikawa T, *et al.* Metronidazole plus ciprofloxacin therapy for active Crohn's disease. *Intern Med* 2003; **42:** 318–21.

Tuberculosis. Reviews[1,2] of data obtained from controlled studies, cohorts, and case series, published up to March 2006, evaluating the clinical efficacy of fluoroquinolones for the treatment of tuberculosis (p.196) concluded that substituting or adding fluoroquinolones (in particular the older fluoroquinolones such as ciprofloxacin or ofloxacin) to established first-line treatment regimens did not confer additional benefits, although the newer fluoroquinolones are reported to have good *in-vitro* (levofloxacin, gatifloxacin, moxifloxacin) and *in-vivo* (gatifloxacin and moxifloxacin) bactericidal activity against *Mycobacterium tuberculosis*.[2]

There are very few controlled studies evaluating the use of fluoroquinolones in multi-drug resistant tuberculosis, but 2 retrospective studies support their effectiveness.[2] WHO guidelines[3,4] recommend that patients with multi-drug resistant tuberculosis and those who relapse after completing standard treatment regimens should receive second-line antituberculous drugs as part of a DOTS-plus regimen; such drugs do include ciprofloxacin and ofloxacin, as well as gatifloxacin, levofloxacin, and moxifloxacin. The usual recommended oral doses during the initial phase are as follows:

- ciprofloxacin: 1 to 1.5 g daily
- gatifloxacin: 400 mg daily
- moxifloxacin: 400 mg daily
- levofloxacin: 750 mg daily
- ofloxacin: 400 mg twice daily

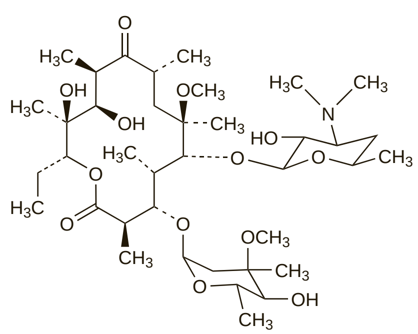
Clarithromycin *(BAN, USAN, rINN)*

A-56268; Abbott-56268; Clarithromycine; Clarithromycinum; Claritromicina; Klarithromycin; Klaritromicinas; Klaritromisin; Klaritromycin; Klaritromysiini; TE-031.
(2*R*,3*S*,4*S*,5*R*,6*R*,8*R*,10*R*,11*R*,12*S*,13*R*)-3-(2,6-Dideoxy-3-*C*,3*O*-dimethyl-α-L-*ribo*-hexopyranosyloxy)-11,12-dihydroxy-6-methoxy-2,4,6,8,10,12-hexamethyl-9-oxo-5-(3,4,6-trideoxy-3-dimethylamino-β-D-*xylo*-hexopyranosyloxy)pentadecan-13-olide; 6-*O*-Methylerythromycin.

Кларитромицин

$C_{38}H_{69}NO_{13}$ = 748.0.
CAS — 81103-11-9.
ATC — J01FA09.
ATC Vet — QJ01FA09.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US*.
Ph. Eur. 6.2 (Clarithromycin). A white or almost white, crystalline powder. Practically insoluble in water; soluble in acetone and in dichloromethane; slightly soluble in methyl alcohol.
USP 31 (Clarithromycin). A white to off-white crystalline powder. Practically insoluble in water; slightly soluble in dehydrated alcohol, in methyl alcohol, and in acetonitrile; soluble in acetone; slightly soluble in phosphate buffer at pH values of 2 to 5. pH of a 0.2% suspension in a mixture of water and methyl alcohol (19:1) is between 8.0 and 10.0. Store in airtight containers.

Adverse Effects and Precautions

As for Erythromycin, p.270. Gastrointestinal disturbances are the most frequent adverse effect but are usually mild and less frequent with clarithromycin than with erythromycin. Smell and taste disturbances, stomatitis, glossitis, tongue and tooth discoloration, and headache have occurred. There have also been reports of transient CNS effects. Other adverse effects include arthralgia, myalgia, hypoglycaemia, leucopenia, and thrombocytopenia. Interstitial nephritis and renal failure have been reported rarely.

Intravenous doses may cause phlebitis and pain at the injection site.

Caution is required in patients with hepatic or renal impairment and doses should be reduced in those with renal impairment (see under Uses and Administration below). It should not be used during pregnancy if possible as high doses have been associated with embryotoxicity in *animal* studies.

Effects on the blood. Single cases of thrombocytopenia[1] and thrombocytopenic purpura[2,3] associated with clarithromycin have been reported. Cases of agranulocytosis have also been reported.[4] A case of thrombocytopenia accompanied by interstitial nephritis, hepatitis, and elevated serum amylase levels was attributed to an allergic reaction to clarithromycin.[5] Toxic epidermal necrolysis and subsequent death due to aplastic anaemia have been reported in a patient after taking clarithromycin for 3 days.[6]

5. Baylor P, Williams K. Interstitial nephritis, thrombocytopenia, hepatitis, and elevated serum amylase levels in a patient receiving clarithromycin therapy. *Clin Infect Dis* 1999; **29:** 1350–1.
6. Baz K, *et al.* Fatal aplastic anaemia in a patient with clarithromycin-induced toxic epidermal necrolysis. *J Eur Acad Dermatol Venereol* 2004; **18:** 104–5.

Effects on the cardiovascular system. QT prolongation and torsade de pointes were associated with use of clarithromycin in 2 patients.[1] Renal impairment in 1 of the patients and hepatic impairment and organic heart disease in both could have increased their susceptibility to these effects.

For mention of an unexpected increase in cardiovascular mortality in patients with stable coronary heart disease given clarithromycin, see Ischaemic Heart Disease, in Uses and Administration of Azithromycin, above.

1. Lee KL, *et al.* QT prolongation and torsades de pointes associated with clarithromycin. *Am J Med* 1998; **104:** 395–6.

Effects on the eyes. Corneal opacities, reversible on stopping treatment, were reported in a patient receiving oral clarithromycin as part of a regimen for disseminated *Mycobacterium avium* complex infection.[1] Corneal subepithelial deposits have also been reported in a patient after prolonged use of clarithromycin eye drops for *Mycobacterium avium* complex keratitis. The deposits did not cause any ocular discomfort and resolved on stopping therapy.[2]

1. Dorrell L, *et al.* Toxicity of clarithromycin in the treatment of Mycobacterium avium complex infection in a patient with AIDS. *J Antimicrob Chemother* 1994; **34:** 605–6.
2. Tyagi AK, *et al.* An unreported side effect of topical clarithromycin when used successfully to treat Mycobacterium avium-intracellulare keratitis. *Cornea* 1999; **18:** 606–7.

Effects on the gastrointestinal tract. Pseudomembranous colitis associated with *Clostridium difficile* developed in a child receiving clarithromycin.[1]

1. Braegger CP, Nadal D. Clarithromycin and pseudomembranous enterocolitis. *Lancet* 1994; **343:** 241–2.

Effects on the liver. Progressive cholestatic jaundice, which subsequently proved fatal, developed in a 59-year-old woman after 3 days of clarithromycin therapy for acute maxillary sinusitis.[1] Fulminant hepatic failure in another patient, which developed during clarithromycin therapy, resolved once the drug was withdrawn.[2] Clarithromycin itself was considered responsible although there was the possibility that it had increased concentrations of isradipine, another known hepatotoxic drug that the patient was also receiving.

2. Tietz A, *et al.* Fulminant liver failure associated with clarithromycin. *Ann Pharmacother* 2003; **37:** 57–60.

Effects on the lungs. On 2 occasions fever and pulmonary infiltration with eosinophilia occurred in a patient given clarithromycin.[1] Another patient developed eosinophilic pneumonia 3 days after starting clarithromycin; symptoms improved when the drug was stopped.[2]

2. Ohnishi H, *et al.* Clarithromycin-induced eosinophilic pneumonia. *Intern Med* 2004; **43:** 231–5.

Effects on mental state. Acute psychoses occurred in 2 patients receiving clarithromycin as part of prophylactic treatment for *Helicobacter pylori* infection and were similar to 3 previously reported cases in either AIDS patients or elderly subjects.[1] Delirium[2] has also been associated with clarithromycin monotherapy in an elderly patient, and visual hallucinations have occurred in a 37-year-old woman being treated with ceftriaxone and clarithromycin for suspected pneumonia.[3] A review[4] of published and spontaneous reports found an association between adverse manic reactions and the use of certain antibacterials; clarithromycin was found to be the antibacterial most frequently implicated.

3. González Carro P, *et al.* Acute pancreatitis and modified-release clarithromycin. *Ann Pharmacother* 2004; **38:** 508–509.

Hypersensitivity. In addition to skin rashes and other hypersensitivity reactions which occasionally occur in patients receiving macrolides, leukocytoclastic vasculitis,[1] Henoch-Schönlein purpura,[2] and toxic epidermal necrolysis[3] have been reported in patients receiving clarithromycin.

1. Gavura SR, Nusinowitz S. Leukocytoclastic vasculitis associated with clarithromycin. *Ann Pharmacother* 1998; **32:** 543–5.
2. Borrás-Blasco J, *et al.* Henoch-Schönlein purpura associated with clarithromycin: case report and review of literature. *Int J Clin Pharmacol Ther* 2003; **41:** 213–16. Correction. *ibid.*; 420.
3. Khaldi N, *et al.* Toxic epidermal necrolysis and clarithromycin. *Can J Clin Pharmacol* 2005; **12:** e264–e268.

Interactions

For a discussion of drug interactions of macrolide antibacterials, see Erythromycin, p.271.

Antidiabetics. For reference to hypoglycaemia resulting from the addition of clarithromycin to *glibenclamide* or *glipizide*, see Antibacterials, p.462.

Antiretroviral drugs. In studies in healthy subjects,[1,2] the HIV-protease inhibitor *ritonavir* inhibited the metabolism of clarithromycin, increasing plasma concentrations and prolonging half-life. The metabolism of ritonavir was not affected significantly. The two drugs may be given together in usual doses to those with normal renal function but licensed product information for clarithromycin recommends that its dose should be reduced in patients with renal impairment receiving ritonavir and it should be noted that this is an extra reduction over and above that which may be needed for the renal impairment alone. Doses of clarithromycin should be reduced by 50% in patients with a creatinine clearance (CC) of 30 to 60 mL/minute and reduced by 75% in those with a CC below 30 mL/minute; the daily dose should not exceed 1 g. It has been suggested that other HIV-protease inhibitors (see also Table of Interactions of Drugs Used in the Treatment of HIV, p.917) and the NNRTI *delavirdine* may have a similar effect on clarithromycin. Use of *efavirenz* with clarithromycin has decreased plasma concentration of clarithromycin and increased its hydroxy metabolite. The combination has been associated with a high incidence of skin rashes. Decreases in the plasma concentration of clarithromycin have also been noted with *nevirapine*.

Decreased concentrations of *zidovudine* (p.915) have been reported in patients also taking clarithromycin and clarithromycin product information recommends that doses of the two drugs should be separated by 1 to 2 hours.

2. Ouellet D, *et al.* Pharmacokinetic interaction between ritonavir and clarithromycin. *Clin Pharmacol Ther* 1998; **64:** 355–62.

Colchicine. For mention of fatal colchicine toxicity associated with concomitant use of clarithromycin, see Macrolides, p.557.

Disulfiram. For a report of an interaction between clarithromycin and disulfiram, see Macrolides, p.2297.

Fluoxetine. For a report of delirium following use of clarithromycin with fluoxetine, see Antibacterials, p.396.

Gastrointestinal drugs. In a study[1] in healthy subjects, concentrations of clarithromycin and its active metabolite were increased in gastric tissue and mucus and, to a lesser extent, in plasma during use of *omeprazole*. In addition, use of clarithromycin with omeprazole resulted in higher and more prolonged plasma concentrations of omeprazole. The investigators suggest that this interaction could account for the synergistic action observed with this combination when used for eradication of *Helicobacter pylori*. However, licensed product information for clarithromycin states that no dosage adjustment to either drug is necessary. Although a study[2] in healthy subjects suggested that some pharmacokinetic parameters of clarithromycin are altered by *cimetidine*, the clinical significance of such changes are unknown.

1. Gustavson LE, *et al.* Effect of omeprazole on concentrations of clarithromycin in plasma and gastric tissue at steady state. *Antimicrob Agents Chemother* 1995; **39:** 2078–83.
2. Amsden GW, *et al.* Oral cimetidine prolongs clarithromycin absorption. *Antimicrob Agents Chemother* 1998; **42:** 1578–80.

Antimicrobial Action

As for Erythromycin, p.271.

Clarithromycin is reported to be more active than erythromycin against susceptible streptococci and staphylococci *in vitro*, as well as against some other species including *Moraxella catarrhalis* (*Branhamella catarrhalis*), *Legionella* spp., *Chlamydia trachomatis*, and *Ureaplasma urealyticum*. Clarithromycin is reported to be more active than erythromycin or azithromycin against some mycobacteria, including *Mycobacterium avium* complex and *M. leprae*. It is reported to have some *in-vitro* activity against the protozoan *Toxoplasma gondii*. The major metabolite, 14-hydroxyclarithromycin, is also active, and may enhance the activity of clarithromycin *in vivo*, notably against *Haemophilus influenzae*. The MICs of this metabolite are equal or twofold higher than those of the parent drug; the former is twofold more active than the latter against *H. influenzae*.

Activity with other antimicrobials. Clarithromycin has been reported to enhance the activity of a number of antimycobacterials including ethambutol, isoniazid, pyrazinamide, and rifampicin against *Mycobacterium tuberculosis*.[1,2]

1. Cavalieri SJ, *et al.* Synergistic activities of clarithromycin and antituberculous drugs against multi drug-resistant Mycobacterium tuberculosis. *Antimicrob Agents Chemother* 1995; **39:** 1542–5.
2. Mor N, Esfandiari A. Synergistic activities of clarithromycin and pyrazinamide against Mycobacterium tuberculosis in human macrophages. *Antimicrob Agents Chemother* 1997; **41:** 2035–6.

Resistance. Erythromycin-resistant isolates of *Streptococcus pneumoniae* are commonly cross-resistant to clarithromycin.[1] The incidence of resistance to clarithromycin and other macrolides is higher among penicillin-resistant strains than among penicillin-sensitive strains.[2] Clarithromycin-resistant isolates of *Helicobacter pylori* have also emerged.[3-6] Genetic mutations responsible for clarithromycin resistance have been identified in *H. pylori*[7] and in *Mycobacterium* spp.[8,9] Since resistance develops rapidly in *M. avium* during clarithromycin monotherapy, combination therapy is usually recommended. However, resistance to clarithromycin in an AIDS patient with systemic *M. avium* complex infection, despite combined treatment with clofazimine, has been described.[10]

Pharmacokinetics

Clarithromycin is rapidly absorbed from the gastrointestinal tract, and undergoes first-pass metabolism; the bioavailability of the parent drug is about 55%. The extent of absorption is relatively unaffected by the presence of food. Peak plasma concentrations occur 2 to 3 hours after an oral dose. At steady state, peak plasma concentrations of clarithromycin and its principal active metabolite, 14-hydroxyclarithromycin, are about 1 and 0.6 micrograms/mL, respectively, after 250 mg orally every 12 hours as tablets. The same dose given as a suspension to fasting subjects produces steady-state plasma concentrations of about 2 micrograms/mL of clarithromycin and about 0.7 micrograms/mL of 14-hydroxyclarithromycin. Steady-state concentrations are reached within 3 to 4 days.

The pharmacokinetics of clarithromycin are non-linear and dose dependent; high doses may produce disproportionate increases in peak concentrations of the parent drug, due to saturation of the metabolic pathways. However, the non-linearity is slight at the recommended doses of 250 to 500 mg every 8 to 12 hours.

Clarithromycin and 14-hydroxyclarithromycin are widely distributed, and tissue concentrations exceed those in serum, in part because of intracellular uptake. Plasma protein binding has been reported to be about 80%. Clarithromycin has been detected in breast milk. It is extensively metabolised in the liver, and excreted in faeces via the bile; 5 to 10% of the parent drug is recovered from the faeces. At steady state, about 20% and 30% of a 250-mg or 500-mg dose as tablets, respectively, and about 40% of a 250-mg dose as suspension, is excreted in the urine as unchanged drug. 14-Hydroxyclarithromycin as well as other metabolites are also excreted in the urine, accounting for 10 to 15% of the dose. The elimination half-lives of clarithromycin and 14-hydroxyclarithromycin are about 3 to 4 and 5 to 6 hours, respectively in patients receiving 250 mg every 12 hours, and about 5 to 7 and 7 to 9 hours, respectively, in those receiving 500 mg every 8 to 12 hours. The half-life is prolonged in renal impairment.

Uses and Administration

Clarithromycin is a macrolide derived from erythromycin with similar actions and uses (p.272). It is given in the treatment of respiratory-tract infections (including otitis media) and in skin and soft-tissue infections. Clarithromycin is also used for the prophylaxis and treatment of nontuberculous mycobacterial infections and has been used as a second-line drug in the treatment of leprosy. It is used in some countries as an alternative to penicillins for prophylaxis of endocarditis.

For details of all these infections and their treatment, see under Choice of Antibacterial, p.162.

Clarithromycin may be given to eradicate *Helicobacter pylori* in treatment regimens for peptic ulcer disease (p.1702). It is used with pyrimethamine as an alternative regimen in the treatment of toxoplasmosis (p.826).

Clarithromycin is given orally or by intravenous infusion. Some clarithromycin preparations are prepared with the aid of lactobionic acid and may be stated to contain clarithromycin lactobionate. Doses are expressed in terms of the equivalent amount of clarithromycin.

Usual oral doses in adults are 250 mg twice daily, increased to 500 mg twice daily if necessary in severe infection. Modified-release tablets allowing once-daily use are available in some countries.

The usual intravenous dose is 500 mg twice daily, given as an infusion over 60 minutes using a solution containing about 0.2% of clarithromycin. Intravenous treatment may continue for 2 to 5 days, but should be changed to oral clarithromycin when possible.

For treatment and prophylaxis of disseminated infection due to *Mycobacterium avium* complex, clarithromycin may be given in an oral dose of 500 mg twice daily; for treatment, it should be given with other antimycobacterials. For leprosy, oral clarithromycin 500 mg daily has been given as part of an alternative multidrug therapy regimen.

For the eradication of *H. pylori* associated with peptic ulcer disease, clarithromycin, usually in an oral dose of 500 mg twice daily, is given with another antibacterial and either a proton pump inhibitor or a histamine H_2-receptor antagonist, for 7 to 14 days.

For details of doses in infants and children, see below.

Doses may need to be reduced in patients with severe renal impairment (see below).

◊ Reviews.

Administration in children. The usual oral dose of clarithromycin for infants and children is 7.5 mg/kg twice daily; those over 12 years of age may be given the usual adult dose (see above).

Although intravenous use is not licensed for children in the UK the *BNFC* suggests a dose of 7.5 mg/kg twice daily for those aged from 1 month to 12 years; older children may be given the adult dose (see above).

For prophylaxis of disseminated infection due to *Mycobacterium avium* complex, clarithromycin may be given in an oral dose of 7.5 mg/kg twice daily; when used for treatment, it should be given with other antimycobacterials and the dose may be increased to 15 mg/kg (to a maximum of 500 mg) twice daily.

For the eradication of *Helicobacter pylori* associated with peptic ulcer disease, the *BNFC* suggests that 7.5 mg/kg twice daily may also be given orally with another antibacterial and a proton pump inhibitor for 7 days to children aged 1 year and over.

Administration in renal impairment. Licensed product information states that in patients with severe renal impairment (creatinine clearance of less than 30 mL/minute) dosage of clarithromycin may need to be halved or the dosing interval doubled.

Ischaemic heart disease. For mention of studies investigating clarithromycin in the prevention of ischaemic heart disease, see under Azithromycin, p.208.

Multiple myeloma. Clarithromycin 500 mg orally twice daily has been added[1] to a regimen of lenalidomide and dexamethasone in treatment-naive patients with multiple myeloma (p.658). The regimen (BiRD) was considered effective and well tolerated, with a higher response rate at lower dexamethasone doses than had been previously reported with lenalidomide and dexamethasone alone. A regimen of clarithromycin, low-dose thalidomide, and dexamethasone (BLT-D) has also been evaluated.[2]

Калия Клавуланат

$C_8H_8KNO_5$ = 237.3.

CAS — 61177-45-5.

NOTE. Compounded preparations of potassium clavulanate may be represented by the following names:

- Co-amoxiclav *x/y* (*BAN*)—amoxicillin (as the trihydrate or the sodium salt) and potassium clavulanate; *x* and *y* are the strengths in milligrams of amoxicillin and clavulanic acid respectively
- Co-amoxiclav (*PEN*)—amoxicillin trihydrate and potassium clavulanate.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn*, and *US*.

Eur. also includes Diluted Potassium Clavulanate.

Ph. Eur. 6.2 (Potassium Clavulanate). The potassium salt of a substance produced by the growth of certain strains of *Streptomyces clavuligerus* or by any other means. A white or almost white, hygroscopic, crystalline powder. Freely soluble in water; slightly soluble in alcohol; very slightly soluble in acetone. A 1% solution in water has a pH of 5.5 to 8.0. Store in airtight containers at a temperature of 2° to 8°.

Ph. Eur. 6.2 (Potassium Clavulanate, Diluted; Kalii Clavulanas Dilutus). A dry mixture of potassium clavulanate and microcrystalline cellulose or anhydrous or hydrated colloidal silicon dioxide. A white or almost white, hygroscopic, powder. A suspension corresponding to 1% of potassium clavulanate in water has a pH of 4.8 to 8.0. Store in airtight containers.

USP 31 (Clavulanate Potassium). A white to off-white powder. Freely soluble in water; soluble in methyl alcohol with decomposition. Stability in aqueous solutions is not good, optimum stability at a pH of 6.0 to 6.3. pH of a 1% solution in water is between 5.5 and 8.0. Store in airtight containers.

Profile

Clavulanic acid is produced by cultures of *Streptomyces clavuligerus*. It has a beta-lactam structure resembling that of the penicillin nucleus, except that the fused thiazolidine ring of the penicillins is replaced by an oxazolidine ring. In general, clavulanic acid has only weak antibacterial activity. It is a potent progressive inhibitor of plasmid-mediated and some chromosomal beta-lactamases produced by Gram-negative bacteria including *Haemophilus ducreyi*, *H. influenzae*, *Neisseria gonorrhoeae*, *Moraxella catarrhalis* (*Branhamella catarrhalis*), *Bacteroides fragilis*, and some Enterobacteriaceae. It is also an inhibitor of the beta-lactamases produced by *Staphylococcus aureus*. Clavulanic acid can permeate bacterial cell walls and can therefore inactivate both extracellular enzymes and those that are bound to the cell. Its mode of action depends on the particular enzyme inhibited, but it generally acts as a competitive, and often irreversible, inhibitor. Clavulanic acid consequently enhances the activity of penicillin and cephalosporin antibacterials against many resistant strains of bacteria. However, it is generally less effective against chromosomally mediated type 1 beta-lactamases; therefore, many *Citrobacter, Enterobacter, Morganella*, and *Serratia* spp., and *Pseudomonas aeruginosa* remain resistant. Some plasmid-mediated extended-spectrum beta-lactamases in *Klebsiella pneumoniae*, some other Enterobacteriaceae, and *Ps. aeruginosa* are also not inhibited by beta-lactamase inhibitors.

Clavulanic acid is given as potassium clavulanate orally and by injection with amoxicillin (co-amoxiclav) (p.202), and by injection with ticarcillin (p.352).

Use of clavulanate with penicillins has been associated with the development of cholestatic jaundice and hepatitis (see under Adverse Effects of Amoxicillin, p.202) and therefore the use of co-amoxiclav has declined (see below).

◊ Because of the risk of cholestatic jaundice co-amoxiclav is not a treatment of choice for common bacterial infections. The UK CSM[1] recommended that it should be reserved for bacterial infections likely to be caused by amoxicillin-resistant beta-lactamase-producing strains and that treatment should not usually exceed 14 days. It may be considered for the following main indications:

- sinusitis, otitis media, recurrent tonsillitis
- acute exacerbations of chronic bronchitis
- bronchopneumonia
- urinary-tract infections, especially when recurrent or complicated, but not prostatitis
- septic abortion, pelvic or puerperal sepsis, and intra-abdominal sepsis
- cellulitis, animal bites, and severe dental abscess with spreading cellulitis.

Clemizole Penicillin *(BAN, rINN)*

Clemizol penicilina; Clemizole Benzylpenicillin; Clémizole Pénicilline; Clemizolum Penicillinum; Klemitsolipenisilliini; Klemizolpenicillin; Penicillin G Clemizole. 1-[1-(4-Chlorobenzyl)benzimidazol-2-ylmethyl]pyrrolidinium (6*R*)-6-(2-phenylacetamido)penicillanate.

Клемизол Пенициллин

$C_{16}H_{18}N_2O_4S,C_{19}H_{20}ClN_3$ = 660.2.

CAS — 6011-39-8.

Profile

Clemizole penicillin is a long-acting preparation of benzylpenicillin (p.213) with similar properties and uses.

Preparations

Proprietary Preparations (details are given in Part 3)
Chile: Prevepen; ***Mex.:*** Megapenil; ***Switz.:*** Megacilline†.

Multi-ingredient: ***Chile:*** Prevepen Forte; ***Mex.:*** Anapenil; Megapenil Forte; ***Port.:*** Prevecilina; ***Spain:*** Neopenyl.

Clindamycin *(BAN, USAN, rINN)*

Clindamicina; Clindamycine; Clindamycinum; Klindamisin; Klindamycin; Klindamysiini; U-21251. Methyl 6-amino-7-chloro-6,7,8-trideoxy-*N*-[(2*S*,4*R*)-1-methyl-4-propylprolyl]-1-thio-L-*threo*-D-*galacto*-octopyranoside.

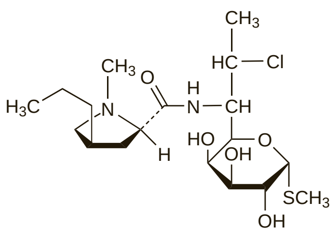
Клиндамицин

$C_{18}H_{33}ClN_2O_5S$ = 425.0.

CAS — 18323-44-9.

ATC — D10AF01; G01AA10; J01FF01.

ATC Vet — QD10AF01; QG01AA10; QJ01FF01.



NOTE. The name Clinimycin, which was formerly used for clindamycin, has also been used for a preparation of oxytetracycline.

Clindamycin Hydrochloride *(BANM, rINNM)*

Chlorodeoxylincomycin Hydrochloride; (7*S*)-Chloro-7-deoxylincomycin Hydrochloride; Clindamycine, chlorhydrate de; Clindamycini hydrochloridum; Hidrocloruro de clindamicina; Klindamicin-hidroklorid; Klindamicino hidrochloridas; Klindamisin Hidroklorür; Klindamycin-hydrochlorid; Klindamycinhydroklorid; Klindamycyny chlorowodorek; Klindamysiinihydrokloridi.

Клиндамицина Гидрохлорид

$C_{18}H_{33}ClN_2O_5S,HCl$ = 461.4.

CAS — 21462-39-5 (anhydrous clindamycin hydrochloride); 58207-19-5 (clindamycin hydrochloride monohydrate).

ATC — D10AF01; G01AA10; J01FF01.

ATC Vet — QD10AF01; QG01AA10; QJ01FF01.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Clindamycin Hydrochloride). A white or almost white, crystalline powder. It contains a variable quantity of water. Very soluble in water; slightly soluble in alcohol. A 10% solution in water has a pH of 3.0 to 5.0. Store in airtight containers.

USP 31 (Clindamycin Hydrochloride). A white or practically white crystalline powder, odourless or has a faint mercaptan-like odour. Freely soluble in water, in dimethylformamide, and in methyl alcohol; soluble in alcohol; practically insoluble in acetone. pH of a 10% solution in water is between 3.0 and 5.5. Store in airtight containers.

Clindamycin Palmitate Hydrochloride

(BANM, USAN, rINNM)

Clindamycine, Chlorhydrate de Palmitate de; Clindamycini Palmitatis Hydrochloridum; Hidrocloruro del palmitato de clindamicina; U-25179E. Clindamycin 2-palmitate hydrochloride.

Клиндамицина Палмитата Гидрохлорид

$C_{34}H_{63}ClN_2O_6S,HCl$ = 699.9.

CAS — 36688-78-5 (clindamycin palmitate); 25507-04-4 (clindamycin palmitate hydrochloride).

ATC — D10AF01; G01AA10; J01FF01.

ATC Vet — QD10AF01; QG01AA10; QJ01FF01.

Pharmacopoeias. In *US.*

USP 31 (Clindamycin Palmitate Hydrochloride). A white to off-white amorphous powder having a characteristic odour. Freely soluble in water, in chloroform, in ether, and in benzene; soluble 1 in 3 of alcohol and 1 in 9 of ethyl acetate; very soluble in dimethylformamide. pH of a 1% solution in water is between 2.8 and 3.8. Store in airtight containers.

Clindamycin Phosphate *(BANM, USAN, rINNM)*

Clindamycine, phosphate de; Clindamycini Dihydrogenophosphas; Clindamycini phosphas; Fosfato de clindamicina; Klindamicin-foszfát; Klindamicino fosfatas; Klindamisin Fosfat; Klindamycin dihydrogen fosfát; Klindamycinfosfat; Klindamysiinifosfaatti; U-28508. Clindamycin 2-(dihydrogen phosphate).

Клиндамицина Фосфат

$C_{18}H_{34}ClN_2O_8PS$ = 505.0.

CAS — 24729-96-2.

ATC — D10AF01; G01AA10; J01FF01.

ATC Vet — QD10AF01; QG01AA10; QJ01FF01.

Pharmacopoeias. In *Eur.* (see p.vii), *Int., Jpn*, and *US.*

Ph. Eur. 6.2 (Clindamycin Phosphate). A white or almost white, slightly hygroscopic powder. It exhibits polymorphism. Freely soluble in water; very slightly soluble in alcohol; practically insoluble in dichloromethane. A 1% solution in water has a pH of 3.5 to 4.5. Store at a temperature not exceeding 30° in airtight containers.

USP 31 (Clindamycin Phosphate). A white to off-white, odourless or practically odourless, hygroscopic, crystalline powder. Soluble 1 in 2.5 of water; slightly soluble in dehydrated alcohol; very slightly soluble in acetone; practically insoluble in chloroform, in ether, and in benzene. pH of a 1% solution in water is between 3.5 and 4.5. Store in airtight containers.

Incompatibility. Solutions of clindamycin salts have an acid pH and incompatibility may reasonably be expected with alkaline preparations, or with drugs unstable at low pH. Licensed product information for the injectable solution of clindamycin states that incompatibility has been reported between clindamycin and the following drugs: ampicillin, aminophylline, barbiturates, calcium gluconate, ceftriaxone, ciprofloxacin, idarubicin, magnesium sulfate, phenytoin, and ranitidine.

Clindamycin phosphate is incompatible with natural rubber closures.

Adverse Effects and Treatment

Clindamycin is reported to produce diarrhoea in up to 20% of patients after systemic use. In some patients severe antibiotic-associated or pseudomembranous colitis (p.171) may develop during therapy or up to several weeks after it, and has proved fatal. It has been reported to be more frequent in middle-aged and elderly women, particularly after surgery; it may also occur rarely after topical use. Clindamycin should be stopped immediately if significant diarrhoea or colitis occurs. Protein supplementation and use of an antibacterial active against *Clostridium* spp. should be considered for severe antibiotic-associated colitis.

Other gastrointestinal effects include nausea, vomiting, abdominal pain or cramps, and oesophagitis; an unpleasant or metallic taste has occasionally been reported after high intravenous doses.

Skin rashes and urticaria, the most common hypersensitivity reactions, occur in up to 10% of patients usually after 1 to 2 weeks of therapy. Erythema multiforme, Stevens-Johnson syndrome, and exfoliative and vesiculobullous dermatitis have been reported rarely, and a few cases of anaphylaxis have occurred.

Other adverse effects include transient leucopenia or occasionally agranulocytosis, eosinophilia, thrombocytopenia, polyarthritis, and abnormalities of liver function tests; in some cases overt jaundice and hepatic damage have been reported. Renal dysfunction, shown by azotaemia, oliguria, and/or proteinuria has been reported rarely.

Although local irritation is rare, intramuscular injection has led to induration and sterile abscess, and thrombophlebitis may occur after intravenous use. Too rapid intravenous infusion can result in rare instances of cardiopulmonary arrest and hypotension. Some parenteral formulations contain benzyl alcohol which may cause fatal 'gasping syndrome' in neonates (see p.1632).

Topical application may be associated with local irritation and contact dermatitis; sufficient clindamycin may be absorbed to produce systemic effects. Cervicitis, vaginitis, or vulvovaginal irritation has been reported with intravaginal use; a small amount of systemic absorption also occurs.

Effects on the cardiovascular system. Cardiac arrest occurred in a 50-year-old woman after rapid injection of 600 mg of undiluted clindamycin phosphate into a central intravenous line. Further injections were given over 30 minutes without cardiovascular complications.[1] There has also been a case of severely prolonged QT interval attributed to the addition of clindamycin to therapy in an elderly woman;[2] the patient developed AV block and subsequent torsade de pointes, and required resuscitation. When clindamycin was stopped, signs of heart block resolved, and the QT interval returned to normal over several days.

1. Aucoin P, *et al.* Clindamycin-induced cardiac arrest. *South Med J* 1982; **75:** 768.
2. Gabel A, *et al.* Ventricular fibrillation due to long QT syndrome probably caused by clindamycin. *Am J Cardiol* 1999; **83:** 813–15.

Effects on the ears. A 14-year-old boy who was treated with topical clindamycin for acne vulgaris developed unilateral tinnitus during therapy and unilateral sensorineural hearing loss 2 months later;[1] symptoms subsequently recurred upon 2 rechallenges.

1. Scissors B, Shwayder T. Topical clindamycin reproducibly causing tinnitus in a 14-year-old boy. *J Am Acad Dermatol* 2006; **54** (suppl): S243–S244.

Effects on the lymphatic system. A report of lymphadenitis associated with clindamycin.[1]

1. Southern PM. Lymphadenitis associated with the administration of clindamycin. *Am J Med* 1997; **103:** 164–5.

Effects on the skin. There have been reports of toxic epidermal necrolysis[1] and acute generalised exanthematous pustulosis[2,3] associated with clindamycin.

1. Paquet P, *et al.* Toxic epidermal necrolysis following clindamycin treatment. *Br J Dermatol* 1995; **132:** 665–6.
2. Valois M, *et al.* Clindamycin-associated acute generalized exanthematous pustulosis. *Contact Dermatitis* 2003; **48:** 169.
3. Kapoor R, *et al.* Acute generalized exanthematous pustulosis induced by clindamycin. *Arch Dermatol* 2006; **142:** 1080–81.

Precautions

Clindamycin should not be given to patients hypersensitive to it or to the closely related drug lincomycin. It should be used with caution in patients with a history of gastrointestinal disease, particularly colitis, and stopped immediately if significant diarrhoea or colitis occurs. Middle-aged and elderly female patients may be at greater risk of severe diarrhoea or pseudomembranous colitis. Caution has also been advised in atopic patients. Periodic tests of liver and kidney function and blood counts have been recommended in patients receiving prolonged therapy, and in infants. Caution is required during parenteral use in neonates, since some parenteral formulations contain benzyl alcohol which may cause fatal 'gasping syndrome' (see p.1632).

AIDS. Clindamycin was poorly tolerated by patients with AIDS in a study of its use for *prophylaxis* of toxoplasmic encephalitis.[1] Despite the use of relatively low doses of clindamycin (300 mg twice daily), 23 of 52 patients reported adverse effects that necessitated temporary or permanent withdrawal of the drug, the most frequent adverse reactions being diarrhoea and skin rash. The clindamycin arm of the study had to be terminated prematurely. Nevertheless, clindamycin has been used successfully in patients with AIDS for the *treatment* of both toxoplasmic encephalitis (see Toxoplasmosis, below) and pneumocystis pneumonia (below).

1. Jacobson MA, *et al.* Toxicity of clindamycin as prophylaxis for AIDS-associated toxoplasmic encephalitis. *Lancet* 1992; **339:** 333–4.

Breast feeding. US licensed product information states that concentrations of clindamycin in breast milk were 0.7 to 3.8 micrograms/mL after doses of 150 mg orally to 600 mg intravenously. No adverse effects have been seen in breast-fed infants whose mothers were receiving clindamycin, and the American Academy of Pediatrics[1] considers that it is therefore usually compatible with breast feeding. Nevertheless, UK product information states that although it is unlikely that a breast-fed infant could absorb significant amounts, caution should be exercised when clindamycin is given during breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 25/05/04)

Interactions

Clindamycin has neuromuscular blocking activity in high doses and may enhance the effect of other drugs with this action (see Atracurium, p.1903), leading to a potential danger of respiratory depression. Clindamycin may antagonise the effects of parasympathomimetics. For mention of synergistic and antagonistic antimicrobial activity with other antibacterials, see Antimicrobial Action, below.

Adsorbents. In 16 healthy subjects given clindamycin alone and with a *kaolin-pectin* suspension it was found that the suspension had no effect on the extent of clindamycin absorption but did markedly reduce the absorption rate.[1]

1. Albert KS, *et al*. Pharmacokinetic evaluation of a drug interaction between kaolin-pectin and clindamycin. *J Pharm Sci* 1978; **67:** 1579–82.

Antimicrobial Action

Clindamycin is a lincosamide antibacterial with a primarily bacteriostatic action against Gram-positive aerobes and a wide range of anaerobic bacteria.

Mechanism of action. Lincosamides such as clindamycin bind to the 50S subunit of the bacterial ribosome, similarly to macrolides such as erythromycin (p.271), and inhibit the early stages of protein synthesis. The action of clindamycin is mainly bacteriostatic, although high concentrations may be slowly bactericidal against sensitive strains.

Spectrum of activity. Clindamycin is active against:

- most aerobic Gram-positive bacteria including streptococci, staphylococci, *Bacillus anthracis*, and *Corynebacterium diphtheriae*
- enterococci are generally resistant
- susceptible Gram-positive anaerobes include *Eubacterium*, *Propionibacterium*, *Peptococcus*, and *Peptostreptococcus* spp., and many strains of *Clostridium perfringens* and *Cl. tetani*
- Gram-negative anaerobes susceptible to clindamycin include *Fusobacterium* spp. (although *F. varium* is usually resistant), *Prevotella* spp., and *Bacteroides* spp., including the *B. fragilis* group
- several *Actinomyces* spp. and *Nocardia asteroides* are reported to be susceptible
- *Mycoplasma* spp. are generally resistant
- most Gram-negative aerobic bacteria, including the Enterobacteriaceae, are resistant to clindamycin; unlike erythromycin, *Neisseria gonorrhoeae*, *N. meningitidis*, and *Haemophilus influenzae* are generally resistant
- fungi, yeasts, and viruses are also resistant; however, clindamycin has been reported to have some antiprotozoal activity against *Toxoplasma gondii* and *Plasmodium* spp.

Activity with other antimicrobials. Synergistic activity has been reported between clindamycin and ceftazidime or metronidazole, and also with ciprofloxacin against some anaerobes. However, there is some evidence that clindamycin inhibits the bactericidal activity of the aminoglycosides, although conflicting reports have suggested variable degrees of synergy against anaerobic organisms. Because of the adjacency of their binding sites on the ribosome, clindamycin may competitively inhibit the effects of macrolides or chloramphenicol. Clindamycin has been reported to diminish the activity of ampicillin *in vitro* against *Staph. aureus*. It is reported to enhance the activity of primaquine against *Pneumocystis jirovecii*. Antagonism between clindamycin and erythromycin has been shown *in vitro*.

Resistance. Most Gram-negative aerobes, such as the Enterobacteriaceae, *Pseudomonas* spp., and *Acinetobacter* spp., are intrinsically resistant to clindamycin, but acquired resistance also occurs in normally sensitive strains. The **mechanisms** of resistance are the same as those for erythromycin, namely methylation of the ribosomal binding site, chromosomal mutation of the ribosomal protein, and, in a few staphylococcal isolates, enzymic inactivation by a plasmid-mediated adenyltransferase. Methylation of the ribosome leads to cross-resistance between the lincosamides and macrolides and streptogramins (the MLS_B phenotype); this type of resistance is usually plasmid-mediated and inducible. Complete cross-resistance exists between clindamycin and lincomycin.

The **incidence** of resistance varies with the organism and the geographical location; it is more frequent in organisms that are also erythromycin-resistant, and some strains of meticillin-resistant *Staph. aureus* are also resistant to clindamycin. In some countries and institutions there is evidence of an increase in resistance amongst the *B. fragilis* group to about 25% of strains or more. Resistance to clindamycin by anaerobes has also been reported in 10 to 20% of *Clostridium* spp. other than *C. perfringens*, 8% of peptostreptococci, 9% of *Fusobacterium* spp., and 11% of *Prevotella* strains.

Action. References suggesting that clindamycin may reduce microbial adherence and enhance phagocytosis by its effects on bacterial slime (glycocalyx)[1-3] and that its antibacterial effects may be independent of plasma concentrations.[4,5]

Resistance. Although there is usually cross-resistance between clindamycin and macrolides (above), a resistance pattern has been identified that results in streptococcal resistance to macrolides while retaining susceptibility to clindamycin.[1]

1. Sutcliffe J, *et al.* Streptococcus pneumoniae and Streptococcus pyogenes resistant to macrolides but sensitive to clindamycin: a common resistance pattern mediated by an efflux system. *Antimicrob Agents Chemother* 1996; **40:** 1817–24.

Pharmacokinetics

About 90% of a dose of clindamycin hydrochloride is absorbed from the gastrointestinal tract; concentrations of 2 to 3 micrograms/mL occur within 1 hour after a 150-mg oral dose, with average concentrations of about 700 nanograms/mL after 6 hours. After doses of 300 and 600 mg, peak plasma concentrations of 4 and 8 micrograms/mL, respectively, have been reported. Absorption is not significantly diminished by food in the stomach but the rate of absorption may be reduced. Clindamycin palmitate hydrochloride is rapidly hydrolysed on oral use to free clindamycin.

After parenteral use, the biologically inactive clindamycin phosphate is also hydrolysed to clindamycin. When the equivalent of 300 mg of clindamycin is injected intramuscularly, a mean peak plasma concentration of 6 micrograms/mL occurs within 3 hours; 600 mg gives a peak concentration of 9 micrograms/mL. In children, peak concentrations may occur within 1 hour. When the same doses are infused intravenously, peak concentrations of 7 and 10 micrograms/mL occur by the end of infusion.

Small amounts of clindamycin may be absorbed after topical application to the skin; bioavailability from topical preparations of the hydrochloride and phosphate (the former in an extemporaneous formulation) has been reported to be about 7.5% and 2% respectively.

About 5% of a dose may be absorbed systemically from an intravaginal cream formulation; absorption from vaginal pessaries is reported to be about 30%.

Clindamycin is widely distributed in body fluids and tissues, including bone, but it does not reach the CSF in significant concentrations. It diffuses across the placenta into the fetal circulation and has been reported to appear in breast milk. High concentrations occur in bile. It accumulates in leucocytes and macrophages. Over 90% of clindamycin in the circulation is bound to plasma proteins. The half-life is 2 to 3 hours, although this may be prolonged in preterm neonates and in patients with severe renal impairment.

Clindamycin undergoes metabolism, presumably in the liver, to the active *N*-demethyl and sulfoxide metabolites, and also to some inactive metabolites. About 10% of a dose is excreted in the urine as active drug or metabolites and about 4% in the faeces; the remainder is excreted as inactive metabolites. Excretion is slow, and takes place over several days. It is not effectively removed from the blood by dialysis.

AIDS patients. Clindamycin was reported to have higher bioavailability, lower plasma clearance, and a lower volume of distribution in patients with AIDS than in healthy subjects.[1] This may partly be explained by increased binding to plasma proteins.[2]

Although it is generally considered that penetration of clindamycin into the CSF is insignificant, parasiticidal CSF concentrations against *Toxoplasma gondii* were achieved with intravenous clindamycin in patients with AIDS.[3]

Uses and Administration

Clindamycin is a lincosamide antibacterial that is a chlorinated derivative of lincomycin. It is a mainly bacteriostatic drug used in the treatment of serious anaerobic infections, notably due to *Bacteroides fragilis.* Clindamycin is also used for some Gram-positive infections due to pneumococci, staphylococci, and streptococci. However, because of its potential for causing pseudomembranous colitis (see Adverse Effects, above) it is usually used only when alternative drugs are unsuitable.

Amongst the conditions that it may be used to treat are liver abscess, actinomycosis, biliary-tract infections, staphylococcal bone and joint infections, the carrier state of diphtheria, endophthalmitis, gas gangrene, various gynaecological infections including bacterial vaginosis, endometritis, and pelvic inflammatory disease (the latter two with an aminoglycoside), intra-abdominal infections including secondary peritonitis, streptococcal pharyngitis (usually to treat the carrier state), serious respiratory-tract infections including empyema and pneumonia (especially lung abscess), septicaemia, and skin and soft-tissue infections involving heavy colonisation with streptococci or anaerobes such as necrotising fasciitis. Clindamycin is also used as part of a multidrug regimen in the treatment of anthrax. It is used in the prophylaxis of endocarditis in penicillin-allergic patients, in the prevention of perinatal streptococcal infections, and with other drugs for the prophylaxis of surgical infection. It may be used as part of a multi-drug regimen for the treatment of inhalation and gastrointestinal anthrax.

For details of these bacterial infections and their treatment, see under Choice of Antibacterial, p.162.

Clindamycin is also applied topically in the treatment of acne (p.1577) and rosacea (below).

Clindamycin has some antiprotozoal actions, and has been used, usually with other antiprotozoals, in various infections (see below) including babesiosis, malaria, and toxoplasmosis. It may also be used with primaquine in the treatment of pneumocystis pneumonia (below).

Clindamycin is given **orally** as capsules containing the hydrochloride or as oral liquid preparations containing the palmitate hydrochloride. The capsules should be taken with a glass of water. Doses are expressed in terms of the base; 1.1 g of clindamycin hydrochloride and 1.6 g of clindamycin palmitate hydrochloride are each equivalent to about 1 g of clindamycin. The usual adult oral dose is 150 to 300 mg every 6 hours; in severe infections the dose may be increased to 450 mg every 6 hours.

Clindamycin is given **parenterally** as the phosphate by intramuscular injection or by intermittent or continuous intravenous infusion over 10 minutes to 1 hour. Doses are again expressed in terms of the base; 1.2 g of clindamycin phosphate is equivalent to about 1 g of clindamycin. For intravenous use, the concentration of clindamycin in diluent for infusion should not exceed 18 mg/mL and the rate of infusion should be not more than 30 mg/minute. Not more than 1.2 g should be given as a single one-hour infusion, and not more than 600 mg should be given as a single intramuscular injection.

The usual parenteral dose is the equivalent of 0.6 to 1.2 g of clindamycin daily in divided doses; in severe infections the dose may be increased to 2.7 g daily and up to 4.8 g daily may be given intravenously in life-threatening situations.

For *prophylaxis* in adult patients at risk of developing endocarditis and who cannot be given a penicillin, an oral dose of clindamycin 600 mg, given 1 hour before procedures such as dental extractions under local or no anaesthesia, has been suggested. For high-risk patients undergoing dental procedures involving general anaesthesia and who cannot be given a penicillin, clindamycin 300 mg given intravenously over at least 10 minutes, at induction or 15 minutes before the procedure, has been suggested. However in the UK the *BNF* and NICE now suggest that such prophylaxis is unnecessary (see p.168).

For details of doses in children, including infants and adolescents, see below.

Topical formulations containing clindamycin phosphate equivalent to 1% of clindamycin are used for the treatment of acne. The hydrochloride may be applied similarly, but systemic absorption may be greater (see Pharmacokinetics, above). Clindamycin phosphate is also available in combination preparations with benzoyl peroxide and tretinoin.

Clindamycin phosphate may be given **intravaginally** as pessaries or as a 2% cream for the treatment of bacterial vaginosis; the equivalent of about 100 mg of clindamycin is given at night for 3 to 7 days.

Administration. A number of studies have suggested that a parenteral regimen of clindamycin 600 mg three times daily is as effective as giving the same dose four times daily,[1] or as giving 900 mg three times daily.[2,3]

3. Chatwani A, *et al.* Clindamycin dosage scheduling for acute pelvic infection. *Am J Obstet Gynecol* 1990; **163:** 240.

SUBCONJUNCTIVAL ROUTE. It has been suggested, should periocular use of clindamycin be necessary, that the injection solution can be given in doses of 15 to 50 mg by subconjunctival injection.[1]

1. Moorfields Eye Hospital NHS Foundation Trust. *Pharmacists Handbook 2006*. London: Moorfields Pharmaceuticals, 2006.

Administration in children. The usual oral dose for infants and children under 12 years of age is the equivalent of 3 to 6 mg/kg of clindamycin every 6 hours. In the UK, the *BNFC* suggests that neonates aged under 14 days may be given this dose every 8 hours and children aged 1 month and over but weighing less than 10 kg should be given a minimum dose of 37.5 mg every 8 hours; children over 12 years of age may be given the usual adult dose (see above).

The usual parenteral dose for infants and children aged from 1 month to 12 years is the equivalent of 15 to 25 mg/kg of clindamycin daily in 3 or 4 divided doses; in severe infections the dose may be increased to 40 mg/kg daily and a minimum dose of 300 mg daily should be given regardless of body-weight. Children over 12 years of age may be given the usual adult dose (see above). In the USA, it is also licensed for parenteral use in those aged under 1 month and 15 to 20 mg/kg daily may be given in 3 or 4 divided doses. It should be borne in mind that some parenteral formulations contain benzyl alcohol which may cause fatal 'gasping syndrome' in neonates (see p.1632).

For the treatment of staphylococcal lung infection in children aged from 1 month to 18 years with cystic fibrosis, the *BNFC* recommends oral doses of 5 to 7 mg/kg (to a maximum of 600 mg) every 6 hours.

For children's doses in babesiosis, malaria, and toxoplasmosis, see below.

Babesiosis. Clindamycin, given with quinine, both for 7 to 10 days, is recommended by some experts in the USA[1,2] for the treatment of babesiosis (p.823) caused by *Babesia microti*. Dosage regimens include:

- clindamycin 1.2 g intravenously twice daily, with quinine 650 mg three or four times daily by mouth
- clindamycin 300 to 600 mg intravenously every 6 hours, with quinine as above
- clindamycin 600 mg orally three times daily, with quinine as above

Children may be given clindamycin 20 to 40 mg/kg daily intravenously or by mouth in 3 or 4 divided doses with quinine 25 mg/kg daily by mouth in 3 divided doses, both for 7 to 10 days.

Malaria. Quinine sulfate plus follow-on treatment with doxycycline, tetracycline, or clindamycin are recommended regimens for the treatment of chloroquine-resistant falciparum malaria (p.594) in non-endemic malaria areas. Doxycycline is generally preferred because it can be given once daily. However, tetracyclines are contra-indicated in children under 8 years of age and in pregnant women, who may be given clindamycin. Clindamycin is given in the usual *adult* dose of 20 mg/kg daily in 3 divided doses (or 450 mg 3 times daily) for 7 days with quinine sulfate 600 to 650 mg 3 times daily for 3 to 7 days, both orally.[1-5] Parenteral quinine (or quinidine) plus follow-on treatment with a tetracycline or clindamycin may be used for severe falciparum malaria in both endemic and non-endemic malaria areas.[2-5] Patients unable to tolerate oral treatment may begin follow-on therapy intravenously.[2,3]

In the UK[5] public health authorities recommend that *children* be given clindamycin at a dose of 7 to 13 mg/kg 3 times daily for 7 days; US[2] public health authorities recommend giving 20 mg/kg daily in 3 divided doses.

Pneumocystis pneumonia. Clindamycin may be used with primaquine as an alternative to co-trimoxazole for the **treatment** of pneumocystis pneumonia (p.521). In the USA, some experts[1,2] recommend giving clindamycin 600 to 900 mg intravenously, or 300 to 450 mg orally, every 6 to 8 hours with primaquine 15 to 30 mg by mouth once daily, both for 21 days. In the UK the *BNF* suggests giving clindamycin 600 mg every 8 hours with primaquine 30 mg daily, both by mouth, for mild to moderate disease (but notes that this combination is associated with considerable toxicity).

A meta-analysis[3] of literature published between January 1975 to August 1999 found that, when compared with other salvage agents (such as atovaquone, co-trimoxazole, eflornithine, pentamidine, and trimetrexate), clindamycin with primaquine was the most effective regimen in patients unresponsive to conventional treatment. The authors also concluded that this latter regimen was effective as primary treatment of mild to moderately severe disease and suggested that it had fewer adverse effects than co-trimoxazole.

Clindamycin with primaquine is not normally recommended for **prophylaxis** although there are reports of it being tried.[4] A retrospective examination[5] of the records of patients who had received prophylaxis found that clindamycin with primaquine was less effective than co-trimoxazole or dapsone, although this could have been due in part to underdosing.

Rosacea. Topical clindamycin[1] has improved inflammatory episodes of rosacea (p.1583), although other features of the skin disorder may not respond. A small study[2] showed that once-daily application of clindamycin 1% plus benzoyl peroxide 5% was effective in the treatment of moderate to severe rosacea.

Toxoplasmosis. Clindamycin with pyrimethamine has been used for the treatment and secondary prophylaxis (chronic maintenance) of toxoplasmosis (p.826) instead of the more usual treatment with pyrimethamine plus sulfadiazine, in patients unable to tolerate sulfonamides; folinic acid is also given to counteract the megaloblastic anaemia associated with pyrimethamine. In adult patients with AIDS and toxoplasmic encephalitis, clindamycin 600 mg every 6 hours orally or intravenously for at least 6 weeks, then maintenance therapy with 300 to 450 mg every 6 to 8 hours by mouth, has been recommended in the USA.[1] Children may be given clindamycin 5 to 7.5 mg/kg 4 times daily by mouth or intravenously for at least 6 weeks, followed by chronic maintenance therapy.[2]

Other studies found acute therapy with pyrimethamine and clindamycin, 600 mg 4 times daily by mouth[3] or 1200 mg every 6 hours intravenously,[4] to be as effective as pyrimethamine and sulfadiazine, but oral maintenance therapy with pyrimethamine and clindamycin 300 mg 4 times daily was less effective than pyrimethamine and sulfadiazine at preventing relapses in a population followed for 3 years or more.[3] Clindamycin with fluorouracil produced beneficial responses in a study involving 16 patients.[5]

In contrast, another study, comparing clindamycin alone (in lower oral doses—300 mg twice daily) with pyrimethamine alone for prophylaxis of toxoplasmic encephalitis, reported an unacceptably high incidence of adverse effects with clindamycin, which forced premature termination of the clindamycin arm—see AIDS under Precautions, above.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Clioquinol). An almost white, light yellow, brownish-yellow, or yellowish-grey powder. Practically insoluble in water; very slightly soluble or slightly soluble in alcohol; sparingly soluble in dichloromethane. Protect from light.

USP 31 (Clioquinol). A voluminous, spongy, yellowish-white to brownish-yellow powder having a slight characteristic odour. It darkens on exposure to light. Practically insoluble in water; soluble 1 in 3500 of alcohol, 1 in 120 of chloroform, and 1 in 4500 of ether; soluble in hot ethyl acetate and in hot glacial acetic acid. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

Clioquinol may rarely cause iodism in sensitive patients. Local application of clioquinol in ointments or creams may occasionally cause severe irritation or hypersensitivity and there may be cross-sensitivity with other halogenated hydroxyquinolines.

Clioquinol stains clothing and linen yellow on contact and may stain the skin and discolour fair hair.

Clioquinol given by mouth has been associated with severe neurotoxicity. In Japan, the epidemic development of subacute myelo-opticoneuropathy (SMON) in the 1960s was associated with the ingestion of normal or high doses of clioquinol for prolonged periods, and the sale of clioquinol and related hydroxyquinolines was subsequently banned there. Symptoms of SMON are principally those of peripheral neuropathy, including optic atrophy, and myelopathy. Abdominal pain and diarrhoea often precede neurological symptoms, such as paraesthesias in the legs progressing to paraplegia in some patients, and loss of visual acuity sometimes leading to blindness. A characteristic green pigment, a chelate of clioquinol with iron, is often seen on the tongue and in the urine and faeces. Cerebral disturbances, including confusion and retrograde amnesia, have also been reported. Although many patients improved when clioquinol was withdrawn, others had residual disablement.

It was suggested that the Japanese epidemic might be due to genetic susceptibility, but a few similar cases of SMON associated with clioquinol or related hydroxyquinoline derivatives, such as broxyquinoline or diiodohydroxyquinoline have been reported from other countries. Oral preparations of clioquinol have now been banned in most countries.

Hypersensitivity. Clioquinol is classified as a contact allergen which can commonly cause sensitisation, especially when applied to eczematous skin; chlorquinaldol can also cause sensitisation, although less frequently.[1] It is important to include clioquinol and chlorquinaldol in routine patch testing since the clinical reaction may be relatively mild and sensitivity easily missed, particularly in the presence of a corticosteroid which suppresses or attenuates the reaction.

1. Anonymous. Skin sensitisers in topical corticosteroids. *Drug Ther Bull* 1986; **24:** 57–9.

Topical application. Absorption of clioquinol through the skin has been noted on topical application.[1,2] The Committee on Drugs of the American Academy of Pediatrics[3] considered that there was a potential risk of toxicity to infants and children from clioquinol and diiodohydroxyquinoline applied topically. Since alternative effective preparations are available for dermatitis, the Committee recommended that products containing either of these compounds should not be used.

Uses and Administration

Clioquinol is a halogenated hydroxyquinoline with antibacterial and antifungal activity and is used in creams and ointments, usually containing 3%, in the treatment of skin infections. It is applied with a corticosteroid in inflammatory skin conditions complicated by bacterial or fungal infections. It is also used in ear drops for otitis externa. The treatment of bacterial and of fungal skin infections is described on p.194 and p.521 respectively.

For a discussion of the risks from topical application of clioquinol, see Adverse Effects and Precautions, above.

Clioquinol was formerly given by mouth in the treatment of intestinal amoebiasis. It was also formerly used for the prophylaxis and treatment of traveller's diarrhoea and similar infections but was of doubtful value. Oral preparations have now been withdrawn because of neurotoxicity (see Adverse Effects and Precautions, above). However, clioquinol by mouth has been investigated for its action as a chelator of copper and zinc in the treatment of Alzheimer's disease (see below).

Alzheimer's disease. A systematic review[1] to evaluate the efficacy of metal protein attenuating compounds, such as clioquinol, for the treatment of cognitive impairment due to Alzheimer's disease, evaluated only one small randomised controlled study comparing clioquinol and placebo; no significant differences were found. Further studies with clioquinol have now been stopped, but studies are on-going with a successor compound, PBT2.

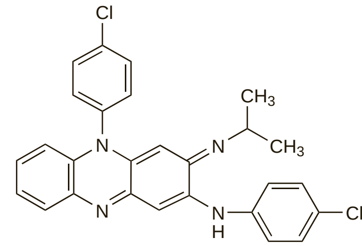
Clofazimine *(BAN, USAN, rINN)*

B-663; Clofazimina; Clofaziminum; G-30320; Klofatsimiini; Klofatzimin; Klofazimin; Klofaziminas; NSC-141046. 3-(4-Chloroanilino)-10-(4-chlorophenyl)-2,10-dihydro-2-phenazin-2-ylideneisopropylamine.

Клофазимин

$C_{27}H_{22}Cl_2N_4$ = 473.4.
CAS — 2030-63-9.
ATC — J04BA01.
ATC Vet — QJ04BA01.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Clofazimine). A fine reddish-brown powder. It exhibits polymorphism. Practically insoluble in water; very slightly soluble in alcohol; soluble in dichloromethane.

USP 31 (Clofazimine). Dark red crystals. Practically insoluble in water; sparingly soluble in alcohol, in acetone, and in ethyl acetate; soluble in chloroform and in benzene. Store in airtight containers. Protect from light.

Adverse Effects

Adverse effects to clofazimine are dose related, the most common being red to brown discoloration of the skin especially on areas exposed to sunlight; leprotic lesions may become mauve to black. These changes are more noticeable in light-skinned people and may limit its acceptance. The conjunctiva and cornea may also show some signs of red to brown pigmentation. The generalised discoloration may take months to years to disappear after stopping therapy. Discoloration of hair, tears, sweat, sputum, breast milk, urine, and faeces may occur, as may nail discoloration with high doses of 300 mg daily. Severe depression related to skin discoloration has been reported rarely.

Gastrointestinal effects are uncommon for doses of clofazimine less than 100 mg daily and usually are not severe. Symptoms of nausea, vomiting, and abdominal pain experienced shortly after the start of treatment may be due to direct irritation of the gastrointestinal tract and such symptoms usually disappear on dose reduction. Use of doses of 300 mg daily or more for several months sometimes produces abdominal pain, diarrhoea, weight loss, gastrointestinal bleeding, and in severe cases the small bowel may become oedematous and symptoms of bowel obstruction may develop. This may be due to deposition of crystals of clofazimine in the wall of the small bowel and in the mesenteric lymph nodes. Crystal deposition may also occur in other organs including the liver and spleen and there have been rare reports of splenic infarction. Symptoms usually regress on withdrawal of treatment although fatalities have been reported.

Clofazimine may produce a dryness of the skin and ichthyosis as well as decreased sweat production and rashes. Pruritus, acneiform eruptions, and photosensitivity reactions have also been reported.

Eye irritation and decreased tear production may occur.

Headache, drowsiness, dizziness, taste disorders, and elevation of blood glucose levels have been reported rarely.

Incidence of adverse effects. The incidence of adverse effects was reviewed in 65 patients[1] who were receiving, or had received, clofazimine in weekly doses of either 700 mg or less as antimycobacterial therapy, or more than 700 mg as anti-inflammatory therapy. Length of treatment ranged from 1 to 83 months. Adverse effects on the skin included discoloration (20% of patients), pigmentation (64.6%), dry skin (35.4%), and pruritus (5%). Ocular adverse effects were conjunctival pigmentation (49.2%), subjective dimness of vision (12.3%), and dry eyes, burning, and other ocular irritation (24.6%). Gastrointestinal adverse effects included abdominal pain (33.8%), nausea (9.2%), diarrhoea (9.2%), and weight loss, vomiting, or loss of appetite (13.8%). The different dose regimens for antimycobacterial therapy or anti-inflammatory effect had similar incidences of adverse effects. Skin pigmentation in 8 patients disappeared on average 8.5 months after stopping therapy with clofazimine, the maximum time required being one year. Adverse effects of clofazimine were considered to be well tolerated.

In another report covering 540 patients receiving clofazimine 100 mg on alternate days or 300 mg daily, the most common adverse effect was skin pigmentation, which occurred in 77.8% of the patients. Ichthyotic changes were reported in 66.7% and pruritus in 20.2%. Gastrointestinal symptoms occurred in 20 patients (about 4%); other effects such as discoloration of sweat, urine, and tears were minor.[2]

2. Kumar B, *et al.* More about clofazimine—3 years experience and review of the literature. *Indian J Lepr* 1987; **59:** 63–74.

Effects on the eyes. Accumulation of clofazimine crystals in the eye can lead to pigmentation of the cornea and conjunctiva. Degeneration of the retinal pigment epithelium has also been attributed to clofazimine therapy in a patient.[1] Slight repigmentation was observed after withdrawal of clofazimine.

1. Forster DJ, *et al.* Bull's eye retinopathy and clofazimine. *Ann Intern Med* 1992; **116:** 876–7.

Effects on the gastrointestinal tract. Gastrointestinal effects are uncommon at doses of clofazimine less than 100 mg daily. However, there have been some reports of severe gastrointestinal adverse events, including fatalities, in patients taking clofazimine.[1-4] An 11-year-old child given clofazimine (150 mg daily) for graft-versus-host disease developed severe enteropathy 2 years after starting treatment.[1] Clofazimine was stopped and symptoms resolved after 5 weeks. Enteropathy has also been reported in a 20-year-old patient who had taken 200 mg of clofazimine daily for 4 years.[2] Clofazimine was stopped but his symptoms did not resolve; he developed peripheral oedema and hypoalbuminaemia and died 2 years later due to cerebral thrombosis. In another report,[4] partial intestinal obstruction developed in a patient after 12 months of treatment with clofazimine 100 mg daily for the treatment of multidrug-resistant tuberculosis. The patient recovered 3 weeks after stopping clofazimine. Splenic infarction has been reported after 11 months treatment with high-dose clofazimine for the management of pyoderma gangrenosum.[5] Chronic abdominal pain due to crystal-storing histiocytosis of mesenteric lymph nodes is well recognised, and may mimic the symptoms of gastrointestinal lymphoma or myeloma.[3]

Effects on the heart. Ventricular tachycardia, thought to be probably torsade de pointes, was reported to be associated with clofazimine.[1]

1. Choudhri SH, *et al.* Clofazimine induced cardiotoxicity—a case report. *Lepr Rev* 1995; **66:** 63–8.

Precautions

Clofazimine should be used with caution in patients with gastrointestinal symptoms such as abdominal pain and diarrhoea. If gastrointestinal symptoms develop during treatment, the dose should be reduced and, if necessary, the interval between doses increased, or the drug should be stopped. Daily doses of more than 100 mg should not be used for more than 3 months because of dose-related adverse effects on the gastrointestinal tract; patients receiving doses greater than 100 mg daily should be under medical supervision.

Patients should be warned that clofazimine may cause a reddish-brown discoloration of breast milk, hair, skin, conjunctiva, tears, sputum, sweat, urine, and faeces. Nails may be discoloured at higher doses.

As clofazimine crosses the placental barrier, neonates of women receiving clofazimine may have skin discoloration at birth.

Breast feeding. The American Academy of Pediatrics[1] considers that the use of clofazimine by mothers during breast feeding may be of concern, since there is the possibility of transfer of a high percentage of the maternal dose and a possible increase in skin pigmentation in the infant. A small study in 8 women calculated that up to 30% of a maternal dose may be ingested by a breast-fed infant.[2]

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 03/10/07)
2. Venkatesan K, *et al.* Excretion of clofazimine in human milk in leprosy patients. *Lepr Rev* 1997; **68:** 242–6.

Pregnancy. Two successful pregnancies in women who received clofazimine throughout pregnancy have been reported[1] but a literature review revealed 3 neonatal deaths in 13 pregnancies, although the deaths could not be directly attributed to clofazimine. However, WHO[2] states that its recommended multiple drug therapy regimens for leprosy, which may include clofazimine, are safe during pregnancy.

Interactions

Some preliminary data have suggested that the anti-inflammatory action of clofazimine in Type 2 lepra reactions may be reduced by dapsone, although US licensed product information (*Lamprene; Novartis, USA*) states that these findings have not been confirmed; the antimycobacterial effect was not affected.

Elevated plasma and urine concentrations of clofazimine have been detected in patients receiving high doses of clofazimine with isoniazid, although skin concentrations were found to be lower.

For a report of the effect of clofazimine on rifampicin absorption, see p.327.

Antimicrobial Action

Clofazimine is bacteriostatic and weakly bactericidal against *Mycobacterium leprae*. Tissue antimicrobial activity in humans cannot be found until after about 50 days of therapy. Clofazimine is active *in vitro* against various other species of *Mycobacterium*. Resistance has been reported rarely and no cross-resistance occurs with rifampicin or dapsone.

Pharmacokinetics

Clofazimine is absorbed from the gastrointestinal tract in amounts varying from 45 to 70%. Absorption is greatest when clofazimine is given in microcrystalline formulations and when it is taken immediately after food. The time to steady-state plasma concentrations has not been determined but exceeds 42 days.

Average plasma concentrations in leprosy patients receiving 100 or 300 mg daily are reported as 0.7 micrograms/mL and 1.0 microgram/mL, respectively.

Because of its lipophilic nature, clofazimine is mainly distributed to fatty tissue and reticuloendothelial cells, including macrophages. Clofazimine is distributed to most organs and tissues and into breast milk; it crosses the placenta but not the blood-brain barrier.

The tissue half-life after a single dose has been reported to be about 10 days; that after multiple oral doses has been variously estimated to be between 25 and 90 days. Clofazimine accumulates in the body and is largely excreted unchanged in the faeces, both as unabsorbed drug and via biliary excretion. About 1% of the dose is excreted in 24 hours in the urine as unchanged clofazimine and metabolites. A small amount of clofazimine is also excreted through sebaceous and sweat glands, and in sputum.

◊ References.

Uses and Administration

Clofazimine is an antimycobacterial and is used as part of multidrug regimens for the treatment of multibacillary leprosy (p.176). It has anti-inflammatory properties and has been given in chronic Type 2 lepra reactions (erythema nodosum leprosum) and in a variety of skin disorders.

Clofazimine is given orally with, or immediately after, food or milk for optimum absorption.

For multibacillary leprosy the most common regimen is that recommended by WHO, in which rifampicin 600 mg and clofazimine 300 mg are both given *once a month*, together with *daily* doses of clofazimine 50 mg and dapsone 100 mg; this treatment continues for 12 months.

For details of doses in children, see below.

Clofazimine 50 mg daily is given with ofloxacin and minocycline in patients unable to take rifampicin.

Clofazimine is not usually given in paucibacillary leprosy. However, it may be used with rifampicin instead of dapsone when the latter has caused severe toxicity.

Clofazimine has been used in the treatment of chronic Type 2 lepra reactions, although the effect may not be evident for 4 to 6 weeks. A dose of up to 300 mg daily has been suggested but it should not be given for longer than 3 months. Corticosteroids may be given with clofazimine, and standard antileprosy treatment should be continued. Clofazimine is not used in Type 1 lepra reactions.

Administration in children. For the treatment of multibacillary leprosy in children WHO recommends that children aged 10 to 14 years may be given oral clofazimine 150 mg plus rifampicin 450 mg and dapsone 50 mg *once a month*, together with dapsone 50 mg *daily* and clofazimine 50 mg on *alternate days*. For children less than 10 years of age the dose should be adjusted according to body weight. As for adults, treatment is given for 12 months.

Sodium content. Each g of cloxacillin sodium contains about 2.1 mmol of sodium.

Interactions

As for Benzylpenicillin, p.214.

Antimicrobial Action

As for Flucloxacillin, p.277.

Pharmacokinetics

Cloxacillin is incompletely absorbed from the gastrointestinal tract, and absorption is reduced by the presence of food in the stomach. After an oral dose of 500 mg, a peak plasma concentration of 7 to 15 micrograms/mL is attained in fasting subjects in 1 to 2 hours. Absorption is more complete when given by intramuscular injection and peak plasma concentrations of about 15 micrograms/mL have been observed 30 minutes after a dose of 500 mg. Doubling the dose can double the plasma concentration. About 94% of cloxacillin in the circulation is bound to plasma proteins. Cloxacillin has been reported to have a plasma half-life of 0.5 to 1 hour. The half-life is prolonged in neonates.

Cloxacillin crosses the placenta and is distributed into breast milk. There is little diffusion into the CSF except when the meninges are inflamed. Therapeutic concentrations can be achieved in pleural and synovial fluids and in bone.

Cloxacillin is metabolised to a limited extent, and the unchanged drug and metabolites are excreted in the urine by glomerular filtration and renal tubular secretion. About 35% of an oral dose is excreted in the urine and up to 10% in the bile. Cloxacillin is not removed by haemodialysis.

Plasma concentrations are enhanced by probenecid. Reduced concentrations in patients with cystic fibrosis have been attributed to both enhanced tubular secretion and enhanced nonrenal clearance of cloxacillin.

Uses and Administration

Cloxacillin is an isoxazolyl penicillin used similarly to flucloxacillin (p.277) in the treatment of infections due to staphylococci resistant to benzylpenicillin.

Cloxacillin is given orally as the sodium salt and doses are expressed in terms of the equivalent amount of cloxacillin; 1.09 g of cloxacillin sodium is equivalent to about 1 g of cloxacillin. It should be given at least 30 minutes before meals as the presence of food in the stomach reduces absorption.

Usual oral doses are 250 to 500 mg four times daily. Children up to 2 years may be given a quarter of the daily adult dose and those over 2 years half the daily adult dose, in divided doses every 6 hours.

Cloxacillin sodium has also been given by intramuscular or slow intravenous injection or infusion. Other routes have included intra-articular or intrapleural injection, and inhalation.

Cloxacillin may be used with other antibacterials, including ampicillin, to produce a wider spectrum of activity.

Cloxacillin benzathine is used in veterinary medicine.

E1-7MOA	D-Leu	H	CH	CH	C H N O

(colistin)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Colistin Sulphate). A mixture of the sulfates of polypeptides produced by certain strains of *Bacillus polymyxa* var. *colistinus* or obtained by any other means. It contains a minimum of 77% of the sum of polymyxin E1, polymyxin E2, polymyxin E3, polymyxin E1-I, and polymyxin E1-7MOA. A white or almost white, hygroscopic powder. Freely soluble in water; slightly soluble in alcohol; practically insoluble in acetone. A 1% solution in water has a pH of 4.0 to 6.0. Store in airtight containers. Protect from light.

USP 31 (Colistin Sulfate). The sulfate salt of an antibacterial substance produced by the growth of *Bacillus polymyxa* var. *colistinus*. It has a potency of not less than 500 micrograms of colistin per mg. A white to slightly yellow, odourless, fine powder. Freely soluble in water; insoluble in acetone and in ether; slightly soluble in methyl alcohol. pH of a 1% solution in water is between 4.0 and 7.0. Store in airtight containers.

Stability. Colistin base is precipitated from aqueous solution above pH 7.5.

Colistimethate Sodium *(BANM, USAN, rINN)*

Colistimetato de sodio; Colistimetato de Sódio; Colistimetato sódico; Colistiméthate sodique; Colistimethatum natricum; Colistimethatum Natrium; Colistin Sulphomethate Sodium; Colistineméthanesulfonate Sodique; Kolistimetaattinatrium; Kolistimetatnatrium; Kolistimetato natrio druska; Kolistimethát sodná sůl; Kolistymetat sodowy; Kolisztimetát-nátrium; Pentasodium Colistinmethanesulfonate; Sodium Colistimethate; Sodium Colistinmethanesulphonate; W-1929.

Колистиметат Натрий

CAS — 30387-39-4 (colistimethate); 8068-28-8 (colistimethate sodium).
ATC — A07AA10; J01XB01.
ATC Vet — QA07AA10; QJ01XB01.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Colistimethate Sodium). It is prepared from colistin by the action of formaldehyde and sodium bisulfite. The potency is not less than 11 500 units/mg, calculated with reference to the dried substance. A white or almost white, hygroscopic powder. Very soluble in water; slightly soluble in alcohol; practically insoluble in acetone. A 1% solution in water has a pH of 6.5 to 8.5. Store in airtight containers. Protect from light.

USP 31 (Colistimethate Sodium). A white to slightly yellow, odourless, fine powder. It has a potency equivalent to not less than 390 micrograms of colistin per mg. Freely soluble in water; insoluble in acetone and in ether; soluble in methyl alcohol. pH of a 1% solution in water is between 6.5 and 8.5.

Stability. After the death of a patient with cystic fibrosis who had been given a liquid solution of colistimethate premixed for inhalation with a nebuliser (see Cystic Fibrosis, under Adverse Effects, below) the US FDA warned[1] that such premixing of colistimethate in an aqueous solution and storing it for longer than 24 hours results in increased concentrations of colistin in solution and increases the potential for lung toxicity. When colistimethate is mixed with water and buffer it undergoes spontaneous hydrolysis to colistin; polymyxin E1, a component of colistin, has been shown to cause pulmonary inflammation in *animal* studies. Inhalation solutions of colistimethate should therefore be given promptly after preparation.

1. FDA. Colistimethate (marketed as Coly-Mycin M and generic products) (issued 28 June 2007). Available at: http://www.fda.gov/cder/drug/InfoSheets/HCP/colistimethateHCP.htm (accessed 18/01/08)

Units

The first International Standard Preparation (1968) for colistin contains 20 500 units/mg of colistin sulfate and the first International Reference Preparation (1968) for colistimethate contains 12 700 units/mg of colistimethate.

Adverse Effects, Treatment, and Precautions
As for Polymyxin B Sulfate, p.318.

Colistin sulfate is poorly absorbed from the gastrointestinal tract and adverse effects do not normally occur with usual oral doses. However, gastrointestinal absorption is limited and unpredictable in infants under 6 months of age and systemic adverse effects such as transient sensory disturbances may occur in this patient group.

Cough and bronchospasm may occur during inhalation; cases of sore throat or sore mouth, possibly due to hypersensitivity or superinfection with *Candida* spp., have also been reported. Neurotoxic reactions such as dizziness, confusion, and visual disturbances can occur during parenteral therapy and patients so affected should not drive or operate machinery. Pain and local irritation are reported to be less troublesome after intramuscular injection of colistimethate sodium than with colistin sulfate or polymyxin B. Overgrowth of non-susceptible organisms, particularly *Proteus* spp., may occur after prolonged use.

Plasma-concentration monitoring during systemic treatment is recommended in neonates, patients with renal impairment, and those with cystic fibrosis. Peak plasma-colistin concentrations of 10 to 15 mg/litre (about 125 to 200 units/mL) are recommended.

Cystic fibrosis. Intravenous colistin sulfate was reported to be associated with a lower rate of severe nephrotoxicity among 19 patients with cystic fibrosis than has been previously reported in other patient populations.[1] However, fatal acute respiratory distress syndrome (ARDS) has been reported in a cystic fibrosis patient after inhalation of colistimethate sodium 75 mg twice daily.[2] The solution used had been compounded 5 weeks previously, and it was considered that ARDS was caused by the conversion of colistimethate sodium to the active form colistin which may cause airway or alveolar injury. The FDA subsequently warned that inhalation solutions should be used promptly after preparation (see Stability, above).

2. McCoy KS. Compounded colistimethate as possible cause of fatal acute respiratory distress syndrome. *N Engl J Med* 2007; **357:** 2310–1.

Effects on the cardiovascular system. Significant, but transient, hypotension occurred in a patient after starting aerosolised colistin inhalation.[1] Intravenous colistin, alone or with aerosolised amikacin, had no such effect on blood pressure.

1. Hakeam HA, Almohaizeie AM. Hypotension following treatment with aerosolized colistin in a patient with multidrug-resistant Pseudomonas aeruginosa. *Ann Pharmacother* 2006; **40:** 1677–80.

Porphyria. Colistin has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions
As for Polymyxin B Sulfate, p.318.

Antimicrobial Action
The antimicrobial spectrum and mode of action of colistin is similar to that of polymyxin B (p.318) but colistin sulfate is slightly, and colistimethate significantly, less active.

Pharmacokinetics
Colistin sulfate and colistimethate sodium are poorly absorbed from the gastrointestinal tract of adults and children; however, limited and unpredictable gastrointestinal absorption occurs in infants under 6 months of age. The drugs are not absorbed through mucous membranes, or intact or denuded skin. Peak plasma concentrations usually occur 2 to 3 hours after an intramuscular injection of colistimethate sodium. Plasma protein binding of colistin is reported to be more than 50% but that of colistimethate sodium is low. Colistin is reversibly bound to body tissues, but binding does not occur with colistimethate. Some colistimethate sodium may be hydrolysed to colistin *in vivo*. The serum half-life of colistimethate sodium is 2 to 3 hours but is prolonged in renal impairment; values of 10 to 20 hours have been reported in patients with a creatinine clearance of less than 20 mL/minute. Half-life may initially be prolonged in neonates but has been reported to fall to 2 to 3 hours after 3 or 4 days.

Colistimethate is mainly excreted by glomerular filtration as changed and unchanged drug and up to 80% of a parenteral dose may be recovered in the urine within 24 hours. Excretion is more rapid in children than in adults; it is reduced in patients with renal impairment. Colistin crosses the placenta but diffusion into the CSF is negligible. It is distributed into breast milk.

Uses and Administration
Colistin is a polymyxin antibacterial that has been used in the treatment of severe Gram-negative infections, especially those due to *Pseudomonas aeruginosa*, although other drugs are usually preferred. Colistimethate sodium is used by inhalation in the management of respiratory infections, especially in patients with cystic fibrosis (p.166). Colistin has been given orally as the sulfate for the treatment of gastrointestinal infections. Colistin sulfate is also given orally for bowel preparation before abdominal surgery, and with other drugs in regimens for selective digestive tract decontamination (SDD) in patients at high risk of endogenous infections (see under Intensive Care, p.175).

The usual oral dose of colistin sulfate is 1.5 to 3 million units given 3 times daily. For bowel preparation, the same dose is given for 24 hours with the course being completed 12 hours before surgery.

Colistin is given parenterally, as colistimethate sodium, by intramuscular injection or slow intravenous injection or infusion. In the UK, usual doses are 1 to 2 million units given 3 times daily (maximum dose 6 million units in 24 hours) for patients weighing more than 60 kg; those weighing up to 60 kg may be given 50 000 units/kg daily in 3 divided doses up to a maximum of 75 000 units/kg daily. In the USA, the usual dose is equivalent to colistin base 2.5 to 5 mg/kg daily in 2 to 4 divided doses. Monitoring of plasma concentrations is required in some patients (see Adverse Effects and Precautions, above).

Colistimethate sodium may also be given by inhalation in respiratory infections as an adjunct to systemic antibacterial therapy. The usual dose is 1 to 2 million units given 2 or 3 times daily. A 3-week course of 2 million units twice daily may be given initially, increased to a maximum of 2 million units given 3 times daily for up to 3 months in frequent recurrent infections; 1 to 2 million units twice daily may be given for long-term therapy. Solutions for inhalation should be freshly prepared (see Stability, above).

Doses and dosage intervals should be adjusted in patients with renal impairment (see below).

For details of doses in infants and children, see below.

Colistimethate sodium has also been given by subconjunctival injection and as a bladder instillation. Both colistin sulfate and colistimethate sodium have been applied topically, often with other antibacterials, in the management of ear, eye, and skin infections.

◊ Reviews.

1. Falagas ME, Kasiakou SK. Colistin: the revival of polymyxins for the management of multidrug-resistant gram-negative bacterial infections. *Clin Infect Dis* 2005; **40:** 1333–41. Correction. *ibid.* 2006; **42:** 1819. [dose]
2. Falagas ME, *et al.* The use of intravenous and aerosolized polymyxins for the treatment of infections in critically ill patients: a review of the recent literature. *Clin Med Res* 2006; **4:** 138–46.
3. Li J, *et al.* Colistin: the re-emerging antibiotic for multidrug-resistant Gram-negative bacterial infections. *Lancet Infect Dis* 2006; **6:** 589–601.

Administration in children. The following doses of colistin sulfate may be given **orally** to children according to weight:
- up to 15 kg: 0.25 to 0.5 million units 3 times daily
- 15 to 30 kg: 0.75 to 1.5 million units 3 times daily
- over 30 kg: the usual adult dose (see above)

Parenteral doses of colistimethate sodium may vary between countries.

UK according to weight:
- up to 60 kg: 50 000 units/kg daily in 3 divided doses up to a maximum of 75 000 units/kg daily (the *BNFC* suggests that this dose may be given to those as young as 1 month of age)
- over 60 kg: the usual adult dose (see above)

USA:
- children may be given the usual adult dose, equivalent to colistin base, of 2.5 to 5 mg/kg daily in 2 to 4 divided doses

Monitoring of plasma concentrations is required in some patients (see Adverse Effects, Treatment, and Precautions, above).

For **inhalation** colistimethate sodium may be given in the following doses according to age:
- under 2 years: 0.5 to 1 million units twice daily (the *BNFC* suggests that this dose may be given to those as young as 1 month of age)
- over 2 years: the usual adult dose (see above)

Doses and dosage intervals should be adjusted in patients with renal impairment (see below).

Administration in renal impairment. Dosage of parenteral and inhaled colistimethate sodium must be adjusted in renal impairment; both reduction in dose and decreased frequency of dosing may be required.

In the UK, the following **parenteral** doses of colistimethate sodium, based on creatinine clearance (CC), have been suggested for patients weighing more than 60 kg:
- CC 20 to 50 mL/minute: 1 to 2 million units every 8 hours
- CC 10 to 20 mL/minute: 1 million units every 12 to 18 hours
- CC less than 10 mL/minute: 1 million units every 18 to 24 hours

US licensed product information suggests the following modified doses (equivalent to colistin base) for adults with renal impairment in terms of plasma-creatinine concentrations:
- 1.3 to 1.5 mg/100 mL: 150 to 230 mg given daily in two divided doses
- 1.6 to 2.5 mg/100 mL: 133 to 150 mg given daily as a single dose or in 2 divided doses
- 2.6 to 4.0 mg/100 mL: 100 to 150 mg given every 36 hours

The following doses **by inhalation** have been suggested based on creatinine concentrations:
- 106 to 129 micromoles/litre: 1 to 1.5 million units every 12 hours
- 130 to 214 micromoles/litre: 1 million units every 12 or 24 hours
- 215 to 340 micromoles/litre: 1 to 1.5 million units every 36 hours

Preparations
BP 2008: Colistimethate Injection; Colistin Tablets;
USP 31: Colistimethate for Injection; Colistin and Neomycin Sulfates and Hydrocortisone Acetate Otic Suspension; Colistin Sulfate for Oral Suspension.

Co-tetroxazine *(BAN)*
Tetroxoprima y sulfadiazina.
CAS — 73173-12-3.

Profile
Co-tetroxazine, a mixture of tetroxoprim and sulfadiazine in the proportion of 2:5, has properties similar to those of co-trimoxazole (below). It has been given orally, mainly in the treatment of infections of the urinary and respiratory tracts, including pneumocystis pneumonia.

Preparations
Proprietary Preparations (details are given in Part 3)
Ger.: Sterinor†; ***Venez.:*** Esterinor†.

Co-trifamole *(BAN)*
CN-3123; Cotrifamol.
ATC — J01EE04.

Profile
Co-trifamole, a mixture of 5 parts of sulfamoxole and 1 part of trimethoprim, has properties similar to those of co-trimoxazole (below) and has been used similarly.

Preparations

Proprietary Preparations (details are given in Part 3)
S.Afr.: Supristol†.

Co-trimazine *(BAN)*

Trimetoprima y sulfadiazina.
CAS — 39474-58-3.
ATC — J01EE02.

Profile

Co-trimazine, a mixture of 5 parts of sulfadiazine and 1 part of trimethoprim, has properties similar to those of co-trimoxazole (below) and has been used similarly.

Preparations are available in some countries which contain trimethoprim and sulfadiazine in proportions different to co-trimazine.

Co-trimoxazole *(BAN)*

Cotrimoxazol; Ko-trimoksazol.
CAS — 8064-90-2.
ATC — J01EE01.

Description. Co-trimoxazole is defined as a mixture of 5 parts of sulfamethoxazole and 1 part of trimethoprim.

Stability. Diluted infusion solutions of co-trimoxazole have a limited stability and eventually form a precipitate: this happens more rapidly at higher concentrations. The manufacturers recommend a dilution of 480 mg in 130 mL, which is usually stable for up to 6 hours, but more concentrated solutions should be used within shorter periods of time, and a dilution of 480 mg in 80 mL should be used within 1 hour. The usual diluent is glucose 5%, although other solutions, including sodium chloride 0.9%, have been stated to be compatible for adequate periods.

Adverse Effects and Treatment

The adverse effects of co-trimoxazole are those of its components (see Sulfamethoxazole, p.340, and Trimethoprim, p.355). Gastrointestinal disturbances (mainly nausea and vomiting) and skin reactions are the most common adverse effects. There have been occasional deaths, especially in elderly patients, mainly due to blood disorders, hepatic necrosis, or severe skin reactions.

A high incidence of adverse effects has been reported in AIDS patients; desensitisation may sometimes be considered (see Immunocompromised Patients under Precautions, below).

Incidence of adverse effects. There has been concern over the safety of co-trimoxazole. In 1985, reporting on 85 deaths associated with the use of co-trimoxazole,[1] predominantly due to blood dyscrasias (50 reports) and skin reactions (14 reports), the UK CSM found that fatalities showed a marked increase with age: below 40 years, there were 0.25 reported deaths per million prescriptions, but for patients over 65 years of age the number of reported deaths per million prescriptions was more than 15-fold greater. However, at that time the CSM felt that it would be unwise to assume that trimethoprim was substantially less liable than co-trimoxazole to cause fatal adverse reactions.[1] Others suggested[2] that most of the deaths associated with the use of co-trimoxazole were typical of sulfonamide toxicity and that the indications for the use of co-trimoxazole should be reduced; this included the suggestion that it should be contra-indicated in the elderly. The CSM stated that their main message was that the risks of treatment with co-trimoxazole were more apparent in the elderly, but that there was no significant difference between the numbers of reports received for serious adverse reactions to trimethoprim and co-trimoxazole when corrected for prescription volumes.[3] In practice, despite further occasional reports of fatalities in elderly patients,[4] there did not appear to have been a marked reduction in the prescribing of this drug in the UK.[5] A similar warning of increased risk from co-trimoxazole in elderly patients was issued by the Adverse Drug Reactions Advisory Committee in Australia.[6]

A large population-based follow-up study in the UK[7] indicated that the risks of serious liver, blood, skin, and kidney disorders with either co-trimoxazole, trimethoprim, or cefalexin were small and were similar to those with many other antibacterials. Although in 1995 the CSM did restrict the use of co-trimoxazole on the grounds that its place in therapy had changed[8] (see under Uses and Administration, below), they also noted that co-trimoxazole continued to show a similar pattern of serious suspected adverse reactions to that reported 10 years earlier and that adverse drug reactions with trimethoprim were similar; blood dyscrasias and generalised skin disorders were the most serious reactions in each case and remained predominantly in elderly patients.

Precautions

As for Sulfamethoxazole, p.340 and Trimethoprim, p.355.

Co-trimoxazole should not be given to patients with a history of hypersensitivity to it or to the sulfonamides or trimethoprim. It should be stopped at the first appearance of skin rash, or if blood disorders develop. It should be avoided in patients with severe hepatic impairment and used with caution in patients with lesser degrees of impairment. Like its components, co-trimoxazole should be used with caution in renal impairment, and dosage adjustment may be necessary; it should not be used in severe renal impairment without monitoring of plasma drug concentrations. An adequate fluid intake should be maintained to reduce the risk of crystalluria, but alkalinisation of the urine, although it increases urinary excretion of the sulfamethoxazole component, decreases urinary trimethoprim excretion. Regular blood counts and urinalyses and renal-function tests should be carried out in patients receiving prolonged treatment with co-trimoxazole. Elderly patients may be more susceptible to adverse effects (see Incidence of Adverse Effects, above). Folate supplementation may be necessary in patients predisposed to folate deficiency, such as elderly patients and when high doses of co-trimoxazole are given for a prolonged period. Co-trimoxazole is contra-indicated in patients with megaloblastic anaemia due to folate deficiency.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were taking co-trimoxazole, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding. Studies have shown that significant concentrations of trimethoprim and sulfamethoxazole are present in breast milk after maternal doses;[2,3] however, the calculated dose to the infant was deemed unlikely to lead to clinical effects.

3. Miller RD, Salter AJ. The passage of trimethoprim/sulphamethoxazole into breast milk and its significance. *Hell Soc Chemother* 1974; **1:** 687–91.

G6PD deficiency. It has been suggested that co-trimoxazole should be avoided by people with G6PD deficiency.[1]

1. WHO. Glucose-6-phosphate dehydrogenase deficiency. *Bull WHO* 1989; **67**: 601–11.

Immunocompromised patients. An extraordinarily high frequency of adverse reactions to co-trimoxazole has been reported in **patients with AIDS** being treated for *Pneumocystis carinii* pneumonia. The comment has been made that, when therapeutic doses of co-trimoxazole are used, hypersensitivity rashes and leucopenia each develop in 30% of patients, compared with less than 5% for each complication in patients without AIDS.[1] Other studies have reported an even higher incidence of toxicity, and the overall incidence of adverse effects, including fever, malaise, and hepatitis, may be 80% or more.[2-4] Adverse reactions also appear to be unusually frequent when prophylactic doses are used.[4] A lower frequency of cutaneous reactions has been reported among African, Haitian, and American black AIDS patients compared with white AIDS patients, suggesting a genetic susceptibility to such reactions.[5]

The occurrence of high serum concentrations of trimethoprim and sulfamethoxazole in patients has been proposed as a contributing factor to the high incidence of adverse effects,[6,7] and it was noted[6] that adverse effects, and in particular myelosuppression, were kept to tolerable levels in a group of patients in whom the **dose** of co-trimoxazole was adjusted to maintain serum-trimethoprim concentrations at 5 to 8 micrograms/mL. In a study in HIV-infected patients given co-trimoxazole for the prophylaxis of pneumocystis pneumonia,[8] a gradual start to therapy (increased over 2 weeks to the full therapeutic dose) was found to improve the tolerability of co-trimoxazole, when compared with patients started on full therapeutic doses. However, others[9] demonstrated no difference in the frequency of adverse effects when the sulfamethoxazole dose was modified.

It was suggested[10] that it was the reactive hydroxylamine **metabolites** of sulfamethoxazole which produced the adverse effects in HIV-infected individuals, but later work by the same authors[11] cast some doubt on this hypothesis.

Some workers have used diphenhydramine alone or with adrenaline to manage hypersensitivity reactions associated with co-trimoxazole therapy, thus allowing continuation of treatment,[12,13] while other workers have tried **desensitisation** to co-trimoxazole in patients with AIDS.[14-19] A systematic review[20] based on 3 small studies concluded that desensitisation was a more effective strategy than continuation. For mention of desensitisation to sulfonamides in patients with AIDS, see under Sulfamethoxazole, p.340.

An increased incidence of myelosuppression, although not, apparently, of other adverse effects, has been reported in **patients with leukaemia** receiving maintenance chemotherapy.[21,22] Multifocal myoclonus and bilateral asterixis occurred in an immunocompromised lymphoma patient 4 days after starting treatment with high dose co-trimoxazole for the treatment of *Nocardia asteroides*. Symptoms resolved completely after stopping co-trimoxazole treatment.[23]

Interference with diagnostic tests. Co-trimoxazole has been reported[1,2] to cause a small reduction in serum-thyroxine and tri-iodothyronine concentrations, probably due to the sulfonamide component.[2] Although co-trimoxazole had not been shown to be a cause of hypothyroidism (since all concentrations remained within the normal range), tests of thyroid function might need to be interpreted with care in patients on such treatment.

1. Cohen HN, *et al.* Effects on human thyroid function of sulphonamide and trimethoprim combination drugs. *BMJ* 1980; **281**: 646–7.
2. Cohen HN, *et al.* Trimethoprim and thyroid function. *Lancet* 1981; **i**: 676–7.

Porphyria. Both sulfonamides and trimethoprim have been associated with acute attacks of porphyria, and are considered unsafe in porphyric patients.

Interactions

Any of the drug interactions reported with sulfamethoxazole (p.341) or trimethoprim (p.356) may occur with co-trimoxazole.

Rifampicin. For reference to potential interaction between co-trimoxazole and rifampicin, see p.327.

Antimicrobial Action

The actions and spectrum of activity of co-trimoxazole are essentially those of its components, sulfamethoxazole (p.341) and trimethoprim (p.356).

Because they act at different points of the folate metabolic pathway a potent synergy exists between its components *in vitro* with an increase of up to about 10-fold in antibacterial activity, and a frequently bactericidal action where the components individually are generally bacteriostatic. The optimum effect against most organisms is seen at a ratio of 1 part trimethoprim to 20 of sulfamethoxazole; although co-trimoxazole is formulated as a 1 to 5 ratio, differences in the pharmacokinetics of the two drugs mean that the ratio of the peak concentrations is approximately 1:20. However, it is not clear that the optimum ratio is achieved at all sites and, given that both drugs are present in therapeutic concentrations, the contribution of synergy to the effects of co-trimoxazole *in vivo* is uncertain.

Resistance to co-trimoxazole develops more slowly *in vitro* than to either component alone. Resistance has increased, and although initially slow, a more rapid increase was seen in many countries during the 1980s, occurring in both Gram-positive and Gram-negative organisms. Resistance has occurred notably among Enterobacteriaceae. Resistant strains of *Brucella melitensis*, *Haemophilus influenzae*, streptococci, and *Vibrio cholerae* have been reported rarely. Although resistant organisms are usually resistant to both components of the mixture, strains resistant to either the sulfonamide or trimethoprim, and with a reduced sensitivity to co-trimoxazole, have been reported.

Pharmacokinetics

As for sulfamethoxazole (p.341) and trimethoprim (p.356). When co-trimoxazole is given orally, plasma concentrations of trimethoprim and sulfamethoxazole are generally around the optimal ratio of 1:20, although they may vary from 1:2 to 1:30 or more. The ratio of the two drugs is usually much lower in the tissues (often around 1:2 to 1:5) since trimethoprim, the more lipophilic drug, penetrates many tissues better than sulfamethoxazole and has a much larger volume of distribution. In urine the ratio may vary from 1:1 to 1:5 depending on the pH.

Uses and Administration

Co-trimoxazole is a mixture of the sulfonamide, sulfamethoxazole, and the diaminopyrimidine, trimethoprim, in the proportion of 5 parts of sulfamethoxazole to 1 part of trimethoprim. It has been used in infections due to susceptible organisms, particularly those of the urinary, respiratory, and gastrointestinal tracts, although the indications for its use are restricted in the UK (see below). Its main uses now are in pneumocystis pneumonia, toxoplasmosis, and nocardiosis.

Its other uses have included the treatment of acne, biliary-tract infections, brucellosis (generally in combination with other drugs), cat scratch disease, chancroid, *Burkholderia cepacia* (*Pseudomonas cepacia*) infections in cystic fibrosis, some forms of AIDS-associated diarrhoea such as the protozoal infection isosporiasis, gonorrhoea, granuloma inguinale, listeriosis, melioidosis, mycetoma, otitis media, pertussis, typhoid and paratyphoid fever, and Whipple's disease. It has also been used for the prophylaxis of infections in immunocompromised patients. For details of the bacterial infections listed above and their treatment, see under Choice of Antibacterial, p.162.

Co-trimoxazole is usually given orally in an adult dose of 960 mg (trimethoprim 160 mg and sulfamethoxazole 800 mg) twice daily; in severe infections 2.88 g daily in 2 divided doses has been given. Lower doses are given for long-term treatment and in patients with renal impairment (see Administration in Renal Impairment, below).

Doses of co-trimoxazole to be given twice daily to children are: from 6 weeks to 5 months of age, 120 mg; 6 months to 5 years, 240 mg; 6 to 12 years, 480 mg. Alternatively, children may be given a dose of 24 mg/kg twice daily. Co-trimoxazole should not generally be given to infants below 6 weeks of age because of the risk of kernicterus from the sulfonamide component (see Pregnancy, p.341, under Precautions of Sulfamethoxazole), although it may be used in infants from 4 weeks of age for the treatment or prophylaxis of pneumocystis pneumonia.

Higher doses of co-trimoxazole of up to 120 mg/kg daily given in 2 to 4 divided doses for 14 to 21 days are used in the treatment of pneumocystis pneumonia in adults and children over 4 weeks of age; serum concentrations should be monitored and folate supplementation possibly considered (but see Pneumocystis Pneumonia, below). For prophylaxis in adults with AIDS, the usual dose of co-trimoxazole (960 mg twice daily) may be given, but has been associated with a high incidence of adverse effects (see Immunocompromised Patients, under Precautions, above). Alternatively the following dose regimens may be used: 960 mg daily (7 days each week); 960 mg daily on alternate days (3 days each week); or 960 mg twice daily on alternate days (3 days each week). Children may be given standard doses (see above) for prophylaxis; doses are given on 3 alternate or consecutive days per week or for 7 days per week. Prophylactic doses in children have also been given in terms of body-surface area; the *BNFC* suggests a dose of 450 mg/m² (to a maximum of 960 mg) twice daily for three days of the week, given either consecutively or on alternate days.

For serious infections, if oral use is not possible, co-trimoxazole may begin by intravenous infusion diluted immediately before use in a suitable diluent. The contents of each ampoule containing 480 mg of co-trimoxazole in 5 mL are added to 125 mL of diluent and infused over 60 to 90 minutes, unless fluid restriction is required, in which case only 75 mL of diluent may be used. Dosage is similar to that by mouth.

◊ The place of co-trimoxazole in therapy was reviewed by the UK CSM in 1995 (see also Incidence of Adverse Effects, above).[1] As a result they recommended that its use should be limited to: pneumocystis pneumonia, toxoplasmosis, and nocardiosis; urinary-tract infections and acute exacerbations of chronic bronchitis, but only when there is bacteriological evidence of sensitivity to co-trimoxazole and good reason to prefer it to a single antibacterial; and acute otitis media in children, but again only when there is good reason to prefer it.

Administration in renal impairment. Doses of co-trimoxazole, both orally and intravenously, should be reduced in patients with renal impairment. The following recommendations for adults and children over 12 years of age are based on creatinine clearance (CC):

- CC above 30 mL/minute: the standard dose
- CC 15 to 30 mL/minute: half the standard dose
- CC below 15 mL/minute: not recommended.

Blastocystis infection. For a mention of the use of co-trimoxazole in the treatment of *Blastocystis hominis* infection, see p.823.

Cyclosporiasis. Patients with *Cyclospora* infection (p.824) have responded to treatment with co-trimoxazole.[1-3]

Granulomatous diseases. Although co-trimoxazole appears to be effective in reducing the incidence of bacterial infection in patients with chronic granulomatous disease,[1-3] a disorder of leucocyte function associated with recurrent life-threatening infection and granuloma formation, its use in systemic vasculitis is much more controversial. There have been a number of reports of benefit from co-trimoxazole in patients with Wegener's granulomatosis (p.1515),[4-7] but even where benefit has been reported relapse appears to be common,[6] and an analysis[8] of the experience of the USA National Institutes of Health in 158 patients, was sceptical of its value: only 1 of 9 patients given 960 mg twice daily by mouth had any prolonged improvement.

Some evidence later emerged that addition of co-trimoxazole to maintenance regimens in patients already in remission reduces the incidence of relapse,[9] although another study suggested that it might actually increase the risk of relapse.[10]

Isosporiasis. A regimen of oral co-trimoxazole 960 mg four times daily for 10 days followed by 960 mg twice daily for 3 weeks was reported to be initially effective in patients with AIDS suffering from isosporiasis (p.824), and produced resolution of diarrhoea within 2 days of beginning treatment; it was, however, associated with a high rate of recurrence.[1] A shorter regimen followed by indefinite prophylaxis may be preferable in persons with AIDS; in a small randomised controlled study, co-trimoxazole 960 mg twice daily for 7 days, followed by 10 weeks' prophylaxis, was effective in HIV-infected patients with isosporiasis.[2]

Nocardiosis. Co-trimoxazole is used in the treatment of nocardiosis (p.181). There is no consensus on the optimum dosage; doses of 2.88 to 3.84 g daily in divided doses for up to 3 months have been used.

Pneumocystis pneumonia. Co-trimoxazole is the preferred drug[1-3] for both the treatment and prophylaxis of pneumocystis pneumonia (p.521). A single dose of 480 mg daily may be effective and better tolerated for prophylaxis than a daily dose of 960 mg.[4] However, some still prefer the latter dose schedule[5] which is also the one preferred by the CDC in the USA[1] and is a licensed dose for prophylaxis in both the UK and USA. Various studies[4-10] have shown intermittent dosing is also effective for the prophylaxis of pneumonia and is better tolerated than daily dosing; the dose has usually been 960 mg three times each week on alternate days[4-9] although 960 mg twice daily three times each week has also been given.[10] The addition of folinic acid has no effect on tolerability and may be associated with a higher rate of therapeutic failure (see HIV Infection and AIDS, p.1944).

Toxoplasmosis. There is some evidence that giving co-trimoxazole for prophylaxis of pneumocystis pneumonia produces an additional benefit in acting prophylactically against toxoplasmic encephalitis in persons with HIV infection or AIDS,[1-5] but the evidence (as for other drugs) has been largely anecdotal or from small retrospective studies. In the USA, the CDC recommends[1] that co-trimoxazole 960 mg daily (as for *Pneumocystis carinii* pneumonia prophylaxis, above) be given to HIV-infected patients who are seropositive for *Toxoplasma* and have a CD4+ count below 100 cells/microlitre.

Co-trimoxazole has also produced promising results in preliminary studies for the treatment of toxoplasmic encephalitis in patients with AIDS,[6] and a systematic review[7] considered it an effective treatment, particularly in resource-poor settings where alternatives such as pyrimethamine with sulfadiazine might not be available.

For a discussion of toxoplasmosis and its management, see p.826.

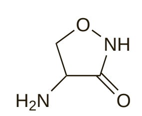
Cycloserine *(BAN, rINN)*

Cicloserina; D-Cycloserin; Cyclosérine; D-Cycloserine; Cycloserinum; Cykloserin; SC-49088; Sikloserin; Sykloseriini. (+)-(*R*)-4-Aminoisoxazolidin-3-one.

Циклосерин

$C_3H_6N_2O_2$ = 102.1.
CAS — 68-41-7.
ATC — J04AB01.
ATC Vet — QJ04AB01.



Description. Cycloserine is an antimicrobial substance produced by the growth of certain strains of *Streptomyces orchidaceus* or *S. garyphalus*, or obtained by synthesis.

Pharmacopoeias. In *Jpn* and *US.*

USP 31 (Cycloserine). A white to pale yellow, crystalline powder, odourless or has a faint odour. It is hygroscopic and deteriorates upon absorbing water. Freely soluble in water. pH of a 10% solution in water is between 5.5 and 6.5. Store in airtight containers.

Adverse Effects and Treatment

The most frequent adverse effects with cycloserine involve the CNS and include anxiety, confusion, disorientation, depression, psychoses possibly with suicidal tendencies, aggression, irritability, and paranoia. Vertigo, headache, drowsiness, speech difficulties, tremor, paresis, hyperreflexia, dysarthria, paraesthesia, coma, and convulsions may also occur. Neurological reactions are dose related and may be reduced by keeping plasma concentrations below 30 micrograms/mL. It has been reported that up to 30% of patients have experienced adverse effects. These reactions usually subside when cycloserine is stopped or the dosage is reduced. Pyridoxine has been used in an attempt to treat or prevent neurological reactions but its value is unproven.

Hypersensitivity reactions including skin reactions and photosensitivity occur rarely. Serum aminotransferase values may be raised, especially in patients with a history of liver disease. Folate and vitamin B_{12} deficiency, megaloblastic anaemia, and sideroblastic anaemia have been reported occasionally when cycloserine has been used with other antituberculous drugs. Heart failure has occurred in patients receiving daily doses of 1 g or more.

Precautions

Cycloserine is contra-indicated in patients with epilepsy, depression, psychosis, severe anxiety, severe renal impairment, or in those who misuse alcohol. Cycloserine should be stopped, or the dose reduced, if skin reactions or symptoms of CNS toxicity develop.

Cycloserine has a low therapeutic index, and dosage should be adjusted according to plasma concentrations, which should be monitored at least weekly in patients with renal impairment, in those taking doses greater than 500 mg daily, and in patients showing signs of neurotoxicity. Plasma concentrations should be maintained below 30 micrograms/mL. Haematological, renal, and hepatic function should be monitored. Patients with mild to moderate renal impairment require lower doses.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving cycloserine,[1] and the American Academy of Pediatrics considers[2] that it is therefore usually compatible with breast feeding.

2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 03/10/07)

Porphyria. Cycloserine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

Patients receiving cycloserine and taking alcohol are at increased risk of convulsions; for reference to increased blood-alcohol concentrations in patients receiving cycloserine, see p.1627.

Neurotoxic effects may be potentiated by use of cycloserine with ethionamide, and concurrent use of cycloserine and isoniazid may result in increased CNS toxicity, such as dizziness and drowsiness.

Antimicrobial Action

Cycloserine interferes with bacterial cell wall synthesis by competing with D-alanine for incorporation into the cell wall. It has variable activity against Gram-positive and Gram-negative bacteria including *Escherichia coli* and *Staphylococcus aureus*.

Cycloserine is active against *Mycobacterium tuberculosis* and some other mycobacteria. Resistance develops if cycloserine is used alone.

Pharmacokinetics

Cycloserine is readily and almost completely absorbed from the gastrointestinal tract. Peak plasma concentrations of 10 micrograms/mL have been obtained 3 to 4 hours after a dose of 250 mg, rising to 20 to 30 micrograms/mL on repeating the dose every 12 hours. The plasma half-life is about 10 hours and is prolonged in patients with renal impairment.

Cycloserine is widely distributed into body tissues and fluids, including the CSF, placenta, and breast milk, producing fetal blood concentrations approaching those in maternal serum.

Cycloserine is excreted largely unchanged by glomerular filtration. About 50% of a single 250-mg dose is excreted unchanged in the urine within 12 hours and about 70% is excreted within 72 hours. As negligible amounts of cycloserine appear in the faeces, it is assumed that the remainder of a dose is metabolised to unidentified metabolites. It is removed by haemodialysis.

Pregnancy and breast feeding. Cycloserine has been shown to pass to the fetus, into amniotic fluid,[1] and into breast milk.[2] Concentrations in breast milk after 250 mg four times daily have been reported to range from 6 to 19 micrograms/mL.[2]

2. Morton RF, *et al.* Studies on the absorption, diffusion, and excretion of cycloserine. *Antibiot Annu* 1955-56; **3:** 169–72.

Uses and Administration

Cycloserine is a second-line antimycobacterial that may be used in the treatment of tuberculosis (p.196) as part of a multidrug regimen when resistance to primary drugs has developed. It has been used in urinary-tract infections, although less toxic drugs are preferred.

The usual adult oral dose in tuberculosis is 250 mg twice daily for 2 weeks, followed by 0.5 to 1 g daily in divided doses. Dosage in patients with mild to moderate renal impairment should be reduced and doses for all patients should be adjusted by monitoring plasma concentrations (see Precautions, above).

For details of doses in infants, children, and adolescents, see below.

Cycloserine has been tried for the adjunctive treatment of schizophrenia. L-Cycloserine has been investigated for the treatment of Gaucher disease (p.2249).

Administration in children. Use of cycloserine is licensed in both the UK and USA for children, although age ranges are not specified in licensed product information. For the treatment of drug-resistant tuberculosis the American Academy of Pediatrics (AAP) suggests a dose of 5 to 10 mg/kg twice daily, to a maximum dose of 1 g daily.

The *BNFC* suggests the following doses:

- children aged 2 to 12 years; 5 mg/kg twice daily
- children aged 12 to 18 years; 250 mg twice daily for 2 weeks then adjusted to a maximum dose of 1 g daily

Doses are adjusted according to blood concentrations and response.

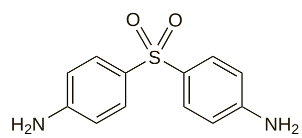
Дапсон

$C_{12}H_{12}N_2O_2S$ = 248.3.

CAS — 80-08-0.

ATC — J04BA02.

ATC Vet — QJ04BA02.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *US*, and *Viet.*

Ph. Eur. 6.2 (Dapsone). A white or slightly yellowish-white, crystalline powder. Very slightly soluble in water; sparingly soluble in alcohol; freely soluble in acetone. It dissolves freely in dilute mineral acids. Protect from light.

USP 31 (Dapsone). A white or creamy-white, odourless crystalline powder. Very slightly soluble in water, freely soluble in alcohol; soluble in acetone and in dilute mineral acids. Protect from light.

Stability. A study[1] of the stability of two extemporaneous oral suspensions of dapsone prepared from commercially available tablets found them to be stable for 3 months when stored at 4° and at 25°.

1. Nahata MC, *et al.* Stability of dapsone in two oral liquid dosage forms. *Ann Pharmacother* 2000; **34:** 848–50.

Adverse Effects

Varying degrees of dose-related haemolysis and methaemoglobinaemia are the most frequently reported adverse effects of dapsone, and occur in most patients given more than 200 mg daily; doses of up to 100 mg daily do not cause significant haemolysis, but patients with G6PD deficiency are affected by doses above about 50 mg daily.

Although agranulocytosis has been reported rarely with dapsone when used alone, reports have been more common when it has been used with other drugs in the prophylaxis of malaria. Deaths due to agranulocytosis, aplastic anaemia, and other blood dyscrasias have been reported.

Rash and pruritus may develop. Serious cutaneous hypersensitivity reactions occur rarely and include maculopapular rash, exfoliative dermatitis, toxic epidermal necrolysis, and Stevens-Johnson syndrome. Fixed drug eruptions have occurred.

A 'dapsone syndrome' may occur after 4 to 8 weeks of treatment and resembles mononucleosis in its presentation (see Hypersensitivity Reactions, below).

Peripheral neuropathy with motor loss has been reported in patients on dapsone for dermatological conditions. Peripheral neuropathy may occur as part of leprosy reaction states and is not an indication to stop dapsone.

Other adverse effects occur infrequently and include nausea, vomiting, anorexia, headache, hepatitis, insomnia, psychosis, and tachycardia.

Carcinogenicity. A survey of 1678 leprosy patients admitted for treatment to the National Hansen's Disease Center in the USA between 1939 and 1977 indicated that, although dapsone has been implicated as a carcinogen in *animals*, the use of dapsone did not appear to affect significantly the risk of cancer in these patients.[1] The International Agency for Research on Cancer concluded[2] that there was limited evidence for the carcinogenicity of dapsone in *animals* and insufficient data to be able to classify the carcinogenic risk in humans.

Effects on the blood. *Haemolysis* is the most frequent serious adverse effect of dapsone and may occur at doses of 200 mg or higher daily.[1] Red blood cells may contain Heinz bodies and there is a reduction in their life span. Well-known risk factors include G6PD deficiency, methaemoglobin reductase deficiency, and haemoglobin M trait; haemoglobin E trait may also increase susceptibility to haemolytic reactions.[2] Haemolytic anaemia has been reported in a neonate after ingestion of dapsone in breast milk.[3]

Methaemoglobinaemia, although common, is rarely symptomatic.[1] However, severe cyanosis was associated with methaemoglobinaemia after an inadvertent overdose with dapsone in an HIV-positive patient with suspected pneumocystis pneumonia.[4] Methaemoglobinaemia has also been reported in an HIV-negative patient with severe renal impairment, who had previously undergone liver and kidney transplantations and who was receiving dapsone for prophylaxis of pneumocystis pneumonia.[5] The metabolite dapsone hydroxylamine is probably responsible for the methaemoglobinaemia and haemolysis associated with dapsone. Studies have shown[6,7] that use of dapsone with cimetidine, which inhibits production of the *N*-hydroxy metabolite, has resulted in a decrease in methaemoglobin levels, at least in the short term.

Agranulocytosis has occurred rarely on use of dapsone in leprosy and skin disease. More cases have been observed when used for malaria prophylaxis[8] (see also under Pyrimethamine, p.610) and dermatitis herpetiformis.[9] The reaction is usually self-limiting once the drug is withdrawn, but fatalities have occurred.[9,10]

Aplastic anaemia has been reported.[11,12] Of 11 fatalities attributed to dapsone reported to the British and Swedish adverse reaction registers[13] between 1968 and 1988, seven were due to white blood cell dyscrasias; none were attributed to red cell dyscrasias, although such reactions formed almost half of all serious reactions reported for dapsone.

Pure red cell aplasia has been reported in an elderly patient taking oral dapsone daily for granuloma annulare.[14]

Thrombocytosis was reported in a patient with AIDS receiving dapsone prophylactically.[15]

Effects on the eyes. There have been rare reports[1-4] of ocular toxicity, usually resulting in permanent loss of visual acuity, after overdoses with dapsone. Toxic effects included blurring of vision,[1,2] optic atrophy,[1] ischaemic retinopathy, ischaemic optic neuropathy,[3] and bilateral macular infarction.[4] These effects were thought to be due to acute hypoxia and obstruction with red cell fragments. A case of anterior ischaemic optic neuropathy[5] has also been reported in a patient taking usual doses of dapsone for dermatitis herpetiformis.

Effects on the liver. Toxic hepatitis and cholestatic jaundice have been reported by licensed product information to occur early in dapsone therapy. Jaundice may also form part of the dapsone syndrome (see Hypersensitivity Reactions, below). Deterioration in liver function tests during dapsone treatment has been noted in a patient with dermatitis herpetiformis and primary sclerosing cholangitis.[1]

1. Kirby B, *et al.* Abnormal liver function tests induced by dapsone in a patient with dermatitis herpetiformis and primary sclerosing cholangitis. *Br J Dermatol* 1999; **141:** 172–3.

Effects on the lungs. Hypersensitivity reactions to dapsone usually affect the skin, but there have been rare reports of dapsone hypersensitivity presenting with fever, wheezing, and pulmonary eosinophilia.[1-4] Pulmonary eosinophilia occurred in one patient taking dapsone for urticaria[1] and in another taking dapsone as part of the WHO multidrug treatment regimen for leprosy.[2] In both patient symptoms resolved when dapsone was stopped and occurred again on rechallenge. Another patient[3] known to develop fever and wheezing when taking dapsone for leprosy was given a dapsone challenge for 5 days. He became acutely ill and had a high absolute eosinophil count; symptoms resolved 2 weeks after stopping dapsone.

Effects on mental state. Psychiatric adverse effects have been reported in leprosy patients receiving dapsone, but the role of dapsone in this effect is poorly defined.[1-4] Manic-depressive reactions have been reported in 2 patients[2,3] with skin disorders and psychosis[4] was reported in a patient being treated for leprosy. These reactions appeared to be idiosyncratic reactions to dapsone. In all cases symptoms resolved when dapsone was stopped.

4. Balkrishna, Bhatia MS. Dapsone-induced psychosis. *J Indian Med Assoc* 1989; **87:** 120–1.

Effects on the nervous system. A case review[1] of 21 patients who had dapsone-induced neuropathy reported that the median time to onset of symptoms was about 1 year; with a range of 11 days to 18 years. Symptoms occurred in patients taking doses varying from 25 to 800 mg/day and after a total cumulative dose of 4 to 1500 g. Most patients had either pure motor or mixed sensory-motor neuropathies, while pure sensory neuropathy was rarely reported. Patients generally recovered, either partially or completely, within one year of stopping dapsone. Progressive multifocal leukoencephalopathy has been reported in a patient with SLE treated with a dapsone-containing regimen, although it was unclear what role dapsone had played.[2]

2. Stahl NI. Progressive multifocal leukoencephalopathy in a minimally immunosuppressed patient with systemic lupus erythematosus treated with dapsone. *J Rheumatol* 2008; **35:** 725–7.

Effects on the pancreas. Acute pancreatitis has been associated with the use of dapsone to treat dermatitis herpetiformis in an 87-year-old man.[1] Symptoms resolved on stopping dapsone but recurred upon rechallenge.

1. Jha SH, *et al.* Dapsone-induced acute pancreatitis. *Ann Pharmacother* 2003; **37:** 1438–40.

Effects on taste. A persistent sweet taste and tingling of the face and lips was described in a patient receiving dapsone for ocular cicatricial pemphigoid.[1] The symptoms resolved when dapsone was stopped.

1. Stafanous SN, Morgan SJ. A previously unrecognised side effect of dapsone. *Br J Ophthalmol* 1997; **81:** 1113–14.

Hyperpigmentation. Hyperpigmented macules were reported in 32 of about 800 children given dapsone with pyrimethamine for 3 months or more for malaria prophylaxis.[1] The reaction was attributed to dapsone.

1. David KP, *et al.* Hyperpigmented dermal macules in children following the administration of Maloprim for malaria chemoprophylaxis. *Trans R Soc Trop Med Hyg* 1997; **91:** 204–8.

Hypersensitivity reactions. Dapsone syndrome is a rare idiosyncratic hypersensitivity reaction, although it has been suggested[1-3] that the incidence has increased since the introduction of multidrug therapy for leprosy. It usually occurs in the first 4 to 8 weeks of therapy, is not dose-related, and resolves within 14 days on stopping dapsone. Dapsone syndrome may also occur within 1 to 2 weeks of stopping the drug, due to its long elimination half-life and high protein binding.[4] Common clinical symptoms may include exanthematous skin rash, fever, hepatitis (cholestatic and hepatocellular injuries), eosinophilia, lymphadenopathy, and mononucleosis. The syndrome has occurred in leprosy patients,[5,6] in patients with skin disorders,[7] in patients with AIDS taking dapsone for prophylaxis of pneumocystis pneumonia,[4] and in patients taking weekly dapsone (with pyrimethamine) for malaria prophylaxis.[8] Fatalities have occurred.[9,10] Desensitisation has been successfully carried out in several patients with AIDS who exhibited hypersensitivity to dapsone.[11,12]

Hypoalbuminaemia. Severe and often life-threatening hypoalbuminaemia has been reported rarely in patients taking dapsone for long periods for dermatitis herpetiformis.[1-3] Hypoalbuminaemia usually resolves rapidly once dapsone is withdrawn.

Treatment of Adverse Effects

In severe overdosage, repeated oral doses of activated charcoal should be given with the aim of preventing absorption of dapsone but also to aid the elimination of dapsone and its monoacetyl metabolite. Methaemoglobinaemia has been treated with slow intravenous injections of methylthioninium chloride 1 to 2 mg/kg repeated after 1 hour if necessary. Methylthioninium chloride should not be given to patients with G6PD deficiency since it will not be effective. Haemolysis has been treated by infusion of concentrated human red blood cells to replace the damaged cells. Supportive therapy includes giving oxygen and fluids.

Patients who develop dapsone syndrome (see Hypersensitivity Reactions, above) may require several weeks of corticosteroid therapy.

Overdosage. References.

Precautions

Dapsone should not be used in patients with severe anaemia. It is recommended that regular blood counts be performed during treatment. Patients deficient in G6PD or methaemoglobin reductase, or with haemoglobin M are more susceptible to the haemolytic effects of dapsone.

Where possible, liver function should be monitored during treatment.

It is now generally considered that the benefits of dapsone in the treatment of leprosy during pregnancy outweigh any potential risks to the pregnant patient or fetus. Some recommend folic acid 5 mg daily for leprosy patients receiving dapsone during pregnancy.

Breast feeding. Dapsone is distributed into breast milk and the American Academy of Pediatrics[1] states that, although usually compatible with breast feeding, use of dapsone in a breast-feeding mother has resulted in sulfonamide detected in the infant's urine.[2] There has also been a report of haemolytic anaemia in a breast-fed infant (see Effects on the Blood, under Adverse Effects, above). A study in 3 lactating women who were given a single dose of dapsone 100 mg plus pyrimethamine and chloroquine estimated that if their infants were breast fed they would receive 4.6, 10, or 14.3%, respectively, of the maternal dose in the 9-day period after it was given.[3]

Interactions

Serum concentrations of dapsone are increased, with a consequent increased risk of adverse effects, when given with probenecid, probably as a result of reduced renal excretion of dapsone. Increased dapsone and trimethoprim concentrations have also been reported in patients receiving both drugs, who may similarly be at greater risk of dapsone toxicity. Rifampicin reduces serum concentrations of dapsone to a level that may compromise efficacy in infections other than leprosy. Rifampicin concentrations are generally unaffected. Dapsone may reduce the anti-inflammatory effects of clofazimine (p.255).

Cimetidine. Cimetidine has been reported to increase the area under the curve for dapsone, but to decrease the area under the curve for the metabolite dapsone hydroxylamine. Haematotoxicity is thought to be related to production of this metabolite (see Effects on the Blood, above).

Pyrimethamine. Although some licensed product information has warned that dapsone-induced haematotoxicity could be potentiated by folic acid antagonists such as pyrimethamine, the tolerability of dapsone plus pyrimethamine was similar to dapsone alone when each treatment was given on a once-weekly basis to patients with HIV infection.[1] Dapsone concentrations were not significantly higher in patients receiving dapsone plus pyrimethamine than in those receiving dapsone alone.

1. Falloon J, *et al.* Pharmacokinetics and safety of weekly dapsone and dapsone plus pyrimethamine for prevention of pneumocystis pneumonia. *Antimicrob Agents Chemother* 1994; **38:** 1580–7.

Trimethoprim. In a study of AIDS patients with pneumocystis pneumonia, the mean peak serum concentrations of dapsone after 7 days were 1.5 micrograms/mL after 100 mg daily and 2.1 micrograms/mL after the same dose with trimethoprim 20 mg/kg daily; concentrations of trimethoprim were also increased.[1] Elevated dapsone concentrations may contribute to the toxicity and the efficacy of this combination.

1. Lee BL, *et al.* Dapsone, trimethoprim, and sulfamethoxazole plasma levels during treatment of Pneumocystis pneumonia in patients with the acquired immunodeficiency syndrome (AIDS). *Ann Intern Med* 1989; **110:** 606–11.

Antimicrobial Action

Dapsone is a sulfone active against a wide range of bacteria and some protozoa, but it is mainly used for its action against *Mycobacterium leprae*. Like the sulfonamides it may inhibit folic acid synthesis in susceptible organisms although this is not considered to be the mechanism of action in *M. leprae*. It is usually considered to be bacteriostatic against *M. leprae*, although it may also possess weak bactericidal activity. It is also active against *Plasmodium* and *Pneumocystis jirovecii*.

As with the sulfonamides, antibacterial activity is inhibited by *p*-aminobenzoic acid.

Secondary (acquired) dapsone resistance of *M. leprae* is mainly associated with dapsone being used on its own. Primary dapsone resistance has also been reported with increasing frequency in areas with secondary resistance. Resistance of *M. leprae* to dapsone should be suspected whenever a patient relapses clinically and bacteriologically.

Drug resistance. Monotherapy with dapsone was the standard of treatment for all forms of leprosy until the 1980's, when concerns about dapsone resistance led WHO to introduce a multidrug treatment (MDT) regimen consisting of dapsone, rifampicin, and clofazimine. Long-term follow-up studies[1,2] designed to evaluate the efficacy of WHO MDT regimen reported relapse rates of 1.1 to 9% after a minimum of 2 years treatment. Drug sensitivity analyses were reported for 15 of these patients; no resistance to clofazimine or rifampicin was reported, while isolates from 3 patients showed dapsone resistance.[1] An evaluation of drug resistance after the introduction of WHO MDT regimen in Nepal[3] concluded that secondary resistance to dapsone does not develop under this regimen. Strains of *Mycobacterium leprae* with multiple resistance to rifampicin, ofloxacin, and dapsone have been isolated from a patient who had previously received dapsone monotherapy followed by treatment with rifampicin plus ofloxacin for 28 days.[4]

Pharmacokinetics

Dapsone is almost completely absorbed from the gastrointestinal tract with peak plasma concentrations occurring 2 to 8 hours after a dose. Steady-state concentrations are not attained until after at least 8 days of daily dosage; doses of 100 mg daily provide trough concentrations of 500 nanograms/mL, which are well in excess of the MIC for *M. leprae*. About 70 to 90% of dapsone in the circulation is bound to plasma proteins and nearly 100% of its monoacetylated metabolite is bound.

Dapsone undergoes enterohepatic recycling. It is widely distributed; it is present in saliva and breast milk and crosses the placenta. The half-life ranges from 10 to 50 hours; with a mean of 20 to 30 hours.

Dapsone is acetylated to monoacetyldapsone, the major metabolite, and other mono and diacetyl derivatives. Acetylation exhibits genetic polymorphism. Hydroxylation is the other major metabolic pathway resulting in hydroxylamine dapsone, which may be responsible for dapsone-associated methaemoglobinaemia and haemolysis.

Dapsone is mainly excreted in the urine, only 20% of a dose as unchanged drug.

Metabolism. Measurement of the relative activity of the two main routes of dapsone metabolism (acetylation and hydroxylation) suggests that the risk of adverse effects is greater in individuals in whom the *N*-hydroxylation route predominates.[1] This is consistent with the hypothesis that the toxicity of dapsone is related to production of an active metabolite. See also Effects on the Blood, above.

Uses and Administration

Dapsone is used as part of multidrug regimens in the treatment of all forms of leprosy (p.176). It has also been used in the prophylaxis of leprosy and in the management of household contacts of leprosy patients. Dapsone is used as an alternative to co-trimoxazole or pentamidine for the treatment and prophylaxis of pneumocystis pneumonia (below), and has been used with pyrimethamine for the prophylaxis of malaria (see under Pyrimethamine, p.611). It is also used in dermatitis herpetiformis and other dermatoses (see Skin Disorders, below). It has been tried for the prophylaxis of toxoplasmosis (p.826) and for the treatment of cutaneous leishmaniasis (p.824) and actinomycetoma (see Mycetoma, p.180).

Dapsone is usually given orally. There are some reports of it being given by intramuscular injection, but such injections can be painful and cause abscess formation.

The most common regimens for **leprosy** are those recommended by WHO. For multibacillary leprosy, rifampicin 600 mg and clofazimine 300 mg are both given *once a month* with dapsone 100 mg and clofazimine 50 mg both *daily* for 12 months. Adults weighing less than 35 kg receive reduced doses of rifampicin and dapsone, and in such patients the dapsone dose is 50 mg or 1 to 2 mg/kg daily.

The WHO regimen for paucibacillary leprosy consists of rifampicin 600 mg once a month and dapsone 100 mg daily; both are given for 6 months. Doses are reduced in low-weight patients as for multibacillary leprosy.

The doses of dapsone used for the prophylaxis and treatment of **pneumocystis pneumonia** are discussed in more detail under pneumocystis pneumonia, below.

The dose needed to treat **dermatitis herpetiformis** has to be titrated for individual patients, but it is usual to start with an oral dose of 50 mg daily, gradually increased to 300 mg daily or more if required. This dose should be reduced to a minimum as soon as possible. Maintenance dosage can often be reduced in patients receiving a gluten-free diet.

In the treatment of **acne**, dapsone is applied topically as a 5% gel twice daily.

For details of doses in infants, children, and adolescents, see below.

Administration in children. For the treatment of multibacillary leprosy in children WHO recommends that children aged 10 to 14 years may be given oral dapsone 50 mg plus rifampicin 450 mg and clofazimine 150 mg *once a month*, together with dapsone 50 mg *daily* and clofazimine 50 mg on *alternate days*; both are given for 12 months. For paucibacillary leprosy WHO recommends oral dapsone 50 mg plus rifampicin 450 mg *once a month*, together with dapsone 50 mg *daily*; both are given for 6 months. For children less than 10 years of age the dose should be adjusted according to body weight.

For details of doses for the treatment of pneumocystis pneumonia in infants, children, and adolescents, see below.

Connective tissue disorders. Relapsing polychondritis (p.1510) has responded to dapsone, as has Behçet's syndrome (p.1499) and SLE. Vasculitic syndromes such as hypersensitivity vasculitis (p.1505) have also improved following dapsone.

Idiopathic thrombocytopenic purpura. Dapsone has been reported[1-4] to be of benefit in some patients, including children, with refractory idiopathic thrombocytopenic purpura (p.1505).

1. Radaelli F, *et al.* Adult refractory chronic idiopathic thrombocytopenic purpura: can dapsone be proposed as second-line therapy? *Br J Haematol* 1999; **104:** 641–2.

4. Damodar S, *et al.* Dapsone for chronic idiopathic thrombocytopenic purpura in children and adults—a report on 90 patients. *Eur J Haematol* 2005; **75:** 328–31.

Pneumocystis pneumonia. Dapsone is used alone or with pyrimethamine[1] for *primary and secondary prophylaxis* of pneumocystis pneumonia (p.521) in patients unable to tolerate co-trimoxazole. In adults a dose of dapsone 100 mg daily in one or two doses is commonly used and has been reported to have similar efficacy to co-trimoxazole.[2] Dapsone has also been given with pyrimethamine in various regimens including:

- dapsone 50 mg daily with pyrimethamine 50 mg once weekly[3]
- dapsone 100 mg plus pyrimethamine 50 mg both given twice weekly[4]
- dapsone 200 mg plus pyrimethamine 75 mg both given once weekly[5]

In children from 1 month to 18 years of age the recommended dose of dapsone is 2 mg/kg daily (to a maximum of 100 mg daily) or 4 mg/kg weekly (to a maximum of 200 mg weekly).[1]

For *treatment* of adults and adolescents, dapsone 100 mg once daily with trimethoprim 5 mg/kg three times daily, for 21 days, has been suggested for mild to moderate disease in patients unable to tolerate co-trimoxazole.[6] Infants and children under 13 years of age may be given a dose of dapsone of 2 mg/kg once daily (to a maximum of 100 mg daily) plus trimethoprim 5 mg/kg three times daily.[7]

Skin disorders. Dapsone is used for the suppression of skin lesions in dermatitis herpetiformis (p.1578). The mechanism of action is unknown but is unrelated to its antimicrobial activity. Reports, generally involving small numbers of patients, suggest that dapsone may also be beneficial for bullous or mucous membrane pemphigoid (p.1582), pyoderma gangrenosum (p.1583), recurrent erythema multiforme (p.1580), and urticaria (p.1584). Topical dapsone is available in the USA for the treatment of acne.

Spider bites. As discussed on p.2239, necrotic araneism resulting from the bite of spiders of the genus *Loxosceles* is usually treated conservatively with surgical repair of any persistent defect. A prospective clinical study[1] of 31 patients with brown recluse spider bites indicated that treatment with dapsone 100 mg daily for 14 days followed by delayed surgical intervention if necessary reduced the incidence of wound complications and residual scarring compared with treatment by immediate surgical excision. A dose of 100 mg twice daily has also been given for 14 days.[2] An evaluation[3] of the management of brown recluse spider bites found that common treatments did not reduce healing time or scarring; dapsone was associated with slower healing rate and an increased risk of scarring.

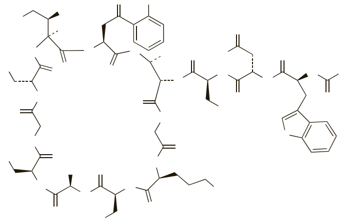
Даптомицин

$C_{72}H_{101}N_{17}O_{26}$ = 1620.7.
CAS — 103060-53-3.
ATC — J01XX09.
ATC Vet — QJ01XX09.



Adverse Effects and Precautions

The most common adverse effects associated with daptomycin are gastrointestinal effects including nausea and vomiting, constipation, diarrhoea, and dyspepsia. Headache, insomnia, dizziness, and fever may occur. Injection site reactions have occurred. Effects on the skin have included rash and pruritus. Abnormal liver function tests and jaundice have been reported. Other reported adverse effects include hypertension or hypotension, renal failure, dyspnoea, and anaemia. There have been rare cases of hypersensitivity, anaphylaxis, and infusion reactions.

Elevated plasma creatine phosphokinase (CPK) concentrations during daptomycin therapy may be associated with muscle pain and/or weakness, myositis, myopathy, and rarely rhabdomyolysis; patients with renal impairment or taking other drugs known to cause myopathy (see Interactions, below) may be at increased risk. All patients should be monitored for the development of muscle pain or weakness, and plasma CPK concentrations measured once weekly. More frequent measurements should be performed in those with an increased risk of myopathy, or with a baseline CPK concentration greater than 5 times the upper limit of normal (ULN), or who develop signs of myopathy. Daptomycin should be stopped in patients with signs of myopathy and CPK concentrations greater than 5 times the ULN, or in those without reported signs of myopathy but with CPK concentrations greater than 10 times the ULN.

Daptomycin should be given with caution and in reduced dosage to patients with renal impairment; clinical response and renal function should be monitored closely.

Consideration should be given to stopping daptomycin therapy in patients who develop signs or symptoms of peripheral neuropathy.

Effects on the lungs. Bronchiolitis obliterans organising pneumonia with eosinophilic infiltration has been reported in an 84-year-old man after 4 weeks of daptomycin therapy;[1] clinical improvement occurred after the drug was stopped. The mechanism of toxicity was unknown and the authors suggested that it might be associated with epithelial injury caused by daptomycin accumulating in the alveolar spaces.

A 60-year-old man receiving daptomycin developed eosinophilic pneumonia resulting in respiratory failure that required mechanical ventilation;[2] he improved after stopping the drug and starting corticosteroid therapy.

2. Hayes D, *et al.* Eosinophilic pneumonia induced by daptomycin. *J Infect* 2007; **54:** e211–e213.

Pregnancy. Intravenous daptomycin, 4 mg/kg daily for 14 days, was successfully used to treat pyelonephritis associated with vancomycin-resistant enterococci (VRE) in a 27-week pregnant woman; no neonatal abnormalities were reported.[1]

1. Shea K, *et al.* Successful treatment of vancomycin-resistant Enterococcus faecium pyelonephritis with daptomycin during pregnancy. *Ann Pharmacother* 2008; **42:** 722–5.

Interactions

There may be an increased risk of myopathy if daptomycin is given with other drugs also known to have this adverse effect, such as statins, fibrates, and ciclosporin. Licensed product information recommends stopping the latter if possible; otherwise, plasma creatine phosphokinase concentrations should be measured more than once weekly in addition to the usual precautions (see Adverse Effects and Precautions, above).

Daptomycin is mainly excreted by renal filtration and caution is advised if given with drugs that reduce renal filtration, such as NSAIDs and selective inhibitors of cyclo-oxygenase-2, since plasma concentrations of daptomycin may be increased.

Daptomycin has been reported to interact with a particular reagent used in some assays of PT-INR resulting in apparent prolongation of PT and elevation of INR.

Antimicrobial Action

Daptomycin is a lipopeptide antibacterial that is reported to have a spectrum of antibacterial activity similar to that of vancomycin (p.359) and greater potency against most Gram-positive bacterial strains *in vitro*; it is inactive against Gram-negative bacteria. Daptomycin disrupts the bacterial cell membrane potential by binding to the cell membranes in a calcium-dependent process, but without entering the cytoplasm, thus inhibiting the synthesis of protein, DNA, and RNA.

Daptomycin has shown activity both *in vitro* and in clinical infection with both meticillin-susceptible and meticillin-resistant *Staphylococcus aureus*, vancomycin-susceptible *Enterococcus faecalis*, and some streptococci.

It is reported to show antimicrobial synergy *in vitro* with aminoglycosides, beta lactams, and rifampicin against *Staph. aureus* (including meticillin-resistant strains) and enterococci (including vancomycin-resistant strains).

Resistance to daptomycin has been shown in clinical studies but only rarely; the mechanism of resistance has not been identified.

◊ Reviews.

1. Boucher HW, Sakoulas G. Perspectives on daptomycin resistance, with emphasis on resistance in Staphylococcus aureus. *Clin Infect Dis* 2007; **45:** 601–8.

Pharmacokinetics

Daptomycin is not absorbed to any significant extent after oral doses. The pharmacokinetics of daptomycin are generally linear at intravenous doses ranging from 4 to 12 mg/kg once daily. Peak plasma concentrations are achieved within 0.5 to 0.8 hours. It is distributed mainly into the extracellular space with a volume of distribution of about 0.1 litres/kg. Daptomycin crosses the blood-brain barrier and the placenta. It is about 90% bound to plasma proteins, mainly serum albumin.

In-vitro studies indicate that daptomycin is not metabolised by, and does not affect, the cytochrome P450 isoenzyme system. Little or no metabolism is thought to take place although 4 minor metabolites have been detected in the urine.

Daptomycin is excreted mainly via renal filtration with about 78% and 6% of a dose recovered in the urine and faeces, respectively. It has an elimination half-life of about 8 hours after an intravenous dose of 4 mg/kg once daily for 7 days and is prolonged in patients with renal impairment; a two- to threefold increase has been reported in those with severe impairment or end-stage renal disease.

Daptomycin is removed by haemodialysis or peritoneal dialysis.

Uses and Administration

Daptomycin is given by intravenous infusion over 30 minutes for the treatment of complicated Gram-positive infections of the skin and soft tissues, and *Staphylococcus aureus* bacteraemia, including right-sided endocarditis, caused by meticillin-susceptible and meticillin-resistant strains.

For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

For the treatment of skin and soft-tissue infections, daptomycin is given in a dose of 4 mg/kg once daily for 7 to 14 days. A higher dose of 6 mg/kg once daily is given for 2 to 6 weeks in the treatment of bacteraemia.

For details of dosage modification in patients with renal impairment, see below.

Daptomycin has also been investigated for the treatment of vancomycin-resistant enterococcal infections, complicated urinary-tract infections, and community-acquired pneumonia.

Administration in renal impairment. In patients with a creatinine clearance of less than 30 mL/minute, including those receiving dialysis, the intravenous dosage of daptomycin should be modified to 4 mg/kg once every 48 hours in the treatment of skin and soft-tissue infections, and to 6 mg/kg once every 48 hours in the treatment of bacteraemia.

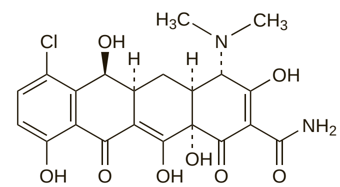
Demeclocycline *(BAN, rINN)*

Demeclociclina; Déméclocycline; Demeclocyclinum; Demeklocyklin; Demeklosykliini; Demethylchlortetracycline. (4*S*,4a*S*,5a*S*,6*S*,12a*S*)-7-Chloro-4-dimethylamino-1,4,4a,5,5a,6,11,12a-octahydro-3,6,10,12,12a-pentahydroxy-1,11-dioxonaphthacene-2-carboxamide; 7-Chloro-6-demethyltetracycline.

Демеклоциклин

$C_{21}H_{21}ClN_2O_8$ = 464.9.
CAS — 127-33-3 (demeclocycline); 13215-10-6 (demeclocycline sesquihydrate).
ATC — D06AA01; J01AA01.
ATC Vet — QD06AA01; QJ01AA01.



Pharmacopoeias. In *US.*
USP 31 (Demeclocycline). A yellow, odourless crystalline powder. Sparingly soluble in water; soluble 1 in 200 of alcohol and 1 in 40 of methyl alcohol; dissolves readily in 3N hydrochloric acid and in alkaline solutions. pH of a 1% solution in water is between 4.0 and 5.5. Store in airtight containers. Protect from light.

Demeclocycline Hydrochloride *(BANM, rINNM)*

Déméclocycline, chlorhydrate de; Demeclocyclini hydrochloridum; Demeklociklin-hidroklorid; Demeklociklino hidrochloridas; Demeklocyklin-hydrochlorid; Demeklocyklinhydroklorid; Demeklocykliny chlorowodorek; Demeklosiklin Hidroklorür; Demeklosykliinihydrokloridi; Demethylchlortetracycline Hydrochloride; Hidrocloruro de demeclociclina.

Демеклоциклина Гидрохлорид

$C_{21}H_{21}ClN_2O_8,HCl$ = 501.3.
CAS — 64-73-3.
ATC — D06AA01; J01AA01.
ATC Vet — QD06AA01; QJ01AA01.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*
Ph. Eur. 6.2 (Demeclocycline Hydrochloride). The hydrochloride of a substance produced by certain strains of *Streptomyces aureofaciens* or by any other means. A yellow powder. Soluble or sparingly soluble in water; slightly soluble in alcohol; very slightly soluble in acetone. It dissolves in solutions of alkali hydroxides and carbonates. A 1% solution in water has a pH of 2.0 to 3.0. Protect from light.
USP 31 (Demeclocycline Hydrochloride). A yellow, odourless, crystalline powder. Soluble 1 in 60 of water and 1 in 50 of methyl alcohol; slightly soluble in alcohol; practically insoluble in acetone and in chloroform; sparingly soluble in solutions of alkali hydroxides and carbonates. pH of a 1% solution in water is between 2.0 and 3.0. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for Tetracycline, p.347.

Phototoxic reactions occur more frequently with demeclocycline than with other tetracyclines and patients should avoid direct exposure to sunlight or artificial ultraviolet light.

Reversible nephrogenic diabetes insipidus with polyuria, polydipsia, and weakness may occur in patients treated with demeclocycline, particularly with prolonged treatment and/or high doses. Plasma creatinine should be monitored in patients receiving demeclocycline for long periods for the treatment of inappropriate secretion of antidiuretic hormone, since tetracycline-induced renal impairment may not otherwise be apparent in the absence of oliguria. For a comment that the usefulness of demeclocycline for this indication may be limited by nephrotoxicity in patients with cardiac or hepatic disease, see Syndrome of Inappropriate ADH Secretion under Uses and Administration, below.

Interactions
As for Tetracycline, p.348.

Antimicrobial Action
As for Tetracycline, p.348.

Demeclocycline is stated to be somewhat more active against certain strains of some organisms including *Neisseria gonorrhoeae* and *Haemophilus influenzae*, as well as to being the most active of the tetracyclines *in vitro* against *Brucella* spp.

Pharmacokinetics
For the general pharmacokinetics of the tetracyclines, see Tetracycline, p.349.

About 60 to 80% of a dose of demeclocycline is absorbed from the gastrointestinal tract. Peak plasma concentrations of about 1.5 to 1.7 micrograms/mL have been reported 3 to 4 hours after a single oral dose of 300 mg, but higher plasma concentrations may be achieved with repeated dosage. Its plasma elimination half-life is about 12 hours, although this may be prolonged in patients with renal impairment; values of 42 to 68 hours have been reported in severe impairment. The renal clearance of demeclocycline is about half that of tetracycline.

Uses and Administration
Demeclocycline is a tetracycline derivative with uses similar to those of tetracycline (p.349). It is excreted more slowly and effective blood concentrations are maintained for a longer period.

Demeclocycline is given orally as the hydrochloride; the usual adult dose is 600 mg daily in 2 or 4 divided doses, preferably 1 hour before or 2 hours after meals. For atypical pneumonia, 900 mg daily in 3 divided doses may be given. It is also sometimes given orally with other tetracycline derivatives.

For details of doses in children and adolescents, see below.

Demeclocycline may also be given to adults in the treatment of chronic hyponatraemia associated with the syndrome of inappropriate antidiuretic hormone secretion, when water restriction has proved ineffective. Initially 900 to 1200 mg is given daily in divided doses, reducing to maintenance doses of 600 to 900 mg daily.

For dosage recommendations in patients with hepatic impairment, see below.

The calcium and magnesium salts of demeclocycline have also been used.

Administration in children. In children, the effects on teeth should be considered and tetracyclines only used when absolutely essential; demeclocycline may be used for the treatment of susceptible infections. In the UK, it is licensed for use in children aged 12 years and over; the usual adult dose (see above) may be given orally. However, in the USA, it may be given to those over 8 years old in usual doses of 7 to 13 mg/kg daily by mouth in 2 or 4 divided doses.

Administration in hepatic impairment. UK licensed product information states that the dosage of demeclocycline should not exceed 1 g daily in patients with known liver disease.

Syndrome of inappropriate ADH secretion. Demeclocycline may be given in the treatment of the syndrome of inappropriate ADH (antidiuretic hormone) secretion (SIADH—p.2182) to antagonise the effect of ADH on the renal tubules; lithium has been given as an alternative. Both lithium and demeclocycline act by interfering with the cellular action of ADH to produce nephrogenic diabetes insipidus. Demeclocycline was reported to be superior to lithium[1] and became the preferred treatment for chronic SIADH if water restriction was unsuccessful,[2] although fluid restriction is probably still the treatment of choice. However, since nephrotoxicity has been reported in patients with cardiac or hepatic disease, the usefulness of demeclocycline in the treatment of hyponatraemic states might be limited; this view was supported by studies in patients with heart failure[3] and cirrhosis.[4]

Dibekacin Sulfate *(rINNM)*

Dibekacin Sulphate *(BANM)*; Dibékacine, Sulfate de; Dibekacini Sulfas; 3′,4′-Dideoxykanamycin B; Sulfato de dibekacina. 6-*O*-(3-Amino-3-deoxy-α-D-glucopyranosyl)-2-deoxy-4-*O*-(2,6-diamino-2,3,4,6-tetradeoxy-α-D-*erythro*-hexopyranosyl)-streptamine sulphate.

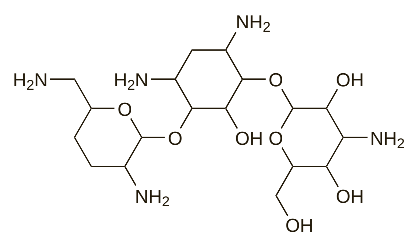
Дибекацина Сульфат

$C_{18}H_{37}N_5O_8,xH_2SO_4$.

CAS — 34493-98-6 (dibekacin); 58580-55-5 (dibekacin sulfate).

ATC — J01GB09.

ATC Vet — QJ01GB09.



(dibekacin)

Pharmacopoeias. In *Jpn.*

Profile
Dibekacin is an aminoglycoside derived from kanamycin with actions and uses similar to those of gentamicin (p.282). It has been given intramuscularly as the sulfate in doses equivalent to dibekacin 1 to 3 mg/kg daily in divided doses. It has also been given in similar doses by slow intravenous infusion. Dosage should be adjusted based on serum-dibekacin concentration monitoring. It has also been used topically for eye infections.

Preparations
Proprietary Preparations (details are given in Part 3)
Belg.: Dikacine†; ***Jpn:*** Panimycin; ***Venez.:*** Dibekan.

Dicloxacillin *(BAN, USAN, rINN)*

BRL-1702; Dicloxacilina; Dicloxacilline; Dicloxacillinum; Diklok-sasilliini; Dikloxacillin; R-13423. (6*R*)-6-[3-(2,6-Dichlorophenyl)-5-methylisoxazole-4-carboxamido]penicillanic acid.

Диклоксациллин

Dicloxacillin Sodium *(BANM, USAN, rINNM)*

Dicloxacilina sódica; Dicloxacilline sodique; Dicloxacillinum natricum; Dicloxacillinum Natricum Monohydricum; Dikloksacilino natrio druska; Dikloksasilliininatrium; Dikloxacilin sodná sůl monohydrát; Dikloxacillinnatrium; Dikloxacillin-nátrium; Natrii Dicloxacillinum; P-1011. Sodium dicloxacillin monohydrate.

Натрий Диклоксациллин

$C_{19}H_{16}Cl_2N_3NaO_5S,H_2O$ = 510.3.

CAS — 343-55-5 (anhydrous dicloxacillin sodium); 13412-64-1 (dicloxacillin sodium monohydrate).

ATC — J01CF01.

ATC Vet — QJ01CF01.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Dicloxacillin Sodium). A white or almost white, hygroscopic, crystalline powder. Freely soluble in water; soluble in alcohol and in methyl alcohol. A 10% solution in water has a pH of 5.0 to 7.0. Store at a temperature not exceeding 25° in airtight containers.

USP 31 (Dicloxacillin Sodium). A white to off-white crystalline powder. Freely soluble in water. pH of a 1% solution in water is between 4.5 and 7.5. Store in airtight containers.

Adverse Effects and Precautions
As for Flucloxacillin, p.277.

Effects on the liver. References.

1. Kleinman MS, Presberg JE. Cholestatic hepatitis after dicloxacillin-sodium therapy. *J Clin Gastroenterol* 1986; **8**: 77–8.

Sodium content. Each g of dicloxacillin sodium contains about 2 mmol of sodium.

Interactions
As for Benzylpenicillin, p.214.

Antimicrobial Action
As for Flucloxacillin, p.277.

Pharmacokinetics
Dicloxacillin is better absorbed from the gastrointestinal tract than cloxacillin but absorption is reduced by the presence of food in the stomach. After an oral dose of 500 mg, peak plasma concentrations of 10 to 18 micrograms/mL in about 1 hour have been reported in fasting subjects. Doubling the dose can double the plasma concentration. About 97% of dicloxacillin in the circulation is bound to plasma proteins. Dicloxacillin has been reported to have a plasma half-life of 0.5 to 1 hour. The half-life is prolonged in neonates.

The distribution of dicloxacillin in body tissues and fluids is similar to that of cloxacillin (p.256).

Dicloxacillin is metabolised to a limited extent and the unchanged drug and metabolites are excreted in the urine by glomerular filtration and renal tubular secretion. About 60% of an oral dose is excreted in the urine. Only small amounts are excreted in the bile. Dicloxacillin is not removed by haemodialysis.

Plasma concentrations are enhanced by probenecid. Reduced concentrations have been reported in patients with cystic fibrosis.

Uses and Administration
Dicloxacillin is an isoxazolyl penicillin used similarly to flucloxacillin (p.277) in the treatment of infections due to staphylococci resistant to benzylpenicillin.

Dicloxacillin is given intravenously and orally as the sodium salt. All doses are expressed in terms of the equivalent amount of dicloxacillin; 1.09 g of dicloxacillin sodium is equivalent to about 1 g of dicloxacillin. Oral doses should be taken at least 1 hour before, or 2 hours after, meals since the presence of food in the stomach reduces absorption. The usual adult oral dose is 250 mg every 6 hours. Similar doses may be given by slow intravenous injection or, preferably, by intravenous infusion. Doses may be doubled in severe infections.

Preparations
USP 31: Dicloxacillin Sodium Capsules; Dicloxacillin Sodium for Oral Suspension.

Proprietary Preparations (details are given in Part 3)

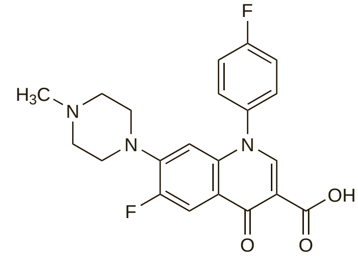
Difloxacin Hydrochloride *(USAN, rINNM)*

A-56619; Abbott-56619; Difloxacine, chlorhydrate de; Difloxacini hydrochloridum; Hidrocloruro de difloxacino. 6-Fluoro-1-(*p*-fluorophenyl)-1,4-dihydro-7-(4-methyl-1-piperazinyl)-4-oxo-3-quinolinecarboxylic acid hydrochloride.

Дифлоксацина Гидрохлорид

$C_{21}H_{19}F_2N_3O_3$,HCl = 435.9.

CAS — 98106-17-3 (difloxacin); 91296-86-5 (difloxacin hydrochloride).



(difloxacin)

Profile

Difloxacin is a fluoroquinolone antibacterial used as the hydrochloride in veterinary medicine for the treatment of susceptible infections in poultry. It was formerly used in humans but was associated with an unacceptable incidence of adverse CNS effects.

Dihydrostreptomycin Sulfate *(rINNM)*

Dihidrosztreptomicin-szulfát; Dihydrostreptomycin sulfát; Dihydrostreptomycin Sulphate *(BANM)*; Dihydrostreptomycine, sulfate de; Dihydrostreptomycini sulfas; Dihydrostreptomycinsulfat; Dihydrostreptomysiinisulfaatti; Sulfato de dihidroestreptomicina. *O*-2-Deoxy-2-methylamino-α-L-glucopyranosyl-(1→2)-*O*-5-deoxy-3-*C*-hydroxymethyl-α-L-lyxofuranosyl-(1→4)-N^1,N^3-diamidino-D-streptamine sulphate.

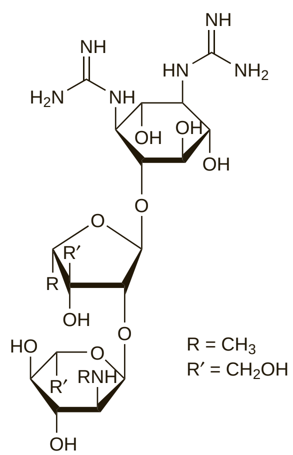
Дигидрострептомицина Сульфат

$(C_{21}H_{41}N_7O_{12})_2,3H_2SO_4$ = 1461.4.

CAS — 128-46-1 (dihydrostreptomycin); 5490-27-7 (dihydrostreptomycin sulfate).

ATC — S01AA15.

ATC Vet — QS01AA15.



(dihydrostreptomycin)

Pharmacopoeias. In *Eur.* (see p.vii) and *US*, both for veterinary use only.

Ph. Eur. 6.2 (Dihydrostreptomycin Sulphate for Veterinary Use; Dihydrostreptomycin Sulphate BP(Vet) 2008). The sulfate of a substance obtained by catalytic hydrogenation of streptomycin or by any other means. The semi-synthetic product is derived from a fermentation product. Stabilisers may be added. A white or almost white, hygroscopic powder. It contains a maximum of 2.0% streptomycin sulfate calculated with reference to the dried drug. Freely soluble in water; practically insoluble in alcohol, in acetone, and in methyl alcohol. A 25% solution in water has a pH of 5.0 to 7.0. Store in airtight containers. Protect from light.

USP 31 (Dihydrostreptomycin Sulfate). A white or almost white amorphous or crystalline powder; the amorphous form is hygroscopic. Freely soluble in water; practically insoluble in acetone, in chloroform, and in methyl alcohol. pH of a solution in water containing the equivalent of dihydrostreptomycin 20% is between 4.5 and 7.0, except that if it is labelled as being solely for oral use, the pH is between 3.0 and 7.0. Store in airtight containers.

Profile

Dihydrostreptomycin is an aminoglycoside antibacterial with actions similar to those of streptomycin (p.333). Since it is more likely than streptomycin to cause partial or complete loss of hearing it is not used parenterally in humans. It is not absorbed after oral doses, and has been given by this route for gastrointestinal infections. It is also used as the sulfate in veterinary medicine.

Preparations

Proprietary Preparations (details are given in Part 3)

Spain: Citrocil.

Multi-ingredient: ***Arg.:*** Gemipasmol†; Vagisan; Vagisan Compuesto; ***Mex.:*** Estrefen; ***Spain:*** Cilinafosal Dihidroestreptomicina; Estreptoenterol†; Salitanol Estreptomicina; Sulfintestin Neomicina.

Dirithromycin *(BAN, USAN, rINN)*

ASE-136BS; Dirithromycine; Dirithromycinum; Diritromicin; Diritromicina; Diritromicinas; Diritromisin; Diritromycin; Diritromysiini; LY-237216. (1*R*,2*R*,3*R*,6*R*,7*S*,8*S*,9*R*,10*R*,12*R*,13*S*,15*R*,17*S*)-7-(2,6-Dideoxy-3-*C*,3-*O*-dimethyl-α-L-*ribo*-hexopyranosyloxy)-3-ethyl-2,10-dihydroxy-15-(2-methoxyethoxymethyl)-2,6,8,10,12,17-hexamethyl-9-(3,4,6-trideoxy-3-dimethylamino-β-L-*xylo*-hexopyranosyloxy)-4,16-dioxa-14-azabicyclo[11.3.1]heptadecan-5-one; (9*S*)-9-Deoxo-11-deoxy-9,11-{imino[(1*R*)-2-(2-methoxyethoxy)-ethylidene]oxy}erythromycin.

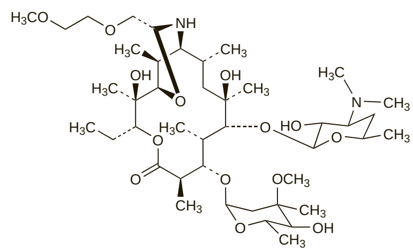
Диритромицин

$C_{42}H_{78}N_2O_{14}$ = 835.1.

CAS — 62013-04-1.

ATC — J01FA13.

ATC Vet — QJ01FA13.



Pharmacopoeias. In *Eur.* (see p.vii) and *US*.

Ph. Eur. 6.2 (Dirithromycin). A white or almost white powder. It exhibits polymorphism. Very slightly soluble in water; very soluble in dichloromethane and in methyl alcohol.

USP 31 (Dirithromycin). A white or practically white powder. Very slightly soluble in water; very soluble in dichloromethane and in methyl alcohol.

Adverse Effects and Precautions

As for Erythromycin, p.270.

The most frequent adverse effects of dirithromycin are gastrointestinal disturbances; headache has also occurred. Dirithromycin should be used with caution in patients with moderate to severe hepatic impairment since its active metabolite erythromycylamine is primarily eliminated in the bile. It should also be used with caution in those with severe renal impairment.

Interactions

For a discussion of drug interactions of macrolide antibacterials, see Erythromycin, p.271.

Cytochrome P450 isoenzymes. Dirithromycin is reported to have little or no effect on hepatic cytochrome P450 isoenzymes and may therefore produce fewer interactions than erythromycin with other drugs metabolised by this enzyme system (see Mechanism, under Interactions of Erythromycin, p.271). The lack of interactions between dirithromycin and theophylline, terfenadine, or warfarin would appear to support this.

Antimicrobial Action

As for Erythromycin, p.271.

Dirithromycin is reported to be generally less active than erythromycin *in vitro*, but may show greater activity *in vivo* than is indicated by *in-vitro* studies and may exert a postantibiotic effect.

Pharmacokinetics

Dirithromycin is readily absorbed after oral doses and undergoes rapid non-enzymatic hydrolysis to its active metabolite erythromycylamine. Absorption is enhanced by food. Bioavailability is about 10%. Daily doses of dirithromycin 500 mg produce peak plasma concentrations of erythromycylamine of about 400 nanograms/mL.

Erythromycylamine is widely distributed and tissue concentrations exceed those in plasma. Protein binding is 15 to 30%. Erythromycylamine is mainly excreted unchanged in the bile with only about 2% in the urine. The mean plasma half-life is about 8 hours and the mean urinary terminal elimination half-life is about 44 hours.

Distribution into milk has been found in studies in *rodents*.

Uses and Administration

Dirithromycin is a prodrug of the macrolide antibacterial erythromycylamine, which has similar properties to those of erythromycin (p.269) and is used in respiratory-tract, skin, and soft-tissue infections caused by susceptible organisms.

Dirithromycin is given orally as enteric-coated tablets in a usual dose of 500 mg once daily.

Doripenem *(USAN, rINN)*

Doripénem; Doripenemum; S-4661. (+)-(4*R*5*S*,6*S*)-6-[(1*R*)-1-Hydroxyethyl]-4-methyl-7-oxo-3-({(3*S*,5*S*)-5-[(sulfamoylamino)methyl]-3-pyrrolidinyl}thio)-1-azabicyclo[3.2.0]hept-2-ene-2-carboxylic acid.

Дорипенем

$C_{15}H_{24}N_4O_6S_2$ = 420.5.

CAS — 148016-81-3.

Adverse Effects and Precautions

As for Imipenem, p.286.

Doripenem is more stable to renal dehydropeptidase I than imipenem and use with cilastatin, which inhibits the enzyme, is not required.

Interactions

Probenecid inhibits the renal excretion of doripenem thereby increasing its plasma concentrations and prolonging its elimination half-life.

Antiepileptics. For reports of decreased plasma-*valproate* concentrations (sometimes with loss of seizure control) attributed to carbapenem antibacterials, see p.510.

Antimicrobial Action

As for Imipenem, p.287,

Doripenem is claimed to have particular activity against *Pseudomonas aeruginosa*.

Pharmacokinetics

After intravenous infusion of doripenem 500 mg over 1 hour, a mean peak plasma concentration of 23 micrograms/mL is attained, falling to 10 micrograms/mL after 1.5 hours and 1 microgram/mL after 6 hours.

Doripenem is less than 10% bound to plasma proteins and is widely distributed into body tissues and fluids. It is metabolised via hydrolysis of its beta-lactam ring by dehydropeptidase I to an open-ringed metabolite (doripenem-M1). The plasma elimination half-life is about 1 hour in adults; the half-life may be prolonged in patients with renal impairment. Doripenem is mainly excreted in the urine by tubular secretion and glomerular filtration. About 70% and 15% of a dose is recovered as unchanged drug and metabolite, respectively, in the urine within 48 hours. Less than 1% is excreted in faeces.

Doripenem is removed by haemodialysis.

Uses and Administration

Doripenem is a carbapenem antibacterial similar to imipenem (p.286). It is more stable to renal dehydropeptidase I than imipenem and need not be given with an enzyme inhibitor such as cilastatin. It is used in the treatment of susceptible infections such as intra-abdominal infections and complicated urinary-tract infections, including pyelonephritis. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

For treatment of susceptible infections doripenem is given by intravenous infusion over 1 hour, in a usual adult dose of 500 mg every 8 hours. For details of reduced doses in renal impairment, see below.

◊ References.

Administration in renal impairment. Doses of doripenem given by intravenous infusion should be reduced in patients with renal impairment according to creatinine clearance (CC):

- CC 30 to 50 mL/minute: 250 mg every 8 hours
- CC greater than 10 to less than 30 mL/minute: 250 mg every 12 hours

Doxycycline Hyclate *(BANM, rINNM)*

Doksiciklino hiklatas; Doksisykliinihyklaatti; Doksycykliny hyklan; Dossiciclina Iclato; Doxiciklin-hiklát; Doxycycline, hyclate de; Doxycycline Hydrochloride; Doxycyclini hyclas; Doxycyklinhyklat; Doxycyklin-hyklát; Hiclato de doxiciclina. Doxycycline hydrochloride hemiethanolate hemihydrate.

Доксициклина Гиклат

$C_{22}H_{24}N_2O_8,HCl,\frac{1}{2}C_2H_5OH,\frac{1}{2}H_2O$ = 512.9.

CAS — 10592-13-9 (doxycycline hydrochloride); 24390-14-5 (doxycycline hyclate).

ATC — A01AB22; J01AA02.

ATC Vet — QA01AB22; QJ01AA02.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Doxycycline Hyclate). A yellow hygroscopic crystalline powder. Freely soluble in water and in methyl alcohol; sparingly soluble in alcohol. It dissolves in solutions of alkali hydroxides and of carbonates. A 1% solution in water has a pH of 2.0 to 3.0. Store in airtight containers. Protect from light.

USP 31 (Doxycycline Hyclate). A yellow crystalline powder. Soluble in water; slightly soluble in alcohol; practically insoluble in chloroform and in ether; soluble in solutions of alkali hydroxides and carbonates. pH of a solution in water containing the equivalent of doxycycline 1% is between 2.0 and 3.0. Store in airtight containers. Protect from light.

Incompatibility. Preparations of doxycycline hyclate have an acid pH and incompatibility may reasonably be expected with alkaline preparations or with drugs unstable at low pH.

Adverse Effects and Precautions

As for Tetracycline, p.347.

Gastrointestinal disturbances with doxycycline are reported to be less frequent than with tetracycline and doxycycline may also cause less tooth discoloration.

Oesophageal ulceration may be a particular problem if capsules or tablets are taken with insufficient fluid or in a recumbent posture: doxycycline should be taken with at least half a glass of water, in an upright position, and well before going to bed. Dispersible tablets or liquid formulations should be used in elderly patients, who may be at greater risk of oesophageal injury.

Unlike many tetracyclines, doxycycline does not appear to accumulate in patients with impaired renal function, and aggravation of impairment may be less likely.

Incidence of adverse effects. For the suggestion that doxycycline may cause fewer adverse effects than minocycline, see p.301.

Anosmia. Anosmia or dysosmia (absent or impaired sense of smell) have occasionally been reported in patients receiving doxycycline, although the association has not been definitely established.[1]

1. Bleasel AF, *et al.* Anosmia after doxycycline use. *Med J Aust* 1990; **152:** 440.

Effects on intracranial pressure. Doxycycline has been associated with benign intracranial hypertension; for further details, see under Tetracycline, p.348.

Porphyria. Doxycycline has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for Tetracycline, p.348.

Doxycycline has a lower affinity for binding with calcium than many tetracyclines. Consequently its absorption is less likely to be affected by milk or food, although it is still affected by calcium-containing antacids and other divalent and trivalent cations such as aluminium, bismuth, iron, magnesium, and zinc; even intravenous doxycycline may be affected, although less so than when given orally.

The metabolism of doxycycline may be accelerated by drugs that induce hepatic enzymes such as alcohol (chronic use), rifampicin, and antiepileptics including carbamazepine, phenobarbital, phenytoin, and primidone.

It has been suggested that doxycycline could increase ciclosporin concentrations, but evidence for this seems to be scant.

Antimicrobial Action

As for Tetracycline, p.348.

Doxycycline is more active than tetracycline against many bacterial species including *Streptococcus pyogenes*, enterococci, *Nocardia* spp., and various anaerobes. Cross-resistance is common although some tetracycline-resistant *Staphylococcus aureus* respond to doxycycline. Doxycycline is also more active against protozoa, particularly *Plasmodium* spp.

Pharmacokinetics

For the general pharmacokinetics of the tetracyclines, see Tetracycline, p.349.

Doxycycline is readily and almost completely absorbed from the gastrointestinal tract and absorption is not significantly affected by the presence of milk or food in the stomach or duodenum. Mean peak plasma concentrations of 2.6 micrograms/mL have been reported 2 hours after a 200-mg oral dose, falling to 1.45 micrograms/mL at 24 hours. After intravenous infusion of the same dose peak plasma concentrations are briefly somewhat higher, but become very similar to those after oral dosage on equilibration into the tissues.

About 80 to 95% of doxycycline in the circulation is reported to be bound to plasma proteins. Its biological half-life varies from about 12 to 24 hours. Doxycycline is more lipid-soluble than tetracycline. It is widely distributed in body tissues and fluids.

In patients with normal renal function about 40% of a dose is slowly excreted in the urine, although more is excreted by this route if the urine is made alkaline. However, the majority of a dose of doxycycline is excreted in the faeces after chelation in the intestines. Although doxycycline has been reported to undergo partial inactivation in the liver, some sources consider this doubtful; however, the kinetics of doxycycline have been reportedly altered in patients receiving drugs that induce hepatic metabolism.

Doxycycline is stated not to accumulate significantly in patients with renal impairment, although excretion in the urine is reduced; increased amounts of doxycycline are excreted in the faeces in these patients. Nevertheless, there have been reports of some accumulation in renal failure. Removal of doxycycline by haemodialysis is insignificant.

◊ Reviews.

1. Saivin S, Houin G. Clinical pharmacokinetics of doxycycline and minocycline. *Clin Pharmacokinet* 1988; **15:** 355–66.

Uses and Administration

Doxycycline is a tetracycline derivative with uses similar to those of tetracycline (p.349). It may sometimes be preferred to other tetracyclines in the treatment of susceptible infections because of its fairly reliable absorption and its long half-life that permits less frequent (often once daily) dosing. It also has the advantage that it can be given (with care) to patients with renal impairment. However, relatively high doses may need to be given for urinary-tract infections because of its low renal excretion.

Doxycycline has antiprotozoal actions and may be given in conjunction with quinine in the management of falciparum malaria resistant to chloroquine (p.594).

Solutions of doxycycline are also used for malignant effusions (p.659).

Doxycycline is usually given orally as the base or its various salts, usually the hyclate. Doses are expressed in terms of doxycycline; doxycycline hyclate 115 mg is equivalent to about 100 mg of anhydrous doxycycline. Doxycycline capsules and tablets should be given with plenty of fluid, with the patient in an upright position, and well before going to bed. Doxycycline may be given with food or milk if gastric irritation occurs. Dispersible tablets or liquid formulations are advisable in elderly patients.

In patients in whom oral therapy is not feasible, doxycycline hyclate may be given by slow intravenous infusion of a solution containing 0.1 to 1 mg/mL, in equivalent doses. Infusions should be given over 1 to 4 hours.

The usual adult dose, either orally or intravenously, is 200 mg of doxycycline on the first day (as a single dose or in divided doses), followed by 100 mg daily. In severe infections the initial dosage is maintained throughout the course of treatment.

In patients with uncomplicated gonococcal infections, doxycycline 100 mg twice daily for 7 days is given orally, although it has occasionally been given in a single dose of 300 mg followed by a second similar dose 1 hour later. For syphilis in penicillin-allergic patients, doxycycline 100 to 200 mg twice daily is given orally for at least 14 days; some authorities suggest giving the same dose for 28 to 30 days to patients with late latent disease and those with syphilis for more than a year should be given 100 mg twice daily for 28 days.

For relapsing fever and louse-borne typhus, doxycycline 100 or 200 mg may be given as a single oral dose. For prophylaxis of scrub typhus, 200 mg may be taken as a single oral dose. For the prophylaxis of leptospirosis, 200 mg may be given orally once a week throughout exposure for up to 21 days and 200 mg is also given when leaving the area of infection risk.

Doxycycline is used in non-endemic areas for the treatment of chloroquine-resistant falciparum malaria in an oral dose of 200 mg daily for at least 7 days after treatment with quinine. Doxycycline 100 mg daily may be used for prophylaxis in areas of high risk or where multidrug resistance exists, and can be used prophylactically for up to 2 years.

For treatment and postexposure prophylaxis of inhalation anthrax, a 60-day course of treatment with oral doses of 100 mg twice daily may be used; one or two other antibacterials should also be given. Although unlicensed, the same regimen is recommended by UK and US public health authorities for the treatment of gastrointestinal anthrax. In the treatment of cutaneous anthrax (also unlicensed), a 7- to 10-day course of treatment with an oral dose of doxycycline 100 mg twice daily is recommended; treatment may need to be extended to 60 days if infection is due to aerosol exposure. If there are signs of systemic involvement, extensive oedema, or lesions on the head and neck, intravenous therapy and a multidrug approach is recommended.

In the treatment of acne, an oral dose of 50 mg daily for 6 to 12 weeks may be adequate, although the *BNF* advocates a dose of 100 mg daily. It is also given in low doses of 40 mg once daily as a modified-release preparation for the treatment of inflammatory lesions associated with rosacea in adults.

Doxycycline may be given orally in low doses of 20 mg twice daily for 3 months as an adjunct to supragingival and subgingival scaling and root planing to adults with periodontitis. For chronic periodontitis, a modified-release subgingival gel containing doxycycline hyclate 10% (released over 7 days) has been inserted into the periodontal pocket.

For details of doses in children and adolescents, see below.

Administration. SUBANTIMICROBIAL DOSES. Doxycycline is given in doses of 20 mg orally twice daily, which are not sufficient to achieve antimicrobial concentrations in the body, as an adjunct in the treatment of periodontal disease. The benefits of treatment are believed to be due to its ability to down-regulate the actions of matrix metalloproteinases, enzymes involved in the breakdown of collagen and which play a key role in the inflammatory and destructive processes of periodontitis.[1] Similar subantimicrobial doses have been investigated, and produced apparent benefit, in patients with acne or rosacea;[2] there was no evidence that even quite prolonged therapy at these doses influenced the development of antibiotic resistance in bacterial flora. A low-dose modified-release preparation containing doxycycline 40 mg is available in some countries for the treatment of inflammatory lesions associated with rosacea.

2. Del Rosso JQ. A status report on the use of subantimicrobial-dose doxycycline: a review of the biologic and antimicrobial effects of the tetracyclines. *Cutis* 2004; **74:** 118–122.

Administration in children. In children, the effects on teeth should be considered and tetracyclines only used when absolutely essential. In the UK, doxycycline is licensed for use in children aged 12 years and over; the usual adult dose (see above) may be given orally. However, in the USA, it may be given to children over 8 years old; those weighing 45 kg or less may be given usual oral or intravenous doses of 4.4 mg/kg on the first day (as a single dose or in divided doses), followed by 2.2 mg/kg daily and those weighing over 45 kg may be given the usual adult dose (see above).

In the USA, doxycycline is licensed in children over 8 years old for prophylaxis of chloroquine-resistant falciparum malaria in areas of high risk or where multidrug resistance exists. The recommended oral dose is 2 mg/kg (to a maximum of 100 mg) once daily.

US[1] public health authorities suggest that doxycycline may be given to children under 8 years old for the treatment of inhalation, gastrointestinal, or cutaneous anthrax, and for postexposure prophylaxis of inhalation anthrax. For the treatment and postexposure prophylaxis of inhalation anthrax, a 60-day course of treatment with initial intravenous doses of 2.2 mg/kg (to a maximum of 100 mg) twice daily followed by the same dose given orally is recommended; the same regimen is also recommended for the treatment of gastrointestinal anthrax. As with the adult regimens, one or two other antibacterials should also be given. In the treatment of cutaneous anthrax, a 7- to 10-day course of treatment with an oral dose of 2.2 mg/kg twice daily is recommended; treatment may need to be extended to 60 days if infection is due to aerosol exposure. In the UK[2] public health authorities only recommend doxycycline for those older than 8 years old and weighing over 45 kg who may be given the usual adult dose (see above).

2. Health Protection Agency. Guidelines for action in the event of a deliberate release: anthrax. Version 5.9, 16 April 2007. Available at: http://www.hpa.org.uk/webc/HPAwebFile/HPAweb_C/1194947401128 (accessed 11/08/08)

Lymphatic filariasis. Filaria have been shown to contain *Wolbachia* endobacteria which are essential for larval development and adult worm fertility and viability. This symbiotic dependency has provided a new approach in the treatment of individuals with lymphatic filariasis (p.137). A double-blind, randomised, placebo-controlled study[1] of 72 patients infected with *Wuchereria bancrofti* found that those given oral doxycycline 200 mg daily for 8 weeks had a significant reduction in the number of adult worms at 14 months; ultrasonography detected adult worms in 22% of those given doxycycline and in 88% of those given placebo. Microfilaraemia was almost completely eliminated at 8 to 14 months follow-up.

See also Onchocerciasis, below.

1. Taylor MJ, *et al.* Macrofilaricidal activity after doxycycline treatment of Wuchereria bancrofti: a double-blind, randomised placebo-controlled trial. *Lancet* 2005; **365:** 2116–21.

Musculoskeletal and joint disorders. For reference to the use of doxycycline in the management of various musculoskeletal and joint disorders, see under Tetracycline, p.350.

Onchocerciasis. As in lymphatic filariasis (above), *Onchocerca volvulus* worms rely on a symbiotic relationship with *Wolbachia* endobacteria, and this has provided a new approach in the treatment of individuals with onchocerciasis (p.137). A 4-month controlled clinical study[1] of 35 patients with onchocerciasis found that those given oral doxycycline 100 mg daily for 6 weeks showed a trend toward more frequent degeneration or death of adult worms and suppressed embryonic development at early stages for the duration of the study period. A subsequent study[2] of 88 patients found that embryogenesis was interrupted for at least 18 months in those given a single standard dose of ivermectin (150 micrograms/kg) plus oral doxycycline 100 mg daily for 6 weeks compared to those given only the standard dose of ivermectin.

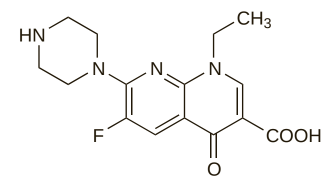
Enoxacin *(BAN, USAN, rINN)*

AT-2266; CI-919; Enoksasiini; Enoksasin; Énoxacine; Enoxacino; Enoxacinum; PD-107779. 1-Ethyl-6-fluoro-1,4-dihydro-4-oxo-7-(1-piperazinyl)-1,8-naphthyridine-3-carboxylic acid.

Эноксацин

$C_{15}H_{17}FN_4O_3 = 320.3.$
CAS — 74011-58-8.
ATC — J01MA04.
ATC Vet — QJ01MA04.



Pharmacopoeias. *Chin.* and *Jpn* include the sesquihydrate.

Adverse Effects and Precautions

As for Ciprofloxacin, p.244.

Reduced dosage may be needed in renal impairment—see Administration in Renal Impairment, under Uses and Administration, below.

Interactions

As for Ciprofloxacin, p.246.

Of the fluoroquinolones, enoxacin has been reported to cause the most marked interaction with theophylline (p.1143) and with caffeine (p.1117).

Antimicrobial Action

As for Ciprofloxacin, p.246, although enoxacin is generally less potent *in vitro.*

Pharmacokinetics

Peak plasma concentrations of 2 to 3 micrograms/mL occur 1 to 2 hours after a 400-mg oral dose of enoxacin. The plasma half-life is about 3 to 6 hours. Plasma protein binding ranges from 18 to 67%. Enoxacin appears to be widely distributed in the body and concentrations higher than those in plasma have been reported in tissues such as lung, kidney, and prostate. High concentrations are achieved in bile, but the extent of biliary excretion is not completely clear.

Enoxacin is eliminated from the body mainly by urinary excretion, but also by metabolism. The major metabolite, 3-oxo-enoxacin, has some antibacterial activity. Urinary excretion of enoxacin is by both tubular secretion and glomerular filtration and may be reduced by probenecid. High concentrations are achieved in the urine since about 60% of an oral dose of enoxacin appears unchanged in the urine within 24 hours; about 10% is recovered as 3-oxo-enoxacin. In renal impairment the half-life of enoxacin may be prolonged and the oxometabolite may accumulate.

Uses and Administration

Enoxacin is a fluoroquinolone antibacterial with actions and uses similar to those of ciprofloxacin (p.247). It is used mainly in the treatment of urinary-tract infections (p.199) and gonorrhoea (p.191).

For urinary-tract infections, enoxacin is given orally in doses of 200 to 400 mg twice daily.

For details of reduced doses in renal impairment, see below.

A single 400-mg dose is given for uncomplicated gonorrhoea.

◊ References.

1. Patel SS, Spencer CM. Enoxacin: a reappraisal of its clinical efficacy in the treatment of genitourinary tract infections. *Drugs* 1996; **51:** 137–60.

Administration in renal impairment. In renal impairment when the creatinine clearance is 30 mL/minute or less the urinary concentrations achieved may be too low to have a therapeutic effect in urinary-tract infections. In other infections, half the usual dose of enoxacin is recommended.

Preparations

Proprietary Preparations (details are given in Part 3)

Enrofloxacin *(BAN, USAN, rINN)*

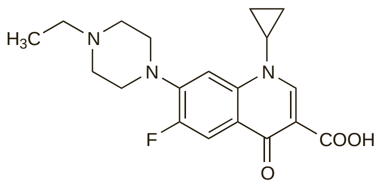
Bay-Vp-2674; Enrofloksasiini; Enrofloxacine; Enrofloxacino; Enrofloxacinum. 1-Cyclopropyl-7-(4-ethylpiperazin-1-yl)-6-fluoro-1,4-dihydro-4-oxoquinoline-3-carboxylic acid.

Энрофлоксацин

$C_{19}H_{22}FN_3O_3$ = 359.4.

CAS — 93106-60-6.

ATC Vet — QJ01MA90.



Profile

Enrofloxacin is a fluoroquinolone antibacterial that is used in veterinary practice.

Ertapenem Sodium *(BANM, USAN, rINNM)*

Ertapenem sódico; Ertapénem Sodique; L-749345; MK-826; MK-0826; Natrii Ertapenemum; ZD-4433. Sodium (4R,5S,6S)-3-({(3S,5S)-5-[(*m*-Carboxyphenyl)carbamoyl]-3-pyrrolidinyl}thio)-6-[(1R)-1-hydroxyethyl]-4-methyl-7-oxo-1-azabicyclo[3.2.0]hept-2-ene-2-carboxylate.

Натрий Эртапенем

$C_{22}H_{24}N_3NaO_7S$ = 497.5.

CAS — 153832-46-3 (ertapenem); 153832-38-3 (ertapenem disodium); 153773-82-1 (ertapenem sodium).

ATC — J01DH03.

ATC Vet — QJ01DH03.

Incompatibility and stability. References.

1. McQuade MS, *et al.* Stability and compatibility of reconstituted ertapenem with commonly used iv infusion and coinfusion solutions. *Am J Health-Syst Pharm* 2004; **61:** 38–45.

Adverse Effects and Precautions

As for Imipenem, p.286.

Ertapenem is more stable to renal dehydropeptidase I than imipenem and use with cilastatin, which inhibits the enzyme, is not required.

Interactions

Probenecid inhibits the renal excretion of ertapenem thereby increasing its plasma concentrations and prolonging its elimination half-life.

Antiepileptics. For reports of decreased plasma-*valproate* concentrations (sometimes with loss of seizure control) attributed to ertapenem, see p.510.

Antimicrobial Action

As for Imipenem, p.287,

Ertapenem is reported to be slightly more active *in vitro* than imipenem but has a narrower spectrum of activity and is not active against *Acinetobacter* or *Pseudomonas aeruginosa*.

Pharmacokinetics

After intravenous infusion of ertapenem 1 g over 30 minutes, a mean plasma concentration of 155 micrograms/mL is attained, falling to 9 micrograms/mL after 12 hours and 1 microgram/mL after 24 hours. After the same dose intramuscularly, a plasma concentration of 67 micrograms/mL is achieved after 2 hours. Bioavailability after intramuscular injection is about 90%.

Ertapenem is more than 90% bound to plasma proteins. It is distributed into breast milk. The plasma half-life is about 4 hours in adults and 2.5 hours in infants and in children aged 3 months to 12 years; the half-life may be prolonged in patients with renal impairment.

Ertapenem is partially metabolised via hydrolysis of its beta-lactam ring by dehydropeptidase I to an open-ringed metabolite. About 80% of a dose is excreted in the urine as both unchanged drug and metabolite. About 10% is excreted in faeces.

Ertapenem is removed by haemodialysis.

Uses and Administration

Ertapenem is a carbapenem beta-lactam antibacterial with actions and uses similar to those of imipenem (p.287). It is more stable to renal dehydropeptidase I than imipenem and need not be given with an enzyme inhibitor such as cilastatin. It is used in the treatment of susceptible infections including intra-abdominal infections, acute gynaecological infections, urinary-tract infections, skin and skin structure infections (including diabetic foot infections), and community-acquired pneumonia. It is also used prophylactically in colorectal surgery. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Ertapenem is given as the sodium salt, but doses are expressed in terms of the base; 1.04 g of ertapenem sodium is equivalent to about 1 g of ertapenem. For treatment, it is given by intravenous infusion over 30 minutes or by intramuscular injection, in a usual adult dose of 1 g once daily. For prophylaxis, a single 1- g dose is given intravenously 1 hour before the start of surgery. For details of reduced doses in renal impairment, see below.

For details of doses in infants and children, see below.

◊ Reviews.

1. Keating GM, Perry CM. Ertapenem: a review of its use in the treatment of bacterial infections. *Drugs* 2006; **65:** 2151–78.

Administration in children. The dose of ertapenem for children aged 3 months to 12 years is 15 mg/kg twice daily (up to a maximum of 1 g daily) given by intravenous infusion over 30 minutes; if appropriate, the intramuscular route may be used.

Administration in renal impairment. Doses of ertapenem should be reduced in patients with renal impairment according to creatinine clearance (CC) and the following data are based on US prescribing information:

- CC 30 mL or less per minute (including end-stage disease where CC is 10 mL or less per minute): 500 mg daily for adults
- haemodialysis: if the 500-mg dose is given in the 6-hour period before dialysis an additional 150 mg should be given after each session.

The UK product licence, however, states that in advanced renal insufficiency and haemodialysis there are inadequate data to make recommendations and that ertapenem should not be used in these patients.

Preparations

Proprietary Preparations (details are given in Part 3)

Erythromycin *(BAN, rINN)*

Eritromicin; Eritromicina; Eritromicinas; Eritromisin; Érythromycine; Erythromycinum; Erytromycin; Erytromycyna; Erytromysiini. Erythromycin A is (2R,3S,4S,5R,6R,8R,10R,11R,12S,13R)-5-(3-amino-3,4,6-trideoxy-*N*,*N*-dimethyl-β-D-*xylo*-hexopyranosyloxy)-3-(2,6-dideoxy-3-*C*,3-*O*-dimethyl-α-L-*ribo*-hexopyranosyloxy)-13-ethyl-6,11,12-trihydroxy-2,4,6,8,10,12-hexamethyl-9-oxotridecan-13-olide.

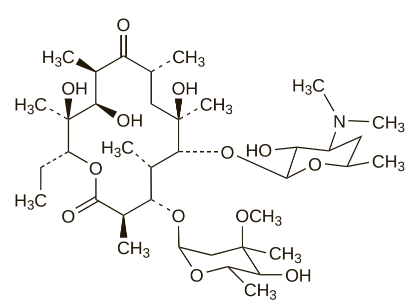
Эритромицин

$C_{37}H_{67}NO_{13}$ = 733.9.

CAS — 114-07-8.

ATC — D10AF02; J01FA01; S01AA17.

ATC Vet — QD10AF02; QJ01FA01; QJ51FA01; QS01AA17.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Erythromycin). It is produced by the growth of a strain of *Streptomyces erythreus* and is a mixture of macrolide antibiotics consisting largely of erythromycin A. It occurs as a white or slightly yellow powder or colourless or slightly yellow crystals; slightly hygroscopic. Slightly soluble in water but less soluble at higher temperatures; freely soluble in alcohol; soluble in methyl alcohol. Protect from light.

USP 31 (Erythromycin). It consists primarily of erythromycin A. A white or slightly yellow, odourless or practically odourless, crystalline powder. Soluble 1 in 1000 of water; soluble in alcohol, in chloroform, and in ether. Store in airtight containers.

Erythromycin Estolate *(BAN, USAN, rINNM)*

Eritromicin-esztolát; Eritromicino estolatas; Erythromycin Propionate Lauryl Sulfate; Erythromycin Propionate Lauryl Sulphate; Érythromycine, estolate d'; Erythromycin-estolát; Erythromycini estolas; Erytromycinestolat; Erytromycyny estolan; Erytromysiiniestolaatti; Estolato de eritromicina; Propionylerythromycin Lauryl Sulphate. Erythromycin 2′-propionate dodecyl sulphate.

Эритромицина Эстолат

$C_{40}H_{71}NO_{14},C_{12}H_{26}O_4S$ = 1056.4.

CAS — 3521-62-8.

ATC — D10AF02; J01FA01; S01AA17.

ATC Vet — QD10AF02; QJ01FA01; QS01AA17.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Erythromycin Estolate). A white or almost white, crystalline powder. Practically insoluble in water; freely soluble in alcohol; soluble in acetone; practically insoluble in dilute hydrochloric acid. Protect from light.

USP 31 (Erythromycin Estolate). A white, odourless or practically odourless, crystalline powder. It has a potency equivalent to not less than 600 micrograms of erythromycin per mg, calculated on the anhydrous basis. Practically insoluble in water; soluble 1 in 20 of alcohol, 1 in 15 of acetone, and 1 in 10 of chloroform. Store in airtight containers.

Erythromycin Ethyl Succinate *(BANM)*

Eritromicina, etilsuccinato de; Eritromicin-etilszukcinát; Eritromicino etilsukcinatas; Erythromycin Ethylsuccinate; Érythromycine, éthylsuccinate d'; Erythromycin-ethylsukcinát; Erythromycini ethylsuccinas; Erytromycinetylsuccinat; Erytromycyny etylobursztynian; Erytromysiinietyylisuksinaatti. Erythromycin 2′-(ethylsuccinate).

Эритромицина Этилсукцинат

$C_{43}H_{75}NO_{16}$ = 862.1.

CAS — 41342-53-4.

ATC — D10AF02; J01FA01; S01AA17.

ATC Vet — QD10AF02; QJ01FA01; QS01AA17.

NOTE. Compounded preparations of erythromycin ethyl succinate may be represented by the following names:

- Co-erynsulfisox (*PEN*)—erythromycin ethyl succinate and acetyl sulfafurazole.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Erythromycin Ethylsuccinate; Erythromycin Ethyl Succinate BP 2008). A white or almost white, hygroscopic crystalline powder. Practically insoluble in water; freely soluble in dehydrated alcohol, in acetone, and in methyl alcohol. Store in airtight containers. Protect from light.

USP 31 (Erythromycin Ethylsuccinate). A white or slightly yellow, odourless or practically odourless, crystalline powder. It has a potency equivalent to not less than 765 micrograms of erythromycin per mg, calculated on the anhydrous basis. Very slightly soluble in water; freely soluble in alcohol, in chloroform, and in macrogol 400. Store in airtight containers.

Erythromycin Gluceptate *(BANM, rINNM)*

Érythromycine, Gluceptate d'; Erythromycini Gluceptas; Gluceptato de eritromicina. Erythromycin glucoheptonate.

Эритромицина Глюцептат

$C_{37}H_{67}NO_{13},C_7H_{14}O_8$ = 960.1.

CAS — 304-63-2; 23067-13-2.

ATC — D10AF02; J01FA01; S01AA17.

ATC Vet — QD10AF02; QJ01FA01; QS01AA17.

Pharmacopoeias. In *US.*

USP 31 (Sterile Erythromycin Gluceptate). It is erythromycin gluceptate suitable for parenteral use. It has a potency equivalent to not less than 600 micrograms of erythromycin per mg, calculated on the anhydrous basis. pH of a 2.5% solution in water is between 6.0 and 8.0.

Erythromycin Lactobionate *(BANM, rINNM)*

Eritromicin-laktobionát; Eritromicino laktobionatas; Érythromycine, lactobionate d'; Erythromycini lactobionas; Erythromycin-laktobionát; Erytromycinlaktobionat; Erytromycyny laktobionian; Erytromysiinilaktov; Éthylèneglycol, monostéarate d'; Lactobionato de eritromicina; Lactobionato de eritromicina. Erythromycin mono(4-O-β-D-galactopyranosyl-D-gluconate).

Эритромицина Лактобионат

$C_{37}H_{67}NO_{13},C_{12}H_{22}O_{12}$ = 1092.2.
CAS — 3847-29-8.
ATC — D10AF02; J01FA01; S01AA17.
ATC Vet — QD10AF02; QJ01FA01; QS01AA17.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Erythromycin Lactobionate). Salt of a product obtained by fermentation using a strain of *Streptomyces erythreus*. White or slightly yellow, hygroscopic powder. Soluble in water; freely soluble in dehydrated alcohol and in methyl alcohol; very slightly soluble in acetone and in dichloromethane. A 2% solution in water has a pH of 6.5 to 7.5. Store in airtight containers.

USP 31 (Sterile Erythromycin Lactobionate). It has a potency equivalent to not less than 525 micrograms of erythromycin per mg, calculated on the anhydrous basis. pH of a solution in water containing the equivalent of erythromycin 5% is between 6.5 and 7.5.

Erythromycin Propionate *(BANM, USAN, rINNM)*

Erythromycin Propanoate; Érythromycine, Propionate d'; Erythromycini Propionas; Propionato de eritromicina; Propionylerythromycin. Erythromycin 2′-propionate.

Эритромицина Пропионат

$C_{40}H_{71}NO_{14}$ = 790.0.
CAS — 134-36-1.
ATC — D10AF02; J01FA01; S01AA17.
ATC Vet — QD10AF02; QJ01FA01; QS01AA17.

Pharmacopoeias. In *Fr.*

Erythromycin Stearate *(BANM, rINNM)*

Eritromicino stearatas; Eritromicin-sztearát; Eritromisin Stearat; Érythromycine, stéarate d'; Erythromycini stearas; Erythromycin-stearát; Erytromycinstearat; Erytromycyny stearynian; Erytromysiinistearaatti; Estearato de eritromicina. Erythromycin octadecanoate.

Эритромицина Стеарат

$C_{37}H_{67}NO_{13},C_{18}H_{36}O_2$ = 1018.4.
CAS — 643-22-1.
ATC — D10AF02; J01FA01; S01AA17.
ATC Vet — QD10AF02; QJ01FA01; QS01AA17.

Pharmacopoeias. In *Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Erythromycin Stearate). A mixture of the stearates of erythromycin and stearic acid. A white or almost white crystalline powder. Practically insoluble in water; soluble in acetone and in methyl alcohol. Solutions may be opalescent.

USP 31 (Erythromycin Stearate). The stearic acid salt of erythromycin with an excess of stearic acid. White or slightly yellow crystals or powder, odourless or may have a slight, earthy odour. Practically insoluble in water; soluble in alcohol, in chloroform, in ether, and in methyl alcohol. Store in airtight containers.

Incompatibility and stability. The stability of erythromycin derivatives is dependent upon pH, with particularly rapid degradation occurring at a pH greater than 10 or less than 5.5. Incompatibility might reasonably be expected, therefore, when erythromycin preparations are mixed with drugs or preparations that have a highly acidic or alkaline pH. In practice, reports of incompatibility are not always consistent, and other factors such as the temperature and concentration of solutions, and the diluents used, may play a role.

Solutions for infusion. For the preparation of solutions of erythromycin lactobionate for infusion, a primary solution containing not more than 5% of erythromycin should be prepared first; only water for injection should be used in preparing the primary solution. It should be further diluted with sodium chloride 0.9% or other suitable intravenous fluid before use. Acidic solutions, such as glucose, should only be used if neutralised with sodium bicarbonate.

Adverse Effects

Erythromycin and its salts and esters are generally well tolerated and serious adverse effects are rare. Gastrointestinal disturbances such as abdominal discomfort and cramp, nausea, vomiting, and diarrhoea are fairly common after both oral and parenteral use, probably because of the stimulant activity of erythromycin on the gut. Gastrointestinal effects are dose related and appear to be more common in young than in older patients. Superinfection with resistant organisms may occur and pseudomembranous colitis has been reported.

Hypersensitivity reactions appear to be uncommon, having been reported in about 0.5% of patients, and include pruritus, urticaria, and skin rash as well as occasional cases of anaphylaxis. Stevens-Johnson syndrome and toxic epidermal necrolysis have also been reported very rarely. Hypersensitivity or irritation may occur after topical application of erythromycin.

A hypersensitivity reaction is thought to be responsible for the hepatotoxicity sometimes reported in patients receiving erythromycin or its derivatives but this has been disputed by some. Most reports of cholestatic hepatitis have been in patients receiving the estolate, and it has been suggested that the propionyl ester linkage is particularly associated with hepatotoxicity, but symptoms have also been reported in patients given the base and most of the other derivatives, both orally and parenterally. Symptoms indicative of cholestasis, including upper abdominal pain (sometimes very severe), nausea and vomiting, abnormal liver function values, raised serum bilirubin, and usually jaundice, may be accompanied by rash, fever, and eosinophilia. Symptoms usually occur in patients who have been taking the drug for more than 10 days, although they may develop more quickly in patients given the drug previously. Hepatic dysfunction seems to be rare in children under 12 years of age. The effects of erythromycin on the liver are generally reversible on stopping treatment. Erythromycin may interfere with tests for serum aspartate aminotransferase, which might make diagnosis of hepatotoxicity more difficult.

A generally reversible sensorineural deafness, sometimes with tinnitus, has been reported in patients given erythromycin and appears to be related to serum concentration, with an increased likelihood of such effects in patients given doses of 4 g or more daily of base or its equivalent, in those given intravenous therapy, and in those with renal or hepatic impairment.

Other adverse effects that have been reported in patients given erythromycin include agranulocytosis, aggravation of muscular weakness in myasthenia gravis patients, and pancreatitis. Prolongation of the QT interval and other arrhythmias, sometimes fatal, including torsade de pointes have been reported particularly with intravenous use. There have also been isolated reports of transient CNS adverse effects including confusion, hallucinations, seizures, and vertigo.

Parenteral formulations of erythromycin are irritant and intravenous dosage may produce thrombophlebitis, particularly at high doses. Intramuscular injection is generally avoided as it may produce severe pain.

◊ General reviews.

Effects on body temperature. A report of hypothermia associated with oral erythromycin in 2 children.[1] Symptoms resolved on stopping the drug. The children were cousins, perhaps indicating a genetic predisposition to the effect. There has also been a similar report of hypothermia in 3 children given azithromycin orally.[2]

Effects on the cardiovascular system. There have been several reports[1-6] of QT prolongation or torsade de pointes associated with erythromycin, particularly with intravenous use.

A review[7] of reports of torsade de pointes received by the FDA Adverse Event Reporting System between 1987 and December 2000 identified 156 cases associated with use of the macrolides azithromycin, clarithromycin, dirithromycin, or erythromycin. Of these reports, half involved the use of other drugs known to prolong the QT interval; co-morbid diseases and physiological abnormalities, including cardiac abnormalities, were also commonly reported. A retrospective analysis[8] of a cohort of patients who suffered sudden death from cardiac causes found that the rate of sudden cardiac death was twice as high among current users of erythromycin as in those not using antibacterials; there was no such increase among former users, nor among current users of amoxicillin. The greatest increase in risk was seen in patients using erythromycin with inhibitors of the cytochrome P450 isoenzyme subfamily CYP3A; such patients had more than 5 times the risk of sudden cardiac death of patients who took neither.

Effects on the gastrointestinal tract. Comparison in patients with upper respiratory-tract infections has suggested that erythromycin ethyl succinate may be associated with less abdominal pain than an equivalent dosage of erythromycin base.[1] Another study has indicated that there was no significant difference in gastrointestinal symptoms between plain and enteric-coated formulations of erythromycin base.[2] Severe nausea and vomiting after rapid intravenous infusion of erythromycin lactobionate stopped in 2 patients who transferred to oral erythromycin base or ethyl succinate.[3] However, the adverse effects may have been due to the rate of infusion, since in 2 further patients symptoms resolved when the lactobionate was given more slowly as a more dilute solution.[3]

There have been a number of studies suggesting an association between erythromycin and infantile hypertrophic pyloric stenosis.[4-6] A retrospective cohort study of 469 infants who had received erythromycin found that 43 were diagnosed with the condition including 36 male infants, although erythromycin had been prescribed almost equally for males and females.[5] All the infants in whom stenosis developed were given erythromycin in the first 2 weeks of life. In another study,[6] involving 7138 infants who received erythromycin between 3 and 90 days of life, use of the drug between 3 and 13 days of life was associated with an almost eightfold increased risk of infantile hypertrophic pyloric stenosis. However, it was believed that the evidence did not support a generalisation of this association to the whole class of macrolides[7] although pyloric stenosis has been reported in breast-fed infants associated with the use of erythromycin or several other macrolides in their mothers (see under Precautions, below).

For reference to the stimulant effects of erythromycin on the gastrointestinal tract, see Decreased Gastrointestinal Motility under Uses and Administration, below.

7. Hauben M, Amsden GW. The association of erythromycin and infantile hypertrophic pyloric stenosis: causal or coincidental? *Drug Safety* 2002; **25:** 929–42.

Effects on the neonate. For a suggestion that erythromycin or other macrolides might be associated with an increased risk of infantile hypertrophic pyloric stenosis in neonates, see under Effects on the Gastrointestinal Tract, above.

Effects on the skin. Skin reactions ranging from mild eruptions to erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis have rarely been reported with macrolides.[1,2]

Overdosage. Acute pancreatitis was reported in a 12-year-old girl after ingestion of about 5 g of erythromycin base.[1] Transient pancreatitis has also been reported in another 15-year-old girl who took 5.328 g of erythromycin base.[2] Erythromycin produces contraction of the sphincter of Oddi resulting in reflux of bile into the pancreas but the resulting pancreatitis is self-limited and remits when sphincter tone returns to normal after the erythromycin is eliminated from the body.

Precautions

Erythromycin and its derivatives should be avoided in those known to be hypersensitive to it, or in those who have previously developed jaundice. All forms of erythromycin should be used with care in patients with existing liver disease or hepatic impairment, and the estolate is best avoided in such patients; liver function should be monitored. Repeated courses of the estolate or use for longer than 10 days increases the risk of hepatotoxicity.

The lactobionate should be used with caution in patients with severe renal impairment; dosage reduction may be necessary particularly in those who develop toxicity. A reduced dose of the estolate has also been recommended in severe renal impairment.

Erythromycin may aggravate muscle weakness in patients with myasthenia gravis.

Erythromycin should be used with care in patients with a history of arrhythmias or a predisposition to QT interval prolongation. Certain medications may also increase the risk of arrhythmias (see Interactions, below).

Erythromycin may interfere with some diagnostic tests including measurements of urinary catecholamines and 17-hydroxycorticosteroids. It has also been associated with falsely-elevated serum aspartate aminotransferase values when measured colorimetrically, although genuine elevations of this enzyme, due to hepatotoxicity, also occur, particularly with the estolate.

Erythromycin is irritant; solutions for parenteral use should be suitably diluted and given by intravenous infusion over 20 to 60 minutes to reduce the incidence of thrombophlebitis. Rapid infusion is also more likely to be associated with arrhythmias or hypotension.

Breast feeding. There has been a report[1] of a breast-fed infant who developed pyloric stenosis thought to be associated with use of erythromycin by the mother. A large Danish population-based cohort study[2] later concluded that the use of macrolides (azithromycin, clarithromycin, erythromycin, roxithromycin, or spiramycin) during breast feeding increased the risk of infantile hypertrophic pyloric stenosis. (See also Effects on the Gastrointestinal Tract, above.) A milk-to-plasma ratio of 0.5 has been reported for erythromycin.[3] However, the American Academy of Pediatrics[4] states that, although erythromycin is concentrated in human breast milk, no adverse effects have been seen in breast-fed infants whose mothers were receiving erythromycin and it is therefore usually compatible with breast feeding.

Porphyria. Erythromycin has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. Of 298 pregnant women who took erythromycin estolate, clindamycin, or placebo for 3 weeks or longer, about 14, 4, and 3% respectively had abnormally high serum aspartate aminotransferase values.[1] Erythromycin estolate should probably not be given to pregnant women.

A study[2] of data from the Swedish Medical Birth Registry of infants born between July 1995 and December 2002 has examined details of infants exposed to erythromycin or phenoxymethylpenicillin during early pregnancy. Of 1844 exposed to erythromycin, 103 (5.6%) had congenital malformations compared with 420 of 9110 (4.7%) for phenoxymethylpenicillin. Of these, 34 (1.8%) and 86 (0.9%) respectively had a cardiovascular malformation, the rate being considered high for erythromycin. This contrasted with a previous study based on a 1980–96 dataset of the Hungarian Case-Control Surveillance of Congenital Abnormalities which found no signs of teratogenicity for erythromycin.[3] Although an increased risk for cardiovascular abnormalities was initially apparent when analysing erythromycin usage throughout pregnancy as reported by the mother, this was not confirmed when assessing usage only in the second or third month nor in the entire pregnancy for medically documented intake. The Swedish data also revealed a possible association between infant pyloric stenosis and early prenatal exposure to erythromycin[2] although others had previously failed to confirm such a risk[4] (see also Effects on the Gastrointestinal Tract, above).

Interactions

Erythromycin and other macrolides have the potential to interact with a large number of drugs through their action on hepatic cytochrome P450 isoenzymes, particularly CYP1A2 and CYP3A4. Macrolides inhibit drug metabolism by microsomal cytochromes by competitive inhibition and by the formation of inactive complexes. Such interactions can result in severe adverse effects, including ventricular arrhythmias with astemizole, cisapride, and terfenadine. Enzyme inhibition is reported to be particularly pronounced with macrolides such as erythromycin and troleandomycin. Other macrolides such as azithromycin and dirithromycin are reported to have little or no effect on hepatic cytochromes, and consequently may produce fewer interactions (see also Mechanism, below).

Macrolides themselves have been reported rarely to prolong the QT interval and should be used with caution with other drugs known to also have this effect.

Other mechanisms by which macrolides cause interactions include suppression of the gastrointestinal flora responsible for the intraluminal metabolism of digoxin and possibly oral contraceptives, and the stimulant effect of macrolides on gastrointestinal motility which is believed to be responsible for the interaction between spiramycin and levodopa. An alternative mechanism by which macrolides increase serum concentrations of digoxin is thought to be via the inhibition of intestinal or renal P-glycoprotein transport of digoxin.

Few drugs are reported to affect erythromycin but cimetidine may increase and theophylline may decrease erythromycin concentrations (see below).

The effect on antimicrobial action when erythromycin is given with other antimicrobials is discussed under Antimicrobial Action, below.

Mechanism

In *rats* and humans, troleandomycin, and erythromycin and some of its derivatives, induce microsomal enzymes; the nitrosoalkane metabolites so formed produce stable inactive complexes with the iron of cytochrome P450. Eventually the oxidative metabolism of other drugs may be decreased. These effects are marked after troleandomycin, moderate after erythromycin, small after oleandomycin, and absent or negligible after josamycin, midecamycin, or spiramycin.[1,2]

In the case of astemizole, cisapride, and terfenadine the UK CSM has warned that there is a risk of inducing ventricular arrhythmias if erythromycin, or possibly other macrolides, are also given,[1,2] and that, in particular, cisapride should not be used with macrolides.[3] The Commission on Human Medicines[4] (formerly CSM) later advised that amisulpride, ergotamine, dihydroergotamine, mizolastine, pimozide, simvastatin, and tolterodine should not be given with erythromycin. A warning was also issued that increased erythromycin concentrations may occur when used with other inhibitors of the cytochrome P450 CYP3A isoenzymes such as the azole antifungals, some calcium-channel blockers including diltiazem and verapamil, and HIV-protease inhibitors. For a report of an increased risk of sudden cardiac death associated with such combinations see Effects on the Cardiovascular System, above.

Antimicrobial Action

Erythromycin is a macrolide antibacterial with a broad and essentially bacteriostatic action against many Gram-positive and to a lesser extent some Gram-negative bacteria, as well as other organisms including some *Mycoplasma* spp., Chlamydiaceae, *Rickettsia* spp., and spirochaetes.

Mechanism of action. Erythromycin and other macrolides bind reversibly to the 50S subunit of the ribosome, resulting in blockage of the transpeptidation or translocation reactions, inhibition of protein synthesis, and hence inhibition of cell growth. Its action is mainly bacteriostatic, but high concentrations are slowly bactericidal against the more sensitive strains. Because macrolides penetrate readily into white blood cells and macrophages there has been some interest in their potential synergy with host defence mechanisms *in vivo*. The actions of erythromycin are increased at moderately alkaline pH (up to about 8.5), particularly in Gram-negative species, probably because of the improved cellular penetration of the nonionised form of the drug.

Spectrum of activity. Erythromycin has a broad spectrum of activity. The following pathogenic organisms are usually sensitive to erythromycin (but see also Resistance, below).

Gram-positive cocci, particularly streptococci such as *Streptococcus pneumoniae* and *Str. pyogenes* are sensitive. However, resistance has been increasingly reported in both organisms, particularly in penicillin-resistant *Str. pneumoniae*. Most strains of *Staphylococcus aureus* remain susceptible, although resistance can emerge rapidly, and some enterococcal strains are also susceptible.

Many other Gram-positive organisms respond to erythromycin, including *Bacillus anthracis*, *Corynebacterium diphtheriae*, *Erysipelothrix rhusiopathiae*, and *Listeria monocytogenes*. Anaerobic *Clostridium* spp. are also usually susceptible, as is *Propionibacterium acnes. Nocardia* spp. vary in their susceptibility.

Gram-negative cocci including *Neisseria meningitidis* and *N. gonorrhoeae*, and *Moraxella catarrhalis* (*Branhamella catarrhalis*) are usually sensitive.

Other Gram-negative organisms vary in their susceptibility, but *Bordetella* spp., some *Brucella* strains, and *Flavobacterium* and *Legionella* spp. are usually susceptible. *Haemophilus ducreyi* is reportedly susceptible, but *H. influenzae* is somewhat less so. The Enterobacteriaceae are usually resistant, although some strains may respond at alkaline pH. *Helicobacter pylori* and most strains of *Campylobacter jejuni* are sensitive (about 1% of the latter are reported to be resistant in the USA).

Among the Gram-negative anaerobes most strains of *Bacteroides fragilis* and many *Fusobacterium* strains are resistant.

Other organisms usually sensitive to erythromycin include *Actinomyces*, Chlamydiaceae, rickettsias, spirochaetes such as *Treponema pallidum* and *Borrelia burgdorferi*, some mycoplasmas (notably *Mycoplasma pneumoniae*), and some of the opportunistic mycobacteria: *Mycobacterium scrofulaceum* and *M. kansasii* are usually susceptible, but *M. intracellulare* is often resistant and *M. fortuitum* usually so.

Fungi, yeasts, and viruses are not susceptible to erythromycin.

Activity with other antimicrobials. As with other bacteriostatic antimicrobials, the possibility of an antagonistic effect if erythromycin is given with a bactericide exists, and some antagonism has been shown *in vitro* between erythromycin and various penicillins and cephalosporins or gentamicin. However, in practice the results of such concurrent use are complex, and depend on the organism; in some cases synergy has been seen. For example, in the UK, the *BNF* recommends the use of amoxicillin with erythromycin or another macrolide such as azithromycin or clarithromycin for the treatment of uncomplicated community-acquired pneumonia if atypical organisms are suspected. Because of the adjacency of their binding sites on the ribosome, erythromycin may competitively inhibit the effects of chloramphenicol or lincosamides such as clindamycin or lincomycin.

Resistance. Several mechanisms of acquired resistance to erythromycin have been reported of which the most common is a plasmid-mediated ability to methylate ribosomal RNA, resulting in decreased binding of the antimicrobial drug. This can result in cross-resistance between erythromycin, other macrolides, lincosamides, and streptogramin B, because they share a common binding site on the ribosome and this pattern of resistance is referred to as the MLS_B phenotype. It is seen in staphylococci, and to a somewhat lesser extent in streptococci, as well as in a variety of other species including *B. fragilis*, *Clostridium perfringens*, *Corynebacterium diphtheriae*, and *Listeria* and *Legionella* spp.

Decreased binding of antimicrobial to the ribosome may also occur as a result of a chromosomal mutation, resulting in an alteration of the ribosomal proteins in the 50S subunit, which conveys one-step high-level erythromycin resistance. This form of resistance has been found in some strains of *Str. pneumoniae*, *H. pylori*, *M. pneumoniae*, *Escherichia coli*, *Str. pyogenes*, *Staph. aureus, and Campylobacter* spp.

Other forms of erythromycin resistance may be due to the production of a plasmid-determined erythromycin esterase that can inactivate the drug, or to decreased drug penetration. The latter may be partly responsible for the intrinsic resistance of Gram-negative bacteria like the Enterobacteriaceae, but has also been shown to be acquired as a plasmid-mediated determinant in some organisms; production of a protein which increases drug efflux from the cell is thought to explain the M phenotype resistance, in which organisms are resistant to 14-and 15-carbon ring macrolides, but retain sensitivity to 16-carbon ring macrolides, lincosamides, and streptogramins.

The incidence of resistance varies greatly with the area and the organism concerned and, although the emergence of resistance is rarely a problem in the short-term treatment of infection, it is quite common in conditions requiring prolonged treatment such as endocarditis due to *Staph. aureus.* The incidence of resistance in streptococci is generally lower than in *Staph. aureus* but shows geographical variation and may be increasing in some countries, including the UK. In addition, localised outbreaks of resistant strains may occur and produce a much higher incidence of resistance.

Antipseudomonal activity. Although macrolides have limited direct antibacterial activity against *Pseudomonas aeruginosa*, prolonged exposure at sub-MICs has produced antipseudomonal effects *in vitro*[1-3] and synergy has been shown with other antipseudomonals.[4] Erythromycin and clarithromycin appear to have the greatest activity. This action has been partly attributed to the ability of macrolides to reduce the protective biofilm produced by some strains of *P. aeruginosa*.[3,5] Other proposed mechanisms of action include modification of the inflammatory response to infection and direct inhibition of other virulence factors such as twitching motility.[3]

5. Yasuda H, *et al.* Interaction between biofilms formed by Pseudomonas aeruginosa and clarithromycin. *Antimicrob Agents Chemother* 1993; **37:** 1749–55.

Resistance. A meta-analysis[1] found that reported macrolide resistance in *Streptococcus pneumoniae* varied greatly from country to country. The percentage of erythromycin-resistant *Str. pneumoniae* in the USA (20.7%) was less than that in Europe (32.0%) although this difference was not considered statistically significant, and higher levels of resistance were found in Asia (57.3%). In Europe, *Str. pyogenes* showed greater resistance to erythromycin (36.8%) than *Str. pneumoniae*. However, across all regions, the mean resistance of *Str. pneumoniae* was statistically equivalent (30.4%) and also similar to that of *Str. pyogenes* (30.0%).

Pharmacokinetics

Erythromycin base is unstable in gastric acid, and absorption is therefore variable and unreliable. Consequently, the base is usually given in film- or enteric-coated preparations, or one of the more acid-stable salts or esters is used. Food may reduce absorption of the base or the stearate, although this depends to some extent on the formulation; the esters are generally more reliably and quickly absorbed and their absorption is little affected by food, so that the timing of doses in relation to food intake is unimportant.

Peak plasma concentrations generally occur between 1 and 4 hours after a dose and have been reported to range from about 0.3 to 1.0 micrograms/mL after 250 mg of erythromycin base, and from 0.3 to 1.9 micrograms/mL after 500 mg. Similar concentrations have been seen after equivalent doses of the stearate. Somewhat higher peak concentrations may be achieved on repeated use 4 times daily. Higher total concentrations are achieved after oral doses of the estolate or ethyl succinate, but only about 20 to 30% of estolate or 55% of ethyl succinate is present as the active base, the rest being present as the inactive ester (in the case of the estolate as the propionate). Peak concentrations of about 500 nanograms/mL of erythromycin base have been reported after 250 mg of the estolate or 500 mg of the ethyl succinate. A peak of 3 to 4 micrograms/mL can be achieved after 200 mg of gluceptate or lactobionate intravenously.

Erythromycin is widely distributed throughout body tissues and fluids, although it does not cross the blood-brain barrier well and concentrations in CSF are low. Relatively high concentrations are found in the liver and spleen, and some is taken up into polymorphonuclear lymphocytes and macrophages. Around 70 to 75% of the base is protein bound, but after doses as the estolate the propionate ester is stated to be about 95% protein bound. Erythromycin crosses the placenta: fetal plasma concentrations are variously stated to be 5 to 20% of those in the mother. It is distributed into breast milk.

Erythromycin is excreted in high concentrations in the bile and undergoes intestinal reabsorption. About 2 to 5% of an oral dose is excreted unchanged in the urine and as much as 12 to 15% of an intravenous dose may be excreted unchanged by the urinary route. Erythromycin is partly metabolised in the liver by the cytochrome P450 isoenzyme CYP3A4 via *N*-demethylation to inactive, unidentified metabolites. The half-life of erythromycin is usually reported to be about 1.5 to 2.5 hours, although this may be slightly longer in patients with renal impairment and has been reported to be between 4 to 7 hours in severe impairment.

Erythromycin is not removed by haemodialysis or peritoneal dialysis.

Uses and Administration

Erythromycin is a macrolide antibacterial with a wide spectrum of activity, that has been used in the treatment of a wide range of infections caused by susceptible organisms.

Its uses have included the treatment of severe campylobacter enteritis, chancroid, diphtheria, legionnaires' disease and other *Legionella* infections, neonatal conjunctivitis, pertussis, respiratory-tract infections including bronchitis, pneumonia (mycoplasmal and other atypical pneumonias as well as streptococcal), and sinusitis, and trench fever, and, combined with neomycin, for the prophylaxis of surgical infection in patients undergoing bowel surgery. It may be used as part of a multi-drug regimen for the treatment of inhalation and gastrointestinal anthrax. It is also used in the prevention of diphtheria in non-immune patients and of pertussis in non- or partially immune patients.

Erythromycin is used as an alternative to penicillin in penicillin-allergic patients with various conditions including actinomycosis, leptospirosis, listeriosis, mouth infections, otitis media (usually with a sulfonamide such as sulfafurazole), pelvic inflammatory disease caused by *Neisseria gonorrhoeae*, pharyngitis, and staphylococcal and streptococcal skin infections. It has been used in the treatment of penicillin-allergic patients with syphilis, but there are doubts about its efficacy. It is also used in the prevention of perinatal or Group A streptococcal infections, rheumatic fever, and infections in splenectomised patients. In penicillin-allergic patients in the early stages of Lyme disease, erythromycin may be used as an alternative to a tetracycline; this use is generally restricted to pregnant women and young children, since it is less effective than other drugs. It is also used as an alternative to the tetracyclines in patients with cholera, *Chlamydia* or *Chlamydophila* infections (such as epididymitis, lymphogranuloma venereum, nongonococcal urethritis, pneumonia, psittacosis, and trachoma), Q fever, and spotted fevers.

For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Both oral and topical erythromycin may be used in acne (see Skin Disorders, below) and rosacea (p.1583).

Administration and dosage. Erythromycin may be given as the base or its salts or esters; doses are expressed in terms of the base. Each 1 g of erythromycin is equivalent to about the following amounts of each salt or ester:

- erythromycin estolate 1.44 g
- erythromycin ethyl succinate 1.17 g
- erythromycin gluceptate 1.31 g
- erythromycin lactobionate 1.49 g
- erythromycin propionate 1.08 g
- erythromycin stearate 1.39 g

The usual oral adult dose is the equivalent of erythromycin 1 to 2 g daily in 2 to 4 divided doses; for severe infections this may be increased to up to 4 g daily in divided doses. Daily doses higher than 1 g should be given in more than 2 divided doses.

For the prevention of streptococcal infections in patients with evidence of rheumatic fever or heart disease, who are unable to take penicillin or sulfonamides, a dose of 250 mg twice daily may be given.

For the management of acne, maintenance doses as low as 250 mg daily have been used but resistant strains of propionibacteria are widespread; the *BNF* recommends a dose of 500 mg twice daily.

In patients who are unable to take erythromycin orally and in those who are severely ill, in whom it is necessary to attain an immediate high blood concentration, erythromycin may be given intravenously as the lactobionate, in doses equivalent to those given orally. The gluceptate has also been used intravenously. To reduce the risk of venous irritation it should be given only by continuous or intermittent intravenous infusion of a solution containing not more than 0.5% of erythromycin. Intermittent infusions should be given every 6 hours over 20 to 60 minutes.

Doses may need to be limited in patients with renal impairment (see below).

For details of doses in children, including infants and adolescents, see below.

Other routes. Erythromycin was formerly given by intramuscular injection, but such injections are painful and are no longer generally recommended. Erythromycin is used as a 0.5% eye ointment for the treatment of superficial ocular infections, including neonatal conjunctivitis, caused by susceptible strains of bacteria and for the prophylaxis of neonatal conjunctivitis caused by *N. gonorrhoeae* or *C. trachomatis*. It may also be applied topically as a 2 to 4% gel or solution for the treatment of acne vulgaris and is also available in combination preparations with benzoyl peroxide, ichthammol, isotretinoin, tretinoin, and zinc acetate.

Propionyl erythromycin mercaptosuccinate has also been used. Erythromycin thiocyanate and erythromycin phosphate are used in veterinary medicine.

◊ Reviews.

1. Zhanel GG, *et al.* Review of macrolides and ketolides: focus on respiratory tract infections. *Drugs* 2001; **61:** 443–98.

Administration. A discussion of the significance of different formulations and salts used for oral preparations of erythromycin concluded that there was no clear evidence that any was superior in terms of clinical effect.[1]

1. Anonymous. Giving erythromycin by mouth. *Drug Ther Bull* 1995; **33:** 77–9.

Administration in children. The usual dose for infants and children is the equivalent of about 30 to 50 mg/kg of erythromycin daily in 2 to 4 divided doses although it may be doubled in severe infections. Based on age, the usual dose in children 2 to 8 years old is 1 g daily and in infants and children up to 2 years old 500 mg daily. Those over 8 years of age may be given the usual adult dose (see above).

For the prevention of streptococcal infections in children with evidence of rheumatic fever or heart disease, who are unable to take penicillin or sulfonamides, a dose of 250 mg twice daily may be given. The *BNFC* suggests a dose of 125 mg twice daily in those aged 1 month to 2 years. In addition, similar doses have been suggested for prophylaxis against pneumococcal infections.

For the management of acne, maintenance doses as low as 250 mg daily have been used but resistant strains of propionibacteria are widespread; the *BNFC* recommends a dose of 500 mg twice daily in those over 12 years of age. It also suggests a dose of 250 mg daily in 1 or 2 divided doses for infants with acne.

Although unlicensed in the UK for use in gastrointestinal stasis, the *BNFC* suggests a dose of 3 mg/kg given 4 times daily for infants and children up to 18 years of age (see also below).

Administration in renal impairment. A maximum dose of erythromycin 1.5 g daily has been suggested by the *BNF* for adult patients with severe renal impairment.

Decreased gastrointestinal motility. Erythromycin stimulates gut motility, apparently by acting as a motilin receptor agonist, although it has been suggested that it may have other actions as well.[1] It has been tried, with some success, for its prokinetic action in a small number of patients with decreased gastrointestinal motility (p.1694) including those with functional dyspepsia,[2] gastroparesis,[3] reflux ileus,[4] acute colonic pseudo-obstruction (Ogilvie's syndrome),[4,5] delayed gastric emptying after pancreatic-duodenal surgery,[6] and neonatal postoperative intestinal dysmotility.[7] It has also been used to increase gastrointestinal motility in critically ill, mechanically ventilated patients[8,9] and in preterm very low birth-weight infants.[10,11] However, the prophylactic or routine use of erythromycin in such circumstances has been cautioned against,[9,10] and a systematic review[12] of neonatal use also suggested that erythromycin should be reserved for a very small subset of high-risk preterm neonates with persistent or severe feed intolerance. Adverse effects associated with the long-term use of erythromycin that is necessary in, for example, diabetic gastroparesis, may also be problematic.[13]

For suggested doses in the treatment of children with gastrointestinal stasis, see Administration in Children, above.

Respiratory disorders. As well as their established antibacterial effect, it has been suggested that the 14-membered ring macrolides (such as clarithromycin, erythromycin, and roxithromycin) and the 15-membered ring macrolides (such as azithromycin) also have immunomodulatory and anti-inflammatory effects that could be useful in the management of respiratory diseases including asthma (p.1108), chronic obstructive pulmonary disease (p.1112), cystic fibrosis (p.166), diffuse panbronchiolitis, and sinusitis (p.193).[1-3] However, a systematic review[4] found insufficient evidence to support or refute the use of macrolides in chronic asthma although some clinical data indicated a positive effect; routine use was not recommended and further trials were warranted. A systematic review[5] on the use of macrolides in cystic fibrosis found evidence of a small but significant improvement in respiratory function at 6 months with azithromycin compared with placebo; the role of other macrolides was unclear and further studies were needed. A randomised, double-blind, placebo-controlled study[6] to evaluate the use of oral azithromycin given three times a week for 12 months for the treatment of cystic fibrosis in children, reported a significant reduction in the number of pulmonary exacerbations needing treatment with antibacterials, even in the absence of infection with *Pseudomonas aeruginosa*. Azithromycin has also been investigated[7-9] in the management of bronchiolitis obliterans in patients who have undergone lung transplantation (p.1815), although its role has yet to be defined.

Skin disorders. *ACNE.* Erythromycin may be used topically or orally in the treatment of acne (p.1577). Topical erythromycin may be used for mild inflammatory acne if benzoyl peroxide is ineffective or poorly tolerated. It is also used as adjunctive treatment in more severe acne. Erythromycin is also available as a complex with zinc acetate that has been reported to be more effective than topical erythromycin alone[1] or oral minocycline.[2] However, development of antibiotic resistance by the skin flora is an increasing problem. Combination therapy with benzoyl peroxide and erythromycin has been reported to be helpful in preventing the selection of antibiotic-resistant mutants[3,4] and to be more effective than topical clindamycin alone.[5] Alternatively, short intervening courses of benzoyl peroxide during antibacterial therapy may help to eliminate any resistant bacteria that have been selected.[6] It has also been recommended that courses of topical antibiotics be continued for no longer than necessary (although treatment should be used for at least 6 months), that the same drug be used if further treatment is required, and that treatment with different oral and topical antibiotics or antibiotic rotation be avoided.[6]

Oral erythromycin may be used as an alternative to a tetracycline in moderate acne. However, resistance to erythromycin is increasing so it may be best reserved for those patients in whom other antibacterials are unsuitable.

Ethambutol Hydrochloride

(BANM, USAN, rINNM)

CL-40881; Etambutol Hidroklorür; Etambutol-hidroklorid; Etambutolhydroklorid; Etambutolihydrokloridi; Etambutolio hidrochloridas; Etambutolu chlorowodorek; Éthambutol, chlorhydrate d'; Ethambutol-dihydrochlorid; Ethambutoli Dihydrochloridum; Ethambutoli hydrochloridum; Hidrocloruro de etambutol. (*S,S*)-*N,N′*-Ethylenebis(2-aminobutan-1-ol) dihydrochloride.

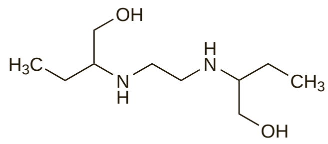
Этамбутола Гидрохлорид

$C_{10}H_{24}N_2O_2,2HCl$ = 277.2.

CAS — 74-55-5 (ethambutol); 1070-11-7 (ethambutol hydrochloride).

ATC — J04AK02.

ATC Vet — QJ04AK02.



(ethambutol)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Ethambutol Hydrochloride). A white or almost white, crystalline powder. Freely soluble in water; soluble in alcohol. A 2% solution in water has a pH of 3.7 to 4.0. Store in airtight containers.

USP 31 (Ethambutol Hydrochloride). A white crystalline powder. Freely soluble in water; soluble in alcohol and in methyl alcohol; slightly soluble in chloroform and in ether.

Adverse Effects and Treatment

The most important adverse effect of ethambutol is retrobulbar neuritis with a reduction in visual acuity, constriction of visual field, central or peripheral scotoma, and green-red colour blindness. One or both eyes may be affected. The degree of visual impairment appears to depend on the dose and duration of therapy; toxicity is observed most frequently at daily doses of 25 mg/kg or more and after at least 2 months of therapy. Recovery of vision usually takes place over a period of a few weeks or months, but in rare cases it may take up to a year or more or the effect may be permanent. Retinal haemorrhage has occurred rarely.

Renal clearance of urate may be reduced and acute gout has been precipitated rarely.

Hypersensitivity reactions including skin rashes, pruritus, leucopenia, fever, and joint pains have occurred but appear to be rare with ethambutol. Other adverse effects which have been reported include confusion, disorientation, hallucinations, headache, dizziness, malaise, jaundice or transient liver dysfunction, peripheral neuropathy, thrombocytopenia, pulmonary infiltrates, eosinophilia, and gastrointestinal disturbances such as nausea, vomiting, anorexia, and abdominal pain.

Teratogenicity has been observed in *animals* (but see also Precautions, below).

Blood concentrations of ethambutol after overdosage may be reduced by haemodialysis or peritoneal dialysis.

Effects on the blood. Neutropenia has been reported in a patient on ethambutol, isoniazid, and rifampicin.[1] Each drug induced neutropenia individually on rechallenge. In another patient also receiving mixed antituberculous therapy, eosinophilia and neutropenia were associated with ethambutol; the effects recurred only on rechallenge with this drug.[2] Skin rash, blood eosinophilia, and pulmonary infiltrates occurred in a patient after 8 weeks of multidrug therapy for miliary tuberculosis. Rechallenge again attributed the adverse event to ethambutol.[3] Thrombocytopenia attributable to ethambutol has been reported in 2 patients.[4,5]

5. Prasad R, Mukerji PK. Ethambutol-induced thrombocytopaenia. *Tubercle* 1989; **70:** 211–12.

Effects on the CNS. A 40-year-old man with advanced HIV infection taking oral ethambutol for *Mycobacterium avium* complex infection had rapid cognitive decline, hallucinations, and delusions within 2 weeks of starting ethambutol treatment; symptoms resolved on stopping treatment.[1]

1. Martin SJ, Bowden FJ. Ethambutol toxicity manifesting as acute onset psychosis. *Int J STD AIDS* 2007; **18:** 287–8.

Effects on the eyes. A review[1] on the ocular toxicity of ethambutol reported that when ethambutol is taken for more than 2 months the incidence of retrobulbar neuritis is about 18% in patients receiving a daily dose of more than 35 mg/kg, reducing to 5 to 6% with a daily dose of 25 mg/kg, and less than 1% with a daily dose of 15 mg/kg. An earlier study reported ophthalmic effects in 10 of 2184 patients receiving ethambutol in doses of 25 mg/kg or less daily, although few of the 10 patients complained of symptoms.[2] In 9 of the 10 patients, ocular changes occurred after the second month of treatment. In the 928 patients who only received 2 months of ethambutol therapy, ocular toxicity was not reported. A prospective study[3] of 229 patients taking ethambutol for *Mycobacterium avium* complex lung disease reported that ocular toxicity was more common in patients given daily doses rather than intermittent (3 times a week) therapy.

While short-term use of ethambutol is usually safe, deterioration of vision leading to long-term blindness has been reported after only a few doses of ethambutol;[4] it was suspected that this was an idiosyncratic reaction. Rapid onset reversible ocular toxicity has also occurred.[5]

Visual defects occurring with ethambutol generally resolve when the drug is stopped.

5. Schild HS, Fox BC. Rapid-onset reversible ocular toxicity from ethambutol therapy. *Am J Med* 1991; **90:** 404–6.

Effects on the kidneys. Interstitial nephritis has been reported[1,2] in 5 patients receiving ethambutol and isoniazid; 3 were also receiving additional antimycobacterials. In another patient, acute renal failure occurred secondary to interstitial nephritis which was thought to have been induced by ethambutol.[3]

1. Collier J, *et al*. Two cases of ethambutol nephrotoxicity. *BMJ* 1976; **2:** 1105–6.
2. Stone WJ, *et al.* Acute diffuse interstitial nephritis related to chemotherapy of tuberculosis. *Antimicrob Agents Chemother* 1976; **10:** 164–72.
3. García-Martín F, *et al.* Acute interstitial nephritis induced by ethambutol. *Nephron* 1991; **59:** 679–80.

Effects on the liver. Although transient abnormalities in liver function commonly occur during the early stages of antituberculosis treatment, drugs other than ethambutol are generally considered responsible. Ethambutol has generated fewer reports of hepatotoxicity to the UK CSM than rifampicin, isoniazid, or pyrazinamide,[1] and the use of regimens containing ethambutol has been recommended for patients unable to tolerate standard regimens due to hepatotoxicity.[1-3]

Effects on the skin. Toxic epidermal necrolysis[1] and lichenoid[2] and erythema multiforme-type drug eruptions[3] have been associated with the use of ethambutol. Delayed hypersensitivity reactions have also been reported.[4] Licensed product information notes that Stevens-Johnson syndrome and dermatitis have also occurred.

4. Bakkum RSLA, *et al.* Delayed-type hypersensitivity reaction to ethambutol and isoniazid. *Contact Dermatitis* 2002; **46:** 359.

Hyperuricaemia. In a controlled study of 71 patients receiving ethambutol 20 mg/kg daily orally with other antimycobacterials, serum-uric acid concentrations increased in 66, mainly in the first 2 weeks of treatment.[1] One patient experienced arthralgia and another acute gouty arthritis. Serum-uric acid concentrations did not change in 60 control patients receiving other antimycobacterials.

1. Khanna BK, Gupta VP. Ethambutol-induced hyperuricaemia. *Tubercle* 1984; **65:** 195–9.

Precautions

Ethambutol is generally contra-indicated in patients with optic neuritis. It should be used with great care in patients with visual defects, the elderly, and in children in whom evaluation of changes in visual acuity may be difficult (see also Children, below). Ocular examination is recommended before treatment with ethambutol and some consider that regular examinations are necessary during treatment, especially in children. Patients should be advised to report visual disturbances immediately and to stop ethambutol pending visual evaluation.

Ethambutol should be given in reduced dosage to patients with renal impairment and dosage adjustments may need to be made according to serum concentrations. The *BNF* recommends peak concentrations of 2 to 6 mg/L and trough concentrations of less than 1 mg/L.

Ethambutol may precipitate attacks of gout.

Although ethambutol crosses the placenta and may be teratogenic in *animals*, problems in humans have not been documented. It is generally considered that the benefits of ethambutol in the treatment of tuberculosis outweigh any potential risks in pregnancy.

Breast feeding. Ethambutol distributes into breast milk to produce concentrations similar to those in plasma. However, no adverse effects have been seen in breast-fed infants whose mothers were receiving ethambutol, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 03/10/07)

Children. Due to the possible difficulty of evaluating changes in visual acuity that may be induced in children receiving ethambutol, the *BNFC* advises that it should be used with caution in children under 5 years of age and unable to report visual changes accurately, whereas in the USA licensed product information has advised against use in those under 13 years of age.

The authors of a review of the use of ethambutol in children concluded that no extra precautions were necessary in children aged 5 years or more, and that it could also be used in younger children without undue fear of adverse effects.[1] Another review suggested that visual toxicity is not a particular problem except perhaps when CNS infection is involved.[2] A literature review[3] on the use of ethambutol in children reported almost no ocular toxicity at daily doses of 15 to 30 mg/kg. Ethambutol is therefore considered safe in children of all ages at a daily dose of 20 mg/kg (range 15 to 25 mg/kg) or a three times weekly dose of 30 mg/kg.

Antimicrobial Action

Ethambutol is active against *Mycobacterium tuberculosis* and some other mycobacteria. Resistant strains of *M. tuberculosis* are readily produced if ethambutol is used alone.

Pharmacokinetics

About 80% of an oral dose of ethambutol is absorbed from the gastrointestinal tract. Absorption is not significantly impaired by food (but see also Bioavailability, below). After a single dose of 25 mg/kg peak plasma concentrations of up to 5 mg/L appear within 4 hours, and are less than 1 mg/L by 24 hours.

Ethambutol is distributed to most tissues, including the lungs, kidneys, and erythrocytes. About 10 to 50% may diffuse into the CSF when the meninges are inflamed. It has been reported to cross the placenta and is distributed into breast milk. The elimination half-life after oral doses is about 3 to 4 hours.

Ethambutol is partially metabolised in the liver to the aldehyde and dicarboxylic acid derivatives which are inactive and then excreted in the urine. Most of a dose appears in the urine within 24 hours as unchanged drug and 8 to 15% as the inactive metabolites. About 20% of the dose is excreted unchanged in the faeces.

Bioavailability. Although the absorption of ethambutol is not generally regarded as being impaired by food, a study in 14 healthy subjects[1] suggested that giving it with a high-fat meal or an antacid could delay absorption and reduce the maximum plasma concentration.

1. Peloquin CA, *et al.* Pharmacokinetics of ethambutol under fasting conditions, with food, and with antacids. *Antimicrob Agents Chemother* 1999; **43:** 568–72.

HIV-infected patients. Malabsorption of ethambutol and other antituberculous drugs may occur in patients with HIV infection and tuberculosis, and may contribute to acquired drug resistance and reduced efficacy of tuberculosis treatment. For further information on the absorption of antituberculous drugs in HIV-infected patients see under Rifampicin, p.328.

Pregnancy and breast feeding. Ethambutol crosses the placenta and is present in fetal tissue in amounts of at least 74.5% of the maternal serum concentration.[1] Ethambutol distributes into breast milk to produce concentrations similar to those in plasma.[2]

1. Holdiness MR. Transplacental pharmacokinetics of the antituberculosis drugs. *Clin Pharmacokinet* 1987; **13:** 125–9.
2. Snider DE, Powell KE. Should women taking antituberculosis drugs breast-feed? *Arch Intern Med* 1984; **144:** 589–90.

Uses and Administration

Ethambutol is used with other antituberculous drugs in the primary treatment of pulmonary and extrapulmonary tuberculosis (p.196) to suppress emergence of resistance to the other drugs used in the regimens. It is also used as a component of regimens for the treatment of nontuberculous mycobacterial infections (p.181).

In the treatment of tuberculosis, ethambutol is given, as the hydrochloride, usually with isoniazid, rifampicin, and pyrazinamide in the initial 8-week phase and sometimes in the continuation phase. It is given orally in a single daily dose of 15 mg/kg, or 30 mg/kg three times weekly. Initial doses of ethambutol 25 mg/kg daily for 60 days may be given to patients who have previously had antimycobacterial therapy, reduced to 15 mg/kg daily thereafter.

For details of doses in infants, children, and adolescents, see below. If it is used in patients with renal impairment, doses should be adjusted according to serum concentrations (see Precautions, above).

Fixed-dose combination products have been developed in order to improve patient compliance and avoid monotherapy, thereby decreasing the risk of acquired drug resistance. Combination products containing ethambutol with isoniazid, isoniazid and rifampicin, and isoniazid, rifampicin, and pyrazinamide are available in some countries.

Administration in children. For the treatment of *drug-resistant* tuberculosis in infants, children, and adolescents the American Academy of Pediatrics suggests a dose of ethambutol 15 to 25 mg/kg daily or 50 mg/kg twice weekly (to a maximum of 2.5 g) by mouth.

For *congenitally acquired* tuberculosis in neonates the *BNFC* suggests a dose of 15 mg/kg once daily. For the treatment of children 1 month and older a dose of 15 mg/kg once daily or 30 mg/kg three times a week for the 2 month initial treatment phase is suggested.

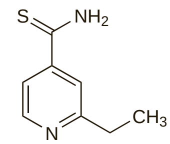
Ethionamide *(BAN, USAN, rINN)*

Ethionamid; Éthionamide; Ethionamidum; 2-Ethylthioisonicotinamide; Etionamid; Etionamida; Etionamidas; Etionamide; Etionamidi; 1314-TH. 2-Ethylpyridine-4-carbothioamide.

Этионамид

$C_8H_{10}N_2S = 166.2.$
CAS — 536-33-4.
ATC — J04AD03.
ATC Vet — QJ04AD03.



Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Ethionamide). Small yellow crystals or a yellow crystalline powder. Practically insoluble in water; sparingly soluble in alcohol; soluble in methyl alcohol.

USP 31 (Ethionamide). A bright yellow powder having a faint to moderate sulfide-like odour. Slightly soluble in water, in chloroform, and in ether; sparingly soluble in alcohol and in propylene glycol; soluble in methyl alcohol. pH of a 1% slurry in water is between 6.0 and 7.0. Store in airtight containers.

Adverse Effects and Treatment

Many patients cannot tolerate therapeutic doses of ethionamide and have to stop treatment. The most common adverse effects are dose-related gastrointestinal disturbances, including nausea, vomiting, diarrhoea, anorexia, excessive salivation, a metallic taste, stomatitis, and abdominal pain. Tolerance may be improved by reducing the dose, adjusting the timing of dosage, or giving an antiemetic.

Mental disturbances including depression, anxiety, and psychosis have been provoked. Dizziness, drowsiness, headache, postural hypotension, and asthenia may also occur occasionally. Peripheral and optic neuropathy, diplopia and blurred vision, and a pellagra-like syndrome have occurred. Pyridoxine or nicotinamide have been suggested for the treatment or prevention of neurotoxic effects. Hepatitis may occur occasionally, with or without jaundice. The incidence of hepatotoxicity is increased when ethionamide is given with rifampicin.

Other adverse effects reported include hypersensitivity reactions, thrombocytopenia and purpura, alopecia, dermatitis (including photodermatitis), endocrine disturbances, hypoglycaemia, and hypothyroidism with or without goitre.

Teratogenic effects have been reported in *animals.*

Effects on the liver. Use of ethionamide or protionamide with rifampicin for the treatment of multibacillary leprosy has been associated with a high incidence of hepatotoxicity. A hepatitis incidence of 4.5 to 5% has been reported for patients on ethionamide or protionamide, rifampicin, and either dapsone or clofazimine.[1,2] In these studies, diagnosis of hepatitis was based on clinical assessment. When laboratory monitoring was used, an incidence of 13% was reported with a regimen of ethionamide or protionamide with rifampicin and dapsone.[3] A regimen of protionamide, dapsone, rifampicin, and clofazimine has been associated with a 22% incidence based on laboratory monitoring.[4] Use of ethionamide with pyrazinamide has also resulted in a high incidence of abnormal liver function tests.[5]

In the above studies rifampicin was given daily during part or all of the regimens. The incidence of hepatotoxicity when ethionamide or protionamide is used with once-monthly rifampicin may be lower; hepatotoxicity was not reported in patients receiving monthly rifampicin and daily protionamide, isoniazid, and dapsone.[6]

2. Pattyn SR, *et al.* Combined regimens of one year duration in the treatment of multibacillary leprosy—II: combined regimens with rifampicin administered during 6 months. *Lepr Rev* 1989; **60:** 118–23.
3. Cartel J-L, *et al.* Hepatitis in leprosy patients treated by a daily combination of dapsone, rifampin, and a thioamide. *Int J Lepr* 1983; **51:** 461–5.
4. Ji B, *et al.* Hepatotoxicity of combined therapy with rifampicin and daily prothionamide for leprosy. *Lepr Rev* 1984; **55:** 283–9.
5. Schless JM, *et al.* The use of ethionamide in combined drug regimens in the re-treatment of isoniazid-resistant pulmonary tuberculosis. *Am Rev Respir Dis* 1965; **91:** 728–37.
6. Ellard GA, *et al.* Long-term prothionamide compliance: a study carried out in India using a combined formulation containing prothionamide, dapsone and isoniazid. *Lepr Rev* 1988; **59:** 163–75.

Precautions

Ethionamide should not be used in severe hepatic impairment. Liver function tests should be carried out before, and regularly during, treatment with ethionamide.

Caution is necessary in patients with depression or other psychiatric illness. Difficulty may be experienced in the management

The symbol † denotes a preparation no longer actively marketed

of diabetes mellitus. Periodic monitoring of blood glucose, thyroid function, and visual function is desirable.

Ethionamide is teratogenic in *animals*.

Porphyria. Ethionamide is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals* or *in-vitro* systems.

Interactions

The adverse effects of other antimycobacterials may be increased when ethionamide is used (see Effects on the Liver, above, and under Cycloserine, Interactions, p.260).

Alcohol. A psychotic reaction has been reported in a patient receiving ethionamide after excessive intake of alcohol.[1]

1. Lansdown FS, *et al.* Psychotoxic reaction during ethionamide therapy. *Am Rev Respir Dis* 1967; **95:** 1053–5.

Antimicrobial Action

Ethionamide is active only against mycobacteria including *Mycobacterium tuberculosis*, *M. kansasii*, *M. leprae*, and some strains of *M. avium* complex.

Resistance develops rapidly if used alone and there is complete cross-resistance between ethionamide and protionamide. Cross-resistance has been reported *in vitro* with isoniazid or with thioacetazone.

Pharmacokinetics

Ethionamide has been given as a sugar-coated tablet or more recently as a more stable film-coated tablet. Both formulations are readily absorbed from the gastrointestinal tract: after an oral dose of 250 mg, sugar-coated tablets produce a peak plasma concentration of about 1.5 micrograms/mL after 1.5 hours, while film-coated tablets give a peak plasma concentration of 2.16 micrograms/mL after about 1 hour. Distribution of ethionamide from the film-coated tablet into body tissues and fluids has not been studied, but is expected to be similar to that of the sugar-coated tablets. Ethionamide from sugar-coated tablets is widely distributed throughout body tissues and fluids. It crosses the placenta and penetrates the uninflamed meninges, appearing in the CSF in concentrations equivalent to those in serum. It is about 30% bound to plasma proteins. The half-life for the sugar-coated tablet is reported to be 2 to 3 hours and 1.92 hours for the film-coated tablet. Ethionamide is extensively metabolised, probably in the liver, to the active sulfoxide and other inactive metabolites and less than 1% of a dose appears in the urine as unchanged drug.

Distribution. After single oral doses of ethionamide 15 or 20 mg/kg in children with tuberculous meningitis, the peak spinal fluid concentration was reached in 1⁄ to 2⁄ hours.[1] A wide range of concentrations was reported but doses of 20 mg/kg were more likely to produce spinal fluid concentrations above 2.5 micrograms/mL, the concentration considered by the authors to be essential for therapeutic success.

1. Donald PR, Seifart HI. Cerebrospinal fluid concentrations of ethionamide in children with tuberculous meningitis. *J Pediatr* 1989; **115:** 483–6.

Uses and Administration

Ethionamide is a thioamide derivative considered to be interchangeable with protionamide. It is used with other antituberculous drugs for the treatment of tuberculosis (p.196) when resistance to primary drugs has developed. It has also been used, as a substitute for clofazimine, in regimens for the treatment of leprosy (p.176) but less toxic alternatives are now preferred.

In the treatment of resistant tuberculosis, adults may be given 15 to 20 mg/kg daily (maximum 1 g daily) orally. Ethionamide may be given in divided doses with meals, or as a single daily dose after the evening meal, or at bedtime, to minimise gastrointestinal adverse effects. For details of doses in infants, children, and adolescents, see below.

Similar doses were used for the treatment of leprosy.

Ethionamide has also been used as rectal suppositories; the hydrochloride has been given intravenously.

Administration in children. For the treatment of drug-resistant tuberculosis in infants, children, and adolescents the American Academy of Pediatrics suggests an oral dose of ethionamide 15 to 20 mg/kg (to a maximum of 1 g) daily, given in 2 to 3 divided doses.

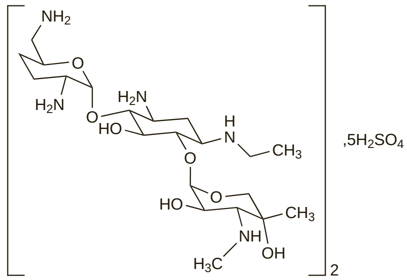
Etimicin Sulfate

Antibiotic 89-07; E-402. 1-*N*-Ethyl gentamicin C_{1a} sulfate.

$(C_{21}H_{43}N_5O_7)_2,5H_2SO_4$ = 1445.6.

CAS — 59711-96-5 (etimicin); 362045-44-1 (etimicin sulfate).



Pharmacopoeias. In *Chin.*

Profile

Etimicin, a derivative of gentamicin C_{1a}, is an aminoglycoside antibacterial with actions similar to those of gentamicin (p.282). It is given intravenously as the sulfate.

Натрий Фаропенем

$C_{12}H_{14}NaNO_5S$ = 307.3.

CAS — 106560-14-9 (faropenem); 141702-36-5 (faropenem medoxomil); 122547-49-3 (faropenem sodium).

Pharmacopoeias. *Jpn* includes the hemipentahydrate.

Profile

Faropenem is a penem antibacterial that is given orally as the sodium salt for the treatment of susceptible infections.

Faropenem medoxomil (*USAN*) (Bay-56-6854) is being investigated for the treatment of respiratory-tract infections and uncomplicated skin and skin structure infections. NOTE. Faropenem medoxomil has also been referred to as faropenem daloxate although such use of the term daloxate is not in keeping with *INN* nomenclature conventions.

Pharmacopoeias. In *Chin.*

Profile

Fleroxacin is a fluoroquinolone antibacterial with actions and uses similar to those of ciprofloxacin (p.243), but is reported to have greater systemic bioavailability and a longer half-life. It is given orally for the treatment of susceptible infections in usual doses of 200 to 300 mg once daily. It has also been given by intravenous infusion.

The incidence of adverse effects associated with fleroxacin has been relatively high.

Breast feeding. The American Academy of Pediatrics[1] states that fleroxacin is usually compatible with breast feeding. However, in a study,[2] in which women were given a single 400-mg dose and breast feeding was withheld for 48 hours, it was concluded that although a breast-fed infant would only receive a moderate amount (maximum 10 mg daily), fleroxacin should not be used in breast-feeding mothers due to the potential for adverse effects such as arthropathy in the infant.

Pharmacopoeias. In *Jpn.*

Profile

Flomoxef is an oxacephalosporin or oxacephem antibacterial with properties similar to latamoxef (p.292). It is given intravenously as the sodium salt and doses are expressed in terms of flomoxef; 1.04 g of flomoxef sodium is equivalent to about 1 g of flomoxef. The usual dose is 1 to 2 g daily in two divided doses.

Натрий Флуклоксациллин

$C_{19}H_{16}ClFN_3NaO_5S,H_2O$ = 493.9.
CAS — 1847-24-1.
ATC — J01CF05.
ATC Vet — QJ01CF05.

Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Flucloxacillin Sodium). A white or almost white, crystalline hygroscopic, powder. Freely soluble in water and in methyl alcohol; soluble in alcohol. A 10% solution in water has a pH of 5.0 to 7.0. Store at a temperature not exceeding 25° in airtight containers.

Incompatibility. As with other penicillins, flucloxacillin sodium is incompatible with aminoglycosides.

Adverse Effects and Precautions

As for Benzylpenicillin p.213.

Hepatitis and cholestatic jaundice have been reported occasionally with flucloxacillin and may be delayed in onset for up to 2 months after treatment has been stopped; older patients and those receiving flucloxacillin for more than 2 weeks are at greater risk. Fatalities have occurred, usually in patients with serious underlying hepatic disease. There have been rare reports of erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis associated with flucloxacillin. Agranulocytosis and neutropenia have been associated rarely with isoxazolyl penicillins such as flucloxacillin. Phlebitis has followed intravenous infusion.

Effects on the liver. In October 2004, the UK CSM issued a reminder[1] that flucloxacillin is associated rarely with an increased risk of hepatitis and cholestatic jaundice. In some patients, almost always those with serious underlying hepatic disease, fatalities have occurred. The onset of hepatic adverse effects may be delayed for up to 2 months after stopping treatment, and is not related to the dose or to the route. Older patients and those receiving flucloxacillin for more than 2 weeks are at increased risk. Flucloxacillin should not be used in patients with a history of hepatic dysfunction related to its use, and should be used only with caution in patients with evidence of other hepatic impairment. Careful enquiry should be made concerning previous hypersensitivity to beta lactams. A cohort study[2] using UK prescription data found that the risk of developing cholestatic liver disease in the 45 days after starting flucloxacillin was 8.5 per 100 000. In contrast to other countries, flucloxacillin continued to be seen as a first-line drug in the UK.

Porphyria. Flucloxacillin has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Sodium content. Each g of flucloxacillin sodium contains about 2 mmol of sodium.

Interactions

As for Benzylpenicillin, p.214.

Antimicrobial Action

Flucloxacillin is bactericidal with a mode of action similar to that of benzylpenicillin, but is resistant to staphylococcal penicillinase. It is active therefore against penicillinase-producing and non-penicillinase-producing staphylococci. Its activity against streptococci such as *Streptococcus pneumoniae* and *Str. pyogenes* is less than that of benzylpenicillin, but sufficient to be useful when these organisms are present with penicillin-resistant staphylococci. Flucloxacillin is virtually ineffective against *Enterococcus faecalis.*

Resistance. The resistance of staphylococci to flucloxacillin and other penicillinase-resistant penicillins is described under meticillin (p.299).

Pharmacokinetics

Flucloxacillin is better absorbed from the gastrointestinal tract than cloxacillin, but absorption is reduced by the presence of food in the stomach. After an oral dose of 0.25 to 1 g, in fasting subjects, peak plasma concentrations in about 1 hour are usually in the range of 5 to 15 micrograms/mL. Plasma concentrations after intramuscular injection of flucloxacillin sodium are similar, but peak concentrations are achieved in about 30 minutes. Doubling the dose can double the plasma concentration. About 95% of flucloxacillin in the circulation is bound to plasma proteins. Flucloxacillin has been reported to have a plasma half-life of approximately 1 hour. The half-life is prolonged in neonates.

The distribution of flucloxacillin into body tissues and fluids is similar to that of cloxacillin (p.256).

Flucloxacillin is metabolised to a limited extent and the unchanged drug and metabolites are excreted in the urine by glomerular filtration and renal tubular secretion. About 66% of an oral dose and 76% of a parenteral dose is excreted in the urine within 8 hours. Only small amounts are excreted in the bile. Flucloxacillin is not removed by haemodialysis or peritoneal dialysis.

Plasma concentrations are enhanced by probenecid.

Uses and Administration

Flucloxacillin is an isoxazolyl penicillin used primarily for the treatment of infections due to staphylococci resistant to benzylpenicillin. These include bone and joint infections, endocarditis, pneumonia, skin infections (including soft-tissue infections), and toxic shock syndrome. For discussions of these infections and their treatment, see under Choice of Antibacterial, p.162.

Administration and dosage. Flucloxacillin is given parenterally and orally as the sodium or magnesium salt. All doses are expressed as flucloxacillin; 1.18 g of flucloxacillin magnesium and 1.09 g of flucloxacillin sodium are each equivalent to about 1 g of flucloxacillin. Oral doses should be taken at least 30 minutes before meals as the presence of food in the stomach reduces absorption. In severe renal impairment a reduction in dosage may be necessary.

The usual adult dose orally or by intramuscular injection is 250 mg four times daily. It is given intravenously in a dose of 0.25 to 1 g four times daily by slow injection over 3 to 4 minutes or by intravenous infusion. All systemic doses may be doubled in severe infections. Up to 8 g daily in 3 or 4 divided doses may be given for osteomyelitis; in endocarditis a dose of 8 g daily in 4 divided doses may be given to patients weighing up to 85 kg, and 12 g daily in 6 divided doses may be used in those weighing more.

Flucloxacillin has been given by other routes in conjunction with systemic therapy. It has been given in a dose of 250 to 500 mg daily by intra-articular injection, dissolved if necessary in a 0.5% solution of lidocaine hydrochloride, or by intrapleural injection in a dose of 250 mg daily. Using powder for injection, 125 to 250 mg has been dissolved in 3 mL of sterile water and inhaled by nebuliser 4 times daily.

Children up to 2 years of age may be given one-quarter the adult dose and those aged 2 to 10 years one-half the adult dose.

Flucloxacillin may be used with other antibacterials, including ampicillin (known as co-fluampicil), to produce a wider spectrum of activity. If flucloxacillin is given with an aminoglycoside the two drugs should not be mixed.

Preparations

BP 2008: Co-fluampicil Capsules; Co-fluampicil Oral Suspension; Flucloxacillin Capsules; Flucloxacillin Injection; Flucloxacillin Oral Solution; Flucloxacillin Oral Suspension.

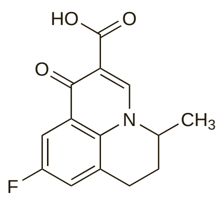
Flumechin; Flumekiini; Flumekin; Flumekvinas; Flumequina; Fluméquine; Flumequinum; R-802. 9-Fluoro-6,7-dihydro-5-methyl-1-oxo-1*H*,5*H*-pyrido[3,2,1-*ij*]quinoline-2-carboxylic acid.

Флумехин

$C_{14}H_{12}FNO_3$ = 261.2.
CAS — 42835-25-6.
ATC — J01MB07.
ATC Vet — QJ01MB07.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Flumequine). A white or almost white microcrystalline powder. Practically insoluble in water; sparingly soluble in dichloromethane; very slightly soluble in methyl alcohol; freely soluble in dilute solutions of alkali hydroxides.

Profile

Flumequine is a 4-quinolone antibacterial with actions and uses similar to those of nalidixic acid (p.303). It may be more active *in vitro* against some Enterobacteriaceae. In the treatment of urinary-tract infections doses of 400 mg are given orally 3 times daily.

Porphyria. Flumequine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Preparations

Proprietary Preparations (details are given in Part 3)

Фосфомицин Трометамол

$C_3H_7O_4P,C_4H_{11}NO_3$ = 259.2.
CAS — 78964-85-9.
ATC — J01XX01.
ATC Vet — QJ01XX01.

Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Fosfomycin Trometamol). A white or almost white, hygroscopic powder. Very soluble in water; slightly soluble in alcohol and in methyl alcohol; practically insoluble in acetone. A 5% solution in water has a pH of 3.5 to 5.5. Store in airtight containers.

Adverse Effects and Precautions

Gastrointestinal disturbances including nausea and diarrhoea, transient increases in serum concentrations of aminotransferases, headache, visual disturbances, and skin rashes have been reported after use of fosfomycin. Eosinophilia and, rarely, angioedema, aplastic anaemia, exacerbation of asthma, cholestatic jaundice, hepatic necrosis, and toxic megacolon, have also occurred.

Antimicrobial Action

Fosfomycin is a bactericidal antibacterial. After active uptake into the cell it is reported to interfere with the first step in the synthesis of bacterial cell walls. It is active *in vitro* against a range of Gram-positive and Gram-negative bacteria including *Staphylococcus aureus*, some streptococci, most Enterobacteriaceae, *Haemophilus influenzae*, *Neisseria* spp., and some strains of *Pseudomonas aeruginosa* although some are resistant. *Bacteroides* spp. are not sensitive.

Bacterial resistance to fosfomycin has been reported and can be chromosomal or, in some organisms, transferred by plasmids encoding multiple resistance (for example in *Serratia marcescens*). However, there appears to be little cross-resistance with other antibacterials.

Fosfomycin has been reported to show antimicrobial synergy with a wide range of antibacterials against organisms such as enterococci, meticillin-resistant *Staph. aureus*, and the enterobacteria. Such synergistic effects have been reported particularly with the beta lactams, but also with aminoglycosides, macrolides, tetracyclines, chloramphenicol, rifamycin, and lincomycin. Antimicrobial antagonism with a beta lactam has also been reported.

There is some suggestion that use of fosfomycin with an aminoglycoside may also reduce the nephrotoxicity of the latter *in vivo*.

◊ References.

1. Barry AL, Brown SD. Antibacterial spectrum of fosfomycin trometamol. *J Antimicrob Chemother* 1995; **35:** 228–30.

Pharmacokinetics

Fosfomycin or fosfomycin calcium are poorly absorbed from the gastrointestinal tract. Peak plasma concentrations 4 hours after a 1-g dose of fosfomycin calcium are about 7 micrograms/mL, and bioavailability has been calculated at about 30 to 40%. Similar bioavailability has been reported for the trometamol salt, and plasma concentrations of about 22 to 32 micrograms/mL have been reported 2 hours after an oral dose equivalent to 3 g fosfomycin. Fosfomycin disodium is given intramuscularly or intravenously: intravenous infusion of a 4-g dose results in peak plasma concentrations of around 120 micrograms/mL. The plasma half-life is about 2 hours. Fosfomycin does not appear to be bound to plasma proteins. It crosses the placenta and is widely distributed in body fluids including the CSF; small amounts have been found in breast milk and bile. The majority of a parenteral dose is excreted unchanged in the urine, by glomerular filtration, within 24 hours.

Urinary concentrations of up to 3 mg/mL have been reported within 2 to 4 hours of an oral dose of fosfomycin trometamol equivalent to 3 g of fosfomycin; therapeutic concentrations of 200 to 300 micrograms/mL remained in urine after 48 hours.

◊ References.

1. Bergan T, *et al.* Pharmacokinetic profile of fosfomycin trometamol. *Chemotherapy* 1993; **39:** 297–301.

Uses and Administration

Fosfomycin is a phosphonic acid antibacterial given orally as the trometamol or calcium salt and intramuscularly or intravenously as the disodium salt in the treatment of a variety of bacterial infections due to susceptible organisms. Doses are expressed in terms of the base; fosfomycin calcium 1.4 g, fosfomycin sodium 1.3 g, and fosfomycin trometamol 1.9 g are each equivalent to about 1 g of fosfomycin.

In the treatment of acute uncomplicated infections of the urinary tract (p.199), fosfomycin trometamol is given as a single dose equivalent to 3 g of fosfomycin. Fosfomycin trometamol has also been used for the prophylaxis of infection in transurethral surgical procedures. For a discussion of surgical infections and their prophylaxis and treatment, see p.195.

The usual oral dose of fosfomycin calcium is the equivalent of 0.5 to 1 g of fosfomycin every 6 to 8 hours. Higher doses have been given parenterally as the sodium salt, with up to 20 g daily having been given intravenously in severe infection.

Fosfomycin has also been used with beta lactam antibacterials.

ATC Vet — QD09AA01; QR01AX08; QS01AA07.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Framycetin Sulphate). A substance produced by growth of selected strains of *Streptomyces fradiae* or *S. decaris* or obtained by any other means. It contains not more than 3% of neomycin C (p.305) and loses not more than 8% of its weight on drying. A white or yellowish-white, hygroscopic powder. The potency is not less than 630 units of neomycin B per mg, calculated with reference to the dried substance. Freely soluble in water; very slightly soluble in alcohol; practically insoluble in acetone. A 1% solution in water has a pH of 6.0 to 7.0. Store in airtight containers. Protect from light.

Profile

Framycetin is an aminoglycoside antibiotic which forms the major component of neomycin (p.305) and has similar actions and uses. Framycetin sulfate is used topically in usual concentrations of 1% for the treatment of infections of the skin, and in concentrations of 0.5% for infections of the eye and ear. It is often used with other antibacterials and corticosteroids in topical preparations.

Framycetin sulfate is poorly absorbed from the gastrointestinal tract and has been given orally for the treatment of gastrointestinal infections and pre-operatively for bowel preparation. It has sometimes been given prophylactically as part of regimens for the selective decontamination of the digestive tract in patients in intensive care.

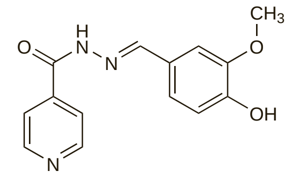
Ftivazide *(rINN)*

Ftivazida; Ftivazidum; Phthivazid; Phthivazidum. 2′-Vanillylideneisonicotinohydrazide monohydrate.

Фтивазид

$C_{14}H_{13}N_3O_3,H_2O$ = 289.3.

CAS — 149-17-7 (anhydrous ftivazide).



(anhydrous ftivazide)

Pharmacopoeias. In *Chin.* and *Int.*

Profile

Ftivazide is an antimycobacterial given orally in the treatment of tuberculosis. It is a derivative of isoniazid.

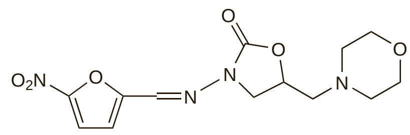
Furaltadone Hydrochloride *(BANM, rINNM)*

Furaltadone, Chlorhydrate de; Furaltadoni Hydrochloridum; Hidrocloruro de furaltadona. (±)-5-Morpholinomethyl-3-(5-nitrofurfurylideneamino)oxazolidin-2-one hydrochloride.

Фуральтадона Гидрохлорид

$C_{13}H_{16}N_4O_6,HCl$ = 360.8.

CAS — 139-91-3 (furaltadone); 59302-14-6 (±-furaltadone).



(furaltadone)

Pharmacopoeias. *Fr.* includes Furaltadone for veterinary use.

Profile

Furaltadone was formerly given orally as an antibacterial but was later withdrawn owing to its toxic effects. Furaltadone hydrochloride is still used topically in preparations for ear disorders. Furaltadone has been used in veterinary medicine.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Indon.:*** Otozambon; ***Thai.:*** Otosamthong.

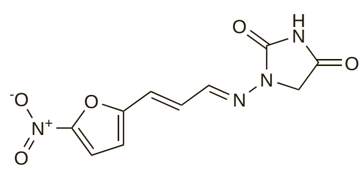
Furazidin

Akritoin; Furagin; Furazidine. 1-{[3-(5-Nitro-2-furyl)allylidene]amino}hydantoin.

Фуразидин

$C_{10}H_8N_4O_5$ = 264.2.

CAS — 1672-88-4.



Profile

Furazidin is a nitrofuran antibacterial with properties similar to those of nitrofurantoin. It is used in the treatment of urinary-tract infections. A usual oral dose is 100 mg given four times daily for one day followed by 100 mg given three times daily for 7 to 8 days.

Preparations

Proprietary Preparations (details are given in Part 3)

Pol.: Furaginum.

Fusafungine *(BAN, rINN)*

Fusafungin; Fusafungina; Fusafunginum.

Фузафунгин

CAS — 1393-87-9.

ATC — R02AB03.

ATC Vet — QR02AB03.

Profile

Fusafungine is a depsipeptide antibacterial produced by *Fusarium lateritium* strain 437. It is active against some Gram-positive and Gram-negative organisms, *Candida albicans*, and *Mycoplasma pneumoniae*. It has also been stated to possess anti-inflammatory activity.

It is used in the form of an aerosol spray in the treatment of infections of the upper respiratory tract, inhaled in usual doses of 500 micrograms every 4 hours into each nostril or via the mouth. These routes may be used simultaneously if necessary.

Preparations

Proprietary Preparations (details are given in Part 3)

Fusidic Acid *(BAN, USAN, rINN)*

Acide fusidique; Ácido fusídico; Acidum fusidicum; Acidum Fusidicum Hemihydricum; Fucidinsyra; Fusidiinihappo; Fusidik Asit; Fusidinsyra; Fuzidinsav; Fuzido rūgštis; Kyselina fusidová hemihydrát; SQ-16603. *ent*-16α-Acetoxy-3β-dihydroxy-4β,8β,14α-trimethyl-18-nor-5β,10α-cholesta-(17*Z*)-17(20),24-dien-21-oic acid hemihydrate.

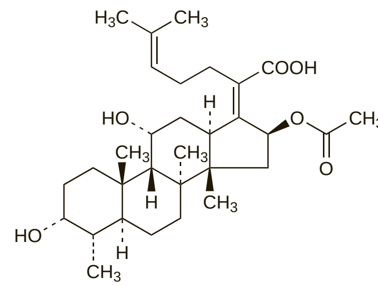
Фузидовая Кислота

$C_{31}H_{48}O_6,\frac{1}{2}H_2O$ = 525.7.

CAS — 6990-06-3 (anhydrous fusidic acid).

ATC — D06AX01; D09AA02; J01XC01; S01AA13.

ATC Vet — QD06AX01; QD09AA02; QJ01XC01; QS01AA13.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Fusidic Acid). An antimicrobial substance produced by the growth of certain strains of *Fusidium coccineum* or by any other means. A white or almost white crystalline powder. Practically insoluble in water; freely soluble in alcohol. Store at a temperature of 2° to 8°. Protect from light.

Sodium Fusidate *(BANM, rINNM)*

Fusidate de Sodium; Fusidate Sodium *(USAN)*; Fusidato sódico; Natrii fusidas; Natrio fuzidatas; Natriumfusidaatti; Natriumfusidat; Natrium-fusidát; Nátrium-fuzidát; Sodium, fusidate de; Sodyum Fusidat; SQ-16360.

Натрий Фузидат

$C_{31}H_{47}NaO_6$ = 538.7.

CAS — 751-94-0.

ATC — D06AX01; D09AA02; J01XC01; S01AA13.

ATC Vet — QD06AX01; QD09AA02; QJ01XC01; QS01AA13.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*

Ph. Eur. 6.2 (Sodium Fusidate). A white or almost white, slightly hygroscopic, crystalline powder. Freely soluble in water and in alcohol. A 1.25% solution in water has a pH of 7.5 to 9.0. Store in airtight containers at a temperature of 2° to 8°. Protect from light.

Incompatibility. UK licensed product information states that reconstituted sodium fusidate injection is incompatible with infusion solutions containing glucose 20% or more, lipid infusions, and peritoneal dialysis fluids; precipitation may occur in solutions with a pH of less than 7.4.

Adverse Effects and Precautions

Apart from mild gastrointestinal upsets, fusidic acid or sodium fusidate appear to be well tolerated when given orally. Treatment with fusidates, orally or especially by the intravenous route, has been associated with jaundice and changes in liver function; normal liver function is usually restored when treatment is stopped. Therefore, fusidates should be given with caution to patients with hepatic impairment, and periodic monitoring of hepatic function is recommended in these patients and in those receiving high or prolonged oral doses. Caution is also required in biliary disease or biliary obstruction.

Venospasm, thrombophlebitis, and haemolysis have occurred in patients given fusidates intravenously. To reduce this it is recommended that solutions be buffered and that the solution should be given as a slow infusion into a large vein where there is a good blood flow. Hypocalcaemia has occurred after use of intravenous doses above those recommended, and has been attributed to the phosphate-citrate buffer in the preparation. Intramuscular or subcutaneous use may lead to tissue necrosis and is contra-indicated.

Hypersensitivity reactions in the form of rashes and irritation may occur with topical fusidates; rash is rare after systemic use.

Fusidic acid competes with bilirubin for binding to albumin *in vitro* and caution has been advised if it is given to premature, jaundiced, acidotic, or seriously-ill neonates because of the risk of kernicterus.

Effects on the blood. There have been occasional reports of granulocytopenia[1-3] and thrombocytopenia[3] after the use of fusidic acid systemically. Sideroblastic anaemia has also been reported.[4] UK licensed product information also states that there have been isolated cases of neutropenia, agranulocytosis, and pancytopenia.

4. Vial T, *et al.* Sideroblastic anaemia during fusidic acid treatment. *Eur J Haematol* 2004; **72:** 358–60.

Interactions

Although the exact metabolic pathways of fusidic acid are not known, an interaction has been suspected with drugs metabolised by the hepatic cytochrome P450 isoenzyme CYP3A4, and UK licensed product information suggests avoiding their use with fusidic acid.

Antivirals. An HIV-infected patient had fusidic acid toxicity after taking fusidic acid orally for one week with his usual antiretroviral treatment of *ritonavir, saquinavir*, and stavudine.[1] The plasma-fusidic acid concentration was about twice that expected and the ritonavir and saquinavir concentrations were also elevated. Fusidic acid was stopped and the patient initially improved. However, 4 days later he presented with jaundice, nausea, weakness, and further increases in liver function tests and hence all medications were stopped. The fusidic acid concentration, as well as those of ritonavir and saquinavir, were found to be still significantly elevated 6 days after fusidic acid had been stopped. The patient was able to restart his antiretroviral therapy later with no problems. The authors suggested that this interaction may be due to mutual inhibition of metabolism between the HIV-protease inhibitors and fusidic acid, and recommended that use of fusidic acid with either saquinavir or ritonavir should be avoided.

1. Khaliq Y, *et al.* A drug interaction between fusidic acid and a combination of ritonavir and saquinavir. *Br J Clin Pharmacol* 2000; **50:** 82–3.

Statins. For reference to the effect of fusidic acid in patients receiving statins, see p.1392.

Antimicrobial Action

Fusidic acid is a steroidal antibacterial with a bacteriostatic or bactericidal activity, mainly against Gram-positive bacteria.

Fusidic acid inhibits bacterial protein synthesis although, in contrast to drugs such as the macrolides or tetracyclines, it does not bind to the bacterial ribosome, but inhibits a factor necessary for translocation of peptide subunits and elongation of the peptide chain. It is capable of inhibiting protein synthesis in mammalian cells but exerts a selective action against susceptible infecting organisms because of poor penetration into the host cell.

Fusidic acid is very active against staphylococci, notably *Staph. aureus* and *Staph. epidermidis* (including meticillin-resistant strains). *Nocardia asteroides* and many clostridial strains are also highly susceptible. The streptococci and enterococci are less susceptible.

Most Gram-negative bacteria are intrinsically resistant but fusidic acid is active against *Neisseria* spp. and *Bacteroides fragilis*. It has some activity against strains of *Mycobacterium tuberculosis* and is highly active against *M. leprae*.

Fungi are resistant, but fusidic acid has some activity against a range of protozoa including *Giardia lamblia* and *Plasmodium falciparum*. High concentrations of fusidate are reported to inhibit viral growth *in vitro*, including that of HIV, although it is unclear whether this represents a surfactant effect, a general cytotoxic effect, or a genuine antiviral action.

No synergy has been shown *in vitro* in most studies between fusidic acid and rifampicin or vancomycin, and antagonism of the effects of ciprofloxacin has been reported. Interactions with the penicillins are complex, with either antagonism of the effect of one or both drugs, or no interaction. However, use of an antistaphylococcal penicillin with fusidic acid may prevent the emergence of fusidic acid-resistant staphylococcal mutants, and such combinations may be clinically effective.

Resistance. Resistance may be chromosomally mediated, representing altered protein synthesis, or plasmid-mediated, which appears to be due to reduced penetration of active drug into the cell. For further details on the increase of resistance to fusidic acid, see below.

Resistance. There has been an increase in the number of reports of fusidic acid resistance in *Staphylococcus aureus* particularly in dermatological isolates. The number of clinical isolates of initially resistant staphylococci has historically been low at about 1 to 2% overall.[1-3] However, in the UK the rate of fusidic acid resistance in staphylococcal isolates increased by up to 200% during the 1990s, and over half of all isolates are resistant in some samples.[3] This has been attributed to the widespread topical use of fusidic acid.[1-3]

The rate of resistance to short courses of fusidic acid used in systemic monotherapy is reported to be about 5%. In contrast, when given systemically with other antibacterials, the rate of resistance remains low at 0.8%.[4] Therefore, it has been suggested that systemic fusidic acid should be restricted to use with other antibacterial agents where clinically indicated in order to reduce the rate of resistance.[3,4]

Pharmacokinetics

Sodium fusidate is well absorbed from the gastrointestinal tract, and a single oral 500-mg dose is reported to produce mean plasma concentrations of about 30 micrograms/mL within 2 to 4 hours, although there is considerable interindividual variation. Oral suspensions of fusidic acid are less well absorbed, with a bioavailability reported to be about 70% of that for sodium fusidate. Absorption may be delayed by food and may be more rapid in children than adults. Some accumulation occurs with repeated dosage and plasma concentrations of 100 micrograms/mL or more have been reported after 500 mg of sodium fusidate given three times daily for 4 days.

Fusidate is widely distributed into tissues and body fluids, including bone, pus, and synovial fluid; it penetrates cerebral abscesses but does not enter CSF in appreciable amounts. It has been found in the fetal circulation and in breast milk. About 95% or more of fusidate in the circulation is bound to plasma proteins.

Fusidate has a plasma half-life of about 10 to 15 hours. It is excreted in the bile, almost entirely as metabolites, some of which have weak antimicrobial activity. About 2% appears unchanged in the faeces. Little is excreted in the urine or removed by haemodialysis.

Uses and Administration

Fusidic acid and its salts are antibacterials used mainly in the treatment of staphylococcal infections, often with other drugs. They have been used in the treatment of abscess, including brain abscess, in bone and joint infections, in staphylococcal infections in patients with cystic fibrosis, in the treatment of staphylococcal endocarditis, and topically in eye infections and infections of the skin. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

The fusidates are given orally or topically as fusidic acid or sodium fusidate, or intravenously as sodium fusidate. Sodium fusidate 1 g is equivalent to about 0.98 g of fusidic acid. Because of differences in absorption (see Pharmacokinetics, above) 250 mg of fusidic acid is therapeutically equivalent to only 175 mg of the sodium salt, so doses of fusidic acid suspension (commonly used in children) appear relatively higher (see below). The diolamine salt was formerly used intravenously in humans but is still used in topical preparations in veterinary medicine.

Sodium fusidate is given as tablets in a usual oral adult dose of 500 mg every 8 hours, although this dose may be doubled in severe infection. For cutaneous staphylococcal infections, a dose of 250 mg twice daily is suitable. When given orally as the suspension the usual adult dose is 750 mg of fusidic acid three times daily.

In severe infections in adults weighing over 50 kg, sodium fusidate 500 mg is given three times daily by slow intravenous infusion. Each 500-mg dose is usually given as a buffered solution (pH 7.4 to 7.6) diluted to 500 mL with sodium chloride or other suitable intravenous solution. For those weighing less than 50 kg, a dose of 6 to 7 mg/kg three times daily is used. For details of doses in children, see below.

Sodium fusidate as a 2% ointment or medicated dressing, or fusidic acid as a 2% cream or gel, are used in the local treatment of skin infections. Eye drops containing fusidic acid 1% are used in eye infections. Topical use may lead to problems of resistance (see Antimicrobial Action, above).

Administration in children. In the UK, the licensed *oral* doses of **fusidic acid suspension**, given three times daily, are:

- up to 1 year old: about 15 mg/kg
- 1 to 5 years: 250 mg
- 5 to 12 years: 500 mg
- over 12 years: usual adult doses (see above)

Suggested doses of **sodium fusidate** by *intravenous* infusion are:

- 1 month and above: if weighing less than 50 kg, 6 to 7 mg/kg three times daily; heavier children may be given usual adult doses (see above)

The *BNFC* suggests that neonates up to 1 month of age may be given an intravenous dose of 10 mg/kg every 12 hours.

Preparations

BP 2008: Fusidic Acid Cream; Fusidic Acid Eye Drops; Fusidic Acid Oral Suspension; Sodium Fusidate Ointment.

Garenoxacin Mesilate *(BANM, rINNM)*

BMS-284756-01; Garenoxacin Mesylate *(USAN)*; Garénoxacine, Mésilate de; Garenoxacini Mesilas; Mesilato de garenoxacino; T-3811ME. 1-Cyclopropyl-8-(difluoromethoxy)-7-[(1*R*)-1-methyl-2,3-dihydro-1*H*-isoindol-5-yl]-4-oxo-1,4-dihydroquinoline-3-carboxylic acid methanesulfonate monohydrate.

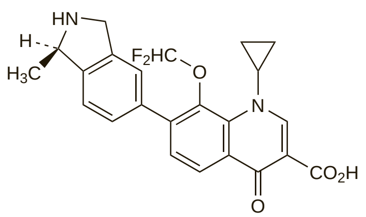
Гареноксацина Мезилат

$C_{23}H_{20}F_2N_2O_4,CH_4O_3S,H_2O = 540.5.$

CAS — 194804-75-6 (garenoxacin); 223652-82-2 (garenoxacin mesilate); 223652-90-2 (garenoxacin mesilate monohydrate).

ATC — J01MA19.

ATC Vet — QJ01MA19.



(garenoxacin)

Profile

Garenoxacin is a fluoroquinolone antibacterial with properties similar to those of ciprofloxacin (p.247). Garenoxacin is used as the mesilate but doses are given in terms of the base: about 507 mg of the mesilate is equivalent to 400 mg of garenoxacin. It is given orally in the treatment of susceptible infections in usual doses equivalent to 400 mg of garenoxacin daily.

Gatifloxacin *(USAN, rINN)*

AM-1155; BMS-206584-01; CG-5501; Gatifloxacine; Gatifloxacino; Gatifloxacinum. (±)-1-Cyclopropyl-6-fluoro-1,4-dihydro-8-methoxy-7-(3-methyl-1-piperazinyl)-4-oxo-3-quinolinecarboxylic acid sesquihydrate.

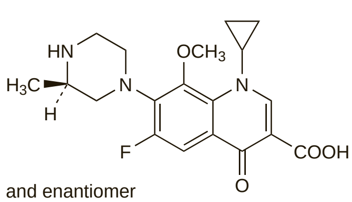
Гатифлоксацин

$C_{19}H_{22}FN_3O_4,1\frac{1}{2}H_2O = 402.4.$

CAS — 160738-57-8 (anhydrous gatifloxacin); 180200-66-2 (gatifloxacin sesquihydrate).

ATC — J01MA16; S01AX21.

ATC Vet — QJ01MA16; QS01AX21.



and enantiomer

Adverse Effects and Precautions

As for Ciprofloxacin, p.244.

Symptomatic hyperglycaemia and/or hypoglycaemia have been reported in patients (usually diabetics) taking gatifloxacin. However, hypoglycaemia, and particularly hyperglycaemia, have occurred in non-diabetic patients. Severe life-threatening events, including hyperosmolar nonketotic hyperglycaemic coma, diabetic ketoacidosis, hypoglycaemic coma, convulsions, and mental status changes have been reported very rarely. Although in most cases the blood-glucose disturbance was reversible, fatalities have been reported. Gatifloxacin should not be given to diabetic patients. Other risk factors for developing blood-glucose disturbances include older age (patients 65 years of age or over), renal impairment, or use of other drugs that alter blood-glucose concentrations, particularly hypoglycaemics. Patients with risk factors should have their blood-glucose concentrations closely monitored and if signs or symptoms of glucose disturbances develop, gatifloxacin should be stopped.

Effects on glucose metabolism. Hypoglycaemia and hyperglycaemia have been associated with gatifloxacin in both diabetic and non-diabetic patients.[1-6] A review[7] of spontaneous adverse effects reported to the FDA in the USA between November 1997 and September 2003 found the rate of blood-glucose disturbances with gatifloxacin to be 10-fold higher when compared with ciprofloxacin, levofloxacin, and moxifloxacin. Subsequent population-based case-control studies[8] in elderly patients given fluoroquinolones (ciprofloxacin, gatifloxacin, levofloxacin, or moxifloxacin), second-generation cephalosporins, or macrolides also found an increased risk of blood-glucose disturbances with gatifloxacin.

While blood-glucose disturbances appear to be mainly associated with gatifloxacin, the possibility that they may also be a class effect of fluoroquinolones cannot be excluded; patients most at risk are the elderly, those with diabetes and/or those taking hypoglycaemic drugs, and patients with impaired renal function.[9] Twenty two case reports of dysglycaemia associated with the use of levofloxacin were received by Health Canada between January 1997 and June 2006; reported cases included 15 diabetic patients.[10] In contrast a review of the effects of moxifloxacin on blood glucose, including data from large postmarketing studies, suggested it had no significant effect.[11]

Interactions

As for Ciprofloxacin, p.246.

Use of gatifloxacin with drugs that alter blood-glucose concentrations increases the risk of blood-glucose disturbances.

Antidiabetics. Given the adverse effects of gatifloxacin, pharmacodynamic interactions with antidiabetics might reasonably be anticipated. Severe and persistent hypoglycaemia occurred in 3 patients taking oral hypoglycaemics (*repaglinide*, *glibenclamide* and *pioglitazone*, and *glimepiride*) when gatifloxacin was added to their therapy.[1]

1. Menzies DJ, *et al.* Severe and persistent hypoglycemia due to gatifloxacin interaction with oral hypoglycemic agents. *Am J Med* 2002; **113:** 232–4.

Antimicrobial Action

As for Ciprofloxacin, p.246.

Gatifloxacin is reported to have greater activity against Gram-positive bacteria, including pneumococci, than ciprofloxacin.

◊ References.

1. Stein GE, *et al.* Bactericidal activities of methoxyfluoroquinolones gatifloxacin and moxifloxacin against aerobic and anaerobic respiratory pathogens in serum. *Antimicrob Agents Chemother* 2003; **47:** 1308–12.

Pharmacokinetics

Gatifloxacin is readily absorbed from the gastrointestinal tract with an absolute bioavailability of 96%. Peak plasma concentrations occur within 1 to 2 hours of an oral dose. Gatifloxacin is widely distributed into body tissues and is about 20% bound to plasma proteins. It undergoes limited metabolism and has an elimination half-life of 7 to 14 hours. Gatifloxacin is excreted primarily unchanged in the urine with less than 1% as metabolites. About 5% is also excreted unchanged in the faeces. Distribution into milk occurs in *animals*.

Uses and Administration

Gatifloxacin is a fluoroquinolone antibacterial with actions and uses similar to those of ciprofloxacin (p.247).

It is given orally, or by intravenous infusion as a 2 mg/mL solution over 60 minutes, for the treatment of susceptible infections, including respiratory- and urinary-tract infections and skin infections. The usual adult dose is 400 mg once daily. A single dose of 400 mg or a dose of 200 mg daily for 3 days may be adequate for uncomplicated urinary-tract infections.

For details of reduced doses to be used in renal impairment, see below.

A single dose of 400 mg may also be given for the treatment of uncomplicated gonorrhoea.

Gatifloxacin is also used as 0.3% eye drops for the treatment of bacterial conjunctivitis.

◊ Reviews.

1. Keam SJ, *et al.* Gatifloxacin: a review of its use in the treatment of bacterial infections in the US. *Drugs* 2005; **65:** 695–724.

Administration in renal impairment. Doses of gatifloxacin should be reduced in patients with renal impairment; the usual initial dose of 400 mg should be followed by reduced maintenance doses of 200 mg daily in those with a creatinine clearance of less than 40 mL/minute and in those on haemodialysis or continuous peritoneal dialysis.

Gemifloxacin Mesilate *(rINNM)*

Gemifloxacin Mesylate *(USAN)*; Gémifloxacine, Mésilate de; Gemifloxacini Mesilas; LB-20304 (gemifloxacin); LB-20304a; Mesilato de gemifloxacino; SB-265805 (gemifloxacin); SB-265805S. (±)-7-[3-(Aminomethyl)-4-oxo-1-pyrrolidinyl]-1-cyclopropyl-6-fluoro-1,4-dihydro-4-oxo-1,8-naphthyridine-3-carboxylic acid 7[4]-(*Z*)-(*O*-methyloxime) methanesulfonate.

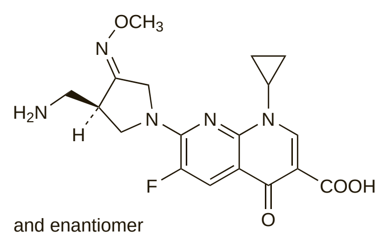
Гемифлоксацина Мезилат

$C_{18}H_{20}FN_5O_4,CH_4O_3S = 485.5.$

CAS — 204519-64-2 (gemifloxacin); 204519-65-3 (gemifloxacin mesilate).

ATC — J01MA15.

ATC Vet — QJ01MA15.



and enantiomer

(gemifloxacin)

Adverse Effects and Precautions

As for Ciprofloxacin, p.244.

Skin rashes may be more common with gemifloxacin and treatment should be stopped if they occur.

Interactions

As for Ciprofloxacin, p.246.

Antimicrobial Action

As for Ciprofloxacin, p.246.

Gemifloxacin is reported to have greater activity against Gram-positive bacteria, including pneumococci, than ciprofloxacin.

◊ References.

1. Morrissey I, Tillotson G. Activity of gemifloxacin against Streptococcus pneumoniae and Haemophilus influenzae. *J Antimicrob Chemother* 2004; **53:** 144–8.

Pharmacokinetics

Gemifloxacin is rapidly absorbed from the gastrointestinal tract with an absolute bioavailability of about 71%. Peak plasma concentrations occur 0.5 to 2 hours after an oral dose. Gemifloxacin is widely distributed into body tissues including the bronchial mucosa and lungs, and is about 55 to 73% bound to plasma proteins. It undergoes limited hepatic metabolism and has an elimination half-life of about 7 hours. It is excreted as unchanged drug and metabolites in the faeces and urine. Urinary excretion is by active tubular secretion and is reduced by probenecid. Distribution into milk has been found in *rats*.

Uses and Administration

Gemifloxacin is a fluoroquinolone antibacterial with actions and uses similar to those of ciprofloxacin (p.247).

It is given orally, as the mesilate, for the treatment of community-acquired pneumonia and acute bacterial exacerbations of chronic bronchitis. Doses are expressed in terms of the base; 399 mg of gemifloxacin mesilate is equivalent to about 320 mg of gemifloxacin. The usual dose is 320 mg once daily for 5 days in patients with bronchitis or for 7 days in those with pneumonia.

For details of reduced doses in patients with renal impairment, see below.

(gentamicin)

NOTE. GNT is a code approved by the BP 2008 for use on single unit doses of eye drops containing gentamicin sulfate where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Gentamicin Sulphate). A mixture of the sulfates of antimicrobial substances produced by *Micromonospora purpurea*, the main components being gentamicins C1, C1a, C2, C2a, and C2b. It contains 20 to 40% of gentamicin C1, 10 to 30% of gentamicin C1a; the sum of gentamicins C2, C2a, and C2b is 40 to 60%. The potency is not less than 590 units/mg, calculated with reference to the anhydrous substance. A white or almost white hygroscopic powder. Freely soluble in water; practically insoluble in alcohol. A 4% solution in water has a pH of 3.5 to 5.5. Store in airtight containers.

USP 31 (Gentamicin Sulfate). The sulfate salt, or a mixture of such salts, of antibiotic substances produced by the growth of *Micromonospora purpurea*. The content of gentamicin C1 is between 25 and 50%, the content of gentamicin C1a is between 10 and 35%, and the sum of the contents of gentamicin C2a and gentamicin C2 is between 25 and 55%. It has a potency equivalent to not less than 590 micrograms of gentamicin per mg, calculated on the dried basis. A white to buff powder. Freely soluble in water; insoluble in alcohol, in acetone, in chloroform, in ether, and in benzene. pH of a 4% solution in water is between 3.5 and 5.5. Store in airtight containers.

Incompatibility. The aminoglycosides are inactivated *in vitro* by various penicillins and cephalosporins via an interaction with the beta-lactam ring, the extent of inactivation depending on temperature, concentration, and duration of contact. The different aminoglycosides vary in their stability, with amikacin apparently the most resistant and tobramycin the most susceptible to inactivation; gentamicin and netilmicin are of intermediate stability. The beta lactams also vary in their ability to produce inactivation, with ampicillin, benzylpenicillin, and antipseudomonal penicillins such as carbenicillin and ticarcillin producing marked inactivation. Inactivation has also been reported with clavulanic acid.

Gentamicin is also incompatible with furosemide, heparin, sodium bicarbonate (the acid pH of gentamicin solutions may liberate carbon dioxide), and some solutions for parenteral nutrition. Interactions with preparations having an alkaline pH (such as sulfadiazine sodium), or drugs unstable at acid pH (for example erythromycin salts), might reasonably be expected.

Given their potential for incompatibility, gentamicin and other aminoglycosides should not generally be mixed with other drugs in syringes or infusion solutions nor given through the same intravenous line. When aminoglycosides are given with a beta lactam, they should generally be given at separate sites.

Stability. There was an average 16% potency loss of gentamicin sulfate from solutions containing 10 and 40 mg/mL when stored at 4° or 25° in plastic disposable syringes for 30 days, and a brown precipitate formed in several. Storage in glass disposable syringes for 30 days produced an average 7% potency loss, which was considered acceptable, but storage for longer resulted in precipitate formation in some cases and was not recommended.[1]

Adverse Effects

The aminoglycosides can produce irreversible, cumulative ototoxicity. This affects both the cochlea (manifest as hearing loss, initially of higher tones, and which, because speech recognition relies greatly on lower frequencies, may not be at first apparent) and the vestibular system (manifest as dizziness or vertigo). The incidence and relative toxicity with different aminoglycosides is a matter of some dispute, but netilmicin is probably less cochleotoxic than gentamicin or tobramycin, and amikacin more so. Netilmicin also exhibits less vestibular toxicity than gentamicin, tobramycin, or amikacin, while streptomycin produces a high incidence of vestibular damage. Vestibular damage is more common than hearing loss in patients receiving gentamicin.

Reversible nephrotoxicity may occur and acute renal failure has been reported, often in association with the use of other nephrotoxic drugs. Renal impairment is usually mild, although acute tubular necrosis and interstitial nephritis have occurred. Decreased glomerular filtration rate is usually seen only after several days, and may even occur after therapy has stopped. Electrolyte disturbances (notably hypomagnesaemia, but also hypocalcaemia and hypokalaemia) have occurred. The nephrotoxicity of gentamicin is reported to be largely due to the gentamicin C_2 component.

Although particularly associated with high plasma concentrations, many risk factors have been suggested for ototoxicity and nephrotoxicity in patients receiving aminoglycosides—see Precautions below.

Aminoglycosides possess a neuromuscular-blocking action and respiratory depression and muscular paralysis have been reported, notably after absorption from serous surfaces. Neomycin has the most potent action and several deaths have been associated with its use.

Hypersensitivity reactions have occurred, especially after local use, and cross-sensitivity between aminoglycosides may occur. Very rarely, anaphylactic reactions to gentamicin have occurred. Some hypersensitivity reactions have been attributed to the presence of sulfites in parenteral formulations, and endotoxic shock has also been reported.

Infrequent effects reported for gentamicin include blood dyscrasias, purpura, nausea and vomiting, stomatitis, and signs of liver dysfunction such as increased serum-aminotransferase values and increased serum-bilirubin concentrations. Neurotoxicity has occurred, with both peripheral neuropathies and central symptoms being reported including encephalopathy, confusion, lethargy, hallucinations, convulsions, and mental depression.

Atrophy or fat necrosis has been reported at injection sites. There have been isolated reports of meningeal irritation, arachnoiditis, polyradiculitis, and ventriculitis after intrathecal, intracisternal, or intraventricular use of aminoglycosides. Subconjunctival injection of gentamicin may lead to pain, hyperaemia, and conjunctival oedema, while severe retinal ischaemia has followed intra-ocular injection.

Endotoxin reactions. Reports of endotoxin reactions associated with intravenous gentamicin have been received by the CDC and the FDA in the USA.[1] Although endotoxin concentrations in the injections used were within USP limits, giving a single daily dose rather than divided doses was thought to have resulted in toxic serum concentrations of endotoxins.[1,2]

1. CDC. Endotoxin-like reactions associated with intravenous gentamicin—California, 1998. *MMWR* 1998; **47:** 877–80.
2. Krieger JA, Duncan L. Gentamicin contaminated with endotoxin. *N Engl J Med* 1999; **340:** 1122.

Treatment of Adverse Effects

Aminoglycosides may be removed by haemodialysis or to a much lesser extent by peritoneal dialysis. Calcium salts given intravenously have been used to counter neuromuscular blockade; the effectiveness of neostigmine has been variable.

◊ For reference to the potential for calcium-channel blockers to reduce aminoglycoside-related nephrotoxicity, see Kidney Disorders, under Uses of Verapamil, p.1424.

Precautions

Gentamicin is contra-indicated in patients with a known history of hypersensitivity to it, and probably in those hypersensitive to other aminoglycosides. It should be avoided in patients with myasthenia gravis, and great care is required in patients with parkinsonism and other conditions characterised by muscular weakness.

The risk of ototoxicity and nephrotoxicity from aminoglycosides is increased at high plasma concentrations and it is therefore generally desirable to determine dosage requirements by individual monitoring. In patients receiving standard multiple-dose regimens of gentamicin, dosage should be adjusted to avoid peak plasma concentrations above 10 micrograms/mL, or trough concentrations (immediately before next dose) exceeding 2 micrograms/mL. Local guidelines on serum concentration should be consulted where once-daily dosage regimens are used. Monitoring is particularly important in patients receiving high doses or prolonged courses, in infants and the elderly, and in patients with renal impairment, who generally require reduced doses. The *BNF* also considers monitoring to be important in patients with cystic fibrosis or significant obesity; again, altered doses may be required. See Pharmacokinetics below for other patient groups in whom pharmacokinetics may be altered. Impaired hepatic function or auditory function, bacteraemia, fever, and perhaps exposure to loud noises have also been reported to increase the risk of ototoxicity, while volume depletion or hypotension, liver disease, or female sex have been reported as additional risk factors for nephrotoxicity. Regular assessment of auditory and renal function is particularly necessary in patients with additional risk factors.

Topical application of gentamicin into the ear is contra-indicated in patients with known or suspected perforation of the ear drum.

Use of aminoglycosides during pregnancy may damage the eighth cranial nerve of the fetus.

Breast feeding. A study[1] involving 10 mothers given gentamicin and their breast-fed infants found measurable gentamicin concentrations in the serum of 5 of the 10 neonates, indicating that appreciable gastrointestinal absorption had occurred. It was, however, considered that these low concentrations would not cause clinical effects and the American Academy of Pediatrics[2] also considers that the use of gentamicin is usually compatible with breast feeding.

Interference with assay procedures. The implications of drug interference with assays for aminoglycosides have been reviewed.[1] Other antimicrobials and antineoplastics may alter the results of microbiological assays but this can be overcome by selection of an appropriate assay organism.

Microbiological assays for aminoglycosides in samples also containing *imipenem* could be accomplished by using cysteine hydrochloride to inactivate imipenem, since it is stable to most beta-lactamases and resistant strains are extremely rare.[2] Because aminoglycosides may be inactivated by *penicillins* and *cephalosporins*, it has been recommended that aminoglycoside sampling times should be chosen to coincide with a trough plasma concentration for the beta lactam. Samples should be frozen if there is to be a delay before they are assayed[3] or a penicillinase added. However, one group of workers have reported loss of gentamicin activity after storage at −60° before assay.[4] Furthermore, there have been reports that concentrations of aminoglycosides in patients also receiving beta lactams have been overestimated using a homogeneous enzyme immunoassay, probably because of an inability to differentiate between active drug and inactivated products.[5,6]

The radionuclide *gallium-67* interferes with radio-enzymatic assays, and it has been suggested that an agar diffusion method should be used in patients who have received a gallium scan.[7,8]

Heparin has been shown to produce underestimation of aminoglycoside concentrations when using microbiological, enzymatic, or immunoassays.[9-11] It has been recommended that either serum should be used or that blood samples should not be collected in heparinised tubes or from indwelling catheter lines. Some consider that concentrations of heparin reached in the blood of patients receiving heparin are too low to affect gentamicin.[12]

Falsely low concentrations have also been reported in microbiological assays in the presence of *zinc* salts.[13]

Heat treatment of whole *blood* to inactivate human immunodeficiency virus leads to an increase in the concentration of gentamicin subsequently found on assay.[14]

Interactions

Use of other nephrotoxic drugs (including other aminoglycosides, vancomycin, some cephalosporins, ciclosporin, cisplatin, and fludarabine), or of potentially ototoxic drugs such as etacrynic acid and perhaps furosemide, may increase the risk of aminoglycoside toxicity. It has been suggested that use of an antiemetic such as dimenhydrinate may mask the early symptoms of vestibular ototoxicity. Care is also required if other drugs with a neuromuscular-blocking action are used (see Atracurium, p.1903). The neuromuscular-blocking properties of aminoglycosides may be sufficient to provoke severe respiratory depression in patients given general anaesthetics or opioids.

There is a theoretical possibility that the antibacterial effects of aminoglycosides could be reduced by bacteriostatic antibacterials, but such combinations have been used successfully in practice.

Since aminoglycosides have been shown to be incompatible with some beta lactams *in vitro* (see Incompatibility, above), these antibacterials should be given separately if both are required; antagonism *in vivo* has been reported only in a few patients with severe renal impairment, in whom aminoglycoside activity was diminished. Aminoglycosides exhibit synergistic activity with a number of beta lactams *in vivo* (see Antimicrobial Action, below).

Renal excretion of zalcitabine may be reduced by aminoglycosides.

For a report of severe hypocalcaemia in a patient treated with aminoglycosides and bisphosphonates, see p.1091.

Gentamicin may inhibit α-galactosidase activity and should not be used with agalsidase alfa or beta.

Antimicrobial Action

Gentamicin is an aminoglycoside antibiotic and has a bactericidal action against many Gram-negative aerobes and against some strains of staphylococci.

Mechanism of action. Aminoglycosides are taken up into sensitive bacterial cells by an active transport process which is inhibited in anaerobic, acidic, or hyperosmolar environments. Within the cell they bind to the 30S, and to some extent to the 50S, subunits of the bacterial ribosome, inhibiting protein synthesis and generating errors in the transcription of the genetic code. The manner in which cell death is brought about is imperfectly understood, and other mechanisms may contribute, including effects on membrane permeability.

Spectrum of activity. The following pathogenic organisms are usually sensitive to gentamicin (but see also Resistance, below).

Many strains of Gram-negative bacteria including species of *Brucella*, *Calymmatobacterium*, *Campylobacter*, *Citrobacter*, *Escherichia*, *Enterobacter*, *Francisella*, *Klebsiella*, *Proteus*, *Providencia*, *Pseudomonas*, *Serratia*, *Vibrio*, and *Yersinia*. Some activity has been reported against isolates of *Neisseria*, although aminoglycosides are rarely used clinically in neisserial infections.

Among the Gram-positive organisms many strains of *Staphylococcus aureus* are highly sensitive to gentamicin. *Listeria monocytogenes* and some strains of *Staph. epidermidis* may also be sensitive to gentamicin, but enterococci and streptococci are usually insensitive to gentamicin.

Some actinomycetes and mycoplasmas have been reported to be sensitive to gentamicin, but mycobacteria are insensitive at clinically achievable concentrations; anaerobic organisms, yeasts, and fungi are resistant.

Activity with other antimicrobials. Gentamicin exhibits synergy with beta lactams, probably because the effects of the latter on bacterial cell walls enhance aminoglycoside penetration. Enhanced activity has been demonstrated with a penicillin (such as ampicillin or benzylpenicillin) and gentamicin against the enterococci, and gentamicin has been combined with an antipseudomonal penicillin such as ticarcillin for enhanced activity against *Pseudomonas* spp., and with vancomycin for enhanced activity against staphylococci and streptococci.

Resistance to the aminoglycosides may be acquired by three main mechanisms. The first is by mutation of ribosomal target sites leading to reduced affinity for binding; this type of resistance is generally only relevant for streptomycin and, even then, it appears to be rare in Gram-negative bacteria. Secondly, penetration of aminoglycosides into bacterial cells is by an oxygen-dependent active transport process and resistance may occur because of elimination or reduction of this uptake; when it occurs this generally results in cross-resistance to all aminoglycosides. Thirdly, and by far the most important cause of resistance to the aminoglycosides, is inactivation by enzymatic modification. Three main classes of enzyme conferring resistance have been found, operating by phosphorylation, acetylation, or addition of a nucleotide group, usually adenyl. Enzyme production is usually plasmid-determined and resistance can therefore be transferred between bacteria, even of different species. Resistance to other antibacterials may be transferred at the same time. In *Staph. aureus*, transfer of resistance is more likely when these drugs are used topically. Each type of enzyme produces characteristic patterns of resistance, but their overlapping and variable affinities for their substrates result in a wide range of permutations of cross-resistance to the different aminoglycosides. The different enzymes vary in their distribution and prevalence in different locations, and at different times, presumably with variations in antibacterial usage, but relationships to the use of specific aminoglycosides are difficult to establish. These variations in drug sensitivity require local testing to determine resistance and establish susceptibility of bacteria to the aminoglycoside being used, but such local variations mean that estimates of the incidence of resistance are of limited value. In general, the occurrence of resistant pathogens seems to have been greater in southern than in northern Europe, and perhaps greater in the USA than in Europe. There has been particular concern over the increasing incidence of high-level gentamicin resistance among enterococci (in up to 50% of isolates from some centres), since they already possess inherent or acquired resistance to many drugs, including vancomycin in some cases. A similar problem exists with gentamicin resistance in meticillin-resistant strains of *Staph. aureus*. Such multiply-resistant strains pose a major therapeutic problem in those centres where they occur, since the usual synergistic combinations with other antibacterials are ineffective. However, results from some centres indicate that rational use of a wider range of aminoglycosides (including amikacin which is not affected by most of the aminoglycoside-degrading enzymes) has resulted in a modest decline in overall aminoglycoside resistance.

Pharmacokinetics

Gentamicin and other aminoglycosides are poorly absorbed from the gastrointestinal tract but are rapidly absorbed after intramuscular injection. Average peak plasma concentrations of about 4 micrograms/mL have been attained in patients with normal renal function 30 to 60 minutes after an intramuscular dose equivalent to gentamicin 1 mg/kg, which is similar to concentrations achieved after intravenous infusion. There may be considerable individual variation. Several doses are required before plasma equilibrium concentrations occur and this may represent the saturation of binding sites in body tissues such as the kidney. Binding of gentamicin to plasma proteins is usually low.

On parenteral use, gentamicin and other aminoglycosides diffuse mainly into extracellular fluids. However, there is little diffusion into the CSF and even when the meninges are inflamed effective concentrations may not be achieved; diffusion into the eye is also poor. Aminoglycosides diffuse readily into the perilymph of the inner ear. They cross the placenta but only small amounts have been reported in breast milk.

Systemic absorption of gentamicin and other aminoglycosides has been reported after topical use on denuded skin and burns and on instillation into, and irrigation of, wounds, body-cavities (except the urinary bladder), and joints.

The plasma elimination half-life for gentamicin has been reported to be 2 to 3 hours though it may be considerably longer in neonates and patients with renal impairment. Gentamicin and other aminoglycosides do not appear to be metabolised and are excreted virtually unchanged in the urine by glomerular filtration. At steady state at least 70% of a dose may be recovered in the urine in 24 hours and urine concentrations in excess of 100 micrograms/mL may be achieved. However, gentamicin and the other aminoglycosides appear to accumulate in body tissues to some extent, mainly in the kidney, although the relative degree to which this occurs may vary with different aminoglycosides. Release from these sites is slow and small amounts of aminoglycosides may be detected in the urine for up to 20 days or more after treatment stops. Small amounts of gentamicin appear in the bile.

The pharmacokinetics of the aminoglycosides are affected by many factors, which may become significant because of the relatively small difference between therapeutic and toxic concentrations, reinforcing the need for monitoring.

- Absorption from intramuscular sites may be reduced in critically ill patients, especially in conditions that reduce perfusion such as shock, resulting in **reduced plasma concentrations**. Plasma concentrations may also be reduced in patients with conditions which expand extracellular fluid volume or increase renal clearance including ascites, cirrhosis, heart failure, malnutrition, spinal cord injury, burns, cystic fibrosis, and possibly leukaemia. Clearance is also reportedly increased in intravenous drug abusers, and in patients who are febrile.
- In contrast, renal impairment or reduced renal clearance for any reason (for example in neonates with immature renal function, or in the elderly in whom glomerular function tends to decline with age) can result in markedly **increased plasma concentrations** and/or prolonged half-lives. However, in neonates initial plasma concentrations may actually be reduced, due to a larger volume of distribution. Plasma concentrations may also be higher than expected for a given dose in obese patients (in whom extracellular volume is low relative to weight), and in patients with anaemia.

Renal clearance, and hence plasma concentrations, of aminoglycosides may vary according to a circadian cycle, and it has been suggested that this should be taken into account when determining and comparing plasma aminoglycoside concentrations.

Uses and Administration

Gentamicin is an aminoglycoside antibiotic used, often with other antibacterials, to treat severe systemic infections due to sensitive Gram-negative and other organisms (see Antimicrobial Action, above). Such infections include biliary-tract infections (acute cholecystitis or cholangitis), brucellosis, cat scratch disease, cystic fibrosis, endocarditis (in the treatment and prophylaxis of endocarditis due to streptococci, enterococci, or staphylococci), endometritis, gastroenteritis, granuloma inguinale, listeriosis, meningitis, otitis externa, otitis media, pelvic inflammatory disease, peritonitis, plague, pneumonia, septicaemia, skin infections such as in burns or ulcers (given systemically for pseudomonal and other Gram-negative infections), tularaemia, and urinary-tract infections (acute pyelonephritis), as well as in the prophylaxis of surgical infection and the treatment of immunocompromised patients and those in intensive care. It may be used as part of a multi-drug regimen for the treatment of inhalation and gastrointestinal anthrax. Gentamicin is also applied topically for localised infections. For details of these infections and their treatment, see under Choice of Antibacterial, p.162.

Gentamicin is often used with other antibacterials to extend its spectrum of activity or increase its efficacy, e.g. with a penicillin for enterococcal and streptococcal infections, or an antipseudomonal beta lactam for pseudomonal infections, or with metronidazole or clindamycin for mixed aerobic-anaerobic infections.

Administration and dosage. Gentamicin is used as the sulfate but doses are expressed in terms of gentamicin base. For many of the infections above it is given intramuscularly every 8 hours to provide a total daily dose of 3 to 5 mg/kg. In the prophylaxis and treatment of streptococcal and enterococcal endocarditis, a dose of 1 mg/kg every 8 hours with a penicillin or vancomycin has been suggested for treatment in the UK; a suggested dose for prophylaxis in high-risk patients is 120 mg before induction of anaesthesia, with a penicillin or vancomycin or teicoplanin. For urinary-tract infections, if renal function is not impaired, 160 mg once daily may be used.

Gentamicin sulfate may also be given intravenously in similar doses to those used intramuscularly, but there is some disagreement as to the appropriate method, since intravenous infusion has been associated with both subtherapeutic and excessive trough concentrations of gentamicin, while bolus intravenous injection may increase the risk of neuromuscular blockade. In the USA, intravenous infusion over 30 minutes to 2 hours is favoured, but sources in the UK differ, with some licensed product information recommending infusion over no more than 20 minutes, in a limited fluid volume, while other products should not be given by slow infusion, recommending bolus injection over at least 2 to 3 minutes, and yet others allow use in a similar way to the USA.

The course of treatment should generally be limited to 7 to 10 days. As gentamicin is poorly distributed into fatty tissue it has been suggested that dosage calculations should be based on an estimate of lean bodyweight.

Doses in infants and children are usually somewhat higher than those in adults but exact dosage recommendations vary. One regimen is gentamicin 3 mg/kg every 12 hours in premature infants and those up to 2 weeks of age, with older neonates and children receiving 2 mg/kg every 8 hours. Alternatively, 2.5 mg/kg every 12 hours in the first week of life, 2.5 mg/kg every 8 hours or 3 mg/kg every 12 hours in infants and neonates, and 1.5 to 2 mg/kg every 8 hours in children has been given.

Dose adjustment and monitoring. Dosage should be adjusted in all patients according to plasma-gentamicin concentrations, and this is discussed in more detail under Administration and Dosage, below.

Once-daily dosage. In many centres, the total daily requirement is increasingly given as a single dose (see Once-daily Dosage, below). In suitable patients this appears to be as safe and effective as conventional regimens, and is more convenient. However, it is not suitable for all patients, especially those with endocarditis, extensive burns, or renal impairment (creatinine clearance less than 20 mL/minute). With once-daily dosage, traditional methods of monitoring peak and trough plasma concentrations may not be applicable and local guidelines on dosage and plasma concentrations should be consulted.

Other routes. Gentamicin has sometimes been given orally for enteric infections and to suppress intestinal flora and has occasionally been given by inhalation in cystic fibrosis. In meningitis it has been given intrathecally or intraventricularly usually in doses of 1 to 5 mg daily with intramuscular therapy. Gentamicin has also been given by subconjunctival injection.

A bone cement impregnated with gentamicin is used in orthopaedic surgery. Acrylic beads containing gentamicin and threaded on to surgical wire are implanted in the management of bone infections.

Gentamicin has also been applied topically for skin infections in concentrations of 0.1%, but such use may lead to the emergence of resistance and is considered inadvisable. Concentrations of 0.3% are used in preparations for topical application to the eyes and ears.

A liposomal formulation of gentamicin is under investigation.

Administration and dosage. *CONCENTRATION MONITORING.* Measurements of aminoglycoside plasma concentrations are routinely performed to individualise dosage regimens, both in terms of dose given and dosing interval, in order to attain the desired therapeutic range as quickly as possible.[1] This entails measurement of both peak concentrations to monitor efficacy and trough concentrations to avoid accumulation and thereby prevent toxicity. Dosage should be adjusted in all patients according to these concentrations, but this is of particular importance where factors such as age, renal impairment, or high dosage may predispose to toxicity. Although there has been some dispute about the relationship between plasma concentrations and toxicity it is generally recommended that, for multiple daily dosing with gentamicin, trough plasma concentrations (measured just before the next dose) should be less than 2 micrograms/mL, and peak concentrations should reach at least 4 micrograms/mL but not exceed 10 micrograms/mL. In the UK, peak concentrations are generally measured 1 hour after intramuscular and intravenous doses, but practice has varied between centres and countries and this may lead to difficulties when comparing figures.

Methods exist for calculating aminoglycoside dosage requirements, though none has been universally accepted. Simple pharmacokinetic methods involve linear dosage adjustment based on peak or trough concentrations or area under the concentration-time curve, or the use of predictive nomograms.[1] For most patients receiving once-daily dosage (see below), the nomogram is the method of choice, primarily because of its simplicity. However, it has not been validated for children and does not work in patients with either a very high clearance of aminoglycosides or a high volume of distribution, such as those with ascites, burns, or cystic fibrosis, or in other conditions such as pregnancy where the fixed dose assumed in the construction of the nomogram is irrelevant. When a nomogram cannot be applied, a more sophisticated pharmacokinetic method is required, using either Bayesian statistics or non-Bayesian methods such as that of Sawchuk and Zaske.[2,3] Bayesian methods are favoured when the patient population's pharmacokinetic parameters are well known because of their good predictive performance. Otherwise, the Sawchuk and Zaske method is the method of choice because of its robustness and the lack of requirement for prior information about the distribution of parameters within the population.[1]

In renal impairment. Although a number of nomograms, schedules, and rules have been devised for the calculation of aminoglycoside dosage in renal impairment, where possible dosage modification should be based on the monitoring of individual pharmacokinetic parameters. Standard dosage calculation methods should not be used for patients undergoing dialysis as they may require supplementary post-dialysis doses.

Individualised regimens based on an initial dose (for moderate to severe infections) of 2 to 2.5 mg/kg, modified in the obese or those with excessive fluid retention, and with subsequent doses after haemodialysis ranging from 1 to 1.8 mg/kg, have been reported to be effective.[1] Serum-aminoglycoside concentrations were not routinely requested unless treatment for more than 4 days was thought likely, and the target concentration was adjusted both for the agressiveness of therapy required and the individual haemodialysis regimen. Typically, about 50% of a dose was eliminated in a haemodialysis session.

1. Dager WE, King JH. Aminoglycosides in intermittent hemodialysis: pharmacokinetics with individual dosing. *Ann Pharmacother* 2006; **40:** 9–14.

Once-daily dosage. The concept of giving aminoglycosides once daily rather than in divided doses is attractive on the grounds of convenience and economy. The rationale cited by proponents of single daily doses for preferring high intermittent plasma concentrations includes the prolonged postantibiotic effect of aminoglycosides (persistent antibacterial activity after plasma concentrations have fallen below the MIC), potentially higher antibacterial concentrations at the site of infection, and theoretical reductions in the incidence of adaptive resistance, with no apparent increase in nephrotoxicity. Clinical studies have generally included small numbers of patients with uncomplicated infections and have excluded patients with altered pharmacokinetic profiles, but several meta-analyses have been published which have concluded that once-daily administration appears to be at least as effective as, and no more toxic than, multiple daily dosing in such patient populations.[1-7] Similar results have been seen in children.[8,9] Many centres now use such regimens in suitable patients.

Several methods for calculating doses and monitoring treatment have been proposed.[10-12] There is insufficient information for pregnant or breast-feeding women, or patients with burns or impaired renal or hepatic function.[12-14] However, preliminary reports suggest that once-daily use may be practical in trauma patients,[15] and children with neutropenia,[16] or cystic fibrosis.[17,18] Once daily dosage may, though, be inappropriate for elderly patients[19] (due to an increased incidence of nephrotoxicity), patients in whom the volume of drug distribution or clearance is difficult to predict or markedly abnormal,[20] and in the treatment of enterococcal endocarditis.[12] In the UK, the *BNF* states that a once-daily high dose regimen should be avoided in patients with endocarditis, extensive burns, or creatinine clearance less than 20 mL/minute. For mention of an increase in endotoxin reactions associated with the use of single daily doses see under Adverse Effects, above.

Ménière's disease. Gentamicin and streptomycin have been used for medical ablation in advanced Ménière's disease (p.564). Although gentamicin given systemically is considered to be more ototoxic than streptomycin, evidence from *animal* studies suggests that intratympanic use may be less ototoxic. This, and a higher incidence of adverse effects with streptomycin, has meant that intratympanic gentamicin is now preferred. Intratympanic gentamicin has been reported to control vertigo symptoms in the majority of patients, although some experience a worsening of their hearing loss immediately after treatment.[1-8] However, the ideal regimen for intratympanic gentamicin has yet to be defined.

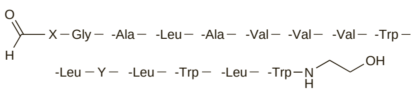
Gramicidin *(BAN, rINN)*

Gramicidin D; Gramicidin (Dubos); Gramicidina; Gramicidinas; Gramicidine; Gramicidinum; Gramisidiini; Gramisidin.

Грамицидин

CAS — 1405-97-6.
ATC — R02AB30.
ATC Vet — QR02AB30.



Gramicidin	X	Y	Mol. Formula
A1	-Val	-Trp	C H N O
A2	-Ile	-Trp	C H N O
B1	-Val	-Phe	C H N O
C1	-Val	-Tyr	C H N O
C2	-Ile	-Tyr	C H N O

NOTE. The name gramicidin was formerly applied to tyrothricin.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Gramicidin). It consists of a family of antimicrobial linear polypeptides usually obtained by extraction from tyrothricin, the complex isolated from the fermentation broth of *Bacillus brevis*. The main component is gramicidin A1, together with gramicidins A2, B1, C1, and C2 in particular. The potency is not less than 900 units/mg calculated with reference to the dried substance. A white or almost white, slightly hygroscopic, crystalline powder. Practically insoluble in water; sparingly soluble in alcohol; soluble in methyl alcohol. Store in airtight containers. Protect from light.

USP 31 (Gramicidin). An antibacterial substance produced by the growth of *Bacillus brevis* (Bacillaceae); it may be obtained from tyrothricin. It has a potency of not less than 900 micrograms of gramicidin per mg, calculated on the dried basis. A white or practically white, odourless, crystalline, powder. Insoluble in water; soluble in alcohol. Store in airtight containers.

Profile

Gramicidin has properties similar to those of tyrothricin (p.358) and is too toxic to be given systemically. It is used topically for the local treatment of susceptible infections usually with other antibacterials such as neomycin and polymyxin B, and often with a corticosteroid as well.

Preparations

USP 31: Neomycin and Polymyxin B Sulfates and Gramicidin Cream; Neomycin and Polymyxin B Sulfates and Gramicidin Ophthalmic Solution; Neomycin and Polymyxin B Sulfates, Gramicidin, and Hydrocortisone Acetate Cream; Neomycin Sulfate and Gramicidin Ointment; Nystatin, Neomycin Sulfate, Gramicidin, and Triamcinolone Acetonide Cream; Nystatin, Neomycin Sulfate, Gramicidin, and Triamcinolone Acetonide Ointment.

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Arg.:*** Antibiocort†; Aseptobron N; Biotaer Nasal; Bucoangin N; Caext; Carnot Colutorio; Desenfriol Caramelos†; Gargaletas; Gramibiotic†; Graneodin; Graneodin N; Kenacomb; Nasomicina; Neo Coltirot; Neo Pelvicillin; Pantometil; Proetztotal; ***Austral.:*** Kenacomb; Neosporin; Otocomb Otic; Otodex; Sofradex; Soframycin; ***Austria:*** Mycostatin V; Topsym polyvalent; Volon A antibiotikahaltig; ***Belg.:*** Mycolog; Polyspectran Gramicidine; ***Braz.:*** Fonergin; Londerm-N; Mud; Neolon-D; Omcilon A M; Onciplus; ***Canad.:*** Antibiotic Cream†; Kenacomb†; Neosporin; Opticort; Optimyxin; Optimyxin Plus; Polycidin†; Polysporin; Polysporin Complete Antibiotic; Polysporin For Kids; Polysporin Plus Pain Relief; Polysporin Triple Antibiotic; Polytopic; ratio-Triacomb; Sofracort; Soframycin; Triacomb†; Viaderm-KC; ***Chile:*** Grifoftal†; Oftabiotico; ***Cz.:*** Sofradex†; ***Denm.:*** Kenalog Comp med Mycostatin; Sofradex; ***Fin.:*** Bafucin; Polysporin; Sofradex; ***Ger.:*** Polyspectran; ***Gr.:*** Kenacomb; Neo-Priphen; ***Hong Kong:*** Kenacomb; Neosporin; Polyoph; Sofradex; Triacomb; ***Hung.:*** Polyspor; ***India:*** Kenacomb; Kenalog-S; Neosporin; Sofracort; ***Indon.:*** Blecidex; Isotic Enpigi; Neosyd; Sofradex; ***Irl.:*** Graneodin; Kenacomb; Neosporin†; Sofradex; Soframycin†; ***Israel:*** Dermacombin; Kenacomb†; ***Ital.:*** Eta Biocortilen VC; Vasosterone Antibiotico; ***Malaysia:*** Kenacomb; Pocin G; Sofradex; ***Mex.:*** Biotarson N; Biotarson O; Kenacomb; Neosporin; Nicobio†; Polixin; Poly-Micron; Septilisin; Sulned; ***Neth.:*** Mycolog; Polyspectran G†; Sofradex; ***Norw.:*** Sofradex; ***NZ:*** Kenacomb; Sofradex; Soframycin; Viaderm-KC; ***Philipp.:*** Kenacomb; Lidex NGN; Neosporin; Novasorin; ***Pol.:*** Dicortineff; Triacomb; ***Port.:*** Dropcina; Kenacomb; ***S.Afr.:*** Kenacomb; Neosporin†; Sofradex; ***Singapore:*** Kenacomb†; Sofradex; ***Spain:*** Flodermol; Fludronef; Intradermo Cort Ant Fung†; Midacina; Oftalmowell; Spectrocin†; Tivitis; Trigon Topico; ***Swed.:*** Bafucin; ***Switz.:*** Angidine; Mycolog N; Mycolog†; Neosporin; Sofradex; Topsym polyvalent; Tyrothricine + Gramicidine; ***Thai.:*** Dermacombin; Kenacomb; Neosporin†; Opsacin†; Polyoph; Sofradex; Topifram; Xanalin; ***Turk.:*** Neosporin; ***UAE:*** Panderm; ***UK:*** Graneodin†; Neosporin; Sofradex; Tri-Adcortyl; ***USA:*** Neosporin; Ocu-Spor-G; Ocutricin; Polymycin; ***Venez.:*** Kenacomb.

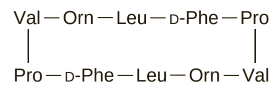
Gramicidin S *(rINN)*

Gramicidin C; Gramicidina S; Gramicidine S; Gramicidinum S; Soviet Gramicidin.

Грамицидин С

$C_{60}H_{92}N_{12}O_{10}$ = 1141.4.

CAS — 113-73-5.



Profile

Gramicidin S is an antibacterial polypeptide, produced by *Bacillus brevis*, and has similar properties to tyrothricin (p.358). It is unsuitable for systemic use and is used topically for the local treatment of susceptible infections and as lozenges for infections of the mouth and throat. The hydrochloride is used similarly.

Preparations

Proprietary Preparations (details are given in Part 3)

Rus.: Grammidin.

Multi-ingredient: ***Indon.:*** FG Ointment; FG Troches.

Halquinol *(BAN)*

Chlorhydroxyquinoline; Chlorquinol; Halquinols *(USAN)*; SQ-16401. A mixture of the chlorinated products of quinolin-8-ol containing 57 to 74% of 5,7-dichloroquinolin-8-ol (chloroxine, p.242), 23 to 40% of 5-chloroquinolin-8-ol (cloxiquine, p.530), and not more than 4% of 7-chloroquinolin-8-ol.

CAS — 8067-69-4.

Profile

Halquinol is a halogenated hydroxyquinoline with properties similar to those of clioquinol (p.254). It is used topically in infected skin conditions.

Preparations

Proprietary Preparations (details are given in Part 3)

UK: Valpeda.

Multi-ingredient: ***Denm.:*** Kenacutan; ***Norw.:*** Kenacutan; ***Swed.:*** Kenacutan.

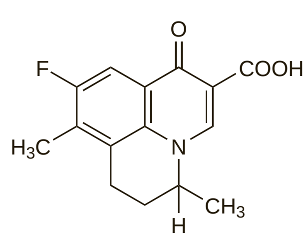
Ibafloxacin *(BAN, USAN, rINN)*

Ibafloksasiini; Ibafloxacine; Ibafloxacino; Ibafloxacinum; R-835; S-25930. 9-Fluoro-6,7-dihydro-5,8-dimethyl-1-oxo- 1*H*,5*H*-benzo[*ij*]quinolizine-2-carboxylic acid.

Ибафлоксацин

$C_{15}H_{14}FNO_3$ = 275.3.

CAS — 91618-36-9.
ATC Vet — QJ01MA96.



Profile

Ibafloxacin is a fluoroquinolone antibacterial that is used in veterinary medicine for the treatment of susceptible infections in cats and dogs.

Imipenem *(BAN, USAN, rINN)*

N-Formimidoyl Thienamycin; Imipemide; Imipeneemi; Imipénem; Imipenem monohydrát; Imipenemas; Imipenemum; Imipenemum Monohydricum; MK-787; MK-0787. (5*R*,6*S*)-6-[(*R*)-1-Hydroxyethyl]-3-(2-iminomethylaminoethylthio)-7-oxo-1-azabicyclo[3.2.0]hept-2-ene-2-carboxylic acid monohydrate.

Имипенем

$C_{12}H_{17}N_3O_4S,H_2O$ = 317.4.

CAS — 64221-86-9 (anhydrous imipenem); 74431-23-5 (imipenem monohydrate).

Description. Imipenem is the *N*-formimidoyl derivative of thienamycin, an antibiotic produced by *Streptomyces cattleya*.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Imipenem). A white, almost white, or pale yellow powder. Sparingly soluble in water; slightly soluble in methyl alcohol. A 0.5% solution in water has a pH of 4.5 to 7.0. Store in airtight containers at a temperature of 2° to 8°.

USP 31 (Imipenem). A white to tan-coloured crystalline powder. Sparingly soluble in water; slightly soluble in methyl alcohol. Store at a temperature not exceeding 8°.

Incompatibility and stability. Imipenem is unstable at alkaline or acidic pH and the commercially available injection of imipenem with cilastatin sodium for intravenous use is buffered to provide, when reconstituted, a solution with pH 6.5 to 7.5. Licensed product information advises against mixing with other antibacterials.

Adverse Effects

Imipenem is always given with the enzyme inhibitor cilastatin and thus clinical experience relates to the combination.

Adverse effects with imipenem-cilastatin are similar in general to those with other beta lactams (see Benzylpenicillin, p.213, and Cefalotin, p.219). Hypersensitivity reactions such as skin rashes, urticaria, eosinophilia, fever, and, rarely, anaphylaxis may occur. Gastrointestinal effects include nausea, vomiting, diarrhoea, tooth or tongue discoloration, and altered taste. Superinfection with non-susceptible organisms such as *Enterococcus faecium*, strains of *Pseudomonas aeruginosa* with acquired resistance, and *Candida* may also occur. Pseudomembranous colitis may develop. Erythema multiforme, exfoliative dermatitis, Stevens-Johnson syndrome, and toxic epidermal necrolysis have been reported rarely. Increases in liver enzymes and abnormalities in haematological parameters, including a positive Coombs' test, have been noted.

Local reactions such as pain or thrombophlebitis may occur after injection.

Seizures or convulsions have been reported with imipenem-cilastatin, particularly in patients with a history of CNS lesions and/or poor renal function, but sometimes in those without predisposing factors for seizures given recommended doses. Mental disturbances and confusion have also been reported.

Cilastatin has protected against the nephrotoxicity seen with high doses of imipenem given experimentally to *animals*. A harmless reddish coloration of urine has been observed in children.

Hypersensitivity. A retrospective analysis[1] involving a total of 211 patients appeared to show that those with a history of reported or documented penicillin allergy had an 11% incidence of hypersensitivity reactions when treated with a carbapenem antibacterial compared with 2.7% for those without such a history of penicillin allergy. There was no difference in the occurrence of allergic-type reactions between imipenem-cilastatin and meropenem.

Superinfection. References.

1. Gray JW, *et al.* Enterococcal superinfection in paediatric oncology patients treated with imipenem. *Lancet* 1992; **339**: 1487–8.

Precautions

Imipenem-cilastatin should not be given to patients known to be hypersensitive to it, and should be given with caution to patients known to be hypersensitive to penicillins, cephalosporins, or other beta lactams because of the possibility of cross-sensitivity.

It should be given with caution to patients with renal impairment, and the dose reduced appropriately. Particular care is necessary in patients with CNS disorders such as epilepsy.

Interactions

Seizures have been reported in patients given ganciclovir with imipenem-cilastatin.

Antiepileptics. For reports of decreased plasma-*valproate* concentrations (sometimes with loss of seizure control) attributed to imipenem, see p.510.

Antimicrobial Action

Imipenem is bactericidal and acts similarly to the penicillins by inhibiting synthesis of the bacterial cell wall. It has a very broad spectrum of activity *in vitro*, including activity against Gram-positive and Gram-negative aerobic and anaerobic organisms, and is stable to hydrolysis by beta-lactamases produced by most bacterial species. Cilastatin, the enzyme inhibitor given with imipenem, appears to have no antibacterial activity.

Most Gram-positive cocci are sensitive to imipenem including most streptococci, and both penicillinase- and non-penicillinase-producing staphylococci, although its activity against meticillin-resistant *Staphylococcus aureus* is variable. Imipenem has good to moderate activity against *Enterococcus faecalis*, but most *E. faecium* are resistant. *Nocardia*, *Rhodococcus*, and *Listeria* spp. are also sensitive.

Among Gram-negative bacteria, imipenem is active against many of the Enterobacteriaceae including *Citrobacter* and *Enterobacter* spp., *Escherichia coli*, *Klebsiella*, *Proteus*, *Providencia*, *Salmonella*, *Serratia*, *Shigella*, and *Yersinia* spp. Its activity against *Pseudomonas aeruginosa* is similar to that of ceftazidime. Imipenem is also active against *Acinetobacter* spp. and *Campylobacter jejuni*, and also against *Haemophilus influenzae* and *Neisseria* spp., including beta-lactamase-producing strains.

Many anaerobic bacteria, including *Bacteroides* spp., are sensitive to imipenem, but *Clostridium difficile* is only moderately susceptible.

Imipenem is not active against *Chlamydia trachomatis*, *Mycoplasma* spp., fungi, or viruses.

There have been reports of antagonism between imipenem and other beta lactams *in vitro*. Imipenem and aminoglycosides often act synergistically against some isolates of *Ps. aeruginosa*.

Imipenem is a potent inducer of beta-lactamases of some Gram-negative bacteria, but generally remains stable to them. Acquired resistance has been reported in *Ps. aeruginosa* during therapy with imipenem.

Pharmacokinetics

Imipenem is not appreciably absorbed from the gastrointestinal tract and is given parenterally.

Imipenem is excreted primarily in the urine by glomerular filtration and tubular secretion and undergoes partial metabolism in the kidneys by dehydropeptidase I, an enzyme in the brush border of the renal tubules, to inactive, nephrotoxic metabolites, with only 5 to 45% of a dose excreted in the urine as unchanged active drug. Imipenem is given with cilastatin sodium (p.243), a dehydropeptidase inhibitor, resulting in increased urinary-imipenem concentrations. Cilastatin does not affect serum concentrations of imipenem.

The pharmacokinetics of imipenem and cilastatin are similar and both have plasma half-lives of about 1 hour; half-lives, especially those of cilastatin, may be prolonged in neonates and in patients with renal impairment. When imipenem with cilastatin is given in doses of 500 or 750 mg intramuscularly, peak plasma-imipenem concentrations of 10 and 12 micrograms/mL respectively are achieved at about 2 hours and prolonged absorption results in plasma-imipenem concentrations of above 2 micrograms/mL for 6 to 8 hours. The bioavailability of imipenem after intramuscular injection is about 75%. Up to 20% of imipenem and 40% of cilastatin is bound to plasma proteins. Imipenem is widely distributed in body tissues and fluids and crosses the placenta. Information on penetration into the CSF is limited, but concentrations appear to be relatively low.

When given with cilastatin about 70% of an intravenous dose of imipenem is recovered unchanged in the urine within 10 hours. A total of 50% of an intramuscular dose is recovered in the urine and urinary concentrations above 10 micrograms/mL are maintained for 12 hours after a dose of 500 or 750 mg. Cilastatin is also excreted mainly in the urine, the majority as unchanged drug and about 12% as *N*-acetyl cilastatin. Both imipenem and cilastatin are removed by haemodialysis.

About 1% of imipenem is excreted via the bile in the faeces.

Uses and Administration

Imipenem is a carbapenem beta-lactam antibacterial, differing from the penicillins in that the 5-membered ring is unsaturated and contains a carbon rather than a sulfur atom. Since imipenem is metabolised in the kidney by the enzyme dehydropeptidase I it is always given with cilastatin (p.243), an inhibitor of the enzyme; this enhances urinary concentrations of active drug and was found to protect against the nephrotoxicity of high doses of imipenem seen in *animal* studies.

Imipenem is used for the treatment of infections caused by susceptible organisms. They include infections in immunocompromised patients (with neutropenia), intra-abdominal infections, bone and joint infections, skin and soft-tissue infections, urinary-tract infections, biliary-tract infections, hospital-acquired pneumonia, and septicaemia. It may also be used for the treatment of gonorrhoea and for surgical infection prophylaxis. It may be used as part of a multi-drug regimen for the treatment of inhalation and gastrointestinal anthrax. For details of these infections and their treatment, see under Choice of Antibacterial, p.162. It is not indicated for CNS infections.

Administration and dosage. Commercial preparations contain imipenem and cilastatin, as the sodium salt, in a ratio of 1 to 1. Doses of the combination are expressed in terms of the amount of anhydrous imipenem. Imipenem is given by intravenous infusion or deep intramuscular injection. When given intravenously, doses of 250 or 500 mg are infused over 20 to 30 minutes, and doses of 750 mg or 1 g over 40 to 60 minutes. The usual intravenous dose in adults and children weighing more than 40 kg is 1 to 2 g daily in divided doses every 6 or 8 hours, depending on the severity of the infection, although up to a maximum daily dose of 4 g or 50 mg/kg has been given in life-threatening infections.

Children of 3 months or more and weighing less than 40 kg may be given 15 to 25 mg/kg every 6 hours by intravenous infusion; the total daily dose should not usually exceed 2 g. Higher doses of up to 4 g daily have been given to children with moderately susceptible *Pseudomonas aeruginosa* infection; up to 90 mg/kg daily has been given to older children with cystic fibrosis. Neonates and infants up to 3 months of age may be given the following doses: 4 weeks to 3 months of age, 25 mg/kg every 6 hours; 1 to 4 weeks of age, 25 mg/kg every 8 hours; up to 1 week of age, 25 mg/kg every 12 hours.

For details of reduced doses in renal impairment, see below.

For surgical infection prophylaxis in adults, imipenem 1 g may be given intravenously on induction of anaesthesia, followed by a further 1 g three hours later, with additional doses of 500 mg at 8 and 16 hours after induction if necessary.

Imipenem may be given intramuscularly in adults with mild to moderate infections in doses of 500 or 750 mg every 12 hours. A single 500-mg intramuscular dose may be given in uncomplicated gonorrhoea.

Administration in renal impairment. Doses of imipenem should be reduced in patients with renal impairment; in the UK, the following are the recommended maximum *intravenous* doses based on creatinine clearance (CC):

- CC 31 to 70 mL/minute: 500 mg every 6 to 8 hours
- CC 21 to 30 mL/minute: 500 mg every 8 to 12 hours
- CC 6 to 20 mL/minute: 250 mg (or 3.5 mg/kg, whichever is the lower) every 12 hours or occasionally 500 mg every 12 hours
- CC 5 mL/minute or less: should only be given imipenem if haemodialysis is started within 48 hours

Imipenem and cilastatin are cleared from the body by haemodialysis and doses should be given after a dialysis session and then every 12 hours.

Information is lacking on the safety or effectiveness of the *intramuscular* route in patients with renal impairment.

Pharmacopoeias. In *Jpn*, which specifies a variable amount of H_2SO_4.

Profile

Isepamicin is a semisynthetic aminoglycoside with actions and uses similar to those of gentamicin (p.282). It is reported not to be degraded by many of the enzymes responsible for aminoglycoside resistance. Isepamicin sulfate is given by intramuscular injection or intravenous infusion in a dose of up to 15 mg/kg daily in 2 divided doses. Once-daily dosage may be possible in selected patients. Dosage should be adjusted based on serum-isepamicin concentration monitoring. In adults, the total daily dose should not exceed 1.5 g.

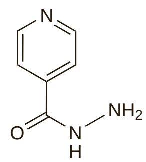
Изониазид

$C_6H_7N_3O$ = 137.1.
CAS — 54-85-3.
ATC — J04AC01.
ATC Vet — QJ04AC01.



NOTE. The name Isopyrin, which has been applied to isoniazid, has also been applied to ramifenazone.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Isoniazid). A white or almost white, crystalline powder or colourless crystals. Freely soluble in water; sparingly soluble in alcohol. A 5% solution in water has a pH of 6.0 to 8.0.

USP 31 (Isoniazid). Colourless, or white, odourless crystals, or white crystalline powder. Soluble 1 in 8 of water and 1 in 50 of alcohol; slightly soluble in chloroform; very slightly soluble in ether. pH of a 10% solution in water is between 6.0 and 7.5. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Incompatibility. It has been recommended that sugars such as glucose, fructose, and sucrose should not be used in isoniazid syrup preparations because the absorption of the drug was impaired by the formation of a condensation product.[1] Sorbitol may be a suitable substitute if necessary.

1. Rao KVN, *et al.* Inactivation of isoniazid by condensation in a syrup preparation. *Bull WHO* 1971; **45:** 625–32.

Sterilisation. Solutions of isoniazid should be sterilised by autoclaving.

Adverse Effects

Isoniazid is generally well tolerated at currently recommended doses. However, patients who are slow acetylators of isoniazid and those with advanced HIV disease appear to have a higher incidence of some adverse effects. Also patients whose nutrition is poor are at risk of peripheral neuritis which is one of the commonest adverse effects of isoniazid. Other neurological adverse effects include psychotic reactions and convulsions. Pyridoxine may be given to prevent or treat these adverse effects. Optic neuritis has also been reported.

Transient increases in liver enzymes occur in 10 to 20% of patients during the first few months of treatment and usually return to normal despite continued treatment. Symptomatic hepatitis occurs in about 0.1 to 0.15% of patients given isoniazid as monotherapy, but this can increase with age, regular alcohol consumption, and in those with chronic liver disease. The influence of acetylator status is uncertain. Elevated liver enzymes associated with clinical signs of hepatitis such as nausea and vomiting, or fatigue may indicate hepatic damage; in these circumstances, isoniazid should be stopped pending evaluation and should only be reintroduced cautiously once hepatic function has recovered. Fatalities have occurred due to liver necrosis.

Haematological effects reported on use of isoniazid include various anaemias, agranulocytosis, thrombocytopenia, and eosinophilia.

Hypersensitivity reactions occur infrequently and include skin eruptions (including erythema multiforme), fever, and vasculitis.

Other adverse effects include nausea, vomiting, dry mouth, constipation, pellagra, purpura, hyperglycaemia, lupus-like syndrome, vertigo, hyperreflexia, urinary retention, and gynaecomastia.

Symptoms of overdosage include slurred speech, metabolic acidosis, hallucinations, hyperglycaemia, respiratory distress or tachypnoea, convulsions, and coma; fatalities can occur.

Carcinogenicity. Concern about the carcinogenicity of isoniazid arose in the 1970s when an increased risk of bladder cancer in patients treated with isoniazid was reported.[1-3] However, no evidence to support a carcinogenic effect of isoniazid was found in more than 25 000 patients followed up for 9 to 14 years in studies organised by the USA Public Health Service[4] and in 3842 patients followed up for 16 to 24 years in the UK.[5]

5. Stott H, *et al.* An assessment of the carcinogenicity of isoniazid in patients with pulmonary tuberculosis. *Tubercle* 1976; **57:** 1–15.

Effects on the blood. In addition to the effects mentioned above, rare reports of adverse effects of isoniazid on the blood include bleeding associated with acquired inhibition of fibrin stabilisation[1] or of factor XIII,[2] and red cell aplasia.[3-5]

For a reference to neutropenia, see Effects on the Blood, under Ethambutol Hydrochloride, p.274.

Effects on the CNS. In addition to the peripheral neuropathy that is a well-established adverse effect of isoniazid, effects on the CNS have also been reported, including ataxia and cerebellar toxicity,[1,2] psychotic reactions[3-5] (generally characterised by delusions, hallucinations, and confusion), and seizures, particularly after overdosage.[6] Encephalopathy has been reported in dialysis patients.[7,8] Encephalopathy may also be a symptom of pellagra, which may be associated with isoniazid treatment.[9]

Effects on the liver. Transient abnormalities in liver function are common during the early stages of antituberculous therapy with isoniazid and other first-line antituberculous drugs, but sometimes hepatotoxicity may be more serious and require a change of treatment. Drug-induced hepatitis usually occurs within the first few weeks of treatment and it may not be possible to identify which drug or drugs are responsible. Isoniazid and pyrazinamide are thought to have a greater potential for hepatotoxicity than rifampicin.[1]

Risk factors for hepatotoxicity include alcoholism, old age, female gender, malnutrition, HIV infection, and chronic hepatitis B and C infections.[1] Speculation that fast acetylators of isoniazid could be at increased risk of hepatotoxicity due to production of a hepatotoxic hydrazine metabolite has not been supported;[2] in fact, slow acetylators have generally been found to have a higher risk than fast acetylators.[3,4] This could reflect a reduced rate of subsequent metabolism to non-toxic compounds. In addition, concentrations of hydrazine in the blood have not been found to correlate with acetylator status.[5,6]

A multicentre study[7] considered the incidence of hepatotoxicity from a short-term regimen of daily isoniazid, rifampicin, and pyrazinamide for 8 weeks in the initial phase followed by daily isoniazid and rifampicin for 16 weeks in the continuing phase. Analysis from 617 patients showed an incidence of hepatotoxic reactions of 1.6%; the incidence of elevated aspartate aminotransferase was 23.2%. In the same study, 445 patients on a 9-month regimen of daily isoniazid and rifampicin had a 1.2% incidence of hepatotoxicity and 27.1% incidence of elevated liver enzymes. A similar incidence of hepatitis of 1.4% among 350 patients on a 9-month regimen of rifampicin and isoniazid has also been reported.[8] A retrospective analysis[9] of 430 children on isoniazid and rifampicin revealed hepatotoxic reactions in 3.3%, the highest incidence being in children with severe disease.

The Joint Tuberculosis Committee of the British Thoracic Society has published recommendations[10] for initial measurement of liver function in all patients and regular monitoring in patients with known chronic liver disease. Details are given concerning the response to deteriorating liver function depending on the clinical situation, and guidelines included for prompt re-introduction of appropriate antituberculosis therapy once normal liver function is restored. Similar guidelines have been produced in the USA.[11,12]

The incidence of hepatotoxicity is lower in patients receiving isoniazid for prophylaxis than in those receiving treatment for active disease. During a 7-year period[13] an incidence of 0.15%

was recorded in 11 141 patients who started prophylactic therapy, whereas it was 1.25% amongst 1427 patients receiving treatment. A similar study[14] in a slightly older patient population reported an incidence of 0.56%. No cases of hepatotoxicity were reported in 556 HIV-infected patients taking a 3-month prophylactic regimen of isoniazid and rifampicin for latent tuberculosis.[15] A meta-analysis[16] concluded that daily isoniazid and rifampicin for 3 months appeared to be as safe as treatment with isoniazid alone for 6 to 12 months.

Effects on the pancreas. Cases of isoniazid-induced pancreatitis have been rarely reported;[1-4] pancreatitis resolved in these patients once treatment with isoniazid was stopped, and recurred on rechallenge. It is recommended if isoniazid-induced pancreatitis is proven that the drug should be permanently avoided.[4] Chronic pancreatic insufficiency, after an acute episode, was reported in a patient given isoniazid, rifampicin, ethambutol, and pyrazinamide and was considered to be a drug hypersensitivity reaction.[5]

Effects on the skin and hair. Isoniazid causes cutaneous drug reactions in less than 1% of patients.[1,2] These reactions include urticaria, purpura, acneform syndrome,[3] a lupus erythematosus-like syndrome[4] (see below), and exfoliative dermatitis.[5] Pellagra is also associated with isoniazid.[6] Isoniazid was considered the most likely cause of alopecia in 5 patients receiving antituberculosis regimens which also included rifampicin, ethambutol, and pyrazinamide.[7]

Lupus. Antinuclear antibodies have been reported to occur in up to 22% of patients receiving isoniazid; however, patients are usually asymptomatic and overt lupoid syndrome is rare.[1,2] The incidence of antibody induction has been reported to be higher in slow acetylators than in fast acetylators,[3] but the difference was not statistically significant and acetylator phenotype is not considered an important determinant of the risk of isoniazid-induced lupus.[1,4,5] The syndrome appeared to be due to isoniazid itself rather than its metabolite acetylisoniazid.[6]

Treatment of Adverse Effects

Pyridoxine hydrochloride 10 mg daily is usually recommended for prophylaxis of peripheral neuritis associated with isoniazid although up to 50 mg daily may be used. A dose of 50 mg three times daily may be given for treatment of peripheral neuritis if it develops.

Nicotinamide has been given, usually with pyridoxine, to patients who develop pellagra.

Isoniazid doses of 1.5 g or more are potentially toxic and doses of 10 to 15 g may be fatal without appropriate treatment. Treatment of overdosage is symptomatic and supportive and consists of activated charcoal, correction of metabolic acidosis, and control of convulsions. Large doses of pyridoxine may be needed intravenously for control of convulsions (see below) and should be given with diazepam. Isoniazid is removed by haemodialysis or peritoneal dialysis.

Overdosage. In adults an initial intravenous dose of pyridoxine hydrochloride equivalent to the estimated amount of isoniazid ingested (or, if the amount ingested is unknown, pyridoxine hydrochloride 5 g) has been recommended by the UK National Poisons Information Service for the management of convulsions; diazepam should also be given. For children the recommended dose of pyridoxine hydrochloride is 70 mg/kg (to a maximum of 5 g). If convulsions continue or recur, this dose may be repeated. Oral activated charcoal (50 g for adults and 10 to 15 g in children) may be considered if this is given within 1 hour of ingestion of isoniazid.

Pyridoxine deficiency. Pyridoxine deficiency associated with isoniazid in doses of 5 mg/kg daily is uncommon. Patients at risk of developing pyridoxine deficiency include those with diabetes, uraemia, alcoholism, HIV infection, and malnutrition.[1,2] Supplementation with pyridoxine should be considered for these at-risk groups as well as for pregnant women and patients with seizure disorders.[1] For the prophylaxis of peripheral neuritis it is common practice to give pyridoxine 10 mg daily, although 6 mg daily might be sufficient.[3] However, in one patient a dose of pyridoxine 10 mg daily failed to prevent psychosis, the symptoms of which only resolved after stopping isoniazid and increasing the pyridoxine dosage to 100 mg daily.[4]

Precautions

Isoniazid should be used with caution in patients with convulsive disorders, a history of psychosis, or hepatic or renal impairment. Patients who are at risk of neuropathy or pyridoxine deficiency, including those who are diabetic, alcoholic, malnourished, uraemic, pregnant, or infected with HIV, should be given pyridoxine, usually in a dose of 10 mg daily, although up to 50 mg daily may be used. If symptoms of hepatitis develop, such as malaise, fatigue, anorexia, and nausea, isoniazid should be stopped pending evaluation.

Liver function should be checked before treatment with isoniazid and special care should be taken in alcoholic patients or those with pre-existing liver disease. Regular monitoring of liver function is recommended in patients with pre-existing liver disease, and the British Thoracic Society has recommended that isoniazid treatment be suspended if serum aminotransferase concentrations are elevated to more than 5 times the normal upper limit or the bilirubin concentration rises. They allow cautious sequential re-introduction of antimycobacterial drugs once liver function has returned to normal: first isoniazid, then rifampicin, and then pyrazinamide. Careful monitoring should be considered for black and Hispanic women, in whom there may be an increased risk of fatal hepatitis.

When visual symptoms occur during isoniazid treatment periodic eye examinations have been suggested.

Breast feeding. Peak concentrations of isoniazid in breast milk were 6 micrograms/mL after a dose of 5 mg/kg and were 16.6 micrograms/mL after a 300-mg dose.[1] However, drug concentrations in the breast milk are too low to prevent or treat tuberculosis in infants. Adverse effects on breast-fed infants have not been reported and the American Academy of Pediatrics thus considers isoniazid to be usually compatible with breast feeding,[2] although such infants should be monitored for toxic reactions.

1. Snider D, Powell KE. Should women taking antituberculosis drugs breast-feed? *Arch Intern Med* 1984; **144:** 589–90.

Porphyria. Isoniazid is considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity.

Pregnancy and the neonate. In a review[1] of antituberculous treatment in pregnant patients it was reported that over 95% of 1480 pregnancies in which isoniazid had been given resulted in a normal term infant. Slightly more than 1% of the infants/fetuses were abnormal and many of these abnormalities were CNS related. Isoniazid is therefore recognised as being suitable for use in regimens for the **treatment** of tuberculosis in pregnant patients.[2,3] Pyridoxine supplementation is recommended[2] (see Treatment of Adverse Effects, above). **Preventive therapy** with isoniazid is generally delayed until after delivery unless other risk factors are present.

Interactions

The risk of hepatotoxicity may be increased in patients receiving isoniazid with a rifamycin or other potentially hepatotoxic drugs, including alcohol.

Isoniazid can inhibit the hepatic metabolism of a number of drugs, in some cases leading to increased toxicity. These include the antiepileptics carbamazepine (p.474), ethosuximide (p.480), primidone, and phenytoin (p.498), the benzodiazepines diazepam and triazolam (p.989), chlorzoxazone (p.1895), theophylline (p.1143), and disulfiram. The metabolism of enflurane (see Effects on the Kidneys, p.1782) may be increased in patients receiving isoniazid, resulting in potentially nephrotoxic levels of fluoride. Isoniazid has been associated with increased concentrations and enhanced effects or toxicity of clofazimine (p.255), cycloserine (p.260), and warfarin (p.1428).

For interactions affecting isoniazid, see below.

Alcohol. The metabolism of isoniazid may be increased in chronic alcoholics: this may lead to reduced isoniazid effectiveness.[1] These patients may also be at increased risk of developing isoniazid-induced peripheral neuropathies and hepatic damage (see Precautions, above).

1. Anonymous. Interaction of drugs with alcohol. *Med Lett Drugs Ther* 1981; **23:** 33–4.

Antacids. Oral absorption of isoniazid is reduced by aluminium-containing antacids; isoniazid should be given at least 1 hour before the antacid.[1]

1. Hurwitz A, Schluzman DL. Effects of antacids on gastrointestinal absorption of isoniazid in rat and man. *Am Rev Respir Dis* 1974; **109:** 41–7.

Antifungals. Serum concentrations of isoniazid were below the limits of detection in a patient also receiving rifampicin and *ketoconazole*.[1] For the effect of isoniazid on ketoconazole, see p.539.

1. Abadie-Kemmerly S, *et al.* Failure of ketoconazole treatment of Blastomyces dermatitidis due to interaction of isoniazid and rifampin. *Ann Intern Med* 1988; **109:** 844–5. Correction. *ibid.* 1989; **111:** 96.

Antivirals. The clearance of isoniazid was approximately doubled when *zalcitabine* was given to 12 HIV-positive patients.[1] In addition, care is needed since *stavudine* and zalcitabine may also cause peripheral neuropathy; use of isoniazid with stavudine has been reported to increase its incidence.[2]

1. Lee BL, *et al.* The effect of zalcitabine on the pharmacokinetics of isoniazid in HIV-infected patients. *Intersci Conf Antimicrob Agents Chemother* 1994; **34:** 3(A4).
2. Breen RAM, *et al.* Increased incidence of peripheral neuropathy with co-administration of stavudine and isoniazid in HIV-infected individuals. *AIDS* 2000; **14:** 615.

Corticosteroids. Giving *prednisolone* 20 mg to 13 slow acetylators and 13 fast acetylators receiving isoniazid 10 mg/kg reduced plasma concentrations of isoniazid by 25 and 40% respectively.[1] Renal clearance of isoniazid was also enhanced in both acetylator phenotypes and the rate of acetylation increased in slow acetylators only.[1]

The clinical significance of this effect is not established.

1. Sarma GR, *et al.* Effect of prednisolone and rifampin on isoniazid metabolism in slow and rapid inactivators of isoniazid. *Antimicrob Agents Chemother* 1980; **18:** 661–6.

Food. Palpitations, headache, conjunctival irritation, severe flushing, tachycardia, tachypnoea, and sweating have been reported in patients taking isoniazid after ingestion of *cheese*,[1,2] *red wine*,[1] and some *fish*.[3,4] Accumulation of tyramine[1] or histamine[3] has been proposed as the cause of these food-related reactions, and they could be mistaken for anaphylaxis.[4]

4. O'Sullivan TL. Drug-food interaction with isoniazid resembling anaphylaxis. *Ann Pharmacother* 1997; **31:** 928.

Opioid analgesics. For a report of an interaction between isoniazid and *pethidine*, attributed to isoniazid's inhibitory actions on monoamine oxidase, see p.114.

Antimicrobial Action

Isoniazid is highly active against *Mycobacterium tuberculosis* and may have activity against some strains of other mycobacteria including *M. kansasii*.

Although it is rapidly bactericidal against actively dividing *M. tuberculosis*, it is considered to be only bacteriostatic against semi-dormant organisms and has less sterilising activity than rifampicin or pyrazinamide.

Resistance of *M. tuberculosis* to isoniazid develops rapidly if it is used alone in the *treatment* of clinical infection, and may be due in some strains to loss of the gene for catalase production. Resistance is delayed or prevented by the combination of isoniazid with other antimycobacterials which appears to be highly effective in preventing emergence of resistance to other antituberculous drugs. Resistance does not appear to be a problem when isoniazid is used alone in *prophylaxis*, probably because the bacillary load is low.

Mycobacterium avium complex. Synergistic activity of isoniazid plus streptomycin and, to a lesser degree, isoniazid plus clofazimine, against *Mycobacterium avium* complex (MAC) has been demonstrated *in vitro* and *in vivo*.[1]

1. Reddy MV, *et al.* In vitro and in vivo synergistic effect of isoniazid with streptomycin and clofazimine against Mycobacterium avium complex (MAC). *Tubercle Lung Dis* 1994; **75:** 208–12.

Pharmacokinetics

Isoniazid is readily absorbed from the gastrointestinal tract and after intramuscular injection. Peak concentrations of about 3 to 7 micrograms/mL appear in blood 1 to 2 hours after an oral fasting dose of 300 mg. The rate and extent of absorption of isoniazid is reduced by food. Isoniazid is not considered to be bound appreciably to plasma proteins and distributes into all body tissues and fluids, including the CSF. It appears in fetal blood if given during pregnancy (see below), and is distributed into breast milk (see under Precautions, above).

The plasma half-life for isoniazid ranges from about 1 to 6 hours, with shorter half-lives in fast acetylators. The primary metabolic route is the acetylation of isoniazid to acetylisoniazid by *N*-acetyltransferase found in the liver and small intestine. Acetylisoniazid is then hydrolysed to isonicotinic acid and monoacetylhydrazine; isonicotinic acid is conjugated with glycine to isonicotinyl glycine (isonicotinuric acid) and monoacetylhydrazine is further acetylated to diacetylhydrazine. Some unmetabolised isoniazid is conjugated to hydrazones. The metabolites of isoniazid have no tuberculostatic activity and, apart from possibly monoacetylhydrazine, they are also less toxic. The rate of acetylation of isoniazid and monoacetylhydrazine is genetically determined and there is a bimodal distribution of persons who acetylate them either slowly or rapidly. Ethnic groups differ in their proportions of these genetic phenotypes. When isoniazid is given daily or 2 or 3 times weekly, clinical effectiveness is not influenced by acetylator status.

In patients with normal renal function, over 75% of a dose appears in the urine in 24 hours, mainly as metabolites. Small amounts of drug are also excreted in the faeces. Isoniazid is removed by haemodialysis.

Distribution. Therapeutic concentrations of isoniazid have been detected in CSF[1,2] and synovial fluid[3] several hours after an oral dose. Diffusion into saliva is good and it has been suggested that salivary concentrations could be used in place of serum concentrations in pharmacokinetic studies.[4]

3. Mouries D, *et al.* Passage articulaire de l'isoniazide et de l'éthambutol: deux observations de synovite tuberculeuse du genou. *Nouv Presse Med* 1975; **4:** 2734.
4. Gurumurthy P, *et al.* Salivary levels of isoniazid and rifampicin in tuberculous patients. *Tubercle* 1990; **71:** 29–33.

HIV-infected patients. Malabsorption of isoniazid and other antituberculous drugs may occur in patients with HIV infection and tuberculosis, and may contribute to acquired drug resistance and reduced efficacy of tuberculosis treatment. For further information on the absorption of antituberculous drugs in HIV-infected patients see Pharmacokinetics, under Rifampicin, p.328.

Pregnancy. Isoniazid crosses the placenta and average fetal concentrations of 61.5 and 72.8% of maternal serum or plasma concentration have been reported.[1] The half-life of isoniazid may be prolonged in neonates.[1]

1. Holdiness MR. Transplacental pharmacokinetics of the antituberculosis drugs. *Clin Pharmacokinet* 1987; **13:** 125–9.

Uses and Administration

Isoniazid is a hydrazide derivative that is the mainstay of the primary treatment of pulmonary and extrapulmonary tuberculosis (p.196). It is used with other antituberculous drugs usually in regimens including rifampicin, ethambutol, and pyrazinamide. Isoniazid is also used in high-risk subjects for the prophylaxis of tuberculosis.

Isoniazid is given in the initial and continuation phases of short-course tuberculosis regimens. The usual adult dose is 5 mg/kg, to a maximum of 300 mg, daily by mouth on an empty stomach. For intermittent therapy, WHO recommends 10 mg/kg three times a week or 15 mg/kg twice a week, while the recommended dose in the UK is 15 mg/kg three times a week and in the USA 15 mg/kg once weekly or two or three times a week is recommended. Caution is required in patients with hepatic impairment and doses may need to be reduced in those with severe renal impairment.

Similar doses to those used orally may be given by intramuscular injection when isoniazid cannot be taken by mouth; it may also be given by intravenous injection. Isoniazid has also been given intrathecally and intrapleurally.

In the treatment of latent tuberculosis, daily doses of 300 mg for 6 months are recommended by WHO and in the UK, while in the USA the preferred treatment regimen is oral isoniazid 5 mg/kg daily or 15 mg/kg twice weekly for 9 months. As an alternative to such regimens, isoniazid may be given with rifampicin for 3 months.

For details of doses in infants, children, and adolescents, see below.

Isoniazid aminosalicylate (pasiniazid) and isoniazid sodium glucuronate have also been used in the treatment of tuberculosis.

Fixed-dose combination products containing 2, 3, or 4 drugs have been developed in order to improve patient compliance and avoid monotherapy, thereby decreasing the risk of acquired drug resistance. Products containing isoniazid in various combinations with rifampicin, ethambutol, and pyrazinamide are available in some countries.

Administration in children. For the treatment of tuberculosis in infants, children, and adolescents the American Academy of Pediatrics (AAP) suggests an oral dose of isoniazid 10 to 15 mg/kg daily or 20 to 30 mg/kg twice weekly by mouth, for both the initial and continuation phases. For children 1 month and older the *BNFC* suggests oral doses of 5 to 10 mg/kg once daily or 15 mg/kg three times a week; WHO recommends 5 mg/kg once daily, or 10 mg/kg three times a week, or 15 mg/kg twice a week.

For the treatment of *latent* tuberculosis the AAP and the American Thoracic society suggest oral doses of 10 to 20 mg/kg daily or 20 to 40 mg/kg twice weekly for 9 months. For children 1 month and older the *BNFC* suggests a dose of 5 mg/kg once daily for 6 months when used alone or for 3 months when given with rifampicin; WHO recommends 5 mg/kg once daily for 6 months.

For daily dosing regimens the maximum oral dose of isoniazid is 300 mg and for intermittent regimens the maximum dose is 900 mg per dose.

Preparations

BP 2008: Isoniazid Injection; Isoniazid Tablets;
USP 31: Isoniazid Injection; Isoniazid Syrup; Isoniazid Tablets; Rifampin and Isoniazid Capsules; Rifampin, Isoniazid, and Pyrazinamide Tablets; Rifampin, Isoniazid, Pyrazinamide, and Ethambutol Hydrochloride Tablets.

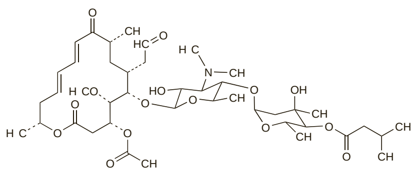
Josamycin *(BAN, USAN, rINN)*

EN-141; Josamicina; Josamicinas; Josamycine; Josamycinum; Josamysiini; Jozamicin; Leucomycin A_3. A stereoisomer of 7-(formylmethyl)-4,10-dihydroxy-5-methoxy-9,16-dimethyl-2-oxo-oxacyclohexadeca-11,13-dien-6-yl 3,6-dideoxy-4-*O*-(2,6-dideoxy-3-*C*-methyl-α-L-*ribo*-hexopyranosyl)-3-(dimethylamino)-β-D-glucopyranoside 4′-acetate 4″-isovalerate.

Джозамицин

$C_{42}H_{69}NO_{15}$ = 828.0.
CAS — 16846-24-5; 56689-45-3.
ATC — J01FA07.
ATC Vet — QJ01FA07.



Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn*.

Ph. Eur. 6.2 (Josamycin). A macrolide antibiotic produced by certain strains of *Streptomyces narbonensis* var. *josamyceticus* var. *nova*, or obtained by any other means. A white or slightly yellowish, slightly hygroscopic powder. It contains a minimum of 900 units/mg calculated with reference to the dried substance. Very slightly soluble in water; soluble in acetone; freely soluble in dichloromethane and in methyl alcohol. Store in airtight containers.

Josamycin Propionate *(BANM, rINNM)*

Josamicino propionatas; Josamycine, propionate de; Josamycini propionas; Josamycinpropionat; Josamycin-propionát; Josamysiinipropionaatti; Jozamicin-propionát; Propionato de josamicina; YS-20P. Josamycin 10-propionate.

Джозамицина Пропионат

$C_{45}H_{73}NO_{16}$ = 884.1.
CAS — 56111-35-4; 40922-77-8.
ATC — J01FA07.
ATC Vet — QJ01FA07.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn*.

Ph. Eur. 6.2 (Josamycin Propionate). It is derived from a macrolide antibiotic produced by certain strains of *Streptomyces narbonensis* var. *josamyceticus* var. *nova*, or obtained by any other means. A white or slightly yellowish, slightly hygroscopic, crystalline powder. It contains a minimum of 843 units/mg, calculated with reference to the dried substance. Practically insoluble in water; soluble in acetone; freely soluble in dichloromethane and in methyl alcohol. Store in airtight containers.

Adverse Effects and Precautions

As for Erythromycin, p.270. Josamycin is reported to produce less gastrointestinal disturbance than erythromycin.

Oedema. A report of josamycin-induced oedema of the foot.[1]

1. Bosch X, *et al.* Josamycin-induced pedal oedema. *BMJ* 1993; **307:** 26.

Interactions

For a discussion of drug interactions of macrolide antibacterials, see Erythromycin, p.271.

Cytochrome P450 isoenzymes. Josamycin is reported to have little or no effect on hepatic cytochrome P450 isoenzymes and may therefore interact less than erythromycin with other drugs metabolised by this enzyme system (see Mechanism, under Interactions of Erythromycin, p.271). The general absence of an interaction between josamycin and theophylline would appear to support this.

Antimicrobial Action

As for Erythromycin, p.271. Some reports suggest that josamycin may be more active against some strains of anaerobic species such as *Bacteroides fragilis*.

Uses and Administration

Josamycin is a macrolide antibacterial with actions and uses similar to those of erythromycin (p.272). It is given orally as the base or the propionate but doses are expressed in terms of the base; 1.07 g of josamycin propionate is equivalent to about 1 g of josamycin. Usual doses in the treatment of susceptible infections are the equivalent of 1 to 2 g of josamycin daily in 2 or more divided doses.

Preparations

Proprietary Preparations (details are given in Part 3)
Austria: Josalid; ***Fr.:*** Josacine; ***Ger.:*** Wilprafen†; ***Hung.:*** Wilprafen†; ***Ital.:*** Iosalide; Josaxin†; ***Jpn:*** Josamy; ***Rus.:*** Wilprafen (Вильпрафен); ***Spain:*** Josamina.

Multi-ingredient: ***Ital.:*** Corti-Fluoral.

Kanamycin Acid Sulfate

Kanamicina, sulfato ácido de; Kanamicino rūgštusis sulfatas; Kanamycin Acid Sulphate *(BANM)*; Kanamycin sulfát kyselý; Kanamycine, sulfate acide de; Kanamycini sulfas acidus; Kanamycinsyrasulfat; Kanamysiinihapposulfaatti; Savanyú kanamicin-szulfát.
ATC — A07AA08; J01GB04; S01AA24.
ATC Vet — QA07AA08; QJ01GB04; QS01AA24.

Kanamycin B	NH_2	NH_2
Kanamycin C	OH	NH_2

(kanamycin)

Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Kanamycin Acid Sulphate). A form of kanamycin sulfate prepared by adding sulfuric acid to a solution of kanamycin sulfate and drying by a suitable method. A white or almost white, hygroscopic powder containing not less than 670 units/mg and 23 to 26% of sulfate, calculated with reference to the dried material. Soluble 1 in about 1 of water; practically insoluble in alcohol and in acetone. A 1% solution in water has a pH of 5.5 to 7.5.

Kanamycin Sulfate *(rINNM)*

Kanamicin-monoszulfát; Kanamicino monosulfatas; Kanamycin A Sulphate; Kanamycin monosulfát monohydrát; Kanamycin Monosulphate; Kanamycin Sulphate *(BANM)*; Kanamycine, monosulfate de; Kanamycine, Sulfate de; Kanamycini monosulfas; Kanamycini Monosulfas Monohydricus; Kanamycini Sulfas; Kanamycinmonosulfat; Kanamycyny siarczan; Kanamysiinimonosulfaatti; Sulfato de kanamicina. 6-*O*-(3-Amino-3-deoxy-α-D-glucopyranosyl)-4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine sulphate monohydrate.

Канамицина Сульфат

$C_{18}H_{36}N_4O_{11},H_2SO_4,H_2O$ = 600.6.
CAS — 59-01-8 (kanamycin); 25389-94-0 (anhydrous kanamycin sulfate).
ATC — A07AA08; J01GB04; S01AA24.
ATC Vet — QA07AA08; QJ01GB04; QS01AA24.

Pharmacopoeias. In *Eur.* (see p.vii) and *US*.
Jpn includes the anhydrous substance.

Ph. Eur. 6.2 (Kanamycin Monosulphate; Kanamycin Sulphate BP 2008). The sulfate of an antimicrobial substance produced by the growth of certain strains of *Streptomyces kanamyceticus*. A white or almost white, crystalline powder containing not less than 750 units/mg and 15.0 to 17.0% of sulfate, calculated with reference to the dried material. Soluble 1 in about 8 of water; practically insoluble in alcohol and in acetone. A 1% solution in water has a pH of 6.5 to 8.5.

USP 31 (Kanamycin Sulfate). A white, odourless crystalline powder. It has a potency equivalent to not less than 750 micrograms of kanamycin per mg, calculated on the dried basis. Freely soluble in water; insoluble in acetone, in ethyl acetate, and in benzene. pH of a 1% solution in water is between 6.5 and 8.5. Store in airtight containers.

Incompatibility. For discussion of the incompatibility of aminoglycosides such as kanamycin with beta lactams, see under Gentamicin Sulfate, p.282. Kanamycin is also reported to be incompatible with various other drugs including some other antimicrobials as well as with some electrolytes.

Adverse Effects, Treatment, and Precautions

As for Gentamicin Sulfate, p.282.

For patients given standard regimens, peak plasma concentrations of kanamycin greater than 30 micrograms/mL, and trough concentrations greater than 10 micrograms/mL, should be avoided. Auditory (cochlear) toxicity is more frequent than vestibular toxicity.

Local pain and inflammation, as well as bruising and haematoma, have been reported at the site of intramuscular injections.

Gastrointestinal disturbances and a malabsorption syndrome, similar to that seen with oral neomycin (p.305), have occurred after oral kanamycin. Oral kanamycin should be avoided in patients with gastrointestinal ulceration.

Breast feeding. Although kanamycin is distributed into breast milk[1] the American Academy of Pediatrics states that no adverse effects have been seen in breast-fed infants whose mothers were receiving kanamycin, and therefore considers[2] that its use is usually compatible with breast feeding.

2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 27/05/04)

Interactions

As for Gentamicin Sulfate, p.283.

Antimicrobial Action

As for Gentamicin Sulfate, p.283. It is active against a similar range of organisms although it is not active against *Pseudomonas* spp. Some strains of *Mycobacterium tuberculosis* are sensitive.
