Antidepressants. Cardiac abnormalities have been reported in 2 patients taking *fluoxetine* with terfenadine.[1,2] Similarly, the use of *nefazodone* with terfenadine has resulted in prolongation of the QT interval.[3]

1. Swims MP. Potential terfenadine-fluoxetine interaction. *Ann Pharmacother* 1993; **27:** 1404–5.

3. Abernethy DR, *et al.* Loratadine and terfenadine interaction with nefazodone: both antihistamines are associated with QTc prolongation. *Clin Pharmacol Ther* 2001; **69:** 96–103.

Antiepileptics. For reference to an interaction between terfenadine and *carbamazepine*, see p.475.

Antifungals. Pharmacokinetic studies have shown that *itraconazole*[1] and *ketoconazole*[2] interfere with the metabolism of terfenadine leading to its accumulation. A high plasma-terfenadine concentration is associated with prolongation of the QT interval, and arrhythmias such as torsade de pointes have been reported in patients given terfenadine with ketoconazole[3] or itraconazole.[1,4] While there has been a pharmacokinetic study[5] that suggested that the interaction between terfenadine and *fluconazole* might not be clinically significant, as the mechanism of the interaction appeared to involve the metabolite of terfenadine and did not lead to accumulation of the cardiotoxic parent compound, this may not always be the case. Studies in a small group of patients who had abnormal patterns of terfenadine metabolism found increases in terfenadine concentrations associated with ECG abnormalities when terfenadine was given with high doses of fluconazole.[6]

Calcium-channel blockers. For reference to an interaction between terfenadine and *nifedipine*, see p.1353.

Grapefruit juice. A study[1] in healthy subjects given terfenadine and grapefruit juice for 7 days found raised plasma-terfenadine concentrations and prolongation of the QT interval. These effects were less pronounced when terfenadine was given 2 hours before grapefruit juice, but were nevertheless quantifiable in some subjects. In another study QT interval changes were not found in healthy subjects given single doses of terfenadine and grapefruit juice.[2] However, the highly variable pharmacokinetics between individuals led the authors to conclude that prolongation of the QT interval was possible following single doses. The probable mechanism of the interaction is inhibition of the metabolism of terfenadine by the cytochrome P450 isoenzyme CYP3A4.

1. Benton RE, *et al.* Grapefruit juice alters terfenadine pharmacokinetics, resulting in prolongation of repolarization on the electrocardiogram. *Clin Pharmacol Ther* 1996; **59:** 383–8.
2. Rau SE, *et al.* Grapefruit juice-terfenadine single-dose interaction: magnitude, mechanism, and relevance. *Clin Pharmacol Ther* 1997; **61:** 401–9.

Pharmacokinetics

Terfenadine is rapidly absorbed from the gastrointestinal tract; peak plasma concentrations are achieved within about 2 hours. It is a prodrug and undergoes extensive first-pass metabolism in the liver to its active metabolite the carboxylic acid derivative fexofenadine (p.579). The other main metabolite is an inactive piperidine-carbinol derivative. About 97% of terfenadine is bound to plasma proteins; fexofenadine is reported to be less extensively bound. Terfenadine does not appear to cross the blood-brain barrier to a significant extent; limited amounts of fexofenadine, but not the parent drug, have been detected in breast milk. An elimination half-life of 16 to 23 hours has been reported for terfenadine. The metabolites, and traces of unchanged drug, are excreted in the urine and the faeces.

Uses and Administration

Terfenadine, a piperidine derivative, is a non-sedating antihistamine. It does not have significant antimuscarinic actions. It is used for the symptomatic relief of allergic conditions including rhinitis (p.565) and conjunctivitis (p.564) and skin disorders such as urticaria (p.565).

The maximum oral dose of terfenadine is 120 mg daily given either as 60 mg twice daily or 120 mg in the morning; a starting dose of 60 mg daily in a single dose or in two divided doses is recommended for rhinitis and conjunctivitis. Children who are over 12 years of age and weigh more than 50 kg may receive the usual adult dosage.

For dosage in renal impairment see below.

Administration in renal impairment. Half the usual oral daily dose of terfenadine has been suggested for patients with creatinine clearance less than 40 mL/minute.

Pharmacopoeias. In *Swiss* and *US*.

USP 31 (Thiethylperazine Maleate). A yellowish granular powder, odourless or has not more than a slight odour. Soluble 1 in 1700 of water and 1 in 530 of alcohol; practically insoluble in chloroform and in ether; slightly soluble in methyl alcohol. pH of a 0.1% solution in water is between 2.8 and 3.8. Store in airtight containers. Protect from light.

Incompatibility. Incompatibility has been reported between injections of thiethylperazine maleate and nalbuphine hydrochloride.[1]

1. Jump WG, *et al.* Compatibility of nalbuphine hydrochloride with other preoperative medications. *Am J Hosp Pharm* 1982; **39:** 841–3.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561.

Interactions

As for the sedating antihistamines in general, p.563.

Uses and Administration

Thiethylperazine, a phenothiazine derivative with a piperazine side-chain, is a sedating antihistamine used as an antiemetic for the control of nausea and vomiting (p.564) associated with surgical procedures and cancer therapy. It has also been used for the management of vertigo (p.565) and motion sickness although there is some doubt over its efficacy for these indications.

Thiethylperazine is given as the maleate or malate and doses are expressed in terms of the appropriate salt. Thiethylperazine maleate 10 mg is equivalent to about 10.53 mg of thiethylperazine malate.

Thiethylperazine *maleate* is given in usual oral doses of 10 mg up to three times daily; the maleate has also been given rectally. Where oral dosage is impractical similar doses of the *malate* may be given by deep intramuscular injection. Thiethylperazine is not recommended for use in children.

Preparations

USP 31: Thiethylperazine Maleate Suppositories; Thiethylperazine Maleate Tablets.

(trimethobenzamide)

Pharmacopoeias. In *US*.

USP 31 (Trimethobenzamide Hydrochloride). A white crystalline powder having a slight phenolic odour. Soluble 1 in 2 of water, 1 in 59 of alcohol, 1 in 67 of chloroform, and 1 in 720 of ether; insoluble in benzene.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561.

Pain at the site of intramuscular injection and local irritation after rectal use have been noted.

Pregnancy. For discussion of the use of antihistamines in pregnancy, including some evidence of an excess number of congenital abnormalities in infants born to mothers exposed to trimethobenzamide, see p.563.

Interactions

As for the sedating antihistamines in general, p.563.

Uses and Administration

Trimethobenzamide hydrochloride, a monoethanolamine derivative, is a sedating antihistamine used as an antiemetic in the control of nausea and vomiting (p.564) including postoperative nausea and vomiting.

The usual dose is 250 or 300 mg orally or 200 mg by deep intramuscular injection or rectally three or four times daily. Children weighing more than about 15 kg have been given 100 to 200 mg three or four times daily by the oral or rectal route. Children weighing less than this have been given 100 mg three or four times daily by the rectal route.

Preparations

(tripelennamine)

Tripelennamine Hydrochloride *(BANM, rINNM)*

Hidrocloruro de tripelenamina; Tripélennamine, Chlorhydrate de; Tripelennamini Hydrochloridum; Tripelennaminium Chloride.

Трипеленнамина Гидрохлорид

$C_{16}H_{21}N_3,HCl$ = 291.8.

CAS — 154-69-8.

ATC — D04AA04; R06AC04.

ATC Vet — QD04AA04; QR06AC04.

Pharmacopoeias. In *US*.

USP 31 (Tripelennamine Hydrochloride). A white crystalline powder. It slowly darkens on exposure to light. Soluble 1 in 1 of water, 1 in 6 of alcohol and of chloroform, 1 in 350 of acetone; insoluble in ether, in ethyl acetate, and in benzene. Its solutions are practically neutral to litmus. Protect from light.

Profile

Tripelennamine, an ethylenediamine derivative, is a sedating antihistamine (p.561) with antimuscarinic and moderate sedative properties. It has been used for the symptomatic relief of hypersensitivity reactions. It may also be used in compound preparations for the symptomatic treatment of coughs and the common cold (p.564).

Tripelennamine has been given orally as the citrate or the hydrochloride. Tripelennamine hydrochloride has also been applied topically to the skin, although, as with other antihistamines, there is a risk of sensitisation.

Abuse. References to the intravenous abuse of tripelennamine alone[1] or with pentazocine in the combination known as T's and blues.[2-4]

2. Showalter CV. T's and blues: abuse of pentazocine and tripelennamine. *JAMA* 1980; **244:** 1224–5.
3. von Almen WF, Miller JM. "Ts and Blues" in pregnancy. *J Reprod Med* 1986; **31:** 236–9.
4. McGwier BW, *et al.* Acute myocardial infarction associated with intravenous injection of pentazocine and tripelennamine. *Chest* 1992; **101:** 1730–2.

Overdosage. A severe toxic reaction, including agitation, hallucinations, and myoclonic jerks occurred in an 8-year-old child who was sprayed over the trunk and extremities with tripelennamine hydrochloride 2.1375 g in the treatment of severe poison ivy poisoning.[1] It was likely that inhalation of the fine mist of the aerosol spray contributed to the reaction but in this patient the initial reaction began 3 hours after exposure suggesting that percutaneous absorption through the multiple skin lesions probably contributed significantly. The original reaction was inadvertently prolonged by subsequent treatment with diphenhydramine hydrochloride and promethazine hydrochloride.

Triprolidine Hydrochloride

(BANM, rINNM)

Hidrocloruro de triprolidina; Triprolidine, Chlorhydrate de; Triprolidini Hydrochloridum. (*E*)-2-[3-(Pyrrolidin-1-yl)-1-*p*-tolylprop-1-enyl]pyridine hydrochloride monohydrate.

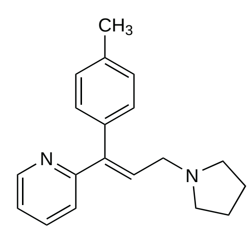
Трипролидина Гидрохлорид

$C_{19}H_{22}N_2,HCl,H_2O$ = 332.9.

CAS — 486-12-4 (triprolidine); 550-70-9 (anhydrous triprolidine hydrochloride); 6138-79-0 (triprolidine hydrochloride monohydrate).

ATC — R06AX07.

ATC Vet — QR06AX07.



(triprolidine)

Pharmacopoeias. In *Br.* and *US*.

BP 2008 (Triprolidine Hydrochloride). A white, odourless or almost odourless, crystalline powder. Freely soluble in water and in alcohol; very soluble in chloroform; practically insoluble in ether.

USP 31 (Triprolidine Hydrochloride). A white crystalline powder, having no more than a slight, but unpleasant, odour. Soluble 1 in 2.1 of water, 1 in 1.8 of alcohol, 1 in 1 of chloroform, and 1 in 2000 of ether. Its solutions are alkaline to litmus. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561. UK product information for acrivastine has warned that acrivastine should not be used in patients hypersensitive to triprolidine.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving triprolidine, and the American Academy of Pediatrics[1] considers that it is therefore usually compatible with breast feeding.

In a study[2] in 3 women of the excretion of triprolidine and pseudoephedrine, taken orally in a combined preparation, triprolidine was found to reach concentrations in breast milk similar to those found in plasma in one subject, and slightly lower than in plasma in the others. It was calculated that 0.06 to 0.2% of the ingested dose was distributed into breast milk over 24 hours. Concentrations of pseudoephedrine in breast milk exceeded those in plasma in all 3 women.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 30/01/04)
2. Findlay JWA, *et al.* Pseudoephedrine and triprolidine in plasma and breast milk of nursing mothers. *Br J Clin Pharmacol* 1984; **18:** 901–6.

Interactions

As for the sedating antihistamines in general, p.563.

Pharmacokinetics

After absorption from the gastrointestinal tract, triprolidine is metabolised; a carboxylated derivative accounts for about half the dose excreted in the urine. Reported half-lives vary from 3 to 5 hours or more. Triprolidine is distributed into breast milk.

2. Miles MV, *et al.* Pharmacokinetics of oral and transdermal triprolidine. *J Clin Pharmacol* 1990; **30:** 572–5.

Uses and Administration

Triprolidine hydrochloride, an alkylamine derivative, is a sedating antihistamine with antimuscarinic and mild sedative effects. It is used for the symptomatic relief of allergic conditions including urticaria (p.565) and rhinitis (p.565), and in pruritic skin disorders (p.565). It is often used in combination with pseudoephedrine hydrochloride for rhinitis and in other compound preparations for the symptomatic treatment of coughs and the common cold (p.564).

It is given orally, the usual dose for adults being 2.5 mg up to four times daily.

Triprolidine tannate has been used similarly.

Triprolidine hydrochloride has also been applied topically to the skin although, as with other antihistamines, there is a risk of sensitisation.

Preparations

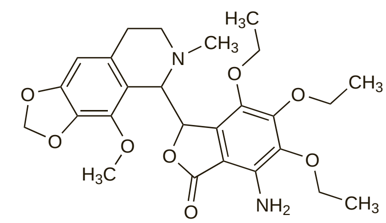
$C_{26}H_{32}N_2O_8$ = 500.5.
CAS — 14504-73-5.
ATC — R06AX21.
ATC Vet — QR06AX21.



Profile

Tritoqualine is stated to inhibit histidine decarboxylase which catalyses the conversion of histidine to histamine. It has no action on histamine H_1-receptors and at therapeutic doses has no sedative or antimuscarinic effects. It has the uses of antihistamines (p.563) and has been given orally in usual doses of 200 to 600 mg daily in 2 or 3 divided doses for the symptomatic relief of hypersensitivity reactions including allergic rhinitis and urticaria.

Preparations

Proprietary Preparations (details are given in Part 3)
Austria: Hypostamin; ***Fr.:*** Hypostamine; ***Ger.:*** Inhibostamin†.

Antimalarials

This chapter describes the main drugs used in the treatment and prophylaxis of malaria, one of the most serious protozoal infections in man. An estimated 40% of the world's population may be at risk of malaria; more than 500 million develop clinical infection, which is often very severe, and 1 to 3 million die each year. WHO produces guidelines for its strategic control and the management of malaria is under constant review. Measures to control malaria include *protection* from mosquito bites, *prophylaxis* with antimalarial drugs, and prompt *treatment* of any infection that develops. They also involve *vector control*; it is now recognised that for many countries vector eradication is an unrealistic aim.

Malaria

Malaria is a serious and potentially fatal disease, particularly in the case of falciparum malaria (see below) and especially in non-immune individuals (patients are classified as *non-immune* if they have not previously or recently been exposed to *Plasmodium* infection and as *semi-immune* or *immune* if they have a history of prolonged exposure). It is such a problem in many parts of the world that a global partnership named Roll Back Malaria[1] has been founded by WHO, United Nations Development Programme, UNICEF, and the World Bank with the aim of significantly reducing the world's malaria burden and halving the number of deaths due to malaria by 2010. Prompt diagnosis and effective treatment of malaria are crucial.[2,3]

Malaria is caused by infection by any of 4 species of *Plasmodium* protozoa. *P. falciparum* causes falciparum (malignant tertian or subtertian) malaria, which is the most serious form and can be rapidly fatal in non-immune individuals if not treated promptly. The other 3 species cause what are often termed 'benign' malarias: *P. vivax* causes vivax (benign tertian) malaria, which is widespread but rarely fatal, although symptoms during the primary attack can be severe; *P. malariae* causes quartan malaria, which is generally mild, but can cause fatal nephrosis; and *P. ovale* causes ovale (ovale tertian) malaria, which is the least common type of malaria and produces clinical features similar to *P. vivax*.[4]

The **life cycle** of *Plasmodium* is complex, comprising a sexual phase (sporogony) in the mosquito (vector) and an asexual phase (schizogony) in man (see Figure 1, below).

- Infection in man is usually caused by *sporozoites* from the bite of an infected female anopheline mosquito. It may rarely be acquired in other ways, congenitally via the placenta, or through blood transfusion, needlestick injuries, or organ transplantation.
- After an infected mosquito bite, sporozoites rapidly enter liver parenchymal cells, where they undergo *exoerythrocytic* or *pre-erythrocytic schizogony* forming *tissue schizonts* which mature and release thousands of *merozoites* into the blood on rupture of the cell.
- Merozoites enter erythrocytes where they transform into *trophozoites*. These produce *blood schizonts* which, as they mature, rupture and release merozoites into the circulation, which can infect other erythrocytes.
  This is termed the *erythrocytic cycle* and it is this periodic release of merozoites that is responsible for the characteristic periodicity of the fever in malaria.
- After several erythrocytic cycles, depending on the type of malaria, some erythrocytic forms develop into sexual *gametocytes*. Ingestion of infected blood containing gametocytes by a biting female mosquito allows the life cycle to be completed with the sexual phase in the mosquito.
- In *P. vivax* and *P. ovale* infections, some of the sporozoites entering the liver cells enter a latent tissue stage in the form of *hypnozoites* which are responsible for recurrence of malaria caused by these organisms.

Recurrences resulting from the persistence of latent tissue forms are often referred to as *relapses* while renewed attacks caused by persistent residual erythrocytic forms are termed *recrudescences*. True relapses do not occur with falciparum or quartan malarias.

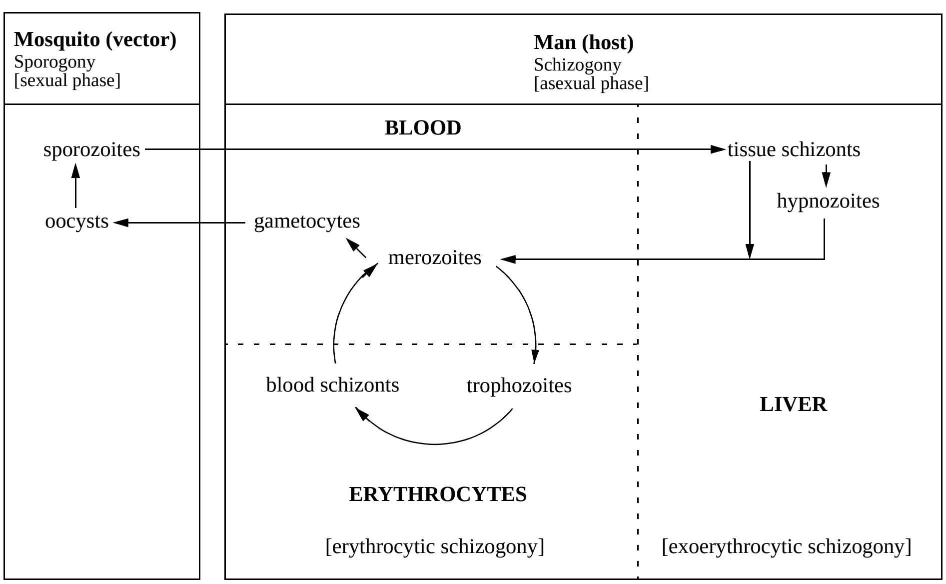
CLINICAL MANIFESTATIONS OF MALARIA

The clinical symptoms of malaria are varied and non-specific; they usually include fever, fatigue, malaise, headache, myalgia, and sweating. Vomiting occurs in about 20% of patients, and mild diarrhoea in less than 5%. As the infection progresses, the spleen enlarges and the patient may develop anaemia and thrombocytopenia. The prognosis worsens with increasing parasite counts, more mature parasites, and more neutrophils containing malaria pigment.[5] Severe falciparum malaria may be complicated by acute renal failure, pulmonary oedema, and cerebral dysfunction. Since none of the clinical features of malaria are diagnostic, a definitive diagnosis depends upon the demonstration of parasites in stained blood films. However, antimalarial drug treatment should not be withheld in the absence of positive blood films if there is clinical suspicion of malaria. Any patient who has been in a malaria area in the previous two months should be considered to have malaria until proved otherwise.

ANTIMALARIAL DRUGS

Antimalarial drugs can be classified by the stage of the parasitic life cycle they affect. Thus:

Figure 1. Life cycle of the malaria parasite *Plasmodium*.



Blood schizontocides act on the erythrocytic stages of the parasite that are directly responsible for the clinical symptoms of the disease. They can produce a clinical cure or suppression of infection by susceptible strains of all 4 species of malaria parasite but, since they have no effect on exoerythrocytic forms, do not produce a radical cure of ovale or vivax malarias.

Tissue schizontocides act on the exoerythrocytic stages of the parasite and are used for causal prophylaxis to prevent invasion of the blood cells, or as anti-relapse drugs to produce radical cures of vivax and ovale malarias.

Gametocytocides destroy the sexual forms of the parasite to interrupt transmission of the infection to the mosquito vector.

Sporontocides have no direct effect on the gametocytes in the human host but prevent sporogony in the mosquito.

Antimalarial drugs can also be classified by the chemical group to which they belong, which in turn determines the stage of the life cycle they affect. The principal antimalarial drugs, classified according to *drug group* and *activity*, are listed in Table 1 p.595.

The naphthyridine derivative pyronaridine is under investigation for its use as an antimalarial. The quinolone antibacterials, and the 4-piperazinoquinoline derivatives, piperaquine and hydroxypiperaquine, have also been studied for their antimalarial activity. The 9-aminoacridines, such as mepacrine, are no longer used in the treatment of malaria.

The differing mechanisms of action of antimalarial drugs sometimes allow the use of combinations of antimalarials to improve efficacy. Such combinations are usually designed to potentiate each other, for instance by acting at sequential steps in the parasite's folic acid pathway (e.g. pyrimethamine with sulfadoxine or dapsone). Alternatively, a combination may be complementary, when the drugs involved act against different stages in the life cycle of the parasite (e.g. the use of chloroquine with primaquine to produce radical cure of *P. vivax* or *P. ovale* infections). The rationale behind the use of such combinations may be to enhance efficacy, particularly when drug resistance is a problem (see below), or it may be an attempt to delay the development of resistance to one or more of the drugs concerned.

Resistance.

Resistance to antimalarials has been documented for *P. falciparum*, *P. vivax*, and *P. malariae* and is seen with all classes of antimalarials except artemisinin and its derivatives.[3] Chloroquine resistance in *P. falciparum* now occurs virtually everywhere that *P. falciparum* malaria is transmitted, with the exception of certain parts of Central America and the Caribbean.[3,6] Resistance in *P. falciparum* to proguanil and pyrimethamine is apparent in many endemic areas. Cross-resistance between proguanil and pyrimethamine may also occur. Resistance in *P. falciparum* to the combination pyrimethamine-sulfadoxine (*Fansidar*) has spread rapidly in South-East Asia, but also occurs in other parts of the world including parts of South America, southern China, and Africa.[3,6] Mefloquine resistance is frequent in some areas of South-East Asia and migrant workers are thought to have spread mefloquine resistance to India and Bangladesh. Resistance has also occurred in the Amazon region of South America and, sporadically, in Africa, but generally, clinical mefloquine resistance outside South-East Asia is rare.[3,6] Resistance to quinine and halofantrine has also been noted. Cross-resistance between halofantrine and mefloquine may occur, as evidenced by reduced responses to halofantrine in some patients who have experienced treatment failure with mefloquine.[6] The emergence of multidrug resistance in *P. falciparum* makes the selection of effective prophylaxis and treatment difficult.

Multidrug resistance is defined as resistance to three or more antimalarial compounds from different chemical classes, of which two of the classes are the 4-aminoquinolines (e.g. chloroquine) and diaminopyrimidines (e.g. pyrimethamine-sulfadoxine (*Fansidar*)). Multidrug resistance occurs in South-East Asia (particularly along the borders of Thailand with Burma and Cambodia) and in the Amazon basin.[3]

P. vivax has developed resistance rapidly to pyrimethamine-sulfadoxine (*Fansidar*) in many areas and resistance to chloroquine and primaquine has also been reported

Table 1. Principal antimalarial drugs.

Antimalarial groups	Principal drugs	Activity
4-Aminoquinolines	Chloroquine Hydroxychloroquine Amodiaquine	Rapid-acting blood schizontocides. Some gametocytocidal activity.
8-Aminoquinolines	Primaquine Tafenoquine	Tissue schizontocide. Also gametocytocidal activity and some activity at other stages of the parasite's life-cycle.
Artemisinin and its derivatives (Sesquiterpene lactones)	Artemether Artesunate	Blood schizontocide.
Biguanides	Proguanil Chlorproguanil	Tissue schizontocides and slow-acting blood schizontocides. Some sporontocidal activity. Dihydrofolate reductase inhibitors.
Diaminopyrimidines	Pyrimethamine	Tissue schizontocide and slow-acting blood schizontocide. Some sporontocidal activity. Dihydrofolate reductase inhibitor. Usually used with antimalarials that inhibit different stages of folate synthesis (sulfonamides or sulfones) to form synergistic combinations.
Dichlorobenzylidines	Lumefantrine	Blood schizontocide.
Hydroxynaphthoquinones	Atovaquone	Blood schizontocide. Usually given in combination with proguanil.
Lincosamides	Clindamycin	Blood schizontocides. Some tissue schizontocidal activity.
4-Methanolquinolines	Cinchona alkaloids Quinine Quinidine	Rapid-acting blood schizontocides. Some gametocytocidal activity.
	Mefloquine	Blood schizontocide.
9-Phenanthrenemethanols	Halofantrine	Blood schizontocide.
Sulfonamides	Sulfadoxine Sulfametopyrazine	Blood schizontocides. Dihydropteroate and folate synthesis inhibitors. Usually given in combination with pyrimethamine.
Sulfones	Dapsone	Blood schizontocide. Folate synthesis inhibitor. Usually given in combination with pyrimethamine
Tetracyclines	Doxycycline Tetracycline	Blood schizontocides. Some tissue schizontocidal activity..

in several parts of the world.[3,6] However, it remains sensitive to chloroquine in South-East Asia, the Indian subcontinent, the Korean peninsula, the Middle East, north-east Africa, and most of South and Central America.[3] Resistance of *P. malariae* to chloroquine was seen recently in Indonesia.[3]

A knowledge of the geographical distribution and degree of resistance is important for the selection of appropriate control measures and for the development of policies for the rational use of antimalarial drugs. Resistance can be prevented, or slowed considerably, by selecting effective drugs and drug combinations according to local patterns of resistance, combining antimalarials with different mechanisms of action, preventing indiscriminate and uncontrolled use, and ensuring very high cure rates through full compliance with the correct antimalarial dose regimens. Malaria control strategies also need to involve other measures such as vector control and health education.[3,7]

TREATMENT OF MALARIA

Malaria is treated with a *blood schizontocide*, selected with due regard to the prevalence of specific patterns of drug resistance in the area of infection. In the case of vivax and ovale malarias (see below) subsequent treatment with a *tissue schizontocide* is needed where it is considered appropriate to prevent relapse.

Antimalarials are generally given orally, although in order to obtain a rapid response in patients with severe or complicated falciparum malaria (see below) it may be necessary to start with parenteral therapy, the patient being transferred to oral therapy when feasible.[3] Where there are only minimal health care facilities and parenteral therapy is not possible or may be delayed, artemisinin or artesunate suppositories may be given.

Treatment of falciparum malaria.

In most parts of the world *P. falciparum* is now resistant to chloroquine and therefore, apart from the rare circumstance of exposure in one of the few remaining areas of chloroquine sensitivity, chloroquine is **not** suitable for treatment. Resistance to pyrimethamine-sulfadoxine (*Fansidar*) has also occurred in most countries where it was used in place of chloroquine.[4]

In **uncomplicated falciparum malaria** (symptomatic malaria without signs of severity or evidence of vital organ dysfunction) combination drug therapy is recommended by WHO[3] for treatment in all *malaria endemic areas* experiencing resistance to monotherapy with chloroquine, amodiaquine, or pyrimethamine-sulfadoxine (*Fansidar*). Drugs with differing mechanisms of action but with similar half-lives should be used to avoid exposure of the parasite to a single drug for a prolonged period and to prevent the emergence and spread of drug-resistant parasites. Pyrimethamine-sulfadoxine (*Fansidar*) and atovaquone-proguanil (*Malarone*) rely on synergy between the 2 components and are operationally considered single products; they should not be considered combination therapy when used alone. The most widely recommended combinations are those that include an artemisinin-based drug as one of the components (ACT). Recommended ACTs are:

- artemether-lumefantrine (*Riamet*)
- artesunate and amodiaquine (in areas where resistance to amodiaquine is low)
- artesunate and pyrimethamine-sulfadoxine (*Fansidar*) (in areas where pyrimethamine-sulfadoxine efficacy is still high)
- artesunate and mefloquine (should only be used in areas of low transmission)
- amodiaquine and pyrimethamine-sulfadoxine (*Fansidar*) is still an effective option for some areas in West Africa where susceptibility remains high and for those countries unable to supply ACTs

In *non-endemic areas* the British Infection Society[8] and the Health Protection Agency Advisory Committee on Malaria Prevention in UK Travellers[9] recommend treating uncomplicated falciparum malaria or mixed infections with one of the following:

- oral quinine sulfate plus follow-on treatment with either doxycycline or clindamycin
- atovaquone-proguanil (*Malarone*)
- artemether-lumefantrine (*Riamet*)

In the USA, the CDC[10] recommends that uncomplicated falciparum malaria acquired in a chloroquine-sensitive area may be treated with oral chloroquine. Hydroxychloroquine may be used as an alternative. Malaria acquired in chloroquine-resistant areas is treated with one of the following:

- quinine sulfate plus doxycycline, tetracycline, or clindamycin
- atovaquone-proguanil (*Malarone*)
- mefloquine (although it should only be considered as a treatment option in patients who cannot use quinine sulfate or atovaquone-proguanil (*Malarone*) due to a higher rate of severe neuropsychiatric events associated with treatment doses)

In **severe or complicated falciparum malaria** including cerebral malaria, parenteral treatment is required to produce adequate blood concentrations as quickly as possible.[3] Patients need to be closely monitored while undergoing parenteral therapy and treatment is changed to an oral antimalarial as soon as the patient's condition permits.

In *malaria endemic areas* that are chloroquine-resistant, or where sensitivity to chloroquine is not known, quinine is usually given intravenously, starting with a loading dose. Intramuscular artemether is an alternative to intravenous quinine. In areas of low transmission intravenous artesunate is the recommended first choice. Intramuscular artemotil should only be used if other above alternatives are not available and intravenous quinidine should only be used if parenteral quinine or artemisinin derivatives are not available. Where there are only minimal health care facilities or when parenteral therapy is not possible or may be delayed, artemisinin, artesunate, artemether, or arterimol suppositories may be given[3]; the nasogastric route may also be used. Follow-on treatment is with either doxycycline or clindamycin (in pregnant women and in children) for 7 days.

In *non-endemic areas* intravenous quinine plus either oral doxycycline or oral clindamycin are recommended by authorities in the UK;[8,9] intravenous artesunate may be available on a named patient basis for the most severe cases if they are not responding to quinine therapy, are possibly infected with quinine-resistant falciparum, or quinine is contra-indicated. In the USA,[10] intravenous quinidine gluconate is used in place of intravenous quinine and intravenous artesunate is under investigation.

Supportive therapy in patients with severe or complicated malaria needs to be directed at reducing hyperpyrexia, controlling convulsions, maintaining fluid balance, and correcting hypoglycaemia. Severe malaria is associated with rapid development of anaemia, and blood transfusions are recommended for children with a haemoglobin concentration of less than 5 g per 100 mL (haematocrit less than 15%) living in areas of high transmission or for those with a haemoglobin level of 7 g per 100 mL (haematocrit threshold of 20%) living in an area of low transmission.[3] Although the benefit of exchange transfusion has not been proven in comparative studies,UK and US guidelines recommend that it be considered for patients with a parasite density of more than 10% or if the patient has cerebral malaria, renal complications, or non-volume overload pulmonary oedema.[9,10] Prophylactic use of anticonvulsants is not recommended and the use of intravenous or intramuscular phenobarbital resulted in increased mortality due to respiratory arrest.[3] Since iron might be involved in the pathogenesis of cerebral malaria, the iron chelator desferrioxamine has been tried in addition to standard antimalarial therapy, but any benefit is yet to be established and WHO advises against its use.[3] Anecdotal reports of the value of corticosteroids in cerebral malaria have not been substantiated by controlled studies and they have no place in the management of this condition.[3,11] Other approaches such as the use of hyperimmune serum or monoclonal antibody to tumour necrosis factor have also been unsuccessful.

Treatment of benign malarias. Benign malarias, which are usually caused by *P. vivax* or, less commonly, by *P. ovale* or *P. malariae*, can be debilitating but are usually less severe than falciparum malaria. Treatment for *P. vivax* and *P. ovale* includes a *radical cure*: that is, cure of both the blood and liver stage infections in order to prevent relapse and recrudescence. Treatment of *P. malariae* does not include radical cure as no hypnozoites are formed during infection. Chloroquine is still generally the drug of choice (but chloroquine-resistant vivax infection has been reported from some areas—notably Papua New Guinea, Indonesia, Myanmar, and Vanuatu). Chloroquine alone is adequate for *P. malariae* infections; for those caused by *P. vivax* or *P. ovale* a tissue schizontocide, usually primaquine, is added for radical cure.[3,8-10] In areas where ACTs are being used as first-line treatment for *P. falciparum* malaria, they may be given with primaquine for *P. vivax* infection as an alternative to chloroquine, with the exception of artesunate and pyrimethamine-sulfadoxine (*Fansidar*) as *P. vivax* resistance to pyrimethamine-sulfadoxine (*Fansidar*) is rapidly developing.[3] WHO[3] recommends that chloroquine-resistant *P. vivax* may be treated with amodiaquine followed by primaquine, while the CDC[10] recommends that patients not responding to chloroquine monotherapy or those with chloroquine-resistant infections should be given quinine sulfate plus doxycycline (or tetracycline) followed by primaquine; an alternative is mefloquine followed by primaquine. UK[9] guidelines recommend that resistant vivax malaria be treated with one of the 3 regimens used for the treatment of uncomplicated falciparum malaria (see above). Radical cure is inappropriate for patients living within an endemic area since re-infection is likely and therefore WHO[3] recommends that it should be limited to patients resident in areas where transmission is *very low* or *absent,* and it may be attempted *during an epidemic*; other patients should simply be treated with a further course of chloroquine in the event of relapse or re-infection. Severe vivax malaria should be treated the same way as severe and complicated falciparum malaria (see above).[3]

Treatment of malaria during pregnancy. Malaria is especially dangerous during pregnancy and the seriousness of the disease usually outweighs any potential risk from treatment. Malaria infection during pregnancy can result in maternal anaemia, hypoglycaemia, pulmonary oedema, miscarriage, premature birth, congenital malaria infection, low birth-weight, and neonatal death.[10,12] Pregnant women living in areas where malaria transmission is low or unstable have little or no acquired immunity and are 2 to 3 times more likely to develop severe disease than non-pregnant women living in the same area;[3,10] however, those living in endemic areas where malaria transmission is high have often acquired partial immunity.

For pregnant women living in *endemic areas* quinine plus follow-on treatment with clindamycin may be given for treatment of uncomplicated falciparum malaria in the first trimester. Data regarding the use of artemisinin derivatives in the first trimester is at present limited; however, ACTs may be given if no other effective treatment is available. In the second or third trimester ACTs, artesunate, or quinine may be given, plus follow-on treatment with clindamycin.[3] For the treatment of severe malaria in the first trimester quinine or artesunate may be used;[2,3] however, care should be taken that patients given quinine do not become hypoglycaemic. Artemisinin derivatives (particularly artesunate) are the drugs of choice for treatment of severe malaria in the second and third trimesters.[2,3]

In *non-endemic areas* it is recommended that falciparum malaria in pregnancy be treated with quinine plus follow-on treatment with clindamycin.[8-10] Atovaquone-proguanil (*Malarone*) or mefloquine may be given as alternatives where first-line treatment is not tolerated or no other treatment options are available.[10] Although fetal abnormalities have been associated with the use of high doses of chloroquine, extensive clinical experience suggests it is safe; its value is limited, however, due to resistance. The CDC recommends oral chloroquine for pregnant women with malaria infections acquired in chloroquine-sensitive areas and with non-falciparum malaria, although chloroquine-resistant *P. vivax* should be treated with quinine.[10] Radical cure for patients with vivax or ovale malaria during pregnancy should be postponed until after delivery due to the risk of intravascular haemolysis in the mother and fetus;[10,12] weekly chloroquine can be given during the remaining weeks of pregnancy. WHO recommends chloroquine or amodiaquine for pregnant women with *P. vivax* malaria.[2]

There may be difficulty if other drugs are required as opinion varies over their suitability. The tetracyclines are contra-indicated due to adverse effects on bone growth and teeth.

Treatment of splenomegaly syndrome. A few individuals infected with *Plasmodium* develop chronic hyperreactive malarial splenomegaly syndrome, an aberrant immunological response formerly known as the tropical splenomegaly syndrome. Traditionally, patients have first received a full course of antimalarial chemotherapy appropriate to the causative species followed by lengthy and probably lifelong chemoprophylaxis; however, a study in 312 patients suggested that pyrimethamine given with folinic acid for 30 days could produce a rapid reduction of splenomegaly which persisted for at least 3 months.[13]

PROPHYLAXIS OF MALARIA

Chemoprophylaxis of malaria may refer to absolute prevention of infection (*causal prophylaxis*) or to suppression of parasitaemia and its symptoms (*clinical prophylaxis*). Causal prophylaxis is provided by tissue schizontocides which destroy the exoerythrocytic forms of the parasite. Clinical prophylaxis is provided by blood schizontocides which, if continued until all exoerythrocytic forms of the parasite are destroyed, will ultimately produce a *suppressive cure*. In *P. falciparum* infections this would be achieved by about a month after the last infected bite, but relapses with *P. vivax* and *P. ovale* may still occur after standard clinical prophylactic regimens due to the presence of latent exoerythrocytic forms (hypnozoites).

The continuing increase in the prevalence of strains of *P. falciparum* resistant to chloroquine and other antimalarials, along with growing evidence of toxicity of some regimens, make recommendations for malaria prophylaxis increasingly difficult. Absolute protection cannot be guaranteed by any chemoprophylactic regimen currently in use and the importance and effectiveness of methods of avoiding bites from infected mosquitoes, such as the use of *protective clothing, bed netting, insect repellents*, and *insecticides* must be stressed.[2,7] WHO recommends the following measures to protect against mosquito bites:

- application of an effective insect repellent to exposed skin, especially between dusk and dawn when mosquitoes commonly bite
- accommodation in buildings with screens over doors and windows
- use of mosquito nets at night, preferably impregnated with pyrethroid insecticides such as permethrin or deltamethrin
- and use of anti-mosquito sprays or insecticide dispensers, or mosquito coils in bedrooms at night

Studies have shown that insecticide-impregnated mosquito nets can reduce mortality substantially.[14] In addition to these measures, travellers should be advised, even if chemoprophylaxis has been taken regularly, to regard **any** fever *after the first week (especially within 3 months)* and for *up to 1 year following possible exposure* as being caused by malaria and to seek medical advice **immediately**. Some authorities advise that travellers should also have antimalarial drugs ready for emergency self-treatment (*standby treatment*) when prompt medical attention is not available (see below).

Chemoprophylaxis should be reserved for those at high **risk**, notably *non-immune visitors*; widespread chemoprophylaxis in *immune or semi-immune* populations is no longer recommended except for women who are *pregnant*. For the elderly, pregnant women, and children, careful consideration should be given as to whether travel to areas where falciparum malaria occurs is absolutely necessary. WHO specifically advises pregnant women not to travel to areas where transmission of *P. falciparum* occurs and also advises against taking babies and young children to malarious areas (particularly where there is transmission of *P. falciparum*).[2] Advice on chemoprophylaxis must be based on a knowledge of the occurrence and susceptibility of *Plasmodium* strains in specific geographical areas. Local variations due to altitude, seasonal variations in temperature and rainfall, the degree of urbanisation, and many other factors further complicate the issue. WHO collates information provided by national health administrations and regularly publishes this information to assist in advising international travellers on the current situation; similar information is provided at national level by local institutes specialising in tropical diseases. However, the situation is so complex that advice differs. Recommendations issued by various authorities are usually for short-term stays and expert advice should be sought if long-term cover is required.

It is generally recommended that chemoprophylaxis should start about 1 week (or longer for mefloquine) before exposure to malaria, or if this is not possible at the earliest opportunity up to 1 or 2 days before exposure; this is partly to ensure that the patient is able to tolerate the drug. Chemoprophylaxis should continue throughout exposure and for at least 4 weeks after leaving the malarious area, with the exception of atovaquone-proguanil (*Malarone*) which may be stopped one week after leaving.

Prophylactic regimens.

Depending upon the risk of infection and the availability and standard of local medical care, WHO[2] has made recommendations on chemoprophylaxis and/or standby treatment for non-immune travellers:

- in areas where there is limited risk of any malaria transmission no chemoprophylaxis is needed; measures to protect against mosquito bites should be used
- in areas where *P. falciparum* is *absent* or still *sensitive to chloroquine*, or there is a risk of *P. vivax*, travellers can take chloroquine for prophylaxis
- in areas with a risk of *P. vivax* and *P. falciparum*, as well as *emerging resistance* to chloroquine, travellers can take chloroquine plus proguanil
- in areas of high risk of *P. falciparum* and where there is *multidrug resistance*, or in areas of low to moderate risk of *P. falciparum* but high levels of multidrug resistance, mefloquine, doxycycline, or atovaquone-proguanil (*Malarone*) is recommended. These recommendations are subject to the local patterns of drug resistance

WHO[2] also recommends that for the small number of travellers who would be unable to obtain prompt medical attention when malaria is suspected (within 24 hours of the onset of symptoms), it may be necessary to provide for a course of self-treatment (**standby treatment**). Clear instructions must be given and persons taking standby medication must seek medical advice as soon as possible and resume any prophylaxis on completing the course. The basis upon which the choice of prophylaxis is made (as detailed above) in turn broadly determines the appropriate choice of standby treatment. Thus one of the following treatment regimens can be used:

- artemether-lumefantrine
- atovaquone-proguanil
- quinine plus doxycycline or clindamycin

In each instance, prophylaxis should be resumed 1 week after the *first* standby treatment dose, except for mefloquine prophylaxis which should be resumed at least 12 hours after the *last* treatment dose of quinine.

In the USA, recommendations for prophylaxis are provided by the CDC.[15] For chloroquine-sensitive malaria, chloroquine alone is advised; hydroxychloroquine is suggested as an alternative. Travellers unable to take either of these 2 options should take atovaquone-proguanil (*Malarone*), doxycycline, or mefloquine. For all areas with chloroquine-resistant malaria, 3 alternatives are available, mefloquine, doxycycline, or atovaquone-proguanil (*Malarone*). Atovaquone-proguanil (*Malarone*) is recommended for emergency standby treatment. The use of primaquine is also advocated during the last 2 weeks of prophylaxis to prevent relapses due to *P. vivax* or *P. ovale* in persons returning from prolonged exposure in areas where relapsing malaria is endemic.

UK experts[16] have also published guidelines for the prophylaxis of malaria. In areas where *P. falciparum* is sensitive to chloroquine, travellers can either take chloroquine or proguanil for prophylaxis. In areas of little chloroquine resistance travellers can take chloroquine plus proguanil, while travellers to areas of high infection risk or where there is chloroquine resistance may take mefloquine, doxycycline, or atovaquone-proguanil (*Malarone*) as prophylaxis. Standby treatment with chloroquine is recommended for travellers to chloroquine-sensitive areas who do not take any prophylaxis or who take proguanil as prophylaxis. Atovaquone-proguanil (*Malarone*), artemether-lumefantrine (*Riamet*), or quinine plus doxycycline are recommended in areas with chloroquine resistance.

Malaria vaccines are under development and several are currently undergoing clinical evaluation (see p.2221).

Prophylaxis during pregnancy. The choice of drugs for prophylaxis during pregnancy is limited and whenever possible women who are pregnant or likely to become so should avoid travelling to malarious areas (see also above). In pregnant women who cannot avoid travelling to endemic areas, chloroquine may be given alone for prophylaxis in the few areas where *P. falciparum* is sensitive to chloroquine, or with proguanil where resistance exists.[2] Folate supplements (folic acid 5 mg daily) need to be taken with proguanil. Mefloquine is normally avoided during the first trimester but may be given during the second and third trimesters and CDC[15] and UK[16] guidelines consider that it may be used *with caution* in the first trimester, especially in areas where there is a high risk of acquiring falciparum malaria. Doxycycline, atovaquone-proguanil (*Malarone*), or primaquine are contra-indicated in pregnant women by most experts; the *BNF* considers that atovaquone-proguanil (*Malarone*) should be avoided during pregnancy unless there is no suitable alternative. In non-pregnant women of child-bearing potential, pregnancy needs to be avoided for 3 months after completing mefloquine prophylaxis and for one week following doxycycline prophylaxis.

For those living in endemic areas, WHO[7] recommends that, in areas of stable transmission of *P. falciparum* malaria, pregnant women and their newborn should sleep under insecticide-treated nets; pregnant women should also be given intermittent preventative treatment (IPT) with an antimalarial drug, usually pyrimethamine-sulfadoxine (*Fansidar*). The first dose should be given after quickening in the second trimester and further doses should be given at intervals at least one month apart. For maximum benefit 2 to 3 doses of IPT should be given. For further information on the use of pyrimethamine in pregnancy, see under Precautions for Pyrimethamine, p.611. In areas of low or unstable malaria transmission, where pregnant women have low immunity to malaria, use of insecticide-treated nets and prompt case management of pregnant women with fever and malarial illness is recommended. In addition, all pregnant women should take iron and folate supplements.

Prophylaxis during breast feeding. It is generally accepted for most antimalarials that the amounts distributed into breast milk and consumed by nursing infants are too small to be harmful, although they are also too small to provide protection.[2,15] However, doxycycline is contra-indicated during breast feeding, and advice regarding atovaquone-proguanil varies: in the UK it is contra-indicated, though it may be used if no suitable alternative is available,[16] but in the USA it may be given once the infant weighs over 5 kg.[15] Although there has been concern that infants given prophylaxis with mefloquine who also ingested the drug from breast milk might be receiving excessive quantities,[15] mefloquine is probably safe to use in breast-feeding mothers.[16]

Prophylaxis in children. Chloroquine and proguanil may be given in scaled down doses to children of all ages but the choice of alternative drugs may be restricted, especially in very young children, and consideration should be given to whether their travel to malarious areas is absolutely necessary (see also above). Mefloquine is an option for use in children and infants weighing 5 kg or more if travelling to areas with chloroquine-resistant *P. falciparum* and atovaquone-proguanil (*Malarone*) may be given to children weighing 11 kg or more; the CDC considers that it may be used in infants weighing at least 5 kg. Doxycycline is contra-indicated in children less than 8 years of age, and higher age limits may apply in some countries such as the UK.[2,15,16]

Prophylaxis in epilepsy. In subjects with a history of epilepsy, the UK guidelines[16] advise that both chloroquine and mefloquine are unsuitable for prophylaxis. In areas without chloroquine resistance, proguanil alone is recommended. In areas with a high risk of chloroquine resistance, atovaquone-proguanil (*Malarone*) or doxycycline may be considered, but the metabolism of doxycycline may be influenced by antiepileptics. Dapsone with pyrimethamine (*Maloprim*) was considered to have been of particular value in travellers with epilepsy, especially children, but is no longer available in the UK.

Prophylaxis in HIV-infected travellers. HIV-infected travellers may take chloroquine routinely for antimalarial prophylaxis but its potential immunosuppressive effects should be recognised; proguanil, mefloquine, or doxycycline can also be used. Although patients with AIDS may be at increased risk of adverse effects to sulfonamides, a combination such as pyrimethamine-sulfadoxine (*Fansidar*) can be used for standby treatment if an alternative is not available.

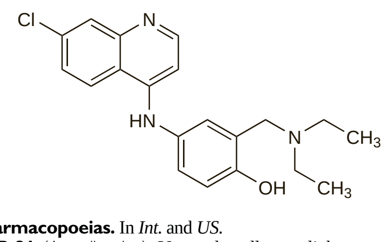
Amodiaquine *(BAN, rINN)*

Amodiaquina; Amodiaquinum. 4-(7-Chloro-4-quinolylamino)-2-(diethylaminomethyl)phenol.

Амодиахин

$C_{20}H_{22}ClN_3O$ = 355.9.
CAS — 86-42-0.
ATC — P01BA06.



Pharmacopoeias. In *Int.* and *US.*

USP 31 (Amodiaquine). Very pale yellow to light tan-yellow, odourless, powder. Practically insoluble in water; slightly soluble in alcohol; sparingly soluble in 1.0N hydrochloric acid. Store in airtight containers.

Amodiaquine Hydrochloride *(BANM, rINNM)*

Amodiaquine, Chlorhydrate d'; Amodiaquini Hydrochloridum; Hidrocloruro de amodiaquina. 4-(7-Chloro-4-quinolylamino)-2-(diethylaminomethyl)phenol dihydrochloride dihydrate.

Амодиахина Гидрохлорид

$C_{20}H_{22}ClN_3O,2HCl,2H_2O$ = 464.8.
CAS — 69-44-3 (anhydrous amodiaquine hydrochloride); 6398-98-7 (amodiaquine hydrochloride dihydrate).
ATC — P01BA06.

Pharmacopoeias. In *Fr.*, *Int.*, and *US.*

USP 31 (Amodiaquine Hydrochloride). A yellow, odourless, crystalline powder. Soluble 1 in 25 of water and 1 in 78 of alcohol; very slightly soluble in chloroform, in ether, and in benzene. Store in airtight containers.

Sorption. For reference to loss of amodiaquine hydrochloride from solutions during membrane filtration, see Chloroquine, p.599.

Adverse Effects and Precautions

As for Chloroquine, p.599, although amodiaquine was associated with hepatitis and a much higher incidence of agranulocytosis when it was used for the prophylaxis of malaria.

Incidence of adverse effects. Early isolated reports of severe neutropenia with amodiaquine usually concerned use in anti-inflammatory doses for rheumatoid arthritis, but there was a cluster of cases in 1986 associated with its use in malaria prophylaxis.[1] In all, 23 cases of agranulocytosis, 7 of which were fatal, were reported in the UK, USA, and Switzerland during a 12-month period ending March 1986. Nearly all of these patients had used the drug at a dosage of 400 mg weekly and the periods of exposure ranged from 3 to 24 weeks.[1] Some of these patients also had evidence of liver damage[1] and there have been other reports of hepatotoxicity associated with the prophylactic use of amodiaquine.[2] Examination of data submitted to the UK CSM[3] suggested that the frequency of adverse reactions to amodiaquine was about 1 in 1700 for serious reactions, 1 in 2200 for blood disorders, 1 in 15 650 for serious hepatic disorders, and 1 in 15 650 for fatal reactions. In contrast the frequency of agranulocytosis in users in France[4] has been estimated to be 1 in 25 000. Worldwide[4] the risk of severe reactions appears to be between 1 in 1000 and 1 in 5000. The manufacturers reportedly had 42 cases of serious adverse effects during amodiaquine prophylaxis, between 1985 and 1991; there were 28 cases of agranulocytosis (9 deaths) and 14 of hepatitis (3 deaths).[5] Whether there was significantly less risk when amodiaquine was given for treatment of malaria rather than prophylaxis was not certain.[6]

It has been suggested that an immunological reaction to amodiaquine quinone imine, which can be produced by autoxidation among other processes, may partially account for amodiaquine's greater tendency to induce agranulocytosis compared with chloroquine.[7,8]

The acute toxicity of amodiaquine appears to differ from that of chloroquine in that there have been no reports of cardiovascular symptoms after overdosage with amodiaquine[9] but intoxication with amodiaquine is also far less frequent than chloroquine poisoning. However, large doses of amodiaquine have been reported to produce syncope, spasticity, convulsions, and involuntary movements.[9]

Pregnancy. A study[1] to assess the safety and efficacy of amodiaquine or amodiaquine plus sulfadoxine-pyrimethamine in 900 pregnant women (in their second or third trimester) reported that PCR-corrected parasitological failure by day 28 was 14%, 11%, 3%, and 0% in those given chloroquine, sulfadoxine-pyrimethamine, amodiaquine alone, and amodiaquine plus sulfadoxine-pyrimethamine, respectively. No serious adverse effects were reported.

WHO considers that amodiaquine may be an alternative to chloroquine for treatment of malaria due to *P. vivax* during pregnancy (see Treatment of Malaria during Pregnancy, under Malaria, p.594).

1. Tagbor H, *et al.* Efficacy, safety, and tolerability of amodiaquine plus sulphadoxine-pyrimethamine used alone or in combination for malaria treatment in pregnancy: a randomised trial. *Lancet* 2006; **368:** 1349–56.

Pharmacokinetics

Amodiaquine hydrochloride is readily absorbed from the gastrointestinal tract. Amodiaquine is rapidly converted in the liver to the active metabolite desethylamodiaquine, only a negligible amount of amodiaquine being excreted unchanged in the urine. The plasma elimination half-life of desethylamodiaquine has varied from 1 to 10 days or more. Amodiaquine and desethylamodiaquine have been detected in the urine several months after use.

Uses and Administration

Amodiaquine is a 4-aminoquinoline antimalarial with an action similar to that of chloroquine (p.602). It is as effective as chloroquine against chloroquine-sensitive strains of *Plasmodium falciparum* and is also effective against some chloroquine-resistant strains, although resistance to amodiaquine has developed and there may be partial cross-resistance between amodiaquine and chloroquine. To prevent the emergence and spread of drug resistant parasites WHO recommends that amodiaquine be given with an artemisinin derivative, such as artesunate, for the treatment of falciparum malaria. Amodiaquine is not recommended for the prophylaxis of malaria because of resistance and the risk of major toxicity.

Amodiaquine is given orally as the hydrochloride, but doses are expressed in terms of amodiaquine base; amodiaquine hydrochloride 260 mg is equivalent to about 200 mg of amodiaquine base. For the treatment of falciparum malaria and uncomplicated chloroquine-resistant vivax malaria a total dose of 30 mg/kg is given over 3 days (10 mg/kg daily for 3 days). Treatment of vivax malaria must be followed by radical cure with primaquine.

A fixed-dose combination product of amodiaquine and artesunate (ASAQ) has been developed in order to improve patient adherence and avoid monotherapy, thereby decreasing the risk of acquired drug resistance, and is available in some countries.

Натрий Артезунат

$C_{19}H_{27}O_8Na$ = 406.4.

Adverse Effects and Precautions

Artemisinin and its derivatives appear to be generally well tolerated, although there have been reports of mild gastrointestinal disturbance (including nausea, vomiting, diarrhoea, and abdominal pain), dizziness, headache, tinnitus, neutropenia, elevated liver enzyme values, and ECG abnormalities including prolongation of the QT interval.

Evidence of severe neurotoxicity has been seen in *animals* given high doses.

◊ General references to adverse effects associated with artemisinin derivatives.

1. Price R, *et al.* Adverse effects in patients with acute falciparum malaria treated with artemisinin derivatives. *Am J Trop Med Hyg* 1999; **60:** 547–55.

Effects on the blood. For a report of severe haemolytic anaemia occurring in patient after taking artemether-lumefantrine, see p.605.

Effects on the heart. Bradycardia was reported in 10 of 34 patients who received artemether orally for 4 days.[1]

1. Karbwang J, *et al.* Comparison of oral artemether and mefloquine in acute uncomplicated falciparum malaria. *Lancet* 1992; **340:** 1245–8.

Effects on the nervous system. Neurotoxicity has been reported in *animals* given artemotil or artemether.[1] An *in-vitro* study[2] has shown that artenimol (dihydroartemisinin), the metabolite common to all artemisinin derivatives currently used, is neurotoxic. There has been a report[3] of acute cerebellar dysfunction manifesting as ataxia and slurred speech in a patient who took a 5-day course of artesunate by mouth.

1. Brewer TG, *et al.* Neurotoxicity in animals due to arteether and artemether. *Trans R Soc Trop Med Hyg* 1994; **88** (suppl 1): 33–6.

3. Miller LG, Panosian CB. Ataxia and slurred speech after artesunate treatment for falciparum malaria. *N Engl J Med* 1997; **336:** 1328.

Pregnancy. Artesunate or artemether was used to treat multidrug-resistant falciparum malaria in 83 pregnant women in Thailand; of 73 pregnancies resulting in live births none showed evidence of any congenital abnormality.[1] Sixteen of the women were given artesunate during the first trimester; of these, 12 had normal deliveries, 1 was lost to study, and 3 had spontaneous abortions.

No undue adverse effects on the neonates occurred in a study[2] involving 45 women treated for multidrug-resistant malaria during their second or third trimester of pregnancy with either artemether or artemether plus mefloquine. Intramuscular artemether was also used to treat chloroquine/quinine-resistant falciparum malaria in 28 pregnant women in eastern Sudan. Artemether was given to 1 woman during the first trimester, to 12 during the second trimester, and to 15 during the third trimester. One baby was delivered at 32 weeks but died 6 hours later; all the other babies were delivered at full term and there were no reports of congenital abnormalities.[3]

WHO[4] recommends that, where available, artesunate is the first option, and artemether is the second, for the parenteral treatment of severe falciparum malaria during the second and third trimesters. In the first trimester, until more evidence becomes available, artesunate may be considered as an option.

4. WHO. *Guidelines for the treatment of malaria.* Geneva: WHO, 2006. Also available at: http://www.who.int/malaria/docs/TreatmentGuidelines2006.pdf (accessed 21/06/06)

Interactions

Use of artemisinin derivatives with drugs that prolong the QT interval should be avoided if possible; caution is advised when artemisinin derivatives are given with other antimalarials that have this propensity.

Grapefruit juice. The oral bioavailability of artemether may be increased if taken with grapefruit juice.[1]

1. van Agtmael MA, *et al.* The effect of grapefruit juice on the time-dependent decline of artemether plasma levels in healthy subjects. *Clin Pharmacol Ther* 1999; **66:** 408–14.

Pharmacokinetics

Peak plasma concentrations have been achieved in about 3 hours after oral doses of artemether, in about 6 hours after intramuscular injection of artemether, and in about 11 hours after rectal artemisinin. Artemisinin derivatives (but not artemisinin) are rapidly hydrolysed to various extents to the active metabolite arterimol (dihydroartemisinin). Reported elimination half-lives have been about 45 minutes after intravenous doses of artesunate, about 4 hours after rectal artemisinin, and about 4 to 11 hours after intramuscular or oral artemether. There are very few published data on the pharmacokinetics of artemotil, but its elimination half-life appears to be longer than that of artemether.

◊ Reviews.

Uses and Administration

Artemisinin is a sesquiterpene lactone isolated from *Artemisia annua*, a herb that has traditionally been used in China for the treatment of malaria. It is a potent and rapidly acting blood schizontocide active against *Plasmodium vivax* and against both chloroquine-sensitive and chloroquine-resistant strains of *P. falciparum*.

Artemisinin has been given orally or rectally in the treatment of malaria; regimens were often empirical with typical rectal doses ranging from 10 to 40 mg/kg daily over a variable number of days. However, it has largely been replaced in practice by its derivatives such as artemether and artesunate.

The following doses are recommended by WHO for the treatment of uncomplicated falciparum malaria.

Artesunate, when used with other antimalarials (amodiaquine, mefloquine, or pyrimethamine-sulfadoxine), is given orally to adults and children in a dose of 4 mg/kg daily, as a single dose, for 3 days.

Artemether is given orally with lumefantrine; 6 doses in total are given, the first at diagnosis and repeated after 8, 24, 36, 48, and 60 hours. Each dose is:

- adults and children weighing over 34 kg, artemether 80 mg with lumefantrine 480 mg
- children 5 to 14 kg, artemether 20 mg with lumefantrine 120 mg
- children 15 to 24 kg, artemether 40 mg with lumefantrine 240 mg
- children 25 to 34 kg, artemether 60 mg with lumefantrine 360 mg

For parenteral use in severe malaria, WHO recommends:

- for adults or children, **artesunate** 2.4 mg/kg intravenously or intramuscularly, repeated after 12 and 24 hours and then once daily thereafter
- as an alternative in children, **artemether** 3.2 mg/kg intramuscularly, followed by 1.6 mg/kg daily thereafter. For both drugs the patient should be transferred to oral therapy as soon as possible

A fixed-dose combination product containing artesunate and amodiaquine (ASAQ) has been developed in order to improve patient adherence and avoid monotherapy, thereby decreasing the risk of acquired drug resistance, and is available in some countries.

Other derivatives of artemisinin, such as artemotil and alpha-beta arteether, are under investigation or commercial development (see Administration of Artemisinin Derivatives, below).

7. Aweeka FT, German PI. Clinical pharmacology of artemisinin-based combination therapies. *Clin Pharmacokinet* 2008; **47:** 91–102.

Administration of artemisinin derivatives. To overcome the poor solubility of *artemisinin* in water a number of dosage forms and routes have been tried. Also, several more potent derivatives with more suitable pharmaceutical properties have been developed, notably the methyl ether derivative, *artemether*, and the ethyl ether derivative, *artemotil*, which are more lipid soluble; the sodium salt of the hemisuccinate ester, *sodium artesunate*, which is soluble in water but appears to have poor stability in aqueous solutions; and *sodium artelinate*, which is both soluble and stable in water. Other derivatives that have been studied include *arteflene.*

Several preparations of artemisinin derivatives are available either commercially or for studies organised by bodies such as WHO. These include oral formulations of artemether, artesunate, artemisinin itself, and *artenimol*; intramuscular formulations of artemotil, artemether, and artesunate; intravenous formulations of *artelinic acid* and artesunate; and suppositories of artemisinin, artesunate, and artinimol.

Malaria. The overall management of malaria and the place of artemisinin derivatives in current recommendations are discussed on p.594. In an attempt to delay the development of resistance to these compounds, WHO at one time recommended that their use be restricted to the treatment of malaria in areas of documented multidrug resistance and that they should not be used at all for prophylaxis. However, the development of resistance to conventional treatment has now led WHO to recommend the use in such circumstances of combination therapies containing artemisinin derivatives (artemisinin-based combination therapies, also known as ACTs). The following combination therapies are recommended:

- artemether-lumefantrine
- artesunate plus amodiaquine
- artesunate plus pyrimethamine-sulfadoxine (*Fansidar*)
- artesunate plus mefloquine

Artemether-lumefantrine is now also recommended in the UK as an alternative to quinine-based therapy for uncomplicated falciparum malaria.

In acute uncomplicated malaria artemisinin derivatives are usually given by mouth. Those used have been artemisinin, artemether, or artesunate. Parenteral therapy is generally necessary in severe malaria and WHO recommends[1] artesunate intravenously or intramuscularly in adults and children, or artemether intramuscularly in children, as alternatives to quinine for severe malaria. A systematic review[2] has suggested that intravenous artesunate should be the drug of choice in adults with severe malaria, particularly if acquired in Asia. Rectal artesunate has been successful and is recommended by WHO[1] if parenteral therapy is not possible.

Schistosomiasis. Findings of a reduced intensity of *Schistosoma mansoni* infection in patients treated with sodium artesunate for malaria[1] prompted further investigation into the use of artemisinin derivatives for the control of schistosomiasis (p.138). A double-blind placebo-controlled study[2] in children negative for *S. mansoni* found a significantly lower incidence of infection in those given artemether orally. There was also a significant reduction in the prevalence of *Plasmodium falciparum* infection. A number of studies in China have confirmed the benefits of artemether or artesunate, often with praziquantel, against *S. japonicum*.[3]

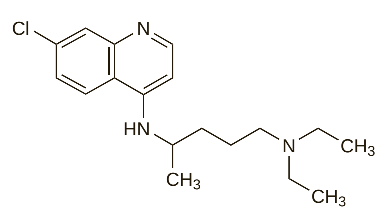
Chloroquine *(BAN, rINN)*

Chloroquinum; Cloroquina; Klorokiini; Klorokin. 4-(7-Chloro-4-quinolylamino)pentyldiethylamine; 7-Chloro-4-(4-diethylamino-1-methylbutylamino)quinoline.

Хлорохин

$C_{18}H_{26}ClN_3$ = 319.9.
CAS — 54-05-7.
ATC — P01BA01.



Pharmacopoeias. In *US.*
USP 31 (Chloroquine). A white or slightly yellow, odourless, crystalline powder. M.p. 87° to 92°. Very slightly soluble in water; soluble in chloroform, in ether, and in dilute acids. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Chloroquine Hydrochloride *(BANM, rINNM)*

Chloroquine, Chlorhydrate de; Chloroquini Hydrochloridum; Hidrocloruro de cloroquina.

Хлорохина Гидрохлорид

$C_{18}H_{26}ClN_3,2HCl$ = 392.8.
CAS — 3545-67-3.
ATC — P01BA01.

Pharmacopoeias. *US* includes an injection.

Chloroquine Phosphate *(BANM, rINNM)*

Chingaminum; Chlorochin-difosfát; Chlorochinium Phosphoricum; Chlorochinum Diphosphoricum; Chlorochiny fosforan; Chlorokvino fosfatas; Chloroquine, phosphate de; Chloroquini Diphosphas; Chloroquini phosphas; Fosfato de cloroquina; Klorokiinifosfaatti; Klorokinfosfat; Klorokin-foszfát; Quingamine; SN-7618.

Хлорохина Фосфат

$C_{18}H_{26}ClN_3,2H_3PO_4$ = 515.9.
CAS — 50-63-5.
ATC — P01BA01.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *US*, and *Viet.*
Ph. Eur. 6.2 (Chloroquine Phosphate). A white or almost white, hygroscopic, crystalline powder. It exists in two forms, one melting at about 195° and the other at about 218°. Freely soluble in water; very slightly soluble in alcohol and in methyl alcohol. A 10% solution in water has a pH of 3.8 to 4.3. Store in airtight containers. Protect from light.
USP 31 (Chloroquine Phosphate). A white, odourless, crystalline powder, which slowly discolours on exposure to light. It exists in two polymorphic forms, one melting between 193° and 195° and the other between 210° and 215°; mixture of the two forms melts between 193° and 215°. Freely soluble in water; practically insoluble in alcohol, in chloroform, and in ether. Its solutions have a pH of about 4.5.

Chloroquine Sulfate *(rINNM)*

Chlorochin-sulfát monohydrát; Chlorochiny siarczan; Chlorokvino sulfatas; Chloroquine, sulfate de; Chloroquine Sulphate *(BANM)*; Chloroquini sulfas; Chloroquini Sulfas Monohydricus; Chloroquini Sulphas; Klorokiinisulfaatti; Klorokinsulfat; Klorokin-szulfát; RP-3377; Sulfato de cloroquina.

Хлорохина Сульфат

$C_{18}H_{26}ClN_3,H_2SO_4,H_2O$ = 436.0.
CAS — 132-73-0 (anhydrous chloroquine sulfate).
ATC — P01BA01.

Pharmacopoeias. In *Eur.* (see p.vii) and *Int.*
Ph. Eur. 6.2 (Chloroquine Sulphate). A white or almost white crystalline powder. Freely soluble in water and in methyl alcohol; very slightly soluble in alcohol. An 8% solution in water has a pH of 4.0 to 5.0. Store in airtight containers. Protect from light.

Sorption. Studies using low concentrations of chloroquine phosphate or chloroquine sulfate indicate that chloroquine exhibits pH-dependent binding to several materials used in medical equipment and membrane filters, including soda glass and various plastics such as cellulose acetate, cellulose propionate, methacrylate butadiene styrene, polypropylene, PVC, ethylvinyl acetate, and polyethylene.[1-3] Although this effect may not be of relevance at doses used clinically,[4] laboratory workers undertaking assays and sensitivity testing must recognise that significant reductions in concentrations can occur when chloroquine is prepared or stored in equipment made from these materials.[2,3] As the effect of borosilicate glass or polystyrene appears to be minimal, it has been suggested that they may be suitable for use in such procedures.[2,3]

Similar sorption has also been reported during membrane filtration of solutions of amodiaquine hydrochloride, mefloquine hydrochloride, or quinine sulfate.[1]

Adverse Effects

Adverse effects experienced with dosage regimens of chloroquine used in the treatment and prophylaxis of malaria are generally less common and less severe than those associated with the higher doses used for prolonged periods in rheumatoid arthritis.

Frequent adverse effects of chloroquine include headache, various skin eruptions, pruritus, and gastrointestinal disturbances such as nausea, vomiting, and diarrhoea. More rarely, mental changes including psychotic episodes, agitation, and personality changes may occur. Convulsions have been reported.

Visual disturbances such as blurred vision and difficulties in focusing have occurred but these are more common with higher doses, when they may be associated with keratopathy or retinopathy, as discussed under Effects on the Eyes, below. Keratopathy usually occurs in the form of corneal opacities and is normally reversible when chloroquine is withdrawn. Retinopathy is the most serious adverse effect of chloroquine on the eyes and it can result in severe visual impairment. Changes may be irreversible and can even progress after chloroquine is stopped. Those taking high doses of chloroquine for prolonged periods appear to be at greatest risk of developing retinopathy.

Other uncommon adverse effects from prolonged use include loss of hair, bleaching of hair pigment, bluish-black pigmentation of the mucous membranes and skin, photosensitivity, tinnitus, reduced hearing, nerve deafness, neuromyopathy, and myopathy, including cardiomyopathy.

Blood disorders have been reported rarely. They include aplastic anaemia, reversible agranulocytosis, thrombocytopenia, and neutropenia.

There have also been rare reports of changes in liver function, including hepatitis and abnormal liver function tests.

Parenteral therapy with chloroquine can be hazardous and rapid intravenous dosage or the use of high doses can result in cardiovascular toxicity and other symptoms of acute overdosage.

Acute overdosage with chloroquine is extremely dangerous and death can occur within a few hours. Initial effects include headache, gastrointestinal disturbances, drowsiness, and dizziness. Hypokalaemia may occur within a few hours of ingestion of chloroquine. Visual disturbances may be dramatic with a sudden loss of vision. However, the main effect of overdosage with chloroquine is cardiovascular toxicity with hypotension and cardiac arrhythmias progressing to cardiovascular collapse, convulsions, cardiac and respiratory arrest, coma, and death.

Effects on the blood. Aplastic anaemia was associated with the use of chloroquine in 3 patients.[1] Two patients had received treatment over several months and one of these was later found to have acute myeloblastic leukaemia after receiving chloroquine treatment initially for discoid lupus erythematosus, and later for cerebral malaria. In the third patient aplastic anaemia developed 3 weeks after a short course of chloroquine for malaria.

1. Nagaratnam N, *et al.* Aplasia and leukaemia following chloroquine therapy. *Postgrad Med J* 1978; **54:** 108–12.

Effects on the eyes. The main adverse effects of chloroquine and hydroxychloroquine on the eye are keratopathy and retinopathy.

Keratopathy, characterised by corneal deposits, may occur within a few weeks of starting treatment. However, patients are often asymptomatic and fewer than 50% of affected patients complain of visual symptoms such as photophobia, haloes around lights, or blurred vision. Keratopathy is completely reversible on withdrawal of treatment and is not usually considered to be a contraindication to continued treatment.[1]

Retinopathy is potentially more serious. The outcome on stopping treatment is unpredictable and changes may be irreversible or may even progress.[2,3] Delayed-onset retinopathy has also been reported in patients many years after cessation of treatment.[4] The reported incidence of retinopathy varies according to the methodology and criteria used.[1,5,6] From studies in patients on long-term antimalarial treatment, it was reported[1] that an accumulation of 100 g of chloroquine [phosphate] (250 mg daily for 1 year) might cause retinopathy; the risk was significantly increased as the total dosage exceeded 300 g. Experience in rheumatology also indicates that the incidence of retinal toxicity is dose-related. While the total cumulative dose, the duration of treatment, and the age of the patient might all affect the incidence of retinal toxicity,[7,8] the daily dose might be the most important factor.[9] It has been suggested that the risk of retinal damage is small with daily doses of up to 4.0 mg of chloroquine phosphate per kg body-weight (= chloroquine base approximately 2.5 mg per kg daily) or up to 6.5 mg of hydroxychloroquine sulfate per kg.[9] In obese patients, excessive dosage should be avoided by calculating dosage on the basis of lean body-weight. It appears that retinopathy is rarely, if ever, associated with the weekly dosages of chloroquine recommended for the prophylaxis of malaria.[10,11]

In the UK, a review group[12] convened by the Royal College of Ophthalmologists made **recommendations** regarding use by rheumatologists and dermatologists. Chloroquine should only be used if hydroxychloroquine or other preferred drugs have failed as there is inadequate data to advise on a safe maximum dose; thus the following recommendations relate only to *hydroxychloroquine* as no guidelines have been published for chloroquine.

- Baseline assessment before treatment with hydroxychloroquine is commenced (maximum daily dosage 6.5 mg/kg lean body-weight) should consist of checking renal and hepatic function, questioning the patient about visual impairment not corrected by glasses, and recording near visual acuity.
- Thereafter, patients should be monitored annually with enquiry about visual symptomatology, rechecking of acuity, and assessment for blurred vision.
- Patients should be referred to an ophthalmologist if problems are detected either before or during treatment.
- Those taking long-term hydroxychloroquine should be subject to occasional ophthalmological review after 5 years' continuous treatment.

UK licensed product information for *chloroquine* recommends ophthalmic examination at 3 to 6 monthly intervals in patients receiving continuous high doses for more than a year, or weekly treatment for more than 3 years, or for those in whom total consumption exceeds 100 g or 1.6 g/kg.

Effects on glucose metabolism. While hypoglycaemia has occurred with quinine (see p.613), it was not generally thought to be associated with chloroquine; however, there has been a report of its occurrence in a patient with reactive hypoglycaemia.[1]

1. Abu-Shakra M, Lee P. Hypoglycemia: an unusual adverse reaction to chloroquine. *Clin Exp Rheumatol* 1994; **12:** 95.

Effects on the heart. Studies in patients with malaria[1] and in healthy subjects[2] indicate that the acute cardiovascular toxicity that may be associated with parenteral use of chloroquine is related to transiently high plasma concentrations produced during the early part of the distribution phase; these findings appear to confirm that the dosage rate is a major determinant of this toxicity. Cardiac conduction abnormalities, including heart block, have also occurred in patients receiving long-term oral therapy with chloroquine,[3] including use in lupus erythematosus,[4,5] as well as after chloroquine overdosage or abuse.[6] Histological changes in endomyocardial biopsy specimens from 2 patients with cardiomyopathy associated with chloroquine or hydroxychloroquine therapy were found to be virtually identical to those seen in the skeletal muscle of patients with chloroquine-induced myopathy[7] (see also Effects on the Muscles, below).

Effects on mental function. Serious psychotic effects (depersonalisation and anxiety) developed in a healthy subject who took a standard 3-day course of oral chloroquine for the treatment of *Plasmodium falciparum* malaria, as part of a clinical study. Three weeks after completing the course she still had serious concentration problems and her symptoms gradually resolved over the next 4 months.[1]

1. Telgt DS, *et al.* Serious psychiatric symptoms after chloroquine treatment following experimental malaria infection. *Ann Pharmacother* 2005; **39:** 551–4.

Effects on the muscles. The myopathy induced by chloroquine is characterised by progressive weakness and atrophy of proximal muscles and can develop insidiously after periods of therapy ranging from a few weeks to a few years.[1] There are often mild sensory changes, depression of tendon reflexes, and abnormal nerve conduction studies suggestive of an associated peripheral neuropathy. The myopathy is reversible on withdrawal of treatment but recovery may take several months. Cardiomyopathy may also occur (see under Effects on the Heart, above). Similar effects have been reported with hydroxychloroquine.[2] In a retrospective review of 4405 patients with rheumatic disorders, 214 had received chloroquine or hydroxychloroquine and, of these, 3 developed myopathy.[3]

3. Avina-Zubieta JA, *et al.* Incidence of myopathy in patients treated with antimalarials: a report of three cases and a review of the literature. *Br J Rheumatol* 1995; **34:** 166–70.

Effects on the nervous system. Apart from neuropathies (see Effects on the Muscles, above) other adverse effects of chloroquine on the nervous system have included isolated reports of extrapyramidal symptoms and other involuntary movements[1,2] (in patients being treated for malaria), nystagmus[3] (in a patient on prolonged treatment for rheumatoid arthritis), and convulsions[4,5] and nonconvulsive status epilepticus[6] (in patients on malaria prophylaxis).

6. Mülhauser P, *et al.* Chloroquine and nonconvulsive status epilepticus. *Ann Intern Med* 1995; **123:** 76–7.

Effects on the skin. *Pruritus* is common in patients given chloroquine for the treatment of malaria and it may become so severe as to compromise treatment. Itching starts a few hours after use but usually remits spontaneously within 72 hours. Although antihistamines are generally thought ineffective,[1,2] a few patients may obtain some relief.[3] The incidence of pruritus is purported to be higher in black patients, but this may only reflect the greater number of black patients surveyed. The aetiology of this reaction is unknown, but this apparent higher incidence has prompted suggestions that it may have a genetic basis[4] or be related to the affinity of chloroquine for melanin.[2] Chloroquine's main metabolite, monodesethylchloroquine, has been implicated,[5] although there is also some evidence suggesting that patients with pruritus metabolise chloroquine more slowly.[6] A survey[1] in Nigeria found that, of 1100 patients, 74% had pruritus during antimalarial therapy; 61% of these reacted to chloroquine, 30% reacted to amodiaquine, 2.5% to Fansidar (pyrimethamine-sulfadoxine), and, 6.5% reacted to all three. In another study in Nigeria,[4] the incidence of pruritus was reported to be 14% (8 of 56 patients) for chloroquine, 27% (14 of 52) for amodiaquine, and 13% (7 of 53) for halofantrine; none of 58 patients receiving quinine or 82 patients receiving mefloquine had pruritus. In contrast, in a study in Thailand only 1.9% of 1189 chloroquine-treated patients reported pruritus.[7]

There have been rare reports of more severe cutaneous reactions associated with chloroquine, including *toxic epidermal necrolysis*,[8,9] *erythema multiforme*,[10] and *Stevens-Johnson syndrome*,[11] although the causal role of chloroquine is not always clear as some of these patients also received other antimalarials, sometimes at an inappropriate dosage. In a more recent case of toxic epidermal necrolysis,[12] chloroquine given alone for malaria prophylaxis was the probable cause. A young patient receiving radiotherapy developed a localised bullous eruption and rapid progressive moist desquamation on the third day of treatment with oral chloroquine for malaria.[13] For a discussion including the possible effect of chloroquine on the incidence of erythema multiforme in patients taking pyrimethamine with sulfadoxine, see Adverse Effects with Sulfonamides, under Pyrimethamine, p.610.

Overdosage. For adverse effects associated with chloroquine overdosage, see Treatment of Adverse Effects, below.

Treatment of Adverse Effects

Acute overdosage with chloroquine can be rapidly lethal and intensive symptomatic supportive treatment should be started immediately. The first steps should be to maintain adequate respiration and to correct any cardiovascular disturbances. Early use of adrenaline with diazepam (see below) may minimise the cardiotoxicity of chloroquine and control arrhythmias. Activated charcoal may be given orally to adults or children who present within 1 hour of ingesting more than the equivalent of 15 mg/kg of chloroquine base; activated charcoal may be left in the stomach to limit any further absorption. Intravenous sodium bicarbonate should be given to correct metabolic acidosis. Other methods to increase the elimination of chloroquine, such as dialysis, are probably of little use.

◊ Chloroquine overdosage is the most severe and frequent cause of intoxication with antimalarial drugs and chloroquine is often used for suicide attempts. Severe toxic manifestations may occur within 1 to 3 hours and fatal outcomes usually occur within 2 to 3 hours of drug ingestion. The major clinical symptoms are of neurological, respiratory, and cardiovascular toxicity;[1] death is usually due to cardiac arrest related to the direct effect of chloroquine on the myocardium.[2] Chloroquine has a low safety margin: doses of 20 mg/kg are considered toxic and 30 mg/kg may be lethal. The mortality rate in some published studies has ranged from 10 to 30%.[1] If gastric lavage is attempted it should be preceded by correction of severe cardiovascular disturbances and institution of artificial ventilation because insertion of the stomach tube may induce sudden cardiac arrest or convulsions; induction of emesis is contra-indicated because of the risk of lung aspiration. Activated charcoal has been recommended to limit absorption of chloroquine that may be left in the gut.[3] There is no evidence to indicate that attempts to increase chloroquine elimination such as acidification of the urine, haemodialysis, peritoneal dialysis, or exchange transfusion, are effective in overdosage. Elimination in the urine is more dependent on haemodynamic status than on infusion of osmotic solutions or acidification. Any clearance achieved by haemoperfusion or haemodialysis is low in comparison with the normal total body clearance.[1]

It is not clear if correction of hypokalaemia is essential, but giving potassium should be avoided in the initial phases of intoxication when conduction disturbances still exist. The degree of hypokalaemia may be correlated with the severity of chloroquine intoxication and might be useful diagnostically.[4] However, chloroquine-induced hypokalaemia may be due to a transport-dependent mechanism rather than to true potassium depletion and overzealous correction could result in hyperkalaemia.[4]

Since there had been no effective treatment for severe chloroquine poisoning, one group of workers tried using early mechanical ventilation, together with adrenaline and high doses of diazepam, both given intravenously, to counteract cardiotoxicity, with encouraging results.[2] Diazepam had earlier been shown to decrease the cardiotoxicity of chloroquine in *animal* studies and there had been several clinical reports of beneficial responses. It was considered that routine use of adrenaline before the onset of cardiac arrhythmia might be beneficial in the treatment of severe chloroquine poisoning.[2] UK licensed product information for chloroquine suggests giving adrenaline by intravenous infusion in a dose of 250 nanograms/kg per minute initially, with increments of 250 nanograms/kg per minute until adequate systolic blood pressure is restored, and diazepam by intravenous infusion in a dose of 2 mg/kg over 30 minutes as a loading dose, followed by 1 to 2 mg/kg per day for up to 2 to 4 days.

Overdosage with hydroxychloroquine has responded to measures similar to those used in the management of chloroquine overdosage.[5]

Precautions

Excessive doses of chloroquine and hydroxychloroquine are associated with retinal or visual field changes and the precautions to be taken in order to minimise such toxicity are discussed under Effects on the Eyes in Adverse Effects, above. There may be a temporary effect on visual accommodation.

Care is necessary when giving chloroquine to patients with hepatic or renal impairment, or to those with severe gastrointestinal disorders, a history of psoriasis, or neurological disorders, especially a history of epilepsy (see below for advice not to use for malaria prophylaxis). Chloroquine should be used with caution in patients with myasthenia gravis as it may aggravate the condition. Patients with G6PD deficiency should be observed for haemolytic anaemia during chloroquine treatment. Full blood counts should be performed at regular intervals during extended treatment with chloroquine. Although there have been reports of fetal abnormalities associated with the use of chloroquine during pregnancy, the risks of malaria are considered to be greater and there appears to be no justification for withholding chloroquine for the treatment or prophylaxis of malaria.

It is important that if chloroquine is given intravenously it should be by slow infusion (typically around 0.8 to 1.25 mg/kg per hour) otherwise severe cardiotoxicity may develop.

Breast feeding. Chloroquine is distributed into breast milk, but not in an amount adequate to provide chemoprophylaxis against malaria for the infant (see under Pharmacokinetics, below). Furthermore, no adverse effects have been seen in breast-feeding infants whose mothers were receiving chloroquine, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 16/04/04)

Epilepsy. After reports[1,2] of convulsions associated with the use of chloroquine for malaria prophylaxis in 4 previously healthy patients and in 2 patients with a history of seizures, it has been suggested that prospective travellers who have a history of epilepsy should be warned of the risk. Although it was initially considered[3] that this should not restrict the use of chloroquine, UK malaria experts have recommended that it should be avoided for malaria prophylaxis in patients with epilepsy.[4]

Porphyria. Although chloroquine is probably safe in porphyric patients, some authorities consider its use to be contentious. Pyrimethamine is also probably safe in porphyric patients. Other drugs used for prophylaxis, such as dapsone and sulfadoxine and combinations containing them, are definitely contra-indicated in porphyric patients. Quinine is of proven safety in patients with porphyria and cell-culture tests have suggested that proguanil and mefloquine may also be safe.

Chloroquine has been tried in the treatment of porphyria cutanea tarda, but this may be associated with hepatotoxicity (see under Uses, below).

Pregnancy. There has been concern about the potential teratogenic effects of chloroquine because of a few case reports including defects in hearing and vision.[1] Two of 169 infants, born to women given chloroquine 300 mg weekly throughout pregnancy, had birth defects compared with 4 of 454 control infants whose mothers had not received antimalarials; the difference was not significant. The data suggested that chloroquine in the recommended prophylactic doses is not a strong teratogen and that its proved antimalarial benefits outweigh any possible risk of low-grade teratogenicity. Also it has been reported that chloroquine prophylaxis during pregnancy did not affect the birth-weight of neonates, compared with a control group.[2]

2. Cot M, *et al.* Effect of chloroquine chemoprophylaxis during pregnancy on birth weight: results of a randomized trial. *Am J Trop Med Hyg* 1992; **46:** 21–7.

Psoriatic arthritis. It is recommended that chloroquine and hydroxychloroquine should not be used in the treatment of psoriatic arthritis as exacerbations of skin lesions can occur. Some patients may go on to develop generalised erythroderma with subsequent exfoliative dermatitis.[1] However, there has been controversy over the reported incidence of this adverse effect.[2,3]

2. Luzar MJ. Hydroxychloroquine in psoriatic arthropathy: exacerbations of psoriatic skin lesions. *J Rheumatol* 1982; **9:** 462–4.
3. Sayers ME, Mazanec DJ. Use of antimalarial drugs for the treatment of psoriatic arthritis. *Am J Med* 1992; **93:** 474–5.

Renal impairment. Although the elimination of chloroquine is prolonged in renal impairment no dosage adjustment is required in the treatment of malaria. Similarly, dosage reduction is not required for chloroquine prophylaxis except in those with severe renal impairment. Doses tend to be reduced when it is given for longer periods to patients with renal impairment.

Interactions

There is an increased risk of inducing ventricular arrhythmias if chloroquine is used with halofantrine (see p.604) or other arrhythmogenic drugs such as amiodarone and moxifloxacin. There is an increased risk of convulsions when chloroquine is given with mefloquine. The absorption of chloroquine can be reduced by antacids or kaolin and its metabolism may be inhibited by cimetidine.

Agalsidase. For the effect of using chloroquine with *agalsidase alfa* or *beta*, see p.2252.

Antiepileptics. Chloroquine may antagonise the antiepileptic activity of *carbamazepine* and *valproate* by lowering the convulsive threshold.

Antimalarials. Chloroquine should not be used with *halofantrine* since the latter prolongs the QT interval and therefore there is an increased potential to induce arrhythmias (see p.604). Use of chloroquine with *mefloquine* increases the risk of convulsions. Also use of chloroquine with *proguanil* may increase the incidence of proguanil-associated mouth ulceration.[1] The activity of chloroquine may be affected when it is given with other *antimalarials*. *Quinine* and chloroquine when used together may be antagonistic.[2] Mixtures of chloroquine with *quinine, mefloquine, amodiaquine, artemisinin,* or *pyrimethamine-sulfadoxine* were antagonistic *in vitro* against *Plasmodium falciparum*.[3]

Antimicrobials. A woman who had previously tolerated chloroquine alone had acute dystonic reactions when also given *metronidazole*.[1] Chloroquine may also reduce the gastrointestinal absorption of *ampicillin* (see p.204).

1. Achumba JI, *et al.* Chloroquine-induced acute dystonic reactions in the presence of metronidazole. *Drug Intell Clin Pharm* 1988; **22:** 308–10.

Ciclosporin. Chloroquine has been reported to increase plasma concentrations of ciclosporin (see p.1826).

Digoxin. Hydroxychloroquine has been reported to increase plasma concentrations of digoxin (see p.1262).

Gastrointestinal drugs. Patients often wish to take chloroquine with food, antacids, or other gastrointestinal drugs to alleviate gastrointestinal irritation. Dosage with *food* may be beneficial as it appears to improve the absorption of chloroquine.[1,2] However, *antacids* or *kaolin* can reduce the absorption of chloroquine and it is therefore recommended that they should be given at least 4 hours apart.[3,4]

Cimetidine and chloroquine should be used with caution as *cimetidine* can significantly reduce the metabolism and elimination of chloroquine and increase its volume of distribution;[5] *ranitidine*, however, appears to have little effect on the pharmacokinetics of chloroquine.[6]

Levothyroxine. For a report of a possible interaction of chloroquine with levothyroxine, see p.2172.

Praziquantel. For a report of possible reduced bioavailability of praziquantel when given with chloroquine, see p.154.

Vaccines. Although chloroquine has been reported to reduce the antibody response to *human diploid rabies vaccine* (see p.2234), the immune response to other vaccines used in routine immunisation schedules (tetanus, diphtheria, measles, poliomyelitis, typhoid, and BCG) has not been found to be altered by chloroquine prophylaxis.[1,2]

2. Wolfe MS. Precautions with oral live typhoid (Ty 21a) vaccine. *Lancet* 1990; **336:** 631–2.

Pharmacokinetics

Chloroquine is rapidly and almost completely absorbed from the gastrointestinal tract when given orally. Absorption is also rapid after intramuscular or subcutaneous use. It is widely distributed into body tissues and has a large apparent volume of distribution. It accumulates in high concentrations in some tissues, such as the kidneys, liver, lungs, and spleen and is strongly bound in melanin-containing cells such as those in the eyes and the skin. It also crosses the placenta. Chloroquine is eliminated very slowly from the body and it may persist in tissues for months or even years after stopping therapy.

Chloroquine is extensively metabolised in the liver, mainly to monodesethylchloroquine with smaller amounts of bisdesethylchloroquine (didesethylchloroquinine) and other metabolites being formed. Monodesethylchloroquine has been reported to have some activity against *Plasmodium falciparum*. Chloroquine and its metabolites are excreted in the urine, with about half of a dose appearing as unchanged drug and about 10% as the monodesethyl metabolite. Chloroquine and its monodesethyl metabolite are both distributed into breast milk.

◊ Chloroquine is rapidly absorbed from the gastrointestinal tract but peak plasma concentrations after oral doses can vary considerably.[1] A mean peak plasma concentration of 76 nanograms/mL has been obtained in healthy adults a mean of 3.6 hours after giving the equivalent of 300 mg of chloroquine base orally as tablets.[2] In children with uncomplicated malaria given the equivalent of 10 mg/kg peak plasma concentrations of 250 nanograms/mL have been reached after 2 hours;[3] a mean peak of 134 nanograms/mL has been obtained after 5 hours in healthy children given a similar dose.[4] Nasogastric use has also produced therapeutic concentrations in children with severe falciparum malaria.[5]

Oral bioavailability is increased if chloroquine is taken with food[6,7] and some beverages[8] and may also be affected by the state of health of the patient; mean values have ranged from about 70% in patients with malaria[9] to 78 or 89% in healthy adults.[2] Although oral bioavailability appears to be unaltered in moderately undernourished adults[10] it has been reported that it may be significantly reduced in children with kwashiorkor.[4]

Preliminary studies with chloroquine suppositories indicated that, although rectal bioavailability is less than half of that of oral chloroquine, sustained therapeutic concentrations may be achieved.[11]

Absorption is also rapid after subcutaneous or intramuscular injection and mean peak plasma concentrations of chloroquine have been obtained within about 30 minutes.[5,9,12]

Chloroquine has a large apparent volume of distribution. A multicompartmental model appears to be necessary to describe the distribution kinetics of chloroquine.[2,13] After intravenous dosage there is a multi-exponential decline in plasma concentrations as chloroquine distributes out of a central compartment that has been estimated to be several orders of magnitude smaller than the total volume of distribution.[5,14] This slow distribution out of the central compartment produces transiently high cardiotoxic concentrations of chloroquine if the overall rate of parenteral delivery is not carefully controlled.

Reported mean values for protein binding have ranged from about 58 to 64%.[15,16] Chloroquine is also bound to platelets and granulocytes so that the plasma concentration is only 10 to 15% of that in whole blood.[17] If these cells are not removed by gentle centrifugation during analysis, erroneously high plasma concentrations will be reported. Furthermore, as chloroquine concentrations determined in serum are higher than those in plasma, probably due to release of chloroquine from platelets during coagulation, it is crucial to state whether analysis has been done on whole blood, serum, or properly separated plasma.

About 50% of a dose of chloroquine is metabolised in the liver, mainly to the *N*-dealkylated metabolite monodesethylchloroquine; smaller amounts of bisdesethylchloroquine, 7-chloro-4-aminoquinoline, and *N*-oxidation products are formed. Some of these metabolites may contribute to the cardiotoxicity associated with chloroquine. In one study, peak plasma concentrations of 7-chloro-4-aminoquinoline were found to be twice those of unchanged chloroquine despite the fact that only relatively small amounts are formed; this appears to be due to its fast rate of formation and long elimination half-life.[18]

A mean of 42 to 47% of a dose has been reported to be excreted in the urine as unchanged chloroquine and 7 to 12% as monodesethylchloroquine.[2] Various estimates of the terminal elimination half-life of chloroquine range from several days to up to 2 months, but its slow release from tissues ensures that small amounts may still be detected after a year.[18,19]

Distribution into breast milk. Studies[1,2] have suggested that it is safe for mothers to breast feed when they are receiving chloroquine for treatment of malaria. Although chloroquine and its monodesethyl metabolite are distributed into breast milk, it has been estimated that the amount that would be consumed by an infant is well below the therapeutic range and separate chemoprophylaxis for the infant is required.

There appears to be no data on the excretion of hydroxychloroquine in milk after doses appropriate for the prevention or treatment of malaria, but hydroxychloroquine has been detected in breast milk from 2 mothers receiving doses of 400 mg daily for SLE or rheumatoid arthritis.[3,4] One group of workers estimated that, calculated on a body-weight basis, a 9-month-old infant could receive about 2% of a maternal dose via breast feeding.[3]

Uses and Administration

Chloroquine is a 4-aminoquinoline antimalarial used in the treatment and prophylaxis of malaria. It has also been used in the treatment of hepatic amoebiasis, lupus erythematosus, light-sensitive skin eruptions, and rheumatoid arthritis.

Chloroquine is used for the prophylaxis and treatment of malaria due to susceptible strains of *Plasmodium ovale, P. vivax*, and *P. malariae*. It has also been used for susceptible strains of *P. falciparum* but in most of the world *P. falciparum* is now resistant to chloroquine, which should *not* therefore be given for treatment. Chloroquine is a rapid-acting blood schizontocide with some gametocytocidal activity against *P. ovale, P. vivax, P. malariae*, and immature gametocytes of *P. falciparum*. Since it has no activity against exoerythrocytic forms, it does not produce a radical cure of vivax or ovale malarias. The mechanism of action of chloroquine against blood schizonts remains unclear, but it may influence haemoglobin digestion by raising intravesicular pH in malaria parasite cells. It also interferes with synthesis of nucleoproteins by the parasite.

Chloroquine may be given as the phosphate, sulfate, or hydrochloride. Doses are normally expressed in terms of chloroquine base, and as a general guide:

- chloroquine base 300 mg is equivalent to about chloroquine phosphate 500 mg or chloroquine sulfate 400 mg
- chloroquine base 40 mg is equivalent to about chloroquine hydrochloride 50 mg

Oral bioavailability is increased when chloroquine is taken with food.

For the **treatment of malaria** caused by *P. vivax*, *P. ovale*, *P. malariae*, and the few remaining strains of chloroquine-sensitive *P. falciparum*, the usual total oral dose for adults and children is the equivalent of a total of about 25 mg of chloroquine base per kg bodyweight given over 3 days. This total dose has been given in a variety of ways. One way is to give 10 mg/kg, followed after 6 to 8 hours by 5 mg/kg, then 5 mg/kg daily for the next 2 days; alternatively, 10 mg/kg may be given daily for the first 2 days and 5 mg/kg on the third day. Sometimes the adult doses are not expressed in terms of body-weight but as 600 mg followed after 6 to 8 hours by 300 mg, then 300 mg daily for the next 2 days.

In severe and complicated malaria when the patient is unable to take oral medication, if chloroquine is to be used it can be given by injection. The intravenous route is preferred and a slow rate of infusion is essential, the required dose of 25 mg/kg being given in several infusions over 30 to 32 hours. Should the patient recover sufficiently to be able to take chloroquine orally then the intravenous regimen should be halted and oral therapy started.

For **prophylaxis of malaria** in areas where *P. falciparum* is absent or in one of the few remaining areas where it is still sensitive to chloroquine, a dose equivalent to 300 mg of chloroquine base is given once each week, beginning about one week before exposure and continuing throughout, and for at least 4 weeks after, exposure. For children, a weekly dose of 5 mg/kg has been recommended (but see also under Malaria, below). In areas of chloroquine-resistant malaria, but with a low risk of infection, chloroquine is given with proguanil; where there is a high risk of infection alternative antimalarial regimens are recommended.

In the treatment of **hepatic amoebiasis**, chloroquine is used with an intestinal amoebicide. The usual dose is the equivalent of 600 mg of chloroquine base daily for 2 days then 300 mg daily for 2 or 3 weeks. A dose of 6 mg/kg daily up to a maximum of 300 mg daily has been suggested for children.

When chloroquine is used for *long-term therapy* in conditions such as rheumatoid arthritis or lupus erythematosus, the dosage in obese patients should be calculated on the basis of lean body-weight in order to avoid excessive dosage.

In **rheumatoid arthritis**, response to treatment may not be apparent for up to 6 months, but if there is no improvement by then treatment should be stopped. The usual dose is the equivalent of chloroquine base 150 mg daily (maximum 2.5 mg/kg daily) or up to 3 mg/kg daily in children. For precautions and guidelines concerning use by rheumatologists see under Effects on the Eyes, above.

In discoid and systemic **lupus erythematosus** chloroquine is used in a dose equivalent to 150 mg (maximum 2.5 mg/kg) of base daily; children are given a dose of up to 3 mg/kg daily.

In the management of **light-sensitive skin eruptions**, adults may be given the equivalent of 150 to 300 mg of chloroquine base daily during periods of intense light exposure; children may be given up to 3 mg/kg.

Amoebiasis. For a discussion of the treatment of amoebiasis with mention of chloroquine for hepatic amoebiasis, see p.822.

Inflammatory disorders. Chloroquine and hydroxychloroquine possess anti-inflammatory properties and they have been tried or used with some benefit in a range of inflammatory conditions which often have an immunological basis, although they rarely constitute first-line therapy in these disorders. Such conditions include rheumatoid arthritis and SLE (see under Hydroxychloroquine, p.604), ulcerative colitis,[1] infantile interstitial pneumonitis,[2,3] asthma,[4] giant cell arteritis,[5] and various skin disorders (see below). The mode of action in these conditions is unclear. Results of studies have been conflicting but it does appear that chloroquine and hydroxychloroquine might have some immunosuppressive effects.[6,7]

Malaria. The overall treatment and prophylaxis of malaria and the place of chloroquine in current recommendations are discussed on p.594.

TREATMENT. In the treatment of patients with chloroquine-sensitive falciparum malaria studies have found chloroquine to be at least as effective as quinine in both uncomplicated and severe infections. However, very few areas exist where *Plasmodium falciparum* remains sensitive to chloroquine. There are also reports of resistance to chloroquine in *P. vivax*.[1]

Treatment with chloroquine is usually by mouth, adults and children being given the equivalent of 25 mg of chloroquine base per kg body-weight over 3 days. Any chloroquine lost through vomiting needs to be replaced by additional doses.[2]

Intravenous therapy has been used if the infection is severe or oral dosage is not possible. There should be close monitoring for hypotension and other signs of cardiovascular toxicity. The intramuscular or subcutaneous routes have been used if intravenous dosage is not possible. Patients should be transferred to oral therapy as soon as possible and treatment continued until a total dose equivalent to 25 mg of the base per kg has been given.

If injections cannot be given a chloroquine suspension or syrup appears to be well absorbed when given by nasogastric tube even in comatose patients. Rectal use in young children has also produced beneficial responses.[3,4]

PROPHYLAXIS. The widespread prevalence of strains of *P. falciparum* resistant to chloroquine has considerably diminished the value of chloroquine for malaria chemoprophylaxis and has made recommendations increasingly complex (see p.594). If chloroquine is used for prophylaxis it is usually given with proguanil. For **adults** a dose equivalent to 300 mg of chloroquine base is given by mouth once each week, beginning about one week before exposure and continuing throughout, and for at least 4 weeks after, exposure. Some countries advise the use of 100 mg daily for 6 days a week. For **children**, a weekly dose of chloroquine base 5 mg/kg has been recommended, although UK malaria experts[5] have suggested the following prophylactic doses for children based on fractions of the adult dose of 300 mg weekly:

- under 6.0 kg (0 to 12 weeks of age), one-eighth the adult dose
- 6.0 to 9.9 kg (3 to 11 months), one-quarter the adult dose
- 10.0 to 15.9 kg (1 year to 3 years 11 months), three-eighths the adult dose
- 16.0 to 24.9 kg (4 years to 7 years 11 months), half the adult dose
- 25.0 to 44.9 kg (8 years to 12 years 11 months), three-quarters the adult dose
- over 45 kg (13 years and over), the adult dose

They noted that body-weight was a better guide to dosage than age for children over 6 months.

Porphyria cutanea tarda. Chloroquine and hydroxychloroquine have been used with some benefit in the treatment of porphyria cutanea tarda (p.1448) and low doses (such as chloroquine phosphate 125 mg or hydroxychloroquine sulfate 200 mg given twice weekly) have been considered by some to be useful in patients unsuitable for phlebotomy.[1-4] However, the acute increase in urinary porphyrins and fall in hepatic porphyrin content produced by these drugs have been associated with a variable degree of hepatotoxicity[5,6] and others prefer to use desferrioxamine.[7]

Skin disorders. In addition to their use in lupus erythematosus hydroxychloroquine and chloroquine have been tried in a number of other skin disorders including polymorphic light eruptions[1] (see Photosensitivity Disorders, p.1581), lichen planus[2,3] (p.1580), cutaneous symptoms of dermatomyositis (p.1510), erythema nodosum,[4,5] and recurrent erythema multiforme (p.1580). It has also been tried in mild type 2 lepra reactions (erythema nodosum leprosum, see p.176).

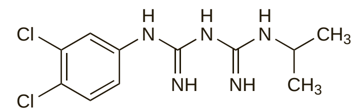
Chlorproguanil Hydrochloride *(BANM, rINNM)*

Chlorproguanil, Chlorhydrate de; Chlorproguanili Hydrochloridum; Hidrocloruro de clorproguanil; M-5943. 1-(3,4-Dichlorophenyl)-5-isopropylbiguanide hydrochloride.

Хлорпрогуанила Гидрохлорид

$C_{11}H_{15}Cl_2N_5,HCl = 324.6.$

CAS — 537-21-3 (chlorproguanil); 15537-76-5 (chlorproguanil hydrochloride).



(chlorproguanil)

Profile

Chlorproguanil is a biguanide antimalarial used for malaria prophylaxis similarly to proguanil (p.609). It is sometimes given with dapsone. Combination with both dapsone and artesunate is also being investigated for malaria treatment.

◊ Reviews.

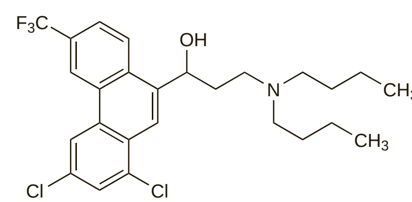
Halofantriinihydrokloridi; Halofantrin hydrochlorid; Halofantrine, Chlorhydrate d'; Halofantrine, chlorhydrate de; Halofantrin-hidroklorid; Halofantrinhydroklorid; Halofantrini hydrochloridum; Halofantrino hidrochloridas; Hidrocloruro de halofantrina; WR-171669. (*RS*)-3-Dibutylamino-1-(1,3-dichloro-6-trifluoromethyl-9-phenanthryl)propan-1-ol hydrochloride; 1,3-Dichloro-α-[2-(dibutylamino)ethyl]-6-trifluoromethyl-9-phenanthrene-methanol hydrochloride.

Галофантрина Гидрохлорид

$C_{26}H_{30}Cl_2F_3NO,HCl = 536.9.$

CAS — 69756-53-2 (halofantrine); 36167-63-2 (halofantrine hydrochloride); 66051-63-6 (±-halofantrine).

ATC — P01BX01.



(halofantrine)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Halofantrine Hydrochloride). A white or almost white powder. It exhibits polymorphism. Practically insoluble in water; sparingly soluble in alcohol; freely soluble in methyl alcohol. Protect from light.

Adverse Effects and Precautions

Adverse effects associated with halofantrine include diarrhoea, abdominal pain, nausea, vomiting, pruritus, and skin rash. Transient elevation of serum transaminases, intravascular haemolysis, and hypersensitivity reactions have also been reported.

Halofantrine can adversely affect the heart particularly by prolonging QT interval. Serious ventricular arrhythmias have been reported and fatalities have occurred. As a result it is contra-indicated in patients known to have a prolonged QT interval or those with cardiac disease or a family history of congenital QT prolongation, and also in those with unexplained syncopal attacks, thiamine deficiency, or electrolyte disturbances, or taking other arrhythmogenic drugs (see also Effects on the Heart, below, and Interactions, below).

Halofantrine is not recommended during pregnancy or breast feeding. It should not be taken on a full stomach since this increases its bioavailability and thus the risk of toxicity; after taking halofantrine, fatty food should be avoided for 24 hours.

Effects on the blood. Halofantrine has been associated with acute intravascular haemolysis.[1,2]

1. Vachon F, *et al.* Halofantrine and acute intravascular haemolysis. *Lancet* 1992; **340:** 909–10.
2. Mojon M, *et al.* Intravascular haemolysis following halofantrine intake. *Trans R Soc Trop Med Hyg* 1994; **88:** 91.

Effects on the heart. Prolonged PR[1,2] and QT[1-5] intervals have been reported in patients given halofantrine and there are individual reports of fatal cardiac arrest[1,5] and of torsade de pointes.[4] In 1994, the UK CSM[6] noted that QT interval prolongation occurred at recommended doses of halofantrine in the majority of patients and that worldwide there had been 14 reports of cardiac arrhythmias associated with halofantrine; 8 patients were known to have died. To reduce the risk of arrhythmias they stressed that halofantrine should *not* be taken with meals, with other drugs that may induce arrhythmias (e.g. quinine, chloroquine, and mefloquine; tricyclic antidepressants; antipsychotics; certain antiarrhythmics; and the antihistamines terfenadine and astemizole), or with drugs causing electrolyte disturbances. They also stated that it should *not* be given to patients known to have prolongation of the QT interval or with any form of cardiac disease associated with QT interval prolongation or ventricular arrhythmia (e.g. coronary heart disease, cardiomyopathy, or congenital heart disease). Some workers[2] have suggested ECG screening of all patients before starting treatment with halofantrine. Others[7] found pretreatment ECGs to be poorly predictive of QT lengthening during treatment. Children may experience serious cardiac effects at standard doses.[8]

8. Sowunmi A, *et al.* Cardiac effects of halofantrine in children suffering from acute uncomplicated falciparum malaria. *Trans R Soc Trop Med Hyg* 1998; **92:** 446–8.

Effects on the skin. For a comparison of the incidence of pruritus associated with halofantrine and other antimalarials, see Effects on the Skin under Adverse Effects of Chloroquine, p.600.

Interactions

Halofantrine prolongs the QT interval and should not be used with other drugs that have the potential to induce cardiac arrhythmias, in particular the antimalarials mefloquine, chloroquine, and quinine, and also tricyclic antidepressants, phenothiazine antipsychotics, some antiarrhythmics (including amiodarone, disopyramide, flecainide, procainamide, quinidine, and the beta blocker sotalol), cisapride, and the antihistamines astemizole and terfenadine. Also, halofantrine should not be given with drugs that cause electrolyte disturbances (such as diuretics) or with HIV-protease inhibitors.

Grapefruit juice. In a study in 12 healthy patients, the bioavailability of halofantrine was reported to be increased when taken with grapefruit juice and this was found to accentuate halofantrine-associated QT prolongation.[1] It was suggested that grapefruit juice should be contra-indicated during use of halofantrine.

1. Charbit B, *et al.* Pharmacokinetic and pharmacodynamic interaction between grapefruit juice and halofantrine. *Clin Pharmacol Ther* 2002; **72:** 514–23.

Tetracycline. Plasma concentrations of halofantrine were increased in 8 healthy subjects who were also given tetracycline.[1]

1. Bassi PU, *et al.* Effects of tetracycline on the pharmacokinetics of halofantrine in healthy volunteers. *Br J Clin Pharmacol* 2004; **58:** 52–5.

Pharmacokinetics

Halofantrine is slowly and erratically absorbed after oral dosage, although it appears in the circulation within about 1 hour, peak concentrations occurring in 3 to 7 hours. Bioavailability of halofantrine is increased when given with or after food, particularly food high in fat content, and it must therefore be taken on an empty stomach because of the risk of cardiac toxicity. The elimination half-life of halofantrine varies considerably between individuals, but is generally about 1 to 2 days. Halofantrine is metabolised in the liver, its major metabolite being desbutylhalofantrine, which appears to be as active as the parent compound. Excretion of halofantrine is primarily via the faeces.

3. Ohrt C, *et al.* Pharmacokinetics of an extended-dose halofantrine regimen in patients with malaria and in healthy volunteers. *Clin Pharmacol Ther* 1995; **57:** 525–32.

Uses and Administration

Halofantrine is a 9-phenanthrenemethanol antimalarial that has been used in the *treatment* of uncomplicated chloroquine-resistant falciparum and of chloroquine-resistant vivax malaria. Halofantrine is a blood schizontocide but has no activity against exoerythrocytic forms. Its value is limited by its unpredictable bioavailability and by cardiotoxicity. It should *not* be used where mefloquine has been used for prophylaxis (for cardiac hazard, see Effects on the Heart, above). Halofantrine should also *not* be used for malaria prophylaxis and is no longer recommended for standby treatment.

In the treatment of malaria, halofantrine hydrochloride has been given orally as 3 doses of 500 mg at intervals of 6 hours, on an empty stomach. Dosage for children is based on 24 mg/kg divided into 3 doses. The following doses have been recommended: 23 to 31 kg body-weight, 3 doses of 250 mg at intervals of 6 hours; 32 to 37 kg, 3 doses of 375 mg at intervals of 6 hours; over 37 kg, adult dose. A second course should be given after a week to patients with little or no previous exposure to malaria.

Hydroxychloroquine Sulfate *(rINNM)*

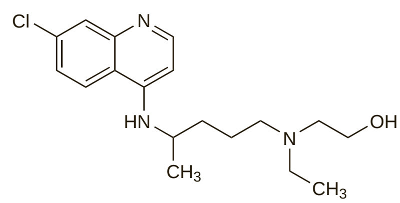
Hydroxychloroquine, Sulfate d'; Hydroxychloroquine Sulphate *(BANM)*; Hydroxychloroquini Sulfas; Oxichlorochin Sulphate; Sulfato de hidroxicloroquina; Win-1258-2. 2-{*N*-[4-(7-Chloro-4-quinolylamino)pentyl]-*N*-ethylamino}ethanol sulphate.

Гидроксихлорохина Сульфат

$C_{18}H_{26}ClN_3O,H_2SO_4$ = 434.0.

CAS — 118-42-3 (hydroxychloroquine); 747-36-4 (hydroxychloroquine sulfate).

ATC — P01BA02.



(hydroxychloroquine)

Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Hydroxychloroquine Sulphate). A white or almost white, odourless or almost odourless, crystalline powder. Freely soluble in water; practically insoluble in alcohol, in chloroform, and in ether. A 1% solution in water has a pH of 3.5 to 5.5. Protect from light.

USP 31 (Hydroxychloroquine Sulfate). A white or practically white, odourless, crystalline powder. It exists in two forms, the usual form melting at about 240° and the other form at about 198°. Freely soluble in water; practically insoluble in alcohol, in chloroform, and in ether. Its solutions in water have a pH of about 4.5. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Chloroquine, p.599.

Breast feeding. Hydroxychloroquine has been detected in human breast milk[1,2] but no adverse effects have been seen in breast-fed infants and the American Academy of Pediatrics considers[3] that it is therefore usually compatible with breast feeding.

1. Nation RL, *et al.* Excretion of hydroxychloroquine in human milk. *Br J Clin Pharmacol* 1984; **17:** 368–9.
2. Østensen M, *et al.* Hydroxychloroquine in human breast milk. *Eur J Clin Pharmacol* 1985; **28:** 357.
3. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 19/04/04)

Effects on the eyes. The main adverse effects of chloroquine and hydroxychloroquine on the eye are keratopathy and retinopathy. With respect to retinopathy, precautions should be taken in patients undergoing long-term treatment, as described under Chloroquine on p.600.

Pregnancy. In a study[1] of 133 pregnancies in 90 women treated with hydroxychloroquine, no statistical difference in pregnancy outcome was found compared with a control group consisting of 70 pregnancies in 53 women. It was concluded that the findings supported preliminary evidence for the safety of hydroxychloroquine treatment in pregnancy, and that treatment should probably therefore be maintained during pregnancy in patients with SLE.

1. Costedoat-Chalumeau N, *et al.* Safety of hydroxychloroquine in pregnant patients with connective tissue diseases: a study of one hundred thirty-three cases compared with a control group. *Arthritis Rheum* 2003; **48:** 3207–11.

Interactions

As for Chloroquine, p.601.

Pharmacokinetics

The pharmacokinetics of hydroxychloroquine are similar to those of chloroquine (see p.602).

◊ References.

Uses and Administration

Hydroxychloroquine sulfate is a 4-aminoquinoline antimalarial with actions similar to those of chloroquine (p.602), but is mainly used in the treatment of systemic and discoid lupus erythematosus and rheumatoid arthritis. It is also used in the treatment of light-sensitive skin eruptions.

Hydroxychloroquine sulfate is given orally.

In **lupus erythematosus** and **rheumatoid arthritis**, response to treatment may not be apparent for up to 6 months but if there is no improvement by then, treatment should be stopped. In the UK, treatment is usually started with 400 mg daily in divided doses with meals. In the USA, recommended initial doses are 400 to 600 mg daily for rheumatoid arthritis and 400 mg once or twice daily for lupus erythematosus. Doses are reduced to the minimum effective dose for maintenance; this is usually 200 to 400 mg daily but should not exceed 6.5 mg/kg daily (or 400 mg daily whichever is the smaller). To avoid excessive dosage in obese patients, special care is needed to calculate the dosage on the basis of lean body-weight. For further details, see under Effects on the Eyes in Chloroquine, p.600. In children, the minimum effective dose should be used up to a maximum of 6.5 mg/kg daily (or 400 mg daily whichever is the smaller).

Hydroxychloroquine sulfate is also used in similar doses for the treatment of **light-sensitive skin eruptions**, but treatment should only be given during periods of maximum exposure to light.

Hydroxychloroquine sulfate may be used in **malaria** both for treatment and prophylaxis, when chloroquine is not available, with the same limitations as for chloroquine. In the USA, a licensed dose for *prophylaxis* of malaria is 400 mg every 7 days; children may be given a weekly prophylactic dose of 6.5 mg/kg (up to a maximum of 400 mg). In *treating* an acute malarial attack, a dose of 800 mg has been used, followed after 6 to 8 hours by 400 mg and a further 400 mg on each of the 2 following days; alternatively, a single dose of 800 mg has been given. In children, an initial dose of 13 mg/kg may be given, followed by 6.5 mg/kg after 6 hours and again on the second and third days.

Inflammatory disorders. For the use of hydroxychloroquine and chloroquine in a range of inflammatory conditions, see under Chloroquine, p.603 and under Rheumatoid Arthritis, below.

Malaria. The role of chloroquine and potentially therefore of hydroxychloroquine in the treatment and prophylaxis of malaria is discussed on p.594.

Porphyria cutanea tarda. For reference to the use of hydroxychloroquine in the treatment of porphyria cutanea tarda, see under the Uses and Administration of Chloroquine, p.603.

Rheumatoid arthritis. Hydroxychloroquine and chloroquine are used orally as disease-modifying antirheumatic drugs (DMARDs) in the management of **rheumatoid arthritis** (p.11) in an attempt to suppress the rate of cartilage erosion or alter the course of the disease.[1] They are considered to be less effective than the other DMARDs but they are usually better tolerated and so may be preferred in patients with milder forms of the disease.[2] Additional benefit has been obtained using antimalarials with other DMARDs especially methotrexate and sulfasalazine,[3-5] although adverse effects may be more common. For reference to precautions to reduce the incidence of retinopathy, see under Effects on the Eyes in Adverse Effects of Chloroquine, p.600.

Generally the lowest effective dose should be used for maintenance to minimise toxicity; for hydroxychloroquine sulfate this should not exceed 6.5 mg/kg lean body-weight daily. Daily doses of 200 or 400 mg are commonly used but one study indicates that there is little advantage in using the higher dose.[6]

Experience with antimalarials to treat **juvenile idiopathic arthritis** (p.10) is limited and the results have been variable.[7,8]

Chloroquine and hydroxychloroquine have also been reported to be of use in **palindromic rheumatism**.[9-11]

Sarcoidosis. Chloroquine and hydroxychloroquine have been tried in the management of sarcoidosis (p.1512) as alternatives or adjuncts to corticosteroid therapy. For references to the use of hydroxychloroquine, see under Chloroquine, p.603.

Skin disorders. For reference to the use of hydroxychloroquine in a variety of skin disorders, see under Chloroquine, p.603.

Systemic lupus erythematosus. Antimalarials have been widely used in the treatment of lupus erythematosus (p.1513), particularly its cutaneous manifestations, although much of the evidence is based on case series and reports.[1] Hydroxychloroquine is most widely used, as it is thought to have fewer adverse effects than chloroquine, although any benefit with chloroquine generally starts to become evident within several weeks of starting treatment, whereas it may take up to 2 months for any effect of hydroxychloroquine to be seen. For extracutaneous disease, antimalarials are often combined with other drugs; treatment may be continued for many years. For reference to precautions to reduce the risk of retinopathy see Effects on the Eyes, under Adverse Effects of Chloroquine, p.600.

1. Wozniacka A, McCauliffe DP. Optimal use of antimalarials in treating cutaneous lupus erythematosus. *Am J Clin Dermatol* 2005; **6:** 1–11.

Venous thromboembolism. Standard prophylaxis for surgical patients at high risk of venous thromboembolism (p.1189) is usually with an anticoagulant. Hydroxychloroquine has been described by some as an antiplatelet agent[1] and although its mechanism of action is uncertain the incidence of fatal pulmonary embolism has been reduced in patients given hydroxychloroquine prophylactically after total hip replacement;[2] the usual daily divided oral dose was about 800 mg from the day before surgery until discharge; larger doses had been used.

USP 31: Hydroxychloroquine Sulfate Tablets.

Proprietary Preparations (details are given in Part 3)

Arg.: Axokine; Evoquin; Metirel; Narbon; Plaquenil; Polirreumin; ***Austral.:*** Plaquenil; ***Austria:*** Plaquenil; ***Belg.:*** Plaquenil; ***Braz.:*** Plaquinol; Reuquinol; ***Canad.:*** Apo-Hydroxyquine; Plaquenil; ***Chile:*** Plaquinol; ***Cz.:*** Plaquenil; ***Denm.:*** Ercoquin; Plaquenil; ***Fin.:*** Oxiklorin; Plaquenil†; ***Fr.:*** Plaquenil; ***Ger.:*** Quensyl; ***Gr.:*** Plaquenil; ***Hong Kong:*** Plaquenil; ***India:*** HCQS; ***Irl.:*** Plaquenil; ***Israel:*** Plaquenil; ***Ital.:*** Plaquenil; ***Malaysia:*** Plaquenil; ***Mex.:*** Plaquenil; ***Neth.:*** Plaquenil; ***Norw.:*** Plaquenil; ***NZ:*** Plaquenil; ***Philipp.:*** Plaquenil; ***Port.:*** Plaquinol; ***Rus.:*** Plaquenil (Плаквенил); ***Singapore:*** Plaquenil; ***Spain:*** Dolquine; ***Swed.:*** Plaquenil; ***Switz.:*** Plaquenil; ***Thai.:*** Hydroquin; Plaquenil; ***UK:*** Plaquenil; ***USA:*** Plaquenil; ***Venez.:*** Plaquinol.

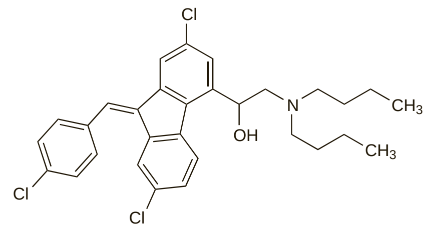
Lumefantrine *(BAN, rINN)*

Benflumelol; Benflumetol; Lumefantrina; Luméfantrine; Lumefantrinum. 2,7-Dichloro-9-[(4-chlorophenyl)methylene]-α-[(dibutylamino)methyl]-9*H*-fluorene-4-methanol.

Люмефантрин

$C_{30}H_{32}Cl_3NO$ = 528.9.

CAS — 82186-77-4.



Pharmacopoeias. In *Chin.*

Adverse Effects and Precautions

Adverse effects associated with lumefantrine in combination with artemether commonly include headache, dizziness, sleep disturbance, palpitations, gastrointestinal disturbances, anorexia, pruritus, rash, cough, arthralgia, myalgia, and fatigue. Lumefantrine-artemether should be given with caution in severe hepatic or renal impairment and ECG and blood potassium monitored.

Effects on the blood. Severe haemolytic anaemia necessitating corticosteroid treatment, blood transfusion, and haemodialysis occurred in a patient after taking 8 lumefantrine-artemether tablets after a malarial attack.[1] It was considered that, given its molecular similarity to other antimalarials known to cause haemolysis, the causative drug was probably lumefantrine.

1. Mérat S, *et al.* Case report: combination artemether-lumefantrine and haemolytic anaemia following a malarial attack. *Trans R Soc Trop Med Hyg* 2003; **97:** 433–4.

Pharmacokinetics

The bioavailability of lumefantrine after oral doses is variable; absorption begins after a lag-time of up to 2 hours and bioavailability is substantially increased when given with food, particularly meals high in fat. Peak plasma concentrations occur after about 6 to 8 hours. Lumefantrine is almost completely protein bound. It is considered to be metabolised mainly in the liver and is excreted in the faeces. The elimination half-life is reported to be between 4 to 6 days in patients with malaria.

◊ References.

Uses and Administration

Lumefantrine is a dichlorobenzylidine derivative given by mouth in combination with artemether (p.598) for the treatment of uncomplicated falciparum malaria. It is a blood schizontocide with a relatively slow onset of action but it has a longer duration of action than artemether.

The following doses are recommended by WHO; 6 doses in total are given, starting at diagnosis and repeated after 8, 24, 36, 48, and 60 hours. Each dose is:

- adults and children weighing over 34 kg, lumefantrine 480 mg with artemether 80 mg
- children 5 to 14 kg, lumefantrine 120 mg with artemether 20 mg
- children 15 to 24 kg, lumefantrine 240 mg with artemether 40 mg
- children 25 to 34 kg, lumefantrine 360 mg with artemether 60 mg

Adverse Effects

Since mefloquine has a long elimination half-life, adverse effects may occur or persist up to several weeks after the last dose.

The most frequent adverse effects of mefloquine are nausea, diarrhoea, vomiting, abdominal pain, anorexia, headache, dizziness, loss of balance, somnolence, and sleep disorders, notably insomnia and abnormal dreams.

Neurological or psychiatric disturbances have also been reported with mefloquine and include sensory and motor neuropathies, tremor, ataxia, visual disturbances, tinnitus and hearing impairment, convulsions, anxiety, depression, confusion, hallucinations, panic attacks, emotional instability, aggression and agitation, and acute psychosis. There have been rare reports of suicidal ideation.

Other adverse effects include skin rashes, pruritus and urticaria, hair loss, muscle weakness, myalgia, liver function disturbances, and very rarely thrombocytopenia and leucopenia. There have been rare occurrences of erythema multiforme and Stevens-Johnson syndrome. Anaphylaxis has occurred rarely. Cardiovascular effects have included hypotension, hypertension, tachycardia or palpitations, bradycardia, QT prolongation, and other minor ECG changes. There have been isolated cases of atrioventricular block.

Incidence of adverse effects. The frequencies of adverse effects reported[1] in 134 soldiers given mefloquine hydrochloride 250 mg weekly for malaria chemoprophylaxis were: diarrhoea (48%), nausea (13%), vomiting (2%), headache (13%), and dizziness (7%). All of 7 healthy subjects who received a dose of mefloquine hydrochloride 15 mg/kg had symptoms that included vertigo, nausea, dizziness, and lightheadedness.[2] The manufacturers reported that dizziness occurred in 24% of patients with malaria treated with 750 mg of mefloquine, in 38% treated with 1000 mg, and in 96% treated with 1500 mg; splitting a dose into two doses given 8 hours apart can reduce the incidence of dizziness.[3] A prospective study involving 3673 patients found that anorexia, nausea, vomiting, dizziness, and sleep disorders were 1.1 to 1.4 times more frequent in patients receiving mefloquine 25 mg/kg for treatment of malaria than in those receiving 15 mg/kg, and that vomiting could be reduced by 40% if the higher dose was split and given as 15 mg/kg followed by a further 10 mg/kg after 16 to 24 hours.[4] The frequency of adverse effects is reported to be higher in subjects who become dehydrated.[5]

There has been concern that the adverse effects of mefloquine, especially neuropsychiatric reactions, might limit its use for the prophylaxis of malaria but, as discussed under Effects on the Nervous System, below, the incidence of adverse effects does not appear to be greater than with other prophylactic schedules.

3. Stürchler D, *et al.* Neuropsychiatric side effects of mefloquine. *N Engl J Med* 1990; **322:** 1752–3.
4. ter Kuile FO, *et al.* Mefloquine treatment of acute falciparum malaria: a prospective study of non-serious adverse effects in 3673 patients. *Bull WHO* 1995; **73:** 631–42.
5. Perry IC. Malaria prophylaxis. *BMJ* 1995; **310:** 1673.

Effects on the blood. Agranulocytosis was reported[1] in a patient with malaria 48 hours after treatment with a 1250-mg course of mefloquine. The patient had previously taken 250 mg of mefloquine weekly for 7 weeks without side-effects. Thrombotic thrombocytopenic purpura has been reported[2] in a patient after taking two standard weekly doses of mefloquine for malaria prophylaxis. Symptoms improved after plasmapheresis.

2. Fiaccadori E, *et al.* Thrombotic-thrombocytopenic purpura following malaria prophylaxis with mefloquine. *J Antimicrob Chemother* 2006; **57:** 160–1.

Effects on the liver. Acute fatty liver was reported[1] in a patient who had recently received mefloquine 250 mg weekly for 5 weeks for malaria prophylaxis. Symptoms resolved with fluid, electrolyte, and albumin replacement, after stopping mefloquine. In another report,[2] acute elevation of liver transaminases, associated with severe acute hepatitis, occurred in a patient with pre-existing mild hepatic impairment following a 6-week course of mefloquine 250 mg weekly.

1. Grieco A, *et al.* Acute fatty liver after malaria prophylaxis with mefloquine. *Lancet* 1999; **353:** 295–6.
2. Gotsman I, *et al.* Mefloquine-induced acute hepatitis. *Pharmacotherapy* 2000; **20:** 1517–19.

Effects on the nervous system. Neuropsychiatric reactions have been associated with the use of mefloquine although various figures have been reported for their frequency. The UK CSM has quoted[1] figures of 1 in 10 000 to 1 in 20 000 for severe reactions to *prophylactic* doses and similarly the manufacturers report that 1 in 10 000 patients given mefloquine prophylaxis will have serious problems. Others consider that the incidence of serious reactions is extremely low,[2] with a frequency of about 1 in 80 000. The manufacturers have also reported that most reactions in patients taking mefloquine for prophylaxis appear to occur after the first dose and have suggested that monitoring after the first dose could identify 40% of those at risk of neuropsychiatric effects.[3] Some authorities consider that over 75% of such reactions to mefloquine are apparent by the third dose.[4] This may allow for tolerability problems with mefloquine prophylaxis to be identified before travel. There has been much discussion on the comparative tolerability of antimalarials used for chemoprophylaxis. The incidence of adverse events, including neuropsychiatric events, was comparable for mefloquine and chloroquine in 2 uncontrolled questionnaire studies, one in tourists[5] and one in US Peace Corps volunteers.[6] However, in a more recent questionnaire in travellers,[7] although the incidence of reported adverse events was similar for mefloquine and chloroquine plus proguanil, neuropsychiatric adverse events were significantly more common in mefloquine recipients. In two randomised controlled studies,[8,9] both in military personnel, there was no difference between CNS symptoms in those given weekly mefloquine and those receiving chloroquine (with or without proguanil). In one of these studies,[9] a subgroup receiving a loading dose of mefloquine daily for 3 days initially had a higher incidence of CNS events. A review[10] of 10 controlled studies found no significant difference in the rates of withdrawal and overall incidence of adverse effects for mefloquine and alternative prophylactic regimens, but mefloquine was more likely than other drugs to cause insomnia and fatigue. Women may be at greater risk of adverse effects than men, and WHO has commented that the occurrence of such adverse effects may mean that only highly motivated occupational subgroups or individuals at high risk of infection with chloroquine-resistant malaria will be willing to continue with mefloquine prophylaxis.[11]

Neuropsychiatric reactions are more frequent after the higher doses of mefloquine used for *treatment* than those used for prophylaxis. Some workers have estimated that overall 1 in 8000 mefloquine users have such reactions, with the incidence 60 times higher after treatment than after prophylaxis.[12] Other workers who have used mefloquine in nearly 14 000 treatments calculated that the overall frequency of serious neuropsychiatric reactions was 1 per 1754 treatments; it therefore appeared that serious neuropsychiatric reactions were 10 times more probable after treatment than with prophylactic use of mefloquine.[13]

A severe neurological syndrome associated with mefloquine treatment, with agitation, delirium, stupor, hyperpyrexia, mydriasis, and generalised rigors responded rapidly to treatment with physostigmine, suggesting a central anticholinergic aetiology.[14]

A discrete post-malaria neurological syndrome (including an acute confusional state or acute psychosis, convulsions, and tremor) has been seen on recovery from falciparum malaria and there appeared to be a strong association with mefloquine although it was not the only risk factor.[15] Nevertheless the risk was considered unacceptable and the recommendation made[15] that, where there was an effective alternative drug, mefloquine should not be used after initial treatment of severe malaria.

Emergence delirium during recovery from general anaesthesia after mefloquine prophylaxis has been reported in 3 cases.[16]

Effects on the oesophagus. Oesophageal ulceration in one patient and discomfort in another 4 was attributed to swallowing mefloquine tablets with insufficient fluid.[1]

1. Phillips M. Antimalarial mefloquine. *Med J Aust* 1994; **161:** 227–8.

Effects on the skin. Isolated cases of Stevens-Johnson syndrome,[1] severe facial lesions,[2] exfoliative dermatitis,[3] toxic epidermal necrolysis,[4] and cutaneous vasculitis[5] have been associated with use of mefloquine for malaria prophylaxis.

For a comparison of the incidence of pruritus induced by various antimalarials, see under Chloroquine, p.600.

5. White AC, *et al.* Cutaneous vasculitis associated with mefloquine. *Ann Intern Med* 1995; **123:** 894.

Overdosage. Cardiac, hepatic, and neurological symptoms have been reported in a patient who inadvertently received 5.25 g of mefloquine over 6 days.[1] All symptoms disappeared rapidly when mefloquine was stopped.

1. Bourgeade A, *et al.* Intoxication accidentelle à la méfloquine. *Presse Med* 1990; **19:** 1903.

Precautions

Tasks requiring fine coordination such as driving should not be undertaken during treatment with mefloquine or for at least 3 weeks afterwards; in the case of prophylactic use, care should be exercised while taking mefloquine and for at least 3 weeks after stopping it. The use of mefloquine for malaria prophylaxis is contra-indicated in patients with a history of psychiatric (including depression) or convulsive disorders. Increased plasma concentrations may occur in patients with hepatic impairment. Mefloquine should be stopped should symptoms suggestive of psychiatric disturbance occur during prophylaxis, and an alternative antimalarial substituted. Mefloquine is teratogenic in *animals* and its use during pregnancy is best avoided; however, in areas of chloroquine-resistant *Plasmodium falciparum*, WHO states that mefloquine may normally be taken for malaria prophylaxis during the second and third trimesters of pregnancy. It is recommended that women should also avoid becoming pregnant during, and for 3 months after, mefloquine use and that mothers should not breast feed while taking mefloquine. Mefloquine should be used with caution in patients with renal impairment and in those with cardiac conduction disorders.

Porphyria. For a discussion of the problems of the use of antimalarials in patients with porphyria and a comment that mefloquine may be safe for use in such patients, see under Precautions for Chloroquine, p.601.

Pregnancy. Licensed product information for mefloquine reports that it is teratogenic in *rodents*. There is limited information on its effects in humans. One study in Thailand cited by WHO[1] found no difference between mefloquine and quinine in pregnancy outcome, but the numbers of treated patients who were in their first trimester were very small and its use should be kept to a minimum in that stage of pregnancy. Further spontaneous reports of exposure to mefloquine during the first trimester of pregnancy collected by the manufacturer revealed 24 fetal abnormalities and 17 spontaneous or missed abortions in 358 pregnancies, although a causal relationship was not established,[2] and a later study by the manufacturer involving 1627 reports of exposure during pregnancy appeared to show a similar incidence of congenital malformation to that in offspring of unexposed women.[3] In 53 army service women who inadvertently used mefloquine in pregnancy, and for whom pregnancy outcome was known, there were 17 elective abortions, 12 spontaneous abortions, one molar pregnancy, and 23 healthy live births, with no major congenital malformations.[4] The rate of spontaneous abortions was considered high.[4] A prospective cohort study involving 236 pregnant women who received an antimalarial in the first trimester did not find an increased risk of spontaneous abortion or anomaly in women who took mefloquine compared with other antimalarials, and the rate of spontaneous abortion was comparable with background rates.[5]

Confidence in the safety of mefloquine has increased, and WHO now considers mefloquine suitable for malaria prophylaxis in the second and third trimesters;[6] WHO has stated its use is not recommended in the first trimester because of limited information on its safety. Authorities in the UK consider that use may sometimes be justified in the first trimester in areas of high risk of acquiring falciparum malaria; inadvertent use is not an indication to terminate pregnancy.[7]

Pregnancy should be avoided during and for 3 months after prophylactic use.

Interactions

Halofantrine should not be given with or after mefloquine because of the increased potential to induce hazardous cardiac arrhythmias, as discussed under Effects on the Heart on p.603. There is an increased risk of convulsions when mefloquine is used with chloroquine, quinidine, or quinine.

Alcohol. There has been a case report[1] of a patient who had neuropsychiatric disturbances after consuming a large quantity of alcohol with mefloquine; subsequent abstinence from alcohol led to complete reversal of the reactions.

1. Wittes RC, Saginur R. Adverse reaction to mefloquine associated with ethanol ingestion. *Can Med Assoc J* 1995; **152:** 515–17.

Antibacterials. Studies in healthy subjects have indicated that *ampicillin*[1] or *tetracycline*[2] could increase blood concentrations of mefloquine. Convulsions have been precipitated in 3 non-epileptic patients who were given mefloquine and the quinolone antibacterials *ciprofloxacin*, *ofloxacin*, or *sparfloxacin*.[3]

1. Karbwang J, *et al.* Effect of ampicillin on mefloquine pharmacokinetics in Thai males. *Eur J Clin Pharmacol* 1991; **40:** 631–3.
2. Karbwang J, *et al.* Effect of tetracycline on mefloquine pharmacokinetics in Thai males. *Eur J Clin Pharmacol* 1992; **43:** 567–9.
3. Mangalvedhekar SS, *et al.* Convulsions in non-epileptics due to mefloquine-fluoroquinolone co-administration. *Natl Med J India* 2000; **13:** 47.

Antidepressants. Licensed product information for mefloquine states that in patients taking tricyclic antidepressants use of mefloquine may theoretically contribute to prolongation of the QT interval.

Antiepileptics. Licensed product information states that mefloquine may reduce seizure control by lowering the plasma concentration of antiepileptics, including carbamazepine, phenobarbital, and phenytoin. For the effect of mefloquine on *valproate*, see p.511. For its effect on *carbamazepine*, see p.475.

Antihistamines. Giving mefloquine with antihistamines may theoretically contribute to the prolongation of QT intervals; however, this is not considered to be an absolute contra-indication.

Antimalarials. It is well established that the use of *halofantrine* with or after mefloquine is contra-indicated because of the risk of hazardous cardiac arrhythmias. Mefloquine and other related compounds such as *quinine*, *quinidine*, and *chloroquine* may be given together only under close medical supervision because of possible additive cardiac toxicity; there is also an increased risk of convulsions.

A study in healthy subjects indicated that use of *primaquine* could increase blood concentrations of mefloquine and might increase the incidence of adverse effects due to mefloquine,[1] but others reported no such interaction.[2]

1. MacLeod CM, *et al.* Interaction of primaquine with mefloquine in healthy males. *J Clin Pharmacol* 1990; **30:** 841.
2. Karbwang J, *et al.* Pharmacokinetics of mefloquine in the presence of primaquine. *Eur J Clin Pharmacol* 1992; **42:** 559–60.

Antipsychotics. The use of mefloquine with *phenothiazines* or *pimozide* may theoretically contribute to prolonged QT intervals, although this is not considered to be an absolute contra-indication.

Cardiovascular drugs. It has been recommended that mefloquine should be used with extreme caution in patients also taking *antiarrhythmics*, *beta blockers*, *calcium-channel blockers*, or *digitalis*, until more was known about the risks of cardiotoxicity, since theoretically these drugs might contribute to prolongation of the QT interval. An increased risk of ventricular arrhythmias has been reported when mefloquine is given with *amiodarone*.

Cardiopulmonary arrest has occurred after a single dose of mefloquine in a patient who was taking *propranolol*.[1]

1. Anonymous. Mefloquine for malaria. *Med Lett Drugs Ther* 1990; **32:** 13–14.

Metoclopramide. Use with metoclopramide may increase plasma concentrations of mefloquine.[1]

1. Na Bangchang K, *et al.* The effect of metoclopramide on mefloquine pharmacokinetics. *Br J Clin Pharmacol* 1991; **32:** 640–1.

Vaccines. Unfortunately, conflicting advice has been issued concerning the use of mefloquine after typhoid vaccination, for details see p.2241.

Pharmacokinetics

The pharmacokinetics of mefloquine may be altered by malaria infection in a manner similar to those of quinine, the main effects being reductions in both its volume of distribution and its overall clearance.

Mefloquine is well absorbed from the gastrointestinal tract but there is marked interindividual variation in the time required to achieve peak plasma concentrations. Mefloquine is about 98% bound to plasma proteins and high concentrations have been reported in red blood cells. It is widely distributed throughout the body. Mefloquine has a long elimination half-life; mean values of about 21 days have been reported for some patients, although like other pharmacokinetic data on mefloquine there is considerable variation in reported figures. Subtherapeutic concentrations of mefloquine may persist in the blood for several months. Mefloquine is metabolised in the liver. Little of a dose is excreted in the urine and *animal* studies suggest excretion of mefloquine and its metabolites is mainly in the bile and faeces.

Mefloquine is distributed into breast milk in small amounts.

◊ Reviews of pharmacokinetic studies of mefloquine reveal considerable interindividual variation for several pharmacokinetic parameters and some evidence that there might be pharmacokinetic differences between ethnic groups.[1,2] Mefloquine is well absorbed by healthy subjects and by patients with uncomplicated malaria after oral doses.[3,4] In patients with complicated malaria adequate blood concentrations have been obtained by the nasogastric route but this route cannot be relied upon for seriously ill patients[5] as absorption may be incomplete.[1] Mefloquine has a large apparent volume of distribution but this is reduced in the presence of malaria.[6,7] In children given mefloquine with sulfadoxine and pyrimethamine as tablets crushed and mixed with a glucose syrup, maximum blood-mefloquine concentrations were higher and reached in a shorter time compared with equivalent doses in adults.[8] In pregnant women with uncomplicated malaria blood concentrations were lower than in non-pregnant women and the apparent volume of distribution was larger.[9] Once-weekly prophylactic doses of mefloquine resulted in steady-state conditions at about 10 doses with no evidence of subsequent accumulation.[10]

Mefloquine is metabolised in the liver[11] largely into 2,8-bis(trifluoromethyl)-4-quinoline carboxylic acid [Ro-21-5104][12] but this metabolite appears to be inactive against *Plasmodium falciparum*.[13] Only a small percentage of a dose is excreted in the urine[14] and *animal* studies suggest excretion of mefloquine and its metabolites is mainly in the bile and faeces.[1] Mefloquine has an extremely long plasma elimination half-life; again there is considerable interindividual variation and mean values ranging from 13.9 to 27.5 days have been quoted, the smaller figure of the range referring to a formulation that did not provide as good absorption as the preparation now in use.[1]

Mefloquine is distributed into breast milk, but a single dose study in 2 women[15] indicated that the concentration of mefloquine in milk was only a small proportion of that seen in plasma.

Uses and Administration

Mefloquine is a 4-methanolquinoline antimalarial related to quinine. It is a blood schizontocide effective against all forms of malaria including chloroquine- or multidrug-resistant strains of *Plasmodium falciparum*, although some strains are naturally resistant to mefloquine. It is used for the treatment of uncomplicated falciparum malaria and chloroquine-resistant vivax malaria, and also for malaria prophylaxis. Mefloquine is also used after treatment with an artemisinin derivative for acute uncomplicated malaria, to reduce the risk of recrudescence.

Mefloquine is given orally as the hydrochloride but variation in the way doses are expressed could lead to confusion. In the UK and elsewhere, doses are expressed in terms of the base and a dose of 250 mg base is equivalent to about 274 mg of mefloquine hydrochloride. In the USA, doses are expressed in terms of the hydrochloride and a dose of 250 mg is therefore equivalent to only about 228 mg of mefloquine base. Doses in the USA could therefore be about 10% less than elsewhere.

Doses recommended in the UK are as follows.

- For the *treatment of malaria*, mefloquine base 20 to 25 mg/kg (up to a maximum of 1.5 g) as a single dose or preferably in 2 or 3 divided doses 6 to 8 hours apart
- For the *prophylaxis of malaria*, a dose of mefloquine base 250 mg once weekly in adults and children over 45 kg. Children weighing 5 to 19 kg may be given one-quarter the adult dose; those weighing 20 to 30 kg, half the adult dose; and those weighing 31 to 45 kg three-quarters the adult dose

  Prophylaxis should be started 1 to 3 weeks before exposure and continued for 4 weeks after leaving the malarious area

For other dosage recommendations, see under Malaria, below.

Malaria. The overall treatment and prophylaxis of malaria and the place of mefloquine in current recommendations are discussed on p.594.

TREATMENT. Clinical studies have shown mefloquine to be effective in the treatment of chloroquine- or multidrug-resistant falciparum malaria. It is also effective in benign malarias, but is not normally required since they usually respond to chloroquine.

Mefloquine has been widely used as an alternative to regimens using quinine for the treatment of chloroquine-resistant or multidrug-resistant strains of *Plasmodium falciparum*. It is now also used with an artemisinin derivative in multidrug resistance (see p.599).

As there is no parenteral formulation of mefloquine currently available it can only be used in patients who can take oral medication and is therefore unsuitable for sole treatment in severe infections. Mefloquine has produced adequate blood concentrations by the nasogastric route, but this route cannot be relied upon in seriously ill patients.[1] If mefloquine is given to patients after parenteral doses of quinine, it is recommended that a period of 12 hours should be allowed after the last dose of quinine to avoid toxicity.

In the UK, the recommended dose for the treatment of malaria is the equivalent of 20 to 25 mg of mefloquine base per kg bodyweight, as a single dose or preferably in two or three divided doses 6 to 8 hours apart, to a maximum of 1.5 g. The manufacturers recommend a lower dose of 15 mg/kg for the partially immune. In the USA, the manufacturers recommend 1250 mg of mefloquine hydrochloride given as a single dose. WHO[2] recommends a dose of mefloquine base of 25 mg/kg given over 2 or 3 days (15 mg/kg followed by 10 mg/kg a day later, or 8.3 mg/kg daily for 3 days).

WHO[3] considers that drugs used for the treatment of uncomplicated falciparum malaria may in principle be carried as a *standby* for use in similar doses for the emergency self-treatment of malaria, although mefloquine is not recommended by WHO as a first-line regimen.

PROPHYLAXIS. It had been hoped that mefloquine could be reserved for the treatment of malaria, but increasing drug resistance to chemoprophylactic regimens has led to it being widely used for malaria prophylaxis. WHO recommends[3] that mefloquine should be used where there is a high risk of falciparum malaria and drug resistance or a moderate to low risk but with high drug resistance. For **adults** the equivalent of 250 mg of mefloquine base is given every week, starting 1 to 3 weeks before departure, and continuing throughout the period of exposure and for 4 weeks after leaving the malarious area. Starting mefloquine prophylaxis 2 to 3 weeks before exposure allows for detection of possible adverse effects before travelling (see Effects on the Nervous System, above, for concerns about neurotoxicity). It is now considered that mefloquine prophylaxis can be given for periods of up to one year instead of the previous limit of 3 months.

Mefloquine is considered to be suitable[3] for prophylaxis in the second and third trimesters of pregnancy. Pregnancy should be avoided during and for 3 months after stopping the drug.

Recommended dosages of mefloquine for prophylaxis in **children** are generally based on 5 mg/kg as a single weekly dose in children weighing over 5 kg.[3] The doses now usually used in the

UK[4] for infants and children from 6 kg body-weight and above 3 months of age are as follows:

- 6 to 15.9 kg (3 months to 3 years 11 months), one-quarter the adult dose
- 16 to 24.9 kg (4 years to 7 years 11 months), half the adult dose
- 25 to 44.9 kg (8 years to 12 years 11 months), three-quarters the adult dose
- 45 kg and over (13 years or more), the adult dose

In the event of breakthrough malaria during malaria prophylaxis there may be a delay of up to several months before the onset of symptoms in contrast to that seen with other forms of prophylaxis.[5] Mefloquine should not be used for treatment if it has been used for prophylaxis.

(piperaquine)

Pharmacopoeias. In *Chin.*

Profile

Piperaquine phosphate is a 4-piperazinoquinoline derivative which has been studied in the treatment and prophylaxis of falciparum malaria. Combined treatment with artenimol is also being investigated. A combination of piperaquine, artinimol, and trimethoprim (*Artecom*) is available in some countries.

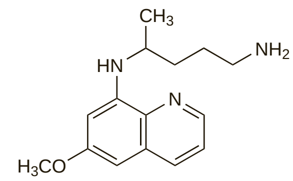
ATC — P01BA03.



(primaquine)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., US,* and *Viet.*

Ph. Eur. 6.2 (Primaquine Diphosphate). An orange crystalline powder. Soluble in water; practically insoluble in alcohol. Protect from light.

USP 31 (Primaquine Phosphate). An orange-red, odourless, crystalline powder. Soluble 1 in 15 of water; insoluble in chloroform and in ether. Its solutions are acid to litmus. Protect from light.

Adverse Effects

Adverse effects with therapeutic doses of primaquine are usually minimal but abdominal pain and gastric distress are more common if taken on an empty stomach. Larger doses may cause nausea and vomiting. Methaemoglobinaemia may occur occasionally. Haemolytic anaemia can occur in persons with G6PD deficiency (see below). Other uncommon effects include mild anaemia and leucocytosis. Hypertension and cardiac arrhythmias have been reported on rare occasions. Primaquine may rarely produce leucopenia or agranulocytosis, usually after overdosage. Other effects associated with overdosage include gastrointestinal symptoms, haemolytic anaemia, and methaemoglobinaemia with cyanosis.

◊ Many adverse effects have been reported after use of primaquine[1] but some, including pruritus and disturbances of visual accommodation, are considered to be inadequately documented or doubtfully attributed to the drug.

Acute intravascular haemolysis is the most serious toxic hazard of primaquine, especially in people with G6PD deficiency, other defects of the erythrocytic pentose phosphate pathway of glucose metabolism, or some types of haemoglobinopathy. In individuals with G6PD deficiency the severity of haemolysis is directly related to the degree of deficiency and to the quantity of primaquine given. In patients with the African variant the standard course of primaquine generally produces a moderate and self-limiting anaemia, while in those with the Mediterranean and related Asian variants, haemolysis can result in progressive haemoglobinaemia and haemoglobinuria which can be fatal. Whenever possible, therapy with primaquine should be delayed until the acute stage of malaria has been brought under control by a blood schizontocide because of the risk of inducing haemolysis and compromising the gastrointestinal tolerance of therapy.

1. Clyde DF. Clinical problems associated with the use of primaquine as a tissue schizontocidal and gametocytocidal drug. *Bull WHO* 1981; **59:** 391–5.

Precautions

Primaquine should be used cautiously in acutely ill patients with any serious systemic disease characterised by a tendency to granulocytopenia such as rheumatoid arthritis or lupus erythematosus. It should also be used with care in patients with G6PD deficiency. Primaquine should be withdrawn if signs of haemolysis or methaemoglobinaemia occur and the blood count should be monitored periodically.

Pregnancy. Radical cure of vivax or ovale malarias with primaquine should be delayed in pregnant women until after delivery.[1]

1. Panisko DM, Keystone JS. Treatment of malaria—1990. *Drugs* 1990; **39:** 160–89.

Interactions

Primaquine should not be used with drugs liable to induce haemolysis or bone marrow depression. Theoretically, mepacrine may increase the plasma concentrations of primaquine resulting in a higher risk of toxicity, and it has been recommended that these drugs should not be used together.

Antimalarials. The pharmacokinetics of primaquine were not altered by *mefloquine* in healthy subjects,[1] although the effect of primaquine on mefloquine pharmacokinetics is uncertain (see under Mefloquine, p.607). In a study in patients with malaria, *quinine* reduced the plasma concentrations of primaquine, although the clinical importance of the interaction was unclear.[1]

1. Edwards G, *et al.* Interactions among primaquine, malaria infection and other antimalarials in Thai subjects. *Br J Clin Pharmacol* 1993; **35:** 193–8.

Pharmacokinetics

Primaquine is readily absorbed from the gastrointestinal tract. Peak plasma concentrations occur about 1 to 2 hours after a dose is taken and then rapidly diminish with a reported elimination half-life of 3 to 6 hours. It is widely distributed into body tissues.

Primaquine is rapidly metabolised in the liver, its major metabolite being carboxyprimaquine, and little unchanged drug is excreted in the urine. Carboxyprimaquine accumulates in the plasma on repeated dosage.

Uses and Administration

Primaquine is an 8-aminoquinoline antimalarial that is effective as a tissue schizontocide against intrahepatic forms of all types of malaria parasite and is used to produce radical cure of vivax and ovale malarias.

Primaquine phosphate is given orally and doses may be expressed in terms of the base; primaquine phosphate 26.4 mg is equivalent to about 15 mg of primaquine base.

When used for *radical cure* of vivax or ovale **malaria**, a course of treatment with a blood schizontocide must be given first to kill any erythrocytic parasites. Primaquine phosphate is then given orally, usually in a dose equivalent to 15 mg of the base daily for 14 days but higher doses or longer courses may be required to overcome resistance in some strains of *P. vivax* (see below); WHO has advised that for uncomplicated malaria in travellers, infections acquired south of the equator should be treated with primaquine 500 micrograms/kg daily for 14 days and those acquired north of the equator with 250 micrograms/kg daily for 14 days. A dose for children is 250 micrograms/kg daily for 14 days.

For patients with G6PD deficiency the use of up to 45 mg (children 750 micrograms/kg) once every 7 days for 8 weeks has been suggested to minimise haemolysis (but see under Adverse Effects, above).

Primaquine is also gametocytocidal and a single dose of 750 micrograms/kg (to a maximum of 45 mg) has been suggested to *prevent transmission* of falciparum malaria particularly in areas where there is potential for re-introduction of malaria.

Primaquine is also used with clindamycin in the treatment of **pneumocystis pneumonia** in AIDS patients (below).

Malaria. The overall treatment and prophylaxis of malaria and the place of primaquine in current recommendations are described on p.594.

Despite the generally successful use of oral primaquine for radical cure of benign malarias,[1] there has been a report[2] of a patient weighing 84 kg who had relapse of vivax malaria after treatment including primaquine 15 mg given daily for 21 days; no further symptoms occurred after a second course of 15 mg given daily for 3 months. It was suggested that a daily dose of 15 mg might be inadequate for patients weighing more than 50 kg and that patients with vivax malaria who have relapsed after the standard course of primaquine, and possibly those with vivax malaria acquired in South-East Asia or Melanesia, should receive a total dose of 6 mg/kg in daily doses of 15 to 22.5 mg. A report from Thailand,[3] where primaquine-resistant strains of *Plasmodium vivax* are increasing, showed that a dose of primaquine 22.5 mg daily for 14 days was safe and more effective in preventing relapses than 15 mg daily in patients with an average body-weight of about 51 kg. There have been several other reports of primaquine-resistant *P. vivax*,[4-7] and the suggestion has been made that higher doses of primaquine (15 mg twice daily for 14 days, to give a total dose of 6 mg/kg assuming a body-weight of 70 kg) should be considered wherever the vivax malaria was acquired.[7,8] A systematic review[9] concluded that when used with chloroquine, a 14-day course of primaquine 15 mg daily was more effective than a 5-day course in preventing relapses of vivax malaria. The 5-day course of primaquine plus chloroquine appeared to be no better than chloroquine alone.

Variable responses to primaquine in the Amazonian region were attributed to considerable variation in the content of primaquine both between and within batches of tablets; primaquine content ranged from 19 to 168% of the labelled content.[10]

In the USA, the CDC[11] have suggested the use of primaquine at the end of prophylaxis to prevent relapses due to *P. vivax* or *P. ovale* in persons returning from prolonged exposure in areas where relapsing malaria is endemic. In those who have taken chloroquine, doxycycline, or mefloquine as prophylaxis, primaquine is usually given during the last 2 weeks of prophylaxis, but may also be taken immediately after prophylaxis is completed. When atovaquone plus proguanil is taken as prophylaxis, primaquine may be given either during the last 7 days and then for an additional 7 days, or for 14 days after atovaquone plus proguanil prophylaxis is completed. The recommended daily dose of primaquine for terminal prophylaxis is 30 mg for adults and 600 micrograms/kg for children.

Primaquine has also been tried for prophylaxis of falciparum and vivax malaria; use for a year produced effective cover and was well tolerated by Javanese men without G6PD deficiency.[12] It was also effective for prophylaxis in Colombian military personnel; it was noted that primaquine prophylaxis could be stopped 1 week after departing the endemic area.[13]

Pneumocystis pneumonia. Primaquine with clindamycin is used in the treatment of pneumocystis pneumonia as an alternative to co-trimoxazole[1] (see p.521). Treatment has usually lasted 3 weeks, with primaquine being given by mouth in daily doses equivalent to 30 mg of the base, and clindamycin usually being given intravenously in doses of 600 mg four times daily or 300 to 450 mg four times daily by mouth.[2] The *BNF* suggests clindamycin 600 mg by mouth every 8 hours with primaquine 30 mg daily by mouth for mild to moderate disease.

A randomised multicentre study[3] compared this latter regimen (primaquine 30 mg daily and clindamycin 600 mg three times daily) with co-trimoxazole and with a combination of dapsone and trimethoprim in 181 AIDS patients who had confirmed mild to moderate pneumocystis pneumonia. Primaquine-clindamycin was as effective as the other two regimens, although the authors suggested that the combination might be best avoided in patients with severe myelosuppression.

Primaquine with clindamycin is not normally recommended for prophylaxis although there are reports of it being tried.[4] A retrospective examination[5] of the records of patients who had received prophylaxis found that clindamycin with primaquine was less effective than co-trimoxazole or dapsone, although this could have been due in part to underdosing.

(proguanil)

Pharmacopoeias. In *Eur.* (see p.vii) and *Int.*

Ph. Eur. 6.2 (Proguanil Hydrochloride). A white or almost white, crystalline powder. Slightly soluble in water; sparingly soluble in dehydrated alcohol; practically insoluble in dichloromethane. Protect from light.

Stability. Although the Ph. Eur. 6.2 directs that proguanil hydrochloride should be protected from light, stability studies[1,2] suggest that it is a very stable compound with only small amounts of its major decomposition product 4-chloroaniline being formed during thermal and photochemical stress.

Adverse Effects and Precautions

Apart from mild gastric intolerance, diarrhoea, and some reports of aphthous ulceration there appear to be few adverse effects associated with usual doses of proguanil hydrochloride. There have been rare reports of hypersensitivity reactions including urticaria and angioedema. Rare cases of seizures and psychotic events have also been reported. Haematological changes have been reported in patients with severe renal impairment. Overdosage may produce epigastric discomfort, vomiting, and renal irritation leading to haematuria.

Proguanil should be used with caution in patients with renal impairment; dosage should be reduced accordingly (see under Uses and Administration, below).

Proguanil may be taken during pregnancy, but UK guidelines recommend that folate supplements (folic acid 5 mg daily) should also be given; however, the combination of proguanil with atovaquone should be avoided as data regarding the safety of atovaquone are lacking.

◊ Until 1985 proguanil was generally taken in a dose of 100 mg daily for malaria prophylaxis with few adverse effects. Although there was no increase in serious adverse effects when the dose was increased to 200 mg daily, and it began to be used with chloroquine, there were an increasing number of reports of reversible aphthous ulceration.[1] Chloroquine may exacerbate this effect.[2] There has also been a report of reversible alopecia in women and scaling of the skin in both men and women using proguanil.[3]

Megaloblastic anaemia and pancytopenia were associated with proguanil accumulation in 2 patients with renal failure.[4]

Stevens-Johnson syndrome has been reported[5] in a patient taking proguanil with atovaquone.

Interactions

Fluvoxamine. Fluvoxamine can virtually abolish[1] the metabolism of proguanil to its active metabolite cycloguanil via an inhibitory effect on the cytochrome P450 isoenzyme CYP2C19.

1. Jeppesen U, *et al.* The CYP2C19 catalyzed bioactivation of proguanil is abolished during fluvoxamine intake. *Eur J Clin Pharmacol* 1997; **52** (suppl): A134.

Warfarin. For a report of haematuria and high prothrombin ratio in a patient stabilised on warfarin who took proguanil for malaria prophylaxis, see p.1429.

Pharmacokinetics

Proguanil is readily absorbed from the gastrointestinal tract after oral doses, peak plasma concentrations occurring within about 4 hours. Proguanil is metabolised in the liver to the active metabolite cycloguanil. Peak plasma concentrations of cycloguanil occur approximately 1 hour after those of the parent drug. The elimination half-lives of both proguanil and cycloguanil are about 20 hours. About 40 to 60% of proguanil is eliminated in the urine, of which 60% is unchanged and 30% cycloguanil. There is also some elimination via the faeces. Proguanil is distributed into breast milk in small amounts (which are not adequate to provide chemoprophylaxis for the infant).

◊ Early studies found proguanil to be well absorbed from the gastrointestinal tract with peak plasma concentrations occurring after about 4 hours.[1] In more recent studies, peak plasma concentrations of proguanil have been achieved within 2 to 4 hours.[2-4] Plasma protein binding for proguanil is 75%.[5] Proguanil is metabolised in the liver[3] to the active metabolite cycloguanil and to *p*-chlorophenylbiguanide which is inactive. Peak plasma concentrations of cycloguanil occur about 5.3 hours after doses of proguanil.[4] Unlike proguanil and *p*-chlorophenylbiguanide, cycloguanil is not concentrated in erythrocytes and thus concentrations of cycloguanil in plasma and whole blood are similar.[4] The elimination half-lives for proguanil and cycloguanil are about 20 hours.[3,4] A review of early studies states that 40 to 60% of a dose of proguanil is excreted in the urine, 60% of this as the unchanged drug, 30% as cycloguanil, and 8% as *p*-chlorophenylbiguanide.[1] About 10% of a dose is excreted in the faeces.[1] However, these values can vary greatly and wide interindividual variations in the ability to metabolise proguanil to cycloguanil have been reported.[3,6,7] Malaria prophylaxis with proguanil might be less effective in poor metabolisers although this has not been proved conclusively[8] and, anyway, other factors such as lack of protection against mosquitoes and sensitivity of the malaria parasite might be more important.[9]

Plasma concentrations of cycloguanil may be reduced in the third trimester of pregnancy.[10]

Uses and Administration

Proguanil is a biguanide compound that has little antimalarial activity until metabolised in the body to the active antimalarial drug cycloguanil. Cycloguanil, like pyrimethamine, inhibits plasmodial dihydrofolate re-

The symbol † denotes a preparation no longer actively marketed

ductase and thus disrupts synthesis of nucleic acids in the parasite. Cycloguanil is active against pre-erythrocytic forms and is a slow-acting blood schizontocide. It also has some sporontocidal activity, rendering the gametocytes non-infective to the mosquito vector.

The value of proguanil is limited by the rapid development of resistance.

Proguanil is used orally as the hydrochloride for the chemoprophylaxis of malaria, with chloroquine or atovaquone. The schizontocidal activity of cycloguanil on erythrocytic forms is too slow for cycloguanil or proguanil to be used alone for the treatment of malaria, but proguanil hydrochloride is given combined with atovaquone for the treatment of uncomplicated falciparum malaria.

For *prophylaxis* of malaria in combination with chloroquine, the usual adult daily dose of proguanil hydrochloride is 200 mg taken after food. For prophylaxis in combination with atovaquone 250 mg, the daily dose of proguanil hydrochloride is 100 mg. It is generally recommended that chemoprophylaxis for travellers should start 1 week before exposure to malaria, but if this is not possible it can be started 1 to 2 days prior to travel. Use should continue throughout exposure and for at least 4 weeks (1 week when proguanil is given with atovaquone) after leaving a malarious area.

In the *treatment* of uncomplicated falciparum malaria, adult doses are proguanil hydrochloride 400 mg together with atovaquone 1 g, each orally as a single dose for 3 consecutive days.

For children's doses in the prophylaxis and treatment of malaria, see below.

Cycloguanil was also formerly given by intramuscular injection as an oily suspension of the embonate.

3. Nakato H, *et al.* A systematic review and meta-analysis of the effectiveness and safety of atovaquone proguanil (Malarone) for chemoprophylaxis against malaria. *J Antimicrob Chemother* 2007; **60:** 929–36.

Administration in children. Dosage recommendations for proguanil with **chloroquine** for **malaria prophylaxis** in children have varied. UK malaria experts[1] have suggested the following prophylactic oral doses for children based on fractions of the adult dose of 200 mg daily:

- under 6.0 kg (0 to 12 weeks of age): one-eighth the adult dose
- 6 to 9.9 kg (3 to 11 months): one-quarter the adult dose
- 10 to 15.9 kg (1 year to 3 years 11 months): three-eighths the adult dose
- 16 to 24.9 kg (4 years to 7 years 11 months): half the adult dose
- 25 to 44.9 kg (8 years to 12 years 11 months): three-quarters the adult dose
- 45 kg and over (13 years or more): the adult dose

They noted that body-weight was a better guide to dosage than age for children over 6 months.

Children may be given proguanil with **atovaquone** for the **prophylaxis** of malaria in the following doses, based on the adult dose of 100 mg of proguanil hydrochloride daily:

- children weighing 11 to 20 kg: one-quarter the adult dose
- 21 to 30 kg: half the adult dose
- 31 to 40 kg: three-quarters the adult dose
- over 40 kg: the adult dose

Doses of proguanil with atovaquone for the **treatment** of malaria, based on the adult dose of 400 mg of proguanil hydrochloride daily, are:

- children weighing 5 to 8 kg: one-eighth the adult dose
- 9 to 10 kg: three-sixteenths the adult dose
- 11 to 20 kg: one-quarter the adult dose
- 21 to 30 kg: half the adult dose
- 31 to 40 kg: three-quarters the adult dose
- 40 kg and over: the adult dose

Administration in renal impairment. Proguanil is excreted by the kidneys and should be given in reduced dosage or avoided in patients with renal impairment. The following oral doses have been recommended based on creatinine clearance (CC):

- CC 20 to 59 mL/minute: 100 mg daily
- CC 10 to 19 mL/minute: 50 mg every other day
- CC less than 10 mL/minute: 50 mg once weekly

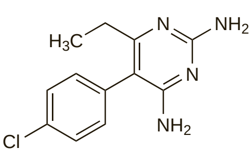
CAS — 58-14-0.

ATC — P01BD01.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *US*, and *Viet.*

Ph. Eur. 6.2 (Pyrimethamine). An almost white crystalline powder or colourless crystals. Practically insoluble in water; slightly soluble in alcohol. Protect from light.

USP 31 (Pyrimethamine). A white, odourless, crystalline powder. Practically insoluble in water; soluble 1 in 200 of alcohol and 1 in 125 of chloroform; slightly soluble in acetone. Store in airtight containers. Protect from light.

Adverse Effects and Treatment

Use of pyrimethamine for prolonged periods, as used to be the case when it was **given alone** for the prophylaxis of malaria, can cause depression of haematopoiesis due to interference with folic acid metabolism. Skin rashes and hypersensitivity reactions also occurred.

Larger doses, such as those used in the treatment of toxoplasmosis, may cause gastrointestinal symptoms such as atrophic glossitis, abdominal pain, and vomiting; haematological effects such as megaloblastic anaemia, leucopenia, thrombocytopenia, and pancytopenia are also more likely to occur. CNS effects including headache, dizziness, and insomnia have also been reported.

Pulmonary eosinophilia has been reported in patients taking pyrimethamine **with other antimalarials**. Severe and sometimes fatal reactions have occurred when pyrimethamine has been used with sulfadoxine (*Fansidar*), including erythema multiforme and the Stevens-Johnson syndrome, and toxic epidermal necrolysis; there have also been isolated reports of hepatotoxicity. Agranulocytosis occurs more frequently when pyrimethamine is used with dapsone (*Maloprim*) and fatalities have been reported.

Acute overdosage with pyrimethamine can cause gastrointestinal effects and CNS stimulation with vomiting, excitability, and convulsions. Tachycardia, respiratory depression, circulatory collapse, and death may follow. Treatment of overdosage is symptomatic.

Adverse effects with dapsone. Between 1972 and 1988, the UK CSM received 76 reports of reactions that were attributed to the use of pyrimethamine with dapsone (*Maloprim*), of which 40 (53%) were considered to be serious, including 6 deaths.[1] The incidence was estimated to be 1 in 9100 for serious reactions and 1 in 60 200 for fatalities. Serious blood disorders including agranulocytosis, granulocytopenia, or leucopenia occurred in 15 patients (estimated incidence of 1 in 20 000), five of whom died. The other death was in a patient with myocarditis. Three patients had cyanosis due to methaemoglobinaemia. Respiratory disorders such as pulmonary eosinophilia, flu-like syndrome, and dyspnoea occurred in 6 patients. In 4 patients skin disorders were the principal effect and included epidermal necrolysis, angioedema, and bullous eruptions. Hepatic disorders were also reported in 4 patients. Three women using pyrimethamine-dapsone during pregnancy delivered malformed babies, one of them being stillborn. Other effects in 4 patients included convulsions, exacerbated epilepsy, pancreatitis, or a generalised allergic reaction.

A review[2] of 21 cases of agranulocytosis associated with pyrimethamine-dapsone concluded that, although agranulocytosis can occur very rarely in patients taking pyrimethamine or dapsone alone, agranulocytosis due to the combination appears to be caused by an idiosyncratic reaction to dapsone exacerbated by pyrimethamine. Of the 18 individuals for whom dosage was certain, 12 had been taking one tablet of pyrimethamine-dapsone twice weekly, twice the recommended dose of one tablet once weekly. Of the 9 patients who died, 6 had been taking one tablet twice weekly and one patient had taken one tablet once weekly; the dosage was uncertain in the remaining patients. The time of onset of symptoms had been 7 to 9 weeks after starting therapy in 16 of 19 of the patients.

Some consider that pyrimethamine with dapsone may produce some degree of immunosuppression and render users more susceptible to common infections. A higher incidence of non-specific upper respiratory-tract infections occurred in military recruits taking the combination than in those not given antimalarial prophylaxis.[3]

Pulmonary eosinophilia has also occurred in patients taking pyrimethamine with dapsone but, as there have also been similar reports of pulmonary toxicity in patients taking pyrimethamine with sulfadoxine (see below) or pyrimethamine with chloroquine, it has been suggested that pyrimethamine is probably the causative agent.[4]

1. Phillips-Howard PA, West LJ. Serious adverse drug reactions to pyrimethamine–sulphadoxine, pyrimethamine–dapsone and to amodiaquine in Britain. *J R Soc Med* 1990; **83:** 82–5.

4. Davidson AC, *et al.* Pulmonary toxicity of malaria prophylaxis. *BMJ* 1988; **297:** 1240–1.

Adverse effects with sulfonamides. Severe and potentially fatal cutaneous reactions such as erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis have been associated with the combined use of pyrimethamine with sulfadoxine (*Fansidar*) for malaria prophylaxis. The reported incidence of these reactions has varied with surveys in the UK,[1] USA,[2] and Sweden[3] yielding similar results and a survey from Switzerland[4] finding a much lower incidence. The overall rate of serious reactions to pyrimethamine-sulfadoxine in the UK has been estimated to be 1 in 2100. The estimates for severe cutaneous reactions were 1 in 4900 in the UK, 1 in 5000 to 1 in 8000 in the USA, 1 in 10 000 in Sweden, and 1 in 150 000 in Switzerland, and the death rates were 1 in 11 100 in the UK, 1 in 11 000 to 1 in 25 000 in the USA, and 1 in 35 000 in Sweden; no fatalities were reported in Switzerland. Workers on the Swiss survey had suggested that the high incidence of cutaneous reactions reported in the USA might have been due to concurrent therapy with chloroquine but this has been disputed.[5] The authors of the UK survey[1] suggested that the lower incidence reported in Switzerland may have been due to the different methods used to estimate the amount of drug usage. Whether this toxicity is due to the combined use of pyrimethamine and sulfadoxine is unclear as the estimated frequency of fatal reactions associated with the use of sulfadoxine alone in Mozambique[6] was 1 in 50 000.

There have been isolated reports of other severe or life-threatening reactions associated with the use of pyrimethamine-sulfadoxine when used alone or with chloroquine, including hepatotoxicity[7-9] (estimated incidence of 1 in 11 100 in the UK[1]), fatal multisystem toxicity,[10] drug fever and photodermatitis,[11] agranulocytosis,[11] and erythroderma resembling Sézary syndrome.[12] Severe pulmonary reactions have also occurred[3,13] but, as similar reactions have also been reported when pyrimethamine has been used with other antimalarials, including dapsone, it has been suggested that pyrimethamine is the causative agent (see Adverse Effects with Dapsone, above). Hyperammonaemia and carnitine deficiency with deterioration in mental status has been reported in a patient given pyrimethamine and sulfadiazine for the treatment of toxoplasmosis.[14]

Severe megaloblastic anaemia in a patient taking pyrimethamine and sulfadiazine for toxoplasmosis of the CNS[15] was treated by withdrawing pyrimethamine and giving folinic acid orally, together with a single platelet infusion.

For a comparison of the incidence of pruritus induced by various antimalarials including pyrimethamine with sulfadoxine, see Effects on the Skin under Chloroquine, p.600.

Precautions

Pyrimethamine may aggravate subclinical folic acid deficiency and it should not be given to patients with conditions associated with folate deficiency such as megaloblastic anaemia. Blood counts are required with prolonged treatment, and when large doses of pyrimethamine are used, as in the treatment of toxoplasmosis, blood counts should be checked twice weekly. Folinic acid, which does not interfere with the action of pyrimethamine against malaria or toxoplasmosis, has been given to prevent haematological toxicity due to pyrimethamine and its use is especially recommended if pyrimethamine is given during pregnancy. (Folic acid may be used as an alternative to folinic acid in malaria, but it interferes with the action of pyrimethamine against toxoplasmosis). For further information concerning use during pregnancy, see below.

Pyrimethamine should be given with caution to patients with renal or hepatic impairment. When patients with convulsive disorders need to receive large doses, as in the treatment of toxoplasmosis, it is recommended that small starting doses should be used.

When pyrimethamine is used with sulfonamides or dapsone, the general precautions applicable to those drugs should also be taken (see under Sulfamethoxazole, p.340 and under Dapsone, p.262) and treatment should be stopped immediately if any skin reactions, sore throat, or shortness of breath occurs.

Breast feeding. Pyrimethamine is distributed into breast milk[1] but as no adverse effects have been reported in breast-fed infants, the American Academy of Pediatrics considers breast feeding to be compatible with the use of pyrimethamine for malaria prophylaxis.[2] However, exposure of the infant to other folate antagonists should be avoided. The large doses of pyrimethamine used for treating toxoplasmosis may distribute into breast milk in sufficient quantities to interfere with folic acid metabolism in nursing infants.

Porphyria. For a discussion of the problems of the use of antimalarials in patients with porphyria and a comment that pyrimethamine is probably safe for use in such patients, see under Precautions for Chloroquine, p.601.

Pregnancy. There have been concerns over the use of pyrimethamine during pregnancy as it has been shown to be teratogenic in *animal* studies.[1] In one report, severe congenital defects in a stillborn infant were attributed to the use of pyrimethamine in early pregnancy,[2] but the association was considered to be questionable.[3] Other instances of congenital malformations with pyrimethamine and dapsone are given under Adverse Effects with Dapsone, above.

Others[4] suggest that intermittent preventive therapy for malaria with pyrimethamine-sulfadoxine has a favourable safety profile in pregnancy. WHO considers that pyrimethamine combinations may be used after the first trimester of pregnancy in the treatment of toxoplasmosis,[5] and that pyrimethamine-sulfadoxine may be used in all trimesters for treatment in high-risk malaria-endemic regions.[6]

Interactions

Use of pyrimethamine with other folate antagonists such as co-trimoxazole, trimethoprim, methotrexate, or phenytoin may exacerbate bone marrow depression.

Lorazepam. Signs of mild liver toxicity in 2 of 5 subjects who received lorazepam and pyrimethamine appeared to confirm earlier suspicions that giving these drugs together could cause hepatotoxicity. Both patients tolerated each drug when given separately.[1]

Zidovudine. Studies *in vitro* and in *animals* suggest that zidovudine could reduce the effectiveness of pyrimethamine in the treatment of toxoplasmic encephalitis.[1] Furthermore, the dose of zidovudine may need to be altered if these drugs are used together as there has been a report that pyrimethamine with sulfadoxine (*Fansidar*) prolonged the serum half-life of zidovudine.[2]

Pharmacokinetics

Pyrimethamine is almost completely absorbed from the gastrointestinal tract and peak plasma concentrations of about 200 nanograms/mL are obtained 2 to 6 hours after a dose of 25 mg orally. It is mainly concentrated in the kidneys, lungs, liver, and spleen and about 80 to 90% is bound to plasma proteins.

It is metabolised in the liver and slowly excreted via the kidney, the average half-life in plasma being about 4 days. Several metabolites have been detected in the urine. Pyrimethamine crosses the placenta. It is distributed into breast milk (see under Breast Feeding in Precautions, above).

Uses and Administration

Pyrimethamine is a diaminopyrimidine antimalarial used with a sulfonamide in the treatment of malaria and toxoplasmosis. Pyrimethamine with sulfadoxine has been tried in the treatment of actinomycetoma and for prophylaxis of pneumocystis pneumonia. Pyrimethamine alone or with sulfadoxine has also been tried in the treatment of isosporiasis.

Pyrimethamine exerts its antimalarial activity by inhibiting plasmodial dihydrofolate reductase, thus indirectly blocking the synthesis of nucleic acids in the malaria parasite. It is active against pre-erythrocytic forms and is also a slow-acting blood schizontocide. It also has some sporontocidal activity; it does not prevent the formation of gametocytes but renders them non-infective to the mosquito vector. It is mainly effective against *Plasmodium falciparum* but has some activity against *P. vivax*.

The development of plasmodial resistance has rendered obsolete the use of pyrimethamine on its own in malaria. Combinations of pyrimethamine with long-acting sulfonamides, such as sulfadoxine or sulfametopyrazine, are now used, although resistance has also developed to them.

For the *treatment* of uncomplicated falciparum **malaria**, pyrimethamine is given orally with sulfadoxine in a fixed dose ratio of 1 to 20 (*Fansidar*). WHO recommends that a single dose of pyrimethamine-sulfadoxine be used with artesunate given for 3 days; in areas of susceptibility and where artesunate is unavailable, amodiaquine may be used with pyrimethamine-sulfadoxine. The following doses of pyrimethamine-sulfadoxine are recommended:

- adults and children aged over 13 years, pyrimethamine 75 mg with sulfadoxine 1.5 g
- infants 5 to 11 months, pyrimethamine 12.5 mg with sulfadoxine 250 mg
- children 1 to 6 years, pyrimethamine 25 mg with sulfadoxine 500 mg
- children 7 to 13 years, pyrimethamine 50 mg with sulfadoxine 1 g

A combination of pyrimethamine with sulfametopyrazine has been used similarly.

Pyrimethamine and pyrimethamine combinations are no longer recommended for *prophylaxis* of malaria. Combined preparations of pyrimethamine with sulfadoxine (*Fansidar*), and with dapsone in a fixed ratio of 1 to 8 (*Maloprim*), have been used in areas of chloroquine or multidrug resistance, although other antimalarials are now preferred.

Pyrimethamine given with a sulfonamide such as sulfadiazine is used in the treatment of **toxoplasmosis**. Alternatively, pyrimethamine may be given with clindamycin in AIDS patients with toxoplasmosis unable to tolerate a sulfonamide. For details of dosage regimens used, see below.

Isosporiasis. Isosporiasis (p.824) usually responds well to treatment with co-trimoxazole, but there is a high incidence of recurrence in immunocompromised patients, such as those with AIDS, and some form of maintenance therapy is generally required. Oral therapy with co-trimoxazole 960 mg given three times weekly or pyrimethamine 25 mg with sulfadoxine 500 mg given weekly were found to be equally effective maintenance regimens.[1] Pyrimethamine given alone in daily doses of 50 to 75 mg with folate therapy may be of use in the treatment of patients sensitive to sulfonamides.[2]

2. Weiss LM, *et al.* Isospora belli infection: treatment with pyrimethamine. *Ann Intern Med* 1988; **109:** 474–5.

Malaria. The overall treatment and prophylaxis of malaria and the place of pyrimethamine-sulfadoxine (Fansidar) in current recommendations are discussed on p.594.

Mycetoma. For reference to the use of pyrimethamine as part of the treatment of actinomycetoma, see under Mycetoma, p.180.

Pneumocystis pneumonia. For a mention of pyrimethamine with either dapsone or sulfadoxine for the prophylaxis of pneumocystis pneumonia, and a discussion of conventional prophylaxis and treatment, see p.521.

Toxoplasmosis. Pyrimethamine is given, usually with sulfadiazine or another appropriate sulphonamide, in the treatment of toxoplasmosis (p.826). Folinic acid is also given to counteract the megaloblastic anaemia associated with these drugs.

Oral doses suggested by WHO[1] are:

- in *pregnancy* (second and third trimesters), pyrimethamine 25 mg daily for 3 to 4 weeks with sulfadiazine 3 g daily in 4 divided doses
- in *neonates*, pyrimethamine 1 mg/kg daily, with sulfadiazine 85 mg/kg daily in 2 divided doses; treatment should be given for 6 months if there is overt neonatal disease, or for 4 weeks to those without overt disease but whose mother was infected during pregnancy
- in *immunodeficiency*, pyrimethamine 200 mg in divided doses on the first day, then 75 to 100 mg daily for at least 6 weeks, followed by a suppressive dose of 25 to 50 mg daily; sulfadiazine is also given in a dose of 4 to 6 g daily in 4 divided doses for at least 6 weeks, followed by a suppressive dose of 2 to 4 g daily
- in *chorioretinitis*, pyrimethamine 75 mg daily for 3 days, then 25 mg daily for 4 weeks, followed in unresponsive patients by 50 mg daily for a further 4 weeks; sulfadiazine is also given in a dose of 2 g daily in 4 divided doses

Pyrimethamine with clindamycin is an alternative in patients unable to tolerate a sulfonamide.

Other drugs that have been tried with pyrimethamine include azithromycin,[2] clarithromycin,[3] and doxycycline.[4,5]

Alternative regimens tried for long-term maintenance therapy in patients with AIDS have included pyrimethamine plus sulfadiazine given twice weekly[6,7] or pyrimethamine alone in doses of 25 mg or 50 mg daily or 50 mg three times weekly.[8-10] However, results from a study involving 396 patients suggested that the mortality rate was higher in those receiving pyrimethamine 25 mg three times weekly for primary prophylaxis than in those receiving placebo.[11] Pyrimethamine with dapsone given once a week can provide effective prophylaxis but was not well tolerated.[12] Pyrimethamine with sulfadoxine, also given once weekly, was of benefit in bone-marrow transplant recipients.[13]

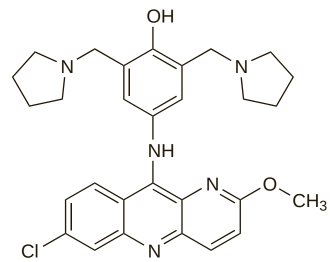
Pyronaridine Phosphate *(rINNM)*

Fosfato de pironaridina; Malaridine Phosphate; Pyronaridine, Phosphate de; Pyronaridini Phosphas. 7-Chloro-2-methoxy-10-[3,5-bis(pyrrolidinomethyl)-4-hydroxyanilino]benzo-[*b*]-1,5-naphthyridine phosphate.

Пиронаридина Фосфат

$C_{29}H_{32}ClN_5O_2,4H_3PO_4 = 910.0.$

CAS — 74847-35-1 (pyronaridine); 76748-86-2 (pyronaridine phosphate).



(pyronaridine)

Pharmacopoeias. In *Chin.*

Profile

Pyronaridine is a naphthyridine derivative used in China in the treatment of vivax malaria and chloroquine-resistant falciparum malaria. Its use has also been investigated in Africa and in Thailand. Combination of pyronaridine with artesunate is also being investigated. Pyronaridine has been given as the phosphate by mouth or by intramuscular or intravenous injection.

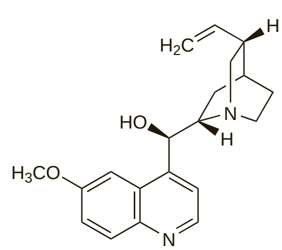
Quinine *(BAN)*

China; Chininum; Kiniini; Kinin; Quinina. (8*S*,9*R*)-6′-Methoxycinchonan-9-ol; (α*R*)-α-(6-Methoxy-4-quinolyl)-α-[(2*S*,4*S*,5*R*)-(5-vinylquinuclidin-2-yl)]methanol.

$C_{20}H_{24}N_2O_2 = 324.4.$

CAS — 130-95-0 (anhydrous quinine).

ATC — P01BC01.



Description. Quinine is the chief alkaloid of various species of *Cinchona* (Rubiaceae). It is an optical isomer of quinidine.

Quinine Bisulfate

Chininum Bisulfuricum; Neutral Quinine Sulphate; Quinina, bisulfato de; Quinine Acid Sulphate; Quinine Bisulphate *(BANM)*; Quinini Bisulfas.

$C_{20}H_{24}N_2O_2,H_2SO_4,7H_2O = 548.6.$

CAS — 549-56-4 (anhydrous quinine bisulfate).

ATC — P01BC01.

Pharmacopoeias. In *Br., Int.*, and *Viet.*

BP 2008 (Quinine Bisulphate). Colourless crystals or a white crystalline powder. It effloresces in dry air. Freely soluble in water; sparingly soluble in alcohol. A 1% solution in water has a pH of 2.8 to 3.4. Protect from light.

Quinine Dihydrochloride *(BANM)*

Chinini Dihydrochloridum; Neutral Quinine Hydrochloride; Quinina, dihidrocloruro de; Quinine Acid Hydrochloride; Quinini Dihydrochloridum.

$C_{20}H_{24}N_2O_2,2HCl = 397.3.$

CAS — 60-93-5.

ATC — P01BC01.

Pharmacopoeias. In *Br., Chin.*, and *Int.*

Viet. includes the injection.

BP 2008 (Quinine Dihydrochloride). A white or almost white powder. Very soluble in water; soluble in alcohol. A 3% solution in water has a pH of 2.0 to 3.0. Protect from light.

Quinine Etabonate

Euquinina; Euquinine; Quinina, etilcarbonato de; Quinine Ethyl Carbonate.

$C_{23}H_{28}N_2O_4 = 396.5.$

CAS — 83-75-0.

ATC — P01BC01.

Pharmacopoeias. In *Jpn.*

Quinine Hydrobromide *(BANM)*

Basic Quinine Hydrobromide; Chinini Bromidum; Quinina, hidrobromuro de; Quinine Monohydrobromide.

$C_{20}H_{24}N_2O_2,HBr,H_2O = 423.3.$

CAS — 549-49-5 (anhydrous quinine hydrobromide).

ATC — P01BC01.

Pharmacopoeias. In *Fr.*

Quinine Hydrochloride *(BANM)*

Basic Quinine Hydrochloride; Chinin hydrochlorid dihydrát; Chinini hydrochloridum; Chininii Chloridum; Chininium Chloratum; Chinino hidrochloridas; Chininum Hydrochloricum; Chininy chlorowodorek; Kiniinihydrokloridi; Kinin-hidroklorid; Kininhydroklorid; Quinina, hidrocloruro de; Quinine, chlorhydrate de; Quinine Monohydrochloride; Quinini Hydrochloridum; Quinini Hydrochloridum Dihydricum.

$C_{20}H_{24}N_2O_2,HCl,2H_2O = 396.9.$

CAS — 130-89-2 (anhydrous quinine hydrochloride); 6119-47-7 (quinine hydrochloride dihydrate).

ATC — P01BC01.

Pharmacopoeias. In *Eur.* (see p.vii), *Int., Jpn*, and *Viet.*

Ph. Eur. 6.2 (Quinine Hydrochloride). White or almost white, or colourless, fine, silky needles, often grouped in clusters. Soluble in water; freely soluble in alcohol. A 1% solution in water has a pH of 6.0 to 6.8. Protect from light.

Quinine Sulfate

Basic Quinine Sulphate; Chinin sulfát dihydrát; Chinini sulfas; Chinino sulfatas; Chininum Sulfuricum; Chininy siarczan; Kiniinisulfaatti; Kininsulfat; Kinin-szulfát; Quinina, sulfato de; Quinine, sulfate de; Quinine Sulphate *(BANM)*; Quinini Sulfas; Quinini Sulfas Dihydricus.

$(C_{20}H_{24}N_2O_2)_2,H_2SO_4,2H_2O = 782.9.$

CAS — 804-63-7 (anhydrous quinine sulfate); 6119-70-6 (quinine sulfate dihydrate).

ATC — P01BC01.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US*, and *Viet.*

Ph. Eur. 6.2 (Quinine Sulphate). A white or almost white, crystalline powder or fine, colourless needles. Slightly soluble in water; sparingly soluble in boiling water and in alcohol. A 1% suspension in water has a pH of 5.7 to 6.6. Protect from light.

USP 31 (Quinine Sulfate). It is the sulfate of an alkaloid obtained from the bark of species of *Cinchona*. White, odourless, fine needle-like crystals, usually lusterless, making a light and readily compressible mass. It darkens on exposure to light. Soluble 1 in 500 of water and 1 in 120 of alcohol; sparingly soluble in water at 100°; slightly soluble in chloroform; freely soluble in alcohol at 80° and in a mixture of 2 parts of chloroform and one part of dehydrated alcohol; very slightly soluble in ether; Its saturated solution in water is neutral or alkaline to litmus. Protect from light.

Sorption. For reference to loss of quinine sulfate from solutions during membrane filtration, see Chloroquine, p.599.

Adverse Effects

Quinine or its salts given in usual therapeutic doses may give rise to a train of symptoms known as cinchonism, characterised in its mild form by tinnitus, impaired hearing, headache, nausea, and disturbed vision, with, in its more severe manifestations, vomiting, abdominal pain, diarrhoea, and vertigo.

Cinchonism may also occur after small doses in patients hypersensitive to quinine, but urticaria and flushing of the skin with intense pruritus are the most frequent reactions seen in these patients. Other effects include fever, skin rashes, and dyspnoea. Angioedema may also occur and asthma can be precipitated. Thrombocytopenia and other blood disorders have been reported. Thrombocytopenic purpura has been associated with quinine hypersensitivity. Haemoglobinuria occurs rarely.

Other adverse effects of quinine include hypoglycaemia, hypoprothrombinaemia, and renal failure.

The main symptoms of overdosage, which can be fatal, include gastrointestinal effects, oculotoxicity, CNS disturbances, and cardiotoxicity. Visual disturbances including sudden blindness are usually slowly reversible but there may be residual damage. Overdosage is discussed in detail below. Quinine can produce cardiovascular toxicity similar to that seen with quinidine, including conduction disturbances, arrhythmias, anginal symptoms, and hypotension leading to cardiac arrest and circulatory failure. Severe or even fatal cardiovascular toxicity can result from rapid intravenous dosage of quinine.

Large amounts of quinine can induce abortion; congenital malformations, particularly of the optic and auditory nerves, have been reported after failure to induce abortion with quinine. However, quinine should not be withheld from pregnant women with life-threatening malaria (see also under Pregnancy in Precautions, below).

Intramuscular injections of quinine can be irritant and have caused pain, focal necrosis, and abscess formation; tetanus has developed in some patients (see under Malaria in Uses and Administration, below).

Effects on the blood. Between 1966 and 1975 the Swedish Adverse Drug Reaction Committee received 43 reports of *thrombocytopenia* attributable to quinine or quinidine[1] and the Boston Collaborative Drug Surveillance Program had 11 similar reports in patients studied between 1972 and 1981.[2] The FDA in the USA subsequently received details of 2 fatalities due to quinine-induced thrombocytopenia.[3] Up to October 2004, there had also been 228 cases of thrombocytopenia reported to the Australian Adverse Drug Reactions Advisory Committee, including 6 fatalities.[4] Quinine-induced thrombocytopenia appears to be a hypersensitivity reaction and beverages containing quinine as a bitter in concentrations as low as 20 micrograms/mL have precipitated thrombocytopenic purpura in previously sensitised individuals.[5]

Although quinine can cause *haemolysis*, there is some doubt over the traditional view that irregular dosage with quinine predisposes patients with malaria to *blackwater fever*, a syndrome of severe haemolytic anaemia, haemoglobinuria, oliguria, and renal failure.[6] Some of the patients affected may have had G6PD deficiency.[6] Haemolytic-uraemic syndrome[7-9] and pancytopenia with coagulopathy and renal impairment[10,11] have also been associated with the use of quinine.

There have also been reports of *disseminated intravascular coagulation*, including one fatality, after use of quinine by patients with quinine hypersensitivity.[12-14] In one case[14] the hypersensitivity reaction closely mimicked septic shock.

There have been isolated reports of *agranulocytosis* due to quinine.[15]

15. Sutherland R, *et al.* Quinine-induced agranulocytosis: toxic effect of quinine bisulphate on bone marrow cultures in vitro. *BMJ* 1977; **1:** 605–7.

Effects on the ears. Although ototoxicity such as tinnitus or deafness is known to be a possible adverse effect of quinine, reversible hearing loss may also occur. While one group of workers[1] found the reduction in auditory acuity to be greatest at higher frequencies, another group[2] have found that hearing loss was generally equal across the range of frequencies tested and appeared to be related to the plasma concentration of quinine.

1. Roche RJ, *et al.* Quinine induces reversible high-tone hearing loss. *Br J Clin Pharmacol* 1990; **29:** 780–2.
2. Karlsson KK, *et al.* Audiometry as a possible indicator of quinine plasma concentration during treatment of malaria. *Trans R Soc Trop Med Hyg* 1990; **84:** 765–7.

Effects on the eyes. Oculotoxicity after overdosage with quinine is well recognised (see below), but there has also been a report of blindness in two patients occurring during supposedly routine therapy.[1]

1. Waddell K. Blindness from quinine as an antimalarial. *Trans R Soc Trop Med Hyg* 1996; **90:** 331–2.

Effects on glucose metabolism. Hypoglycaemia is now recognised to be a frequent complication encountered in falciparum malaria and it is often associated with a poor prognosis. Children, pregnant women, and patients with severe disease appear to be particularly at risk. It is important to recognise that hypoglycaemia rather than cerebral malaria may be the cause of coma. Hypoglycaemia may also be induced by antimalarial therapy; first episodes of hypoglycaemia have been detected after patients received quinine[1-3] or quinidine[4] intravenously, although others have not found that quinine led to the development of hypoglycaemia.[5,6]

Quinine has also been reported to induce hypoglycaemia during treatment for leg cramps.[7]

Effects on the heart. Cardiotoxicity after overdosage with quinine is well recognised, and prolongation of the QT interval has been noted with therapeutic doses. There has also been a report[1] of fatal ventricular fibrillation with QT prolongation in an elderly patient who received standard doses of quinine by slow intravenous infusion for falciparum malaria. It was noted that the patient had some prolongation of the QT interval before starting quinine and also that her free quinine concentrations were unusually high despite total quinine concentrations considered to be within the therapeutic range.

1. Bonington A, *et al.* Fatal quinine cardiotoxicity in the treatment of falciparum malaria. *Trans R Soc Trop Med Hyg* 1996; **90:** 305–7.

Effects on the kidneys. See Effects on the Blood, above.

Effects on the liver. Although hepatitis has been associated with quinidine therapy (see p.1383), there appear to be few reports of hepatotoxicity due to quinine usage. Granulomatous hepatitis has been reported in 2 patients taking quinine,[1,2] but the diagnosis in the first of these cases was challenged as the histological findings were considered to be more indicative of non-specific reactive hepatitis.[3] Hepatotoxicity due to quinine hypersensitivity has been reported in another patient.[4] Symptoms of hepatotoxicity occurred within 24 hours in a further patient taking quinine for nocturnal leg cramps.[5]

Effects on the skin. Urticaria, cutaneous flushing, various skin rashes, and pruritus are the commonest symptoms of hypersensitivity reactions to quinine.

Topical contact with quinine may cause contact as well as photocontact allergy, but quinine can also induce photosensitivity reactions after systemic dosage.[1,2] Photosensitivity associated with quinine intake from excessive consumption of tonic water has been reported.[3] There have also been reports of eczematous dermatitis,[1] oedema and erythema,[4] and lichen planus.[4] Both phototoxic[4] and photoallergic[1] mechanisms have been suggested. Fatal cutaneous vasculitis related to quinine treatment for nocturnal cramps has been reported.[5]

For a comparison of the incidence of pruritus induced by various antimalarials, see under Chloroquine, p.600.

5. Price EJ, *et al.* Quinine-induced cutaneous vasculitis. *Br J Clin Pract* 1992; **46:** 138–9.

Hypersensitivity. For reference to hypersensitivity reactions associated with quinine, see Effects on the Blood, Effects on the Liver, and Effects on the Skin, above.

Overdosage. Cinchonism may occur with therapeutic doses of quinine and symptoms include nausea, vomiting, tinnitus, deafness, headache, vasodilatation, and slightly disturbed vision. These symptoms may also occur in acute overdosage, but the visual disorders may be severe and there may be CNS disturbances and cardiotoxicity. A lethal dose or lethal plasma-quinine concentration has not been established but fatalities have been reported[1] in adults after doses of 2 to 8 g and in children after 1 g.

An analysis[2] of 165 cases of acute quinine poisoning revealed that: 21% had no symptoms, nausea with or without vomiting occurred in 47%, visual disturbances in 42%, tinnitus in 38%, other auditory disturbances in 23%, sinus tachycardia in 23%, and other ECG abnormalities in 8%. Mild impairment of consciousness was reported in 14% of the patients while 7 (4%) patients had deeper grades of coma. Of the 5 patients who died, 4 developed intractable ventricular arrhythmias and the fifth had a Jacksonian fit followed by cardiac arrest.

The effects of oculotoxicity may include blurred vision, defective colour perception, visual field constriction, and total blindness.[2,3] The onset of symptoms may vary from a few hours to a day or more after ingestion.[2,3] Suggested mechanisms for the oculotoxicity of quinine include an action on the retinal vasculature to produce ischaemia or a direct toxic effect on the retina.[1] Visual loss in one group of patients[3] was associated with plasma-quinine concentrations in excess of 10 micrograms/mL. However, in another group plasma-quinine concentrations were considered to be an imprecise guide to predicting visual disturbances.[2] The speed and degree of visual recovery varies. Of 70 patients with visual disturbances after quinine poisoning, 39 subsequently had a period of total blindness.[2] Permanent visual deficits remained in 19 of these but no patient had permanent bilateral blindness. All of the 31 patients who had had blurred vision recovered full visual acuity.

It is considered that the actions of quinine on the myocardium are similar to those of quinidine but that it is less potent.[1] Sinus tachycardia and minor ECG changes are the most common cardiovascular effects. Conduction abnormalities and ventricular dysrhythmias may occur with severe poisoning. Ventricular tachycardia is mostly associated with cardiogenic shock or circulatory collapse. Hypokalaemia may also occur.[1]

Treatment of Adverse Effects

In acute overdosage with quinine or its salts multiple doses of activated charcoal may be given to adults or children who present within one hour of ingesting more than the equivalent of 30 mg/kg of quinine base or any amount in a child under 2 years of age; gastric lavage may also be considered for use in adults. Other measures aimed at enhancing the elimination of quinine are largely ineffective. Treatment is mostly symptomatic with attention being given to maintaining blood pressure, respiration, and renal function, and to treating arrhythmias.

Vasodilators and stellate ganglion block have been used to prevent or reverse visual impairment but there is little evidence to support their use.

◊ It has been suggested that, as quinine has antimuscarinic effects, gastric emptying may be delayed and considerable amounts of drug might be removed from the stomach beyond the usual 4 hours.[1] Others consider that gastric lavage is of doubtful value as quinine is rapidly absorbed and vomiting has often occurred before admission.[2] However, studies in healthy subjects and poisoned patients suggest that oral activated charcoal may increase the elimination of quinine.[3,4] Other methods of increasing elimination are probably ineffective. In a study involving 16 patients with quinine poisoning forced acid diuresis, haemodialysis, haemoperfusion, or plasma exchange were all found to be ineffective in increasing quinine elimination.[5]

Stellate ganglion block has been recommended to prevent or reverse retinal damage, the rationale being that quinine-induced oculotoxicity might arise from retinal arteriolar constriction. However, clinical studies have failed to find sufficient improvement to justify its use.[6,7] Intravenous nitrates produced beneficial responses in 2 patients.[8]

Precautions

Quinine and its salts are contra-indicated in patients with a history of hypersensitivity to quinine or quinidine and in patients with tinnitus or optic neuritis. They should not be used in the presence of haemolysis. They should be used with caution in patients with atrial fibrillation, cardiac conduction defects, or heart block. Quinine should be avoided in patients with myasthenia gravis as it may aggravate their condition.

Pregnancy in a patient with malaria is not generally regarded as a contra-indication to the use of quinine.

As quinine has been implicated in precipitating blackwater fever it is generally contra-indicated in patients who have already suffered an attack. Quinine may also cause haemolysis in some types of G6PD deficiency and should be used with care.

It is important that when quinine is given intravenously it should be given by slow infusion and the patient observed closely for signs of cardiotoxicity. Blood-glucose concentrations should also be monitored. Problems that have been associated with intramuscular use are discussed under Malaria in Uses and Administration, below.

Breast feeding. Although quinine is distributed into breast milk in small amounts,[1] the American Academy of Pediatrics considers that the use of quinine is probably compatible with breast feeding.[2]

1. Phillips RE, *et al.* Quinine pharmacokinetics and toxicity in pregnant and lactating women with falciparum malaria. *Br J Clin Pharmacol* 1986; **21:** 677–83.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 19/04/04)

Liver disease. See under Pharmacokinetics, below.

Porphyria. For a discussion of the problems of the use of antimalarials in patients with porphyria and a comment that quinine is considered to be safe for use in such patients, see under Precautions for Chloroquine, p.601.

Pregnancy. The use of quinine in large doses as an abortifacient in the past has led to concern over its use during pregnancy, but no evidence of an oxytocic effect was found when it was used to treat severe falciparum malaria in women in the third trimester of pregnancy.[1]

Congenital abnormalities including damage to the auditory and optic nerves have been seen, usually after attempted abortions, but WHO[2] considers quinine to be safe when used in normal therapeutic doses during pregnancy (although the problem of hypoglycaemia in the second and third trimesters may mean that artemisinin derivatives are preferred). Jitteriness attributed to quinine withdrawal has been reported in an infant whose mother had drunk large quantities of tonic water containing quinine during the last 17 weeks of pregnancy.[3]

As malaria is potentially serious during pregnancy and poses a threat to the mother and fetus, there appears to be little justification for withholding treatment in the absence of a suitable alternative. However, pregnant patients treated for malaria are at special risk from hypoglycaemia exacerbated or caused by quinine-induced hyperinsulinaemia (see under Effects on Glucose Metabolism in Adverse Effects, above) and should be managed appropriately.

Renal impairment. See under Pharmacokinetics, below.

Interactions

As quinine shares many of the actions of quinidine, interactions seen between quinidine and other drugs (see p.1384) might also occur with quinine. Both have actions on skeletal muscle and may potentiate the effects of drugs with neuromuscular-blocking activity (see under Antiarrhythmics on p.1903). There is an increased risk of inducing ventricular arrhythmias if quinine is given with halofantrine (see p.604) or other arrhythmogenic drugs such as amiodarone, the antihistamines astemizole and terfenadine, cisapride, and the antipsychotic pimozide. There may be an increased risk of convulsions when quinine is given with mefloquine.

Amantadine. For a report of quinine reducing renal clearance of amantadine, see Antiarrhythmics, p.793.

Anticoagulants. Quinine can cause hypoprothrombinaemia and thereby enhance the effect of anticoagulants. In one report, reductions in *warfarin* dosage were necessary after ingestion of large amounts of tonic water containing quinine (see p.1429).

Antimalarials. Quinine and *chloroquine* may be antagonistic when used for falciparum malaria (see p.601). For a report of quinine reducing plasma concentrations of *primaquine*, see p.608.

Ciclosporin. For a report of quinine decreasing plasma concentrations of ciclosporin, see p.1826.

Digoxin. Quinidine has been reported to increase serum-digoxin concentrations (see Quinidine under Antiarrhythmics, p.1261) and quinine has reduced total body clearance of digoxin (see Antimalarials, p.1262).

Flecainide. For a report of quinine inhibiting the metabolism of flecainide, see p.1289.

Histamine H_2-antagonists. *Cimetidine* has been reported to reduce the clearance of quinine and prolong its elimination half-life in a study in healthy subjects; no significant effect was seen with *ranitidine*.[1]

1. Wanwimolruk S, *et al.* Effects of cimetidine and ranitidine on the pharmacokinetics of quinine. *Br J Clin Pharmacol* 1986; **22:** 346–50.

Rifampicin. Elimination of quinine has been reported to increase in patients also receiving rifampicin.[1]

1. Wanwimolruk S, *et al.* Marked enhancement by rifampicin and lack of effect of isoniazid on the elimination of quinine in man. *Br J Clin Pharmacol* 1995; **40:** 87–91.

Tobacco smoking. A single-dose study in healthy subjects has suggested that blood concentrations of quinine are lower in heavy smokers than in non-smokers, potentially impairing efficacy.[1]

1. Wanwimolruk S, *et al.* Cigarette smoking enhances the elimination of quinine. *Br J Clin Pharmacol* 1993; **36:** 610–14.

Pharmacokinetics

The pharmacokinetics of quinine are altered significantly by malaria infection, the major effects being reductions in both its apparent volume of distribution and its clearance.

Quinine is rapidly and almost completely absorbed from the gastrointestinal tract and peak concentrations in the circulation are attained about 1 to 3 hours after oral doses of the sulfate or bisulfate. Plasma protein binding is about 70% in healthy subjects and rises to 90% or more in patients with malaria. Quinine is widely distributed throughout the body. Concentrations attained in the CSF of patients with cerebral malaria have been reported to be about 2 to 7% of those in the plasma.

Quinine is extensively metabolised in the liver and rapidly excreted mainly in the urine. Estimates of the proportion of unchanged quinine excreted in the urine vary from less than 5 to 20%. Excretion is increased in acid urine. The elimination half-life is about 11 hours in healthy subjects but may be prolonged in patients with malaria. Small amounts of quinine also appear in the bile and saliva.

Quinine crosses the placenta and is distributed into breast milk (see Breast Feeding, above).

Administration in liver disease. Reduced clearance of quinine and prolonged elimination half-life have been reported in patients with acute hepatitis B given a single intravenous dose.[1] The results suggested that quinine accumulation after multiple doses could be greater in patients with hepatitis, even once hepatic function had returned to normal. In another study[2] patients with moderate chronic liver disease were given quinine orally; the half-life was prolonged but total clearance was not affected.

2. Auprayoon P, *et al.* Pharmacokinetics of quinine in chronic liver disease. *Br J Clin Pharmacol* 1995; **40:** 494–7.

Administration in renal impairment. As urinary clearance comprises only 20% of total clearance of quinine, it appears that high plasma concentrations reported in patients with severe falciparum malaria and acute renal failure may be related more to the severity of the malaria, and associated pharmacokinetic changes, rather than to any reduction in the glomerular filtration rate.[1] There were significant changes in the pharmacokinetics of quinine in 6 patients with chronic renal failure after a single oral dose.[2] The changes included a prolonged half-life, but there was no clear relationship between severity of renal failure and the degree of impairment of quinine clearance.

Uses and Administration

Quinine is a cinchona alkaloid and a 4-methanolquinoline antimalarial that is a rapid-acting blood schizontocide with activity against *Plasmodium falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. It is active against the gametocytes of *P. malariae* and *P. vivax*, but not against mature gametocytes of *P. falciparum*. The precise mechanism of action of quinine is unclear but it may interfere with lysosome function or nucleic acid synthesis in the malaria parasite. Since it has no activity against exoerythrocytic forms, quinine does not produce a radical cure in vivax or ovale malarias. The increasing spread of resistance to chloroquine has been responsible for the re-emergence of quinine as an important drug in the treatment of falciparum malaria. Quinine is not generally used for malaria prophylaxis.

Quinine is also used to treat the protozoal infection babesiosis and for the relief of nocturnal leg cramps.

Quinine has mild analgesic and antipyretic properties and is sometimes included in preparations used for the symptomatic relief of the common cold and influenza; additional salts that have been used for this purpose include the camsilate and the gluconate.

Quinine is also used as a bitter and a flavour.

Quinine is given as a number of salts and 100 mg of anhydrous quinine is equivalent to about:

- 169 mg of quinine bisulfate
- 122 mg of quinine dihydrochloride
- 122 mg of quinine etabonate
- 130 mg of quinine hydrobromide
- 122 mg of quinine hydrochloride
- 121 mg of quinine sulfate

For the treatment of **malaria** quinine is given orally, usually as the sulfate, hydrochloride, or dihydrochloride, or parenterally as the dihydrochloride; quinine etabonate is sometimes used orally because unlike other quinine salts, which are intensely bitter, it is tasteless. They all contain about the same amount of quinine and any of them can be used when the dose is cited in terms of "quinine salt"; this is not the case for the bisulfate, which contains a correspondingly smaller amount of quinine. Quinine formate is sometimes given parenterally.

A course of treatment with quinine for falciparum malaria usually lasts 7 days and in uncomplicated infections treatment should preferably be given by the oral route. The usual *oral* dose is 600 mg of quinine salt given every 8 hours for 7 days. For children, a dose of 10 mg of quinine salt per kg body-weight given every 8 hours for 7 days is recommended.

In severe or complicated falciparum malaria, or when the patient is unable to take oral medication, quinine should be given parenterally by slow intravenous infusion, but this can be hazardous and patients generally need monitoring, particularly for signs of cardiotoxicity. Therapy should be changed to the oral route as soon as possible to complete the course. To obtain therapeutic concentrations rapidly with parenteral therapy, quinine is often given in an initial loading dose followed by maintenance doses. A recommended *intravenous* dosage regimen suggested by WHO is an initial loading dose of 20 mg of quinine dihydrochloride per kg (up to a maximum of 1.4 g) given over 4 hours with maintenance infusions being started 8 hours later, calculated from the start of the previous infusion. Alternatively, in intensive care units, an initial loading dose of 7 mg/kg may be given over 30 minutes followed immediately by the first of the maintenance infusions. Maintenance infusions consist of 10 mg/kg (up to a maximum of 700 mg) given over 4 hours every 8 hours. A loading dose should not be given if the patient has received quinine, quinidine, mefloquine, or halofantrine, during the previous 24 hours. If parenteral therapy is required for more than 48 hours the maintenance dose of quinine dihydrochloride should be reduced to 5 to 7 mg/kg.

If intravenous infusion is not possible, quinine dihydrochloride has been given *intramuscularly*. Doses, including the loading dose, are the same as those used intravenously; the drug should be diluted in sodium chloride 0.9% to a concentration of 60 to 100 mg of the dihydrochloride per mL, and the total dose divided between two injection sites, preferably each anterior thigh (not the buttock). However, intramuscular injection can be irritant and there have been concerns regarding its safety and efficacy (see under Malaria, below).

When used for the relief of nocturnal **leg cramps**, quinine is given at night in an oral dose of 200 to 300 mg of the sulfate or bisulfate. Quinine benzoate has also been used.

Babesiosis. Although there is no established specific treatment for babesiosis (p.823), a combination of quinine and clindamycin has been used for *Babesia microti* infections.[1,2] For suggested doses see under Clindamycin, p.253. Quinine with azithromycin was reported to be effective in a patient who had not responded to quinine with clindamycin.[3]

3. Shaio MF, Yang KD. Response of babesiosis to a combined regimen of quinine and azithromycin. *Trans R Soc Trop Med Hyg* 1997; **91:** 214–15.

Flavouring. The Joint FAO/WHO Expert Committee on Food Additives concluded that quinine levels in soft drinks of up to 100 mg/litre (as quinine base) were not of toxicological concern.[1] However, because of the possibility of hypersensitivity reactions in some individuals, the committee recommended that consumers be informed of the presence of quinine in food or beverages.

1. FAO/WHO. Evaluation of certain food additives and contaminants: forty-first report of the joint FAO/WHO expert committee on food additives. *WHO Tech Rep Ser 837* 1993.

Malaria. Quinine has had an important role in the treatment of falciparum malaria (see p.594) being used where there is chloroquine or multidrug *Plasmodium falciparum* resistance,[1-4] and also (in view of the widespread problem of *P. falciparum* resistance) where the infective species is not known, or if the infection is mixed. Treatment should be with one of the quinine salts given orally, with a dose of 600 mg of quinine salt for adults, or 10 mg/kg for children, every 8 hours for 7 days. The dose of quinine salt applies to the hydrochloride, dihydrochloride, sulfate, and etabonate, but not to the bisulfate. Any quinine lost through vomiting within one hour of an oral dose should be replaced by additional doses.[1]

The oral route may not provide effective treatment in severe infection and in such cases quinine should be given as the dihydrochloride by slow intravenous infusion, with the patient being observed closely, particularly for any signs of cardiotoxicity.[4] Loading doses of quinine are often used to obtain therapeutic blood concentrations as soon as possible in severely ill patients but they should not be given to patients who have received quinine, quinidine, mefloquine, or halofantrine, within the previous 24 hours.

WHO[3,4] has given recommendations for intravenous regimens comprising an initial loading dose and maintenance infusions (for details see Uses and Administration, above). Patients are transferred to oral therapy as soon as possible, and treatment continued until a total of at least 7 days of therapy has been given. If intravenous formulations of quinine are unavailable quinidine may be used as an alternative; for further details, see under the Uses and Administration of Quinidine, p.1385.

If facilities for intravenous infusion, including monitoring, are not available quinine may be given by deep intramuscular injection.[4] A loading dose of quinine dihydrochloride 20 mg/kg is given by injection in divided sites followed by injections of 10 mg/kg every 8 hours;[4] a dose interval of 12 hours has also been used. Patients should be transferred to oral therapy as soon as possible. The use of the intramuscular route has been controversial because of concerns over safety and efficacy. However, some studies have shown that it can safely be used in adults and children with severe infections.[5-8] Intramuscular injections of quinine can be irritant and have caused pain, focal necrosis, and abscess formation; fatal tetanus has developed in some patients.[9] It has been suggested that some such reactions may be related to the use of preparations formulated in urethane or other irritant substances. Diluted solutions of quinine dihydrochloride 60 mg/mL adjusted to neutral pH appear to be less painful than the usual undiluted preparation of 300 mg/mL.

If facilities do not exist to give quinine parenterally then patients with severe malaria should receive quinine by mouth or nasogastric tube.

Quinine as formerly standardised used to contain a higher concentration of cinchona alkaloids and there might be synergy between mixtures of these alkaloids.[10] In practice no advantage has been shown by such mixtures over quinine alone in the treatment of chloroquine-resistant falciparum malaria.[11]

Muscle spasm. Quinine (usually as quinine sulfate or bisulfate) has traditionally been used for nocturnal cramps (p.1887) but there has been concern over its efficacy and potential for adverse effects, especially in the elderly. In the USA, for example, the FDA ruled that quinine products should no longer be used for the management of nocturnal cramps.[1,2] A similar ban has been imposed in Australia.[3] Meta-analyses[4,5] concluded that although quinine was effective in the treatment of nocturnal cramps in ambulatory patients the risk of serious adverse effects should be borne in mind. It was recommended that patients should be closely monitored while the efficacy of quinine is assessed over a period of at least 4 weeks. Some[6] have recommended that treatment be stopped every 3 months to see whether it is still needed.

Haemodialysis-induced cramp (p.1671) has been reported to respond to treatment with quinine[7,8] but similar concerns apply.

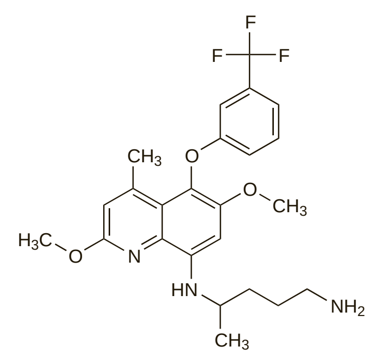
Tafenoquine *(BAN, rINN)*

Tafenoquina; Tafénoquine; Tafenoquinum; WR-238605. (±)-8-[(4-Amino-1-methylbutyl)amino]-2,6-dimethoxy-4-methyl-5-[(α,α,α-trifluoro-*m*-tolyl)oxy]quinoline; (*RS*)-N^4-[2,6-Dimethoxy-4-methyl-5-(3-trifluoromethylphenoxy)quinolin-8-yl]pentane-1,4-diamine.

Тафенохин

$C_{24}H_{28}F_3N_3O_3$ = 463.5.
CAS — 106635-80-7.



Profile

Tafenoquine is an 8-aminoquinoline antimalarial. It acts as a tissue schizontocide and is under investigation as the succinate for the radical cure and prevention of relapse in vivax malaria. It may also have a role in the prophylaxis of falciparum malaria.

Antimigraine Drugs

Cluster headache, p.616
Medication-overuse headache, p.616
Migraine, p.616
Post-dural puncture headache, p.617
Tension-type headache, p.617

This chapter reviews the management of headache, in particular migraine and cluster headache, and the drugs used mainly for their treatment. The mechanisms of head pain or headache are not fully understood but may involve neurovascular changes (as in migraine and cluster headache), muscle contraction (tension headache), nerve lesions (neuralgias), direct head injury, infection (meningitis), or referred pain (sinusitis, toothache, eye disorders). Headache is also an adverse effect of many drugs including, paradoxically, those used to treat it. The International Headache Society has published guidelines to aid the diagnosis of the various headache types. Patients may have more than one headache disorder simultaneously and require separate treatment for each.

Cluster headache

Cluster headache (migrainous neuralgia, histaminic cephalalgia, Horton's syndrome) is of unknown aetiology but may be neurovascular in origin.[1-5] Patients experience one or more short-lived attacks of intense unilateral head pain, usually at the same time of day (often at night). These are associated with autonomic symptoms such as conjunctival injection or lachrymation, miosis or ptosis, nasal congestion or rhinorrhoea, forehead or facial sweating, and eyelid oedema. Restlessness during the attacks is characteristic. The period during which attacks occur is called a cluster period; it may last several weeks or months. In the typical episodic form of cluster headache, cluster periods are followed by periods of remission lasting for months or years but in the more rare chronic form, patients may have cluster periods lasting for more than a year, or with short periods of remission in between. Substances such as alcohol, histamine, or glyceryl trinitrate can precipitate headache attacks during cluster periods, but not during periods of remission. There is speculation that sleep-disordered breathing[6] and increased body heat[7] may also trigger cluster headaches.

The **treatment** of individual acute attacks during a cluster period is difficult because the headache is short-lived and oral analgesics are unlikely to be absorbed fast enough to produce much benefit.[1,3,4] Inhalation of 100% oxygen is rapid and effective in aborting attacks, but has practical difficulties; inhaled ergotamine has also been used. Some consider subcutaneous sumatriptan to be the acute therapy of choice in cluster attacks.[4,5] Dihydroergotamine is also effective but generally has to be given by injection and is usually reserved for use in emergency settings. Intranasal dihydroergotamine and intranasal sumatriptan have also been used.[1,4] Oral zolmitriptan may be considered for patients who cannot tolerate subcutaneous or intranasal sumatriptan and oxygen, or who prefer oral medication.[4] Intranasal instillation of lidocaine has been reported to be of some benefit but most patients do not obtain complete pain relief.[1,3,4]

Since individual attacks are difficult to treat it is probably more effective to manage cluster headache by **prophylaxis** once a cluster period has started. Ergotamine may be used for prevention in episodic cluster headache; it is given by mouth or rectally for limited periods of up to 2 weeks. It is often given for only 5 to 6 days in each week, which allows the patient to assess whether the cluster period has ended. Other drugs that have been used, either alone or with ergotamine, include verapamil, lithium carbonate, and prednisolone. Some consider verapamil to be the preventive therapy of choice[1,4,8] particularly in patients with chronic long-lasting cluster periods.[5] Lithium may also be useful for the chronic form of the disorder. Methysergide and corticosteroids are considered by some to be the drugs of choice in those with short-lasting cluster periods (less than 2 months).[5] Pizotifen and valproate have also been tried;[1,3,5] other drugs under investigation include gabapentin, melatonin, and topiramate.[4]

Paroxysmal hemicrania is a rare variant of cluster headache and differs mainly in the high frequency and shorter duration of individual attacks. One of its features, which may be diagnostic, is its invariable response to indometacin.

Medication-overuse headache

Overuse of drugs such as ergotamine, triptans, and analgesics (including opioids and combination preparations containing caffeine or butalbital) to treat headache or migraine can lead to dependence and paradoxical chronic daily headache in headache-prone patients.[1-3] Such headaches do not appear to occur with regular use of analgesics to treat other disorders except occasionally in patients with a history of migraine.[1] Medication-overuse headaches, also referred to as rebound, analgesic abuse, or analgesic-induced headaches, can be difficult to treat and are relieved by withdrawal of the offending drug, but the primary headache may still persist and revert to its previous pattern of occurrence. Furthermore, stopping abruptly can exacerbate headache and produce other symptoms of withdrawal. This may then lead the patient to resume treatment to relieve the headache thereby setting up a vicious circle.

Options for outpatient treatment include either abrupt[4] or gradual withdrawal of the overused drug. Substitution with long-acting NSAID or intramuscular dihydroergotamine has been tried in withdrawal from ergotamine or analgesics;[4-6] prednisolone has also been used.[4] However, withdrawal symptoms may persist for up to 2 weeks and detoxification from ergotamine or analgesics may require hospitalisation; intravenous metoclopramide and repetitive intravenous dihydroergotamine may be required to control nausea and vomiting and intractable headache, respectively.[5] Although withdrawal from triptans has been reported to be of shorter duration with no intensive withdrawal symptoms, triptan overuse produces headaches at a faster rate and at lower dosages compared with ergotamine and analgesics, and is associated with an increase in migraine attack frequency.[1] General advice on the prevention of medication-overuse headache has included limiting the frequency of use of such drugs,[1,3,5] and starting prophylactic therapy in migraine patients having more than 2 headache days a week.[3,4]

Migraine

Migraine is characterised by recurrent attacks of headache which typically last 4 to 72 hours. Attacks persisting for longer than 72 hours are referred to as status migrainosus. The headache is usually a unilateral pulsating pain that is aggravated by movement and is usually of sufficient severity to disturb or prevent daily activities. It is frequently accompanied by nausea, vomiting, or other gastrointestinal disturbances and there may be photophobia and phonophobia. Migraine with aura (classic migraine) is characterised by an aura consisting of visual or sensory symptoms that lasts less than an hour. The headache usually follows the aura directly, or within 1 hour, but may begin simultaneously with the aura. In addition, aura can occur without headache. Migraine without aura (common migraine) is the more common form occurring in about 75% of patients with migraine. Premonitory symptoms may occur before a migraine attack (with or without aura). Familial hemiplegic migraine is a rare syndrome in which migraine with aura may be preceded or accompanied by dysphasia, confusion, and hemiparesis. Basilar-type migraine is another rare form of migraine with aura in which there may be disturbances of the brain stem or occipital lobes accompanied by symptoms such as decreased level of consciousness, vertigo, ataxia, dysarthria, and diplopia.

Migraine is described as a neurovascular headache. Traditionally, intracranial vasoconstriction was considered responsible for the aura and extracranial vasodilatation for the headache. However, it appears that vascular events may be secondary to neuropathic changes and the liberation of vasoactive substances including serotonin (5-HT), catecholamines, histamine, kinins, neuropeptides such as calcitonin gene-related peptide (CGRP), and prostaglandins.

There are several factors that may precipitate migraine attacks. These include anxiety, physical and emotional stress, a change in sleep pattern, bright lights, fasting, some foods, and menstruation. Menstrual migraine has no specific definition, but it is believed to occur around the time of menstruation and to be characterised by attacks without aura. Migraine may also be precipitated by drugs including combined oral contraceptives and oestrogens, and glyceryl trinitrate. The frequency of migraine attacks can be reduced if such precipitating factors can be identified and avoided. Quiet, darkness, and sleep can ease an attack, with sleep heralding recovery.

Treatment. There is evidence that therapy tailored to the severity of individual disease from the outset (stratified care) is preferable to beginning with simple analgesics and adjusting treatment subsequently according to response (step strategy).

Simple **analgesics** (paracetamol or aspirin and other NSAIDs) are effective if taken at the earliest signs of an attack. Weak opioid analgesics such as codeine are sometimes included in oral compound analgesic preparations. However, many consider that opioids are best avoided, especially in patients who experience frequent headaches, to decrease the risk of medication-overuse headaches. Other drugs used with analgesics in antimigraine preparations have included caffeine and the sympathomimetic vasoconstrictor isometheptene.

If the initial treatment of migraine is delayed, absorption of oral drugs may be compromised by development of gastric stasis and nausea and vomiting; **antiemetics** such as buclizine and cyclizine, and the **prokinetic** drugs metoclopramide and domperidone are often included in compound antimigraine preparations. Prokinetic drugs also have the advantage of promoting gastric emptying and normal peristalsis. Dispersible and effervescent analgesic preparations are preferable because of their more rapid absorption. If nausea and vomiting are prominent rectal administration may be necessary.

Attacks not responding to simple analgesics or NSAIDs may be treated with specific antimigraine drugs such as the selective serotonin ($5\text{-}HT_1$) agonists (e.g. sumatriptan) or the ergot derivatives ergotamine and dihydroergotamine; poor absorption and adverse effects limit the use of ergot derivatives and selective serotonin ($5\text{-}HT_1$) agonists are generally preferred.

Serotonin ($5\text{-}HT_1$) agonists are highly effective in relieving the pain and nausea of a migraine attack. There are a number of **triptans** available; patient characteristics and preferences vary in response to use and can sometimes be unpredictable. Some patients experience recurrence of the headache within 24 to 48 hours and often respond to a second dose. Finding the best triptan to suit the individual patient may involve trial and error. Triptans should not be used in patients with major risk factors for, or suffering from, cardiovascular disease. The main concern with all triptans is their potential for coronary vasoconstriction and no triptan appears to be safer than the others.

If **ergotamine** is used it should be given at the first warning of an attack; the earlier it is given, the more effective the treatment. Since its oral bioavailability is poor and may be reduced further during a migraine attack, ergotamine has sometimes been given in sublingual or rectal preparations. Ergotamine can also exacerbate nausea and vomiting; metoclopramide or domperidone, or in severe cases the phenothiazines chlorpromazine or prochlorperazine, may be given. Dihydroergotamine may be of use if parenteral treatment is required; it can also be given intranasally but there is less experience with this route.

Patients who rapidly develop severe migraine may be given **parenteral** dihydroergotamine or sumatriptan. Some consider parenteral metoclopramide to be suitable first-line treatment. If there is no response to these drugs, dopamine antagonists such as chlorpromazine or prochlorperazine given parenterally may be effective in relieving the pain of acute migraine attacks. Prolonged attacks (status migrainosus) may require intravenous administration of dihydroergotamine with metoclopramide.

Other drugs that may be given alone or in combination include corticosteroids or pethidine. Lidocaine has been given intravenously for the emergency treatment of migraine; intranasal lidocaine has also been tried. The opioid agonist-antagonist butorphanol, given by nasal spray, has been advocated, but its place in therapy, if any, remains to be established. Other drugs under investigation include botulinum A toxin and CGRP antagonists; intravenous valproic acid has also shown promise in aborting acute attacks.

Guidelines have been issued for the treatment of migraine in **children and adolescents**. For acute treatment, ibuprofen and paracetamol were found to be effective in children aged 6 years and over; sumatriptan nasal spray should be considered in those aged 12 years and over.

Prophylactic treatment should be considered for patients in whom abortive measures are ineffective or migraine attacks occur frequently, or for those with less frequent but severe or prolonged attacks. Some recommend prophylaxis if attacks occur more often than once or twice a month. Prophylaxis can reduce the severity and/or frequency of attacks but does not eliminate them completely and patients still need additional abortive or symptomatic treatment. Drugs suggested for prophylaxis have a range of actions which reflects uncertainty over the pathogenesis of migraine. It is important to give prophylactic drugs for an adequate period before assessing their efficacy. Once an optimum effect has been achieved the need for continuing prophylaxis should be reviewed at intervals of about 3 to 6 months.

The main prophylactic drugs are **beta blockers**, tricyclic **antidepressants**, and the **antiepileptics**, topiramate and valproate. Propranolol is considered by many to be the prophylactic drug of choice. Lethargy appears to be the most common adverse effect. Other beta blockers reported to be effective are those that, like propranolol, possess no intrinsic sympathomimetic activity, which include atenolol, metoprolol, nadolol, and timolol. The potential for beta blockers to interact with some serotonin ($5\text{-}HT_1$) agonists and ergotamine should be borne in mind. Tricyclic antidepressants, particularly amitriptyline, given in gradually increasing doses at night are useful for preventing migraine, especially in patients who also have depression or tension-type headache, although antimuscarinic adverse effects may occur. Valproate is also used for preventing migraine. Nausea appears to be the most common adverse effect. Topiramate is the main alternative to valproate. Weight loss and paraesthesia are commonly reported adverse effects. Topiramate and valproate are particularly useful in patients who also have epilepsy or bipolar disorder.

Other drugs have been used for the prophylaxis of migraine: pizotifen, an antihistamine and serotonin antagonist, has been widely used but evidence for its efficacy is limited; it may be tried in children. Of the drugs with calcium-channel blocking activity, flunarizine appears to be effective, and has been suggested for use in children, and verapamil may be useful, but evidence for the efficacy of other calcium-channel blockers such as diltiazem, nifedipine, or nimodipine is less convincing; NSAIDs may be worth trying. The use of methysergide, a potent serotonin antagonist, has declined because of serious adverse effects, in particular retroperitoneal fibrosis. MAOIs such as phenelzine have been used occasionally but are best reserved for severe cases refractory to other forms of prophylactic treatment. Cyproheptadine, an antihistamine and serotonin antagonist, has been used for migraine prophylaxis, particularly in children. Other drugs used for the prophylaxis of migraine have included butterbur, clonidine, cyclandelate, indoramin, feverfew, and the ergot derivative metergoline. Positive results have been seen with magnesium and riboflavin. Other drugs still under investigation, which have shown potential for prevention of migraine attacks are: baclofen, botulinum A toxin, candesartan, gabapentin, lisinopril, and venlafaxine.

Post-dural puncture headache

For the management of headache associated with lumbar puncture or spinal anaesthesia, see Post-dural Puncture Headache under Local Anaesthetics, p.1851.

Tension-type headache

Tension-type headaches, also referred to as muscle-contraction headaches, are probably the commonest form of headache. They are characterised by bilateral pain, which unlike migraine is continuous and non-pulsatile. The pain is often described by the patient as feeling like a tight band pressed around the head. Headaches of this type may be precipitated by many factors including psychosocial stress or muscular stress. Many patients also have associated symptoms of anxiety or depression. Tension-type headaches and migraine often co-exist and may then be referred to as combination or mixed headaches. Some patients only experience isolated acute attacks of tension-type headache (episodic tension-type headache), but others may develop chronic tension-type headache which is difficult to treat.

Treatment is aimed at removing the underlying causes where these can be identified. Simple massage may help if muscle contraction is a prominent component of the pain. Non-opioid analgesics, such as aspirin or other NSAIDs and paracetamol, may be tried for individual acute attacks of headache, but analgesic overuse must be avoided as this can lead to chronic headache resistant to other measures (see Medication-overuse Headache, above). Opioids alone or in combination preparations with other analgesics should also be avoided. Hypnotics or sedatives have sometimes been used in combination preparations with analgesics in the management of tension-type headache that disrupts sleep but, because of the potential for abuse, they should be avoided in chronic headaches. Muscle relaxants appear to have little place in the management of tension-type headache; although some patients may respond, results are generally disappointing. Other drugs that have been tried include valproate and botulinum A toxin. **Prophylaxis** is preferable to regular short-term use of analgesics in controlling chronic tension-type headache. Tricyclic antidepressants, particularly amitriptyline, are generally considered as first choice, although benefit is rarely complete. The mode of action is unclear and appears to be independent of any antidepressant action. In most cases, improvement is seen with low doses, but full antidepressant doses are necessary in the presence of underlying depression. Addition of a beta blocker such as propranolol may sometimes be of benefit for patients with some migraine features.

Almotriptan Malate *(BANM, USAN, rINNM)*

Almotriptan, Malate d'; Almotriptani Malas; LAS-31416 (almotriptan); Malato de almotriptán; PNU-180638E (almotriptan malate). 1-[({3-[2-(Dimethylamino)ethyl]indol-5-yl}methyl)sulfonyl]pyrrolidine malate (1:1).

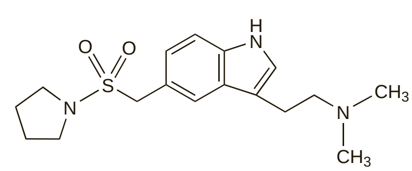
Альмотриптана Малат

$C_{17}H_{25}N_3O_2S,C_4H_6O_5$ = 469.6.

CAS — 154323-57-6 (almotriptan); 181183-52-8 (almotriptan malate).

ATC — N02CC05.

ATC Vet — QN02CC05.



(almotriptan)

Adverse Effects and Precautions

As for Sumatriptan, p.625.

Almotriptan should not be used in patients with severe hepatic impairment since clearance is likely to be markedly impaired, and should be given with caution, and in reduced doses, to patients with mild to moderate hepatic impairment. The dose of almotriptan should also be reduced in patients with severe renal impairment.

Patients with hypersensitivity to sulfonamides may theoretically exhibit a similar reaction to almotriptan.

Incidence of adverse effects. Results from studies involving more than 2500 patients with migraine suggested that adverse effects of almotriptan were infrequent.[1] The commonest adverse effects reported were dizziness, nausea and vomiting, headache, paraesthesia, fatigue, and drowsiness, all of which occurred in less than 3% of patients. The incidence of chest symptoms was 0.2% in 2 large phase III studies.

1. Dodick DW. Oral almotriptan in the treatment of migraine: safety and tolerability. *Headache* 2001; **41:** 449–55.

Interactions

As for Sumatriptan, p.626.

Pharmacokinetics

After oral doses, peak plasma-almotriptan concentrations are obtained in about 1 to 3 hours, with a bioavailability of about 70%. Protein binding is about 35%. Almotriptan is metabolised, mainly by monoamine oxidase type A to the inactive indole acetic acid derivative and to a lesser extent by cytochrome P450 isoenzymes CYP3A4 and CYP2D6 to the inactive gamma-aminobutyric acid derivative. More than 75% of an oral dose is excreted in the urine and the remainder in faeces. About 40 to 50% of the dose in the urine and 5% in the faeces is excreted as unchanged drug. The plasma elimination half-life is about 3.5 hours in healthy subjects, increasing to about 7 hours in severe renal impairment.

Distribution into milk has been found in studies in *rats*.

Uses and Administration

Almotriptan malate is a selective serotonin ($5\text{-}HT_1$) agonist with actions and uses similar to those of sumatriptan (p.627). It is used for the acute treatment of the headache phase of migraine attacks. It should not be used for prophylaxis. Almotriptan is given orally as the malate, and doses are expressed in terms of the base; almotriptan malate 8.75 mg is equivalent to about 6.25 mg of almotriptan.

The usual dose of almotriptan is 12.5 mg in the UK and 6.25 or 12.5 mg in the USA. If this is ineffective, a second dose should not be taken for the same attack. If symptoms recur within 24 hours after an initial response, a second dose may be taken after an interval of at least 2 hours. No more than 2 doses should be taken in a 24-hour period. For doses in hepatic and renal impairment see below.

Administration in hepatic or renal impairment. In patients with hepatic or severe renal impairment, no more than 12.5 mg of almotriptan should be taken in 24 hours; a starting dose of 6.25 mg may be used. Almotriptan is contra-indicated in patients with severe hepatic disease.

Migraine. For comparison of the relative benefits of different triptans in migraine, see under Sumatriptan, p.627.

ATC Vet — QN02CA01.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Dihydroergotamine Tartrate). Colourless crystals or a white or almost white crystalline powder. Very slightly soluble in water; sparingly soluble in alcohol. A 0.1% suspension in water has a pH of 4.0 to 5.5. Protect from light.

Adverse Effects and Treatment

As for Ergotamine Tartrate, p.620, although vasoconstriction may be less pronounced and the frequency of nausea and vomiting lower with dihydroergotamine mesilate than with ergotamine tartrate. Dihydroergotamine does not appear to produce physical dependence.

Effects on the cardiovascular system. There are conflicting reports on the risk of vasospasm in patients given dihydroergotamine with heparin for thromboembolism prophylaxis. Vasospastic or necrotic reactions have been reported on several occasions during such therapy.[1-4] In an Austrian study of 147 290 patients given drug prophylaxis for thromboembolism, complications attributable to ergotism were seen in 142 of 61 092 (0.23%) who received dihydroergotamine and heparin.[5] Others,[6] however, observed only 1 case of vasospasm in 5100 trauma patients (0.02%) given the combination. In 1989 the Swedish Adverse Drug Reactions Advisory Committee reported[7] that up to the end of September 1987 the manufacturer had received 201 reports of vasospastic reactions associated with the use of *Orstanorm* (dihydroergotamine + lidocaine) with heparin. Permanent damage occurred in 59% of these patients. Vasospastic reactions had occurred more frequently in patients who had undergone surgery for trauma and the prognosis for such patients was generally poorer than for others. Since the risk of permanent damage appeared to be related to treatment length the Committee recommended that this preparation should not be given for more than 7 days. The possibility of such reactions and the contra-indications of dihydroergotamine should be borne in mind when using this form of prophylaxis (see Venous Thromboembolism, under Uses, below).

Fibrosis. For reference to fibrosis associated with the administration of dihydroergotamine, see Methysergide Maleate, p.623.

Precautions

As for Ergotamine Tartrate, p.620.

Cardiovascular disorders. For specific contra-indications and precautions in cardiovascular disorders, see under Ergotamine, p.621.

Porphyria. Dihydroergotamine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for Ergotamine (p.621).

Use with other vasoconstrictive drugs, including supplementary antimigraine treatment with ergotamine or sumatriptan, should be avoided.

Pharmacokinetics

Peak plasma-dihydroergotamine concentrations have been attained within about 1 to 2 hours after oral doses, about 30 minutes after intramuscular injection, about 15 to 45 minutes after subcutaneous injection, and about 45 to 55 minutes after intranasal doses. However, the bioavailability of dihydroergotamine after oral doses is very low; values ranging from less than 0.1 to 1.5% have been reported. Although dihydroergotamine is incompletely absorbed from the gastrointestinal tract, the low bioavailability is considered to be determined primarily by extensive first-pass hepatic metabolism. Bioavailability after intranasal doses is 43%. Dihydroergotamine is 90 to 95% bound to plasma proteins.

Dihydroergotamine undergoes extensive metabolism, the major metabolite, 8′-β-hydroxydihydroergotamine, being active. Plasma concentrations of this metabolite are greater than those of dihydroergotamine. A further oxidation step produces 8′,10′-dihydroxydihydroergotamine, which is also active. Other metabolites are also formed. Most of a dose is excreted as metabolites, mainly in the bile; 5 to 10% is excreted in the urine of which only trace amounts are of unchanged drug. The elimination of dihydroergotamine is biphasic; half-lives of about 1 to 2 hours and 22 to 32 hours have been reported for the 2 phases, respectively.

Uses and Administration

Dihydroergotamine is a semisynthetic ergot alkaloid that has weaker oxytocic and vasoconstrictor effects than ergotamine (p.621). Its activity as a 5-HT_1 agonist is believed to contribute to its antimigraine action. It is used in the treatment of migraine and cluster headache, and in the treatment of orthostatic hypotension. It has also been used for the prophylaxis of venous thromboembolism (see below).

Dihydroergotamine is commonly used as the mesilate by subcutaneous, intramuscular, or intravenous injection, although it may also be given as a nasal spray or orally.

For the treatment of migraine and to terminate an acute attack of cluster headache, dihydroergotamine mesilate is usually given by subcutaneous or intramuscular injection in doses of 1 mg repeated, if necessary, after 30 to 60 minutes up to a maximum daily dose of 3 mg. If a more rapid effect is desired it may be given intravenously in doses of 0.5 or 1 mg up to a maximum daily dose of 2 mg. The total weekly dose given by any route of injection should not exceed 6 mg. The usual nasal dose of dihydroergotamine mesilate for an acute attack of migraine is 500 micrograms sprayed into each nostril as a 0.4% solution followed after 15 minutes by an additional 500 micrograms in each nostril. A total intranasal dose of 2 mg per attack should not be exceeded. In the USA, the maximum dose in 24 hours is 3 mg and in a 7-day period is 4 mg, while maximum daily doses of up to 4 mg with a maximum dose of 12 mg in a 7-day period have been given in other countries. In some countries it is given orally; up to 10 mg daily has been given orally for the treatment of acute attacks of migraine. Lower oral doses have been given in some countries for migraine prophylaxis.

Dihydroergotamine mesilate has also been used alone or with etilefrine hydrochloride (p.1284) in the treatment of orthostatic hypotension, in usual oral doses of up to 10 mg daily in divided doses. Doses of up to 40 to 60 mg have been used in some patients.

Dihydroergotamine tartrate has been used for indications similar to those of the mesilate.

Medication-overuse headache. Dihydroergotamine may be used in the treatment of medication-overuse headache (p.616), including symptoms of ergotamine withdrawal.

Migraine and cluster headache. Although sumatriptan is often the treatment of choice to abort acute attacks of migraine (p.616) that do not respond to simple analgesic preparations, parenteral dihydroergotamine, especially with an antiemetic, is an alternative for patients who develop severe or refractory migraine.[1-3] Preparations for intranasal[4,5] use are also available; in some countries, it is given orally. In a comparative study, relief of migraine was slower after subcutaneous dihydroergotamine than after subcutaneous sumatriptan, but headache recurred less often.[6] In other studies, intranasal dihydroergotamine was not as effective as subcutaneous[5] or intranasal[7] sumatriptan.

Dihydroergotamine is also used in the treatment of cluster headache (p.616), usually in emergency settings, where it is given to abort individual headache attacks.

Orthostatic hypotension. Dihydroergotamine may be of use in patients with refractory orthostatic hypotension (p.1530). It is sometimes used in preparations with sympathomimetics such as etilefrine. After parenteral dihydroergotamine, standing blood pressure is increased, but total peripheral resistance and supine blood pressure are also increased.[1] It does not prevent postprandial hypotension, presumably because it does not constrict the splanchnic veins, although use with caffeine may overcome this problem. The main disadvantage of dihydroergotamine, however, is that it is ineffective, or at best weakly effective, when given by mouth, although there has been some evidence that oral ergotamine tartrate may be of value.

Dihydroergotamine has been suggested for use in the prevention of hypotension associated with epidural[2] or spinal anaesthesia,[3] the usual management of which is discussed in Treatment of Adverse Effects of Local Anaesthetics, p.1851. It has also been tried in the management of hypotension associated with haemodialysis.[4]

Venous thromboembolism. Standard prophylaxis for surgical patients at high risk of venous thromboembolism is usually with heparin or low-molecular-weight heparin (p.1189). Dihydroergotamine can reduce venous stasis by vasoconstriction of capacitance vessels and has enhanced postoperative prophylaxis when used with heparin.[1] Doses of dihydroergotamine mesilate 500 micrograms with heparin 5000 units, both given subcutaneously 2 hours before surgery, have been used. This regimen has then been given every 8 to 12 hours for 5 to 14 days depending on the risk of thrombosis. The use of dihydroergotamine with low-molecular-weight heparin has been shown to be of similar efficacy to dihydroergotamine with heparin[2,3] but might offer a more convenient dosing schedule. However, although dihydroergotamine might enhance the effect of heparin, a US National Institutes of Health consensus conference warned of the potential risk associated with its vasoconstrictive effects, and the contraindications to its use.[4] In 1989 the Swedish Adverse Drug Reactions Advisory Committee recommended that dihydroergotamine with heparin should not be given for more than 7 days (see Effects on the Cardiovascular System, under Adverse Effects, above).

Eletriptan Hydrobromide

(BANM, USAN, rINNM)

Eletriptaanihydrobromidi; Élétriptan, Bromhydrate d'; Eletriptanhydrobromid; Eletriptani Hydrobromidum; Hidrobromuro de eletriptán; UK-116044-04. 3-{[(*R*)-1-Methyl-2-pyrrolidinyl]methyl}-5-[2-(phenylsulfonyl)ethyl]indole hydrobromide.

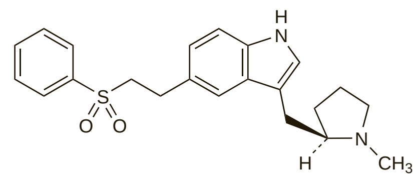
Элетриптана Гидробромид

$C_{22}H_{26}N_2O_2S,HBr = 463.4.$

CAS — 143322-58-1 (eletriptan); 177834-92-3 (eletriptan hydrobromide).

ATC — N02CC06.

ATC Vet — QN02CC06.



(eletriptan)

Adverse Effects and Precautions

As for Sumatriptan, p.625.

Eletriptan should not be used in patients with severe hepatic or severe renal impairment. Blood pressure effects of eletriptan are increased in renal impairment and therefore the dose should be reduced in patients with mild to moderate renal impairment. No dosage adjustment is needed in mild or moderate hepatic impairment.

Breast feeding. Eletriptan is distributed into breast milk and the manufacturer has suggested that infant exposure can be minimised by avoiding breast feeding for 24 hours after treatment.

Interactions

As for Sumatriptan, p.626.

Eletriptan should not be given with potent inhibitors of the cytochrome P450 isoenzyme CYP3A4 such as erythromycin and ketoconazole; increased plasma levels of eletriptan have been noted after such combinations. It is recommended that eletriptan should not be taken within at least 72 hours of treatment with such drugs.

Pharmacokinetics

After oral doses eletriptan is rapidly and well absorbed (at least 81%) and has a bioavailability of about 50%. Peak plasma concentrations are attained within 1.5 hours. Eletriptan is about 85% protein bound. It is primarily metabolised by the hepatic cytochrome P450 isoenzyme CYP3A4. Non-renal clearance accounts for about 90% of the elimination of eletriptan and the plasma elimination half-life is about 4 hours. A small amount is distributed into breast milk.

Uses and Administration

Eletriptan hydrobromide is a selective serotonin (5-HT_1) agonist with actions and uses similar to those of sumatriptan (p.627). It is used for acute treatment of the headache phase of migraine attacks. It should not be used for prophylaxis. Eletriptan is given orally as the hydrobromide, but doses are expressed in terms of the base; eletriptan hydrobromide 24.2 mg is equivalent to about 20 mg of eletriptan.

The usual dose is 40 mg; if this is ineffective, a second dose should not be taken for the same attack. If symptoms recur within 24 hours after an initial response, a second dose may be taken after an interval of at least 2 hours. Doses of 80 mg may be used in subsequent attacks, but should not be repeated within a 24-hour period. For doses in renal impairment, see below.

Administration in renal impairment. In the UK, a dose of 20 mg of eletriptan is recommended in patients with mild to moderate renal impairment. The maximum daily dose should not exceed 40 mg. Eletriptan should not be used in severe impairment.

Migraine. For comparison of the relative benefits of different triptans in migraine, see under Sumatriptan, p.627.

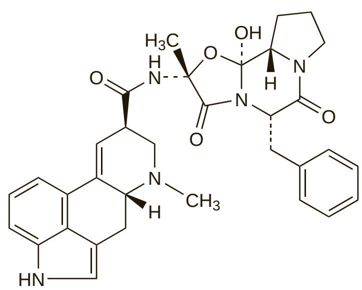
ATC Vet — QN02CA02.



(ergotamine)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Ergotamine Tartrate). Slightly hygroscopic, colourless crystals or a white or almost white crystalline powder. It may contain 2 molecules of methanol of crystallisation. Slightly soluble in alcohol. Aqueous solutions slowly become cloudy owing to hydrolysis; this may be prevented by the addition of tartaric acid. A 0.25% suspension in water has a pH of 4.0 to 5.5. Store in airtight glass containers at a temperature of 2° to 8°. Protect from light.

USP 31 (Ergotamine Tartrate). Colourless odourless crystals or a white or yellowish-white crystalline powder. Soluble 1 in about 3200 of water, but soluble 1 in about 500 of water in the presence of a slight excess of tartaric acid; soluble 1 in 500 of alcohol. Store at a temperature not exceeding 8°. Protect from light.

Stability in solution. References.

Adverse Effects

The adverse effects of ergotamine may be attributed either to its effects on the CNS, or to vasoconstriction of blood vessels and possible thrombus formation.

After therapeutic doses nausea and vomiting commonly occur as a result of the direct emetogenic effect of ergotamine; some patients may also experience abdominal pain. Weakness and muscle pains in the extremities and numbness and tingling of the fingers and toes may occur. There may occasionally be localised oedema and itching in hypersensitive patients. Treatment should be stopped if symptoms of vasoconstriction develop. Susceptible patients, especially those with sepsis, liver disease, kidney disease, or occlusive peripheral vascular disease, may show signs of acute or chronic poisoning with normal doses of ergotamine.

Symptoms of acute overdosage include nausea, vomiting, diarrhoea, extreme thirst, coldness, tingling, and itching of the skin, a rapid and weak pulse, hypertension or hypotension, shock, confusion, convulsions, and unconsciousness; fatalities have been reported. Further symptoms of peripheral vasoconstriction or of cardiovascular disturbances, as seen in chronic ergotamine poisoning, may also occur but may be delayed.

In chronic poisoning or ergotism, resulting from therapeutic overdosage or the use of ergotamine in susceptible patients, severe circulatory disturbances may develop. The extremities, especially the feet and legs, become numb, cold, tingling, and pale or cyanotic, with muscle pain; there may be no pulse in the affected limb. Eventually gangrene develops in the toes and sometimes the fingers. Anginal pain, tachycardia or bradycardia, and hypertension or hypotension have been reported. Myocardial infarction has occurred rarely. Pleural and peritoneal fibrosis may occur with excessive use and there have been rare cases of fibrosis of the cardiac valves. Chronic, intractable headache (rebound headache) may occur and is also a major withdrawal symptom following the development of ergotamine dependence (see under Precautions, below). Other adverse effects include confusion and convulsions. On rare occasions symptoms of vasoconstriction of blood vessels in the brain, eye, intestines, and kidneys occur. Anorectal ulceration, sometimes leading to rectal necrosis and stenosis or rectovaginal fistula, has been reported after excessive use of suppositories containing ergotamine.

Effects on the cardiovascular system. Reports[1-9] of adverse cardiovascular effects associated with ergotamine, including mention of fatalities.

Fibrosis. For reference to fibrosis associated with the use of ergotamine tartrate, see Methysergide Maleate, p.623.

Treatment of Adverse Effects

Treatment of acute poisoning with ergotamine is symptomatic. Although the benefit of gastric decontamination is uncertain, activated charcoal may be given to patients who present within 1 hour of ingesting a toxic dose (more than 125 micrograms/kg in adults) or any amount in a child or adult with peripheral vascular disease, ischaemic heart disease, severe infection, or hepatic or renal impairment. Alternatively, gastric lavage may be considered in adults within 1 hour of ingesting a potentially life-threatening overdose. In chronic poisoning, withdrawal of ergotamine may be all that is required in some patients.

In both acute and chronic poisoning, attempts must be made to maintain an adequate circulation to the affected parts of the body in order to prevent the onset of gangrene. In severe arterial vasospasm vasodilators such as sodium nitroprusside by intravenous infusion have been given; heparin and dextran 40 have also been advocated to minimise the risk of thrombosis. Analgesics may be required for severe ischaemic pain.

Cardiovascular effects. Sodium nitroprusside has been used in severe ergotamine poisoning for its vasodilating and hypotensive actions; it should, however, be used with care if hypotension is a symptom of poisoning. It is usually given by intravenous infusion[1-4] although there have also been reports of intra-arterial infusion for ergotamine-induced ischaemia;[5,6] for details of precautions to be observed, see p.1397.

Many other drugs have been used in the treatment of circulatory disturbances induced by ergotamine. These include captopril by mouth,[7] alprostadil by intra-arterial infusion,[8,9] and glyceryl trinitrate by intravenous infusion.[10,11]

Precautions

Ergotamine tartrate is contra-indicated in patients with severe or uncontrolled hypertension, shock, severe or persistent sepsis, peripheral vascular disease, ischaemic heart disease, temporal arteritis, hyperthyroidism, or hepatic or renal impairment. It is also contra-indicated in those with basilar or hemiplegic migraine. Ergotamine tartrate should be used with care in patients with anaemia. It is contra-indicated in pregnancy because of its oxytocic effect (see also below).

Patients should be warned to keep within the recommended dosage. Some symptoms of overdosage may mimic those of migraine. Numbness or tingling of the extremities generally indicates that ergotamine should be stopped. Although ergotamine is used for limited periods in the prevention of episodic cluster headache, it should not be given prophylactically in other circumstances, as prolonged use may give rise to gangrene. Dependence has occurred with regular use of ergotamine tartrate even if dosage recommendations are adhered to (see below).

Dizziness and feelings of anxiety have been reported; if affected, patients should avoid driving or operating machinery.

Breast feeding. Although the American Academy of Pediatrics includes ergotamine among those drugs that may be given with caution to breast-feeding mothers,[1] it notes that maternal use in doses equivalent to those given for the treatment of migraine has been associated with vomiting, diarrhoea, and convulsions in nursing infants. UK licensed product information recommends that ergotamine tartrate should be avoided during breast feeding; the distribution of unchanged drug and metabolites into breast milk presents a risk of ergotism in the infant and repeated doses of ergotamine may impair lactation.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 01/06/04)

Cardiovascular disorders. In the USA, dihydroergotamine is contra-indicated in patients with ischaemic heart disease and other cardiovascular disorders such as hypertension, peripheral arterial disease, or coronary artery vasospasm and it is also recommended that it should not be given to those with a family history of ischaemic heart disease, to postmenopausal women or men aged over 40, or to those with other ischaemic risk factors such as hypertension, hypercholesterolaemia, smoking, diabetes, or obesity, unless cardiovascular evaluation to exclude such disease has been carried out. Similar precautions and contra-indications, which resemble those that apply to serotonin (5-HT_1) agonists such as sumatriptan (p.626), may be applicable to other ergot derivatives used in migraine such as ergotamine.

In other countries, warnings concerning the use of ergot derivatives in patients with risk factors for myocardial ischaemia appear to be less stringent, although caution is clearly advisable.

Dependence. Dependence can develop insidiously when ergotamine tartrate is used for more than 2 days each week, even if total daily or weekly dosage recommendations are observed.[1] Individual reports indicate a state of addiction characterised by a predictable and irresistible pattern of drug usage, the development of tolerance to adverse effects, and a syndrome of withdrawal on stopping the drug. Ergotamine-dependent patients suffer from daily, or almost daily, migraine headaches, often referred to as medication-overuse headaches or 'rebound headaches', which are only alleviated by ergotamine. Intensifying headache with autonomic disturbances occurs within 24 to 48 hours of withdrawal of ergotamine and may continue for 72 hours or longer. As with other medication-overuse headaches (p.616), supportive and symptomatic measures should be taken to treat the withdrawal syndrome.

1. Saper JR. Ergotamine dependency—a review. *Headache* 1987; **27:** 435–8.

Porphyria. Ergotamine tartrate has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. Ergotamine is contra-indicated in pregnancy because of its oxytocic effect. Accidental dosage of ergotamine in the form of a *Cafergot* suppository (ergotamine tartrate 2 mg and caffeine 100 mg) to a patient at 39 weeks of pregnancy caused uterine contractions and fetal tachycardia.[1] An emergency caesarean section was undertaken because of suspected placental abruption but no clear signs of retroplacental haemorrhage were found. The neonate recovered quickly after delivery and had developed normally during the next 10 years.

Jejunal atresia has been reported[2] in an infant born prematurely to a woman who had taken ergotamine tartrate 6 to 8 mg daily, as *Cafergot* tablets, throughout her pregnancy. Two cases of Möbius syndrome (a condition characterised by facial paralysis as a result of hypoplasia of cranial nerve nuclei) have been associated with exposure to ergotamine during the first trimester of pregnancy.[3,4] In the first report[3] the mother had inadvertently been given three *Cafergot* suppositories within a period of 1 to 2 hours and at the time had experienced uterine cramping and a bloody vaginal discharge. The second mother[4] had used 2-mg ergotamine suppositories on a regular basis during the first 8 weeks of pregnancy.

Interactions

The vasoconstrictor effects of ergotamine are enhanced by sympathomimetics such as adrenaline. There is also an increased risk of peripheral vasoconstriction during use of ergotamine with beta blockers.

Ergotamine is metabolised by the cytochrome P450 isoenzyme CYP3A4 and consequently it should not be given with potent inhibitors of this isoenzyme; elevated ergotamine concentrations sufficient to cause ergotism may occur with azole antifungals, macrolide antibacterials such as erythromycin and clarithromycin, and HIV-protease inhibitors including indinavir and ritonavir. Use of tetracycline with ergotamine may also increase the risk of ergotism and should be avoided.

Ergotamine should not be used with or given until several hours after stopping a serotonin (5-HT_1) agonist, since there is an additional risk of prolonged vasospastic reactions; at least 6 hours is advised for almotriptan, rizatriptan, sumatriptan, and zolmitriptan, and at least 24 hours for eletriptan and frovatriptan. Conversely, a delay is advised before starting a serotonin agonist in patients who have been receiving ergotamine: almotriptan, eletriptan, frovatriptan, rizatriptan, sumatriptan, or zolmitriptan should not be given until at least 24 hours after stopping the use of preparations containing ergotamine.

Antibacterials. Acute reactions ranging from minor ergotism[1] to severe vasospasm[2] have been reported in patients given *erythromycin* in addition to ergotamine. There are also reports of acute ergotism in patients receiving ergotamine tartrate and *clarithromycin*[3,4] or *troleandomycin*.[5] The theoretical possibility exists that there may be a similar interaction with *azithromycin*. Ergotism has also been reported in patients receiving erythromycin[6] or troleandomycin[7] with dihydroergotamine.

6. Leroy F, *et al.* Dihydroergotamine-erythromycin-induced ergotism. *Ann Intern Med* 1988; **109:** 249.
7. Franco A, *et al.* Ergotisme aigu par association dihydroergotamine-triacétyloléandomycine. *Nouv Presse Med* 1978; **7:** 205.

Antidepressants. There have been isolated case reports[1] of the serotonin syndrome (p.416) in patients receiving dihydroergotamine with *amitriptyline*, *imipramine*, *paroxetine*, or *sertraline*.

1. Mathew NT, *et al.* Serotonin syndrome complicating migraine pharmacotherapy. *Cephalalgia* 1996; **16:** 323–7.

Antimigraine drugs. Arterial occlusion has been reported[1] in 2 patients given *methysergide* with a high parenteral dosage of ergotamine for cluster headache; the combination should be avoided. Use of ergotamine as supplementary antimigraine medication in patients receiving *dihydroergotamine* is not recommended.

For reports of arterial vasoconstriction in patients taking *beta blockers* and antimigraine drugs, see below. See also Interactions, above for a comment on the risk of vasospastic reactions with serotonin (5-HT_1) agonists such as *sumatriptan*.

1. Joyce DA, Gubbay SS. Arterial complications of migraine treatment with methysergide and parenteral ergotamine. *BMJ* 1982; **285:** 260–1.

Antivirals. There have been reports of ergotism in patients who received ergotamine and combination antiviral treatment for HIV infection. It was suggested that the ergotism might have been caused by inhibition of ergotamine metabolism by *ritonavir* in 4 cases,[1-4] *indinavir* in one,[5] and *nelfinavir*[6] in another. One of the patients receiving ritonavir,[4] who had taken three 1-mg tablets of ergotamine tartrate over the 4 days before presentation, also developed signs of cerebrovascular involvement and eventually went into an irreversible coma.

The metabolism of ergot alkaloids may be inhibited by *delavirdine* or *efavirenz*.

6. Mortier E, *et al.* Ergotism related to interaction between nelfinavir and ergotamine. *Am J Med* 2001; **110:** 594.

Beta blockers. Peripheral vasoconstriction was reported in a patient with migraine after addition of *propranolol* to regular use of *Cafergot* (ergotamine and caffeine) suppositories twice daily.[1] This combination has been used without complication by others, who suggested that excessive dosage of ergotamine tartrate, rather than an interaction between ergotamine and propranolol, was responsible.[2] However, arterial vasoconstriction has been reported after use of methysergide with propranolol and *oxprenolol* with ergotamine.[3] Such combinations should therefore be used with caution.

3. Venter CP, *et al.* Severe peripheral ischaemia during concomitant use of beta blockers and ergot alkaloids. *BMJ* 1984; **289:** 288–9.

Glyceryl trinitrate. Glyceryl trinitrate has been reported to increase the oral bioavailability and plasma concentrations of dihydroergotamine in patients with orthostatic hypotension.[1]

1. Bobik A, *et al.* Low oral bioavailability of dihydroergotamine and first-pass extraction in patients with orthostatic hypotension. *Clin Pharmacol Ther* 1981; **30:** 673–9.

Tacrolimus. Ergotamine may inhibit the metabolism of tacrolimus by cytochrome P450 isoenzymes (see p.1845).

Pharmacokinetics

Absorption of ergotamine from the gastrointestinal tract is poor and may be further decreased by the occurrence of gastric stasis during migraine attacks. Bioavailability is also diminished by a high first-pass hepatic metabolism. Ergotamine has been given rectally or by inhalation in an attempt to overcome these effects, with some improvement in absorption, but bioavailability is still about 5% or less. Absorption of sublingual ergotamine is very poor. There is considerable interindividual variation in the bioavailability of ergotamine, regardless of the route. Caffeine is sometimes included in oral and rectal preparations of ergotamine to improve the latter's absorption, although whether it does so is not clear. Drugs such as metoclopramide are sometimes given with the aim of alleviating gastric stasis and thus improve the absorption of ergotamine.

Plasma protein binding is about 93 to 98%. Ergotamine is metabolised extensively in the liver via the cytochrome P450 isoenzyme CYP3A4; the majority of metabolites are excreted in the bile. About 4% of a dose is excreted in the urine. Some of the metabolites are pharmacologically active. The elimination of ergotamine is biphasic; half-lives of about 2 and 21 hours have been reported for the 2 phases, respectively. Ergotamine or its metabolites have been detected in breast milk.

Uses and Administration

Ergotamine is an alkaloid derived from ergot (p.2010). It has marked vasoconstrictor effects, and a partial agonist action at serotonin (5-HT) receptors; it also has a powerful oxytocic action on the uterus, although less so than ergometrine (p.2009). It is used in migraine and cluster headache, and has been tried in orthostatic hypotension.

Ergotamine is commonly used as the tartrate. It is usually given orally, but has also been given sublingually, rectally, and by oral inhalation. It was formerly given by subcutaneous or intramuscular injection. Caffeine is sometimes given with ergotamine tartrate with the intention of improving the latter's absorption, although whether it does so is not clear. Antiemetics such as cyclizine hydrochloride are sometimes included in combination preparations with ergotamine tartrate.

Ergotamine is used in migraine unresponsive to non-opioid analgesics. However, its adverse effects limit its use and prevent use for prophylaxis. It is most effective when given as early as possible in a migraine attack, preferably during the prodromal phase.

The usual oral dose is 1 to 2 mg of ergotamine tartrate, repeated, if necessary, half an hour later. Usually not more than 6 mg should be given in 24 hours, although some manufacturers recommend not more than 4 mg in 24 hours and others not more than 8 mg per attack. The recommended minimum interval between successive 24-hour courses is 4 days, and the total weekly dose is limited to a maximum of 12 mg, although again some manufacturers recommend a lower weekly limit of 8 mg. It is also recommended that patients should receive no more than 2 courses per month. Similar doses may be given sublingually.

Ergotamine tartrate may also be given rectally as suppositories, especially if the oral route is not effective or not practicable. The rectal dose of ergotamine tartrate is 2 mg repeated, if necessary, one hour later. Usually, not more than 4 mg should be given in 24 hours and not more than 8 mg in one week with an interval of at least 4 days between successive 24-hour courses.

A more rapid onset of action may be achieved by oral inhalation. One dose containing 360 micrograms of ergotamine tartrate has been inhaled at the onset of the attack and repeated, if necessary, at 5-minute intervals. Not more than 6 inhalation doses should be taken in 24 hours and not more than 12 in one week, with an interval of at least 4 days between successive 24-hour courses.

Ergotamine is used in patients with cluster headache to treat individual attacks of headache but since such attacks are short-lived oral inhalation may be preferable to oral, sublingual, or rectal routes. Doses used are similar to those given to treat migraine. It has also been used to prevent headache attacks during cluster periods, when it is usually given daily in low doses for up to 2 weeks, either orally or rectally (see below).

Migraine and cluster headache. Ergotamine was formerly one of the main drugs used to treat acute attacks of migraine (p.616) unresponsive to non-opioid analgesics, but triptan serotonin (5-HT_1) agonists such as sumatriptan are now preferred. Since ergotamine may exacerbate the nausea and vomiting that commonly develops as a migraine attack progresses it is often necessary to give an antiemetic as well. Poor oral bioavailability may be reduced further during a migraine attack and ergotamine has sometimes been given sublingually, rectally, or by inhalation. Adverse effects limit the dose that can be used for an individual attack and prevent the long-term use that would be required for migraine prophylaxis.

Ergotamine may be used similarly in cluster headache (p.616) to treat individual headaches during a cluster period. Ergotamine is also used in low doses given by mouth or rectally for limited periods of up to 2 weeks in the prophylaxis of headache attacks during a cluster period. Regimens that have been tried for such prophylaxis include 1 to 2 mg of ergotamine tartrate given 1 to 2 hours before an expected attack or 1 to 2 hours before bedtime for nocturnal attacks. The total maximum dose of ergotamine tartrate that may be given weekly for the prevention of cluster headache is less well established than for the treatment of migraine. Ergotamine is often given for only 5 to 6 days in each week, which allows the patient to assess whether the cluster period has ended.

2. Tfelt-Hansen P, *et al.* Ergotamine in the acute treatment of migraine: a review and European consensus. *Brain* 2000; **123:** 9–18.

Orthostatic hypotension. Ergotamine and dihydroergotamine may be of use in patients with refractory orthostatic hypotension (p.1530). Ergotamine is believed[1] to be less selective than dihydroergotamine (p.619) in its actions and affects both venous capacitance and peripheral resistance.[2,3] However, the oral bioavailability of ergotamine is greater[2] than that of dihydroergotamine and there have also been some reports of successful treatment with inhaled[3,4] or rectal[5] ergotamine.

Feverfew

Camomille, grande; Matricaria; Mattram; Nat' kopretiny řimbaby; Őszi margitvirág; Reunuspäivänkakkara; Tanaceti parthenii herba; Vaistinių skaistenių žolė.

Pharmacopoeias. In *Eur.* (see p.vii) and in *US*. US also describes Powdered Feverfew.

Ph. Eur. 6.2 (Feverfew). The dried, whole or fragmented aerial parts of *Tanacetum parthenium*. It contains not less than 0.2% of parthenolide ($C_{15}H_{20}O_3$ = 248.3), calculated with reference to the dried drug. It has a camphoraceous odour. Protect from light.

USP 31 (Feverfew). It consists of the dried leaves of *Tanacetum parthenium* (Asteraceae), collected when the plant is in flower. Store in a dry place. Protect from light.

Adverse Effects and Precautions

Mouth ulceration and soreness have been reported following ingestion of feverfew, and may be due to sensitisation; if they occur feverfew should be withdrawn. Contact dermatitis has been reported. Feverfew is reputed to have abortifacient properties and it is suggested that preparations should not be used in pregnancy.

Effects on the blood. There have been suggestions that feverfew may increase the risk of bleeding during surgery or in patients taking anticoagulants. However, although inhibition of platelet aggregation has been reported *in vitro* or in *animals* a review[1] of clinical studies noted that feverfew did not appear to affect haematological safety parameters.

1. Pittler MH, Ernst E. Feverfew for preventing migraine. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2004 (accessed 27/04/05).

Interactions

It has been suggested that feverfew may enhance the effects of anticoagulants (but see Effects on the Blood, above).

Uses and Administration

Feverfew consists of the dried leaves of the plant *Tanacetum parthenium* (Asteraceae). It is a traditional herbal remedy used in the prophylaxis of migraine. Its effects have been attributed to the plant's content of sesquiterpene lactones, notably parthenolide. A preparation of the dried leaf powder, which has been standardised to provide a minimum of 0.2% parthenolide, is available in some countries. A suggested oral dose is 250 mg daily; a lower dose of 100 mg daily has also been given..

Migraine. Feverfew is a traditional herbal remedy used in the prophylaxis of migraine (p.616). Studies of standardised preparations of the freeze-dried powdered leaf have produced variable results in preventing or ameliorating migraine attacks, and systematic reviews[1,2] suggest that its effectiveness in preventing migraine remains to be established.

1. Vogler BK, *et al.* Feverfew as a preventive treatment for migraine: a systematic review. *Cephalalgia* 1998; **18:** 704–8.
2. Pittler MH, Ernst E. Feverfew for preventing migraine. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2004 (accessed 27/04/05).

Rheumatoid arthritis. Feverfew has been used as a herbal medicine for the treatment of arthritis but although it has anti-inflammatory activity *in vitro*, a clinical trial[1] found it to be ineffective in rheumatoid arthritis.

1. Pattrick M, *et al.* Feverfew in rheumatoid arthritis: a double blind, placebo controlled study. *Ann Rheum Dis* 1989; **48:** 547–9.

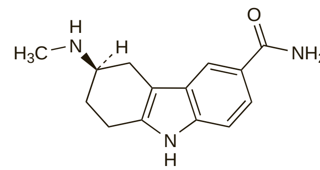
ATC Vet — QN02CC07.



Frovatriptan Succinate *(BANM, USAN, rINNM)*

Frovatriptan, Succinate de; Frovatriptani Succinas; SB-209509AX (frovatriptan or frovatriptan succinate); Succinato de frovatriptán; VML-251 (frovatriptan or frovatriptan succinate).

Фроватриптана Суксинат

$C_{14}H_{17}N_3O,C_4H_6O_4,H_2O$ = 379.4.
CAS — 158930-17-7.
ATC — N02CC07.
ATC Vet — QN02CC07.

Adverse Effects and Precautions

As for Sumatriptan, p.625.

Frovatriptan should not be used in patients with severe hepatic impairment. No dosage adjustment is needed in mild or moderate hepatic impairment.

Interactions

As for Sumatriptan, p.626.

Fluvoxamine is a potent inhibitor of the cytochrome P450 isoenzyme CYP1A2 and has been shown to increase the blood levels of frovatriptan by 27 to 49%.

Pharmacokinetics

After oral doses, peak plasma-frovatriptan concentrations are attained in 2 to 4 hours, and bioavailability is about 20% in men and 30% in women. Food may delay the time to peak plasma concentrations by about 1 hour. Frovatriptan is 15% protein bound. It is primarily metabolised by the hepatic cytochrome P450 isoenzyme CYP1A2. About 32% of an oral dose is excreted in the urine and 62% in faeces. The plasma elimination half-life of frovatriptan is about 26 hours.

Distribution into milk has been found in studies in *rats*.

◊ References.

2. Elkind AH, *et al.* Pharmacokinetics of frovatriptan in adolescent migraineurs. *J Clin Pharmacol* 2004; **44:** 1158–65.

Uses and Administration

Frovatriptan is a selective serotonin (5-HT_1) agonist with actions and uses similar to those of sumatriptan (p.627). It is used for the acute treatment of the headache phase of migraine attacks. It should not be used for prophylaxis. Frovatriptan is given orally as the succinate although doses are expressed in terms of the base; frovatriptan succinate 3.9 mg is equivalent to about 2.5 mg of frovatriptan.

The recommended dose is 2.5 mg; if this is ineffective, a second dose should not be taken for the same attack. If symptoms recur after an initial response, the dose may be repeated after an interval of at least 2 hours. The maximum dose of frovatriptan in 24 hours is 5 mg in the UK although, in the USA, a maximum daily dose of 7.5 mg is allowed.

Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Methysergide Maleate). A white or almost white crystalline powder which may have a yellow or pink tinge; odourless or almost odourless. Slightly soluble in water and in methyl alcohol; practically insoluble in chloroform and in ether. A 0.2% solution in water has a pH of 3.7 to 4.7. Store at a temperature of 2° to 8°. Protect from light.

USP 31 (Methysergide Maleate). A white to yellowish-white or reddish-white, crystalline powder. Is odourless or has not more than a slight odour. Soluble 1 in 200 of water and 1 in 165 of alcohol; soluble 1 in 3400 of chloroform; practically insoluble in ether. pH of a 1 in 500 solution is between 3.7 and 4.7. Store in airtight containers at a temperature of 2° to 8°. Protect from light.

Adverse Effects

Gastrointestinal effects such as nausea, vomiting, heartburn, and abdominal pain are common on initial treatment with methysergide maleate, as are dizziness and drowsiness. Other CNS effects reported include ataxia, insomnia, weakness, restlessness, lightheadedness, euphoria, and hallucinations. Peripheral or localised oedema, leg cramps, and weight gain have occurred and there have been occasional reports of skin rashes, loss of hair, joint and muscle pain, neutropenia, and eosinophilia. Orthostatic hypotension and tachycardia have been observed. There have been isolated reports of myocardial infarction particularly in patients with ischaemic heart disease or when given with other vasoconstrictive drugs, both of which are contra-indications for methysergide therapy.

Arterial spasm has occurred in some patients, and may present as paraesthesia of the extremities or anginal pain, as with ergotamine (p.620); if such symptoms occur methysergide should be withdrawn, although rebound headaches may be experienced if it is withdrawn suddenly. Vascular insufficiency of the lower limbs may represent arterial spasm or fibrotic changes. Treatment should be stopped at the first signs of impaired peripheral circulation. Retroperitoneal fibrosis, with obstruction of abdominal blood vessels and ureters, pleuropulmonary fibrosis, and fibrotic changes in heart valves have occurred in patients on long-term treatment. Methysergide must be withdrawn immediately if fibrosis occurs. Retroperitoneal fibrosis is usually reversible, but other fibrotic changes are less readily reversed.

Fibrosis. Fibrosis has been associated with the long-term use of methysergide maleate. In one early report[1] in 27 patients retroperitoneal fibrosis was attributed to use of methysergide for periods of 9 to 54 months in doses ranging from 2 to 28 mg daily. There was partial or complete regression of fibrosis in 13 of the patients whose treatment was withdrawn. Improvement usually began within a few days, in some cases with the aid of prednisone. The other 14 patients were treated by surgery; those few who continued taking methysergide had difficult postoperative courses. Cardiac murmurs occurred in 7 patients, and regressed wholly or partially in 3 after therapy was stopped. Fibrotic changes affecting the aorta, heart valves, and pulmonary tissues occurred in a few of the patients. Others have reported the development of endocardial fibrosis indicated by cardiac murmurs in 48 patients receiving methysergide.[2] The murmurs gradually regressed in 27 when methysergide was stopped. Retroperitoneal fibrosis was present in 9 patients and pleuropulmonary fibrosis in 2. A patient with fibrosis of the iliac vein has been described.[3]

A few cases of retroperitoneal fibrosis associated with ergotamine tartrate or dihydroergotamine have also been noted.[1] These 2 drugs have also been implicated in a few other cases of retroperitoneal fibrosis or other fibrotic disorders in patients taking high doses for long periods.[4-7]

7. Malaquin F, *et al.* Pleural and retroperitoneal fibrosis from dihydroergotamine. *N Engl J Med* 1989; **321:** 1760.

Treatment of Adverse Effects

As for Ergotamine Tartrate, p.620.

Methysergide maleate should be withdrawn immediately if fibrosis develops. Corticosteroids have been used to treat fibrosis, although surgery may be required.

Precautions

As for Ergotamine Tartrate, p.620.

In addition, methysergide maleate is contra-indicated in valvular heart disease, pulmonary and collagen diseases, diseases of the urinary tract, phlebitis and cellulitis of the lower extremities, and debilitated states. It should be used with caution in patients with peptic ulcer disease because it may increase gastric acidity. Patients should be closely supervised. Methysergide should not be given continuously for more than 6 months and should normally be withdrawn gradually (see Uses and Administration, below). However, it should be withdrawn immediately if symptoms of fibrosis or arterial spasm develop.

Porphyria. Methysergide is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals* or *in-vitro* systems.

Interactions

Interactions involving those ergot alkaloids used primarily in the management of migraine are discussed under ergotamine (p.621). References specific to methysergide may be found there under the headings Antimigraine Drugs and Beta Blockers.

Pharmacokinetics

Methysergide maleate is rapidly absorbed from the gastrointestinal tract with maximum plasma concentrations being obtained within about one hour of ingestion. It is 66% bound to plasma proteins. Methysergide undergoes extensive first-pass hepatic metabolism to methylergometrine (p.2011). About 50% of an oral dose is excreted in the urine as unchanged drug and metabolites. The elimination of methysergide is biphasic; half-lives of about 2.7 hours and 10 hours have been reported for the 2 phases respectively.

◊ References.

1. Bredberg U, *et al.* Pharmacokinetics of methysergide and its metabolite methylergometrine in man. *Eur J Clin Pharmacol* 1986; **30:** 75–7.

Uses and Administration

Methysergide maleate is a semisynthetic ergot alkaloid. It is a potent serotonin antagonist and, compared with ergotamine, has only weak vasoconstrictor and oxytocic effects. It may be used to prevent severe recurrent migraine (p.616) and headache attacks during cluster periods (p.616), although its use has declined because of adverse effects. It is ineffective in the treatment of acute attacks.

Methysergide is given orally as the maleate but doses are often expressed in terms of the base; 1.33 mg of methysergide maleate is equivalent to about 1 mg of methysergide. A usual dosage is 2 to 6 mg daily given in divided doses with meals. It is suggested that treatment should be started with 1 mg at bedtime and doses increased gradually over about 2 weeks; the minimum effective dose should be used. In some other countries doses are expressed in terms of the maleate, a usual dose of which is 4 to 8 mg daily. Careful and regular observation of the patient is essential because of the high incidence of adverse effects and it is recommended that treatment should only be carried out under hospital supervision. If treatment still proves to be ineffective after 3 weeks, further use is unlikely to be of benefit. Treatment should not be continued for more than 6 months, after which it should be gradually withdrawn over 2 or 3 weeks and then stopped for at least a month for reassessment. Some have considered that treatment courses should not exceed 3 months without a break.

Methysergide maleate has also been used to control diarrhoea associated with carcinoid syndrome (p.643) in high doses equivalent to 12 to 20 mg of methysergide daily.

As a serotonin antagonist, methysergide might be expected to help reverse the serotonin syndrome (p.416).

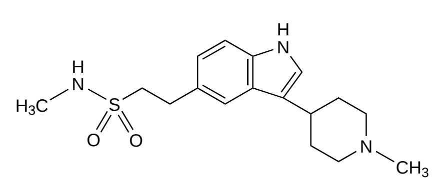
Naratriptan Hydrochloride

(BANM, USAN, rINNM)

GR-85548A; GR-85548X (naratriptan); Hidrocloruro de naratriptán; Naratriptan, Chlorhydrate de; Naratriptani Hydrochloridum. *N*-Methyl-3-(1-methyl-4-piperidyl)indole-5-ethanesulfonamide hydrochloride.

Наратриптана Гидрохлорид

$C_{17}H_{25}N_3O_2S,HCl$ = 371.9.
CAS — 121679-13-8 (naratriptan); 121679-19-4 (naratriptan hydrochloride); 143388-64-1 (naratriptan hydrochloride).
ATC — N02CC02.
ATC Vet — QN02CC02.



(naratriptan)

Pharmacopoeias. In *US.*

USP 31 (Naratriptan Hydrochloride). A white to pale yellow solid. Soluble in water. Store in airtight containers at a temperature not exceeding 30°.

The symbol † denotes a preparation no longer actively marketed

Adverse Effects and Precautions

As for Sumatriptan, p.625.

Naratriptan should not be used in patients with severe hepatic or renal impairment (creatinine clearance less than 15 mL/minute) and should be used with caution in mild or moderate renal or hepatic impairment. Patients with hypersensitivity to sulfonamides may theoretically exhibit a similar reaction to naratriptan.

Medication-overuse headache. For a report of an association between naratriptan and medication-overuse headache, see under Adverse Effects of Sumatriptan, p.626.

Interactions

As for Sumatriptan, p.626.

Pharmacokinetics

After oral doses, peak plasma-naratriptan concentrations occur at 2 to 3 hours, and bioavailability is reported to be 63% in men and 74% in women. Plasma protein binding is about 29%. Naratriptan undergoes some hepatic metabolism by a wide range of cytochrome P450 isoenzymes. It is mainly excreted in the urine with 50% of a dose being recovered as unchanged drug and 30% as inactive metabolites. The elimination half-life is 6 hours, and is significantly prolonged in patients with renal or hepatic impairment.

Distribution into milk has been found in studies in *rats*.

Uses and Administration

Naratriptan is a selective serotonin (5-HT_1) agonist with actions and uses similar to those of sumatriptan (p.627). It is used for the acute treatment of the headache phase of migraine attacks. It should not be used for prophylaxis. It is given orally as the hydrochloride, and doses are expressed in terms of the base; naratriptan hydrochloride 1.11 mg is equivalent to about 1 mg of naratriptan.

The recommended dose of naratriptan in the UK is 2.5 mg, and in the USA it is 1 or 2.5 mg. If no response is obtained with the initial dose, a second dose should not be taken for the same attack. If symptoms recur after an initial response, the dose may be repeated after an interval of 4 hours, to a maximum of 5 mg in any 24-hour period. For doses in hepatic or renal impairment see below.

Administration in hepatic or renal impairment. Naratriptan is contra-indicated in patients with severe hepatic or severe renal impairment (creatinine clearance less than 15 mL/minute). In patients with mild to moderate hepatic or renal impairment, the recommended maximum dose in 24 hours is 2.5 mg and a lower starting dose should be considered.

Migraine. For comparison of the relative benefits of different triptans in migraine, see under Sumatriptan, p.627.

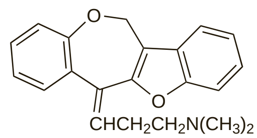
Oxetorone Fumarate *(USAN, rINNM)*

Fumarato de oxetorona; L-6257; Oxétorone, Fumarate d'; Oxetoroni Fumaras. 3-(6,12-Dihydrobenzofuro[3,2-*c*][1]benzoxepin-6-ylidene)-*NN*-dimethylpropylamine hydrogen fumarate.

Оксеторона Фумарат

$C_{21}H_{21}NO_2,C_4H_4O_4$ = 435.5.
CAS — 26020-55-3 (oxetorone); 34522-46-8 (oxetorone fumarate).
ATC — N02CX06.
ATC Vet — QN02CX06.



(oxetorone)

Profile

Oxetorone fumarate is an antihistamine and serotonin antagonist used orally in the treatment of migraine (p.616) and cluster headache (p.616) in doses of up to 180 mg daily. Oxetorone was reported to have induced hyperplastic changes in breast tissue and the uterine endometrium of *rodents*.

ATC Vet — QN02CX01.

Pharmacopoeias. In *Br.*

BP 2008 (Pizotifen Malate). A white or slightly yellowish-white, odourless or almost odourless, crystalline powder. Very slightly soluble in water; slightly soluble in alcohol and in chloroform; sparingly soluble in methyl alcohol. Protect from light.

Adverse Effects and Precautions

As for the sedating antihistamines in general, see p.561.

Increased appetite and weight gain may occur with pizotifen. Drowsiness may be troublesome.

Incidence of adverse effects. Adverse effects were noted in 22 of 47 patients with severe migraine given pizotifen 1 to 2 mg daily.[1] These reactions included weight increase (15), muscle pain or cramps (3), heavy or restless legs (3), fluid retention (3), drowsiness (2), more frequent milder headaches (2), facial flushing (1), reduced libido (1), exacerbation of epilepsy (1), and dreaming (2). Adverse effects necessitating withdrawal occurred in 11 patients.

1. Peet KMS. Use of pizotifen in severe migraine: a long-term study. *Curr Med Res Opin* 1977; **5:** 192–9.

Interactions

As for the sedating antihistamines in general, see p.563.

Antihypertensives. After a report[1] of loss of blood pressure control when treatment with pizotifen was started in a patient receiving *debrisoquine* the manufacturer suggested that since pizotifen had a similar chemical structure to the tricyclic antidepressants it might antagonise the actions of adrenergic neurone blockers in a similar manner.

1. Bailey RR. Antagonism of debrisoquine sulphate by pizotifen (Sandomigran). *N Z Med J* 1976; **1:** 449.

Pharmacokinetics

Pizotifen is well absorbed from the gastrointestinal tract, peak plasma concentrations occurring about 5 hours after a single oral dose. Over 90% is bound to plasma proteins. Pizotifen undergoes extensive metabolism. Over half of a dose is excreted in the urine, chiefly as metabolites; a significant proportion is excreted in the faeces. The primary metabolite of pizotifen (*N*-glucuronide conjugate) has a long elimination half-life of about 23 hours.

Distribution into milk has been found in *animal* studies.

Uses and Administration

Pizotifen is a sedating antihistamine (p.561) that has strong serotonin antagonist and weak antimuscarinic properties. It also antagonises the action of tryptamine. Pizotifen is used, usually as the malate, for the prophylaxis of migraine and for the prevention of headache attacks during cluster periods. It is not effective in treating an acute attack. Doses of pizotifen malate are expressed in terms of the base; pizotifen malate 1.45 mg is equivalent to about 1 mg of pizotifen.

The usual adult oral dose is 1.5 mg daily either in three divided doses or as a single dose at night; children aged over 2 years may also be given up to 1.5 mg daily, although the maximum single dose (at night) should not exceed 1 mg. Gradual increase from an initial dose of 500 micrograms may help to avoid undue drowsiness. Doses in adults may vary from 500 micrograms up to a maximum of 4.5 mg daily; not more than 3 mg should be given as a single dose.

Pizotifen hydrochloride has also been used in the management of migraine.

Abdominal migraine. Abdominal migraine is a recurrent disorder seen mainly in children and characterised by episodic midline abdominal pain lasting for up to 72 hours. The pain is severe enough to disrupt normal activities and may be associated with pallor, anorexia, nausea, and vomiting.[1,2] Sleep, and sometimes vomiting, terminate the attack.

Pizotifen was found to be effective for the prophylaxis of abdominal pain in children with abdominal migraine.[3] Prophylactic treatment with propranolol or cyproheptadine may also be of benefit.[4]

4. Worawattanakul M, *et al.* Abdominal migraine: prophylactic treatment and follow-up. *J Pediatr Gastroenterol Nutr* 1999; **28:** 37–40.

Migraine and cluster headache. Pizotifen has been widely used for the prophylaxis of migraine (p.616) but evidence for its efficacy is limited. It has also been tried in the management of cluster headache (p.616) to prevent headache attacks during a cluster period.

Rizatriptan Benzoate *(BANM, USAN, pINNM)*

Benzoato de rizatriptán; MK-0462; MK-462; Rizatriptan, Benzoate de; Rizatriptani Benzoas. 3-[2-(Dimethylamino)ethyl]-5-(1*H*-1,2,4-triazol-1-ylmethyl)indole monobenzoate; Dimethyl{2-[5-(1*H*-1,2,4-triazol-1-ylmethyl)indol-3-yl]ethyl}amine monobenzoate.

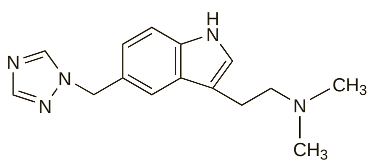
Ризатриптана Бензоат

$C_{15}H_{19}N_5,C_7H_6O_2$ = 391.5.

CAS — 144034-80-0 (rizatriptan); 145202-66-0 (rizatriptan benzoate).

ATC — N02CC04.

ATC Vet — QN02CC04.



(rizatriptan)

Adverse Effects and Precautions

As for Sumatriptan, p.625. Toxic epidermal necrolysis has also been reported with rizatriptan.

Rizatriptan should not be used in patients with severe hepatic or renal impairment and should be given with caution to patients with mild or moderate hepatic or renal impairment.

Interactions

As for Sumatriptan, p.626.

Propranolol increases plasma-rizatriptan concentrations and it is recommended that lower doses of rizatriptan should be used in patients receiving both drugs (see Uses and Administration, below).

Pharmacokinetics

After oral doses, peak plasma-rizatriptan concentrations are obtained in about 1 to 1.5 hours or 1.6 to 2.5 hours depending on the formulation. Bioavailability is about 40 to 45%. Food may delay the time to peak plasma concentrations of the tablet formulation by about 1 hour. Plasma protein binding is low (14%).

Rizatriptan is metabolised primarily by monoamine oxidase type A to the inactive indole acetic acid derivative. The active metabolite *N*-monodesmethyl-rizatriptan is formed to a minor degree; other minor metabolites are also produced. About 14% of an oral dose is excreted in the urine as unchanged rizatriptan, 51% as the indole acetic acid metabolite, and 1% as *N*-monodesmethyl-rizatriptan. The plasma half-life is about 2 to 3 hours.

Distribution into milk has been found in studies in *rats*.

Uses and Administration

Rizatriptan is a selective serotonin (5-HT_1) agonist with actions and uses similar to those of sumatriptan (p.627). It is used for the acute treatment of the headache phase of migraine attacks. It should not be used for prophylaxis. Rizatriptan is given as the benzoate, and doses are expressed in terms of the base; rizatriptan benzoate 14.53 mg is equivalent to about 10 mg of rizatriptan.

The usual dose in the UK of rizatriptan is 10 mg orally. If this is ineffective, a second dose should not be taken for the same attack. If symptoms recur after an initial response, a further dose of 10 mg may be taken after an interval of at least 2 hours. In the USA a dose of 5 or 10 mg is used. The recommended maximum dose in 24 hours is 20 mg in the UK and 30 mg in the USA. A reduced dose of 5 mg is recommended in patients also receiving propranolol, with the maximum dose in 24 hours reduced to 10 mg in the UK and 15 mg in the USA. It is also recommended that doses of the 2 drugs should be separated by at least 2 hours. For doses in hepatic or renal impairment, see below.

Administration in hepatic or renal impairment. In patients with mild to moderate hepatic or renal impairment, the dose of rizatriptan should be reduced to 5 mg. If the headache recurs following an initial response, a further dose of 5 mg may be taken after an interval of at least 2 hours. The recommended maximum dose in 24 hours in these patients is 10 mg in the UK. Rizatriptan should not be used in patients with severe hepatic or renal impairment.

Migraine. For comparison of the relative benefits of different triptans in migraine, see under Sumatriptan, p.627.

Adverse Effects

The most commonly reported adverse effects of serotonin (5-HT_1) agonists such as sumatriptan include dizziness, flushing, weakness, drowsiness, and fatigue. Nausea and vomiting may occur. Dyspnoea and sensory disturbance including paraesthesia and hypoaesthesia have been reported. Pain or sensations of heaviness, heat or cold, pressure, or tightness have also been commonly reported, can affect any part of the body including the throat and chest, and may be intense. These symptoms may be due to vasospasm, which on rare occasions has resulted in severe cardiovascular events including cardiac arrhythmias, myocardial ischaemia, or myocardial infarction. There have been isolated reports of associated cerebrovascular events in patients receiving sumatriptan. Transient increases in blood pressure may occur soon after treatment. Hypotension, bradycardia or tachycardia, palpitations, Raynaud's syndrome, and ischaemic colitis have been reported. Visual disturbances have also occurred.

Medication-overuse headache has been reported with sumatriptan and may necessitate withdrawal of the drug. Sumatriptan has occasionally been associated with minor disturbances in liver function. There have also been rare reports of seizures with sumatriptan. Hypersensitivity reactions ranging from skin rashes to, more rarely, anaphylaxis have occurred.

Transient pain at the injection site is common after subcutaneous sumatriptan injections; stinging, burning, erythema, bruising, and bleeding have also been reported. Irritation of the nasal mucosa and throat and epistaxis have been reported after intranasal use.

Incidence of adverse effects. In a Dutch postmarketing survey[1] completed by 1187 patients the most common adverse reactions attributed to sumatriptan were paraesthesia (reported by 11.7% of patients), dizziness (8.1%), feeling of heaviness (8.0%), chest pain (7.9%), nausea and/or vomiting (7.3%), drowsiness/sedation (7.0%), flushing (5.1%), fatigue (4.6%), pressure in throat (3.3%), headache (3.1%), injection site reaction (3.0%), palpitations (2.8%), abdominal pain (2.6%), muscle pain (2.4%), and dyspnoea (2.2%).

The safety and tolerability of the triptans have been reviewed.[2]

1. Ottervanger JP, *et al.* Adverse reactions attributed to sumatriptan: a postmarketing study in general practice. *Eur J Clin Pharmacol* 1994; **47:** 305–9.
2. Nappi G, *et al.* Tolerability of the triptans: clinical implications. *Drug Safety* 2003; **26:** 93–107.

Effects on the cardiovascular system. About 10 months after sumatriptan injection had been made available commercially, the UK CSM noted that it had received 34 reports of pain or tightness in the chest and 2 reports of myocardial ischaemia.[1] The Netherlands Centre for Monitoring of Adverse Reactions to Drugs declared about the same time that it had received 12 reports of chest or anginal pain mostly associated with oral sumatriptan.[2] A later postmarketing survey based on data from Dutch general practitioners identified chest pain in 1.3% of 1727 patients,[3] a figure considered to be lower than that seen in earlier studies, but in a subsequent questionnaire completed by 1187 of these patients 7.9% reported chest pain.[4] The Australian Adverse Drug Reactions Advisory Committee (ADRAC)[5] stated in December 1994 that it had received 114 reports of chest pain since sumatriptan had been marketed in mid 1992. Most patients had recovered quickly but 2 had died. The first developed a fatal myocardial infarction after coronary artery dissection but the causal relation with sumatriptan was unclear. The second patient who had hypertrophic obstructive cardiomyopathy developed ventricular fibrillation a few hours after the onset of chest pain and this led to fatal cardiac arrest.

One group of workers[6] who studied the effect of sumatriptan 16 mg given subcutaneously suggested that the symptoms of chest pain might be due to an effect of sumatriptan on oesophageal function, but others have argued against this suggestion.[7] ADRAC[5] considered that the reaction in the 28 reports of throat tightness they had received by December 1994 was a different reaction to that of chest pain, and probably resulted from changes in oesophageal motility.

Several reports have provided details of individual cases of the adverse cardiovascular effects of sumatriptan including arrhythmias (ventricular tachycardia,[8] ventricular fibrillation,[8,9] or atrial fibrillation[10]), acute myocardial infarction,[11-15] and unstable an-

The symbol † denotes a preparation no longer actively marketed

gina.[16] Most of these reports concerned subcutaneous sumatriptan, but myocardial infarction occurred in 1 case,[13] and fatal cardiac arrhythmia in another,[9] after oral use. Acute myocardial infarction[11] and cardiac arrhythmias[9] have been reported in patients with no predisposing factors.

A review[17] of published reports on chest pain as well as relevant data held by the UK manufacturer considered that the risk of myocardial ischaemia following vasoconstriction induced by sumatriptan was small. However, the contra-indications and cautions given under Precautions, below, should be observed. A recent study[18] of over 63 500 migraine patients in the UK General Practice Research Database failed to find an increased risk of cardiovascular death in those patients treated with serotonin agonists.

18. Hall GC, *et al.* Triptans in migraine: the risks of stroke, cardiovascular disease, and death in practice. *Neurology* 2004; **62:** 563–8.

Effects on the cerebrovascular system. Adverse cerebrovascular effects have been reported after the use of subcutaneous sumatriptan including hemiparesis,[1] stroke,[2,3] and intracerebral haemorrhage.[4] Cerebral vasospasm has also been reported[5] with the use of oral sumatriptan. However, a study[6] of over 63 500 migraine patients in the UK General Practice Research Database failed to find an increased risk of stroke in those patients treated with serotonin agonists.

6. Hall GC, *et al.* Triptans in migraine: the risks of stroke, cardiovascular disease, and death in practice. *Neurology* 2004; **62:** 563–8.

Effects on the gastrointestinal tract. Ischaemic colitis and mesenteric ischaemia have been reported in a few patients receiving sumatriptan,[1-3] including repeated episodes in 2 patients,[2] each within hours of a dose; some of these episodes were associated with doses above the recommended daily maximum.[2]

Oesophageal constriction or throat tightness has been reported in some patients taking sumatriptan and may be due to a direct effect on the oesophagus (see Effects on the Cardiovascular System, above).

3. Naik M, *et al.* Sumatriptan-associated ischemic colitis. *Dig Dis Sci* 2002; **47:** 2015–16.

Effects on the respiratory system. See Asthma under Precautions, below.

Hypersensitivity. Reactions to sumatriptan such as skin rashes and, more rarely, anaphylaxis have been noted by the manufacturer. Published reports include angioedema occurring in a patient 5 minutes after subcutaneous sumatriptan,[1] and urticaria occurring 20 to 24 hours after oral or subcutaneous sumatriptan in another patient.[2]

1. Dachs R, Vitillo J. Angioedema associated with sumatriptan administration. *Am J Med* 1995; **99:** 684–5.
2. Pradalier A, *et al.* Delayed urticaria with sumatriptan. *Cephalalgia* 1996; **16:** 280–1.

Medication-overuse headache. Sumatriptan may have a similar risk of misuse to that associated with analgesics and ergotamine compounds in patients with medication-overuse headache (p.616). There have been reports[1-3] of patients using one or more daily doses of sumatriptan to control migraine. Many of the patients had a history of abuse of other antimigraine drugs and were using sumatriptan to prevent recurrence of headache. Whether misuse of sumatriptan was due to addiction or rebound headache as seen with ergotamine, is unknown. A postmarketing study in 952 patients receiving sumatriptan found that 36 of the patients (4%) used sumatriptan daily or more than 10 times each week. This overuse was related to poor efficacy and not to rebound headache.[4] One study[5] and an anecdotal report[6] suggest that, rather than producing euphoria or other effects associated with drugs of abuse such as morphine, sumatriptan is more likely to be associated with dysphoria and apathetic sedation.

The development of medication-overuse headache has also been reported with naratriptan and zolmitriptan.[7]

Precautions

Sumatriptan and other serotonin ($5-HT_1$) agonists should only be used where there is a clear diagnosis of migraine or cluster headache and care should be taken to exclude other potentially serious neurological conditions. They should not be used for prophylaxis and should not be given to patients with basilar, hemiplegic, or ophthalmoplegic migraine.

Serotonin ($5-HT_1$) agonists are contra-indicated in patients with uncontrolled hypertension, ischaemic heart disease (coronary artery disease), a history of myocardial infarction, coronary vasospasm (Prinzmetal's angina), peripheral vascular disease, or a previous cerebrovascular accident or transient ischaemic attack. Unrecognised cardiovascular disease should be excluded before the use of serotonin ($5-HT_1$) agonists in postmenopausal women, men over 40 years of age, and those with risk factors for ischaemic heart disease. If chest pain and tightness occur during use, appropriate investigations should be performed. Sumatriptan should not be used intravenously because of the increased risk of producing coronary vasospasm.

Drowsiness may occur after treatment with serotonin ($5-HT_1$) agonists and patients thus affected should not drive or operate machinery.

Sumatriptan should be used with caution in patients with hepatic or renal impairment, and should generally be avoided if impairment is severe.

There have been rare reports of seizures after use of sumatriptan and it should therefore be used with caution in patients with a history of epilepsy or other conditions predisposing to seizures. Patients with hypersensitivity to sulfonamides may exhibit a similar reaction to sumatriptan.

Asthma. The manufacturers reviewed data from more than 75 clinical studies of sumatriptan involving 12 701 patients and reported[1] that the incidence of adverse events related to asthma did not differ between patients with or without the condition. Earlier there had been concern over the safety of sumatriptan in patients with asthma after 2 reports of bronchospasm and a report of a patient with asthma who died during a study of sumatriptan although the patient had not received sumatriptan in the month before her death.

1. Lloyd DK, Pilgrim AJ. The safety of sumatriptan in asthmatic migraineurs. *Cephalalgia* 1993; **13:** 201–4.

Breast feeding. No adverse effects have been observed in breast-feeding infants whose mothers were receiving sumatriptan, and the American Academy of Pediatrics considers that it is therefore usually compatible with breast feeding.[1] However, the manufacturers have suggested that infant exposure can be minimised by avoiding breast feeding for 12 hours after treatment.

The distribution of sumatriptan into breast milk after a 6-mg subcutaneous dose has been studied in 5 lactating mothers.[2] The mean total recovery of sumatriptan in breast milk was estimated to be 14.4 micrograms or 0.24% of the dose. It was calculated that on a weight-adjusted basis an infant could receive a maximum of 3.5% of the maternal dose.

2. Wojnar-Horton RE, *et al.* Distribution and excretion of sumatriptan in human milk. *Br J Clin Pharmacol* 1996; **41:** 217–21.

Cerebrovascular disorders. A patient with a superior sagittal sinus thrombosis who presented with headache and was misdiagnosed as having migraine variant developed a cortical stroke within minutes of a second 6-mg subcutaneous injection of sumatriptan.[1] The importance of establishing a diagnosis of typical migraine or cluster headache before using sumatriptan was emphasised and caution given against its use in any patient who may have unstable cerebrovascular disease or raised intracranial pressure. Additionally, there was no clinical evidence that a second injection would relieve a headache when the initial injection had been ineffective.

1. Cavazos J, *et al.* Sumatriptan-induced stroke in sagittal sinus thrombosis. *Lancet* 1994; **343:** 1105–6.

Pregnancy. Sumatriptan crosses the placenta; however, only a very small quantity reaches the fetus. A literature review concluded that exposure to sumatriptan in pregnancy posed no additional risk of birth defects compared with that in the general population,[1] but as for other drugs sumatriptan should only be used in pregnancy when the benefit justifies the potential risk to the fetus.

1. Hilaire ML, *et al.* Treatment of migraine headaches with sumatriptan in pregnancy. *Ann Pharmacother* 2004; **38:** 1726–30.

Interactions

Sumatriptan and other serotonin ($5-HT_1$) agonists should not be given with ergotamine or related compounds (including methysergide) since there is an increased risk of vasospastic reactions. In addition, a delay is advised before starting a serotonin ($5-HT_1$) agonist in patients who have been receiving ergotamine or related compounds: sumatriptan, almotriptan, eletriptan, frovatriptan, rizatriptan, or zolmitriptan should not be given until at least 24 hours after stopping the use of preparations containing ergotamine. Conversely, ergotamine should not be given until 6 hours after stopping these drugs or at least 24 hours in the case of eletriptan and frovatriptan. Serotonin ($5-HT_1$) agonists should not be given together.

Sumatriptan or rizatriptan should not be used with, and for 2 weeks after stopping, an MAOI. Use with the selective monoamine oxidase type B inhibitor selegiline is thought unlikely to provoke an interaction, but see p.817. Opinion varies on the concomitant use of zolmitriptan and inhibitors of monoamine oxidase type A such as moclobemide. In the UK licensed product information recommends that the maximum dose of zolmitriptan should be reduced when used with inhibitors of monoamine oxidase type A whereas in the USA it contra-indicates such combinations. There have been rare reports of serotonin syndrome associated with the use of triptan serotonin ($5-HT_1$) agonists with SSRIs or serotonin and noradrenaline reuptake inhibitors (SNRIs), but see also under Antidepressants, below.

◊ Oral sumatriptan appeared to delay gastric emptying and might affect the absorption of other drugs, as judged by its delaying effect on paracetamol absorption in migraine patients.[1]

1. Rani PU, *et al.* Sumatriptan delays paracetamol absorption in migraine patients. *Clin Drug Invest* 1996; **11:** 300–304.

Antidepressants. Sumatriptan and rizatriptan are metabolised mainly by monoamine oxidase type A and licensed product information advises that patients taking *MAOIs*, including reversible selective type A inhibitors such as moclobemide, should not be given triptan serotonin ($5-HT_1$) agonists. Clearance of zolmitriptan was decreased after moclobemide and in the UK a reduced dose of zolmitriptan is advised if the drug is used with an inhibitor of monoamine oxidase type A; in the USA, the use of these drugs together is contra-indicated. *SSRIs* such as fluoxetine may also interact with serotonin ($5-HT_1$) agonists with an increased risk of serotonin syndrome (p.416), and it has been suggested that *lithium* and sumatriptan may interact similarly. However, a review of the use of sumatriptan with MAOIs, SSRIs, or lithium found little evidence of an increased risk of serotonin syndrome.[1] It was concluded that most patients tolerate the combination of sumatriptan and an SSRI or lithium without incident. However, it was suggested that the use of sumatriptan with an MAOI should continue to be avoided until further data supporting safety becomes available. As there have since been rare reports of serotonin syndrome associated with the use of triptans with SSRIs or *serotonin and noradrenaline reuptake inhibitors (SNRIs)*, licensed product information for the triptans states that when such use is clinically warranted, appropriate observation of the patient is advised, particularly when starting treatment, with dose increases, or with addition of another serotonergic drug. Product information for zolmitriptan also advises a reduction in dosage if it is given with fluvoxamine as the latter may inhibit zolmitriptan metabolism through its effects on the cytochrome P450 isoenzyme CYP1A2.

Increased serotonergic effects with increased incidence of adverse effects have been reported following the use of *St John's wort* with triptans.[2] Patients should be advised to stop taking St John's wort if treatment with a serotonin ($5-HT_1$) agonist is necessary.

1. Gardner DM, Lynd LD. Sumatriptan contraindications and the serotonin syndrome. *Ann Pharmacother* 1998; **32:** 33–8.
2. CSM/MCA. Reminder: St John's wort (Hypericum perforatum) interactions. *Current Problems* 2000; **26:** 6–7. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON007462&RevisionSelectionMethod=LatestReleased (accessed 16/06/06)

Antimigraine drugs. Although the efficacy and tolerability of subcutaneous sumatriptan in the acute treatment of migraine did not appear to be affected in patients already taking *dihydroergotamine* orally for migraine prophylaxis,[1] the bioavailability of oral dihydroergotamine is low and it could not be assumed that it was safe to use parenteral dihydroergotamine with sumatriptan.[2] Licensed product information for sumatriptan contra-indicates its use with *ergotamine* or other related compounds and also recommend that it should not be given until at least 24 hours after stopping ergotamine or related compounds (see Interactions, above).

Acute myocardial infarction has been reported[3] in a premenopausal woman with controlled hypertension and no known coronary artery disease after subcutaneous use of sumatriptan within a few hours of taking *methysergide* by mouth.

Antipsychotics. For reference to a potential interaction between sumatriptan and *loxapine*, see Chlorpromazine, p.974.

Pharmacokinetics

Sumatriptan is rapidly but incompletely absorbed when given orally and undergoes first-pass metabolism, resulting in a low absolute bioavailability of about 14%. Peak plasma concentrations after oral doses are achieved in about 2 hours. Bioavailability is much higher (96%) after subcutaneous doses with peak concentrations occurring within 25 minutes. Bioavailability after intranasal doses is 16% of that achieved subcutaneously, with peak concentrations occurring in about 1.5 hours. Plasma protein binding is low at about 14 to 21%.

The elimination half-life of sumatriptan is about 2 hours. Sumatriptan is extensively metabolised in the liver predominantly by monoamine oxidase type A and is excreted mainly in the urine as the inactive indole acetic acid derivative and its glucuronide. Sumatriptan and its metabolites also appear in the faeces. Small amounts of sumatriptan are distributed into breast milk (see Breast Feeding, above).

Uses and Administration

Sumatriptan is a selective serotonin agonist that acts at $5-HT_1$ receptors and produces vasoconstriction of cranial arteries. Drugs like sumatriptan, which are commonly known as triptans, are believed to act mainly at $5-HT_{1B}$ and $5-HT_{1D}$ subtype receptors and are therefore sometimes referred to as $5HT_{1B/1D}$-receptor agonists.

Sumatriptan is used for the acute treatment of migraine attacks and of cluster headache. It should not be used for prophylaxis. It may be given orally or subcutaneously as the succinate and intranasally as the base. Doses are expressed in terms of the base; sumatriptan succinate 70 mg is equivalent to about 50 mg of sumatriptan.

For the acute treatment of **migraine** sumatriptan should be used as soon as possible after the onset of the headache phase, but efficacy is independent of the duration of the attack before starting treatment. If no response is obtained with the initial dose by any route, a second dose should not be given for the same attack.

- It is given *orally* to adults aged 18 years and over; the recommended dose in the UK is 50 mg, although some patients may require 100 mg. A clinical response can be expected after about 30 minutes. If symptoms recur after an initial response, further doses may be given provided that there is a minimum interval of 2 hours between doses and that not more than 300 mg is taken in any 24-hour period. In the USA a lower dose of 25 mg may be used, although some patients require 50 or 100 mg. This may be followed by a second dose of up to 100 mg if the headache returns or the patient has a partial response provided that the total daily dose does not exceed the recommended maximum of 200 mg. A minimum interval of 2 hours is recommended between doses. For oral doses in children and hepatic impairment, see below.
- When used *intranasally* a clinical response can be expected in 15 minutes. In the UK, patients aged 18 years and over may be given a single dose of 20 mg into one nostril, although 10 mg may be effective in some patients. In the USA, a dose of 5, 10, or 20 mg may be used. If symptoms recur, a second dose may be given at least 2 hours after the first dose. Not more than 40 mg should be used in a 24-hour period. For intranasal doses in adolescents, see below.
- In patients aged 18 years and over sumatriptan may be self-administered by *subcutaneous injection* in a single dose of 6 mg; a clinical response may be expected after 10 to 15 minutes. If symptoms recur, a second dose of 6 mg may be injected at least one hour after the first dose; not more than 12 mg should be given in a 24-hour period. In the USA, it may also be used in single doses of 4 mg if adverse effects are dose-limiting.

For the acute treatment of **cluster headache,** sumatriptan succinate is given by subcutaneous injection in similar doses to those used for migraine.

Administration in children. Sumatriptan may be given for the treatment of acute migraine in children and adolescents. Although not licensed for oral paediatric use in the UK, the *BNFC* suggests that a single *oral* dose of 25 mg may be given to children aged 6 to 10 years and 50 mg to those aged 10 to 12 years, repeated once after at least 2 hours if symptoms recur after an initial response; older children may be given the usual adult dose (see above).

In the UK, *intranasal* sumatriptan is licensed for use in adolescents aged 12 to 17 years in a dose of 10 mg into one nostril; the dose may be repeated after at least 2 hours if symptoms recur within 24 hours although not more than 20 mg should be used within a 24-hour period. The *BNFC* suggests that either this dose or an unlicensed dose equivalent to the usual adult dose (see above) may be used in those aged 12 years and over.

If no response is obtained with the initial dose by any route, a second dose should not be given for the same attack.

Administration in hepatic impairment. Sumatriptan should be used with caution in patients with hepatic impairment. A dose of up to 50 mg by mouth is considered suitable. It should not be given to patients with severe impairment.

High-altitude disorders. Sumatriptan has been tried with some success in a small study[1] for the prevention of symptoms of acute mountain sickness (p.1168).

1. Jafarian S, *et al.* Sumatriptan for prevention of acute mountain sickness: randomized clinical trial. *Ann Neurol* 2007; **62:** 273–7.

Migraine and cluster headache. The use of sumatriptan and other triptans in the treatment of cluster headache (p.616) and migraine (p.616) has been reviewed.[1-8]

In **migraine** serotonin ($5-HT_1$) agonists are preferred to ergotamine for the treatment of acute attacks unresponsive to non-opioid analgesics.

There are several *different triptans* clinically available. In a meta-analysis of 53 trials (involving 24 089 patients) and a separate analysis of all direct comparative trials of 5 of the triptans and sumatriptan, all were found to be more effective than placebo.[5] At the marketed doses, all oral triptans (almotriptan, eletriptan, naratriptan, rizatriptan, sumatriptan, and zolmitriptan) were effective and well tolerated. Almotriptan, eletriptan, or rizatriptan were considered to provide the highest likelihood of consistent success. A review of the efficacy of the 5 triptans available in the USA also showed pain relief at 2 hours was comparable for all.[6] Almotriptan 12.5 mg offered high tolerability and good efficacy; eletriptan 80 mg provided high efficacy and low recurrence; and rizatriptan 10 mg was associated with consistent and rapid freedom from pain.[5] Frovatriptan was not included in the analyses, but publicly available data suggested lower efficacy. Only sumatriptan, though, has parenteral formulations and the 6-mg subcutaneous formulation is still the fastest and most effective acute treatment.[5]

About 21 to 57% of patients who initially respond to sumatriptan have a *recurrence* of their headache within 24 to 48 hours; this may be related in part to its short half-life. Such recurrences usually respond to a second dose[9,10] but if a first dose is ineffective subsequent doses for the same attack are of no benefit and should not be given. Sumatriptan is considered[11] to be effective when given at any time once the headache phase of migraine has started but giving it during migraine aura appears to be of little benefit since it does not affect the aura or prevent or delay the development of headache.[12] Repeated or long-term use does not appear to be associated with reduced efficacy.[13,14] For reports of an association between sumatriptan and medication-overuse headache, see under Adverse Effects, above.

Sumatriptan's effectiveness appears to be maintained in *menstrual migraine*, a condition which is considered to be less responsive to treatment than nonmenstrual migraine.[15] Frovatriptan,[16] rizatriptan,[17] and zolmitriptan[18] have also been found to be effective in menstrual migraine.

Experience of subcutaneous use in *children* has been reported.[19] Results of a randomised, placebo-controlled study[20] of intranasal sumatriptan in adolescents aged 12 to 17 years showed evidence of efficacy, tolerability, and safety in this age group; it was felt that the nasal spray might be particularly well suited for adolescent use. Intranasal sumatriptan has also been tried in younger children (aged 8 years and over) with some success.[21]

Subcutaneous sumatriptan has also been shown to be effective in relieving acute attacks of headache in patients with **cluster headache**. In studies about 75% of patients have obtained relief within 15 minutes of a 6-mg subcutaneous injection;[22,23] the use of higher doses was found to be of no advantage. Long term efficacy appears to be maintained[24] but the significance of the transient increase in the frequency of attacks seen in some patients remains to be determined.[25] It does not appear to be effective for the prevention of headache during cluster periods.[26] Another triptan found to be effective in the treatment of episodic cluster headache is zolmitriptan.[27]

Zolmitriptan *(BAN, USAN, rINN)*

311C90; Tsolmitriptaani; Zolmitriptán; Zolmitriptanum. (*S*)-4-{3-[2-(Dimethylamino)ethyl]indol-5-ylmethyl}-1,3-oxazolidin-2-one.

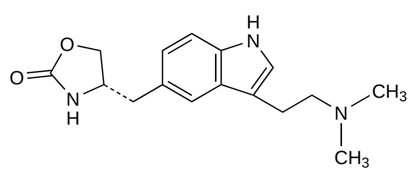
Золмитриптан

$C_{16}H_{21}N_3O_2$ = 287.4.

CAS — 139264-17-8.

ATC — N02CC03.

ATC Vet — QN02CC03.



Adverse Effects and Precautions

As for Sumatriptan, p.625.

Zolmitriptan should also be avoided in patients with Wolff-Parkinson-White syndrome or arrhythmias associated with accessory cardiac conduction pathways. It should be given with caution in patients with moderate to severe hepatic impairment.

Ischaemia. A spinal cord lesion related to the use of zolmitriptan has been reported in a 50-year-old woman;[1] clinical features suggested that the lesion was an ischaemic infarct.

1. Vijayan N, Peacock JH. Spinal cord infarction during use of zolmitriptan: a case report. *Headache* 2000; **40:** 57–60.

Medication-overuse headache. For a report of an association between zolmitriptan and medication-overuse headache, see under Adverse Effects of Sumatriptan, p.626.

Interactions

As for Sumatriptan, p.626.

It is recommended that the maximum dose of zolmitriptan in 24 hours should be reduced in patients receiving cimetidine (see Uses and Administration, below). A similar reduction in zolmitriptan dosage is anticipated if it is given with drugs, such as fluvoxamine and ciprofloxacin, that inhibit the cytochrome P450 isoenzyme CYP1A2. Opinion varies on the use of zolmitriptan with inhibitors of monoamine oxidase type A such as moclobemide. In the UK licensed product information recommends that the maximum dose of zolmitriptan should be reduced when used with inhibitors of monoamine oxidase type A (see Uses and Administration, below), whereas in the USA such combinations are contra-indicated.

Beta blockers. *Propranolol* increased plasma-zolmitriptan concentrations in a study in 12 healthy subjects, but the changes were not thought to be clinically important enough to warrant dosage adjustment during concomitant use.[1]

1. Peck RW, *et al.* The interaction between propranolol and the novel antimigraine agent zolmitriptan (311C90). *Br J Clin Pharmacol* 1997; **44:** 595–9.

Pharmacokinetics

The absolute bioavailability of zolmitriptan after oral and intranasal doses is about 40%, and peak plasma concentrations are achieved in about 1.5 to 3 hours after oral doses, depending on the formulation, and in about 3 hours with the intranasal spray. Plasma protein binding is about 25%. Zolmitriptan undergoes hepatic metabolism, principally to the indole acetic acid, and also the *N*-oxide and *N*-desmethyl analogues. The *N*-desmethyl metabolite (183C91) was more active than the parent compound in *animal* studies, and would be expected to contribute to the therapeutic effect of zolmitriptan. The primary metabolism of zolmitriptan is mediated mainly by the cytochrome P450 isoenzyme CYP1A2 while monoamine oxidase type A is responsible for further metabolism of the *N*-desmethyl metabolite. Over 60% of a dose is excreted in the urine, mainly as the indole acetic acid, and about 30% appears in the faeces, mainly as unchanged drug. The elimination half-life is 2.5 to 3 hours, and is prolonged in patients with liver disease.

Distribution into milk has been found in studies in *rats*.

Uses and Administration

Zolmitriptan is a selective serotonin ($5\text{-}HT_1$) agonist with actions and uses similar to those of sumatriptan (p.627). It is used for the acute treatment of migraine attacks. Zolmitriptan should not be used for prophylaxis.

The recommended dose in the UK is 2.5 mg orally. A clinical response can be expected within 1 hour. If symptoms persist or return within 24 hours, a second dose may be taken not less than 2 hours after the first dose. If a patient does not achieve satisfactory relief with a dose of 2.5 mg, subsequent attacks may be treated with doses of 5 mg. The maximum dose of zolmitriptan in 24 hours is 10 mg. Recommended doses in the USA are somewhat lower; the dose is 1.25 or 2.5 mg with a maximum dose of 10 mg in 24 hours.

When used intranasally a clinical response can be expected in 15 minutes. The usual dose is 5 mg as a single dose into one nostril. If symptoms persist or return within 24 hours, a second dose may be given after at least 2 hours, up to a maximum of 10 mg daily.

Dose reductions are recommended in patients taking certain other drugs. The maximum dose of zolmitriptan in 24 hours should be 5 mg in those receiving cimetidine or an inhibitor of monoamine oxidase type A (although use with inhibitors of monoamine oxidase type A is contra-indicated in the USA). A similar reduction is also recommended in those taking drugs, such as fluvoxamine and ciprofloxacin, that inhibit the cytochrome P450 isoenzyme CYP1A2.

For dosage in hepatic or renal impairment see below.

Administration in hepatic impairment. A study[1] has indicated that while there is no need to reduce the size of the initial dose of zolmitriptan in patients with moderate or severe hepatic impairment, accumulation may occur with repeated doses in patients with severe impairment and their total daily dosage should be reduced.

A maximum oral dose of 5 mg in 24 hours is recommended by licensed product information in the UK in patients with moderate to severe impairment. A dose of less than 2.5 mg is recommended in the USA.

1. Dixon R, *et al.* Effect of hepatic impairment on the pharmacokinetics of zolmitriptan. *J Clin Pharmacol* 1998; **38:** 694–701.

Administration in renal impairment. Although renal clearance of zolmitriptan and its metabolites was reduced in patients with moderate to severe impairment,[1] the resulting effect was unlikely to be of clinical importance and adjustment of zolmitriptan dosage in patients with renal impairment was considered unnecessary.

Antimyasthenics

This chapter includes those drugs used for their anticholinesterase action in the treatment of myasthenia gravis and related neuromuscular disorders. Other groups of drugs playing an important role in the management of myasthenia are the corticosteroids (p.1490) and some drugs with immunosuppressant actions discussed in the chapters on Antineoplastics (p.635) and Immunosuppressants (p.1810).

Eaton-Lambert myasthenic syndrome

Eaton-Lambert myasthenic syndrome is a rare auto-immune disease of the neuromuscular junction. Unlike myasthenia gravis (below), in which autoantibodies affect acetylcholine receptors, antibodies in Eaton-Lambert syndrome act presynaptically to reduce release of acetylcholine. Weakness mostly affects the proximal muscles, particularly those of the limbs; respiratory and ocular muscles are usually spared. Autonomic symptoms including dry mouth, constipation, and impotence are common. Over half of patients also have small cell carcinoma of the lung. Successful treatment of the tumour often leads to some improvement in symptoms.

The symptomatic treatment of Eaton-Lambert syndrome involves the use of drugs that increase the availability of acetylcholine at the neuromuscular junction. Response to treatment with *anticholinesterases* alone is poor and treatment with *amifampridine*, which increases acetylcholine release, appears to be more effective, particularly when given with an anticholinesterase such as *pyridostigmine*. The use of similar drugs such as *guanidine* and *fampridine* is limited by severe adverse effects. Low-dose guanidine has been tried with pyridostigmine where amifampridine is not readily available. Although there has been some improvement with the combination, the incidence of adverse effects, especially gastrointestinal reactions, is still high. Immunosuppressants including *azathioprine* and *corticosteroids* are also used, and unlike in treatment for myasthenia gravis, corticosteroids do not appear to induce an initial exacerbation of symptoms. Plasma exchange or high-dose intravenous *normal immunoglobulin* have been tried in patients with severe weakness.

Myasthenia gravis

Myasthenia gravis is an auto-immune disorder characterised by defective neuromuscular transmission and consequent muscular weakness. It is caused by the formation of autoantibodies to elements of the neuromuscular junction. In most patients, antibodies to the nicotinic acetylcholine receptor are present. However, about 10 to 15% of patients have so-called 'seronegative myasthenia', in whom antibodies to other elements such as muscle-specific tyrosine kinase (MuSK) may be present instead; the proportion of such patients is much higher among those with ocular myasthenia (disease confined to the extra-ocular muscles). The thymus appears to be involved in many patients and some have a thymoma. Classifications of the disease may be based on the distribution and severity of symptoms, on the age of onset, and on the presence or absence of thymoma. Other types of myasthenia include transient neonatal myasthenia due to transplacental passage of receptor antibodies, which may persist for 1 to 6 weeks in the infants of myasthenic mothers, penicillamine-induced myasthenia, and congenital myasthenia (see under Amifampridine, p.630).

Diagnosis of myasthenia gravis.

Antibody testing remains the gold standard for diagnosis of myasthenia gravis. Patients may often be tested first for their reaction to an anticholinesterase. Intravenous edrophonium preceded by atropine (Tensilon test) is the most commonly used anticholinesterase test because of its rapid onset and short duration of action. Severe adverse effects can occasionally occur so testing should only be undertaken when facilities for endotracheal intubation and controlled ventilation are immediately available. A positive result is considered to be a rapid but temporary increase in muscle strength. Repetitive nerve stimulation is also used as a diagnostic test but, like the anticholinesterase test, is not specific for myasthenia gravis. Computed tomography or magnetic resonance imaging may be used to detect thymoma.

Treatment of myasthenia gravis.

- Symptomatic treatment is with an *anticholinesterase*; pyridostigmine and neostigmine are those most commonly used. Most patients prefer pyridostigmine as it produces less muscarinic adverse effects and has a longer duration of action, although the quicker onset of action of neostigmine may offer an advantage at the beginning of the day. The dose must be adjusted to give the optimum therapeutic response but muscle strength may not be restored to normal and some patients must live with a degree of disability. The effect may vary for different muscles and the dosage should be adjusted so that the bulbar and respiratory muscles receive optimum treatment. Generally, anticholinesterases only provide partial remission and their effects tend to diminish with continued treatment. Overdosage may lead to a 'cholinergic crisis' (see Adverse Effects of Neostigmine, p.631). Edrophonium may be employed to establish whether the patient is underdosed or overdosed.
- *Corticosteroids* are the main immunosuppressive drugs used for treatment. They are also useful in patients with ocular myasthenia, who as a group respond poorly to anticholinesterases and to thymectomy, provided that their disability is severe enough to warrant long-term corticosteroid treatment with its attendant adverse effects. Many start with low doses such as 5 to 20 mg of prednisolone daily or on alternate days, to reduce the risk of steroid-induced exacerbations of weakness, and increase the dose slowly thereafter according to response; an improvement is usually seen after a few weeks. Others use more aggressive regimens to obtain a more rapid response and start with large doses such as 60 to 80 mg of prednisolone daily. Whichever method is used, once clinical benefit has been obtained the regimen should be modified to alternate-day dosage, with the dose being slowly tapered when the patient is in remission. Patients taking corticosteroids require less anticholinesterase therapy and, if the dosage of the anticholinesterase is not reduced, an initial deterioration in the myasthenia may occur in the first few weeks of treatment (see also under Interactions of Neostigmine, p.632). It is rarely possible to withdraw corticosteroids completely but some patients may be maintained satisfactorily on as little as 10 mg on alternate days. If remission cannot be maintained on low-dose prednisolone, addition of azathioprine at a dosage of 2 to 3 mg/kg daily may be considered.
- Addition of *azathioprine* to treatment may allow a reduction in the dose of both corticosteroids and anticholinesterases. Azathioprine may also be of use when corticosteroids are contra-indicated or when response to corticosteroids alone is insufficient, but it has a much slower onset of action than corticosteroids and is not usually used alone. *Ciclosporin* is effective in some patients unresponsive to standard combinations but serious adverse effects including nephrotoxicity may limit its use; the time to response is similar to that with corticosteroids. Other drugs such as *cyclophosphamide* and *methotrexate* have also been tried and benefit has been reported with *mycophenolate mofetil* and *tacrolimus*. However, a recent systematic review has found that only a small number of randomised controlled studies have been conducted on the use of immunosuppressive drugs for myasthenia gravis and most have been short-term. The review of this limited evidence concluded that, apart from cyclophosphamide used alone or ciclosporin used alone or with corticosteroids, there was no clear evidence of benefit from use of other immunosuppressants.
- Plasma exchange provides a dramatic but short-lived improvement and is useful as a short-term measure in myasthenic crisis to improve ill patients while other therapies take effect, but there is no evidence that repeated plasma exchange combined with immunosuppression is superior to immunosuppression alone. A similar short-term benefit has been seen from the use of high-dose intravenous *normal immunoglobulins*; however, a systematic review considered further study to be warranted.
- Thymectomy may be offered to all patients sufficiently fit to undergo surgery unless they have minimal symptoms, purely ocular disease, or late onset or seronegative disease. Thymectomy is usually avoided in prepubertal children because of concern over the effect on growth and the developing immune system; it has been suggested that symptomatic treatment with anticholinesterases should be continued until adolescence, when the disease often improves spontaneously. After thymectomy, remission or improvement may be expected in about 80% of patients without thymomas, although this may take some years; the response is poorer in those with thymomas.

Ambenonium Chloride *(BAN, rINN)*

Ambenonii Chloridum; Ambénonium, Chlorure d'; Ambenoniumklorid; Ambenoniumkloridi; Ambestigmini Chloridum; Cloruro de ambenonio; Win-8077. *N,N'*-Oxalylbis(*N*-2-aminoethyl-*N*-2-chlorobenzyldiethylammonium) dichloride.

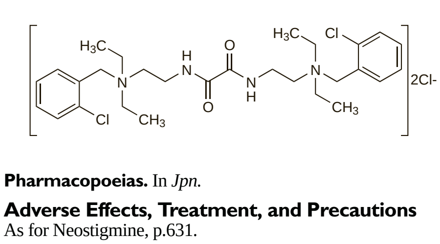
Амбенония Хлорид

$C_{28}H_{42}Cl_4N_4O_2$ = 608.5.

CAS — 7648-98-8 (ambenonium); 115-79-7 (anhydrous ambenonium chloride); 52022-31-8 (ambenonium chloride tetrahydrate).

ATC — N07AA30.

ATC Vet — QN07AA30.



Pharmacopoeias. In *Jpn.*

Adverse Effects, Treatment, and Precautions

As for Neostigmine, p.631.

Ambenonium produces fewer muscarinic adverse effects than neostigmine. As there is only slight warning of overdosage, routine use of atropine with ambenonium is contra-indicated because the muscarinic symptoms of overdosage may be suppressed leaving only the more serious nicotinic effects (fasciculation and paralysis of voluntary muscle).

Pharmacokinetics

Ambenonium chloride is poorly absorbed from the gastrointestinal tract. It does not appear to be hydrolysed by cholinesterases.

Uses and Administration

Ambenonium is a quaternary ammonium compound that is a reversible inhibitor of cholinesterase activity with actions similar to those of neostigmine (p.632), but of longer duration. Ambenonium chloride is given orally in the treatment of myasthenia gravis (p.629) in usual doses of 5 to 25 mg three or four times daily, adjusted according to response. It may be of value in patients who cannot tolerate neostigmine or pyridostigmine.

Amifampridine *(rINN)*

Amifampridina; Amifampridinum; 3,4-Diaminopyridine. Pyridine-3,4-diamine.

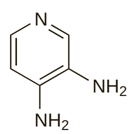
Амифампридин

$C_5H_7N_3$ = 109.1.

CAS — 54-96-6.

ATC — N07XX05.

ATC Vet — QN07XX05.



Profile

Amifampridine has similar actions and uses to fampridine (p.631) but is reported to be more potent in enhancing the release of acetylcholine from nerve terminals. It is used in the Eaton-Lambert myasthenic syndrome (below) and other myasthenic conditions. It has been tried in multiple sclerosis and in botulism. There have been isolated reports of seizures and amifampridine is therefore contra-indicated in patients with epilepsy.

Congenital myasthenia. Congenital or hereditary myasthenia is a heterogeneous group of rare disorders associated with various defects in neuromuscular transmission including presynaptic impairment of acetylcholinesterase release, postsynaptic abnormality of acetylcholine receptors, or a deficiency of acetylcholinesterase.[1] Symptoms may be similar to those of myasthenia gravis (p.629) but there are no immunological abnormalities. Although some forms may respond to anticholinesterases, therapy is usually unsatisfactory. Experience in 16 patients[2] has suggested that amifampridine used alone or with anticholinesterases may be of benefit. Clinical improvement was seen in 5 of 11 patients with congenital myasthenia who were given amifampridine as part of a placebo-controlled study; 3 of the 11 responded to placebo.[3] There have also been reports of benefit from the use of quinidine sulfate in patients with the slow-channel congenital myasthenic syndrome.[4]

1. Engel AG. Congenital myasthenic syndromes. *Neurol Clin North Am* 1994; **12:** 401–37.
2. Palace J, *et al.* 3,4-Diaminopyridine in the treatment of congenital (hereditary) myasthenia. *J Neurol Neurosurg Psychiatry* 1991; **54:** 1069–72.
3. Anlar B, *et al.* 3,4-Diaminopyridine in childhood myasthenia: double-blind, placebo-controlled trial. *J Child Neurol* 1996; **11:** 458–61.
4. Harper CM, Engel AG. Quinidine sulfate therapy for the slow-channel congenital myasthenic syndrome. *Ann Neurol* 1998; **43:** 480–4.

Eaton-Lambert myasthenic syndrome. Daily doses of up to 100 mg of amifampridine by mouth have been found[1] to be effective in the treatment of both the motor and autonomic deficits of patients with Eaton-Lambert syndrome (p.629). A usual starting dose of 10 mg given three or four times daily increasing if necessary to a maximum of 20 mg given five times daily has been used.[2] However, some workers have recommended limiting the dose to 80 mg daily because of the increased risk of seizures with higher doses.[3] Adverse effects appear to be mainly mild and dose related,[1] although there is a report of cardiac arrest following toxicity.[4] Most patients experience some form of paraesthesia up to 60 minutes after a dose.[1-3] Amifampridine can produce mild excitatory effects and some patients may experience difficulty in sleeping.

1. McEvoy KM, *et al.* 3,4-Diaminopyridine in the treatment of Lambert-Eaton myasthenic syndrome. *N Engl J Med* 1989; **321:** 1567–71.

3. Sanders DB, *et al.* A randomized trial of 3,4-diaminopyridine in Lambert-Eaton myasthenic syndrome. *Neurology* 2000; **54:** 603–7.
4. Boerma CE, *et al.* Cardiac arrest following an iatrogenic 3,4-diaminopyridine intoxication in a patient with Lambert-Eaton myasthenic syndrome. *J Toxicol Clin Toxicol* 1995; **33:** 249–51.

Multiple sclerosis. Amifampridine has been tried in the management of multiple sclerosis (p.892). In a crossover study[1] involving 36 patients with multiple sclerosis, amifampridine given in a dosage of up to 100 mg daily improved symptoms of leg weakness to a greater extent than placebo but paraesthesia and abdominal pain which occurred in most patients were dose-limiting in some. A systematic review[2] of the use of aminopyridines for symptomatic management of multiple sclerosis was unable to come to any conclusion, and commented on the problem of publication bias in this area.

Distigmine Bromide *(BAN, rINN)*

BC-51; Bispyridostigmine Bromide; Bromuro de distigmina; Distigmiinibromidi; Distigminbromid; Distigmine, Bromure de; Distigmini Bromidum; Hexamarium Bromide. 3,3′-[*N,N′*-Hexamethylenebis(methylcarbamoyloxy)]bis(1-methylpyridinium bromide).

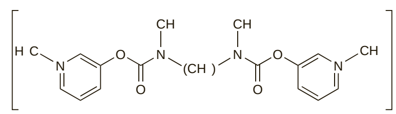
Дистигмина Бромид

$C_{22}H_{32}Br_2N_4O_4$ = 576.3.

CAS — 15876-67-2.

ATC — N07AA03.

ATC Vet — QN07AA03.



Pharmacopoeias. In *Jpn.*

Adverse Effects, Treatment, and Precautions

As for Neostigmine, p.631. The anticholinesterase action of distigmine, and hence its adverse effects, may be prolonged, and if treatment with atropine is required it should be maintained for at least 24 hours. Distigmine may stimulate uterine contractions and UK licensed product information has advised that it should be avoided in pregnancy.

Interactions

As for Neostigmine, p.632.

Pharmacokinetics

Distigmine is poorly absorbed from the gastrointestinal tract.

Uses and Administration

Distigmine is a quaternary ammonium compound that is a reversible inhibitor of cholinesterase activity with actions similar to those of neostigmine (p.632) but more prolonged. Maximum inhibition of plasma cholinesterase occurs 9 hours after a single intramuscular dose, and persists for about 24 hours.

Although it is rarely used, distigmine bromide may be given orally with short-acting parasympathomimetics for the treatment of **myasthenia gravis** (p.629); patients being treated with parasympathomimetics tend to prefer pyridostigmine. The initial dose is 5 mg daily before breakfast, increased at intervals of 3 to 4 days if necessary to a maximum of 20 mg daily; children may be given up to 10 mg daily according to age.

Distigmine is one of several drugs that have been used in the prevention and treatment of **postoperative gastrointestinal atony** (see Decreased Gastrointestinal Motility, p.1694). It has also been used in **postoperative urinary retention** (p.2180), although it has been superseded by catheterisation. A dose of 500 micrograms of distigmine bromide was injected intramuscularly about 24 to 72 hours after surgery and repeated at intervals of 1 to 3 days until normal function was restored. Alternatively it has been given orally in a dose of 5 mg daily thirty minutes before breakfast. A similar oral dose, given daily or on alternate days, has been used in the management of **neurogenic bladder**.

Preparations

Proprietary Preparations (details are given in Part 3)

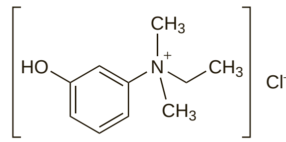
Edrophonium Chloride *(BAN, rINN)*

Cloruro de edrofonio; Edrofonio chloridas; Edrofonium-chlorid; Edrofoniumklorid; Edrofoniumkloridi; Edrofonyum Klorür; Edrophonii chloridum; Édrophonium, chlorure d'. Ethyl(3-hydroxyphenyl)dimethylammonium chloride.

Эдрофония Хлорид

$C_{10}H_{16}ClNO$ = 201.7.

CAS — 312-48-1 (edrophonium); 116-38-1 (edrophonium chloride).



Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Edrophonium Chloride). A white or almost white crystalline powder. Very soluble in water; freely soluble in alcohol; practically insoluble in dichloromethane. A 10% solution in water has a pH of 4.0 to 5.0. Protect from light.

USP 31 (Edrophonium Chloride). A white odourless crystalline powder. Soluble 1 in 0.5 of water and 1 in 5 of alcohol; insoluble in chloroform and in ether. A 10% solution in water is practically colourless and the pH is between 4.0 and 5.0.

Adverse Effects, Treatment, and Precautions

As for Neostigmine, p.631.

Interactions

As for Neostigmine, p.632.

Uses and Administration

Edrophonium is a quaternary ammonium compound that is a reversible inhibitor of cholinesterase activity. It has actions similar to those of neostigmine (p.632) but its effect on skeletal muscle is claimed to be particularly prominent. It has a rapid onset but short duration of action. In patients with myasthenia gravis, there is immediate subjective improvement and muscle strength increases. This effect usually lasts only for about 5 to 15 minutes, after which time the typical signs and symptoms return; because of its brief action the drug is not suitable for the routine treatment of myasthenia gravis.

Edrophonium chloride is used in **myasthenia gravis** (p.629) both diagnostically and to distinguish between under- or over-treatment with other anticholinesterases.

- The usual *diagnostic procedure* is to inject 2 mg intravenously and, if no adverse reaction occurs within 30 to 45 seconds, to continue with the injection of a further 8 mg. In the UK the recommended total dose for children is 100 micrograms/kg, one-fifth of the dose being given initially, followed 30 seconds later by the remainder if no adverse effects develop; the *BNFC* suggests that this dose may be given to those aged from 1 month to 12 years. In the USA a total dose of 5 mg for children weighing less than 34 kg and 10 mg for heavier children is recommended, with one-fifth of the dose being given initially followed by increments of 1 mg every 30 to 45 seconds; the recommended total dose for infants is 500 micrograms.

  When intravenous injection is difficult edrophonium chloride may be given by intramuscular injection; the usual dose in adults is 10 mg while children below 34 kg in weight may be given 2 mg and heavier children 5 mg; a suggested dose for infants is 0.5 to 1 mg given intramuscularly or subcutaneously. Atropine should always be available when the test is carried out in order to treat any severe muscarinic reactions that may occur.
- To *detect under- or over-treatment*, test doses of 1 to 2 mg of edrophonium chloride are given intravenously to distinguish severe symptoms of myasthenia gravis due to inadequate therapy from the effects of overdosage with anticholinesterase drugs. If treat-

ment has been inadequate, edrophonium chloride will produce an immediate amelioration of symptoms, whereas in cholinergic crises due to over-treatment the symptoms will be temporarily aggravated. In the UK, the *BNFC* recommends that edrophonium chloride may be used in children aged from 1 month to 12 years to detect under- or over-treatment in a dose of 20 micrograms/kg. Licensed product information suggests testing one hour after the last dose of treatment but the *BNF* and the *BNFC* recommend testing just before the next dose is due. Testing should only be undertaken when facilities for endotracheal intubation and controlled ventilation are immediately available.

Edrophonium chloride was originally introduced for the **reversal of neuromuscular blockade** in anaesthesia. In the UK, the recommended dose in adults and children for the reversal of the effects of competitive neuromuscular blockers is 500 to 700 micrograms/kg given by intravenous injection over several minutes either with or after atropine sulfate 7 micrograms/kg; the *BNFC* suggests that this dose may be given to children as young as 1 month of age. In the USA, a dose of 10 mg of edrophonium chloride is given over 30 to 45 seconds and repeated as required up to a maximum of 40 mg. The brevity of its action limits its value. Prolonged apnoea may occur in patients treated with a depolarising neuromuscular blocker, such as suxamethonium; to determine if this is caused by a phase II block (see p.1912), edrophonium chloride 10 mg may be given intravenously with atropine.

Edrophonium bromide has been used similarly to edrophonium chloride.

Reversal of neuromuscular blockade. For a discussion of whether edrophonium might be more suitable than neostigmine for reversal of residual block after the use of the shorter-acting competitive neuromuscular blockers, see under Uses and Administration of Neostigmine, p.633.

Snake bite. For the use of anticholinesterases in the treatment of snake bite, see under Uses and Administration of Neostigmine, p.633.

Tetrodotoxin poisoning. Management of poisoning due to tetrodotoxin, a heat stable neuromuscular blocking toxin found in various marine animals, such as puffer fish, is mainly symptomatic and supportive. Reports[1,2] on the effectiveness of intravenous anticholinesterases such as edrophonium or neostigmine in reversing muscle weakness in tetrodotoxin poisoning have been conflicting. Although it appears that anticholinesterases may only be effective during partial block produced by tetrodotoxin, some consider[3] that, as there is no specific antidote, any measure that brings about improvement may be tried.

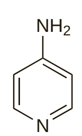
Fampridine *(USAN, rINN)*

EL-970; Fampridina; Fampridinum. 4-Aminopyridine; 4-Pyridinamine.

Фампридин

$C_5H_6N_2$ = 94.11.
CAS — 504-24-5.



Profile

Fampridine enhances the release of acetylcholine from nerve terminals and has been used intravenously to reverse the effects of competitive neuromuscular blockers. It has also been tried orally and intravenously in the management of neurological disorders such as Eaton-Lambert myasthenic syndrome (p.629), Guillain-Barré syndrome (p.2228), multiple sclerosis (p.892), spinal cord injury, and Alzheimer's disease (see Dementia, p.362), and for the reversal of neuromuscular blockade in patients with botulism (p.2207). Typical oral doses appear to be around 30 to 50 mg daily.

Fampridine has also been considered as a specific antidote in poisoning with calcium-channel blockers (see Overdosage under Treatment of Adverse Effects of Nifedipine, p.1352).

Adverse effects seen in clinical trials include insomnia, seizures, paraesthesia, dizziness, and nausea; these effects, especially seizures, may limit its use.

Multiple sclerosis. Fampridine has potassium-channel blocking activity and has been tried in the treatment of multiple sclerosis to improve conduction in demyelinated fibres. Improvements have been reported in walking, dexterity, and vision, but only small numbers of patients have been studied. A systematic review[1] was unable to come to a conclusion about its safety and efficacy, noting that publication bias posed a problem in this area.

Overdosage. An 8-month-old boy experienced dramatic opisthotonic posturing and vermiform tongue fasciculations after ingestion of up to 20 mg of fampridine;[1] the child was also noted to be tachycardic and tachypnoeic. His symptoms resolved after treatment with benzodiazepines.

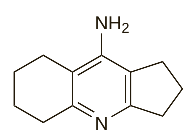
Ipidacrine *(rINN)*

Amiridin (base or hydrochloride); Ipidacrina; Ipidacrinum; NIK-247 (hydrochloride). 9-Amino-2,3,5,6,7,8-hexahydro-1*H*-cyclopenta[*b*]quinoline.

Ипидакрин

$C_{12}H_{16}N_2$ = 188.3.
CAS — 62732-44-9 (ipidacrine); 90043-86-0 (ipidacrine hydrochloride); 118499-70-0 (ipidacrine hydrochloride monohydrate).



Profile

Ipidacrine, an analogue of tacrine (p.370), is a cholinesterase inhibitor. It is used in the management of various neurological disorders including CNS and peripheral nervous system disorders, demyelinating disease, myasthenia gravis (p.629) and other myasthenic syndromes, Alzheimer's disease (see Dementia, p.362), and gastrointestinal atony. For myasthenic syndromes an oral dose of 20 to 40 mg has been given up to 5 times daily. A usual dosage in Alzheimer's disease is 10 to 20 mg given 2 or 3 times daily but this may be increased gradually up to 200 mg daily given in divided doses.

Ipidacrine has also been given by injection as the hydrochloride.

Preparations

Proprietary Preparations (details are given in Part 3)
Rus.: Axamon (Аксамон).

Neostigmine *(BAN)*

Neostigmiini; Neostigmin; Neostigmina; Neostigminum. 3-(Dimethylcarbamoyloxy)trimethylanilinium ion.

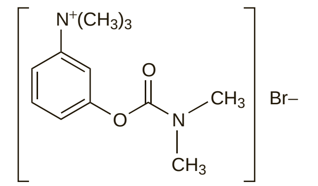
$C_{12}H_{19}N_2O_2$ = 223.3.
CAS — 59-99-4.
ATC — N07AA01; S01EB06.
ATC Vet — QA03AB93; QN07AA01; QS01EB06.

Neostigmine Bromide *(BANM, pINN)*

Bromuro de neostigmina; Neostig. Brom.; Neostigmiinibromidi; Neostigminbromid; Néostigmine, bromure de; Neostigmini bromidum; Neostigminii Bromidum; Neostigminium-bromid; Neostigmino bromidas; Neostigminum Bromatum; Neosztigmin-bromid; Synstigminium Bromatum.

Неостигмина Бромид

$C_{12}H_{19}BrN_2O_2$ = 303.2.
CAS — 114-80-7.
ATC — N07AA01; S01EB06.
ATC Vet — QN07AA01; QS01EB06.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Neostigmine Bromide). Hygroscopic, colourless crystals or a white or almost white, crystalline powder. Very soluble in water; freely soluble in alcohol. Protect from light.

USP 31 (Neostigmine Bromide). Store in airtight containers.

Neostigmine Metilsulfate *(BANM)*

Neostig. Methylsulph.; Neostigmiinimetilsulfaatti; Neostigmina, metilsulfato de; Neostigmine Methylsulfate; Neostigmine Methylsulphate; Néostigmine, métilsulfate de; Neostigmini metilsulfas; Neostigminii Metilsulfas; Neostigminium-methylsulfát; Neostigminmetilsulfat; Neostigminmetylsulfat; Neostigmino metilsulfatas; Neostygminy metylosiarczan; Neosztigmin-metilszulfát; Proserinum.

$C_{13}H_{22}N_2O_6S$ = 334.4.
CAS — 51-60-5.
ATC — N07AA01; S01EB06.
ATC Vet — QN07AA01; QS01EB06.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Neostigmine Metilsulfate). Hygroscopic, colourless crystals or a white or almost white, crystalline powder. Very soluble in water; freely soluble in alcohol. Store in airtight containers. Protect from light.

USP 31 (Neostigmine Methylsulfate). Store in airtight containers.

Adverse Effects

The adverse effects of neostigmine are chiefly due to excessive cholinergic stimulation and most commonly include increased salivation, nausea and vomiting, abdominal cramps, and diarrhoea. Allergic reactions have been reported; rashes have been associated with the use of the bromide salt. Neostigmine penetrates the blood-brain barrier poorly and CNS effects are usually only seen with high doses.

Overdosage may lead to a 'cholinergic crisis', characterised by both muscarinic and nicotinic effects. These effects may include excessive sweating, lachrymation, increased peristalsis, involuntary defaecation and urination or desire to urinate, miosis, ciliary spasm, nystagmus, bradycardia and other arrhythmias, hypotension, muscle cramps, fasciculations, weakness and paralysis, tight chest, wheezing, and increased bronchial secretion combined with bronchoconstriction. CNS effects include ataxia, convulsions, coma, slurred speech, restlessness, agitation, and fear. Death may result from respiratory failure, due to a combination of the muscarinic, nicotinic, and central effects, or cardiac arrest.

It has been reported that a paradoxical increase in blood pressure and heart rate may result from nicotinic stimulation of sympathetic ganglia, especially where atropine has been given to reverse the muscarinic effects (see Treatment of Adverse Effects, below).

In patients with myasthenia gravis, in whom other symptoms of overdosage may be mild or absent, the major symptom of cholinergic crisis is increased muscular weakness, which must be differentiated from the muscular weakness caused by an exacerbation of the disease itself (myasthenic crisis).

The adverse effects of parasympathomimetics applied topically for their miotic action are discussed under Pilocarpine on p.1885.

Treatment of Adverse Effects

If a life-threatening amount of neostigmine has been taken by mouth and the patient presents within 1 hour, the stomach may be emptied by lavage; giving activated charcoal to decrease absorption should also be considered. When necessary maintenance of respiration should take priority. Atropine sulfate should be given in usual doses of 1 to 2 mg, preferably intravenously, or else intramuscularly and repeated as necessary to control the muscarinic effects; doses of up to 4 mg have been suggested. Nicotinic effects, including muscle weakness and paralysis, are not antagonised by atropine; small doses of a competitive neuromuscular blocker have been suggested for the control of muscle twitching. Use of the cholinesterase reactivator pralidoxime as an adjunct to atropine has also been suggested (see p.1460). Further supportive treatment should be given as required.

Precautions

Neostigmine is contra-indicated in patients with mechanical gastrointestinal or urinary-tract obstruction, or peritonitis. It should be used with extreme caution in patients who have undergone recent intestinal or bladder surgery and in patients with bronchial asthma. It should be used with caution in patients with cardiovascular disorders including arrhythmias, bradycardia, recent myocardial infarction, and hypotension, as well as in patients with vagotonia, epilepsy, hyperthyroidism, parkinsonism, renal impairment, or peptic ulcer disease. When neostigmine is given by injection, atropine should always be available to counteract any excessive muscarinic reactions; atropine may also be given before, or with, neostigmine to prevent or minimise muscarinic adverse effects but this may mask the initial symptoms of overdosage and lead to cholinergic crisis.

UK licensed product information states that as the severity of myasthenia gravis often fluctuates considerably during pregnancy, particular care is needed to avoid cholinergic crisis caused by overdosage; it has also been reported that neonatal myasthenia may follow large doses during pregnancy. The amount of neostigmine distributed into breast milk is very small but breast-fed infants need to be monitored.

Large oral doses of neostigmine should be avoided in conditions where there may be increased absorption from the gastrointestinal tract. It should be avoided in patients known to be hypersensitive to neostigmine; the bromide ion from neostigmine bromide may contribute to any allergic reaction.

The precautions of parasympathomimetics applied topically for their miotic action are discussed under Pilocarpine on p.1885.

Neuromuscular disorders. Residual non-depolarising neuromuscular block in a patient with dystrophia myotonica was only partly reversed by neostigmine and atropine, and following a second dose of both drugs complete neuromuscular block developed.[1] In a second patient, with a history of progressive muscle dystrophy, the use of neostigmine to reverse residual non-depolarising blockade gave rise to a tonic response in the indirectly stimulated muscle. The type and degree of the response to neostigmine, and probably other anticholinesterases, cannot be predicted in patients with neuromuscular disease.

A patient with sero-negative ocular myasthenia gravis had exaggerated responses to both vecuronium and neostigmine.[2] The dose of neuromuscular blockers and their antagonists used in patients with myasthenia gravis should be titrated carefully regardless of the severity of the condition.

2. Kim J-M, Mangold J. Sensitivity to both vecuronium and neostigmine in a sero-negative myasthenic patient. *Br J Anaesth* 1989; **63:** 497–500.

Interactions

Drugs with neuromuscular blocking activity, such as the aminoglycosides, clindamycin, colistin, cyclopropane, and the halogenated inhalational anaesthetics, may antagonise the effects of neostigmine. Those such as quinine, chloroquine, hydroxychloroquine, quinidine, procainamide, propafenone, lithium, and the beta blockers, that have the potential to aggravate myasthenia gravis, can reduce the effectiveness of treatment with parasympathomimetics. Prolonged bradycardia has also occurred in patients receiving beta blockers when given neostigmine. Anticholinesterases, such as neostigmine, can inhibit the metabolism of suxamethonium and enhance and prolong its action; combined use is not recommended.

Ophthalmic use of anticholinesterases, such as ecothiopate, should be undertaken with care in patients receiving neostigmine systemically for myasthenia gravis, because of possible additive toxicity.

Antimuscarinics such as atropine antagonise the muscarinic effects of neostigmine.

Beta blockers. There have been several reports of bradycardia and hypotension when neostigmine or physostigmine were given to patients receiving beta blockers[1-4] but no significant changes in heart rate were noted in a study of pyridostigmine given to 8 patients taking beta blockers.[5] Beta blockers have the potential to aggravate the symptoms of myasthenia gravis and may therefore reduce the effectiveness of parasympathomimetic treatment.

1. Sprague DH. Severe bradycardia after neostigmine in a patient taking propranolol to control paroxysmal atrial tachycardia. *Anesthesiology* 1975; **42:** 208–10.

5. Arad M, *et al.* Safety of pyridostigmine in hypertensive patients receiving beta blockers. *Am J Cardiol* 1992; **69:** 518–22.

Calcium-channel blockers. Use of calcium-channel blockers such as *verapamil* with neuromuscular blockers may produce an enhanced muscle block which is resistant to reversal with neostigmine[1] but which can be reversed by edrophonium.[2]

2. Jones RM, *et al.* Verapamil potentiation of neuromuscular blockade: failure of reversal with neostigmine but prompt reversal with edrophonium. *Anesth Analg* 1985; **64:** 1021–5.

Corticosteroids. Although use of glucocorticoids alone may improve strength in myasthenic patients, use of *methylprednisolone* in patients receiving neostigmine or pyridostigmine has exacerbated symptoms and produced profound weakness needing assisted ventilation.[1] Since the adverse effects of combined therapy usually occur before any expected benefits it has been suggested that the glucocorticoid should be given on alternate days in small doses which are increased gradually until the optimal effect is achieved.[2]

2. Jubiz W, Meikle AW. Alterations of glucocorticoid actions by other drugs and disease states. *Drugs* 1979; **18:** 113–21.

Pharmacokinetics

Neostigmine is a quaternary ammonium compound and, as the bromide, is poorly absorbed from the gastrointestinal tract. After parenteral doses as the metilsulfate, neostigmine is rapidly eliminated and is excreted in the urine both as unchanged drug and metabolites. Neostigmine undergoes hydrolysis by cholinesterases and is also metabolised in the liver. Protein binding to human serum albumin is reported to range from 15 to 25%. Penetration into the CNS is poor. Neostigmine crosses the placenta and very small amounts are distributed into breast milk.

◊ Neostigmine appears to be poorly and variably absorbed when given orally. In 3 myasthenic patients peak plasma concentrations were obtained 1 to 2 hours after a single 30-mg dose by mouth and the mean plasma half-life was 0.87 hours; bioavailability was estimated to be 1 to 2%.[1] Mean plasma half-lives of 0.89 and 1.20 hours have been obtained after intravenous[1] and intramuscular[2] injections of neostigmine metilsulfate, respectively, although again only a few patients were studied. Metabolism and biliary excretion may play significant roles in the elimination of neostigmine.[2] About 80% of a dose may be excreted in the urine within 24 hours: about 50% of a dose as unchanged drug and 15% as 3-hydroxyphenyltrimethylammonium.[2] Mean plasma elimination half-lives for neostigmine have been found to be shorter in infants (0.65 hours) and children (0.80 hours) compared with adults (1.12 hours) but this does not appear to be related to its duration of effect in antagonising neuromuscular blockade.[3] For the half-life in anephric patients, see Administration in Renal Impairment, below.

Uses and Administration

Neostigmine is a quaternary ammonium compound that inhibits cholinesterase activity and thus prolongs and intensifies the physiological actions of acetylcholine (p.1877). It probably also has direct effects on skeletal muscle fibres. The anticholinesterase actions of neostigmine are reversible.

Neostigmine is used in the treatment of myasthenia gravis, and has been used as an alternative to edrophonium in the diagnosis of myasthenia gravis (p.629). It is used in anaesthesia to reverse the neuromuscular blockade produced by competitive neuromuscular blockers (see below). It is also used in the management of paralytic ileus. Neostigmine has been used in the management of postoperative urinary retention (p.2180) but has generally been superseded by catheterisation. It has also been used to lower intra-ocular pressure in the management of glaucoma and to reduce rises in intra-ocular pressure associated with ophthalmic surgery, although other parasympathomimetics are usually used when such miotics are required.

Neostigmine is given as the bromide and as the metilsulfate. Neostigmine bromide is given orally and has been used topically as eye drops; the metilsulfate is given by intramuscular, intravenous, or subcutaneous injection.

Licensed product information states that 500 micrograms of neostigmine metilsulfate by intravenous injection is equivalent in effect to about 1 to 1.5 mg of neostigmine metilsulfate by intramuscular or subcutaneous injection, or 15 mg of neostigmine bromide orally.

In the treatment of **myasthenia gravis**, neostigmine bromide is given orally in a total daily dose usually between 75 and 300 mg, divided throughout the day, and if necessary the night, according to response; larger portions of the total dose may be given at times of greater fatigue. The maximum daily dose that most patients can tolerate is 180 mg. A usual total daily oral dose in children is 15 to 90 mg. In patients in whom oral therapy is impractical neostigmine metilsulfate may be given in doses of 0.5 to 2.5 mg by intramuscular or subcutaneous injection at intervals, giving a total daily dose usually in the range 5 to 20 mg. Single doses in children have ranged from 200 to 500 micrograms.

In the treatment of neonatal myasthenia gravis doses in the range 50 to 250 micrograms of the metilsulfate by intramuscular or subcutaneous injection, or 1 to 5 mg of the bromide orally, have been given usually every 4 hours (30 minutes before feeds); treatment is rarely needed beyond 8 weeks of age.

To **reverse neuromuscular blockade** produced by competitive neuromuscular blockers, the usual adult dose in the UK is 50 to 70 micrograms/kg given by intravenous injection over a period of 60 seconds; in the USA lower doses of 0.5 to 2 mg are used. Additional neostigmine may be given until the muscle power is normal but a total of 5 mg should not be exceeded. Similar doses may be used in children; the *BNFC* recommends a dose of 50 to 80 micrograms/kg in neonates and children, to a maximum of 2.5 mg in those under 12 years of age. The patient should be well ventilated until complete recovery of normal respiration is assured. To counteract any muscarinic effects in adults 0.6 to 1.2 mg of atropine sulfate is given by intravenous injection with or before the dose of neostigmine;

neonates and children up to 18 years of age may be given 20 micrograms/kg of atropine sulfate (to a maximum of 600 micrograms in those aged 1 month and over). It has been suggested that in the presence of bradycardia atropine sulfate should be given several minutes before neostigmine. Glycopyrronium bromide has been used as an alternative to atropine sulfate.

In the treatment of paralytic **ileus** and postoperative **urinary retention**, oral doses of 15 to 30 mg of the bromide, or more usually 500 micrograms of the metilsulfate by subcutaneous or intramuscular injection, have been used.

Administration in renal impairment. The dosage of neostigmine may need to be adjusted in patients with renal impairment. The mean serum elimination half-life of 79.8 minutes obtained in patients with normal renal function was found to be prolonged to 181.1 minutes in anephric patients.[1]

1. Cronnelly R, *et al.* Renal function and the pharmacokinetics of neostigmine in anesthetized man. *Anesthesiology* 1979; **51:** 222–6.

Decreased gastrointestinal motility. Parasympathomimetics enhance gastric contractions and increase intestinal motility and have been used in conditions associated with decreased gastrointestinal motility (p.1694). Good results have been reported with intravenous neostigmine in the treatment of acute colonic pseudo-obstruction,[1,2] a condition that appears to be due to parasympathomimetic dysfunction. These results have been confirmed in a randomised double-blind study.[3] It has therefore been suggested that parasympathomimetics should be tried before colonic decompression or surgery when conservative management has failed or a rapid resolution is required.[3] Neostigmine has also been used in the treatment of severe constipation due to disrupted intestinal motility.[4,5]

Local anaesthesia. Intrathecal neostigmine has been added to spinal local anaesthetics or opioids as an adjunct to prolong regional analgesia and improve haemodynamic stability. A systematic review[1] of studies of such use found that although neostigmine in doses up to 500 micrograms produced a very modest increase in analgesia in the perioperative and peripartum setting, it did not appear to improve haemodynamic stability and the incidence of adverse effects was greatly increased, even at low doses. The disadvantages were felt to outweigh whatever benefits such therapy might have.

Reversal of neuromuscular blockade. Anticholinesterases have often been used after surgery to antagonise residual neuromuscular block induced by long-acting competitive neuromuscular blockers. However, there has been continuing debate[1-3] on whether anticholinesterases can be used in reduced doses or even omitted for intermediate-acting blockers such as atracurium and vecuronium and shorter-acting blockers such as mivacurium.

Decreasing the anticholinesterase dose may reduce adverse effects. Although it is not clear whether omitting neostigmine reversal reduces nausea and vomiting,[3,4] it avoids any adverse effects neostigmine may have on gut anastomoses. One commentator[1] considered that the wide variation in recovery time with aminosteroid blockers such as rocuronium was an indication for always using at least a small dose of anticholinesterase when these drugs were used. However, it was suggested that, if the block was being carefully monitored and recovery was established, a reduced dose of 1.25 mg of neostigmine might be preferable after a benzylisoquinolinium blocker such as atracurium or mivacurium. In children, smaller doses of an anticholinesterase could be used, even after an aminosteroid blocker, and after a blocker such as mivacurium, they might not be needed at all.

Others have preferred to reserve neostigmine reversal for cases where it was deemed clinically necessary: in a study[4] using such a protocol, 68% of those receiving rocuronium were given neostigmine, against 10% of those receiving mivacurium.

It has been suggested that because of its shorter duration of action edrophonium might be more suitable than neostigmine to antagonise residual block for neuromuscular blockers with shorter action and in particular, that edrophonium might be more appropriate than neostigmine for use with mivacurium. Neostigmine inhibits the plasma cholinesterase responsible for the metabolism of mivacurium and its use can in theory delay rather than speed recovery, although in practice there is considered to be little evidence for such an effect.[1] Edrophonium also has lesser effects on the vagus, a more rapid onset of action, and may be associated with a lower incidence of nausea and vomiting than neostigmine.[5] Neostigmine can cause clinically significant neuromuscular blockade if it is given to a patient who has already recovered a large degree of neuromuscular function[6,7] but edrophonium appears not to have this effect.[8] However, the antagonism produced by edrophonium is not adequately and reliably sustained especially after profound block.[9,10]

Snake bite. The general management of snake bites is discussed on p.2239. Numerous reports from India have claimed benefit for anticholinesterases in the treatment of neurotoxic snake bites but failure to distinguish between cobra and krait bites, lack of controls, and inadequate information about other therapy weaken the claims.[1] However, edrophonium has been shown in 2 double-blind studies to be more effective than placebo[2] and antivenom[3] in the treatment of snake bite due to the Philippine cobra (*Naja naja philippinensis*). Neostigmine has also been reported[4] to have been effective in reversing paralysis in 2 patients bitten by *Micrurus frontalis* (a coral snake). Similarly, another patient made a remarkable recovery when treated with neostigmine after being bitten by an Asiatic cobra (*Naja naja kaouthia*).[5] Anticholinesterases would be expected to be of little value for bites from snakes whose venom contains neurotoxins which act presynaptically, including the Asian krait, the Australian tiger snake, and the taipan[6] and, although beneficial results have been reported in individual patients,[7] overall results are considered to be inconsistent.[2,8] However, it is recommended that a test dose of edrophonium preceded by atropine should be given to patients with neurological signs after a snake bite by any species and if improvement occurs, a longer acting anticholinesterase such as neostigmine can be given.[2,3]

Pyridostigmine Bromide *(BAN, rINN)*

Bromuro de piridostigmina; Piridostigmin Bromür; Piridostigmino bromidas; Piridosztigmin-bromid; Pyridostig. Brom.; Pyridostigmiinibromidi; Pyridostigminbromid; Pyridostigmine, bromure de; Pyridostigmini bromidum; Pyridostigminii Bromidum; Pyridostigminium-bromid. 3-Dimethylcarbamoyloxy-1-methylpyridinium bromide.

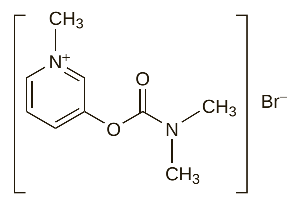
Пиридостигмина Бромид

$C_9H_{13}BrN_2O_2 = 261.1.$

CAS — 155-97-5 (pyridostigmine); 101-26-8 (pyridostigmine bromide).

ATC — N07AA02.

ATC Vet — QN07AA02.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Pyridostigmine Bromide). A white or almost white deliquescent crystalline powder. Very soluble in water and in alcohol. Store in airtight containers. Protect from light.

USP 31 (Pyridostigmine Bromide). A white or practically white, hygroscopic, crystalline powder, having an agreeable characteristic odour. Freely soluble in water, in alcohol, and in chloroform; practically insoluble in ether; slightly soluble in petroleum spirit. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Neostigmine, p.631. It has been stated that muscarinic adverse effects occur less frequently with pyridostigmine treatment than with neostigmine.

Breast feeding. Pyridostigmine was present in the breast milk of 2 nursing mothers, receiving maintenance therapy for myasthenia gravis, in a concentration between 36 and 113% of that in maternal plasma,[1] but in both cases the dose ingested per kg body-weight by the nursing infant was 0.1% or less of that ingested by the mother. Maternal medication with pyridostigmine should be no obstacle to breast feeding, at least with doses in the range of 180 to 300 mg daily.

On the basis of this study, the American Academy of Pediatrics considers[2] that pyridostigmine is usually compatible with breast feeding.

1. Hardell L-I, *et al.* Pyridostigmine in human breast milk. *Br J Clin Pharmacol* 1982; **14:** 565–7.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 15/02/06)

Effects on the joints. Several years after starting oral pyridostigmine bromide 60 mg five times daily, a middle-aged woman had episodes of bilateral arthralgia and hyperalgesia of her hips, knees, toes, and shoulders.[1] Symptoms resolved when pyridostigmine was stopped and rechallenge was positive on several occasions.

1. Rostedt A, Stålberg E. Joint pain and hyperalgesia due to pyridostigmine bromide in a patient with myasthenia gravis. *Neurology* 2004; **62:** 835–6.

Psychosis. Postoperative psychosis in a patient with myasthenia gravis who received large doses of pyridostigmine bromide was attributed to bromide intoxication,[1] but this diagnosis has been challenged.[2]

1. Rothenberg DM, *et al.* Bromide intoxication secondary to pyridostigmine bromide therapy. *JAMA* 1990; **263:** 1121–2.
2. Senecal P-E, Osterloh J. Confusion from pyridostigmine bromide: was there bromide intoxication? *JAMA* 1990; **264:** 454–5.

Renal impairment. During use of pyridostigmine for the reversal of neuromuscular blockade produced by competitive neuromuscular blockers, pyridostigmine kinetics were not significantly different after renal transplantation in 5 patients compared with those in 5 patients with normal renal function. However, in 4 anephric patients the elimination half-life was significantly increased and the plasma clearance significantly decreased.[1] It appeared that about 75% of the plasma clearance of pyridostigmine depended on renal function.

1. Cronnelly R, *et al.* Pyridostigmine kinetics with and without renal function. *Clin Pharmacol Ther* 1980; **28:** 78–81.

Interactions

As for Neostigmine, p.632.

Pharmacokinetics

Pyridostigmine bromide is poorly absorbed from the gastrointestinal tract. It undergoes hydrolysis by cholinesterases and is also metabolised in the liver. Pyridostigmine is excreted mainly in the urine as unchanged drug and metabolites. Pyridostigmine crosses the placenta and very small amounts are distributed into breast milk (see Breast Feeding, above). Penetration into the CNS is poor.

◊ It has been suggested[1] that data from pharmacokinetic studies of pyridostigmine might have varied because of the analytical methods used or inappropriate storage conditions of plasma samples; it was recommended that samples should be acidified and stored at −75°. Mean terminal elimination half-life was 200 minutes in 11 healthy subjects given 60 mg of pyridostigmine by mouth; maximum plasma concentrations were obtained 1 to 5 hours after dosing. The mean terminal elimination half-life after a 4-mg intravenous infusion in 10 of these subjects was 97 minutes.[1] Oral bioavailability was calculated to vary from 11.5 to 18.9%. In an earlier study food did not appear to affect bioavailability but did delay the time taken to achieve peak plasma concentrations.[2] It appears that 75% of the plasma clearance of pyridostigmine depends on renal function.[3] 3-Hydroxy-*N*-methylpyridinium has been identified as one of the 3 metabolites isolated from the urine of patients taking pyridostigmine.[4]

Uses and Administration

Pyridostigmine is a quaternary ammonium compound that is a reversible inhibitor of cholinesterase activity with actions similar to those of neostigmine (p.632), but is slower in onset and of longer duration. It is given as the bromide.

Pyridostigmine is mainly used in the treatment of myasthenia gravis (p.629) although its use in neonatal myasthenia has declined in favour of neostigmine. It has also been used in the treatment of paralytic ileus. Pyridostigmine is sometimes used to reverse the neuromuscular blockade produced by competitive neuromuscular blockers but is generally considered less satisfactory than neostigmine. It has also been used as prophylaxis against the neuromuscular effects of nerve gas poisoning (below). Pyridostigmine has been used in the management of postoperative urinary retention (p.2180) but has generally been superseded by catheterisation.

For **myasthenia gravis**, total daily oral doses in the UK may range from 300 mg to 1.2 g; however, the *BNF* states that daily doses of 450 mg should not be exceeded in order to avoid receptor downregulation. It also notes that patients receiving pyridostigmine in doses over 360 mg daily may need more aggressive therapy. In the USA, licensed doses are somewhat higher, ranging up to 1.5 g daily.

The dose should be divided throughout the day and, if necessary, the night, according to response; larger portions of the total daily dose may be given at times of greater fatigue.

A suggested oral dose in the USA for children is 7 mg/kg daily in 5 or 6 divided doses. An alternative regimen used in the UK is an initial dose of 30 mg for children under 6 years or 60 mg for those aged 6 to 12 years. This is increased gradually by increments of 15 to 30 mg daily until a satisfactory response is obtained, which is usually within the dosage range of 30 to 360 mg daily.

Pyridostigmine has also been given as modified-release tablets, usually once or twice daily but these offer less flexibility of dosage. If necessary it has also been given by intramuscular injection or in severe cases by very slow intravenous injection. However, the intravenous route is hazardous and, if used, atropine must be available to counteract any severe muscarinic reactions.

In the treatment of neonatal myasthenia doses in the range of 50 to 150 micrograms/kg by intramuscular injection or 5 to 10 mg orally (30 to 60 minutes before feeds) have been given every 4 to 6 hours. Alternatively, oral doses may be based on neonatal weight: in the UK, the *BNFC* recommends an initial dose of 1 to 1.5 mg/kg, increased gradually to a maximum of 10 mg and repeated throughout the day. Treatment is rarely needed beyond 8 weeks of age.

To **reverse neuromuscular blockade** produced by *competitive neuromuscular blockers*, doses of 10 to 20 mg have been given intravenously, with or preceded by atropine sulfate 0.6 to 1.2 mg to counteract any muscarinic effects. Glycopyrronium bromide has been used as an alternative to atropine.

In the USA pyridostigmine is licensed for prophylaxis against the neuromuscular effects of the nerve gas poison *soman* in military combat use only; the recommended oral dose is 30 mg every 8 hours started at least several hours before exposure to soman. If nerve gas poisoning occurs, pyridostigmine should be stopped and the patient should be treated with atropine and pralidoxime immediately.

In the treatment of paralytic **ileus** and postoperative **urinary retention** pyridostigmine bromide has been given in oral doses of 60 to 240 mg.

Decreased gastrointestinal motility. Parasympathomimetics such as pyridostigmine enhance gastric contractions and increase intestinal motility; they have been used in conditions associated with decreased gastrointestinal motility (p.1694).

Pyridostigmine, generally in doses of 60 mg up to 3 times daily, has been used to relieve severe constipation in patients with impaired intestinal motility due to Parkinson's disease.[1]

1. Sadjadpour K. Pyridostigmine bromide and constipation in Parkinson's disease. *JAMA* 1983; **249:** 1148.

Growth hormone deficiency. Although the value of stimulated growth hormone secretion tests in children has been questioned (see Growth Retardation, p.1798), pyridostigmine with somatorelin has been found to be a potent and reproducible test for distinguishing adults with severe growth hormone deficiency from normal subjects.[1] However, the combination is not effective in patients over 55 years of age,[2] and somatorelin with arginine is generally preferred where an alternative to the gold standard of the insulin-tolerance test is required.[1]

2. Vierhapper H, *et al.* The use of the pyridostigmine growth hormone-releasing hormone stimulation test to detect growth hormone deficiency in patients with pituitary adenomas. *Metabolism* 2002; **51:** 34–7.

Nerve gas poisoning. Pyridostigmine has been used prophylactically to protect soldiers against attack with nerve gas agents (p.2351) that inhibit acetylcholinesterase.[1] Pyridostigmine binds reversibly to acetylcholinesterase and provides a protected store from which acetylcholinesterase is later released.[1-3] Prophylaxis with pyridostigmine greatly enhances the efficacy of treatment with atropine and pralidoxime against exposure to *soman* but it is not effective alone and may not be uniformly effective against other nerve agents.[1] Giving 30 mg of pyridostigmine every 8 hours provides the optimum level of protection[2] and, although adverse effects are common at this dosage, the performance of military duties is not impaired.[4] However, neurological symptoms in veterans suffering the so-called Gulf War Syndrome appear to be more common in those who reported exposure to a range of potentially toxic substances which include pyridostigmine.[5] It has been suggested that these symptoms may be evidence of organophosphate-induced polyneuropathy resulting from exposure to a combination of organophosphorus compounds and other cholinesterase inhibitors such as pyridostigmine.[6] A study in *hens*[7] (a species susceptible to anticholinesterases) has also found symptoms of enhanced neurotoxicity when pyridostigmine, the insect repellent diethyltoluamide, and the pyrethroid insecticide permethrin were used together.

Orthostatic hypotension. Pyridostigmine has been investigated in the treatment of orthostatic hypotension (p.1530). A review[1] of 4 single-dose studies and a follow-up survey (involving a total of 106 patients and generally reporting an improvement in haemodynamic measurements) concluded that there was insufficient long-term data to support the routine use of pyridostigmine in the treatment of orthostatic hypotension.

1. Gales BJ, Gales MA. Pyridostigmine in the treatment of orthostatic intolerance. *Ann Pharmacother* 2007; **41:** 314–18.

Post-poliomyelitis syndrome. Although pyridostigmine has been reported[1] in some patients to reduce fatigue associated with post-poliomyelitis syndrome a double-blind placebo-controlled study failed to find any benefit.[2] Doses used[3] have included 30 mg daily increased gradually to about 60 mg three times daily but adverse effects are common.

Soft-tissue sarcoma, p.676

Antineoplastic drugs are used in the treatment of malignant neoplasms when surgery or radiotherapy is not possible or has proved ineffective, as an adjunct to surgery or radiotherapy, or, as in leukaemia, as the initial treatment. Therapy with antineoplastics is notably successful in a few malignant conditions and may be used to palliate symptoms and prolong life in others.

The two main groups of cytotoxic drugs used in the treatment of malignant disease are the alkylating agents and the antimetabolites. Nitrogen mustards, ethyleneimine compounds, and alkyl sulfonates are the main **alkylating agents**. Other compounds with an alkylating action are the various nitrosoureas. Cisplatin and dacarbazine appear to act similarly.

The **antimetabolites** may be subdivided into folic acid, purine, or pyrimidine antagonists.

Several natural products, or their derivatives, are used for their actions as **mitotic inhibitors**; they include the vinca alkaloids and the taxanes. Other drugs act as **topoisomerase inhibitors**, interfering with the coiling and uncoiling of DNA during replication. Drugs thought to act in this way include the podophyllotoxin derivatives such as etoposide, and camptothecin derivatives such as irinotecan and topotecan.

Some **antibiotics** such as the anthracyclines, bleomycin, and mitomycin C, also interfere with nucleic acids and are effective as antineoplastics.

Further described in this section are **other drugs** that act by various routes to affect the growth and proliferation of malignant cells. Better understanding of the biology of tumour cells has led to the development of new classes of these, including **tyrosine kinase inhibitors** such as imatinib. Some neoplasms express receptors to endogenous sex hormones, and various **hormone antagonists**, including, notably, the **aromatase inhibitors** are used in their management.

In recent years considerable interest has focused on immunological approaches to the treatment of malignant disease and a number of **monoclonal antibodies** have been, or are being, developed. The use of biological response modifiers such as interleukins continues to be the subject of investigation and attempts to develop vaccines against individual neoplasms also continue.

Glucocorticoids (see Corticosteroids, p.1495) are used with antineoplastics in the treatment of malignant disease, especially in acute leukaemias and lymphomas. Other agents used in antineoplastic therapy include sex hormones (p.2058) and radiopharmaceuticals (p.2052).

Adverse Effects

The acute effects of antineoplastic drugs often include nausea and vomiting, sometimes extremely severe. In addition, many of these compounds are irritant or vesicant, and produce local pain, irritation, and inflammation at the administration site; extravasation may lead to ulceration and necrosis. Hypersensitivity reactions may also occur.

Many of the adverse effects of antineoplastics are an extension of their therapeutic action, which is not selective for malignant cells but affects all rapidly-dividing cells: antineoplastic therapy is made possible only by increased sensitivity or less effective recovery of malignant cells compared with normal cells, and dosage is carefully controlled and timed, and, where possible, localised, to maximise the differences.

In consequence, adverse effects may be expected from most antineoplastics in tissues where normal cell division is fairly rapid, e.g. the bone marrow, lymphoreticular tissue, gastrointestinal mucosa, skin, and gonads, as well as in the fetus. The effects may not manifest for days or weeks, depending both on the drugs used and the rate of division in the tissue concerned, and may sometimes be cumulative. Perhaps the most common serious effect, and one which has often limited the doses that can be given, is bone-marrow depression. Because of their effects on the various types of white blood cell many antineoplastics also cause profound suppression of normal immunity, and patients may be at greatly increased risk of severe and disseminated infection.

The rapid destruction of large numbers of cells during antineoplastic therapy of certain highly sensitive tumours, and the consequent release of breakdown products, may also lead to problems with hyperuricaemia and acute renal failure due to uric acid nephropathy (the 'tumour lysis syndrome').

Additionally, some drugs may have specific toxicities that are not necessarily related to their therapeutic action, such as cardiotoxicity due to anthracycline antibiotics, nephrotoxicity with cisplatin, or the effects of bleomycin on the lung. Again these can be cumulative, and may limit the total lifetime dose that can be given.

In the very long term, patients who have undergone successful antineoplastic chemotherapy may develop secondary malignancies, suggesting that antineoplastics may themselves be carcinogenic. In addition, most are potentially mutagenic and teratogenic, and use in pregnancy, particularly in the first trimester, may lead to fetal abortion, stunting, or malformation.

Carcinogenicity. There is clear evidence that some antineoplastic drugs may themselves be carcinogenic, although it is difficult to control for the possible effects of primary disease, combination chemotherapy, and combined treatment with radiotherapy.[1]

Most convincingly associated with secondary malignancies are the various **alkylating agents**[2-5] including the nitrosoureas, and the topoisomerase II inhibitor **podophyllotoxin derivatives** such as etoposide and teniposide.[2,3,5,6] Leukaemias, particularly acute myeloid leukaemia, are the most common forms of secondary disease.[1-3] Leukaemia associated with alkylating agents usually occurs about 5 to 7 years after treatment, and is often preceded by a preleukaemic myelodysplasia.[2,3] The nitrosoureas are associated with a relatively high frequency of secondary leukaemia, and busulfan and melphalan are considered to be more leukaemogenic than cyclophosphamide.[3] Leukaemia associated with the podophyllotoxin derivatives has a shorter latency period of 2 to 3 years, with sudden onset and no myelodysplastic phase.[2,3] Solid tumours can also occur as secondary malignancies and include bladder cancer associated with cyclophosphamide used to treat non-Hodgkin's lymphoma,[4] and bone sarcomas, and breast and lung cancers after the use of various alkylating agents.[4,7]

There is little evidence of carcinogenicity associated with **antimetabolites** such as methotrexate, although it has been suggested that they may act as co-carcinogens.[8] Fludarabine therapy has been reported to be associated with the development of myelodysplasia and acute myeloid leukaemias,[9] although a review of the purine nucleoside analogues, cladribine and fludarabine, concluded that no significant increase in the risk of secondary malignancy had been shown, but also that long-term follow-up of patients was needed.[10] Immunosuppression caused by antimetabolites including methotrexate, cladribine, and fludarabine, may also allow the development of Epstein-Barr virus-related lymphoma.[10,11] **Platinum derivatives** such as carboplatin and cisplatin have been found in large cohort studies[12,13] to have a dose-response relationship with the development of secondary leukaemia. Combinations that may also be associated with leukaemias include cisplatin with doxorubicin,[14] and other anthracycline-based regimens.[15] Another drug that has been associated with the development of secondary malignancies is **procarbazine**.[3,4,16,17]

Estimates of **risk** have varied very widely between studies, and have been calculated in various ways, making direct comparison impossible. Factors influencing the incidence of secondary malignancy include the use of combination chemotherapy regimens, combined treatment modalities, exposure to environmental carcinogens, predisposing genetic risk factors, ethnicity, age at time of treatment, gender, and spontaneous occurrence.[2,3]

The risk of secondary acute myeloid leukaemia appears to be associated primarily with the **cumulative dose** of antineoplastics.[2] Of patients at risk for secondary leukaemias, those with Hodgkin's disease have been most extensively studied. The cumulative 10-year incidence of secondary myeloid leukaemia has been reported to range from less than 1% up to 10%.[2,3] The highest risk is associated with the use of MOPP (chlormethine, vincristine, procarbazine, prednisone) and relative risk increases with cumulative dose of chlormethine.[2,3] Splenectomy or radiation of the spleen doubles the risk of leukaemia, as does an age of more than 45 years at the time of treatment.[2] Secondary solid tumours, such as lung cancer, in patients with Hodgkin's disease have also been attributed to the use of regimens such as MOPP.[4] The risk of secondary acute myeloid leukaemia, in patients treated with adjuvant chemotherapy for breast cancer, increases with cumulative doses of melphalan and cyclophosphamide, and high-dose regimens of doxorubicin with cyclophosphamide.[2,3] In patients treated for multiple myeloma, the increased risk of secondary leukaemia has been attributed to the prolonged use of melphalan.[2,3] Patients treated for testicular cancer appear to be at increased risk of secondary leukaemia associated with cumulative doses of podophyllotoxin derivatives (more than 2 g/m^2 etoposide), and the addition of high cisplatin doses may increase this risk.[2,3] Another review[18] of studies using etoposide or teniposide for various cancers found no relationship between the cumulative dose of these and secondary leukaemia, and suggested that other drugs used in treatment regimens had a greater effect on the development of secondary malignancy. There is growing evidence that the use of high-dose therapy with alkylating agents and/or anthracyclines, followed by autologous stem cell transplantation, is associated with an increased risk of secondary myelodysplasias and leukaemias, and a cumulative incidence of about 9% at 5 years.[2] However, it is unclear whether this is due to the high-dose therapy or to previous chemotherapy that has caused bone-marrow damage.[2,3]

Radiotherapy is an established cause of secondary malignancy. It remains unclear, however, to what extent the use of chemotherapy combined **with radiotherapy** could have an additive effect on the risk of secondary leukaemias, and how dose and treatment regimen influence this effect.[3] Similarly, the role of combined modality treatment in the development of secondary solid tumours has not been defined, even though the radiation-enhancing effect of some antineoplastics is known and used in chemoradiation regimens for this reason.[4]

In many cases the risk of secondary malignancy is far less than that of undertreating, or of failing to treat, the primary disease.[2,4] However, secondary malignancies may be more resistant to treatment and more aggressive than primary disease,[3,19] and the risk of inducing malignant neoplasia is certainly a consideration in the use of alkylating agents and podophyllotoxin derivatives to treat non-malignant disease,[3] and is an increasing challenge in the design of suitable treatment regimens for primary neoplastic disease.

EFFECTS ON CHROMOSOMES. Visible chromosome gaps, breaks, and structural rearrangements are found in blood lymphocytes from patients who have received substantial doses of combination chemotherapy, and the changes persist for years after the end of treatment. A more sensitive, if transient, measure of genetic damage is the increased rate of sister chromatid exchange (SCE) that occurs with even quite small doses of cytotoxic drugs.[1] Evidence from a study[2] in patients given chlorambucil suggests that as the dose increases so the capacity of the cells to cope with induced genetic damage is progressively exceeded, and thus SCE frequency reflects cumulative toxicity throughout the course of treatment.

In patients who develop acute myeloid leukaemia after alkylating agent therapy, the most common chromosomal losses involve deletions of chromosome 13, loss of the entire chromosomes 5 and 7, or deletions of part or the whole long arm of chromosomes 5 and 7. Molecular alterations of the suppressor gene p53 have also been found.[3] Balanced translocations, usually involving chromosomes 11 and 21, are associated with treatment using topoisomerase II inhibitors.[3,4]

Effects on the bladder. Cyclophosphamide (p.702) and ifosfamide (p.731) are the antineoplastics most frequently associated with adverse effects on the bladder, but see also Busulfan, p.690, Chlorambucil, p.696, and Mitomycin, p.752.

Effects on the blood. ***BONE-MARROW DEPRESSION.*** Bone-marrow depression, or myelosuppression, is common to the majority of cytotoxic antineoplastics, and is probably the single most important dose-limiting adverse effect, although its significance has been somewhat reduced in recent years by improvements in supportive care, including the availability of colony-stimulating factors and the development of techniques such as peripheral blood stem cell transfusion.

The formation and development of blood cells takes place in the bone marrow. A common progenitor, the pluripotent stem cell, gives rise to 3 major cell lines from which red cells, white cells, and platelets are derived (see Haematopoiesis, p.1042). All the cellular elements of blood may be affected by antineoplastic therapy, resulting in pancytopenia, but in many cases the toxicity appears to be greater for particular cell types. In addition, the different cell types have very different half-lives in the circulation. White blood cells and platelets tend to have the shortest half-lives in circulation. Hence the most usual manifestation of bone-marrow depression is leucopenia, leading to an increased risk of infection; thrombocytopenia is also fairly common. Erythrocytes have the longest life (about 120 days) and anaemia is somewhat less frequent, and may be associated with megaloblastic changes in the bone marrow.

The onset, duration, and severity of bone-marrow depression vary considerably with different antineoplastics. Relatively mild myelosuppression at worst seems to occur with conventional regimens of bleomycin (p.687), mitotane (p.753), streptozocin (p.771), and vincristine (p.787). Megaloblastic anaemia occurring with hydroxycarbamide (p.729) may be treatable by blood transfusions, if necessary, without interrupting therapy.

Many of the alkylating agents are associated with severe and sometimes irreversible bone-marrow depression, particularly at high doses. Busulfan (p.690) and the nitrosoureas such as carmustine (p.694) pose a particular problem because the nadir of white-blood cell and platelet counts may not be reached for up to 6 weeks after a dose. These drugs affect both resting and actively cycling stem cells.

Many antimetabolites are also associated with myelosuppression and some such as cytarabine (p.705) may produce megaloblastic anaemia in addition to leucopenia and thrombocytopenia. Cytarabine has a biphasic effect on granulocytes, producing an initial nadir about 7 to 9 days after a dose, and a second and more severe one after 15 to 24 days. Unlike alkylating agents, antimetabolites affect actively proliferating, but not resting, stem cells. Cladribine (p.701) and fludarabine (p.721) produce a prolonged and profound lymphopenia.

Of the other drugs mitomycin (p.752) and procarbazine (p.765) in particular have both been associated with prolonged, delayed myelosuppression. Recovery from the bone-marrow toxicity of mitomycin may take months and about 25% of cases do not recover. Cisplatin (p.698) and anthracyclines such as doxorubicin (p.712) can cause severe myelosuppression, although other toxic effects may be more important in determining dose; myelosuppression is dose-limiting with carboplatin (p.693). Cisplatin-induced renal toxicity may lead to anaemia by decreasing erythropoietin production. Bone-marrow depression is also a significant adverse effect of vinblastine (p.786) vindesine, and vinorelbine, although the effects of vincristine on the bone marrow are much less marked, as mentioned above. Neutropenia is common with the camptothecin derivatives irinotecan (p.737) and topotecan (p.780) and can be dose-limiting. The monoclonal antibody alemtuzumab (p.677) and the conjugated antibody gemtuzumab ozogamicin (p.728) also produce severe and prolonged myelosuppression.

For further details, see under the individual monographs. For the management of bone-marrow depression, including discussion of the appropriate thresholds for treatment, see under Treatment of Adverse Effects, below.

See also Effects on Immune Response, below.

Effects on body-weight. Although the effects of antineoplastics on the gastrointestinal tract (below) may lead to anorexia, malabsorption, and malnutrition, and hence to weight loss, antineoplastic therapy for breast cancer has also been associated with weight gain, sometimes dramatic.[1] Weight gain appeared to be more likely in premenopausal women, in those receiving multidrug regimens, and in those treated for longer periods of time. A study of premenopausal women found that reduced physical activity may be a contributing factor to the development of this form of weight gain.[2] A subsequent small study has suggested that adjuvant regimens based on doxorubicin and cyclophosphamide, with or without a taxane, may not be associated with significant weight gain, although patients may undergo unfavourable changes in body-mass composition.[3] Weight gain has also been noted after long-term follow-up of paediatric leukaemia patients.[4,5] Causes include cranial irradiation and corticosteroid therapy,[6] although some have suggested that weight gain depends more on inherent characteristics of the patients than the treatment given.[7]

Concurrent use of corticosteroids may also lead to weight gain.

Effects on bones and joints. Osteoporosis occurs as both an acute[1] and late complication of chemotherapy, but as multicomponent regimens are used and because the pathogenesis of osteoporosis is likely to be multifactorial, it is difficult to assess the impact of individual drugs.[2] However, chemotherapy that causes hypogonadism will decrease bone mineral density in the majority of patients.[2] This includes regimens for a variety of neoplasms, including breast, prostate and testicular cancers, lymphomas, and haematological malignancies. In particular, regimens containing cyclophosphamide, chlormethine, busulfan, or procarbazine may cause ovarian insufficiency and therefore have the potential to lead to osteoporosis in females. Males may be protected from the effects of pronounced hypogonadism, as the cells that produce testosterone only replicate slowly.[2]

In addition, several drugs may exert direct effects on the bone. Methotrexate has been found to increase bone resorption and inhibit bone formation to produce a massive uncoupling of bone turnover.[2] Other drugs, including doxorubicin, have been shown to be toxic to bone in *animals*.[2] High-dose conditioning regimens used for bone marrow transplantation may have a direct dose-dependent toxicity on bone marrow osteoprogenitor cells, contributing to osteopenia.[3]

Corticosteroids are believed to cause bone loss by decreasing osteoblast activity, an effect which may be alleviated by chlorambucil. Surprisingly, corticosteroids have not been implicated in bone loss for most chemotherapy regimens, perhaps because the duration of treatment is short.[2] Nevertheless, osteoporosis and fractures have occurred in young patients with acute lymphoblastic leukaemia, treated with regimens containing high total doses of corticosteroids.[4,5] However, the disease itself, other chemotherapy, and radiotherapy are also likely to be contributory factors in the development of osteopenia in these patients. Osteonecrosis has also been reported with high doses of corticosteroids used in the treatment of leukaemias and solid tumours in adults and children.[4,6,7] Adolescent patients may be at increased risk because their bones are in the process of maturation.[4,6]

A study in children with leukaemia has suggested that the effects of chemotherapy on gastrointestinal and renal handling of nutrients may lead to alterations in calcium and magnesium homoeostasis and hence to abnormal turnover of bone mineral.[8] Renal phosphate loss following damage to the renal tubule caused by ifosfamide can lead to osteomalacia.[2]

Effects on the cardiovascular system. ***THROMBOEMBOLISM.*** Patients with cancer are at increased risk of thromboembolic disease, and thrombosis can be the earliest clinical sign of malignancy.[1] The risk of thromboembolism may be further increased by the use of antineoplastics. Deep-vein thrombosis and pulmonary embolism have been reported with a variety of chemotherapeutic regimens. Studies in patients with breast cancer have found that adjuvant chemotherapy can significantly increase the risk of venous thromboembolism.[2] An increase in venous thromboembolism, including CNS thromboses, has also been found with the use of asparaginase in the treatment of acute lymphoblastic leukaemia[2] (see also Effects on the Blood, under Asparaginase, p.682). Regimens that include bevacizumab, lenalidomide, or thalidomide have also reported high rates of venous thromboembolism.[3] Arterial thrombosis, including acute myocardial infarction, angina, stroke, and peripheral artery thrombosis, has also been reported with various regimens.[2] Mechanisms proposed for the possible role of antineoplastics in these effects include activation of coagulation, suppression of anticoagulant proteins and fibrinolysis, and a direct toxic effect on vascular endothelium.[1,2]

Several reports of arterial and venous thromboembolism have implicated combinations of bleomycin with cisplatin and another drug such as a vinca alkaloid or etoposide.[4-6] Such combinations, widely used for testicular cancer, have also been implicated in producing vasospastic reactions including angina[7] and Raynaud's syndrome,[8,9] although there is no evidence of a relationship between thromboembolism and vasospasm.[4]

In men with germ cell cancer there is some evidence that those with liver metastases, or receiving high-dose dexamethasone as antiemetic therapy, are at increased risk of thromboembolic complications.[10]

Treatment of venous thrombosis usually consists of low-molecular-weight or unfractionated heparin therapy and long-term secondary prophylaxis with warfarin,[11] but patients with cancer may be at greater risk of recurrent thrombosis. A multicentre, randomised study found that a low-molecular-weight heparin was more effective than an oral anticoagulant in reducing the risk of recurrent venous thromboembolism without increasing the risk of bleeding,[12] and many now recommend low-molecular-weight heparin therapy for both initial and continuing treatment of cancer patients with venous thromboembolism.[3,11] Patients with arterial thrombosis may require heparin and warfarin, or anti-platelet therapy.[13]

Thromboembolic complications may also be associated with the indwelling catheters used to provide vascular access for antineoplastic therapy.[14,15] Prophylaxis with low-dose warfarin or a low-molecular-weight heparin may reduce the risk.[15]

Effects on electrolytes. Fluid and electrolyte disturbances are common in patients with cancer.[1,2] These can be caused by the disease process, or adverse effects of treatment such as surgery, chemotherapy, antibacterials and diuretics. Mechanisms of chemotherapy-induced electrolyte disturbances include loss of appetite, gastrointestinal electrolyte loss due to vomiting and diarrhoea, impaired intestinal absorption due to mucosal damage, direct nephrotoxicity causing renal electrolyte loss, and a syndrome of inappropriate antidiuretic hormone secretion or a condition resembling it. Hypoparathyroidism, which may be a complication of neck surgery, also affects electrolyte balance and is associated with hyperphosphataemia and hypocalcaemia. As well as the acute signs and symptoms of electrolyte disturbances, changes in electrolyte homoeostasis may result in abnormal bone turnover (see Effects on Bones and Joints, above). Release of the contents of cells destroyed by chemotherapy is well-known to be associated with hyperuricaemia, hyperphosphataemia, hyperkalaemia, and hypocalcaemia (see Tumour Lysis Syndrome, below).

Disturbances of electrolyte homoeostasis have been reported particularly with cisplatin (p.699), cyclophosphamide (p.702), and ifosfamide (see Effects on the Kidneys, p.731).

2. Filippatos TD, *et al.* Alterations in electrolyte equilibrium in patients with acute leukemia. *Eur J Haematol* 2005; **75:** 449–60.

Effects on the gastrointestinal tract. Apart from anorexia, and nausea and vomiting (see below), many antineoplastics produce gastrointestinal disturbances. Mucosal inflammation (mucositis), notably as stomatitis and sometimes proctitis, is quite common, as are mucosal cellular changes, xerostomia, impaired absorption, and diarrhoea. In some cases gastrointestinal damage may progress to ulceration, haemorrhage, and perforation.

Antimetabolites affecting pyrimidine metabolism, such as cytarabine (p.705) and fluorouracil (p.722), and the antifolates such as methotrexate (p.745), seem to be particularly associated with severe gastrointestinal effects, especially at high doses, but there appear to be few antineoplastics that do not cause some degree of gastrointestinal disturbance. Irinotecan (p.737) can produce both an initial transient diarrhoea related to cholinergic stimulation, and more severe prolonged diarrhoea with a delayed onset, which may be dose-limiting and potentially fatal.

Use with radiotherapy may increase the toxicity of some drugs on the gastrointestinal tract. The neutropenia induced by many antineoplastic regimens can also lead to secondary gastrointestinal effects, such as stomatitis and gastrointestinal inflammation, associated with infection.

CLOSTRIDIUM DIFFICILE INFECTION. Antineoplastic therapy has occasionally been associated with the development of *Clostridium difficile*-induced gastrointestinal disease, even in the absence of concomitant antibacterial therapy.[1] Most patients had received multiple drug regimens. Methotrexate, fluorouracil, cyclophosphamide, and doxorubicin have all been associated with a number of cases but this may simply reflect the frequency of their use. A retrospective analysis[2] of a group of patients treated for acute leukaemia or receiving bone marrow transplantation found that predictive variables for *C. difficile* diarrhoea included the use of low intensity chemotherapy, but speculated that patients receiving high intensity chemotherapy may be subjected to more strict isolation and infection control procedures, thereby reducing the risk of nosocomial transmission. Another review[3] of 875 courses of myelosuppressive chemotherapy found 61 episodes of *C. difficile* diarrhoea, and that in 36% of those episodes the patients had received high-dose cytarabine. In 35 of the 61 episodes, patients had also received prior intravenous antibacterials.

For discussion of the treatment of such disease, see Antibiotic-associated Colitis, p.171

MUCOSITIS. The suffering associated with oral mucositis is by far the worst part of treatment for many patients undergoing curative chemotherapy or bone marrow transplantation, and for those undergoing oral radiotherapy.[1-3] Apart from pain and dysphagia the ulcerated mucosa provides a portal of entry for infection; loss of weight and malnutrition can further impair immune function, and if symptoms are severe enough the treatment cycle may have to be interrupted. Before the patient starts any intensive chemotherapy or local or systemic radiotherapy the oral cavity must be assessed with a view to eliminating sources of infection and chronic irritation. For comment on the prophylaxis and treatment of mucositis, see under Treatment of Adverse Effects, below.

NAUSEA AND VOMITING. Nausea and vomiting are common adverse effects of antineoplastic therapy, and for many patients, represent a major drawback to treatment. Once experienced, anticipatory vomiting may occur at the sight of medical staff, or a needle. The problem may be severe enough in some cases to hinder or completely prevent further treatment.

Antineoplastic or cytotoxic drugs may induce vomiting by both a central action on the chemoreceptor trigger zone and a peripheral action on the gastrointestinal tract. Several neurotransmitters have been implicated over the years including acetylcholine, histamine, enkephalins, dopamine, and serotonin or 5-hydroxytryptamine (5-HT). The cerebral cortex is probably responsible for anticipatory vomiting. Antineoplastics may not all induce emesis by a common pathway, but 5-HT_3-receptor mechanisms are clearly important in the pathogenesis of *acute* cisplatin-associated vomiting. This was suspected when the antiemetic metoclopramide, a dopamine antagonist, was found to have serotonin (5-HT) antagonist activity at the high doses used against cisplatin emesis and confirmed when specific 5-HT_3 antagonists such as ondansetron proved to be effective. Different mechanisms are probably involved in *delayed* emesis since 5-HT_3 antagonists are less effective.

Some patients are more susceptible to emesis than others. The emetic potential of antineoplastics also varies in terms of severity and incidence, and may depend to some extent on the dose, route, and schedule of administration. Some combination therapy has resulted in a higher incidence of vomiting than would be expected from the constituents.

- Vomiting may be *very severe* with cisplatin, dacarbazine, dactinomycin, chlormethine, high-dose cyclophosphamide, and streptozocin, and occurs in most patients.
- *Moderate* vomiting is likely with the taxanes, doxorubicin, more modest doses of cyclophosphamide, and high-dose methotrexate.
- Vinca alkaloids, fluorouracil, lower doses of methotrexate, chlorambucil, bleomycin, and etoposide have *low* emetogenic potential.

The *onset and duration* of vomiting also varies from drug to drug. With cisplatin the onset may be between 4 and 8 hours after a dose, while the duration may be up to 48 hours or occasionally even longer; a persistent feeling of nausea, and sometimes vomiting, lasting for several days may also occur. After chlormethine, vomiting may begin within a half to 2 hours, whereas after cyclophosphamide there may be a latent interval of 9 to 18 hours, but in both cases vomiting is generally less prolonged than with cisplatin. Acute emesis (that occurring within 24 hours) has generally been easier to control than delayed emesis (that occurring more than 24 hours after chemotherapy) or anticipatory emesis.

The management of chemotherapy-induced nausea and vomiting is discussed on p.1700.

Effects on the heart. The cardiotoxicity of antineoplastics has been reviewed.[1-3] Cardiotoxicity is the major dose-limiting toxicity with anthracyclines such as doxorubicin and daunorubicin, manifesting most seriously as drug-induced cardiomyopathy, which is frequently fatal, and for which no specific treatment exists. Some of the newer anthracycline analogues such as epirubicin or idarubicin were developed to be less toxic to the heart, although this has not always been easy to prove in controlled studies. Dexrazoxane may prevent heart damage in patients taking anthracyclines, but has no effect on survival.[4] Cardiotoxicity has also been associated with other antineoplastics, although less frequently. High-dose cyclophosphamide or ifosfamide may produce myocarditis, arrhythmias, and congestive heart failure, sometimes delayed by up to 2 weeks, while fluorouracil has been associated with angina pectoris and myocardial infarction, perhaps due to a combination of vasospastic effects and activation of coagulation. Amsacrine has been associated with arrhythmias, sometimes fatal. As well as cardiac effects associated with a capillary leak syndrome, arrhythmias can occur with interleukin-2. Trastuzumab use can be associated with cardiomyopathy resulting in heart failure. Occasional reports of cardiotoxicity associated with busulfan, carmustine, cisplatin, cytarabine, etoposide, mitomycin, paclitaxel, pentostatin, and vincristine also exist. Newer drugs that have been associated with cardiotoxicity include bevacizumab, sorafenib, and sunitinib.

For a discussion of the thromboembolic events seen with antineoplastics see Effects on the Cardiovascular System, above.

Effects on immune response. Lymphocytes are produced by stem cells in the bone marrow and at other sites, including the thymus, and are involved in humoral and cell-mediated immunity. Most antineoplastics have a depressant effect on bone marrow (see Effects on the Blood, above) and many have immunosuppressant properties although the degree of suppression varies considerably and may depend on the dose and schedule used. Immunosuppression decreases the patient's resistance to infection and has been implicated in the development of malignancies. Response to vaccines may also be reduced, and there is a possibility of generalised infections with live viral vaccines (see Interactions, p.2202).

For a discussion on the effects of immunosuppressant therapy on the immune response and the infections associated with it, see Corticosteroids, p.1492.

Effects on the kidneys. Nephrotoxicity is well-recognised as an adverse effect of cisplatin (p.699), ifosfamide (p.731), and methotrexate (p.746), but renal toxicity may occur with other antineoplastics including the nitrosoureas, mitomycin (due to haemolytic-uraemic syndrome), azacitidine, gemcitabine, and pentostatin.[1]

1. Kintzel PE. Anticancer drug-induced kidney disorders: incidence, prevention and management. *Drug Safety* 2001; **24:** 19–38.

Effects on the liver. Occasional reports of hepatotoxicity exist for many antineoplastics including aminoglutethimide (p.679), busulfan (p.690), dacarbazine (p.707), dactinomycin (p.707), doxorubicin (p.713), floxuridine (p.720), flutamide (p.725), gemtuzumab, (p.728), hydroxycarbamide (p.729), imatinib (p.733), methotrexate (p.746), mitomycin (p.752), mitoxantrone (p.754), oxaliplatin (p.758), tamoxifen (p.773), and tioguanine (p.779). However, the relationship of the drug to the adverse effect is not always easy to establish.

An early but detailed review suggested that methotrexate, mercaptopurine, cytarabine, carmustine, streptozocin, asparaginase, and plicamycin could probably be classified as hepatotoxic. There was considered to be insufficient evidence to classify fluorouracil, cyclophosphamide, busulfan, dacarbazine, the anthracyclines, the vinca alkaloids, and the podophyllum derivatives as hepatotoxic, although this classification was not definitive.[1] Hepatic veno-occlusive disease has occurred after the use of high doses of chemotherapy for conditioning regimens before bone marrow transplantation.[2] Chemotherapy used in combination or with radiotherapy may also increase the risk of hepatotoxicity.[2] Liver toxicity may not be confined to patients: one report described 3 cases of liver damage in nurses working on an oncology ward.[3]

Effects on the lungs. Lung injury leading to pulmonary fibrosis occurs in about 10% of all patients who receive bleomycin, being fatal in 1 to 2%. Clinically, the reaction usually presents several months after completion of therapy as non-productive cough and dyspnoea. The reaction is dose-related, being more likely at total doses over 400 000 international units (400 USP units), although it has occurred at much lower doses, and is more common in elderly patients. Injury may be exacerbated by the use of combination chemotherapy regimens and radiotherapy, and supplemental oxygen given even years after the use of bleomycin may precipitate pulmonary oedema.[1] Hypersensitivity pneumonitis, which is more amenable to treatment, has also been reported.[2]

Pulmonary damage has also been reported with an increasing number of antineoplastics apart from bleomycin.[1,3,4] Among the alkylating agents cyclophosphamide has been reported to produce lung injury in less than 1% of cases, although this may be increased where it is a component of combination regimens or given with radiotherapy. Busulfan may produce lung toxicity including insidious pulmonary fibrosis in as many as 4% of patients, usually developing several years after initiation of therapy, and with increased risk the longer that therapy lasts. A few reports exist of interstitial pneumonitis and fibrosis associated with chlorambucil and melphalan, but these appear to be extremely rare. The prognosis in patients with alkylating-agent-induced fibrosis is often poor, with mortality rates of 50% or more.

The antimetabolite methotrexate can produce symptoms similar to hypersensitivity pneumonitis in up to 7% of patients, sometimes with pleuritis and acute respiratory failure due to pulmonary oedema, but it is not clear whether a true hypersensitivity mechanism is involved, and symptoms are usually reversible even without stopping therapy. High-dose cytarabine has also been associated with pulmonary oedema. Gemcitabine (p.727) has been associated with interstitial pneumonitis and potentially life-threatening symptoms have occurred when given with thoracic radiotherapy.

Other antineoplastics known to be associated with pulmonary toxicity include mitomycin (usually in less than 10% of patients though the incidence may be much higher in combination regimens); the vinca alkaloids (generally in combination, and usually producing acute respiratory failure); chlorozotocin; procarbazine; and possibly teniposide. The nitrosoureas, and particularly carmustine, have also emerged as pulmonary toxins. Carmustine has been associated with an insidious chronic pulmonary fibrosis, which in some early studies occurred in as many as 30% of patients and had a high mortality. Symptoms are associated particularly with cumulative doses in excess of about 1.4 g/m^2, although toxicity has occurred at cumulative doses as low as 240 mg/m^2. The onset of symptoms may be very delayed: some workers reported fibrosis occurring up to 17 years after treatment in patients who received carmustine as children.[5] Pneumonia and fibrosis have also been reported in patients receiving rituximab (p.767), and fatal lung disease has occurred in patients given gefitinib (p.727).

Effects on mental function. Combination chemotherapy has been associated with psychiatric morbidity (anxiety, depression, behavioural changes) in both adults[1] and children.[2] It has been pointed out that patients receiving cancer chemotherapy inevitably suffer emotional distress, associated in part with the adverse effects of treatment. Patients should be fully informed of aims and likely outcomes of treatment, and adverse effects minimised, in order to keep emotional distress to a minimum.[3] Chemotherapy can also cause cognitive impairment,[4,5] affecting functions such as memory, reasoning, concentration, and language skills. Drugs may have direct central neurological toxic effects, or may indirectly affect brain function through adverse effects such as anaemia. Most studies have examined cognitive impairment in women being treated with chemotherapy for breast cancer, but many other cancer patients experience cognitive impairment, which they describe as 'chemo-brain' or 'chemo-fog'.

A number of individual antineoplastics have been associated with mental symptoms, including methotrexate (p.746), mitotane (p.753), and the vinca alkaloids (see Vinblastine, p.786). In many cases such symptoms can be attributed to direct central neurotoxicity (see also under Effects on the Nervous System, below).

5. Minisini A, *et al.* What is the effect of systemic anticancer treatment on cognitive function? *Lancet Oncol* 2004; **5:** 273–82.

Effects on the nervous system. Neurotoxic effects have been reported for many antineoplastics, including altretamine (p.678), asparaginase (p.682), busulfan (p.690), carboplatin (see under Incidence of Adverse Effects, p.693), carmustine (p.694), chlorambucil (p.696), chlormethine (p.697), cisplatin (p.698), cladribine (p.701), cytarabine (p.705), etanidazole (p.718), etoposide (p.718), fludarabine (p.721), fluorouracil (p.723), gemcitabine (p.728), hydroxycarbamide (p.729), ifosfamide (p.732), lomustine (p.741), methotrexate (p.746), mitotane (p.753), mitoxantrone (p.754), oxaliplatin (p.758), paclitaxel (p.759), pentostatin (p.763), procarbazine (p.765), tegafur (p.776), vinblastine (p.786), vincristine (p.787), and vindesine (p.788). In some cases these effects may be associated with particular routes such as the intrathecal. See under the individual monographs for further details. Radiotherapy can also cause damage to the nervous system so combination of the two modalities may lead to additive effects.

EFFECTS ON THE EARS. Several antineoplastics have been associated with ototoxicity,[1] including vincristine and vinblastine, but cisplatin in particular is associated with high-frequency hearing loss and tinnitus. In addition, agents such as the nitrogen mustards and bleomycin are potentially ototoxic.

1. Seligmann H, *et al.* Drug-induced tinnitus and other hearing disorders. *Drug Safety* 1996; **14:** 198–212.

Effects on reproductive potential. ***CHROMOSOMES.*** If patients are fertile after treatment with antineoplastics, no significant increase has been seen in fetal chromosome damage, fetal abnormality, or the miscarriage rate. A review[1] of reports of survivors of *childhood cancers* found that adverse pregnancy outcomes were limited to particular groups of survivors. Female survivors of Wilms' tumours who had been treated with abdominal radiation, with or without chemotherapy, appeared to be at increased risk of complications including miscarriage, low birth-weight neonates, and neonatal death. After treatment of childhood Hodgkin's disease using both radiotherapy and chemotherapy, female survivors and partners of male survivors might be at increased risk of miscarriage; however, treatment with radiotherapy or chemotherapy alone did not increase this risk. For other cancers, data were more limited, but suggested that the risk of adverse pregnancy outcomes was not increased in survivors.

Regarding the risk of congenital abnormalities in the offspring of survivors of childhood cancers, most studies have shown no excess of major or minor malformations.[1,2] There was also no evidence that the risk of cancer is increased in the offspring. However, because of the small numbers in many studies and heterogeneity regarding treatments used, it is possible that effects of individual drugs could have been masked. Long-term follow-up is needed as increasing numbers of children survive to adulthood after successful chemotherapy.

For *adult patients*, there is also a lack of evidence of adverse pregnancy outcomes and congenital abnormalities in offspring after chemotherapy. In a large series[3] of women treated with methotrexate, alone or in combination, for gestational trophoblastic tumours, there was no evidence of an increase in adverse outcomes or abnormalities, although women who had received three or more drugs in combination were less likely to have a live birth. A large case-control study carried out in Canada, and involving over 85 000 parents of children with congenital anomalies, also has failed to confirm a higher incidence of congenital abnormality in the offspring of patients treated with radiotherapy or alkylating agents.[4] However, despite these generally reassuring results, it has been suggested that women should delay conception for a year after cessation of chemotherapy to allow mature ova that might have been damaged to be eliminated,[5] and that monitoring outcomes in patients who become pregnant shortly after exposure to cytotoxic drugs is desirable.[2]

GONADS. The effects of cytotoxic drugs on the gonads have been reviewed.[1-7] In male patients, antineoplastic drugs may damage the seminiferous tubules, resulting in testicular atrophy with decreased sperm count and motility. Testosterone secretion may also be reduced after damage to Leydig cells. In women, cytotoxic drugs act on the ovary to produce loss of primordial follicles with failure of ovulation, oligomenorrhoea or amenorrhoea, and failure of endocrine function resulting in loss of libido and menopausal symptoms. The degree of damage and its reversibility depend on the drug and its dose and the age and sex of the patient. Age is particularly important for women at the time of treatment, with older women (35 to 40 or over) being more sensitive, probably a reflection of the decrease in oocyte numbers with age.

Although dose also plays a role, estimates of the toxicity of various antineoplastics (as single agents) have been published.[4-6] The risk of gonadal dysfunction is high with alkylating agents (busulfan, chlorambucil, chlormethine, cyclophosphamide, ifosfamide, melphalan), nitrosoureas (carmustine, lomustine), and procarbazine. Medium risk drugs include carboplatin, cisplatin, and doxorubicin. Low risk drugs include bleomycin, dactinomycin, fluorouracil, mercaptopurine, methotrexate, vinblastine, and vincristine.

Severe gonadal dysfunction in both men and women has been associated with combination chemotherapy regimens for Hodgkin's disease. Chlormethine and procarbazine are thought to be mainly responsible for the infertility produced. There is some evidence that currently favoured regimens such as ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) result in less damage to gonadal cells than the earlier MOPP regimen (chlormethine, vincristine, procarbazine, and prednisone). Prolonged gonadal dysfunction has also been seen in patients given combination chemotherapy for acute lymphoblastic leukaemia; girls appear to be at less risk than boys, especially if treated in the prepubertal period.

Techniques for fertility preservation have been reviewed.[3-6] Established methods with the highest likelihood of success are sperm cryopreservation (sperm banking) for men and IVF with embryo cryopreservation for women. Other methods for women, for which there is less experience and investigation is underway, include oocyte cryopreservation for future IVF, gonadal tissue cryopreservation for autologous transplantation, and ovarian suppression using oral contraceptives or gonadotrophin-releasing hormone analogues. Such techniques are of little benefit for the preservation of fertility in patients treated as young children, however, because of gonadal immaturity.

SEXUAL FUNCTION. Loss of libido and decline in sexual performance seem to be relatively common in men receiving combination chemotherapy,[1,2] and may persist after chemotherapy has ended.[1] However, it may sometimes be difficult to distinguish the effects of chemotherapy from those of the disease and the patient's reaction to it: at least one study has shown that gonadal function is disturbed in patients with Hodgkin's disease before treatment.[2] Erectile dysfunction can also result from local damage caused by pelvic surgery or irradiation.[3] Evidence for decreased libido in women is harder to find, but failure of endocrine function after chemotherapy may lead to loss of libido and menopausal symptoms.[4]

Effects on the skin and nails. Alopecia occurs with many antineoplastics, and may be severe with doxorubicin and other anthracyclines, cyclophosphamide, ifosfamide, etoposide, or teniposide, the taxanes docetaxel and paclitaxel, and topotecan. The alkylating agents and some antibiotic antineoplastics are often associated with hyperpigmentation, most commonly of skin, although pigmentation of nails, hair, and teeth has occurred. Some drugs, such as the taxanes, cause dystrophic changes in the nails. Certain drugs may interact with UV light or x-ray radiation to enhance its effects on the skin and may cause radiation recall, photosensitivity, or, in the case of methotrexate, reactivation of UV light burns. Hypersensitivity to antineoplastics may produce cutaneous reactions including allergic rashes, angioedema, and pruritus. In addition to the above there may be local reactions to irritant and vesicant drugs after extravasation. Finally, certain drugs are associated with specific dermatological reactions: acneform follicular rashes have been reported with cetuximab, bleomycin may produce hyperkeratotic and sclerotic lesions, dactinomycin is associated with an erythematous papular or pustular rash mimicking septic emboli, fluorouracil may produce inflammation of solar keratoses, and plicamycin is associated with a distinctive flushing phenomenon. A palmar-plantar erythrodysesthesia syndrome has been seen with a number of antineoplastics (see below).

See also Local Toxicity, below. References may also be found under individual monographs.

PALMAR-PLANTAR ERYTHRODYSESTHESIA SYNDROME. Palmar-plantar erythrodysesthesia (PPE; hand-foot syndrome) associated with chemotherapy[1] usually presents as a tingling sensation in the palms and soles, which progresses in a few days to burning pain and well-defined swelling and erythema. In severe cases there is desquamation, ulceration, blistering, and severe pain. The reaction appears to be caused by a direct toxic effect and seems to be dose-dependent, affected by both peak drug concentration and total cumulative dose. The drugs most often associated with PPE or similar syndromes are cytarabine (p.705), docetaxel (p.711), doxorubicin (p.712), and fluorouracil (p.723). PPE also occurs with the tyrosine kinase inhibitors, such as lapatinib (p.739), sorafenib (p.770), and sunitinib (p.771). It has also been reported for bevacizumab (p.684), capecitabine (p.692), cisplatin (see under Hypersensitivity, p.699), cyclophosphamide (p.702), and methotrexate (p.746). PPE is usually managed by reducing the drug dose, increasing the dosage interval, or withdrawing the drug, along with symptomatic treatment and wound care. Systemic corticosteroids and pyridoxine have been used in prophylaxis and treatment. Topical dimethyl sulfoxide has been used for PPE caused by liposomal doxorubicin.

Hyperuricaemia. Overproduction of purines is a known complication of antineoplastic therapy and may result in hyperuricaemia (p.552). Hyperuricaemia is also an important part of the tumour lysis syndrome—see below.

Local toxicity. Local toxicity due to intravenous cancer chemotherapy may include local irritation, extravasation necrosis, and hypersensitivity. **Venous irritation**, presenting as vasospasm and pain or endothelial chemical burn of the vessel, resulting in a painful, streaky, long-lasting sterile phlebitis, may be due to the drug, or, as with carmustine, due to the diluent (alcohol). Irritation and phlebitis have been reported particularly with fluorouracil, carmustine, vinorelbine, and chlormethine.

Up to 6% of patients treated with peripheral intravenous chemotherapy experience **extravasation** (see below), usually with pain, erythema, and swelling at the site of injection. Severe necrosis requiring surgical intervention can develop, particularly with antibiotic antineoplastics such as doxorubicin.

Local **hypersensitivity** reactions, usually self-limiting, must be distinguished from extravasation. In hypersensitivity reactions there is no swelling at the injection site, and pain is felt as a dull ache along the course of the vein, as opposed to the stinging commonly noted after extravasation.

Tumour lysis syndrome. The tumour lysis syndrome represents a biochemical disturbance due to massive release of cellular breakdown products from tumour cells sensitive to therapy. The amount of breakdown products is sufficient to overwhelm normal excretory and metabolic mechanisms for their clearance, and the cardinal features of the syndrome are hyperkalaemia, hyperuricaemia, and hyperphosphataemia accompanied by hypocalcaemia. Clinical symptoms may include urate nephropathy or nephrocalcinosis leading to renal impairment, and cardiac arrhythmias associated with the potassium abnormalities. The syndrome is seen particularly when bulky chemosensitive disease is present, and may be more likely in patients with pre-existing renal impairment or hyperuricaemia. It is most frequent in patients with Burkitt's or lymphoblastic lymphoma, or an acute leukaemia. Of patients with solid tumours, reports have implicated those with germ-cell tumours, small-cell lung cancer, or neuroblastoma although, surprisingly, the syndrome has also been reported in patients with breast cancer, which is normally less rapidly responsive to chemotherapy. For comment on prevention and treatment, see under Treatment of Adverse Effects, below.

Treatment of Adverse Effects

Intensive supportive care may be necessary to prevent or control the adverse effects of antineoplastic therapy. Antiemetic therapy should be given to reduce, and if possible prevent, nausea and vomiting, since once experienced it may become a conditioned response, and may not respond to antiemetics. Intensive oral care is desirable to minimise the effects of stomatitis (see also Mucositis, below), while corticosteroids, and if necessary nutritional supplements, may be of some help in patients with anorexia. Chemotherapy-induced diarrhoea may also require treatment (see below).

Techniques attempting to prevent the occurrence of alopecia have met with varying success (see below). Scalp tourniquets and local hypothermia have been used to minimise concentrations of antineoplastics in the scalp after intravenous injection. However, such methods may allow the development of a cancer-cell sanctuary and should not be used in patients with leukaemia or other conditions with circulating malignant cells.

Of particular importance is the management of bone-marrow depression. Colony-stimulating factors and epoetins can be used to promote the formation of replacement blood elements (see Anaemia, below). Active measures may be necessary to combat infection and bleeding. Transfusions of blood products may be required; granulocyte transfusions have been given for infections unresponsive to antibiotics, although their value is a matter of debate, while transfusion of blood platelets or use of growth factors such as oprelvekin (interleukin-11) may be of value in preventing thrombocytopenia-induced bleeding.

Extravasation of antineoplastics can pose serious problems. Infusion should be stopped immediately once extravasation is noticed and any drug remaining at the site aspirated if possible but the details of treatment are controversial (see below). If ulceration occurs plastic surgery may be required.

Hyperuricaemia secondary to tumour lysis in patients with leukaemias or lymphomas can be prevented by the addition of allopurinol or rasburicase to treatment schedules, and by adequate hydration and, if necessary, alkalinisation of the urine (see Tumour Lysis Syndrome, below). Good hydration is also important to minimise the nephrotoxic effects of drugs such as cisplatin and methotrexate.

Specific treatments exist for the toxicity of certain antineoplastics (for example the use of calcium folinate to reduce methotrexate toxicity, or mesna to control the bladder toxicity of cyclophosphamide or ifosfamide). For further details of the treatment of specific adverse effects see under the individual monographs.

Alopecia. Attempts to prevent or reduce chemotherapy-induced alopecia have relied on either restriction of scalp blood flow with a tourniquet or the use of local hypothermia.[1] Both of these techniques have been based on the rationale that a temporary decrease in blood flow to the scalp will decrease the exposure of hair follicles to the antineoplastic. Therefore, most benefit would be expected for alopecia caused by drugs with a short half-life and for which both active drug and metabolites are rapidly cleared from the circulation.

Studies of scalp tourniquets carried out in the 1970s found head discomfort to be the main side-effect. They used different chemotherapy regimens, definitions for success, and tourniquet techniques, making conclusions difficult, and tourniquets were largely replaced by local hypothermia techniques.

Most studies of local hypothermia have attempted to prevent doxorubicin-induced alopecia. Again, chemotherapy regimens, devices used, and exposure times have varied between studies. Varying degrees of efficacy have been reported, but hypothermia has generally been of benefit, particularly with single-agent chemotherapy. The dose of chemotherapy may be relevant, with hypothermia being less effective at doxorubicin doses above 50 mg. Headache and cold intolerance may occur, but scalp hypothermia is generally well tolerated.

Despite the successes there is concern that this technique may provide a sanctuary for circulating malignant cells, with the potential risk of metastasis, and there are reports of scalp metastases after the use of hypothermia.[1,2] One reviewer suggested that the use of scalp hypothermia might therefore be restricted to patients receiving single-agent chemotherapy with a palliative intent, or those with solid tumours that rarely metastasise to the scalp.[1] The technique should probably be avoided in patients with leukaemias.[2]

In the USA commercial distribution of cooling caps designed to produce localised scalp hypothermia was halted by the FDA in 1990 because of concerns about their effectiveness and their potential to create sanctuary sites and interfere with drug distribution elsewhere in the head. However, they continue to be available in many countries.

For reference to the use of minoxidil to decrease the duration of alopecia after doxorubicin-containing chemotherapy, see p.1343.

Bone-marrow depression. Bone-marrow depression in patients receiving chemotherapy may require a modification of the dose regimen in subsequent cycles, either by delaying or reducing doses, although it is recognised that this may sometimes reduce efficacy.

Licensed drug information for a number of myelosuppressive antineoplastics recommends that if neutropenia or thrombocytopenia occurs subsequent doses should be withheld until white cell counts have returned to 3000 to 3500 cells/mm^3 or more, and blood platelets to about 100 000 cells/mm^3. In practice, however, improved supportive care means that many expert centres routinely give treatment at lower blood counts than these. The values at which it is acceptable to treat will be influenced by whether the regimen is likely to result in further significant falls, and whether the intent is curative (in which case maintaining treatment intensity is particularly important) or palliative (when avoiding toxicity becomes a prime consideration); local protocols may contain further guidance and should be consulted where available. However, it has been suggested[1] that with appropriate management treatment is usually possible at neutrophil counts of 1500 cells/mm^3 and platelet counts above 100 000 cells/mm^3.

For guidelines on the use of haematopoietic growth factors in the management of anaemia, neutropenia, and thrombocytopenia, see below.

ANAEMIA. Chemotherapy-induced anaemia can be managed with transfusion of red cells (p.1078), or treatment with epoetin (p.1061) or darbepoetin (p.1058).[1-4] Iron supplementation may be of benefit in anaemic cancer patients receiving erythropoietic therapy, even in those who are iron-replete.[4]

Guidelines for the use of epoetins and darbepoetin have been issued jointly by the American Society of Clinical Oncology and the American Society of Hematology,[5] and guidelines have also been issued by the US National Comprehensive Cancer Network.[3] In the treatment of chemotherapy-induced anaemia, the use of epoetins or darbepoetin can improve haemoglobin concentration and reduce the need for transfusion of red cells, but whether this improves symptoms and quality of life requires further study. The use of epoetins or darbepoetin is recommended when haemoglobin has fallen to 10 g per 100 mL or less. For patients with a concentration between 10 and 12 g per 100 mL, the decision to use epoetins depends on clinical circumstances, and may be considered for patients at a higher risk of adverse effects related to anaemia, including elderly patients with limited cardiopulmonary reserve, or patients with underlying coronary artery disease and symptomatic angina. In the UK, the use of epoetins or their analogues is not generally recommended[4] for chemotherapy-related anaemia except, in combination with intravenous iron, in patients in whom anaemia is profound and likely to affect survival, and who cannot be given blood transfusions, or in women given platinum-based chemotherapy for ovarian cancer in whom haemoglobin has fallen to 8 g per 100 mL or less.

NEUTROPENIA. Use of granulocyte or granulocyte-macrophage colony-stimulating factors (G-CSF or GM-CSF), alone or with autologous bone marrow transplants or peripheral blood stem-cells, can markedly reduce the period of neutropenia after high-dose chemotherapy regimens (see Filgrastim, p.1070, and Molgramostim, p.1073).

The American Society of Clinical Oncology has issued detailed guidelines for the use of colony-stimulating factors (CSFs) in patients receiving chemotherapy.[1] These point out that in current practice infectious mortality resulting from febrile neutropenia is rare, and that the incidence with common chemotherapy regimens seldom exceeds 20% in previously untreated patients; however, episodes of febrile neutropenia prolong hospital stay, expose the patient to further interventions, and may result in delay or dose-reduction of further chemotherapy cycles. Unfortunately, although colony-stimulating factors can markedly reduce the incidence of febrile neutropenia, there was little evidence of improved clinical outcomes from the use of CSFs in most situations.

- Use of colony-stimulating factors for **primary prophylaxis** in previously untreated patients should not normally be considered except where the risk of febrile neutropenia was 20% or more, or where the risk was less than 20% but bone-marrow compromise or comorbidity indicated a patient at high risk (and even here the evidence for improved clinical outcome was modest).
- There was no evidence of clinical benefit from the use of colony-stimulating factors in **secondary prophylaxis**. In patients with a previous episode of febrile neutropenia the usual option (except where it would compromise the chances of cure) was dose reduction of the chemotherapy regimen.
- For adjunctive **treatment** of episodes of neutropenia, it was recommended that CSFs should not be routinely used for patients who were *afebrile*; there was also strong and consistent evidence against routine use for uncomplicated fever and neutropenia in *febrile* patients. Use might be considered in high-risk patients with febrile neutropenia.
- Although CSFs could permit **increased dose-density or dose-intensity** of chemotherapy, this was considered only justified within the context of a clinical study, since the limited data suggest survival benefit from dose-dense regimens with CSF support in only a few specific settings. Use in patients receiving combined **chemoradiotherapy** was not recommended.
- In patients with **haematological malignancies**, CSFs should be considered after induction chemotherapy in patients with acute myeloid leukaemias (patients aged over 55 may be most likely to benefit), after consolidation chemotherapy, and after initial induction or postremission chemotherapy in patients with acute lymphoblastic leukaemia; a subset of patients with myelodysplastic syndrome, severe neutropenia, and recurrent infection, might also benefit, but use in patients with refractory or relapsed myeloid leukaemia was not thought to be of benefit.
- CSFs were recommended as adjuncts to **progenitor cell transplantation** to help mobilise peripheral blood stem cells and to speed autologous engraftment.
- As **older patients** treated with curative chemotherapy for diffuse aggressive lymphoma are at increased risk of febrile neutropenia and infections, and dose reduction strategies have been associated with a reduced response rate and survival, prophylactic CSF was recommended for such patients aged 65 and older.
- Although the guidelines in adults were held to be generally applicable to **children**, it was noted that the potential for secondary myeloid leukaemia or myelodysplastic syndrome associated with CSFs was of concern in children with acute lymphoblastic leukaemia.

Guidelines issued by the US National Comprehensive Cancer Network[2] adopt a similar attitude to the use of CSFs, and suggest that they should be used for prophylaxis in all patients with a more than 20% risk of febrile neutropenia or neutropenia sufficient to compromise treatment, and may be considered in patients in whom this risk is judged to be between 10 and 20%. Factors that contribute to risk categorisation include the type of chemotherapy regimen and patient risk factors such as age, type of disease, disease stage, general health, and performance status.

For details on the management of infections in neutropenic patients, see Infections in Immunocompromised Patients, p.174.

THROMBOCYTOPENIA. Chemotherapy-induced thrombocytopenia can be managed with transfusion of platelets (p.1076). Recombinant thrombopoietin[1] (p.1080), interleukin-3 (p.1073), and interleukin-6 have been evaluated for their ability to increase platelet numbers *in vivo*. Interleukin-11 has also been studied and is now available as oprelvekin (p.1074), which can reduce chemotherapy-induced thrombocytopenia.[2,3] Interleukin-1 (p.2325) has also been investigated in the prevention or treatment of thrombocytopenia.

The American Society of Clinical Oncology has issued guidelines for the use of platelet transfusion.[4] They recommend that prophylactic platelet transfusion be given for thrombocytopenia resulting from impaired bone-marrow function to reduce the risk of haemorrhage when the platelet count falls below a predefined threshold. This threshold will vary depending on the patient's diagnosis, clinical condition, and treatment modality. A threshold of 10 000 cells/mm^3 has been recommended for patients being treated for acute leukaemia, with haematopoietic stem cell transplantation, or for solid tumours. A higher threshold of 20 000 cells/mm^3 may need to be considered for patients with signs of haemorrhage, high fever, rapid fall of platelet count, coagulation abnormalities, patients receiving aggressive therapy for bladder tumours, or those with necrotic solid tumours who are at increased risk of bleeding from these sites.

Diarrhoea. Patients receiving chemotherapy should be monitored for onset, duration, and severity of diarrhoea. Uncomplicated mild to moderate diarrhoea may be managed conservatively with dietary modification and loperamide. Severe diarrhoea, and mild to moderate cases that are complicated by moderate to severe cramping, nausea and vomiting, decreased performance status, fever, sepsis, neutropenia, frank bleeding, or dehydration, may require more aggressive management including intravenous fluids, octreotide, and antibacterials.[1]

1. Benson AB, *et al.* Recommended guidelines for the treatment of cancer treatment-induced diarrhea. *J Clin Oncol* 2004; **22:** 2918–26.

Extravasation. Extravasation is the leakage of a drug into subcutaneous tissue during parenteral dosage. Extravasation injuries can range from mild erythema to ulceration, and severe necrosis in some cases if not dealt with promptly. Antineoplastics vary in their propensity to cause extravasation injury:[1]

- *vesicant antineoplastics* cause pain, inflammation and blistering of the local skin, tissue death and necrosis; they include amsacrine, the anthracyclines (doxorubicin and its derivatives), carmustine, dacarbazine, dactinomycin, mitomycin, chlormethine, paclitaxel, plicamycin, streptozocin, and the vinca alkaloids
- *exfoliants* can cause inflammation and exfoliation, but are less likely to cause tissue death, and include cisplatin, docetaxel, mitoxantrone, oxaliplatin, and topotecan
- carboplatin, irinotecan, and the podophyllotoxin derivatives (etoposide and teniposide) are examples of *irritant* drugs which may cause inflammation and irritation, but rarely cause breakdown of tissue. Fluorouracil, methotrexate, and raltitrexed can cause mild to moderate inflammation of local tissue.

Measures to prevent the occurrence of extravasation include giving vesicant or irritant drugs via a central line, or peripherally via a recently sited cannula; vesicants are generally given by intravenous injection into a fast-running infusion. Glyceryl trinitrate patches applied distally to the cannula may be used to dilate veins where venous access is a problem. The site of administration should be regularly checked, and the patient asked to report any untoward sensations.

If extravasation should occur the infusion should be stopped immediately and as much as possible of the infiltrating drug removed by aspiration. Beyond this, however, the management of extravasation is not well standardised and there has been disagreement as to the most appropriate course; there is little data from controlled studies and much practice is based on anecdotal reports and individual experience. Intravenous and subcutaneous injection of a corticosteroid (usually hydrocortisone) has been suggested, although some consider it ineffective or possibly even disadvantageous. Topical application of a 1% hydrocortisone cream to inflamed skin has also been suggested, and antihistamines and, if necessary, analgesics, may be given orally. In most cases application of a cold dressing or ice pack is appropriate. However, after extravasation of the taxanes, vinca alkaloids, or cisplatin, the use of warm packs with hyaluronidase to enhance uptake from the skin has been recommended; a similar procedure has been suggested for large volume extravasations of the podophyllotoxin derivatives.

The use of specific antidotes is a particularly contentious area, since few are clinically validated and some (such as the use of sodium bicarbonate 8.4% for anthracycline extravasations) may do more harm than good. Brief infiltration of a less concentrated (2.1%) sodium bicarbonate solution, followed after a few minutes by aspiration, is still, however, advocated by some in the management of extravasations of the anthracyclines, carmustine, and plicamycin. Better accepted in the management of anthracycline and mitomycin extravasation is the topical application of dimethyl sulfoxide about every 6 hours, sometimes alternated with hydrocortisone 1% cream. Dexrazoxane is also used for the management of anthracycline extravasation. Sodium thiosulfate 3 or 4% has been used to infiltrate the site of extravasations of cisplatin, dactinomycin, or chlormethine.

The role of surgery is also important. It is unequivocally necessary in cases where other methods have failed to prevent evolving tissue damage, but there is some dispute as to the role of early surgery to remove drug-laden tissue and prevent the development of more serious ulceration and necrosis. Techniques of saline flushout and liposuction have been developed for removing drug and non-viable tissue while preserving overlying skin.

Some references to the management of extravasation are given below.[1-6]

6. Ener RA, *et al.* Extravasation of systemic hemato-oncological therapies. *Ann Oncol* 2004; **15:** 858–62.

Hypersensitivity. Desensitisation protocols have been described for cancer patients with hypersensitivity reactions to chemotherapy, including taxanes, platinum agents, and monoclonal antibodies.[1]

1. Castells M. Rapid desensitization for hypersensitivity reactions to chemotherapy agents. *Curr Opin Allergy Clin Immunol* 2006; **6:** 271–7.

Mucositis. Many drugs have been tried for the *prophylaxis* of mucositis caused by antineoplastic therapy, by modifying exposure of the oral mucosa to chemotherapy, modifying epithelial proliferation, or reducing the potential for infection and inflammatory complications of mucositis.[1] Some drugs showed limited evidence of benefit in small studies, including benzydamine, betacarotene, granulocyte-macrophage colony-stimulating factor, povidone-iodine, propantheline bromide, vitamin E, and tretinoin. There are conflicting reports of benefit from studies of sucralfate and chlorhexidine. Other options that have been tried with less success include aciclovir, allopurinol, dinoprostone, glutamine, misoprostol, pentoxifylline, and bacterial and fungal decontamination.

A large systematic review[2] considered many of these and found that some drugs showed evidence of benefit, albeit weak, including amifostine, benzydamine, calcium phosphate, honey, hydrolytic enzymes, iseganan, and zinc sulfate; local cooling with ice chips and Chinese medicinal herb mixtures also showed some benefit. Practice guidelines[3] also suggested that local cooling may prevent oral mucositis associated with bolus fluorouracil or edatrexate; that ranitidine or omeprazole may prevent epigastric pain after treatment with cyclophosphamide, methotrexate, and fluorouracil, or after fluorouracil with or without folinic acid; and that amifostine may reduce oesophagitis associated with chemoradiotherapy for non-small cell lung cancer. Palifermin may prevent oral mucositis in patients with haematological neoplasms given high-dose chemotherapy and total body irradiation before autologous stem cell transplantation. Local cooling may be used in patients given high-dose melphalan.

There will be some overlap between measures for prophylaxis and treatment of mucositis, and another systematic review[4] of *treatment* strategies found that there was some evidence that topical allopurinol or granulocyte-macrophage colony-stimulating factor might improve chemotherapy-induced oral mucositis, but the evidence was weak and unreliable. Given the number of variables involved in the development of mucositis it is unlikely that any one prophylactic or treatment regimen will prove suitable for all patients.

Tumour lysis syndrome. Management of tumour lysis syndrome is based on hydration, correction of metabolic abnormalities, and supportive treatment of renal failure.[1-3] Aggressive hydration with isotonic sodium chloride reduces concentrations of uric acid, phosphate, and potassium, and should be considered in all patients at risk of the syndrome, except those at risk of volume overload. Management of acute hyperkalaemia may include cardiac membrane stabilisation with calcium gluconate, intracellular shift of potassium using insulin (with glucose) or inhaled beta$_2$ agonists, and increased excretion of potassium by diuretics or dialysis. In the management of hyperuricaemia[1,3,4] allopurinol may be given prophylactically to reduce the formation of uric acid, and rasburicase may be used for both prophylaxis and treatment by increasing uric acid oxidation. Adequate hydration, sometimes with urinary alkalinisation using sodium bicarbonate, also improves the solubility and hence renal excretion of uric acid.

Precautions

In view of their severe toxicity and possible carcinogenicity these drugs should generally be reserved for severe or life-threatening disease, and it is widely suggested that their use should be confined to experienced staff in specialised centres.

Immunosuppression and bone-marrow depression are features of many of these drugs and their use is associated with an increased risk of infections caused by pathogenic or opportunistic micro-organisms, and a reduced capacity to cope with them. Where possible, immunosuppressant drugs should not be given to patients with acute infections, and dosage reduction or withdrawal should be considered if infection develops, until the infection has been controlled. For cautions regarding the use of vaccines in patients receiving these drugs see Interactions, below. For discussion of the treatment of infections in immunosuppressed patients, see p.174. Special care is necessary in debilitated patients.

Blood counts and measurement of haemoglobin concentrations should be carried out routinely to help predict the onset of bone-marrow depression. Great caution is needed when the marrow is already depressed from radiotherapy or therapy with other antineoplastics, and modification of dosage regimens may be required. The blood counts below which treatment is contra-indicated will vary depending on the regimen to be used and the therapeutic intent of that treatment (see Bone-Marrow Depression, above); local protocols, including those for the use of colony-stimulating factors, should always be consulted.

Although positive evidence of teratogenicity in humans is not available for all antineoplastics, pregnancy should be avoided in women receiving them: in particular they should not be given, if possible, during the first trimester. Mothers receiving antineoplastic therapy should not breast feed. Because some regimens may result in permanent infertility, the storage of semen samples for male patients, and embryos for females before such therapy may be desirable.

Many antineoplastics are vesicant or irritant. Care must be taken to avoid extravasation since severe pain and tissue damage may ensue. They must be handled with great care and contact with skin and eyes avoided; they should not be inhaled. In many countries official or professional guidelines on precautions for the safe handling of cytotoxic drugs have been issued.

For precautions specific to particular drugs, see under the individual monographs.

Administration in the elderly. The use of antineoplastics in the elderly should take into consideration age-related physiological changes including decline in renal and hepatic function, reduced haematopoietic reserve, and reduced gastrointestinal and cardiac function. Other factors to consider are comorbid conditions and potential drug interactions with associated medications.[1-4] Neoplastic disorders in the elderly have been undertreated because of an impression that these diseases are less aggressive,[5] and the effects of chemotherapy more likely to be severe.[1,2,5,6] Elderly patients have often been excluded from clinical trials for reasons that included physician bias, protocol eligibility criteria with restrictions on comorbidities, and poor patient functional status.[7] There is evidence, however, that healthy older patients can tolerate chemotherapy as well as younger patients.[1,2] However, there have been few studies of chemotherapy specifically in elderly patients,[4,5] and selection of a suitable dosage regimen is more difficult as a consequence, although there is increasing effort to address this lack of data.[2,5,6] Old people vary as much as any other group in their response to drugs, and the consensus is that they should not be excluded from any form of treatment on the grounds of age alone.

Administration at home. Outpatients taking oral antineoplastic therapy at home do not receive the same level of monitoring as inpatients, and should be cautioned to report any adverse effects, since such treatments may still produce severe toxicity.

Contraception. The *BNF* recommends that intra-uterine devices for contraception be used with caution in patients with drug- or disease-induced immunosuppression, because of the risk of infection; such devices are contra-indicated in marked immunosuppression.

Handling and disposal. Many antineoplastics are potent and potentially highly toxic drugs that must be handled with due care. In many countries official or professional guidelines are available for the handling, reconstitution, and disposal of antineoplastics, and most centres or institutions in which these drugs are used will have individual handling policies based on these.[1]

Recommendations generally include:

- that these drugs be reconstituted by trained personnel;
- that reconstitution take place in designated areas, designed to protect personnel and the environment—for example, the use of safety cabinets;
- that protective clothing be worn, including gloves, eye protection, and masks if necessary (it should be noted that gloves may vary in their resistance to penetration, depending upon their thickness, the material of which they are made, and the drug in question[1,2]);
- that waste should be disposed of carefully in suitable separate containers, clearly labelled as to their contents (it should be noted that the patient's body fluids and excreta may contain appreciable amounts of antineoplastic agents and it has been suggested that they and materials such as bed linen contaminated with them should also be treated as hazardous waste[3,4]);
- that adequate procedures should be in place for accidental contamination due to spillages;
- that staff exposure to antineoplastic agents be recorded and monitored;
- that pregnant staff should avoid handling these drugs if possible.

Pregnancy. Antineoplastics may be used during pregnancy for their immunosuppressant properties in auto-immune disease, and for the treatment of cancer, which can complicate 1 in 1000 pregnancies.[1-3] Although the use of potentially teratogenic drugs would normally be avoided during pregnancy, the risk to the mother of inadequate treatment may outweigh whatever risks exist of abnormality in the fetus.[1]

The highest incidence of adverse effects appears to occur after exposure during the first trimester:[1-4] about 10 to 20% of fetuses exposed to cytotoxics during this period have major malformations, compared with 3% in the general population.[1] Malformations reflect the gestational age at exposure. The fetus is particularly vulnerable when exposed during organogenesis (weeks 2 to 8 after conception), and the heart, neural tube, and limbs are affected earlier than the palate and ear; after organogenesis, the eyes, genitalia, haematopoietic system, and CNS remain vulnerable to continued exposure.[3]

The risk of fetal malformations after exposure during the second and third trimesters is probably no higher than the background rate, but there may still be an increased risk of still-birth, fetal growth restriction, premature birth, and maternal or fetal myelosuppression.[1-3]

The delayed effects of antineoplastics on development have not been well-documented. Despite concerns that premature birth and low birth-weight could contribute to retardation of growth, development, and intellect,[5] long-term follow-up of a limited number of children has not shown any evidence of abnormalities.[3-5] Similarly, although maternal antineoplastic therapy has been implicated in a case of childhood neuroblastoma and papillary thyroid cancer, the child's fraternal twin, exposed to the same drugs *in utero*, was healthy.[3] There have been no reports of secondary leukaemias in exposed offspring, but the longer term risk is unknown.[3]

The teratogenicity of any drug depends on the timing of exposure, the dose, and the characteristics affecting placental transfer,[3] as well as the actions of the drug. Of the antineoplastics, the greatest risk seems to be associated with alkylating agents and antimetabolites, in particular aminopterin, fluorouracil, and methotrexate.[1,2,6] The vinca alkaloids and doxorubicin (but not epirubicin or idarubicin) may entail less risk,[2,3] although the former have produced malformations in *animals*.[1] Other drugs reported to be teratogenic or potentially teratogenic include busulfan,[1] chlorambucil,[1,6] chlormethine,[1] cyclophosphamide,[1,6] cytarabine,[1] mercaptopurine,[6] and the podophyllotoxin derivatives.[1] The problems with thalidomide and its congeners are well known.

There are no specific dosage recommendations for the use of antineoplastics during pregnancy, but physiological changes occurring in the mother can alter the pharmacokinetics of drugs.[1-3] This could potentially increase the toxicity of the antineoplastic, or decrease its efficacy.[2] Anecdotal evidence suggests that adverse effects may be less marked during pregnancy, perhaps reflecting reduced peak or free-drug concentrations in the blood.[3] Myelosuppressive chemotherapy should be avoided 3 weeks before the anticipated delivery so that the mother is neither neutropenic nor thrombocytopenic.[1-3] For the same reason, chemotherapy should be avoided after 35 weeks of gestation, when spontaneous delivery is more likely to occur.[3] The timing of delivery is also critical for the neonate, as chemotherapy given shortly before delivery may not be eliminated through the placenta, prolonging exposure in the newborn.[1,3]

There has also been concern that long-term *occupational exposure* to antineoplastics might have an adverse effect on the fetus of pregnant healthcare workers: a study in 650 Finnish nurses found that women who experienced fetal loss were more than twice as likely to have had first trimester exposure to antineoplastic drugs as women who successfully gave birth.[7] These results have been criticised on the grounds that such results are not generally seen in cancer patients,[8,9] who presumably are exposed to much higher doses of antineoplastics. However, similar results were seen in a cross-sectional analysis of 7094 pregnancies involving 2815 nursing and pharmacy staff.[10] Another study[11] has suggested that the rate of ectopic pregnancy may be increased in nurses occupationally exposed to antineoplastics, but the small number of ectopic pregnancies involved (15 in 734 pregnancies) means that the association with antineoplastics may be due to chance. A further, larger, case-control study[12] by the same investigators found no evidence of an increased rate of ectopic pregnancy, and suggested that occupational exposure to higher levels of antineoplastics in the past possibly explained the earlier findings. Again, such an effect does not appear to have been reported in women treated with antineoplastics.

Interactions

Because of their effects on the gastrointestinal mucosa antineoplastics have the potential to interfere with the absorption of drugs given orally. Antineoplastics that have an immunosuppressant effect may reduce the response to vaccines, and there is a possibility of generalised infection with live vaccines. Use with live vaccines should generally be avoided.

Many antineoplastics are inhibitors of certain isoenzymes of cytochrome P450 and some antineoplastics are also metabolised by these enzymes, and in consequence the possibility of interactions between antineoplastics, or between antineoplastics and other medication, cannot be discounted.

Interactions affecting specific drugs are covered under the individual monographs.

Antivirals. The potential for interaction between antiretrovirals and antineoplastics has been reviewed.[1] Although clinical evidence of interactions is scanty, various HIV-protease inhibitors and NNRTIs can inhibit or induce cytochrome P450 isoenzymes, and thus have the potential to interact with a number of antineoplastics including taxanes, vinca alkaloids, and cyclophosphamide.

Effects on other drugs. Antineoplastics have been reported to affect a number of drugs including:

- digoxin (reduced absorption, see p.1262)
- oral anticoagulants (increased or decreased effect, see Warfarin, p.1429)
- phenytoin (increased or decreased effect, see p.499)
- suxamethonium (prolonged effect, see p.1911)
- vaccines (decreased response, see p.2202).

Herbal medicines. The potential for interactions between antineoplastics and herbal medicines has been reviewed.[1] There is a general lack of information and reports, and warnings are largely based on theory and extrapolation from herbal interactions with other drugs.

Pharmacokinetics

Many antineoplastics have intra- and interindividual pharmacokinetic variability that can be influenced by a number of factors. Patient age, disease state, and drug interactions can affect drug absorption, distribution, metabolism, and excretion. Genetic polymorphisms also affect drug disposition and are under investigation, but the clinical use of such information is currently limited. Various methods have been tried or are being investigated as ways of tailoring initial drug dosage and therapeutic drug monitoring for individual patients in order to improve treatment efficacy and minimise toxicity. Such methods include population pharmacokinetic modelling and individual pharmacogenetic typing; examples include carboplatin dosing based on glomerular filtration rate (p.693) and genotyping of patients thought to be at increased risk of irinotecan toxicity (p.737).

Action

Much of the development of cancer chemotherapy has been based on an understanding of the way in which tumour cells grow, and the way in which the drugs affect this growth.

After cell division the daughter cells enter a period of growth, $\mathbf{G_1}$, which lasts for different lengths of time in different tissues. This is followed by a period of DNA synthesis, **S**, in which the amount of chromosomal material is doubled, then a postsynthetic, or premitotic, phase, $\mathbf{G_2}$, then finally by mitotic cell division, **M**. As an alternative to re-entering the cycle, the products of cell division may enter a kinetically-dormant, nonproliferative stage, $\mathbf{G_0}$, although it is not exactly clear what recruits such 'resting' cells back into the cell cycle.

The rate of cell division varies for different tumours; the doubling time for Burkitt's lymphoma and acute lymphoblastic leukaemia is less than 5 days, whereas the mean doubling time for seminoma is about 20 days, that for small-cell lung cancer about 50 days, and those for colon cancer and advanced breast cancer about 100 and 150 days respectively. The range of reported doubling times may also vary widely for a particular tumour type. Most common cancers increase very slowly in size in comparison with sensitive normal tissues, including those from which they derive, and the rate may decrease further in large tumours. This difference allows normal cells to recover more quickly than malignant ones from chemotherapy, and is the rationale behind cyclic dosage schedules. The lethal body tumour burden is reached when the tumour cell mass approaches or exceeds 1×10^{12} cells, equivalent to about 1 kg of tissue, and representing about 40 doublings.

Cell killing by cytotoxic agents is generally a first order process, so a given dose or course of antineoplastic kills a fixed percentage of tumour cells rather than a fixed number. Thus a drug that killed 99% of tumour cells would leave behind 10^{10} cells from a tumour containing 10^{12} cells, but only 10^2 cells from one containing 10^4, reinforcing the importance of treating malignant neoplasms as early as possible.

Cytotoxic drugs act to damage the reproductive integrity of cells. Some are active at a particular stage of the cell cycle. The antimetabolites interfere with DNA synthesis, as does hydroxycarbamide, and are thus active against cells in S phase, while the vinca alkaloids inhibit microtubular function and act on cells in phase M. Other drugs such as the alkylating agents, the anthracyclines, and cisplatin are not phase-specific, but since their actions are dependent at least in part on damaging DNA they are more effective against proliferating cells, particularly in S phase. It is now thought that many antineoplastics exert their ultimate effect by inducing cellular apoptosis (programmed cell death). Some drugs, such as bleomycin or vinblastine also have the property of arresting the cycle in a particular phase, and attempts have been made to synchronise tumour cell division in this way, to maximise the number of cells in a sensitive phase when a particular drug is used. However, in practice this approach has been less successful than early experimental results suggested.

Some drugs used in the treatment of neoplasms do not attack the tumour cells directly but are given in order to increase cell vulnerability to other modalities: these include radiosensitisers (which have proved of only limited benefit to date), and photosensitisers such as porfimer sodium, used in photodynamic therapy (PDT).

Apart from attacking cell division, increased understanding of the molecular biology of tumour cells has begun to open the possibility of other approaches to the treatment of malignant neoplasms. Some monoclonal antibodies are designed to bind to specific cell-surface proteins or receptors, enabling the immune system to recognise and attack tumour cells (targeted therapy). Control of tumour growth through inhibition of angiogenesis is also being used. Other areas of investigation include inducing tumour cells to differentiate into non-malignant forms, manipulation of cellular apoptosis and signal transduction, inhibiting the expression of abnormal growth factors, telomerases and other oncogene products (including the use of ribozymes or of 'antisense' compounds which inhibit oncogenic messenger RNA), and prevention or inhibition of metastasis. Gene therapy (p.2310) is another form of treatment under consideration. However, such approaches remain largely experimental.

Resistance

Resistance to antineoplastics is one of the greatest limitations to the use of chemotherapy in malignant disease. Resistance may be intrinsic to the tumour or may be acquired during chemotherapy, which effectively acts to select resistant cells from a heterogeneous population; the latter is one reason that relapses, or malignancies in heavily-pretreated patients, may be particularly difficult to treat.

The mechanisms of resistance in cancer cells are complex and imperfectly understood, but appear to include:

- hypoxia and imperfect drug penetration in the centre of large, solid tumours
- the small proportion of cells actively dividing and thus vulnerable to antineoplastics (particularly in slow-growing tumours)
- decreased cellular uptake or increased efflux of antineoplastic
- increased metabolic breakdown or decreased activation of antineoplastic
- increased expression of target enzymes
- metabolism via alternative biochemical pathways to those blocked by the antineoplastic
- more efficient repair of damaged DNA
- possibly the expression of genes which inhibit drug-induced apoptosis.

Several of these mechanisms may be in operation at one time. Much interest has been expressed in the potential use of drugs which can modulate or inhibit mechanisms of resistance, and in particular in compounds such as valspodar, verapamil, quinidine, and ciclosporin, which have the ability to block the action of p-glycoprotein, a membrane glycoprotein which acts as an efflux pump for a range of cytotoxic substances and which is responsible for the multi-drug resistant (MDR) phenotype. However, for sustained benefit it seems likely that several drugs would be required, each to overcome a different mechanism of resistance, and it would be necessary to ensure that toxicity of antineoplastics to normal cells was not also enhanced.

If the emergence of heritable resistant phenotypes is a natural part of tumour-cell biology (the Goldie-Coldman hypothesis) it implies that the larger and older the tumour, the more likely is resistance to occur. This would confirm the benefits of surgery and radiotherapy to shrink the primary tumour, and of starting chemotherapy as soon as possible after (a preferably early) diagnosis.

Antiresistance agents. Some drugs have been reported to partially abolish multidrug resistance to antineoplastics *in vitro*.[1,2] These include:

- verapamil, its enantiomers and analogues such as Ro-11-2933
- other calcium-channel blockers including prenylamine, diltiazem, nifedipine analogues such as nicardipine and bepridil
- various phenothiazines and thioxanthenes including trifluoperazine and the *trans*-isomer of flupentixol
- structural analogues of the anthracyclines and vinca alkaloids
- progesterone and other steroid hormones, as well as, to some extent, anti-oestrogens such as tamoxifen
- ciclosporin and various of its nonimmunosuppressive analogues (such as valspodar)
- miscellaneous drugs including amiodarone, quinidine, propranolol, reserpine, yohimbine, dipyridamole, erythromycin, cefoperazone, and ceftriaxone

However, despite reported effects on resistance *in vitro* clinical results may be less impressive: studies in which verapamil was added to therapy for small cell lung cancer[3] or multiple myeloma[4] failed to show any benefit, and second-generation P-glycoprotein inhibitors such as valspodar have unpredictable pharmacokinetic interactions with cytotoxics.[5] Nevertheless, there is ongoing development of P-glycoprotein inhibitors, and drugs such as tariquidar are undergoing clinical studies.[5] It has been suggested that tumour growth may rely on a malignant equivalent of stem cells, with innate multi-drug resistance, and that this may make overcoming resistance without damaging normal stem cells particularly difficult.[6]

Choice of Antineoplastic

The following section describes the treatment of some of the major malignant neoplasms, and in particular the role of combination chemotherapy with antineoplastics.

Table 1 (p.644) lists published initial doses for some well-known combination chemotherapy regimens. Doses may be modified (particularly in subsequent cycles) to allow for patient status and toxic effects, although in some cases this may be at the expense of efficacy. Regimens can also vary slightly between institutions, or may be modified as part of the ongoing evolution of cancer chemotherapy; such therapy should preferably take place only in expert centres. The same acronym has sometimes been used for regimens containing different drugs, or using the same drugs in different doses or in different ways, and the reader should consult the literature for further details.

Role of chemotherapy

In 1999, in an update of a previous consultation document on cancer chemotherapy,[1] WHO listed those drugs it considered essential for the rational management of malignant neoplasms.

The list divides drugs into 3 categories [note: drugs in italics in this list were not in the previous 1994 list]:

- 17 essential drugs that are used to treat curable cancers or cancers for which the cost-benefit ratio clearly favours drug treatment (bleomycin, *chlorambucil*, cisplatin, cyclophosphamide, *cytarabine*, dactinomycin, daunorubicin, doxorubicin, etoposide, fluorouracil, mercaptopurine, methotrexate, prednisolone, procarbazine, tamoxifen, vinblastine, and vincristine)
- 12 drugs that may have advantages in certain clinical situations (*busulfan*, *carboplatin*, *flutamide*, folinic acid, *gonadorelin analogues*, *interferon alfa*, *melphalan*, *megestrol*, mitomycin, *mitoxantrone*, *paclitaxel*, and *vinorelbine*)
- 13 drugs judged as not essential for the effective delivery of cancer care (*aminoglutethimide*, *anastrozole*, *altretamine*, *carmustine*, dacarbazine, *docetaxel*, *epirubicin*, *gemcitabine*, *ifosfamide*, *irinotecan*, *lomustine*, *raltitrexed*, and *topotecan*).

WHO considers that for some tumours such as hepatocellular carcinoma and lung cancer the development of effective prevention programmes through hepatitis B immunisation and tobacco control is currently of greater priority than therapy.[1]

Despite the real benefits achieved in selected conditions, reassessment of the role and value of chemotherapy for malignant neoplasms led a number of oncologists in the 1980s and 90s to express the view that it had not lived up to its promise. Braverman[2] suggested in 1991 that for many or most patients medical management should be confined to symptom management and enrolment in a hospice programme, with a considerable reduction in the prescription of antineoplastics and a confinement of studies to drugs with novel mechanisms of action, or refinement of regimens known to be effective, a view he subsequently re-iterated.[3] Similar views were expressed by others, pointing out the failure of treatment for most common adult tumours,[4] and suggesting that widespread use of chemotherapy was not justified outside clinical trials or specialised centres.[5,6] Bailar and Smith, in a statistical review in 1986, suggested that the 'war against cancer' was being lost, and that concentration on prevention rather than treatment might produce more promising results.[7] Despite acknowledging some areas of progress, an update of this review including data up to the end of 1994 came to the same conclusion.[8] Others also pointed out the failure to adequately address methods for cancer prevention.[9]

Such views naturally provoked controversy, and others considered that developments in the use of adjuvant and intensive regimens, as well as the continuing development of new agents, were significant and should not be denigrated.[10-14] However, the frequent reference to the hoped-for benefits of a greatly-improved knowledge of the molecular biology of cancer, and in particular the use of biological response modifiers,[11,15] or gene therapy,[16] did seem to concede that chemotherapeutic regimens could be improved. Whether dose intensification is one appropriate route for improvement is a matter of some debate,[17,18] and, so far, clear evidence of effectiveness has been reported only for certain leukaemias and lymphomas.[1]

It has been suggested that perhaps attempts to destroy cancer cells are based on a false analogy between oncology and microbiology, and that a more appropriate goal would be the restoration of mechanisms of cellular control, enabling the patient to live with their cancer. Understanding of malignancy as a process, involving complex interactions between the malignant cell and its environment, in which intervention may be feasible to restore regulation of cellular growth, offers a potentially useful approach to cancer treatment. Although such an approach remains largely theoretical at present,[9,19,20] some drugs currently available, such as imatinib and trastuzumab, offer glimpses of its potential.

Management of malignant disease

Carcinoid tumours and other secretory neoplasms. All neoplastic cells have some abnormalities of metabolism, and many secrete characteristic metabolic products. Where the substance secreted has hormonal or pharmacological properties profound clinical effects may result, particularly since secretion is generally unregulated by normal homoeostatic mechanisms. Examples of syndromes associated with such secretory neoplasms include acromegaly (p.1798), Cushing's syndrome (p.2344), hyperprolactinaemia (p.2079), and other endocrine disorders associated with pituitary adenomas; phaeochromocytoma (p.1179); and carcinoid syndrome and the various syndromes associated with pancreatic endocrine tumours. Multiple endocrine neoplasia type 1 (MEN1) and type 2 (MEN2) are inherited conditions in which many tumours occur in often more than one endocrine organ; tumours in this disorder are often secretory.[1,2]

Table 1. Common chemotherapy regimens for malignant disease.

Regimen	Drugs and Administration	Cycle	Typically used for	References
ABCM	Doxorubicin 30 mg/m^2 iv day 1; carmustine 30 mg/m^2 iv day 1; cyclophosphamide 100 mg/m^2 oral days 22–25; and melphalan 6 mg/m^2 oral days 22–25.	42 days	Multiple myeloma	1
ABVD	Doxorubicin 25 mg/m^2 iv days 1, 15; bleomycin 10 000 IU/m^2 iv[(b)] days 1, 15; vinblastine 6 mg/m^2 iv days 1, 15; and dacarbazine 375 mg/m^2 iv days 1, 15.	28 days	Lymphomas	2, 3
AC	Doxorubicin 60 mg/m^2 iv day 1 and cyclophosphamide 600 mg/m^2 iv day 1.	21 days (for 4 cycles; some studies used up to 8 cycles)	Breast cancer	4–6
AC + paclitaxel	As above, then followed by paclitaxel 175 mg/m^2 iv day 1.	21 days (further 4 cycles)	Breast cancer	7
AC + trastuzumab	Doxorubicin 60 mg/m^2 iv day 1; cyclophosphamide 600 mg/m^2 iv day 1; and trastuzumab 4 mg/kg iv loading dose on day 1 then 2 mg/kg once each week.	21 days (for 6 cycles)	Breast cancer (HER2 overexpressing)	8
ACE	Doxorubicin 45 mg/m^2 iv day 1; cyclophosphamide 1 g/m^2 iv day 1; and etoposide 50 mg/m^2 iv days 1–5.	21 days	Small cell lung cancer	9
AT	Doxorubicin 60 mg/m^2 iv day 1 and paclitaxel 200 mg/m^2 iv day 1.	21 days (for 4 cycles)	Breast cancer	4
AT	Doxorubicin 50 mg/m^2 iv day 1 and docetaxel 75 mg/m^2 iv day 1.	21 days (for up to 8 cycles)	Breast cancer (metastatic)	5
BEAM (Mini-BEAM)	Carmustine 60 mg/m^2 iv day 1; etoposide 75 mg/m^2 iv days 2–5; cytarabine 100 mg/m^2 twice daily iv days 2–5; and melphalan 30 mg/m^2 iv day 6.	usually 28 to 42 days	Lymphomas (salvage)	10
BEP	Bleomycin 30 000 IU iv[(b)] days 2, 9, 16; etoposide 100 mg/m^2 iv days 1–5; and cisplatin 20 mg/m^2 iv days 1–5.	21 days (for 4 cycles)	Testicular cancer	11
CAF	Cyclophosphamide 500 mg/m^2 iv day 1; doxorubicin 50 mg/m^2 iv day 1; and fluorouracil 500 mg/m^2 iv day 1.	21 days	Breast cancer	12
CAP	Cyclophosphamide 750 mg/m^2 iv day 1; doxorubicin 50 mg/m^2 iv day 1; and prednisone 40 mg/m^2 oral days 1–5.	28 days	Chronic lymphocytic leukaemia	13
CAP	Cyclophosphamide 500 mg/m^2 iv day 1; doxorubicin 50 mg/m^2 iv day 1; and cisplatin 50 mg/m^2 iv day 1 (these doses are optimised from the original 600 mg/m^2, 45 mg/m^2, and 50 mg/m^2 respectively).	21 days (for 6 cycles)	Ovarian cancer	14, 15
CAV	Cyclophosphamide 900 mg/m^2 iv day 1; doxorubicin 45 mg/m^2 iv day 1; and vincristine 2 mg iv day 1.	21 days (for 6 cycles)	Small cell lung cancer	16
CHOP	Cyclophosphamide 750 mg/m^2 iv day 1; doxorubicin 50 mg/m^2 iv day 1; vincristine 1.4 mg/m^2 (max. 2 mg) iv day 1; and prednisone 100 mg oral days 1–5.	21 days (for 6 to 8 cycles)	Lymphomas, chronic lymphocytic leukaemia	17, 18
CMF	Cyclophosphamide 100 mg/m^2 oral days 1–14; methotrexate 40 mg/m^2 iv days 1, 8; and fluorouracil 600 mg/m^2 iv days 1, 8.	28 days	Breast cancer	6, 19

Key to abbreviations: hrs – hours; im – intramuscular; iv – intravenous

Table 1. Common chemotherapy regimens for malignant disease.*(Continued)*

Regimen	Drugs and Administration	Cycle	Typically used for	References
CMF	Cyclophosphamide 600 mg/m^2 iv day 1; methotrexate 40 mg/m^2 iv day 1; and fluorouracil 600 mg/m^2 iv day 1.	21 days	Breast cancer	20
CMF	Cyclophosphamide 750 mg/m^2 iv day 1; methotrexate 40 mg/m^2 iv days 1, 8; and fluorouracil 600 mg/m^2 iv days 1, 8.	28 days	Breast cancer	6
CMV	Cisplatin 100 mg/m^2 iv day 2; methotrexate 30 mg/m^2 iv days 1, 8; and vinblastine 4 mg/m^2 iv days 1, 8.	21 days	Bladder cancer	21
COP (CVP)	Cyclophosphamide 800 mg/m^2 iv day 1; vincristine 2 mg iv day 1; and prednisone 60 mg/m^2 oral days 1–5, then tapered over days 6–8.	21 days (for 6 cycles)	Lymphomas (the original report of this regimen used a 14-day cycle)	22
CP	Cisplatin 100 mg/m^2 iv day 1 and cyclophosphamide 600 mg/m^2 iv day 1 *or* carboplatin 300 mg/m^2 iv day1 and cyclophosphamide 600 mg/m^2 iv day 1.	28 days (for 6 cycles)	Ovarian cancer	23
CYVADIC	Cyclophosphamide 500 mg/m^2 iv day 1; vincristine 1.5 mg/m^2 iv[a] days 1, 5; doxorubicin 50 mg/m^2 iv day 1; and dacarbazine 250 mg/m^2 iv days 1–5.	21 days	Sarcoma (alternative versions of this regimen using vincristine on day 1 only have also been reported)	24
Dartmouth regimen	Dacarbazine 220 mg/m^2 iv days 1–3, 22–24; cisplatin 25 mg/m^2 iv days 1–3, 22–24; carmustine 150 mg/m^2 iv day 1; and tamoxifen 10 mg oral twice daily.	42 days	Melanoma (metastatic)	25, 26
DHAP	Dexamethasone 40 mg oral or iv days 1–4; cytarabine 2 g/m^2 iv over 3 hrs, repeated after 12 hrs, day 2; and cisplatin 100 mg/m^2 iv over 24 hrs, day 1.	21–28 days	Lymphomas (salvage)	27
EAP	Etoposide 120 mg/m^2 iv days 4–6; doxorubicin 20 mg/m^2 iv days 1, 7; and cisplatin 40 mg/m^2 iv days 2, 8.	21–28 days	Stomach cancer	28, 29
EC	Etoposide 100 mg/m^2 iv days 1–3 and carboplatin 450 mg/m^2 iv day 1.	28 days	Small cell lung cancer	30
EC	Etoposide 100 mg/m^2 iv days 1–3 and carboplatin 325 mg/m^2 iv day 1.	21 days	Non-small cell lung cancer	31
ECF	Epirubicin 50 mg/m^2 iv day 1; cisplatin 60 mg/m^2 iv day 1; and fluorouracil 200 mg/m^2 daily continuous iv.	21 days (for up to 8 cycles)	Stomach cancer	32
EDAP	Etoposide 100–200 mg/m^2 continuous iv, days 1–4; dexamethasone 40 mg oral or iv days 1–5; cytarabine 1 g/m^2 iv day 5; and cisplatin 20 mg/m^2 continuous iv, days 1–4.	21–28 days	Multiple myeloma (salvage), lymphomas	33
EMA-CO (or EMA-EP)	Etoposide 100 mg/m^2 iv days 1, 2; methotrexate 300 mg/m^2 iv over 12 hrs, day 1; folinic acid 15 mg oral or im, twice daily for 4 doses, starting day 2; and dactinomycin 500 micrograms iv days 1, 2. *with* cyclophosphamide 600 mg/m^2 iv day 8 and vincristine 1 mg/m^2 iv[a] day 8. *or* etoposide 150 mg/m^2 iv day 8 and cisplatin 75 mg/m^2 iv day 8.	14 days	Gestational trophoblastic tumours	34
EP (PE)	Etoposide 80 mg/m^2 iv days 1–3 and cisplatin 80 mg/m^2 iv day 1.	21 days	Small cell lung cancer (standard dose – other versions exist)	35

Key to abbreviations: hrs – hours; im – intramuscular; iv – intravenous

Table 1. Common chemotherapy regimens for malignant disease.*(Continued)*

Regimen	Drugs and Administration	Cycle	Typically used for	References
EP (PE)	Etoposide 80 mg/m^2 iv days 1–5 and cisplatin 27 mg/m^2 iv days 1–5.	21 days	Small cell lung cancer (high dose)	35
EP (PE)	Etoposide 100 mg/m^2 iv day 1, *then* 200 mg/m^2 oral days 2–4 and cisplatin 75 mg/m^2 iv day 1.	21 days	Small cell lung cancer	36
EPOCH	Etoposide 50 mg/m^2 continuous iv days 1–4; vincristine 400 micrograms/m^2 continuous iv[(a)] days 1–4; doxorubicin 10 mg/m^2 continuous iv days 1–4; cyclophosphamide 750 mg/m^2 iv day 5; and prednisone 60 mg/m^2 oral days 1–5.	21 days	Lymphomas (salvage)	37
ESHAP	Etoposide 40 mg/m^2 iv days 1–4; methylprednisolone 250–500 mg iv days 1–5; cisplatin 25 mg/m^2 continuous iv days 1–4; and cytarabine 2 g/m^2 iv day 5.	21–28 days (for up to 8 cycles)	Lymphomas (salvage)	38
FAM	Fluorouracil 600 mg/m^2 iv days 1, 8, 29, 36; doxorubicin 30 mg/m^2 iv days 1, 29; and mitomycin 10 mg/m^2 iv day 1.	56 days	Stomach cancer, pancreatic cancer	39–41
FAMTX	Fluorouracil 1.5 g/m^2 iv day 1; doxorubicin 30 mg/m^2 iv day 15; methotrexate 1.5 g/m^2 iv day 1, 1 hour before fluorouracil; and folinic acid 15 mg/m^2 oral every 6 hrs for 3 days, starting 24 hrs after methotrexate.	28 days	Stomach cancer	29, 32
FOLFIRI	Irinotecan 180 mg/m^2 iv day 1; folinic acid 200 mg/m^2 iv day 1; fluorouracil 400 mg/m^2 iv bolus day 1, then 2.4 g/m^2 continuous iv infusion (increased to 3 g/m^2 from cycle 3 if tolerated) over 46 hours.	14 days	Colorectal cancer	69
FOLFOX4	Oxaliplatin 85 mg/m^2 iv day 1; folinic acid 200 mg/m^2 iv days 1, 2; fluorouracil 400 mg/m^2 iv bolus then 600 mg/m^2 continuous iv infusion, days 1, 2.	14 days	Colorectal cancer (in addition to FOLFOX6, below, other variants of the FOLFOX regimen exist; combination with bevacizumab or cetuximab is also being tried)	70
FOLFOX6	Oxaliplatin 100 mg/m^2 iv day 1; folinic acid 200 mg/m^2 iv day 1; fluorouracil 400 mg/m^2 iv bolus day 1, then 2.4 g/m^2 continuous iv infusion (increased to 3 g/m^2 from cycle 3 if tolerated) over 46 hours.	14 days	Colorectal cancer	69
5FU/Folinic acid	Fluorouracil 370 mg/m^2 iv days 1–5 and folinic acid 200 mg/m^2 iv days 1–5.	28–35 days	Colorectal cancer	42
5FU/Folinic acid (Mayo regimen, Poon regimen)	Fluorouracil 425 mg/m^2 iv days 1–5 and folinic acid 20 mg/m^2 iv day 1–5.	28–35 days	Stomach cancer, colorectal cancer	42, 43
5FU/Folinic acid (de Gramont regimen)	Fluorouracil 400 mg/m^2 iv bolus then 600 mg/m^2 continuous iv infusion, days 1, 2 and folinic acid 200 mg/m^2 iv days 1, 2.	14 days	Colorectal cancer	44
Gemcitabine + cisplatin	Gemcitabine 1 g/m^2 iv days 1, 8, 15 and cisplatin 70 mg/m^2 iv day 2.	28 days	Bladder cancer (metastatic)	45
ICE (ICbE)	Ifosfamide 5 g/m^2 iv over 24 hrs, day 1 (with mesna); carboplatin 400 mg/m^2 iv day 1; and etoposide 100 mg/m^2 iv days 1–3.	28 days (for 6 cycles)	Small cell lung cancer	46
IFL (Douillard 1-week regimen)	Irinotecan 80 mg/m^2 iv, day 1; fluorouracil 2.3 g/m^2 continuous iv infusion, day 1; folinic acid 500 mg/m^2 iv, day 1.	7 days	Colorectal cancer	71
IFL (Douillard 2-week regimen)	Irinotecan 180 mg/m^2 iv, day 1; fluorouracil 400 mg/m^2 iv bolus then 600 mg/m^2 continuous iv infusion, days 1, 2; folinic acid 200 mg/m^2 iv, days 1, 2.	14 days	Colorectal cancer	71
Key to abbreviations: hrs – hours; im – intramuscular; iv – intravenous				

Table 1. Common chemotherapy regimens for malignant disease.*(Continued)*

Regimen	Drugs and Administration	Cycle	Typically used for	References
IFL (Saltz regimen)	Irinotecan 125 mg/m^2 iv; fluorouracil 500 mg/m^2 iv; and folinic acid 20 mg/m^2 iv all once a week for 4 weeks.	42 days	Colorectal cancer	47
Hyper-CVAD	*Course A:* Cyclophosphamide 300 mg/m^2 iv every 12 hrs, days 1–3; doxorubicin 50 mg/m^2 iv day 4; vincristine 2 mg iv days 4, 11; and dexamethasone 40 mg iv or oral, days 1–4, 11–14. *CNS prophylaxis* Methotrexate 12 mg intrathecal, day 2 and cytarabine 100 mg intrathecal, day 8. *Course B:* Methotrexate 200 mg/m^2 iv over 2 hrs, then 800 mg/m^2 iv over 24 hrs, day 1; folinic acid 15 mg iv every 6 hrs for 8 doses, from 24 hrs after methotrexate (increased to 50 mg iv every 6 hrs if methotrexate levels are high); methylprednisolone 50 mg iv every 12 hrs, days 1–3; and cytarabine 3 g/m^2 every 12 hrs, days 2, 3.	4 cycles of A alternated with 4 cycles of B, given over as short a period as possible; the number of A cycles in which CNS prophylaxis is given varies with expected risk of CNS disease	Lymphomas, adult acute lymphoblastic leukaemia (some variants of this regimen exist, including the substitution of daunorubicin 60mg/m^2 for doxorubicin in course A, the omission of methylprednisolone and addition of oral bicarbonate in course B, and simplification of methotrexate and folinic acid dosing; mesna, which was given in course A of the original regimen, is usually omitted)	48
M2	Vincristine 30 micrograms/kg iv[(a)] day 1; carmustine 500 micrograms/kg iv day 1; cyclophosphamide 10 mg/kg iv day 1; melphalan 250 micrograms/kg oral days 1–4 *or* 100 micrograms/kg oral days 1–7 *or* 1–10; and prednisone 1 mg/kg oral, days 1–7, then taper and discontinue by day 21 unless hypercalcaemia or bone disease persist.	35 days	Multiple myeloma	49
MACOP-B	Methotrexate 400 mg/m^2 iv days 8, 36, 64 (as 100 mg/m^2 iv bolus, then 300 mg/m^2 iv over 4 hrs); folinic acid 15 mg oral every 6 hrs for 6 doses, from 24 hrs after methotrexate; doxorubicin 50 mg/m^2 iv days 1, 15, 29, 43, 57, 71; cyclophosphamide 350 mg/m^2 iv days 1, 15, 29, 43, 57, 71; vincristine 1.4 mg/m^2 iv[(a)] days 8, 22, 36, 50, 64, 78; bleomycin 10 000 IU/m^2 iv[(b)] days 22, 50, 78; and prednisone 75 mg oral, daily for 10 weeks then tapered over 15 days.	12 weeks	Lymphomas	50
MIC	Mitomycin 6 mg/m^2 iv day 2; ifosfamide 3 g/m^2 iv day 2; and cisplatin 120 mg/m^2 iv day 1.	21 days	Non-small cell lung cancer	51
MIC	Mitomycin 6 mg/m^2 iv day 1; ifosfamide 3 g/m^2 iv day 1; and cisplatin 50 mg/m^2 iv day 1.	21 days	Non-small cell lung cancer	52
MOPP	Chlormethine 6 mg/m^2 iv days 1, 8; vincristine 1.4 mg/m^2 (max. 2 mg), days 1, 8; procarbazine 100 mg/m^2 oral days 1–14; and prednisone 40 mg/m^2 oral days 1–14, cycles 1, 4.	28 days (for 6 cycles)	Lymphomas, Hodgkin's disease	3, 53
M-VAC	Methotrexate 30 mg/m^2 iv days 1, 15, 22; vinblastine 3 mg/m^2 iv days 2, 15, 22; doxorubicin 30 mg/m^2 iv day 2; and cisplatin 70 mg/m^2 iv day 2.	usually 28 days	Bladder cancer	45, 54, 55
MVP	Mitomycin 8 mg/m^2 iv day 1, cycles 1 and 2, day 15 cycle 3; vinblastine 4 mg/m^2 iv day 1, cycle 1 2 mg/m^2 iv day 8, cycle 1 4.5 mg/m^2 iv days 15, 22, cycle 1 4.5 mg/m^2 iv days 1, 15, cycle 2 and later; and cisplatin 120 mg/m^2 iv day 1	28 days	Non-small cell lung cancer (neoadjuvant)	56
MVP	Mitomycin 8 mg/m^2 iv day 1, cycles 1 and 2, day 15 cycle 3; vindesine 3 mg/m^2 iv days 1, 8, 15, 22, day 1 of cycle 2, then every 2 weeks until the 15th week; and cisplatin 120 mg/m^2 iv day 1, for 3 cycles.	28 days	Non-small cell lung cancer (neoadjuvant)	56, 57
Key to abbreviations: hrs – hours; im – intramuscular; iv – intravenous				

Table 1. Common chemotherapy regimens for malignant disease.*(Continued)*

Regimen	Drugs and Administration	Cycle	Typically used for	References
MVP	Mitomycin 8 mg/m^2 iv day 1, cycles 1 and 2, day 15 cycle 3; vinorelbine 25 mg/m^2 iv once a week for 16 weeks; and cisplatin 120 mg/m^2 iv day 1, for 3 cycles.	28 days	Non-small cell lung cancer (neoadjuvant)	57
PAC	Cisplatin 50 mg/m^2 iv day 1; doxorubicin 50 mg/m^2 iv day 1; and cyclophosphamide 500 mg/m^2 iv day 1.	21 days (for up to 8 cycles)	Thymoma	58
Paclitaxel and carboplatin	Paclitaxel 175 mg/m^2 iv day 1 and carboplatin – adjust dose to AUC of 7.5 mg/mL/minute by Calvert formula, iv day 1.	21 days (for 6 cycles)	Ovarian cancer	59
Paclitaxel and cisplatin	Paclitaxel 135 mg/m^2 continuous iv over 24 hrs, day 1 and cisplatin 75 mg/m^2 iv day 1.	21 days (for 6 cycles)	Ovarian cancer	60
Paclitaxel (standard) and trastuzumab	Paclitaxel 175 mg/m^2 iv on day 1 and trastuzumab 4 mg/kg iv loading dose on day 1 then 2 mg/kg once each week.	21 days	Breast cancer (HER2 overexpressing)	8
Paclitaxel (weekly) and trastuzumab	Paclitaxel 90 mg/m^2 iv on day 1 and trastuzumab 4 mg/kg iv loading dose on day 1 then 2 mg/kg once each week.	7 days	Breast cancer (HER2 overexpressing)	61
PCV	Procarbazine 60 mg/m^2 oral days 8–21; lomustine 110 mg/m^2 oral day 1; and vincristine 1.4 mg/m^2 iv[a] days 8, 29.	42–56 days	Gliomas (adjuvant)	62
PE	*See* EP			
ProMACE-CytaBOM	Prednisone 60 mg/m^2 oral days 1–14; doxorubicin 25 mg/m^2 iv day 1; cyclophosphamide 650 mg/m^2 iv day 1; etoposide 120 mg/m^2 iv day 1; cytarabine 300 mg/m^2 iv day 8; bleomycin 5000 IU/m^2 iv[b] day 8; vincristine 1.4 mg/m^2 iv[a] day 8; methotrexate 120 mg/m^2 iv day 8; and folinic acid 25 mg/m^2 oral every 6 hrs for 4 doses, from 24 hrs after methotrexate.	21 days	Lymphomas	63
PVB	See VBP			
SMF	Streptozocin 1 g/m^2 iv days 1, 8, 29, 36; mitomycin 10 mg/m^2 iv day 1; and fluorouracil 600 mg/m^2 iv days 1, 8, 29, 36.	56 days	Pancreatic cancer	41
Stanford V regimen	Doxorubicin 25 mg/m^2 iv days 1, 15; vinblastine 6 mg/m^2 iv days 1, 15; chlormethine 6 mg/m^2 iv day 1; vincristine 1.4 mg/m^2 iv (max 2mg) days 8, 22; bleomycin 5000 IU/m^2 iv[b] days 8, 22; etoposide 60 mg/m^2 iv days 15, 16; prednisone 40 mg/m^2 oral on alternate days for 10 weeks then tapered by 10 mg on alternate days.	28 days (for 3 cycles)	Hodgkin's disease	64
VAD	Vincristine 400 micrograms iv days 1–4; doxorubicin 9 mg/m^2 iv days 1–4; and dexamethasone 40 mg oral days 1–4, 9–12, 17–20.	28 days (usually for 4 cycles)	Multiple myeloma	65
VBAP	Vincristine 1 mg iv day 1; carmustine 30 mg/m^2 iv day 1; doxorubicin 30 mg/m^2 iv day 1; and prednisone 60 mg/m^2 oral or parenteral (may be rounded to 100 mg oral) days 1–4.	21 or 28 days	Multiple myeloma	66, 67
VBP	Vinblastine 150 micrograms/kg iv days 1, 2; bleomycin 30 000 IU iv[b] days 2, 9, 16; and cisplatin 20 mg/m^2 iv days 1–5.	21 days	Germ-cell (ovarian, testicular) cancer	11
VCMP	Vincristine 1 mg iv day 1; melphalan 9 mg/m^2 oral days 1–4; cyclophosphamide 500 mg/m^2 iv day 1; and prednisone 60 mg/m^2 oral or parenteral, days 1–4.	28 days	Multiple myeloma	67

Key to abbreviations: hrs – hours; im – intramuscular; iv – intravenous

Table 1. Common chemotherapy regimens for malignant disease.*(Continued)*

Regimen	Drugs and Administration	Cycle	Typically used for	References
VeIP	Vinblastine 110 micrograms/kg iv days 1, 2; ifosfamide 1.2 g/m^2 iv days 1–5 (with mesna); and cisplatin 20 mg/m^2 iv days 1–5.	21 days (for 4 cycles)	Germ-cell (especially testicular) cancer	68
VIP	Etoposide 75mg/m^2 iv days 1–5; ifosfamide 1.2 g/m^2 iv days 1–5 (with mesna); and cisplatin 20mg/m^2 iv days 1–5.	21 days (for 4 cycles)	Germ-cell (especially testicular) cancer	68
Key to abbreviations: hrs – hours; im – intramuscular; iv – intravenous				

(a) Although not always reflected in the original papers it is now generally accepted that the total dose of vincristine should not exceed 2 mg, in order to minimise neurotoxicity
(b) Doses of bleomycin have been given in international units (IU) in this table, but doses in the original papers may be quoted in mg-potency or USP units. One mg-potency or one USP unit is equivalent to 1000 international units

Carcinoid syndrome. Carcinoid tumours (also known as gastroenteropancreatic neuroendocrine tumours) occur mainly in the gastrointestinal tract or lungs (bronchi), although they occasionally arise in other organs with a common embryological origin. Although they are relatively common, accounting for about 30% of all small bowel tumours, symptomatic carcinoid syndrome is rare, both because the tumours vary in their behaviour depending on their embryological origin and because the liver is capable of metabolising those tumour products which are secreted into the portal circulation; only if the carcinoid tumour secretes into the systemic circulation, notably after metastasis to the liver, do symptoms occur. Tumours of embryological fore-gut origin, usually found in the lung or stomach, predominantly secrete histamine or serotonin (5-HT); mid-gut tumours, with a usual primary site in the small intestine, are the most likely to metastasise and produce carcinoid syndrome, and predominantly secrete serotonin; hind-gut tumours, in the distal colon or rectum, are commonly benign, and do not secrete active substances.

The characteristic symptoms of carcinoid syndrome include episodic flushing of the face and upper trunk (which may be provoked by alcohol, food, or stress), secretory diarrhoea, wheezing and dyspnoea, weight loss, pellagra, painful hepatomegaly, and right-sided valvular heart disease, which sometimes progresses to right heart failure and death.[3,4]

The management of carcinoid tumours usually involves surgical resection,[3,4] and this can be curative, particularly if the primary tumour has not metastasised.[2,5-7] Antineoplastic chemotherapy has limited benefit,[2,5] except perhaps in patients with atypical variants of carcinoid tumours.[6] There is some evidence that treatment with interferon alfa can stabilise the disease or occasionally produce tumour regression,[7] but its value has not been borne out in practice[4] and adverse effects have limited its use.[6] Hepatic arterial occlusion by ligation or embolisation to destroy the blood supply of hepatic metastases has produced symptomatic palliation, but its effects are temporary,[5,6] and do not improve survival.[4] Results may be better in combination with systemic chemotherapy in selected patients.[8] Antineoplastics such as doxorubicin have also been given into the hepatic artery for treating hepatic metastases.[6] There is growing interest in the use of radiolabelled somatostatin analogues for the management of tumours that express high levels of somatostatin receptors;[3,4,9] promising results have been reported with palliative use in inoperable or metastatic disease.[2] Newer therapies such as gefitinib and bevacizumab are also being tried.[4] Radiofrequency ablation is also under investigation.[2]

For symptomatic relief of carcinoid syndrome somatostatin analogues such as octreotide or lanreotide are highly effective[4,10] and are the treatment of choice.[2,5-7] The availability of depot intramuscular preparations has simplified treatment, removing the need for multiple daily subcutaneous injections. However, with prolonged use a few patients develop resistance even to the highest doses.[5] Octreotide is also used in the perioperative management of these patients to treat or prevent carcinoid crisis, when it may be given intravenously.[2,5,11] Other drugs that reduce the effects of serotonin have been tried, including cyproheptadine, ondansetron, ketanserin, and methysergide.[4,5]

Apart from such specific pharmacological therapies, antidiarrhoeals such as codeine and loperamide are sometimes helpful in controlling diarrhoea. Wheezing (bronchoconstriction) and heart failure are managed conventionally. Supplementation with nicotinamide is advisable to prevent pellagra. It is also important to avoid provocative factors such as stress, alcohol, and particular foods.[4,5]

Pancreatic endocrine tumours. Neoplasms of the pancreatic islet cells (pancreatic endocrine tumours) are uncommon compared with those of the exocrine pancreas (see Malignant Neoplasms of the Pancreas, p.671). Pancreatic endocrine tumours, whether benign or malignant, often secrete clinically significant amounts of hormone; the hormone secreted, and hence the resultant clinical syndrome, depends on which of the several types of hormone-secreting islet cells is the origin of the tumour (for example, insulinomas arise in islet beta cells).[12] Primary therapy for solitary pancreatic endocrine tumours is surgical resection;[3] metastatic tumours may require a combination of symptomatic drug therapy, chemotherapy, radiotherapy, and surgical debulking. The most frequently used antineoplastic is streptozocin, either alone or with other drugs such as fluorouracil or doxorubicin.[12-14] Chlorozotocin is also active.[13] As with carcinoid tumours, hepatic metastases may be treated with hepatic artery embolisation.[7,8,12] Improved results have been reported with the combination of hepatic artery embolisation and chemotherapy.[2] Somatostatin analogues and interferon alfa may be used to control symptoms of pancreatic endocrine tumours.[7] Other therapies depend on the specific tumour type. In patients with **insulinoma** (tumours originating in the islet beta cells) excessive insulin secretion results in hypoglycaemia. Where surgical resection is not feasible or not successful diazoxide may be used to control hypoglycaemia.[2,3] Beneficial results have also been achieved with octreotide. Intake of frequent small meals containing complex carbohydrates is also important.[12] Up to 90% of insulinomas are benign and do not metastasise. In **glucagonoma** the primary neoplasm derives from the alpha cell[12] and the clinical syndrome (a characteristic skin rash known as necrolytic migratory erythema, diabetes mellitus or glucose intolerance, weight loss, and anaemia) results from excessive glucagon secretion. Surgical resection is indicated for localised disease but 50 to 80% of cases have metastasised at presentation. Octreotide usually decreases glucagon secretion and improves symptoms. Another well-characterised syndrome results from tumours which release vasoactive intestinal polypeptide (VIP). Such **VIPomas** result in profound but intermittent secretory diarrhoea, with consequent hypokalaemia and acidosis;[12] the syndrome is sometimes known as pancreatic cholera. Metabolic imbalances should be corrected by fluid and electrolyte supplementation. Octreotide controls the secretory diarrhoea, and it may be useful for symptom control before surgery as well as for palliation in metastatic disease. About 80% of vipomas are malignant.[12]

Of the other pancreatic endocrine tumours **gastrinoma** is the commonest: it results in Zollinger-Ellison syndrome, the treatment of which is discussed on p.1704. Rarer tumours include **somatostatinoma** and **PPoma** (secreting pancreatic polypeptide).[12]

Gestational trophoblastic tumours. The gestational trophoblastic diseases arise from the trophoblast, the first tissue to differentiate in the early embryo: they are associated with conception and pregnancy and affect women of reproductive age. They may be divided into molar pregnancy (complete or partial hydatidiform mole), invasive mole (chorioadenoma destruens), choriocarcinoma, and placental site trophoblastic tumour. A persistent gestational trophoblastic tumour (invasive mole or choriocarcinoma) may develop in about 25% of women after evacuation of a complete molar pregnancy, and about 2 to 4% after a partial molar pregnancy.[1] Choriocarcinoma may also occur after normal delivery, abortion, or ectopic pregnancy.

All these tumours secrete human chorionic gonadotrophin (hCG), and measurement of the urinary or serum concentrations, which are generally proportional to the total tumour mass, is important in diagnosis of disease and monitoring of treatment.

The trophoblastic tumours vary in aggressiveness but some, such as choriocarcinoma, are highly invasive and rapidly fatal if untreated; however, appropriate treatment, based on the perceived risk category, can result in an excellent prognosis. Prognostic factors for increased risk include high titres of hCG, liver or brain metastases, and failure of previous single-agent chemotherapy as well as, perhaps, greater age. With current treatment, including local irradiation for metastases, virtually 100% of patients with localised disease should be cured, as are over 70% of patients with more advanced stages.

Prophylactic chemotherapy has been used in women considered at particular risk of persistent gestational trophoblastic tumour after evacuation of a complete molar pregnancy, but the practice is controversial.[1,2]

In patients who develop low- or moderate-risk choriocarcinoma or invasive mole, the treatment of choice is single-agent chemotherapy with methotrexate or dactinomycin.[1-7] The combination EMA-CO (etoposide, methotrexate, dactinomycin, cyclophosphamide, and vincristine) is probably the current preferred treatment in high-risk patients.[1,2,4,5,7-9] Methotrexate, dactinomycin, and etoposide is also used.[5,7] A combination of methotrexate, dactinomycin, and either cyclophosphamide or chlorambucil was the preferred combination in the past. Comparative studies are lacking.[9] In refractory disease, the salvage regimen EMA-EP uses etoposide and cisplatin in place of cyclophosphamide and vincristine in EMA-CO. Other regimens have used etoposide and cisplatin with either bleomycin or ifosfamide.[8]

Brain metastases are generally treated by local irradiation, given with chemotherapy. Modified EMA-CO, using a higher dose of systemic methotrexate and adding intrathecal methotrexate, is also used.[7] Liver metastases have been treated with irradiation, local chemoembolisation, or surgical resection.[2,7,8]

Patients with placental site trophoblastic tumour, which is relatively insensitive to chemotherapy, may be best treated by hysterectomy in the early stages.[1,2] In high-risk patients, a platinum-based regimen is preferred to EMA-CO.[4]

Histiocytic syndromes. Histiocytic syndromes cover a broad range of proliferative disorders of histiocytes (macrophages and dendritic cells), for which the classification and diagnostic criteria are evolving.[1] Langerhans-cell histiocytosis (histiocytosis X) is one such disorder characterised by proliferation of CD1 positive Langerhans cells (a form of dendritic cell).[1] Terms that were formerly used for different clinical manifestations of Langerhans-cell histiocytosis include eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe syndrome,[1-4] but these are now considered obsolete.[1] Langerhans-cell histiocytosis mainly presents in childhood, and is of uncertain aetiology: it is not clear whether it should be considered a malignancy.[4,5]

The clinical presentation of Langerhans-cell histiocytosis is highly variable.[2,3,6,7] The classic feature is single or multiple bone lesions, and skin lesions may also occur (single system, localised, or restricted disease).[3-5,7] The disorder may also involve lymph nodes or visceral organs, ultimately causing dysfunction of the liver, lungs, or bone marrow (extensive or multisystem disease).[4,5] Sequelae to the disease include diabetes insipidus, growth failure, and orthopaedic handicap.[3,6] The morbidity and prognosis depends upon the number of organ systems involved, and whether normal function of these organs is affected. Patients with restricted disease have a generally benign course, and single lesions often regress spontaneously. However, if a bone lesion does not resolve, or risks causing fracture or deformity before it resolves, or is causing disabling symptoms, it may be treated with curettage, intralesional corticosteroids, or radiotherapy.[3-5,7] Systemic chemotherapy may be suitable in some patients with multifocal bone disease; vinblastine with prednisone or prednisolone is a suggested regimen.[4] Similarly, single skin lesions may be allowed to resolve without treatment or treated with surgery, topical corticosteroids, methoxsalen plus UV light (PUVA), or topical chlormethine.[4,5]

In more extensive disease the prognosis is not as good, mainly due to organ dysfunction.[3,6,7] Systemic chemotherapy has been widely used, because the disease tends to be progressive in these patients, but its degree of benefit is uncertain.[2,3,6,7] Corticosteroids and vinblastine for about 6 to 12 months are the most commonly used drugs; 6-mercaptopurine and methotrexate have also been used with reports of efficacy.[4] A comparative study in children with multisystem disease found treatment with vinblastine or etoposide for 6 months to be equally effective.[8] The overall response rate was 62%, but about half of the patients had switched to the alternate arm or other therapy during the drug treatment period. Half of those patients who became disease-free did have a reactivation, but these were generally milder than the original disease. Patients who failed to respond within the first 6 weeks of therapy were at increased risk for treatment failure. Subsequent study showed that vinblastine with etoposide was not superior to vinblastine alone (when combined with corticosteroids and 6-mercaptopurine).[4] Systemic corticosteroids have also been used for recalcitrant skin disease or multisystem disease in children[9] and for pulmonary Langerhans-cell histiocytosis in adults.[10] In patients who have not responded to combination chemotherapy, a number of treatments may be considered including ciclosporin,[4,7] the nucleoside analogues cladribine or pentostatin,[11] thalidomide,[9] and bone marrow transplantation.[4,6,7] Anti-CD1 monoclonal antibodies[5] may offer improved therapeutic or diagnostic options in the future.

Leukaemias, acute. The acute leukaemias are malignancies affecting haematopoietic precursor cells. They are relatively rare (about 1 to 3 cases per 100 000 of population), and of uncertain cause in the majority of cases, although radiation, carcinogenic substances, or oncogenic retroviruses have been implicated in some types, and certain individuals appear to have a genetic predisposition to these diseases.

After the initiating event or events the progeny of the affected cell do not differentiate normally but proliferate in an uncontrolled fashion. The result is the accumulation in the blood and bone marrow of immature cell types (blasts) at the expense of normal functional blood cells.

The acute leukaemias may be broadly divided into **acute lymphoblastic leukaemia** (ALL), in which the neoplastic proliferation affects lymphoid cell lines, and the **acute myeloid leukaemias** (AML), variously known as acute myelogenous leukaemias or acute non-lymphoblastic leukaemias, which affect myeloid cell lines. These broad groups can be divided in various ways. ALL is subdivided by an immunophenotypic classification that distinguishes disease of B- and T-cell lineage; it was formerly divided morphologically into L1, L2, and L3 subtypes. For AML the French-American-British (FAB) classification has been widely used. This distinguishes, by lineage and estimated degree of differentiation:

- M0, undifferentiated AML
- M1, AML with minimal maturation
- M2, AML with maturation
- M3, acute promyelocytic leukaemia
- M4, acute myelomonocytic leukaemia
- M5, acute monocytic leukaemia
- M6, erythroid leukaemia
- M7, megakaryocytic leukaemia.

However, knowledge of the genotype, via cytogenetic or molecular analysis, is becoming increasingly important in the treatment of leukaemia. Consequently, a revised classification system has been proposed under the auspices of WHO, which uses a combination of morphology, immunophenotype, genetic, biological, and clinical features. In this classification,[1,2] AML is divided into 4 main groups:

- AML with recurrent cytogenic translocations
- AML with myelodysplasia-related features
- AML, therapy-related
- AML not otherwise specified.

The terms *de novo* and secondary AML are widely used but are without standardised definitions. It has been proposed that *de novo* AML should refer to AML in patients with no clinical history of myelodysplastic syndrome, myeloproliferative disorder, or exposure to potentially leukaemogenic agents; secondary AML should refer to patients with AML secondary to these disorders or proven leukaemogenic exposure.[3]

In the WHO classification of lymphoid neoplasms, the Revised European-American Lymphoma (REAL) classification has been adopted, in which acute lymphoblastic leukaemias and lymphoblastic lymphomas are considered to be a single disease with different presentations.[1]

Acute leukaemia usually presents with fatigue, anaemia, infection (due to granulocytopenia), and easy bruisability or bleeding (mainly due to thrombocytopenia). Onset is usually rapid with ALL, although AML may be preceded by myelodysplasia lasting months or years. Bone pain, and enlargement of liver, spleen and lymph nodes due to infiltration of leukaemic cells may occur. Other organs may also be affected, and various metabolic disturbances, including hyperuricaemia, hyponatraemia, and hypokalaemia may be present.

If untreated the acute leukaemias are normally fatal, usually within months. However, these malignancies are among those in which medical treatment can make a substantial difference to life expectancy, and in some cases a permanent remission may be effected.

ACUTE LYMPHOBLASTIC LEUKAEMIA. With current chemotherapy regimens, long-term disease free survival can be achieved in over 80% of children and 30 to 40% of adults with acute lymphoblastic leukaemia (ALL).[1] While there is a lack of consensus on some prognostic factors, it is generally accepted that age less than 1 year or greater than 10 years, and high white cell count at the time of diagnosis indicate patients at higher risk of relapse.[2] These factors probably reflect the presence of specific genotypes. Chromosomal translocations that activate specific genes are a defining characteristic of ALL; although genetic abnormalities do not entirely account for treatment outcome they do provide prognostic information. In general, patients with changes such as hyperdiploidy, TEL-AML1 fusion, or t(1;19)/E2A-PBX1 fusion have the most favourable outcome, whereas those with t(9;22)/BCR-ABL fusion (the Philadelphia chromosome) or t(4;11)/MLL-AF4 fusion have a poorer outcome. More than 50% of cases of T-cell ALL have activating mutations that involve NOTCH1, a gene encoding a receptor that regulates normal T-cell development.[2]

Standard treatment regimens for T-cell and precursor B-cell ALL generally consist of 2 to 3 years of therapy divided into several phases: a short remission-induction phase; an intensification (consolidation) phase; therapy for prophylaxis of CNS disease, starting during the induction phase, and sometimes continuing for an extended period; and a prolonged continuation (maintenance) phase, sometimes including re-induction therapy.[1-3] Treatment for mature B-cell ALL (Burkitt cell leukaemia or lymphoma, see Burkitt's Lymphoma, below) is different in terms of the drugs used, and the maintenance phase is not required.[1,2]

The aim of **induction therapy** is to induce complete remission, and a slow early response to this therapy has been reported to be an indicator of poor prognosis.[4] Measurement of minimal residual disease at completion of induction therapy is particularly useful in determining prognosis.[3]

Standard induction regimens include vincristine and a corticosteroid (prednisolone or prednisone, or dexamethasone), plus asparaginase in children and an anthracycline such as doxorubicin in adults. However, it is now accepted that better remission rates and more prolonged remissions can be achieved with more intensive induction therapy using 4 to 5 drugs—often vincristine, a corticosteroid, asparaginase, and an anthracycline, with or without cyclophosphamide.[3] The use of imatinib in Philadelphia chromosome-positive ALL has greatly enhanced remission-induction rates and duration of disease-free survival.[2]

The use of dexamethasone, rather than prednisolone, in the induction regimen appears to yield improved event-free survival and a lower incidence of CNS relapse,[5] and increasing its dose may result in a greater marrow blast response.[6] However, some have reported a higher incidence of fatal sepsis with the use of dexamethasone.[7] There was some suggestion that use of asparaginase derived from *Escherichia coli* may be associated with better event-free survival than that derived from *Erwinia chrysanthemi*,[8] and that pegaspargase may be more effective than asparaginase.[9] However, the dose intensity and duration of asparaginase treatment appears to be more important than the type of asparaginase used.[2]

For mature B-cell ALL, a short-term intensive regimen of cyclophosphamide, high-dose methotrexate, and cytarabine is commonly used,[2] sometimes with the addition of ifosfamide and/or etoposide.[4]

About 60% of children and 35% of adults who achieve an initial remission will subsequently relapse with meningeal involvement unless **CNS therapy** directed at the sanctuary sites in the meninges is undertaken. Effective prophylaxis can reduce the incidence of CNS relapse to around 2 to 5%.[4,5] Standard therapy consisted of cranial irradiation and intrathecal methotrexate. However, concerns regarding the neurotoxicity of cranial irradiation and its ability to cause secondary brain tumours have led to the investigation of chemotherapy alone, particularly in children.[3,5,10] Regimens include intrathecal methotrexate combined with high-dose systemic methotrexate, and triple intrathecal chemotherapy with methotrexate, cytarabine and a corticosteroid. These regimens are started during induction therapy and continued intermittently for an extended period. Early intensification of triple intrathecal chemotherapy may be important in the prevention of CNS relapse, and successful CNS therapy may in turn prevent bone-marrow relapse.[11] Cranial irradiation may still be required in high-risk patients.[2,5]

Intensification (consolidation) therapy involves continuation of intensive chemotherapy regimens after the achievement of complete remission. Although the importance of this phase is rarely disputed, consensus is lacking on the best regimens and duration of treatment.[2] Drugs used in intensification regimens include high-dose cytarabine, etoposide, teniposide, high-dose methotrexate, mercaptopurine, tioguanine, and the antineoplastics used in induction regimens; often 4- to 5-drug combinations are used. The UKALL Trial X showed that addition of intensification therapy at 5 and 20 weeks from the beginning of induction, (using cytarabine, etoposide, tioguanine, and daunorubicin), produced 5-year disease-free survival of 71% compared with 57% in those who received only maintenance therapy.[10] Benefit was seen even in children considered at low risk of treatment failure. Further intensification may benefit those children with a slow response to initial therapy and high-risk of relapse.[12]

Continuation (maintenance) therapy is generally given for some 2 to 3 years after remission;[1-3,10] three years rather than two years of maintenance therapy is associated with a lower risk of relapse but not a markedly different survival rate.[13] The standard combination of drugs consists of daily mercaptopurine and weekly methotrexate.[2] Many protocols provide for periods of **re-induction** therapy (repeating induction therapy),[2] and such intensive therapy is associated with an absolute improvement of about 4% in long-term survival.[13] It has been suggested that individualisation of methotrexate dosage to take account of the patient's ability to clear the drug can improve the outcome.[14]

It is generally agreed that patients who maintain remission for 4 years after the end of maintenance therapy are at little risk of relapse and may be regarded as effectively cured.

Patients who relapse after stopping treatment can usually be brought to **second remission**, often by a repeat of their original induction therapy. However, if relapse occurs during treatment the prognosis is poor, and chemotherapy is unlikely to bring lasting benefit. However, clofarabine monotherapy can induce remission in some children with refractory or relapsed ALL.[15] Newer drugs that have been investigated with promising initial results include nelarabine, sphingosomal vincristine, and novel BCR-ABL inhibitors.[1]

The role of **stem cell transplantation** (p.1811) in the treatment of ALL is a matter of some controversy. Comparisons between transplantation and intensive chemotherapy have yielded inconsistent results.[2] Consequently, allogeneic transplantation is usually reserved for high-risk patients such as those who do not have a complete remission with induction therapy, and those with Philadelphia-positive ALL (who remain at high-risk even when treated with a tyrosine kinase inhibitor).[2] The lack of suitable HLA-matched family donors has led to the investigation of autologous purged marrow, or the use of marrow from mismatched family donors; however, generally neither of these options has proved more effective than chemotherapy.[16] Studies suggest that matched unrelated donors or cord-blood transplantation have results comparable with those obtained with matched related donors.[2]

ACUTE MYELOID LEUKAEMIAS. Treatment of acute myeloid leukaemias (AML) is problematic because normal stem-cell precursors are sensitive to the drugs used, and therapy aimed at myeloid leukaemic clones results in destruction of part of the normal stem-cell pool. Wherever possible, treatment of AML should be in the context of clinical studies.[1-3]

Induction of remission is usually possible with intensive chemotherapy. Complete remission has been stated to be achievable in up to 80% of younger patients and about 50% of older patients (who form the majority of those with AML), but patients suffer severe neutropenia during induction and remission rate is to some extent dependent upon the standard of supportive care. Remission rates are lower in those with adverse prognostic factors such as poor performance status, AML secondary to myelodysplasia or antineoplastics, high white cell count, features of multidrug resistance, and unfavourable cytogenetics.[4,5] Established regimens are based on cytarabine with the anthracycline daunorubicin.[1-4,6,7] Although idarubicin may be preferred to daunorubicin,[8] especially in younger adult patients,[9] in children it is no more effective but may be associated with more toxicity.[10] Mitoxantrone is another alternative to daunorubicin,[8] and there is little evidence[1,4,8] that one anthracycline is better than another for induction protocols. Addition of etoposide or tioguanine to induction protocols of cytarabine and daunorubicin appears to be equally effective in younger adults and children,[11,12] but in older patients an induction regimen which added tioguanine was found to be more effective than one with etoposide.[13]

As in acute lymphoblastic leukaemia (see above) there is a trend towards the use of more intensive induction regimens.[6,12] Use of high-dose cytarabine compared with standard doses potentially improves survival in younger patients with favourable cytogenetics, but in the elderly neurotoxicity outweighs any benefit;[8] a combination of cytarabine with fludarabine may be an alternative in these patients.[5] The use of haematopoietic growth factors is controversial; some allow for their use as an optional adjunct to intensive chemotherapy,[2] while others recommend against their routine use in AML.[1]

Once remission is induced, consolidation or **postremission therapy** is essential in preventing relapse.[1,6,8] Options include further chemotherapy, or allogeneic or autologous bone marrow transplantation (see Haematopoietic Stem Cell Transplantation, p.1811).[1,2,7] There is no consensus on the best postremission therapy.[2,7] Some advocate the use of high-dose cytarabine in those with favourable or intermediate risk; others are candidates for allogeneic stem cell transplantation.[2,7]

Patients who relapse or who fail to achieve complete remission will require **salvage** therapy. Standard salvage regimens can include high-dose cytarabine or fludarabine plus cytarabine.[7] Allogeneic stem cell transplantation can also be used for salvage therapy or for those in second or subsequent remission.[2,7] Investigational therapy is also an option.[7] Gemtuzumab ozogamicin may be useful in elderly patients.[1] Non-myeloablative chemotherapy with allogeneic transplantation may be an alternative in older patients.[5,7,14] Low-dose **maintenance** chemotherapy (with cytarabine and tioguanine) may improve disease-free survival but not overall survival,[4] and prolonged maintenance therapy is generally considered unnecessary in patients with AML.[1,6,12] Where debility or other medical conditions make standard or investigational therapy impossible in the elderly, **palliative** treatment with oral hydroxycarbamide, is often given; low-dose cytarabine may also be of benefit.[1,3,7] Good results have been reported with a combination of idarubicin and etoposide in elderly patients.[5]

Acute promyelocytic leukaemia (APL) is a subtype of AML accounting for 10% of AML cases in adults. It is important to distinguish APL from other forms since, unlike other subtypes, standard therapy is tretinoin **differentiation** therapy. Although most patients with APL can achieve complete remission after treatment with tretinoin alone, remission durations are short and most patients relapse.[15] Induction therapy with tretinoin and chemotherapy (an anthracycline and cytarabine) improved event-free survival compared with chemotherapy alone, and has become routine in APL,[16] although there is good evidence that cytarabine can be omitted.[8,15,17] Anthracycline-based consolidation therapy is mandatory,[16] and, again, although most studies have included cytarabine, the role of high-dose cytarabine has been questioned.[15,17] Although maintenance therapy with tretinoin alone has been reported to be of benefit,[17,18] resistance has developed with continuous treatment,[19] and retinoic acid syndrome is a major toxicity.[15,17] Prolonged maintenance therapy (intermittent tretinoin plus continuous mercaptopurine and methotrexate for 2 years) also appears to reduce the rate of relapse in APL.[19] The synthetic retinoid, tamibarotene (AM-80), has been used to induce remission in patients who relapsed after successful remission induction with tretinoin.[20] Low doses of arsenic trioxide have also been effective in inducing complete remission in patients with APL who have relapsed,[17,21] although fatalities have been reported with its use.[15] Arsenic trioxide has been successfully combined with tretinoin for induction and consolidation.[8] It has also been used alone as first-line therapy, but current recommendations tend to restrict such use to patients for whom chemotherapy is contra-indicated.[16] Autologous and allogeneic stem cell transplantation have also been tried as salvage therapy.[16,22]

The efficacy of tretinoin appears to be achievable only because the characteristic chromosomal abnormalities in APL result in an abnormal retinoic acid receptor. The development of drugs that can effect differentiation in other forms of AML, and indeed in other neoplasms, seems likely to be a long and difficult task.

Other experimental therapies under investigation for AML include clofarabine,[3,7,23] azacitidine, imatinib,[12] and decitabine.[3] The ciclosporin analogue valspodar, an inhibitor of multidrug resistance, has been investigated, but was associated with excessive early mortality.[24]

Leukaemias, chronic. The chronic leukaemias may be broadly divided into those in which the neoplastic proliferation affects lymphoid cell lines, and those affecting the myeloid cell lines.

Chronic leukaemias affecting the *lymphoid cell lines* include chronic lymphocytic leukaemia (CLL), which is B-cell in about 95% of cases and T-cell in about 5%, and hairy-cell leukaemia, which affects B-cells. The revised European-American lymphoma classification,[1] and a proposed WHO classification of haematologic malignancies,[2] consider lymphoid leukaemias and lymphomas of the same cell type to be one disease with different clinical presentations. Thus B-cell CLL is the same disease as B-cell small lymphocytic lymphoma.

Chronic neoplasms affecting the *myeloid cell lines* include the myeloproliferative disorders chronic myeloid leukaemia (CML), polycythaemia vera, and primary (essential) thrombocythaemia, and the myelodysplastic syndromes. All of these may undergo transformation to acute myeloid leukaemia.

CHRONIC LYMPHOCYTIC LEUKAEMIA. Chronic lymphocytic leukaemia (CLL) typically occurs in people over 60 years of age, and accounts for about 30% of leukaemias in the West although it is rarer in the Far East. Stages of CLL are defined according to the American Rai system or the European Binet system, with both having prognostic value.[1-6] The clinical course is variable: low-risk patients (Rai stage O; Binet stage A) have a median survival of about 10 years, while high-risk patients (Rai stage III/IV; Binet stage C) have a median survival of about 1.5 years; median survival in the intermediate stages is about 6 years.[1,2] The mutational status of the immunoglobulin IGHV gene also affects prognosis; attempts to use surrogate markers of this status included CD38 and ZAP-70, and these have assisted in further risk stratification.[6-9]

In patients at low risk and those at intermediate risk with indolent disease cytotoxic chemotherapy is usually deferred until signs and symptoms of disease progression occur.[1,2,4-7] In these patient groups, trials of immediate versus deferred chemotherapy for early-stage CLL have shown no significant advantage, or disadvantage, for immediate chemotherapy in terms of 10-year survival.[10] Patients with high-risk or progressive disease are usually treated with immediate chemotherapy.

When therapy is required, it is essentially symptomatic and palliative. Continuous or intermittent chlorambucil has been most widely used, and is given for as long as the patient responds; response rates range from about 40 to 70%.[2,3,7] Fludarabine is also used as initial therapy, and while response rates have been found to be higher than with chlorambucil,[11] there appears to be no overall advantage in terms of survival.[1,2,4,5,7,12] Compared with chlorambucil, the increased incidence of opportunistic infections is a disadvantage of fludarabine treatment.[4] The order in which alkylating agents and purine analogues are given is not thought important, provided patients who relapse on one treatment then receive the other.[9]

Although chlorambucil is often used with a corticosteroid (prednisone or prednisolone), there is some doubt as to whether this has a real advantage over chlorambucil alone.[1,2,10] Corticosteroid therapy is, however, the treatment of choice where patients present with cytopenias due to an immune mechanism.[1] The most commonly used combination chemotherapy is with cyclophosphamide and prednisone or prednisolone plus either vincristine (COP or CVP) or doxorubicin (CAP), or both (CHOP).[1-3] However, combination chemotherapy does not appear to offer any advantage over chlorambucil alone.[10] Similarly, comparisons of fludarabine with CAP and CHOP found fludarabine gave better response rates in patients with advanced disease, but similar survival-times.[1,2,5,8] The combination of fludarabine and cyclophosphamide may be synergistic,[13] and produced good overall response rates,[12] although overall survival did not differ compared with fludarabine alone.[6] However, consistent benefit from this combination in terms of progression-free survival has led some to consider it the first-line treatment of choice,[7,14] except for poor-risk patients, in whom response is unlikely.[14] Cladribine with or without corticosteroids has also been used in previously untreated patients; results were comparable with single-agent fludarabine.[8] Cladribine may also be used for CLL refractory to alkylating agents. Compared with chlorambucil and prednisone, cladribine and prednisone gave higher response rates but increased toxicity, and overall survival was not statistically different.[15] Pentostatin has also been investigated.[1] Pentostatin with cyclophosphamide was well-tolerated and produced good overall response rates in a small group of patients refractory to fludarabine.[7,12]

In patients who fail treatment with conventional therapy, the monoclonal antibodies alemtuzumab and rituximab have produced encouraging results.[3,6,12,16-18] Combinations of these antibodies with other drugs have been studied in CLL,[4,5,7,8,19] and the use of rituximab with fludarabine especially has shown marked clinical efficacy.[6,7,9,20] Alemtuzumab may be used as first-line therapy in patients with certain cytogenetic abnormalities associated with a poor prognosis, or as consolidation therapy after fludarabine-based induction therapy.[7] It is also effective in refractory patients with high-risk disease.[7]

Treatment of relapses depends upon response to initial therapy.[6,8] After long remissions, patients will usually respond again to induction treatment.[6] Alternative agents, or combination chemotherapy with or without monoclonal antibodies may then be tried.[6,8]

Haematopoietic stem cell transplantation (HSCT) has been investigated for CLL.[6] Autologous HSCT is unlikely to provide a cure[8] and relapse is inevitable.[7] The principles of allogeneic HSCT include the graft-versus-leukaemia effect and the absence of stem cell contamination.[8] However, transplant-related mortality has been high. Non-myeloablative conditioning protocols are under investigation.[6-8] Allogeneic HSCT is suggested for younger patients with non-response or early relapse after purine analogues, or those who relapse within 2 years of an initial response with purine-analogue based therapy or autologous HSCT, or in patients with certain cytogenetic abnormalities with a poor prognosis.[7]

Other drugs that have been investigated for CLL include bortezomib,[7] denileukin diftitox,[7] lenalidomide,[6,7,21] lumiliximab,[6,7] oblimersen sodium,[7] ofatumumab,[6] and thalidomide.[21]

CHRONIC MYELOID LEUKAEMIA. Chronic myeloid (myelogenous) or chronic granulocytic leukaemia (CML) is a rare disease, occurring usually in older patients, and representing about 15% of all adult leukaemias. It is associated in over 90% of cases with the presence in blood cells of an abnormal chromosome, the Philadelphia chromosome (Ph), which results from a reciprocal translocation between the long arms of chromosomes 9 and 22, with the fusion of the BCR gene and the ABL gene. The product of this gene, the protein BCR-ABL, is leukaemogenic. Ph-negative disease (atypical CML) carries a worse prognosis, and some classification systems consider it to be a separate disease.[1-3]

CML occurs in 3 different phases. It is usually diagnosed in the chronic phase, which may last for several years, which when untreated, progresses to an advanced phase; this consists of an often rapidly fatal blastic phase (blast crisis), which is often preceded by a transition period, the accelerated phase.[1,3-7]

The development of imatinib, an inhibitor of the BCR-ABL protein tyrosine kinase, constituted a revolutionary change in the management of CML.[1-5,8,9] The International Randomized Study of Interferon and STI571 (IRIS), found imatinib to be better than interferon alfa with low-dose cytarabine for newly diagnosed CML in **chronic phase**.[10,11] Follow-up study found responses to be durable in a high proportion of patients.[12] The optimal dose has not been determined, and high-dose imatinib is under investigation.[4,8] However, since relapse is common after stopping imatinib, therapy should be continued indefinitely in responsive patients.[1,8] Resistance may also be a problem.[2,3,5,7-9,13-15] For patients who do not respond to initial therapy with imatinib, or are in haematological relapse, options include increasing the dose of imatinib, the use of second-generation tyrosine kinase inhibitors such as dasatinib or nilotinib, considering allogeneic haematopoietic stem cell transplantation (HSCT), or investigational therapy.[1,3,6,7] For patients unable to tolerate imatinib or other tyrosine kinase inhibitors, interferon alfa (with or without low-dose cytarabine) or hydroxycarbamide may be reasonable alternatives.[1,2,4,8]

Early allogeneic HSCT (p.1811) has the potential to cure CML due to a graft-versus-leukaemia effect, but it is still associated with appreciable morbidity and mortality, including graft-versus-host disease,[9] and results with imatinib have challenged the role of HSCT as first-line therapy for chronic phase CML.[1] While HSCT is still an option in suitable patients such as younger patients with HLA-identical sibling donors,[4,5] or those with high-risk disease and low transplantation risk,[2] most recommend an initial period of therapy with imatinib since the response can either reinforce or weaken the indication for HSCT.[6,8,9] Ongoing advances in alternative donor sources (such as the use of HLA-matched unrelated donors and cord blood), improved HLA typing techniques, and less toxic non-myeloablative regimens are broadening the use of HSCT.[1,5] Autologous HSCT has also been investigated, but no advantage over interferon-based regimens has been shown.[8] Options in patients who relapse after HSCT include the use of donor lymphocyte infusions, tyrosine kinase inhibitors, or interferon alfa.[1,2]

Although now no longer a first-line treatment, in most patients, interferon alfa is associated with improved survival compared with busulfan or hydroxycarbamide,[16] and the addition of low-dose cytarabine to interferon alfa improves response rates but increases toxicity compared with interferon alfa alone.[17] Hydroxycarbamide is somewhat more effective, and better tolerated, than busulfan.[18]

Occasionally, patients present in **advanced phase**. Those in early blast crisis may be treated initially with imatinib or other tyrosine kinase inhibitors, and then proceed to allogeneic HSCT.[4,8] A longer trial of imatinib is possible for patients diagnosed in accelerated phase.[8] For those who progress to advanced disease while on imatinib, options include dasatinib or nilotinib, HSCT, or investigational therapy.[1]

Investigational therapies for CML include omacetaxine mepesuccinate, farnesyl transferase inhibitors such as lonafarnib and tipifarnib, hypomethylating agents such as azacitidine and decitabine, histone deacetylase inhibitors, and vaccines.[5,15] Combinations of imatinib with other drugs are also under investigation.[2]

HAIRY-CELL LEUKAEMIA. Hairy-cell leukaemia is a rare, chronic, B-cell lymphoproliferative disorder marked by the presence of white blood cells with prominent cytoplasmic villi, pancytopenia, and splenomegaly. Many patients are asymptomatic and there is no clear advantage to early treatment before symptoms appear.[1-3] When treatment is required, splenectomy was formerly used as initial therapy, but response duration tended to be short. Interferon alfa-2a or -2b given for one year produces at least a partial response in most cases but patients have a tendency to relapse once therapy is stopped,[1,2,4] although maintenance therapy with low-dose interferon alfa may prolong remission.[4]

Better results have been reported with the purine analogues cladribine and pentostatin, and these have now emerged as first-line treatments for this disease.[1,2,4-6] Durable complete remission rates of 50% or more are seen after relatively short courses of therapy.[4,7-9] Toxicity is generally acceptable.[4,8] They do not appear to show cross-resistance; cladribine has been used successfully in patients resistant to, or intolerant of, pentostatin,[2,4] and others[6] have used pentostatin in patients who do not respond to cladribine. For patients who relapse, re-treatment with initial therapy is advocated, although interferon alfa is an option in those patients relapsing after treatment with a purine analogue.[2] There are reports of remission after use of rituximab in patients with refractory disease,[2,4,10,11] and it has been suggested for use in those who fail cladribine and pentostatin.[6] Other immunotherapy under investigation for hairy-cell leukaemia includes the recombinant immunotoxins LMB-2[12] and BL22.[13]

MYELODYSPLASTIC SYNDROMES. Myelodysplastic syndromes are low-grade neoplasms of haematopoietic stem cells characterised by ineffective haematopoiesis that results in anaemia, neutropenia, or thrombocytopenia in various combinations. They have been described as smouldering leukaemia or preleukaemia, and transformation to acute myeloid leukaemia (AML) occurs in some patients.

The clinical course of myelodysplastic syndromes is variable, and a precise individual determination of prognostic score is important in planning treatment.[1-3] In the few younger patients with suitable HLA-matched siblings, allogeneic haematopoietic stem cell transplantation (HSCT) has curative potential.[1,2,4-6] As most patients are older, with medical conditions precluding the use of standard conditioning regimens, novel transplant conditioning regimens of reduced intensity are being investigated.[6,7]

Patients who are likely to have an indolent course are best treated conservatively with observation and supportive care (transfusions, antibacterials, or epoetins plus colony-stimulating factors).[1-5,7] Iron chelation therapy may be needed in patients who develop iron overload (p.1442) from blood transfusions.[3,7] Azacitidine, decitabine, or lenalidomide may be considered where a low serum-erythropoietin concentration does not respond to epoetins (with or without colony-stimulating factors). Patients with serum-erythropoietin above 500 mU/mL and a good probability of response to immunosuppressive therapy should be given antilymphocyte immunoglobulins with or without ciclosporin, or possibly ciclosporin alone.[3,7] Those likely to have a poor response to immunosuppressants should be given treatment with azacitidine, decitabine, lenalidomide, investigational agents, or considered for allogeneic HSCT.[3] Azacitidine or decitabine are also treatment options for patients with serious cytopenias; if not responsive, immunosuppressive therapy, investigational agents, or allogeneic HSCT can be tried.[3] Lenalidomide is effective for patients with chromosome 5q deletions,[8-10] and is recommended as first-line therapy in these patients.[3,7]

The treatment of progressive or advanced myelodysplastic syndromes or those that have transformed to AML may involve intensive chemotherapy similar to that for AML (see p.652), but remission rates are lower,[1,2,4,5] and relapse common.[7] However, many patients are elderly with poor performance status, and are unable to tolerate intensive chemotherapy. They may be treated with supportive care and haematopoietic growth factors alone.[7] Low-intensity chemotherapy such as azacitidine or decitabine may be tried in such patients,[3] but has had limited success.[2,4] Other antineoplastics and immunomodulating agents investigated for use in myelodysplastic syndromes include amifostine, arsenic trioxide, thalidomide, and topotecan.[2,4-7,11] Attempts to induce cellular differentiation have generally been disappointing.[4]

POLYCYTHAEMIA VERA. Polycythaemia vera (polycythaemia rubra vera) is a Philadelphia-negative chronic myeloproliferative disorder,[1] associated in about 95% of patients with a mutation in the Janus kinase 2 (JAK2) gene.[1-3] It is characterised by an increased red cell mass and packed cell volume, and is often associated with increases in white cell and platelet counts and splenomegaly.[1,4] It is a disease of later life, with a median age at presentation of about 60 years.[4] The symptoms are related to hyperviscosity due to the increased number of cells in the blood, with the most common features being fatigue, headache, visual disturbances, paraesthesia, pruritus (characteristically exacerbated by warmth), and erythromelalgia (burning pain and erythema of the hands and feet). More serious symptoms include intermittent claudication, angina pectoris, and transient ischaemic attacks.[1] Patients often present with either arterial or venous thrombosis (cerebrovascular accident, myocardial infarction, pulmonary embolism) or occasionally, with haemorrhage, particularly involving the skin and gastrointestinal tract; splenic pain or gout may also be presenting features.[1,4]

Untreated, the disease is associated with a high risk of morbidity and mortality, and patients can undergo myelofibrotic transformation into blast crisis and acute myeloid leukaemia.[1,4] The aims of treatment are therefore to reduce the risk of thrombosis and haemorrhage, minimise transformation risk, and manage complications, or pregnancy.[4]

The mainstay of treatment is periodic phlebotomy to maintain the haematocrit within normal values,[5,6] along with aspirin in low doses (40 to 100 mg daily)[1] sufficient to reduce thrombosis without increasing the risk of major bleeding.[7] This may be all that is required in younger patients at low risk of thrombosis. In patients at high risk of thrombosis, including those who have a high phlebotomy requirement, some form of myelosuppressive therapy may also be considered. Chlorambucil, which was formerly used for this purpose, has largely been stopped because of a high incidence of leukaemia in patients so treated.[4-6] In patients with a life expectancy of less than 10 years, radioactive phosphorus-32 is probably appropriate, and produces good results with few immediate adverse effects.[5,8] However, like the alkylating agents it is associated with an increased risk of secondary malignancies.[6] In younger patients hydroxycarbamide,[1,4,6,8] busulfan,[5,6] or in some countries pipobroman,[5,9] have been preferred because they were considered to have lower risk of inducing leukaemia. However, there is some evidence[9,10] that they too may have leukaemogenic potential, especially when used in combination,[11] and some recommend that busulfan and pipobroman be reserved for elderly patients.[1,4] Non-cytotoxic therapies that have been shown to be effective include interferon alfa.[1,4-6,10,12] This may be preferred in younger patients requiring treatment.[4,5,8] Anagrelide, another antiplatelet drug, has also been tried in polycythaemia vera. It is effective in controlling the platelet count, but does not control progression of polycythaemia vera, and its adverse effects may make it difficult for some patients to tolerate.[4]

PRIMARY THROMBOCYTHAEMIA. Primary thrombocythaemia (essential thrombocythaemia) is a rare Philadelphia-negative myeloproliferative disorder in which abnormal platelet production results in elevated platelet counts.[1,2] The Janus kinase 2 (JAK2) genetic mutation occurs in about 50 to 60% of patients.[3] The disorder occurs mainly during later life and unlike other myeloproliferative disorders, is associated with generally near-normal life expectancy.[1] However, microvascular occlusion marked by conditions such as erythromelalgia (burning pain and erythema of the hands and feet), paraesthesia, or migraine, and arterial or venous thrombosis (e.g. cerebrovascular accident, myocardial infarction, pulmonary embolism) may occur. The risk for thrombosis is highest in patients with a history of thrombosis and in those aged over 60 years. In less than 10% of patients the disease eventually enters a spent phase marked by fibrosis and marrow hypoplasia, or transforms to acute leukaemia.

Asymptomatic patients and those at low risk of thrombosis are generally not treated, but when to begin treatment is controversial.[1,4-6] Some consider that primary antithrombotic prophylaxis seems rational even in asymptomatic patients if there are no contra-indications to this therapy. Low-dose aspirin (40 to 100 mg daily) is considered to be effective, without increasing the risk of major bleeding. Acute microvascular symptoms may be managed with higher doses of aspirin (100 to 300 mg daily).[2] In patients at risk of thrombosis, drugs that lower platelet counts are used, including cytotoxics.[1,2,4,6,7] Phosphorus-32 and alkylating agents such as busulfan or pipobroman are little used now because of their known potential to induce leukaemia.[2,7,8] Hydroxycarbamide can reduce thrombotic events,[7,9] and has tended to be preferred because it was thought to have lower risk of inducing leukaemia, but it too appears to have leukaemogenic potential.[6-11] The increased risk of leukaemia from therapy is particularly relevant in younger patients, for whom non-cytotoxic drugs may be preferred. Some non-cytotoxic therapies have also been shown to reduce platelet counts. Anagrelide[8,10] is often substituted for hydroxycarbamide,[2,6,7,9] but its value has been questioned by a comparison[12] of 2 regimens using aspirin with either anagrelide or hydroxycarbamide. Although the reductions in platelet count were similar for both groups, patients taking anagrelide were found to be at greater risk of arterial thrombosis, serious haemorrhage, and transformation to myelofibrosis (but the rate of venous thromboembolism was lower). Interferon alfa can also effectively reduce platelet counts;[6,7,10] it is a good alternative for younger patients who face lifelong treatment,[2] and is the treatment of choice in pregnant women.[2,6,8,9] Haematopoietic stem cell transplantation may be considered in younger patients who have advanced, complicated disease.[6]

Lymphomas. The malignant lymphomas are neoplastic disorders of the lymphoreticular cells. These cells are primarily located in the lymph nodes, but because of their wide distribution in the body lymphomas may arise in extranodal and extralymphatic tissues such as lung, gastrointestinal tract, and skin.

The term covers a heterogeneous group of diseases, comprising two main subgroups: Hodgkin's disease, and the non-Hodgkin's lymphomas (NHL). The cellular origin of Hodgkin's disease is uncertain; the NHL are monoclonal malignancies arising from B cells in about 80% of cases, with the remainder from cells of T lineage and from undifferentiated cells.

Management of patients with malignant lymphoma is largely determined by interpretation of histological features, and, especially for NHL, by an allocation of subtype and grade. Various classification systems have been proposed for NHL of which the National Cancer Institute Working Formulation has been widely used.[1] Under the Working Formulation, NHL are divided into:

- *low grade*, including small lymphocytic, follicular small cleaved cell, and follicular mixed small cleaved and large cell lymphoma
- *intermediate grade*, including follicular large cell, diffuse large cell, diffuse small cleaved cell, and diffuse mixed types
- *high grade*, including large cell immunoblastic, lymphoblastic, and small non-cleaved cell (including Burkitt's) lymphomas

The International Lymphoma Study Group has proposed a revised European-American lymphoma (REAL) classification,[2] and this has subsequently also been published under the auspices of WHO.[3] It is based on a division into B-cell, T-cell and natural killer cell, and Hodgkin's neoplasms. In this classification, B-cell lymphomas include B-cell small lymphocytic lymphoma, MALT lymphoma, follicular lymphoma (35% of adult NHL, rare in children), diffuse large B-cell lymphoma (30% of adult NHL, 5% of NHL in children), and Burkitt's lymphoma (rare in adults; 30% of NHL in children) and Waldenström's macroglobulinaemia (lymphoplasmacytic lymphoma). Plasma-cell myeloma (multiple myeloma) is also a B-cell neoplasm. T-cell lymphomas include precursor T-cell lymphoblastic lymphoma (rare in adults; 45% of NHL in children) and mycosis fungoides; and Hodgkin's lymphoma is subdivided into nodular lymphocyte-predominant and classical (nodular sclerosis and mixed cellularity) forms.

HODGKIN'S DISEASE. Hodgkin's disease (Hodgkin's lymphoma) is characterised histologically by the presence of a particular type of giant cell, the Reed-Sternberg cell. It is more common in males than in females, and in the West is seen particularly in young adults and in the elderly, although the age distribution differs elsewhere.

It usually presents as painless enlargement of one or more lymph nodes, particularly in the neck or axillae. About a third of all patients also have constitutional symptoms of fever, weight loss, and night sweats, which indicate poorer prognosis. In advanced disease, signs of organ infiltration may occur, as may infectious complications. The mass of the tumour may result in compression of vital organs.

Hodgkin's disease can be treated by radiotherapy or chemotherapy or both, and the choice of treatment depends on the volume and histological subtype of the tumour, the age of the patient, and, particularly, the stage of the disease.[1-3] The Ann Arbor classification (with Cotswold modifications) recognises 4 stages:

- Stage I, with involvement of a single lymph node region or extralymphatic site
- Stage II, in which spread is restricted to lymph nodes and sites on one side of the diaphragm only
- Stage III, involving spread on both sides of the diaphragm with possible splenic and extralymphatic involvement
- Stage IV, where the patient has diffuse or disseminated disease in one or more extralymphatic organs or tissues.

Stages are subclassified A or B according to the absence or presence respectively of the aforementioned constitutional symptoms. X indicates bulky disease and E the involvement of single extranodal sites. Survival rates after treatment for Hodgkin's disease are generally excellent, and there is increasing emphasis on tailoring therapy to decrease early and late treatment-related morbidity while not compromising survival.[1,2] For prognostic and therapeutic considerations, patients are grouped into early stage favourable, early stage unfavourable or intermediate, and advanced stage disease.

In the treatment of early stage disease (stages I, II, and IIIA), radiotherapy alone was standard therapy for adult patients with limited disease, especially in those with good prognosis. However, there have been concerns about relapse rates and an increased risk of secondary malignancy after radiotherapy. Adjuvant chemotherapy (combined modality treatment) has been investigated in order to improve disease-free survival, reduce doses and volumes of radiotherapy, and avoid the need for surgical staging. A comprehensive meta-analysis of adjuvant chemotherapy in patients with early stage disease found a reduced risk of resistant or recurrent disease, but this did not translate to a significant improvement in 10-year survival.[4] A systematic review[5] came to the same conclusion. Most patients in the meta-analysis received the MOPP regimen (see below) and extended field radiotherapy, and some feel that the ABVD regimen (see below) and involved field radiotherapy may prove more effective in terms of toxicity and survival.[6] Combined modality treatment is now the preferred treatment for favourable early stage disease,[3,6-9] although the optimal chemotherapy regimen and radiation dose have yet to be determined. It is also generally accepted as the treatment of choice in those with unfavourable early stage disease, using the ABVD regimen.[3,6-9] Combined modality treatment is also preferred in children,[2,10] although evidence to support this is scanty.[11]

Chemotherapy alone is generally considered to be the treatment of choice in advanced disease (stages IIIB and IV), although the value of adding radiotherapy has still been debated. Meta-analyses or systematic reviews of combined modality therapy in advanced disease have found no survival benefit from additional radiotherapy, although it may have a role in initial bulky or residual disease.[5,12]

There are several 4-drug standard regimens available and the choice lies between one of these, alternating cycles of 2 different regimens, or a hybrid cycle that involves giving 7 or 8 drugs in the same course of treatment. However, the single most important factor governing the outcome of chemotherapy is thought to be dose intensity of the drugs given.

The earliest of the successful 4-drug regimens was combination chemotherapy with chlormethine, vincristine, procarbazine, and prednisone or prednisolone (MOPP). A number of MOPP-variant regimens exist which may be as effective and less toxic; these include substitution of chlorambucil or cyclophosphamide for chlormethine (LOPP or COPP, respectively), vinblastine for vincristine (MVPP), and both chlorambucil and vinblastine substituted in one regimen (ChlVPP). However, an alternative to the MOPP-based regimens, a non-cross resistant combination of doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) was found to be as effective as MOPP with a reduced risk of inducing sterility or secondary leukaemia. Better results were later reported with ABVD alone, or with MOPP/ABVD, than with MOPP alone, and ABVD has become the basis of standard treatment for advanced stage Hodgkin's disease.[3,10,13,14]

Attempts to improve the results of ABVD or MOPP have centred on dose intensified hybrid regimens. The German Hodgkin's Lymphoma study group found improved results with a hybrid regimen of bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone (BEACOPP) compared with COPP/ABVD; overall survival was highest with an increased dose of BEACOPP, although toxicity was increased.[15] The Stanford V regimen (doxorubicin, vinblastine, chlormethine, vincristine, bleomycin, etoposide and prednisone, with consolidative radiotherapy) is also used,[3,14] although a randomised study[16] comparing ABVD, Stanford V, and a MOPP-hybrid regimen found Stanford V to be inferior in terms of response and survival rates. Further comparative studies of ABVD versus BEACOPP or Stanford V are underway.[3,17]

Salvage treatment options for patients who relapse depend on the initial treatment and the interval between treatment and relapse. Patients who are candidates for salvage therapy can be divided into 4 groups:

- those initially treated with radiotherapy who have a recurrence, in whom standard chemotherapy regimens are effective
- those who never achieve complete remission with standard chemotherapy, in whom prognosis is very poor, and who are candidates for an intensive salvage chemotherapy regimen with autologous haematopoietic stem cell transplantation (HSCT)
- those whose original remission lasted for over a year, of whom some will respond to re-treatment with standard therapy, but in whom intensive salvage chemotherapy regimens with HSCT may be considered
- and those whose remission is short, less than one year, in whom standard chemotherapy may be used to reduce tumour volume before intensive salvage chemotherapy and HSCT.[8,18]

A common intensive salvage regimen consists of carmustine, etoposide, cytarabine, and melphalan (BEAM). Although intensive chemotherapy and HSCT is considered by some[8,14] to be the treatment of choice in relapsed patients, others[5] note that benefit on overall survival remains to be established.

Immunotherapies under investigation for Hodgkin's disease include the anti-CD20 monoclonal antibody rituximab,[6] and other monoclonal antibodies, some radiolabelled, to CD25 and CD30.[10] Gemcitabine is also being studied in refractory disease.[10]

NON-HODGKIN'S LYMPHOMAS. The non-Hodgkin's lymphomas are a heterogeneous group of malignancies that vary considerably in their behaviour, prognosis, and management.[1] Classifications have grouped them by grade (low, intermediate, or high) or cellular origin (B-cell or T-cell), and histology (see Lymphomas, above). The most recent WHO classification, while still separating B- and T-cell lymphoid neoplasms, does not group the non-Hodgkin's lymphomas into a distinct clinical framework.[2] The non-Hodgkin's lymphomas include Burkitt's lymphoma, MALT lymphoma, and mycosis fungoides, all of which are discussed separately.

The usual presentation of lymphomas is lymphadenopathy, which in low-grade lymphoma may develop insidiously over a long period. There may be constitutional symptoms of fever, night sweats, and weight loss. Extranodal involvement may occur, as may symptoms due to organ compression by the tumour mass. Lymphomas of T-cell origin have a worse prognosis than B-cell lymphomas of the same type, and excess tumour bulk, involvement of bone marrow or gastrointestinal tract, and elevated serum-lactic dehydrogenase concentrations are also adverse prognostic factors. Staging is of somewhat less importance as a determinant of treatment and prognosis than in Hodgkin's disease.

About 40% of all lymphomas seen in North America and western Europe are *indolent* and of low grade; **follicular lymphoma** is the commonest form.[3] Follicular lymphomas may be subclassified histologically into 3 grades according to the number of centroblasts, and grade 3, which is more aggressive, should be treated as for diffuse large B-cell lymphoma[2,4] (see below). The approach to therapy of other follicular lymphoma differs dramatically in patients with localised or disseminated (advanced) disease.[2]

In the few patients with limited disease at presentation, radiotherapy is potentially curative,[1,5-8] with most patients achieving long-term freedom from disease, and low rates of relapse.[1] The addition of chemotherapy to radiotherapy does not convincingly prolong remission or improve overall survival.[2,6] Patients who do relapse after therapy should be treated as those with more disseminated disease.[2] Even in more advanced disease, which is rarely curable,[1,5,7] follicular lymphoma may follow a fairly chronic course, with a median survival of 8 or more years[4,5,8] although transformation to more aggressive forms may occur.[1]

Treatment in advanced disease has not been shown to affect survival, and a conservative approach of withholding treatment until symptoms require it is considered viable.[2,3,5,6,8,9] The choice of first-line chemotherapy for advanced disease is controversial.[4] Single-agent therapy with chlorambucil or cyclophosphamide, sometimes with a corticosteroid such as prednisone in the initial stages, may be preferred.[5,6,9] However, others[2] recommend this only for elderly or infirm patients, and then only after rituximab, which is the preferred first-line treatment in these patients. Patients treated with combination chemotherapy tend to have remission earlier but the remissions do not last longer than those achieved more slowly with single-agent therapy,[1] and overall survival has not improved.[5,6] Nonetheless, because intensification of chemotherapy has improved response rates, combination therapy such as CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisolone) has become widely used.[5] Some[9] consider this regimen too toxic for indolent lymphomas unless rapid tumour debulking is required. CVP (cyclophosphamide, vincristine, and prednisone) has also been used.[4] The addition of rituximab to combination chemotherapy has increased overall response rate, response duration, and progression-free survival and hence some recommend rituximab either alone or with other regimens (chemoimmunotherapy) as first-line options; caution is advised in patients with hepatitis B.[2] The use of interferon alfa with chemotherapy for first-line treatment has produced conflicting results. However, when interferon alfa was used with anthracycline-containing regimens, improvements in response rate and prolonged remission were reported;[5,9] prolonged survival has not been proven.[6] Interferon alfa as maintenance therapy appears to improve disease-free survival, but only if complete remission has been obtained with initial chemotherapy.[1,5] Overall, a meta-analysis[10] of 10 studies found that the ability of interferon alfa to prolong remission duration and survival may depend on it being used with relatively intensive chemotherapy and given in unit doses of at least 5 million units (at least 36 million units/month). Results using the purine analogues, fludarabine and cladribine, for initial therapy have been promising, with high remission rates.[5]

Relapse of indolent lymphomas is generally inevitable. Although further remissions can be achieved with repeat of the initial alkylating agent, or an alternative alkylator, response rates and duration of remission tend to decrease.[6] Fludarabine and cladribine have shown responses in about half of those relapsing or refractory to initial chemotherapy.[5,6] Pentostatin has also been tried, with less response, but most studies were in patients refractory to the purine analogues, which show cross-resistance.[5] Radioimmunotherapy with radiolabelled monoclonal antibodies such as tositumomab and ibritumomab are alternative options for relapsed or refractory follicular lymphoma,[2,11] although myelosuppression may be a problem[8,11] and there may be practical difficulties to their use. High-dose chemotherapy followed by autologous[12,13] or allogeneic[14,15] haematopoietic stem cell transplantation (HSCT) may be an appropriate option for relapsed patients.[2,4,6] In those candidates considered for autologous HSCT, initial therapy should not be excessively myelotoxic, and in the case of allogeneic HSCT, nonmyeloablative approaches may be considered.[2]

Intermediate- to high-grade lymphomas, of which **diffuse large B-cell lymphoma** (DLCL) is the most common form,[2,16] are *aggressive*, and survival is measured in months in untreated patients. However, unlike indolent lymphomas, they are potentially curable with intensive therapy.[7] DLCL occurs most often in patients aged 50 to 60 years, but also occurs in children. As with follicular lymphoma, approach to therapy differs in patients with localised or advanced disease.[2] Up to 20% of patients with aggressive lymphomas have localised disease at presentation, and combined modality treatment with a brief course of CHOP (see above) and rituximab followed by involved field radiotherapy is the treatment of choice.[2,4] Combination chemotherapy is also the treatment of choice in advanced aggressive lymphomas: cure can be achieved in about 35% of patients. Many of the regimens used have included the vinca alkaloids and doxorubicin with alkylating agents: CHOP and CVP (cyclophosphamide, vincristine, and prednisone) have been widely used.[3,16] More intensive second and third generation regimens such as MACOP-B (an intensive 12-week programme of cyclic methotrexate, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin), m-BACOD (with dexamethasone rather than prednisone), and ProMACE-CytaBOM (prednisone, doxorubicin, cyclophosphamide, etoposide, cytarabine, bleomycin, vincristine, and methotrexate), were then developed, and showed initial promising results. However, randomised studies failed to show any advantage for these second and third generation regimens over the less toxic and simpler CHOP regimen,[9,16,17] and many consider CHOP plus rituximab to be the standard for care.[2,4,18,19] High-dose chemotherapy with autologous HSCT has been tried for initial therapy in patients with diffuse aggressive non-Hodgkin's lymphoma, but remains investigational.[2,9,12,17]

On relapse, patients are treated with salvage chemotherapy regimens such as miniBEAM, (carmustine, etoposide, cytarabine, melphalan), DHAP (dexamethasone, cytarabine, and cisplatin), ICE (ifosfamide, carboplatin, etoposide), ESHP or ESHAP (etoposide, methylprednisolone, cytarabine, cisplatin), or MINE (mitoxantrone, ifosfamide, mesna, etoposide); all these regimens may be given with or without rituximab.[2,16] Patients are then evaluated for high-dose chemotherapy and autologous HSCT, which is considered the treatment of choice in suitable patients who respond to the salvage regimens.[1,2,16] In a randomised study, it was found to be superior to further courses of DHAP.[20] However, in disease resistant to salvage chemotherapy, its role has not been established,[16] and patients whose disease progresses are considered not likely to benefit from currently available standard therapy.[2]

High-grade lymphomas such as **precursor T-lymphoblastic lymphoma** (T-LBL) and Burkitt's lymphoma (see below) are *highly aggressive* and untreated patients survive only weeks. They occur mainly in children and young adults, and are often widely disseminated with bone marrow, peripheral blood, and CNS involvement. In children with lymphoblastic lymphoma, good results have been seen with protocols based on those used for acute lymphoblastic leukaemia (see above), including the use of CNS prophylaxis.[21] It is unclear whether a similar approach would be beneficial in adults with lymphoblastic leukaemia: CHOP continues to be widely used, with generally poor results.[21] HSCT is an option in lymphoblastic lymphoma.[12]

AIDS-related lymphomas. Non-Hodgkin's lymphoma is often a late complication of AIDS,[1] and its incidence in HIV-infected individuals is about 60 times greater than in the general population.[1-3] Histologically, it is usually diffuse large cell lymphoma (see Non-Hodgkin's Lymphomas, above) or small non-cleaved lymphoma (Burkitt's lymphoma—see below).[1,2,4] About 50% of these are associated with the presence of Epstein-Barr virus. The other common HIV-associated lymphoma is primary CNS lymphoma, which is invariably associated with Epstein-Barr virus.[1,4] More recently, primary effusion lymphoma or body cavity-based lymphoma has been identified,[1,2,4] which is associated with human herpes virus 8. Although Hodgkin's disease (see above) is not considered an AIDS-defining illness, epidemiological studies have shown it to be associated with HIV infection.[5] The introduction of HAART for HIV infection (p.856) may reduce the risk of lymphomas by improving immune function,[2,4,6] but, conversely, may increase the incidence by allowing patients to survive long enough for lymphoma to develop.[1,2] The incidence of primary CNS lymphoma has decreased with the advent of HAART.[1,6] There is some evidence of tumour response when antiretroviral therapy is started in a patient who already has a lymphoma.[4]

A few patients with AIDS-related non-Hodgkin's lymphomas present with localised disease, and may benefit from radiotherapy, but most have disseminated disease, often extranodal, at presentation.[1,2,4] Optimal management is not established.[7] The common chemotherapy regimens used are similar to those used in non-HIV infected patients, combining cyclophosphamide, vincristine, doxorubicin, and corticosteroids (CHOP), and sometimes additional drugs such as bleomycin and methotrexate (m-BACOD).[1,3,4,6,7] However, although standard dose or even intensive chemotherapy regimens have been used successfully in selected patients, in general patients with AIDS tolerate chemotherapy poorly, and intensive regimens may even shorten their survival. The addition of rituximab has been investigated, but results have been disappointing and there is an increased risk of neutropenic sepsis and death in these patients.[6] A low-dose modification of m-BACOD has produced responses and survival comparable to standard dose m-BACOD,[8] and low-dose chemotherapy is likely to be preferred in patients with relatively poor immune function (CD4 cell count less than 200 cells/microlitre[3]).[3] Results of trials using cyclophosphamide, doxorubicin, and etoposide (CDE), sometimes with didanosine, have been promising.[1] A dose-adjusted regimen of etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin (EPOCH) has also been studied,[6] and has been given with HAART.[1] The use of colony-stimulating factors with chemotherapy has reduced neutropenia and febrile episodes, but there has been no effect on remission rates or overall survival.[1] Most studies used granulocyte-macrophage colony-stimulating factor, but this may increase HIV-1 replication.[1] The prognosis for patients with poor immune status remains poor, and median survival remains only about 4 to 8 months.[3]

Primary CNS lymphoma has a very poor prognosis in patients with HIV infection, with a median survival of 3 months. Palliative radiotherapy is commonly used,[2,4] and may be combined with chemotherapy,[1,3] but it remains uncertain whether therapy improves survival.[6] Intrathecal cytarabine or methotrexate may be used to treat the meningitis associated with primary CNS lymphoma.[1]

Patients with Hodgkin's disease are more likely to present with B symptoms, at an advanced stage, with extranodal disease, and concomitant Epstein-Barr virus infection. Bone marrow involvement may be found in more than 50% of patients. Before HAART, patients with Hodgkin's disease and infected with HIV had a median survival of 1 to 2 years. Outcomes in the HAART era may be improving, although optimal treatment is undecided. Regimens that have been tried include the BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) and Stanford V regimens.[5]

Burkitt's lymphoma. Burkitt's lymphoma is a small non-cleaved cell lymphoma (SNCL) of B-cell origin, which is highly aggressive and is seen particularly in children; the rare cases in adults are most often associated with immunodeficiency such as AIDS. There is an endemic form in equatorial Africa, which is associated with Epstein-Barr virus and often involves the jaws and other facial bones.

The main treatment for Burkitt's lymphoma is chemotherapy. Regimens are generally based on high-dose cyclophosphamide, in various combinations with high-dose methotrexate, high-dose cytarabine, vincristine, doxorubicin, etoposide, and prednisone or prednisolone. Ifosfamide may be substituted for cyclophosphamide.[1-3] Cytarabine and methotrexate are also given intrathecally for CNS prophylaxis.[1,4] Although some groups have used an initial phase of low-intensity chemotherapy to reduce the risk of tumour lysis syndrome,[1] others[3] have shown that shorter duration, dose-intensive chemotherapy has resulted in improved survival.

In children complete remission is common and prognosis good: probability of long-term disease-free survival is usually greater than 80%.[3] Prognosis has been less good in adults, but with the increasing use of more intensive regimens similar to those used in children, is improving. About half of all adult cases are reported to be curable with intensive chemotherapy regimens.[2,4] It is possible that intensive regimens coupled with haematopoietic stem cell transplantation or monoclonal antibodies such as rituximab may improve results further.[2]

MALT lymphoma. Marginal zone B-cell lymphomas of mucosa-associated lymphoid tissue (MALT) occur most commonly in the stomach, but may also occur in the salivary gland, breast, thyroid, eye, or lung. They tend to be indolent and remain localised for long periods of time, but can transform to a more aggressive type.

Most gastric MALT lymphomas are associated with *Helicobacter pylori* infection.[1,2] The bacterium stimulates the formation of MALT in the stomach, which normally lacks organised lymphoid tissue, and there is evidence that it indirectly stimulates tumour growth. Eradication of *H. pylori* infection using antibacterial and antisecretory therapy, as described in Peptic Ulcer Disease, p.1702, has been shown to result in regression of gastric MALT lymphoma in a number of patients.[1-4] Increasing experience of the use of *H. pylori* eradication indicates that the lymphoma regression after eradication can take up to 14 months; eradication suppresses but does not necessarily eradicate the neoplastic clone; only lymphomas limited to the mucosa or submucosa regress after eradication; and that lymphoma can recur.[5] Thus, patients who are *H. pylori*-positive with early stage primary gastric MALT lymphomas may be treated solely with *H. pylori* eradication regimens and long-term endoscopic follow-up.[2,6] The best treatment for patients without *H. pylori* infection, those whose tumours do not respond to eradication, and those with more advanced tumour stage at presentation remains to be established. Surgery has been widely used, but radiation therapy is the treatment of choice for localised disease.[2,6] Rituximab monotherapy may be considered for early stage disease if radiation therapy is contra-indicated; single-agent or combination chemotherapy is recommended in advanced disease.[2]

It has been suggested that screening for and eradication of *H. pylori* is worth investigating as a means of preventing gastric cancer.[7]

Non-gastrointestinal low-grade MALT lymphomas have been treated with surgery or radiation therapy if localised, and with single-agent or combination chemotherapy (similar to that used for other low-grade non-Hodgkin's lymphomas—see above) if advanced.[2,6,8]

Mantle cell lymphoma. Mantle cell lymphoma is a rare, aggressive lymphoma of B-cell origin. Patients are often elderly and more often male. Most patients present with advanced stage disease. Clinical features include fever, weight loss, drenching night sweats, and gastrointestinal symptoms.[1]

There is no established standard of care for mantle cell lymphoma.[2] For the few patients presenting with localised disease, radiotherapy significantly improves progression-free survival, and is recommended first-line, with or without chemotherapy.[1,2] Systemic combination chemotherapy, although non-curative, is recommended in advanced disease.[1,2] Rituximab plus chemotherapy is recommended first-line.[1-3] Chemotherapy options include CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), HyperCVAD/MA (cyclophosphamide, vincristine, doxorubicin, and dexamethasone alternating with high-dose methotrexate and cytarabine), and EPOCH (etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin).[1-3] An alternative first-line treatment in suitable patients is high-dose radiochemotherapy and autologous haematopoietic stem cell transplantation (HSCT).[1-3] Allogeneic HSCT may be curative, but only a few patients are suitable and it is associated with considerable morbidity and mortality; it may be considered in suitable patients with relapsed disease after first-line therapy.[1] For patients who cannot tolerate more intensive therapy, some recommend CHOP with or without rituximab[2] or anthracycline- or fludarabine-containing regimens.[1] Patients who relapse after initial therapy or with progressive disease may be treated with bendamustine (with or without rituximab), bortezomib, purine analogue-containing regimens (with or without rituximab), or thalidomide (alone or with rituximab).[1-3] Radioimmunotherapy, with radiolabelled monoclonal antibodies ibritumomab and tositumomab, has also been investigated for relapsed or refractory disease.[1,3]

Mycosis fungoides. Mycosis fungoides is the most common of the cutaneous T-cell lymphomas. It is considered to have 3 stages: a premycotic erythematous or patch phase, characterised by a pruritic rash resembling psoriasis, which may persist for years or even decades; an infiltrative or plaque phase, in which some patches become thickened, darker plaques with marked T-cell infiltration; and a tumour phase where lesions enlarge and ulcerate. Ultimately there may be visceral involvement or potentially fatal sepsis secondary to skin breakdown. A variant of mycosis fungoides presents as widespread pruritic erythroderma, accompanied by abnormal T-cells in the blood, and is known as the Sézary syndrome.

There are many therapeutic options for mycosis fungoides, but few have been evaluated in controlled trials. Treatment depends on disease stage and spread.[1-7] Patients with limited and slowly progressive *patch phase disease* have a good prognosis (median survival similar to age-matched controls) and may be managed with topical and local therapies. Topical therapies include emollients, corticosteroids, chlormethine, carmustine, or bexarotene. Phototherapy, using UV B light, or a psoralen plus UV A light

(PUVA), is a useful alternative when topical treatments are ineffective or not tolerated. Mycosis fungoides is very radiosensitive, and for clearly localised patches, or isolated patches that have failed to respond to other treatments, local x-ray or electron beam radiotherapy may be used.

The initial therapy for patients with widespread *patch/plaque phase disease* is also topical, using chlormethine or PUVA. Topical retinoids are not recommended for generalised skin involvement, as they can cause irritation.[7] Patients who fail to respond to a single drug may be treated with combinations such as chlormethine with either PUVA or electron beam therapy,[1] or PUVA with interferon alfa.[1,4] Total skin electron beam therapy may be used, but it may not be widely available and is usually only given once; it is generally used for thickened plaques or for disease that has not responded to other local therapies.

In the *tumour phase*, combination therapy as described above is often used initially. Alternatively, systemic retinoids (such as bexarotene, isotretinoin, or tretinoin), interferons, vorinostat, denileukin diftitox, or low-dose methotrexate may be tried.[7] Systemic chemotherapy may be used for palliation in recalcitrant disease and advanced disease with extracutaneous involvement, but responses are often of short duration. Options include single-agent liposomal doxorubicin, gemcitabine, chlorambucil, pentostatin, etoposide, cyclophosphamide, and temozolomide.[7] Combination regimens include CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone), CVP (CHOP without doxorubicin), or CAVE (cyclophosphamide, doxorubicin, vincristine, etoposide).[1]

Mycosis fungoides with erythrodermic features is treated similarly except that skin irradiation tends to be avoided or used in very low doses as it causes severe desquamation.[1] Extracorporeal photopheresis may be useful for disease with erythrodermic features.[1,4,6,7]

Therapies for *persistent or recurrent* mycosis fungoides include denileukin diftitox, bexarotene, and vorinostat.[2,3,5,6,8-11] Allogeneic haematopoietic stem cell transplant may be considered for patients with advanced disease that is progressive or refractory to multiple treatment options.[7]

Waldenström's macroglobulinaemia. Waldenström's macroglobulinaemia (primary macroglobulinaemia) is a clinical syndrome associated with lymphoplasmacytic lymphoma in which the abnormal lymphocytes secrete a monoclonal serum paraprotein of immunoglobulin M type resulting in increased plasma viscosity. Patients are mainly elderly, and more often male. Although often asymptomatic, patients can present with weakness and fatigue, anaemia, hepatosplenomegaly, and lymphadenopathy. Some develop the hyperviscosity syndrome (characterised by oronasal bleeding, visual disturbances and retinal haemorrhage, neurological disturbances such as headache, vertigo, peripheral neuropathy, and hearing loss, and, rarely, heart failure).

Asymptomatic patients require no treatment and may remain stable for some years. Where treatment is required, it has usually been with alkylating agents such as chlorambucil (with or without prednisone, or prednisolone) or, more recently, with cladribine or fludarabine.[1-8] Single-agent oral cyclophosphamide has also been used.[3,8,9] Rituximab is also recommended by some as a reasonable first choice, although patients should be closely monitored for symptoms of hyperviscosity;[5-8,10] plasmapheresis may be performed to reduce plasma viscosity.[3,4,6-10] Data on the use of rituximab are limited, and others consider its role has yet to be defined.[4,9]

When disease stabilises, treatment may be stopped and begun again on relapse, with either the same drug, or an alternative first-line agent.[3,10] Autologous haematopoietic stem cell transplantation (HSCT) may be considered for relapsed disease, although studies are limited and complete response rare;[3,4,8] it is recommended that exposure to alkylating agents or nucleoside analogues be limited if HSCT is considered.[5,6,9,10] Although there are few studies, combination chemotherapy does not appear to produce better responses than single-agent chlorambucil;[1,2,4] combination therapy with newer drugs remains investigational.[9,10] However, cyclophosphamide-containing regimens[10] are recommended in relapsed or refractory disease, if the re-use of a first-line drug is not feasible.

High-dose corticosteroids may be used to treat systemic vasculitis arising from deposition of paraproteins.[9,10] Splenectomy, although rarely indicated, may be used to manage painful splenomegaly and hypersplenic syndromes.[4,9,10] Small studies have reported benefit with thalidomide (with or without dexamethasone and/or clarithromycin),[3-6,8-10] high-dose dexamethasone,[10] or interferon alfa.[3,5,9,10]

PLASMA CELL NEOPLASMS. *Multiple myeloma.* Multiple myeloma (myelomatosis) is a lymphoproliferative disorder of B-cell origin, involving the development of an abnormal plasma-cell precursor. It occurs mainly in the elderly, and accounts for only 1% or less of all malignancies. It is more common in black than in white patients and in men than in women.

The proliferation of the abnormal clone tends to suppress normal haematopoiesis, resulting in anaemia and immunosuppression, with an increased risk of serious infection. Perhaps the most characteristic complication, however, is skeletal destruction, apparently due to release of an osteoclast stimulating factor, resulting in osteoporosis, lytic lesions and fractures, and bone pain, as well as consequent hypercalcaemia. In addition, the plasma cells release large quantities of monoclonal immunoglobulins, known as paraproteins, which can produce a hyperviscosity syndrome and in some cases may interfere with platelet function. Renal failure of various causes and neurological problems due to compression are also common.

Multiple myeloma is not curable with presently-available treatment, and **therapy** is concerned with prolongation of survival and alleviation of symptoms.[1-3] Those patients with stable, indolent or smouldering myeloma, or benign monoclonal gammopathy, are followed carefully but not treated until overt progressive disease occurs. Early treatment may inhibit disease progression, but overall survival and response rates are not affected.[4]

In patients with overt disease some form of haematopoietic stem cell **transplantation** (HSCT) may now be the treatment of choice.[5,6] If a syngeneic transplant (from an identical twin) is unavailable, high-dose chemotherapy combined with autologous peripheral blood stem cell (PBSC) transplantation improves response rate, event-free survival, and overall survival compared with standard chemotherapy. Evidence for these benefits is strongest for patients younger than 55 years old.[7] Although some[8] consider standard-dose chemotherapy to be the preferred initial treatment in patients older than 70 years, other reviews[5,6] have concluded that autologous PBSC transplantation is safe for the majority of patients older than 65 years, and guidelines have suggested its consideration in this group[3] if they have good functional status and limited co-morbidity. With tandem transplantation, patients receive a second planned autologous HSCT,[9] since it was shown that patients who did not enter remission after one transplant could achieve remission after another.[10] Some recommend tandem transplants in those who do not have at least a very good partial response after the first,[11] and as such, some centres routinely collect enough stem cells for two transplants.[9,12] Allogeneic HSCT has been used for multiple myeloma, sometimes after autologous HSCT, but few patients are suitable, and transplant-related morbidity and mortality are high with conventional myeloablative chemotherapy regimens; non-myeloablative regimens (miniallogeneic HSCT) are under investigation.[9-12]

Patients may be treated with vincristine, doxorubicin, and dexamethasone (VAD) for 3 to 4 months before transplantation,[11,12] although dexamethasone alone, or with thalidomide, has become a standard induction therapy.[2,9] Liposomal doxorubicin has been substituted for standard doxorubicin in the VAD regimen.[2] Some recommend lenalidomide with dexamethasone as standard induction therapy,[11] and other options include bortezomib-based regimens.[2,9,11] Oral induction with cyclophosphamide, idarubicin, and dexamethasone has also been tried.[13] Peripheral stem cells are collected after giving high-dose cyclophosphamide and granulocyte colony-stimulating factor.[5,8] Although some suggest the use of alkylating agents and interferon alfa after stem cell collection,[8] earlier alkylator therapy interferes with stem cell mobilisation,[2,9,11,12] and can result in poor engraftment.[6,7] The standard conditioning regimen before transplantation is considered to be high-dose melphalan.[3,5,6,8,9,12] Total body irradiation is no longer recommended, as combined with lower dose melphalan, it resulted in higher toxicity and no significant survival benefit compared with high-dose melphalan alone.[5-7] Similarly, stem cells are not purged of contaminating myeloma cells as a randomised study[14] showed no benefit.

Where transplantation is infeasible or inappropriate, **chemotherapy** may be given to induce remission and prolong survival. The standard first-line regimen has long been a combination of oral melphalan and corticosteroids, usually prednisolone or prednisone.[1,3,6,9,10,12] This MP regimen produces an objective response in about half of all patients, and prolongs median survival to between 2 and 3 years.[1,6] The contribution of corticosteroids to the regimen has been controversial although a trend towards increased survival was noted[5] compared with melphalan alone, and high-dose dexamethasone given alone has been reported to be effective in producing remissions.[6] Cyclophosphamide is active,[5] and has been substituted for melphalan.[1,3] The addition of thalidomide to melphalan and prednisone has led to better response rates and progression-free survival, and it is recommended as standard induction for elderly patients ineligible for HSCT; however, toxicity is higher than with the MP regimen.[11,15] More intensive first-line combination regimens have also been used, particularly in younger, fitter patients. Examples include the ABCM regimen (doxorubicin, carmustine, cyclophosphamide, and melphalan), alternating combinations of VMCP (vincristine, melphalan, cyclophosphamide, and prednisone) with VBAP (vincristine, carmustine, doxorubicin, and prednisone), the VAD regimen (vincristine, doxorubicin, and dexamethasone), and the M2 or VBMCP protocol (vincristine, carmustine, melphalan, cyclophosphamide, and prednisolone).[1,6] However, although response rates are higher, meta-analysis[16] has not shown these combination regimens to be more effective than melphalan and prednisone in terms of survival. The use of interferon alfa as induction therapy is controversial, although a systematic review[5] found it improved progression-free survival. The combination of thalidomide and dexamethasone has also shown promise for initial therapy in advanced disease, although toxicity may limit its use.[2]

Maintenance chemotherapy has not been shown convincingly to improve total duration of remissions or survival,[1] and although progression-free survival improved with interferon alfa treatment, overall survival benefit was considered to be minimal.[5] A study[17] found prednisone given on alternate days to be effective maintenance treatment in those patients responding to induction therapy. Some recommend no maintenance therapy for standard risk patients except within investigational studies; high-risk patients may be given thalidomide and prednisone as maintenance if not previously treated with thalidomide.[11] Thalidomide has also been used as maintenance after autologous HSCT,[2] and may be offered to patients not achieving a very good partial response after tandem HSCT.[15] Lenalidomide and bortezomib are under investigation as maintenance therapies.[2]

In patients who fail to respond to initial treatment, or who subsequently **relapse**, various regimens have been tried. A systematic review found no particular regimen to be more effective than another.[5] Salvage regimens for progressive disease include VAD with the addition of cyclophosphamide, EDAP (etoposide, dexamethasone, cytarabine, and cisplatin), and high-dose cyclophosphamide.[1,2] About 60 to 70% of patients who relapse more than 6 months after stopping first-line therapy will respond to re-use of the initial regimen.[1,9] Thalidomide, with or without dexamethasone, has been shown to be effective in refractory myeloma.[2,3,5,18] Good responses have been reported with bortezomib[2,3,19,20] in relapsed, refractory myeloma, and there is some suggestion of an additive response with dexamethasone. Bortezomib is also used with liposomal doxorubicin, as is lenalidomide, with or without dexamethasone.[2]

Although chemotherapy aimed at the myelomatous clone will produce symptomatic relief as disease is brought under control, **supportive and symptomatic care** is also important. Bisphosphonates such as clodronate, pamidronate, and zoledronate have been found to be effective in reducing skeletal complications,[21,22] and are recommended in those patients with bone disease.[2,3,23] Some recommend that bisphosphonate therapy be stopped after 2 years in patients with responsive or stable disease.[23,24] Radiotherapy is used for impending fracture or impending spinal cord compression, and is often effective in relieving uncontrolled bone pain.[2,6] Erythropoietin therapy can improve anaemia and reduce the need for transfusion.[1,2,5,6,8] A high fluid intake is essential in patients with renal dysfunction or hypercalcaemia (for the appropriate management of the latter, see p.1668). Vigorous antibacterial treatment may be needed if infection occurs (see Infections in Immunocompromised Patients, p.174) and plasma exchange may alleviate the hyperviscosity syndrome.[2,8,9]

Drugs under investigation for the treatment of multiple myeloma include oblimersen, and arsenic trioxide.[12]

Malignant effusions. The amount of interstitial fluid is normally regulated by a complex equilibrium between capillary filtration, osmotic pressure, and physical hydrostatic or hydraulic forces. Malignant neoplasms can disturb this equilibrium by obstruction of capillary or lymphatic drainage as well as causing active exudation of additional fluid after metastatic implantation. Malignant effusions are associated most often with lung, breast, and ovarian malignancies and lymphomas. Symptoms vary, and the fluid build-up may be asymptomatic; both pleural and pericardial effusions can produce cough, pleuritic chest pain, and dyspnoea and pericardial effusions may progress to cardiac tamponade. Peritoneal effusions may lead to malignant ascites. The main aim of treatment for malignant effusions is effective palliation of symptoms, and depends in part on the tumour type, patient performance status, and prognosis.[1-7] If the tumour is chemosensitive, systemic chemotherapy may resolve the effusion. Simple fluid drainage (thoracentesis or pericardiocentesis) will relieve symptoms until fluid build-up recurs, and in patients with very poor prognosis (life expectancy less than 1 month), may suffice for palliation.

In malignant ascites, paracentesis is usually effective temporarily; evidence for the value of diuretics is weak, but spironolactone may be of benefit in some patients, either alone or with a loop diuretic. In other patients with refractory tumours, fluid drainage followed by sclerotherapy is likely to be preferred. The principle involved is the instillation of an irritant agent into the pleural or pericardial cavity to promote inflammatory and fibrotic changes which result in the membranes adhering together and abolition of the space between the membranes in which fluid accumulates. When this is done to treat pleural effusions (pleurodesis) success of sclerotherapy is dependent on adequate fluid drainage beforehand and full re-expansion of the lung to bring the pleural surfaces together. Intrapleural thrombolytics such as streptokinase have been used to improve fluid drainage in cases of loculation of the effusion.[6,7]

Many drugs have been used for sclerotherapy, and the most common are a tetracycline (doxycycline or tetracycline), bleomycin, or talc. The choice between these three remains controversial, and opinions on the preferred option differ.[1,4-8] However, a systematic review[9] found talc to be the sclerosant of choice for malignant pleural effusions. Other sclerosants that have been used, with varying reported rates of success, include interferon alfa, mepacrine, mitoxantrone, picibanil, povidone-iodine, silver nitrate, *Corynebacterium parvum*, and *Staphylococcus aureus* superantigen.[8] Following drainage of the effusions the sclerosant is instilled in a small volume (20 to 50 mL) of liquid through the drainage tube. Talc may also be given as a powder insufflation (rather than slurry), but this involves a surgical procedure under general anaesthesia. Sclerotherapy results in painful inflammation, and local anaesthetics or analgesics should be given. For patients who fail sclerotherapy, or for whom this is not considered suitable, there are various surgical options to manage effusions.[1-7,10]

Malignant neoplasms of the bladder. Cancer of the bladder is the fourth or fifth most common cancer in Europe and the USA, where over 90% of bladder cancers are transitional cell in type. About two-thirds of all cases occur in men, and the median age at diagnosis is 65 years. Known risk factors include smoking and exposure to aniline dyes. In countries where it is endemic, schistosomiasis is an important cause of squamous cell bladder cancer. Most patients present with haematuria; there may also be urinary frequency or dysuria.

Urothelial tumours fall into 3 major groups, non-invasive, invasive, and metastatic, which differ in prognosis and management.[1] About 70% of cases are non-muscle-invasive (superficial), 25% are muscle-invasive, and 5% are metastatic.[2]

Of the *non-muscle invasive* tumours, about 70% are low-grade transitional cell carcinomas confined to the mucosa (Ta), and have a low risk of progression to muscle invasive disease and a 50% chance of recurrence. Most of the remainder are higher-grade transitional cell carcinomas that have invaded the submucosa (T1), and a small percentage are high-grade carcinoma in situ (CIS). These high-grade tumours have a high risk of progression to muscle invasive disease, and a 50 to 90% chance of recurrence. The standard initial treatment for primary or recurrent superficial disease is surgery, in the form of transurethral resection. In an attempt to prolong remission and reduce the recurrence rate antineoplastics have been instilled into the bladder after complete resection (prophylactic or adjuvant intravesical therapy).[2] Effective agents include doxorubicin, epirubicin, mitomycin, and thiotepa. These increase the disease-free interval, but do not reduce the risk of progression to invasive disease, nor prolong survival.[3] Good results have also been reported with intravesical BCG,[2,4] and meta-analyses[5,6] have found it to produce lower recurrence rates than mitomycin. A single dose of intravesical chemotherapy may be given within 24 hours of resection in patients with primary resected low-grade tumours.[1] Adjuvant intravesical therapy with an antineoplastic (usually mitomycin) or BCG is recommended for patients with recurrent Ta tumours or primary higher grade T1, and BCG is generally preferred to antineoplastics in primary CIS.[1,7] Maintenance intravesical BCG therapy for CIS is recommended for those showing a complete response. Those with recurrent or persistent disease can be given a second course of BCG or mitomycin. If residual disease is still present, cystectomy should be considered; intravesical therapy with a different agent (mitomycin, valrubicin, interferon alfa, or BCG plus interferon alfa) is an alternative to cystectomy. Radical cystectomy is recommended if disease progresses.[1] Photodynamic therapy using porfimer sodium or 5-aminolevulinic acid has also been investigated.[8]

Management of *muscle-invasive* bladder cancer that has not yet metastasised is a matter of some controversy, but conventional therapy has revolved around radical surgery.[1,2] However, such conventional therapy offers a 5-year survival rate of only about 50%.[9] Alternatives include systemic chemotherapy before or after cystectomy,[1,7] or bladder-sparing options such as chemotherapy with radiotherapy.[1] The optimal regimen remains to be defined but regimens incorporating cisplatin and methotrexate, such as M-VAC (methotrexate, vinblastine, doxorubicin, and cisplatin), appear to be widely used. These can delay recurrence of disease, but evidence for improved survival has been conflicting. For example, a large study comparing neoadjuvant therapy using CMV (cisplatin, methotrexate, and vinblastine) before cystectomy or radiotherapy, found this regimen to result in a higher response rate, but not to significantly prolong survival.[10] Although another study[11] has reported that neoadjuvant M-VAC provides a survival benefit over cystectomy alone, the strength of these results has been questioned.[12,13] A meta-analysis[14] that included both these studies concluded that neoadjuvant platinum-based combination chemotherapy did improve survival. However, the benefit was only modest, and there was no evidence of benefit for single-agent platinum therapy.

Patients with unresectable or *metastatic* disease, or who subsequently develop metastatic disease, are usually treated with systemic chemotherapy or radiotherapy.[1] For patients with good prognosis, a combination regimen such as

M-VAC or CMV may be used. Various combinations of gemcitabine, taxanes, and cisplatin have shown clinical benefit,[1] and gemcitabine plus cisplatin has been shown to provide similar survival advantage to M-VAC with better tolerability: some now consider that it should be the preferred regimen in advanced disease.[1,9,15,16]

Malignant neoplasms of the bone. Solid cancers often metastasise to the skeleton and metastatic bone disease is a common problem with cancers of the breast, prostate, and lung. Bone metastases are often responsible for cancer pain (the general management of which is discussed on p.5) and also result in immobility, bone fractures, bone-marrow failure, spinal cord compression, and hypercalcaemia.[1] The most common sites of metastasis are the spine, hip, and femur. Primary bone malignancies are rare, and are usually sarcomas. Multiple myeloma (see Plasma Cell Neoplasms, p.658) also produces bone involvement.

Management of **bone metastases** is essentially palliative since cure is rarely possible.[1,2] External beam radiotherapy is the best treatment for localised metastatic bone pain, with responses occurring in over 70% of patients. Radiation delivered by bone seeking isotopes such as samarium-153 or strontium-89 is an alternative.[3-6] Bisphosphonates are of benefit in patients with severe bone pain that is too widespread for local use of radiotherapy and does not respond to other analgesics.[2,7]

Structural weakness due to extensive bone loss may require structural support.[1,2] Surgical fixation or stabilisation can treat or prevent fractures. Surgical excision and reconstruction with methylmethacrylate bone cement may also be required.

Bone metastases cause local osteolysis and various inhibitors of bone resorption have been tried, not only to correct hypercalcaemia of malignancy (p.1083), but also to relieve bone pain and reduce the risk of fractures. Several randomised studies in patients with metastatic bone disease from breast cancer or multiple myeloma have shown 25 to 50% reductions in skeletal events with the use of the bisphosphonates, clodronate or pamidronate.[2,8] Similar results have also been reported for zoledronate.[9,10] Ibandronate is also used.[11,12] A systematic review[13] concluded that bisphosphonates significantly decrease skeletal morbidity, except for spinal cord compression. Various organisations have produced guidelines to suggest which patients are best treated with bisphosphonates.[2,14,15] The clearest evidence is in patients who already have lytic destruction of bone. Treatment should start when bone metastases are diagnosed and continue until no longer clinically relevant; they do not affect survival.[13] Benefits in terms of skeletal events are only seen after about 6 months of treatment.[12] There is much interest in the use of bisphosphonates to prevent the development of bone metastases. However, preliminary evidence of their efficacy is conflicting,[16] and further large controlled studies are considered warranted.[2,15]

Systemic antineoplastic therapy should also be given if the primary tumour is chemosensitive. Endocrine treatment is usually preferred for patients with breast and prostatic cancers, and can produce useful control of symptoms from bone metastases.[1,2] Patients who also have visceral metastases or who have hormone resistant tumours should probably be treated with cytotoxic antineoplastics.[2]

New drugs under investigation include denosumab and atrasentan.[11]

Malignant neoplasms of the brain. Most primary brain malignancies are gliomas, such as astrocytoma and glioblastoma multiforme. The frequency and natural history of brain tumours differ between children and adults. Low-grade astrocytomas, and medulloblastomas are the commonest primary brain tumours in children and anaplastic astrocytomas and glioblastoma multiforme are the most common in adults. However, metastatic brain cancer is the most common cause of intracranial tumours in adults, being up to ten times more common than primary brain tumours. The cancers that most often metastasise to the brain are lung cancer, breast cancer, and melanoma. CNS involvement in patients with acute leukaemia (see Acute Lymphoblastic Leukaemia, p.651) or lymphoma (see Non-Hodgkin's Lymphomas, p.656) is also quite common.

The symptoms of primary and metastatic cranial neoplasms are those of local pressure and damage to the brain (such as focal seizures and visual field defects), of displacement of brain structures (like oculomotor paresis with tentorial herniation), and of raised intracranial pressure (such as impaired consciousness and papilloedema). The single most frequent symptom is headache, which is seen in about 60% of cases.

The mainstay of treatment for most primary brain tumours is surgery to relieve compression and cerebral oedema, establish diagnosis, and where feasible resect as much of the tumour as possible.[1-7] High-dose corticosteroids and computed tomography have reduced the morbidity of surgery, both for biopsy and excision. For benign tumours (such as pilocytic astrocytomas) resection may be curative; for malignant tumours (such as anaplastic astrocytomas, glioblastoma multiforme, and medulloblastomas) there is some evidence that extensive resection prolongs survival, but this may be biased by the selection of younger fitter patients for surgery. Adjuvant radiotherapy is widely used after surgical resection for malignant tumours in adults and children. Surgery alone or with radiotherapy is also used for single brain metastases.[8] For multiple brain metastases, most patients are treated with radiotherapy and corticosteroids. Radiosurgery is an investigational technique developed to reduce the radiation dose received by normal brain tissue. Radioactive implants (brachytherapy) are also being investigated.

The role of adjuvant chemotherapy for primary brain malignancies has been less certain, in part because of the difficulty in finding drugs that can cross the blood-brain barrier; until the advent of temozolomide, treatment was usually based on nitrosoureas such as carmustine and lomustine. The PCV regimen, in which procarbazine, lomustine, and vincristine are given, has often been preferred in the treatment of gliomas after surgical resection and radiation therapy.[2] The value of this regimen was called into question by a large randomised trial of adjuvant PCV plus radiotherapy versus radiotherapy alone in high-grade astrocytoma, in which PCV provided no additional survival benefit.[9] However, a meta-analysis including this and 11 smaller studies found that giving some form of adjuvant chemotherapy (usually based on nitrosoureas) modestly improved survival in adults with high-grade glioma.[10] Temozolomide, an oral alkylating agent, is also being used for the treatment of recurrent gliomas.[11] Its use during and after radiotherapy in newly diagnosed glioblastoma, usually after debulking surgery, has improved survival,[12] and it has increasingly replaced the nitrosoureas in the management of glioma.[7,13-15]

In young children chemotherapy may be used as a stopgap measure to delay, or reduce the frequency of, radiotherapy, which can cause neurodevelopmental damage.[1,3] Studies in children under 3 years of age given combination chemotherapy regimens (often including cyclophosphamide, vincristine, cisplatin or carboplatin, and etoposide or methotrexate), after surgical resection of tumour found that radiotherapy could be safely delayed in most and that a few children might never require it.[3] Adjuvant chemotherapy (for example, vincristine and lomustine with or without cisplatin) has also been used to allow a reduction in radiation therapy in children aged between 3 and 10 years.[3] This chemotherapy regimen has also been used in children with poor-risk medulloblastoma.

Since present regimens for primary brain tumours are far from optimal, alternatives continue to be tried.[7] Newer antineoplastics include bevacizumab and irinotecan.[7,13,15] Newer delivery techniques include implantation of biodegradable polymers impregnated with carmustine (which has been shown to improve survival in patients with malignant glioma),[7] and the transient disruption of the blood-brain barrier to allow cytotoxics to cross. Other treatments investigated include single or multitargeted kinase inhibitors, ligand-toxin conjugates, antisense oligonucleotides, and gene therapy.

Whole-brain radiation therapy is the common choice for most patients with brain metastases. Surgery may be suitable for those with a single brain metastasis, especially if prognosis is favourable and systemic disease controlled.[16]

The value of chemotherapy in cerebral metastatic disease remains to be defined:[8,17] the primary tumour may be intrinsically resistant to chemotherapy, or metastasis may develop despite treatment of the primary tumour, which will encourage the selection of resistant species. Furthermore, although the blood-brain barrier may not be completely intact in these patients, allowing some passage of antineoplastics into the brain, drug delivery of the less lipid-soluble drugs to cerebral metastases may not be sufficient, or sufficiently consistent, to produce a response. Nonetheless cerebral metastases of some chemosensitive primary tumours may respond to therapy. Temozolomide with or without radiotherapy is under investigation, as are other agents such as topotecan, paclitaxel, gefitinib, and radiosensitisers.[16]

A brain cancer vaccine (DCVax®-Brain) is also being investigated.

Malignant neoplasms of the breast. Cancer of the breast is the most common malignant neoplasm in women. The disease is rare under the age of 25, and increases in incidence with age, although the rate of increase slows after the menopause. Risk factors include a family history (women with inherited BRCA1 or BRCA2 mutations are at higher risk), and reproductive hormonal factors such as early menarche, late menopause, nulliparity, and older age at birth of first child. Oral contraceptives and postmenopausal HRT are also associated with a small excess risk (see Carcinogenicity, Breast, on p.2059 and p.2071 respectively).

Ductal carcinoma in situ (DCIS) is a tumour localised to the breast ducts with no evidence of invasion. Invasive breast cancer can be divided into three main groups:

- early breast cancer (operable, primary, stage I/II)
- locally advanced disease (inoperable local, stage III)
- advanced disease (metastatic; stage IV)

Breast cancer is an extremely heterogeneous disorder, and the clinical course is consequently very variable; such factors as patient age and menopausal status, tumour size and grade, involvement of axillary lymph nodes or skin, and presence of hormone receptors within the tumour may be a guide to the extent and aggressiveness of disease, and hence have prognostic significance for treatment.[1-3] Early testing for overexpression of HER2 (human epidermal growth factor receptor-2) is increasingly important, since it is of value in determining response to certain treatments.[3]

Up to 20% of all cancers of the breast detected by mammographic screening are **ductal carcinoma in situ** (DCIS),[4-7] the management of which still has some areas of controversy. Most patients with DCIS will be offered breast-conserving surgery,[3,6,8] although mastectomy, which was historically preferred, is still the treatment of choice in high-risk patients.[3-7] Radiotherapy is usually recommended after successful breast-conserving surgery,[3,6,8] as it reduces the rate of recurrence and the risk of developing invasive disease (although it does not affect survival); there may be a subgroup of women in whom it is unnecessary, but there is controversy as to how to define the group. In the USA the use of adjuvant tamoxifen is also suggested,[3-5] but studies have produced conflicting reports of benefit on recurrence,[5,7] and again, there is no proven effect on survival; French guidelines suggest that the use of adjuvant hormonal therapy be confined to clinical trials.[6] Adjuvant use of newer oestrogen modulators such as anastrozole is also under investigation.[5,7]

In patients with **early disease** (stage I or II; a relatively small tumour with no or limited nodal involvement) the prognosis is fairly good. Primary treatment is surgical.[1,3,9] Breast-conserving surgery followed by postoperative radiotherapy has been shown to have equivalent local recurrence rates and 10-year survival (about 60%) to mastectomy.[10] The use of postoperative radiotherapy after breast-conserving surgery reduces local recurrence rates, but does not appear to affect overall survival.[10,11] Radiotherapy is not usually used after mastectomy, but there are some studies indicating that it may have additional benefits in patients at high risk of recurrence.[12,13]

Further adjuvant therapy with cytotoxic chemotherapy or hormonal manipulations such as tamoxifen and ovarian ablation by surgery, radiotherapy, or gonadorelin analogues has been given to try to eradicate the micrometastases which cause relapses. Overviews of a large number of trials by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) have confirmed the benefits of adjuvant therapy and attempted to determine which women derive most benefit and which regimens are most effective.[14-18] Analyses from these[18] and the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-14 and B-20 trials[19] permitting up to 15 years of follow-up have shown that:

- all women with early-stage breast cancer benefit from adjuvant therapy (although the size of the benefit varies)
- the benefit continues to increase with time, suggesting that adjuvant therapy is curative in a proportion of women who would otherwise relapse
- about 6 months of anthracycline-based chemotherapy reduces the annual death rate due to breast cancer by about 38% in women under 50 years of age at diagnosis, and about 20% in those aged 50 to 69 at diagnosis (too few women over 70 were given chemotherapy to estimate benefit in this group)
- this survival advantage occurs largely independent of oestrogen receptor (ER) status, nodal status, or other tumour characteristics
- adjuvant regimens including an anthracycline are more effective than those without a drug of this class
- in women with ER-positive disease, about 5 years of treatment with adjuvant tamoxifen reduces the annual death rate due to breast cancer by around 31%, largely independent of age, other tumour characteristics, or the use of chemotherapy
- combined chemotherapy and tamoxifen therefore increases the survival benefit further: for middle-aged women with ER-positive disease the breast-cancer mortality rate over 15 years would be approximately halved by 6 months of anthracycline-based chemotherapy followed by 5 years of adjuvant tamoxifen
- ovarian ablation (by surgery or irradiation) or ovarian suppression with a gonadorelin analogue also appear to reduce the mortality due to breast cancer, but that the advantage only applies where other adjuvant therapies are not given

Although these data help in making therapeutic decisions, the size of the benefit will always be less in patients with good prognosis; in the most favourable cases (small tumours with no involved nodes) the incremental benefit may be too small to warrant adjuvant treatment.[3] Tailoring systemic adjuvant therapy to the patient is important, and age and clinical characteristics alone are not adequate grounds to make the judgement: appropriate prognostic markers should be considered.[19,20]

The large analyses have led to the widespread adoption of anthracycline-based regimens for adjuvant *chemotherapy*, replacing earlier historical regimens such as CMF (cyclophosphamide, methotrexate, and fluorouracil) with those such as FAC or CAF (cyclophosphamide, doxorubicin, fluorouracil), AC (doxorubicin plus cyclophosphamide), and their many variants. However, they do not take account of more recent developments in molecular profiling of the tumour, nor of newer drugs that have become available for adjuvant therapy.

The EBCTCG analysis could not show any difference in effectiveness between anthracycline regimens,[18] but regimens based on epirubicin have gained in popularity in many centres, since its lower cardiotoxicity compared with doxorubicin means that higher doses can be given. Addition of a taxane (docetaxel or paclitaxel) to an anthracycline-based regimen appears to improve disease-free and overall survival.[21,22] There is evidence that HER2-receptor status is prognostic for response to anthracycline-based regimens.[3] There is also increasing interest in the early use of trastuzumab in women with HER2-overexpressing tumours. Studies of adjuvant trastuzumab have shown significant improvements in disease-free survival and overall survival,[3,23-26] although there are concerns about cardiotoxicity.[27] The benefits of trastuzumab are independent of ER status.[3]

Reducing dose intensity of chemotherapy results in poorer survival, and this has led to the hypothesis that higher doses may offer more benefit, particularly in patients at high risk of recurrence. However, despite some positive reports of high-dose chemotherapy with stem-cell support, randomised studies have largely failed to show any benefit of high-dose over standard-dose therapy.[28,29]

The results of the analyses above established 5 years of tamoxifen as the standard of care for adjuvant *hormonal therapy* in ER-positive disease (it is now accepted that it should not be given to women with ER-negative tumours,[1,3,9] in whom it is of little value). However, some guidelines now suggest that aromatase inhibitors should be substituted for, or added to, tamoxifen, in postmenopausal women with ER-positive disease,[3,30] an area that is still being intensively studied.[31] There is evidence that 5 years of anastrozole is an effective alternative to tamoxifen,[31,32] and 2 years of treatment with letrozole was found to further reduce the risk of recurrence compared with tamoxifen.[33] Two to 3 years of tamoxifen followed by an aromatase inhibitor (anastrozole, exemestane, or letrozole) has also been investigated and appears promising.[31,34-36] In addition, although extending tamoxifen beyond 5 years is not advocated, there may be significant benefits to following a full course of tamoxifen with extended therapy with an aromatase inhibitor;[31] the optimum length of such therapy has yet to be determined. US guidelines allow for 5 years of letrozole after a full course of tamoxifen.[3] The relative efficacy of the different aromatase inhibitors available (and whether steroidal and nonsteroidal inhibitors vary in their effects and could beneficially be combined) is also under investigation.[31]

Aromatase inhibitors are not effective for hormonal therapy in premenopausal women with ER-positive disease,[3] although combination of ovarian suppression with a gonadorelin analogue (or ovarian ablation by surgery or irradiation) and aromatase inhibitor therapy is being studied.[37]

The optimum sequencing of surgery, radiotherapy, and chemotherapy/hormonal therapy continues to be investigated. Concurrent chemo- and radiotherapy is not feasible with current regimens because of toxicity; on the basis of limited data,[38,39] radiotherapy given after chemotherapy is preferred,[3] as it appears to be more effective. Whether tamoxifen should be given concurrently or sequentially with radiotherapy remains unclear, despite several studies addressing the question.[39] Where both chemotherapy and hormonal therapy are given, it is recommended that chemotherapy should precede hormonal therapy.[3] The use of neoadjuvant chemotherapy before surgery in locally advanced disease (see below) has led to its investigation in early disease. While studies have shown its use allows an increase in breast-conserving surgery, there is no clear evidence of an improvement in disease-free or overall survival.[40]

In **locally advanced** breast cancer (stage III) the few patients for whom initial surgery is feasible may be treated as those with high-risk early breast cancer (see above). However, most patients begin with anthracycline-based neoadjuvant chemotherapy, which usually results in sufficient tumour shrinkage to allow surgical management, as well as allowing assessment of the responsiveness of the tumour to subsequent treatment.[3,8] Radiotherapy and adjuvant chemotherapy are used after surgery, and tamoxifen is also added if the disease is oestrogen-receptor positive.[3]

The aims of therapy in **advanced disease** (stage IV) are palliation and prolongation of life; cure is generally not possible with current regimens,[1,3] and it is often appropriate to select therapy on the basis of its adverse effects, to achieve optimal risk/benefit ratios.[41] In women with ER-positive, limited, or asymptomatic disease, *hormonal therapy* is preferred: US guidelines advocate an aromatase inhibitor (anastrozole, letrozole, or exemestane), or an antioestrogen (usually tamoxifen) for first-line hormonal therapy in postmenopausal patients; second-line therapy options include fulvestrant, toremifene, progestogens such as megestrol, androgens such as fluoxymesterone, or oestrogens such as ethinylestradiol.[3,36] Premenopausal women should undergo ovarian ablation (by surgery or irradiation) or suppression with a gonadorelin analogue, and then be treated as for postmenopausal women. Initial hormonal therapy is continued until disease progression or unacceptable adverse effects occur at which point up to 2 further hormonal regimens may be tried. If these fail, or symptomatic visceral disease develops, the patient is a candidate for chemotherapy.

A number of drugs have some activity in *chemotherapy* of metastatic breast cancer. The taxanes, and in particular docetaxel (which is considered the reference drug in metastatic breast cancer[42]) are acknowledged to be effective,[43] and anthracyclines (doxorubicin, epirubicin, and the related drug mitoxantrone) are also widely used, although a systematic review suggested that their benefits in terms of tumour response did not extend to improved survival.[44] The benefits of platinum-based therapy have not been established.[45] Capecitabine, gemcitabine, and vinorelbine are active agents.[3]

There is considerable uncertainty as to whether combination regimens offer any substantial benefit over sequential use of single drugs.[3,42,46] Although a systematic review of older regimens suggested benefit from combination chemotherapy,[46] and this is the usual standard of care where therapy has curative intent,[42] some do not consider the evidence of benefit from combination therapy persuasive,[3] and toxicity is likely to be increased. Nonetheless, established combination regimens, including CMF and various anthracycline- and taxane-based regimens are in use,[3,8] along with newer combinations, such as gemcitabine plus paclitaxel, vinorelbine plus epirubicin, or paclitaxel plus bevacizumab.[3] Ixabepilone with or without capecitabine, is another option.[3,47] In patients with HER2-overexpressing tumours, trastuzumab may be added to chemotherapy:[3] the combination is markedly more effective in this group than chemotherapy alone,[42] although use with anthracyclines may be problematic because of the increased risk of cardiotoxicity.[3]

Higher response rates have been achieved by intensive regimens, combined with autologous bone marrow transplants or stem cells in some studies. However, the results of randomised trials have been disappointing, and a systematic review found no improvement in overall survival with the use of stem-cell supported high-dose therapy in metastatic breast cancer.[48]

The use of bisphosphonates in women with bone metastases reduces bone pain and skeletal complications such as fracture, spinal cord compression, and hypercalcaemia (see Malignant Neoplasms of the Bone, above). Radiotherapy is also used for bone pain, and for the treatment of brain metastases (see Malignant Neoplasms of the Brain, above).

PROPHYLAXIS OF BREAST CANCER. The recognition of factors increasing the risk of breast cancer, and particularly the identification of specific genes that confer a high risk, has spurred the search for effective ways of preventing the disease. Current options, other than regular screening to detect the cancer at early stages, include surgery (prophylactic mastectomy and/or oophorectomy), drug therapy (below), and possibly some life-style modifications.[1-3]

Treatment with tamoxifen as part of the adjuvant management of early breast cancer is associated with a reduced risk of developing cancer in the other breast (see above). This led to the suggestion that prophylactic tamoxifen might prevent the development of breast cancer in women at risk, and to trials to test this hypothesis. These studies were not without controversy, since the risk/benefit for tamoxifen use in healthy women differed from that in women with breast cancer. The first study to be reported was the US National Surgical Adjuvant Breast and Bowel Project (NSABP) P-1 study,[4] which randomised 13 388 women to 5 years of treatment with tamoxifen or placebo. Participants were either aged 60 years or older, had a history of lobular carcinoma in situ, or had a 5-year predicted risk of developing breast cancer of greater than 1.66% (as assessed by number of first-degree relatives with breast cancer, number of previous breast biopsies, presence of atypical hyperplasia, and reproductive factors). In this study there was a highly significant 49% reduction in the occurrence of invasive breast cancer in women given tamoxifen (21.4 cancers prevented per 1000 women treated). The incidence of non-invasive breast cancer was reduced to a similar extent. Tamoxifen reduced the incidence of oestrogen-receptor positive, but not oestrogen-receptor negative, tumours. Adverse effects of tamoxifen included a modest increase in the risk of endometrial cancer and vascular events (stroke and pulmonary embolism). Although this study was prematurely unblinded, and all women were offered a 5-year course of tamoxifen, follow-up continued for 7 years and the incidence of breast cancer remained relatively constant for the 2 years after tamoxifen therapy was stopped.[5] Preliminary results from 2 smaller randomised European studies did not confirm the benefit of tamoxifen in breast cancer prevention. The Italian study[6] was in hysterectomised women with no particular risk for breast cancer, and because of its size may not have been sufficiently powered to detect an effect of tamoxifen. The full follow-up[7] of 5 years of treatment in this study found no difference in breast cancer incidence between tamoxifen and placebo groups. A subgroup analysis of women at high risk of oestrogen-receptor positive breast cancer did find a protective effect from tamoxifen, and there was an apparent protective effect for women in this group who used HRT. However, this group was not identified at randomisation of the study and these results need to be confirmed. The British study[8] of 8 years of tamoxifen or placebo was in women with a first-degree family history of breast cancer, and their median age was younger than in the US study. Although preliminary results showed no benefit from tamoxifen, follow-up for a median of about 13 years did find a reduction in the risk of oestrogen-receptor positive tumours.[9] This reduced risk also appeared to improve with longer follow-up. Initial results of a further placebo-controlled study (IBIS-I)[10] of women at increased risk of breast cancer found that during 5 years of tamoxifen use, the risk of all breast cancers was reduced by 32%. As in other studies, the reduction occurred in oestrogen-receptor positive tumours. Similar adverse effects were found with tamoxifen use, but there was also an unexpected increase in deaths from all causes in tamoxifen users. This may be associated with the excess in thromboembolic events reported, although statistical variability could not be ruled out. Extended follow-up[11] for a further median of 8 years found that the beneficial effect of tamoxifen was maintained, and that reduction in the risk of oestrogen-receptor positive tumours increased with longer follow-up. However, the rate of adverse effects of tamoxifen reduced after treatment stopped. A retrospective analysis[12] of the NSABP P-1 data for women who had developed invasive breast cancer found that in carriers of the oncogene BRCA2, but not BRCA1 carriers, there was a reduction in breast cancer similar to the reduction in oestrogen-receptor positive cancer among all women in the study. The numbers available, however, were too small to be statistically significant, and it is therefore still not known if tamoxifen can reduce the risk of breast cancer in patients with these mutations.

Another anti-oestrogen, raloxifene, has reportedly shown a reduction in breast cancer risk while its effects on osteoporosis were being studied.[13] A further large placebo-controlled study[14] that included the incidence of breast cancer as a primary outcome also found a reduction with about 5 years of raloxifene use. There was a 55% lower risk of invasive oestrogen-receptor positive cancer (absolute risk reduction of 1.2 cancers per 1000 women treated for 1 year), but there was no effect on oestrogen-receptor negative disease. The effect of raloxifene has also been directly compared with tamoxifen in women with a predicted increased risk of breast cancer.[15] After up to 5 years of use, the incidence of invasive disease was similar in both groups, suggesting that raloxifene is as effective as tamoxifen in reducing the risk of developing invasive breast cancer in this group of women. The aromatase inhibitors, anastrozole and exemestane, are also under investigation.[16]

From these studies, tamoxifen prophylaxis has been shown to reduce the incidence of oestrogen-receptor breast cancer in women at increased risk, but there are limited data for women with BRCA1 and 2 mutations. Although the follow-up studies to date suggest that a course of tamoxifen is not merely delaying the development of breast cancer during treatment, it is not known whether this is a life-long effect; it is also not known whether overall survival will be improved. Long-term follow-up of large placebo-controlled studies is needed to provide answers to these questions. Until then, it is likely there will be continued disagreement on whether tamoxifen should be used for primary prevention, and if so, in whom, and for how long. Nevertheless, the use of tamoxifen for 5 years has been recommended for women who meet specified criteria for increased risk.[2,17] Raloxifene has been proposed by some as an alternative for women who are postmenopausal,[2] but others[17] do not recommend its use for breast cancer prevention. Surgery is often considered for women at high risk associated with genetic factors such as BRCA1 and 2 mutations,[2,3] and women with a history of lobular carcinoma in situ or thoracic radiation.[2]

Other candidates for the prevention of breast cancer include plant oestrogens (phytoestrogens) such as those in soya. Epidemiological evidence suggests that diets high in these compounds may be protective, but there are many confounding factors and inconsistencies in the data available.[18] It was thought that retinoids might also be protective, but a secondary prevention trial of fenretinide failed to show any benefit.[19]

Epidemiological data suggests that life-style modifications have the potential to reduce breast cancer risk. These include weight loss, increase in exercise, and dietary factors.[1,2] They may be proposed as part of an approach to a healthy life-style, but their real value in reducing breast cancer risk is unproven.

MALIGNANT NEOPLASMS OF THE MALE BREAST. Breast cancer can occur in men, although it has a much lower incidence than in women. Risk factors are not well understood, but it may sometimes be associated with abnormalities of sex hormone metabolism, including those acquired through liver disease or testicular trauma. In addition, the inherited mutation BRCA2, which is associated with an increased risk of breast cancer in women, also increases the risk of breast cancer in men. Breast cancer in men occurs at a slightly older median age than in women (60 to 70 years), and is more likely to be oestrogen-receptor positive. Survival by stage appears to be similar to that in women, with an overall 5-year survival about 40 to 65%.

Treatment is similar to that for women.[1-5] Primary management is mastectomy and axillary lymph node dissection. Because of the rarity of the disease large controlled trials are lacking but studies in limited numbers of men and extrapolation from results in women suggest that adjuvant therapy should be considered on the same basis as for women. Radiotherapy may be used to reduce the rate of local recurrence in those considered at high risk. Adjuvant tamoxifen or chemotherapy may also be used, with tamoxifen being the most common. Chemotherapy is probably more appropriate in those with oestrogen-receptor negative tumours, locally advanced disease, or positive nodes. Adjuvant trastuzumab should be considered for men with high-risk HER2-positive disease. In advanced metastatic disease tamoxifen is generally the first choice treatment although there is evidence of benefit from aromatase inhibitors such as anastrozole or letrozole. Combination chemotherapy is reserved for unresponsive or relapsing disease; regimens that have been used include cyclophosphamide, methotrexate, and fluorouracil (CMF), cyclophosphamide, doxorubicin, and fluorouracil (CAF), or doxorubicin and vincristine. Hormonal ablation by adrenalectomy or orchidectomy is also effective, but has become less popular since the advent of tamoxifen. Any role of trastuzumab or bevacizumab in men with metastatic breast cancer has yet to be established.

Malignant neoplasms of the cervix. Cancer of the uterine cervix is one of the most common cancers in women, accounting for about 12% of all female malignancies. It is associated with vaginal intercourse and the presence of human papillomavirus (HPV); high-risk types of the virus (HPV-16 and 18) that produce proteins E6 and E7 inactivate host tumour suppressor proteins and thus encourage malignant transformation. Smoking and long-term use of oral contraceptives (p.2060) may also be risk factors. Widespread screening has meant that in many women the disease has been detected in the preinvasive or early stages, when the prognosis is excellent to good.

Preinvasive cervical lesions (cervical intraepithelial neoplasia; CIN) may resolve spontaneously if low-grade, and may be monitored by repeat screening.[1] High-grade CIN (cervical dysplasia) and cervical carcinoma in situ may progress to invasive carcinoma and are usually excised using diathermy or laser techniques. Conisation of the cervix (cone biopsy) may be used to rule out the presence of invasive disease. Investigational therapies include photodynamic therapy, and topical fluorouracil.

Invasive cervical cancers are mostly squamous cell in origin (80 to 90%), with 10 to 20% being adenocarcinoma. Invasive cervical cancers may be divided into early-stage (I and IIA), locally advanced (stages IIB to IVA), and metastatic (IVB). The earliest stage of invasive cervical cancer may be treated by conisation of the cervix (which maintains fertility) or simple hysterectomy.[1-3] Other early-stage cancers may be treated by surgery (radical hysterectomy) or by radiotherapy.[3] Some patients treated with surgery may require adjuvant radiotherapy. Early-stage patients with poor prognostic factors have better survival if both chemotherapy and radiotherapy are given after surgery (adjuvant chemoradiotherapy).[2,4] Most regimens include cisplatin alone or combined with fluorouracil.[3,5,6] Hydroxycarbamide has also been used by some centres, but is less effective than cisplatin.[5] Patients with locally advanced cervical cancer are usually treated with primary chemoradiotherapy using cisplatin-based regimens.[2,4-7] The evidence for chemotherapy is stronger for stage IIB than for stages III/IVA. Neoadjuvant chemotherapy has been tried and although there is some indication that its use before surgery might be of benefit, no survival advantage has been shown; it does not appear to be beneficial before radiotherapy.[8] For local recurrence of disease, treatment options include radiotherapy if it has not already been used, more extensive surgery, or cisplatin-based chemoradiotherapy.[2,3,9] Treatment for metastatic disease consists of palliative radiotherapy, chemotherapy, or chemoradiotherapy.[2] Cisplatin, carboplatin, paclitaxel, or topotecan may all be considered for first-line therapy; if cisplatin has previously been used as a radiosensitiser a combination regimen of cisplatin with paclitaxel, topotecan, or gemcitabine, or carboplatin with paclitaxel, may be favoured.[3] Drugs that have been tried for second-line treatment include docetaxel, epirubicin, fluorouracil, ifosfamide, irinotecan, mitomycin, and vinorelbine.[3,9] Combination chemotherapy has been investigated and many regimens have shown higher response rates and improvements in progression-free survival but not overall survival; however, cisplatin plus topotecan has shown an improvement in overall survival.[10] Scottish guidelines[7] recommend offering treatment with cisplatin plus topotecan (in cisplatin-naïve patients), or cisplatin plus paclitaxel, to all women with stage IVB or recurrent disease.

An HPV vaccine has been developed to prevent cervical cancer.[11]

Malignant neoplasms of the endometrium. Cancer of the endometrium is a disease primarily of postmenopausal women, and is more common in developed than developing countries. Most of the risk factors for endometrial cancer are associated with increased oestrogen exposure. Factors resulting in increased endogenous exposure include obesity, anovulatory infertility, early menarche, and late menopause. Exogenous factors include use of oestrogens without progestogens for hormone replacement therapy (p.2072), and tamoxifen therapy (see Carcinogenicity, p.773). Postmenopausal vaginal bleeding is the most common sign of endometrial cancer, and allows the disease to be diagnosed at an early stage when the prognosis is good (80% of women have early stage disease at presentation). In menopausal or premenopausal women, diagnosis may be delayed because abnormal bleeding patterns may not be so obvious. Most endometrial cancers are adenocarcinomas. A small percentage are clear-cell or serous carcinomas, which are highly aggressive and have a poorer prognosis. Endometrial hyperplasia is generally regarded as a precancerous lesion; endometrial hyperplasia with cytological atypia, in particular, is associated with progression to adenocarcinoma.

Surgery is the primary therapy for endometrial cancers that are stage I to III;[1-5] oophorectomy is performed, as well as total abdominal hysterectomy, because of the significant incidence of ovarian metastases. No further treatment is required in women with stage I disease who are at low risk of recurrence. In those with stage I disease and a higher risk of recurrence, adjuvant brachytherapy or pelvic irradiation are used. In all other women, adjuvant radiotherapy is given, the field being tailored depending on the disease stage. Adjuvant progestogen therapy has not been shown to be effective.[6] There are a few studies of adjuvant chemotherapy in women at high risk of recurrence, but further data from randomised trials are required to assess its role.[7] For women with advanced disease (stage IV), systemic therapy with progestogens or cytotoxic chemotherapy can be considered, although response rates are only up to 30%,[1,3] and evidence for a survival benefit is questionable.[8] Progestogens are likely to be preferred because of their better tolerability. Tamoxifen also produces minor benefit; alternation with progestogens may prolong the response to hormonal therapy.[5] Well-differentiated tumours, long disease-free interval, and positive hormone receptor status are factors that suggest increased response to progestogens. When progestogens are ineffective, chemotherapy may be tried. The drugs of choice are probably doxorubicin, cisplatin or carboplatin, paclitaxel, and cyclophosphamide.[5,8,9] The combination of carboplatin and paclitaxel has become standard in many centres in the management of advanced or recurrent endometrial cancer.[5,9] Investigational therapies include dactinomycin, gonadorelin analogues such as goserelin, and anastrozole.[3]

Malignant neoplasms of the eye. Tumours of the orbit of the eye in adults are most commonly metastases from primary lesions elsewhere in the body, usually in the breast or lung, and local radiotherapy (external beam radiation or plaque radiotherapy) may be required for control of visual symptoms unresponsive to chemotherapeutic treatment of primary disease.[1]

Primary eye tumours are rare. In children, the most common intra-ocular tumour is retinoblastoma (see below), and the most common orbital tumour is rhabdomyosarcoma (see Soft-tissue Sarcomas, below). In adults, primary CNS lymphoma can originate in the eye (ocular lymphoma), and is treated with radiotherapy to the globe. However, the most common primary ocular cancer in adults is **intra-ocular melanoma** (posterior uveal melanoma), which accounts for 80% of all primary ocular cancers. Treatment options for small ocular melanomas include observation or local treatment (radiation, brachytherapy, cryotherapy, local resection, photocoagulation, or hyperthermia).[2,3] Large melanomas are treated by removal of the eye (enucleation). Treatment of medium-sized tumours is controversial, with some preferring treatments that preserve vision, and some enucleation. At present there are no good data to support the use of adjuvant chemotherapy. In the few patients with metastatic uveal melanoma, resection and intra-arterial chemotherapy or chemoembolisation may be used for isolated hepatic metastases.[2] Most of the combination chemotherapy regimens for palliative therapy have included dacarbazine.[2]

Ocular surface neoplasms (lesions of the conjunctival or corneal epithelium) are usually treated with local excision. Where surgery is not feasible, topical application of mitomycin (0.04%) or fluorouracil (1%) has been tried.[4]

Malignant neoplasms of the gastrointestinal tract. Considered as a whole (and excluding skin cancers, which are often poorly registered) the gastrointestinal tract is the most frequent site of malignancies worldwide, although the frequencies of the various types of gastrointestinal cancer vary greatly from country to country. Direct exposure to various environmental carcinogens is thought to play an important role in many of these cancers. Treatment may include surgery, radiotherapy, and chemotherapy, but the prognosis in most forms of gastrointestinal cancer is not encouraging.

Gastrointestinal cancers vary in their management depending on the site. Discussed in more detail below are:

- oesophageal cancer
- stomach cancer
- colorectal cancerand its prophylaxis
- anal cancer

Other cancers may sometimes manifest in the gastrointestinal tract, including the various endocrine neoplasms responsible for carcinoid syndrome (p.643), and MALT lymphomas (p.657).

MALIGNANT NEOPLASMS OF THE OESOPHAGUS. Oesophageal cancer has perhaps the greatest variation in incidence between different geographical regions of any cancer, and is endemic in many parts of the world. The two major histological types are squamous cell carcinoma and adenocarcinoma.[1-3] Squamous cell carcinoma is strongly associated with tobacco and alcohol use, and may occur as a second primary tumour in patients with tumours of the upper aerodigestive tract (see Malignant Neoplasms of the Head and Neck, below). Adenocarcinoma is more common in non-endemic regions, including many developed countries,[2] and is associated with Barrett's oesophagus (see Gastro-oesophageal Reflux Disease, p.1696). Oesophageal cancer usually develops as a growth or ulcerative lesion of the oesophagus with extensive infiltration of the mucosa and invasion of neighbouring structures. Lymphatic and blood-borne metastasis occurs at a relatively early stage. Symptoms of pain and dysphagia due to obstruction occur late, and overall, more than half of all patients have unresectable or metastatic disease at initial presentation. Metastatic disease is associated with a median survival of less than 1 year.[1]

Patients with stages I to III disease may be offered either surgical resection or a combination of chemotherapy (with cisplatin and fluorouracil) and radiotherapy.[2-4] Surgical patients who are node-positive, or otherwise considered to be at higher risk, may be given postoperative chemotherapy with radiotherapy.[2] The 5-year survival rate varies with the stage of the disease at initial presentation, from about 50 to 80% in the few with stage I disease, to 10 to 15% in those with stage III disease.[1] In consequence, there has been great interest in adjuvant treatment (pre-operative or postoperative).[5]

There is no clear evidence that pre-operative radiotherapy alone improves survival.[1,3,6] However, there has been conflicting evidence on the value of chemoradiotherapy or chemotherapy used before surgery, with some trials showing improved survival, and others no additional benefit.[1,3] A systematic review[7] found that pre-operative chemoradiotherapy significantly improved the 3-year mortality rates compared with surgery alone, and a later meta-analysis[8] found a significant survival benefit for neoadjuvant chemoradiotherapy (versus surgery alone) in patients with oesophageal adenocarcinoma or squamous cell carcinoma. Pre-operative chemoradiotherapy has thus become a common approach for patients with resectable oesophageal cancer.[2,4] Meta-analysis[8] also suggested some survival benefit of neoadjuvant chemotherapy without radiotherapy in those with adenocarcinoma, but not for those with squamous cell carcinoma. A systematic review[9] found that pre-operative chemotherapy may offer a survival advantage compared with surgery alone, although the evidence was considered to be inconclusive. However, some do not recommend the use of chemotherapy, either pre- or post-operatively, as standard of care.[2]

In half to two-thirds of patients the disease is too advanced at presentation for anything but palliation. Those with poor performance status should be offered supportive care.[2] This may include brachytherapy, laser therapy, stent placement, or photodynamic therapy with photosensitisers such as porfimer sodium to relieve obstruction.[2] Brachytherapy may be a better primary therapy for obstruction than a stent.[10] In those patients with good performance status, chemotherapy may also offer some palliation of the disease. Standard options include cisplatin-based, fluoropyrimidine-based, irinotecan-based, oxaliplatin-based or taxane-based combinations.[2,5,11] Chemoradiotherapy may also be used.[5]

MALIGNANT NEOPLASMS OF THE STOMACH. Cancer of the stomach is one of the most common cancers worldwide, with particularly high incidence in the Far East, Russia, and parts of Latin America, although the incidence is declining almost everywhere. (In contrast the incidence of cancers at the gastro-oesophageal junction appears to be increasing.[1]) Over 90% of malignant gastric neoplasms are adenocarcinomas. Less frequent gastric neoplasms include lymphomas (see MALT lymphoma, above) and carcinoid tumours (see above). Dietary factors, such as high consumption of salted or smoked foods, are thought to play a role in the development of gastric cancer. *Helicobacter pylori* infection, and resultant gastritis, plays a role in gastric lymphomas, and may also be a factor in gastric cancer. However, it is not yet clear if elimination of *Helicobacter pylori* infection will prove useful in preventing the development of gastric cancer.[2,3]

Early disease is relatively asymptomatic or produces nonspecific gastrointestinal symptoms such as dyspepsia. There is concern that the use of antisecretory drugs for these symptoms may delay the diagnosis of gastric cancer (see Gastric Carcinoma, under Omeprazole Precautions, p.1754). Gastric epithelial dysplasia is a premalignant condition, and warrants follow-up and possible surgical intervention. Similarly, persistent gastric ulcers may be malignant. More advanced disease, which is the norm at presentation in most western countries, may produce discomfort or pain, anaemia, weight loss, and anorexia; obstruction, haemorrhage, and perforation may develop. Extension to the liver and pancreas, and lymphatic and blood-borne (portal) metastases may occur.

Surgery is the mainstay of treatment for locoregional disease.[4,5] There is some uncertainty, however, about the appropriate extent of surgery and associated lymph-node dissection.[1,5,6] Typical 5-year survival rates in western patients have ranged from about 50 to 80% in those with stage I disease to 13% in those with stage III;[6,7] although much higher survival rates (over 96% in stage I disease and nearly 45% in stage III) have been reported in Japan,[6] Japanese and western patients may not be equivalent, a fact that has made comparisons difficult.

Because of the poorer survival rates in patients with more advanced locoregional disease, adjuvant treatments have been tried.[1,6,7] Postoperative radiotherapy has not been shown to produce a survival benefit, and the value of pre-operative radiotherapy is uncertain. However, there has been considerable interest in the possible value of pre- or postoperative chemotherapy or chemoradiotherapy.[1,6,7] Postoperative (adjuvant) chemotherapy has failed to show a significant survival benefit, except for results with tegafur (plus gimestat and potassium oxonate: S-1) in a Japanese population;[5,8] it has not become standard practice in western countries.[8] Perioperative chemotherapy with preoperative and postoperative cycles of epirubicin, cisplatin, and fluorouracil (ECF) has, however, improved progression-free and overall survival in patients with operable adenocarcinomas.[9] This strategy is recommended for centres with a multi-disciplinary approach.[5,8] A large US study[10] found that median survival was improved from 27 to 36 months in patients given postoperative chemoradiotherapy (using a fluorouracil and folinic acid regimen), and this strategy is recommended for centres where surgery is used as the primary therapy.[5,8] Chemoradiotherapy is also an option for primary treatment of inoperable locoregional disease.[5] Palliative chemotherapy with any of the regimens used for metastatic disease is also an option in these patients.[5]

Treatment for advanced disease is purely palliative, and options include supportive care with or without chemotherapy.[5] Supportive care includes the relief of luminal obstruction with, for example, stent placement, laser surgery, or photodynamic therapy. Chemotherapy may have substantial palliative effect and modest survival gains, and may be considered in those with good performance status. There is no gold standard regimen, although combination therapy is preferred to single-agent therapy for palliation.[5,11] A systematic review[12] found that combination regimens including fluorouracil, anthracyclines, and cisplatin produced significant survival benefits; ECF was considered the regimen of choice since it was best tolerated, and it is considered standard therapy in some countries.[11] Fluorouracil, doxorubicin, and mitomycin (FAM) has been widely used;[5] other combinations include the substitution of methotrexate for mitomycin, or cisplatin for doxorubicin, in the FAM regimen (FAMTX, and MFC, respectively),[5,11] and the use of docetaxel instead of epirubicin in ECF (DCF).[5] However, ECF has shown better response and median survival than FAMTX.[5,11] Investigational drugs include docetaxel, paclitaxel, gemcitabine, irinotecan, raltitrexed, and oral drugs such as capecitabine, etoposide, oxaliplatin, and rubitecan. Bevacizumab is also under investigation.[5,7,11]

MALIGNANT NEOPLASMS OF THE COLON AND RECTUM. Colorectal cancers are very common in developed areas such as the USA and western Europe, but rare among African and Asian populations. Genetic and dietary factors are thought to be related to development of the disease.[1] Inherited predisposition syndromes include familial adenomatous polyposis and hereditary non-polyposis colorectal cancer.[2,3] Most large bowel cancers arise within pre-existing intestinal polyps. Over 50% occur in the rectum and about 20% in the sigmoid colon. There may be direct invasion of neighbouring structures and metastatic spread to the lymph nodes, and to lungs, bone, and in particular, liver. Signs and symptoms include blood in the stools, altered bowel habit, anaemia, and weight loss; there may be local obstruction (depending on location) or perforation.

The first-line treatment for **early-stage** and **locally-advanced** disease (stages I to III; Dukes A to C) is surgery.[4,5] Survival in early-stage disease is good: published 5-year overall survival rates are 80 to 95% in patients with stage I disease, but fall to 25 to 60% (depending on prognostic factors such as nodal involvement and degree of tumour invasiveness) in those with stage III disease.[2] Adjuvant or neoadjuvant therapies have thus been widely investigated and incorporated into treatment.[4,5]

US guidelines for *colon cancer*[4] consider adjuvant therapy unnecessary in stage I disease, but recommend adjuvant chemotherapy in most patients with resectable stage II or stage III disease.

There is good evidence that fluorouracil-based adjuvant therapy improves survival in stage III disease,[6-10] and it has been regarded as the standard of care.[2,9,11,12] Recent results with the FOLFOX regimen (infusional fluorouracil, folinic acid, and oxaliplatin) have suggested that it can improve disease-free (but not overall) survival in this group.[13] Oral fluoropyrimidines have also been shown to improve survival after resection;[14] guidelines suggest that intravenous fluorouracil plus folinic acid, FOLFOX, or oral capecitabine are all suitable adjuvant regimens.[4] Results with the IFL regimen, which adds irinotecan to bolus fluorouracil and folinic acid, have not proved satisfactory because of its toxicity,[2,10,12] and FOLFIRI (infusional fluorouracil with folinic acid and irinotecan) has not been shown to be superior to fluorouracil/folinic acid in the adjuvant setting.[4]

In contrast, the evidence in favour of adjuvant therapy in patients with stage II colon cancer is much weaker:[12,15] US guidelines recommend its consideration, particularly in patients with poor prognostic features and within the context of a clinical study,[4] but its routine use is not advised:[16] such therapy would not improve survival by more than 5%.

Neoadjuvant therapy and radiotherapy seem to play little role in the management of early colon cancer, and the latter is not generally recommended,[2] although it may be considered where there is tumour penetration of fixed structures.[4] In contrast, in the management of early stage *rectal cancer* they play an important role. Local recurrence is common with rectal cancer, and radiotherapy or chemoradiotherapy can help reduce this. US guidelines suggest that surgery alone may be considered in patients with stage I disease.[5] Traditionally, adjuvant chemoradiotherapy was considered the standard of care for patients with stage II or stage III rectal cancer, but more recently neoadjuvant (pre-operative) treatment has been advocated on the basis of better local tumour control and lower morbidity:[2] it decreases tumour volume and thus enhances sphincter preservation.[5] A meta-analysis[17] found that adjuvant radiotherapy reduced the risk of local recurrence; the risk of death from rectal cancer may have been reduced, particularly for pre-operative radiotherapy but there was little impact on overall survival. A subsequent large randomised study also found that pre-operative chemoradiotherapy (fluorouracil infusion plus fractionated pelvic radiotherapy) improved local control and was associated with less toxicity than postoperative treatment, but did not improve overall survival.[18]

US guidelines recommend pre-operative chemoradiotherapy with fluorouracil, alone or with folinic acid, as the chemotherapy component in most patients with stage II or III disease;[5] it is suggested that oral capecitabine may be a valid alternative to fluorouracil. After surgery, adjuvant chemotherapy with a fluorouracil regimen, FOLFOX, or capecitabine is recommended, although the latter 2 options are extrapolations from results in colon cancer; a combined chemoradiotherapy regimen may be used in some patients.

Palliative treatments for **advanced** colorectal cancer (stage IV; metastatic disease) include surgery, radiotherapy, and chemotherapy.[1,2,4,5,10,19,20] Metastasis usually occurs first to the liver: about 20 to 25% of patients have detectable liver metastases at initial diagnosis in the UK, and a further 40 to 50% develop metastases within 3 years of primary surgery. Somewhat under 10% of these cases are localised and resectable,[19] and surgery offers a chance of prolonged survival.[2,19] Systemic neoadjuvant chemotherapy can reduce tumour volume and render some previously unresectable metastases suitable candidates for surgery.[2,4] Another potential approach is the adjuvant use of intraportal chemotherapy directed at the liver. In a meta-analysis of 10 studies,[21] the reduction in hepatic metastases with intraportal vein chemotherapy given for about 1 week after surgery was not significant, although there was a trend towards increased 5-year survival. It was concluded that additional trial evidence was required.[21]

Conventional palliative chemotherapy is based on the use of fluorouracil, and has been shown to produce modest survival benefits.[22] Adding folinic acid improves the efficacy,[23] and the combination has long been regarded as standard. Although it has been suggested that regimens based on continuous infusion of fluorouracil are more effective than those using bolus dosage,[2,24] others consider that although response rates are improved, median survival is similar, and that differences in toxicity and convenience of administration are more significant in making the choice.[20] Oral fluorouracil prodrugs such as capecitabine, or tegafur with uracil, are considered a valid alternative to intravenous fluorouracil.[3,25,26]

Several newer drugs have now been shown to improve response rates and survival when used for chemotherapy in these patients. In particular, regimens including irinotecan or oxaliplatin, such as FOLFIRI or FOLFOX, are now considered options for first-line management of metastatic colorectal cancer.[3-5,11,27,28] There is also evidence for both improved response and survival when bevacizumab (an antagonist of vascular endothelial growth factor) is added to chemotherapy.[29-31] Similarly, cetuximab, a blocker of the epidermal growth factor receptor, appears to improve response rate and decrease the rate of progression if given with irinotecan,[32] and preliminary results suggest that it is effective when combined with a FOLFOX regimen.[28] US guidelines currently recommend combining bevacizumab with one of the first-line regimens—FOLFOX, FOLFIRI, a fluorouracil/folinic acid regimen, or Cape Ox (capecitabine plus oxaliplatin)—in patients with metastatic disease who are able to tolerate intensive therapy,[4,5] although the data to support some of these combinations are not yet available. An alternative regimen (without the bevacizumab), or cetuximab plus irinotecan, or monotherapy with a drug not included in the original regimen (such as irinotecan, cetuximab, or panitumumab), may be tried in those who fail to respond. Capecitabine, or fluorouracil/folinic acid with or without bevacizumab, are options in those unable to tolerate the more intensive regimens.[4,5,11]

Other drugs and regimens continue to be investigated. Immunological therapies under investigation include monoclonal antibodies, and vaccination with autologous tumour cells or against tumour-associated antigens; gene therapy is another area of research.[33]

Prophylaxis of cancer of the colon and rectum. Various drugs and dietary factors have been shown in epidemiological studies to be associated with a reduced risk of colorectal cancer, and some of these have been investigated in prospective randomised trials.[1-3]

- Aspirin and NSAIDs are the most widely studied.[1-10] In short-term randomised trials, both sulindac and celecoxib have reduced the size and number of colonic polyps in patients with familial adenomatous polyposis.[4] However, prophylactic surgical removal of the colon is still considered the standard of care for these patients.[1,11] Furthermore, despite significant reductions in adenoma formation in high-risk patients, cyclo-oxygenase-2 (COX-2) inhibitors have also been associated with cardiovascular toxicity.[12] There is some evidence of a dose-response effect, since the greatest prophylactic effect of aspirin in average-risk populations appears to be associated with doses substantially greater than those required for prevention of cardiovascular disease.[5,6,8,13] The effect of aspirin may depend on COX-2 expression: it appears only to reduce the risk of colorectal cancers that overexpress COX-2.[14]
- Calcium supplementation has shown a moderate reduction in the formation of new adenomas in patients with a history of colorectal adenomas,[15] and is well tolerated, but the evidence is not strong enough to recommend general supplementation to prevent colorectal cancer.
- Despite the epidemiological evidence for dietary fibre, a number of large randomised studies of fibre supplements or high-fibre diets have not found any reduction in the formation of new adenomas in patients with a history of colorectal adenomas.[1,2,16]
- Antoxidant vitamins have also been investigated, but evidence for their benefit is conflicting (see Prophylaxis of Malignant Neoplasms, p.1927).
- Epidemiological evidence[17] suggests that long-term use of statins is associated with a marked reduction in the risk of colorectal cancer. Prospective studies are required to confirm these results. A meta-analysis[18] did not support this hypothesis, although a modest reduction in risk or an effect with higher doses of statins could not be ruled out.
- Other potential chemopreventive agents on the basis of epidemiological evidence include folic acid, selenium, and menopausal HRT.[1-3] For the suggestion that folate may have dual modulatory effects on carcinogenesis, see Carcinogenicity, under Folic Acid, p.1940.

An important component of the care of patients with inherited predisposition or other risk factors for colon cancer is regular screening.[2,11,19] Various screening methods are also under investigation for use in normal risk individuals.[20,21]

MALIGNANT NEOPLASMS OF THE ANUS. Cancers of the anal canal mucosa are most commonly squamous cell carcinomas. Risk factors include immunosuppression, genital human papillomavirus infection, and sexual activity. Combined chemotherapy and radiotherapy is the usual primary treatment.[1,2] Fluorouracil with mitomycin is often used, and the combination of fluorouracil and cisplatin is also used in locally advanced disease. For patients who do not respond, or who subsequently relapse, surgical resection with the formation of a colostomy is preferred, possibly with further fluorouracil and cisplatin therapy. There is no standard therapy for metastatic disease,[1] although platinum-based regimens may be preferable.[2]

Malignant neoplasms of the head and neck. Cancers of the head and neck are classically defined as those of the mucosal surfaces of the upper aerodigestive tract and include neoplasms of the oral cavity (accounting for 40%), pharynx (15%), and larynx (25%). Most are squamous cell carcinomas, and the highest incidence is in men aged over 50 years. Overall, cancers of the head and neck account for about 5% of all malignant neoplasms in the West, but are the most common causes in other parts of the world. The major risk factor for these cancers is the use of tobacco (whether chewed, inhaled, or smoked). Alcohol acts synergistically with tobacco to increase the risk. Human papillomavirus infection appears to be a risk factor for some squamous cancers of the oropharynx. Endemic nasopharyngeal cancer in parts of India, China, and North Africa is associated with Epstein-Barr virus and the consumption of salt-cured fish.

Premalignant lesions include leucoplakia and erythroplakia, and these can progress to invasive cancer. About one-third of cancers are diagnosed at early stages (I and II), and the rest are usually locally advanced (stage III and IVA). Although early-stage disease can be successfully treated, there is a high incidence of second primary cancers in the head and neck, lung, or oesophagus. Therefore, there is interest in the development of chemopreventive drugs to reduce this risk. Fewer than 30% of patients with locally advanced disease are cured. The treatment of head and neck cancer is complex, and is affected by the site and extent of disease, pathological findings, lymph node involvement, the patient's functional status, and comorbidities; the experience and skill of the team carrying out surgery and radiotherapy will also influence treatment recommendations.[1]

In early-stage resectable cancers, such as those of the oral cavity and oropharynx, surgery or radiotherapy (external beam irradiation or brachytherapy) are the mainstays of treatment.[1,2] Postoperative chemoradiotherapy may be used when extracapsular nodal spread or positive margins are found.[1] For anatomically unresectable early-stage disease, such as in the nasopharynx, radiotherapy alone is generally used, but primary chemoradiotherapy should be considered for patients with adverse prognostic factors such as nodal spread.[1]

Locally advanced disease is usually treated with combination therapy. Resectable disease is managed with surgery and adjuvant radiotherapy.[1] The addition of chemotherapy has been studied in resectable disease, but induction chemotherapy (given before surgery and radiotherapy) has not been found to consistently improve survival rates.[3] Postoperative chemoradiotherapy has produced inconsistent results, and there is insufficient evidence that it has any advantage over adjuvant radiotherapy.[3] In unresectable locally advanced disease, and in resectable disease when the aim is to avoid the need for surgery and thereby allow organ preservation, chemotherapy with radiotherapy is generally used, and different regimens have been tried. Concurrent chemoradiotherapy, without surgery, has increased survival compared with radiotherapy alone,[3,4] and concurrent treatment appears to improve overall survival more than radiotherapy with either neoadjuvant or adjuvant chemotherapy.[5] Induction chemotherapy followed by concurrent chemoradiotherapy has also been studied; limited data suggest that it may reduce distant failure rates and improve survival.[3] Some therefore recommend concurrent chemoradiotherapy as the most effective treatment for cancers of the nasopharynx[1,6] and larynx.[1]

Palliative chemotherapy is used in metastatic or recurrent disease.[1,3,6] Salvage surgery or a repeat course of radiotherapy are other options, depending on previous treatment. Drugs used for single-agent treatment include cisplatin, carboplatin, paclitaxel, docetaxel, fluorouracil, methotrexate, ifosfamide, bleomycin, cetuximab, and gemcitabine (for nasopharyngeal cancer). Combination regimens such as cisplatin and fluorouracil are commonly used and produce more responses, but no clear improvement in survival. Other common combinations include cisplatin or carboplatin with a taxane, and cisplatin plus cetuximab. The choice of best supportive care or single-agent or combination chemotherapy should be dictated by the patient's performance status, as the benefits of chemotherapy are limited.[1]

A local injection of cisplatin in a gel formulation containing adrenaline has been investigated in recurrent and refractory head and neck cancer.[7] Photodynamic therapy (see under Porfimer Sodium, p.764) using temoporfin is a more recent development for palliative management. Head and neck cancers have high levels of p53 gene mutations, and gene therapy is under investigation.[8] Chemoprevention by treatment of pre-malignant disease is also under investigation (see Leucoplakia, p.688).

Malignant neoplasms of the kidney. Cancer of the kidney is relatively uncommon. About 80% of such cancers in adults are renal cell carcinoma, with the remainder mostly cancer of the renal pelvis. The disease is about twice as common in men as in women. Risk factors include smoking, obesity, hypertension, and phenacetin use. Disease is often clinically silent; there may however be haematuria, flank and back pain, and a palpable mass in the flank or abdomen. About 45% of patients have early-stage disease at presentation (I and II), 25% have locally advanced disease (stage III), and 30% metastatic disease (stage IV). The most common sites for metastases are the lung, liver, and bone, although unusual sites for metastases are a known feature of renal cancer.

Radical nephrectomy is the main treatment for early-stage disease although partial nephrectomy may be considered in some patients.[1-4] Minimally invasive procedures such as radiofrequency ablation and cryotherapy are under investigation for treatment of small tumours.[4,5] Radical nephrectomy is also used in selected patients with stage III disease. After radical nephrectomy 20 to 30% of patients with localised tumours will relapse, usually at distant sites.[3] This suggests that adjuvant therapy could be useful in reducing the risk of relapse.[1] However, radiotherapy is not beneficial, and no systemic therapy has been shown to reduce relapse (interferon alfa or interleukin-2 are not effective).[1,3,4] Standard care therefore remains close observation.[3]

In metastatic disease, nephrectomy may be considered in a few patients for palliation of symptoms. In addition, nephrectomy and surgical removal of solitary metastases may be appropriate in some patients.[3,6,7] In patients with minimal disease volume and good performance status, cytokine therapy with interleukin-2 or interferon alfa may be considered.[1,3,8] These cytokines have resulted in overall response rates of 10 to 20%, with a few long-term responses.[6,9] Higher response rates have been reported with high-dose interleukin-2 than low-dose therapy,[3,10] although overall survival is not improved.[11] A modest survival benefit has been suggested for interferon alfa.[11] Two studies[12,13] of nephrectomy before interferon alfa therapy compared with interferon alone, in patients with good performance status, found that although overall response rates were similar there was a small survival benefit from nephrectomy. Attempts have been made to improve the response rates to interleukin-2 and interferon alfa by combining them, or adding antineoplastics or retinoids, but responses have generally been poor or toxicity significant.[6,9] There are also attempts to improve the tolerability of interleukin-2 by the use of continuous infusion, lower doses given by the subcutaneous route,[1,2,9,14] and inhalation.[9,14] Renal cell carcinoma is largely resistant to chemotherapy with conventional antineoplastics, and hormonal therapy with progestogens or anti-oestrogens has also had poor success.[1,2,9] The most extensively studied antineoplastics are vinblastine, fluorouracil, and floxuridine. However, reviews of up to 83 studies involving thousands of patients and over 70 different drugs found that only floxuridine and fluorouracil appeared to have even modest activity.[6,15] No antineoplastic can be considered standard in the treatment of metastatic disease,[2,9,16] and supportive care remains a mainstay of therapy.[3]

Because of the treatment resistance of renal cell carcinoma, there is an urgent need to develop innovative approaches. Targeted therapies block angiogenesis and can induce tumour shrinkage and/or tumour necrosis;[8] there is evidence of efficacy with the tyrosine kinase inhibitors sorafenib and sunitinib, and promising results have been seen with temsirolimus and bevacizumab.[3,4,8,17,18] Evolving therapies include vaccination therapy with autologous or allogeneic dendritic cell vaccines, or peptides, and allogeneic haematopoietic stem cell transplantation.[4,10,19,20]

WILMS' TUMOUR. In children most cases of renal tumours are due to Wilms' tumour (nephroblastoma). This is one of the most frequent solid tumours in childhood with a peak incidence between 1 and 5 years of age and accounting for about 6% of all childhood malignancies. The usual presentation is an asymptomatic abdominal mass; abdominal pain is less frequent and haematuria occurs only in about a quarter of patients. Metastasis in advanced disease is usually to the lungs and liver. Most primary tumours occur in one kidney, but some 5% involve both kidneys.

Unlike other forms of renal cancer Wilms' tumour responds well to chemotherapy. The basis of treatment is surgery, combined with chemotherapy, and if necessary radiotherapy. Management varies with disease stage and also varies between different study groups.[1-7] The US National Wilms' Tumour Study (NWTS) group and some other groups recommend initial surgery (nephrectomy) to confirm diagnosis and perform precise staging.[1,2] Postoperative chemotherapy regimens and radiotherapy are based on stage and histology.[5,7] Others, including the European Société Internationale d'Oncologie Pédiatrique (SIOP), use neoadjuvant chemotherapy to reduce the tumour size and make surgery easier.[4,5,7] Although there continues to be controversy about the relative merits of the two approaches,[7] overall survival for patients treated by either approach is very similar, being more than 90% for patients with favourable histology. The aim of the various study protocols has been to identify low-risk children who require less intensive therapy, and those with poor prognosis who require more intensive therapy or alternative investigative regimens.

Current SIOP neoadjuvant chemotherapy consists of 4 weeks of dactinomycin and vincristine for clinically localised disease, and 6 weeks of dactinomycin, vincristine, and epirubicin for metastatic disease.[3,4] Adjuvant chemotherapy regimens for disease with favourable histology are broadly similar between NWTS and SIOP.[2-4] In early disease, chemotherapy consists of vincristine combined with dactinomycin; in more advanced disease radiotherapy, and an anthracycline (doxorubicin or epirubicin) are added. Patients with unfavourable histology and stage I disease are treated the same as those with favourable histology early-stage disease.[3] Combination adjuvant chemotherapy regimens for patients with unfavourable histology and a poorer prognosis add drugs such as etoposide, carboplatin, and an alkylating agent (cyclophosphamide or ifosfamide), which may be combined with an anthracycline or vincristine; radiotherapy may also be used.[2-4] The duration of adjuvant chemotherapy is dependent on the disease stage. In children with recurrent disease, survival is usually poor: salvage rates of about 20 to 30% have been reported for those with favourable histology. A regimen of cyclophosphamide, carboplatin, and etoposide is being investigated.[3] Treatment with high-dose chemotherapy and autologous haematopoietic stem-cell rescue has shown promising results.[5] Bilateral Wilms' tumour is not usually treated with primary bilateral nephrectomy because of the need to retain renal function. It may be biopsied to assess histology and stage and then treated with neoadjuvant chemotherapy.[2,3,5] Surgery is then performed, preserving as much of the kidneys as is possible. Survival has been reported to be comparable with that in other patients.[2] Because of these results, some have suggested the use of partial nephrectomy in patients with small unilateral tumours.[2] However, most tumours are too large or too centrally located for partial nephrectomy to be routinely indicated.[5]

Malignant neoplasms of the liver. Hepatocellular carcinoma (hepatoma) accounts for more than 90% of primary liver cancers. It is relatively uncommon in northern Europe and America but is the most common cancer among men in large parts of Africa and Asia. The incidence in men ranges from 2 to 8 times that in women. Chronic infection with hepatitis B or hepatitis C virus is by far the most important factor associated with development of liver cancer, although other risk factors include ingestion of foodstuffs contaminated with aflatoxins (see p.2249), alcoholic liver disease, haemochromatosis, and the long-term use of anabolic steroids (see Effects on the Liver, under Testosterone, p.2130) and, rarely, combined oral contraceptives, (see p.2060). Over 70% of patients with hepatocellular carcinoma have cirrhosis of the liver.

Clinical manifestations of liver cancer include increasing obstructive jaundice, pain, malaise, and the presence of an epigastric mass; there may be metastasis to the lungs, kidney, bones, brain or other sites, or invasion of local structures.

Although diagnosis of *early disease* may be improved by screening at-risk groups, few patients have their tumours identified at a stage allowing prolongation of survival with surgical resection or liver transplantation.[1-3] **Liver transplantation** (p.1815) may be considered in those patients with very small tumours (stage I) and who have advanced cirrhosis and are therefore not suitable for surgical resection.[1,4] Patients with larger tumours or more advanced stages of disease are not candidates for transplantation because of the high rates of recurrence in the transplanted liver.[2,3] **Surgical resection** is considered in patients with no cirrhosis or mild liver impairment whose tumours are considered resectable (stages I to III). However, recurrence rates are high, and 5-year survival is only about 30%.[1,3,5]

As a result, **adjuvant** or **neoadjuvant chemotherapy** has been investigated in early-stage disease. Hepatocellular carcinoma is relatively resistant to chemotherapy, and a review of 8 studies concluded that none of the regimens of adjuvant or neoadjuvant therapy examined produced improvement in survival or disease-free survival.[6] However, a later review[7] of 21 studies found that chemotherapy injected into the hepatic artery after curative resection, usually with embolisation (see below), did improve survival and decrease recurrence. Neoadjuvant therapy may be considered to reduce tumour burden before transplantation[5] or to permit resection.[8] In patients who have small tumours and are not candidates for surgery or transplantation, percutaneous intratumoral alcohol injection is an option.[1,3-5,8,9] Other ablative therapies include radiofrequency ablation and cryosurgery.[5,9,10]

Most patients present with *advanced stage* cancer and significant liver impairment. Options in unresectable disease include palliative medical treatments or supportive care.[1-3,5] **Systemic chemotherapy** has been tried, but has no standard role. Treatment with doxorubicin alone has been associated with a response rate of 3 to 30% and no increase in survival,[1,3,11] and this has not been bettered by combination chemotherapy. More recently, a significant survival benefit in selected patients has been seen with sorafenib.[10] Doxorubicin has also been given by intra-arterial infusion into the hepatic artery, as have fluorouracil, floxuridine, and other drugs such as cisplatin and mitomycin.[1,3] Transcatheter arterial **chemoembolisation** combines intra-arterial chemotherapy with temporary occlusion of the artery (embolisation) using substances such as gelatine foam or iodised oil; this prolongs the duration of contact between drug and tumour, and attempts to induce tumour necrosis by ischaemia.[1,3,5] Although use of these techniques has given higher response rates than systemic therapy, there has been no evidence of an improvement in survival.[1-3,11] However, repeated chemoembolisation was shown to improve survival compared with conservative treatment without chemotherapy in a study of selected patients with small unresectable tumours.[12] Systematic review[13] confirmed a survival benefit with chemoembolisation, using doxorubicin or cisplatin, and suggested this method as standard therapy for selected patients with small unresectable tumours, and well-preserved liver function. **Other options** that have been tried include interferon alfa and tamoxifen.[1,3-5,11] Despite some initial positive data for tamoxifen, large randomised clinical trials failed to show any survival benefit for therapy at conventional doses,[14,15] and meta-analyses[13,16] confirmed this. Adoptive immunotherapy, using activated T-cells cultured with interleukin-2 and a monoclonal anti-CD3 antibody, has been reported to lower recurrence after resection.[17] Trials of octreotide have produced conflicting results.[4]

In contrast to the poor response of hepatocellular carcinoma to therapy, better progress has been made in strategies for its **prevention**. Neonatal vaccination against hepatitis B has dramatically decreased the incidence of chronic infection in children in Taiwan, and reduced the incidence of hepatocellular carcinoma. This may be a more promising approach in areas where the disease is common.[2] There is evidence that interferon alfa can delay or prevent the development of hepatocellular carcinoma in cirrhotic patients with hepatitis C infection.[18] Chemoprevention may also be a useful approach after surgical resection: use of a synthetic retinoid, peretinoin, was found to reduce the development of second primary tumours after resection.[19,20]

The liver is the most common site of *metastatic disease*.[21] For most malignancies the presence of liver metastases is indicative of generalised dissemination, but isolated metastatic liver disease is common in colorectal cancer (p.665) and rarer cancers such as some neuroendocrine tumours (see Carcinoid Tumours, above). In contrast to disseminated disease, treatment of such isolated liver metastases can prolong survival. Surgical resection is the preferred treatment if feasible. Palliative or cytoreductive surgery is beneficial in hepatic metastases from neuroendocrine tumours because of their slow growth.[21] Combined resection and adjuvant chemotherapy (hepatic arterial or systemic) is under investigation for colorectal liver metastases. Unresectable colorectal liver metastases have been treated with systemic or hepatic intra-arterial chemotherapy, with modest survival benefits.[22] Neoadjuvant chemotherapy, given either systemically or intra-arterially, has also shown some promise in rendering metastatic colorectal cancer resectable.[23]

Malignant neoplasms of the lung. Lung cancer is the most common non-skin cancer in the developed countries and the second most common overall worldwide. About 20 to 25% of all lung cancers are small cell lung cancers (SCLC) derived from endocrine cells in the bronchial mucosa; the remainder, comprising chiefly squamous cell carcinomas (40 to 45% of cases), adenocarcinoma (25 to 30%), and large-cell carcinoma (about 10%), are known collectively as non-small cell lung cancer (NSCLC). More than 80% of all lung cancers are associated with tobacco smoking, and there is also evidence that exposure to the cigarette smoke of others can increase the risk in non-smokers. Other risk factors may include occupational exposure to substances such as asbestos, and the effects of environmental toxins such as air pollutants.

Symptoms due to a lesion in a main bronchus (the most common site) include persistent cough, dyspnoea, haemoptysis, weight loss and sometimes chest pain. Metastatic spread is common, and may affect sites such as brain, liver, and bone. It occurs early with adenocarcinoma and SCLC, but late with squamous cell carcinoma.

Disease staging plays an important role in determining treatment. The management of SCLC differs significantly from that of non-small cell types.

The mainstay of treatment for **small cell lung cancer** is chemotherapy.[1-5] In limited disease (disease limited to one hemithorax with hilar and mediastinal lymph node involvement that can be encompassed within one tolerable radiotherapy field) the combination of chemotherapy and chest radiotherapy has been shown to improve survival[6,7] and is recommended therapy.[2-5] The most common chemotherapy regimen is 4 to 6 cycles of etoposide and cisplatin (EP or PE),[1,3-5,7,8] which offers a survival advantage over the previously used regimen of cyclophosphamide, doxorubicin, and vincristine (CAV). The optimum scheduling of chemotherapy and radiotherapy has been investigated and concurrent therapy found to be superior to sequential radiotherapy.[3,5] In comparing early and late concurrent therapy, a meta-analysis[9] of 7 studies found that a small improvement in overall survival at 2 years was associated with early radiotherapy (begun within 9 weeks of starting chemotherapy, or before the third cycle of chemotherapy) compared with late radiotherapy. There was also evidence that the use of hyperfractionated radiotherapy (given twice daily) and platinum-based regimens contributed to this benefit. In general, for limited disease it is recommended[2,3,5,7] that concurrent chest radiotherapy should be started with the first or second chemotherapy cycle. Response rates of 70 to 90% are reported, but median survival rates are only 14 to 20 months and the 2-year survival rate is about 40%.[5]

Only a few patients present with resectable early stage disease. Careful pre-operative staging is essential to rule out nodal involvement, and all patients should receive adjuvant chemotherapy. If nodal metastases are found, the addition of postoperative chest radiotherapy should be considered. Patients with later disease stages do not benefit from surgery.[3,5]

In extensive SCLC (spread beyond one hemithorax and may include malignant pleural or pericardial effusion or haematogenous spread) chemotherapy alone is used to palliate symptoms and prolong survival. The combination of etoposide and cisplatin (or carboplatin) is also used in these patients[3,5,7] but response is poorer than that for limited disease, with response rates of 60 to 70% and a 2-year survival rate of less than 5%.[5] The use of consolidation or maintenance chemotherapy has been studied in both limited and extensive disease. Most studies have found no improvement in progression-free or overall survival, and the general recommendation is that such extra therapy, with its associated toxicity, should not be used.[1-5,8] This view has been challenged by a meta-analysis[10] of 14 studies suggesting that there is evidence for benefit from maintenance therapy, although it is unclear which patients might benefit and which regimen would be most effective. Other strategies that have been tried, but with little consistent evidence of improved results, include the combination of irinotecan and cisplatin, the addition of further drugs to EP (such as ifosfamide, paclitaxel, or cyclophosphamide plus an anthracycline), and the use of dose-intense or dose-dense regimens.[1,5,8]

Patients who have responded to initial treatment still have a more than 50% risk of developing brain metastases. Prophylactic cranial irradiation reduces this risk and improves survival in patients in complete remission.[11] It is generally recommended for all patients with limited disease who achieve remission, and for those with extensive disease who achieve remission and have good prognostic factors and performance status.[2-5,7,8]

The value of chemotherapy in relapsed SCLC depends in part on the duration of remission before relapse, with greater responses the longer the remission.[3,5,7,8] UK guidelines recommend second-line chemotherapy only in patients whose disease responded to first-line treatment.[2] Patients may be given the same initial therapy if they have relapsed after more than 6 months. Patients who relapse within 3 months of achieving remission are considered to have refractory disease; second-line drugs include ifosfamide, paclitaxel, docetaxel, and gemcitabine, although response is likely to be poor. Response rates are better if relapse occurs between 3 and 6 months after remission, and topotecan has been suggested as the best option. Other drugs that may be considered include irinotecan, gemcitabine, a taxane, ifosfamide, oral etoposide, vinorelbine, or the CAV regimen.[5,7,8] Drugs under investigation for SCLC include amrubicin, pemetrexed, and picoplatin.[7,8] Second-line chemotherapy should be given until the patient receives maximal benefit, becomes refractory, or develops unacceptable toxicity. Radiotherapy may also be given for localised symptomatic palliation.[5]

In patients with **non-small cell lung cancer** presenting with tumour localised to the lung (generally stage I and II), the treatment of choice is surgery.[2,12-15] In patients with resectable disease who have medical contra-indications to surgery, radical radiotherapy is used with curative intent. In patients who are surgically staged, about 26 to 47% of patients with localised disease are still alive after 5 years.[14] To improve on these results, there has been great interest in the role of adjuvant therapies. In early-stage disease, use of radiotherapy after complete resection has been shown to result in worse survival than surgery alone,[16] and is not recommended.[13] Conversely, some recommend[2,14] that postoperative radiotherapy be considered if there is residual disease after surgery, although there is a lack of good evidence for a reduction in local recurrence in this setting. Chemotherapy has also been investigated as an adjuvant therapy and is recommended after complete resection.[2,12-15] There is some evidence that cisplatin-based postoperative therapy improves survival, but that alkylating agent-based therapy decreases survival.[17] Results of a large international trial suggest that 5-year survival and disease-free survival were significantly increased in patients given adjuvant chemotherapy compared with those given surgery alone. Chemotherapy consisted of 3 to 4 cycles of cisplatin combined with etoposide or a vinca alkaloid (vinblastine, vindesine, or vinorelbine).[18] A further study[19] of cisplatin with vinorelbine conducted in north America also supported these findings. Reviews[20-22] of these and other studies have concluded that adjuvant cisplatin-based chemotherapy does offer a survival benefit after complete resection of NSCLC. There is also some evidence of improved survival from studies in Japan[23,24] using continuous postoperative oral tegafur with uracil. In resectable disease, the use of pre-operative (neo-adjuvant) therapy is being investigated in an attempt to treat micrometastases and improve resection by tumour shrinkage;[12,25,26] effects on overall survival are conflicting.[22,25,26]

The choice of treatment will be affected by the site of the tumour and nodal spread, with some guidelines[13] suggesting pre-operative chemotherapy while others[14] recommend pre-operative concurrent chemoradiotherapy in selected patients. UK guidelines[2] only recommend such treatment as part of a clinical study.

In patients with unresectable locally advanced disease (stage IIIB and unresectable IIIA), the use of platinum-based chemotherapy either before or with radiotherapy has resulted in a modest increase in survival according to the findings of a number of meta-analyses[17,27-29] and has become recommended therapy.[13,30] Regimens usually include cisplatin plus either etoposide, a vinca alkaloid, or a taxane. The issue of dosage and sequencing has been investigated;[30,31] concurrent chemotherapy with radiotherapy (chemoradiotherapy) is considered by some to be superior to sequential therapy,[12,14,31,32] but others[2] recommend sequential chemoradiotherapy or caution[29] that the magnitude of increased benefit with concurrent therapy is not yet clear. Chemoradiotherapy followed by surgery (trimodality therapy) is also under investigation.[30] Encouraging results[32] suggest that this approach of chemotherapy, radiation, and surgery may improve progression-free survival when compared with chemotherapy and radiation alone.

Chemotherapy may also be used for advanced metastatic disease (stage IV), which is detected in 40 to 50% of patients at presentation, although response is poor with a 5-year survival rate of only about 1%. Meta-analyses have shown a modest improvement in survival and symptom control in patients given chemotherapy compared with those given best supportive care.[17,33] Furthermore, combination chemotherapy has improved responses compared with single drug therapy,[34] particularly platinum-based combinations.[35] When compared with combinations of newer drugs (including vinorelbine, gemcitabine, taxanes, and irinotecan), platinum-based regimens still have a higher response, but they cause more toxicity and 1-year survival is not significantly different.[35] In general, cisplatin-based chemotherapy has become the standard of care for advanced disease,[2,12-15,30] although no particular regimen has been identified as superior.[36,37] Regimens include cisplatin or carboplatin combined with either gemcitabine, irinotecan, etoposide, vinblastine, vinorelbine, docetaxel, or paclitaxel.[14,15] Older triple regimens such as mitomycin, vinblastine, and cisplatin (MVP) or mitomycin, ifosfamide, and cisplatin (MIC) are no better and are no longer advocated.[12,37] A combination of carboplatin and paclitaxel with the monoclonal antibody bevacizumab may be an option for patients with non-squamous cell histology and good performance status.[14] For patients who fail initial therapy for advanced disease, docetaxel[13,14,30] as a single agent is generally recommended for second-line treatment. Alternative drugs that may be considered include erlotinib, gemcitabine, or pemetrexed.[12-15,38,39] Topotecan is also under investigation.[40] Despite initial promise, disappointing results using gefitinib either alone[15,41] or with platinum-based chemotherapy[42,43] have been reported. The success of gefitinib may depend on identifying patients with specific mutations of the epidermal growth factor receptor (EGFR) gene.[44]

Bronchoscopic photodynamic therapy, with porfimer sodium, may be considered for the palliative treatment of bronchial obstruction.[14,45] Photodynamic therapy may also be used as an alternative to surgery in patients with very early-stage (in situ) endobronchial NSCLC.[45] Other palliative options for obstructed airways include endobronchial brachytherapy or stent placement, or laser treatment. External beam radiotherapy may be useful for symptom control and surgery may be suitable in some cases of resectable local recurrence.[14]

Despite the recent advances in chemotherapy for NSCLC, the median survival for this disease remains poor, and there is a need to identify alternative approaches to treatment. Those in preclinical development include gene therapy[46] with the tumour suppressor gene p53, and cancer vaccine immunotherapy.[47]

Given the poor prognosis of lung cancers, and the high incidence of second primaries in patients curatively treated for early-stage disease, there has been great interest in **prophylaxis.** The most important factor in primary and secondary prevention is cessation of tobacco smoking, for which a number of interventions may be tried (see Smoking Cessation, p.2354). Diets rich in fruit and vegetables have been associated with a lower incidence of malignant disease, and have prompted the investigation of antioxidant vitamins. However, primary prevention studies in those at risk of lung cancer have failed to show any benefit for vitamin supplements, and in the case of betacarotene, an increase in lung cancer was seen in those most at risk (see Prophylaxis of Malignant Neoplasms, p.1927). Other drugs under investigation are retinoids and NSAIDs.[48]

While a meta-analysis[49] concluded that screening of patients with chest radiography or sputum cytology was ineffective, the Early Lung Cancer Action Project found that computed tomography improves the likelihood of detection of nodules suggestive of lung cancer in high-risk patients.[50] Since most of those cancers detected were at an early stage, resection was possible, and it is theorised that this technique may reduce mortality,[51] although it remains investigational.

Metastatic lung disease. The lung is the second most frequent site for metastatic disease, occurring in about 30% of cancer patients. Surgical resection may be used to treat pulmonary metastases when there are no effective systemic therapies, no extrapulmonary metastases, the pulmonary metastasis is completely resectable, and the patient is able to undergo surgery.[52] Specific cancers for which surgical resection of pulmonary metastases is considered include soft-tissue sarcoma, osteosarcoma, and sometimes breast cancer.

MALIGNANT MESOTHELIOMA. Malignant mesothelioma is a relatively rare tumour of the lining of the lung, yet its incidence is increasing. Occupational exposure to asbestos is the causative factor in most cases, with a mean latent interval of about 40 years between first exposure and death. Typical clinical manifestations include chest pain or dyspnoea or both. Neurological entrapment and pericardial involvement may occur. The disease is progressive, and median survival is poor. Histologically, disease may be epithelioid, sarcomatoid, or a mixture of the two. The epithelioid type is the most common, and may be confused with adenocarcinoma (see non-small cell lung cancer, above). In patients with small epithelioid tumours, radical surgery may be considered, but otherwise is seldom appropriate. Pleurodesis is usually the treatment of choice in the management of pleural effusions associated with mesothelioma; pleurectomy is an alternative. Palliative radiotherapy may be effective for pain relief,[1] but is generally of limited value.[2,3]

Responses to single-agent chemotherapy have been in the region of 10 to 20%. Doxorubicin, epirubicin, mitomycin, cyclophosphamide, ifosfamide, cisplatin, and carboplatin have all been tried.[1,4] Irinotecan, topotecan, gemcitabine, vinorelbine, docetaxel, and paclitaxel have also been investigated.[1,4] Combination chemotherapy, mostly with doxorubicin- or cisplatin-based regimens, have not shown any survival advantage over single-agent therapy.[4] However, encouraging results were obtained in a large phase 3 study using pemetrexed and cisplatin, and this combination is generally considered to be standard first-line therapy.[1,2,4-6] The addition of raltitrexed to cisplatin has also improved response rates and overall survival,[7] and some benefits have been seen with gemcitabine plus cisplatin,[2,3] which has been suggested as second-line therapy.[2,6] Other regimens, including vinorelbine compared with mitomycin, vinblastine, and cisplatin (MVP),[5] and raltitrexed with oxaliplatin[4] are being investigated. Gene therapy, immunomodulation, and angiogenesis inhibitors are also being tried.[1-3]

Malignant neoplasms of the ovary. Ovarian cancers account for about 5% of all malignancies in women. The most common form (90% of cases) is **epithelial ovarian cancer**, which ranks as fourth in the leading causes of cancer deaths in women. The lethality of this disease is related to the absence of symptoms in most women during its early stages: in about three-quarters of all patients disease is advanced at diagnosis and has spread to the peritoneum or beyond. It is predominantly a disease of older women, the median age at diagnosis being 61 years. The risk of epithelial ovarian cancer appears to be related to the number of ovulatory cycles a women has in her lifetime, thus nulliparity increases the risk, whereas multiparity, breast feeding, and combined oral contraceptives (p.2061) decrease the risk. Other risk factors are a family history (particularly when associated with the BRCA1 and BRCA2 genes), and possibly fertility drugs (see Clomifene, p.2086), perineal talc use (p.1615), and menopausal HRT (p.2073).

The main treatment for epithelial ovarian cancer in most patients is surgical removal of womb, ovaries and fallopian tubes, and omentum, with debulking of any remaining gross disease.[1-3] The use of adjuvant chemotherapy depends on disease stage.

The minority of patients who have localised disease at diagnosis have a good prognosis. Patients with well differentiated early disease (stage IA) have a 5-year disease-free survival of at least 90%; adjuvant therapy has not been shown to improve survival in this group,[4] and conservative fertility-sparing surgery is possible in women of childbearing age.[1,3] In those subgroups with poorly differentiated or more extensive localised disease (stage IC and II) postoperative platinum-based chemotherapy has been reported to improve both recurrence-free and overall survival at 5 years,[5] and is usually considered appropriate.[1-3,6] Adjuvant intraperitoneal phosphorus-32 and oral melphalan have also been used.

Prognosis is less good in patients with advanced disease (stage III and IV), who presently form the majority at diagnosis. Patients with extra-pelvic disease or positive nodes who have only minimal residual disease after surgery have a 5-year survival rate of less than 30% but in patients with distant metastases or suboptimal debulking there is a less than 10% chance of long-term survival. Many adjuvant regimens have been tried in advanced ovarian cancer, often based on platinum derivatives, alkylating agents, and sometimes also anthracyclines. Cisplatin or carboplatin with cyclophosphamide (CP) and sometimes doxorubicin (CAP) have been widely used. In 1991, a meta-analysis[7] failed to reach any definite conclusions about the relative benefits of differing chemotherapeutic regimens, but did suggest that immediate treatment was better than delaying until relapse, that platinum-based regimens were probably better than those without a platinum derivative, that combination regimens were better than single-agent platinum where the doses were equivalent, and that carboplatin was as effective as cisplatin. A later updated analysis[8] by the same group reached similar conclusions. Two similar analyses in 1991 and 1992 suggested that regimens of cisplatin, doxorubicin, and cyclophosphamide offered a survival advantage over cisplatin with cyclophosphamide alone.[9,10] Subsequent to these analyses, a large randomised study (ICON2) was instigated to compare carboplatin alone with cyclophosphamide, doxorubicin and cisplatin. This study[11] found no difference in progression-free or overall survival (median 33 months) between the 2 treatment arms, and single-agent carboplatin was less toxic. In the early 1990s, the finding of significant activity for paclitaxel in ovarian cancer led to various studies incorporating this drug. Two studies[12,13] comparing cisplatin plus cyclophosphamide with cisplatin plus paclitaxel found improved overall survival for the paclitaxel-containing arm (median 38 and 36 months versus 24 and 26 months). Substitution of carboplatin for cisplatin resulted in similar overall survival,[14] and subsequently a number of reviews and guidelines have recommended paclitaxel plus cisplatin or carboplatin as the first-line adjuvant treatment of ovarian cancer.[1-3] Conversely, another study[15] found cisplatin alone (100 mg/m^2) to be no different to cisplatin (75 mg/m^2) plus paclitaxel (135 mg/m^2) in terms of overall survival (median 30 versus 26 months) and progression-free survival, although cisplatin alone was poorly tolerated. This study also contained a single-agent paclitaxel arm (200 mg/m^2), which had poorer progression-free survival, but similar overall survival (26 months) to the other arms. Results of a further study (ICON3)[16] also failed to demonstrate an improvement in progression-free or overall survival for carboplatin plus paclitaxel (median 17 and 36 months) compared with carboplatin alone or cisplatin-based CAP (median 16 and 35 months); single-agent carboplatin had a more favourable toxicity profile. Subsequent guidelines[6,17] have recommended that platinum-based therapy alone or with paclitaxel are both reasonable options for first-line adjuvant therapy.

Other therapies used in the adjuvant setting include interval surgical debulking in those with suboptimal debulking at primary surgery,[3,18] and intraperitoneal chemotherapy in those with minimal residual disease after primary surgery.[3,19-21] The use of neoadjuvant chemotherapy is controversial,[3] although it has been suggested to reduce morbidity and permit subsequent surgical debulking, and studies of this strategy followed by interval surgery are underway.[18,19]

In patients with recurrent disease, the choice of therapy depends on the time since initial therapy and the drugs used.[1,3,22] Relapse occurring more than 6 months after initial therapy is potentially platinum-sensitive and may be re-treated with the initial therapy. In patients who are potentially not sensitive to platinum derivatives, paclitaxel may be used if it was not used previously. Combining paclitaxel with platinum chemotherapy may further improve survival in patients who are platinum-sensitive.[23] Other drugs with activity include topotecan, liposomal doxorubicin, altretamine, capecitabine, cyclophosphamide, docetaxel, epirubicin, oral etoposide, gemcitabine, ifosfamide, irinotecan, tamoxifen, and vinorelbine.[3,18,19,22,24] Bevacizumab is also active.[3,19] The monoclonal antibodies oregovomab and pemtumomab are under investigation, as are ovarian cancer vaccines.[25] Some success has been reported using high-dose chemotherapy followed by autologous stem cell transplantation,[26] although an improvement in survival has not been shown.[3,18]

Prophylaxis. The identification of genes conferring an inherited predisposition to ovarian cancer, and the difficulty in identifying the disease and its poor prognosis has led to increased interest in prevention. Oral contraceptives are known to be protective in the general population, and there is growing evidence that women with mutation of the BRCA1 or BRCA2 gene might benefit similarly (see Ovary, under Carcinogenicity in Hormonal Contraceptives, p.2061). Prophylactic oophorectomy may be considered in women with BRCA1 mutations after child-bearing or at age 35 years.[27,28] The risk/benefit ratio of this procedure is not known, and a few women who undergo this procedure subsequently develop a primary peritoneal cancer.

Ovarian germ-cell cancers account for less than 3% of ovarian cancers and typically occur in women aged 20 to 30 years. Unlike epithelial ovarian cancer, most patients present with early disease, and even in advanced disease, combination chemotherapy can be curative.[3,29] Conservative fertility-sparing surgery is the main therapy. Adjuvant chemotherapy is used except in those with stage I disease able to undergo frequent follow-up. Common regimens are similar to those used in male germ-cell tumours, such as bleomycin, etoposide, and cisplatin (BEP) or vinblastine, bleomycin, and cisplatin (VBP).[3,29,30]

Ovarian stromal tumours account for about 7% of ovarian cancers[31] and are mainly treated with fertility-sparing surgery.[3] For those with high-risk stage I tumours, recommendations include observation, radiotherapy, or cisplatin-based chemotherapy. For those with tumour stages II to IV, options include radiotherapy for limited disease, or platinum-based regimens such as BEP, paclitaxel plus carboplatin, or docetaxel plus carboplatin.[3]

Malignant neoplasms of the pancreas. Pancreatic adenocarcinoma (cancer of the exocrine pancreas) accounts for about 95% of pancreatic tumours. A very small percentage of pancreatic tumours arise in the endocrine pancreas, and have different clinical features and treatment (see under Carcinoid Tumours and Other Secretory Neoplasms, above). Although rare below the age of 30 the incidence of pancreatic adenocarcinoma rises steadily with age; overall, it accounts for about 3% of all cancers, but is the fifth leading cause of cancer deaths. Pancreatic adenocarcinoma is ductal in origin and metastasises early to the lymph nodes, and by the time of diagnosis more than half of all patients have liver metastases, more than a quarter have peritoneal seeding, and a third have invasion of the duodenum causing ulceration. The most frequent symptom at presentation in patients with cancer of the pancreatic head is jaundice, often with other symptoms indicative of obstruction of the bile duct. In lesions of the body and tail of the pancreas severe and relentless pain may develop. Diabetes mellitus is a manifestation of the disease, but there is also some evidence that it may be a predisposing factor. About 30% of pancreatic cancers are probably due to tobacco smoking.

Pancreatic adenocarcinoma has a very poor prognosis because of its usually advanced stage at diagnosis and lack of effective therapies.[1] Apart from a small number of patients with resectable carcinoma of the head of the pancreas, in whom radical surgery results in a 5-year survival of about 10 to 20% most patients with pancreatic adenocarcinoma will be dead within 1 year. Adjuvant therapy with irradiation and fluorouracil has been used in those with resectable disease,[1] based on early evidence that it optimised the chance for long-term survival. However, the results of a large randomised study[2,3] suggested that there was no benefit from adjuvant fluorouracil-based chemoradiotherapy but that there might be a survival benefit from prolonged chemotherapy alone. A subsequent review[4] that included this later study concluded that there was benefit with the use of adjuvant fluorouracil, but that chemoradiotherapy should not yet be dismissed from further study because trials to date had used radiotherapy regimens that were now considered to be suboptimal, a view also adopted by US guidelines.[5] Adjuvant gemcitabine is also effective,[6] and some consider it the preferred drug if single-agent therapy is used.[5,7] It is also recommended for use with fluorouracil-based chemoradiation. Capecitabine is an alternative to gemcitabine or fluorouracil for monotherapy.[5] Pre-operative (neoadjuvant) chemoradiotherapy is also under investigation, but a survival benefit has not been proven, and toxicity can be severe.[1,8,9]

In patients with symptomatic localised unresectable disease, chemoradiotherapy may be used.[5] Most studies have reported a modest survival benefit from the combination of radiotherapy and fluorouracil.[1,5,9,10] Evidence suggests that radiotherapy with gemcitabine can yield similar outcomes.[5] A period of chemotherapy followed by chemoradiation may be preferable to first-line chemoradiation. Chemotherapy alone is also an option in these patients,[5] and a systematic review[11] found insufficient evidence to recommend chemoradiation over chemotherapy alone; gemcitabine monotherapy or gemcitabine-based combination therapy is advocated.[5] Use of neoadjuvant chemoradiotherapy to improve resectability rates in locally advanced disease is investigational.[5,8,10] In patients with advanced (metastatic) disease, supportive care alone remains appropriate for those with poor performance status. Palliative chemotherapy may be considered in those with adequate performance status,[5] but benefits are modest (pancreatic adenocarcinoma is a chemoresistant tumour).[1,12] Despite this, a meta-analysis[13] found a survival advantage for chemotherapy over best supportive care. Single-agent fluorouracil has been widely used.[6,8,14] Combination regimens, such as FAM (fluorouracil, doxorubicin, mitomycin) SMF (streptozocin, mitomycin, fluorouracil), and FAP (fluorouracil, doxorubicin, cisplatin), have not proved more effective than fluorouracil alone.[8,9] However, there is evidence[5,15] that gemcitabine can produce slightly better survival than fluorouracil in patients who can tolerate it, and it has been recommended as the standard of care.[1,5,8,9,16] There is also some evidence that its effectiveness may be improved if it is given at a fixed dose rate of 10 mg/m^2 per minute, rather than by conventional infusion.[5,14] Gemcitabine has also been investigated in combination with other drugs such as cisplatin, docetaxel, irinotecan, oxaliplatin, or capecitabine, as well as with newer targeted therapies such as bevacizumab, cetuximab, trastuzumab, or erlotinib.[5,14,17] A meta-analysis[13] found a survival benefit for gemcitabine-based combination therapy compared with gemcitabine alone. Combinations showing benefit in terms of progression-free survival or overall survival include gemcitabine with capecitabine (GEMCAP), cisplatin (GEMCIS), oxaliplatin (GEMOX), or erlotinib.[5,6,14,18] The combination of cisplatin, epirubicin, fluorouracil, and gemcitabine (PEFG) has also shown impressive results.[14] Rubitecan is one of many other antineoplastics under investigation for advanced pancreatic cancer,[12,14] and other therapies that have been investigated include somatostatin analogues, other hormonal strategies, and biological therapies.[19] A preliminary study suggested that flutamide (an anti-androgen) might be beneficial[20] but flutamide with gemcitabine proved of no more benefit than gemcitabine alone.[21] Pancreatic cancer vaccines are also under investigation.[6,17]

Malignant neoplasms of the prostate. Prostatic cancer is the most commonly diagnosed non-skin malignancy in men in the western world, and the second most common cause of cancer deaths in men: about one in 6 men can be expected to develop clinically evident carcinoma of the prostate during his lifetime. The incidence rises steadily with age. More than 95% of all prostate cancer is adenocarcinoma, which begins as a hard mass in the peripheral portion of the gland and infiltrates surrounding tissues slowly. Metastasis may occur in advanced disease, notably to bone. Presenting symptoms of advanced disease are usually those of urinary outflow obstruction, or pelvic or back pain due to bone metastases. However, as a result of the slow rate of tumour growth and usually advanced age at diagnosis, many patients die of other illnesses without having suffered significant disability from the cancer.

Controversy exists regarding all aspects of the management of prostate cancer, from screening to the best treatment for each stage of the disease. Much of this is because of the lack of clear data to guide treatment decisions. Factors that guide treatment decisions include the extent (stage) of the tumour, tumour grade (Gleason score), the patient's life expectancy (based on age and comorbid conditions), and patient preference.[1-4]

There is great controversy over the value of **screening** for early disease by detection of prostate specific antigen (PSA), and other tests, because of the uncertainties regarding interpretation of the test results, and controversy over the management of asymptomatic early localised disease.[5-8] Screening studies are currently underway.

In patients with **localised disease**, detected incidentally or by screening, the choices are radical prostatectomy, radical external beam radiotherapy, brachytherapy, or deferred treatment (watchful waiting).[8-10] There is currently no evidence to suggest one form of therapy is more effective than another, except perhaps for poorly differentiated tumours, which have a faster rate of progression and may benefit from earlier therapy.[4] Because of the lack of differences in efficacy, treatment morbidity and patient preferences are particularly important. Adverse effects of surgery include impotence and incontinence, and for radiotherapy, radiation proctitis, impotence and incontinence, and these complications may be severe in up to 5% of patients.[4] In medically fit patients with a life expectancy of 10 years or more many clinicians would consider radical prostatectomy or radiotherapy with curative intent,[1,4,8,11] although it should be noted that these patients are the ones for whom treatment complications are likely to have the most impact on quality of life.[4] In men with a life expectancy of less than 10 years and with low-grade tumours, there is a definite role for deferring treatment.[1,4,9,11] Interstitial implantation of radioisotopes (brachytherapy) is an alternative to external beam radiotherapy; a more localised dose is possible but inadequate dose distribution can occur and some patients may also need adjuvant external beam radiotherapy.[11] Cryosurgery, and ultrasound or radiofrequency interstitial tumour ablation are other options for localised disease, but are less well investigated.[11] In patients who undergo radical surgery and who are found to have positive margins, adjuvant radiotherapy or hormonal therapy may be used. Neoadjuvant hormonal therapy has been used before radiotherapy, but its role in early disease remains to be established. Hormonal therapy has also been used alone when there is a risk of disease progression but local therapy is not deemed necessary.[11]

For patients with **locally advanced disease**, options include radiotherapy with or without neoadjuvant or adjuvant hormonal therapy, hormonal treatment alone, or, in those who are asymptomatic, deferred treatment.[1,4,12,13] Although radiotherapy alone produces good local control, most patients eventually develop metastatic disease. There is increasing evidence that the use of hormonal therapy before or after radiotherapy improves disease-free and overall survival.[12-14] Deferred treatment was less effective than immediate treatment in one study,[15] but the form of follow-up for deferred treatment was not regulated. In patients for whom deferred treatment is considered, close surveillance is required. Surgery alone is rarely used in locally advanced disease[1] but there is some evidence to suggest that adjuvant hormonal therapy may delay disease progression, and neoadjuvant hormonal therapy is under investigation.[12]

PSA may be used to monitor the efficacy of therapy and detect biochemical relapse, but the interpretation of the test and when to instigate further treatment in patients with no clinical evidence of disease is controversial.[12,16]

For patients with **metastatic disease** cure is not possible and therapy is aimed at prolonging survival and palliating symptoms. The basis of therapy is hormonal manipulation: about 80% of patients will respond to such therapy, but resistance eventually develops. The first choice is between orchidectomy or a gonadorelin analogue, which have been shown to be equally effective.[4,17,18]

An alternative to orchidectomy or gonadorelin analogues is the use of an anti-androgen (such as flutamide, nilutamide, or bicalutamide) alone.[18] However, there is some evidence that these may be less effective and cause more treatment withdrawals (due to gastrointestinal intolerance),[17] although they may have less adverse effect on libido. Although historically oestrogens such as diethylstilbestrol have been used in patients with prostate cancer they are now less favoured because of their cardiovascular adverse effects.

The combined use of anti-androgens such as flutamide with ablation of testicular androgen production (by surgery or gonadorelin analogues) has the advantage of blocking the effects of adrenal androgen production as well (maximal or complete androgen blockade). An early meta-analysis[19] seemed to indicate that this approach did not produce a better survival rate compared with conventional castration, and an update of this meta-analysis[20] confirmed that any survival advantage from maximum androgen blockade using nonsteroidal anti-androgens was likely to be in the region of 3%. Any benefit also seems to appear only after 5 years of follow-up.[8]

The gonadorelin antagonist abarelix can also be used for hormone suppression. It has a more rapid onset of effect than the gonadorelin analogue leuprorelin and does not stimulate tumour flare.[21,22] Abarelix may be an alternative for men who are not suitable candidates for orchidectomy or gonadorelin analogue therapy.

In patients who relapse after or during hormonal therapy, second-line hormonal therapy may be tried, although responses are variable. Drugs that have been used include aminoglutethimide, high-dose bicalutamide, corticosteroids, ketoconazole, and megestrol.[16] Some patients treated with anti-androgens have a paradoxical response to withdrawal of the drug, but it is not possible to predict which patients will respond. Gonadorelin analogue therapy must be continued, to maintain testosterone suppression.[23]

Chemotherapy for recurrent **hormone-refractory prostate cancer** is still in clinical trials and has no routine place in therapy. Some patients with soft-tissue disease may benefit from an anthracycline.[4] Mitoxantrone has a palliative benefit and improves quality of life, but does not prolong survival.[24] Docetaxel given every 3 weeks improved survival compared with mitoxantrone,[25] both in a regimen with continuous prednisone. Docetaxel also reduced pain, but was associated with a higher incidence of adverse effects; a regimen using docetaxel weekly had a similar outcome to mitoxantrone. A combination of docetaxel with estramustine also improved survival[26] compared with mitoxantrone plus prednisone, but again with an increased incidence of adverse effects. Some consider docetaxel-based chemotherapy to be the standard of care.[24] Combinations of docetaxel are under investigation, including with vinorelbine, capecitabine, or high-dose calcitriol.[24] Combinations of estramustine with etoposide, vinblastine, or vinorelbine have also shown favourable results.[16,27] Other drugs that might reasonably be used after initial treatment with docetaxel-based therapy include oral cyclophosphamide, either alone or with vincristine and dexamethasone. Newer drugs under investigation include satraplatin and ixabepilone.[24,28]

Preliminary results have indicated that a herbal combination preparation, PC-SPES, may have beneficial effects in both androgen-dependent and androgen-independent disease. It has been used widely as a complementary medicine, but there have been reports of adverse cardiovascular effects and contamination with diethylstilbestrol and warfarin, resulting in the withdrawal of this product from most markets.[29,30] Although suramin originally showed promise, later results were less favourable, and it appears its development has ceased. Bone metastases are usually treated with palliative radiotherapy (see p.660). Bone-targeted therapy with strontium-89 has been tried,[27,31] and gene therapy is under investigation.[32] Prostate cancer growth is thought to be stimulated by endothelin-1, a small peptide that acts at endothelin-A receptors; atrasentan is an endothelin-A receptor antagonist under investigation, and early studies have shown improvements in time to disease progression and markers of bone metastases.[24,27] Vaccines are also under development for treatment of prostate cancer.[8,24,33]

Because of the difficulties involved in managing prostate cancer there has been interest in the concept of disease **prophylaxis**. One small study of finasteride in men at high risk of prostate cancer showed little evidence to support such use.[34] In healthy men, a large controlled trial[35] found that seven years of finasteride prophylaxis reduced the incidence of prostate cancer by about 25% compared with placebo, but this benefit was offset by an increased risk of high-grade tumours associated with finasteride. Dutasteride is also under investigation.[36] Results from a case-control study have suggested an association between warfarin use and a decreased risk of prostate cancer.[37] There is preliminary evidence that selenium (see p.1961) or vitamin E (see p.1927) supplementation may also reduce the risk of prostate cancer, and a large randomised study is underway to further investigate this.

Malignant neoplasms of the skin. Basal cell carcinoma is the most common form of skin cancer, accounting for about 80% of cases. The second most common skin cancer is squamous cell carcinoma. These 2 types of carcinoma (collectively referred to as nonmelanoma skin cancers) are the most common malignancies among white populations, but because many are not recorded the exact incidence is uncertain and they are often omitted from calculations of the relative frequency of malignancy. A small but increasing proportion of all skin cancers are melanomas, arising from melanocytes (pigment cells). Other cancers that manifest in the skin include cutaneous T-cell lymphomas (see Mycosis Fungoides, above) and Kaposi's sarcoma (see below).

Nonmelanoma and melanoma skin cancers are related to solar radiation, and the incidence is greatest in those regions where light-skinned populations live closest to the equator. Individuals at particular risk include those with fair skin, blue eyes, red hair, a tendency to freckle, and to burn rather than tan. Use of methoxsalen with ultraviolet light (PUVA) has also been associated with an increased incidence of skin cancers (see Effects on the Skin, under Methoxsalen, p.1605). Other risk factors for nonmelanoma skin cancers include various inherited disorders such as xeroderma pigmentosum (see Photosensitivity Disorders, p.1581) and albinism (see Pigmentation Disorders, p.1582). Immunosuppressive therapy, as used after solid organ transplantation (see p.1810 *et seq.*), is associated with a very large increase in risk of squamous cell carcinoma.

Prophylaxis. Although nonmelanoma and melanoma skin cancers are related to solar radiation, and measures to reduce sun exposure are therefore advocated for prophylaxis, the relationship appears to differ between the types.

- Squamous cell carcinoma and its precursor lesions are clearly linked to cumulative chronic sun exposure.[1,2] These lesions are more common on frequently exposed skin (head, neck, and back of hands), and are more common in individuals with outdoor occupations. In addition, there is evidence that regular sunscreen use can reduce the incidence of new actinic keratoses and increase remission of existing lesions,[3] and reduce incident squamous cell carcinomas.[4]
- Although basal cell carcinomas are also common on sun-exposed skin (head and neck), it appears that they may be more related to a history of severe sunburns, particularly in childhood and adolescence, rather than to cumulative sun exposure.[1] In 1 study,[4] there was no difference in incidence of basal cell carcinomas between sunscreen users and non-users.
- Cutaneous melanoma is more common on skin exposed to the sun occasionally (particularly the legs in women, and the back in men), and appears to be more common in indoor than outdoor workers. This suggests that intermittent sun exposure may be more risky than regular exposure for this cancer.[1,2] Although the use of sunscreens is advocated for protection against melanoma, some reports have suggested that sunscreen use may actually increase the risk. However, systematic reviews[5,6] have found no good evidence for an association between sunscreens and the increasing incidence of melanoma, but did find that studies varied in accounting for confounding factors such as patient complexion and recall bias. Also, people at higher risk of sunburn and melanoma may also be more likely to use sunscreens, and some people may use sunscreens to allow for prolonged sun exposure, thus receiving a higher cumulative amount of UV radiation. Sunscreen formulation, sun protection factor (SPF) rating, and protection against UVA, have also changed considerably over the last few decades, making it difficult to compare study results.

Chemoprevention has also been investigated as a means of reducing the incidence of squamous and basal cell cancers, particularly in those most at risk. Retinoids such as acitretin, etretinate, and isotretinoin have been shown to reduce the incidence of new squamous cell carcinomas in individuals with xeroderma pigmentosum, and in renal transplant recipients.[7] Conversely, neither betacarotene (p.1927) nor selenium (p.1961) has reduced the incidence of squamous or basal cell carcinomas in patients previously treated for these disorders. There is some evidence that a low-fat diet may reduce the incidence of actinic keratosis in patients with a history of nonmelanoma skin cancer.[8]

BASAL CELL AND SQUAMOUS CELL CARCINOMA. The great majority of skin cancers are basal cell carcinomas, which are completely curable if diagnosed early and treated appropriately. Although they rarely metastasise, they have a tendency to be locally destructive. The remainder are mainly squamous cell carcinomas, which, although curable when treated early, have a greater risk of metastatic spread. Common precursor lesions for squamous cell carcinoma are actinic keratosis (solar keratosis) and Bowen's disease (squamous cell carcinoma in situ).

- Treatments for **actinic keratosis** and **Bowen's disease** include cryosurgery, curettage, excision, radiotherapy, laser treatment, photodynamic therapy (see Porfimer Sodium, p.764) using 5-aminolevulinic acid or methyl aminolevulinate, and topical fluorouracil or topical imiquimod.[1-5] Topical diclofenac or topical salicylic acid may be used for actinic keratosis.[2-4] The choice of treatment depends on the site and size of the lesion, evidence for efficacy, ease of application, and availability.[1]
- Treatment options for superficial low-risk **basal cell carcinomas** include curettage and electrodesiccation or cryosurgery.[6-9] Topical fluorouracil may be used for superficial lesions in some instances, as are topical imiquimod or photodynamic therapy using 5-aminolevulinic acid, methyl aminolevulinate, or porfimer.
- For superficial tumours at high-risk sites, and for most **squamous cell carcinomas**, excision with postoperatively determined margins or Mohs' micrographic surgery (tumour margins examined during the procedure) is more appropriate.[6-11] Radiotherapy is an alternative in patients at risk of surgical complications or where surgery would be difficult or extensive.

The prognosis with appropriate treatment is good, with 5-year disease free survival of over 90%. However, about 50% of patients will subsequently develop another skin cancer, and regular monitoring to detect this as early as possible is desirable.[7] In addition, patients should be educated about sun protection measures, and chemoprevention with retinoids may be appropriate for some high-risk patients (see Prophylaxis, in Malignant Neoplasms of the Skin, above).

MELANOMA. Although cutaneous melanoma is rare it is the most aggressive skin cancer, accounting for the majority of all skin cancer deaths. Melanoma may arise in apparently normal skin or from an existing naevus. Early signs of a naevus that may indicate development of a melanoma are change in size, shape, or colour. Other signs include itching, ulceration, and bleeding. The most common site in women is the legs, and in men the back. For a discussion of sun protection measures in the prevention of melanoma, see Prophylaxis, in Malignant Neoplasms of the Skin, above.

Surgical resection is the mainstay of curative treatment for melanomas, and the margins of excision are determined by tumour depth.[1-6] Patients with thin tumours (less than 1 mm) can be treated with wide local excision only; patients with intermediate (1 to 4 mm) or thick (more than 4 mm) melanoma are at high risk for nodal disease, and lymph node dissection may also be performed if node biopsy is positive. Because of the high risk of recurrence after surgery in the latter group, there is great interest in adjuvant therapies. The most common adjuvant treatment is interferon alfa;[3,5,6] high-dose interferon has shown a clinical benefit in terms of relapse-free survival, but the effect on overall survival is less clear.[4,7-10] As toxicity is a significant problem with high-dose therapy, both low-dose extended-duration[11] and intermediate[12] dosage regimens have been studied, but neither have shown benefit in relapse-free or overall survival. Isolated limb perfusion with melphalan has been used as adjuvant therapy, but a review of four randomised trials failed to show any survival benefit for this compared with surgery alone.[13] Similarly, systemic chemotherapy has not proved useful in the adjuvant setting.[14] Various melanoma vaccines (e.g. GM2 ganglioside, autologous melanoma-associated antigens) are being investigated for adjuvant use,[15] but high-dose interferon alfa has been shown to produce greater clinical benefit than vaccination with GM2.[9] Isolated recurrences are treated with surgical resection.

For patients who present with metastatic melanoma the 5-year survival rate is poor.[14] There is no evidence to show that any systemic treatments are better than best supportive care in these patients.[16] Because of this, surgery is still considered an option, and a few patients may survive long term after resection of isolated metastases. For patients with a finite number of in-transit metastases (tumour involves skin or subcutaneous tissue more than 2 cm from the primary tumour but not beyond the regional lymph nodes) that cannot be fully excised or are unresectable, options include intralesional injection with BCG vaccine or interferon alfa, topical imiquimod, isolated limb perfusion with melphalan, or radiation therapy.[3] Chemotherapy has been tried in disseminated disease,[4-6,17] and dacarbazine, with a response rate of about 20%, is the most common single agent. However, the response duration is usually only 4 to 6 months, and complete responses are rare. The orally active analogue temozolomide produces similar responses,[18] and is an alternative.[3] Nitrosoureas (such as carmustine, lomustine, and semustine) have response rates around 15% as single agents.[17] Fotemustine appears to be more active, particularly in the treatment of brain metastases. Other drugs with a response rate of about 15% include cisplatin, vinblastine, vindesine, docetaxel, and paclitaxel; response duration has generally been poor.

Combination regimens have been used, such as CVD (cisplatin, a vinca alkaloid, and dacarbazine). Tamoxifen has also been added to regimens, on the hypothesis that melanoma is oestrogen-dependent; an example is the CDBT or Dartmouth regimen (cisplatin, dacarbazine, carmustine, and tamoxifen). However, a randomised study found that this regimen was no more effective than dacarbazine alone,[19] and there is a lack of evidence that tamoxifen potentiates the action of cytotoxics in melanoma.[17] Although the combination of temozolomide and interferon alfa has been reported to increase response rates compared with temozolomide alone, overall survival was no different and toxicity was worse.[20]

Cytokines such as interferon alfa and interleukin-2 have similar activity to chemotherapy in metastatic melanoma.[17] Cytotoxic chemotherapy has been given with these cytokines and there have been some reports of improved response rates, but large controlled studies are needed to confirm a benefit. Melanoma vaccines are also being used or investigated in metastatic or recurrent disease,[15] as are gene therapy, antiangiogenic agents such as thalidomide,[17] and the antisense oligonucleotide oblimersen.[21]

Malignant neoplasms of the testis. Testicular cancer only accounts for about 1% of all male malignancies but it is the most common cancer in young men. Patients with a history of cryptorchidism are at increased risk. About 95% of testicular tumours arise in germ cells, and 40% or so of these are pure seminomas. The remainder are collectively known as nonseminomatous germ cell tumours (NSGCT) in the WHO classification, and are commonly of mixed cell types with or without a seminoma component. Nonseminomatous tumours have been referred to as teratomas in the British classification system, but this term has a more specific meaning in the WHO classification.[1]

Metastasis first occurs to the lymph nodes, then, in advanced disease, to distant sites such as lung, liver, brain, and bones. The leading symptom is a hard, painless swelling of the testis, but once metastasis occurs the patient may present with back pain (due to enlargement of retroperitoneal lymph nodes), cough, dyspnoea, gynaecomastia due to chorionic gonadotrophin production, or weight loss.

Surgical removal of the testis (orchidectomy) when diagnosis is confirmed is fundamental to the treatment of all types of testicular cancer, but further therapy depends upon the disease type and stage.[1-4]

In patients with **nonseminomatous** disease with the tumour confined to the testis (stage I), options after orchidectomy include surveillance or a short course of adjuvant chemotherapy. With surveillance, about 20 to 30% of patients will relapse and are subsequently treated with curative chemotherapy. Surveillance is thus not appropriate for patients who are unable to undergo regular follow-up. Similarly, in the UK, patients who have prognostic factors suggesting a high risk of relapse such as vascular or lymphatic invasion have been treated with adjuvant chemotherapy with 2 cycles of BEP (bleomycin, etoposide, and cisplatin),[1,3] which will prevent relapse in the vast majority of cases.[1] In the USA, retroperitoneal lymph-node dissection may be carried out to further stage the disease before making a decision regarding surveillance or adjuvant chemotherapy.[4] If resected nodes are clear, patients undergo surveillance, but if they involve tumour (stage II) the decision to give adjuvant chemotherapy is based on the degree of nodal involvement and the ability of the patient to undergo regular follow-up.[4]

Where metastasis to the lymph nodes (stage II) or beyond (stage III) has occurred, standard postorchidectomy therapy is now combination chemotherapy with BEP,[1,3,4] or EP (etoposide and cisplatin),[4] which have largely replaced the effective but more toxic PVB regimen (cisplatin, vinblastine, and bleomycin).[2,5] Based on serum markers and the presence or absence of non-pulmonary visceral metastases, patients with metastatic disease can be categorised into good, intermediate, and poor-risk groups.[4] Consequently, there has been interest in minimising the treatment in patients with good prognosis in order to reduce long-term morbidity. In such patients, 3 cycles of BEP,[1,4,6,7] or 4 cycles of EP, may be adequate.[2,4,6] The substitution of carboplatin for cisplatin has resulted in a 10% lower relapse-free survival, and slightly reduced overall survival, and is not usually recommended,[2,6] although some have reported good results with such a regimen in children.[8] There is evidence that overall survival is improved by increased dose-intensity of etoposide and perhaps bleomycin.[9] Standard management for patients with intermediate- or poor-risk disease is 4 cycles of BEP.[1,4,6,7] However, less than 50% of poor-risk patients achieve a durable response and they may be offered more intensive chemotherapy such as accelerated therapy, dose escalation with use of haematopoietic growth factors, or high-dose chemotherapy with stem cell support, with the aim of improving responses. So far, those intensive treatments evaluated in randomised clinical studies have not proved more effective than BEP, and have often been more toxic.[2,3] Studies are ongoing.[2] Secondary resection of residual tumour after chemotherapy is usual.[1-4]

Patients who fail, or who relapse after, standard chemotherapy have a poor prognosis, with an overall survival of only 20 to 25%.[2] A common salvage regimen is cisplatin and ifosfamide with either vinblastine or paclitaxel.[4,6] High-dose chemotherapy with stem cell support may also be considered.[1,2,4,6,7,10] Drugs with activity as single agents in relapsed disease include paclitaxel, oxaliplatin, and gemcitabine.[1,2,6,7]

Seminoma is extremely sensitive to radiation, and adjuvant radiotherapy is the treatment of choice after orchidectomy in limited disease (stage I) and disease with low tumour burden (stages IIA and IIB).[1-4,6,7] About three-quarters of patients have stage I disease at diagnosis and cure rates are between 95 and 100%. However, seminoma also responds very well to chemotherapy such as adjuvant single-agent carboplatin;[6,7] it has been compared with adjuvant radiotherapy for stage I disease. One study[11] found that after 4 years the relapse rates were similar, but long-term follow-up was required. Chemotherapy is also being used in some patients with stage IIB disease.[1] Patients with stages IIC to III seminoma have a relapse rate of over 35% after adjuvant radiotherapy, and adjuvant chemotherapy is preferred.[1,2,4] Standard regimens are BEP (3 cycles for good prognosis patients and 4 cycles for others[4]), or EP,[1,4] which produce survival rates of about 90%.[2] Salvage regimens for relapsed or unresponsive seminoma are similar to those used for nonseminomatous disease.[4]

Malignant neoplasms of the thymus. Thymomas are tumours of the mediastinum, arising from thymic tissue. They are rare, and most commonly present in patients between 40 and 60 years of age. Thymoma originates from the epithelium of the thymus but may also contain a lymphocyte component, which is probably not neoplastic. Up to 50% of patients are asymptomatic, and others have local symptoms such as cough, chest pain, dyspnoea, and obstruction of the vena cava; paraneoplastic syndromes such as myasthenia gravis, red cell aplasia, and hypogammaglobulinaemia may also develop.

Thymomas may be classified based on cell type; they are also staged as non-invasive (encapsulated, stage I), invasive (localised, stage II; extensive, stage III; and disseminated, IVa), and metastatic (IVb). The majority of patients present with non-invasive disease, and can be treated solely by surgical resection with low recurrence rates and long-term survival approaching 100%.[1-3] Use of adjuvant radiation therapy for stage II and III thymoma is controversial.[4] Some recommend postoperative radiotherapy after complete surgical resection,[1,2] whereas others consider it to be beneficial only in patients with incomplete resection; late complications of radiation therapy may occur.[4]

In patients with unresectable invasive disease, primary radiation therapy has been used to shrink the thymoma to make it resectable.[2] Radiotherapy alone has also been used, with conflicting results.[2] There is increasing interest in combined modality approaches to improve survival in this group.[1-4] Chemotherapy has also been used to shrink tumours, allowing for resection.[2] Postoperative radiotherapy and/or chemotherapy is then given.[2,4,5] Chemotherapy regimens used in this approach are similar to those used in metastatic disease.

Therapy for recurrent or metastatic disease is not well established because of the rarity of the condition.[1-3] Case series and phase II studies have shown that the tumour is chemosensitive. Evidence that cisplatin had activity against thymoma has led to much interest in cisplatin-containing regimens such as cisplatin, doxorubicin, and cyclophosphamide (PAC), and the same drugs with addition of vincristine.[1-4] Ifosfamide is also active as a single agent against thymoma, and has been given with cisplatin and etoposide.[1,3] A combination of carboplatin and paclitaxel is under investigation.[3] Interleukin-2 has not proved beneficial.[1,3] There is some evidence that thymomas possess somatostatin receptors, and there have been a few reports of the benefit of octreotide.[1,3]

Malignant neoplasms of the thyroid. Thyroid cancer accounts for only about 1% of all malignancies. The incidence is reportedly higher in women than men, in patients who received irradiation of the thyroid during childhood, and in populations where goitre is endemic. The natural history varies with the cell type and degree of differentiation. Well-differentiated papillary or follicular tumours (which constitute about 70% and 15% of cases, respectively) are very slow to grow and metastasise, sometimes persisting for years with little change in size and extent, although they may prove more aggressive in children. In contrast medullary carcinomas (5 to 10% of cases), which develop from the cells responsible for calcitonin secretion, and undifferentiated (anaplastic) tumours (5%) metastasise early and follow a much more rapid and aggressive course. About 25% of medullary cancers are hereditary, including those due to multiple endocrine neoplasia type 2.

The well-differentiated types usually present as a thyroid nodule, although most nodules are not malignant, while with anaplastic tumours there is usually bulky disease and often difficulty in breathing due to encroachment on the tracheal lumen.

In patients with **well-differentiated tumours** total or partial thyroidectomy is the treatment of choice.[1-6] This may be followed by a course of iodine-131 to destroy any residual tumour, although in low-risk patients the prognosis after surgery alone is so favourable that iodine-131 is not usually recommended.[1-6] Levothyroxine treatment should be given to all patients to suppress thyroid stimulating hormone (TSH) production, and must be continued for life.[1-7] Ten-year survival of up to 85% in patients with follicular tumours and up to 93% with papillary tumours has been seen.[4] External radiation therapy may be considered in patients with evidence of extrathyroid extension at the time of surgery.[4,5] Disease recurrence is commonly treated with further surgery, ablative iodine-131 therapy or external radiation therapy.[1,2,4-6]

In patients with **medullary cancers** total thyroidectomy and neck dissection are indicated, with levothyroxine treatment if needed.[2-4] Ten-year survival of 60 to 70% has been reported.[7,8] Adjuvant external beam radiotherapy may be used in patients at high risk of regional recurrence[3,4] but routine use has not shown any survival benefit.[2] Prophylactic thyroidectomy may be considered in patients with a hereditary predisposition to medullary cancer.[3,8] Resection may relieve symptoms in patients with **anaplastic tumours**, but cure is impossible and treatment is purely palliative, with survival measured in months.[3,4,7,9] Neither medullary[8] nor anaplastic tumours[7] are sensitive to iodine-131. External radiation therapy is commonly used.[2,3,9]

Chemotherapy has been tried in anaplastic thyroid cancer, as well as in unresponsive disease of other cell types, with limited benefit.[2,6] Drugs tried, often in combination regimens, include cisplatin, cyclophosphamide, bleomycin, dacarbazine, doxorubicin, fluorouracil, paclitaxel, and vincristine.[4,7-9] The vascular targeting agent combretastatin A4 phosphate is under investigation.[4]

Neuroblastoma. Neuroblastoma accounts for about 7% of all childhood malignancies overall but is probably the most frequent neoplasm in the first year of life. Three-quarters of all cases present before the age of 5 years. The tumour is derived from cells of the neural crest, and may occur anywhere within the sympathetic nervous system, notably the sympathetic ganglia and the adrenal medulla. Clinical behaviour ranges from spontaneous remission to rapid metastatic progression and death. Sites of metastasis include lymph nodes, bone marrow, liver, and skin. Adverse prognostic factors include age over 1 year at diagnosis, stage IV (distant metastases), and amplification of the oncogene MYCN.

Progress in the treatment of neuroblastoma over the last 20 years has increased 10-year survival to about 60% overall, although in patients with disseminated disease the gains have been modest.[1]

In those with localised disease (stage I or II) surgical resection alone is appropriate, with good long-term survival prospects. In addition, asymptomatic infants less than one year of age with localised tumours and limited dissemination (stage IV special) usually have a high rate of tumour regression, and can be considered for surgical resection then close observation.[1] Low-dose chemotherapy generally arrests tumour progression should this occur.

In those with localised but unresectable disease (stage II and III), subtotal surgical resection may be followed by standard-dose chemotherapy.[1] Chemotherapy regimens include cyclophosphamide and doxorubicin, sometimes with vincristine for good prognosis patients, and with the addition of cisplatin and etoposide (or teniposide) for poorer prognosis patients. Further surgery may be given, with further chemotherapy and/or radiotherapy used in those with residual disease.[1]

Disseminated disease (stage IV) and tumours with adverse prognostic features such as MYCN amplification are often more resistant to chemotherapy, and more intensive therapy is used.[1,2] Surgery and radiation therapy may be combined with chemotherapy. Regimens used for remission induction include cyclophosphamide, doxorubicin, cisplatin, etoposide or teniposide, and vincristine. Another option is cisplatin, etoposide, and vindesine alternating with vincristine, dacarbazine, ifosfamide, and doxorubicin.[1] After remission induction, consolidation with myeloablative chemotherapy and autologous stem cell or bone marrow rescue may be used. Maintenance therapy with oral cyclophosphamide is being investigated. Isotretinoin, fenretinide, and monoclonal antibodies are also being investigated for their ability to maintain remissions after chemotherapy.[1,3] Targeted radiation, using iodine-131-labelled *m*-iodobenzylguanidine, which is actively taken up by cells synthesising catecholamines, may be used for scanning, and is also being investigated for treatment.[4]

Retinoblastoma. Retinoblastoma is the most common eye tumour in children and accounts for about 3% of all childhood malignancies (for other malignant neoplasms of the eye, see above). In 60 to 70% of cases the tumour is sporadic and non-hereditary, producing a unilateral, unifocal lesion. In the remaining 30 to 40% of cases there is an abnormal tumour suppressor gene (RB1) inherited: these tumours are typically bilateral and are sometimes associated with an intracranial neuroblastic tumour (trilateral retinoblastoma or pinealoblastoma). In addition, patients with the hereditary form are at very high risk of secondary primary malignancies, particularly osteosarcoma and soft tissue sarcomas. The most common manifestations of retinoblastoma are leukocoria (white pupil), strabismus (squint) and nystagmus. Retinoblastoma is confined to the eye(s) (intra-ocular) at presentation in about 80% of patients, although the majority have extensive disease within the eye. Nevertheless, 5-year disease-free survival after treatment in these patients is over 90%. In contrast, patients with extra-ocular disease in the tissues around the eye, or with metastatic spread to the CNS and beyond, have a 5-year survival of less than 10% despite treatment.

The aim of treatment for intra-ocular retinoblastoma is to cure the disease, and to preserve as much vision as possible.[1-5] In patients with unilateral tumours, enucleation (removal of the eye) is the standard primary treatment when there is no expectation of useful vision (e.g. extensive disease within the eye). In bilateral retinoblastoma, standard treatment was enucleation of the advanced eye and external beam radiation therapy in the less advanced eye. However, there is increasing use of therapies to preserve the eye and to reduce the use of external radiotherapy which further increases the risk of secondary malignancies.[2-4,6] These include local treatments such as cryotherapy, thermotherapy, and plaque radiotherapy. Intravenous neoadjuvant chemotherapy may be given before local treatment to reduce tumour size (chemoreduction); regimens usually include carboplatin, etoposide (or teniposide), and vincristine.[2-4] Ciclosporin has also been included to overcome the multidrug resistance gene, P-glycoprotein.[3,6]

Patients who are found to have optic nerve involvement (micrometastatic retinoblastoma) on enucleation are at high risk of recurrence. Although there is no consensus on further treatment, these patients are often given adjuvant chemotherapy (cyclophosphamide, doxorubicin, and vincristine) and radiotherapy.[3]

Patients with orbital extension may be treated with enucleation, radiotherapy, and intensive chemotherapy.[3] Regimens typically include cyclophosphamide, doxorubicin, and vincristine, and may include carboplatin and etoposide. Intrathecal methotrexate and cranial irradiation may be added for CNS involvement or trilateral retinoblastoma. Metastatic disease may be treated similarly, but although combination chemotherapy may produce a response it is rarely curative in such advanced disease. High-dose chemotherapy with autologous stem cell rescue has been tried in metastatic disease, but it has not been effective for disease involving the CNS.[4]

Sarcomas. The sarcomas are tumours arising from mesodermal cells which form the bone and connective tissue (as opposed to carcinomas, which arise from ectodermal and endodermal cells, and leukaemias and lymphomas which arise from the bone marrow and immune system).

Sarcomas are uncommon, and vary considerably in their sites, presentation, and prognosis. The primary malignancies of bone include osteosarcoma and Ewing's sarcoma, which most often occur in older children and adolescents, and chondrosarcoma which is most common in later life. Soft tissue sarcomas include those of fibrous tissue (fibrosarcoma), skeletal muscle (rhabdomyosarcoma), smooth muscle (leiomyosarcoma), adipose tissue (liposarcoma), and blood vessels (a group which includes Kaposi's sarcoma).

BONE SARCOMA. The commonest primary malignant tumour of bone is **osteosarcoma** (osteogenic sarcoma) which accounts for about 3 to 4% of all childhood malignancies. It is composed of malignant osteoblasts which form an osteoid matrix within which new bone formation may occur. Most osteosarcomas are aggressive high-grade malignancies which destroy overlying cortical bone and invade adjacent soft tissue, as well as spreading along the medulla. Metastasis, almost exclusively via the vascular system to the lungs and other distant sites, is usual and occurs early.

The main therapy is surgery, with an increasing trend to more conservative, limb-sparing operations rather than amputation. Adjuvant chemotherapy is an important component of therapy, however, as metastasis of the tumour is common.[1-4] Combinations of cisplatin, doxorubicin, ifosfamide, and high-dose methotrexate are recommended.[3,4] Neoadjuvant chemotherapy is often given before surgery to attack micrometastases, shrink the primary tumour and enable evaluation of the tumour response.[3,5] Aggressive treatment regimens can result in long-term relapse-free survival rates of 70%, although patients with overt metastatic disease at presentation have a poorer prognosis.[4,5] Osteosarcomas are relatively resistant to radiation therapy;[4] however, for unresectable high-grade osteosarcoma, radiotherapy followed by adjuvant chemotherapy is recommended.[3]

Like osteosarcoma, **Ewing's sarcoma** is seen mainly in adolescents and older children. It is a round cell tumour that most often arises in the pelvis or the long bones of the limbs. There may be diffuse erosion of the bone and marked periosteal reaction. It spreads through the medullary cavity, and metastases to lung and other bones are common.

Initial treatment is neoadjuvant chemotherapy for several months.[3,4] Combinations of cyclophosphamide, ifosfamide, etoposide, doxorubicin, and vincristine are recommended,[3,4] given good results from addition of ifosfamide and etoposide to standard regimens.[4,6] Dactinomycin has also been used in standard regimens,[4,6] although its use for localised disease is controversial.[4] Typically, patients are then given local therapy (surgery, radiation, or both), with additional adjuvant chemotherapy.[3,4] Ewing's sarcoma is relatively radiosensitive,[4] and unresponsive or progressive disease is best managed with radiation therapy with or without surgery, followed by chemotherapy or best supportive care.[3] The prognosis of recurrent Ewing's sarcoma is poor.[3] High-dose chemotherapy with stem cell rescue has been investigated for relapsed or progressive disease, with promising initial results.[3,4]

Chemotherapy appears to have little place in the treatment of other bone sarcomas such as **chondrosarcoma**[3,4] or **osteoclastoma** (giant cell tumours of bone);[4] it has been used in high-grade **fibrosarcomas** and in **histiocytoma** but its value is uncertain.

KAPOSI'S SARCOMA. Kaposi's sarcoma is a tumour of endothelial or spindle cell origin. In its classical form it manifests as red or violet cutaneous lesions of the limbs in elderly men, usually of Jewish or Mediterranean ancestry. An endemic form is also seen in certain areas of Africa.[1] Lesions may eventually affect the whole of the skin, upper airways, gastrointestinal tract, lungs, and lymph nodes, but in general disease is only very slowly progressive, and may require no treatment. Patients given immunosuppressive therapy may be at greater risk of developing Kaposi's sarcoma, particularly if they are from ethnic groups that are susceptible to the classic or endemic forms of the disease.[1] In recent years an epidemic form of the disease has appeared in patients with disease due to HIV infection (p.856). HIV-associated Kaposi's sarcoma is more aggressive, with a greater tendency to disseminated and metastatic disease.

A novel herpesvirus (human herpesvirus 8, HHV8) has been implicated in the pathogenesis of Kaposi's sarcoma. HHV8 induces changes in endothelial cells that make them more susceptible to inflammatory cytokines and angiogenesis.[2] Some antivirals, such as cidofovir and to a lesser extent foscarnet and ganciclovir, have shown activity against HHV8 *in vitro*, but they have not been equally successful in treating Kaposi's sarcoma *in vivo*. Treatment with HAART has greatly reduced the occurrence of Kaposi's sarcoma in AIDS patients, and may cause regression of milder forms of the disease, but this is thought to be due to improvements in immune function rather than a direct effect on Kaposi's sarcoma.[3] The development of Kaposi's sarcoma is likely to be multifactorial, and as infection with HHV8 alone does not produce disease, and the replication of HHV8 in sarcoma cells is low, antiviral therapy alone is unlikely to be sufficient to control symptoms.[3]

Patients with classic or endemic Kaposi's sarcoma are often treated with surgery or radiotherapy of individual lesions.[1] Extensive or recurrent disease may be treated with vinca alkaloids, bleomycin, doxorubicin, and dacarbazine, alone or in combination.[1] Etoposide and interferon alfa have also been tried.[1] Patients with immunosuppression-associated Kaposi's sarcoma may be treated similarly to those with the classic form, or preferably by alteration of the immunosuppressive regimen if this can be done without graft loss.[1] Clinical and histological regression of cutaneous Kaposi's sarcoma has been described in a small number of renal transplant recipients when ciclosporin and mycophenolate mofetil were replaced with sirolimus.[4]

The epidemic form of Kaposi's sarcoma is associated with HIV infection, and seen particularly in homosexual patients. HAART may control Kaposi's sarcoma, and is considered first-line therapy,[5-7] but the response is unpredictable, so specific therapy is often needed.[1] Localised disease may be managed with cryotherapy or radiotherapy, but intralesional vinblastine, interferon alfa, and topical alitretinoin are also used.[2,5-8] Photodynamic therapy is also used.[6,7]

Systemic chemotherapy is generally reserved for patients with more extensive disease or mucosal or visceral involvement.[5,7] In patients with a CD4 cell count of 200 cells/mm^3 or above, treatment with interferon alfa, in combination with zidovudine, has been advocated by some, but systemic chemotherapy is the treatment of choice.[1-3,5,6] The main combination regimens use a vinca alkaloid and bleomycin, with or without doxorubicin.[2,3] Liposomal formulations of doxorubicin and daunorubicin have produced response rates of 40-85%, and may be less toxic than conventional chemotherapy;[2,3,8] it has been suggested that a liposomal anthracycline is the drug of choice in extensive disease.[1,2,5-7] Paclitaxel is also used as a single agent in advanced disease.[2,3,7,8] However, although highly effective, doses may need to be reduced if given to patients taking HAART because of the risk of drug interactions.[5,7] Although data are limited, docetaxel may be a reasonable alternative.[7] Some response has also been reported for oral etoposide.[1]

Control of Kaposi's sarcoma has been reported in a few patients given high-dose intramuscular chorionic gonadotrophin, but tumour regression ceased and regrowth occurred when dosage was reduced or withdrawn.[9] Further reports of intralesional or systemic use have included partial remissions and disease stabilisation, as well as no effect or disease progression. The reasons for these contradictory results are unclear, but they may be due to variability in chorionic gonadotrophin preparations, which contain a mixture of biological contaminants. A cytotoxic ribonuclease and the degradation product of the β-hCG subunit have been proposed as active contaminants against Kaposi's sarcoma, but other contaminants may stimulate the tumour.[10] Other lines of investigation include the use of sulfated polysaccharide peptidoglycans, imatinib, other inhibitors of angiogenesis including thalidomide, and the retinoids.[1,5-8]

SOFT-TISSUE SARCOMA. Soft-tissue sarcomas are a varied group of malignant tumours that originate from mesenchymal stem cells residing in muscle, fat, or connective tissue,[1,2] and whose subtypes vary in terms of prognosis and response to different treatments.[3] The majority of soft-tissue sarcomas occur in the limb or limb girdle; some occur within the abdomen (retroperitoneal), in the head or neck, or in the gastrointestinal tract.[4,5] Patients have a 5-year survival rate of about 50 to 60%;[4] survival in those with extremity sarcomas is better than that in patients with retroperitoneal sarcomas.[2] Tumours often metastasise to the lung; those arising in the abdomen metastasise to the liver and peritoneum.[4]

Rhabdomyosarcoma is the commonest soft-tissue sarcoma in childhood, and is thought to arise from progenitor cells for skeletal muscle. The most frequent sites are the head and neck, genito-urinary tract, and extremities. Some genetic disorders are associated with rhabdomyosarcoma.[6,7] All patients are presumed to have micrometastatic disease at diagnosis; histologically the most common types are embryonal, which occurs at an earlier age, and alveolar, which is more common in adolescents.[7]

The **gastrointestinal stromal tumours** (GISTs) are soft-tissue sarcomas arising in the gastrointestinal tract, most commonly in the stomach and small bowel.[4,8,9] Symptoms may include abdominal pain, anorexia, weight loss, haemorrhage, changes in bowel movements, bowel obstruction, or perforation. Patients with liver metastases may have oedema of the lower extremity, ascites, or jaundice.[10] Spread to the lungs and other locations is seen only in advanced cases.[4]

Surgery is the primary **therapy** for soft-tissue sarcomas,[1,2,4,8] and may be curative for localised disease.[5,11] Radiotherapy, as external-beam therapy or brachytherapy, may be given with surgery, or alone if surgery is inappropriate or declined by the patient.[5] Radiation may be given pre-operatively, during surgery, or postoperatively;[1] optimal timing is unclear.[5,8] Similar rates of local control and progression-free survival have been reported for pre- and postoperative radiotherapy, although pre-operative treatment has been associated with a greater incidence of wound complications, especially in lower extremity tumours.[4] Postoperative radiation can cause acute and delayed bowel toxicity in those with retroperitoneal tumours, and significant toxicity has occurred with the use of brachytherapy, especially when used in the upper abdomen.[2]

Surgery and/or radiotherapy may be combined with chemotherapy. Pre-operative chemotherapy may allow for more efficient resection of the tumour.[1,8] The use of postoperative chemotherapy is controversial,[5,8] except for some tumours such as extraosseous Ewing's sarcoma or rhabdomyosarcoma. For these tumours, combinations of vincristine, dactinomycin, doxorubicin, cyclophosphamide, ifosfamide, or etoposide form the basis of most regimens.[5-8]

For those with unresectable or metastatic disease, chemotherapy may be palliative; ifosfamide and doxorubicin are routinely used in this setting.[5] These may be used as single agents or in combination; other acceptable single agent choices are dacarbazine, gemcitabine, or liposomal doxorubicin.[4] Data support the use of adjuvant doxorubicin-based chemotherapy to improve disease-free survival;[12] however, overall survival is not improved. For palliative treatment in advanced soft-tissue sarcoma, a systematic review[13] concluded that combination chemotherapy did not significantly increase survival rates compared with single-agent doxorubicin. A retrospective analysis[14] found that, in patients with high-risk disease, clinical benefits of doxorubicin-based chemotherapy were not sustained beyond 1 year. There is no consensus on the best second-line chemotherapy regimen for patients with metastatic disease refractory to doxorubicin- or ifosfamide-based regimens.[2,3] Dose-intensified combination regimens, with colony-stimulating factor support, have been investigated as adjuvant therapy[15] and in advanced disease;[16] although both these studies found a delay in disease progression, a beneficial effect on overall survival was only found in the former. Intensive combination chemotherapy benefited a subgroup of children with metastatic rhabdomyosarcoma and fewer than 2 unfavourable risk factors, in terms of event-free survival and overall survival. However, most patients have more than 2 risk factors; these patients should be considered for novel first-line therapies. No evidence was found for improved outcome after consolidation therapy with high-dose melphalan and autologous bone marrow or peripheral-blood stem cell rescue.[17] Response to topotecan has been reported in a study of metastatic rhabdomyosarcoma,[18] and trabectedin has shown some activity in advanced soft-tissue sarcomas.[3,5] Tasonermin and melphalan can be used together for isolated limb perfusion of unresectable soft-tissue sarcomas, but severe toxicity may limit use of this regimen. Potential salvage therapy options after failure of first-line therapy include paclitaxel, docetaxel, gemcitabine, trofosfamide, temozolomide, and various combinations thereof.[3]

Surgery is used for localised, resectable disease arising in the gastrointestinal tract, although this does not routinely cure GISTs; median time to recurrence after resection is about 2 years. Adjuvant imatinib is under investigation in this setting. Imatinib produces durable clinical benefit and objective responses in most patients with GISTS, including those with metastatic or unresectable disease. If the tumour responds to imatinib, surgical resection may be indicated. In patients with imatinib-resistant GIST, or who experience life-threatening adverse effects such as hepatotoxicity and fluid retention with imatinib, sunitinib may be considered.[4,8,9,19]

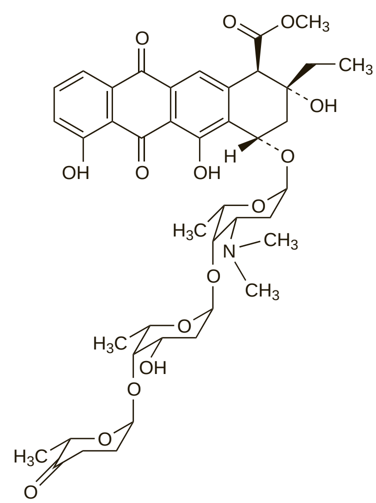
Aclarubicin *(BAN, USAN, rINN)*

Aclacinomycin A; Aclarubicina; Aclarubicine; Aclarubicinum; Aklarubicin; Aklarubisiini; Aklarubisin; NSC-208734. Methyl (1*R*,2*R*,4*S*)-4-(*O*-{2,6-dideoxy-4-*O*-[(2*R*,6*S*)-tetrahydro-6-methyl-5-oxopyran-2-yl]-α-L-*lyxo*-hexopyranosyl}-(1→4)-2,3,6-trideoxy-3-dimethylamino-L-*lyxo*-hexopyranosyloxy)-2-ethyl-1,2,3,4,6,11-hexahydro-2,5,7-trihydroxy-6,11-dioxonaphthacene-1-carboxylate.

Акларубицин

$C_{42}H_{53}NO_{15}$ = 811.9.
CAS — 57576-44-0.
ATC — L01DB04.
ATC Vet — QL01DB04.



Description. Aclarubicin is an anthracycline antineoplastic antibiotic isolated from *Streptomyces galilaeus*.

Aclarubicin Hydrochloride *(BANM, rINNM)*

Aclarubicine, Chlorhydrate d'; Aclarubicini Hydrochloridum; Hidrocloruro de aclarubicina.

Акларубицина Гидрохлорид

$C_{42}H_{53}NO_{15}$,HCl = 848.3.
CAS — 75443-99-1.
ATC — L01DB04.
ATC Vet — QL01DB04.

Pharmacopoeias. In *Jpn.*

Stability. In a study of the stability of anthracycline antineoplastic agents in 4 infusion fluids—glucose 5%, sodium chloride 0.9%, lactated Ringer's injection, and a commercial infusion fluid—stability appeared to be partly related to pH; aclarubicin was most stable in sodium chloride injection, with a pH of 6.2, and any increase or decrease in pH appeared to affect stability adversely.[1]

1. Poochikian GK, *et al*. Stability of anthracycline antitumor agents in four infusion fluids. *Am J Hosp Pharm* 1981; **38:** 483–6.

Adverse Effects, Treatment, and Precautions

As for Doxorubicin Hydrochloride, p.712. Alopecia and cardiotoxicity may be less pronounced than with doxorubicin, and extravasation of aclarubicin causes less local tissue inflammation. Bone-marrow depression is dose-limiting, with platelet counts reaching a nadir 1 to 2 weeks after dosage, while leucopenia is greatest after 2 to 3 weeks; recovery generally occurs within 4 weeks. Myelosuppression may be particularly severe in patients who have received mitomycin or a nitrosourea.

Incidence of adverse effects. An early review[1] noted that a strikingly high incidence of ECG changes had been seen with aclarubicin, but that although acute cardiotoxicity occurred, the chronic cardiomyopathy classically associated with the anthracyclines (see p.713) appeared to be rare. Alopecia was also rare, although gastrointestinal disturbances and mucositis were as common or more common than with doxorubicin.

1. Warrell RP. Aclacinomycin A: clinical development of a novel anthracycline antibiotic in the haematological cancers. *Drugs Exp Clin Res* 1986; **12:** 275–82.

Pharmacokinetics

Aclarubicin is rapidly distributed into tissues after intravenous injection. Clearance is triphasic, with a terminal elimination half-life of about 3 hours; the principal active metabolite has a terminal half-life of about 13 hours. Aclarubicin is extensively metabolised and only about 1% of the total dose is eliminated unchanged. It is excreted in urine, chiefly as metabolites; some is also eliminated in bile.

Uses and Administration

Aclarubicin is an anthracycline antibiotic with antineoplastic actions similar to those of the other anthracyclines (see Doxorubicin Hydrochloride, p.714), although it inhibits RNA synthesis more strongly than DNA synthesis. It has been used as the hydrochloride in the treatment of malignant blood disorders, such as acute myeloid leukaemia (p.652). Aclarubicin hydrochloride 104 mg is equivalent to about 100 mg of aclarubicin. The usual initial dose as a single agent has been the equivalent of 175 to 300 mg/m^2 of aclarubicin, divided over 3 to 7 consecutive days, as intravenous infusions over 30 to 60 minutes. Where appropriate and tolerated, maintenance doses of the equivalent of 25 to 100 mg/m^2 may be given as a single infusion every 3 to 4 weeks. The total dose that can be given over the patient's life-time depends upon cardiological status but most patients have not received more than 400 mg/m^2. Dosages may need to be reduced when given as part of a combination regimen.

◊ An early review of studies in patients with relapsed acute myeloid leukaemia confirmed the activity of aclarubicin, with reported complete remission rates of the order of 12 to 24%.[1] Doses varied from 10 to 30 mg/m^2 daily to higher doses of 75 to 120 mg/m^2 for 2 to 4 days; in general a total dose of about 300 mg/m^2 appeared to be necessary to induce remission. Less information was available concerning activity in acute lymphoblastic leukaemia, but response rates were lower than those in acute myeloid leukaemia. Results in the malignant lymphomas were generally disappointing.

Longer-term follow-up has confirmed that remission rates and survival are similar for induction regimens in acute myeloid leukaemia using either aclarubicin or daunorubicin.[2,3]

Alemtuzumab *(BAN, rINN)*

Alemtutsumabi; Alemtuzumabum; Campath-1; Campath-1H. Immunoglobulin G 1 (human-rat monoclonal CAMPATH-1H γ1-chain antihuman antigen CD52), disulfide with human-rat monoclonal CAMPATH-1H light chain, dimer.

Алемтузумаб

CAS — 216503-57-0.
ATC — L01XC04.
ATC Vet — QL01XC04.

NOTE. The name FluCam has been used for a regimen of alemtuzumab with fludarabine. Distinguish from Flucam, which is ampiroxicam (p.19).

Adverse Effects, Treatment, and Precautions

For general discussions, see Antineoplastics, p.635, p.639, and p.641.

Alemtuzumab commonly causes bone marrow depression, which may be severe and prolonged; fatalities have occurred. Auto-immune anaemia and auto-immune thrombocytopenia and haemolytic anaemia have been reported less commonly; however, fatalities have been reported. Single doses greater than 30 mg, or cumulative weekly doses greater than 90 mg should not be used, because of the increased incidence of pancytopenia. Complete blood and platelet counts should be measured weekly during alemtuzumab therapy, and more frequently if anaemia, neutropenia, or thrombocytopenia occur. Treatment should be interrupted if severe myelosuppression or evidence of haematological toxicity are seen and stopped permanently if auto-immune anaemia or auto-immune thrombocytopenia develops. Lymphopenia may be profound with alemtuzumab therapy, and opportunistic infections are common, and occasionally life-threatening. Antimicrobial prophylaxis is recommended from the start of therapy until after completion; if serious infection occurs, treatment should be interrupted. Recovery of lymphocyte counts may take 6 months or longer after stopping treatment.

Alemtuzumab commonly causes an acute cytokine release syndrome. The reaction usually includes rigors, fever, nausea and vomiting, hypotension, rash, urticaria, pruritus, shortness of breath, headache, and diarrhoea. Rarer, more serious reactions may include bronchospasm, syncope, pulmonary infiltrates, acute respiratory distress syndrome, respiratory arrest, myocardial infarction, and cardiac arrest. Cardiac adverse effects have been fatal in some instances. These infusion-related reactions are most common at the start of therapy: the dose must be increased gradually when beginning treatment, or if it is interrupted for 7 days or more. Pre-medication with an oral or intravenous corticosteroid, oral antihistamine, and analgesic should also be used, particularly before the first dose, and with dose increases. If acute infusion reactions persist, the infusion time may be extended to 8 hours from the time of reconstitution.

Other adverse effects include fatigue, anorexia, asthenia, malaise, arthralgia, myalgia, bone pain, back pain, chest pain, hypertension, cyanosis, and bradycardia or tachycardia. Localised oedema, stomatitis, mucositis, and abdominal pain have been reported, as have dizziness, paraesthesia, tremor, and taste loss. Confusion, insomnia or somnolence, depression, or anxiety may occur. Electrolyte disturbances include hyponatraemia and hypocalcaemia. Coughing, haemoptysis, sinusitis, bronchitis, and pharyngitis have been reported.

Alemtuzumab is contra-indicated for patients with active systemic infection, or underlying immunodeficiency.

Infection. Reactivation of hepatitis B[1] and CMV[2] has been reported with the use of alemtuzumab. Patients who have been pretreated with purine analogues or those with advanced disease and not responding to alemtuzumab therapy appear to be at highest risk for infectious complications. Recommendations for screening and prophylaxis[3] and guidelines for management[4] have been published. Six infection-related deaths have been reported[5] after previously untreated patients with B-cell chronic lymphocytic leukaemia were treated with fludarabine and rituximab, followed by alemtuzumab. These deaths may have resulted from a prolonged period of immunosuppression due to the sequencing of these drugs without sufficient recovery time. In the EU, alemtuzumab is licensed for use in patients for whom fludarabine combination chemotherapy is not appropriate.

Important safety information: six infection-related deaths reported after treatment with MabCampath (alemtuzumab) following Fludarabine+Rituximab induction in patients with B-Cell Chronic Lymphocytic Leukemia (CLL) (issued 11th February 2008). Available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON014104&RevisionSelectionMethod=Latest (accessed 12/05/08)

Interactions

There are no formal interaction studies with alemtuzumab; however, it is recommended that it should not be given within 3 weeks of other chemotherapy drugs, and that patients should not receive live viral vaccines for at least 12 months after receiving alemtuzumab.

Pharmacokinetics

In patients with B-cell chronic lymphocytic leukaemia, distribution of alemtuzumab is mainly to the extracellular fluid and plasma. Over 12 weeks, clearance has been found to decrease with repeated dosing, with consequent accumulation in plasma, and the rate of elimination to approach zero-order kinetics. The half-life is reported to be 8 hours after a first dose of 30 mg, and 6 days after the last 30 mg dose. Steady-state concentrations are reached after about 6 weeks of therapy.

Uses and Administration

Alemtuzumab is a humanised derivative of campath-1G, a rat monoclonal antibody to the CD52 antigen found on lymphocytes. Alemtuzumab is used in the treatment of B-cell chronic lymphocytic leukaemia (p.653). The dose of alemtuzumab must be increased gradually to avoid infusion-related reactions (see above). Alemtuzumab should be diluted in 100 mL sodium chloride 0.9% or glucose 5%. The initial dose is 3 mg daily, given as an intravenous infusion over 2 hours (it may be increased up to 8 hours in some patients, see above). This dose should be repeated daily until it is tolerated; the dose should then be increased to 10 mg daily. When this dose is tolerated, the maintenance dose of 30 mg can be started; this dose escalation usually takes 3 to 7 days. A maximum maintenance dose of 30 mg given three times weekly on alternate days can then be used for up to 12 weeks. The dose should be modified according to haematological toxicity.

Alemtuzumab is under investigation for induction therapy in transplantation (see Organ and Tissue Transplantation, p.1810, *et seq*). It is also under investigation for the treatment of multiple sclerosis.

Administration. Subcutaneous use of alemtuzumab has been investigated as a means of reducing adverse infusion reactions associated with intravenous dosage. Studies have found it to be safe and effective.[1,2] Similar blood concentrations are achieved to those after intravenous use, although accumulation in the blood took longer to achieve with subcutaneous use, and higher cumulative doses were required.[3] Prolonged treatment with subcutaneous low-dose alemtuzumab (10 mg three times weekly for 18 weeks) has been reported to be as effective as intravenous infusion in patients with chronic lymphocytic leukaemia and a poor prognosis.[4]

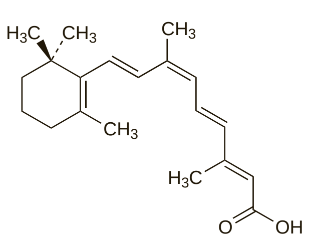
Alitretinoin *(BAN, USAN, rINN)*

AGN-192013; Alitretinoiini; Alitretinoína; Alitrétinoïne; Alitretinoinum; ALRT-1057; BAL-4079; LG-100057; LGD-1057; NSC-659772; 9-*cis*-Retinoic Acid. (2*E*,4*E*,6*Z*,8*E*)-3,7-Dimethyl-9-(2,6,6-trimethyl-1-cyclohexen-1-yl)-2,4,6,8-nonatetraenoic acid.

Алитретиноин

$C_{20}H_{28}O_2$ = 300.4.
CAS — 5300-03-8.
ATC — L01XX22.
ATC Vet — QL01XX22.



Adverse Effects and Precautions

Local skin toxicity may occur with topical application of alitretinoin, in particular erythema and oedema, and in some patients this may be dose-limiting. Pain, paraesthesia, rashes, pruritus, exfoliative dermatitis, and other skin disorders may also occur locally. Lymphadenopathy, phlebitis, cellulitis, and bacterial infections have been reported. Alitretinoin may have a weak photosensitising effect, and patients should minimise exposure of treated areas to sunlight or other ultraviolet light during therapy.

Interactions

Use of products containing diethyltoluamide is not recommended during alitretinoin therapy, as *animal* studies indicate an increase in diethyltoluamide toxicity with concurrent use.

Pharmacokinetics

Systemic absorption of topical alitretinoin is not considered to be extensive. *In-vivo* studies of oral doses indicate that alitretinoin is metabolised to 4-oxo-9-*cis*-retinoic acid.

Uses and Administration

Alitretinoin is a retinoid related to tretinoin (p.1618). It is used topically, as a 0.1% gel, in the management of cutaneous lesions in patients with AIDS-related Kaposi's sarcoma (p.675). It is applied directly to the lesions twice daily, increasing to up to 4 times daily if tolerated. Doses should be increased at intervals of at least 2 weeks. If local toxicity occurs, application frequency should be reduced, or treatment temporarily stopped, until the symptoms subside. EU licensed product information states that if no response is seen after 12 weeks, therapy should be stopped; however, US licensed product information states that some patients have required over 14 weeks to respond. Treatment may be continued as long as the patient responds. Oral formulations of alitretinoin are under investigation for the treatment of chronic hand dermatitis refractory to topical corticosteroids.

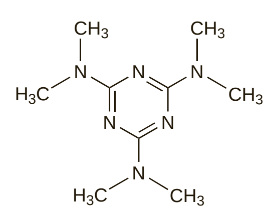
Altretamine *(BAN, USAN, rINN)*

Altretamiini; Altretamin; Altretamina; Altrétamine; Altretaminum; Hexamethylmelamine; HMM; NSC-13875; WR-95704. 2,4,6-Tris(dimethylamino)-1,3,5-triazine; N^2,N^2,N^4,N^4,N^6,N^6-Hexamethyl-1,3,5-triazine-2,4,6-triamine.

Альтретамин

$C_9H_{18}N_6$ = 210.3.
CAS — 645-05-6.
ATC — L01XX03.
ATC Vet — QL01XX03.



Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Altretamine). A white crystalline powder. Insoluble in water; soluble in chloroform. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

For a general outline see Antineoplastics, p.635, p.639, and p.641.

Bone-marrow depression is usually moderate, manifesting as leucopenia, thrombocytopenia, and anaemia, and may require dosage reduction; blood counts should be monitored regularly. Nausea and vomiting are common and usually moderate although they may be dose-limiting. Prolonged or high-dose therapy may be associated with neurotoxicity, both peripheral (neuropathies) and central (ataxia, depression, confusion, drowsiness, and hallucinations); neurological examination should be performed regularly and treatment interrupted or the dose reduced as appropriate. Renal toxicity may also be dose-limiting. Other rare adverse effects include rashes, alopecia, and hepatic toxicity.

Handling. Altretamine is irritant; avoid contact with skin and mucous membranes.

Interactions

For a general outline of antineoplastic drug interactions, see p.642. Pyridoxine appears to reduce the activity of altretamine.

Antidepressants. Severe and potentially life-threatening orthostatic hypotension developed in 3 patients who took *amitriptyline* or *imipramine* with altretamine and in a fourth patient who took *phenelzine* and altretamine.[1] One patient was able to tolerate the antineoplastic with *nortriptyline.*

1. Bruckner HW, Schleifer SJ. Orthostatic hypotension as a complication of hexamethylmelamine antidepressant interaction. *Cancer Treat Rep* 1983; **67:** 516.

Pharmacokinetics

Altretamine is well absorbed from the gastrointestinal tract after oral doses, but is rapidly demethylated in the liver producing variation in plasma-altretamine concentrations. The principal metabolites are pentamethylmelamine and tetramethylmelamine, which are excreted in urine. The elimination half-life has been reported to be 4 to 10 hours.

◊ References.

1. Damia G, D'Incalci M. Clinical pharmacokinetics of altretamine. *Clin Pharmacokinet* 1995; **28:** 439–48.

Uses and Administration

Altretamine is an antineoplastic agent structurally similar to the alkylating agent tretamine (triethylenemelamine) although its mode of action may be different. It is given orally and is licensed for use as a single agent in the palliative treatment of ovarian carcinoma (p.670). Altretamine has also been tried in lung cancer. The usual dose as a single agent in ovarian cancer is 260 mg/m^2 daily in four divided doses, for 14 or 21 consecutive days out of a 28-day cycle. Up to 12 cycles may be given. Therapy should be interrupted for at least 14 days, and subsequently restarted at a lower dose of 200 mg/m^2 daily, if the white cell count falls below 2000 cells/mm^3 or the platelet count below 75 000 cells/mm^3 or if neurotoxic or intolerable gastrointestinal symptoms occur. Lower doses are also used in combination regimens.

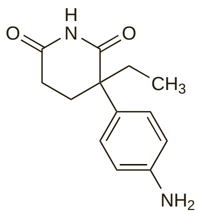
ATC Vet — QL02BG01.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US*.

Ph. Eur. 6.2 (Aminoglutethimide). A white or slightly yellow, crystalline powder. Practically insoluble in water; freely soluble in acetone; soluble in methyl alcohol.

USP 31 (Aminoglutethimide). A white or creamy-white, fine, crystalline powder. Very slightly soluble in water; readily soluble in most organic solvents. It forms water-soluble salts with strong acids. The pH of a 0.1% solution in dilute methyl alcohol (1 in 20) is between 6.2 and 7.3.

Adverse Effects

The most frequent adverse effects reported with aminoglutethimide include drowsiness, lethargy, and skin rashes (sometimes with fever); these generally diminish after the first 6 weeks of therapy. Dizziness and nausea occasionally occur. Leucopenia, thrombocytopenia, agranulocytosis, or severe pancytopenia have occurred rarely. Adrenal insufficiency may rarely occur, and there have been reports of other endocrine disturbances including hypothyroidism, and virilisation. Other rare effects include ataxia, headache, depression, gastrointestinal disturbances, hypercholesterolaemia, and orthostatic hypotension.

Overdosage may lead to CNS depression and impairment of consciousness, electrolyte disturbances, and respiratory depression.

Effects on the liver. Aminoglutethimide has been associated with reports of cholestatic jaundice, accompanied by rash[1,2] and fever,[2] and probably due to an idiosyncratic hypersensitivity reaction.[1] It has been suggested that liver function tests should be carried out in patients receiving aminoglutethimide who develop fever and eruptions.[2]

1. Gerber SB, Miller KB. Cholestatic jaundice and aminoglutethimide. *Ann Intern Med* 1982; **97:** 138.
2. Perrault DJ, Domovitch E. Aminoglutethimide and cholestasis. *Ann Intern Med* 1984; **100:** 160.

Effects on the lungs. Pulmonary infiltrates in a patient who developed progressive dyspnoea on starting therapy with aminoglutethimide were found to be due to diffuse alveolar damage and haemorrhage; thrombocytopenia was present but prothrombin and bleeding times were normal. The patient's gas exchange and chest radiographs improved on stopping aminoglutethimide and giving corticosteroids.[1] Blood and pulmonary eosinophilia, which resolved on stopping aminoglutethimide therapy, has also been reported.[2]

1. Rodman DM, *et al.* Aminoglutethimide, alveolar damage, and hemorrhage. *Ann Intern Med* 1986; **105:** 633.
2. Bell SC, Anderson EG. Pulmonary eosinophilia associated with aminoglutethimide. *Aust N Z J Med* 1998; **28:** 670–1.

Lupus. SLE occurred in a patient who received aminoglutethimide, and resolved when the drug was withdrawn.[1] In another report, however, a patient with a lupus-like syndrome had a reduction in disease activity when tamoxifen therapy was changed to aminoglutethimide.[2]

1. McCraken M, *et al.* Systemic lupus erythematosus induced by aminoglutethimide. *BMJ* 1980; **281:** 1254.
2. Etherington J, *et al.* Effect of aminoglutethimide on the activity of a case of a connective tissue disorder with features of systemic lupus erythematosus. *Lupus* 1993; **2:** 387.

Precautions

Aminoglutethimide inhibits adrenal steroid production so supplementary glucocorticoid therapy with hydrocortisone must normally be given, although supplementation may not be necessary in patients with Cushing's syndrome. Some patients also require a mineralocorticoid. It has been suggested that aminoglutethimide should be temporarily withdrawn in patients who undergo shock or trauma, or develop intercurrent infection.

Blood pressure, blood counts, and serum electrolytes should be regularly monitored during aminoglutethimide therapy and periodic monitoring of liver and thyroid function is recommended.

Aminoglutethimide should not be given during pregnancy as pseudohermaphroditism may occur in the fetus.

Aminoglutethimide frequently causes drowsiness: patients so affected should not drive or operate machinery.

Porphyria. Aminoglutethimide has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

The rate of metabolism of some drugs is increased by aminoglutethimide; patients also taking warfarin or other coumarin anticoagulants, theophylline, tamoxifen, medroxyprogesterone, or oral hypoglycaemics, may require increased dosages of these drugs. The metabolism of dexamethasone is also accelerated, which limits its value for corticosteroid supplementation in patients receiving aminoglutethimide. Use with diuretics may lead to hyponatraemia, while alcohol may potentiate the central effects of aminoglutethimide.

◊ See also references to aminoglutethimide's interactions with *digitoxin* (p.1259), *theophylline* (p.1144), *progestogens* (p.2126), *tamoxifen* (see Antineoplastics, p.774), and *anticoagulants* (under Warfarin, p.1429).

Pharmacokinetics

Aminoglutethimide is well absorbed after oral doses, with peak plasma concentrations occurring after 1 to 4 hours. It is metabolised in the liver, primarily to *N*-hydroxylaminoglutethimide and *N*-acetylaminoglutethimide, and appears to induce its own metabolism. The half-life, which is reported to be about 13 hours after a single dose, is decreased to around 9 hours after about 2 weeks of continuous therapy. Aminoglutethimide is excreted in urine, about half a dose being excreted unchanged and the remainder as metabolites. Only about 20 to 25% of a dose is bound to plasma protein.

Half-life. A study in 17 patients showed that the plasma half-life of aminoglutethimide had a mean value of 15.5 hours after single doses but fell to 8.9 hours during multiple-dose therapy.[1] This marked reduction could largely be attributed to a decrease in the volume of distribution; auto-induction of metabolism might be of less importance in decreasing half-life than had been previously suggested.

1. Lønning PE, *et al.* Single-dose and steady-state pharmacokinetics of aminoglutethimide. *Clin Pharmacokinet* 1985; **10:** 353–64.

Uses and Administration

Aminoglutethimide is an analogue of glutethimide (p.1000) and was formerly used for its weak anticonvulsant properties. Aminoglutethimide blocks the production of adrenal steroids and acts as an aromatase inhibitor to block the conversion of androgens to oestrogens (the major source of oestrogens in women without ovarian function). It was used in the treatment of metastatic breast cancer (p.661) in postmenopausal or oophorectomised women and as palliative treatment in men with advanced prostatic cancer (p.671).

Aminoglutethimide has also been used in the treatment of Cushing's syndrome (p.2344). Usual oral doses range from 1 to 2 g daily, in divided doses.

The *dextro*-isomer of aminoglutethimide, dexaminoglutethimide has been investigated.

Preparations

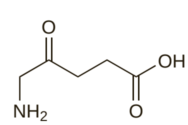
5-Aminolevulinic Acid

ALA; 5-ALA; δ-Aminolaevulinic Acid; 5-Aminolaevulinic Acid; 5-Aminolevulínico, ácido. 5-Amino-4-oxopentanoic acid.

$C_5H_9NO_3$ = 131.1.
CAS — 106-60-5.
ATC — L01XD04.
ATC Vet — QL01XD04.



Aminolevulinic Acid Hydrochloride *(USAN)*

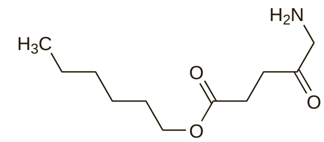
Aminolaevulinic Acid Hydrochloride; Aminolevulínico, hidrocloruro ácido. 5-Aminolevulinic acid hydrochloride.

$C_5H_9NO_3$, HCl = 167.6.
CAS — 5451-09-2.
ATC — L01XD04.
ATC Vet — QL01XD04.

Hexaminolevulinate Hydrochloride *(USAN)*

P-1026. Hexyl 5-amino-4-oxopentanoate hydrochloride.

$C_{11}H_{21}NO_3$,HCl = 251.8.
CAS — 140898-91-5.



(hexaminolevulinate)

Methyl Aminolevulinate Hydrochloride *(USAN)*

Methyl Aminolaevulinate Hydrochloride; Metilaminolevulinato, hidrocloruro de; P-1202. Methyl 5-amino-4-oxopentanoate hydrochloride.

$C_6H_{11}NO_3$,HCl = 181.6.
CAS — 79416-27-6.
ATC — L01XD03.
ATC Vet — QL01XD03.

Adverse Effects and Precautions

The mechanism of action of topical 5-aminolevulinic acid or its derivatives generally results in local phototoxicity, manifest as a localised burning or stinging sensation, erythema, oedema, pruritus, scabbing, or pain. Symptoms are usually mild to moderate, and transient. During treatment, patients should be advised to avoid sunlight or prolonged exposure to bright light.

Other common adverse effects on the skin include scaling or crusting, ulceration, suppuration, blistering, bleeding, sensation of heat, erosion or exfoliation, and skin infection. Urticaria, rash, and changes in skin pigmentation may also occur. Application site discharge, eczema, and allergic contact dermatitis have been reported. Other common adverse effects include paraesthesia and headache. Nausea, fatigue, eye swelling or eye pain, and wound haemorrhage have been reported.

Handling. US licensed product information warns that nitrile gloves should be worn during application and removal of methyl aminolevulinate hydrochloride cream; vinyl or latex gloves do not provide adequate protection.

Hypersensitivity. Allergic reactions to aminolevulinic acid[1] and methyl aminolevulinate[2] have been reported.

1. Gniazdowska B, *et al.* Allergic contact dermatitis from δ-aminolevulinic acid used for photodynamic therapy. *Contact Dermatitis* 1998; **38:** 348–9.
2. Wulf HC, Philipsen P. Allergic contact dermatitis to 5-aminolaevulinic acid methylester but not to 5-aminolaevulinic acid after photodynamic therapy. *Br J Dermatol* 2004; **150:** 143–5.

Porphyria. 5-Aminolevulinic acid and its derivatives are considered to be unsafe in patients with porphyria.

Interactions

Use with other known photosensitisers such as griseofulvin, thiazide diuretics, sulfonylureas, phenothiazines, sulfonamides, and tetracyclines might increase the photosensitivity reaction commonly seen with 5-aminolevulinic acid or its derivatives.

St John's wort. A patient taking St John's wort had a pronounced phototoxic reaction consisting of an erythematous rash and swelling of the face, neck, and hands, 6 hours after receiving oral aminolevulinic acid. Although both drugs have been associated with photosensitivity, the authors suggested a synergistic effect had occurred. Tests *in vitro* appeared to confirm this.[1]

1. Ladner DP, *et al.* Synergistic toxicity of δ-aminolaevulinic acid-induced protoporphyrin IX used for photodiagnosis and hypericum extract, a herbal antidepressant. *Br J Dermatol* 2001; **144:** 916–8.

Pharmacokinetics

After intravenous and oral doses of aminolevulinic acid hydrochloride equivalent to 100 mg of aminolevulinic acid, the mean half-life of aminolevulinic acid is stated to be about 0.83 hours and 0.7 hours, respectively; oral bioavailability is about 50 to 60%. *In-vitro* studies of dermal absorption found that the mean cumulative absorption of methyl aminolevulinate through healthy human skin after 24 hours was 0.26% of a dose and a skin depot containing 4.9% of the dose was formed.

◊ References.

Uses and Administration

5-Aminolevulinic acid is a naturally occurring haem precursor that is metabolised in the body to protoporphyrin IX, a photosensitiser, and then to haem. It has been formulated for topical use in photodynamic therapy (see under Porfimer Sodium, p.764). It is used to treat actinic keratoses and basal cell carcinoma (see below). Aminolevulinic acid hydrochloride is applied topically as a 20% solution in the treatment of non-hyperkeratotic actinic keratoses of the face or scalp. This is followed, 14 to 18 hours later, by illumination with blue wavelength light sufficient to supply a dose of 10 J/cm^2. Treatment may be repeated once after 8 weeks if necessary.

Methyl aminolevulinate hydrochloride is a derivative of 5-aminolevulinic acid that is applied topically for the treatment of non-hyperkeratotic, non-pigmented actinic keratoses of the face or scalp when other therapies are considered inappropriate. It is also used for the treatment of superficial and/or nodular basal cell carcinoma unsuitable for other therapies. In some countries, methyl aminolevulinate is licensed for the treatment of Bowen's disease (squamous cell carcinoma *in situ*) when surgical excision is inappropriate. A cream containing the equivalent of 16% methyl aminolevulinate is applied to the lesions and covered with an occlusive dressing. After 3 hours the cream is removed and the lesions are exposed to red wavelength light in a dose of 75 J/cm^2; exposure to the cream for more than 4 hours should be avoided. For actinic keratoses, one session of photodynamic therapy is given, and again after 3 months if necessary. For basal cell carcinoma or Bowen's disease two sessions are given a week apart.

Patients should avoid sunlight or bright light sources for about 2 days after application.

Hexaminolevulinate hydrochloride is used as a diagnostic agent for the detection of bladder cancer (p.659), and is under investigation for the photodynamic therapy of bladder cancer.

Malignant neoplasms. The use of topical aminolevulinic acid or methyl aminolevulinate in the photodynamic therapy (PDT) of *actinic keratosis* and *basal cell carcinoma* (p.673) has been reviewed.[1-5] Both aminolevulinic acid and methyl aminolevulinate are considered to be effective in clearing non-hyperkeratotic actinic keratoses of the face and scalp, with response rates comparable to topical 5-fluorouracil and cryotherapy; cosmetic response is superior to that with cryotherapy.[6,7] More than 80% of lesions cleared completely after 2 treatments with aminolevulinic acid PDT; a recurrence rate of 19% was reported over 12 months.[8] Single treatment with methyl aminolevulinate is effective for thin lesions but thicker, non-responsive lesions may benefit from repeated treatment.[9] No significant differences in efficacy were seen between PDT with aminolevulinic acid or methyl aminolevulinate in the treatment of scalp actinic keratosis.[10] Aminolevulinic acid is considered as effective as cryotherapy but with superior healing and cosmetic results for superficial basal cell carcinoma; it is less effective for nodular disease.[6] Intralesional use has been investigated to improve penetration of the photosensitiser, with good preliminary results.[11] Methyl aminolevulinate topical PDT may be preferable for difficult-to-treat basal cell carcinoma.[12,13] Aminolevulinic acid is as effective in *Bowen's disease* (squamous cell carcinoma *in situ*) as cryotherapy or 5-fluorouracil, but with fewer adverse effects.[6] Topical methyl aminolevulinate PDT was more effective and cosmetically acceptable compared with topical 5-fluorouracil for pre-malignant skin disease in a small study in organ transplant recipients.[14]

PDT using oral 5-aminolevulinic acid as the photosensitiser, at doses of 30 or 60 mg/kg, has been used to treat *Barrett's oesophagus*, which is a major risk factor for oesophageal adenocarcinoma (p.664).[15,16] A small study found similar clinical responses with low-dose (30 mg/kg) and high-dose (60 mg/kg) aminolevulinic acid protocols.[17] Good long-term results have been reported with aminolevulinic acid PDT in patients with early neoplasia or high-grade intraepithelial neoplasia.[18]

Aminolevulinic acid is also under investigation for the photodynamic detection and treatment of *brain tumours* (p.660).[19] It has also been used for the fluorescence detection of *pleural malignancies*.[20]

An intravesical solution of aminolevulinic acid has been instilled for the detection[21] and management[22] of superficial *bladder cancer* (p.659). Hexaminolevulinate is used for the diagnosis of bladder cancer, and it appears to be more effective than standard white light cystoscopy.[23-25]

A topical application of 5-aminolevulinic acid 3% has been tried in the treatment of *cervical intraepithelial neoplasia*, with poor response.[26]

Skin disorders. 5-Aminolevulinic acid has been used topically in the photodynamic therapy (PDT) of skin conditions such as psoriasis, recalcitrant viral warts, acne vulgaris, and cutaneous T-cell lymphoma.[1] Variable results have been reported with this therapy in patients with plaque psoriasis; in one study therapy was generally well-tolerated,[2] but in the other all patients reported stinging or burning during irradiation.[3] A study comparing 5-aminolevulinic acid and methyl aminolevulinate for PDT of acne found both to be equally effective, although methyl aminolevulinate seemed to be better tolerated.[4] Topical methyl aminolevulinate-based PDT has been found to be effective in the treatment of facial acne vulgaris.[5,6] PDT with 5-aminolevulinic acid has been reported to significantly improve an infected leg ulcer resistant to conventional therapies.[7] A topical 10% solution has been used with intraurethral PDT to treat condylomata acuminata.[8]

Preparations

Proprietary Preparations (details are given in Part 3)

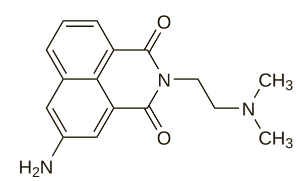
Austria: Metvix; ***Belg.:*** Metvix; ***Cz.:*** Hexvix; MC 506; Metvix; ***Denm.:*** Metvix; ***Fin.:*** Hexvix; Metvix; ***Fr.:*** Metvixia; ***Ger.:*** Metvix; ***Gr.:*** Hexvix; ***Ital.:*** Metvix; ***Neth.:*** Hexvix; Metvix; ***Norw.:*** Hexvix; Metvix; ***NZ:*** Metvix; ***Port.:*** Gliolan; Hexvix; Metvix; ***S.Afr.:*** Metvix; ***Spain:*** Metvix; ***Swed.:*** Hexvix; Metvix; ***Switz.:*** Metvix; ***UK:*** Metvix; Porphin; ***USA:*** Levulan Kerastick; Metvixia.

Amonafide *(rINN)*

Amonafida; Amonafidum; M-FA-142; Nafidimide; NSC-308847.
3-Amino-*N*-[2-(dimethylamino)ethyl]naphthalimide.

Амонафид

$C_{16}H_{17}N_3O_2$ = 283.3.
CAS — 69408-81-7.



Profile

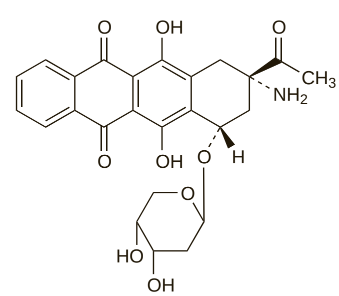
Amonafide is a topoisomerase inhibitor. Amonafide malate is under investigation for the treatment of acute myeloid leukaemia. Amonafide hydrochloride has also been investigated, but studies were stopped due to serious adverse effects.

Amrubicin *(USAN, rINN)*

Amrubicina; Amrubicine; Amrubicinum; SM-5887. (+)-(7*S*,9*S*)-9-Acetyl-9-amino-7-[(2-deoxy-β-D-*erythro*-pentopyranosyl)-oxy]-7,8,9,10-tetrahydro-6,11-dihydroxy-5,12-naphthacenedione.

Амрубицин

$C_{25}H_{25}NO_9$ = 483.5.
CAS — 110267-81-7 (amrubicin); 110311-30-3 (amrubicin hydrochloride).



Profile

Amrubicin is a synthetic anthracycline derivative related to compounds such as doxorubicin (p.712). Amrubicin hydrochloride is used as an antineoplastic in the treatment of lung cancer, and is under investigation in the treatment of superficial bladder cancers, and lymphomas.

Preparations

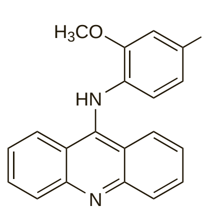
Proprietary Preparations (details are given in Part 3)
Jpn: Calsed.

Amsacrine *(BAN, USAN, pINN)*

Acridinyl Anisidide; *m*-AMSA; Amsacrina; Amsacrinum; Amsakriini; Amsakrin; CI-880; NSC-249992. 4′-(Acridin-9-ylamino)methanesulphon-*m*-anisidide.

Амсакрин

$C_{21}H_{19}N_3O_3S$ = 393.5.
CAS — 51264-14-3.
ATC — L01XX01.
ATC Vet — QL01XX01.



Incompatibility. Amsacrine is incompatible with sodium chloride 0.9% injection and with other chloride-containing solutions,[1,2] apparently because of the poor solubility of the hydrochloride salt in aqueous solution.[2] Amsacrine reacts with certain plastics.[1]

1. D'Arcy PF. Reactions and interactions in handling anticancer drugs. *Drug Intell Clin Pharm* 1983; **17:** 532–8.
2. Trissel LA, *et al.* Visual compatibility of amsacrine with selected drugs during simulated Y-site injection. *Am J Hosp Pharm* 1990; **47:** 2525–8.

Adverse Effects, Treatment, and Precautions

For a general outline see Antineoplastics, p.635, p.639, and p.641.

Bone-marrow depression is usually dose-limiting and may be severe. The nadir of the white cell count has been reported at about 12 days after treatment, with recovery usually by the 25th day. Pancytopenia and haemorrhage may develop. Nausea and vomiting (mild to moderate), stomatitis (mild to life-threatening), rashes, and alopecia may occur. Grand mal seizures, renal dysfunction, hepatotoxicity, and cardiotoxicity have also been reported. Amsacrine is irritant: there may be phlebitis and local tissue necrosis particularly when given in high concentrations.

Amsacrine should be given with caution to patients with liver or kidney disease, who may require dosage adjustments.

Interactions

For a general outline of antineoplastic drug interactions, see p.642. Use with diuretics or nephrotoxic drugs such as the aminoglycosides may theoretically increase the risk of cardiotoxicity with amsacrine by precipitating hypokalaemia.

Pharmacokinetics

Amsacrine is poorly absorbed after oral doses. When given intravenously it has a reported terminal half-life of about 5 to 8 hours. It is metabolised in the liver and excreted primarily in the bile, mostly as metabolites. It is reported to be about 98% protein bound.

Uses and Administration

Amsacrine is an antineoplastic agent that appears to act by intercalation with DNA and inhibition of nucleic acid synthesis. It may also exert an action on cell membranes. Cells in G_2 or S phases may be most sensitive to its actions.

It is used for the induction and maintenance of remission in adult acute leukaemias, particularly acute myeloid leukaemia.

Amsacrine is prepared as a solution in lactic acid and dimethylacetamide, and is given, diluted in glucose 5%, by intravenous infusion over 60 to 90 minutes.

For the induction of remission, amsacrine may be given at a dose of 90 mg/m^2 daily for 5 to 8 days, depending on clinical response. Courses may be repeated at 2- to 4-week intervals according to response, and the dose may be increased to 120 mg/m^2 daily in subsequent courses if tolerated. Maintenance doses of 150 mg/m^2 as a single dose or divided over 3 consecutive days have been given every 3 to 4 weeks, adjusted if necessary according to response.

Complete blood counts should be performed regularly, and cardiac, liver, kidney, and CNS function should be monitored.

Doses should be reduced in patients with hepatic or renal impairment (see below).

Administration in hepatic impairment. In moderate to severe hepatic impairment, dosage of amsacrine may need to be reduced by up to 50%. Some licensed product information recommends an initial reduction of 20 to 30%, to a dose between 60 and 75 mg/m^2 daily.

Administration in renal impairment. In moderate to severe renal impairment, dosage of amsacrine may need to be reduced by up to 50%. Some licensed product information recommends an initial reduction of 20 to 30%, to a dose between 60 and 75 mg/m^2 daily.

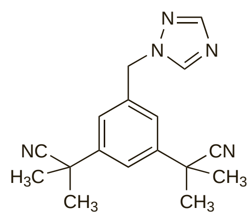
Anastrozole *(BAN, USAN, rINN)* ⊗

Anastrotsoli; Anastrozol; Anastrozolum; ICI-D1033; ZD-1033. 2,2′-Dimethyl-2,2′-[5-(1*H*-1,2,4-triazol-1-ylmethyl)-1,3-phenylene]bis(propiononitrile); α,α,α′,α′-Tetramethyl-5-(1*H*-1,2,4-triazol-1-ylmethyl)-*m*-benzenediacetonitrile.

Анастрозол

$C_{17}H_{19}N_5$ = 293.4.
CAS — 120511-73-1.
ATC — L02BG03.
ATC Vet — QL02BG03.



Adverse Effects, Treatment, and Precautions

The most frequent adverse effects are gastrointestinal disturbances including anorexia, nausea and vomiting, and diarrhoea; asthenia; hot flushes; dizziness; drowsiness; headache; and rash. Other reported effects include hair thinning, vaginal dryness or bleeding, myalgia, arthralgia, and bone fractures, Abnormalities in liver enzyme values, thromboembolism, and increases in total cholesterol, have occurred in some patients receiving anastrozole. Very rare cases of erythema multiforme, Stevens-Johnson syndrome, and allergic reactions (including angioedema, urticaria, and anaphylaxis) have occurred.

Reductions in bone mineral density can occur during use of anastrozole. Patients with or at risk of osteoporosis should therefore have their bone density assessed at the start of therapy and at regular intervals thereafter. Treatment or prophylaxis for osteoporosis should be started as appropriate and carefully monitored.

The use of anastrozole is contra-indicated in premenopausal women (particularly in pregnancy).

Effects on the liver. A case of acute hepatitis was attributed to anastrozole, 3 weeks after starting therapy.[1]

1. de la Cruz L, *et al.* Severe acute hepatitis in a patient treated with anastrozole. *Lancet* 2007; **369:** 23–4.

Effects on the musculoskeletal system. In a series of 77 postmenopausal women treated with anastrozole for metastatic breast cancer, 12 complained of joint pains within 2 months of beginning therapy. Based on this experience and the incidence of arthralgia reported during clinical studies, the authors estimated that arthralgia occurs in 10 to 15% of patients treated with anastrozole, possibly as a result of the very low oestrogen concentrations achieved.[1]

Adjuvant anastrozole therapy for postmenopausal women with early breast cancer was associated with accelerated bone loss, but the risk appeared to be confined to those with osteopenia at baseline.[2] These patients should be assessed for the risk of osteoporosis before starting therapy, and the decision to treat should be made on an individual basis.[3]

2. Eastell R, *et al.* Effect of anastrozole on bone mineral density: 5-year results from the anastrozole, tamoxifen, alone or in combination trial 18233230. *J Clin Oncol* 2008; **26:** 1051–8.
3. Chien AJ, Goss PE. Aromatase inhibitors and bone health in women with breast cancer. *J Clin Oncol* 2006; **24:** 5305–12.

Pharmacokinetics

Anastrozole is rapidly and almost completely absorbed from the gastrointestinal tract after oral doses, with peak plasma concentrations within about 2 hours. Food decreases the rate of absorption, though this is not considered clinically significant. Anastrozole is 40% bound to plasma proteins. It is metabolised in the liver, and excreted in urine, chiefly as metabolites. The terminal plasma elimination half-life is about 40 to 50 hours, and steady-state concentrations are achieved after about 7 days in patients receiving once-daily doses.

Uses and Administration

Anastrozole is a potent and selective nonsteroidal inhibitor of the aromatase (oestrogen synthetase) system, which converts adrenal androgens to oestrogens in peripheral tissue. It is used in the treatment of advanced or locally advanced breast cancer, and as adjuvant treatment in early breast cancer (p.661), in postmenopausal women in an oral dose of 1 mg daily. Responses are unlikely in patients with oestrogen receptor-negative disease. Adjuvant therapy may be continued for up to 5 years, although the optimum duration is uncertain.

Endometriosis. In a small, open-label study,[1] *oral* anastrozole 1 mg, given daily with a low-strength oral contraceptive for 6 months, reduced pelvic pain scores in women with refractory endometriosis (p.2091). Adverse effects were mild, although most patients had breakthrough bleeding, which exacerbated pain. The authors supposed that a higher dose of oral contraceptive should be considered in future studies.

In a small pilot study of patients with rectovaginal endometriosis,[2] anastrozole 250 micrograms was given *vaginally* once daily for 6 months. Dysmenorrhoea improved significantly although chronic pelvic pain was unchanged. Adverse effects were mild.

Antineoplaston A10

3-Phenylacetylamino-2,6-piperidinedione.
$C_{13}H_{14}N_2O_3$ = 246.3.

Profile

Antineoplaston A10, one of a group of peptide derivatives isolated from blood and urine, has been investigated for the treatment of breast cancer, brain stem glioma, and other malignant neoplasms although its value has been questioned (see below).

◊ A critical review of the antineoplastons[1] noted that most work had been done with antineoplaston A10, which is insoluble in aqueous solutions, and its derivatives antineoplaston AS2.5 (phenylacetylglutamine), and antineoplaston AS2.1 (a 4:1 mixture of phenylacetic acid and phenylacetylglutamine), which had not been independently shown to be active against cancer. However, some interest in the antineoplastons subsequently continued.[2-4]

AP-12009

TGF-β2 antisense oligonucleotide; Transforming growth factor-β2-specific phosphorothioate antisense oligodeoxynucleotide.

Profile

AP-12009 is an antisense oligonucleotide that specifically suppresses the production of transforming growth factor-beta-2, an immunosuppressive protein produced by tumour cells. It is under investigation for the treatment of high-grade glioma (see Malignant Neoplasms of the Brain, p.660).

AS-1411

AGRO-100.

Profile

AS-1411 is a selective oligonucleotide ligand (aptamer) that binds to the protein nucleolin, inducing apoptosis in cancer cells. It is under investigation for the treatment of renal cell carcinoma, pancreatic cancer, and acute myelogenous leukaemia.

Asparaginase *(USAN)*

Asparaginasa; L-Asparaginase; L-Asparagine Amidohydrolase; L-Asparaginaz; L-Asparaginaasi; L-Asparaginas; L-Asparaginasum; MK-965; NSC-109229; Re-82-TAD-15.
CAS — 9015-68-3.
ATC — L01XX02.
ATC Vet — QL01XX02.

NOTE. Asparaginase (*USAN*) is an enzyme isolated from *Escherichia coli*, or obtained from other sources. See also Colaspase and Crisantaspase, below.

Incompatibility. Asparaginase is incompatible with rubber. Licensed product information recommends that it should not be mixed with other drugs.

Storage. Asparaginase should be stored at 2° to 8° (see also Stability, below).

Colaspase *(BAN)*

CAS — 9015-68-3.
ATC — L01XX02.
ATC Vet — QL01XX02.

NOTE. Colaspase (*BAN*) is asparaginase obtained from selected strains of *Escherichia coli*, such as ATCC 9637.

Pharmacopoeias. *Chin.* includes Asparaginase obtained from *Escherichia coli* ASI 357.

Crisantaspase *(BAN)*

Crisantaspasum; Erwinia L-asparaginase; Krisantaspaasi; Krisantaspas.
CAS — 9015-68-3.
ATC — L01XX02.
ATC Vet — QL01XX02.

NOTE. Crisantaspase (*BAN*) is asparaginase obtained from cultures of *Erwinia chrysanthemi* (*E. carotovora*).

Pegaspargase *(USAN, rINN)*

PEG-L-asparaginase; Pegaspargasa; Pégaspargase; Pegaspargasum. A conjugate of colaspase with a polyethylene glycol of molecular weight 5000; Monomethoxypolyethylene glycol succinimidyl L-asparaginase.
Пэгаспаргаза
CAS — 130167-69-0.
ATC — L01XX24.
ATC Vet — QL01XX24.

Stability. Although asparaginase was routinely kept under refrigeration,[1] information from a manufacturer (*Merck Sharp & Dohme*) indicated that it would remain stable for 48 hours at 15° to 30°. Licensed product information for pegaspargase states it should not be used if stored at room temperature for more than 48 hours.

1. Vogenberg FR, Souney PF. Stability guidelines for routinely refrigerated drug products. *Am J Hosp Pharm* 1983; **40:** 101–2.

Storage. Pegaspargase should be stored at 2° to 8°.

Units

One international unit of asparaginase splits 1 micromole of ammonia from L-asparagine in 1 minute under standard conditions.

Adverse Effects

Asparaginase is a protein and may produce anaphylaxis and other hypersensitivity reactions including fever, rashes, and bronchospasm; there does not appear to be cross-sensitivity between asparaginase derived from *Escherichia coli* and that from *Erwinia chrysanthemi*. Hypersensitivity to pegaspargase is less common, but about 30% of patients hypersensitive to the native enzyme experience hypersensitivity to pegaspargase treatment.

Liver function abnormalities occur in many patients, and there may be decreased blood concentrations of fibrinogen and clotting factors, alterations in blood lipids and cholesterol, and hypoalbuminaemia. Hyperammonaemia, due to the production of ammonia from asparagine, may occur. Uraemia, and occasionally renal failure, have been reported. Pancreatitis may occur and may be fatal: there may also be hyperglycaemia due to decreased insulin production, and death from ketoacidosis has occurred.

Gastrointestinal disturbances, including nausea and vomiting, and CNS disturbances, including drowsiness, depression, coma, hallucinations, and a Parkinson-like syndrome, have also been reported. Transient bone-marrow depression has occurred rarely, as has marked leucopenia.

Effects on the blood. Central thrombosis or intracranial haemorrhage as well as peripheral thrombosis and haemorrhage have been reported after asparaginase therapy.[1-4] Although the precise mechanism for this effect remains unclear, asparaginase appears to deplete certain clotting factors as well as antithrombin III, plasminogen, and fibrinogen.[4] These decreases may be dependent on the formulation and resultant asparaginase activity of preparations,[5] and there is some suggestion that crisantaspase may affect coagulation factors less severely than colaspase.[6] A multicentre, retrospective survey[3] of paediatric patients with acute lymphoblastic leukaemia found that use of corticosteroids with colaspase may be an additional risk factor for thromboembolic events.

Precautions

Asparaginase is contra-indicated in patients with pancreatitis, and should be avoided in pregnancy. It should be given cautiously to patients with hepatic impairment. Facilities for the management of anaphylaxis (see p.1205) should be available during treatment. Some manufacturers recommend an intradermal test dose at the start of asparaginase treatment to check for hypersensitivity, as described under Uses, below, although such tests may not always be predictive. Retreatment with asparaginase may be associated with an increased risk of allergic reactions. Serum amylase concentrations should be monitored regularly as should blood glucose concentrations. Asparaginase has been reported to interfere with tests of thyroid function by transient reduction of concentrations of thyroxine-binding globulin.

Interactions

If asparaginase is given before, rather than after, methotrexate the activity of the latter may be reduced (see below). Vincristine neurotoxicity may possibly be increased by use with intravenous asparaginase (see p.787).

Methotrexate. Asparaginase inhibits protein synthesis and cell replication, and therefore may interfere with the action of drugs such as methotrexate that require cell replication for their antineoplastic effect.[1] It has been suggested that a 24-hour interval between methotrexate and a subsequent dose of asparaginase permits at least an additive therapeutic effect.[2]

1. Jolivet J, *et al.* Prevention of methotrexate cytotoxicity by asparaginase inhibition of methotrexate polyglutamate formation. *Cancer Res* 1985; **45:** 217–20.
2. Capizzi RL. Asparaginase-methotrexate in combination chemotherapy: schedule-dependent differential effects on normal versus neoplastic cells. *Cancer Treat Rep* 1981; **65** (suppl 4): 115–21.

Pharmacokinetics

After intravenous injection the plasma half-life of the native enzyme has varied from about 8 to 30 hours; half-lives of up to 49 hours may be seen after intramuscular dosage. The mean half-life of pegaspargase is reported to be between 6 and 14 days. Asparaginase is found in the lymph at about 20% of the concentration in plasma. There is virtually no diffusion into the CSF. Little is excreted in the urine.

Uses and Administration

Asparaginase is an enzyme that acts by breaking down the amino acid L-asparagine to aspartic acid and ammonia. It interferes with the growth of those malignant cells which, unlike most healthy cells, are unable to synthesise L-asparagine for their metabolism, but resistance to its action develops fairly rapidly. Its action is reportedly specific for the G_1 phase of the cell cycle.

Asparaginase is used mainly for the induction of remissions in acute lymphoblastic leukaemia (p.651). Regimens vary, and dosage should follow local protocols, but it may be given intravenously in a dose of 1000 units/kg daily for 10 days after treatment with vincristine and prednisone or prednisolone, or intramuscularly in a dose of 6000 units/m^2 given every third day for 9 doses during treatment with vincristine and prednisone or prednisolone. Alternatively it may be given as pegaspargase, in doses of 2500 units/m^2 every 14 days, preferably by intramuscular injection although the intravenous route may also be used.

Asparaginase is not generally used alone as an induction agent but doses of 200 units/kg daily have been given intravenously for 28 days to adults and children. If pegaspargase is used alone doses are the same as for combination regimens. Children appear to tolerate asparaginase better than adults.

Although not entirely reliable, an intradermal test dose of about 2 units has been recommended in the USA, to test for hypersensitivity, before treatment with colaspase or where more than a week has elapsed between doses. Desensitisation has been advocated if no alternative antineoplastic treatment is available. Anaphylaxis with crisantaspase is stated to be rare; however, in the UK if there has been an interruption in treatment, therapy should be resumed with a low dose of 10 units/kg daily and increased to the full dose over 5 days if tolerated. A test dose is not advocated, although reference to local leukaemia protocols is recommended. The incidence of hypersensitivity is also lower in patients given pegaspargase, and again a test dose is not advocated. Pegaspargase has been successfully used in patients hypersensitive to the native enzyme.

For intravenous use a solution of asparaginase in Water for Injections or sodium chloride 0.9% should be given over not less than 30 minutes through a running infusion of sodium chloride 0.9% or glucose 5%. When given intramuscularly no more than 2 mL of a solution in sodium chloride 0.9% should be injected at a single site.

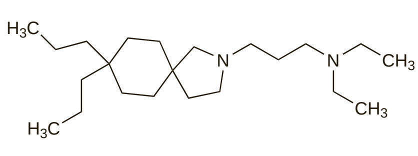
Atiprimod *(rINN)*

Atiprimodum. 2-[3-(Diethylamino)propyl]-8,8-dipropyl-2-azaspiro[4.5]decane.

Атипримод

$C_{22}H_{44}N_2$ = 336.6.

CAS — 123018-47-3 (atiprimod); 130065-61-1 (atiprimod hydrochloride); 183063-72-1 (atiprimod maleate).



Profile

Atiprimod is an antineoplastic that is under investigation for the treatment of carcinoid tumours and multiple myeloma.

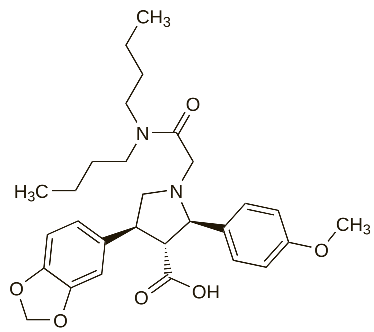
Atrasentan Hydrochloride *(USAN, rINNM)*

A-147627.1; Abbott-147627; ABT-627; Atrasentan, Chlorhydrate d'; Atrasentani Hydrochloridum; Hidrocloruro de atrasentán. (2*R*,3*R*,4*S*)-1-[(Dibutylcarbamoyl)methyl]-2-(*p*-methoxyphenyl)-4-[3,4-(methylenedioxy)phenyl]-3-pyrrolidinecarboxylic acid hydrochloride.

Атразентана Гидрохлорид

$C_{29}H_{38}N_2O_6$,HCl = 547.1.

CAS — 173937-91-2 (atrasentan); 195733-43-8 (atrasentan hydrochloride).



(atrasentan)

Profile

Atrasentan hydrochloride is a selective endothelin-A receptor antagonist that inhibits the effect of endothelin-1, a protein that may be involved in cancer progression. It is under investigation in the treatment of prostate cancer, and has been tried in other malignant neoplasms.

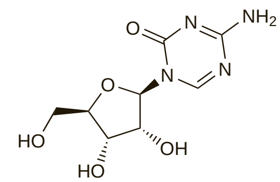
Azacitidine *(USAN, rINN)*

Azacitidina; 5-Azacitidina; Azacitidinum; 5-Azacytidine; Ladakamycin; NSC-102816; U-18496. 4-Amino-1-β-D-ribofuranosyl-1,3,5-triazin-2(1*H*)-one.

Азацитидин

$C_8H_{12}N_4O_5$ = 244.2.

CAS — 320-67-2.



Adverse Effects and Precautions

The adverse effects of azacitidine are generally similar to those seen with cytarabine (p.705). Hypokalaemia, dyspnoea, and bruising are common.

Pharmacokinetics

Azacitidine is rapidly absorbed after subcutaneous use; the bioavailability relative to intravenous use is about 89%. The mean plasma half-life after subcutaneous injection is about 40 minutes. Azacitidine and its metabolites are excreted primarily in the urine; about 50% and 85% is recovered after subcutaneous and intravenous dosing, respectively. The mean elimination half-life is about 4 hours after subcutaneous or intravenous use.

◊ References.

1. Marcucci G, *et al.* Bioavailability of azacitidine subcutaneous versus intravenous in patients with the myelodysplastic syndromes. *J Clin Pharmacol* 2005; **45:** 597–602.
2. Tsao CF, *et al.* Azacitidine pharmacokinetics in an adolescent patient with renal compromise. *J Pediatr Hematol Oncol* 2007; **29:** 330–3.

Uses and Administration

Azacitidine is an antimetabolite antineoplastic with general properties similar to those of cytarabine (p.705). It also inhibits cellular pyrimidine synthesis. Azacitidine is used in myelodysplastic syndromes (p.654); it has also been used in the treatment of acute myeloid leukaemia (p.652).

For the treatment of myelodysplastic syndromes, azacitidine is given subcutaneously or intravenously in a dose of 75 mg/m^2 daily for 7 days, in 4-week cycles. If there is no benefit after 2 cycles, and no toxicity other than nausea and vomiting has occurred, the dose may be increased to 100 mg/m^2 daily. Treatment for at least 4 cycles is usually needed.

Azacitidine should be used with caution in renal impairment and doses adjusted accordingly (see below).

8. O'Dwyer K, Maslak P. Azacitidine and the beginnings of therapeutic epigenetic modulation. *Expert Opin Pharmacother* 2008; **9:** 1981–6.

Administration in renal impairment. Adverse renal effects of azacitidine include abnormalities in renal-function tests, renal tubular acidosis, renal failure, and death. US licensed product information recommends that if serum-bicarbonate concentrations fall to below 20 mEq/litre, the dose of azacitidine should be halved for the next course. If there are rises in serum concentrations of urea or creatinine, the next cycle of azacitidine should be delayed until these return to normal or baseline, and the dose should be halved on the next treatment course.

Preparations

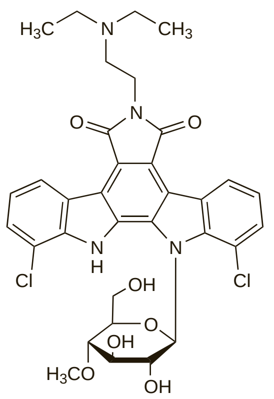
Proprietary Preparations (details are given in Part 3)
USA: Vidaza.

Becatecarin *(USAN, rINN)*

Becatecarina; Bécatécarine; Becatecarinum; BMS-181176; BMY-27557; NSC-655649; XL-119. 1,11-Dichloro-6-[2-(diethylamino)ethyl]-12-(4-*O*-methyl-β-D-glucopyranosyl)-12,13-dihydro-5*H*-indolo[2,3-*a*]pyrrolo[3,4-*c*]carbazole-5,7(6*H*)-dione.

Бекатекарин

$C_{33}H_{34}Cl_2N_4O_7$ = 669.6.
CAS — 119673-08-4.



Profile

Becatecarin is an antineoplastic under investigation in the treatment of bile-duct and other tumours.

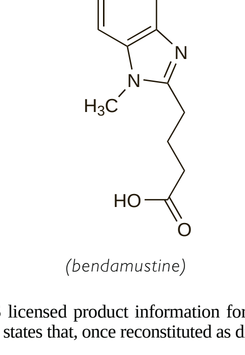
Bendamustine Hydrochloride *(USAN, rINNM)*

Bendamustine, Chlorhydrate de; Bendamustini Hydrochloridum; Hidrocloruro de bendamustina; IMET-3393; SDX-105. 5-[Bis(2-chloroethyl)amino]-1-methyl-2-benzimidazolebutyric acid hydrochloride.

Бендамустина Гидрохлорид

$C_{16}H_{21}Cl_2N_3O_2$, HCl = 394.7.
CAS — 16506-27-7 (bendamustine); 3543-75-7 (bendamustine hydrochloride).



(bendamustine)

Stability. US licensed product information for bendamustine hydrochloride states that, once reconstituted as directed and further diluted with sodium chloride 0.9%, the final infusion solution is stable for 24 hours when refrigerated (2° to 8°) or for 3 hours when stored at room temperature (15° to 30°) and exposed to light.

Adverse Effects, Treatment, and Precautions

Bendamustine commonly causes myelosuppression and doses may need to be reduced (see Uses and Administration, below); patients are therefore susceptible to infection. Other common adverse effects include gastrointestinal disturbances, fever, asthenia, fatigue, malaise, dry mouth, somnolence, cough, headache, mucosal inflammation, and stomatitis. Infusion reactions are common; symptoms include fever, chills, pruritus, and rash. Anaphylactic reactions have been reported rarely, especially during the second and subsequent cycles of therapy. Prophylactic antihistamines, antipyretics, and corticosteroids should be considered. If severe infusion reactions occur, stopping therapy should be considered. Tumour lysis syndrome has been reported, usually within the first treatment cycle, and may lead to acute renal failure and death. Adequate volume status should be maintained and potassium and uric acid concentrations should be monitored; allopurinol may be used in patients at high risk. Skin reactions such as bullous exanthema can occur with bendamustine; therapy may need to be withheld or stopped. Worsening hypertension, including hypertensive crisis, has also occurred. Increases in creatinine concentrations and liver enzyme values have been reported; bendamustine should be used with caution in patients with renal or hepatic impairment.

Interactions

Bendamustine is extensively metabolised by cytochrome P450 isoenzyme CYP1A2. Inhibitors of CYP1A2, such as fluvoxamine and ciprofloxacin, may increase exposure to bendamustine. Conversely, CYP1A2 inducers, such as omeprazole, can reduce exposure to bendamustine; tobacco smoking also may increase exposure to bendamustine.

Pharmacokinetics

Bendamustine is about 95% bound to plasma proteins; data suggest it is not likely to displace nor to be displaced by highly protein-bound drugs. Bendamustine distributes freely into human red blood cells. It is mainly metabolised by hydrolysis via the cytochrome P450 isoenzyme CYP1A2. Little or no accumulation in plasma is anticipated for intravenous doses of bendamustine given on days 1 and 2 of a 28-day cycle. About 90% of the drug is eliminated, mainly via the faeces.

Uses and Administration

Bendamustine is an antineoplastic alkylating agent. It is given intravenously as the hydrochloride for the treatment of chronic lymphocytic leukaemia (p.653); it may also be used in non-Hodgkin's lymphoma, Hodgkin's disease, multiple myeloma, and breast cancer.

For the treatment of chronic lymphocytic leukaemia, bendamustine hydrochloride is given in a dose of 100 mg/m^2, in 500 mL of sodium chloride 0.9%, infused over 30 minutes on days 1 and 2 of a 28-day cycle, for up to 6 cycles.

Doses are modified if toxicity occurs; dose delays may be warranted until neutrophils and platelets have recovered to acceptable concentrations. For severe haematological or non-haematological toxicity, doses should be reduced to 50 mg/m^2 on days 1 and 2 of each cycle. If severe haematological toxicity recurs, the dose should be further reduced to 25 mg/m^2. Dose re-escalation in subsequent cycles may be considered.

Administration in hepatic impairment. US licensed product information states that, although no meaningful effect on the pharmacokinetics of bendamustine was seen in mild hepatic impairment, data are limited, and therefore caution should be exercised when using bendamustine in these patients. Bendamustine should not be used in moderate or severe hepatic impairment due to a lack of data.

Administration in renal impairment. US licensed product information states that, although no meaningful effect on the pharmacokinetics of bendamustine was seen in renal impairment, data are limited, and therefore caution should be exercised in patients with mild or moderate renal impairment. Bendamustine should not be used in patients with creatinine clearance less than 40 mL/minute, due to a lack of data.

Preparations

Proprietary Preparations (details are given in Part 3)
Ger.: Ribomustin; ***USA:*** Treanda.

Bevacizumab *(rINN)*

Bévacizumab; Bevacizumabum; rhuMAb-VEGF. Immunoglobulin G1 (human-mouse monoclonal rhuMAb-VEGF γ-chain anti-human vascular endothelial growth factor), disulfide with human-mouse monoclonal rhuMAb-VEGF light chain, dimer.

Бевацизумаб

CAS — 216974-75-3.
ATC — L01XC07.
ATC Vet — QL01XC07.

Stability. UK licensed product information states that bevacizumab is chemically and physically stable for 48 hours at 2° to 30° in sodium chloride 0.9%, although immediate use is recommended from a microbiological point of view. If the solution is not used immediately, storage for longer than 24 hours at 2° to 8° cannot be recommended, unless dilution has taken place in controlled and validated aseptic conditions. In the USA, licensed product information states that bevacizumab solutions for infusion may be stored at 2° to 8° for up to 8 hours.

Bevacizumab should not be mixed with glucose.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

Bevacizumab may impair wound healing; therapy should not be started for at least 28 days after major surgery or until the surgical incision is fully healed; it should also be withheld before elective surgery. Gastrointestinal perforation complicated by intra-abdominal abscesses or fistula formation is more common in patients receiving bevacizumab; fatalities have been reported. Bevacizumab should be stopped permanently in patients who develop gastrointestinal perforation, or fistulas, or wound dehiscence needing medical intervention. Very rare cases of nasal septum perforation have been reported.

Leucopenia, anaemia, neutropenia, thrombocytopenia, and febrile neutropenia have also occurred; severe neutropenia with infection has caused fatalities. Haemorrhage may occur; fatal pulmonary haemorrhage presenting as haemoptysis has been reported. There is an increased risk of serious thromboembolic events associated with the use of bevacizumab including stroke, transient ischaemic attacks, myocardial infarction, angina, and death. Bevacizumab may cause congestive heart failure; the risk is higher in those patients who have concurrent or previous treatment with anthracyclines. Hypertension, possibly dose-dependent, has occurred; blood pressure should be monitored, and therapy stopped in patients who develop hypertensive crisis or hypertensive encephalopathy.

Proteinuria may develop; bevacizumab should be stopped in patients who develop nephrotic syndrome. Other adverse effects include asthenia, pain, abdominal pain, gastrointestinal disturbances, stomatitis, headache, epistaxis, dyspnoea, upper respiratory infection, and exfoliative dermatitis. Peripheral sensory neuropathy, syncope, somnolence, supraventricular tachycardia, palmar-plantar erythrodysesthesia syndrome, and muscular weakness have been commonly reported. Infusion reactions, manifesting as hypertension, wheezing, chest pain, headaches, rigors, and diaphoresis may occur rarely with the first dose of bevacizumab; treatment should be interrupted.

There have been rare reports of reversible posterior leukoencephalopathy syndrome, a neurological disorder; this may present as seizures, headache, altered mental status, visual disturbance, or cortical blindness, with or without associated hypertension. Bevacizumab therapy should be stopped, and patients treated symptomatically.

Effects on the cardiovascular system. For a discussion of the incidence of hypertension associated with use of bevacizumab, see Effects on the Kidneys, below.

Effects on the kidneys. A systematic review and subsequent meta-analysis of 7 studies in 1850 patients with various cancers estimated the incidence and risk of developing hypertension and proteinuria with bevacizumab therapy.[1] The relative risk (RR) of developing proteinuria was 1.4 with low-dose bevacizumab (95% confidence interval 1.1 to 1.7) and even higher with high-dose therapy (RR 2.2; 95% confidence interval 1.6 to 2.9). For hypertension, the RR was 3.0 for low-dose bevacizumab (95% confidence interval 2.2 to 4.2) and 7.5 for high-dose therapy (95% confidence interval 4.2 to 13.4). US licensed product information states that hypertension can persist after stopping bevacizumab; therapy should be stopped permanently in those with hypertensive crisis or hypertensive encephalopathy. (For the suggestion that hypertension is a problem with angiogenesis inhibitors in general see Effects on the Cardiovascular System in Sorafenib, p.770.) The safety of continued treatment in patients with moderate to severe proteinuria has not been evaluated; therapy should be interrupted if proteinuria is equal to or greater than 2 g per 24 hours, and may be resumed when it is less than this.

Nephrotic syndrome has also been reported with use of bevacizumab;[2,3] therapy should be stopped in these patients. In one case,[3] there was evidence of a haemolytic-uraemic syndrome; renal biopsy revealed a glomerular thrombotic microangiopathy. Bevacizumab was stopped, with favourable response; however, sunitinib therapy was started but had to be stopped due to a recurrence of severe haemolytic-uraemic syndrome.

A patient who received 3 doses of bevacizumab was diagnosed with acute renal failure secondary to interstitial nephritis. His renal function resolved slowly after stopping therapy; haemodialysis was required.[4]

4. Barakat RK, *et al.* Interstitial nephritis secondary to bevacizumab treatment in metastatic leiomyosarcoma. *Ann Pharmacother* 2007; **41:** 707–10.

Effects on the nervous system. There are reports of reversible posterior leukoencephalopathy syndrome (RPLS) attributed to bevacizumab.[1,2] Presenting symptoms included lethargy, seizures, hypertension, acute bilateral loss of vision, headache, and confusion. Recovery was rapid after symptomatic treatment.

The symptoms of RPLS may be difficult to distinguish from those of uncontrolled hypertension, and patients presenting with the above signs and symptoms should be examined neurologically.[3]

3. Health Canada. Association of AVASTIN (bevacizumab) with hypertensive encephalopathy and reversible posterior leukoencephalopathy syndrome (RPLS) (issued 24th October 2006). Available at: http://www.hc-sc.gc.ca/dhp-mps/medeff/advisories-avis/public/_2006/avastin_pc-cp-eng.php (accessed 30/07/08)

Effects on the spleen. Splenic infarction has been reported in a patient given bevacizumab, fluorouracil, folinic acid, and irinotecan. Bevacizumab was stopped. Four further chemotherapy cycles were given. The splenic infarcts partially regressed, although the patient died from metastatic progression. The authors attributed the splenic infarction to bevacizumab, which has been associated with arterial thromboembolic events.[1]

1. Malka D, *et al.* Splenic infarction and bevacizumab. *Lancet Oncol* 2006; **7:** 1038.

Fistula formation. US licensed product information for bevacizumab states that the incidence of gastrointestinal perforation, including fistula formation and/or intra-abdominal abscess, in bevacizumab-treated patients with colorectal cancer or non-small cell lung cancer was 2.4% and 0.9%, respectively. The Canadian manufacturer (*Roche, Canada*) has stated that there have been uncommon reports of other types of fistulas such as bronchopleural, urogenital, and biliary fistulas, across various indications. While cancer itself might have been a risk factor for fistula formation, a role for bevacizumab could not be excluded; most events occurred within the first 6 months of therapy.[1] There have been reports of tracheo-oesophageal fistula formation in association with use of bevacizumab, including some fatalities.[1,2] Therapy should be permanently stopped in patients with tracheo-oesophageal or gastrointestinal fistulas.

1. Roche, Canada. Health Canada endorsed important safety information on AVASTIN (bevacizumab): association of AVASTIN (bevacizumab) with tracheo-esophageal fistula (issued June 2007). Available at: http://www.hc-sc.gc.ca/dhp-mps/alt_formats/hpfb-dgpsa/pdf/medeff/avastin_hpc-cps_2_e.pdf (accessed 13/06/07)
2. Genentech, USA. Important drug warning regarding AVASTIN (bevacizumab) (issued April 2007). Available at: http://www.fda.gov/medwatch/safety/2007/Avastin_DHCP_TEF_Final_April2007.pdf (accessed 13/06/07)

Interactions

◊ The US manufacturer of bevacizumab has recommended that it should not be used with *sunitinib* after several patients receiving the combination had developed microangiopathic haemolytic anaemia.[1]

1. Genentech, USA. Important drug warning subject: microangiopathic hemolytic anemia (MAHA) in patients treated with Avastin (bevacizumab) and sunitinib malate (issued July 2008). Available at: http://www.fda.gov/medwatch/safety/2008/MAHA_DHCP.pdf (accessed 30/07/08)

Pharmacokinetics

Bevacizumab has an initial half-life of 1.4 days and a terminal half-life of about 20 days. The predicted time to steady state is about 100 days. Male patients and those with a higher tumour burden have higher clearances of bevacizumab than females and those with tumour burdens below the median, respectively; although no evidence of lesser efficacy has been seen due to this higher clearance, the relationship between exposure to bevacizumab and clinical outcome is not known.

Uses and Administration

Bevacizumab is a recombinant humanised monoclonal antibody that binds to vascular endothelial growth factor (VEGF), thereby inhibiting the angiogenesis that occurs during tumour growth. Bevacizumab is used with fluoropyrimidine-based chemotherapy in the treatment of metastatic colorectal cancer (p.665). It is also used with paclitaxel for the first-line treatment of patients with metastatic breast cancer (p.661), and with platinum-based chemotherapy in the first-line treatment of patients with unresectable, locally advanced, recurrent or metastatic, non-squamous, non-small cell lung cancer (p.668). Bevacizumab is used with interferon alfa for the first-line treatment of advanced and/or metastatic renal cell cancer (p.667).

Bevacizumab is usually given diluted in 100 mL of sodium chloride 0.9%; the final concentration should be kept within the range of 1.4 to 16.5 mg/mL. The first dose should be given as an intravenous infusion over 90 minutes; if this is well tolerated the second dose should be given over 60 minutes, and if this is well tolerated then subsequent doses may be given over 30 minutes.

In the treatment of **colorectal cancer**, bevacizumab is given in a dose of 5 or 10 mg/kg once every 2 weeks, or 7.5 or 15 mg/kg once every 3 weeks; doses depend on the combination of drugs used in the regimen.

For **breast cancer**, the recommended dose of bevacizumab is 10 mg/kg given once every 2 weeks, or 15 mg/kg given once every 3 weeks.

For **non-small cell lung cancer**, the recommended dose of bevacizumab is 7.5 or 15 mg/kg given once every 3 weeks. In the UK, combination therapy is given for up to 6 cycles, followed by bevacizumab monotherapy until disease progression.

For **renal cell carcinoma**, bevacizumab is given in a dose of 10 mg/kg once every 2 weeks.

There are no recommended dose reduction regimens should adverse effects occur with bevacizumab; therapy should either be permanently stopped or temporarily suspended.

Bevacizumab is under investigation for various other neoplasms, such as head and neck, ovarian, and prostate cancer. A related monoclonal antibody, ranibizumab (p.2377) has been developed for the treatment of neovascular (wet) age-related macular degeneration, and it has been suggested that bevacizumab might also be of benefit.

Bexarotene *(BAN, USAN, rINN)*

Beksaroteeni; Beksaroten; Bexaroten; Bexarotène; Bexaroteno; Bexarotenum; LG-100069; LGD-1069. *p*-[1-(5,6,7,8-Tetrahydro-3,5,5,8,8-pentamethyl-2-naphthyl)vinyl]benzoic acid.

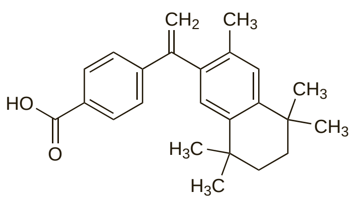
Бексаротен

$C_{24}H_{28}O_2$ = 348.5.

CAS — 153559-49-0.

ATC — L01XX25.

ATC Vet — QL01XX25.



Adverse Effects and Precautions

The main adverse effects noted after oral therapy with bexarotene include hyperlipidaemia, hypothyroidism, leucopenia, headache, oedema, altered liver function, rash, and pruritus. Exfoliative dermatitis, alopecia, and skin disorders may occur. Other common adverse effects include anaemia, insomnia, dizziness, eye or ear disorders, gastrointestinal disturbances, arthralgia, and myalgia. Acute pancreatitis has been associated with hypertriglyceridaemia, and patients with risk factors for pancreatitis should generally not be given bexarotene. If triglyceride concentrations rise during therapy, dose reductions are recommended, and lipid-lowering therapy may be instituted (with the exception of gemfibrozil, see below). The most common adverse events associated with topical therapy are rash, pruritus, and pain. Bexarotene capsules and gel should not be used during pregnancy because of the risk of fetal malformation.

1. Assaf C, *et al.* Minimizing adverse side-effects of oral bexarotene in cutaneous T-cell lymphoma: an expert opinion. *Br J Dermatol* 2006; **155:** 261–6.

Interactions

Gemfibrozil. Gemfibrozil inhibits clearance of bexarotene, resulting in extremely high triglyceride levels and pancreatitis.[1]

1. Talpur R, *et al.* Optimizing bexarotene therapy for cutaneous T-cell lymphoma. *J Am Acad Dermatol* 2002; **47:** 672–84.

Uses and Administration

Bexarotene is an agonist at the retinoid X receptor, which is involved in the regulation of cell differentiation and proliferation. It is used in the treatment of cutaneous T-cell lymphoma (see Mycosis Fungoides, p.657), in a usual initial oral dose of 300 mg/m^2 daily as a single dose taken with a meal. Dosage is adjusted according to toxicity. For the topical treatment of refractory disease a 1% gel may be applied on alternate days for the first week, gradually increased at weekly intervals to up to 4 times daily, depending on tolerance.

Bicalutamide *(BAN, USAN, rINN)*

Bicalutamida; Bicalutamidum; Bikalutamid; Bikalutamidi; ICI-176334. (*RS*)-4′-Cyano-α′,α′,α′-trifluoro-3-(4-fluorophenylsulphonyl)-2-hydroxy-2-methylpropiono-*m*-toluidide.

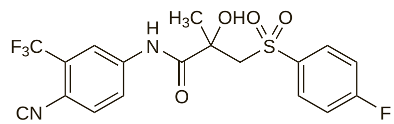
Бикалутамид

$C_{18}H_{14}F_4N_2O_4S$ = 430.4.

CAS — 90357-06-5.

ATC — L02BB03.

ATC Vet — QL02BB03.



Pharmacopoeias. In *US.*

USP 31 (Bicalutamide). A fine, white to off-white powder. Sparingly to slightly soluble in alcohol; freely soluble in acetone and in tetrahydrofuran; soluble in acetonitrile. Store in airtight containers.

Adverse Effects and Precautions

As for Flutamide, p.725. Pruritus, asthenia, alopecia, hair regrowth, and dry skin occur commonly with bicalutamide. Hypersensitivity reactions, including angioedema and urticaria, have been reported infrequently.

Cardiovascular effects including angina, heart failure, arrhythmias, and ECG changes have been reported rarely. Interstitial pneumonitis and pulmonary fibrosis have also been reported rarely.

Effects on the gastrointestinal tract. There is some evidence that bicalutamide is associated with a lower incidence of diarrhoea than flutamide.[1]

1. Schellhammer P, *et al.* A controlled trial of bicalutamide versus flutamide, each in combination with luteinizing hormone-releasing hormone analogue therapy, in patients with advanced prostate cancer. *Urology* 1995; **45:** 745–52.

Effects on the lungs. For a review of cases of pneumonitis associated with anti-androgens including bicalutamide, see under Flutamide, p.725.

Gynaecomastia. For a discussion of gynaecomastia, a frequent adverse effect of anti-androgen therapy, and its management, see under Flutamide, p.725.

Interactions

Bicalutamide inhibits various cytochrome P450 isoenzymes, particularly CYP3A4, *in vitro*, and licensed product information recommends that terfenadine, astemizole, and cisapride should not be given with bicalutamide, and that other drugs with a narrow therapeutic index that are metabolised by cytochrome P450 isoenzymes should be used with caution. *In vitro* studies have shown that bicalutamide can displace warfarin from its protein binding sites (see also Antineoplastics, p.1429).

Pharmacokinetics

Bicalutamide is well absorbed after oral doses. It undergoes extensive metabolism in the liver, the active *R*-enantiomer mainly by oxidation, the inactive *S*-enantiomer mainly by glucuronidation. It is excreted as metabolites in urine and faeces. The half-life of the *R*-enantiomer is about 6 to 7 days, and may be prolonged still further in severe hepatic impairment. The *S*-enantiomer is cleared more rapidly. Bicalutamide is about 96% bound to plasma proteins.

◊ References.

1. Cockshott ID. Bicalutamide: clinical pharmacokinetics and metabolism. *Clin Pharmacokinet* 2004; **43:** 855–78.

Uses and Administration

Bicalutamide is a nonsteroidal anti-androgen with actions and uses similar to those of flutamide (p.725). It is used orally in the treatment of prostatic cancer (p.671). When used with a gonadorelin analogue in the palliative treatment of advanced prostatic cancer the usual dose is 50 mg daily. In the UK treatment is started at least 3 days before starting the gonadorelin analogue to suppress any flare reaction, but in the USA treatment is started at the same time. A similar dose is used with surgical castration, starting on the same day as surgery.

Bicalutamide in a dose of 150 mg daily may be given as monotherapy or adjuvant therapy to surgery or radiotherapy in men with locally advanced disease at high risk for disease progression. It has been used as monotherapy in localised disease, but there is some evidence to suggest that in men without high risk of disease progression, who would otherwise be managed with watchful waiting, the immediate use of bicalutamide may increase the risk of death.

Bleomycin Sulfate *(USAN, pINNM)*

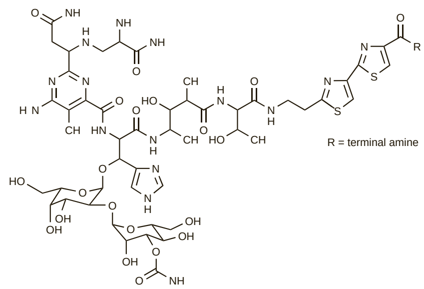
Bleomicino sulfatas; Bleomicin-szulfát; Bleomycin Sulphate *(BANM)*; Bléomycine, sulfate de; Bleomycini sulfas; Bleomycinsulfat; Bleomycin-sulfát; Bleomysiinisulfaatti; Sulfato de bleomicina.

Блеомицина Сульфат

CAS — 11056-06-7 (bleomycin); 67763-87-5 (bleomycin hydrochloride); 9041-93-4 (bleomycin sulfate).

ATC — L01DC01.

ATC Vet — QL01DC01.



(bleomycin)

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, *Jpn*, and *US*.
Int. and *Jpn* also include Bleomycin Hydrochloride. *Chin.* includes Bleomycin A5 Hydrochloride for Injection.

Ph. Eur. 6.2 (Bleomycin Sulphate). The sulfate of a mixture of glycopeptides obtained by the growth of *Streptomyces verticillus* or by any other means; the two principal components of the mixture are *N*-[3-(dimethylsulphonio)propyl]bleomycinamide (bleomycin A_2) and *N*-[4-(carbamimidoylamino)butyl]bleomycinamide (bleomycin B_2). A white or yellowish-white, very hygroscopic powder. It loses not more than 3% of its weight when dried. Very soluble in water; slightly soluble in dehydrated alcohol; practically insoluble in acetone. A 0.5% solution in water has a pH of 4.5 to 6.0. Store in airtight containers at a temperature of 2° to 8°.

USP 31 (Bleomycin Sulfate). The sulfate salt of a mixture of basic cytotoxic glycopeptides, produced by the growth of *Streptomyces verticillus* or produced by other means. It has a potency of not less than 1.5 units and not more than 2.0 units/mg. It contains between 55 and 70% of bleomycin A_2 and between 25 and 32% of bleomycin B_2; the content of bleomycin B_4 is not more than 1%. The combined percentage of bleomycin A_2 and B_2 is not less than 90%. A cream-coloured, amorphous powder. It loses not more than 6% of its weight when dried. Very soluble in water. A solution in water containing 10 units/mL has a pH of 4.5 to 6.0. Store in airtight containers.

Incompatibility. A loss of bleomycin activity was reported when bleomycin sulfate solutions were mixed with solutions of carbenicillin, cefazolin or cefalotin sodium, nafcillin sodium, benzylpenicillin sodium, methotrexate, mitomycin, hydrocortisone sodium succinate, aminophylline, ascorbic acid, or terbutaline.[1] The interactions of bleomycin have been summarised as the chelation of divalent and trivalent cations (especially copper), inactivation by compounds containing sulfhydryl groups, and precipitation by hydrophobic anions; solutions of bleomycin should not be mixed with solutions of essential amino acids, riboflavin, dexamethasone, or furosemide.[2]

2. D'Arcy PF. Reactions and interactions in handling anticancer drugs. *Drug Intell Clin Pharm* 1983; **17:** 532–8.

Stability. Bleomycin sulfate solutions appear to be equally stable in plastic or glass,[1,2] despite some earlier studies suggesting loss of potency in plastic.[3,4] There is some evidence[5] that bleomycin is more stable in sodium chloride 0.9% than glucose 5%, and sodium chloride 0.9% is the diluent recommended by the licensed product information. UK licensed product information states that bleomycin sulfate is chemically and physically stable, once reconstituted and diluted as directed, for 10 days when refrigerated at 2° to 8° and protected from light. From a microbiological point of view, solutions should be used immediately; storage for longer than 24 hours at 2° to 8° is not recommended, unless prepared under controlled and validated aseptic conditions.

Units

8910 units of bleomycin complex A_2/B_2 are contained in 5 mg of bleomycin complex in one ampoule of the first International Reference Preparation (1980). The Ph. Eur. 6.2 specifies a potency of not less than 1500 international units per mg, calculated with reference to the dried substance. These units differ from those used by the USP: Bleomycin Sulfate (USP 31) contains 1.5 to 2.0 units of bleomycin in each mg. A change in the labelling of preparations in the UK, from units equivalent to those of the USP to international units in line with the Ph. Eur., resulted in an apparent but artefactual increase in UK doses by a factor of 1000.

In some countries doses were *formerly* described in terms of mg-potency, where 1 mg-potency corresponded to 1 unit. In the original preparation 1 mg-potency was equivalent to 1 mg-weight but improvements in purification of the product led to a situation in which ampoules labelled as containing 15 mg (i.e. 15 units) contained far fewer mg-weight of bleomycin.

Adverse Effects and Treatment

For a general outline see Antineoplastics, p.635 and p.639.

The most frequent adverse effects with bleomycin involve the skin and mucous membranes and include rash, erythema, pruritus, vesiculation, hyperkeratosis, nail changes, alopecia, hyperpigmentation, striae, and stomatitis. Fever is also common, and acute anaphylactoid reactions with hyperpyrexia and cardiorespiratory collapse have been reported in about 1% of patients with lymphoma. There is little depression of the bone marrow. Local reactions and thrombophlebitis may occur at the site of parenteral dosage.

The most serious delayed effect is pulmonary toxicity; interstitial pneumonitis occurs in about 10% of patients and progresses to fibrosis and death in about 1% of patients treated with bleomycin. Pulmonary toxicity is more likely in elderly patients and those given total doses greater than 400 000 international units (400 USP units). It is also more likely in patients who have had previous radiotherapy to the chest.

Effects on the lungs. Pneumonitis induced by bleomycin can progress to fatal pulmonary fibrosis. The presentation is often delayed; clinical manifestations include non-productive cough, dyspnoea, and sometimes fever (see Effects on the Lungs, p.638). Pneumomediastinum has also been reported as an initial manifestation of fatal pulmonary toxicity due to bleomycin.[1] Risk factors for toxicity include increased age,[2,3] deteriorating renal function,[2] and concurrent or previous radiotherapy. The reaction is dose-related, and maximum doses have been set (see Uses and Administration, below). Other factors that may be implicated include the regimen used, concomitant oxygen supplementation, smoking history, underlying lung disease, and growth factor support.[2,3] For further details of some of these risk factors, see under Interactions, below. There is no standard treatment for bleomycin-induced pneumonitis. Bleomycin therapy is usually stopped, and corticosteroids may be given[3] although strong evidence to support their use is lacking.[2] There is some suggestion that giving bleomycin by intravenous infusion rather than bolus injection may reduce pulmonary toxicity.[2]

3. Martin WG, *et al.* Bleomycin pulmonary toxicity has a negative impact on the outcome of patients with Hodgkin's lymphoma. *J Clin Oncol* 2005; **23:** 7614–20.

Effects on the skin, hair, and nails. Permanent nail loss and nail loss followed by regrowth with dystrophy have been reported after intralesional injection of bleomycin for periungual warts.[1-3] In 2 cases this was preceded by blistering and ulceration,[1] or swelling, severe pain, and a burning sensation.[2] All 3 patients had received injections on one or two previous occasions when 2 patients had reported only mild pain.[1,3] Other reported cutaneous adverse effects of bleomycin include flagellate erythema, Raynaud's phenomenon, gangrene, fibrotic or sclerotic skin changes, hyperpigmentation, and neutrophilic eccrine hidradenitis (an inflammatory dermatosis with erythematous plaques and nodules, neutrophilic infiltrates of eccrine glands, and degeneration of eccrine cells). Acute generalised exanthematous pustulosis and alopecia have also been reported.[4]

4. Yamamoto T. Bleomycin and the skin. *Br J Dermatol* 2006; **155:** 869–75.

Effects on the vascular system. Although thromboembolic disorders and Raynaud's syndrome have been associated with use of bleomycin in combination regimens, particularly with cisplatin and the vinca alkaloids or etoposide (see Effects on the Cardiovascular System, p.636) there is some evidence for an association of Raynaud's syndrome with the use of bleomycin alone.[1,2]

There have also been cases of Raynaud's phenomenon reported after intralesional injection of bleomycin for treatment of warts on the hands and feet.[3-6] See also Effects on the Skin, Hair, and Nails, above.

Precautions

For reference to the precautions necessary with antineoplastics, see p.641.

Bleomycin should be used with caution in the elderly, in patients with renal impairment or pulmonary infection or pre-existing impairment of pulmonary function, and in those who have received radiotherapy, particularly to the thorax. Patients should undergo regular chest X-rays. If these show infiltrates, or if breathlessness occurs, bleomycin should be stopped.

In view of the risk of an anaphylactoid reaction it has been suggested that patients with lymphomas should receive two test doses of 2000 international units (2 USP units) or less initially (but see Administration, below).

AIDS. Cutaneous adverse effects occurred in 12 of 50 patients being treated with bleomycin for AIDS-associated Kaposi's sarcoma and increased in severity until bleomycin was withdrawn.[1] Bleomycin should be stopped in people with AIDS if cutaneous adverse effects are seen, and rechallenge should be avoided. However, the incidence of adverse effects did not appear to be higher in these patients than in cancer patients, and patients with AIDS seem to be less sensitive to bleomycin than to antibacterials such as co-trimoxazole and penicillins.

1. Caumes E, *et al.* Cutaneous side-effects of bleomycin in AIDS patients with Kaposi's sarcoma. *Lancet* 1990; **336:** 1593.

Diving. Since the partial pressure of oxygen in the inspired air of a scuba diver increases with increasing depth, a theoretical possibility exists of a toxic [pulmonary] reaction to oxygen in bleomycin-treated patients who subsequently go diving, and such a risk would increase with the depth and duration of each dive.[1] However, the risks associated with diving after uncomplicated bleomycin-based treatment have been questioned;[2] the authors considered that resuming diving was acceptable 6 to 12 months after completing treatment with BEP (bleomycin, etoposide, and cisplatin), and recommended caution only in those who developed pulmonary function impairment when given bleomycin.

Pregnancy. For a report of use of a bleomycin-containing chemotherapy regimen in a pregnant woman and subsequent adverse effects on the infant, see Pregnancy, under Cisplatin, p.699.

Interactions

For a general outline of antineoplastic drug interactions, see p.642. There may be an increased risk of pulmonary toxicity in patients given bleomycin who receive oxygen, for example as part of a general anaesthetic procedure; a reduction in inspired oxygen concentration has been recommended.

Antineoplastics. Enhanced pulmonary toxicity, in some cases fatal, has been reported in patients given bleomycin and *cisplatin*,[1-4] presumably because cisplatin-induced renal impairment led to a decrease in bleomycin elimination. It seems reasonable to assume that similar interactions might occur if bleomycin were given with other nephrotoxic agents. It has been suggested that apart from a decrease in bleomycin dosage if nephrotoxicity occurs with such a combination, giving bleomycin by constant infusion rather than intermittent bolus might be less toxic.[1,5]

A study to investigate whether substitution of etoposide with *gemcitabine* would lead to a less leukaemogenic BEACOPP regimen was stopped early because of unexpectedly common pulmonary toxicity; one patient died. This toxicity was considered to be due to the use of gemcitabine with bleomycin.[6]

Colony-stimulating factors. An increased incidence of pulmonary toxicity has been reported in patients receiving bleomycin as part of the ABVD regimen (with doxorubicin, vinblastine, and dacarbazine) who were given granulocyte colony-stimulating factor to alleviate neutropenia.[1] Another case of rapidly developing and fatal pneumonitis in a patient given BEP (bleomycin, etoposide, and cisplatin) with granulocyte colony-stimulating factor has been reported.[2]

Analyses of study data failed to show increased pulmonary toxicity when granulocyte colony-stimulating factor was added to bleomycin-containing regimens in patients with germ cell tumours or non-Hodgkin's lymphomas.[3-5] In a retrospective review of patients with Hodgkin's lymphoma, however, use of bleomycin with granulocyte colony-stimulating factor was associated with a statistically significant increase of pulmonary toxicity.[6]

6. Martin WG, *et al.* Bleomycin pulmonary toxicity has a negative impact on the outcome of patients with Hodgkin's lymphoma. *J Clin Oncol* 2005; **23:** 7614–20.

Oxygen. Because bleomycin is thought to cause pulmonary toxicity partly by induction of free radicals, use with high concentrations of oxygen could be hazardous,[1] and reductions in inspired oxygen concentration have been recommended by licensed product information where oxygen supplementation is unavoidable. *Animal* studies show an increased risk of mortality with use of bleomycin and oxygen, although data in humans are lacking. The need for oxygen restriction in bleomycin-treated patients has, however, been questioned.[2]

2. Donat SM, Levy DA. Bleomycin associated pulmonary toxicity: is perioperative oxygen restriction necessary? *J Urol (Baltimore)* 1998; **160:** 1347–52.

Pharmacokinetics

Bleomycin is thought to be poorly absorbed from the gastrointestinal tract. Absorption is rapid after parenteral, intraperitoneal, or intrapleural use. Bioavailability is 100% and 70% after intramuscular and subcutaneous dosage, respectively. A bioavailability of 45% has been reported after intraperitoneal or intrapleural use. Plasma protein binding is low. Enzymic degradation of bleomycin occurs, primarily in plasma, the liver and other organs, and to a much lesser extent in skin and lungs. Elimination is biphasic: mean initial and terminal half-lives of 0.5 and 4 hours respectively have been reported after an intravenous bolus. Elimination may be more prolonged after continuous intravenous infusion and mean half-lives of 1.3 and 9 hours respectively have been reported. About two-thirds of a dose is excreted unchanged in the urine; the rate of excretion is determined by renal function. Drug concentrations in the CSF are low. Bleomycin crosses the placenta.

Uses and Administration

Bleomycin is an antineoplastic antibiotic that binds to DNA and causes strand scissions, and is probably most effective in the G_2 and M phases of the cell cycle. It is widely used to treat malignant disease; particularly squamous cell carcinomas, including those of the cervix and external genitalia, oesophagus, skin, and head and neck; Hodgkin's disease and other lymphomas; malignant neoplasms of the testis, and malignant effusions. It has also been tried in other malignancies, including carcinoma of the bladder, lung, and thyroid, and some sarcomas, including Kaposi's sarcoma.

Bleomycin is often used with other antineoplastics, notably with doxorubicin, vinblastine, and dacarbazine (ABVD) for Hodgkin's disease, and with etoposide and cisplatin (BEP) in testicular tumours. Bleomycin is given as the sulfate by either the intramuscular, intravenous, or subcutaneous route. It may also be given intra-arterially or instilled intrapleurally or intraperitoneally. If intramuscular injections are painful they may be given in a 1% solution of lidocaine.

Doses are calculated in terms of the base, and are given in ***units****, but the units used for preparations in the UK, which were formerly equivalent to those of the USP, are now international units equivalent to those of the Ph. Eur. (see Units, above). Since 1000 international units is equivalent to 1 USP unit, UK doses now appear to be 1000 times greater than those previously in use, or than those in use in the USA, and care is recommended in evaluating the literature.*

In the UK the licensed dose as a single agent for **squamous cell** or **testicular tumours** is 15 000 international units (15 USP units) three times a week, or 30 000 international units twice a week, by intramuscular or intravenous injection, although in practice treatment of malignancy will generally be with combination regimens. This may be repeated, at usual intervals of 3 to 4 weeks, up to a total cumulative dose of 500 000 international units. The dose and total cumulative dose should be reduced in those over 60 years of age (see below). Doses should be adjusted according to tolerance, and may need to be adjusted as part of combination chemotherapy. Continuous intravenous infusion at a rate of 15 000 international units per 24 hours for up to 10 days or 30 000 international units per 24 hours for up to 5 days may also be used. In patients with **lymphoma** a dose of 15 000 international units once or twice weekly by intramuscular injection has been suggested, to a total dose of 225 000 international units. Again, dosage should be reduced in older patients and in combination regimens if necessary. In the treatment of **malignant effusions** a solution of 60 000 international units in 100 mL of sodium chloride 0.9% may be instilled into the affected serous cavity. Treatment may be repeated as necessary up to a total cumulative dose of 500 000 international units depending on the patient's age. Local anaesthetics or analgesics are given concomitantly.

In the USA licensed doses for **lymphomas** as well as **squamous cell** and **testicular** neoplasms are 250 to 500 international units/kg (0.25 to 0.5 USP units/kg), or 10 000 to 20 000 international units/m^2 (10 to 20 USP units/m^2), given once or twice weekly. In view of the risk of an anaphylactoid reaction it has been suggested that patients with lymphomas should receive two test doses of 2000 international units (2 USP units) or less initially (but see Administration, below). In patients with Hodgkin's disease, once a 50% response has been achieved it may be maintained with 1000 international units (1 USP unit) of bleomycin daily, or 5000 international units (5 USP units) weekly.

In the UK, licensed product information suggests that a **total dose** of 500 000 international units (500 USP units) should not be exceeded. Total cumulative dose should not exceed 300 000 international units in those aged 60 to 69 years, 200 000 international units in those 70 to 79, and 100 000 international units in those 80 and over; the weekly dose should be no more than 60 000, 30 000 and 15 000 international units respectively. In the USA the recommended maximum total dose is 400 000 international units (400 USP units); it is generally agreed that patients receiving 400 000 international units or more are at increased risk of pulmonary toxicity (see Adverse Effects, above).

Dosage should be reduced in patients with renal impairment (see below).

Bleomycin hydrochloride has also been given parenterally for malignant neoplasms, and bleomycin sulfate has been applied topically for the local treatment of skin tumours.

Administration. Although test doses have been suggested as a way of avoiding anaphylactoid reactions in patients with lymphoma being treated with bleomycin, a review[1] of the literature concluded that the evidence did not support such a strategy, since the onset of the reaction was unpredictable, and not associated with any particular dose. It had also been suggested that reactions were less frequent with intramuscular rather than intravenous dosage, but evidence for this was conflicting.

There is some suggestion that giving bleomycin by intravenous infusion rather than bolus injection in combination regimens may result in reduced pulmonary toxicity.[2,3]

3. Sleijfer S. Bleomycin-induced pneumonitis. *Chest* 2001; **120:** 617–24.

Administration in renal impairment. A significant portion of a dose of bleomycin is excreted largely unchanged in the urine, and dose reduction should be considered in patients with renal impairment. UK licensed product information suggests a 50% dose reduction when the serum creatinine concentration is between 20 and 40 micrograms/mL and further reduction for serum creatinine above this. US licensed product information gives the following proposed percentages of the initial dose, based on creatinine clearance (CC):

- CC 5 to 10 mL/minute: 40%
- CC 10 to 20 mL/minute: 45%
- CC 20 to 30 mL/minute: 55%
- CC 30 to 40 mL/minute: 60%
- CC 40 to 50 mL/minute: 70%
- CC 50 mL/minute and above: 100%

Leucoplakia. Leucoplakia is used to describe a white patch or plaque in the mouth which cannot be otherwise characterised. Such lesions are of concern because they may be pre-malignant, and patients with evidence of dysplasia may be at higher risk of transformation (see also Malignant Neoplasms of the Head and Neck, p.666). Leucoplakia must be distinguished from other conditions such as candidiasis, lichen planus, and oral hairy leucoplakia which is associated with HIV infection.[1]

Leucoplakia is often associated with tobacco smoking, and smoking cessation can result in regression.[1] Where active treatment is desirable, small and easily accessible lesions can be removed surgically or by laser therapy, although they may recur.[1] For extensive patches or those in which surgery would be difficult, the treatments described include topical bleomycin 1%, dissolved in dimethyl sulfoxide and applied for 5 minutes daily for 14 consecutive days. In a group of 19 patients with dysplastic leucoplakia, improvement in the appearance of lesions and histological evidence of remission of the dysplasia occurred in the majority of patients. Sustained effects were also found on long-term follow-up for up to 10 years.[2]

There have been reports of partial or complete remission of leucoplakia in studies of vitamin A or betacarotene given orally long-term,[3-5] but lesions have recurred when supplementation was stopped.[4] Topical treatment with retinoids such as tretinoin or isotretinoin has also been tried, with similar results to those of oral vitamin A and retinoid treatments.[6,7] A small open study has also suggested that topical calcipotriol may be effective.[8]

A systematic review of treatments for leucoplakia found that there were few controlled trials reported, and that although these treatments might be effective in the resolution of lesions, the rate of relapse was high, and there was no evidence that they prevent malignant transformation.[9]

Malignant effusions. Bleomycin is used for the sclerotherapy of malignant pleural and pericardial effusions (p.659).

Malignant neoplasms. Bleomycin is used in regimens for the management of Hodgkin's disease (p.655), non-Hodgkin's lymphomas, including AIDS-related lymphomas (see p.656 and p.657), and for germ-cell tumours of the ovary and testis (see p.670, and p.673), as well as for some other malignancies including those of the head and neck, (p.666), and Kaposi's sarcoma (p.675).

Pneumothorax. In a patient with AIDS and pneumocystis pneumonia who developed pneumothorax, instillation of bleomycin into each pleural cavity was successful in resolving the pneumothorax after tetracycline sclerotherapy failed to do so.[1]

1. Hnatiuk OW, *et al.* Bleomycin sclerotherapy for bilateral pneumothoraces in a patient with AIDS. *Ann Intern Med* 1990; **113:** 988–90.

Warts. A number of studies have examined the local use of bleomycin sulfate to treat severe or resistant warts (p.1584) of the common, plane, plantar, eponychial, and mosaic types, usually by intralesional injection.[1-3] At the doses used, adverse effects, other than pain at the injection site,[1-3] do not seem to be common; however, nail dystrophy and Raynaud's phenomenon have been reported (see under Effects on the Nails and Effects on the Vascular System, under Adverse Effects, above). Bleomycin has also been applied as a pressure-sensitive adhesive tape,[4] and various techniques for better intralesional use have been investigated.[5-7]

Bortezomib *(BAN, USAN, rINN)*

Bortézomib; Bortezomibum; LDP-341; MG-341; MLN-341; PS-341. *N*-((1*S*)-1-Benzyl-2-{[(1*R*)-1-(dihydroxyboranyl)-3-methylbutyl]amino}-2-oxoethyl)pyrazinecarboxamide; {(1*R*)-3-Methyl-1-[(2*S*)-3-phenyl-2-(pyrazin-2-carboxamido)propanamido]butyl}boronic acid; .

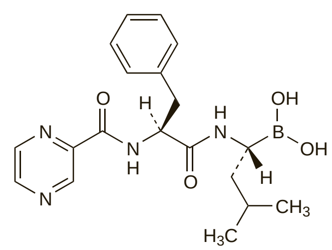
Бортезомиб

$C_{19}H_{25}BN_4O_4$ = 384.2.

CAS — 179324-69-7.

ATC — L01XX32.

ATC Vet — QL01XX32.



Adverse Effects, Treatment, and Precautions

For a general outline see Antineoplastics, p.635, p.639, and p.641.

The most common adverse effects of bortezomib include haematological toxicities (especially transient thrombocytopenia), decreased appetite, gastrointestinal disturbances, peripheral neuropathy, fatigue, fever, dyspnoea, rash, and myalgia. Complete blood counts including platelet counts should be monitored and therapy withheld or given at reduced doses if necessary. Peripheral neuropathy may also be dose-limiting.

Other common adverse effects include hyperglycaemia, hypokalaemia, insomnia, anxiety, confusion, depression, blurred vision, eye pain, dizziness, dysgeusia, tremor, epistaxis, cough, rhinorrhoea, pruritus, arthralgia, oedema, and orthostatic hypotension. Tumour lysis syndrome, hypersensitivity, and seizures have been reported. Tachycardia, arrhythmias, palpitations, angina pectoris, and myocardial infarction have occurred. Congestive heart failure may be exacerbated and pulmonary oedema has been reported. There have been rare reports of acute respiratory distress syndrome, some of them fatal.

Renal impairment is common in patients with multiple myeloma and acute renal failure has developed in patients on bortezomib. Licensed product information in the UK considers that patients with compromised renal function should be monitored, and dose reductions considered if needed although in the USA this is considered unnecessary. Hepatotoxicity, which may be reversible, has included increases in liver enzyme values, hyperbilirubinaemia, and acute liver failure; bortezomib should be used with caution in hepatic impairment.

The impact of proteasome inhibition by bortezomib on disorders associated with protein accumulation such as amyloidosis is unknown and caution is advised in these patients.

Effects on the nervous system. Treatment with bortezomib is often associated with peripheral neuropathy, mainly sensory, although cases of motor neuropathy have been reported. Results from an analysis[1] found that the peripheral neuropathy associated with bortezomib seemed to be cumulative and dose-related, and increased in prevalence through the first 5 treatment cycles. Prolonged bortezomib exposure beyond this time did not seem to increase the incidence or severity of neuropathy. Development of neuropathy appeared to be independent of the previous neurotoxic therapy. In most patients, neuropathic pain resolved or improved after dose modification or upon completion of therapy.

1. Richardson PG, *et al.* Frequency, characteristics, and reversibility of peripheral neuropathy during treatment of advanced multiple myeloma with bortezomib. *J Clin Oncol* 2006; **24:** 3113–20.

Effects on the skin. In 3 studies of bortezomib in patients with non-Hodgkin's lymphoma, 26 of 140 patients developed an erythematous maculopapular rash. Six patients underwent biopsy; all cases revealed a small vessel necrotising vasculitis. Although some patients had dosage reductions implemented or therapy interrupted upon development of the rash, others were treated continuously without dose reduction, with no apparent adverse clinical consequences. In fact, analysis of the data supported a strong relationship between bortezomib-associated cutaneous vasculitis and a positive clinical response in patient with non-Hodgkin's lymphoma.[1] A macular brown-red eruption developed in a patient at the site of bortezomib infusions; abundant venous flushing was given from the fourth infusion, and the eruption did not recur, although hyperpigmentation persisted for several months.[2]

1. Gerecitano J, *et al.* Drug-induced cutaneous vasculitis in patients with non-Hodgkin lymphoma treated with the novel proteasome inhibitor bortezomib: a possible surrogate marker of response? *Br J Haematol* 2006; **134:** 391–8.
2. Mataix J, *et al.* Persistent supravenous eruption induced by intravenous bortezomib therapy. *Br J Dermatol* 2008; **158:** 863–4.

Interactions

Bortezomib is metabolised in the liver via the cytochrome P450 isoenzymes CYP3A4, CYP2C19, and CYP1A2; CYP2D6 and CYP2C9 are also thought to play minor roles. Consequently, patients should be monitored closely when bortezomib is used with other drugs that induce or inhibit these isoenzymes. Hypoglycaemia and hyperglycaemia have occurred in diabetic patients receiving oral antidiabetics who were given bortezomib. Caution may be required if bortezomib is used with drugs that are associated with peripheral neuropathy or hypotension.

Pharmacokinetics

After a single intravenous dose of bortezomib, plasma concentrations decline in a biphasic manner; a distribution phase with a half-life of less than 10 minutes is followed by a terminal elimination phase of about 5 to 15 hours. After multiple doses, clearance decreases and there is an increase in the terminal elimination phase. Protein binding has been reported to be over 80%. *In-vitro* studies indicate that bortezomib is primarily oxidatively metabolised via the cytochrome P450 isoenzymes CYP3A4, CYP2C19, and CYP1A2; minor metabolism via CYP2D6 and CYP2C9 also occurs. The major metabolic pathway is deboronation to inactive metabolites.

Uses and Administration

Bortezomib is an inhibitor of the 26S proteasome, a large protein complex in cells that is responsible for breaking down regulatory proteins of the cell cycle. Such inhibition disrupts tumour cell turnover and induces apoptosis. Bortezomib is used for the treatment of multiple myeloma (p.658) in patients who have failed at least one previous therapy. In the USA, it is also used similarly for mantle cell lymphoma in patients given at least one previous therapy. Bortezomib is given in initial doses of 1.3 mg/m^2 intravenously on days 1, 4, 8, and 11 of a 21-day cycle. At least 72 hours should elapse between consecutive doses of bortezomib. In the UK, licensed product information recommends that patients with a confirmed complete response should receive 2 additional cycles of bortezomib, and that those who respond but do not achieve complete remission receive a total of 8 cycles. In the USA, extended therapy of more than 8 cycles may be given, either on the standard schedule recommended above, or on a maintenance schedule of one dose weekly for 4 weeks (days 1, 8, 15, and 22 of a 35-day cycle).

The dose should be reduced, or treatment withdrawn, according to toxicity, particularly when peripheral neuropathy, neuropathic pain, and haematological toxicity occur.

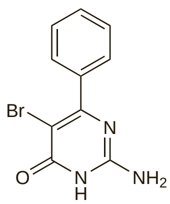
Bropirimine *(BAN, USAN, rINN)*

ABPP; Bropirimina; Bropiriminum; U-54461; U-54461S. 2-Amino-5-bromo-6-phenyl-4(3*H*)-pyrimidinone.

Бропиримин

$C_{10}H_8BrN_3O$ = 266.1.
CAS — 56741-95-8.



Profile

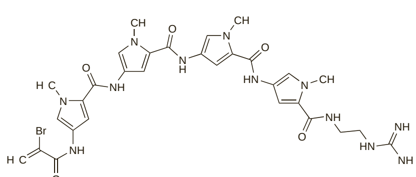
Bropirimine is reported to have immunomodulatory actions, possibly due to the induction of interferons. It has been investigated in the management of carcinoma in situ of the bladder (p.659).

Brostallicin *(rINN)*

Brostalicina; Brostallicine; Brostallicinum; PNU-166196 (hydrochloride). 4-(2-Bromoacrylamido)-*N*‴-(2-guanidinoethyl)-1,1′,1″,1‴-tetramethyl-*N*,4′:*N*′,4″:*N*″,4‴-quater[pyrrole-2-carboxamide].

Бростальлицин

$C_{30}H_{35}BrN_{12}O_5$ = 723.6.
CAS — 203258-60-0.



Profile

Brostallicin is an antineoplastic that binds to DNA. It is under investigation for the treatment of soft-tissue sarcomas.

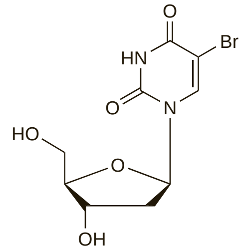
Broxuridine *(rINN)*

Bromodeoxyuridine; Broxuridina; Broxuridinum; BUDR; NSC-38297. 5-Bromo-2′-deoxyuridine; 5-Bromo-1-(2-deoxy-β-D-ribofuranosyl)pyrimidine-2,4(1*H*,3*H*)-dione.

Броксуридин

$C_9H_{11}BrN_2O_5$ = 307.1.
CAS — 59-14-3.



Profile

Broxuridine is a thymidine analogue which acts as a radiosensitiser to enhance the effects of radiotherapy. It is also reported to possess antiviral activity. A related compound brivudine (p.867) is used as an antiviral.

Broxuridine has been given by intra-arterial infusion, with radiotherapy and other antineoplastic agents, in the treatment of tumours of the brain, head, and neck. It has also been used diagnostically.

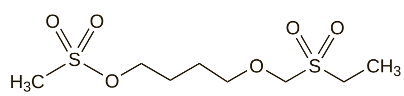
Busulfan *(BAN, rINN)*

Bussulfam; Busulfaani; Busulfanas; Busulfano; Busulfanum; Busulphan; Buszulfán; CB-2041; GT-41; Myelosan; NSC-750; WR-19508. Tetramethylene di(methanesulphonate); Butane-1,4-diol di(methanesulphonate).

Бусульфан

$C_6H_{14}O_6S_2$ = 246.3.
CAS — 55-98-1.
ATC — L01AB01.
ATC Vet — QL01AB01.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Busulfan). A white or almost white, crystalline powder. Very slightly soluble in water and in alcohol; freely soluble in acetone and in acetonitrile. Store in airtight containers. Protect from light.

USP 31 (Busulfan). A white, crystalline powder. Very slightly soluble in water; slightly soluble in alcohol; soluble 1 in 45 of acetone. Store in airtight containers.

Adverse Effects and Treatment

For a general outline see Antineoplastics, p.635 and p.639.

The major adverse effect of busulfan with standard doses is bone-marrow depression, manifest as leucopenia, thrombocytopenia, and sometimes, anaemia. The nadir of the granulocyte count usually occurs after about 10 to 30 days with recovery occurring over up to 5 months, but busulfan has sometimes caused irreversible or extremely-prolonged bone-marrow depression.

Hyperpigmentation is common, and in a few cases after long-term therapy may be part of a syndrome simulating Addison's disease.

Rarely, progressive interstitial pulmonary fibrosis, known as 'busulfan lung', can occur on prolonged treatment. Gastrointestinal disturbances are rare at usual therapeutic doses but may be dose-limiting where high doses are given before bone marrow transplantation. Other rare adverse effects include dry skin and other skin reactions, liver damage, gynaecomastia, cataract formation, and, at high doses, CNS effects including convulsions.

Busulfan may result in impaired fertility and gonadal function. As with other alkylating agents, it is potentially carcinogenic, mutagenic, and teratogenic.

Effects on the bladder. Haemorrhagic cystitis occurred in a patient who had received prolonged therapy with busulfan.[1] High-dose busulfan used in conditioning regimens for haematopoietic stem cell transplantation may increase the risk of late-onset haemorrhagic cystitis.[2,3]

1. Pode D, *et al.* Busulfan-induced hemorrhagic cystitis. *J Urol (Baltimore)* 1983; **130:** 347–8.

3. Leung AYH, *et al.* Clinicopathological features and risk factors of clinically overt haemorrhagic cystitis complicating bone marrow transplantation. *Bone Marrow Transplant* 2002; **29:** 509–13.

Effects on the liver. Jaundice in the terminal phase of chronic myeloid leukaemia in a 31-year-old man was attributed to busulfan which had been taken for 6 years.[1] Busulfan toxicity involving the liver was also reported in a patient who had taken busulfan for 54 months,[2] while hepatitis possibly associated with busulfan therapy has also been described.[3] Dose-dependent veno-occlusive disease (VOD) has been reported in 20 to 40% of patients receiving high-dose busulfan before bone marrow transplantation.[4] Licensed product information from 1 manufacturer (*Pierre Fabre, UK*) states that previous radiotherapy, progenitor cell transplantation, or three cycles of chemotherapy or more, can increase the risk of hepatic VOD; another (*GSK*) lists concurrent use of multiple alkylating agents, or total doses of busulfan in excess of 16 mg/kg, as possible risk factors. A reduced incidence of hepatic VOD has been seen in those patients given high-dose busulfan and cyclophosphamide when the first dose of cyclophosphamide has been delayed for more than 24 hours after the last dose of busulfan.

4. Hassan M. The role of busulfan in bone marrow transplantation. *Med Oncol* 1999; **16:** 166–76.

Effects on the nervous system. High-dose busulfan, used in conditioning regimens for bone marrow transplantation, has been associated with the development of convulsions,[1-4] both generalised[1,3,4] and myoclonic.[2,4] As a result, the use of prophylactic antiepileptic therapy has been suggested as a component of such regimens.[1,3,4] However, some do not consider the routine use of prophylactic antiepileptics justified,[5] and the potential for phenytoin to increase the metabolism of busulfan, thereby possibly decreasing its myeloablative efficacy, has been pointed out.[6] In addition, phenytoin plasma concentrations have been found to be subtherapeutic in patients who developed convulsions despite a standard prophylactic dose,[4] and the regimen was subsequently adjusted to take account of plasma concentrations. Clobazam has been suggested as an alternative to phenytoin for prophylaxis of busulfan-induced seizures.[7] Licensed product information from one manufacturer (*GSK, UK*) recommends the use of prophylactic anticonvulsants, and prefers a benzodiazepine to phenytoin. However, other manufacturers suggest use with phenytoin; *Otsuka* in the USA state that the recommended dose of their parenteral product is based on studies in which phenytoin was given, and that if other anticonvulsants are used exposure should be monitored, as a 15% increase in plasma-busulfan may be expected, with increased risk of toxicity.

7. Schwarer AP, *et al.* Clobazam for seizure prophylaxis during busulfan chemotherapy. *Lancet* 1995; **346:** 1238.

Effects on the skin and hair. For the effect of radiotherapy in activating skin lesions in busulfan-treated patients, see under Precautions, below.

Permanent alopecia has been reported after use of busulfan.[1]

1. Tosti A, *et al.* Permanent alopecia after busulfan chemotherapy. *Br J Dermatol* 2005; **152:** 1056–8.

Precautions

For reference to the precautions necessary with antineoplastics, see p.641. Careful attention should be given to monitoring blood counts during therapy. This should be done at least weekly at the start of standard dose therapy. With high dose therapy blood counts should be monitored daily, as should liver function. Prophylactic anticonvulsants should be used during high dose therapy (see Effects on the Nervous System, above).

Busulfan should be stopped if lung toxicity develops. The use of oxygen may exacerbate possible lung toxicity; if anaesthesia is required the concentration of oxygen should be minimised.

Handling. Busulfan is irritant; avoid contact with skin and mucous membranes.

Porphyria. Busulfan is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Radiotherapy. Severe cutaneous reactions occurred in patients given radiotherapy at least 30 days after combined chemotherapy with high-dose busulfan.[1]

It is possible that radiotherapy could worsen subclinical lung injury caused by busulfan.

1. Vassal G, *et al*. Radiosensitisation after busulphan. *Lancet* 1987; **i:** 571.

Interactions

For a general outline of antineoplastic drug interactions, see p.642. Phenytoin increases the clearance of busulfan (see Effects on the Nervous System, above).

Antifungals. Giving *itraconazole* with busulfan resulted in a decrease in the clearance of busulfan; *fluconazole* had no such effect.[1] Busulfan doses may need to be decreased if itraconazole is also given.

1. Buggia I, *et al*. Itraconazole can increase systemic exposure to busulfan in patients given bone marrow transplantation. *Anticancer Res* 1996; **16:** 2083–8.

Antineoplastics. When *tioguanine* was given with busulfan for chronic myeloid leukaemia, a number of cases of hepatic nodular regenerative hyperplasia, with abnormal liver function tests, portal hypertension, and oesophageal varices were noted. There were no cases in patients treated with busulfan alone, and the mechanism of this possible interaction is unclear.[1,2]

1. Key NS, *et al*. Oesophageal varices associated with busulfan-thioguanine combination therapy for chronic myeloid leukaemia. *Lancet* 1987; **ii:** 1050–2.
2. Shepherd PCA, *et al*. Thioguanine used in maintenance therapy of chronic myeloid leukaemia causes non-cirrhotic portal hypertension. *Br J Haematol* 1991; **79:** 185–92.

Antiprotozoals. In a study[1] of patients who received high-dose busulfan as part of a myeloablative regimen before stem cell transplantation, the use of *metronidazole* significantly increased plasma concentrations of busulfan and the degree of associated toxicity, including elevation of liver function tests, veno-occlusive disease, and mucositis.

1. Nilsson C, *et al*. The effect of metronidazole on busulfan pharmacokinetics in patients undergoing hematopoietic stem cell transplantation. *Bone Marrow Transplant* 2003; **31:** 429–35.

Pharmacokinetics

Busulfan is readily absorbed from the gastrointestinal tract and rapidly disappears from the blood with a half-life of 2 to 3 hours. It is extensively metabolised, and excreted in the urine almost entirely as sulfur-containing metabolites. It crosses the blood-brain barrier.

Metabolism. In a study of the pharmacokinetics of high-dose busulfan in 5 patients receiving 1 mg/kg orally every six hours for 4 days, the mean elimination half-life decreased from about 3.4 hours after the first dose to about 2.3 hours after the final dose, suggesting that busulfan may induce its own metabolism.[1]

1. Hassan M, *et al*. Pharmacokinetic and metabolic studies of high-dose busulphan in adults. *Eur J Clin Pharmacol* 1989; **36:** 525–30.

Therapeutic drug monitoring. A review concluded that therapeutic drug monitoring of busulfan would maximise engraftment and minimise toxicity and relapse in haematopoietic stem cell transplantation. In regimens using busulfan with cyclophosphamide, steady-state plasma concentrations of busulfan above 600 micrograms/litre appeared to favour engraftment.[1] A pharmacokinetic analysis found that in patients with graft rejections, busulfan trough concentrations were below 150 nanograms/mL; steady state concentrations also tended to be lower in this group but not significantly so.[2]

The bioavailability of oral busulfan is variable, particularly in children; intravenous conditioning regimens, adjusted on the basis of first-dose pharmacokinetics and therapeutic drug monitoring, have been used to overcome this problem.[3,4] A study found a significant correlation between busulfan concentration in plasma and saliva after oral dosing in children; busulfan saliva analysis may therefore be a useful, non-invasive alternative to plasma analysis.[5]

5. Rauh M, *et al*. Quantification of busulfan in saliva and plasma in haematopoietic stem cell transplantation in children : validation of liquid chromatography tandem mass spectrometry method. *Clin Pharmacokinet* 2006; **45:** 305–16.

Uses and Administration

Busulfan is an antineoplastic with a cell-cycle non-specific alkylating action unlike that of the nitrogen mustards, and having a selective depressant action on bone marrow. In small doses, it depresses granulocytopoiesis and to a lesser extent thrombocytopoiesis but has little effect on lymphocytes. With larger doses, severe bone-marrow depression eventually ensues.

Because of its selective action, busulfan has been used in the palliative treatment of chronic myeloid leukaemia (p.653). It provides symptomatic relief with a reduction in spleen size and a general feeling of well-being. The fall in leucocyte count is usually accompanied by a rise in the haemoglobin concentration. Permanent remission is not induced and resistance to its beneficial effects gradually develops.

Busulfan may be used in patients with polycythaemia vera (p.654) and in some patients with myelofibrosis and primary thrombocythaemia (p.654). It is also used at high doses as part of a conditioning regimen to prepare patients for bone marrow transplantation, a procedure discussed on p.1811 under Haematopoietic Stem Cell Transplantation.

The licensed initial oral dosage of busulfan in **chronic myeloid leukaemia** is 60 micrograms/kg daily, with a usual maximum single daily dose of 4 mg. This is continued until the white cell count has fallen to between 15 000 and 25 000 cells/mm^3 (typically 12 to 20 weeks). It should be stopped earlier if the platelet count falls below 100 000 cells/mm^3. Higher doses may be given if the response after 3 weeks is inadequate but this increases the risk of irreversible damage to the bone marrow and calls for special vigilance. Complete blood counts should be made at least every week and the trends followed closely; if haemorrhagic tendencies occur or there is a steep fall in the white cell count indicating severe bone-marrow depression, busulfan should be withdrawn until marrow function has returned.

Once an initial remission has been attained treatment is stopped and not resumed until the white cell count returns to 50 000 cells/mm^3. If this occurs within 3 months continuous maintenance treatment with a usual dose of 0.5 to 2 mg daily may be given.

In patients with **polycythaemia vera** the usual oral dose is 4 to 6 mg daily, continued for 4 to 6 weeks with careful monitoring of blood counts. Further courses are given when relapse occurs; alternatively, maintenance therapy may be given at half the dose required for induction. Doses of 2 to 4 mg daily have been given for **essential thrombocythaemia** or myelofibrosis.

In conditioning regimens for **bone marrow transplantation** busulfan has been given in usual doses of 3.5 to 4 mg/kg daily in divided doses for 4 days orally (total dose 14 to 16 mg/kg), with cyclophosphamide, for ablation of the recipient's bone marrow. When given by intravenous infusion in a regimen with phenytoin (see Effects on the Nervous System, above), a recommended dose is 3.2 mg/kg ideal body-weight daily for 4 days (total dose 12.8 mg/kg); actual body-weight is used for the calculation if it is less than the ideal weight. The daily dose is given as 4 infusions of 800 micrograms/kg at intervals of 6 hours; each dose should be diluted in sodium chloride 0.9% or glucose 5% to a final concentration of about 500 micrograms/mL, and given over 2 hours through a central venous catheter using an infusion pump. UK licensed product information states that cyclophosphamide dosing should not be started for at least 24 hours after the last dose of busulfan; US information permits use no sooner than 6 hours after the last busulfan dose.

In the UK, busulfan is licensed for use with cyclophosphamide or melphalan as a conditioning regimen prior to haematopoietic stem cell transplantation in children. The recommended dose for children up to 17 years of age is weight-based as follows:

- less than 9 kg: busulfan 1 mg/kg
- 9 to 16 kg: busulfan 1.2 mg/kg
- 16 to 23 kg: busulfan 1.1 mg/kg
- 23 to 34 kg: busulfan 950 micrograms/kg
- greater than 34 kg: busulfan 800 micrograms/kg

This dose is given every 6 hours over 4 days to a total of 16 doses, diluted and infused as for adults. Cyclophosphamide or melphalan should not be started for at least 24 hours after the last dose of busulfan.

Capecitabine *(BAN, USAN, rINN)*

Capecitabina; Capécitabine; Capecitabinum; Kapecitabin; Kapesitabiini; Kapesitabin; Ro-09-1978/000. Pentyl 1-(5-deoxy-β-D-ribofuranosyl)-5-fluoro-1,2-dihydro-2-oxo-4-pyrimidinecarbamate.

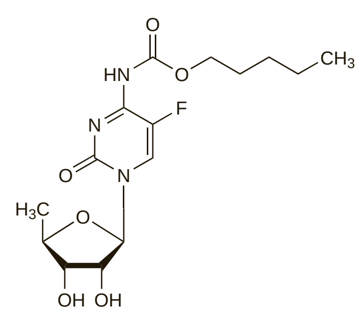
Капецитабин

$C_{15}H_{22}FN_3O_6$ = 359.4.

CAS — 154361-50-9; 158798-73-3.

ATC — L01BC06.

ATC Vet — QL01BC06.



Pharmacopoeias. In *US*.

USP 31 (Capecitabine). A white to off-white crystalline powder. Sparingly soluble in water; soluble in alcohol and in acetonitrile; freely soluble in methyl alcohol. Store in airtight containers at a temperature of 20° to 25°, excursions permitted between 15° and 30°.

Adverse Effects and Precautions

As for Fluorouracil, p.722. Diarrhoea (which may be severe), nausea and vomiting, abdominal pain, stomatitis, and palmar-plantar erythrodysesthesia syndrome (erythema and desquamation of hands and feet) occur commonly with capecitabine, and may be dose-limiting. Other common adverse effects include fatigue, asthenia, and anorexia. Rashes, alopecia, erythema, dryness of the skin, pruritus, skin pigmentation disorders, and nail disorders can occur. Other adverse effects are fever, pain, arthralgia, constipation, dyspepsia, paraesthesia, headache, dizziness, insomnia, hypo- or hypercalcaemia, and dehydration. Dermatitis, cardiotoxicity, and bone-marrow depression have all been reported. Hyperbilirubinaemia has occurred. Doses should be reduced in patients with moderate renal impairment and the drug is contra-indicated in those with severe renal or hepatic impairment.

Effects on blood lipids. Severe hypertriglyceridaemia has been reported with oral capecitabine;[1] patients had high baseline triglyceride concentrations at the start of capecitabine. Despite the introduction of lipid-lowering therapy, triglyceride concentrations remained above baseline, and only decreased several weeks after stopping capecitabine.

1. Kurt M, *et al.* Capecitabine-induced severe hypertriglyceridemia: report of two cases. *Ann Pharmacother* 2006; **40:** 328–31.

Effects on the eyes. A report of severe ocular irritation with corneal deposits and impaired visual acuity in 2 patients given capecitabine.[1] Symptoms resolved within several weeks of stopping the drug.

1. Walkhom B, *et al.* Severe ocular irritation and corneal deposits associated with capecitabine use. *N Engl J Med* 2000; **343:** 740–1.

Effects on the heart. Acute ischaemic chest pain has been reported, usually within a few days of starting capecitabine.[1-3] Symptoms from case reports[1] and incidence in Phase III studies[4] were similar to those in patients given fluorouracil. While symptoms have generally been reported to be reversible, fatal myocardial infarction has occurred.[2] One patient had also had cardiotoxicity with fluorouracil treatment,[1] but others had no apparent risk factors.[2]

3. Videnovic A, *et al.* Capecitabine-induced multifocal leukoencephalopathy: a report of five cases. *Neurology* 2005; **65:** 1792–4.

Effects on the skin and nails. While hand-foot syndrome appears to be common in patients treated with capecitabine (see Palmar-plantar Erythrodysesthesia Syndrome, below), other skin eruptions have been rarely reported.[1] Onychomadesis (total separation of the nail-bed) and onycholysis have occurred.[2,3] Pyogenic granuloma has been seen with the use of capecitabine,[1] as has re-pigmentation of chemotherapy-induced vitiligo.[4]

3. Chen G-Y, *et al.* Exudative hyponychial dermatitis associated with capecitabine and docetaxel combination chemotherapy for metastatic breast carcinoma: report of three cases. *Br J Dermatol* 2003; **148:** 1071–3.
4. Schmid-Wendtner M-H, *et al.* Leopard-like vitiligo with capecitabine. *Lancet* 2001; **358:** 1575.

Hypersensitivity. A patient was successfully given fluorouracil by continuous infusion despite previous hypersensitivity to capecitabine. The authors supposed that the hypersensitivity was likely to have been caused by capecitabine or intermediate metabolites, and suggested a lack of cross-sensitivity between capecitabine and fluorouracil.[1]

1. Liu CY. Fluorouracil for allergic reactions to capecitabine. *Ann Pharmacother* 2002; **36:** 1897–9.

Palmar-plantar erythrodysesthesia syndrome. Hand-foot syndrome (palmar-plantar erythrodysesthesia syndrome, p.639) has been reported to be common with use of capecitabine given either as monotherapy[1] or as part of combination chemotherapy regimens.[2,3] The syndrome developed within the first 2 cycles of monotherapy,[1] but within the first 3 cycles in combination therapy,[3] which was attributed to dose modifications of capecitabine in the latter case. Use with docetaxel, and previous chemotherapy-induced stomatitis were found to be significant risk factors for its occurrence.[3] The only effective management is treatment interruption and dose modification.[4] Supportive measures to reduce pain and discomfort and prevent secondary infection are important.[5] General recommended strategies include submersion of hands and feet in cold water, wound care, and avoidance of extreme temperature changes, tight-fitting clothing, or skin friction. Emollient creams may be of benefit for both prophylaxis and treatment. Other strategies that have been proposed include the use of amifostine, topical or systemic corticosteroids, and nicotine patches; however, use of these drugs for capecitabine-induced hand-foot syndrome remains unproven. While pyridoxine cannot be recommended for prophylaxis, some consider it a reasonable choice for treatment, since benefit has been reported with its use with topical emollients.[4] Concurrent treatment with celecoxib has been reported to reduce the incidence of hand-foot syndrome induced by capecitabine.[6,7] For reference to the use of vitamin E to alleviate hand-foot syndrome caused by capecitabine and docetaxel, see Chemotherapy-induced Toxicity, under Uses of Vitamin E, p.1994.

As a result of capecitabine-induced hand-foot syndrome, fingerprint misidentification has been reported.[8]

Tumour lysis syndrome. A fatal case of tumour lysis syndrome (p.639) has been reported after the use of capecitabine.[1]

1. Kurt M, *et al.* Tumor lysis syndrome following a single dose of capecitabine. *Ann Pharmacother* 2004; **38:** 902.

Interactions

As for Fluorouracil, p.723. Altered coagulation parameters and bleeding have occurred in patients on warfarin or phenprocoumon given capecitabine. Increased phenytoin plasma concentrations and symptoms of toxicity during use with capecitabine have been reported. Capecitabine must not be given with sorivudine or its analogues as fatal fluoropyrimidine toxicity may occur (see also Antivirals, under Interactions of Fluorouracil, p.723). Antacids containing aluminium or magnesium hydroxides cause a small increase in capecitabine plasma concentration. The maximum tolerated dose of capecitabine is reduced when it is given with either folinic acid or interferon alfa.

Pharmacokinetics

Capecitabine is readily absorbed from the gastrointestinal tract, with peak plasma concentrations occurring at about 1.5 hours. Food reduces the rate and extent of absorption. Plasma protein binding of capecitabine is less than 60%. Capecitabine is hydrolysed in the liver to 5′-deoxy-5-fluorocytidine (5′-DFCR), which is then converted to 5′-deoxy-5-fluorouridine (5′-DFUR; doxifluridine—p.712) and subsequently to 5-fluorouracil in body tissues. 5-Fluorouracil is further metabolised, as discussed on p.723. About 3% of a dose of capecitabine is excreted in the urine unchanged.

Uses and Administration

Capecitabine is a prodrug that is converted to fluorouracil (p.723) in body tissues. It is given orally for the treatment of metastatic colorectal cancer (p.665) and is also used for the adjuvant treatment of patients after surgery for Dukes C colon cancer. Capecitabine is given with docetaxel for the treatment of locally advanced or metastatic breast cancer (p.661) after failure of anthracycline-containing chemotherapy. It may be given as monotherapy after failure of taxanes and anthracycline-containing regimens for patients with breast cancer and for whom further anthracycline-containing therapy is not indicated. Capecitabine with lapatinib (p.739) is used for the treatment of patients with advanced or metastatic breast cancer whose tumours overexpress human epidermal receptor type 2 (HER2). Capecitabine is also used with a platinum-based regimen for the first-line treatment of gastric cancer (p.664).

For *monotherapy* in **colon**, **colorectal**, or in **breast** cancer, the recommended initial oral dose is 1.25 g/m^2 given twice daily; doses are given for 14 days, followed by a 7-day rest period. Adjuvant treatment for colon cancer is recommended for a total of 6 months. For *combination* therapy in **breast** cancer, when given with docetaxel, capecitabine is given in the same dose as listed above; docetaxel is given at 75 mg/m^2 as a 1-hour intravenous infusion every 3 weeks. However, when used with lapatinib tosilate, a different regimen is used, see Uses and Administration, under Lapatinib Tosilate, p.739.

In *combination* therapy in **colorectal** or **gastric** cancer, the recommended initial oral dose of capecitabine is 0.8 to 1 g/m^2 twice daily for 14 days, followed by a 7-day rest period. Alternatively, capecitabine 625 mg/m^2 twice daily is given continuously.

Capecitabine tablets should be swallowed with water within 30 minutes after a meal. Doses should be modified in subsequent cycles according to toxicity. Capecitabine doses should be reduced in patients with renal impairment (see below).

Capecitabine is also under investigation in the treatment of other malignancies.

Administration in renal impairment. Renal impairment increases systemic exposure to 5′-deoxy-5-fluorouridine, a metabolite of capecitabine. An increase in the severity of adverse effects appears to correlate with decreased renal function and increased exposure to this metabolite.[1]

Licensed product information suggests the following dosage adjustments based on creatinine clearance (CC):

- mild renal impairment, CC 51 to 80 mL/minute: no dosage adjustment necessary
- moderate renal impairment, CC 30 to 50 mL/minute: when the starting dose is 1.25 g/m^2 twice daily, a dose reduction of 25%, to about 950 mg/m^2 twice daily is recommended; however, when the starting dose is 1 g/m^2 twice daily, no dose reduction is required
- severe renal impairment, CC below 30 mL/minute: capecitabine is contra-indicated

Carboplatin *(BAN, USAN, rINN)*

Carboplatine; Carboplatino; Carboplatinum; CBDCA; JM-8; Karboplatiini; Karboplatin; Karboplatina; NSC-241240. *cis*-Diammine(cyclobutane-1,1-dicarboxylato)platinum.

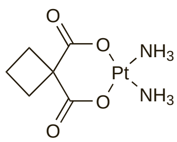
Карбоплатин

$C_6H_{12}N_2O_4Pt$ = 371.3.

CAS — 41575-94-4.

ATC — L01XA02.

ATC Vet — QL01XA02.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Carboplatin). A colourless, crystalline powder. Sparingly soluble in water; very slightly soluble in alcohol and in acetone. Protect from light.

USP 31 (Carboplatin). A 1% solution in water has a pH of 5.0 to 7.0. Store in airtight containers. Protect from light.

Incompatibility. Carboplatin reacts with aluminium causing loss of potency and forming a precipitate. Needles, syringes, catheters or giving sets that contain aluminium should not be used for preparing or giving carboplatin.

Stability. About 5% of the initial carboplatin concentration was lost over 24 hours when solutions were diluted in sodium chloride 0.9% and stored at 25°; lesser amounts of degradation were seen at lower sodium chloride concentrations, but carboplatin was apparently stable over this period if diluted with glucose 5%.[1] The authors suggested that chloride-containing infusion solutions are not suitable for carboplatin, not only because of the loss of active drug but because of the possibility that conversion to cisplatin may be occurring, with a risk of increased toxicity.[1] This has been contested by the manufacturers (*Bristol-Myers, USA*), who found that only 0.5% or 0.7%, depending on formulation, of a carboplatin solution in sodium chloride 0.9%, had been converted to cisplatin after 24 hours.[2] However, the total degradation of carboplatin was not measured. In another study, the authors calculated the time to 5% degradation of carboplatin at 25° as 29.2 hours in sodium chloride 0.9% compared with 52.7 hours in water.[3] They concluded that carboplatin should not be diluted in sodium chloride 0.9% when intended for continuous infusion over a prolonged period.[3] Carboplatin in glucose 5% was reported to be stable for 7 days at 25° in PVC bags when protected from light.[4]

4. Diaz Amador F, *et al.* Stability of carboplatin in polyvinyl chloride bags. *Am J Health-Syst Pharm* 1998; **55:** 602, 604.

Adverse Effects, Treatment, and Precautions

As for Cisplatin, p.698; nephrotoxicity and gastrointestinal toxicity are less severe than with cisplatin and reversible myelosuppression is the dose-limiting toxicity; platelet counts reach a nadir between 14 and 21 days after a dose, with recovery within 35 days, but recovery from leucopenia may be slower. Myelosuppression may be more severe and prolonged in patients with impaired renal function. Carboplatin should therefore be given at reduced doses to these patients and should be avoided if creatinine clearance is 20 mL/minute or less. Weekly blood counts and regular renal and hepatic function tests are recommended in all patients during therapy. Neurological function including assessment of hearing should also be monitored.

Incidence of adverse effects. The manufacturers analysed the adverse effects of carboplatin in studies involving 710 patients.[1] Myelosuppression was the dose-limiting toxicity: leucopenia occurred in 55% of the evaluable patients. Leucopenia and thrombocytopenia result in symptomatic events such as infection or bleeding in a minority of patients. Anaemia was frequent (59%) and required transfusional support in about one-fifth of the patients. Nephrotoxicity and serum electrolyte loss were much less of a problem; no high-volume fluid hydration or electrolyte supplementation was given during treatment. Vomiting occurred in about half the patients, and a further 25% had nausea without vomiting. Peripheral neurotoxicity was reported in 6% of evaluable patients and clinical ototoxicity occurred in only 8 cases or about 1% (but see also Effects on the Ears, below). Increases in liver enzyme values have also been reported, as well as, more rarely, alopecia, skin rash, a flu-like syndrome, and local effects at the injection site.

1. Canetta R, *et al.* Carboplatin: the clinical spectrum to date. *Cancer Treat Rev* 1985; **12** (suppl A): 125–36.

Effects on the ears. Carboplatin is less ototoxic than cisplatin, but ototoxicity is still common with carboplatin when used in high doses, for example, as part of conditioning regimens for bone marrow transplantation.[1,2] There was some evidence that sodium thiosulfate reduced carboplatin-induced hearing loss, when carboplatin was used for CNS malignancy.[3,4]

Effects on the eyes. Cortical blindness developed in 2 patients with impaired renal function receiving high-dose carboplatin;[1] although 10 cases of visual disturbances in patients receiving carboplatin had been reported to the manufacturers, none of these had sudden blindness and it was thought that the effect represented CNS toxicity in the presence of poor renal excretion. It was concluded that it was unwise to give high-dose carboplatin to patients whose glomerular filtration rate is less than 50 mL/minute.

1. O'Brien MER, *et al.* Blindness associated with high-dose carboplatin. *Lancet* 1992; **339:** 558.

Effects on the kidneys. Although carboplatin is reported to be much less nephrotoxic than cisplatin it is not devoid of adverse effects on the kidney.[1-8] Salt wasting nephropathy (similar to that seen with cisplatin),[1] and decreased creatinine clearance[2] and glomerular filtration rate[3] have occurred, as has acute renal failure, including in 2 patients given intraperitoneal carboplatin[4] (although these patients had been heavily pretreated with cisplatin). It has been suggested that renal toxicity may be more likely at cumulative carboplatin doses of about 750 mg/m^2 or more,[3] and there is some evidence to suggest that intensive hydration may ameliorate nephrotoxic effects.[2]

Hypersensitivity. In one series, 12% of 205 patients treated with carboplatin developed a hypersensitivity reaction after a median of 8 courses of platinum therapy.[1] Symptoms were at least moderately severe in half of the patients. Reactions to cisplatin would be anticipated in patients who have been previously sensitised to carboplatin—for 1 such case see p.699. In another study,[2] patients receiving more than 7 courses of carboplatin therapy were given a skin test before each course in an attempt to identify patients at risk for hypersensitivity reactions. The test consisted of 0.02 mL of an undiluted aliquot of their planned infusion, injected intradermally 1 hour before the dose. A negative skin test accurately predicted the absence of a hypersensitivity reaction. In a further extended report[3] by the same group, the skin test had been given about 30 minutes before carboplatin doses in 126 women who had already received at least 6 courses of a platinum-based regimen for a gynaecological cancer. Of 668 negative skin tests, a hypersensitivity reaction developed on 10 occasions (in 7 patients), giving a false-negative rate of 1.5%. None of the reactions were severe. Of the 39 patients who had a positive skin test, 7 elected to receive the dose of carboplatin; 6 of these developed a hypersensitivity reaction but none were severe.

The use of a desensitisation regimen has been successful in a small number of patients,[4] although others have not found it useful.[5]

Pregnancy. For a report of the successful use of carboplatin-based chemotherapy during pregnancy, with no adverse effects on the infant, see Pregnancy, under Cisplatin, p.699.

Interactions

As for Cisplatin, p.700.

Pharmacokinetics

Intravenous carboplatin exhibits a biphasic elimination and is excreted primarily in the urine, about 70% of a dose being excreted within 24 hours, almost all unchanged. The terminal half-life of intact carboplatin is reported to be about 1.5 to 6 hours. Platinum from carboplatin slowly becomes protein bound, and is subsequently excreted with a half-life of 5 days or more.

Uses and Administration

Carboplatin is an analogue of cisplatin with similar actions and uses (see p.700). It is used in the treatment of advanced ovarian cancers and of small-cell lung cancer, both alone and combined with other antineoplastics. It has also been tried as an alternative to cisplatin in other solid tumours (see below).

Carboplatin is given by intravenous infusion over 15 minutes to 1 hour. In the UK an initial dose of 400 mg/m^2 is licensed for use as a single agent in previously untreated patients with normal renal function, reduced by 20 to 25% (300 to 320 mg/m^2) in patients who have previously been treated with myelosuppressive therapy or who have poor performance status. In the USA an initial dose of 360 mg/m^2 is licensed as a single agent in previously treated patients with recurrent disease, and an initial dose of 300 mg/m^2 when used with cyclophosphamide in previously untreated patients.

Dosage adjustments are necessary in patients with renal impairment (see below) and when carboplatin is given as part of a combination regimen. The dose in mg may be calculated using the Calvert formula as described under Administration, below. Subsequent doses should be adjusted according to the nadir of the white cell and platelet counts (see also Bone-marrow Depression, p.639), and should not be given more frequently than every 4 weeks.

Administration. Pharmacokinetic studies by Calvert and colleagues[1] have indicated that the dose of carboplatin to produce a desired area under the concentration-time curve (AUC) could be calculated, based on the patient's glomerular filtration rate (GFR), as:

$$\text{Dose in mg} = \text{target AUC} \times (\text{GFR} + 25)$$

It should be noted that the resultant dose is given in mg and not in mg/m^2. This formula was found to be useful in patients with higher than normal as well as reduced GFR. Suggested target AUCs were 5 mg/mL per minute in previously treated patients and 7 mg/mL per minute in those who had not previously received chemotherapy. In combination therapy the appropriate AUC value depended on the other drugs used: an AUC of 4.5 mg/mL per minute gave acceptable results when carboplatin was used with bleomycin and etoposide for testicular teratoma.

However, determination of GFR may be a problem: clearance of technetium-99m-labelled diethylenetriamine penta-acetic acid (DTPA) or chromium-51-labelled edetic acid is more accurate than 24-hour creatinine clearance, with the first of these more convenient than the second.[2] (It has been suggested that creatinine clearance should not be used to estimate GFR for the Calvert equation.[3]) Nonetheless, radioisotopic determination of

GFR is still an elaborate procedure, and may be less accurate in children than adults.[4] Chatelut and colleagues have proposed formulae for determining clearance of carboplatin in both adults[5] and children.[4]

It has been suggested that the Calvert and Chatelut formulae are not sufficiently accurate for use in children, or in adults with very severe renal impairment. Bayesian methods are the technique of choice where serum carboplatin concentrations can be monitored.[3] However, a study in children showed that dosage based on determination of the GFR results in more consistent carboplatin exposure than dosage based on body-surface area.[6]

6. Thomas H, *et al.* Prospective validation of renal-function-based carboplatin dosing in children with cancer: a United Kingdom Children's Cancer Study Group Trial. *J Clin Oncol* 2000; **18:** 3614–21.

Administration in renal impairment. The initial dose of carboplatin is usually determined using a formula (see Administration, above). If this approach is not adopted, the UK licensed product information recommends the following doses based on the patient's creatinine clearance (CC):

- CC 40 mL/minute or more: 400 mg/m^2
- CC 20 to 39 mL/minute: 250 mg/m^2

However, in the USA, the licensed information recommends:

- CC 41 to 59 mL/minute: 250 mg/m^2
- CC 16 to 40 mL/minute: 200 mg/m^2

Malignant neoplasms. A preliminary review[1] of carboplatin, concluded that it was active in ovarian cancer (p.670), with similar responses to those seen with cisplatin; its activity in small-cell lung cancer (p.668), seminoma, and squamous cell carcinomas of the head and neck seemed likely to be comparable, whereas results in gastrointestinal and breast cancers, lymphomas and leukaemias, melanoma, mesothelioma, renal carcinoma, and sarcoma were, generally unimpressive. A subsequent review[2] suggested that in testicular cancer, where there was a prospect of cure, cisplatin, which appeared to give better results in some studies should be preferred. However, in ovarian cancer, where treatment was largely palliative, carboplatin had the advantage of being better tolerated. A further review[3] of randomised studies concurred that carboplatin was equivalent to cisplatin in suboptimally debulked ovarian cancer and extensive-stage small-cell lung cancer, and was inferior to cisplatin in testicular cancer. It was also concluded that carboplatin was inferior to cisplatin in head and neck and oesophageal cancers. There was insufficient comparative evidence for other cancers for which cisplatin has a role.

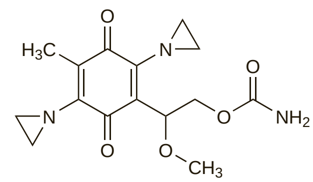
Carboquone *(rINN)*

Carbazilquinone; Carbocuona; Carboquonum; Karbokvon; Karbokvoni. 2,5-Bis(aziridin-1-yl)-3-(2-hydroxy-1-methoxyethyl)-6-methyl-*p*-benzoquinone carbamate.

Карбохон

$C_{15}H_{19}N_3O_5$ = 321.3.
CAS — 24279-91-2.
ATC — L01AC03.
ATC Vet — QL01AC03.



Profile

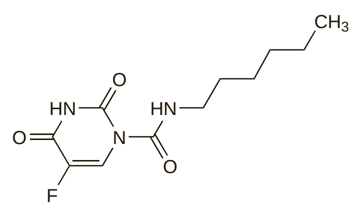
Carboquone is an alkylating agent that has been used in the treatment of a variety of malignant neoplasms including those of the lung, stomach, and ovary; it has also been used in lymphomas and in chronic myeloid leukaemia. It has been given by the intravenous or intra-arterial route, or orally.

Carmofur *(rINN)*

Carmofurum; HCFU; Karmofuuri. 5-Fluoro-*N*-hexyl-3,4-dihydro-2,4-dioxo-1-(2*H*)-pyrimidinecarboxamide; 1-Hexylcarbamoyl-5-fluorouracil.

Кармофур

$C_{11}H_{16}FN_3O_3$ = 257.3.
CAS — 61422-45-5.
ATC — L01BC04.
ATC Vet — QL01BC04.



Pharmacopoeias. In *Chin.* and *Jpn.*

Profile

Carmofur is an orally active derivative of fluorouracil (p.722) and has similar actions. It is used in the adjuvant treatment of colorectal cancer, and has been used in breast and ovarian cancers. Carmofur has been associated with the development of neurological disorders including leukoencephalopathy.

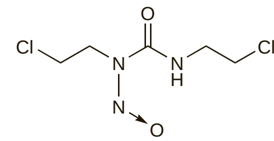
Carmustine *(BAN, USAN, rINN)*

BCNU; BiCNU; Carmustina; Carmustinum; Karmustiini; Karmustin; Karmustinas; Karmusztin; NSC-409962; WR-139021. 1,3-Bis(2-chloroethyl)-1-nitrosourea.

Кармустин

$C_5H_9Cl_2N_3O_2$ = 214.0.
CAS — 154-93-8.
ATC — L01AD01.
ATC Vet — QL01AD01.



Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Carmustine). A yellowish, granular powder. Very slightly soluble in water; freely soluble in dehydrated alcohol; very soluble in dichloromethane. It melts at about 31° with decomposition. Store at a temperature of 2° to 8° in airtight containers. Protect from light.

Stability. The manufacturers state that, when reconstituted, resulting carmustine solutions (undiluted or further diluted in sodium chloride 0.9% or glucose 5%) are stable for 8 hours at room temperature, or 24 hours at 2° to 8°, when protected from light. There is some evidence that carmustine interacts with plastic giving sets and containers, and licensed product information recommends the use of polyethylene or glass.

A study has indicated that diluted solutions of carmustine undergo increased degradation in the presence of sodium bicarbonate, with only 73% of the original concentration of carmustine remaining after 90 minutes, much of the loss being in the first 15 minutes.[1]

1. Colvin M, *et al.* Stability of carmustine in the presence of sodium bicarbonate. *Am J Hosp Pharm* 1980; **37:** 677–8.

Adverse Effects and Treatment

For a general outline see Antineoplastics, p.635 and p.639. Delayed and cumulative bone-marrow depression is the most frequent and serious adverse effect of intravenous carmustine. Platelets and leucocytes are mainly affected, with platelet nadirs occurring at 4 to 5 weeks after a dose and leucocyte nadirs at 5 to 6 weeks; although thrombocytopenia is usually more severe, leucopenia may also be dose-limiting. Other adverse effects include pulmonary fibrosis (mainly but not exclusively at high cumulative doses—see also Effects on the Lungs, p.638), renal and hepatic damage, and neuroretinitis. Nausea and vomiting, beginning up to 2 hours after a dose, is common but can be reduced by prophylactic antiemetic therapy. Venous irritation may follow intravenous injection and transient hyperpigmentation has been noted after contact of a solution with the skin. Flushing of the skin and suffusion of the conjunctiva may occur on rapid intravenous infusion. Hypotension, tachycardia, chest pain, headache, and hypersensitivity reactions have been reported.

Convulsions, cerebral oedema, and various neurological symptoms have been reported in patients given carmustine-containing polymer implants; abnormalities of wound healing at the site of implantation, and an increased incidence of intracranial infection have also been reported.

As with other alkylating agents, carmustine is potentially carcinogenic, mutagenic, and teratogenic.

Effects on the eyes. Ocular toxicity has been reported in patients given carmustine,[1,2] and seems to be more likely when given into the carotid artery,[1,2] although it was also seen with high-dose intravenous therapy. There is some evidence that the alcohol diluent used to prepare carmustine solutions may contribute to the retinopathy.[2]

1. Shingleton BJ, *et al.* Ocular toxicity associated with high-dose carmustine. *Arch Ophthalmol* 1982; **100:** 1766–72.
2. Greenberg HS, *et al.* Intra-arterial BCNU chemotherapy for treatment of malignant gliomas of the central nervous system. *J Neurosurg* 1984; **61:** 423–9.

Effects on the lungs. Studies have found a high incidence of fatal pulmonary fibrosis (see also Effects on the Lungs, p.638) in patients treated with carmustine for gliomas during childhood; patients who were treated before 5 or 6 years of age were more likely to die of pulmonary fibrosis than those treated at a later age.[1,2] However, there are reports of pulmonary toxicity and upper lobe pulmonary fibrosis occurring in adults given carmustine and high-dose chemotherapy.[3]

3. Parish JM, *et al.* Upper lobe pulmonary fibrosis associated with high-dose chemotherapy containing BCNU for bone marrow transplantation. *Mayo Clin Proc* 2003; **78:** 630–4.

Extravasation. For mention of the use of sodium bicarbonate as a specific antidote after carmustine extravasation, see under Treatment of Adverse Effects of Antineoplastics, p.640.

Precautions

For reference to the precautions necessary with antineoplastics, see p.641. Carmustine should be used with extreme caution in children, who are at particular risk of severe delayed pulmonary toxicity. It should also be used with caution in patients with reduced lung function. Lung function should be monitored before and frequently during therapy. Blood counts should be monitored weekly during therapy, and for at least 6 weeks after the last dose. Renal and hepatic function should also be monitored periodically.

Handling and disposal. Carmustine has been shown to permeate latex, PVC, and rubber gloves, the degree of permeation tending to increase with time,[1-3] up to an equilibrium value.[2] The permeation rate appears not to depend solely on glove thickness and material, and may be different for different gloves made from the same material.[2] The time for initial penetration was reported to vary between 4.7 and 66.0 minutes in one study,[2] and gloves could be chosen accordingly depending on the anticipated length of exposure. Double-gloving, particularly with thicker PVC[1] or ethylmethacrylate[3] gloves, may offer some additional protection.

3. Mellström GA, *et al.* Barrier effect of gloves against cytostatic drugs. *Curr Probl Dermatol* 1996; **25:** 163–9.

Interactions

For a general outline of antineoplastic drug interactions, see p.642.

Cimetidine. Reductions in white cell counts and platelet counts well below those normally attributed to treatment with carmustine alone were seen in 6 of 8 patients receiving their first course of carmustine and steroids with cimetidine given prophylactically,[1] and in 9 patients in a further study.[2] Cimetidine was also reported to exacerbate the neutropenia and leucopenia in a patient receiving lomustine.[3]

2. Volkin RL, *et al.* Potentiation of carmustine-cranial irradiation-induced myelosuppression by cimetidine. *Arch Intern Med* 1982; **142:** 243–5.
3. Hess WA, Kornblith PL. Combination of lomustine and cimetidine in the treatment of a patient with malignant glioblastoma: a case report. *Cancer Treat Rep* 1985; **69:** 733.

Pharmacokinetics

Intravenous carmustine is rapidly metabolised, and no intact drug is detectable after 15 minutes; metabolites have a much longer half-life and are presumed to be responsible for its activity. It is primarily excreted in the urine; some is also excreted as carbon dioxide, via the lungs. Carmustine readily crosses the blood-brain barrier, appearing in CSF in substantial concentrations almost immediately after intravenous injection. Carmustine diffuses from polymer implants into surrounding brain tissue; however, tissue and plasma concentrations after implantation have not been determined.

Uses and Administration

Carmustine is a cell-cycle phase non-specific antineoplastic belonging to the nitrosourea group of compounds, which are considered to function as alkylating agents. It is believed to alkylate DNA and RNA, and may also inhibit enzymatic processes by carbamoylation of amino acids in proteins. Carmustine is used in the treatment of brain tumours, and in combination chemotherapy for multiple myeloma. It may be given as second-line therapy in Hodgkin's disease, non-Hodgkin's lymphoma, and some other malignancies (see below).

Carmustine is licensed for use as a single agent either as a single dose of 150 to 200 mg/m^2 or divided into doses of 75 to 100 mg/m^2 given on 2 successive days. Doses are given by intravenous infusion over 1 to 2 hours in sodium chloride 0.9% or glucose 5%. Lower doses are usually given in combination therapy, except for conditioning before stem-cell transplantation. Doses may be repeated every 6 weeks provided that blood counts have returned to acceptable levels. Subsequent doses must be adjusted according to the haematological response (see also Bone-marrow Depression, p.639).

Polymer implants containing carmustine have been developed for implantation into the brain in the localised treatment of high-grade malignant glioma or recurrent glioblastoma multiforme. Each implant contains 7.7 mg of carmustine: up to 8 such implants are inserted into the cavity left by surgical removal of the tumour.

Amyloidosis. For mention of chemotherapy with epirubicin, cyclophosphamide, and carmustine to suppress amyloidosis after cardiac transplantation, see p.743.

Malignant neoplasms. Carmustine has been used in chemotherapeutic regimens for a number of malignancies. Because of its ability to pass the blood-brain barrier it has been extensively used in malignant neoplasms of the brain (p.660). As an extension of such use, carmustine-releasing wafers have been implanted directly into the brain.[1] In a multicentre study[2] in patients with recurrent malignant glioma, biodegradable poly(carboxyphenoxypropane/sebacic acid)anhydride polymer wafers containing carmustine implanted into the brain after tumour resection produced a median survival of 31 weeks compared with 23 weeks for placebo. A subsequent small cohort study[3] failed to find a clear survival benefit associated with wafer implantation in recurrent glioma, and reported a higher rate of complications including seizures, cerebral oedema, CSF leaks, sepsis, and wound infections. The limitations of this small study were acknowledged by the authors, and a review[4] that included these studies concluded that despite limited data, carmustine wafers do provide some survival benefit. A randomised trial in 240 patients found that treatment with carmustine wafers reduced the risk of death by 28% compared with placebo;[5] this survival advantage was maintained at 1, 2, and 3 years, with statistical significance at 3 years.[6] The adverse effect profile was similar for carmustine and placebo groups,[5] and a retrospective review[7] found carmustine wafers to be well tolerated with a low incidence of surgical complications such as infection. However, it was noted that, in some patients, neurological symptoms developed during an attempted tapering of dexamethasone dosage after carmustine with radiotherapy and that close supervision of patients is warranted. Treatment effects or necrosis can radiographically mimic recurrent tumour in a proportion of patients;[7] implantation of wafers caused morphological changes of the brain immediately adjacent to the implants.[8]

Other conditions in which carmustine has been employed, include malignant melanoma (p.673), Hodgkin's disease (p.655), and multiple myeloma (p.658).

Cetuximab *(USAN, rINN)*

C-225; Cétuximab; Cetuximabum. Immunoglobulin G1 (human-mouse monoclonal C225 γ1-chain anti-human epidermal growth factor receptor), disulfide with human-mouse monoclonal C225 κ-chain, dimer.

Цетуксимаб

CAS — 205923-56-4.

ATC — L01XC06.

ATC Vet — QL01XC06.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

Adverse effects associated with cetuximab include skin reactions, asthenia, and gastrointestinal disturbances. Skin reactions present mainly as an acneform rash, and, if severe, require dosage adjustment (see Uses and Administration, below). Infusion reactions suggestive of a cytokine release syndrome can occur, usually with the first dose. Mild reactions include chills, fever, and dyspnoea; severe reactions include bronchospasm, urticaria, hypotension, and loss of consciousness, and fatalities have occurred. Premedication with a histamine H_1-antagonist is recommended, and dose adjustment may be necessary (see below). Cardiopulmonary arrest and/or sudden death has been reported in patients treated with cetuximab and radiation therapy, and cetuximab should be given with caution to head and neck cancer patients with coronary artery disease, congestive cardiac failure, or arrhythmias. Hypomagnesaemia can occur; patients should be monitored for this and accompanying hypocalcaemia and hypokalaemia both during, and for up to 8 weeks after stopping, cetuximab therapy. Interstitial lung disease and pneumonitis have been reported rarely.

Effects on the skin, hair, and nails. Acneform follicular rashes have been reported with cetuximab therapy;[1,2] lesions were pustular and papular,[2-4] and commonly occurred on the face, scalp, chest, and upper back.[1-5] It has been suggested that there is a relationship between rash and response to therapy or survival, i.e. that rash might be a surrogate marker of cetuximab activity;[6] doubling the cetuximab dose in patients without severe initial skin reactions is reported to increase their response rate to therapy.[7] A few cases of lengthening eyelash and eyebrow hair[8] and abnormal growth of chest hair[9] have been described. Paronychia has also been reported,[1,5,10] as have intraoral aphthous ulcers.[1]

Treatment with oral isotretinoin 500 micrograms/kg daily has been reported to successfully clear acneform skin lesions in 2 patients; topical therapy with metronidazole 0.75% gel or erythromycin 1% was also used.[11] Prophylactic oral minocycline 100 mg daily, started on the same day as cetuximab and given for 8 weeks, significantly reduced total facial lesion counts in the first 4 weeks when compared with placebo; this difference tapered by the end of 8 weeks of treatment. Topical tazarotene showed no clinical benefit and caused local irritation that forced tazarotene to be stopped in many patients.[12]

Some have suggested that the clinical findings of papulopustular rash, nail and periungual abnormalities, alterations in hair texture and growth, and dry skin and pruritus, constitute a syndrome unique to the epidermal growth factor receptor (EGFR) inhibitors, believed to be due to EGFR inhibition in the epidermis, hair follicle, and nail matrix.[13]

Erythema and focal epidermolysis, progressing to severe radiation dermatitis with necrosis, has been reported in patients given radiation therapy with cetuximab.[14]

Hypomagnesaemia. A patient given cetuximab developed profound hypomagnesaemia, requiring intravenous supplementation with up to 10 g magnesium sulfate daily, throughout the duration of cetuximab therapy. This case prompted a review of 154 patients treated with cetuximab, of whom 34 had their magnesium concentrations measured at least once. Among these 34 patients, 6 had grade 3 and 2 had grade 4 hypomagnesaemia; this equated to an incidence of 24% of grade 3/4 hypomagnesaemia. In each of these cases the need for supplementation subsided after stopping cetuximab, with resolution of the hypomagnesaemia within several weeks.[1] However, it was not clear whether all patients had a normal magnesium concentration before treatment, nor was there any indication of the median time to development of hypomagnesaemia.

Another retrospective review of 114 patients did address these issues.[2] It found 48 patients had normal baseline magnesium concentrations before starting cetuximab. Of these 48 evaluable patients, 13 developed grade 3 or grade 4 hypomagnesaemia (27%); median time to onset of grade 3/4 hypomagnesaemia was 5.5 months. There was a significant association between duration of cetuximab therapy and grade of hypomagnesaemia. Magnesium replacement therapy was given to those patients with grade 3/4 toxicity. Initial attempts at oral replacement with up to 1.6 g magnesium oxide three times daily were ineffective, and intravenous supplementation was needed. However, the effects of infusion did not extend beyond 48 to 72 hours, with some patients requiring daily magnesium sulfate infusions of up to 10 g daily. Furthermore, in some patients, magnesium supplementation became less effective with continued cetuximab treatment. Of 3 patients evaluable for recovery from hypomagnesaemia after stopping cetuximab, 2 were found to correct their magnesium concentrations without supplementation after 1 month. However, 1 patient required prolonged and ongoing supplementation for more than 5 months, at 4 g infused 3 times weekly (having received 8 g daily while on cetuximab).[2] A prospective study[3] found that a progressive decrease in serum magnesium concentrations was seen in 97% of patients after treatment with cetuximab, panitumumab, or matuzumab. The authors concluded that magnesium wasting was specifically due to inhibition of the epidermal growth factor receptor (EGFR), and suggested hypomagnesaemia might be a class effect of the monoclonal antibodies directed against EGFR. However, incidence and severity may vary between products. There was also high interindividual variability; increasing age was associated with more severe hypomagnesaemia.

Pharmacokinetics

The pharmacokinetics of cetuximab have been reported to be non-linear and dose-dependent. Steady-state concentrations are reached after 3 weeks. Cetuximab has a long elimination half-life of about 70 to 100 hours.

Uses and Administration

Cetuximab is a monoclonal antibody that binds to the epidermal growth factor receptor (EGFR). It is used in the treatment of EGFR-expressing metastatic colorectal cancer (p.665), either with irinotecan in patients refractory to irinotecan-based chemotherapy, or as monotherapy in patients intolerant to irinotecan. Cetuximab with radiotherapy is also used for the treatment of locally advanced squamous cell cancer of the head and neck (p.666). It is also approved as monotherapy for the treatment of patients with recurrent or metastatic squamous cell carcinoma of the head and neck for whom prior platinum-based therapy has failed. It is under investigation for non-small cell lung cancer and other solid tumours.

Cetuximab 400 mg/m^2 is given as a loading dose by intravenous infusion over 2 hours. This is followed by once weekly maintenance doses of 250 mg/m^2 given over 1 hour. Premedication with a histamine H_1-antagonist is recommended, and patients should be closely monitored for at least 1 hour after the end of the cetuximab infusion. A low-protein-binding 0.22-micrometre in-line filter should be used, and the infusion given via an infusion or syringe pump.

In combined therapy for colorectal cancer, irinotecan should not be given for at least 1 hour after the end of cetuximab infusion. In head and neck carcinoma, cetuximab therapy is started one week before radiation therapy and continued until the end of the radiation therapy period. Cetuximab is usually given 1 hour before radiation therapy. When used as monotherapy, cetuximab is continued until disease progression or unacceptable toxicity occurs.

Cetuximab doses should be permanently halved in patients who have experienced a mild to moderate infusion reaction, and stopped permanently if a severe reaction has occurred (see Adverse Effects and Precautions, above). When a severe acneform rash has occurred, the next dose should be delayed by 1 to 2 weeks. After the first occurrence, the full maintenance dose may be given if there has been improvement in the rash; after a second occurrence the next dose should be delayed and reduced to 200 mg/m^2; after a third occurrence the next dose should be delayed and reduced to 150 mg/m^2. If there is no improvement in the rash when therapy has been delayed, or if the rash has occurred 4 times, cetuximab should be stopped.

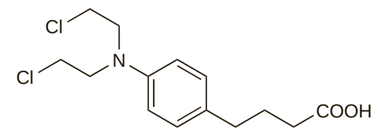
ATC — L01AA02.
ATC Vet — QL01AA02.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int.*, and *US.*
Ph. Eur. 6.2 (Chlorambucil). A white or almost white, crystalline powder. Practically insoluble in water; freely soluble in alcohol and in acetone. Protect from light.
USP 31 (Chlorambucil). An off-white, slightly granular powder. M.p. 65° to 69°. Very slightly soluble in water; soluble 1 in 2 of acetone; soluble in dilute alkali. Store in airtight containers. Protect from light.

Storage. The manufacturers recommend that tablets of chlorambucil should be stored at 2° to 8° and kept dry.

Adverse Effects and Treatment

For a general outline see Antineoplastics, p.635 and p.639.

A reversible progressive lymphocytopenia tends to develop during treatment with chlorambucil. Neutropenia may continue to develop up to 10 days after the last dose. Irreversible bone-marrow depression can occur particularly when the total dosage for the course approaches 6.5 mg/kg.

Other reported adverse effects include gastrointestinal disturbances, hepatotoxicity, skin rashes (rarely Stevens-Johnson syndrome or toxic epidermal necrolysis), peripheral neuropathy, and central neurotoxicity, including seizures. Interstitial pneumonia and pulmonary fibrosis have occurred; the latter is usually reversible but fatalities have been recorded. Chlorambucil in high doses may produce azoospermia and amenorrhoea; sterility has developed particularly when chlorambucil has been given to boys at or before puberty.

Overdosage may result in pancytopenia and in neurotoxicity, including agitation, ataxia, and grand mal seizures.

Like other alkylating agents, chlorambucil is potentially mutagenic, teratogenic, and carcinogenic, and an increased incidence of acute leukaemias and other secondary malignancies has been reported in patients who have received the drug.

Effects on the bladder. Chlorambucil-induced cystitis was reported in a 73-year-old woman given 2 mg daily for over 2 years for the treatment of lymphocytic lymphoma.[1]

1. Daoud D, *et al.* Sterile cystitis associated with chlorambucil. *Drug Intell Clin Pharm* 1977; **11:** 491.

Effects on the eyes. Visual impairment and optic atrophy in a patient who had been receiving chlorambucil for 5 years to control non-Hodgkin's lymphoma were thought to be due to the drug,[1] although ocular effects are extremely rare with chlorambucil.

1. Yiannakis PH, Larner AJ. Visual failure and optic atrophy associated with chlorambucil therapy. *BMJ* 1993; **306:** 109.

Effects on the nervous system. There have been a small number of reports of seizures in patients given chlorambucil. A review[1] of these suggested that in adults, patients with a history of seizures, or those given high doses of chlorambucil may be at increased risk. The reports in children consisted mainly of patients being treated for nephrotic syndrome, possibly because the condition may alter the pharmacokinetics of chlorambucil.

1. Salloum E, *et al.* Chlorambucil-induced seizures. *Cancer* 1997; **79:** 1009–13.

Precautions

For reference to the precautions necessary with antineoplastics, see p.641. Chlorambucil should be avoided, or given with great care and at reduced doses, for at least 4 weeks after treatment with radiotherapy or other antineoplastics (unless only low doses of radiation have been given to parts remote from the bone marrow and the neutrophil and platelet counts are not depressed). The dose should be reduced if there is lymphocytic involvement of the bone marrow or if it is hypoplastic. Chlorambucil should be given with care to patients with impaired renal function; consideration should also be given to dose reduction in patients with gross hepatic dysfunction. Children with nephrotic syndrome, patients receiving high-dose pulse therapy with chlorambucil, and those with a history of seizures, may be at increased risk of seizures. Regular blood counts are required during therapy.

Handling and disposal. Chlorambucil is irritant; avoid contact with skin and mucous membranes.

Urine produced for up to 48 hours after a dose of chlorambucil should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; **235:** 289–91.

Porphyria. Chlorambucil is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals.*

Interactions

For a general outline of antineoplastic drug interactions, see p.642.

Pharmacokinetics

Chlorambucil is rapidly and almost completely absorbed from the gastrointestinal tract after oral doses and is reported to have a terminal half-life in plasma of about 1.5 hours. It is extensively metabolised in the liver, primarily to active phenylacetic acid mustard, which has a slightly longer plasma half-life of about 1.8 to 2.5 hours, and which like chlorambucil also undergoes some spontaneous degradation to further derivatives. Chlorambucil and its metabolites are extensively protein bound. It is excreted in the urine almost entirely as metabolites with less than 1% unchanged.

Uses and Administration

Chlorambucil is an antineoplastic derived from chlormethine (p.697) and has a similar mode of action. It acts on lymphocytes and to a lesser extent on neutrophils and platelets. Chlorambucil is most valuable in those conditions associated with the proliferation of white blood cells, especially lymphocytes, and is used in the treatment of chronic lymphocytic leukaemia and lymphomas, including Hodgkin's disease. It is also used in Waldenström's macroglobulinaemia and has been given in gestational trophoblastic tumours. Although formerly widely used in the management of polycythaemia vera it has largely been superseded.

Chlorambucil also has immunosuppressant properties and has been given in auto-immune disorders including amyloidosis, Behçet's syndrome, glomerular kidney disease, primary biliary cirrhosis, polymyositis, rheumatoid arthritis, and sarcoidosis.

The use of chlorambucil in these disorders is discussed further elsewhere, as indicated by the cross-references given below.

Chlorambucil is better tolerated than chlormethine hydrochloride and serious bone-marrow toxicity is not usually a problem with normal doses. When used as a single-agent antineoplastic for chronic lymphocytic leukaemia and lymphomas, chlorambucil is licensed for oral use in usual initial doses of 100 to 200 micrograms/kg daily (usually 4 to 10 mg once daily), for 3 to 8 weeks. A dose of 100 micrograms/kg daily may be adequate for the treatment of non-Hodgkin's lymphoma; 150 micrograms/kg daily until the total leukocyte count falls below 10 000 cells/mm^3 may be used in chronic lymphocytic leukaemia; and in Hodgkin's disease, 200 micrograms/kg daily is usually required. Lower doses may be given as part of a combination regimen. If lymphocytic infiltration of the bone marrow is present or if the bone marrow is hypoplastic, the daily dose should not exceed 100 micrograms/kg. Alternatively, high-dose chlorambucil may be given intermittently. For example, in chronic lymphocytic leukaemia it may be given in an initial single dose of 400 micrograms/kg increased by 100 micrograms/kg at each 2- or 4-week dose interval until control of lymphocytosis is achieved or toxicity occurs.

Once a remission has been established the patient may receive continuous maintenance with 30 to 100 micrograms/kg daily. However, short intermittent courses appear to be safer and are generally preferred for maintenance.

In patients with Waldenström's macroglobulinaemia chlorambucil is licensed in an initial oral dose of 6 to 12 mg daily until leucopenia develops. Maintenance therapy with doses of 2 to 8 mg daily may then be given indefinitely.

Total and differential white cell counts and haemoglobin and platelet examinations are recommended each week during treatment with chlorambucil.

Amyloidosis. Chlorambucil may be of use in preserving kidney function and improving survival in patients with amyloidosis secondary to rheumatic disease,[1-4] the management of which is discussed in more detail on p.743.

1. Berglund K, *et al.* Alkylating cytostatic treatment in renal amyloidosis secondary to rheumatic disease. *Ann Rheum Dis* 1987; **46:** 757–62.
2. Berglund K, *et al.* Results, principles and pitfalls in the management of renal AA-amyloidosis; a 10-21 year followup of 16 patients with rheumatic disease treated with alkylating cytostatics. *J Rheumatol* 1993; **20:** 2051–7.

4. Savolainen HA. Chlorambucil in severe juvenile chronic arthritis: longterm followup with special reference to amyloidosis. *J Rheumatol* 1999; **26:** 898–903.

Blood disorders, non-malignant. Chlorambucil may produce a response in cold auto-immune haemolytic anaemia (p.1043).

Connective tissue and muscular disorders. Chlorambucil has been used as a corticosteroid-sparing agent in patients with Behçet's syndrome (p.1499). It has occasionally been tried in polymyositis (p.1510). In both these conditions, the potential benefits must be weighed against the possibility of toxicity.

Kidney disorders, non-malignant. Chlorambucil has been used in some forms of glomerular kidney disease (p.1504). In minimal change nephropathy, in which cytotoxics are reserved for the most severe cases because of fears about toxicity, cyclophosphamide is generally preferred to chlorambucil because it is perceived as entailing somewhat less risk; chlorambucil has been used with corticosteroids in patients with membranous nephropathy,[1-3] but again cyclophosphamide may be better tolerated.

1. Ponticelli C, *et al.* Methylprednisolone plus chlorambucil as compared with methylprednisolone alone for the treatment of idiopathic membranous nephropathy. *N Engl J Med* 1992; **327:** 599–603.
2. Reichert LJM, *et al.* Preserving renal function in patients with membranous nephropathy: daily oral chlorambucil compared with intermittent monthly pulses of cyclophosphamide. *Ann Intern Med* 1994; **121:** 328–33.
3. Ponticelli C, *et al.* A 10-year follow-up of a randomized study with methylprednisolone and chlorambucil in membranous nephropathy. *Kidney Int* 1995; **48:** 1600–4.

Liver disorders, non-malignant. No treatment has proven unequivocally successful in the management of primary biliary cirrhosis (p.2408). Chlorambucil is one of a number of drugs for which reports of benefit exist.[1]

1. Hoofnagle JH, *et al.* Randomized trial of chlorambucil for primary biliary cirrhosis. *Gastroenterology* 1986; **91:** 1327–34.

Malignant neoplasms. Chlorambucil is used in the management of a number of haematological malignancies including chronic lymphocytic leukaemia (p.653), Hodgkin's disease (p.655), indolent low-grade non-Hodgkin's lymphomas (p.656), and Waldenström's macroglobulinaemia (p.658). It was formerly used in polycythaemia vera (p.654) but is now largely superseded.

Ocular disorders, non-malignant. Chlorambucil is one of the immunosuppressants that may be considered for patients with uveitis (p.1515) unresponsive to corticosteroids in tolerable doses.[1-3]

2. Chave TA, *et al.* Chlorambucil as a steroid-sparing agent in bullous pemphigoid. *Br J Dermatol* 2004; **151:** 1107–8.

Rheumatoid arthritis. Chlorambucil has been used for its immunosuppressant properties in a few patients with severe rheumatoid arthritis (p.11), especially with vasculitis, who have failed to respond to other drugs. However, the use of cytotoxic immunosuppressants other than methotrexate is considered debatable.

Sarcoidosis. Where drug therapy is required for sarcoidosis (p.1512), corticosteroids are the usual treatment. Chlorambucil is one of a number of cytotoxic immunosuppressants that have been tried, with variable results, as a second-line therapy.

Preparations

BP 2008: Chlorambucil Tablets;
USP 31: Chlorambucil Tablets.

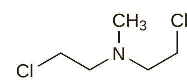
Chlormethine Hydrochloride *(BANM, rINNM)*

Chlorethazine Hydrochloride; Chlorméthine, Chlorhydrate de; Chlormethini Hydrochloridum; Hidrocloruro de clormetina; HN2 (chlormethine); Klormetin Hidroklorür; Mechlorethamine Hydrochloride; Mustin Hidroklorür; Mustine Hydrochloride; Nitrogen Mustard (chlormethine); NSC-762; WR-147650. Bis(2-chloroethyl)methylamine hydrochloride; 2,2′-Dichloro-*N*-methyldiethylamine hydrochloride.

Хлорметина Гидрохлорид

$C_5H_{11}Cl_2N,HCl = 192.5.$
CAS — 51-75-2 (chlormethine); 55-86-7 (chlormethine hydrochloride).
ATC — L01AA05.
ATC Vet — QL01AA05.



(chlormethine)

Pharmacopoeias. In *Br., Chin., Int.,* and *US.*

BP 2008 (Chlormethine Hydrochloride). A white or almost white, hygroscopic, vesicant, crystalline powder or mass. Very soluble in water. Store at a temperature of 8° to 15°.

USP 31 (Mechlorethamine Hydrochloride). A white, hygroscopic, crystalline powder. A 0.2% solution in water has a pH of 3.0 to 5.0. Store in airtight containers. Protect from light.

Stability. Solutions of chlormethine hydrochloride lose their activity very rapidly, particularly at neutral or alkaline pH.

A study[1] using an assay specific for chlormethine found that a 0.1% solution in Water for Injections or sodium chloride 0.9% injection underwent a loss of about 10% when stored for 6 hours at room temperature, and of about 4 to 6% when stored for the same period at 4°; similar results were obtained whether the solution was stored in glass vials or plastic syringes. Solutions in 500 mL of sodium chloride or glucose 5% injection and stored in PVC infusion bags were still less stable, with 15% and 10% degradation respectively after 6 hours at room temperature.

Chlormethine hydrochloride has been used in extemporaneous ointment preparations in the treatment of mycosis fungoides.[2] One formulation of chlormethine hydrochloride, dissolved in acetone and worked into white soft paraffin, was reported[3] to be stable for at least 84 days when stored at 4°, and for at least 40 days at 37°.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

Chlormethine hydrochloride is extremely toxic and its use is invariably accompanied by adverse effects. Severe nausea and vomiting may begin within an hour of injection of the drug and last for some hours; antiemetics should be given before treatment. It causes varying degrees of bone-marrow depression depending on the dose. In heavily pretreated patients, or when the total dose for a single course exceeds 400 micrograms/kg, there is a risk of severe and possibly fatal depression with anaemia, lymphocytopenia, granulocytopenia, and thrombocytopenia with consequent haemorrhage. Depression of lymphocytes may be apparent within 24 hours of a dose and maximum suppression of granulocytes and platelets occurs within 7 to 21 days; haematological recovery may be adequate after 4 weeks.

Tinnitus, vertigo, deafness, headache, drowsiness, and other neurological symptoms have been reported, as have episodes of jaundice. Skin reactions to chlormethine hydrochloride include maculopapular rashes. Hypersensitivity is frequent when topical preparations are used.

Chlormethine hydrochloride has a powerful vesicant action on the skin and mucous membranes and great care must be taken to avoid contact with the eyes. Thrombophlebitis is a potential hazard of chlormethine particularly if it is not sufficiently diluted. Extravasation of the injection causes severe irritation and even sloughing. If extravasation occurs during injection, it has been suggested that the involved area should be infiltrated with an isotonic 4% solution of sodium thiosulfate, followed by the application of an ice compress intermittently for 6 to 12 hours, although the role of specific antidotes in antineoplastic extravasation is somewhat contentious (see p.640).

Chlormethine hydrochloride may produce temporary or permanent inhibition of fertility. There is some evidence of mutagenicity, teratogenicity, and carcinogenicity.

Effects on the nervous system. Severe immediate neurotoxicity developed[1] in 14 of 21 evaluable patients who underwent bone marrow transplantation after preparation with cytotoxic regimens including chlormethine 0.3 to 2 mg/kg. Symptoms developed a median of 4 days after treatment and included headache, hallucinations, confusion, convulsions, paraplegia, and tremor. Symptoms resolved in most, although in some they had not done so before their death. Six of the patients who recovered from acute toxicity developed a delayed neurotoxicity, beginning a median of 169 days after the first chlormethine injection and characterised by symptoms including confusion, somnolence, personality change, dementia, focal motor seizures, and hydrocephalus. Patients older than 21 years, those who had received CNS irradiation, and those treated concomitantly with other cytotoxic agents were at increased risk of neurotoxicity.

1. Sullivan KM, *et al.* Immediate and delayed neurotoxicity after mechlorethamine preparation for bone marrow transplantation. *Ann Intern Med* 1982; **97:** 182–9.

Handling and disposal. Chlormethine hydrochloride is a strong vesicant; avoid contact with skin and mucous membranes.

The manufacturers state that *unused injection* solutions of chlormethine hydrochloride may be neutralised by mixing with an equal volume of a solution containing sodium thiosulfate 5% and sodium bicarbonate 5% and allowing to stand for 45 minutes. Equipment used in the preparation and administration of such solutions may be treated similarly. Alternatively a solution containing sodium carbonate 2.5% or sodium hydroxide in a mixture of industrial methylated spirit and water has been suggested for the decontamination of equipment.

Urine produced for up to 48 hours after a dose of chlormethine should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; **235:** 289–91.

Pharmacokinetics

On intravenous injection, chlormethine is rapidly converted to a reactive ethyleneimmonium ion. It usually disappears from the blood in a few minutes. A very small proportion is excreted unchanged in the urine.

Uses and Administration

Chlormethine belongs to the group of antineoplastic drugs described as alkylating agents. It also possesses weak immunosuppressant properties.

Chlormethine hydrochloride has been used in the treatment of advanced Hodgkin's disease (p.655), historically with a vinca alkaloid, procarbazine, and prednisone or prednisolone (the MOPP regimen). Chlormethine has also been tried in non-Hodgkin's lymphomas, notably mycosis fungoides (p.657), and some other malignancies including chronic leukaemias, tumours of the breast, ovary, and lung, and in polycythaemia vera. Chlormethine has been used in the management of malignant effusions but is not the agent of choice.

In the MOPP regimen chlormethine hydrochloride has been given in doses of 6 mg/m^2. However, when licensed for use as a single agent, the usual dose of chlormethine hydrochloride is 400 micrograms/kg, preferably as a single dose, although it may be divided into 2 or 4 equal doses on successive days. It is given by intravenous injection in a strength of 1 mg/mL in Water for Injections or sodium chloride 0.9%. Injection over 2 minutes into the tubing of a fast running intravenous infusion of sodium chloride 0.9% or glucose 5% may reduce the incidence of thrombophlebitis and the risk of extravasation.

The response should be assessed by the trend of the blood counts. Treatment with chlormethine may be repeated when the bone-marrow function has recovered.

Intracavitary injections of 200 to 400 micrograms/kg have been given in the treatment of malignant, especially pleural, effusions. In mycosis fungoides with extensive skin involvement, very dilute solutions of chlormethine (e.g. 200 micrograms/mL) have been applied topically.

Histiocytic syndromes. Dilute solutions of chlormethine (200 micrograms/mL) have been applied topically for the cutaneous symptoms of Langerhans-cell histiocytosis (p.650).[1,2] Such therapy was reported to effectively clear skin lesions in most patients, and be well tolerated. However, although no malignant skin disease developed during the follow-up of one group of children, the long-term effects of topical chlormethine are of concern in young patients.[2]

1. Sheehan MP, *et al.* Topical nitrogen mustard: an effective treatment for cutaneous Langerhans cell histiocytosis. *J Pediatr* 1991; **119:** 317–21.
2. Hoeger PH, *et al.* Long term follow up of topical mustine treatment for cutaneous Langerhans cell histiocytosis. *Arch Dis Child* 2000; **82:** 483–7.

Mycosis fungoides. Chlormethine is used topically in the management of mycosis fungoides (p.657). A retrospective cohort analysis[1] of 203 patients treated with chlormethine found a partial response rate of 33% and a complete response rate of 50%. The median time to achieve complete response was 12 months and the time to relapse was also 12 months. Mild disease of limited skin involvement responded better than generalised patch/plaque disease, and more patients with mild disease obtained long-term remission. Maintenance therapy was used in some patients, but on cessation the relapse rate was similar to patients who did not receive maintenance therapy. Treatment had usually been applied as either an aqueous solution or an ointment containing chlormethine 100 to 200 micrograms/mL.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Cisplatin). A yellow powder or yellow or orange-yellow crystals. Slightly soluble in water; practically insoluble in alcohol; sparingly soluble in dimethylformamide. A 0.1% solution in sodium chloride 0.9% has a pH of 4.5 to 6.0 immediately after preparation. Store in airtight containers. Protect from light.

USP 31 (Cisplatin). Store in airtight containers. Protect from light.

Incompatibility. Cisplatin is rapidly degraded in the presence of bisulfite or metabisulfite,[1,2] and admixture with preparations containing these as preservatives may result in loss of activity.[2] Sodium bicarbonate may also increase the loss of cisplatin from solution, and in some cases may cause precipitation.[3] The stability of cisplatin when mixed with fluorouracil is reported to be limited, with 10% loss of cisplatin in 1.2 to 1.5 hours.[4] Mixtures with etoposide[5] in sodium chloride 0.9% injection formed a precipitate if mannitol and potassium chloride were present as additives, but not when the diluent was glucose 5% with sodium chloride 0.45%. Turbidity has been reported[6] within 4 hours of mixing 0.1% solutions of cisplatin and thiotepa in glucose 5%. Cisplatin exhibits variable incompatibility with paclitaxel, depending on the paclitaxel concentration and the temperature.[7]

Cisplatin reacts with aluminium causing loss of potency and precipitate formation. Needles, syringes, catheters or giving sets that contain aluminium should not be used for preparing or giving cisplatin.

Stability. Decomposition of cisplatin in aqueous solutions is primarily due to reversible substitution of water for chloride, and its stability is enhanced in sodium chloride solutions because of the excess of chloride ions available.[1,2] A solution in sodium chloride 0.9% injection has been reported to lose 3% of the drug in less than one hour and to remain stable at this equilibrium value for 24 hours at room temperature.[1] Stability is decreased if exposed to intense light, but the effect of normal lighting conditions is apparently smaller.[1,2] It has been recommended that admixtures of cisplatin with mannitol and magnesium sulfate (in glucose 5% with sodium chloride 0.45%) stored at room temperature in PVC bags should be used within 48 hours, but may be stored for 4 days at 4° or frozen and stored at –15° for up to 30 days.[3] However, solutions containing 600 micrograms/mL or more of cisplatin precipitate out when refrigerated and are slow to redissolve.[1]

Adverse Effects and Treatment

For a general outline see Antineoplastics, p.635 and p.639.

Severe nausea and vomiting occur in most patients during treatment with cisplatin; nausea may persist for up to a week.

Serious toxic effects on the kidneys, bone marrow, and ears have been reported in up to about one third of patients given a single dose of cisplatin; the effects are generally dose-related and cumulative.

Damage to the renal tubules may be evident during the second week after a dose of cisplatin and renal function must return to normal before further cisplatin is given. Adequate hydration, and use of osmotic diuretics such as mannitol to increase urine volume and thus decrease the urinary concentration of platinum, can reduce the incidence of nephrotoxicity. Electrolyte disturbances, particularly hypomagnesaemia and hypocalcaemia, may occur, possibly as a result of renal tubular damage. Hyperuricaemia is also seen.

Bone-marrow depression may be severe with higher doses of cisplatin. Nadirs in platelet and leucocyte counts occur between days 18 and 23 and most patients recover by day 39; anaemia is common and may be partly related to decreased production of erythropoietin after renal damage.

Ototoxicity may be more severe in children. It can manifest as tinnitus, loss of hearing in the high frequency range, and occasionally deafness or vestibular toxicity. Other neurological effects reported include peripheral neuropathies, loss of taste, and seizures. Ocular toxicities include optic neuritis, papilloedema, and cerebral blindness.

Anaphylactoid reactions and cardiac abnormalities have occurred. Injection site reactions, including localised oedema, pain, erythema, skin ulceration and phlebitis may occur. Extravasation may lead to tissue cellulitis, fibrosis, and necrosis.

Platinum derivatives are potentially mutagenic and teratogenic, and there is some evidence they may be associated with the development of secondary leukaemias—see Carcinogenicity, p.635.

Effects on the blood. Cisplatin-induced anaemia appears to be disproportionate to the effects on other blood cells, and to correlate with renal tubular dysfunction.[1] It may therefore be due to an erythropoietin deficiency state resulting from cisplatin-induced renal tubular damage. Haemolysis has also been reported.[2]

2. Rothmann SA, Weick JK. Cisplatin toxicity for erythroid precursors. *N Engl J Med* 1981; **304:** 360.

THROMBOEMBOLISM. For discussion of thromboembolic events possibly associated with cisplatin-containing chemotherapy regimens see Effects on the Cardiovascular System, p.636.

Effects on the ears. Ototoxicity is a well-established adverse effect of cisplatin.[1] It appears to be due to generation of reactive oxygen species that cause apoptosis of hair cells in the cochlea,[1] and results in hearing loss, particularly at high frequencies.[1,2] Risk factors include younger age,[1] larger cumulative doses[1] (one study[2] identified doses above 60 mg/m^2 as risk factors), pre-existing hearing loss or renal disease,[1] and irradiation of the brain or base of the skull.[1,3] Various substances including thiols, amifostine, ebselen, allopurinol, and salicylates have been investigated in *animals* for their protective effect against cisplatin-induced neurotoxicity[1] but although some promising results have been seen, benefit is yet to be demonstrated in large clinical studies, and there is some concern about the risk of reducing the antineoplastic effect of cisplatin as well. However, a small study comparing cisplatin chemoradiation with or without sodium thiosulfate tentatively concluded that thiosulfate did seem to offer some protection against hearing loss.[4]

Effects on electrolytes. Renal-magnesium wasting and, less commonly, symptomatic hypomagnesaemia occurs with cisplatin therapy.[1,2] Adding magnesium to the pre- and posthydration fluids has been suggested.[2] When hypocalcaemia is also present, tetany may result,[1,3] although this has responded to electrolyte infusion without the need to interrupt chemotherapy.[1] Cisplatin therapy may also be associated with significant hypokalaemia[1] and hyponatraemia.[4,5]

5. Mariette X, *et al.* Cisplatin and hyponatremia. *Ann Intern Med* 1988; **108:** 770–1.

Effects on the kidneys. Nephrotoxicity is a well-established adverse effect of cisplatin, may be dose-limiting, and can manifest as acute or chronic renal failure, polyuria, or chronic hypomagnesaemia.[1] The mechanism appears to involve primarily damage to the proximal renal tubule; selective magnesium loss may be due to a specific membrane or transport system abnormality. Sulfhydryl metabolism and oxidative stress play a role in toxicity, and measures that reduce glutathione depletion and scavenge intracellular free oxygen radicals have been tried in an attempt to modulate nephrotoxicity.[1-3] However, the primary measures for reducing renal damage have been aggressive hydration with chloride-containing solutions, and the use of mannitol (see also Prophylaxis, below). It has been suggested that cisplatin may mobilise lead accumulated in bone and cause temporary accumulation in the kidney, with concomitant toxicity,[4] but this has been vigorously disputed.[5-7]

PROPHYLAXIS. Hydration with 1 to 2 litres of fluid before treatment, and infusion of cisplatin in a further 2 litres of infusion fluid containing an osmotic diuretic such as mannitol reduces the nephrotoxicity of cisplatin, but does not abolish it. Maintaining adequate hydration and urinary output post-treatment is also important. Giving cisplatin over 6 to 8 hours rather than 1 to 2 hours may also decrease renal toxicity.

Sulfur-containing nucleophiles can inactivate cisplatin, and have therefore been investigated for their chemoprotective potential. Amifostine is a prodrug that is selectively activated by normal tissue, and has been shown to protect normal tissue (principally the kidney) against the cytotoxicity of cisplatin without affecting antitumour activity (for references, see Cytoprotection, p.1437). Glutathione (p.1448) is a similar agent, which may be selectively taken up by kidney and neural tissue. Sodium thiosulfate (p.1466) does not show selective activation or uptake, and its use is therefore limited to situations where cisplatin is given locally (e.g. intraperitoneal[1,2]) or directly (e.g. intra-arterial[3]).

Effects on the nervous system. The features of cisplatin-induced peripheral neuropathy are consistent with damage predominantly to sensory fibres, with numbness, tingling, and decreased vibratory sensation and deep tendon reflexes, progressing in severe cases to disabling sensory ataxia.[1] The toxicity is dose-dependent, with symptoms usually appearing in patients who have received cumulative doses of 300 to 600 mg/m^2, although individuals vary in susceptibility. Neuropathy is reversible but recovery may take a year or more. The pathophysiology is unknown. Peripheral neuropathy can be a dose-limiting toxicity for cisplatin and agents such as Org-2766 (a corticotropin analogue) and amifostine (p.1436) have been investigated for their potential in protecting peripheral nerves.[1-3] Vitamin E has been reported to be effective in reducing peripheral neuropathy.[4] Glutathione is also under investigation for the prevention of neurotoxicity (see p.1448). However, a systematic review considered that the evidence for most of the interventions intended to reduce cisplatin neurotoxicity was insufficient to demonstrate benefit.[5] Autonomic neuropathy, with, in some cases, consequent orthostatic hypotension, has also been described after treatment with cisplatin-containing regimens.[6] Apart from ototoxicity (see above), cisplatin has also been associated with central neurotoxicity, including focal encephalopathy, seizures, aphasia, confusion, agitation, and cortical blindness.[7-10] It has been suggested that the mechanism of focal encephalopathy may be vascular,[7] although this is uncertain.

Extravasation. For discussion of the management of extravasation, including methods to manage cisplatin extravasation, see under Treatment of the Adverse Effects of Antineoplastics, p.640.

Hypersensitivity. Anaphylactoid reactions to intravenous cisplatin generally appear within a few minutes of dosage and have manifested as facial oedema, wheezing, tachycardia, and hypotension.[1] A high incidence of anaphylactoid reaction has also been seen after intravesical instillation in patients with bladder cancer,[2] but intraperitoneal or intrapleural use does not seem to be associated with an enhanced risk of hypersensitivity,[3] although anaphylactoid reactions have occurred when cisplatin is given intraperitoneally.[4] Anaphylactoid symptoms and ischaemia of the hands accompanied severe exfoliative dermatitis in one patient on the second cycle of cisplatin-based chemotherapy;[5] she had earlier experienced exfoliative dermatitis associated with carboplatin. Palmar-plantar erythrodysesthesia (p.639) has also occurred.[6]

6. Vakalis D, *et al.* Acral erythema induced by chemotherapy with cisplatin. *Br J Dermatol* 1998; **139:** 750–1.

Nausea and vomiting. For discussion of the management of chemotherapy-induced nausea and vomiting, see under Nausea and Vomiting, p.1700.

Precautions

For reference to the precautions necessary with antineoplastics, see p.641. Cisplatin is generally contra-indicated in patients with renal or hearing impairment, or bone-marrow depression. Renal and neurological function and hearing should be monitored during treatment, and regular blood counts performed. Electrolytes should be measured before starting therapy, and before each subsequent course. Adequate hydration and urinary output must be maintained before, and for 24 hours after, a dose.

Patients are recommended to use appropriate contraceptive measures during treatment and for 6 months after stopping treatment.

Breast feeding. Platinum concentrations in a patient receiving cisplatin were 0.9 micrograms/mL in breast milk and 0.8 micrograms/mL in plasma.[1] Although most of the platinum in breast milk is probably protein-bound the authors considered that a mother should not breast feed while receiving cisplatin chemotherapy. However, in another report,[2] cisplatin was undetectable in breast milk and the American Academy of Pediatrics[3] considers its use to be compatible with breast feeding.

Handling and disposal. Methods for the destruction of *cisplatin wastes* by reduction with zinc powder under acidic conditions or by reaction with ditiocarb sodium have been described.[1] Residue produced by the degradation of cisplatin by either method showed no mutagenicity *in vitro*.

Urine produced for up to 7 days after a dose of cisplatin should be handled wearing protective clothing.[2]

Pregnancy. Cisplatin was given with etoposide and bleomycin to a pregnant woman at 26 weeks of gestation for carcinoma of uncertain primary origin. At 27 weeks of gestation, she developed profound neutropenia followed by septicaemia and went into premature labour. The infant developed profound leucopenia and neutropenia by day 3, which was attributed to chemotherapy given 6 days before delivery; prophylactic antibacterials including gentamicin were given. Hair loss at the age of 10 days was attributed to etoposide. At 1 year of age, the child exhibited moderate bilateral sensorineural hearing loss; this was considered to be either due to cisplatin exposure *in utero* or to gentamicin use.[1] However, there are other reports of cisplatin use during the second or third trimester of pregnancy with no subsequent apparent adverse effects on the infant.[2-5] In most cases, cisplatin had been given with cyclophosphamide,[2-4] although in one instance it was given with paclitaxel.[5] In one report, cisplatin-induced maternal ototoxicity led to it being replaced after 2 courses by carboplatin.[4]

1. Raffles A, *et al.* Transplacental effects of maternal cancer chemotherapy: case report. *Br J Obstet Gynaecol* 1989; **96:** 1099–1100.

5. Sood AK, *et al.* Paclitaxel and platinum chemotherapy for ovarian carcinoma during pregnancy. *Gynecol Oncol* 2001; **83:** 599–600.

Radiotherapy. Enhanced ototoxicity has been reported in patients given cisplatin for brain tumours who also had cranial irradiation.[1,2]

1. Granowetter L, *et al.* Enhanced cis-platinum neurotoxicity in pediatric patients with brain tumors. *J Neurooncol* 1983; **1:** 293–7.
2. Mahoney DH, *et al.* Ototoxicity with cisplatin therapy. *J Pediatr* 1983; **103:** 1006.

Interactions

For a general outline of antineoplastic drug interactions, see p.642. Use with other myelosuppressive, nephrotoxic or ototoxic drugs may exacerbate the adverse effects of cisplatin. The effects of cisplatin on renal function may also affect the pharmacokinetics of other drugs excreted by the renal route.

Antibacterials. Although the use of cisplatin with other nephrotoxic or ototoxic drugs requires great caution, there is some evidence that *aminoglycosides* can be used in patients who have recently received cisplatin if appropriate supportive care is available.[1]

1. Cooper BW, *et al.* Renal dysfunction during high-dose cisplatin therapy and autologous hematopoietic stem cell transplantation: effect of aminoglycoside therapy. *Am J Med* 1993; **94:** 497–504.

Antineoplastics. The ototoxicity of cisplatin was reportedly enhanced by *ifosfamide*,[1] a drug that is not ototoxic when given alone, although it does have nephrotoxic potential, making reports of increased nephrotoxicity in patients who have received both unsurprising.[2,3]

For a report of increased toxicity with *etoposide*, see p.718. Cisplatin may reduce the clearance of *paclitaxel*, see p.759.

2. Rossi R, Ehrich JHH. Partial and complete de Toni-Debré-Fanconi syndrome after ifosfamide chemotherapy of childhood malignancy. *Eur J Clin Pharmacol* 1993; **44** (suppl 1): S43–S45.
3. Martinez F, *et al.* Ifosfamide nephrotoxicity: deleterious effect of previous cisplatin administration. *Lancet* 1996; **348:** 1100–1.

Cardiovascular drugs. A patient whose renal function was unaffected by cisplatin alone developed nephrotoxicity when given cisplatin and antihypertensive therapy with *furosemide, hydralazine, diazoxide*, and *propranolol*.[1] Previous results in *animals* suggest that furosemide may aggravate cisplatin nephrotoxicity, while the other antihypertensives might have contributed to a transient fall in renal-blood flow with resultant increased renal-tubular cisplatin concentration.

1. Markman M, Trump DL. Nephrotoxicity with cisplatin and antihypertensive medications. *Ann Intern Med* 1982; **96:** 257.

Gastrointestinal drugs. For mention of 2 retrospective studies, one showing a decreased area under the plasma-concentration time curve of high-dose cisplatin with *ondansetron* and the other an increase, see p.703.

Pharmacokinetics

After intravenous doses cisplatin disappears from the plasma in a biphasic manner and half-lives of 25 to 49 minutes and 3 to 4 days have been reported for total platinum. More than 90% of the platinum from a dose is protein bound within 2 to 4 hours; only the unbound fraction has significant antineoplastic activity. Cisplatin is concentrated in the liver, kidneys, and large and small intestines. Penetration into the CNS appears to be poor. Excretion is mainly in the urine but is incomplete and prolonged: up to about 50% of a dose has been reported to be excreted in urine over 5 days, and platinum may be detected in tissue for several months afterwards. The unbound fraction, which is more rapidly cleared, may be actively secreted by the renal tubules. Cisplatin is well-absorbed on intraperitoneal use. Cisplatin may be distributed into breast milk (see Breast Feeding, above).

Uses and Administration

The antineoplastic cisplatin is a platinum-containing complex that may act similarly to the alkylating agents. Its antineoplastic actions are cell-cycle non-specific and are dependent upon its *cis* configuration; they appear to be related to its hydrolysis in the body to form reactive aquated species. Although it causes immunosuppression, stimulation of the host immune response against the tumour has been suggested as contributing to cisplatin's antineoplastic action.

Cisplatin is of value in the treatment of tumours of the testis, usually as a major component of combination chemotherapy regimens, and particularly with bleomycin and etoposide (BEP), or with bleomycin and a vinca alkaloid. It is also used in metastatic ovarian tumours, cervical tumours, lung cancer, advanced bladder cancer, and squamous cell carcinoma of the head and neck. It has been reported to be active against many other solid tumours, as indicated by the cross references given below.

Cisplatin is given by intravenous infusion in sodium chloride 0.9% or in a mixture of sodium chloride and glucose. In monotherapy, it is usually given as a single dose of 50 to 120 mg/m^2 every 3 to 4 weeks. Alternatively, 15 to 20 mg/m^2 is given daily for 5 days, every 3 to 4 weeks. Lower doses are generally used for combination chemotherapy regimens than for single agent therapy; 20 mg/m^2 or more is given once every 3 to 4 weeks. A dose of 20 mg/m^2 daily for 5 days every 3 to 4 weeks has been used in combination chemotherapy of testicular tumours.

Licensed product information recommends that cisplatin is given in 2 litres of chloride-containing infusion fluid. In practice, volumes of less than 2 litres have been used in expert centres. The infusion may be given over 1 to 2 hours, although licensed product information generally recommends a longer infusion time of 6 to 8 hours in order to reduce renal and gastrointestinal toxicities.

To aid diuresis and protect the kidneys, 37.5 g of mannitol (e.g. 375 mL of mannitol 10%) is usually added to the infusion or is infused separately immediately before cisplatin. In order to begin diuresis the patient is usually hydrated by the infusion of 1 to 2 litres of a suitable fluid over several hours before giving cisplatin. Adequate hydration must also be maintained for up to 24 hours after a dose. Renal, haematological, auditory, and neurological function should be monitored during therapy, and dosage adjusted accordingly.

Cisplatin has also been given by the intra-arterial and intraperitoneal routes, and by instillation into the bladder. It is being investigated as a liposomal formulation, and as a collagen-based injectable gel containing cisplatin and adrenaline (MPI-5010) to localise the effect. An oral formulation of cisplatin is also under investigation.

Various analogues of cisplatin have been developed or investigated including those with fewer adverse effects (e.g. carboplatin, p.693; nedaplatin, p.755), an altered spectrum of activity (oxaliplatin, p.757), or activity on oral dosage (satraplatin, p.769).

Administration. Various adjustments to the administration of cisplatin have been suggested in an attempt to improve effectiveness while reducing toxicity.

Hydration before and after a dose of cisplatin, together with the use of mannitol to promote diuresis, is now standard (see Uses and Administration, above). Higher doses of cisplatin (up to 200 mg/m^2 per treatment cycle) have been successfully given by infusion in hypertonic sodium chloride, accompanied by intensive hydration.[1,2] Sodium chloride 3% infusion solution has been used.[3] However, while such a regimen may limit nephrotoxicity, other toxic effects, such as peripheral neuropathy, are not prevented;[1,2,4,5] myelosuppression may be less if the total dose is given in 2 divided doses rather than divided over 5 days.[2] High-dose cisplatin has been given once weekly; haematological toxicity may be dose-limiting with this regimen.[3]

Toxicity has been reported to be reduced when cisplatin was given by continuous intra-arterial[6] or intravenous[7] infusion. It has also been suggested that giving cisplatin in the evening rather than the morning results in less damage to renal function, apparently because of circadian variations in urine production.[8] However, another study[9] found that morning, rather than evening, doses of cisplatin resulted in less renal damage. Noting the inconsistency with previous reports, the authors concluded that use of a prolonged hydration protocol and concomitant furosemide might have been responsible for these results (see also under Interactions, Cardiovascular Drugs, above). It was also found that morning dosage of cisplatin may be more emetogenic than evening dosage, although the use of prophylactic ondansetron before cisplatin reduced this apparent circadian effect on vomiting.

A suggested alternative way to increase the platinum dose without producing incapacitating toxicity has been the combination of cisplatin and carboplatin.[10]

Various drugs have been investigated to reduce toxicity, including amifostine, glutathione, and thiosulfate, as discussed under Effects on the Kidneys, and Effects on the Nervous System, above.

A retrospective study of patients with bladder cancer found that calculation of creatinine clearance (CC) by mathematical formulas was inadequate in determining renal eligibility for treatment with cisplatin, especially in patients over 65 years of age; up to 44% of patients who were treated with cisplatin based on measured CC would have been deemed ineligible using mathematical calculations.[11]

Malignant neoplasms. Cisplatin is used in the management of many solid malignancies, notably those of the bladder, cervix, lung, ovary, and testis, as discussed on p.659, p.663, p.668, p.670, and p.673 respectively. Other malignancies where cisplatin may be employed, as discussed in the introduction to this chapter, include non-Hodgkin's lymphomas (p.656), tumours of brain (p.660), endometrium (p.663), oesophagus, stomach, and anus (p.664, p.664, and p.666), head and neck (p.666), and thymus (p.674), neuroblastoma (p.674), and sarcoma of bone and soft tissue (p.675 and p.676).

Cladribine *(BAN, USAN, rINN)*

2-Chlorodeoxyadenosine; Cladribina; Cladribinum; Kladribiini; Kladribin; RWJ-26251; RWJ-26251-000. 2-Chloro-2′-deoxyadenosine.

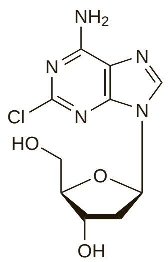
Кладрибин

$C_{10}H_{12}ClN_5O_3$ = 285.7.

CAS — 4291-63-8.

ATC — L01BB04.

ATC Vet — QL01BB04.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Cladribine). A white or almost white crystalline powder. It exhibits polymorphism. Slightly soluble in water and in methyl alcohol; soluble in dimethyl sulfoxide; practically insoluble in acetonitrile. Store at a temperature of 2° to 8°. Protect from light.

USP 31 (Cladribine). Store at a temperature of 2° to 8°. Protect from light.

Stability. Cladribine shows increased degradation in glucose 5%, therefore this diluent should not be used. Cladribine in sodium chloride 0.9% is stable for at least 24 hours at room temperature and ambient lighting in PVC infusion containers.

The manufacturers recommend that cladribine should be stored at 2° to 8° and protected from light.

Adverse Effects and Treatment

For a general outline see Antineoplastics, p.635 and p.639.

Cladribine produces severe myelosuppression, including neutropenia, anaemia, and thrombocytopenia, especially at high doses. Transfusion of blood products may be required. Prolonged CD4 lymphopenia with a nadir at 4 to 6 months also develops. Prolonged bone-marrow hypocellularity may also occur, although it is not clear if this is due to the drug or underlying disease. Haemolytic anaemia has also been reported. Severe infections can occur, and may be fatal. Myelodysplastic syndrome has been reported rarely.

Other adverse effects include fever, chills, diaphoresis, fatigue, malaise, mild nausea and gastrointestinal disturbances, rashes, pruritus, purpura, headache, anxiety, dizziness, abnormal breath and/or chest sounds, cough, dyspnoea, oedema, tachycardia, hypotension, arthralgia, and myalgia. Reversible, mild increases in bilirubin and hepatic transaminases are common. Rare adverse events include hepatic, renal, or cardiac failure, atrial fibrillation, and hypereosinophilia; tumour lysis syndrome can occur, and may be fatal.

Very high doses of cladribine have been associated with severe renal and nervous system toxicity as well as myelosuppression. Severe neurotoxicity is rare at currently recommended doses, but confusion, neuropathy, ataxia, insomnia, and somnolence have occurred.

Carcinogenicity. As with some other antimetabolites (see p.635), Epstein-Barr virus-related lymphoma has been reported after cladribine therapy.[1] A study found that in patients with chronic lymphocytic leukaemia, treatment with cladribine did not increase the risk of secondary malignancies when compared with treatment with alkylating agents and combination therapy. However, lung cancers occurred more frequently with cladribine treatment.[2]

1. Niesvizky R, *et al.* Epstein-Barr virus-associated lymphoma after treatment of macroglobulinemia with cladribine. *N Engl J Med* 1999; **341:** 55.
2. Robak T, *et al.* Second malignancies and Richter's syndrome in patients with chronic lymphocytic leukaemia treated with cladribine. *Eur J Cancer* 2004; **40:** 383–9.

Precautions

For the precautions necessary with antineoplastics, see p.641. Careful haematological monitoring is recommended, especially during the first 4 to 8 weeks of therapy. Renal and hepatic function should also be monitored periodically.

Pharmacokinetics

Plasma-cladribine concentrations after intravenous infusion show either a biphasic or triphasic decline, with terminal half-lives ranging from 3 to 22 hours. A biexponential decline has been reported after subcutaneous injection, with an initial and terminal half-life of about 2 and 11 hours, respectively. Cladribine is extensively distributed and penetrates into the CNS. It is about 20% bound to plasma proteins. Cladribine is phosphorylated within cells by deoxycytidine kinase to form 2-chlorodeoxyadenosine-5′-monophosphate which is further phosphorylated to the diphosphate by nucleoside monophosphate kinase and to the active metabolite 2-chlorodeoxyadenosine-5′-triphosphate (CdATP) by nucleoside diphosphate kinase.

◊ References.

1. Liliemark J. The clinical pharmacokinetics of cladribine. *Clin Pharmacokinet* 1997; **32:** 120–31.

Uses and Administration

Cladribine is a chlorinated purine nucleoside analogue that inhibits DNA synthesis and repair, particularly in lymphocytes and monocytes. It is used as an antimetabolite antineoplastic for the treatment of lymphoid malignancies including hairy-cell leukaemia (p.654) and chronic lymphocytic leukaemia (p.653). It has also been used in indolent low-grade non-Hodgkin's lymphomas (p.656), histiocytic syndromes (p.650), and in Waldenström's macroglobulinaemia (p.658).

The recommended intravenous dose of cladribine in hairy-cell leukaemia is a single course of 90 micrograms/kg (3.6 mg/m^2) daily for 7 days by continuous infusion. If the patient does not respond to the initial course, they are unlikely to respond to further doses. Cladribine is also given subcutaneously in a dose of 140 micrograms/kg (5.6 mg/m^2) daily for 5 consecutive days.

For the treatment of chronic lymphocytic leukaemia the recommended intravenous dose is 120 micrograms/kg (4.8 mg/m^2) daily for 5 consecutive days of a 28-day cycle; the infusion is given over 2 hours. Response should be determined every 2 cycles, and once maximum response has occurred a further 2 cycles of treatment are recommended, up to a maximum of 6 cycles. Patients who do not respond with a lymphocyte reduction of 50% or more after 2 cycles should not receive further therapy. Cladribine is also given subcutaneously in a dose of 100 micrograms/kg (4 mg/m^2) daily for 5 consecutive days. This dose of subcutaneous cladribine is also licensed in some countries for the treatment of indolent non-Hodgkin's lymphoma and Waldenström's macroglobulinaemia.

An oral formulation of cladribine is under investigation for the management of multiple sclerosis (see below); parenteral cladribine has also been used. Oral cladribine has also been investigated for chronic lymphocytic leukaemia.

Clofarabine *(BAN, USAN, rINN)*

Cl-F-Ara-A; Clofarabina; Clofarabinum. 2-Chloro-9-(2-deoxy-2-fluoro-β-D-arabinofuranosyl)-9*H*-purin-6-amine.

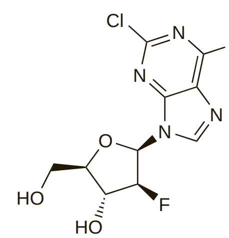
Кьофарабин

$C_{10}H_{11}ClFN_5O_3$ = 303.7.

CAS — 123318-82-1.

ATC — L01BB06.

ATC Vet — QL01BB06.



Adverse Effects, Treatment, and Precautions

As for Fludarabine Phosphate, p.721, although neurotoxicity is less severe. Capillary leak syndrome resulting from cytokine release has occurred with clofarabine, causing respiratory distress, hypotension, pleural and pericardial effusions, and multi-organ failure. Prophylactic corticosteroids may be useful, but clofarabine must be stopped immediately if signs or symptoms of capillary leak syndrome develop (respiratory status and blood pressure should be monitored during infusion). Other adverse effects include anxiety, flushing, tachycardia, hypotension, hepatotoxicity, haematuria, myalgia, arthralgia, and headache.

Renal and hepatic function, and complete blood counts, should be monitored during clofarabine therapy. Hydration should be maintained during treatment to minimise the risk of tumour lysis syndrome and other adverse effects.

Pharmacokinetics

Clofarabine is about 47% bound to plasma proteins. About 50 to 60% of a dose is excreted unchanged in the urine and it has a terminal half-life of about 5 hours.

Uses and Administration

Clofarabine, a purine nucleoside analogue, is used as an antimetabolite antineoplastic in the treatment of relapsed or refractory acute lymphoblastic leukaemia (p.651) in patients aged 1 to 21 years. A dose of 52 mg/m^2 is given daily for 5 days, by intravenous in-

The symbol † denotes a preparation no longer actively marketed

fusion over 2 hours. A longer infusion time should be considered in children weighing less than 20 kg to reduce anxiety and irritability, and to avoid high clofarabine concentrations. The course may be repeated every 2 to 6 weeks, depending on the patient's recovery from bone-marrow depression and other adverse effects. Treatment is usually assessed after 2 treatment cycles.

Clofarabine is under investigation for the treatment of acute myeloid leukaemia, myelodysplastic syndrome, and solid tumours.

Combretastatin A4 Phosphate

CS-A4 (combretastatin A4); NSC-348103 (combretastatin). 2-Methoxy-5-[(1*Z*)-2-(3,4,5-trimethoxyphenyl)ethenyl]-phenol dihydrogen phosphate.

$C_{18}H_{21}O_8P$ = 396.3.

CAS — 82855-09-2 (combretastatin); 117048-59-6 (combretastatin A4); 222030-63-9 (combretastatin A4 phosphate).

Profile

Combretastatin A4 phosphate is a synthetic derivative of combretastatin compounds originally isolated from the African bush-willow tree (Cape bush-willow; *Combretum caffrum*). It is described as a vascular targeting agent that reduces blood flow to tumours by disrupting the endothelial cells of newly formed blood vessels, and is under investigation for the treatment of thyroid and ovarian cancers.

Corynebacterium parvum

C. parvum; NSC-220537; *Propionibacterium acnes.*

Profile

Inactivated *Corynebacterium parvum* has been used in the treatment of malignant effusions, and has been tried as an adjuvant to cancer chemotherapy for its immunostimulant properties. It has also been used in the treatment of musculoskeletal and joint disorders.

Fever and pain have occurred after intracavitary injection. There have been reports of nephrotoxicity after intravenous use.

Preparations

Proprietary Preparations (details are given in Part 3)
Ger.: Arthrokehlan A.

Cyclophosphamide *(BAN, rINN)*

B-518; Ciclofosfamida; Ciklofosfamidas; Ciklofoszfamid; Cyclophosphamidum; Cyclophosphamidum Monohydricum; Cyclophosphanum; Cyklofosfamid; Cyklofosfamid monohydrát; NSC-26271; Siklofosfamid; Syklofosfamidi; WR-138719. 2-[Bis(2-chloroethyl)amino]perhydro-1,3,2-oxazaphosphorinan 2-oxide monohydrate.

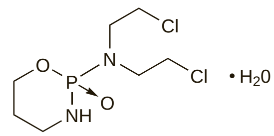
Циклофосфамид

$C_7H_{15}Cl_2N_2O_2P,H_2O$ = 279.1.

CAS — 6055-19-2 (cyclophosphamide monohydrate); 50-18-0 (anhydrous cyclophosphamide).

ATC — L01AA01.

ATC Vet — QL01AA01.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Cyclophosphamide). A white or almost white, crystalline powder. Soluble in water; freely soluble in alcohol. A freshly prepared 2% solution in water has a pH of 4.0 to 6.0.

USP 31 (Cyclophosphamide). A white, crystalline powder. It liquefies upon loss of its water of crystallisation. Soluble in water and in alcohol. A 1% solution in water has a pH of 3.9 to 7.1 when determined 30 minutes after preparation. Store in airtight containers at 2° to 30°.

Adverse Effects and Treatment

For a general outline see Antineoplastics, p.635 and p.639. The major dose-limiting effect is myelosuppression. After single doses the nadir of the white cell count may occur in around 1 to 2 weeks with full recovery usually in 3 to 4 weeks. Thrombocytopenia and anaemia may occur but tend to be less common and less severe.

Haemorrhagic cystitis may develop after high or prolonged dosage, and can be life-threatening. Adequate hydration to maintain urine output at 100 mL/hour and use of mesna (see p.1449) are generally recommended in an attempt to reduce urotoxicity. If mesna is used, frequent emptying of the bladder should be avoided. Doses of cyclophosphamide should be given early in the day.

Alopecia occurs in about 20% of patients given low doses and in practically all patients given high doses. Hair loss starts after 3 weeks of treatment but regrowth is usually evident after 3 months, even with continued treatment. Hyperpigmentation of skin, especially that of the palms and soles, and of the nails, has been reported.

Nausea and vomiting commonly occur, and may be reduced by prophylactic antiemetics. Mucositis may also occur.

Other adverse effects include a syndrome resembling inappropriate secretion of antidiuretic hormone (which may require diuretic therapy), disturbances of carbohydrate metabolism, gonadal suppression (common and occasionally resulting in sterility), interstitial pulmonary fibrosis, and, especially at high doses, cardiotoxicity.

Cyclophosphamide, in common with other alkylating agents, has carcinogenic, mutagenic, and teratogenic potential and secondary malignancies have occurred in patients given previous antineoplastic therapy including cyclophosphamide—see p.635.

Effects on the bladder. *Sterile haemorrhagic cystitis* (p.2178) can occur after high-dose infusions of cyclophosphamide or after prolonged low-dose oral use.[1,2] It is believed to be secondary to renal excretion of alkylating metabolites, particularly the acrolein metabolite, that cause sloughing, thinning, and inflammation of the bladder wall. Damage ranges from minor bleeding to diffuse necrotic ulceration, and can lead to anaemia, constriction of the bladder, bladder perforation, and death.[2] Symptoms may be delayed, and have been reported to occur up to 6 months after stopping the drug.[3] An increased incidence of cystitis when patients on a high-dose cyclophosphamide regimen were transferred from one brand to another has been reported,[4] apparently because one was labelled in terms of the anhydrous substance and one as the monohydrate, resulting in a 6.4% difference in the content of active substance.[5]

Measures used to prevent haemorrhagic cystitis include intravenous hydration with diuresis, frequent voiding, or bladder catheterisation with irrigation, to increase urine output and dilute the excreted metabolites. Mesna may be used as a uroprotectant to reduce exposure to the metabolites.[2] If bleeding occurs, various drugs have been instilled intravesically, including sodium chloride 0.9%, alum, or prostaglandins.[2,6-9] Silver nitrate, formaldehyde, or phenol instillations have been used but are painful and patients require anaesthesia.[2] There is limited information to suggest that conjugated oestrogens given orally or intravenously may be effective.[2,10] Nonpharmacological techniques are reserved for refractory cases and include arterial embolisation or surgery.[2]

In addition to the shorter term effects, cyclophosphamide has been reported to be associated with the development of *bladder carcinoma.*[1,11-14] A history of cyclophosphamide-induced cystitis may be associated with an increased risk of bladder carcinoma[1,11] but some studies have not found a link,[13] and bladder malignancies can develop in patients who have not experienced cystitis while receiving cyclophosphamide.[12] For a discussion of the carcinogenic effects of antineoplastics, including cyclophosphamide, see p.635.

Effects on the blood. Amifostine has been reported to protect against the myelosuppressive effects of cyclophosphamide, and may be used to reduce neutropenia-related infection associated with the combination of cyclophosphamide and cisplatin (see p.1437).

Effects on carbohydrate metabolism. Acute onset type 1 diabetes occurred in a patient treated with cyclophosphamide, doxorubicin, vincristine and prednisone (CHOP), and was thought to be due to the cyclophosphamide.[1]

1. Atlan-Gepner C, *et al.* A cyclophosphamide-induced autoimmune diabetes. *Lancet* 1998; **352:** 373–4.

Effects on electrolytes. Water intoxication has been reported with cyclophosphamide,[1-4] usually in high doses (30 to 50 mg/kg or more) although symptoms have been reported after a dose of 20 mg/kg in a patient with renal disease,[3] and in another patient with SLE but apparently normal renal function who received 10 mg/kg.[4] One case of severe hyponatraemia leading to convulsions and death has been reported.[5] Symptoms resemble the syndrome of inappropriate antidiuretic hormone secretion (SIADH)[5] but plasma concentrations of antidiuretic hormone do not appear to be raised in these patients.[3]

5. Harlow PJ, *et al.* A fatal case of inappropriate ADH secretion induced by cyclophosphamide therapy. *Cancer* 1979; **44:** 896–8.

Effects on the eyes. Recurrent transient myopia, apparently due to increased hydration of the lens of the eye, was induced by an intravenous bolus of cyclophosphamide in an adolescent with SLE.[1]

CMV retinitis has occurred in patients during or after cyclophosphamide therapy; presenting symptoms included floaters and blurred or decreased vision.[2]

1. Arranz JA, *et al.* Cyclophosphamide-induced myopia. *Ann Intern Med* 1992; **116:** 92–3.
2. Agrawal A, *et al.* Visual symptoms in patients on cyclophosphamide may herald sight threatening disease. *Br J Ophthalmol* 2003; **87:** 122–3.

Effects on reproductive potential. Severe gonadal failure with transient or permanent azoospermia is common in men treated with cyclophosphamide. Suppression of germ-cell function with intramuscular testosterone in 5 men during cyclophosphamide therapy for nephrotic syndrome was associated with a more rapid return of spermatogenesis compared with 10 patients who did not receive the androgen.[1]

1. Masala A, *et al.* Use of testosterone to prevent cyclophosphamide-induced azoospermia. *Ann Intern Med* 1997; **126:** 292–5.

Effects on the skin. An erythematous pruritic rash, similar to the palmar-plantar erythrodysesthesia syndrome (p.639) but occurring on the dorsal surfaces of the hands and feet, occurred 6 days after the first high dose of cyclophosphamide in a patient being prepared for bone marrow transplantation.[1] Previous cyclophosphamide-containing chemotherapy did not produce this reaction. The symptoms improved somewhat on treatment with triamcinolone ointment, and subsequently desquamation of the hands occurred with decreased purplish discoloration and oedema of the feet. There has also been a report of 2 patients who developed Stevens-Johnson syndrome, with some features suggestive of overlapping toxic epidermal necrolysis.[2]

1. Matsuyama JR, Kwok KK. A variant of the chemotherapy-associated erythrodysesthesia syndrome related to high-dose cyclophosphamide. *DICP Ann Pharmacother* 1989; **23:** 776–9.
2. Assier-Bonnet H, *et al.* Stevens-Johnson syndrome induced by cyclophosphamide: report of two cases. *Br J Dermatol* 1996; **135:** 864–6.

Hypersensitivity. Occasional anaphylaxis has been reported with cyclophosphamide;[1] analysis of data by the Boston Collaborative Drug Surveillance Program detected only one allergic skin reaction among 210 patients given cyclophosphamide, resulting in a calculated incidence of 4.8 reactions per 1000 recipients.[2]

Precautions

For reference to the precautions necessary with antineoplastics, see p.641.

Cyclophosphamide should not be given to patients with bone-marrow aplasia, acute infection, or drug- or radiation-induced urothelial toxicity. It should be given with care to those with diabetes mellitus. Care is also needed in elderly or debilitated patients, or those with renal or hepatic impairment or who have undergone adrenalectomy. Liberal fluid intake and frequent micturition are advised to reduce the risk of cystitis but care must be taken to avoid water retention and intoxication. Urine should be examined regularly for red cells, which may precede haemorrhagic cystitis. The haematological profile should be monitored regularly.

The use of cyclophosphamide in pregnancy should be avoided where possible.

Breast feeding. Cyclophosphamide has been detected in breast milk,[1] and there are reports of neutropenia,[2] and leucopenia and thrombocytopenia,[3] in infants who have been breast fed by women receiving cyclophosphamide. The American Academy of Pediatrics considers[4] that cyclophosphamide may interfere with cellular metabolism, causing neutropenia and possibly immune suppression in the infant, and has unknown effects on growth, and an association with carcinogenesis.

4. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 29/06/04)

Handling and disposal. *Residues* of cyclophosphamide or ifosfamide destroyed using alkaline hydrolysis in the presence of dimethylformamide showed no mutagenicity *in vitro*.[1] An alternative method, involving refluxing of cyclophosphamide with hydrochloric acid, neutralising, and then reacting with sodium thiosulfate, was effective for the degradation of cyclophosphamide, but residues from ifosfamide were still highly mutagenic *in vitro* and this second method should therefore not be used to degrade ifosfamide.

Urine and faeces produced for up to 72 hours and 5 days respectively after an oral dose of cyclophosphamide should be handled wearing protective clothing.[2] As cyclophosphamide was present in sweat and saliva, protective clothing was advised for 72 hours after a dose when bathing the patient or carrying out oral procedures.

2. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; **235:** 289–91.

Porphyria. Cyclophosphamide is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Interactions

For a general outline of antineoplastic drug interactions, see p.642. Since cyclophosphamide must undergo hepatic metabolism before it is active, interactions are possible with drugs that inhibit or stimulate the mixed function oxidase enzymes responsible. There may be an increased risk of cardiotoxicity in patients who have also received doxorubicin or other cardiotoxic drugs.

Allopurinol. Although the Boston Collaborative Drug Surveillance Program reported an increased incidence of bone-marrow depression in patients given allopurinol with cyclophosphamide than in those given cyclophosphamide without allopurinol (15 of 26 compared with only 6 of 32),[1] a subsequent study in patients given combination chemotherapy, including cyclophosphamide, for lymphomas failed to find any difference in the nadirs of the platelet and white blood cell counts in cycles in which allopurinol was given.[2] Although allopurinol pretreatment in 4 patients resulted in a longer cyclophosphamide half-life in a study in 26 patients given cyclophosphamide, urinary excretion of cyclophosphamide was unchanged.[3] A longer cyclophosphamide half-life was also seen in a study in children given allopurinol.[4]

2. Stolbach L, *et al.* Evaluation of bone marrow toxic reaction in patients treated with allopurinol. *JAMA* 1982; **247:** 334–6.
3. Bagley CM, *et al.* Clinical pharmacology of cyclophosphamide. *Cancer Res* 1973; **33:** 226–33.
4. Yule SM, *et al.* Cyclophosphamide pharmacokinetics in children. *Br J Clin Pharmacol* 1996; **41:** 13–19.

Antibacterials. *Chloramphenicol* given before cyclophosphamide prolonged the mean cyclophosphamide serum half-life from 7.5 to 11.5 hours and reduced the peak activity in all of 5 subjects.[1] Giving *sulfaphenazole* before cyclophosphamide significantly inhibited the rate of biotransformation of cyclophosphamide in 2 of 7 subjects and enhanced it in 2; it remained unchanged in 3. A study in patients with non-Hodgkin's lymphoma found that giving *ciprofloxacin* before cyclophosphamide affected pharmacokinetic parameters of cyclophosphamide. The area under the concentration-time curve (AUC) of cyclophosphamide was increased and clearance was lower; AUC of the active metabolite of cyclophosphamide, 4-hydroxycyclophosphamide, was decreased and clearance increased.[2]

1. Faber OK, *et al.* The effect of chloramphenicol and sulphaphenazole on the biotransformation of cyclophosphamide in man. *Br J Clin Pharmacol* 1975; **2:** 281–5.
2. Afsharian P, *et al.* The effect of ciprofloxacin on cyclophosphamide pharmacokinetics in patients with non-Hodgkin lymphoma. *Eur J Haematol* 2005; **75:** 206–11.

Anticoagulants. For reference to the interaction of cyclophosphamide with *warfarin*, see p.1429.

Antifungals. Analysis of cyclophosphamide metabolism in patients enrolled in a study comparing itraconazole with fluconazole found that those given itraconazole had higher exposure to toxic metabolites of cyclophosphamide. Both the antifungals appeared to alter cyclophosphamide metabolism and the authors cautioned against use of azole antifungals with antineoplastics that are metabolised via cytochrome P450 isoenzymes.[1]

1. Marr KA, *et al.* Cyclophosphamide metabolism is affected by azole antifungals. *Blood* 2004; **103:** 1557–9.

Barbiturates. Although patients receiving cyclophosphamide developed higher peak plasma concentrations of active cyclophosphamide metabolites when given enzyme-inducing agents such as barbiturates, the active metabolites also disappeared rapidly.[1]

1. Bagley CM, *et al.* Clinical pharmacology of cyclophosphamide. *Cancer Res* 1973; **33:** 226–33.

Chlorpromazine. The half-life of cyclophosphamide was about 200% greater in 2 children also taking chlorpromazine than in children not given the phenothiazine.[1]

1. Yule SM, *et al.* Cyclophosphamide pharmacokinetics in children. *Br J Clin Pharmacol* 1996; **41:** 13–19.

Ciclosporin. For reference to the effect of cyclophosphamide on ciclosporin concentrations, see Interactions, Antineoplastics, p.1826.

Colony-stimulating factors. Fatal respiratory insufficiency associated with alveolar fibrosis developed in an infant given cyclophosphamide and doxorubicin followed by *filgrastim*.[1] Since pulmonary toxicity with cyclophosphamide is normally associated with high cumulative doses it was suggested that in this case the effects might have been exacerbated by the granulocyte colony-stimulating factor. (The pulmonary toxicity of bleomycin has also been suggested to be exacerbated by colony-stimulating factors, as discussed on p.688).

1. van Woensel JBM, *et al.* Acute respiratory insufficiency during doxorubicin, cyclophosphamide, and G-CSF therapy. *Lancet* 1994; **344:** 759–60.

Corticosteroids. Single doses of *prednisone* have been found to inhibit the activation of cyclophosphamide but after longer-term treatment the rate of activation has increased.[1] A study in children found that pretreatment with *dexamethasone* was associated with increased clearance of cyclophosphamide and a decrease in its half-life relative to children not given the corticosteroid.[2]

1. Faber OK, Mouridsen HT. Cyclophosphamide activation and corticosteroids. *N Engl J Med* 1974; **291:** 211.
2. Yule SM, *et al.* Cyclophosphamide pharmacokinetics in children. *Br J Clin Pharmacol* 1996; **41:** 13–19.

Gastrointestinal drugs. In a retrospective study in patients receiving high-dose cyclophosphamide, cisplatin, and carmustine,[1] the area under the plasma-concentration time curve (AUC) for cyclophosphamide (measured as the parent compound) was 17% lower when *ondansetron* rather than prochlorperazine was added to the antiemetic regimen. In addition, the AUC for cisplatin was 10% higher with the ondansetron regimen. In a similar study,[2] the AUCs for both cyclophosphamide and cisplatin were lower in patients receiving an antiemetic regimen including ondansetron rather than prochlorperazine. The authors of both studies noted that the relevance of these findings to toxicity and antitumour effect of the antineoplastics remained to be determined.

1. Gilbert CJ, *et al.* Pharmacokinetic interaction between ondansetron and cyclophosphamide during high-dose chemotherapy for breast cancer. *Cancer Chemother Pharmacol* 1998; **42:** 497–503.
2. Cagnoni PJ, *et al.* Modification of the pharmacokinetics of high-dose cyclophosphamide and cisplatin by antiemetics. *Bone Marrow Transplant* 1999; **24:** 1–4.

NSAIDs. Acute life-threatening water intoxication was reported in a patient given low-dose cyclophosphamide with *indometacin*.[1] The patient had previously received treatment with cyclophosphamide (for multiple myeloma) without significant adverse effect.

1. Webberley MJ, Murray JA. Life-threatening acute hyponatraemia induced by low dose cyclophosphamide and indomethacin. *Postgrad Med J* 1989; **65:** 950–2.

Suxamethonium. For reference to a possible interaction between cyclophosphamide and suxamethonium, see under Suxamethonium Chloride, p.1911.

Pharmacokinetics

After oral doses, cyclophosphamide is well absorbed from the gastrointestinal tract with a bioavailability greater than 75%. It is widely distributed in the tissues and crosses the blood-brain barrier. It undergoes activation by the mixed function oxidase systems in the liver. The initial metabolites are 4-hydroxycyclophosphamide and its acyclic tautomer, aldophosphamide, which both undergo further metabolism; aldophosphamide may undergo non-enzymatic conversion to active phosphoramide mustard. Acrolein is also produced and may be responsible for bladder toxicity. Cyclophosphamide is excreted principally in urine, as metabolites and some unchanged drug. It crosses the placenta, and is found in breast milk.

◊ Reviews.

Absorption. Cyclophosphamide was detected in the urine of 5 patients after application to intact skin, showing that cyclophosphamide can be absorbed via this route.[1] Absorption continued after the site of application had been cleaned, suggesting that cyclophosphamide had penetrated subcutaneous lipid and was slowly released to the circulation from this depot. Cyclophosphamide was also identified in the urine of 2 oncology nurses but appeared more quickly than in patients, suggesting a faster route of absorption, perhaps by inhalation of aerosols generated during dissolution of the drug.

1. Hirst M, *et al.* Occupational exposure to cyclophosphamide. *Lancet* 1984; **i:** 186–8.

Uses and Administration

Cyclophosphamide is an antineoplastic that is converted in the body to active alkylating metabolites with properties similar to those of chlormethine (p.698). It also possesses marked immunosuppressant properties.

Cyclophosphamide is widely used, often with other agents, in the treatment of malignant diseases as indicated by the cross-references below. It is given for Burkitt's and other non-Hodgkin's lymphomas, multiple myeloma, and mycosis fungoides. It is also used in gestational trophoblastic tumours and malignancies of the brain, breast, endometrium, lung, and ovary; in childhood malignancies such as neuroblastoma, retinoblastoma, Wilms' tumour; and in sarcomas and some leukaemias.

The immunosuppressant properties of cyclophosphamide have been used in organ and tissue transplantation. It has also been used in the management of disorders thought to have an auto-immune component including amyloidosis, Behçet's syndrome, glomerular kidney disease, idiopathic thrombocytopenic purpura, aplastic anaemia, cryptogenic fibrosing alveolitis, polymyositis, scleroderma, SLE, and vasculitic syndromes including the Churg-Strauss syndrome, polyarteritis nodosa, and Wegener's granulomatosis, as indicated by the cross references below.

Cyclophosphamide is usually given orally or by intravenous injection.

In the BP 2008 the content of Cyclophosphamide Injection is expressed in terms of the equivalent amount of anhydrous cyclophosphamide whereas the content of Cyclophosphamide Tablets is given in terms of the monohydrate; the USP 31 expresses content in terms of anhydrous cyclophosphamide for both injection and tablets. Confusion has arisen when patients were changed from a preparation in which the content was expressed as the monohydrate to one in which it was expressed as the anhydrous substance (see Effects on the Bladder, above). 53.45 mg of cyclophosphamide monohydrate is equivalent to 50 mg of anhydrous cyclophosphamide. *Doses below are given in terms of anhydrous cyclophosphamide.*

The dosage given may vary considerably depending on the disease being treated, the condition of the patient including the state of the bone marrow, and use with radiotherapy or other chemotherapy. The white cell count is usually used to guide the dose.

In the UK, examples of licensed regimens are:

- *low-dose*: cyclophosphamide 2 to 6 mg/kg weekly as a single intravenous dose or in divided oral doses
- *moderate-dose*: 10 to 15 mg/kg weekly as a single intravenous dose.
- *high-dose*: 20 to 40 mg/kg as a single intravenous dose every 10 to 20 days, although higher doses have been used

Alternative regimens include:

- 100 to 300 mg daily in divided oral doses
- 80 to 300 mg/m^2 daily as a single intravenous dose
- 300 to 600 mg/m^2 weekly as a single intravenous dose
- 600 to 1500 mg/m^2 as a single intravenous dose or short infusion at 10 to 20 day intervals

The use of mesna is generally recommended with single doses of cyclophosphamide over 2 g, but one manufacturer suggests its use with doses as low as 10 mg/kg.

In the USA, an initial dose of 40 to 50 mg/kg has been licensed for single agent therapy of malignancy, given intravenously in divided doses over 2 to 5 days although in practice treatment of malignancy will generally be with combination regimens. Other licensed regimens include:

- 3 to 5 mg/kg twice weekly intravenously
- 10 to 15 mg/kg every 7 to 10 days intravenously
- 1 to 5 mg/kg daily orally

A daily oral dose of 2 to 3 mg/kg has been used in children with minimal change nephropathy leading to the nephrotic syndrome, in whom corticosteroids have been unsuccessful.

In patients who are to undergo bone marrow transplantation very high doses of cyclophosphamide such as 60 mg/kg daily for 2 days may be given as part of the conditioning regimen.

Cyclophosphamide has also been given intramuscularly, intraperitoneally, and intrapleurally, as well as intra-arterially, and by local perfusion (but passage through the liver is required for its activation—see Pharmacokinetics, above). A liquid preparation of cyclophosphamide for oral use may be prepared using the powder for injection.

Regular blood counts are essential during therapy with cyclophosphamide and treatment should be withdrawn or delayed if leucopenia or thrombocytopenia becomes severe (see also Bone-marrow Depression, p.639). Patients should be adequately hydrated and urine output maintained.

Amyloidosis. Although there is no unequivocally effective treatment for amyloidosis (p.743), cyclophosphamide may reduce the decline in renal function and prolong survival;[1-3] it has also been used with epirubicin and carmustine to suppress the disease in a patient who had undergone heart transplantation for cardiac amyloid.[4] Good responses have also been reported to cyclophosphamide given in a regimen with thalidomide and dexamethasone.[5]

Blood disorders, non-malignant. Cyclophosphamide has been used in patients with idiopathic thrombocytopenic purpura (p.1505), but cytotoxic immunosuppressants tend to be a treatment of last resort. Responses generally occur within 8 weeks.[1] In patients with refractory life-threatening disease, high-dose cyclophosphamide[1] may be tried. Combination chemotherapy including cyclophosphamide has also produced responses in a few patients.[2]

In the management of warm auto-immune haemolytic anaemia (p.1043) low-dose cyclophosphamide may be used in patients refractory to corticosteroids and splenectomy. A small number of patients with severe refractory disease have been treated with high-dose cyclophosphamide with some success.[3]

Cyclophosphamide is often used in preparation for bone marrow transplantation in patients with aplastic anaemia (p.1042), and complete remission has also been reported with high-dose cyclophosphamide alone.[4,5] However, a randomised trial[6] of high-dose cyclophosphamide plus ciclosporin compared with conventional immunosuppression was stopped early when a higher mortality was seen in those given cyclophosphamide. Further follow-up[7] also found that relapse rates were no different.

Cyclophosphamide with a corticosteroid has been tried in the rare condition of acquired haemophilia (p.1048).

Cogan's syndrome. For reference to the use of cyclophosphamide with corticosteroids for Cogan's syndrome, see p.1502.

Connective tissue and muscular disorders. Cyclophosphamide is one of a number of immunosuppressants that have been tried for disease control in Behçet's syndrome (p.1499); such drugs may permit a reduction in the use of corticosteroids, although they carry their own risks of toxicity. In polymyositis (p.1510) cyclophosphamide may have a role where there is lung disease; the role of immunosuppressants other than azathioprine or methotrexate is poorly defined. In patients with SLE (p.1513), cyclophosphamide has been used with some success for severe disease or disease refractory to corticosteroids alone, and appears to be more effective than corticosteroids for lupus nephritis.

Kidney disorders, non-malignant. Cyclophosphamide is used with corticosteroids in the treatment of some forms of glomerular kidney disease (p.1504). In children with nephrotic syndrome, oral cyclophosphamide 2 to 3 mg/kg daily for 8 weeks may be added to a course of corticosteroid therapy in relapsing disease; intravenous cyclophosphamide 500 mg/m^2 monthly for 6 months also substantially reduces the risk of relapse.[1] Addition of cyclophosphamide to corticosteroid therapy also improves the prospect of remission in focal glomerulosclerosis. Oral cyclophosphamide helps to stabilise progressive disease in patients with membranous nephropathy[2] although intermittent intravenous pulses are reported to be ineffective.[3] Such treatment is usually reserved for those whose disease is severe and progressive enough to justify it, but is probably better tolerated than other alkylating agents such as chlorambucil.[4] Cyclophosphamide has been given with methylprednisolone for rapidly progressive glomerulonephritis,[5] and has been used as part of the aggressive management of renal lesions in Goodpasture's syndrome.

5. Bruns FJ, *et al.* Long-term follow-up of aggressively treated idiopathic rapidly progressive glomerulonephritis. *Am J Med* 1989; **86:** 400–6.

Liver disorders, non-malignant. For mention of the use of cyclophosphamide in auto-immune hepatitis inadequately controlled by corticosteroids and azathioprine see Chronic Active Hepatitis, p.1501.

Lung disorders, non-malignant. Cyclophosphamide may be useful with corticosteroids in patients with cryptogenic fibrosing alveolitis, as mentioned under Diffuse Parenchymal Lung Disease, p.1502.

Malignant neoplasms. Cyclophosphamide is one of the most widely used drugs for the chemotherapy of malignancy, and mention of its role may be found in the discussions of the management of gestational trophoblastic tumours (p.650); the non-Hodgkin's lymphomas, including AIDS-related lymphoma, Burkitt's lymphoma, and mycosis fungoides (p.656, p.657, p.657, p.657); malignancies of the brain (p.660), breast (p.661), endometrium (p.663), lung (p.668), ovary (p.670) and thymus (p.674); multiple myeloma (p.658); Wilms' tumour, neuroblastoma, and retinoblastoma (p.667, p.674, and p.675 respectively); and sarcomas of bone (p.675) and rhabdomyosarcoma (p.676). Cyclophosphamide is also used in the management of acute lymphoblastic leukaemia (p.651) and chronic lymphocytic leukaemia (p.653).

Neuromuscular disorders. Cyclophosphamide has been tried in myasthenia gravis (p.629) in patients who require immunosuppressants but are intolerant of or unresponsive to corticosteroids and azathioprine. Cyclophosphamide has also been tried in regimens for the management of multiple sclerosis (p.892), but the reported benefits have generally been slight and outweighed by toxicity, such that it is usually reserved for patients with severe disease resistant to standard therapies.

Ocular disorders, non-malignant. Immunosuppressive agents, including cyclophosphamide, have been used in scleritis and uveitis (see p.1512 and p.1515) unresponsive to corticosteroids in tolerable doses.

Organ and tissue transplantation. Cyclophosphamide is used in high doses, usually with busulfan or irradiation, in conditioning regimens for bone marrow transplantation (see Haematopoietic Stem Cell Transplantation, p.1811). It has been tried as part of immunosuppressant regimens after transplantation of heart grafts (p.1812).

Paraquat poisoning. For reference to the use of cyclophosphamide in paraquat poisoning, see p.2048.

Pemphigus and pemphigoid. Corticosteroids are the main treatment for blistering in pemphigus and pemphigoid (p.1582). Immunosuppressive therapy, including cyclophosphamide,[1,2] has been used with corticosteroids to permit a reduction in corticosteroid dosage. Cyclophosphamide with a corticosteroid is also reported to be of value in ocular mucous membrane pemphigoid,[3] although treatment may not completely prevent cicatrisation.[4] Oral cyclophosphamide is considered an alternative to azathioprine in pemphigus vulgaris and pulsed intravenous doses might be considered in severe or recalcitrant cases.[5] There is less support for cyclophosphamide in bullous pemphigoid and it should only be considered if other treatments have failed or are contra-indicated.[6] However, oral or intravenous cyclophosphamide with corticosteroids may be considered for first-line treatment of severe or rapidly progressive mucous membrane pemphigoid.[7]

Rheumatoid arthritis. Cyclophosphamide has been used as a disease-modifying antirheumatic drug in rheumatoid arthritis (p.11), usually in patients with severe disease unresponsive to other drugs; its severe toxicity limits its usefulness.[1] It is of most value in controlling antibody-mediated systemic complications of the disease such as vasculitis[2] through inhibition of B-cell function.

1. Suarez-Almazor ME, *et al.* Cyclophosphamide for treating rheumatoid arthritis. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2000 (accessed 12/05/05).
2. Choy E, Kingsley G. How do second-line agents work? *Br Med Bull* 1995; **51:** 472–92.

Sarcoidosis. Where drug therapy is required for sarcoidosis (p.1512), corticosteroids are the usual treatment. Cyclophosphamide is one of a number of cytotoxic immunosuppressants that have been tried, with variable results, as a second-line therapy; its use has been limited by toxicity.

Scleroderma. As discussed on p.1817 the role of drug treatment for scleroderma is not well determined, but cyclophosphamide may be useful with or without a corticosteroid for patients with lung involvement.

Vasculitic syndromes. Treatment of the systemic vasculitides has revolved around the use of corticosteroids and cyclophosphamide. The benefits are uncertain in polyarteritis nodosa (p.1510) and Takayasu's arteritis (p.1514), but the benefits of combined therapy are generally accepted in Churg-Strauss syndrome (p.1501) and microscopic polyangiitis (p.1510), and cyclophosphamide is the mainstay of effective treatment of Wegener's granulomatosis (p.1515). A number of regimens are in use; in particular intermittent high-dose intravenous ('pulsed') use is being evaluated in comparison with continuous therapy.[1]

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

The major dose-limiting adverse effect of cytarabine is bone-marrow depression, manifest as leucopenia (particularly granulocytopenia), thrombocytopenia, and anaemia, sometimes with striking megaloblastic changes. Myelosuppression appears to be more evident after continuous infusions. Leucopenia is biphasic, with a nadir at 7 to 9 days after a dose and another, more severe, at 15 to 24 days. The nadir of the platelet count occurs at about 12 to 15 days. Recovery generally occurs in a further 10 days.

Gastrointestinal disturbances may occur: nausea and vomiting may be more severe when doses are given rapidly (but other adverse effects are reported to be worse when the drug is given by infusion). Other adverse effects reported include hepatic dysfunction, renal dysfunction, neurotoxicity, bleeding complications, rashes, oral and anal ulceration, gastrointestinal haemorrhage, oesophagitis, and conjunctivitis. A syndrome of bone and muscle pain, fever, malaise, conjunctivitis, and rash, sometimes described as flu-like, has been reported 6 to 12 hours after cytarabine doses, and may be treated or prevented with corticosteroids. Anaphylactoid reactions and pancreatitis have occurred rarely. There may be local pain, cellulitis, and thrombophlebitis at the site of injection.

Intrathecal use of the liposomal cytarabine formulation commonly causes chemical arachnoiditis manifesting as neck stiffness or pain, nausea, vomiting, headache, and fever. Dexamethasone should be used prophylactically to reduce the incidence and severity of this complication. Other rare adverse effects include encephalopathy, and focal seizures. Intrathecal use of conventional cytarabine formulations has rarely been associated with severe spinal cord toxicity, necrotising encephalopathy, blindness, and other neurotoxicities. If given intrathecally, preservative-free diluents must be used.

High-dose therapy has been associated with particularly severe gastrointestinal and CNS effects, including severe ulceration of the gastrointestinal tract, pneumatosis cystoides leading to peritonitis, necrotising colitis and bowel necrosis, peripheral neuropathy, and cerebral and cerebellar dysfunction, with personality changes, somnolence, and coma. There may also be corneal toxicity leading to punctate keratitis and haemorrhagic conjunctivitis, sepsis, liver abscess, severe skin rash leading to desquamation, alopecia, and cardiac disorders including pericarditis and fatal cardiomyopathy. Pulmonary oedema, sometimes fatal, has occurred.

Cytarabine is teratogenic in *animals* (but see Pregnancy, below).

In addition to frequent white blood cell and platelet counts, blood-uric acid should be monitored because of the risk of hyperuricaemia secondary to lysis of neoplastic cells, and renal and hepatic function should be periodically assessed. Cytarabine should be given with care to patients with impaired liver function; dosage reduction may be necessary.

◊ The toxicity of cytarabine has been reviewed.[1] The principal toxicity of standard dosage regimens is myelosuppression but bleeding complications and gastrointestinal toxicity are also major problems at standard doses. With the high-dose regimens neurological toxicity may be dose-limiting: severe and sometimes irreversible symptoms have been seen in some 6 to 10% of patients receiving a cumulative dose of 36 g/m^2. Ocular toxicity may occur in up to 80% of patients at the highest doses. Since cytarabine toxicity is largely dose-related, low-dose cytarabine is generally well tolerated, even in elderly patients (who are more susceptible): its only significant toxicity is myelosuppression.

1. Stentoft J. The toxicity of cytarabine. *Drug Safety* 1990; **5:** 7–27.

Effects on the nervous system. Although paraplegia has been reported with intrathecal cytarabine[1] (see also under Benzyl Alcohol, p.1631) and peripheral neuropathy has occurred in a patient who had received only conventional intravenous doses,[2] the majority of cases of neurotoxicity associated with cytarabine appear to be in patients given high-dose regimens.[3-7] Although some cases have manifested as demyelinating peripheral neuropathy,[3,4] including a syndrome of painful legs and involuntary movements in the toes which showed some response to carbamazepine,[3] most studies have reported in particular a syndrome of cerebellar toxicity,[5-8] with symptoms such as dysarthria, nystagmus, and ataxia. Toxicity appears to be dose-related: in one series[5] CNS toxicity occurred in none of 12 patients given total doses of up to 24 g/m^2 of cytarabine, 3 of 19 receiving 36 g/m^2, and 1 of 12 given 48 g/m^2, none of which were life-threatening or irreversible, whereas 4 of 6 given 54 g/m^2 (as 4.5 g/m^2 every 12 hours for 12 doses) developed neurotoxicity, which was fatal in one and irreversible in another. However, persistent, severe cerebellar toxicity has also been reported in a patient who had received a total dose of only 36 g/m^2 (as 3 g/m^2 every 12 hours).[8] There is some evidence[6] that patients aged over 50, and those who have recently received conventional-dose cytarabine[7] may be at increased risk. Intracranial hypertension (pseudotumor cerebri) has occurred rarely.[9]

Effects on the skin. A syndrome of pain and erythema of the palms and soles, progressing to bullae and desquamation, has been seen in patients receiving intermediate- or high-dose cytarabine.[1-3] The syndrome is similar to the palmar-plantar erythrodysesthesia syndrome (p.639) reported in patients receiving chemotherapy not including cytarabine,[4] although some considered the two forms of toxicity distinct.[5] Cutaneous small vessel necrotising vasculitis has been reported after high-dose therapy with cytarabine.[6]

The symbol † denotes a preparation no longer actively marketed

Pregnancy. Although there has been a report of limb and ear deformities in the infant of a woman given cytarabine at the estimated time of conception and 4 to 8 weeks later,[1] no congenital abnormalities were noted in 17 infants, 5 therapeutic abortions, and one still-birth (after pre-eclamptic toxaemia) resulting from over 20 known cases in which cytarabine was given during pregnancy.[2]

1. Wagner VM, *et al.* Congenital abnormalities in baby born to cytarabine treated mother. *Lancet* 1980; **ii:** 98–9.
2. Morgenstern G. Cytarabine in pregnancy. *Lancet* 1980; **ii:** 259.

Interactions

For a general outline of antineoplastic drug interactions, see p.642.

Antifungals. Cytarabine has been reported to inhibit the action of *flucytosine*—see p.534.

Antineoplastics. Acute pancreatitis has been reported in patients given cytarabine who had previously received *asparaginase* therapy.[1] Subclinical damage to the pancreas by asparaginase may have rendered it susceptible to cytarabine.

For a report of hepatic dysfunction in patients who had received cytarabine and *daunorubicin* see under Daunorubicin Hydrochloride, p.709.

Giving cytarabine after *fludarabine* is reported to result in a fivefold increase in intracellular cytarabine concentrations in leukaemic cells,[2] producing improved clinical response rates.

2. Avramis VI, *et al.* Pharmacokinetic and pharmacodynamic studies of fludarabine and cytosine arabinoside administered as loading boluses followed by continuous infusions after a phase I/II study in pediatric patients with relapsed leukemias. *Clin Cancer Res* 1998; **4:** 45–52.

Pharmacokinetics

Cytarabine is not effective orally due to rapid deamination in the gastrointestinal tract; less than 20% of an oral dose is absorbed. After intravenous injection it disappears rapidly from the plasma with an initial half-life of about 10 minutes; the terminal elimination half-life ranges from 1 to 3 hours. It is converted by phosphorylation to an active form, which is rapidly deaminated, mainly in the liver and the kidneys, to inactive 1-β-D-arabinofuranosyluracil (uracil arabinoside, ara-U). The majority of an intravenous dose is excreted in the urine within 24 hours, mostly as the inactive metabolite with about 10% as unchanged cytarabine.

There is only moderate diffusion of cytarabine across the blood-brain barrier after intravenous injection, but, because of low deaminase activity in the CSF, concentrations achieved after continuous intravenous infusion or intrathecal injection are maintained for longer in the CSF than are those in plasma, with a terminal elimination half-life of 3.5 hours. After intrathecal doses of the liposomal formulation, a terminal elimination half-life of 100 to 263 hours was seen. Cytarabine also crosses the placenta.

Uses and Administration

Cytarabine, a pyrimidine nucleoside analogue, is an antimetabolite antineoplastic that inhibits the synthesis of deoxyribonucleic acid. Its actions are specific for the S phase of the cell cycle. It also has antiviral and immunosuppressant properties. Cytarabine is one of the mainstays of the treatment of acute myeloid leukaemias, together with an anthracycline, (see p.652), and is used for the prophylaxis of meningeal leukaemia, as well as in regimens for consolidation, in patients with acute lymphoblastic leukaemia (p.651). It has also been investigated in the blast crisis of chronic myeloid leukaemia (p.653) and the myelodysplasias (p.654) (see also Low-dose Therapy, under Administration, below). It may be used in salvage regimens for Hodgkin's disease (p.655), as part of the complex regimens sometimes employed in aggressive intermediate- and high-grade non-Hodgkin's lymphomas (p.656), and for meningeal lymphoma.

Cytarabine is usually given intravenously. Higher doses can be tolerated when given by rapid injection rather than slow infusion, because of the rapid clearance of cytarabine, but there is little evidence of clinical advantage either way. Cytarabine may be given intrathecally for leukaemic or lymphomatous meningitis.

For the induction of remission in adults and children with acute leukaemias many dosage regimens have been used: 100 mg/m^2 twice daily by rapid intravenous injection, or 100 mg/m^2 daily by continuous intravenous infusion, have often been employed. These doses are generally given for 5 to 10 days, depending on therapeutic response and toxicity. Children reportedly tolerate high doses better than adults.

For maintenance 1 to 1.5 mg/kg once or twice weekly has been given intravenously or subcutaneously; other regimens have been used.

In the treatment of refractory disease high-dose regimens have been used, with cytarabine given in doses of up to 3 g/m^2 every 12 hours for up to 6 days. These doses should be given by intravenous infusion over at least 1 hour.

In leukaemic meningitis cytarabine has been given intrathecally, often in a dose of 10 to 30 mg/m^2 every 2 to 4 days; it has also been used prophylactically. A liposomal formulation is available in some countries for intrathecal use, and permits less frequent dosing because of its longer duration of action: the recommended dose for lymphomatous meningitis is 50 mg intrathecally every 2 weeks for 5 doses then every 4 weeks for 5 doses.

White cell and platelet counts should be determined regularly during treatment with cytarabine and therapy should be stopped immediately if the count falls rapidly or to low values (see also Bone-marrow Depression, p.639).

Cytarabine ocfosfate is an orally active prodrug of cytarabine under investigation in chronic myeloid leukaemia.

Administration. INTRATHECAL. Intrathecal doses of the liposomal formulation of cytarabine result in prolonged drug exposure when compared with intrathecal doses of the conventional formulation (see Pharmacokinetics, above). In a randomised study,[1] the liposomal formulation given once every 2 weeks produced a higher response rate and improved Karnofsky score compared with the conventional formulation given twice a week in patients with lymphomatous meningitis secondary to lymphoma. The use of liposomal formulations intrathecally to treat leukaemic or lymphomatous meningitis has been reviewed.[2,3]

LOW-DOSE THERAPY. Because of initial suggestions that low doses of cytarabine might induce differentiation and maturation of leukaemic cells, low-dose therapy has been tried in patients with myelodysplastic syndrome and acute myeloid leukaemia. Although complete remission may occur in about 20% of patients with myelodysplastic syndromes a similar proportion succumb to treatment-related mortality, and remissions do not appear to be particularly long-lasting. Bone-marrow suppression may be marked even at these doses.[1] Low-dose subcutaneous cytarabine (20 mg twice daily for 10 days, at intervals of 4 to 6 weeks) was found to be superior to hydroxycarbamide (with or without all-trans retinoic acid) in elderly patients with acute myeloid leukaemia. Although the authors considered the prognosis for these patients to still be unsatisfactory, they suggested that therapy with low-dose cytarabine could represent a baseline against which other promising treatments might be compared.[2]

Leukoencephalopathy. There are anecdotal reports[1-3] of marked improvement in patients with progressive multifocal leukoencephalopathy secondary to AIDS or chemotherapy-induced immunosuppression who were given intravenous or intrathecal cytarabine. However, a randomised multicentre study[4] indicated that cytarabine was ineffective and had no role in this condition (see also Infections in Immunocompromised Patients, p.859). Others[5] have suggested that even intrathecal dosage may not provide adequate delivery of cytarabine to target cells, and that delivering the drug directly into the brain under pressure might be an alternative. Cytarabine has also been used with cidofovir.[6]

Dacarbazine *(BAN, USAN, rINN)*

Dacarbazina; Dacarbazinum; Dakarbatsiini; Dakarbazin; DIC; DTIC; Imidazole Carboxamide; NSC-45388; WR-139007. 5-(3,3-Dimethyltriazeno)imidazole-4-carboxamide.

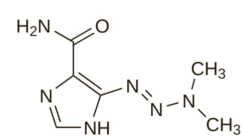
Дакарбазин

$C_6H_{10}N_6O$ = 182.2.

CAS — 4342-03-4 (dacarbazine); 64038-56-8 (dacarbazine citrate).

ATC — L01AX04.

ATC Vet — QL01AX04.



Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Dacarbazine). A white or slightly yellowish, crystalline powder. Slightly soluble in water and in anhydrous alcohol; practically insoluble in dichloromethane. Store at 2° to 8°. Protect from light.

USP 31 (Dacarbazine). Store in airtight containers at 2° to 8°. Protect from light.

Incompatibility. Dacarbazine has been reported to be incompatible with hydrocortisone sodium succinate but not with the sodium phosphate.[1] It has been reported to be incompatible with heparin,[2] although only with concentrated dacarbazine solutions (25 mg/mL).

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

Leucopenia and thrombocytopenia with dacarbazine, although usually moderate, may be severe. The nadir of the white cell count usually occurs 21 to 25 days after a dose. Anorexia, nausea, and vomiting occur in more than 90% of patients initially but tolerance may develop after repeated doses. Less frequent adverse effects include diarrhoea, skin reactions, alopecia, a flu-like syndrome, facial flushing and paraesthesia, headache, blurred vision, seizures, and rare but potentially fatal hepatotoxicity. There may be local pain at the injection site; extravasation produces pain and tissue damage. Anaphylaxis has occurred occasionally.

Dacarbazine should be used with caution in hepatic and renal impairment, and consideration given to reducing the dose. Haematological monitoring is required during therapy. Dacarbazine is potentially carcinogenic, mutagenic, and teratogenic.

Effects on the bladder. A report[1] of haemorrhagic cystitis associated with dacarbazine treatment for melanoma. The patient developed gross haematuria with inflammation and oedema of the bladder wall 2 weeks after completing 3 cycles of monotherapy with dacarbazine; the condition responded to symptomatic management with saline lavage and oral and intravenous hydration. Two subsequent transient episodes of haematuria resolved spontaneously.

1. Mohammadianpanah M, *et al.* Hemorrhagic cystitis in a patient receiving conventional doses of dacarbazine for metastatic malignant melanoma: case report and review of the literature. *Clin Ther* 2007; **29:** 1161–5.

Effects on the liver. Dacarbazine has been associated with fatal hepatic vascular toxicity, caused by thrombosis of the hepatic veins, necrosis, and extensive haemorrhage.[1] As the reaction usually occurs during the second course of dacarbazine it is thought to be immune mediated, and early corticosteroid treatment has been tried with a few reported cases of patient survival.[2] Other adverse hepatic effects have included[3] necrosis without inflammation, granulomatous hepatitis, and acute toxic hepatitis during the first course of dacarbazine. Morphological studies have suggested that dacarbazine may exert a toxic effect on the microfilamentous cytoskeleton of the hepatocytes.[3]

3. Dancygier H, *et al.* Dacarbazine (DTIC)-induced human liver injury. *Gut* 1982; **23:** A447.

Handling. Dacarbazine is irritant; avoid contact with skin and mucous membranes.

Interactions

For a general outline of antineoplastic drug interactions, see p.642.

Levodopa. For a report of dacarbazine reducing the effects of levodopa, see Antineoplastics, p.807.

Pharmacokinetics

Dacarbazine is poorly absorbed from the gastrointestinal tract. On intravenous injection it is rapidly distributed with an initial plasma half-life of about 20 minutes; the terminal half-life is reported to be about 5 hours. The volume of distribution is larger than body water content, suggesting localisation in some body tissues, probably mainly the liver. Only about 5% is bound to plasma protein. It crosses the blood-brain barrier to a limited extent; concentrations in CSF are about 14% of those in plasma. Dacarbazine is extensively metabolised in the liver by the cytochrome P450 isoenzymes CYP1A2 and CYP2E1 (and possibly in the tissues by CYP1A1) to its active metabolite 5-(3-methyl-1-triazeno)imidazole-4-carboxamide (MTIC), which spontaneously decomposes to the major metabolite 5-aminoimidazole-4-carboxamide (AIC). About half of a dose is excreted unchanged in the urine by tubular secretion.

Uses and Administration

Dacarbazine is a cell-cycle non-specific antineoplastic that is thought to function as an alkylating agent after it has been activated in the liver. Dacarbazine is used mainly in the treatment of metastatic malignant melanoma (p.673). It is also given to patients with Hodgkin's disease (p.655), notably with doxorubicin, bleomycin, and vinblastine (ABVD). Dacarbazine is used with other drugs in the treatment of soft-tissue sarcoma (p.676), and may be given in neuroblastoma (p.674), Kaposi's sarcoma (p.675), and other tumours.

Dacarbazine is given by the intravenous route. Injections may be given over 1 to 2 minutes. The reconstituted solution can be further diluted with up to 300 mL of glucose 5% or sodium chloride 0.9% and given by infusion over 15 to 30 minutes.

Dacarbazine is licensed for use as a single agent for **metastatic melanoma** in doses of 2 to 4.5 mg/kg daily for 10 days, repeated at intervals of 4 weeks, or 200 to 250 mg/m^2 daily for 5 days, repeated at intervals of 3 weeks. It can also be given in a dose of 850 mg/m^2 by intravenous infusion at 3-week intervals. In the treatment of **Hodgkin's disease** doses of 150 mg/m^2 daily for 5 days repeated every 4 weeks, or 375 mg/m^2 every 15 days have been given with other agents. In the treatment of **soft-tissue sarcoma**, dacarbazine 250 mg/m^2 is given daily for 5 days repeated every 3 weeks; it is usually given with doxorubicin.

Actinomycin C_1; Actinomycin D; Dactinomicina; Dactinomycine; Dactinomycinum; Daktinomisin; Daktinomycin; Daktinomysiini; Daktynomycyna; Meractinomycin; NSC-3053. $N^{2.1},N^{2'.1'}$-(2-Amino-4,6-dimethyl-3-oxo-3*H*-phenoxazine-1,9-diyldicarbonyl)-bis[threonyl-D-valylprolyl(*N*-methylglycyl)(*N*-methylvaline) 1.5–3.1-lactone].

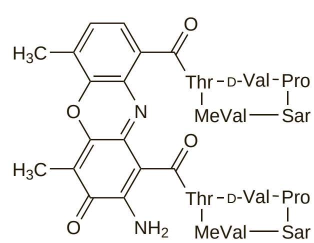
Дактиномицин

$C_{62}H_{86}N_{12}O_{16}$ = 1255.4.

CAS — 50-76-0.

ATC — L01DA01.

ATC Vet — QL01DA01.



Description. Dactinomycin is an antineoplastic antibiotic produced by *Streptomyces parvulus* and other species of *Streptomyces.*

Cactinomycin (actinomycin C; HBF-386; NSC-18268) is a mixture of dactinomycin (actinomycin D) (10%), actinomycin C_2 (45%), and actinomycin C_3 (45%) produced by *Streptomyces chrysomallus.*

Pharmacopoeias. In *Chin., Int., Jpn, Pol.,* and *US.*

USP 31 (Dactinomycin). A bright red, somewhat hygroscopic, crystalline powder, affected by light and heat. It has a potency of not less than 950 and not more than 1030 micrograms/mg, calculated on the dried basis. Soluble in water at 10° and slightly soluble in water at 37°; freely soluble in alcohol; very slightly soluble in ether. Store at a temperature not exceeding 40° in airtight containers. Protect from light.

Adsorption. Dactinomycin binds to cellulose ester filters,[1] and such filtration should be avoided.[2] Although it has been suggested that significant amounts of drug may be adsorbed to glass or plastic,[3] dactinomycin is reportedly compatible with glass and PVC infusion containers,[4] and giving into the tubing of a fast-running intravenous infusion is recommended—see Uses and Administration, below.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

Apart from nausea and vomiting adverse effects are often delayed, beginning 2 to 4 days after the completion of a course of treatment and reaching a maximum after 1 to 2 weeks. Fatalities have occurred. Bone-marrow depression and gastrointestinal effects (particularly stomatitis and diarrhoea) may prove dose-limiting. Bone-marrow depression is apparent 1 to 7 days after therapy and may be manifest first as thrombocytopenia; the nadir of the platelet and white cell counts usually occurs within 14 to 21 days, with recovery in 21 to 25 days. Other adverse effects include oral and gastrointestinal effects such as cheilitis, oesophagitis, gastrointestinal ulceration, and proctitis; fever, malaise, hypocalcaemia, erythema, myalgia, alopecia, pneumonitis, and kidney and liver abnormalities. Anaphylactoid reactions have occurred. Dactinomycin is very irritant and extravasation results in severe tissue damage.

The effects of radiotherapy are enhanced by dactinomycin and severe reactions may follow the use of high doses. Erythema and pigmentation of the skin may occur in areas previously irradiated. An increase in incidence of second primary tumours has been seen in patients treated with radiation and dactinomycin.

Dactinomycin should not be given to patients with varicella or herpes zoster, as severe and even fatal systemic disease may occur. Its use is best avoided in infants under 1 year as they are reported to be highly susceptible to the toxicity of dactinomycin. Blood counts and renal and hepatic function should be monitored frequently.

Effects on the liver. Although doses less than about 50 micrograms/kg or 1.5 mg/m^2 do not seem to be associated with an unacceptable degree of hepatotoxicity,[1] giving dactinomycin as a single dose of 60 micrograms/kg (about 1.8 mg/m^2) every 3 weeks to children with Wilms' tumour was associated with a high incidence of severe hepatotoxicity;[2] reduction of the dose to 45 micrograms/kg every 3 weeks reduced this incidence to levels comparable with a standard regimen of 15 micrograms/kg daily for 5 successive days.[3] Others have not seen such a high incidence of hepatotoxicity with doses of 60 micrograms/kg (despite some raised liver enzyme values), but in this case the high dose was given only every 6 weeks.[4] In general, dactinomycin should be given with caution to children with a history of antecedent liver damage, including abdominal irradiation or recent halothane anaesthesia.[1]

Reversible veno-occlusive disease has been seen particularly in children with Wilms' tumour who have received dactinomycin and vincristine. One study[5] found age of less than 1 year to be a risk factor and a study in children with rhabdomyosarcoma given dactinomycin, vincristine, and cyclophosphamide also found that young age (under 3 years) was associated with a greater risk of severe hepatic toxicity.[6] A literature review[7] noted a significant predominance of veno-occlusive disease in right-sided Wilms' tumour, possibly because the tumour mass could interfere with blood flow in the hepatic veins, which might make the liver more susceptible to the effects of dactinomycin.

7. Tornesello A, *et al.* Veno-occlusive disease of the liver in right-sided Wilms' tumours. *Eur J Cancer* 1998; **34:** 1220–3.

Handling. Dactinomycin is irritant; avoid contact with skin and mucous membranes.

Interactions

For a general outline of antineoplastic drug interactions, see p.642.

Pharmacokinetics

Intravenous doses of dactinomycin are rapidly distributed with high concentrations in bone marrow and nucleated cells. It undergoes only minimal metabolism and is slowly excreted in urine and bile. The terminal plasma half-life is reported to be about 36 hours. It does not cross the blood-brain barrier but is thought to cross the placenta.

In children. A study[1] involving 31 patients aged between 1 and 20 years given dactinomycin in intravenous doses of 0.7 to 1.5 mg/m^2 found that the pharmacokinetics of the drug were variable, but could be described by a 3-compartment model. Peak plasma concentrations varied from 3.2 to 99.2 nanograms/mL, and both peak plasma concentration and exposure were inversely related to body-weight. Since there was evidence that exposure was also related to more severe toxicity, younger patients might be at greater risk with a regimen based on surface area; conversely the practice of capping the dose at 2 mg in older patients might result in underdosage.

For evidence that younger patients do experience more liver toxicity with dactinomycin, see Effects on the Liver, above.

1. Veal GJ, *et al.* Pharmacokinetics of dactinomycin in a pediatric patient population: a United Kingdom Children's Cancer Study Group Study. *Clin Cancer Res* 2005; **11:** 5893–9.

Uses and Administration

Dactinomycin is a highly toxic antibiotic with antineoplastic properties. It inhibits the proliferation of cells in a cell-cycle non-specific way by forming a stable complex with DNA and interfering with DNA-dependent RNA synthesis. It may enhance the cytotoxic effects of radiotherapy (see also Adverse Effects, above). Dactinomycin also has immunosuppressant properties.

It has been used, usually with other drugs or radiotherapy, in the treatment of Wilms' tumour (p.667), gestational trophoblastic tumours (p.650), nonseminomatous testicular cancer (p.673), and sarcomas such as rhabdomyosarcoma (p.676) and Ewing's sarcoma (p.675).

In the treatment of Wilms' tumour, childhood rhabdomyosarcoma, or Ewing's sarcoma, an intravenous dose of 15 micrograms/kg daily for 5 days has been used in combination regimens. In adults, gestational trophoblastic tumours have been treated with 12 micrograms/kg daily for 5 days as a single agent, or 500 micrograms on days 1 and 2 of combination regimens. Metastatic nonseminomatous testicular cancer has been treated with 1 mg/m^2 on day 1 of combination regimens. The dose intensity for adults or children should not exceed 15 micrograms/kg or 400 to 600 micrograms/m^2 daily for 5 days per 2-week cycle, and lower doses may need to be used in some chemotherapy combinations or with radiotherapy. Using a regional perfusion technique to localise the drug has permitted the use of higher doses, 50 micrograms/kg being suggested for an isolated lower extremity or pelvis and 35 micrograms/kg for an upper extremity.

Great care must be taken to avoid extravasation and it should be given, for preference, into the tubing of a fast-running intravenous infusion. Platelet and white cell counts should be performed frequently to detect bone-marrow depression; if either count shows a marked decrease the drug should be withheld until recovery occurs, which may take up to 3 weeks (see also Bone-marrow Depression, p.639).

Preparations

USP 31: Dactinomycin for Injection.

Dasatinib *(USAN, rINN)*

BMS-354825; Dasatinibum. *N*-(2-Chloro-6-methylphenyl)-2-({6-[4-(2-hydroxyethyl)-1-piperazinyl]-2-methyl-4-pyrimidinyl}amino)-5-thiazolecarboxamide.

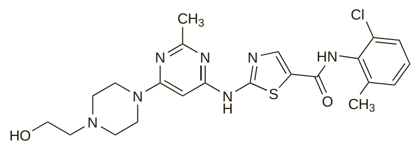
Дазатиниб

$C_{22}H_{26}ClN_7O_2S$ = 488.0.

CAS — 302962-49-8.

ATC — L01XE06.

ATC Vet — QL01XE06.



Adverse Effects, Treatment, and Precautions

The most common adverse effects of dasatinib include fluid retention, gastrointestinal disturbances, and bleeding. Fluid retention may be severe, and can result in pleural and pericardial effusion, pulmonary oedema, and ascites. Severe CNS haemorrhages, sometimes fatal, have been reported. Gastrointestinal haemorrhage may require interruption of therapy, and transfusions. Myelosuppression, manifest as neutropenia, thrombocytopenia, or anaemia, occurs more frequently in patients with advanced chronic myeloid leukaemia (CML) or acute lymphoblastic leukaemia than in patients in chronic phase. Recovery generally occurs after dose interruption and/or reduction, although treatment may need to be stopped. Febrile neutropenia has been reported. In patients with chronic phase CML, myelosuppression and fluid retention occur more often with twice daily dosing than once daily dosage. Other adverse effects include headache, pyrexia, musculoskeletal pain, fatigue, skin rashes, dyspnoea, cough, dizziness, chest pain, neuropathy, chills, and pruritus. Infections, including pneumonia, have been reported. Cardiac failure and arrhythmias can occur. Dasatinib has the potential to prolong the QT interval, and should be given with caution to patients at risk of this, such as those with hypokalaemia, hypomagnesaemia, or those on antiarrhythmic therapy, or receiving cumulative high doses of anthracyclines.

Effects on the skin. Panniculitis has been reported with the use of dasatinib, which resolved upon stopping therapy. In one case, dasatinib was restarted with prednisone, and no recurrence of panniculitis was noted. In another patient, however, a rash recurred on restarting therapy that was not sensitive to corticosteroid treatment.[1]

1. Assouline S, *et al.* Panniculitis during dasatinib therapy for imatinib-resistant chronic myelogenous leukemia. *N Engl J Med* 2006; **354:** 2623–4.

Interactions

Dasatinib is metabolised by the cytochrome P450 isoenzyme CYP3A4, and drugs that inhibit this enzyme, such as azole antifungals, macrolide antibacterials, HIV-protease inhibitors, and nefazodone may increase blood concentrations of dasatinib. Equally, inducers of CYP3A4 (such as carbamazepine, dexamethasone, phenobarbital, phenytoin, and rifampicin) may reduce blood concentrations of dasatinib. When use with such drugs cannot be avoided, dose adjustment of dasatinib may be necessary (see Uses and Administration, below). Since St John's wort may decrease dasatinib concentrations unpredictably, these drugs should not be given together.

Dasatinib is a substrate of the cytochrome P450 isoenzyme CYP3A4, and may alter blood concentrations of other drugs that are substrates of this enzyme.

Since the solubility of dasatinib is dependent on pH, use with antacids should be avoided. If antacid therapy is needed, it should be given at least 2 hours before or 2 hours after the dose of dasatinib. Similarly, histamine H_2-receptor antagonists or proton pump inhibitors such as famotidine or omeprazole should not be given with dasatinib as long-term suppression of gastric acid secretion is likely to reduce dasatinib exposure.

Pharmacokinetics

Maximum plasma concentrations of dasatinib are achieved between 0.5 and 6 hours after an oral dose. The mean terminal half-life is about 5 hours. Consumption of a high-fat meal may increase exposure to dasatinib, but this effect is not considered to be of clinical significance. Dasatinib is extensively distributed and metabolised. Metabolism occurs primarily by the cytochrome P450 isoenzyme CYP3A4, forming an active metabolite. Plasma protein binding of dasatinib and its active metabolite is about 96% and 93%, respectively. Elimination is mainly via the faeces; about 4% is recovered in the urine.

Uses and Administration

Dasatinib is a tyrosine kinase inhibitor that is used for the treatment of adults with all phases of chronic myeloid leukaemia (CML; p.653) who have resistance or intolerance to previous therapy, including imatinib. It is also used for the treatment of adults with Philadelphia chromosome-positive acute lymphoblastic leukaemia (ALL; p.651) who are resistant to or intolerant of prior therapy.

A recommended oral starting dose of dasatinib in chronic phase CML is 100 mg once daily: tablets, which should be swallowed whole, not crushed or chewed, should be taken consistently either in the morning or the evening. The recommended starting dose for accelerated, myeloid, or lymphoid blast phase CML or Philadelphia chromosome-positive ALL is 70 mg twice daily. Dosage may be adjusted according to response and tolerability; doses of up to 140 mg once daily have been used in patients with chronic phase CML, and up to 100 mg twice daily in those with advanced phase, or with ALL. Treatment is continued until disease progression or unacceptable toxicity occurs.

If concurrent use of potent inhibitors or inducers of cytochrome P450 isoenzyme CYP3A4 cannot be avoided, dose adjustments are considered necessary. A dose increase should be considered in those patients given strong CYP3A4 inducers, and the patient should be monitored for toxicity. For those given a strong CYP3A4 inhibitor, the dose of dasatinib should be reduced to 20 mg daily. If this is not tolerated, then either drug should be stopped; if the inhibitor is stopped, a washout period of about 1 week should be allowed before the dose of dasatinib is increased.

(daunorubicin)

NOTE. Daunorubicin citrate is used in the preparation of liposomal preparations (see Uses and Administration, below).

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Daunorubicin Hydrochloride). The hydrochloride of a substance produced by certain strains of *Streptomyces coeruleorubidus* or *S. peucetius* or obtained by any other means. It is manufactured by methods designed to minimise or eliminate the presence of histamine. An orange-red, hygroscopic, crystalline powder. It contains between 95 and 102% of the hydrochloride (anhydrous and solvent-free basis). Freely soluble in water and in methyl alcohol; slightly soluble in alcohol; practically insoluble in acetone. A 0.5% solution in water has a pH of 4.5 to 6.5. Store in airtight containers. Protect from light.

USP 31 (Daunorubicin Hydrochloride). An orange-red, hygroscopic, crystalline powder. It has a potency equivalent to not less than 842 and not more than 1030 micrograms of the base per mg. Freely soluble in water and in methyl alcohol; slightly soluble in alcohol; practically insoluble in acetone; very slightly soluble in chloroform. A 0.5% solution in water has a pH of 4.5 to 6.5. Store at a temperature not exceeding 40° in airtight containers. Protect from light.

Incompatibility. Daunorubicin is incompatible with heparin sodium,[1] and has also been reported to be incompatible with a solution of dexamethasone sodium phosphate.

1. D'Arcy PF. Reactions and interactions in handling anticancer drugs. *Drug Intell Clin Pharm* 1983; **17:** 532–8.

Stability. In a study[1] of the stability of anthracycline antineoplastic agents in 4 infusion fluids (glucose 5%, sodium chloride 0.9%, lactated Ringer's injection, and a commercial infusion fluid) daunorubicin hydrochloride was stable in all 4, the percentage remaining after 24 hours being 98.5%, 97.4%, 94.7%, and 95.4% respectively. Stability appeared to be partly related to pH; daunorubicin was more stable as the pH of the mixture became more acidic, with the best stability in glucose 5% with a pH of 4.5. Although daunorubicin solutions are degraded by light, the effect is reported not to be significant at concentrations of 500 micrograms/mL or above; however, below this concentration precautions should be taken to protect solutions from light, and storage should be in polyethylene or polypropylene containers to minimise adsorptive losses.[2] It has been suggested that formulation with the food colouring Scarlet GN, which absorbs light over the same spectral region as daunorubicin, would stabilise daunorubicin solutions to light.[3]

Liposomal daunorubicin should be diluted with glucose 5% solution as aggregation of the liposomes may result with sodium chloride. In addition, licensed product information advises that liposomal daunorubicin should not be mixed with substances containing benzyl alcohol or other detergent-like molecules, which can lead to premature rupture of the liposomes.

Adverse Effects, Treatment, and Precautions

As for Doxorubicin, p.712 and p.713.

Cardiotoxicity is more likely when the total cumulative dose of daunorubicin exceeds 550 to 600 mg/m^2 in adults, 300 mg/m^2 in children, or in children aged under 2 years, 10 mg/kg. The cumulative dose should be limited to 400 mg/m^2 in patients who have had previous radiation therapy to the mediastinum. Product information for liposomal daunorubicin recommends determining ventricular ejection fraction after cumulative doses of 320 mg/m^2, and every 160 mg/m^2 thereafter. Daunorubicin should be used in reduced doses in hepatic and renal impairment.

Liposomal formulations of daunorubicin may be associated with a reduced potential for local tissue necrosis although current clinical experience is limited and such toxicity remains a possibility. An acute syndrome of back pain, flushing, and chest tightness may occur during infusion, but generally resolves on slowing or temporarily stopping the infusion.

Effects on the heart. For a discussion of the cardiotoxicity of anthracyclines, and its management, see Effects on the Heart, under Doxorubicin, p.713.

Effects on the skin and nails. For reports of hyperpigmentation in patients given daunorubicin, see under Doxorubicin, p.713.

Handling and disposal. Daunorubicin hydrochloride is irritant; avoid contact with skin and mucous membranes.

For a method for the destruction of daunorubicin in wastes see under Doxorubicin, p.713.

Interactions

As for Doxorubicin, p.713.

Antineoplastics. Hepatic dysfunction was reported[1] in 13 patients given daunorubicin 180 to 450 mg/m^2. Ten of them had also received *tioguanine* or *cytarabine*, or a combination of these. The authors also noted that other studies had suggested that the related drug doxorubicin might enhance the hepatotoxicity of *mercaptopurine*, and thought that a similar interaction could occur between daunorubicin and tioguanine.

1. Penta JS, *et al.* Hepatotoxicity of combination chemotherapy for acute myelocytic leukemia. *Ann Intern Med* 1977; **87:** 247–8.

Pharmacokinetics

After intravenous injection, daunorubicin is rapidly distributed into body tissues, particularly the liver, lungs, kidneys, spleen, and heart with an initial distribution half-life of about 45 minutes. It is rapidly metabolised in the liver, and is excreted in bile and urine as unchanged drug and metabolites. The major metabolite, daunorubicinol, has antineoplastic activity. Up to 25% of a dose is excreted in urine in an active form over several days (the terminal plasma elimination half-lives of daunorubicin and its major metabolite are reported to be 18.5 and 26.7 hours respectively); an estimated 40% is excreted in bile. Daunorubicin does not appear to cross the blood-brain barrier, but crosses the placenta.

The pharmacokinetics of liposomal doxorubicin are significantly different from those of the conventional drug formulation, with a decreased uptake by normal tissues (although tumour neovasculature is reported to have increased permeability to the liposomes), and a terminal half-life of 4 to 5 hours.

Uses and Administration

Daunorubicin is an antineoplastic anthracycline antibiotic with actions similar to those of doxorubicin (p.714), to which it is closely related. It is used with other antineoplastics to induce remissions in acute leukaemias. Daunorubicin is given in combination regimens for acute lymphoblastic leukaemia (see p.651) and acute myeloid leukaemias (see p.652). It has also been tried in some other malignancies. A liposomal formulation of daunorubicin has been developed for use in the management of Kaposi's sarcoma in patients with AIDS (see also p.675).

Daunorubicin is usually given as the hydrochloride, but doses are expressed in terms of the base. Daunorubicin hydrochloride 21.4 mg is equivalent to about 20 mg daunorubicin.

In combination treatment regimens for adult acute leukaemia, the usual dose is 30 to 45 mg/m^2 daily on days 1 to 3 of the first course, and days 1 and 2 of subsequent courses. Daunorubicin is given as a solution in sodium chloride 0.9% into a fast-running infusion of sodium chloride or glucose. Courses may be repeated after 3 to 6 weeks. A dose of 25 mg/m^2 has been given intravenously once a week, in combination regimens, to children with acute lymphoblastic leukaemia. For children less than 2 years of age, or less than 0.5 m^2, a dose of 1 mg/kg has been used instead.

The total cumulative dose in adults should not exceed 550 to 600 mg/m^2; in patients who have received radiotherapy to the chest it may be advisable to limit the total dose to about 400 mg/m^2. Lower limits apply in children: a total cumulative dose of no more than 300 mg/m^2, or in children aged under 2 years 10 mg/kg, is recommended. Dosage should be reduced in patients with impaired hepatic or renal function (see below), and elderly patients with inadequate bone marrow reserves.

In the treatment of Kaposi's sarcoma, liposomal daunorubicin is given intravenously every 2 weeks starting with a dose of 40 mg/m^2, and continued for as long as disease control can be maintained. It is diluted with glucose 5% (sodium chloride 0.9% should not be used) to a concentration between 0.2 and 1 mg/mL, and given over 30 to 60 minutes.

Blood counts should be determined frequently during treatment as daunorubicin has a potent effect on bone-marrow function (see also Bone-marrow Depression, p.639). Cardiac function should be monitored at regular intervals to detect signs of cardiotoxicity.

Administration in hepatic impairment. Doses of daunorubicin should be reduced in hepatic impairment. Some licensed product information recommends that patients with serum-bilirubin concentrations of 12 to 30 micrograms/mL should receive 75% of the usual dose, and those with concentrations greater than 30 micrograms/mL should be given 50% of the usual dose.

Administration in renal impairment. Doses of daunorubicin should be reduced in renal impairment. Some licensed product information recommends that patients with serum-creatinine concentrations of 105 to 265 micromoles/litre should receive 75% of the usual dose, and those with concentrations greater than 265 micromoles/litre should be given 50% of the usual dose.

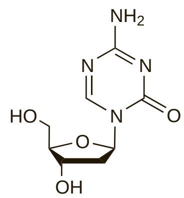
Decitabine (BAN, USAN, rINN)

5-Aza-2′-deoxycytidine; DAC; Decitabina; Décitabine; Decitabinum; NSC-127716. 4-Amino-1-(2-deoxy-β-D-*erythro*-pentofuranosyl)-1,3,5-triazin-2(1*H*)-one.

Децитабин

$C_8H_{12}N_4O_4$ = 228.2.

CAS — 2353-33-5.



Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641. The most common adverse effect of decitabine is myelosuppression, which may be severe and dose-limiting. Fatalities have been reported. Other common adverse effects include fatigue, pyrexia, gastrointestinal disturbances, petechiae, and hyperglycaemia. Cardiorespiratory arrest, increased blood bilirubin, intracranial haemorrhage, abnormal liver function tests, pulmonary oedema, atrial fibrillation, central line infection, or febrile neutropenia may force treatment to be stopped or delayed. Other adverse effects which may be dose-limiting include lethargy, oedema, tachycardia, depression, or pharyngitis.

Pharmacokinetics

On intravenous dosage decitabine exhibits biphasic disposition. Plasma protein binding is negligible. The exact route of metabolism and excretion is not known; one pathway appears to be deamination by cytidine deaminase, which is found principally in the liver, but also in granulocytes, the intestinal epithelium, and whole blood. A terminal elimination half-life of about 0.5 hours has been reported after a 72-hour infusion.

Uses and Administration

Decitabine is an antineoplastic antimetabolite structurally related to cytarabine (p.705). It is reported to cause DNA hypomethylation by the inhibition of DNA methyltransferase, which has the potential to alter gene expression (re-activate silent genes) and limit disease progression and resistance. Decitabine is used in the treatment of myelodysplastic syndromes (p.654). It is given by intravenous infusion over 3 hours, diluted to a final concentration of 0.1 to 1 mg/mL in sodium chloride 0.9%, glucose 5%, or lactated Ringer's injection. The recommended dose is 15 mg/m^2 every 8 hours for 3 days; this 3-day cycle is repeated every 6 weeks, for a minimum of 4 cycles. Treatment may be continued as long as the patient continues to benefit. If haematological recovery from a cycle is incomplete, cycle length may be increased to as much as every 10 weeks and the dose reduced to 11 mg/m^2 every 8 hours upon restarting therapy; this dose may be maintained or increased in subsequent cycles as clinically indicated. Decitabine treatment should also be delayed if serum creatinine is 2 mg per 100 mL or greater, or if total bilirubin is 2 or more times the upper limit of normal, or if the patient has an active or uncontrolled infection.

Decitabine is also under investigation for the treatment of chronic myeloid leukaemia (p.653) and acute myeloid leukaemia (p.652). It is also reported to increase fetal haemoglobin in patients with sickle-cell disease (p.1044).

Denileukin Diftitox (USAN, rINN)

$DAB_{389}IL2$; Denileucina diftitox; Denileukin Difitox (BAN); Dénileukine Diftitox; Denileukinum Diftitoxum; LY-335348.

Денилейкин Дифтитокс

CAS — 173146-27-5.
ATC — L01XX29.
ATC Vet — QL01XX29.

Adverse Effects and Precautions

Denileukin diftitox can cause an acute hypersensitivity reaction within 24 hours of infusion with symptoms reminiscent of a cytokine release syndrome. Anaphylaxis and death have also been reported. A more delayed flu-like syndrome may also occur up to several days after infusion. Vascular leak syndrome, characterised by hypotension, oedema, or hypoalbuminaemia, may also be delayed. Gastrointestinal disturbances, chills, fever, and asthenia are common. Other adverse effects include rash, predisposition to cutaneous infections, and thrombotic events. Visual loss has been reported; although recovery was reported in some patients, in most cases impairment persisted.

Uses and Administration

Denileukin diftitox is a recombinant interleukin fusion toxin comprised of interleukin-2 linked to the A and B fragments of diphtheria toxin. It is given by intravenous infusion for the management of persistent or recurrent cutaneous T-cell lymphoma (see Mycosis Fungoides, p.657), in patients whose malignant cells express the CD25 interleukin-2 receptor. The concentration of denileukin diftitox must be at least 15 micrograms/mL during all steps in the preparation of the solution for infusion. The recommended dose is 9 or 18 micrograms/kg daily, given over 15 minutes or more, for 5 consecutive days every 3 weeks.

Preparations

Proprietary Preparations (details are given in Part 3)
USA: Ontak.

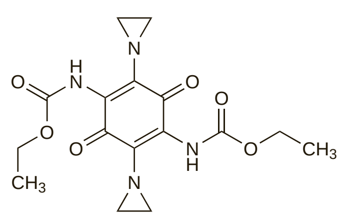
Diaziquone (USAN, rINN)

Aziridinylbenzoquinone; AZQ; CI-904; Diazicuona; Diaziquonum; NSC-182986. Diethyl 2,5-bis-(1-aziridinyl)-3,6-dioxo-1,4-cyclohexadiene-1,4-dicarbamate.

Диазихон

$C_{16}H_{20}N_4O_6$ = 364.4.

CAS — 57998-68-2.



Profile

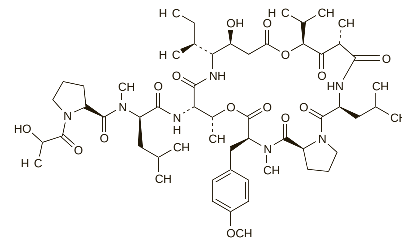
Diaziquone has been investigated as an antineoplastic in the treatment of malignant brain tumours and acute myeloid leukaemia. It is thought to act as an alkylating agent. Adverse effects include bone-marrow suppression, manifesting chiefly as leucopenia and thrombocytopenia, gastrointestinal disturbances, and alopecia. Anaphylactoid reactions have occurred.

Didemnin B

Didemnina B; NSC-325319.

$C_{57}H_{89}N_7O_{15}$ = 1112.4.

CAS — 77327-05-0.



Profile

The didemnins are biologically active peptides extracted from a marine sea squirt of the genus *Trididemnum*. They possess antineoplastic and antiviral properties; didemnin B is reported to be more active than didemnin A or didemnin C and has been investigated as an antineoplastic, although results have not generally been favourable. Nausea and vomiting are dose-limiting; myelosuppression, cardiac and renal toxicity, liver dysfunction, other gastrointestinal disturbances, myalgia, fatigue, and phlebitis may occur. Hypersensitivity reactions, possibly due to the polyoxyl castor oil vehicle, are common.

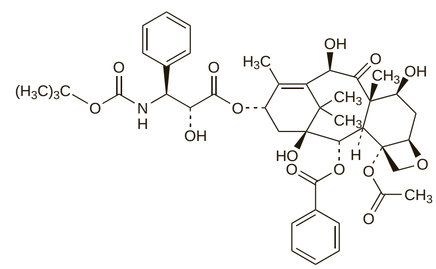
Docetaxel (BAN, USAN, rINN)

Docétaxel; Docetaxelum; Docetaxol; Docetaxolum; Dosetaksel; Dosetaksoli; NSC-628503; RP-56976. (2*R*,3*S*)-*N*-Carboxy-3-phenylisoserine, *N*-*tert*-butyl ester, 13-ester with 5β-20-epoxy-1,2α,4,7β,10β,13α-hexahydroxytax-11-en-9-one 4-acetate 2-benzoate; *tert*-Butyl {(1*S*,2*S*)-2-[(2*S*,5*R*,7*S*,10*R*,13*S*)-4-acetoxy-2-benzoyloxy-1,7,10-trihydroxy-9-oxo-5,20-epoxytax-11-en-13-yloxycarbonyl]-2-hydroxy-1-phenylethyl}carbamate.

Доцетаксел

$C_{43}H_{53}NO_{14}$ = 807.9.

CAS — 114977-28-5 (anhydrous docetaxel); 148408-66-6 (docetaxel trihydrate).
ATC — L01CD02.
ATC Vet — QL01CD02.



Adverse Effects, Treatment, and Precautions

As for Paclitaxel, p.759. Neutropenia, anaemia and skin reactions are common with docetaxel and may be severe. Fluid retention, resulting in oedema, ascites, pleural and pericardial effusion, and weight gain, is also common, and may be cumulative; premedication with a corticosteroid can reduce fluid retention as well as the severity of hypersensitivity reactions. Asthenia and fatigue have also been reported. Rare cases of ototoxicity, hearing impairment or loss have occurred. Very rare cases of acute myeloid leukaemia and myelodysplastic syndrome have been reported with combination chemotherapy regimens containing docetaxel; haematological follow-up may be required.

Docetaxel should not be used in patients hypersensitive to polysorbate 80, which is contained in the formulation. Patients with hepatic impairment show increased sensitivity to toxic effects of docetaxel, and should be given the drug with great care and in reduced doses, if at all.

Effects on the eyes. Excessive tear formation (epiphora) severe enough to interfere with reading and driving has been reported in patients given docetaxel. Canalicular stenosis has been described as the mechanism for this effect, and docetaxel has been measured in tear fluid suggesting that irritation of the ocular surface and fibrosis of the tear drainage ducts may be caused by direct contact with docetaxel.[1] Epiphora and canalicular stenosis are more severe and occur more frequently in patients who receive weekly docetaxel than in those who receive the drug every 3 weeks.[2,3] The mean cumulative dose of docetaxel was found to be higher in those patients who developed stenosis.[2] Management of this adverse effect includes probing and irrigation of the lachrymal ducts and canalicular silicone tubing placement, or surgery followed by tube placement. The condition is generally reversible and tubing can be removed 4 to 6 weeks after stopping docetaxel therapy.[4] The use of topical tobramycin and dexamethasone on a tapering regimen can eliminate the need for silicone intubation or surgery in some patients.[3]

Very rare cases of transient visual disturbances such as flashing lights and scotomata have occurred during docetaxel infusion, and in association with hypersensitivity reactions. These were reversible upon stopping the infusion. For reference to a report of glaucoma possibly related to docetaxel, see Paclitaxel, p.759.

2. Esmaeli B, *et al.* Canalicular stenosis secondary to weekly versus every-3-weeks docetaxel in patients with metastatic breast cancer. *Ophthalmology* 2002; **109:** 1188–91.
3. Esmaeli B, *et al.* Prospective study of incidence and severity of epiphora and canalicular stenosis in patients with metastatic breast cancer receiving docetaxel. *J Clin Oncol* 2006; **24:** 3619–22.
4. Ahmadi MA, Esmaeli B. Surgical treatment of canalicular stenosis in patients receiving docetaxel weekly. *Arch Ophthalmol* 2001; **119:** 1802–4.

Effects on the gastrointestinal tract. Ischaemic colitis has occurred in patients treated with docetaxel.[1-3] Some patients also received vinorelbine, which may have exacerbated this complication.[1,2]

1. Ibrahim NK, *et al.* Colitis associated with docetaxel-based chemotherapy in patients with metastatic breast cancer. *Lancet* 2000; **355:** 281–3.
2. de Matteis A, *et al.* Intestinal side-effects of docetaxel/vinorelbine combination. *Lancet* 2000; **355:** 1098–9.
3. Hussein MAH, *et al.* Docetaxel-related ischemic colitis. *J Clin Oncol* 2005; **23:** 9424–5.

Effects on the heart. For comment on the increased risk of heart failure when docetaxel is given with trastuzumab and after anthracyclines, see under Interactions, below.

Effects on the musculoskeletal system. For reference to cases of taxane-induced arthralgia and myalgia successfully treated with gabapentin, see Paclitaxel, p.759.

Effects on the skin and nails. Palmar-plantar erythrodysesthesia syndrome (p.639) has been reported with the use of docetaxel.[1] For reference to the use of vitamin E to alleviate palmar-plantar erythrodysesthesia syndrome caused by docetaxel and capecitabine, see Chemotherapy-induced Toxicity, under Uses of Vitamin E, p.1994. Cases of radiation recall dermatitis associated with docetaxel have also been reported.[2-4] There is a further report of recall dermatitis at sites previously treated with a laser.[5] A hyperpigmented eruption developed in a patient at the site of docetaxel injection after insufficient venous flushing; no eruption occurred after a second infusion with abundant venous flushing.[6] Licensed drug information states that very rare cases of bullous eruption such as erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis have been reported with docetaxel, but that other factors may have contributed to the development of these reactions.

For further reference to reports of scleroderma and adverse effects on the nails after the use of docetaxel, see Paclitaxel, p.759.

In a multicentre study, patients given docetaxel wore a frozen glove on the right hand, leaving the left hand unprotected to serve as a control. The use of the glove significantly reduced skin and nail toxicity.[7]

7. Scotté F, *et al.* Multicenter study of a frozen glove to prevent docetaxel-induced onycholysis and cutaneous toxicity of the hand. *J Clin Oncol* 2005; **23:** 4424–9.

Hypersensitivity. For a discussion of taxane-induced hypersensitivity, including references to desensitisation protocols, see under Paclitaxel, p.759.

Tumour lysis syndrome. Fatal cases of tumour lysis syndrome (p.639) have been reported after the second-line use of docetaxel.[1,2]

1. Sorscher SM. Tumor lysis syndrome following docetaxel therapy for extensive metastatic prostate cancer. *Cancer Chemother Pharmacol* 2004; **54:** 191–2.
2. Ajzensztejn D, *et al.* Tumor lysis syndrome after treatment with docetaxel for non-small-cell lung cancer. *J Clin Oncol* 2006; **24:** 2389–91.

Interactions

For a general outline of antineoplastic drug interactions, see p.642.

◊ Docetaxel is metabolised by cytochrome P450 isoenzyme CYP3A, and theoretically has the potential to interact with other drugs that are inhibitors or inducers of this enzyme.[1]

1. Royer I, *et al.* Metabolism of docetaxel by human cytochromes P450: interactions with paclitaxel and other antineoplastic drugs. *Cancer Res* 1996; **56:** 58–65.

Antifungals. In a pharmacokinetic study, no consistent effects on docetaxel concentrations were seen with the addition of *ketoconazole*. Significant inter- and intrapatient variability was observed and a potential interaction could not be excluded.[1] In another study in 7 patients, however, the clearance of docetaxel was significantly reduced by 49% when given with ketoconazole.[2]

1. Van Veldhuizen PJ, *et al.* Docetaxel and ketoconazole in advanced hormone-refractory prostate carcinoma: a phase I and pharmacokinetic study. *Cancer* 2003; **98:** 1855–62.
2. Engels FK, *et al.* Effect of cytochrome P450 3A4 inhibition on the pharmacokinetics of docetaxel. *Clin Pharmacol Ther* 2004; **75:** 448–54.

Antineoplastics. The clearance of a dose of docetaxel was markedly reduced[1] when it was given after 4 days of treatment with *topotecan,* rather than on day 1; this resulted in worsened neutropenia.

Sorafenib may increase systemic exposure to docetaxel.

An increased incidence of febrile neutropenia and gastrointestinal disorders, including 2 fatalities, was reported in patients given docetaxel with *doxorubicin,*[2] although others[3] considered this high incidence unrepresentative of usual toxicity rates with this combination.

Heart failure has been reported in patients given docetaxel with other cytotoxic drugs, especially *trastuzumab,* and particularly after anthracycline-containing therapy. UK licensed drug information therefore recommends that patients given docetaxel with trastuzumab should undergo baseline cardiac assessment and cardiac function should be monitored during treatment.

2. Brain EGC, *et al.* Life-threatening sepsis associated with adjuvant doxorubicin plus docetaxel for intermediate-risk breast cancer. *JAMA* 2005; **293:** 2367–71.
3. Martin M, *et al.* Life-threatening complications from doxorubicin-docetaxel chemotherapy for breast cancer. *JAMA* 2005; **294:** 2166.

Pharmacokinetics

On intravenous dosage docetaxel is rapidly distributed to body tissues. Docetaxel is more than 95% bound to plasma proteins. It is extensively metabolised via hepatic cytochrome P450 isoenzyme CYP3A4 and excreted chiefly in the faeces as metabolites. Only about 6% of a dose is excreted in urine. The terminal elimination half-life is about 11 hours. Clearance is reduced in hepatic impairment.

Uses and Administration

Docetaxel is a semisynthetic taxane similar to paclitaxel (see p.760). It is manufactured from a taxane precursor derived from the needles of the European yew tree *Taxus baccata*. Docetaxel is used for locally advanced or metastatic breast cancer (p.661). It may be used as first-line treatment with doxorubicin; in the treatment of refractory disease, it is used alone or with capecitabine. In the treatment of metastatic breast cancer that overexpresses HER2 (human epidermal growth receptor 2), docetaxel may be used with trastuzumab as initial therapy. For adjuvant treatment of operable, node-positive breast cancer, docetaxel is given with doxorubicin and cyclophosphamide. Docetaxel is also indicated for the treatment of locally advanced or metastatic non-small cell lung cancer (p.668), either with cisplatin for initial treatment of unresectable disease, or after failure of previous platinum-based chemotherapy. It is used with prednisone or prednisolone in hormone-refractory metastatic prostate cancer (p.671). Docetaxel is given with cisplatin and fluorouracil in the first-line treatment of patients with metastatic gastric adenocarcinoma, including adenocarcinoma of the gastro-oesophageal junction (p.664); it is also used in this combination for the induction treatment of patients with locally advanced squamous cell carcinoma of the head and neck (p.666).

Docetaxel is given by intravenous infusion in glucose 5% or sodium chloride 0.9% at a concentration not exceeding 0.74 mg/mL. Infusion is normally over 1 hour. Premedication with an oral corticosteroid, such as dexamethasone 16 mg daily, for 3 days starting 1 day before docetaxel is recommended with many regimens.

The licensed dose for docetaxel as a single agent in the treatment of **breast cancer** after failure of previous chemotherapy is 60 to 100 mg/m^2 once every 3 weeks. A dose of 75 mg/m^2 once every 3 weeks is given in combination therapy with doxorubicin, or capecitabine, or when used as adjuvant therapy with doxorubicin and cyclophosphamide. When used with trastuzumab, docetaxel is given at a dose of 100 mg/m^2 once every 3 weeks.

The dose for **non-small cell lung cancer** is 75 mg/m^2 once every 3 weeks, for both first-line combination therapy and monotherapy after failure of previous chemotherapy.

For **gastric adenocarcinoma** docetaxel 75 mg/m^2 is given before cisplatin and fluorouracil; treatment is repeated every 3 weeks.

In the induction treatment of **head and neck cancer**, the recommended dose of docetaxel is 75 mg/m^2, given before cisplatin and fluorouracil; treatment is given every 3 weeks for 3 cycles, followed by chemoradiotherapy, or for 4 cycles when followed by radiotherapy alone.

For **prostate cancer**, the dose of docetaxel is 75 mg/m^2 once every 3 weeks, with prednisone or prednisolone 5 mg orally twice daily given continuously. The use of prednisone or prednisolone reduces the need for a premedication corticosteroid; dexamethasone 8 mg may be given at 12 hours, 3 hours, and 1 hour before docetaxel.

Regular blood counts are required, and dosage in subsequent courses should be reduced in patients who experience severe or febrile neutropenia (see also Bone-marrow Depression, p.639), or severe cutaneous reactions or peripheral neuropathy. The dose of docetaxel should be reduced in hepatic impairment, see below.

Administration. Docetaxel has been investigated as a low-dose weekly infusion, in patient groups such as the elderly, those with poor performance status, or refractory disease.[1-6] Weekly doses of 30 to 40 mg/m^2 are considered to be of similar efficacy to the standard three-weekly dosage regimen.[7] A pharmacokinetic study in 20 elderly patients suggested that a suitable starting dose might be 26 mg/m^2, increased provided there was no toxicity.[8]

Administration in hepatic impairment. UK licensed product information recommends that doses of docetaxel monotherapy should be reduced from 100 mg/m^2 to 75 mg/m^2 in mild to moderate hepatic impairment, defined as alanine aminotransferase (ALT/SGPT) and/or aspartate aminotransferase (AST/SGOT) more than 1.5 times the upper limit of normal (ULN), and alkaline phosphatase more than 2.5 times the ULN. Hepatic function should be monitored; use should be avoided if possible in severe hepatic impairment. US licensed information advises against the use of docetaxel in patients with bilirubin above ULN, or in those with mild to moderate hepatic impairment (defined as for the UK, above).

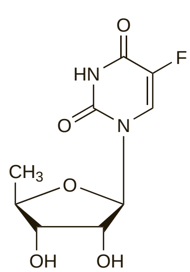
Doxifluridine *(rINN)*

5′-Deoxy-5-fluorouridine; 5-DFUR; Doxifluridina; Doxifluridinum; FUDR; Ro-21-9738.

Доксифлуридин

$C_9H_{11}FN_2O_5$ = 246.2.
CAS — 3094-09-5.



Pharmacopoeias. In *Jpn.*

Profile

Doxifluridine is an antineoplastic that probably acts through its conversion in the body to fluorouracil (p.722). It is given orally in the management of malignant neoplasms of the breast (p.661) and gastrointestinal tract (p.664), and of other solid tumours, in doses of 0.8 to 1.2 g daily in divided doses. It has also been given by the intravenous route.

Pharmacokinetics. Doxifluridine is metabolised to fluorouracil and 5,6-dihydrofluorouracil. It is orally active with a bioavailability of 34 to 47%.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Doxorubicin Hydrochloride). The hydrochloride of a substance isolated from certain strains of *Streptomyces coeruleorubidus* or *S. peucetius* or obtained by any other means. It contains between 98 and 102% of the hydrochloride, calculated on the anhydrous substance. An orange-red, hygroscopic, crystalline powder. Soluble in water; slightly soluble in methyl alcohol. A 0.5% solution in water has a pH of 4.0 to 5.5. Store in airtight containers.

USP 31 (Doxorubicin Hydrochloride). A red-orange, hygroscopic, crystalline or amorphous powder. It contains not less than 98% and not more than 102% of $C_{27}H_{29}NO_{11}$,HCl, calculated on the anhydrous, solvent-free basis. Soluble in water, in sodium chloride 0.9%, and in methyl alcohol; practically insoluble in chloroform, in ether, and in other organic solvents. A 0.5% solution in water has a pH of 4.0 to 5.5. Store in airtight containers. It may exist in an amorphous form, which should be stored at –25° to –10°.

Incompatibility. Admixture of doxorubicin hydrochloride with cefalotin sodium, dexamethasone, diazepam, or hydrocortisone sodium succinate is reported to result in immediate precipitation;[1] similarly precipitation has occurred when doxorubicin hydrochloride was mixed with furosemide or heparin sodium.[2] A mixture of fluorouracil or aminophylline with doxorubicin hydrochloride is reported to darken in colour from red to purple, indicating degradation of doxorubicin.[1] For mention of the compatibility of doxorubicin with paclitaxel, see p.759.

Liposomal doxorubicin differs in its incompatibilities from conventional formulations: whereas the latter are reportedly incompatible with allopurinol, cefepime, and ganciclovir, there was no visual evidence of this with the liposomal formulation. However, it was incompatible with a number of drug solutions including amphotericin B, docetaxel, gallium nitrate, hydroxyzine hydrochloride, metoclopramide hydrochloride, miconazole, mitoxantrone hydrochloride, morphine sulfate and some other opioids, paclitaxel, sodium bicarbonate, and some antibacterials.[3]

Stability. Although sensitive to light at low concentrations, doxorubicin is not subject to significant photodegradation at clinical concentrations and special precautions to protect solutions from light during administration do not appear to be necessary.[1,2] Solutions in sodium chloride solution 0.9% were reported[3] to be stable for 24 days when stored in PVC minibags at 25° and for even longer if stored in minibags or polypropylene syringes at 4°. Stability in solution seems to be partly related to pH, with doxorubicin becoming more stable[3-5] at acid pH. A fall in pH of the solution also significantly decreases the loss of doxorubicin by adsorption and precipitation onto the surface of a positively-charged in-line filter.[6]

Some liposomal doxorubicin formulations should be diluted only with glucose 5%. If not used immediately, they may be stored for 24 hours at 2° to 8°.

Adverse Effects and Treatment

For general discussions see Antineoplastics, p.635 and p.639.

Doxorubicin and other anthracyclines cause pronounced bone-marrow depression, which may be dose-limiting. White cell count reaches a nadir 10 to 15 days after a dose and usually recovers by about 21 days.

The anthracyclines may produce cardiac toxicity, both as an acute, usually transient disturbance of cardiac function marked by ECG abnormalities and, sometimes, arrhythmias; and as a delayed, sometimes fatal, irreversible congestive heart failure, which may occur suddenly. Severe cardiotoxicity is more likely in adults receiving total cumulative doses of doxorubicin greater than 450 to 550 mg/m^2, and may occur months or even years after use.

Gastrointestinal disturbances include moderate or sometimes severe nausea and vomiting; stomatitis and oesophagitis may progress to ulceration. More rarely, facial flushing, conjunctivitis, and lachrymation may occur. Alopecia occurs in the majority of patients. The urine may be coloured red. Occasional hypersensitivity reactions may occur. Hyperuricaemia may occur due to tumour lysis syndrome.

Doxorubicin and other anthracyclines are very irritant and thrombophlebitis and streaking of the skin over the vein used for injection has been reported; extravasation is serious and may produce extensive local necrosis and ulceration. Intravesical instillation can cause bladder and urethral irritation, haematuria, and haemorrhagic cystitis.

Combination therapy including doxorubicin has rarely been associated with secondary acute myeloid leukaemia (see also Carcinogenicity, p.635).

Formulations of liposomal doxorubicin may be associated with a reduced potential for local tissue necrosis, and possibly a reduced incidence of cardiotoxicity, although current clinical experience is limited, and such toxicity remains a possibility. Conversely, palmar-plantar erythrodysesthesia (p.639) appears to be more common, and may be dose-limiting. In addition, an acute pseudo-allergic reaction may be seen on initial infusion, but generally resolves on slowing or temporarily stopping the infusion.

Effects on the heart. Cardiotoxicity has been a major factor in limiting the use of the anthracyclines, doxorubicin and daunorubicin.[1-5] Toxicity is essentially of 2 kinds: acute, usually reversible ECG changes, including a wide range of arrhythmias, and a delayed, usually irreversible dose-related cardiomyopathy, resulting in congestive heart failure.[3-5] The latter may be further subdivided into chronic effects, occurring up to about a year afterwards, and late-onset toxicity occurring years after treatment.[4] Delayed toxicity may be fatal in as many as 60% of patients who develop it.[2]

The single most important determinant of cardiac toxicity appears to be the *cumulative dose*, with the risk of toxicity becoming ever greater at cumulative doxorubicin doses of 550 mg/m^2 or more,[2] and daunorubicin doses of 600 mg/m^2 or more.[1] However, patients vary widely in sensitivity,[4] and these values represent relatively arbitrary choices on a continuum of risk: there is no single safe dose.[2] Even at doses that produce no symptoms, subclinical myocardial damage may occur, and in children this may result in diminished cardiac reserve and heart disease in later life.[3,6,7] The *dosage schedule* also appears to be important; relatively high single doses on an infrequent schedule (presumably resulting in higher peak concentrations) appear to be more cardiotoxic than lower, weekly doses, or continuous infusion.[2,3,5,8-10] Cardiotoxicity is also reported to be more likely in *children and elderly* patients, and in those who have received prior *radiotherapy* to the chest.[1-5] There is reason to believe that previous *cardiovascular disease* may also increase the risk,[2-4] although such patients are commonly excluded from studies of anthracycline therapy.[2] *Females* may be at greater risk than males.[11] Use with cyclophosphamide, trastuzumab, or *other antineoplastics* with cardiotoxic potential may increase the likelihood of cardiomyopathy.

The late development of cardiac toxicity is of some concern: although in one study the mean time to development of symptoms was 33 days after a dose, with a range of 0 to 231 days,[2] several reports have indicated that late cardiac failure may occur up to 18 years after anthracycline therapy.[4,12,13]

Prevention. Given that doxorubicin-induced cardiac failure has been reported to occur in between 0.4 and 9% of all recipients, and that the fatality rate is high, much effort has gone into ways of predicting and preventing anthracycline-induced cardiotoxicity. Although ECG changes are commonly monitored, most of the changes are not predictive of cardiomyopathy and severe cardiac toxicity can occur without ECG changes. However, a persistent reduction in the voltage of the QRS wave is generally indicative of the need to perform further tests. Non-invasive cardiac monitoring, by means of echocardiography or radionuclide angiography, is useful in predicting the development of cardiomyopathy, but may give normal results until damage is quite advanced; sensitivity may be improved with exercise stress tests.[3-5] Endomyocardial biopsy is the most sensitive indicator of cardiomyopathy, but it is invasive and not widely available. The Childrens Cancer Study Group[14] has issued guidelines for monitoring using ECG, echocardiography, and radionuclide angiocardiography in patients receiving anthracyclines. The role of such techniques in predicting late-onset cardiotoxicity remains to be clarified.[4] There is some preliminary evidence to suggest that concentrations of cardiac troponins and natriuretic peptides could be used as predictive markers of myocardial damage.[15]

Dexrazoxane (p.1443) has shown some protective effect against the cardiotoxicity of doxorubicin and other anthracyclines, and is used to reduce cardiomyopathy in women receiving doxorubicin for metastatic breast cancer.

Alteration of the dosage schedule to weekly rather than three-weekly dosage, or the use of continuous infusion, has also been advocated as a way of reducing doxorubicin cardiotoxicity,[8-10] as has giving anthracyclines formulated in liposomes.[4]

Several anthracycline derivatives have been developed with the aim of reducing the inherent cardiotoxicity of this class of compounds, including aclarubicin (p.676), epirubicin (p.716), and mitoxantrone (p.754). However, although this strategy has met with some success, almost all these compounds exhibit some degree of cardiotoxicity.

Treatment. The result of treatment for such cardiotoxicity has generally been poor. Options have included digoxin, diuretics, low-salt diet, and bed rest. However, beta blockers may be useful, and results in patients with epirubicin-induced cardiotoxicity[16] have indicated that treatment with an ACE inhibitor can improve cardiac function and survival. Study is underway to determine whether ACE inhibitors can also prevent the initial toxicity if given immediately after an anthracycline.[17] Heart transplantation has been used.[5]

Effects on the liver. Hepatitis and non-specific hepatocellular damage has been reported in patients receiving doxorubicin as part of combination therapy.[1] A characteristic hepatotoxicity can also be produced by the combination of radiotherapy with doxorubicin.[2]

Effects on the skin and nails. Hyperpigmentation has occurred in patients given daunorubicin, doxorubicin, or idarubicin.[1-6] Reports described pigmentation of the skin and transverse hyperpigmented bands of the nails. Effects on the skin resolved over several weeks, and bands on the nails moved with normal nail growth. Dark-skinned patients appear to be more susceptible to this adverse effect. Biopsy has found an increase in melanin granules in the affected tissues. An unusual blue-grey pigmentation of the face was reported in a patient given doxorubicin.[7]

Palmar-plantar erythrodysesthesia syndrome. Discussion of palmar-plantar erythrodysesthesia syndrome (p.639) associated with the use of liposomal doxorubicin, and recommendations for its management.[1] The most effective way of preventing the syndrome was to maintain doses at not more than 10 mg/m^2 weekly (typically as a single infusion of 40 mg/m^2 every 4 weeks). At such doses, the syndrome, if it occurred was typically mild and easily managed. Dose-intensity modification was also thought likely to be beneficial in managing the syndrome if it developed, although evidence to support this was lacking.

Precautions

For a general discussion see Antineoplastics, p.641.

Doxorubicin and other anthracyclines are generally contra-indicated in patients with heart disease. The total cumulative dose should be limited, and cardiac function should be monitored during treatment (see Effects on the Heart, above). Blood counts should be monitored and doses should not be repeated while there is bone-marrow depression or ulceration of the mouth. Doxorubicin should be given with great care in reduced doses to patients with hepatic impairment; dosage reduction may also be necessary in children and the elderly. Extravasation results in severe tissue damage and doxorubicin and other anthracyclines should not be given by intramuscular or subcutaneous injection. The adverse effects of irradiation may be enhanced by doxorubicin and skin reactions previously induced by radiotherapy may recur; the maximum cumulative dose should be reduced to no more than 400 mg/m^2 in patients who have received radiotherapy to the chest or heart. Different liposomal formulations may not be interchangeable with conventional formulations, or with each other.

Breast feeding. Doxorubicin and its metabolites have been detected in breast milk.[1] The American Academy of Pediatrics considers[2] that doxorubicin is concentrated in breast milk, that it may possibly cause immune suppression in the infant, has unknown effects on growth, and an association with carcinogenesis.

1. Egan PC, *et al.* Doxorubicin and cisplatin excretion into human milk. *Cancer Treat Rep* 1985; **69:** 1387–9.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 29/06/04)

Handling and disposal. Doxorubicin hydrochloride is irritant; avoid contact with skin and mucous membranes.

A method for the destruction of doxorubicin or daunorubicin *wastes* using sulfuric acid and potassium permanganate.[1] Residues produced by degradation of daunorubicin by this method showed no mutagenicity *in vitro*; some mutagenicity was seen with high concentrations of residues from doxorubicin.

Urine and faeces produced for up to 7 days after a dose of doxorubicin should be handled wearing protective clothing.[2]

2. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; **235:** 289–91.

Pregnancy. Although doxorubicin has been reported to be undetectable in amniotic fluid[1,2] it has been found in fetal tissue (liver, kidney, and lungs) at concentrations several times those in maternal plasma,[2] indicating that it does cross the placenta. The effect of anthracyclines on the outcome of 160 pregnancies has been analysed.[3] Most women had received combination chemotherapy that included doxorubicin or daunorubicin, for haematological malignancies or breast cancer. Most outcomes (73%) were normal. There were 5 malformations, most often associated with regimens that also included antimetabolites or alkylating agents; the malformations were highly variable. Fetal toxicity was associated with chemotherapy use for solid tumours during the first trimester, and the risk of severe fetal toxicity was significantly increased with doxorubicin doses above 70 mg/m^2 per cycle. Fetal cardiac toxicity occurred in 2 cases and was associated with anthracycline use during the second and third trimesters. It has been suggested that the use of epirubicin may reduce the risk of fetal myocardiopathy. Fetal death was more frequent in women with acute leukaemia; it was associated with disease progression and the authors recommended that chemotherapy should not be postponed.

2. D'Incalci M, *et al.* Transplacental passage of doxorubicin. *Lancet* 1983; **i:** 75.
3. Germann N, *et al.* Anthracyclines during pregnancy: embryo–fetal outcome in 160 patients. *Ann Oncol* 2004; **15:** 146–50.

Interactions

For a general outline of antineoplastic drug interactions, see p.642. The cumulative dose of doxorubicin should be reduced in patients who have received other cardiotoxic drugs such as daunorubicin or cyclophosphamide. Doxorubicin is reported to inhibit the intracellular activation of stavudine and hence its antiviral effect.

Antibacterials. Hypersensitivity reactions to doxorubicin or daunorubicin have been reported in 2 patients with recent exposure to *clindamycin*, one of whom had exhibited hypersensitivity to that antibiotic.[1] The possibility of cross-sensitivity between anthracyclines and clindamycin should be considered.

1. Arena FP, Sherlock S. Doxorubicin hypersensitivity and clindamycin. *Ann Intern Med* 1990; **112:** 150.

Antineoplastics. Giving doxorubicin with or after drugs, such as *streptozocin*[1] or *methotrexate*,[2] that can impair hepatic function, has resulted in increased doxorubicin toxicity, possibly due to reduced hepatic clearance. A high incidence of cardiotoxicity (manifest as congestive heart failure) has been reported in patients given doxorubicin with *paclitaxel* (which also has cardiotoxic effects).[3] Any interaction may be schedule dependent.[4] Similarly an increased incidence of cardiotoxicity has been seen when *trastuzumab* was given with or after anthracyclines (see Effects on the Heart under Trastuzumab, p.782).

Valspodar inhibits P-glycoprotein, and a pharmacokinetic study[5] found that it decreased clearance of doxorubicin and prolonged the terminal half-life, increasing exposure to doxorubicin and myelosuppressive effects. The authors suggested that the dose of doxorubicin might need to be reduced by about 60%.

Sorafenib may increase systemic exposure to doxorubicin.

For a suggestion that doxorubicin might enhance the hepatotoxicity of *mercaptopurine*, see under Daunorubicin Hydrochloride, p.709.

For a report of an increased incidence of febrile neutropenia and gastrointestinal complications when doxorubicin is used with *docetaxel*, see Antineoplastics, under Docetaxel, p.711.

In a pharmacokinetic study, both paclitaxel and docetaxel increased exposure to liposomal doxorubicin, although the effect was less pronounced with docetaxel.[6]

Immunosuppressants. Increased plasma-doxorubicin concentrations and myelotoxicity have occurred when *ciclosporin* was used to modulate tumour resistance.[1] Severe neurological toxicity occurred in another patient given doxorubicin after long-term ciclosporin therapy.[2] It has been suggested that the use of ciclosporin or its analogues (see Antineoplastics, above for the effect of valspodar) to modulate doxorubicin resistance should be undertaken with caution.[3]

3. Beck WT, Kuttesch JF. Neurological symptoms associated with cyclosporin plus doxorubicin. *Lancet* 1992; **340:** 496.

Thalidomide. In a comparison of two treatment regimens for multiple myeloma (thalidomide, dexamethasone, cisplatin, cyclophosphamide, and etoposide, with or without doxorubicin), there was an increased risk of deep-vein thrombosis in those patients who received the combination that included doxorubicin.[1] The authors cited a previous study[2] in which the addition of thalidomide to an antineoplastic regimen increased the risk of deep-vein thrombosis, and concluded that patients with multiple myeloma treated with the combination of doxorubicin and thalidomide are at increased risk.

2. Zangari M, *et al.* Increased risk of deep-vein thrombosis in patients with multiple myeloma receiving thalidomide and chemotherapy. *Blood* 2001; **98:** 1614–15.

Pharmacokinetics

After intravenous injection, doxorubicin is rapidly cleared from the blood, and distributed into tissues including lungs, liver, heart, spleen, and kidneys. It undergoes rapid metabolism in the liver to metabolites including the active metabolite doxorubicinol (adriamycinol). About 40 to 50% of a dose is stated to be excreted in bile within 7 days, of which about half is as unchanged drug. Only about 5% of a dose is excreted in urine within 5 days. It does not cross the blood-brain barrier but may cross the placenta and is distributed into breast milk. The disappearance of doxorubicin from the blood is triphasic: mean half-lives are 12 minutes, 3.3 hours and about 30 hours.

The pharmacokinetics of liposomal formulations are somewhat different from the conventional drug. The use of macrogols in the surface layer of the liposomes (pegylation) reduces removal of liposomes by macrophages. This results in prolonged circulation in the plasma, with relatively little tissue distribution, but tumour neovasculature is reported to permit penetration of liposomes into tumour tissue. Pharmacokinetics are reported to be biphasic with mean half-lives of 5 hours and 55 to 75 hours respectively. A non-pegylated liposomal formulation also exists and is reported to produce higher peak plasma concentrations of total doxorubicin than conventional formulations, but lower free (not liposome-encapsulated) concentrations. Clearance is reduced, and peak plasma concentrations of doxorubicinol delayed.

Uses and Administration

Doxorubicin is an anthracycline antineoplastic antibiotic. It is thought to have multiple modes of action including intercalation of DNA leading to an inhibition of DNA and RNA synthesis, inhibition of topoisomerase II, free radical formation, and alterations in cell membranes. Doxorubicin is a cell-cycle non-specific agent. It also has antibacterial and immunosuppressant properties.

Doxorubicin is effective against a wide range of tumours as indicated by the cross-references given below. Doxorubicin is used, often with other antineoplastics, in the treatment of Hodgkin's disease, non-Hodgkin's lymphomas, acute leukaemias, bone and soft-tissue sarcomas, neuroblastoma, Wilms' tumour, and malignant neoplasms of the bladder, breast, lung, ovary, and stomach. It has also been used in other tumours. Liposomal doxorubicin is used in the management of Kaposi's sarcoma in patients with AIDS, for the treatment of metastatic breast and ovarian cancers, and with bortezomib for the treatment of multiple myeloma.

Doxorubicin hydrochloride is given by intravenous injection into a fast-running infusion of sodium chloride 0.9% or glucose 5% over 3 minutes or more. When used as a single agent, the dose is 60 to 75 mg/m^2, or 1.2 to 2.4 mg/kg, once every 3 weeks. Alternatively, doses of 20 to 25 mg/m^2 have been given daily for 3 days every 3 weeks, although dividing the dose in this way may increase the incidence of mucositis. A regimen of 20 mg/m^2 as a single weekly dose may be used, and is reported to be associated with a lower incidence of cardiotoxicity.

Doses may need to be reduced if doxorubicin is given with other antineoplastics: a dose of 30 to 60 mg/m^2 every 3 weeks has been suggested. Doses should also be reduced in patients with liver dysfunction (see below). The maximum total dose should not exceed 450 to 550 mg/m^2; in patients who have received radiotherapy to the chest, or other cardiotoxic drugs, it may be advisable to further limit the total dose.

In the management of AIDS-related Kaposi's sarcoma *pegylated liposomal* doxorubicin hydrochloride is given in an intravenous dose of 20 mg/m^2 infused over 30 minutes once every 2 to 3 weeks. For the treatment of breast and ovarian cancers, the suggested dose of this liposomal formulation is 50 mg/m^2 infused over 1 hour once every 4 weeks. In the treatment of multiple myeloma, liposomal doxorubicin hydrochloride is given at a dose of 30 mg/m^2 on day 4 of the bortezomib regimen (see p.689); it is given as an infusion over 1 hour immediately after the bortezomib infusion. In all these conditions, treatment should be continued for as long as the patient responds satisfactorily and tolerates treatment. The pegylated liposomal formulation should be diluted only with glucose 5%; generally, doses below 90 mg are diluted in 250 mL, and doses over 90 mg are diluted in 500 mL.

A *non-pegylated liposomal* formulation is also available and contains a doxorubicin citrate complex prepared with the aid of doxorubicin hydrochloride. It is given in the treatment of metastatic breast cancer in doses equivalent to doxorubicin hydrochloride 60 to 75 mg/m^2 every 3 weeks, with cyclophosphamide 600 mg/m^2. Doses are given by intravenous infusion over 1 hour, diluted in sodium chloride 0.9% or glucose 5% to a final concentration of 0.4 to 1.2 mg/mL doxorubicin.

Blood counts should be made routinely during treatment with doxorubicin (see also Bone-marrow Depression, p.639) and cardiac function should be monitored at regular intervals for early signs of cardiotoxicity.

Doxorubicin hydrochloride has also been instilled into the bladder in the local treatment of malignant neoplasms. For this purpose 50 mL of a 1 mg/mL solution may be instilled into the bladder for about one hour; treatment may be given at weekly to monthly intervals. Doxorubicin has also been given intra-arterially.

Various novel formulations of doxorubicin have been investigated. Doxorubicin with carbon/iron carrier particles (MTC-DOX) is a magnetically targeted treatment, using an external magnet to keep the drug at the tumour site, that has been investigated for hepatocellular carcinoma. A polymer of doxorubicin and polyisohexylcyanoacrylate in nanoparticle form is under investigation for the treatment of hepatocellular carcinoma. Doxorubicin-eluting beads, for injection directly into the brain, are under investigation for the treatment of glioma.

Administration in hepatic impairment. Doses of doxorubicin should be adjusted as follows in patients with liver dysfunction:

- serum-bilirubin concentrations of 12 to 30 micrograms/mL: half the normal dose
- serum-bilirubin greater than 30 micrograms/mL: quarter of the usual dose.

Slightly different schedules may apply to liposomal products but may vary between preparations.

Amyloidosis. For mention of the use of doxorubicin in patients with amyloidosis (and of the increased risk this may carry in cardiac amyloidosis) see p.743.

Malignant neoplasms. Doxorubicin plays a major role in combination regimens for chemotherapy of solid malignancies; it is often employed for tumours of the breast and lung (see p.661 and p.668) and for Wilms' tumour and neuroblastoma or retinoblastoma in children (see p.667, p.674, and p.675) and has been used for malignancies of the bladder (p.659); for various gynaecological cancers including those of the endometrium, and ovary (see p.663, and p.670); for cancer of the liver, stomach, and pancreas (p.667, p.664, p.671); and for neoplasms of prostate, and thymus (p.671 and p.674). It is also used in the treatment of sarcomas of bone and soft-tissue (see p.675 and p.676) and liposomal doxorubicin is used in patients with Kaposi's sarcoma (see p.675).

In addition, doxorubicin is a component of the ABVD regimen used to treat Hodgkin's disease (see p.655) and is part of the CHOP regimen used for non-Hodgkin's lymphoma (p.656). Doxorubicin is also used in Burkitt's lymphoma (p.657), mycosis fungoides (p.657), and the lymphomas associated with AIDS (see p.657). It has been employed in acute lymphoblastic leukaemia (p.651), in chronic lymphocytic leukaemia as part of the CHOP regimen (though with uncertain benefit—see p.653), and in multiple myeloma (p.658).

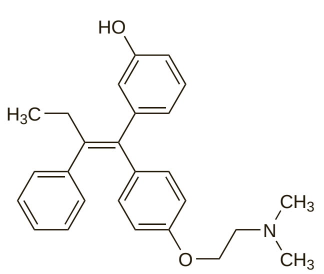
Droloxifene *(USAN, rINN)* ⊗

Droloxifène; Droloxifeno; Droloxifenum; 3-Hydroxytamoxifen; K-21060E. (*E*)-α-{*p*-[2-(Dimethylamino)ethoxy]phenyl}-α′-ethyl-3-stilbenol.

Дролоксифен

$C_{26}H_{29}NO_2$ = 387.5.
CAS — 82413-20-5.



Profile

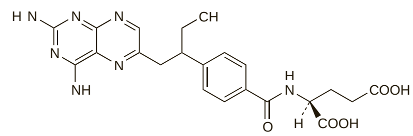
Droloxifene is a selective oestrogen receptor modulator related to tamoxifen (p.772) and with similar general properties. It has been investigated in the hormonal treatment and prophylaxis of breast cancer and is under study for osteoporosis.

Edatrexate *(USAN, rINN)*

CGP-30694; Édatrexate; Edatrexato; Edatrexatum. *N*-(*p*-{1-[(2,4-Diamino-6-pteridinyl)methyl]propyl}benzoyl)-L-glutamic acid.

Эдатрексат

$C_{22}H_{25}N_7O_5$ = 467.5.
CAS — 80576-83-6.



Profile

Edatrexate is an analogue of methotrexate (p.745) and has similar general properties. It has been investigated as an antineoplastic in the treatment of various malignant neoplasms. Mucositis may be dose limiting.

Edrecolomab *(USAN, rINN)*

17-1A Antibody; C1; Édrécolomab; Edrecolomabum; Monoclonal Antibody 17-1A. Immunoglobulin G2a (mouse monoclonal 17-1A γ-chain anti-human colon cancer tumor-associated antigen), disulfide with mouse monoclonal 17-1A light chain, dimer.

Эдреколомаб

CAS — 156586-89-9.
ATC — L01XC01.
ATC Vet — QL01XC01.

Profile

Edrecolomab is a monoclonal antibody of murine origin directed at epithelial cell surface glycoproteins that has been used as adjuvant therapy after surgery in patients with colorectal cancer (p.665), although reports of improved survival do not seem to have been borne out. It has been given by intravenous infusion over 2 hours, in an initial dose of 500 mg, followed by 4 further doses of 100 mg at monthly intervals. The drug is of murine origin and most patients develop antibodies after use. Hypersensitivity reactions, including anaphylactic reactions, have occurred.

It has also been tried for other malignant neoplasms including pancreatic cancer and advanced breast cancer.

CAS — 170787-99-2.
ATC — L01XD06.
ATC Vet — QL01XD06.

Profile

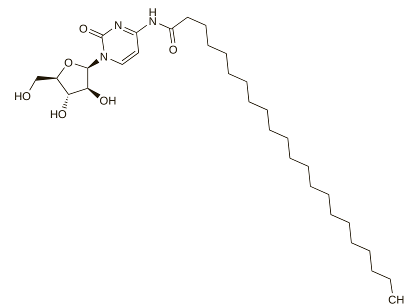
Efaproxiral is an allosteric modifier of haemoglobin that enhances the diffusion of oxygen to hypoxic tumour tissue, making it more sensitive to radiotherapy. It has been investigated in the treatment of brain metastases from solid tumours.

Enocitabine *(rINN)*

Behenoyl Cytarabine; Behenoylcytosine Arabinoside; BH-AC; Enocitabina; Énocitabine; Enocitabinum; NSC-239336. *N*-(1-β-D-Arabinofuranosyl-1,2-dihydro-2-oxo-4-pyrimidinyl)docosanamide.

Эноцитабин

$C_{31}H_{55}N_3O_6$ = 565.8.
CAS — 55726-47-1.



Profile

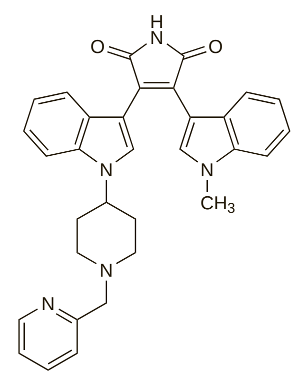
Enocitabine is an antineoplastic that is converted in the body to cytarabine (p.705). It has been used similarly in the treatment of acute leukaemias.

Enzastaurin Hydrochloride *(USAN, rINNM)*

Enzastaurine, Chlorhydrate d'; Enzastaurini Hydrochloridum; Hidrocloruro de enzastaurina; LY-317615. 3-(1-Methyl-1*H*-indol-3-yl)-4-{1-[1-(pyridin-2-ylmethyl)piperidin-4-yl]-1*H*-indol-3-yl}-1*H*pyrrole-2,5-dione hydrochloride.

Энзастаурина Гидрохлорид

$C_{32}H_{29}N_5O_2$,HCl = 552.1.
CAS — 359017-79-1.



(enzastaurin)

Profile

Enzastaurin hydrochloride is a protein kinase C inhibitor that is under investigation for the treatment of gliomas and non-Hodgkin's lymphoma.

Epirubicin Hydrochloride

(BANM, USAN, rINNM)

4′-Epiadriamycin Hydrochloride; 4′-Epidoxorubicin Hydrochloride; Épirubicine, chlorhydrate d′; Epirubicin-hidroklorid; Epirubicin-hydrochlorid; Epirubicinhydroklorid; Epirubicini hydrochloridum; Epirubicino hidrochloridas; Epirubisiinihydrokloridi; Epirubisin Hidroklorür; Hidrocloruro de epirubicina; IMI-28; Pidorubicin Hydrochloride. (8*S*,10*S*)-10-(3-Amino-2,3,6-trideoxy-α-L-*arabino*-hexopyranosyloxy)-8-glycolloyl-7,8,9,10-tetrahydro-6,8,11-trihydroxy-1-methoxynaphthacene-5,12-dione hydrochloride.

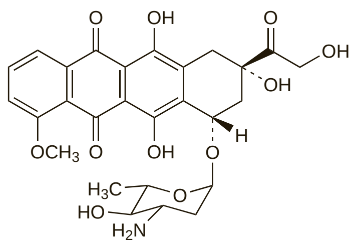
Эпирубицина Гидрохлорид

$C_{27}H_{29}NO_{11},HCl = 580.0.$

CAS — 56420-45-2 (epirubicin); 56390-09-1 (epirubicin hydrochloride).

ATC — L01DB03.

ATC Vet — QL01DB03.



(epirubicin)

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*

Ph. Eur. 6.2 (Epirubicin Hydrochloride). A substance obtained by chemical transformation of a substance produced by certain strains of *Streptomyces peucetius*. An orange-red powder. Soluble in water and in methyl alcohol; slightly soluble in dehydrated alcohol; practically insoluble in acetone. A 0.5% solution in water has a pH of 4.0 to 5.5. Store at 2° to 8° in airtight containers. Protect from light.

Incompatibility. Licensed product information states that epirubicin hydrochloride is incompatible with heparin or fluorouracil, resulting in precipitation, and that it is hydrolysed in alkaline solutions.

Stability. Epirubicin was not subject to significant photodegradation at clinical concentrations,[1,2] and special precautions to protect solutions from light during use do not appear to be necessary. However, photodegradation may be significant at lower concentrations (below 500 micrograms/mL).[1]

1. Wood MJ, *et al.* Photodegradation of doxorubicin, daunorubicin and epirubicin measured by high-performance liquid chromatography. *J Clin Pharm Ther* 1990; **15:** 291–300.
2. Pujol M, *et al.* Stability study of epirubicin in NaCl 0.9% injection. *Ann Pharmacother* 1997; **31:** 992–5.

Adverse Effects, Treatment, and Precautions

As for Doxorubicin, p.712. Cardiotoxicity and myelotoxicity may be less than with doxorubicin. Cardiotoxicity is more likely when the cumulative dose exceeds 0.9 to 1 g/m^2.

Effects on the heart. For further discussion of the cardiotoxicity of anthracyclines, see under Adverse Effects of Doxorubicin, p.713.

Interactions

As for Doxorubicin, p.713.

Antineoplastics. Increased exposure to epirubicin, and a consequent increase in myelotoxicity, has been reported in patients given epirubicin immediately after *paclitaxel*, compared with patients who received epirubicin before paclitaxel.[1] Similar interactions have been seen when paclitaxel was given before other anthracyclines.[2] These and other studies[3,4] have suggested that paclitaxel given in this way is associated with a reduced conversion of epirubicin to the less myelotoxic metabolite, epirubicinol, although the interaction is complex, and may involve both disposition and pharmacodynamics.

1. Venturini M, *et al.* Sequence effect of epirubicin and paclitaxel treatment on pharmacokinetics and toxicity. *J Clin Oncol* 2000; **18:** 2116–25.
2. Danesi R, *et al.* Pharmacokinetic optimisation of treatment schedules for anthracyclines and paclitaxel in patients with cancer. *Clin Pharmacokinet* 1999; **37:** 195–211.
3. Grasselli G, *et al.* Clinical and pharmacologic study of the epirubicin and paclitaxel combination in women with metastatic breast cancer. *J Clin Oncol* 2001; **19:** 2222–31.
4. Danesi R, *et al.* Pharmacokinetics and pharmacodynamics of combination chemotherapy with paclitaxel and epirubicin in breast cancer patients. *Br J Clin Pharmacol* 2002; **53:** 508–18.

Cimetidine. Cimetidine increased the formation of the active metabolite of epirubicin in a study in 8 patients; there was also a substantial increase in systemic exposure to unchanged epirubicin.[1] The mechanisms and potential clinical significance of the interaction were unclear.

1. Murray LS, *et al.* The effect of cimetidine on the pharmacokinetics of epirubicin in patients with advanced breast cancer: preliminary evidence of a potentially common drug interaction. *Clin Oncol* 1998; **10:** 35–8.

Pharmacokinetics

After intravenous doses epirubicin is rapidly and extensively distributed into body tissues, and undergoes metabolism in the liver, with the formation of epirubicinol (13-hydroxyepirubicin) and appreciable amounts of glucuronide derivatives. Epirubicin is eliminated mainly in bile, with a terminal plasma elimination half-life of about 30 to 40 hours. About 10% of a dose is recovered in urine within 48 hours. Epirubicin does not cross the blood-brain barrier.

◊ References.

Uses and Administration

Epirubicin is an anthracycline antibiotic with antineoplastic actions similar to those of doxorubicin (p.714). It is used, alone or with other antineoplastics, in acute leukaemias, lymphomas, multiple myeloma, and in solid tumours including Wilms' tumour (p.667), cancer of the bladder (p.659), breast (p.661), and stomach (p.664).

Epirubicin hydrochloride is given by intravenous injection of a solution in sodium chloride 0.9% or Water for Injections into a fast-running infusion of sodium chloride 0.9% or glucose 5% over 3 to 5 minutes, or by infusion over up to 30 minutes. It is given as a single agent in usual doses of 60 to 90 mg/m^2 as a single dose every 3 weeks; this dose may be divided over 2 or 3 days if desired. A regimen of 12.5 to 25 mg/m^2 once a week has also been tried in palliative care. High-dose regimens, of 120 mg/m^2 or more every 3 weeks, or 45 mg/m^2 for 3 consecutive days every 3 weeks have been used.

Doses may need to be reduced if epirubicin is given with other antineoplastics. Doses should also be reduced in patients with liver impairment (see below) and in those whose bone-marrow function is impaired by age or previous chemotherapy or radiotherapy.

A total cumulative dose of 0.9 to 1 g/m^2 should not generally be exceeded, because of the risk of cardiotoxicity.

Epirubicin has also been given by intravesical instillation in the local treatment of bladder cancer. Instillation of 50 mg weekly as a 0.1% solution (in sodium chloride 0.9% or sterile water) for 8 weeks has been suggested, reduced to 30 mg in 50 mL weekly if chemical cystitis develops; for carcinoma *in-situ*, the dose may be increased, if tolerated, to 80 mg in 50 mL weekly. For the prophylaxis of recurrence in patients who have undergone transurethral resection, 50 mg weekly for 4 weeks, followed by 50 mg instilled once a month for 11 months is the suggested regimen. The solution should be retained in the bladder for 1 hour.

Blood counts should be made routinely during treatment with epirubicin (see also Bone-marrow Depression, p.639) and cardiac function should be carefully monitored. Liver function should be assessed before and if possible during therapy.

5. Earl H, Iddawela M. Epirubicin as adjuvant therapy in breast cancer. *Expert Rev Anticancer Ther* 2004; **4:** 189–95.

Administration in hepatic impairment. Doses of epirubicin should be halved in patients with moderate liver dysfunction (serum bilirubin concentrations of 12 to 30 micrograms/mL), while those with severe liver impairment (serum bilirubin greater than 30 micrograms/mL) should be given a quarter of the usual dose.

Amyloidosis. For reference to a regimen including epirubicin used to control disease in a patient with amyloidosis, see p.743.

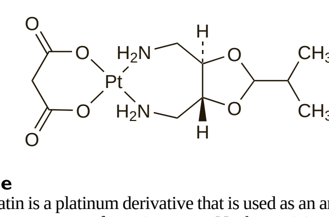
Eptaplatin *(rINN)*

Eptaplatine; Eptaplatino; Eptaplatinum; Heptaplatin; SKI-2053R. *cis*-[(4*R*,5*R*)-2-Isopropyl-1,3-dioxolane-4,5-bis(methylamine)-*N*,*N*′][malonato(2−)-*O*,*O*′]platinum.

Эптаплатин

$C_{11}H_{20}N_2O_6Pt = 471.4.$

CAS — 146665-77-2.



Profile

Eptaplatin is a platinum derivative that is used as an antineoplastic in the treatment of gastric cancer. Nephrotoxicity is the main adverse effect.

Preparations

Proprietary Preparations (details are given in Part 3)

Kor.: Sunpla.

Erlotinib Hydrochloride *(USAN, rINNM)*

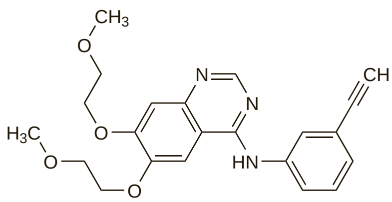
CP-358774-01; Erlotinib, Chlorhydrate d'; Erlotinibi Hydrochloridum; Hidrocloruro de erlotinib; NSC-718781; OSI-774. *N*-(3-Ethynylphenyl)-6,7-bis(2-methoxyethoxy)quinazolin-4-amine hydrochloride.

Эрлотиниба Гидрохлорид

$C_{22}H_{23}N_3O_4$,HCl = 429.9.

CAS — 183321-74-6 (erlotinib); 183319-69-9 (erlotinib hydrochloride).

ATC — L01XE03.



(erlotinib)

Adverse Effects, Treatment, and Precautions

The most common adverse effects associated with erlotinib hydrochloride are rash and diarrhoea. Moderate or severe diarrhoea should be treated with an appropriate antidiarrhoeal such as loperamide; dose reduction may be needed. In more severe or persistent cases leading to dehydration, therapy should be stopped temporarily. Other common adverse effects include other gastrointestinal disturbances, gastrointestinal bleeding, fatigue, alopecia, stomatitis, pruritus, dry skin, paronychia, conjunctivitis, keratoconjunctivitis sicca, epistaxis, and abdominal pain. Alterations in liver function tests have occurred. Rare cases of hepatic failure, including fatalities, have been reported. Interstitial lung disease has also been reported; fatalities have occurred. Erlotinib treatment should be interrupted if unexplained pulmonary symptoms occur, such as dyspnoea, cough, and fever.

Interactions

Inhibitors of the cytochrome P450 isoenzyme CYP3A4, such as ketoconazole, can increase erlotinib concentrations and use with potent inhibitors should be avoided as increased toxicity may occur. Conversely, CYP3A4 inducers, such as rifampicin, can reduce erlotinib concentrations and may reduce its efficacy. Dose adjustments may be required (see Uses and Administration, below). Caution is also required with ciprofloxacin or potent inhibitors of CYP1A2, as erlotinib exposure may be increased, and dose reductions may be needed if adverse effects occur. Use with P-glycoprotein inhibitors such as ciclosporin and verapamil may cause altered distribution or elimination of erlotinib. Caution is advised when erlotinib is used with antacids, proton pump inhibitors, or histamine H_2-receptor antagonists, as erlotinib absorption may be impaired. Exposure to erlotinib is reduced in smokers compared with non-smokers.

Pharmacokinetics

Erlotinib is absorbed from the gastrointestinal tract, with a bioavailability of about 60%; this may increase up to almost 100% in the presence of food. Peak plasma concentrations are reached about 4 hours after a dose, and it is about 93% bound to plasma proteins. Erlotinib is metabolised predominantly by the cytochrome P450 isoenzyme CYP3A4, and to a lesser extent by CYP1A2. Metabolic pathways include demethylation, to metabolites OSI-420 and OSI-413, oxidation, and aromatic hydroxylation. Erlotinib has an elimination half-life of about 36 hours. More than 80% of a dose is excreted as metabolites in the faeces.

Uses and Administration

Erlotinib inhibits the intracellular phosphorylation of tyrosine kinase associated with the epidermal growth factor receptor. It is used for the management of locally advanced or metastatic non-small cell lung cancer (p.668) that is unresponsive to other therapy. It is also used with gemcitabine in the first-line treatment of patients with locally advanced, unresectable, or metastatic pancreatic cancer (p.671). It is given orally as the hydrochloride but doses are expressed in terms of the base: erlotinib hydrochloride 109 mg is equivalent to about 100 mg of erlotinib.

The usual dose for non-small cell lung cancer is 150 mg daily, taken at least 1 hour before or 2 hours after food. In the treatment of pancreatic cancer, the recommended dose is 100 mg daily, taken at least 1 hour before or 2 hours after food. Treatment is continued until disease progression or unacceptable toxicity occurs. Where dosage adjustment is necessary, reductions are made in 50 mg steps.

If concurrent use of potent inhibitors or inducers of cytochrome P450 isoenzyme CYP3A4 cannot be avoided, dose adjustments of erlotinib are considered necessary. When used with a potent CYP3A4 inhibitor, the dose of erlotinib may need to be reduced, especially if severe adverse effects occur. When given with a potent CYP3A4 inducer, increases in the dose of erlotinib should be considered at 2-week intervals with monitoring. The maximum dose of erlotinib when used with rifampicin is 450 mg. If the inducer is then stopped, the erlotinib dose will need to be immediately reduced to the indicated starting dose.

Erlotinib is also under investigation in the treatment of malignant glioma.

Administration in hepatic or renal impairment. Erlotinib is metabolised by the liver. UK licensed product information states that although erlotinib exposure was similar in patients with moderate hepatic impairment (Child-Pugh score 7 to 9) compared with those with adequate hepatic function, caution is advised when using erlotinib in hepatic impairment. Dose reduction or interruption of therapy should be considered if adverse effects occur. Use in severe hepatic impairment is not recommended due to a lack of data.

UK licensed product information also states that no dose adjustments appear necessary in patients with mild to moderate renal impairment, but that use of erlotinib in patients with severe renal impairment is not recommended. There are no data available for patients with a creatinine clearance less than 15 mL/minute or those with a serum creatinine concentration greater than 1.5 times the upper normal limit.

Estramustine Sodium Phosphate *(BANM, rINNM)*

Estramustin Fosfat Sodyum; Estramustine, Phosphate Sodique de; Estramustine Phosphate Sodium *(USAN)*; Fosfato sódico de estramustina; Natrii Estramustini Phosphas; NSC-89199 (estramustine phosphate); Ro-21-8837/001; Ro-22-2296/000 (estramustine). Estra-1,3,5(10)-triene-3,17β-diol 3-[bis(2-chloroethyl)carbamate] 17-(disodium phosphate); Disodium 3-[bis(2-chloroethyl)-carbamoyloxy]estra-1,3,5(10)-trien-17β-yl orthophosphate.

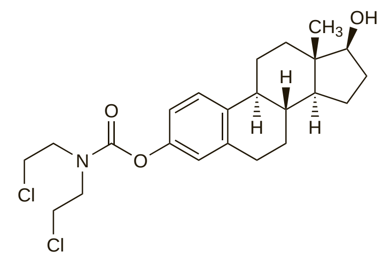
Натрия Эстрамустина Фосфат

$C_{23}H_{30}Cl_2NNa_2O_6P$ = 564.3.

CAS — 2998-57-4 (estramustine); 4891-15-0 (estramustine phosphate); 52205-73-9 (estramustine sodium phosphate).

ATC — L01XX11.

ATC Vet — QL01XX11.



(estramustine)

Pharmacopoeias. In *Br.*

BP 2008 (Estramustine Sodium Phosphate). A white or almost white powder. Freely soluble in water and in methyl alcohol; very slightly soluble in dehydrated alcohol and in chloroform. A 0.5% solution in water has a pH of 8.5 to 10.0. Protect from light.

Adverse Effects, Treatment, and Precautions

Oestrogenic adverse effects are fairly common, and may include gynaecomastia, fluid retention, and cardiovascular effects. Gastrointestinal disturbances, hepatic dysfunction, loss of libido, hypersensitivity reactions, and occasionally leucopenia and thrombocytopenia may occur. Estramustine is contra-indicated in patients with peptic ulceration and severe hepatic or cardiovascular disease. Diabetes mellitus may be exacerbated, and the drug should be given with care to patients with disorders such as congestive heart failure, epilepsy, hypertension, migraine, and renal impairment which may be adversely affected by additional fluid retention. Care is also required in patients with conditions predisposing to hypercalcaemia, and serum calcium should be monitored in hypercalcaemic patients.

Porphyria. Estramustine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

Estramustine sodium phosphate should not be given with milk products or products high in calcium, which may interfere with its absorption. Hypersensitivity reactions including angioedema have occurred rarely in patients given estramustine who were also receiving an ACE inhibitor.

Pharmacokinetics

Up to 75% of a dose of estramustine sodium phosphate is absorbed from the gastrointestinal tract and rapidly dephosphorylated. Estramustine is found in the body mainly as its oxidised isomer estromustine; both forms accumulate in the prostate. Some hydrolysis of the carbamate linkage occurs in the liver, releasing estradiol, estrone, and the normustine group. Estramustine and estromustine have plasma half-lives of 10 to 20 hours, and are excreted with their metabolites mainly in the faeces.

Uses and Administration

Estramustine is a combination of estradiol and normustine and has weaker oestrogenic activity than estradiol and weaker antineoplastic activity than most other alkylating agents. Estramustine phosphate is given orally as the disodium salt. Doses are calculated in terms of estramustine phosphate; 108 mg of estramustine sodium phosphate is equivalent to about 100 mg of estramustine phosphate. Estramustine phosphate with meglumine has been given by intravenous injection.

Estramustine sodium phosphate is licensed for use in the treatment of advanced prostatic carcinoma (p.671). An estramustine phosphate dose of about 14 mg/kg daily in divided doses is used. The usual initial dose is 560 to 840 mg daily, which may be adjusted to between 140 mg and 1.4 g daily according to the response and gastrointestinal tolerance. It should be given not less than 1 hour before or 2 hours after meals.

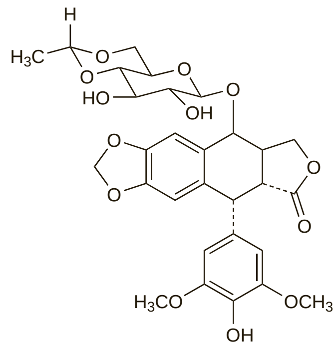
Этопозид

$C_{29}H_{32}O_{13}$ = 588.6.
CAS — 33419-42-0.
ATC — L01CB01.
ATC Vet — QL01CB01.



NOTE. The trivial name epipodophyllotoxin has occasionally been used incorrectly for this derivative.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Etoposide). A white or almost white, crystalline powder. Practically insoluble in water; slightly soluble in alcohol and in dichloromethane; sparingly soluble in methyl alcohol. Store in airtight containers.

USP 31 (Etoposide). A fine, white to off-white, crystalline powder. Very slightly soluble in water; slightly soluble in alcohol, in chloroform, in dichloromethane, and in ethyl acetate; sparingly soluble in methyl alcohol. Store in airtight containers. Protect from light.

Etoposide Phosphate *(USAN)*

BMY-40481; Etopósido, fosfato de. {5*R*-[5α,5aβ,8aα,9β(*R**)]}-5-[3,5-Dimethoxy-4-(phosphonooxy)phenyl]-9-[(4,6-*O*-ethylidene-β-D-glucopyranosyl)oxy]-5,8,8a,9-tetrahydrofuro-[3′,4′:6,7]naphtho[2,3-*d*]-1,3-dioxol-6(5a*H*)-one; 4′-Demethylepipodophyllotoxin 9-(4,6-*O*-ethylidene-β-D-glucopyranoside) 4′-(dihydrogen phosphate).

$C_{29}H_{33}O_{16}P$ = 668.5.
CAS — 117091-64-2.
ATC — L01CB01.
ATC Vet — QL01CB01.

Incompatibility. For reference to precipitation when mannitol or potassium chloride was added to mixtures of etoposide and cisplatin in sodium chloride injection, see Cisplatin, p.698.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

The dose-limiting toxicity of etoposide is myelosuppression, mainly seen as leucopenia, but also thrombocytopenia, and sometimes anaemia. The nadir of the granulocyte count usually occurs 7 to 14 days after a dose, with recovery by about 21 days. Nausea and vomiting are common; there may also be anorexia, diarrhoea, and mucositis. Gastrointestinal toxicity may be more common after oral dosage. Reversible alopecia occurs in about two-thirds of all patients. Hypersensitivity or anaphylactoid reactions can occur, characterised by flushing, chills, fever, tachycardia, bronchospasm, dyspnoea, and hypotension. Apnoea and fatal reactions associated with bronchospasm have been reported. Peripheral or central neuropathies, including transient cortical blindness, have been reported rarely, as have weakness, fatigue, somnolence, aftertaste, fever, rashes, urticaria, skin pigmentation, pruritus, and dysphagia. Stevens-Johnson syndrome and toxic epidermal necrolysis have occurred rarely. Tumour lysis syndrome, sometimes fatal, has been reported after use of etoposide with other chemotherapeutic drugs. Disturbances of liver function have been reported, mainly at high doses. There have been occasional reports of cardiotoxicity. Local irritation and thrombophlebitis may occur at the site of injection. Care should be taken to avoid extravasation although tissue damage (possibly associated with the vehicle) is rare.

Rapid intravenous doses may cause hypotension; etoposide should be given by infusion over at least 30 minutes. Etoposide should not be given to patients with severe hepatic impairment nor by the intracavitary route.

Some adverse effects associated with intravenous etoposide may be due to the formulation of the vehicle.

There is evidence that etoposide may be associated with the development of secondary leukaemias—see Carcinogenicity, p.635.

Breast feeding. Some licensed product information states that it is not known whether etoposide is excreted into breast milk. However, in breast milk samples from a woman given consolidation therapy, including etoposide,[1] for acute promyelocytic leukaemia, etoposide concentrations were maximal just after a dose, but decreased rapidly to undetectable levels within 24 hours on each of three days. She started to breast feed her baby 3 weeks after the completion of therapy, and no abnormalities were observed in the infant up to 16 months of age.

1. Azuno Y, *et al.* Mitoxantrone and etoposide in breast milk. *Am J Hematol* 1995; **48:** 131–2.

Effects on the gastrointestinal tract. Pneumatosis intestinalis (the presence of gas within the bowel wall), a rare condition, has been reported after intravenous[1] and oral[2] etoposide. It is supposed that myelosuppressive drugs might interfere with the mucosal integrity of the intestinal tract, and that the intestinal mucosa might be highly sensitive to etoposide.

1. Hashimoto S, *et al.* Pneumatosis cystoides intestinalis after chemotherapy for hematological malignancies: report of 4 cases. *Intern Med* 1995; **34:** 212–15.
2. Shih I-L, *et al.* Pneumatosis coli after etoposide chemotherapy for breast cancer. *J Clin Oncol* 2007; **25:** 1623–5.

Effects on the nervous system. A report of an acute dystonic reaction in a child given etoposide as part of a combined maintenance regimen for acute lymphoblastic leukaemia;[1] the patient had been receiving the same regimen uneventfully for over a year but symptoms (which responded to diphenhydramine) recurred on rechallenge with etoposide.

1. Ascher DP, Delaney RA. Acute dystonia from etoposide. *Drug Intell Clin Pharm* 1988; **22:** 41–2.

Handling and disposal. *Urine and faeces* produced for up to 4 and 7 days respectively after a dose of etoposide should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; **235:** 289–91.

Hypersensitivity. Hypersensitivity reactions to intravenous etoposide are characterised by one or more of: hypotension, bronchospasm, flushing, exanthema, dyspnoea, fever, chills, tachycardia, tightness in the chest, cyanosis, and hypertension. Although originally thought rare, some investigators[1] have reported an incidence of up to about 50%, particularly in younger patients. The mechanism is uncertain, but a literature review[1] supported the hypothesis that it might not be antibody-mediated, since reducing the rate of infusion can prevent reactions, as can reducing etoposide concentration in the infusion solution. However, an immunogenic mechanism cannot be excluded as hypersensitivity appears to have been reported less frequently with the oral formulation, which unlike the infusion does not contain polysorbate 80. In addition, there are reports[2-4] of successful use of etoposide phosphate formulations (which do not contain polysorbate 80) after hypersensitivity reactions to etoposide, suggesting that the solvent may be responsible.

4. Collier K, *et al.* Successful treatment with etoposide phosphate in patients with previous etoposide hypersensitivity. *J Oncol Pharm Pract* 2008; **14:** 51–5.

Pregnancy. For a report of hair loss in an infant, attributed to etoposide given to the mother before delivery, see Pregnancy, under Cisplatin, p.699.

Interactions

For a general outline of antineoplastic drug interactions, see p.642. Phenylbutazone, salicylic acid, and sodium salicylate can affect the protein binding of etoposide. Caution is advised when etoposide phosphate is given with drugs such as levamisole hydrochloride that are known to inhibit phosphatase activities.

Antineoplastics. Giving etoposide 2 days after a dose of *cisplatin* was associated with a marked decrease in etoposide clearance and more toxicity, compared with the same dose given 21 days after a dose of cisplatin, in a study involving 17 children.[1] There was no evidence of a persistent decrease in etoposide clearance associated with the cumulative dose of cisplatin, however. In a randomised, crossover study,[2] cisplatin or *carboplatin* were given alternately during 2 courses of etoposide. Although increases in the area under the concentration-time curve of etoposide were seen in the second course, effects were modest and, given the pharmacokinetic variability seen with etoposide, the authors considered any clinical impact to be small.

1. Relling MV, *et al.* Etoposide pharmacokinetics and pharmacodynamics after acute and chronic exposure to cisplatin. *Clin Pharmacol Ther* 1994; **56:** 503–11.
2. Thomas HD, *et al.* Randomized cross-over clinical trial to study potential pharmacokinetic interactions between cisplatin or carboplatin and etoposide. *Br J Clin Pharmacol* 2002; **53:** 83–91.

Ciclosporin. High-dose ciclosporin therapy was found to increase the exposure to etoposide by 80%, and to reduce etoposide clearance by 38%. Leucopenia was increased. Etoposide doses should be halved when the drug is given with high-dose ciclosporin.[1] In a study[2] of children who received etoposide and mitoxantrone for acute myeloid leukaemia, the addition of ciclosporin with a 40% reduction in the doses of the antineoplastics still resulted in a 71% reduction in the clearance of etoposide, and a 42% reduction for mitoxantrone. However, there was wide interpatient variability, and the rates of stomatitis and infection were similar between the groups, with or without ciclosporin.

1. Lum BL, *et al.* Alteration of etoposide pharmacokinetics and pharmacodynamics by cyclosporine in a phase I trial to modulate drug resistance. *J Clin Oncol* 1992; **10:** 1635–42.
2. Lacayo NJ, *et al.* Pharmacokinetic interactions of cyclosporine with etoposide and mitoxantrone in children with acute myeloid leukemia. *Leukemia* 2002; **16:** 920–7.

Grapefruit juice. In a randomised crossover study[1] of 6 patients, grapefruit juice appeared to reduce the oral bioavailability of etoposide. Initially the authors had expected the opposite since etoposide is demethylated by cytochrome P450 isoenzyme CYP3A4. Although no definite conclusions could be made due to the small number of patients studied, a possible mechanism might have been alteration of P-glycoprotein mediated transport.

1. Reif S, *et al.* Effect of grapefruit juice intake on etoposide bioavailability. *Eur J Clin Pharmacol* 2002; **58:** 491–4.

Pharmacokinetics

Absorption after oral doses is variable, but on average about 50% of the dose of etoposide is absorbed. The pharmacokinetics of etoposide are subject to considerable interindividual variation. It is rapidly distributed, and concentrations in plasma fall in a biphasic manner, with a terminal half-life of 4 to 11 hours. Etoposide is about 94% bound to plasma protein. It is metabolised by the cytochrome P450 isoenzyme CYP3A4. Etoposide is excreted in urine and faeces as unchanged drug and metabolites: about 45% of a dose is reported to be excreted in urine over 72 hours. It crosses the blood-brain barrier poorly; concentrations in CSF are 1 to 10% of those in plasma. It is distributed into breast milk (see Breast Feeding, above).

Uses and Administration

Etoposide is a semisynthetic derivative of podophyllotoxin with antineoplastic properties; it interferes with the function of topoisomerase II thus inhibiting DNA synthesis, and is most active against cells in the late S and G_2 phases of the cell cycle.

It is used, usually with other antineoplastics, in the treatment of tumours of the testis, small cell cancer of the lung, and in acute leukaemias. It has also been tried in other solid tumours including those of the brain, gastrointestinal tract, ovary, and thymus, and some childhood neoplasms; in lymphomas, and in the treatment of Kaposi's sarcoma associated with AIDS. For further discussion, see the cross-references indicated under Malignant Neoplasms, below.

Etoposide is given by slow intravenous infusion over at least 30 minutes, as a solution in sodium chloride 0.9% or glucose 5% injection. In general, the concentration of the infusion should be between 200 to 400 micrograms/mL, although recommendations vary depending on the preparation; precipitation may occur at higher concentrations. Etoposide phosphate, a prodrug, has improved solubility in water. 113.6 mg of etoposide phosphate is equivalent to 100 mg of etoposide. Intravenous doses are calculated in terms of etoposide, and are identical to those of the base, but it may be given in concentrations up to the equivalent of etoposide 20 mg/mL. Etoposide phosphate solutions may be infused over 5 minutes to 3.5 hours. Etoposide may also be given orally.

Regimens vary; the usual intravenous dose of etoposide ranges from 50 to 120 mg/m^2 daily for 5 days. Somewhat lower doses have been suggested in lung cancer. Alternatively, 100 mg/m^2 has been given on alternate days to a total of 300 mg/m^2. The usual oral dose of etoposide is 100 to 240 mg/m^2 daily for 5 consecutive days. Courses may be repeated after 3 to 4 weeks. Doses should be reduced in renal impairment (see below).

Administration. Although precipitation of etoposide may occur at high infusion concentrations (see Uses and Administration, above), high doses of etoposide have been infused undiluted to avoid giving large volumes of fluid to the patient.[1-3] Etoposide was infused through a central line, and this method has been reported to be safe and effective;[2] pharmacokinetic studies suggested unaltered systemic bioavailability when compared with diluted infusions.[3] However, cracking of plastic syringes and infusion cassettes has been reported, possibly due to the polyethylene glycol component of the formulation. This appears particularly problematic when devices containing ABS plastic (a polymer produced from acrylonitrile, butadiene, and styrene) are used; alternative devices may be preferable.[1]

Etoposide has been injected into the ventricles of the brain in the treatment of patients with neoplastic meningitis.[4]

1. Schwinghammer TL, *et al.* Cracking of ABS plastic devices used to infuse undiluted etoposide injection. *Am J Hosp Pharm* 1988; **45:** 1277.
2. Creger RJ, *et al.* Infusion of high doses of undiluted etoposide through central venous catheters during preparation for bone marrow transplantation. *Cancer Invest* 1990; **8:** 13–16.
3. Ehninger G, *et al.* Unaltered pharmacokinetics after the administration of high-dose etoposide without prior dilution. *Cancer Chemother Pharmacol* 1991; **28:** 214–16.
4. Chamberlain MC, *et al.* Phase II trial of intracerebrospinal fluid etoposide in the treatment of neoplastic meningitis. *Cancer* 2006; **106:** 2021–7.

Administration in renal impairment. Some licensed product information for etoposide or etoposide phosphate recommends that patients with a creatinine clearance of between 15 and 50 mL/minute be given 75% of the recommended dose. No recommendations are given for those patients having a creatinine clearance of below 15 mL/minute, although one product (*Vepesid; BMS, USA*) suggests that further dose reduction in these patients be considered.

Blood disorders, non-malignant. For reference to the use of combination chemotherapy, including etoposide, in a few patients with refractory idiopathic thrombocytopenic purpura, see p.1505.

Histiocytic syndromes. Systemic chemotherapy is often tried in patients with extensive Langerhans-cell histiocytosis (p.650), although its value is uncertain. Etoposide is one of the drugs widely used for this purpose.

Hypereosinophilic syndrome. Etoposide has been reported to produce clinical responses in patients with the hypereosinophilic syndrome.[1]

1. Bourrat E, *et al.* Etoposide for treating the hypereosinophilic syndrome. *Ann Intern Med* 1994; **121:** 899–900.

Malignant neoplasms. Etoposide has been used for a variety of solid tumours: in particular it is part of curative regimens used in the treatment of testicular cancer and germ-cell tumours of the ovary (see p.673 and p.670), and is used with cisplatin and other drugs in the treatment of lung cancer (p.668). Other solid neoplasms in which it is sometimes employed include those of the brain (p.660), stomach (p.664), and thymus (p.674), as well as in neuroblastoma (p.674), Wilms' tumour (p.667), retinoblastoma (p.675), and rhabdomyosarcoma (p.676); it has also formed part of systemic regimens for bone sarcomas (p.675), disseminated Kaposi's sarcoma (see p.675), and gestational trophoblastic tumours (p.650). Etoposide is used in regimens for Hodgkin's disease (see p.655); it is also sometimes used in aggressive intermediate- and high-grade non-Hodgkin's lymphomas (p.656), and may produce short-term responses in mycosis fungoides (p.657). It is also used in Burkitt's lymphoma (p.657). Etoposide may have benefits when added to induction protocols for acute myeloid leukaemia (p.652), and when used as part of intensification therapy in acute lymphoblastic leukaemia (p.651). It has formed part of salvage regimens in multiple myeloma (p.658).

Vasculitic syndromes. For mention of the use of etoposide to induce remission in patients with Wegener's granulomatosis resistant to standard therapy with cyclophosphamide and corticosteroids, see p.1515.

Exemestane *(BAN, USAN, rINN)* ⊗

Eksemestaani; Eksemestan; Exemestan; Exémestane; Exemestano; Exemestanum; FCE-24304. 6-Methyleneandrosta-1,4-diene-3,17-dione.

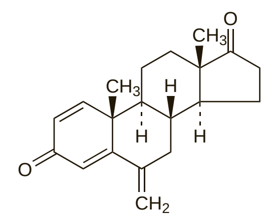
Эксеместан

$C_{20}H_{24}O_2$ = 296.4.

CAS — 107868-30-4.

ATC — L02BG06.

ATC Vet — QL02BG06.



Adverse Effects and Precautions

The most frequently reported adverse effects for exemestane are gastrointestinal disturbances, hot flushes, arthralgia, myalgia, sweating, fatigue, and dizziness. Other reported effects include headache, insomnia, somnolence, depression, skin rashes, alopecia, asthenia, and peripheral and leg oedema. Thrombocytopenia and leucopenia have been reported occasionally. Reductions in bone mineral density can occur with long-term use of exemestane. Density should therefore be assessed at the start of therapy, in those with osteoporosis or at risk of it, and patients monitored during therapy.

The use of exemestane is contra-indicated in premenopausal women (particularly in pregnancy).

Effects on the musculoskeletal system. Exemestane therapy has been found to decrease bone mineral density (BMD) in postmenopausal women with early breast cancer.[1,2] In one study, the decrease in BMD was seen within 6 months of switching therapy from tamoxifen, and was significant at the lumbar spine and hip.[2] In a Scandinavian study, BMD loss with exemestane compared with placebo was modest from the femoral neck, and not significant at the lumbar spine;[1] however, it was noted that the changes in the placebo group were greater than expected, possibly due to the lack of calcium and vitamin D supplementation, and that there is a high incidence of hip fracture in Scandinavia. Patients starting exemestane therapy should be assessed for baseline BMD;[1] while those with normal BMD are considered to not need further assessment beyond lifestyle advice, those with osteopenia should have their BMD monitored, and therapeutic interventions made as appropriate.[2]

1. Lønning PE, *et al.* Effects of exemestane administered for 2 years versus placebo on bone mineral density, bone biomarkers, and plasma lipids in patients with surgically resected early breast cancer. *J Clin Oncol* 2005; **23:** 5126–37.
2. Coleman RE, *et al.* Skeletal effects of exemestane on bone-mineral density, bone biomarkers, and fracture incidence in postmenopausal women with early breast cancer participating in the Intergroup Exemestane Study (IES): a randomised controlled study. *Lancet Oncol* 2007; **8:** 119–27.

Interactions

The metabolism of exemestane is mediated by the cytochrome P450 isoenzyme CYP3A4. Rifampicin, a potent inducer of CYP isoenzymes, can decrease plasma concentrations of exemestane. Use with other drugs that induce this isoenzyme may reduce the efficacy of exemestane. Exemestane should also be used cautiously with drugs that are substrates for CYP3A4 and that have a narrow therapeutic index. Significant effects on exemestane clearance by cytochrome P450 isoenzyme inhibitors are considered unlikely. Exemestane should not be given with oestrogen-containing drugs as these would negate its pharmacological action.

Pharmacokinetics

Exemestane is rapidly absorbed from the gastrointestinal tract. Its bioavailability is limited by first-pass metabolism, but is increased when taken with food. Exemestane is widely distributed, and is extensively bound to plasma proteins. It is metabolised via oxidation by the cytochrome P450 isoenzyme CYP3A4, and via reduction by aldoketoreductase. Metabolites are excreted in the urine and faeces, and less than 1% of a dose is excreted unchanged in the urine. Exemestane has a terminal elimination half-life of about 24 hours.

Uses and Administration

Exemestane is a selective inhibitor of the aromatase (oestrogen synthase) system, similar to formestane (p.726). It is used in the treatment of advanced breast cancer (p.661), in postmenopausal women who are no longer responsive to anti-oestrogen therapy. It is also used for adjuvant treatment of postmenopausal women with oestrogen-receptor positive early breast cancer, after 2 to 3 years of initial adjuvant tamoxifen treatment; a total of 5 years of adjuvant hormonal therapy should be given. The recommended oral dose is 25 mg once daily, preferably after a meal.

In patients receiving potent inducers of the cytochrome P450 isoenzyme CYP3A4 (such as rifampicin or phenytoin), the recommended oral dose of exemestane is 50 mg once daily, after a meal.

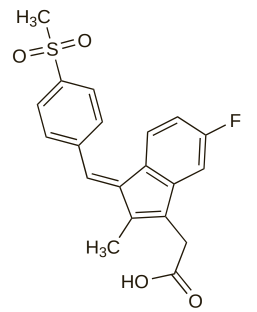
Exisulind *(rINN)*

Exisulindum; FGN-1; Sulindac Sulfone. 5-Fluoro-2-methyl-1-[(*Z*)-*p*-(methylsulfonyl)benzylidene]indene-3-acetic acid.

Эксисулинд

$C_{20}H_{17}FO_4S$ = 372.4.

CAS — 59973-80-7.



Profile

Exisulind is a sulfone metabolite of sulindac (p.126) that is reported to induce apoptosis in cancerous and precancerous cells. It has been studied for the treatment of familial adenomatous polyposis, with variable results. It is also being investigated for the prevention and treatment of malignant neoplasms, including those of the breast, prostate, and lung.

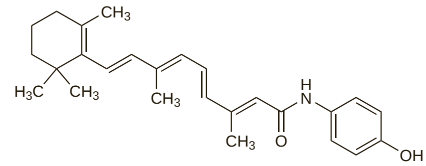
Fenretinide *(USAN, rINN)*

Fenretinida; Fenrétinide; Fenretinidum; 4-HPR; 4-Hydroxyphenylretinamide; McN-R-1967. *all-trans*-4′-Hydroxyretinanilide.

Фенретинид

$C_{26}H_{33}NO_2$ = 391.5.

CAS — 65646-68-6.



Profile

Fenretinide is a retinoid derivative that is given orally and is being studied in the management of breast and prostate cancer, malignant bone tumours, soft-tissue sarcoma, and some other malignancies. It has also been tried in oral lichen planus and leucoplakia. Fenretinide has been investigated in the treatment of psoriasis, but was associated with unacceptable adverse effects such as night blindness and severe toxic erythema.

◊ Fenretinide has been studied for the treatment of breast cancer and cutaneous malignancies but early results were disappointing and night blindness and mucocutaneous effects have been associated with this use.[1] Fenretinide has been investigated for the prevention of breast cancer (p.662), but a large randomised study of secondary prevention failed to show any benefit.[2] A follow-up of the same study[3] found that patients receiving fenretinide had a lower incidence of ovarian carcinoma during the 5-year treatment period, but that this apparently protective effect disappeared after treatment was stopped. Combinations of tamoxifen and fenretinide, given intermittently (for treatment or prevention), have been reported to be well tolerated.[4-6]

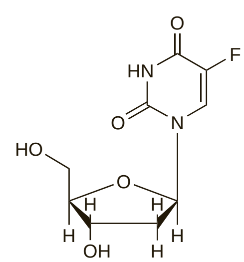
Floxuridine *(USAN, rINN)*

Floxuridina; Floxuridinum; 5-Fluorouracil Deoxyriboside; FUDR; NSC-27640; WR-138720. 2′-Deoxy-5-fluorouridine; 5-Fluoro-2′-deoxyuridine; 1-(2-Deoxy-β-D-ribofuranosyl)-5-fluoropyrimidine-2,4(1*H*,3*H*)-dione.

Флоксуридин

$C_9H_{11}FN_2O_5$ = 246.2.

CAS — 50-91-9.



Pharmacopoeias. In *US.*

USP 31 (Floxuridine). Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Fluorouracil, p.722. Adverse reactions after intra-arterial infusion often include local reactions, thromboembolic complications, and infection or bleeding at the catheter site, or blockage of the catheter. Erythema, stomatitis, and gastrointestinal disturbances are relatively common. There have also been signs of liver dysfunction.

Effects on the liver. Serious biliary toxicity has been reported in over half of all patients receiving hepatic arterial infusions of floxuridine, usually manifesting as sclerosing cholangitis or acalculous cholecystitis;[1] as a result some surgeons routinely remove the gallbladder at the time of infusion pump implantation.[2] Extrahepatic biliary stenosis with jaundice and cholestasis has also been described;[3] the authors suggest that this could lead to intrahepatic biliary damage from bile stasis and infection, recurrent cholangitis, and biliary sclerosis. Floxuridine infusions have also been associated with a case of fatal progressive cirrhosis of the liver in the absence of overt cholestasis.[4] Pseudoaneurysms of the hepatic artery, leading to serious retroperitoneal or gastrointestinal bleeding, have also been described.[5]

5. Samaras P, *et al.* Hemorrhage associated with hepatic artery pseudoaneurysms after regional chemotherapy with floxuridine: case report. *Int Semin Surg Oncol* 2008; **5:** 17.

Interactions

As for Fluorouracil, p.723.

Pharmacokinetics

Floxuridine is poorly absorbed from the gastrointestinal tract and it is usually given by injection. Floxuridine is metabolised mainly in the liver to fluorouracil after rapid injection. When given by slow intra-arterial infusion, more of the drug is metabolised to floxuridine monophosphate (F-dUMP). It is excreted as carbon dioxide via the lungs; some is excreted, as unchanged drug and metabolites, in urine. Floxuridine crosses the blood-brain barrier to some extent and is found in CSF.

Uses and Administration

Floxuridine is an antineoplastic which acts as an antimetabolite, either by conversion to fluorouracil (after rapid injection), or, when given by slow intra-arterial infusion, partly via floxuridine monophosphate (F-dUMP), which produces greater inhibition of DNA synthesis.

Floxuridine is used in the palliative treatment of hepatic metastases of colorectal cancer—see Malignant Neoplasms of the Liver, p.667. It has been tried in some other solid neoplasms. Doses of 100 to 600 micrograms/kg daily are given by continuous hepatic arterial infusion, usually with the aid of an infusion pump, until toxicity occurs.

White cell and platelet counts should be carried out regularly during therapy and treatment should be stopped if the white cell count falls rapidly or if the white cell or platelet count falls below acceptable levels (see also Bone-marrow Depression, p.639), or if major adverse effects occur.

Fludarabine Phosphate

(BAN, USAN, rINNM)

2-F-ara-AMP; Fludarabiinifosfaatti; Fludarabin Fosfat; Fludarabine Monophosphate; Fludarabine, phosphate de; Fludarabinfosfat; Fludarabin-fosfát; Fludarabini phosphas; Fludarabino fosfatas; 2-Fluoro-ara-AMP; Fosfato de fludarabina; NSC-312887. 9-β-D-Arabinofuranosyl-2-fluoroadenine 5′-dihydrogenphosphate.

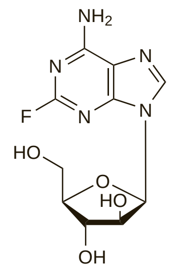
Флударабина Фосфат

$C_{10}H_{13}FN_5O_7P$ = 365.2.

CAS — 21679-14-1 (fludarabine); 75607-67-9 (fludarabine phosphate).

ATC — L01BB05.

ATC Vet — QL01BB05.



(fludarabine)

NOTE. The name FluCam has been used for a regimen of fludarabine with alemtuzumab. Distinguish from Flucam, which is ampiroxicam (p.19).

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Fludarabine Phosphate). A white or almost white, hygroscopic, crystalline powder. Slightly soluble in water; very slightly soluble in dehydrated alcohol; freely soluble in dimethylformamide. Store in airtight containers at a temperature of 2° to 8°. Protect from light.

USP 31 (Fludarabine Phosphate). A white to off-white, hygroscopic, crystalline powder. Slightly soluble in water and in 0.1M hydrochloric acid; practically insoluble in dehydrated alcohol; freely soluble in dimethylformamide. Store at 2° to 8°. Protect from light.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

Bone-marrow suppression from fludarabine is dose-limiting, manifesting as neutropenia, thrombocytopenia, and anaemia; the nadir of the white cell and platelet counts usually occurs after about 13 to 16 days. Myelosuppression can be severe and cumulative; prolonged lymphopenia with concomitant risk of opportunistic infections may occur. Bone marrow hypoplasia or aplasia resulting in pancytopenia may sometimes be fatal.

Other common adverse effects include fever, fatigue, chills, cough, weakness, malaise, anorexia, gastrointestinal disturbances, mucositis, stomatitis, oedema, and skin rashes. Pulmonary toxicity, including pulmonary fibrosis, pneumonitis, and dyspnoea can occur. Other adverse effects include dysuria, haematuria, epistaxis, and abnormalities in hepatic or pancreatic enzymes. Tumour lysis syndrome has been reported, especially in patients with large tumour burdens. Auto-immune disorders, including auto-immune haemolytic anaemia, have been reported, and may be life-threatening or fatal. Patients should be monitored for signs of haemolysis and therapy stopped if it occurs. Rarely reported effects include heart failure, arrhythmias, anaphylaxis, and haemorrhagic cystitis. Neurological disturbances include peripheral neuropathy, agitation, confusion, visual disturbances, hearing loss, headache, sleep disorders, and seizures; high doses have been associated with progressive encephalopathy, blindness, coma, and death.

Exacerbation of existing skin cancer lesions as well as new onset of skin cancer has been reported in some patients. Transfusion-associated graft-versus-host disease has been seen after transfusion of non-irradiated blood in patients treated with fludarabine, and fatalities have occurred; patients should only receive irradiated blood.

Dosage should be reduced in renal impairment (see below). It should also be avoided in patients with decompensated haemolytic anaemia.

Carcinogenicity. A study in patients with chronic lymphocytic leukaemia who were treated with fludarabine found that there was no significantly increased risk of secondary malignancy following therapy, despite the immunosuppressive properties of this drug.[1] A review[2] of this and other studies concluded that no significant increase in the risk of secondary malignancy had been shown, but also that long-term follow-up of patients treated with fludarabine was needed.

2. Van Den Neste E, *et al.* Second primary tumors and immune phenomena after fludarabine or 2-chloro-2′-deoxyadenosine treatment. *Leuk Lymphoma* 2001; **40:** 541–50.

Effects on the eyes. See under Effects on the Nervous System, below.

Effects on the lungs. Pulmonary toxicity manifest as dyspnoea, fever, hypoxaemia, and radiographic evidence of interstitial and alveolar infiltrates was diagnosed in 9 patients of a cohort of 105 treated with fludarabine.[1] Lung biopsies were performed in 6 patients and showed diffuse chronic interstitial inflammation and fibrosis. Patients with chronic lymphocytic leukaemia appeared to be at greater risk of developing this complication than those with non-Hodgkin's lymphoma.

1. Helman DL, *et al.* Fludarabine-related pulmonary toxicity: a distinct clinical entity in chronic lymphoproliferative syndromes. *Chest* 2002; **122:** 785–90.

Effects on the nervous system. High doses (of the order of 100 mg/m^2 daily intravenously) of fludarabine are associated with severe, life-threatening neurotoxicity. However, a few cases of progressive multifocal leukoencephalopathy have also been reported in patients given fludarabine in usual doses.[1-4] The prolonged immunosuppression caused by fludarabine might increase the risk of developing this fatal demyelinating disease, which is caused by opportunistic JC virus infection. Ocular toxicity, including irreversible loss of vision, has also been reported occasionally, including with low-dose regimens.[5]

5. Ding X, *et al.* Ocular toxicity of fludarabine: a purine analog. *Expert Rev Ophthalmol* 2008; **3:** 97–109.

Graft-versus-host disease. Transfusion-associated graft-versus-host disease has been reported when blood products were used in patients treated with fludarabine.[1] Fludarabine-treated patients should receive irradiated red cells and platelets (to inactivate any viable T-cells) if they require a transfusion.

1. Williamson LM, *et al.* Fludarabine treatment and transfusion-associated graft-versus-host disease. *Lancet* 1996; **348:** 472–3.

Infection. A review[1] of patients treated with fludarabine-containing regimens showed that therapy was associated with serious infections including listeriosis, pneumocystis pneumonia, mycobacterial infections, and opportunistic fungal and viral infections. The risk was exacerbated by previous or current corticosteroid therapy. Prophylactic therapy with co-trimoxazole, triazole antifungals, aciclovir, and colony-stimulating factors was recommended in at-risk patients. A high incidence of herpesvirus infections was also found in another review[2] of patients treated with fludarabine. Combination therapy using chlorambucil and fludarabine resulted in more infections than when either was used alone,[3] but single-agent fludarabine was associated with more major infections and herpesvirus infections than chlorambucil alone. The frequency of serious infection has also been reported[4] to be increased in patients after their conditions became refractory to fludarabine and they were being treated with conventional chemotherapy.

For reports of progressive multifocal leukoencephalopathy caused by opportunistic JC virus infection in patients receiving fludarabine, see Effects on the Nervous System, above.

Interactions

Increased pulmonary toxicity, sometimes fatal, has been reported in patients given fludarabine with pentostatin. Pretreatment with cytarabine may reduce the metabolic activation of fludarabine, but pretreatment with fludarabine results in increased intracellular concentrations of cytarabine—see p.706. The therapeutic efficacy of fludarabine may also be reduced by dipyridamole and other inhibitors of adenosine uptake.

Aminoglycosides. Severe ototoxicity occurred when a short course of *gentamicin* was given to a patient who had recently completed a course of fludarabine.[1]

1. O'Brien RK, Sparling TG. Gentamicin and fludarabine ototoxicity. *Ann Pharmacother* 1995; **29:** 200–1.

Corticosteroids. For a suggestion that use of fludarabine with corticosteroids may increase the risk of infection, see Infection, above.

Pharmacokinetics

Intravenous fludarabine phosphate is rapidly dephosphorylated to fludarabine which is taken up by lymphocytes and rephosphorylated to the active triphosphate nucleotide. Peak intracellular concentrations of fludarabine triphosphate are seen about 4 hours after a dose. Fludarabine has a bioavailability of about 50 to 65% after oral doses of the phosphate.

Clearance of fludarabine from the plasma is triphasic with a terminal half-life of about 20 hours. Elimination is mostly via renal excretion: 60% of a dose is excreted in the urine. The pharmacokinetics of fludarabine exhibit considerable interindividual variation.

Uses and Administration

Fludarabine is a fluorinated nucleotide analogue of the antiviral vidarabine (p.912); it acts as a purine antagonist antimetabolite. It is used for its antineoplastic properties in the treatment of chronic lymphocytic leukaemia. Fludarabine phosphate is given by bolus injection or by intravenous infusion over 30 minutes in a usual dose of 25 mg/m^2 daily for 5 consecutive days. Alternatively it may be given orally in a dose of 40 mg/m^2 daily for 5 consecutive days. Courses may be repeated every 28 days, usually for up to 6 cycles.

Haematological function should be monitored regularly; the dosage may need to be reduced, or further courses delayed, if blood counts indicate severe or persistent myelosuppression (see also Bone-marrow Depression, p.639). Doses should be reduced in renal impairment (see below).

2. Plosker GL, Figgitt DP. Oral fludarabine. *Drugs* 2003; **63:** 2317–23.

Administration in renal impairment. Doses of fludarabine phosphate should be reduced by up to 50% in patients with mild to moderate renal impairment (creatinine clearance between 30 and 70 mL/minute); the drug should not be given in more severe renal impairment.

Malignant neoplasms. Fludarabine is the preferred second-line therapy for chronic lymphocytic leukaemia once initial alkylating agent therapy fails,[1] and may also be used for initial therapy (see p.653). It has also been tried in other malignancies. Listed below are some references to the use of fludarabine phosphate for the treatment of chronic lymphocytic leukaemia,[2,3] and its potential activity against a variety of other malignancies, including indolent low-grade non-Hodgkin's lymphoma[4,5] (p.656), mycosis fungoides,[6] heavy chain disease,[7] prolymphocytic leukaemia,[8,9] hairy cell leukaemia,[10] and Waldenström's macroglobulinaemia.[11,12]

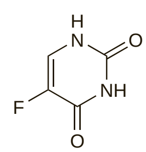
CAS — 51-21-8.

ATC — L01BC02.

ATC Vet — QL01BC02.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Fluorouracil). A white or almost white, crystalline powder. Sparingly soluble in water; slightly soluble in alcohol. A 1% solution in water has a pH of 4.5 to 5.0. Protect from light.

USP 31 (Fluorouracil). A white to practically white, practically odourless, crystalline powder. Sparingly soluble in water; slightly soluble in alcohol; practically insoluble in chloroform and in ether. Store in airtight containers. Protect from light.

Incompatibility. Preparations of fluorouracil are alkaline, and compatibility problems may be expected with acidic drugs and preparations, or those which are unstable in the presence of alkali. Fluorouracil is reported to be incompatible with cytarabine,[1] diazepam,[2] doxorubicin[2] (and presumably other anthracyclines that are unstable at alkaline pH), and calcium folinate.[3] Although fluorouracil has been stated to be incompatible with methotrexate[1] a study of the long-term stability of an admixture of the 2 drugs in sodium chloride 0.9% injection suggests otherwise.[4]

1. McRae MP, King JC. Compatibility of antineoplastic, antibiotic and corticosteroid drugs in intravenous admixtures. *Am J Hosp Pharm* 1976; **33:** 1010–13.

4. Vincké BJ, *et al.* Extended stability of 5-fluorouracil and methotrexate solutions in PVC containers. *Int J Pharmaceutics* 1989; **54:** 181–9.

Stability. Despite one report[1] that fluorouracil had limited stability when dissolved in glucose 5% at room temperature (10% loss from solution in 43 hours when stored in PVC and in only 7 hours when stored in glass), others[2] found such a solution to be stable for at least 16 weeks when stored in PVC at 5°. When stored at room temperature in PVC, solutions of fluorouracil may lose water by evaporation, which slowly increases their concentration.[2,3] Results of a study of fluorouracil and methotrexate admixtures in sodium chloride 0.9% suggest that extended stability (up to 13 weeks) is possible in this diluent at 5° in PVC bags.[3] Commercial solutions of fluorouracil for injection have been reported to be stable for 7 days at 37° in a portable infusion pump, although at 25° one brand showed evidence of precipitation.[4] Fluorouracil solutions may be incompatible with synthetic elastomers: microscopic precipitation has been reported as soon as 4 hours after placement into polyisoprene reservoirs of elastomeric infusers and in polypropylene syringes with an elastomeric joint.[5] Some have questioned the validity of this finding.[6,7]

Adverse Effects and Treatment

For general discussions see Antineoplastics, p.635 and p.639.

The main adverse effects of fluorouracil are on the bone marrow and the gastrointestinal tract, and may be dose-limiting. Toxicity is schedule dependent: reducing the rate of injection to a slow infusion is associated with less haematological toxicity but does not decrease gastrointestinal toxicity. With protracted continuous infusion in particular, the palmar-plantar erythrodysesthesia syndrome (erythema and painful desquamation of the hands and feet) may occur. Gastrointestinal toxicity may be exacerbated if fluorouracil is given with folinic acid.

Leucopenia, thrombocytopenia, stomatitis, gastrointestinal ulceration and bleeding, diarrhoea, or haemorrhage from any site, are signs that treatment should be stopped. The nadir of the white cell count may occur from 7 to 20 days after a dose, and counts usually return to normal after about 30 days. Thrombocytopenia is usually at a maximum 7 to 17 days after a dose. Anaemia may also occur. Nausea and vomiting, rashes, and alopecia are common. Ocular irritation, central neurotoxicity (notably cerebellar ataxia), and myocardial ischaemia have occurred.

Local inflammatory and photosensitivity reactions have occurred after topical use. Dermatitis and, rarely, erythema multiforme have been reported.

Effects on the eyes. Systemic fluorouracil therapy has been associated with various types of ocular toxicity including several cases of excessive lachrymation and watering of the eyes.[1] In one patient this was associated with symptoms suggesting fibrosis of the tear duct,[1] and possibly representing local irritation due to the presence of fluorouracil in tear fluid,[2] although symptoms have not always resolved on stopping the drug.[1] More seriously a case of bilateral total corneal epithelial erosion has been described.[3] Optic neuropathy, culminating in near blindness, has also occurred in a patient given fluorouracil as part of a combination regimen.[4] Severe ulceration and corneal abscess with hyopyon has followed local injection of fluorouracil into the eye in a diabetic patient with idiopathic band keratopathy.[5]

5. Hickey-Dwyer M, Wishart PK. Serious corneal complication of 5-fluorouracil. *Br J Ophthalmol* 1993; **77:** 250–1.

Effects on the heart. Life-threatening cardiotoxicity (arrhythmias, ventricular tachycardia, and cardiac arrest, secondary to transmural ischaemia) has been reported to occur in 0.55% of patients given fluorouracil,[1] although the incidence of angina and less severe cardiotoxicity associated with coronary artery spasm may be higher.[1-3] Possible risk factors include pre-existing heart disease or mediastinal radiotherapy, and prolonged infusion of the drug, but symptoms can also occur in patients without these risk factors.[2-4] Therefore, at present, it is not possible to reliably predict patients at risk.[5] Some suggest that the use of a trometamol buffer in the fluorouracil formulation may contribute to the formation of cardiotoxic degradation products.[6]

6. Lukaschek J, *et al.* Cardiotoxicity and neurotoxicity of high-dose continuous fluorouracil as a result of degradation compounds in the drug vials. *J Clin Oncol* 2004; **22:** 5022–5.

Effects on the nervous system. Central neurotoxicity, including cerebellar ataxia, confusion, disorientation, and emotional lability is reported to occur rarely in patients receiving fluorouracil, although the incidence may be increased with high-dose or intensive regimens. Patients with disorders of pyrimidine metabolism may be at increased risk of neurotoxicity.[1-3] It has also been suggested that fluorouracil may produce neurotoxicity by causing thiamine deficiency, and that thiamine may be used to treat it.[4]

4. Pirzada NA, *et al.* Fluorouracil-induced neurotoxicity. *Ann Pharmacother* 2000; **34:** 35–8.

Effects on the skin. In addition to reports of fluorouracil-associated dermatitis and photosensitivity a syndrome of erythema, pain, and desquamation of the skin of palms and soles has been reported[1-4] (the palmar-plantar erythrodysesthesia syndrome, p.639). Although particularly associated with continuous infusion[1,2] the syndrome can also occur after bolus doses.[3,4] Symptoms generally respond to stopping the drug, but addition of oral pyridoxine to chemotherapy regimens has been reported to prevent or resolve symptoms,[5] as has application of a nicotine patch in one patient.[6]

Rash and confusion developing in an elderly man with malabsorption and poor nutritional intake who received fluorouracil for a biliary-tract tumour were diagnosed as pellagra.[7] Symptoms responded to nicotinic acid therapy.

Hypersensitivity. Although local hypersensitivity reactions are included in licensed product information as potential adverse effects of topical fluorouracil, hypersensitivity reactions to systemic fluorouracil have been reported very rarely.[1-6] For a report of the successful use of fluorouracil in a patient allergic to capecitabine, suggesting that cross-sensitivity does not occur between the two, see p.692.

Precautions

For general discussions see Antineoplastics, p.641. Fluorouracil should be given with care to weak or malnourished patients, to those with a history of heart disease, or to those with hepatic or renal insufficiency. Patients with a history of high-dose pelvic irradiation or treatment with alkylating agents, and those with widespread metastases to the bone marrow should also be treated with extreme caution. Blood cell counts should be determined frequently during therapy. Fluorouracil should not be used in patients with dihydropyrimidine dehydrogenase (DPD) enzyme deficiency as this can lead to increased toxicity.

Topical fluorouracil should not be used on mucous membranes. There is a possibility of increased absorption if used excessively or on ulcerated or inflamed skin. Occlusive dressings may increase inflammatory actions. Exposure to UV light during treatment should be avoided. Creams are preferably applied using a non-metal applicator or gloved hand; if bare fingertips are used the hands must be washed immediately afterwards.

Handling and disposal. Fluorouracil is irritant; avoid contact with skin and mucous membranes.

Urine and faeces produced for up to 48 hours and 5 days respectively after an oral dose of fluorouracil should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; **235:** 289–91.

Metabolic disorders. For reference to increased risk of neurotoxicity in patients with a defect of pyrimidine metabolism given fluorouracil, see under Effects on the Nervous System, above.

Interactions

For a general discussion of antineoplastic drug interactions, see p.642. The actions of fluorouracil may be modified by other drugs including allopurinol, cimetidine, folinic acid, methotrexate, and metronidazole (see also under Administration, below).

◊ References.

1. Jansman FGA, *et al.* Assessing the clinical significance of drug interactions with fluorouracil in patients with colorectal cancer. *Am J Health-Syst Pharm* 2005; **62:** 1788–93.

Antineoplastics. *Oxaliplatin*, which is given with fluorouracil and folinic acid in the treatment of colorectal cancer, reduced fluorouracil clearance in a study[1] of 29 patients with colorectal cancer. The effect was delayed and prolonged, lasting about 15 days, and an increase in toxicity correlated with raised fluorouracil concentrations. The mechanism of this interaction is unclear. In contrast, however, another study[2] found no effect of oxaliplatin on fluorouracil pharmacokinetics; the study was not designed to investigate a delayed effect and the dose of oxaliplatin was lower than that used in the first study.

Sorafenib has been reported to have variable effects on fluorouracil exposure.

For reference to the effect of fluorouracil on the action of *paclitaxel*, see Antineoplastics, p.759. For the increased risk of haemolytic-uraemic syndrome that may be seen if fluorouracil is used with *mitomycin*, see Effects on the Kidneys, p.752.

1. Boisdron-Celle M, *et al.* Influence of oxaliplatin on 5-fluorouracil plasma clearance and clinical consequences. *Cancer Chemother Pharmacol* 2002; **49:** 235–43.
2. Joel SP, *et al.* Lack of pharmacokinetic interaction between 5-fluorouracil and oxaliplatin. *Clin Pharmacol Ther* 2004; **76:** 45–54.

Antiprotozoals. *Metronidazole* increased the toxicity of fluorouracil in patients with colorectal cancer, apparently by reducing the clearance of the antineoplastic. No enhanced antineoplastic effect was seen with the combination *in vitro*.[1]

1. Bardakji Z, *et al.* 5-Fluorouracil–metronidazole combination therapy in metastatic colorectal cancer. *Cancer Chemother Pharmacol* 1986; **18:** 140–4.

Antivirals. Giving *interferon alfa-2b* with fluorouracil has produced a marked increase in the initial plasma concentration of fluorouracil and a decrease in fluorouracil clearance.[1]

Severe leucopenia, fatal in some cases, has been reported in patients given fluorouracil or fluorouracil prodrugs (such as tegafur) with *sorivudine*.[2,3] A metabolite of sorivudine appears to inhibit dihydropyrimidine dehydrogenase, the primary enzyme responsible for the inactivation of fluorouracil.[3]

1. Czejka MJ, *et al.* Clinical pharmacokinetics of 5-fluorouracil: influence of the biomodulating agents interferon, dipyridamole and folic acid alone and in combination. *Arzneimittelforschung* 1993; **43:** 387–90.
2. Yawata M. Deaths due to drug interaction. *Lancet* 1993; **342:** 1166.
3. Diasio RB. Sorivudine and 5-fluorouracil; a clinically significant drug-drug interaction due to inhibition of dihydropyrimidine dehydrogenase. *Br J Clin Pharmacol* 1998; **46:** 1–4.

Gastrointestinal drugs. Pretreatment with *cimetidine* for 4 weeks increased plasma concentrations of fluorouracil after intravenous and oral doses in 6 patients.[1] The effect was probably due to a combination of hepatic enzyme inhibition and reduced hepatic blood flow. No such effect was seen after single doses of cimetidine in 5 patients or pretreatment for just 1 week in 6. Care is required in patients given both drugs together.

1. Harvey VJ, *et al.* The influence of cimetidine on the pharmacokinetics of 5-fluorouracil. *Br J Clin Pharmacol* 1984; **18:** 421–30.

Pharmacokinetics

Absorption of fluorouracil from the gastrointestinal tract is unpredictable and fluorouracil is usually given intravenously. Little is absorbed when fluorouracil is applied to healthy skin.

After intravenous injection fluorouracil is cleared rapidly from plasma with a mean half-life of about 16 minutes. It is distributed throughout body tissues and fluids (including crossing the blood-brain barrier to appear in the CSF), and disappears from the plasma within about 3 hours. Within the target cell fluorouracil is converted to 5-fluorouridine monophosphate and floxuridine monophosphate (5-fluorodeoxyuridine monophosphate), the former undergoing conversion to the triphosphate which can be incorporated into RNA while the latter inhibits thymidylate synthetase. About 15% of an intravenous dose is excreted unchanged in the urine within 6 hours. The remainder is inactivated primarily in the liver and is catabolised via dihydropyrimidine dehydrogenase (DPD) similarly to endogenous uracil. A large amount is excreted as respiratory carbon dioxide; urea and other metabolites are also produced.

◊ References.

Chronopharmacology. Plasma concentrations of fluorouracil during continuous intravenous infusion are reported to undergo circadian variations of as much as 50% of the mean, peak concentrations occurring in the middle of the night.[1] The variation may be due to a circadian variation in the activity of the enzyme dihydropyrimidine dehydrogenase in blood,[2] but striking inter-patient variations in peak concentrations of fluorouracil and peak enzyme activity suggest that any adjustment of infusion times would need to be individualised.[2] It has been suggested that pharmacokinetic monitoring should be investigated as a means of individualising fluorouracil doses with the aim of improving efficacy and reducing toxicity.[3]

Uses and Administration

Fluorouracil, an analogue of the pyrimidine uracil, is an antineoplastic that acts as an antimetabolite. After intracellular conversion to the active deoxynucleotide it interferes with the synthesis of DNA by blocking the conversion of deoxyuridylic acid to thymidylic acid by the cellular enzyme thymidylate synthetase. It can also interfere with RNA synthesis.

Fluorouracil is used alone or in combination in the adjuvant and palliative treatment of gastrointestinal cancer. In this setting it may be combined with folinic acid (see Administration, below). Fluorouracil is often given with cyclophosphamide and methotrexate or doxorubicin in the adjuvant treatment of breast cancer. It may also be used in the palliation of other malignant neoplasms such as those of the head and neck, liver, and pancreas. In addition, it may be used topically for treating malignant or premalignant lesions of the skin. Its use in these malignancies is further discussed under Choice of Antineoplastic as indicated by the cross-references given below.

Many dosage regimens have been used. Although it is most often given in combination regimens for the treatment of malignancy, many of the licensed dosage regimens relate to single-agent use. Such licensed regimens include:

- by *intravenous injection*, usual doses of 12 mg/kg daily (to a maximum of 0.8 to 1 g daily) for 3 or 4 days. If there is no evidence of toxicity, this may be followed after 1 day by 6 mg/kg on alternate days for 3 or 4 further doses. An alternative schedule is to give 15 mg/kg intravenously once a week throughout the course. The course may be repeated after 4 to 6 weeks or maintenance doses of 5 to 15 mg/kg to a maximum of 1 g may be given weekly.
- by *intravenous infusion*, usual doses of 15 mg/kg daily (to a maximum of 1 g daily) being infused in 500 mL of sodium chloride 0.9% or glucose 5% over 4 hours and repeated on successive days until toxicity occurs or a total of 12 to 15 g has been given. *Continuous infusion* may also be used. The course may be repeated after 4 to 6 weeks.
- by continuous *intra-arterial infusion*, in doses of 5 to 7.5 mg/kg daily (regional perfusion).
- by *mouth*, although the parenteral route is generally preferred, a dose of 15 mg/kg, to a maximum of 1 g in one day, has been given once weekly for maintenance.

Suggested regimens with folinic acid include:

- 200 mg/m^2 of folinic acid (as calcium folinate) by slow intravenous injection followed immediately by an intravenous bolus of fluorouracil 370 mg/m^2; the treatment is given daily for 5 consecutive days, and may be repeated every 4 to 5 weeks
- lower doses of folinic acid (20 mg/m^2) followed by fluorouracil 425 mg/m^2 for 5 consecutive days, repeated every 4 to 5 weeks (the Mayo regimen)
- an initial dose of 200 mg/m^2 of folinic acid, followed by fluorouracil 400 mg/m^2 as an initial intravenous bolus injection and then 600 mg/m^2 by continuous intravenous infusion. This dosage is given for 2 consecutive days every 2 weeks (the de Gramont regimen)

The white cell count should be determined frequently during treatment with fluorouracil and therapy stopped immediately if the count falls rapidly or if the white cell or platelet count falls below acceptable levels (see also Bone-marrow Depression, p.639) or if severe adverse effects occur. Doses should be reduced by up to half in patients with poor nutritional status, impaired bone-marrow, hepatic, or renal function, and within 30 days of major surgery.

Fluorouracil is used topically in the treatment of solar (actinic) keratoses and other superficial tumours and premalignant conditions of the skin including Bowen's disease and superficial basal cell carcinomas. For actinic keratosis it is usually applied as a 0.5 to 5% cream or as a 1 to 5% solution in propylene glycol once or twice daily for 2 to 4 weeks; the higher strength may be applied for at least 3 to 6 weeks for superficial basal cell carcinomas.

Administration. Modulation of fluorouracil by other drugs has been tried in an effort to enhance its effects, particularly in the treatment of colorectal cancer (p.665).

Folinic acid has been extensively used to modulate the effects of fluorouracil, and has become the agent of choice. Various regimens have been used, modifying the fluorouracil schedule (continuous infusion versus bolus), folinic acid dose (low-dose versus high-dose) and the regimen frequency (monthly, bimonthly, or weekly). Despite numerous studies, the optimum regimen in terms of efficacy and tolerability has yet to be determined.

In the adjuvant setting, a large-scale randomised trial[1] found no difference in efficacy between low-dose and high-dose folinic acid when added to fluorouracil given either once weekly for 30 doses, or for 5 consecutive days per month over 6 months. Fluorouracil and low-dose folinic acid may therefore become the preferred regimen in the adjuvant setting.

In the palliation of advanced disease, meta-analyses have revealed the value of the addition of folinic acid to fluorouracil,[2] and the use of infusions rather than bolus fluorouracil,[3] in terms of response rates. An updated meta-analysis confirmed the benefit of addition of folinic acid to fluorouracil in terms of response rate, and found a small but statistically significant advantage in terms of overall survival. Survival benefit was restricted to trials using the same dose of fluorouracil in the treatment arms (fluorouracil alone versus fluorouracil and folinic acid), suggesting that the benefit of modulation with folinic acid could be compensated by an increase of fluorouracil dose in the fluorouracil alone arm. However, increased toxicity from high-dose fluorouracil might occur.[4] The data for low-dose folinic acid versus high-dose are less clear.[5] In 1 randomised trial,[6] a bimonthly infusion regimen of fluorouracil plus high-dose folinic acid (the de Gramont regimen[7]) was more effective than a monthly bolus regimen of fluorouracil plus low-dose folinic acid. Further studies comparing the effect of high- and low-dose folinic acid added to the same schedule of continuous infusion fluorouracil are required.

Interferon alfa also appears to modify[8] the actions of fluorouracil (see also under Interactions, above), and has been investigated in combination with fluorouracil and folinic acid. Although some early results were promising, later randomised controlled trials failed to show any benefit for the addition of interferon alfa to fluorouracil or fluorouracil plus folinic acid.[8] It is not clear whether interferon beta will prove of any greater benefit.

Based on the results of early adjuvant studies, *levamisole* was used as standard therapy to modulate fluorouracil, particularly in the USA. However, more recent trials indicate that levamisole is no more effective than placebo when added to fluorouracil,[1] or to fluorouracil plus folinic acid.[9]

Methotrexate has also been used to modulate fluorouracil. Meta-analysis of several studies of fluorouracil preceded by methotrexate found that the combination doubled the response rate to fluorouracil in metastatic colorectal cancer and produced some survival benefits.[10] (Combination in the reverse order, i.e. methotrexate preceded by fluorouracil, may reduce methotrexate toxicity—see under Treatment of Adverse Effects, p.747.)

Eye disorders. Aside from its use in glaucoma surgery (below), fluorouracil has been used adjunctively in other ocular surgery. It has also shown promising results in the treatment of ocular surface malignancies.[1]

1. Abraham LM, *et al.* The clinical applications of fluorouracil in ophthalmic practice. *Drugs* 2007; **67:** 237–55.

Glaucoma. A regimen of subconjunctival injections of fluorouracil is effective in improving the outcome of glaucoma filtering surgery[1-3] in selected patients when used as an adjunct to prevent the formation of scar tissue (see p.1873). However, in view of the increased risk of late-onset conjunctival wound leaks caution has been suggested in its use in eyes with a good prognosis.[3] Although one study[4] found that fluorouracil improved the success rate of combined glaucoma filtering surgery and cataract surgery earlier studies had failed to demonstrate any advantage.[5,6] A systematic review[7] of these and 2 other studies concluded that fluorouracil reduced the risk of surgical failure of trabeculectomy in eyes at high risk of failure, and in those undergoing surgery for the first time, but noted that the methodological quality of the studies was not high, and that this practice has largely been superseded by the use of intra-operative mitomycin. However, a later survey[8] in the UK found that the use of antimetabolites in glaucoma surgery was much less common than in the USA or Japan, and that fluorouracil was strongly preferred to mitomycin.

Intra-operative topical application of fluorouracil has been tried as an alternative to subconjunctival injection with conflicting results.[9-11]

Malignant neoplasms. Fluorouracil plays an important role in the adjuvant treatment of gastrointestinal cancer, as discussed on p.664, and has been widely used in adjuvant regimens for early breast cancer (p.661). It may also be employed in the management of a wide variety of other malignancies including pancreatic endocrine tumours (p.643), cancers of the cervix (p.663) and head and neck (p.666), liver metastases (p.667), and tumours of the exocrine pancreas (p.671). It is reported to have only modest activity in neoplasms of the kidney (p.667). In addition, it is sometimes applied topically as part of the management of malignant or pre-malignant lesions of the skin (see Basal Cell and Squamous Cell Carcinoma, p.673), or surface neoplasia of the eye (p.664).

The role of fluorouracil in chemoradiotherapy of various malignancies has been reviewed.[1]

Toxoplasmosis. For mention of the use of fluorouracil with clindamycin to treat cerebral toxoplasmosis, see p.253.

Warts. Fluorouracil has been used, as a 1% or, more usually, a 5% cream or solution in the treatment of genital warts (condylomata acuminata).[1-3] It has been tried as an adjuvant to laser therapy in severe papillomavirus-associated vulvar disease,[4] with variable results, and in men with subclinical or clinically apparent penile lesions.[5] A preparation of fluorouracil 3% in a collagen gel basis, together with adrenaline as a local vasoconstrictor, has been tried by injection into genital warts.[6] A combination of fluorouracil 0.5% and salicylic acid 10% has also been stated to be effective in the topical treatment of common and plantar warts.[7] For a discussion of the various agents, including cytotoxics such as fluorouracil, employed to produce destruction of warts, see p.1584.

Flutamide *(BAN, USAN, rINN)*

Flutamid; Flutamida; Flutamidas; Flutamidi; Flutamidum; Sch-13521. α′,α′,α′-Trifluoro-4′-nitroisobutyro-*m*-toluidide; α,α,α-Trifluoro-2-methyl-4′-nitro-*m*-propionotoluidide.

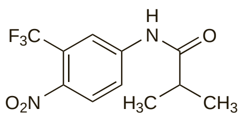
Флутамид

$C_{11}H_{11}F_3N_2O_3$ = 276.2.

CAS — 13311-84-7.

ATC — L02BB01.

ATC Vet — QL02BB01.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Flutamide). A pale yellow, crystalline powder. Practically insoluble in water; freely soluble in alcohol and in acetone. Protect from light.

USP 31 (Flutamide). A pale yellow, crystalline powder. Practically insoluble in water, in liquid paraffin, and in petroleum spirit; freely soluble in acetone, in ethyl acetate, and in methyl alcohol; soluble in chloroform and in ether. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

The most frequently reported adverse effects with flutamide are hot flushes and reversible gynaecomastia or breast tenderness, sometimes accompanied by galactorrhoea. Nausea, vomiting, diarrhoea, increased appetite, anorexia, and sleep disturbances may occur. There have been reports of skin reactions, including epidermal necrolysis, and of liver damage, sometimes fatal. Other adverse effects reported in patients receiving flutamide include anaemias, haemolysis, headache, dizziness, malaise, blurred vision, anxiety, depression, decreased libido, impotence, and hypertension. Abdominal pain, chest pain, dyspnoea, and cough have been reported rarely. Discoloration of the urine to amber or yellow-green can be caused by the presence of flutamide and/or its metabolites.

Flutamide should be used with care in patients with cardiovascular disease because of the possibility of fluid retention. It should also be used with caution in patients with hepatic impairment and is contra-indicated in those with severe impairment. Regular liver function testing is recommended in all patients: therapy should be stopped or dosage reduced if there is evidence of hepatotoxicity.

Effects on the blood. A report[1] of methaemoglobinaemia in an elderly man was attributed to flutamide. A study[2] of 45 patients given flutamide found no cases of methaemoglobinaemia, but the authors noted a further 3 published case reports.

2. Schulz M, *et al.* Lack of methemoglobinemia with flutamide. *Ann Pharmacother* 2001; **35:** 21–5.

Effects on the liver. Hepatitis occurred in a 79-year-old man taking flutamide 750 mg daily as sole therapy after a prostatectomy,[1] but a subsequent study[2] in 1091 patients given flutamide 250 mg three times daily as part of a regimen for prostate cancer found marked signs of liver damage only in 4, of whom only 2 had clinical evidence of hepatotoxicity. In the USA, the FDA had 46 reports of patients with hepatotoxicity associated with flutamide up to December 1994. Of these patients, 20 died from progressive liver disease.[3] Further cases have continued to be reported.[4-6] Early tapering of the dose, stopping therapy, or switching to another anti-androgen may resolve hepatotoxic effects.[7] Patients with chronic viral hepatitis may be at higher risk of developing hepatotoxicity with anti-androgen therapy.[8]

8. Pu Y-S, *et al.* Antiandrogen hepatotoxicity in patients with chronic viral hepatitis. *Eur Urol* 1999; **36:** 293–7.

Effects on the lungs. In a review[1] of 78 cases of pneumonitis reported to the FDA between 1998 and 2000 that were associated with bicalutamide, flutamide, or nilutamide, it was found that 14 patients had died of respiratory failure. It was estimated that the incidence of pneumonitis was highest for nilutamide (0.77%), but lower for flutamide (0.04%) and bicalutamide (0.01%).

1. Bennett CL, *et al.* Pneumonitis associated with nonsteroidal antiandrogens: presumptive evidence of a class effect. *Ann Intern Med* 2002; **137:** 625.

Effects on the skin. Photosensitivity reactions have been reported in patients receiving flutamide.[1,2] Some consider it to be an early manifestation of SLE.[2]

1. Fujimoto M, *et al.* Photosensitive dermatitis induced by flutamide. *Br J Dermatol* 1996; **135:** 496–7.
2. Kaur C, Thami GP. Flutamide-induced photosensitivity: is it a forme fruste of lupus? *Br J Dermatol* 2003; **148:** 603–4.

Gynaecomastia. Gynaecomastia (p.2092) and breast pain are frequent adverse effects of nonsteroidal anti-androgens used to treat prostate cancer. Nearly 90% of patients treated with bicalutamide in the Early Prostate Cancer programme experienced breast pain, gynaecomastia, or both.[1] Some patients who develop gynaecomastia will accept it as a tolerable adverse effect of therapy but others will require specific treatment, and a number of different measures have been tried for both prevention and treatment. The risk of breast changes can be reduced by the use of prophylactic low-dose irradiation of the breast area before nonsteroidal anti-androgen therapy is started. However, skin irritation can occur, and the long-term risk for development of breast cancer is unknown. Irradiation is unlikely to be effective once breast enlargement has occurred but it can help to reduce pain. Empirical use of oral analgesics or topical local anaesthetics may be considered for breast pain. Specific surgical treatment to reduce breast tissue includes liposuction and breast tissue excision.[2,3]

Hormonal therapy using tamoxifen or anastrozole has been suggested, largely based on reports of benefit in various patient groups with gynaecomastia.[1,2] Two randomised controlled studies[4,5] of men who were treated with bicalutamide for prostate cancer found that prophylactic tamoxifen was effective for the prevention of gynaecomastia and breast pain, but that anastrozole was no better than placebo. One of these studies[5] also assessed the use of these drugs as treatment and found that gynaecomastia and breast pain resolved in at least 65% of patients treated with tamoxifen, but only in about 18% of those treated with anastrozole. Tamoxifen is considered to be more effective than radiotherapy for prevention of gynaecomastia.[3]

Interactions

Flutamide may increase the effect of warfarin, see Antineoplastics, p.1429.

Pharmacokinetics

Flutamide is reported to be rapidly and completely absorbed from the gastrointestinal tract with peak plasma concentrations occurring 1 hour after a dose. It is rapidly and extensively metabolised; the major metabolite (2-hydroxyflutamide) possesses anti-androgenic properties. The half-life of the metabolite is about 6 hours. Both flutamide and 2-hydroxyflutamide are more than 90% bound to plasma proteins. Excretion is mainly in the urine with only minor amounts appearing in the faeces.

◊ References.

1. Radwanski E, *et al.* Single and multiple dose pharmacokinetic evaluation of flutamide in normal geriatric volunteers. *J Clin Pharmacol* 1989; **29:** 554–8.

Uses and Administration

Flutamide is a nonsteroidal compound with anti-androgenic properties which appears to act by inhibiting the uptake and/or binding of androgens in target tissues. It is used, usually with gonadorelin analogues, in the palliative treatment of prostatic carcinoma (p.671). The usual oral dose is 250 mg three times daily. When used in combination therapy UK licensed product information recommends that flutamide treatment should be started at least 3 days before the gonadorelin analogue to suppress any 'flare' reaction; however, in some other countries it is recommended that treatment with both agents be begun simultaneously for optimum effect.

Congenital adrenal hyperplasia. For mention of the use of flutamide with testolactone to block androgenic effects in congenital adrenal hyperplasia, see p.1502.

Hirsutism. Anti-androgens (usually cyproterone or spironolactone) are widely used for the drug treatment of hirsutism (p.2089). Flutamide has no particular advantage in this context;[1,2] one study has found flutamide to be more effective than spironolactone in inhibiting hirsutism,[3] but others found them to be of similar efficacy,[4,5] and the risk of hepatotoxicity with flutamide is a problem.[2] Nonetheless, flutamide has continued to be investigated.[6-8]

Malignant neoplasms. Androgen blockade, which may include the use of flutamide, is used in the management of metastatic hormone-responsive prostate cancer (p.671); once the cancer begins to progress despite such therapy, stopping flutamide occasionally produces paradoxical disease regression. Promising preliminary results have also followed the use of flutamide in patients with adenocarcinoma of the pancreas (p.671).

Polycystic ovary syndrome. Flutamide has been used, usually with metformin, in the management of polycystic ovary syndrome (p.2080);[1-4] additive effects have been reported with this combination.

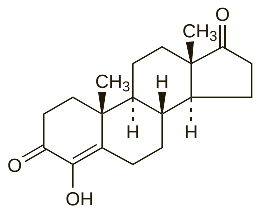
Formestane *(BAN, rINN)* ⊗

CGP-32349; Formestaani; Formestan; Formestano; Formestanum; 4-Hydroxyandrostenedione; 4-OHA; 4-OHAD. 4-Hydroxyandrost-4-ene-3,17-dione.

Форместан

$C_{19}H_{26}O_3$ = 302.4.
CAS — 566-48-3.
ATC — L02BG02.
ATC Vet — QL02BG02.



Adverse Effects, Treatment, and Precautions

The most frequent adverse effects of formestane are local irritation and pain at the site of injection. Patients may experience hot flushes due to oestrogen deprivation. Other occasional or rare adverse effects include rashes and pruritus, alopecia or hypertrichosis, drowsiness, dizziness, emotional lability, oedema of the leg, thrombophlebitis, vaginal spotting or bleeding, gastrointestinal disturbances, pelvic or muscle cramps, arthralgia, exacerbation of bone pain, and a vasovagal reaction. Hypersensitivity reactions to the drug or the formulation have occurred.

Care should be taken to avoid intravascular injection. Injection into or near the sciatic nerve may result in pain and nerve trauma. Caution is required if patients drive or operate machinery.

Effects on carbohydrate metabolism. Recurrent hypoglycaemic episodes developed in a diabetic patient previously well maintained on gliclazide after addition of formestane to treatment for metastatic breast cancer.[1] Episodic hypoglycaemia continued after dosage reduction, and eventually withdrawal, of gliclazide, suggesting that the effect was not simply an interaction with the sulfonylurea.

1. Brankin E, *et al.* Hypoglycaemia associated with formestane treatment. *BMJ* 1997; **314:** 869.

Pharmacokinetics

Intramuscular formestane is reported to form a depot that slowly releases active drug into the systemic circulation; maximum plasma concentrations occur about 30 to 48 hours after a single dose and then decline fairly rapidly over 2 to 4 days before declining more slowly, with an apparent elimination half-life of 5 to 6 days. The systemic uptake has been estimated at 20 to 25% of the dose in 14 days. Formestane is about 85% bound to plasma protein in the circulation. It is metabolised by conjugation to the inactive glucuronide: less than 1% of the dose is excreted in urine unchanged.

Uses and Administration

Formestane is an inhibitor of the aromatase (oestrogen synthetase) system which is responsible for the production of oestrogens from androgens. It has been used for its anti-oestrogenic properties in the endocrine treatment of advanced breast cancer in postmenopausal women (p.661).

It is given by intramuscular injection, as an aqueous suspension, in doses of 250 mg every 2 weeks. Injections should be given into each buttock alternately.

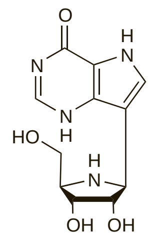
CAS — 209799-67-7 (forodesine); 284490-13-7 (forodesine hydrochloride).



(forodesine)

Profile

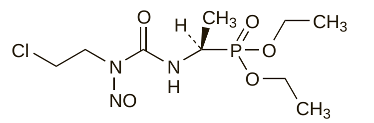
Forodesine is an inhibitor of purine nucleoside phosphorylase. It is under investigation in the treatment of T-cell lymphomas, chronic lymphocytic leukaemia, and acute lymphoblastic leukaemia.

Fotemustine *(BAN, rINN)*

Fotemustin; Fotemustina; Fotémustine; Fotemustinum; S-10036. (±)-Diethyl {1-[3-(2-chloroethyl)-3-nitrosoureido]ethyl}phosphonate.

Фотемустин

$C_9H_{19}ClN_3O_5P$ = 315.7.
CAS — 92118-27-9.
ATC — L01AD05.
ATC Vet — QL01AD05.



Profile

Fotemustine is a nitrosourea derivative and alkylating agent with actions similar to those of carmustine (p.694). It is used in the treatment of disseminated malignant melanoma, particularly where cerebral metastases are present (p.673) and has been tried in primary malignancies of the brain (p.660). When used as a single agent it is licensed for intravenous or intra-arterial infusion in usual doses of 100 mg/m^2 weekly for 3 weeks to induce remission, followed after 4 to 5 weeks, if blood counts permit, by maintenance dosage with 100 mg/m^2 every 3 weeks. Intravenous infusions are given over 1 hour and intra-arterial infusions over 4 hours. Liver function should be monitored regularly during induction treatment. Regular blood counts should be taken and dosage should be reduced or withheld if white cell or platelet counts are below acceptable levels (see also Bone-marrow Depression, p.639). Bone-marrow suppression may be delayed, with the nadir of the white cell counts 5 or 6 weeks after dosing. Solutions for infusion must be freshly prepared and protected from light.

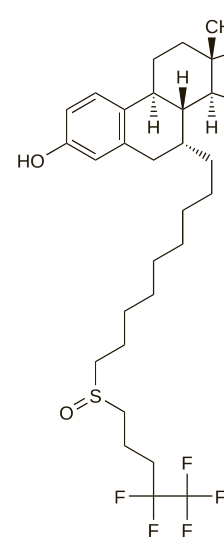
Fulvestrant *(BAN, USAN, rINN)* ⊗

Fulvestrantum; ICI-182780; ZD-9238. 7α-[9-(4,4,5,5,5-Pentafluoropentylsulfinyl)nonyl]estra-1,3,5(10)-triene-3,17β-diol.

Фульвестрант

$C_{32}H_{47}F_5O_3S$ = 606.8.
CAS — 129453-61-8.
ATC — L02BA03.
ATC Vet — QL02BA03.



Pharmacopoeias. In *US.*

USP 31 (Fulvestrant). A mixture of the diastereoisomers A and B. A white powder. Freely soluble in alcohol. Store at a temperature of 2° to 8°. Protect from light.

Adverse Effects and Precautions

The most commonly reported adverse effects of fulvestrant are nausea, vomiting, constipation, diarrhoea, abdominal pain, headache, back pain, hot flushes, and pharyngitis. Injection site reactions can occur. Other adverse effects include rash, asthenia, urinary-tract infections, venous thromboembolism, and elevations in liver enzyme values. Myalgia, vertigo, and leucopenia have been reported. Hypersensitivity reactions, including angioedema and urticaria, can occur. Vaginal bleeding has been reported rarely. Fulvestrant should be given with caution to those with severe renal impairment (creatinine clearance less than 30 mL/minute) and in those with mild to moderate hepatic impairment; use is contra-indicated in those with severe hepatic impairment. In patients with bleeding tendencies, thrombocytopenia, or taking anticoagulants, fulvestrant should also be used with caution, if at all.

Pharmacokinetics

Fulvestrant is slowly absorbed after intramuscular injection; maximum plasma concentrations are reached after about 7 days. Steady-state concentrations are reached after about 3 to 6 doses (given monthly). Fulvestrant is highly bound to plasma proteins. It is metabolised primarily in the liver to a number of metabolites, some of which have oestrogen antagonist activity, and is excreted in the faeces. After intramuscular injection fulvestrant has a half-life of about 40 to 50 days.

◊ References.

1. Robertson JFR, *et al.* Pharmacokinetic profile of intramuscular fulvestrant in advanced breast cancer. *Clin Pharmacokinet* 2004; **43:** 529–38.

Uses and Administration

Fulvestrant is an oestrogen antagonist that downregulates the oestrogen receptor and is used for the treatment of oestrogen-receptor positive, locally advanced or metastatic breast cancer in postmenopausal women (p.661); it is given when disease has relapsed or progressed during or after treatment with anti-oestrogens. The recommended dose is 250 mg, given intramuscularly at monthly intervals. It is injected into the buttock, either as a single injection or as two concurrent doses.

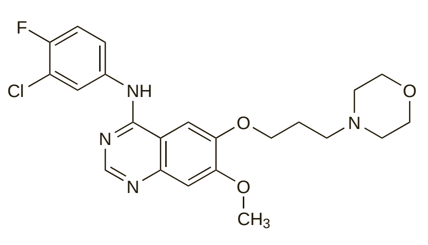
Gefitinib *(BAN, USAN, rINN)*

Géfitinib; Gefitinibum; ZD-1839. *N*-(3-Chloro-4-fluorophenyl)-7-methoxy-6-[3-(morpholin-4-yl)propoxy]quinazolin-4-amine.

Гефитиниб

$C_{22}H_{24}ClFN_4O_3$ = 446.9.
CAS — 184475-35-2.
ATC — L01XE02.
ATC Vet — QL01XE02.



Profile

Gefitinib is a selective inhibitor of the tyrosine kinase activity of the epidermal growth factor receptor. It blocks signal transduction pathways implicated in the growth of tumour cells. It is given orally for the management of locally advanced or metastatic non-small cell lung cancer (p.668) unresponsive to other therapy; the usual dose is 250 mg daily. In the USA, use is restricted to those patients who are currently receiving and benefiting from gefitinib, or to those who have previously benefited from therapy. Adverse effects include rashes and diarrhoea. There have been reports of severe diffuse parenchymal lung disease, including fatalities. There are also reports of tumour haemorrhage, sometimes fatal, after use of gefitinib in patients with head and neck cancer. Gefitinib is under investigation in the management of other solid tumours.

Effects on survival. In chemotherapy-naive patients with advanced non-small cell lung cancer, gefitinib, given with gemcitabine plus cisplatin,[1] or paclitaxel plus carboplatin,[2] showed no survival advantage over chemotherapy without gefitinib. In a large study in patients with non-small cell lung cancer given gefitinib or placebo, after failure of one or two previous treatment regimens, no survival benefit was shown with gefitinib;[3] recommendations restricting the use of gefitinib to selected patients have been made in the USA (see above).[4] However, a subset analysis of study data found an improvement in survival in a subgroup of patients of Asian origin.[5] In reports of the IMEX study in patients with head and neck cancer, no survival advantage for gefitinib was found when compared with methotrexate; an increased incidence of tumour haemorrhage was seen in those treated with gefitinib.[6] Studies have suggested that there are subgroups of patients with non-small cell lung cancer who have specific biomarkers or mutations in the epidermal growth factor receptor gene which correlate with clinical response to gefitinib.[7-10]

A small retrospective study found that further treatment with gefitinib prolonged survival in patients who were initially responsive, but who had subsequent disease progression upon stopping therapy.[11]

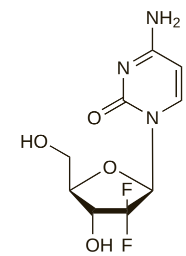
Gemcitabine Hydrochloride

(BANM, USAN, rINNM)

Gemcitabine, chlorhydrate de; Gemcitabini hydrochloridum; Hidrocloruro de gemcitabina; LY-188011 (gemcitabine). 4-Amino-1-(2-deoxy-2,2-difluoro-β-D-ribofuranosyl)pyrimidin-2(1*H*)-one hydrochloride; 2′-Deoxy-2′,2′-difluorocytidine hydrochloride.

Гемцитабина Гидрохлорид

$C_9H_{11}F_2N_3O_4,HCl$ = 299.7.
CAS — 95058-81-4 (gemcitabine); 122111-03-9 (gemcitabine hydrochloride).
ATC — L01BC05.
ATC Vet — QL01BC05.



(gemcitabine)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Gemcitabine Hydrochloride). A white or almost white powder. Soluble in water; slightly soluble in methyl alcohol; practically insoluble in acetone. A 1% solution in water has a pH of 2.0 to 3.0.

USP 31 (Gemcitabine Hydrochloride). A white to off-white solid. Soluble in water; practically insoluble in alcohol and in polar organic solvents; slightly soluble in methyl alcohol. pH of a 1% solution in water is between 2.0 and 3.0. Store in airtight containers.

Incompatibility. Gemcitabine hydrochloride was reported to be physically incompatible with aciclovir sodium, amphotericin B, cefoperazone sodium, cefotaxime sodium, furosemide, ganciclovir sodium, imipenem with cilastatin sodium, irinotecan, methotrexate sodium, methylprednisolone sodium succinate, mezlocillin sodium, mitomycin, piperacillin sodium, piperacillin sodium with tazobactam, and prochlorperazine edisilate during simulated Y-site administration.[1]

1. Trissel LA, *et al.* Compatibility of gemcitabine hydrochloride with 107 selected drugs during simulated Y-site injection. *J Am Pharm Assoc* 1999; **39:** 514–18.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

The major dose-limiting adverse effect of gemcitabine is bone-marrow depression, although this is reported to be modest and rarely requires stopping therapy. Gastrointestinal disturbances occur, especially nausea and vomiting, but these are usually of mild to moderate severity. Rashes, often associated with pruritus, and flu-like symptoms are relatively common. Oedema, dyspnoea, and alopecia are also commonly reported. Pulmonary oedema has been reported infrequently; interstitial pneumonitis, pulmonary fibrosis, and acute respiratory distress syndrome have occurred. Therapy should be stopped if pulmonary toxicity occurs. There are rare cases of hypotension, anaphylactoid reactions, and severe desquamative and bullous skin eruptions. Haematuria, proteinuria, transient liver enzyme elevations, and serious hepatotoxicity, including liver failure and death, have been reported. It should therefore be used with caution in patients with impaired renal or hepatic function. Haemolytic-uraemic syndrome and/or thrombocytopenic purpura have been reported and have led to irreversible renal failure; gemcitabine should be stopped at the first signs of microangiopathic haemolytic anaemia. Congestive heart failure, myocardial infarction, or arrhythmias may occur rarely.

Gemcitabine may produce somnolence: patients so affected should not drive or operate machinery. Severe toxicity, in the form of potentially life-threatening oesophagitis and pneumonitis has been seen in patients given radical radiotherapy to the thorax concurrently with gemcitabine.

Effects on the nervous system. A report of autonomic neuropathy associated with gemcitabine therapy.[1] Symptoms resolved 4 weeks after stopping therapy.

1. Dormann AJ, *et al.* Gemcitabine-associated autonomic neuropathy. *Lancet* 1998; **351:** 644.

Effects on the skin. A patient who received gemcitabine 1 week after having had phototherapy developed a severe sunburn reaction in those areas exposed to UVB. The erythema resolved spontaneously, but recurred with each subsequent dose of gemcitabine, and became progressively more intense. A short course of high-dose prednisone was given with topical triamcinolone, and the patient was safely rechallenged with 2 further doses of gemcitabine.[1]

1. Badger J, *et al.* Photo therapy recall with gemcitabine following ultraviolet B treatment. *J Clin Oncol* 2005; **23:** 7224–5.

Peripheral ischaemia. Pain, coldness, colour changes, and distal claudication in the feet have been reported in patients treated with gemcitabine and cisplatin.[1] Pain and colour changes in the fingertips have also been reported after gemcitabine monotherapy.[2]

1. Barceló R, *et al.* Distal ischemic changes related to combination chemotherapy with cisplatin and gemcitabine: description of four cases. *Ann Oncol* 2000; **11:** 1191–4.
2. Yildiz R, *et al.* Digital ischemic changes after gemcitabine therapy in a patient with metastatic non-small-cell lung cancer. *Ann Pharmacother* 2007; **41:** 901–2.

Interactions

Antineoplastics. In a study[1] of 14 patients with lung cancer, the use of *paclitaxel* before gemcitabine caused a decrease in the systemic clearance, volume of distribution, and interpatient pharmacokinetic variability of gemcitabine. This resulted in plasma concentrations of gemcitabine slightly higher than the desired range. However, there was no apparent relationship between pharmacokinetic changes and toxicity, and the clinical significance of this possible interaction is unclear.

A trial investigating a modified chemotherapy regimen in which gemcitabine was substituted for etoposide was stopped because of unexpected pulmonary toxicity. This was considered to be due to the combination of gemcitabine and *bleomycin*, as the adverse effect was apparent in other studies using this combination.[2]

1. Shord SS, *et al.* Gemcitabine pharmacokinetics and interaction with paclitaxel in patients with advanced non-small-cell lung cancer. *Cancer Chemother Pharmacol* 2003; **51:** 328–36.
2. Bredenfeld H, *et al.* Severe pulmonary toxicity in patients with advanced-stage Hodgkin's disease treated with a modified bleomycin, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone, and gemcitabine (BEACOPP) regimen is probably related to the combination of gemcitabine and bleomycin: a report of the German Hodgkin's lymphoma study group. *J Clin Oncol* 2004; **22:** 2424–9.

Pharmacokinetics

After intravenous doses gemcitabine is rapidly cleared from the blood and metabolised by cytidine deaminase in the liver, kidney, blood, and other tissues. Clearance is about 25% lower in women than in men. Almost all of the dose is excreted in urine as 2′-deoxy-2′,2′-difluorouridine (dFdU), only about 1% being found in the faeces. Intracellular metabolism produces mono-, di-, and triphosphate metabolites, the latter two active. The half-life of gemcitabine ranges from 42 to 94 minutes depending on age and gender. The intracellular half-life of the triphosphate is stated to range from 0.7 to 12 hours.

Uses and Administration

Gemcitabine is an analogue of cytarabine (p.705) that is metabolised intracellularly to active diphosphate and triphosphate nucleosides, which inhibit DNA synthesis and induce apoptosis. It is primarily active against cells in S phase. It is given in the management of solid tumours including those of the bladder, breast, lung, ovary, and pancreas (see p.659, p.661, p.668, p.670, and p.671, respectively).

Gemcitabine is given intravenously as the hydrochloride. Doses are calculated in terms of the base; gemcitabine hydrochloride 1.14 g is equivalent to about 1 g of gemcitabine. Doses are reconstituted in sodium chloride 0.9%. The concentration of the infusion solution should not exceed the equivalent of gemcitabine 40 mg/mL. Gemcitabine is given by infusion over 30 to 60 minutes; doses are subsequently adjusted according to response and toxicity.

In the treatment of **pancreatic cancer**, an initial course of gemcitabine 1 g/m^2 once weekly for up to 7 weeks may be given, followed after a one-week recovery period by a regimen of infusions once weekly for 3 consecutive weeks out of 4.

In **non-small cell lung cancer**, gemcitabine may be given as a single agent; 1 g/m^2 once weekly for 3 consecutive weeks out of 4 is recommended. Alternatively, it may be given before cisplatin. Two schedules have been used; gemcitabine 1.25 g/m^2 is given on days 1 and 8 of a 21-day cycle, or gemcitabine 1 g/m^2 is given on days 1, 8 and 15 of a 28-day cycle.

In the treatment of **bladder cancer**, gemcitabine is given before cisplatin. The recommended dose of gemcitabine is 1 g/m^2 on days 1, 8, and 15 of a 28-day cycle.

In **breast cancer**, gemcitabine is usually given after a taxane such as paclitaxel. A dose of gemcitabine 1.25 g/m^2 is given on days 1 and 8 of a 21-day cycle.

In **ovarian cancer**, gemcitabine is given before carboplatin. The recommended dose of gemcitabine is 1 g/m^2 on days 1 and 8 of a 21-day cycle.

Gemtuzumab Ozogamicin *(USAN, rINNM)*

CDP-771; CMA-676; Gemtuzumab ozogamicina; Gemtuzumab Ozogamicine; Gemtuzumab Zogamicin; Gemtuzumabum Ozogamicinum; WAY-CMA-676. Immunoglobulin G4 (human-mouse monoclonal hP67.6 κ4-chain anti-human antigen CD 33), disulfide with human-mouse monoclonal hP67.6 κ-chain, dimer conjugate with ozogamicin.

Гемтузумаб Озогамицин

CAS — 220578-59-6.

ATC — L01XC05.

ATC Vet — QL01XC05.

Adverse Effects and Precautions

For general discussions see Antineoplastics, p.635 and p.641.

Myelosuppression is common with gemtuzumab ozogamicin, and thrombocytopenia may be prolonged. Infusion-related reactions characteristic of a cytokine release syndrome (including fever, chills, dyspnoea, and hypotension) and hypersensitivity may occur; prophylactic use of an antihistamine and paracetamol is recommended. Pulmonary sequelae may be fatal. Hepatotoxicity, including severe veno-occlusive disease, has also been reported. Electrolyte imbalances, especially hypokalaemia and hypomagnesaemia, and gastrointestinal disturbances may occur.

Blood and platelet counts, electrolytes, and liver function tests should be regularly monitored.

Hypersensitivity. A 75-year-old man with acute myeloid leukaemia developed severe respiratory distress and died after being given gemtuzumab ozogamicin and platelets on the same day. He had previously had the drug and platelets on separate occasions with no untoward effects. It was suggested that this combination contributed to a fatal hypersensitivity reaction.[1]

1. Hanbali A, *et al.* Fatal hypersensitivity reaction to gemtuzumab ozogamicin associated with platelet transfusion. *Am J Health-Syst Pharm* 2007; **64:** 1401–2.

Uses and Administration

Gemtuzumab ozogamicin is a recombinant humanised monoclonal antibody conjugated with calicheamicin, a cytotoxic antibiotic. The antibody binds specifically to the CD33 antigen, which is expressed on leukaemic myeloblasts but not normal haematopoietic stem cells. Gemtuzumab ozogamicin is licensed for the second-line treatment of CD33-positive acute myeloid leukaemia (p.652) in elderly patients who are unable to tolerate conventional chemotherapy. It is given in 100 mL of sodium chloride 0.9% via an in-line 1.2 micron filter. The licensed dose is 9 mg/m^2 given by intravenous infusion over 2 hours, repeated once after 14 days. Lower doses are under investigation as part of combined induction or consolidation regimens.

Hydroxycarbamide *(BAN, rINN)*

Hidroksikarbamid; Hidroksikarbamidas; Hidroxicarbamida; Hidroxikarbamid; Hydroksikarbamidi; Hydroksiüre; Hydroxikarbamid; Hydroxycarbamidum; Hydroxymočovina; Hydroxyurea *(USAN)*; NSC-32065; SQ-1089; WR-83799.

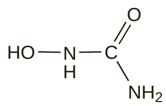
Гидроксикарбамид

NH_2.CO.NHOH = 76.05.

CAS — 127-07-1.

ATC — L01XX05.

ATC Vet — QL01XX05.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Hydroxycarbamide). A white or almost white, hygroscopic, crystalline powder. It exhibits polymorphism. Freely soluble in water; practically insoluble in alcohol. Store in airtight containers. Protect from light.

USP 31 (Hydroxyurea). A white to off-white powder. It is somewhat hygroscopic and decomposes in the presence of moisture. Freely soluble in water and in hot alcohol. Store in airtight containers in a dry atmosphere.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

Bone-marrow suppression, including megaloblastic changes, is the main adverse effect of hydroxycarbamide. The erythema caused by irradiation may be exacerbated. Other adverse effects reported have included gastrointestinal disturbances, impairment of renal function, pulmonary oedema, dermatological reactions, alopecia, and neurological reactions such as headache, dizziness, drowsiness, disorientation, hallucinations, and convulsions. There are rare reports of acute pulmonary reactions consisting of pulmonary infiltrates or fibrosis, dyspnoea and fever. Symptoms resembling cutaneous vasculitis, including vasculitic ulcerations and gangrene, have occurred in patients with myeloproliferative disorders treated with hydroxycarbamide, especially in those also given interferon. There are reports of hepatotoxicity and pancreatitis, some fatal, in patients with HIV infection, given hydroxycarbamide and antiretrovirals (see also HIV Infection and AIDS, below); peripheral neuropathy has also occurred.

Pre-existing anaemia should be corrected before beginning therapy with hydroxycarbamide and the haemoglobin concentration, white cell and platelet counts, and hepatic and renal function should be determined repeatedly during treatment. Treatment should be interrupted if the white cell or platelet count fall below acceptable levels (see also Bone-marrow Depression, p.639). If anaemia occurs when hydroxycarbamide is used as an antineoplastic, it may be corrected by transfusions of whole blood without stopping therapy. If anaemia (haemoglobin less than 4.5 g per 100 mL, or reticulocyte count less than 80 000 cells/mm^3 when haemoglobin is less than 9 g per 100 mL) occurs when the drug is used for sickle-cell disease, therapy should be interrupted. Megaloblastic changes are usually self-limiting.

Hydroxycarbamide should be used with caution in patients with impaired renal function. Uric acid concentrations should be monitored, and a high fluid intake maintained during treatment. The elderly may be more sensitive to its adverse effects.

Breast feeding. In breast-milk samples from a woman given hydroxycarbamide 500 mg three times daily, the mean concentration of the drug was found to be about 6 mg/litre. It was estimated that, had the infant been breast-fed, it would have received about 3 to 4 mg daily. Although this amount appears to be low, women are advised not to breast feed while taking hydroxycarbamide.[1]

1. Sylvester RK, *et al.* Excretion of hydroxyurea into milk. *Cancer* 1987; **60:** 2177–8.

Carcinogenicity. Secondary leukaemias have occurred in patients receiving hydroxycarbamide for myeloproliferative disorders, although the extent to which this is due to the treatment or the underlying disorder is unknown.

Skin cancers have also been associated with its use. These are often multiple and include both squamous cell and basal cell carcinomas.

4. Best PJM, Petitt RM. Multiple skin cancers associated with hydroxyurea therapy. *Mayo Clin Proc* 1998; **73:** 961–3.

Effects on the liver. Fever and hepatitis have been reported[1,2] in patients receiving hydroxycarbamide. Symptoms recurred when patients were rechallenged with the drug.

1. Heddle R, Calvert AF. Hydroxyurea induced hepatitis. *Med J Aust* 1980; **1:** 121.
2. Westerman DA, *et al.* Hydroxyurea-induced fever and hepatitis. *Aust N Z J Med* 1998; **28:** 657–9.

Effects on the skin and nails. Reports of skin reactions with hydroxycarbamide include hyperpigmentation of the skin,[1] and of nails (melanonychia).[2]

Hydroxycarbamide therapy has been associated with scaly erythematous skin lesions often resembling those of dermatomyositis.[1,3,4] Such lesions usually occur after several years of treatment and the course is usually benign. However, withdrawal of the drug is usually necessary for healing or improvement, in which case resolution may take several months.[1,4] Hydroxycarbamide can also cause painful leg ulcers, often on the malleoli, which may require stopping treatment.[1,5,6] Leg ulcers often coexist with dermatomyositis-like eruptions and may be caused by the same mechanism,[7] although mechanical injury may have a role in malleolar ulceration.[5] Licensed product information notes that vasculitic toxicities, including vasculitic ulceration and gangrene, have been associated with hydroxycarbamide use in patients with myeloproliferative disorders (particularly if also given interferon). However, histologically, perivascular lymphocytic infiltration without vasculitis has been reported in both early dermatomyositis-like lesions[1] and in leg ulcers.[5,8]

Skin cancers have also occurred, see Carcinogenicity above.

Interactions

For a general discussion of antineoplastic drug interactions, see p.642.

Pharmacokinetics

Hydroxycarbamide is readily absorbed from the gastrointestinal tract and distributed throughout the body. Peak plasma concentrations are reached within 2 hours. Up to 50% of a dose is metabolised by the liver; hydroxycarbamide is excreted in urine as metabolites and unchanged drug. Some is excreted as carbon dioxide via the lungs. About 80% of a dose is reported to be excreted in the urine within 12 hours. Hydroxycarbamide crosses the blood-brain barrier and the placenta, and is distributed into breast milk.

Uses and Administration

Hydroxycarbamide is an antineoplastic that may cause inhibition of DNA synthesis by acting as a ribonucleotide reductase inhibitor. It is S-phase specific. Hydroxycarbamide is used in the treatment of chronic myeloid leukaemia, and may be used in the myeloproliferative disorders polycythaemia vera and primary (essential) thrombocythaemia. It has also been tried, often combined with radiotherapy, in some solid malignancies (see Malignant Neoplasms, below). Hydroxycarbamide has also produced benefit in the haemoglobinopathies, particularly in sickle-cell disease (see below).

In the treatment of chronic myeloid leukaemia and solid tumours, hydroxycarbamide is given orally, typically in a single dose of 20 to 30 mg/kg daily or in a single dose of 80 mg/kg every third day. Generally, the continuous regimen is used for chronic myeloid leukaemia, and the intermittent regimen for solid tumours. When used with radiotherapy, hydroxycarbamide is started 7 days before radiotherapy. If a beneficial effect is evident after 6 weeks, therapy may be continued indefinitely.

In essential thrombocythaemia, the initial dose of hydroxycarbamide is about 15 mg/kg daily; starting doses of 15 to 20 mg/kg daily are recommended for polycythaemia vera. Doses are subsequently adjusted according to platelet counts.

In sickle-cell disease initial doses of 15 mg/kg daily are suggested, increased if necessary by 5 mg/kg daily every 12 weeks according to response and blood counts, up to a maximum of 35 mg/kg daily. The *BNFC* recommends 10 to 20 mg/kg once daily initially for children aged from 1 to 18 years; increments thereafter are similar to those for adults.

Blood counts and hepatic and renal function should be monitored during therapy; treatment may need to be interrupted if leucopenia or thrombocytopenia occur (see Adverse Effects, Treatment, and Precautions, above).

Administration in renal impairment. Results from a single-dose study in patients with sickle-cell disease indicated that systemic exposure to hydroxycarbamide correlates to renal function.[1] An initial dose of 7.5 mg/kg daily was suggested for patients with sickle-cell disease and a creatinine clearance of less than 60 mL/minute.

1. Yan J-H, *et al.* The influence of renal function on hydroxyurea pharmacokinetics in adults with sickle cell disease. *J Clin Pharmacol* 2005; **45:** 434–45.

Haemoglobinopathies. Hydroxycarbamide is considered a promising treatment for the haemoglobinopathies. It can stimulate fetal haemoglobin production, which in turn can reduce haemoglobin polymerisation and the numbers of deformed, dense, and damaged erythrocytes.[1] In adult patients with **sickle-cell disease** (p.1044), a randomised controlled study produced evidence that initial doses of 15 mg/kg daily, adjusted according to response and tolerance to up to 35 mg/kg daily, reduced the rate of sickle-cell crisis compared with placebo.[2] An observational follow-up study[3] of this group found that patients taking hydroxycarbamide for frequent sickle-cell episodes appeared to have reduced mortality. A report in 2 adults has suggested that it might reverse splenic dysfunction.[4] A systematic review[5] has noted that despite the benefits, the paucity of long-term studies limits conclusions on the toxicity of treatment with hydroxycarbamide.

Despite some concerns about giving a potential carcinogen to children,[6] studies in paediatric populations have also reported evidence of benefit in terms of decreased hospitalisation[7,8] and sickle-cell crisis.[8,9] Hydroxycarbamide may be an alternative to blood transfusions in children who have had a stroke.[8,10,11] Although a small trial[12] has suggested benefit in paediatric patients in terms of splenic preservation, long-term prevention of organ damage remains to be established.[13,14]

It has been suggested that use of the drug with erythropoietin might enhance the production of fetal haemoglobin, but results from studies of the combination have been conflicting.[15,16]

There appear to have been few studies of hydroxycarbamide specifically in **thalassaemia** (p.1045). Initial oral doses of 8.2 to 10.3 mg/kg daily, increased until toxicity occurred, did produce increases in fetal haemoglobin in 3 patients, but these were not sustained.[17] Others have reported[18] that rises in fetal haemoglobin did not necessarily correlate with clinical improvement. Conversely, sustained responses have been seen in other studies.[19-22] Use with sodium phenylbutyrate has produced conflicting results.[23-25]

HIV infection and AIDS. Unlike most drugs used to treat HIV, which target viral enzymes, hydroxycarbamide inhibits ribonucleotide reductase, a host cellular enzyme that is less prone to mutation and subsequent development of resistance.[1] The drug acts synergistically with didanosine (p.870). Of 25 HIV-positive patients given didanosine 200 mg twice daily with hydroxycarbamide 15 mg/kg daily in 2 divided doses, all showed a drop in viral load and an increase in CD4+ lymphocyte count.[2] Viraemia was not detectable in 13 of 24 patients evaluated at 6 months and 10 of 20 patients evaluated at 1 year. In 2 of these patients who subsequently received no antiviral treatments for 1 year there was no viral rebound, although some proviral DNA was detected.[3] In another study in 6 patients, didanosine 200 mg twice daily with hydroxycarbamide 250 mg four times daily (suggested to be a better regimen because of the short half-life of the antineoplastic) produced a sharp decrease in viraemia, which was maintained for up to 72 weeks.[4] A rebound occurred in 1 patient on interrupting treatment but viral replication was again suppressed when treatment was restarted.

Combinations with didanosine and other HIV drugs have also been tried.[1] A controlled study[5] of hydroxycarbamide, didanosine, and stavudine indicated significantly enhanced activity when the antivirals were used with the antineoplastic rather than placebo. However, in a long-term follow-up[6] there was a high withdrawal rate amongst patients receiving this combination, due to virological failure and adverse effects such as peripheral neuropathy and fatigue. Another study[7] (ACTG 5025) was terminated due to the high risk of toxicity, including fatal pancreatitis, in patients receiving the hydroxycarbamide regimens. The authors noted that the use of a higher daily dosage of 1200 mg of hydroxycarbamide (rather than the usual 1000 mg daily) and increased exposure to didanosine (itself associated with pancreatitis) may have contributed to toxicity. An analysis of 2613 patients[8] determined that the use of hydroxycarbamide with didanosine, or didanosine and stavudine, resulted in a fourfold increase in the risk for development of pancreatitis, compared to didanosine alone. In a study of patients who had failed protease-inhibitor based regimens,[9] the addition of the antineoplastic to reverse transcriptase inhibitor-based therapy significantly improved virologic response. Despite an increased incidence of adverse events associated with its use, hydroxycarbamide was considered to be a valuable alternative in these patients. A small randomised study[10] of patients with chronic HIV infection given structured treatment interruptions with cycles of HAART, or HAART and hydroxycarbamide, found that use of the latter decreased viral load. There is some suggestion that a lower dose of hydroxycarbamide (300 mg twice daily) may have better antiretroviral activity, and fewer adverse effects, than higher doses.[11] For further discussion of the management of HIV infection and AIDS, see p.856.

Malignant neoplasms. Hydroxycarbamide is used in the treatment of chronic myeloid leukaemia (p.653), and may be used in the myeloproliferative disorders polycythaemia vera (p.654) and primary (essential) thrombocythaemia (p.654). Hydroxycarbamide has been tried, often with radiotherapy, in some solid malignancies such as tumours of the cervix (p.663), head and neck (p.666), and ovary (p.670).

Psoriasis. An immunosuppressant (usually methotrexate or ciclosporin) may be useful in patients with severe refractory psoriasis (p.1583). Hydroxycarbamide has also been tried, although experience is limited.[1,2]

Ibritumomab Tiuxetan *(BAN, USAN, rINN)*

Ibritumomab tiuxetán; Ibritumomab Tiuxétan; Ibritumomabum Tiuxetanum; IDEC-129; IDEC-Y2B8. Immunoglobulin G1, anti(human CD20 (antigen))(mouse monoclonal IDEC-Y2B8 γ1-chain), disulfide with mouse monoclonal IDEC-Y2B8 κ-chain, dimer tiuxetan conjugate.

Ибритумомаб Тиуксетан

CAS — 206181-63-7.

Adverse Effects and Precautions

For general discussions, see Antineoplastics, p.635 and p.641.

Myelosuppression is common after doses of ibritumomab tiuxetan, and may be prolonged. Fatal intracranial haemorrhage has occurred. Infections and hypersensitivity reactions may also be severe. As ibritumomab tiuxetan is given with rituximab, severe infusion reactions due to the cytokine release syndrome may occur (see under Rituximab, p.767). Severe cutaneous and mucocutaneous reactions, some fatal, have been reported and therapy should be stopped if they occur. Gastrointestinal disturbances are common. Other adverse effects include anorexia, asthenia, fever, cough, dyspnoea, dizziness, headache, insomnia, anxiety, arthralgia, myalgia, and peripheral oedema. Patients should be monitored for signs of extravasation in order to avoid radiation-associated tissue damage. If extravasation occurs, the infusion should be stopped immediately and restarted in another vein.

Complete blood and platelet counts should be monitored weekly, or more frequently if cytopenia is present, until haematological recovery. Ibritumomab tiuxetan should not be given to patients with extensive marrow involvement, impaired bone marrow reserve, or platelet or neutrophil counts below acceptable levels (see also Bone-marrow Depression, p.639). Care should be taken during and after radiolabelling with indium-111 or yttrium-90 to minimise radiation exposure.

Effects on the skin. Severe cutaneous and mucocutaneous reactions have been reported after use of ibritumomab tiuxetan with rituximab, some of them with a fatal outcome.[1,2] Reactions included erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis, bullous dermatitis, and exfoliative dermatitis. Onset was reported to vary from days to months. Treatment should be stopped if any patient experiences such a reaction.

Uses and Administration

Ibritumomab is a murine monoclonal antibody to CD20 antigen, which is conjugated with tiuxetan to provide a chelation site for radioactive isotopes. Radiolabelled ibritumomab tiuxetan is used in the treatment of relapsed or refractory, low-grade or follicular B-cell non-Hodgkin's lymphoma (p.656). Patients are pretreated with a low dose of rituximab (p.767). In the USA this is followed by slow intravenous injection of ibritumomab tiuxetan chelated with indium-111 (p.2054) for imaging to confirm that biodistribution of tumour cells is acceptable. A second rituximab treatment is given 7 to 9 days after the first, followed by ibritumomab tiuxetan chelated with yttrium-90 (p.2057) for radio-immunotherapy.

Idarubicin Hydrochloride

(BANM, USAN, rINNM)

4-Demethoxydaunorubicin Hydrochloride; Hidrocloruro de idarubicina; Idarubicine, chlorhydrate d'; Idarubicinhydroklorid; Idarubicini hydrochloridum; Idarubisiinihydrokloridi; Idarubisin Hidroklorür; IMI-30; NSC-256439 (idarubicin). (7*S*,9*S*)-9-Acetyl-7-(3-amino-2,3,6-trideoxy-α-L-*lyxo*-hexopyranosyloxy)-7,8,9,10-tetrahydro-6,9,11-trihydroxynaphthacene-5,12-dione hydrochloride.

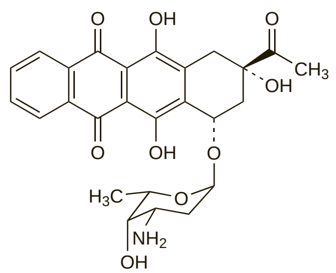
Идарубицина Гидрохлорид

$C_{26}H_{27}NO_9,HCl = 534.0.$

CAS — 58957-92-9 (idarubicin); 57852-57-0 (idarubicin hydrochloride).

ATC — L01DB06.

ATC Vet — QL01DB06.



(idarubicin)

Pharmacopoeias. In *Jpn* and *US.*

USP 31 (Idarubicin Hydrochloride). A red-orange to red-brown powder. Slightly soluble in water; insoluble in acetone and in solvent ether; soluble in methyl alcohol. A 0.5% solution in water has a pH between 5.0 and 6.5. Store in airtight containers.

Incompatibility. Licensed product information states that precipitation occurs when idarubicin hydrochloride is mixed with heparin, and that it will degrade in alkaline solution.

Adverse Effects, Treatment, and Precautions

As for Doxorubicin, p.712. Raised liver enzymes and bilirubin can occur with idarubicin. Severe enterocolitis with perforation has been reported rarely. A cumulative total dose limit has not yet been defined. UK licensed product information states that total cumulative oral doses up to 400 mg/m^2 have a low probability of cardiotoxicity, and no significant cardiotoxicity was seen in patients treated with mean cumulative intravenous doses of 93 mg/m^2. Cardiomyopathy has been reported in some patients with cumulative intravenous doses of 150 to 290 mg/m^2. It has been suggested that idarubicin may be associated with less cardiotoxicity than doxorubicin. Idarubicin should be given with caution, and in reduced doses, to patients with renal or hepatic impairment.

Effects on the skin and nails. For a report of transverse hyperpigmented bands of the nails in a patient who received idarubicin, see under Doxorubicin, p.713.

Pharmacokinetics

On intravenous dosage idarubicin is rapidly distributed into body tissues and extensively tissue bound, with a volume of distribution which may be in excess of 2000 litres. It is extensively metabolised, both in the liver and extrahepatically; the principal metabolite, idarubicinol (13-dihydroidarubicin) has equal antineoplastic activity. Peak concentrations of idarubicin and idarubicinol in bone marrow and nucleated blood cells are 400 (idarubicin) and 200 (idarubicinol) times greater than those in plasma; cellular concentrations of drug and metabolite decline with apparent terminal half-lives of 15 and 72 hours respectively, whereas plasma half-lives are reported to be 20 to 22 hours and about 45 hours respectively. Idarubicin is excreted in bile, and to a lesser extent in urine, as unchanged drug and metabolites.

Idarubicin is also absorbed orally, but estimates of its oral bioavailability vary from about 20 to 50%.

◊ References.

Uses and Administration

Idarubicin is an anthracycline antibiotic with antineoplastic actions similar to those of doxorubicin (p.714). It is used as the hydrochloride, alone or with other drugs, for the induction of remission in patients with acute myeloid leukaemias (p.652). It is also used as a second-line treatment in acute lymphoblastic leukaemia (p.651), and advanced breast cancer (p.661). It has been tried in multiple myeloma (p.658) and non-Hodgkin's lymphoma (p.656).

Idarubicin hydrochloride is given by intravenous injection into a fast-running infusion of sodium chloride 0.9% or glucose 5% over 5 to 15 minutes. The suggested dose in adult acute myeloid leukaemia is 12 mg/m^2 daily for 3 days, with cytarabine. A similar dose, as a single agent, has been given in acute lymphoblastic leukaemia. An alternative dosage schedule in acute myeloid leukaemia is 8 mg/m^2 given daily for 5 days, either alone or in combination therapy. In children with acute lymphoblastic leukaemia a dose of 10 mg/m^2 daily for 3 days as a single agent has been suggested. When the intravenous route cannot be used, idarubicin hydrochloride may be given by mouth. A suggested dose in adult acute myeloid leukaemia as a single agent is 30 mg/m^2 daily for 3 days; 15 to 30 mg/m^2 may be given daily for 3 days when used with other drugs.

In patients with refractory breast cancer idarubicin hydrochloride has been given orally in doses of 45 mg/m^2, as a single dose or divided over 3 consecutive days; the treatment may be repeated every 3 or 4 weeks depending on the haematological recovery.

Blood counts should be performed frequently in patients receiving idarubicin, and monitoring of cardiac, hepatic, and renal function is recommended. Doses should be reduced in patients with hepatic or renal impairment (for further information on the former, see below). In patients who receive a second course of idarubicin dosage should be reduced by 25% if severe mucositis developed with the first course; therapy should be delayed until the patient has recovered from this toxicity.

◊ The actions and uses of idarubicin have been reviewed.[1] A study in leukaemia cells *in vitro* suggested that idarubicin was more active than a conventional anthracycline, daunorubicin, against cells with the multidrug resistance (MDR) phenotype.[2] A collaborative overview of randomised studies for acute myeloid leukaemia found that idarubicin-based therapy achieved better remission rates and overall survival than daunorubicin-based regimens.[3] Its oral bioavailability has been suggested to offer an advantage in the management of malignancies in older patients.[4]

Administration in hepatic impairment. UK licensed product information for idarubicin hydrochloride recommends that a dose reduction be considered in patients with hepatic impairment. Although no specific doses are suggested, it is noted that a 50% reduction in dosage has been used with some other anthracyclines in patients with acute leukaemias whose bilirubin levels were between 12 and 20 micrograms/mL. Furthermore, in studies in breast cancer a 50% dosage reduction of oral idarubicin has sometimes been used in those whose bilirubin rose to 20 to 30 micrograms/mL, with withdrawal if levels rose above this. However, in other studies idarubicin was not used if bilirubin values were above 20 micrograms/mL.

In the USA, similar cautions apply but product information only suggests that idarubicin should be withheld if bilirubin levels exceed 50 micrograms/mL.

Preparations

USP 31: Idarubicin Hydrochloride for Injection.

Ifosfamid; Ifosfamida; Ifosfamidas; Ifosfamidi; Ifosfamidum; Ifoszfamid; Iphosphamide; Isophosphamide; MJF-9325; NSC-109724; Z-4942. 3-(2-Chloroethyl)-2-(2-chloroethylamino)perhydro-1,3,2-oxazaphosphorinane 2-oxide.

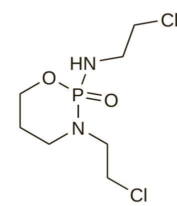
Ифосфамид

$C_7H_{15}Cl_2N_2O_2P = 261.1.$

CAS — 3778-73-2.

ATC — L01AA06.

ATC Vet — QL01AA06.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Ifosfamide). A white or almost white, hygroscopic, fine crystalline powder. Soluble in water; freely soluble in dichloromethane. Store in airtight containers.

USP 31 (Ifosfamide). A white, crystalline powder. M.p. about 40°. Freely soluble in water; very soluble in alcohol, in methyl alcohol, in isopropyl alcohol, in dichloromethane, and in ethyl acetate; very slightly soluble in hexanes. A 10% solution in water has a pH of between 4.0 and 7.0. Store in airtight containers at a temperature not exceeding 25°.

Incompatibility. Ifosfamide appears to be compatible when mixed in solution with mesna.[1,2] However, ifosfamide appears to be incompatible with benzyl alcohol used as a preservative in Water for Injections: solutions made up with water preserved in this way became turbid, with the formation of aqueous and oily phases, at concentrations of ifosfamide greater than 60 mg/mL.[3]

2. Rowland CG, *et al.* Infusion of ifosfamide plus mesna. *Lancet* 1984; **ii:** 468.
3. Behme RJ, *et al.* Incompatibility of ifosfamide with benzyl-alcohol-preserved bacteriostatic water for injection. *Am J Hosp Pharm* 1988; **45:** 627–8.

Stability. Ifosfamide undergoes a reversible chemical rearrangement in aqueous solution, which is sensitive to changes in pH.[1] The ratio of these compounds to one another in biological fluids may have a bearing on the toxicity and efficacy of ifosfamide.

1. Küpfer A, *et al.* Intramolecular rearrangement of ifosfamide in aqueous solutions. *Lancet* 1990; **335:** 1461.

Adverse Effects, Treatment, and Precautions

As for Cyclophosphamide, p.702. Toxic effects on the urinary tract may be more severe with ifosfamide and may involve the kidneys as well as the bladder. CNS adverse effects have been reported, especially confusion, drowsiness, depressive psychosis, hallucinations, and rarely, seizures.

Effects on the heart. Severe myocardial depression, with heart failure and ventricular arrhythmias, has been reported in patients given high-dose ifosfamide.[1] Symptoms were reversible with appropriate treatment in most cases although one patient died of cardiogenic shock.

1. Quezado ZMN, *et al.* High-dose ifosfamide is associated with severe, reversible cardiac dysfunction. *Ann Intern Med* 1993; **118:** 31–6.

Effects on the kidneys. In addition to its effects on the bladder ifosfamide may be associated with serious nephrotoxicity. Both proximal and distal tubular damage,[1,2] and to a lesser extent glomerular effects,[2] are seen, and the Fanconi syndrome (with development of hypophosphataemic rickets in a number of children),[2-6] and nephrogenic diabetes insipidus[1,6] may result. Progressive chronic renal failure after high-dose ifosfamide has been described.[7] Life-threatening hypokalaemia possibly due to a renal lesion has also occurred.[8] Results in *rats* suggest that generation of toxic metabolites within the kidney itself may be responsible, and that repairable renal damage occurs after the first dose, which is aggravated by repeated toxic insults.[9] This is in agreement with clinical results, since although renal damage has been seen after a single dose, perhaps representing an idiosyncratic reaction,[10,11] most cases have been in children receiving relatively high doses long-term. Renal damage appears to persist after withdrawal of ifosfamide in these patients and may be largely irreversible.[12]

A combination of younger age and high cumulative doses of ifosfamide was found to convey the highest risk of toxicity, but use with cisplatin may also increase the risk.[13] The maximum safe dose of ifosfamide has been debated.[13-15] It has been suggested that cumulative doses of ifosfamide of 100 g/m^2 or more should be avoided in children in an attempt to reduce the incidence of nephrotoxicity,[14] although subsequent reviews have suggested that lower cumulative doses may be toxic, especially in younger children.[13,15]

Effects on the nervous system. Use of ifosfamide (with mesna for urothelial protection) may be associated with the development of severe encephalopathy, with EEG abnormalities, disorientation, hallucinations, catatonia, and coma; occasionally CNS depression has led to circulatory collapse and death.[1,2] The effect has been suggested to be due to a metabolite, perhaps chloroacetaldehyde,[3] a hypothesis supported by the increased incidence of encephalopathy after oral rather than intravenous doses.[4,5] Others suggest that the dechloroethylated metabolites may contribute, and in particular the *R*-enantiomer of 3-dechloroethyl-ifosfamide which is a metabolite of *S*-ifosfamide.[6] There is some uncertainty about the contributory role of mesna, if any: encephalopathy has not been seen when mesna is given with cyclophosphamide,[7] and has been seen when ifosfamide is given alone,[5] but an exacerbatory role for mesna cannot be ruled out,[8] perhaps via its chelating properties.[1,7]

A nomogram has been proposed to identify patients at greatest risk of toxicity,[9,10] such as those with renal or hepatic impairment,[9] although doubts have been raised as to its general applicability.[11] A retrospective review of 237 patients given ifosfamide, of whom 38 developed encephalopathy, found no evidence that age or ifosfamide dose influenced the development of the condition, and serum creatinine values were in the normal range in the affected group, although they were slightly higher than in those not affected; however, low serum albumin did seem to be associated with greater risk.[12] It has also been suggested that the drug be given by continuous infusion over several days where possible, since this route has by far the lowest incidence of encephalopathy (7%, versus 26% with intravenous bolus and 43% with oral doses).[4] Care may also be required when giving other antineoplastics to patients who have had encephalopathy after ifosfamide, since a case of encephalopathy with bleomycin (not normally associated with neurotoxicity) has been reported in such a patient.[13]

A few reports suggests that methylthioninium chloride can effectively prevent or reverse signs of encephalopathy, and a number of mechanisms have been proposed (see Glutaric Aciduria under Uses of Methylthioninium Chloride, p.1451)

Handling and disposal. A study[1] found that ifosfamide 8% solution penetrated all of 4 brands of latex glove and one PVC glove, although the diffusion rate was 4 or more times slower than through cadaver skin. Permeation was greater through the PVC glove than the latex gloves, partly due to its lesser thickness, although permeation was not dependent on thickness alone and varied between gloves of the same brand as well as between brands. They recommended that latex gloves of a suitable brand should be worn when handling ifosfamide, and changed at least every 2 hours. For reference to a method for the destruction of ifosfamide waste, see under Cyclophosphamide, p.703.

1. Corlett SA, *et al.* Permeation of ifosfamide through gloves and cadaver skin. *Pharm J* 1991; **247:** R39.

Interactions

As for Cyclophosphamide, p.703. For a general outline of antineoplastic drug interactions, see p.642. For reference to the effects of ifosfamide on oral anticoagulants, see under Warfarin Sodium, p.1429. For a report of the enhancement of cisplatin-induced ototoxicity and nephrotoxicity, see under Cisplatin, p.700.

Antibacterials. Oral *rifampicin* given twice daily for 6 days, starting 3 days before intravenous ifosfamide (as a 24-hour infusion), increased the clearance of ifosfamide by over 100%; however, exposure to metabolites of ifosfamide was relatively unchanged. The authors considered that rifampicin might decrease the therapeutic efficacy of ifosfamide.[1]

1. Kerbusch T, *et al.* Modulation of the cytochrome P450-mediated metabolism of ifosfamide by ketoconazole and rifampin. *Clin Pharmacol Ther* 2001; **70:** 132–41.

Antifungals. *Ketoconazole* given orally for 4 days, starting 1 day before intravenous ifosfamide (given as a 24-hour infusion), decreased ifosfamide clearance. However, ifosfamide metabolism to active metabolites was decreased, and urinary excretion of ifosfamide was increased. Ketoconazole may decrease the therapeutic efficacy of ifosfamide.[1]

1. Kerbusch T, *et al.* Modulation of the cytochrome P450-mediated metabolism of ifosfamide by ketoconazole and rifampin. *Clin Pharmacol Ther* 2001; **70:** 132–41.

Pharmacokinetics

Ifosfamide is normally given intravenously, although it is well absorbed from the gastrointestinal tract. The pharmacokinetics of ifosfamide are reported to exhibit considerable interindividual variation. It is a prodrug that is extensively metabolised, chiefly by cytochrome P450 isoenzymes such as CYP3A4 and CYP2B6 in the liver, to a variety of active and inactive metabolites; there is some evidence that metabolism is saturated at very high doses. Although the manufacturers state that a mean terminal elimination half-life of about 15 hours has been reported after a single high-dose intravenous bolus, most studies at lower doses appear to have recorded elimination half-lives of about 4 to 8 hours. After repeated doses (fractionated therapy) there is a decrease in the elimination half-life, apparently due to autoinduction of metabolism. Ifosfamide is distributed into the CSF. It is excreted largely in urine, as unchanged drug and metabolites.

3. Kerbusch T, *et al.* Clinical pharmacokinetics and pharmacodynamics of ifosfamide and its metabolites. *Clin Pharmacokinet* 2001; **40:** 41–62.

◊ In a study[1] in 20 patients receiving intravenous ifosfamide over 3 or 5 days, the median elimination half-life of ifosfamide was 3.85 hours in patients under 60 years of age compared with 6.03 hours in those over age 60; this difference appeared to be due to an increased volume of distribution in the older age group. The autoinduction of metabolism typically seen with multiple doses of ifosfamide was not affected by age. The increased clearance seen over time during a 5-day cycle of ifosfamide treatment[2] was not sustained over the 21 days between cycles, but was reproducible and of similar magnitude in the subsequent cycle.

In another study[3] the half-life of the *S*-enantiomer of ifosfamide was found to be 5.98 hours after an intravenous bolus of the racemate, compared with 7.12 hours for the *R*-enantiomer.

Uses and Administration

Ifosfamide is an alkylating agent with properties similar to those of cyclophosphamide (p.703), of which it is a congener. It is used in the treatment of solid tumours including those of the cervix, lung, ovary, testis, and thymus, as well as in sarcoma and in the treatment of lymphomas. For further mention of these uses see the cross-references given below.

Ifosfamide is given intravenously, either by injection as a solution diluted to less than 4%, or by infusion. Licensed dosage regimens include a total dose of 8 to 12 g/m^2 divided over 3 to 5 days, with the course repeated at 2 to 4 week intervals; a total dose of 6 g/m^2 divided over 5 days, repeated every 3 weeks; and doses of 5 to 6 g/m^2, to a maximum of 10 g, given as a single 24-hour infusion, repeated at 3 to 4 week intervals. The interval between courses also depends on the blood count (see also Bone-marrow Depression, p.639). Oral ifosfamide has also been studied but is associated with neurotoxicity (see Effects on the Nervous System, above).

Ifosfamide should be given with mesna (see Administration, below), and adequate hydration should be maintained, to avoid urological toxicity; fluid intake should not be less than 2 litres daily.

Administration. Mesna (p.1449) can combine with urotoxic ifosfamide metabolites in the kidney to form stable and non-toxic compounds. It is therefore given prophylactically with ifosfamide. It has a shorter half-life than ifosfamide so repeated doses are needed to provide adequate protection of the bladder. A common schedule uses intravenous mesna at 60% of the ifosfamide dose, divided into 3 doses given with, or 15 minutes before, ifosfamide, then 4 and 8 hours after ifosfamide.[1] Mesna may also be given orally, but higher doses are required.

1. Siu LL, Moore MJ. Use of mesna to prevent ifosfamide-induced urotoxicity. *Support Care Cancer* 1998; **6:** 144–54.

Malignant neoplasms. Ifosfamide may be used as an alternative to cyclophosphamide in lymphomas such as Burkitt's lymphoma (p.657). It is also used in a variety of solid neoplasms, including in palliative regimens for advanced cervical cancer (p.663); in the treatment of lung cancer (p.668); in ovarian cancer (p.670) and second-line and salvage regimens for testicular cancer (p.673); in thymoma (p.674); in adjuvant therapy for bone sarcomas (p.675) and rhabdomyosarcoma (p.676).

(imatinib)

Adverse Effects and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

The most common adverse effects of imatinib mesilate include gastrointestinal disturbances, superficial oedema, myalgia, muscle cramps, rashes, fatigue, and headache. There are reports of erythema multiforme and Stevens-Johnson syndrome. Other adverse effects include dizziness, taste disturbances, paraesthesia, insomnia, eye disorders or visual disturbances, epistaxis, dyspnoea, dry skin, alopecia, night sweats, pyrexia, weakness, and rigors. Hepatotoxicity may occur; fatal cases of hepatic necrosis have been reported. Aseptic necrosis of bone, mainly in the femoral head, has been reported rarely.

Myelosuppression, manifest as neutropenia, thrombocytopenia, or anaemia, occurs more frequently in leukaemic patients, and may be associated with the underlying disease. Gastrointestinal bleeding, however, is more frequent in those patients treated for stromal tumours. Ulceration can occur; gastrointestinal perforation, fatal in some cases, has been reported rarely.

Severe fluid retention can occur, which may result in pleural and pericardial effusion, pulmonary oedema, and ascites. Some fatalities have been reported, and treatment may need to be stopped if there is unexpected, rapid weight gain. Elderly patients and those with a history of cardiac disease may be at increased risk. Isolated cases of left ventricular dysfunction have been reported; patients with cardiac disease or risk factors for cardiac failure should be monitored. There are reports, including fatalities, of cerebral oedema, increased intracranial pressure and papilloedema.

Imatinib mesilate should be taken with food and a large glass of water to minimise gastrointestinal irritation. Complete blood counts and liver function should be monitored regularly.

Effects on the heart. Ten patients receiving imatinib developed severe congestive heart failure without obvious cause; all patients had normal left ventricular function before imatinib was started. Mitochondrial abnormalities were found after myocardial biopsy on 2 of the patients. These findings were confirmed by studies on *mice* and *in vitro*. The authors suggested that patients be closely followed for clinical manifestations of left ventricular dysfunction.[1]

Subsequent evaluation by the manufacturer (*Novartis*) established that the frequency of reported cardiac events was less than 1%. However, they recommended that patients with known cardiac disease or risk factors for cardiac failure be monitored accordingly, that those developing clinical manifestations suggestive of congestive cardiac failure be thoroughly evaluated and treated, and that elderly patients or those with underlying heart disease be evaluated for baseline left ventricular ejection fraction.[2]

Effects on the lungs. Interstitial pneumonitis has been reported with imatinib;[1-8] presenting symptoms included dry cough and dyspnoea. Doses of imatinib ranged from 100 mg to 600 mg daily. In most cases, the pneumonitis resolved after stopping imatinib and starting corticosteroid therapy. The mechanism was unclear, and may involve a hypersensitivity reaction. In an analysis of 27 cases of interstitial lung disease associated with imatinib therapy,[8] 30% of patients showed a hypersensitivity reaction radiological pattern. Pre-existing lung disease may be a risk factor.

Effects on the skin, hair, and nails. There are reports of acute generalised exanthematous pustulosis in patients receiving imatinib.[1,2] The authors noted that severe skin reactions had been reported in some other patients receiving the drug, and speculated that the effect might be dose-dependent and related to its pharmacological action. In subsequent reports[3-5] of cutaneous adverse effects, this dose-dependency has also been observed, with effects especially at doses of 600 mg daily and above. In a report of a livedoid pattern of rash in 3 patients taking imatinib, the authors noted that adverse skin reactions to imatinib tend to be strongly dose-dependent, are self-limiting, and do not usually affect the mucous membranes.[6] Epidermal necrolysis occurred in a patient who underwent stem cell transplantation after treatment with imatinib.[7] The authors suggested that prolonged inhibition of platelet-derived growth factor by imatinib may have impaired the repair of skin damage caused by the conditioning therapy. In a report of 19 patients exhibiting skin reactions, the authors suggested that the actions of imatinib on platelet-derived growth factor may have caused an increase in dermal interstitial fluid pressure, capable of inducing oedema and the subsequent erythema and desquamation that was observed. Rare reactions included psoriasis, hyaline cell syringoma, and malpighian epithelioma, all of which occurred after at least 1 year of therapy.[8] Follicular mucinosis[9] and panniculitis[10] have also been reported with use of imatinib, as has Stevens-Johnson syndrome.[11,12] Palmoplantar hyperkeratosis and nail dystrophy can occur.[13] Repigmentation of grey hair has also been reported.[14]

Oral corticosteroids have been used to resolve most cases of skin eruptions.[8] In other instances, re-introduction of imatinib at low doses, gradually increased to full dosage, has been successfully tolerated.[8,12,15] In one patient, who developed exfoliative dermatitis with imatinib and had recurrent reactions despite decreased doses, a once-weekly dose of imatinib was associated with a less severe rash that eventually disappeared over a period of 4 months.[16]

Effects on the spleen. There are isolated reports of splenic rupture in patients receiving imatinib mesilate.[1]

1. Elliott MA, *et al.* Adverse events after imatinib mesylate therapy. *N Engl J Med* 2002; **346:** 712–13.

Gynaecomastia. Gynaecomastia was noted in 7 of 38 men assessed for hormone concentrations while enrolled in studies of imatinib; the authors attributed the disorder to reductions in testosterone concentrations due to imatinib.[1]

1. Gambacorti-Passerini C, *et al.* Gynaecomastia in men with chronic myeloid leukaemia after imatinib. *Lancet* 2003; **361:** 1954–56.

Hypophosphataemia. Hypophosphataemia and associated changes in bone and mineral metabolism were reported in a study of patients receiving imatinib. Patients with normal serum-phosphate concentrations also had similar changes in bone turnover. Hypophosphataemia was apparently related to patient age and imatinib dose; it was also associated with decreased serum concentrations of calcium and vitamin D.[1] In a review of data, the manufacturers (*Novartis*) noted an incidence of 50% of patients in 2 studies; overall 1.5% had grade 4 hypophosphataemia. However, the reported incidence of hypophosphataemia as an adverse effect of imatinib was only 3%. They suggested that phosphate concentrations be monitored in patients taking imatinib until further elucidation of the effect of the drug on bone is available.[2] While some have questioned the association between treatment with imatinib and hypophosphataemia,[3] others have also reported hypophosphataemia during treatment with the drug.[4] The effect, however, appears to be reversible on stopping imatinib.

Pregnancy. Two of 3 pregnancies in 2 patients taking imatinib were successful; the infants were both small for weight, but healthy and without congenital abnormalities. In the third case, a first trimester miscarriage occurred. Both women continued imatinib throughout their pregnancies.[1]

In another report,[2] 10 women became pregnant while being treated with imatinib for chronic myeloid leukaemia. Imatinib therapy was stopped upon discovery of the pregnancy; exposure to imatinib ranged from 4 to 9 weeks. Two patients had a spontaneous abortion shortly after stopping imatinib, and another patient elected to have a therapeutic abortion. Seven other pregnancies went to term, resulting in 8 babies. One infant had hypospadias which was surgically corrected without complications; all other infants were healthy. The partners of 8 male patients also conceived while the men were receiving imatinib, one of them twice. All male patients continued therapy with imatinib. One spontaneous abortion occurred. Of the 8 babies born, 1 was found to have a mild rotation of the small intestine requiring surgery shortly after birth. The authors considered it possible that the brief exposure to imatinib may have slightly increased the risk of spontaneous abortion. While concluding that normal pregnancies are possible during imatinib therapy, the authors of both reports emphasised that possible teratogenic effects cannot be ruled out, and that patients should still be advised to use appropriate and effective contraception.

A similar warning was issued in a review of outcome data from 125 pregnancies involving exposure to imatinib. The authors noted that 63 pregnancies had resulted in the live birth of normal infants; a further 35 women terminated the pregnancy (in 3 cases because fetal abnormalities were found), and 18 ended in spontaneous abortion.[3] However, there were 9 infants with congenital abnormalities, several of which were strikingly similar, a fact that was considered to be of some concern.

Interactions

Imatinib mesilate is metabolised by the cytochrome P450 isoenzyme CYP3A4, and drugs that inhibit this enzyme, such as azole antifungals and macrolide antibacterials, may increase blood concentrations of imatinib. Equally, inducers of CYP3A4 (such as carbamazepine, dexamethasone, St John's wort, phenobarbital, phenytoin, and rifampicin) may reduce blood concentrations of imatinib; imatinib dosage may need to be increased in these patients (see Uses and Administration, below).

In vitro studies have indicated that imatinib itself inhibits the cytochrome P450 isoenzymes CYP3A4, CYP2C9, and CYP2D6, and may increase blood concentrations of drugs that are substrates of these enzymes.

The dose of levothyroxine may need to be increased before imatinib is given to patients with hypothyroidism (see Antineoplastics under Interactions of Levothyroxine, p.2172).

Antifungals. In a small study in healthy subjects, *ketoconazole* significantly increased imatinib exposure; mean maximum plasma concentration and area under the concentration-time curve increased, and clearance of imatinib decreased. The half-life of imatinib appeared relatively unchanged. To avoid overexposure, single subtherapeutic doses of imatinib had been used (200 mg); the authors noted that clinical significance might arise with use of imatinib in daily doses of 800 mg or more.[1]

1. Dutreix C, *et al.* Pharmacokinetic interaction between ketoconazole and imatinib mesylate (Glivec) in healthy subjects. *Cancer Chemother Pharmacol* 2004; **54:** 290–4.

St John's wort. Exposure to imatinib was significantly reduced when it was given after 2 weeks of treatment with St John's wort; area under the concentration-time curve was decreased, maximum plasma concentration and half-life of imatinib were reduced, and clearance increased.[1,2]

1. Frye RF, *et al.* Effect of St John's wort on imatinib mesylate pharmacokinetics. *Clin Pharmacol Ther* 2004; **76:** 323–9.
2. Smith PF, *et al.* The influence of St. John's wort on the pharmacokinetics and protein binding of imatinib mesylate. *Pharmacotherapy* 2004; **24:** 1508–14.

Pharmacokinetics

Imatinib mesilate is well absorbed after oral doses with peak blood concentrations occurring after 2 to 4 hours. The mean bioavailability is about 98%. Imatinib is reported to be about 95% bound to plasma proteins. Plasma elimination half-lives of imatinib and its major active metabolite, the *N*-demethylated piperazine derivative, are about 18 and 40 hours respectively. The major enzyme responsible for the metabolism of imatinib is cytochrome P450 isoenzyme CYP3A4; isoenzymes CYP1A2, CYP2D6, CYP2C9, and CYP2C19 also play a minor role. About 81% of a dose is eliminated within 7 days in the faeces (68%) and urine (13%). It is excreted mostly as metabolites, with only 25% as unchanged drug.

Uses and Administration

Imatinib mesilate is a tyrosine kinase inhibitor that inhibits the BCR-ABL tyrosine kinase created by the Philadelphia chromosome abnormality in chronic myeloid leukaemia (p.653) and acute lymphoblastic leukaemia (p.651). It also inhibits the tyrosine kinase for platelet-derived growth factor and stem cell factor, c-kit (CD117), which is overexpressed in gastrointestinal stromal tumours (see Soft-tissue Sarcoma, p.676). Imatinib is also indicated for patients with myelodysplastic syndromes (p.654), hypereosinophilic syndrome, aggressive systemic mastocytosis (p.1138), and dermatofibrosarcoma protuberans. Imatinib is given orally as the mesilate but doses are expressed as the base. Imatinib mesilate 119.5 mg is equivalent to about 100 mg of imatinib.

In the treatment of **chronic myeloid leukaemia**, patients in chronic phase may be given the equivalent of 400 mg of the base daily, increased to 600 mg daily or 400 mg twice daily if required. Patients in blast crisis or accelerated phase are given 600 mg daily, increased to 400 mg twice daily if necessary.

In the treatment of patients with newly diagnosed **acute lymphoblastic leukaemia**, imatinib 600 mg daily may be given with induction, consolidation, or maintenance chemotherapy. The same dose may be given as monotherapy for patients with relapsed or refractory disease.

In the treatment of unresectable or metastatic malignant **gastrointestinal stromal tumours**, doses of 400 or 600 mg daily are recommended.

For patients with **myelodysplastic disease**, the recommended dose of imatinib is 400 mg daily. For **mastocytosis**, 400 mg daily is given, unless there is associated eosinophilia, in which case a starting dose of 100 mg daily is recommended, increased to 400 mg if response is inadequate. Similarly, the recommended dose for **hypereosinophilic syndrome** is 400 mg daily, although a subset of patients with FIP1L1-platelet-derived growth factor receptor-α fusion kinase should be started on 100 mg daily, increased to 400 mg if response is insufficient. Patients with **dermatofibrosarcoma protuberans** may be given 400 mg twice daily.

Doses should be taken with food, and accompanied by plenty of water, to minimise gastric irritation. Dose adjustments may be necessary if myelosuppression or hepatotoxicity occurs; blood counts and liver function should be regularly monitored (see Administration in Hepatic Impairment, below).

Doses of imatinib should be increased by 50%, and clinical response should be carefully monitored, in patients given potent CYP3A4 inducers such as rifampicin or phenytoin. For children's doses, see Administration in Children, below.

Administration in children. In the UK, the licensed dose of imatinib for children with chronic myeloid leukaemia (CML) is 340 mg/m^2 daily, for those in chronic or advanced phase; a total dose of 800 mg should not be exceeded. The dose may be increased to 570 mg/m^2 daily (maximum total dose 800 mg) in children with disease progression, with unsatisfactory haematological response after at least 3 months of treatment, with no cytogenetic response after 12 months of treatment, or with loss of a previously achieved haematological or cytogenetic response.

In the USA, the recommended dose of imatinib is 340 mg/m^2 daily in children with newly diagnosed CML; the dose should not exceed 600 mg. For children with chronic phase CML recurring after stem cell transplantation or who are resistant to interferon alfa therapy, the recommended dose of imatinib is 260 mg/m^2 daily.

Treatment can be given as a once-daily dose, or split into morning and evening doses. There is no experience with the use of imatinib in children under 2 years of age.

Administration in hepatic impairment. Imatinib is metabolised in the liver. Licensed product information in the UK recommends that patients with mild, moderate, or severe liver impairment should be given the minimum recommended dose of 400 mg daily. In the USA, patients with mild and moderate impairment should be given initial doses of 400 mg daily, but in those with severe hepatic impairment, 300 mg daily is recommended. In both countries, degrees of hepatic impairment are defined as:

- mild: total bilirubin equal to 1.5 times the upper limit of normal (ULN); aspartate aminotransferase (AST/SGOT) greater than ULN. AST/SGOT can be normal or less than ULN if the total bilirubin is greater than ULN
- moderate: total bilirubin greater than 1.5 to 3 times the ULN
- severe: total bilirubin greater than 3 to 10 times the ULN

If, during treatment, elevations in bilirubin greater than 3 times the ULN or in liver transaminases greater than 5 times the ULN occur, imatinib should be withheld until bilirubin levels have returned to less than 1.5 times the ULN and transaminase levels to less than 2.5 times the ULN. Treatment may then be continued at a reduced daily dose. In adults the dose is reduced from 800 mg to 600 mg, from 600 mg to 400 mg, and from 400 mg to 300 mg. In children, the dose should be reduced from 340 mg/m^2 daily to 260 mg/m^2 daily, or from 260 mg/m^2 daily to 200 mg/m^2 daily.

Hypereosinophilic syndrome. Imatinib has been reported to produce clinical responses in patients with the hypereosinophilic syndrome (HES).[1-4] Some reports suggest that imatinib also has activity in mast-cell disease, even in the absence of associated eosinophilia.[5] However, not all patients with HES respond to imatinib.[4] Many patients with the myelodysplastic variant of HES express a novel kinase derived from an abnormal fusion of platelet-derived growth factor receptor-α gene with a neighbouring gene, FIP1L1. Almost all patients with this FIP1L1-platelet-derived growth factor receptor-α fusion kinase will respond to imatinib, but a subset of patients with HES without known imatinib targets have also been reported to respond to the drug.[6,7]

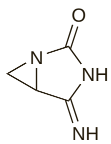
Imexon *(rINN)*

BM-06002; Imexón; Imexonum. (5*R*,*S*)-4-Amino-1,3-diazabicyclo[3.1.0]hex-3-en-2-one.

Имексон

$C_4H_5N_3O$ = 111.1.

CAS — 59643-91-3.



Profile

Imexon is a cyanoaziridine compound that appears to act as an antineoplastic in several ways, one of which is by causing mitochondrial disruption in the cancer cell, thus inducing apoptosis. It is under investigation for the treatment of malignant neoplasms, including ovarian cancer, pancreatic adenocarcinoma, multiple myeloma, and metastatic malignant melanoma.

Interleukin-2

BG-8301 (teceleukin); Epidermal Thymocyte Activating Factor; ETAF; IL-2; Interleucina 2; T-cell Growth Factor.

Description. Interleukin-2 is a naturally-occurring 133-amino-acid glycoprotein with a molecular weight of about 15 000. It is available from natural sources or as a product of recombinant DNA technology (rIL-2).

In addition to aldesleukin (below) modified forms of interleukin-2 produced by recombinant DNA technology have included celmoleukin and teceleukin.

Aldesleukin *(BAN, USAN, rINN)*

Aldesleukiini; Aldesleukina; Aldesleukine; Aldesleukinum; Aldeslökin; Des-alanyl-1, Serine-125 Human Interleukin-2; Recombinant Interleukin-2; 125-L-Serine-2–133-interleukin 2 (human reduced).

Альдеслейкин

CAS — 110942-02-4.

ATC — L03AC01.

ATC Vet — QL03AC01.

Description. Aldesleukin (modified human recombinant interleukin-2) is produced by recombinant DNA technology using an *Escherichia coli* strain containing an analogue of the human interleukin-2 gene. It differs from native interleukin-2 in that it is not glycosylated, it has no N-terminal alanine, and it has serine substituted for cysteine at position 125.

Incompatibility. Aldesleukin 33 800 units/mL in glucose 5% lost significant biological activity when mixed with other drugs including ganciclovir sodium, lorazepam, pentamidine isetionate, prochlorperazine edisilate, and promethazine hydrochloride.[1] However, the incompatibility was not detectable by spectrophotometric methods and only lorazepam was visually incompatible, suggesting that these methods may be invalid for assessing the compatibility of proteins.

1. Alex S, *et al.* Compatibility and activity of aldesleukin (recombinant interleukin-2) in presence of selected drugs during simulated Y-site administration: evaluation of three methods. *Am J Health-Syst Pharm* 1995; **52:** 2423–6.

Stability. Aldesleukin lost 75 to 100% of activity when reconstituted with glucose 5% or sodium chloride 0.9% in a plastic syringe and given over 24 hours with a syringe driver.[1,2] Loss of activity was not seen if aldesleukin was reconstituted with water alone[2] or with the addition of albumin.[1,2] It was suggested that loss of activity could be suspected because of lack of toxicity,[1,2] and that the lack of toxicity in some published studies could be due to this.[1,3] However, the authors of these studies indicated that they had reconstituted aldesleukin with albumin.[4,5] Reconstitution with low concentrations of albumin has been advocated to avoid bioavailability problems,[1,4,6] but is not recommended for currently licensed preparations. Vials of aldesleukin are reconstituted with water for injection.

However, UK licensed product information allows for further dilution of reconstituted aldesleukin with up to 500 mL of glucose 5%, containing human albumin 0.1%, when infused over a 24-hour period; the albumin should be added and mixed with the glucose before addition of the reconstituted aldesleukin.

For short intravenous infusion, the US licensed product information indicates that dilution in glucose 5% outside of a specified range (below 30 micrograms/mL and above 70 micrograms/mL) results in increased variability in drug delivery.

Reconstitution or dilution of aldesleukin preparations with sodium chloride 0.9% is not recommended because increased aggregation occurs.

Units

100 units of human interleukin-2 are contained in one ampoule of the first International Standard Preparation (1987). The activity of interleukin-2 has also been expressed in Nutley and Cetus units: 100 international units is reportedly equivalent to about 83.3 Nutley units and to about 16.7 Cetus units. US licensed product information states that 18 million international units of aldesleukin are equivalent to 1.1 mg of protein.

Adverse Effects and Treatment

Toxicity is related to dose and route and is often severe; fatalities have been recorded. Decreased vascular resistance and increased capillary permeability (the 'capillary leak syndrome') is common in patients given aldesleukin, and results in hypotension, reduced organ perfusion, and oedema. The incidence and severity of this syndrome is lower after subcutaneous than intravenous dosage. Fluid replacement may be necessary to treat the resultant hypovolaemia and dopamine or other pressor agents may be needed to help maintain organ perfusion. Capillary leak syndrome may also be associated with cardiac effects including tachycardia, angina, myocardial infarction; respiratory effects such as dyspnoea, pulmonary oedema, and respiratory failure; renal abnormalities including uraemia and oliguria or anuria; mental status changes including irritability, depression, confusion, and drowsiness. Therapy should be stopped if patients develop severe lethargy or somnolence, as continuing may result in coma. Raised liver enzymes, gastrointestinal disturbances, fever and flu-like symptoms (malaise, rigors, chills, arthralgia, and myalgia), rashes, pruritus, anaemia, leucopenia, and thrombocytopenia, are also relatively common. Paracetamol (but not NSAIDs, see Effects on the Kidneys, below) may be used prophylactically for fever. Pethidine may be used to control rigors. Antiemetics and antidiarrhoeals may also be required. Antihistamines may benefit some patients with pruritic rash. Injection site reactions are common after subcutaneous doses; necrosis has occurred. Aldesleukin therapy is associated with impaired neutrophil function, and an increased risk of bacterial infections (see below), including sepsis and bacterial endocarditis; this has been reported mainly after intravenous use, and antibacterial prophylaxis may be necessary.

Bacterial infections. The incidence of sepsis and bacteraemia is increased in patients receiving interleukin-2 via intravenous catheters,[1,2] and possibly subcutaneously,[3] although others have not found this to be the case.[4,5] The increased incidence of non-opportunistic bacterial infection may be a particular problem in patients with AIDS who are treated with interleukin-2.[6] The mechanism is uncertain, but may be related to impairment of neutrophil function by the cytokine.[7]

Effects on endocrine function. It has been suggested that patients with adrenal metastases may be particularly susceptible to adrenal haemorrhage and consequent failure during interleukin therapy.[1] Results also suggested that lack of endogenous steroid production may increase the risk of early severe interleukin-2 toxicity.[1]

Effects on thyroid function have also been reported, with the development of hypothyroidism[2-4] and goitre.[3]

Effects on the kidneys. Intravenous aldesleukin therapy was associated with varying degrees of acute renal dysfunction in almost all of 99 adult patients.[1] The clinical syndrome of hypotension, oliguria, fluid retention, and associated azotaemia with intense tubular avidity for filtered sodium all support prerenal acute renal failure as the cause of renal dysfunction. However, renal function values returned to baseline levels within 7 days in 62% of patients and in 95% by 30 days. Patients with elevated pretreatment serum-creatinine values, particularly those aged over 60 years, and those who had previously undergone a nephrectomy, were at risk of more severe and prolonged changes in renal function, and might be particularly vulnerable to the use of indometacin for associated fever and chills, which could potentiate renal impairment through its effects on intrarenal prostaglandin production. Similar effects were noted in a study[2] of 15 children given continuous infusion of aldesleukin. A further study[3] of the renal haemodynamic effects of aldesleukin infusion found it to have a specific renal vasoconstrictor effect; changes in renal prostaglandin synthesis contributed to the decreased renal blood flow.

1. Belldegrun A, *et al.* Effects of interleukin-2 on renal function in patients receiving immunotherapy for advanced cancer. *Ann Intern Med* 1987; **106:** 817–22.

3. Geertsen PF, *et al.* Renal haemodynamics, sodium and water reabsorption during continuous intravenous infusion of recombinant interleukin-2. *Clin Sci* 1998; **95:** 73–81.

Effects on the skin. Pseudosystemic sclerosis has been reported after use of aldesleukin; a reduction in skin thickening was seen after aldesleukin therapy was stopped and corticosteroids started.[1]

1. Marie I, *et al.* Pseudosystemic sclerosis as a complication of recombinant human interleukin 2 (aldesleukin) therapy. *Br J Dermatol* 2007; **156:** 182–3.

Precautions

Aldesleukin should be given with great care, if at all, to patients with pre-existing cardiac or pulmonary disease, and those with severe renal or hepatic impairment. It should be avoided in patients with CNS metastases or seizure disorders.

Risk factors for toxicity and poor response include restricted physical activity (Eastern Cooperative Oncology Group performance status of 1 or greater), 2 or more metastatic sites, and a period of less than 24 months between diagnosis of primary tumour and consideration for aldesleukin therapy. UK licensed product information states that aldesleukin should not be used to treat metastatic renal cell carcinoma in patients with all three of these risk factors.

Aldesleukin may worsen auto-immune diseases, and should be used with caution in patients with these conditions. Bacterial infections should be adequately treated before beginning therapy. Aldesleukin may increase effusions from serosal surfaces, and these should generally be treated before starting aldesleukin therapy.

Vital signs, blood counts, renal and hepatic function, serum electrolytes, and pulmonary and cardiac function should be monitored before starting treatment and then regularly during therapy.

Activity. For mention of the loss of activity when aldesleukin was given by continuous infusion without albumin, see Stability above.

Inflammatory bowel disease. Two patients with a history of Crohn's disease had a recurrence of the condition when given aldesleukin. It was suggested that interleukin-2 should be contraindicated in such patients.[1]

1. Sparano JA, *et al.* Symptomatic exacerbation of Crohn disease after treatment with high-dose interleukin-2. *Ann Intern Med* 1993; **118:** 617–18.

Psoriasis. Exacerbations of psoriasis developed in 3 patients during therapy with aldesleukin alone or with lymphokine-activated killer cells. The psoriatic symptoms remitted with topical therapy.[1]

1. Lee RE, *et al.* Interleukin 2 and psoriasis. *Arch Dermatol* 1988; **124:** 1811–15.

Interactions

Corticosteroids (which reduce some of the adverse effects of interleukin-2) may also reduce its antineoplastic properties: use together should generally be avoided. The use of iodinated contrast media after aldesleukin therapy may result in symptoms resembling the immediate adverse effects of aldesleukin. Although most events were reported to occur within 2 to 4 weeks of the last dose of aldesleukin, some occurred several months afterward.

Antivirals. For the effect of interleukin-2 on plasma concentrations of *indinavir*, see p.884.

NSAIDs. NSAIDs are effective in preventing or reducing fever and myalgia caused by interleukin-2. However, there is concern that they could exacerbate renal toxicity (see also Effects on the Kidneys, above). Use of *indometacin* in patients receiving interleukin-2 led to more severe weight gain, oliguria, and azotaemia in 1 study.[1] However, *ibuprofen* was used successfully to reduce interleukin-2 toxicity in another study.[2]

1. Sosman JA, *et al.* Repetitive weekly cycles of interleukin-2 II: clinical and immunologic effects of dose, schedule, and addition of indomethacin. *J Natl Cancer Inst* 1988; **80:** 1451–61.
2. Eberlein TJ, *et al.* Ibuprofen causes reduced toxic effects of interleukin 2 administration in patients with metastatic cancer. *Arch Surg* 1989; **124:** 542–7.

Pharmacokinetics

After intravenous bolus, the serum distribution and elimination half-lives of aldesleukin are 13 and 85 minutes, respectively. After subcutaneous doses, the absorption half-life is 45 minutes and the elimination half-life is 5.3 hours, while bioavailability ranges between 35 and 47%.

Aldesleukin is metabolised to amino acids by the kidneys.

Uses and Administration

Interleukin-2 is a lymphokine which stimulates the proliferation of T-lymphocytes and thus amplifies immune response to an antigen; it also has actions on B-lymphocytes, and induces the production of interferon-γ and the activation of lymphokine-activated killer (LAK) cells and natural killer (NK) cells. Interleukin-2 is used in the immunotherapy of metastatic renal cell carcinoma in selected patients (see p.667). It is also used in metastatic melanoma (p.673), and has been tried in non-Hodgkin's lymphoma and acute myeloid leukaemia.

Interleukin-2 is usually given by intravenous infusion or subcutaneous injection of one of its recombinant forms, such as aldesleukin.

Many dosage regimens have been tried. In the UK, the recommended dose of aldesleukin for metastatic renal cell carcinoma is 18 million units given subcutaneously once daily for 5 days, followed by 2 days rest for the first week. For the next 3 weeks, 18 million units are then given on days 1 and 2 of each week, and 9 million units on days 3 to 5 of each week, followed by 2 days rest. This 4-week cycle may be repeated after an interval of 1 week. Doses may be delayed or reduced if the regimen is not tolerated.

Intravenous infusion of aldesleukin is now rarely used because of an association with capillary leak syndrome (see Adverse Effects and Treatment, above). If it is used, 18 million units/m^2 per 24 hours is given as a continuous intravenous infusion for 5 days, followed by 2 to 6 days of rest. Then another 5 days of infusion is given, followed by 3 weeks of rest. This constitutes one induction cycle; a second cycle may be given after the 3-week rest period of the first cycle. After either subcutaneous or intravenous use, up to 4 maintenance cycles may be given, at 4-week intervals, to patients who respond or whose disease stabilises. In the USA, aldesleukin is given by intravenous infusion for metastatic renal cell carcinoma or metastatic melanoma. The recommended dose is an infusion of 600 000 units/kg over 15 minutes, every 8 hours for up to 14 doses. This 5-day cycle is repeated after 9 days. Further courses may be given at intervals of at least 7 weeks in patients who respond. Doses should be withheld for toxicity.

Aldesleukin given by inhalation is being investigated in the treatment of renal cell carcinoma.

Interleukin-2 has also been given in adoptive immunotherapy with LAK cells or tumour-infiltrating lymphocytes (TIL), which are harvested from the patient, activated *ex vivo*, and then re-infused.

Interleukin-2 is also being tried in patients with HIV infection and AIDS in an attempt to restore immune response (see below) and has been given in some other infections or immune diseases.

Other interleukins are under investigation (see also Interleukin-1, p.2325). Conjugates of interleukin-2 with macrogol (PEG-IL2; pegaldesleukin) have also been investigated and liposome-encapsulated interleukin-2 has also been investigated for the treatment of renal, brain and CNS tumours.

A mixture of naturally occurring cytokines, including interleukins, interferons, chemokines, and colony-stimulating factors (Multikine®) is under investigation for neoadjuvant therapy in patients with squamous cell carcinoma of the head and neck.

HIV infection and AIDS. The immunodeficiency of HIV infection and AIDS (p.856) has been associated with a defect in interleukin-2 production. Interleukin-2 stimulates the proliferation of lymphocytes and activates natural killer cells and a number of studies have therefore examined the potential benefits of adding interleukin-2 to the treatment of patients with HIV infection.[1,2] Following earlier pilot studies, trials of antiretroviral therapy plus interleukin-2 have shown it to produce a much greater increase in CD4 cell counts than antiretroviral therapy alone,[3-7] even where therapy included HAART. Given the efficacy of current therapies, demonstrating additional benefits on survival or disease progression is difficult, although some studies have been undertaken.[1] In the interim, a pooled analysis[8] of earlier results showed a non-significant trend towards improved clinical outcome.

Although teceleukin has been tried[3] most studies of interleukin-2 therapy in HIV have used aldesleukin. Doses and routes have varied: in general doses seem to have ranged from 6 to 18 million units daily by intravenous infusion, or 3 to 30 million units daily subcutaneously, given in most cases for a 5-day cycle every 8 weeks. Subcutaneous dosage appears to be as effective as intravenous,[4,9] is more convenient,[4] and may be less toxic.[10] There is evidence that 5-day dose cycles of 3, 4.5 or 7.5 million units twice daily by subcutaneous injection are effective,[5,6,9,11-13] whereas cycles with a lower dose of 1.5 million units twice daily are not.[5,11,13] A meta-analysis[14] of 3 trials found that subcutaneous doses of 7.5 million units twice daily for 5 days every 8 weeks resulted in greater increases in CD4 cell counts after 3 cycles of therapy than doses of 4.5 million units or 1.5 million units. However, others have reported benefit from a dose as low as 3 million units daily when used with HAART in patients with advanced disease.[15] Continuous low-dose daily therapy appears to accelerate the normalisation of T-cell and natural killer cell concentrations over the course of several months.[10]

Adverse effects are common, particularly at higher doses and with intravenous infusion rather than subcutaneous use.[7,10] However, concerns about a potential stimulant effect on viral replication with a consequent increase in viral load do not seem to have been borne out.[4-7,9] Some studies have reported reduced viral loads in interleukin-treated patients,[6,16] including decreases in hepatitis C viral load in those HIV patients co-infected with hepatitis C.[9,17]

The macrogol conjugate of interleukin-2, PEG-IL2, has also been investigated in this context, but results have been disappointing, since it appears markedly less effective than aldesleukin in stimulating CD4 counts.[4,18]

Postherpetic neuralgia. A 46-year-old HIV patient with chronic, treatment-resistant postherpetic neuralgia (p.9) received 1 cycle of subcutaneous interleukin-2 (7.5 million units twice daily for 5 consecutive days) within the context of a clinical HIV study. He reported immediate resolution of his postherpetic neuralgia, and no recurrence of pain occurred during 3 years of follow-up.[1]

Ipilimumab *(USAN, rINN)*

Ipilimumabum; MDX-010; MDX-CTLA-4. Immunoglobulin G1, anti-(human CTLA-4 (antigen)) (human γ1-chain), disulfide with human κ-chain, dimer.

Ипилимумаб

CAS — 477202-00-9.

Profile

Ipilimumab is an antibody to the cytotoxic-T-lymphocyte-associated antigen 4 (CTLA-4), which is a cell surface receptor involved in the downregulation of T-cell activation. Ipilimumab is under investigation for the treatment of melanoma and various solid tumours. Adverse effects include enterocolitis, hypophysitis, dermatitis, arthritis, uveitis, hepatitis, nephritis, and aseptic meningitis.

Iratumumab *(USAN, rINN)*

Iratumumabum; MDX-060. Immunoglobulin G1, anti-(tumor necrosis factor ligand superfamily member 8 (CD30 ligand)) (human monoclonal MDX-060 heavy chain), disulfide with human monoclonal MDX-060 light chain, dimer.

Иратумумаб

CAS — 640735-09-7.

Profile

Iratumumab is an anti-CD30 monoclonal antibody that is under investigation for the treatment of Hodgkin's disease. Reported adverse effects include a rise in liver transaminases, and acute respiratory distress syndrome.

Irinotecan Hydrochloride

(BANM, USAN, rINNM)

Camptothecin 11 (irinotecan); CPT-11 (irinotecan); DQ-2805; Hidrocloruro de irinotecán; Irinotécan, Chlorhydrate d'; Irinotecani Hydrochloridum; Irinotekaanihydrokloridi; Irinotekan Hidroklorür; Irinotekanhydroklorid; U-101440E. (+)-7-Ethyl-10-hydroxycamptothecine 10-[1,4′-bipiperidine]-1′-carboxylate hydrochloride trihydrate; (*S*)-4,11-Diethyl-3,4,12,14-tetrahydro-4-hydroxy-3,14-dioxo-1*H*-pyrano[3′,4′:6′,7′]indolizino[1,2-*b*]quinolin-9-yl [1,4′-dipiperidine]-1′-carboxylate hydrochloride trihydrate.

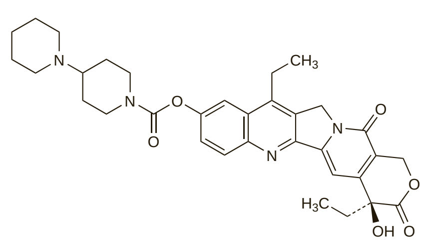
Иринотекана Гидрохлорид

$C_{33}H_{38}N_4O_6,HCl,3H_2O = 677.2.$

CAS — 97682-44-5 (irinotecan); 136572-09-3 (irinotecan hydrochloride trihydrate).

ATC — L01XX19.

ATC Vet — QL01XX19.



(irinotecan)

Adverse Effects, Treatment, and Precautions

For general discussions, see Antineoplastics, p.635, p.639, and p.641. Neutropenia and diarrhoea may be dose-limiting in patients given irinotecan. The nadir of the white cell count usually occurs about 8 days after a dose, with recovery by about day 22. Anaemia also occurs and, less commonly, thrombocytopenia. Gastrointestinal disturbances are common: acute diarrhoea, occurring within 24 hours of a dose, may be part of a cholinergic syndrome which can also include sweating, hypersalivation, abdominal cramps, lachrymation, and miosis. These symptoms can be controlled with atropine. However a more severe, prolonged diarrhoea may occur, beginning more than 24 hours after a dose, and can be life-threatening; prompt management with high-dose loperamide and fluid replacement is required (see Effects on the Gastrointestinal Tract, below), and irinotecan treatment should be interrupted and any further doses reduced. Other adverse effects include nausea and vomiting, weakness, alopecia, and skin reactions. Hypertension has occurred rarely during or after infusion. There are rare reports of hypersensitivity reactions, interstitial pneumonia, pneumonitis, intestinal perforation, pancreatitis, muscular contraction or cramps, and paraesthesia.

Irinotecan should not be given to patients with inflammatory bowel disease. The risk of diarrhoea may be increased in the elderly and in patients who have had radiotherapy to the abdomen or pelvis. Radiotherapy also increases the risk of myelosuppression. Blood counts should be monitored weekly and liver function tests should be regularly performed.

Severe toxicity resulting in an increased number of deaths has been reported when irinotecan was given with fluorouracil and folinic acid (see under Interactions, below).

Effects on the gastrointestinal tract. *Acute* diarrhoea occurring as part of a cholinergic syndrome with irinotecan is rarely severe. The syndrome is usually treated or prevented with atropine, but pretreatment with hyoscine butylbromide has also been tried.[1,2] In contrast, *delayed* diarrhoea can be dose-limiting or even fatal in some patients. Standard treatment involves fluid and electrolyte replacement and a high-dose loperamide regimen consisting of 4 mg loperamide immediately after the first loose stool, then 2 mg every 2 hours until 12 hours after the last liquid stool. During the night, the patient may take 4 mg every 4 hours. The high-dose therapy should not be given for more than 48 hours and should never be given prophylactically. Specific recommendations[3] state that if the diarrhoea persists for more than 24 hours despite loperamide therapy, patients should also take an oral fluoroquinolone for 7 days. If the diarrhoea persists for more than 48 hours, patients should be hospitalised for parenteral hydration. Other treatments have been tried, including acetorphan, activated charcoal, budesonide, glutamine, and octreotide.[2,4-9] A regimen of thalidomide with irinotecan has been reported to have a striking lack of gastrointestinal adverse effects such as diarrhoea and nausea.[2,10] However, a pharmacokinetic study found no decrease in gastrointestinal toxicity when these 2 drugs were given together, see Thalidomide, under Interactions, below.

Diarrhoea may be caused by direct intestinal damage due to SN-38, the active metabolite of irinotecan; reduction of intestinal SN-38 concentrations using the poorly absorbed aminoglycoside neomycin as prophylaxis was reported to ameliorate diarrhoea in 6 of 7 patients experiencing this adverse effect.[11]

Genetic factors. Irinotecan is hydrolysed to SN-38, an active metabolite, which is inactivated by glucuronidation by uridine diphosphate glucuronosyltransferase (UGT) enzymes.[1] Genetic variation in the UGT family may affect irinotecan pharmacodynamics. Although UGT1A1*28 polymorphism appears to be only one of several identified causes of altered SN-38 pharmacokinetics,[1,2] it has been strongly associated with the development of severe neutropenia, and genotyping has been proposed as a method of identifying patients at risk of severe toxicity from irinotecan.[3,4] However, genotyping does not predict for all toxicities, and a significant association between the UGT1A1*28 homozygous genotype and diarrhoea has not been proven. Furthermore, a normal UGT1A1 genotype does not ensure lack of toxicity, although the risk is less; the possibility of underdosing in those with the normal genotype may need to be considered.[5] Despite these limitations, it has been suggested that every patient receiving irinotecan for the first time be tested for UGT1A1 genotype.[5]

Licensed product information in the USA states that reduced initial doses should be considered for patients known to be homozygous for the UGT1A1*28 allele; while heterozygous patients may also be at risk, results of studies have been variable and such patients may tolerate normal initial doses of irinotecan. However, the most appropriate dose reduction in the homozygous population is not known. Some have suggested an initial 20% dose reduction, with escalation to full dosage in subsequent courses in the event of little or no toxicity.[5] A prospective study[6] found that the UGT1A1*28 genotype (homozygous or heterozygous) was significantly associated with haematological toxicity, but only during the first cycle of irinotecan-containing chemotherapy. This called into question the need for a dose reduction in irinotecan for patients with this genotype, particularly since homozygous patients showed a trend to improve clinical response. A study in paediatric patients[7] found that, for low-dose, protracted schedules of irinotecan (doses ranged from 15 to 75 mg/m^2 daily, given either intravenously or orally, for 5 days, for 2 consecutive weeks), UGT1A1 genotyping was not a useful prognostic indicator of severe toxicity.

Interactions

Irinotecan is partly metabolised by cytochrome P450 CYP3A isoenzymes. Inducers of this system such as carbamazepine, phenobarbital, or phenytoin reduce exposure to irinotecan and its active metabolite SN-38; use with St John's Wort is contra-indicated. Conversely, inhibitors of this system such as ketoconazole increase exposure to irinotecan and SN-38; use with ketoconazole is contra-indicated.

Antidepressants. In a small, crossover study[1] of cancer patients, use of *St John's wort* during irinotecan therapy was found to decrease plasma concentrations of SN-38, the active metabolite of irinotecan. Myelosuppression was also reduced with this combination. The interaction is thought to be due to the induction of the cytochrome P450 isoenzyme CYP3A4 by St John's wort.

1. Mathijssen RHJ, *et al.* Effects of St. John's wort on irinotecan metabolism. *J Natl Cancer Inst* 2002; **94:** 1247–9.

Antineoplastics. Although previously reported to be effective, and not associated with excessive toxicity,[1] a regimen of irinotecan with bolus *fluorouracil* and folinic acid was found to be associated with an excess of early deaths in 2 further studies, which were consequently terminated.[2] Deaths were associated with a variety of events including dehydration (due to diarrhoea, nausea, and vomiting), neutropenia, and sepsis. It has been suggested that use of irinotecan with fluorouracil by continuous infusion might be better tolerated,[3,4] and a small study[5] found that the sequence may be important. Irinotecan followed by an infusion of fluorouracil over 48 hours, was associated with less dose-limiting toxicity, and higher maximum tolerated doses, than fluorouracil infusion followed by irinotecan.

Sorafenib may increase systemic exposure to irinotecan.

5. Falcone A, *et al.* Sequence effect of irinotecan and fluorouracil treatment on pharmacokinetics and toxicity in chemotherapy-naive metastatic colorectal cancer patients. *J Clin Oncol* 2001; **19:** 3456–62.

Smoking. A study found that tobacco smoking significantly affected the pharmacokinetics and toxicity of irinotecan.[1] Clearance of irinotecan was faster in smokers, and systemic exposure to the active metabolite SN-38 (see Pharmacokinetics, below) was almost 40% lower in smokers. This effect probably contributed to the significantly lower haematological toxicity seen in smokers; no significant difference in diarrhoea was seen between smokers and non-smokers. Smoking may induce cytochrome P450 isoenzyme CYP3A, or possibly affect carboxylesterase activity. The study did not determine an effect of smoking on the outcome of treatment with irinotecan. However, smokers may need a higher dose of irinotecan relative to non-smokers, since the lower exposure to irinotecan and SN-38 may indicate a potential risk of treatment failure.

1. van der Bol JM, *et al.* Cigarette smoking and irinotecan treatment: pharmacokinetic interaction and effects on neutropenia. *J Clin Oncol* 2007; **25:** 2719–26.

Thalidomide. A pharmacokinetic study found that the metabolism of irinotecan to SN-38 was significantly decreased by thalidomide. Despite reports of reduced gastrointestinal toxicity when these 2 drugs were given together (see Effects on the Gastrointestinal System, above), 3 out of 19 patients enrolled in the study had severe delayed diarrhoea after being given irinotecan with thalidomide.[1]

Pharmacokinetics

Irinotecan exhibits biphasic or triphasic pharmacokinetics, with a terminal half-life of about 14 hours. After intravenous doses it is hydrolysed by carboxylesterase in body tissues to active SN-38 (7-ethyl-10-hydroxycamptothecin). SN-38 exhibits a biphasic elimination profile with a terminal half-life of about 14 hours. Plasma protein binding for irinotecan and SN-38 is about 65% and 95%, respectively. SN-38 is mainly eliminated by glucuronidation, predominantly by the enzyme uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1). Irinotecan is also partly metabolised by cytochrome P450 isoenzymes CYP3A4 and perhaps CYP3A5. More than 50% of an intravenous dose of irinotecan is excreted as unchanged drug, with about 30% in the faeces via the bile and about 20% in the urine.

Uses and Administration

Irinotecan is a semisynthetic derivative of the alkaloid camptothecin, obtained from the shrub *Camptotheca acuminata*. The camptothecin derivatives are inhibitors of the enzyme topoisomerase I and thus interfere with the coiling and uncoiling of DNA during replication and prevent nucleic acid synthesis. This action is specific for S phase.

Irinotecan is used, alone or with fluorouracil-based chemotherapy, in the treatment of colorectal cancer (p.665). It is also indicated for use with cetuximab in the treatment of EGFR-expressing metastatic colorectal cancer, after the failure of other regimens containing irinotecan. It has been tried in the management of other solid tumours including those of the lung (p.668).

It is given as the hydrochloride, by intravenous infusion, in at least 250 mL of glucose 5%, or sodium chloride 0.9%. In the treatment of refractory colorectal malignancies one suggested single-agent dose regimen is irinotecan hydrochloride 125 mg/m^2 infused over 90 minutes once a week for 4 weeks, followed by a 2-week rest period. Additional courses may be given if required, with doses modified according to toxicity. Another regimen requires an initial dose of 350 mg/m^2 over 30 to 90 minutes repeated every 3 weeks and adjusted according to toxicity (for dosage in hepatic impairment, see below).

For the suggestion that initial doses should be modified to reduce toxicity in those with certain genotypes, see Genetic Factors, above.

Irinotecan may also be given as part of a regimen with fluorouracil and folinic acid in the first-line treatment of metastatic colorectal cancer. Numerous regimens exist. The irinotecan hydrochloride component of the course may be given at a dose of 180 mg/m^2 over 30 to 90 minutes every 2 weeks. Alternatively, 125 mg/m^2 may be given weekly, usually on days 1, 8, 15, and 22 of a 42-day cycle. (For reference to toxicity from such regimens see under Interactions, above.)

Treatment cycles may be continued indefinitely as long as patients continue to benefit.

In the treatment of EGFR-expressing metastatic colorectal cancer, when used with cetuximab, irinotecan is given usually at the same dose as was used in the last cycles of the previous irinotecan-containing regimen; irinotecan should not be given for at least 1 hour after the end of the cetuximab infusion.

A formulation of irinotecan with hyaluronic acid is being developed.

Administration in hepatic impairment. In patients with hyperbilirubinaemia, the clearance of irinotecan is decreased, exposure to the active metabolite SN-38 is increased, and the risk of haematological toxicity is increased. US licensed product information recommends a reduction in the initial dose of irinotecan for those patients with increased bilirubin concentrations. However, doses in patients with bilirubin greater than 2 mg/100 mL cannot be determined due to insufficient data.

In the UK, licensed product information recommends the following dosage reduction for monotherapy regimens in which irinotecan hydrochloride is normally given at 350 mg/m^2 every 3 weeks (see Uses and Administration, above):

- in patients with bilirubin up to 1.5 times the upper limit of normal range (ULN), no dosage reduction is considered necessary and irinotecan hydrochloride 350 mg/m^2 is recommended;
- in patients with bilirubin ranging from 1.5 to 3 times the ULN, irinotecan hydrochloride 200 mg/m^2 may be given;
- in patients with bilirubin over 3 times the ULN, the use of irinotecan is not recommended.

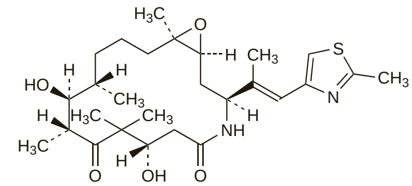
Ixabepilone *(USAN, rINN)*

Azaepothilone B; BMS-247550-01; Ixabepilona; Ixabépilone; Ixabepilonum. (1*S*,3*S*,7*S*,10*R*,11*S*,12*S*,16*R*)-7,11-Dihydroxy-8,8,10,12,16-pentamethyl-3-[(1*E*)-1-methyl-2-(2-methylthiazol-4-yl)ethenyl]-17-oxa-4-azabicyclo[14.1.0]heptadecane-5,9-dione.
Иксабепильон
$C_{27}H_{42}N_2O_5S$ = 506.7.
CAS — 219989-84-1.
ATC — L01DC04.
ATC Vet — QL01DC04.



Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

Peripheral neuropathy is common with ixabepilone, and dose reduction, or delaying or stopping treatment may be necessary (see Uses and Administration, below). Dose-dependent myelosuppression can occur, manifested mainly as neutropenia; febrile neutropenia and fatalities have been reported. Frequent blood counts are recommended. Ixabepilone is formulated in polyoxyl castor oil and should be avoided in patients hypersensitive to this substance; patients should be premedicated with a histamine H_1- and histamine H_2-antagonist about 1 hour before infusion. Therapy should be stopped if a hypersensitivity reaction occurs, and symptomatic treatment given. Subsequent cycles may be given with additional corticosteroid therapy, and extension of the infusion time should be considered.

Other adverse effects include gastrointestinal disturbances, anorexia, myalgia, arthralgia, fatigue, alopecia, insomnia, headache, taste disorders, dizziness, increased lachrymation, dyspnoea, cough, skin rashes, nail disorders, palmar-plantar erythrodysesthesia syndrome, pruritus, skin exfoliation or hyperpigmentation, and hot flushes.

Interactions

Ixabepilone undergoes extensive metabolism by cytochrome P450 isoenzyme CYP3A4. Inhibitors of CYP3A4, such as ketoconazole, can increase exposure to ixabepilone. Conversely, CYP3A4 inducers can reduce exposure to ixabepilone. Use of ixabepilone with strong inhibitors or inducers of CYP3A4 should be avoided. If strong inhibitors are used, dose adjustments may be required (see Uses and Administration, below). Grapefruit juice may also increase plasma concentrations of ixabepilone and should be avoided. St John's wort may decrease plasma concentrations of ixabepilone unpredictably and should also be avoided.

Pharmacokinetics

Ixabepilone is extensively distributed. Plasma protein binding is about 67 to 77%. It is extensively metabolised in the liver, mainly by oxidation via cytochrome P450 isoenzyme CYP3A4. It is eliminated mainly as metabolites; about 86% of a dose is eliminated within 7 days, 65% in faeces, and 21% in the urine. The terminal elimination half-life is reported to be about 52 hours.

Uses and Administration
